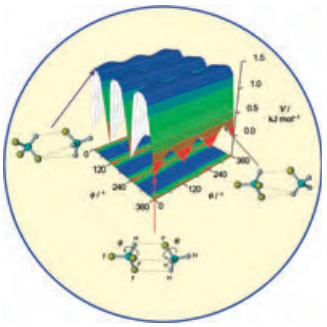
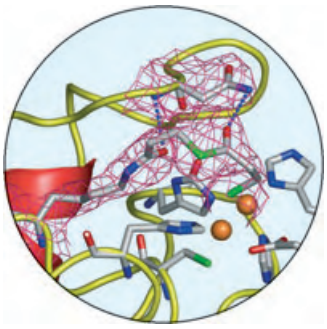
Cover Picture



Oliver Oeckler, Thomas Weber, Lorenz Kienle, Hansjürgen Mattausch, and Arndt Simon*



Diffuse diffraction data from disordered compounds can be interpreted with new numerical algorithms; however, there are few examples of quantitative structure refinement against all data and not only Bragg reflections. In the Communication on page 3917 ff., the authors demonstrate the application of evolutionary algorithms to solve the structure of an aluminum-stabilized lanthanum subiodide. The cover picture shows a diffraction pattern of the compound in the background and a section of the disordered structure model in the center.

Medicinal Chemistry
Protein tyrosine phosphatases have been analyzed as targets for therapeutic intervention for several years. H. Waldmann and L. Bialy discuss recent research activities in the development of small-molecule inhibitors of these enzymes in their Review on page 3814 ff.

Molecular Dynamics
Molecular clusters formed by hydrogen bridges can be highly dynamic systems, as described for a fluoromethane–trifluoromethane complex by W. Caminati et al. in their Communication on page 3840 ff.

Bioorganic Chemistry
Pathogenic bacteria that produce metallo-β-lactamases are recognized as a serious threat because of their resistance to antibiotics. In their Communication on page 3861 ff. H. Kurosaki et al. introduce an irreversible inhibitor for the metallo-β-lactamase IMP-1.

Inhibitors of Protein Tyrosine Phosphatases: Next-Generation Drugs?

Communications

A preferred conformation of the internally highly dynamic fluoromethane–trifluoromethane molecular complex results from the stabilization of the two subunits by three weak CH···F hydrogen bonds and electrostatic dipole–dipole interactions (see picture). The two subunits are not rigidly locked, but exhibit large amplitude motions by almost freely spinning around their symmetry axes as shown.

If you look for holes, you will find them in a novel 3D metal–organic framework complex with zeolite MTN topology. The framework of $[\{Cd(H_2O)_3\}_{34}(N_4C_6H_{12})_{17}]Cl_{68}\cdot 46\,H_2O\cdot 68$ DMF greatly expands the original structure of MTN and contains large cages with a volume of about 2522 Å^3 (see structure). MTN = zeolite socony mobil – thirty-nine, DMF = *N*,*N*-dimethylformamide.

Coordination Polymers

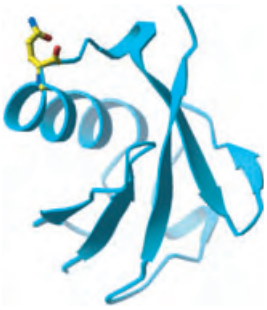
A Metal–Organic Framework with the Zeolite MTN Topology Containing Large Cages of Volume 2.5 nm^3



Burrowing water: The apohost phase of a substituted hydrophobic calixarene, grown by sublimation, forms lattice voids but not channels. Exposure of the crystals to liquid water results in a single-crystal-to-single-crystal phase transformation during which water molecules become embedded in the lattice voids (see picture); thus the classical view of diffusion might not be appropriate at the atomic scale.

Water Transport

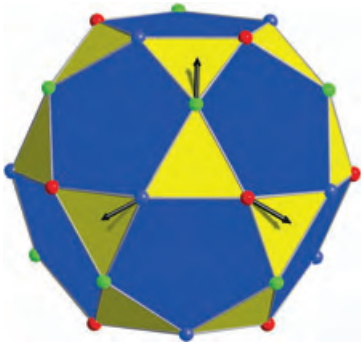
Diffusion of Water in a Nonporous Hydrophobic Crystal



Striking similarity: An efficient synthetic route to native ubiquitin and its diastereomer [D-Gln 35]ubiquitin was realized by combining a one-pot native chemical ligation process with protein desulfurization. High-resolution X-ray crystallographic studies of the protein diastereomer (see picture) revealed a striking conservation of molecular structure.

Protein Structures

Total Chemical Synthesis and X-ray Crystal Structure of a Protein Diastereomer: [D-Gln 35]Ubiquitin

Sphere we go: A spherical capsule is prepared simply by the interaction of linkers to pentagonal structural units. The metal centers (M) of the $\{(Mo^{VI})Mo^{VI}_5\}_{12}M_{30}$ type Keplerates formed (M = V^{IV}, Fe^{III}) describe an icosidodecahedron (see picture). For M = Fe^{III} the magnetic configuration of the 30 spin centers (colored spheres) can be pictured geometrically in terms of three sets, each of 10 spins, with different angular orientations (arrows). With M = V^{IV} the compound behaves according to the demands of quantum mechanics and a clear geometrical picture of the magnetism is not possible.

Polyoxometalates

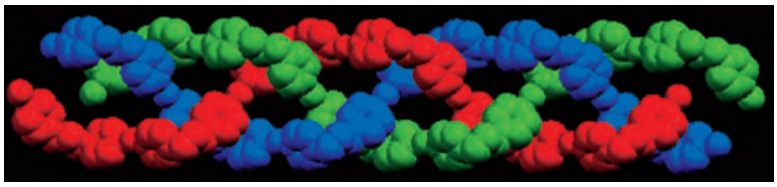
Irreversible Inhibition of Metallo-β-lactamase (IMP-1) by 3-(3-Mercaptopropionylsulfanyl)propionic Acid Pentafluorophenyl Ester



Resistance is futile: Pathogenic bacteria that produce metallo-β-lactamases are recognized as a serious threat because of their resistance to antibiotics. The title compound has now been shown to be an irreversible inhibitor for a metallo-β-lactamase (IMP-1). The X-ray crystallographic structure (see picture) has revealed that the inhibitor binds to IMP-1 with formation of a covalent amide bond with the amino group (N^{ζ}) of Lys 224.

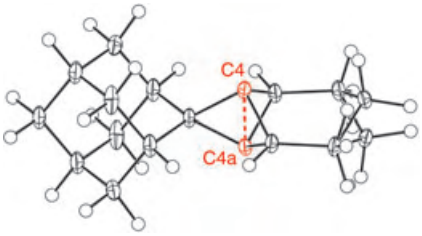
Single-Molecule Experiments in Synthetic Biology: An Approach to the Affinity Ranking of DNA-Binding Peptides



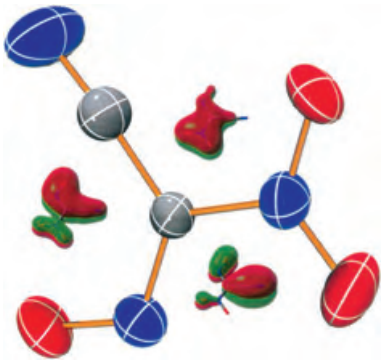
Peptide–DNA recognition: The specific binding of peptides to DNA representing a section of the binding sequence of a transcription activator has been demonstrated for the first time at the single-molecule level with AFM (experimental principle, see picture). The results underscore the importance of peptide length and cooperative effects as well as the contribution of single-point mutations on specific binding.

Propellanes

M. Messerschmidt, S. Scheins, L. Grubert, M. Pätzel, G. Szeimies, C. Paulmann, P. Luger* — **3925 – 3928**

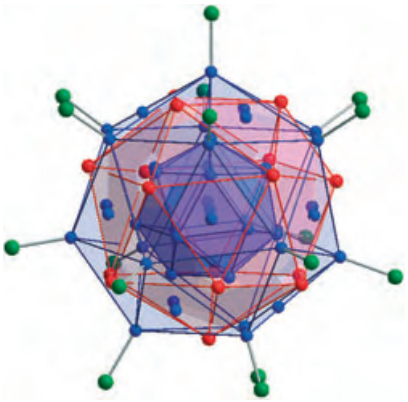
Electron Density and Bonding at Inverted Carbon Atoms: An Experimental Study of a [1.1.1]Propellane Derivative

Synchrotron radiation was required for high-resolution diffraction experiments to determine the electron density and analyze the topology of a new [1.1.1]propellane derivative. A bond path with a bond critical point of significant electron density was found between the "inverted" bridgehead atoms C4···C4a (see picture), which is characteristic for a covalent bond; however, no charge accumulation at the bond critical point was seen.



Stable Methanides

H. Brand, P. Mayer, A. Schulz,* J. J. Weigand — **3929 – 3932**



Nitro(nitroso)cyanomethanides

More bangs for the buck. Explosive nitro(nitroso)cyanomethanides $M'[C(NO_2)(NO)(CN)]$ ($M' =$ alkali metal, NMe_4) were prepared in a simple, two-step, high-yielding procedure, fully characterized, and shown to be stable at ambient temperature. The thermal properties were studied, and the structures of several nitro(nitroso)cyanomethanide salts were determined by X-ray diffraction. The structure and bonding in these compounds are discussed on the basis of calculations.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Molecular alloys: The composition and properties of the title compounds suggests that they can be regarded as molecular alloys. The single-crystal structures of these phosphine-stabilized compounds are determined (see picture for structure of $[Cu_{45}Sb_{16}(PEt_2Me)_{16}]$; Sb red, Cu blue, P green) and confirmed by density functional theory (DFT) calculations.

Hans Bethe (1906–2005) and Ligand Field Theory

Hans Albrecht Bethe, probably the last of the pioneer generation of quantum mechanics and certainly one of the most important physicists of the 20th century, died on March 6, 2005, at almost 99 years of age. Rather than to extend another note of appreciation for Bethe's contributions to such fields as nuclear physics or astrophysics, it is more appropriate for this Journal to recall what chemistry owes him. Hans A. Bethe was born July 2, 1906 in Strassburg. He graduated from the University of Munich in 1928 after conducting research with Arnold Sommerfeld on electron scattering in crystals. He was active at various German universities and became assistant professor at the University of Munich in 1930. In 1929 his seminal paper on crystal field theory was published.[1] Between 1930 and 1935 Bethe worked in Rome (with Enrico Fermi) and at various English universities. After his departure from Nazi Germany he was offered a professorship at Cornell University (Ithaca, NY) in 1935 where, with the exception of some interruptions during World War II, he stayed until the end of his life.

Bethe's review on the theory of one- and two-electron atoms for the *Handbuch der Physik* of 1933 was the precursor of the famous *Bethe–Salpeter*.[2] For the serious study of atoms and molecules, this classic cannot be ignored. Of equal fundamental importance is a series of papers on nuclear physics[3] that soon became known as the Bethe bible. Most of Bethe's papers had no direct relation to chemistry. Nevertheless, his contributions to quantum electrodynamics (QED) are relevant even for theoretical chemistry. For example, his explanation of the Lamb shift, the QED correction to one-electron levels,[4] is gaining importance in the theory of heavy atoms and their molecules. Bethe's studies of the many-body problem in nuclear physics[5] have stimulated the treatment of the many-electron problem in quantum chemistry.

In 1967 Hans Bethe received the Nobel Prize in physics "*for his contributions to the theory of nuclear reactions, especially his discoveries concerning the energy production in stars*". His creation of crystal field theory may well have been deserving of the Nobel Prize in chemistry. Most of what can be learned about the formalism of the theory from modern textbooks of inorganic chemistry is found in Bethe's original papers.[1] Bethe investigated how the electronic states of open-shell ions, mainly those of transition metals, are influenced by the surrounding ions in a crystal. He proposed that the influence of the ligands can be described by an electrostatic 'crystal field'. This field lowers the symmetry with respect to the free atomic ions, which leads to a shift and splitting of the atomic states. The energy level scheme is determined by three parameters, the ligand field strength, the asymmetric portion of the electron interaction, and the spin–orbit interaction. Bethe distinguished three limiting cases of strong, intermediate, and weak fields. Currently, the term weak field is used for what Bethe described as the intermediate field (in which the electron interaction dominates over the ligand field strength), whereas the original weak field of Bethe is now known as the coupling case of the rare-earths (in which the spin–orbit interaction dominates). In the strong field, terms with low spin are preferred, as predicted by the aufbau principle. The present-day weak field favors terms with high spin in the spirit of Hund's rules. To appreciate Bethe's achievement fully, one must realize that around 1930, the theory of the representations of point groups had not yet been developed; he had to work them out himself. He also invented the double groups that are needed to describe relativistic states.

Bethe's theory had been applied to the magnetic properties of molecular complexes in the early 1930s.[6,7] However, more than 20 years would pass before ligand field theory, built upon crystal field theory, would become the standard model for understanding the spectra of transition metal complexes.[8–10] It is now known that the description of the effect of the ligands in terms of an electrostatic field is not very realistic, and that energy level splitting by the ligand environment is instead the result of chemical (overlap-dependent) forces.[11] One quality of Bethe's theory is that most of its results are the consequence of symmetry, and do not necessarily depend on the electrostatic model. For a considerable time, crystal field theory in Bethe's original meaning was distinguished from ligand field theory as a modification for molecular complexes, but this distinction is now of little more than historical interest. As even transition metal complexes are currently applicable to ab-initio calculations, crystal field theory is outdated as a scheme for approximate computations. However, it is still a valid model for a qualitative understanding of the spectra and other properties of transition metal complexes. It plays a similar fundamental role in inorganic chemistry as does the Debye–Hückel theory in organic chemistry.

Bethe was a participant in the Manhattan Project (the construction of the atomic bomb in the U.S.) as head of the theory group at Los Alamos. After the war, he became one of the most prominent advocates (even as an advisor to US presidents) for a change in energy policy and of nuclear disarmament and weapons test bans. Those who knew Hans Bethe well, describe him as a very modest and extremely friendly person.

MASAKATSU SHIBASAKI and YOSHINORI YAMAMOTO, (eds.)

Multimetallic Catalysts in Organic Synthesis

The reference comprehensively covers this hot topic presenting the information hitherto scattered throughout smaller reviews or single book chapters to provide an introduction to this rapidly expanding field.
In ten chapters, the international team of expert authors treats asymmetric syntheses, new transformations, and organometallic reactions using homo- and hetero-bimetallic catalysts. Written for advanced researchers, this very timely publication is of significant benefit to organic and organometallic chemists in both academia and industry.

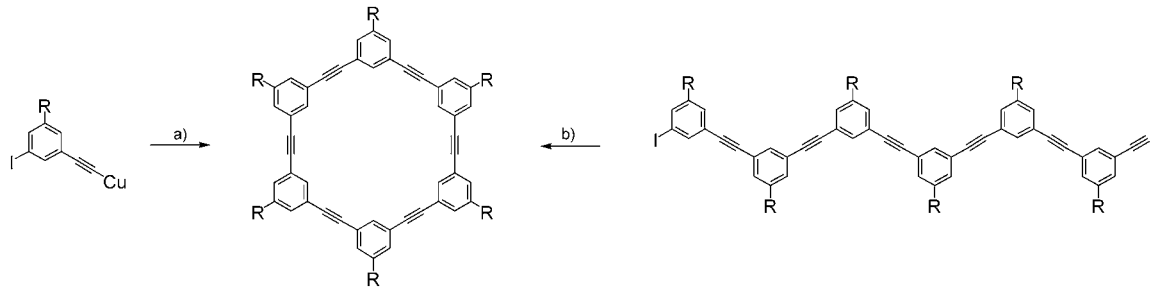
Macrocycle Synthesis

Shape-Persistent Phenylene-Acetylene Macrocycles: Large Rings—Low Yield?



*Sigurd Höger**

Keywords:
alkynes · cyclophanes · macrocycles · metathesis · supramolecular chemistry

Shape-persistent macrocycles have gathered increasing interest over the past several years.[1] Rings that contain phenylethynyl, phenylbutadiynyl, or both moieties (phenylacetylene macrocycles, PAMs) are especially valuable candidates for investigations of the supramolecular chemistry of nanometer-scale rings. First, palladium-catalyzed aryl–alkyne bond formation is easily carried out (Sonogashira–Hagihara coupling); the coupling protocols have a great functional-group tolerance and acetylene protecting groups of various stabilities and polarities have been well-described. Second, the spacers between the aromatic rings avoid steric constrains between groups that are necessarily attached to the rigid backbone, to ensure the tractability of the macrocycles. The shape and size of the molecules depend on the substitution pattern of the arenes. Although pure *para*-substituted cyclic phenylacetylenes have been investigated,[2] most PAMs contain *meta*- or *ortho*-substituted arenes at their corners and *para*-substituted arenes for the expansion of interior space.

In 1974, Staab and Neunhoeffer reported the synthesis of the *m*-cyclophane **1a** by the intermolecular, sixfold Stephens–Castro coupling of the copper salt of *m*-iodophenylacetylene (Scheme 1).[3] The easily available starting material allowed the synthesis of 800 mg product, although the yield was only 4.6%. A much higher yield in the synthesis of this compound was reported by Moore and Zhang nearly 20 years later.[4] Instead of forming the ring precursor (and other oligomers) and the cyclization in a one-pot reaction, an α-iodo-ω-ethynyl precursor was prepared separately and then cyclized under high-dilution conditions in the final step to give **1b** in excellent (75%) yield. Apart from the high yield in the cyclization step (along with an easy purification of the product), this is the method of choice for the preparation of macrocycles with varying functional groups on the phenyl building blocks, as the precursor is built up stepwise. Cyclic pentamers, heptamers, and other defined oligomers that were not described until now are also available in high yield through this approach.

The repetitive precursor synthesis, however, is also responsible for the major disadvantage of this approach: it requires numerous deprotection/coupling steps. In addition to these two extreme strategies, numerous intermediate approaches can be found in the literature, for example, the dimerization of half-rings, trimerization of ring thirds, and so on. Similar approaches are also described for phenylenyl, phenylbutadienyl, and other shape-persistent rings.[5] Regardless of the specific C–C coupling reaction used, all protocols generally suffer from the same handicap: simple precursors are easily accessible, but give low yields of the desired shape-persistent ring, whereas high yields in the cyclization step require a time- and material-intensive multistep preparation of precursors.

Templates are an attractive way to overcome this problem and Sanders and co-workers were able to show that ethynylphenyl-substituted Zn porphyrins can be cyclodimerized or cyclotrimerized, depending on the specific pyridyl template present in the reaction media.[6] We showed that covalent templates also increase the yield of the desired cyclic products dramatically, thus allowing the preparation of symmetrically and even nonsymmetrically functionalized PAMs in high yields.[7] However, the supramolecular and covalent template approaches require the presence of appropriate functional groups that bind (or are bound) to the template.

Another approach involves preparation of the macrocycle under thermodynamic control. For cases in which the desired structure is the most stable under the given conditions and the cyclization reaction is reversible, it might be possible to obtain a single macrocyclic product in quantitative yield despite having begun the synthesis with small building blocks.[8,9]

Imine formation is a convenient way to generate macrocycles in high yields.[10,11] In recent years, the synthesis of arylacetylene macrocycles containing imine bonds was described, in which the cyclization step involves the formation of a Schiff base (Figure 1). For example, Moore and Zhao prepared the imine-containing macrocycle **2** in nearly quantitative yield by the condensation of the appropriate diamine and dialdehyde.[12] In this case, however, both starting materials (half rings) needed to be prepared separately through a multistep sequence.

Recently, shape-persistent imine-containing macrocycles have also been obtained from smaller building blocks. MacLachlan and Gallant prepared the soluble 30-membered ring **3** in 70% yield through the thermodynamically favored [3+3] cyclocondensation of the corresponding dialdehyde and diamine.[13] The product behaves like a crown ether, as it binds alkali metal ions. Based on titrations monitored by UV/Vis and NMR spectroscopy, it was suggested that upon complexation, the macrocycles aggregate toward tubular assemblies. Last year, the extension of this reaction sequence toward the preparation of larger macrocycles was presented. Condensation of the corresponding dialdehydes and diamines gave the macrocyclic products **4** and **5** in a one-pot, template-free synthesis in 68 and 40% yield, respectively.[14] Subsequent metallation of **4** has shown that this macrocycle can coordinate multiple transition metals in its salen-like pockets, and titration of **4** with Zn^{2+} strongly increases its fluorescence. Therefore, large rigid macrocycles with adjustable diameters and intraannular binding sites are available in good yield having started with rather simple building blocks.

Likewise, Moore and Zhang described a new approach toward arylacetylene macrocycles by using the reversibility of the alkyne metathesis reac-

tion.[15] Starting from the simple bisacetylene **6a** and a highly active Mo^{VI} alkylidyne catalyst, the macrocycle **7** was obtained in high yield (81%) when the reaction was carried out on the milligram scale under open driven conditions to remove the by-product, 2-butyne (Scheme 2).[16]

Several *m*-cyclophanes of this type were synthesized with similar yields, demonstrating the general applicability of this concept. However, attempts to increase the scale of the reaction were not successful; mainly oligomeric products were produced. It was suggested that either the 2-butyne by-product could not be removed quickly enough from the reaction mixture if the metathesis is performed on the gram scale, or that air could have led to decomposition of the catalysts. Accordingly, an alternative approach for shifting the metathesis equilibrium was explored.[17] Instead of removing a volatile by-product under vacuum, an insoluble by-product may separate from the reaction mixture in a closed system. Indeed, under optimized reaction conditions, it was possible to prepare more than 5 g (77%) of **7** in one batch when the benzoylbiphenyl-substituted arylacetylene **6b** was cyclized in CCl_4.

30 years after the report of Staab and Neunhoeffer on *m*-cyclophane **1**, arylacetylene macrocycles have now become available in high yields even with the use of small molecules as precursors. Although the structural variability that can be obtained through repetitive precursor synthesis is not yet known, the syntheses described herein will clearly open new possibilities for future investigations of the structure–property relationships in this interesting class of compounds.

Ionic Liquids

Liquid Inorganic–Organic Nanocomposites: Novel Electrolytes and Ferrofluids

Bernd Smarsly and Helena Kaper*

Keywords:
conducting materials · ferrofluids · ionic liquids · organic–inorganic hybrid materials · polyoxometalates

Inorganic–organic nanocomposite materials have been frequently proposed in the past years as the key to various challenges in the field of future technology such as energy supply, storage and production (fuel cells, batteries, solar cells) and information technology. Ideally, the partitioning of the inorganic and organic species on the nanometer scale is expected to create a homogenous composite showing the advantageous physico-chemical properties of both moieties.[1] To date, for the organic moiety, the main focus of research has been on polymers (e.g. in proton-exchange membranes in fuel cells).[2] Attractive candidates for the inorganic parts are semiconductors, (such as TiO_2, CdS) and magnetic oxides. One of the most prominent recent examples of such nanocomposites are novel solid-state solar cells. They are based on films containing semiconductive, nanocrystalline TiO_2, an electrolyte, and a sensitizing dye.[3] Further important examples of inorganic components are magnetic nanoparticles, such as Fe_2O_3, which could be used for any kind of fluidic magnetic material.[4] Considering these potential applications, composites should fulfill the following requirements (among others): high conductivity of the electrolyte, low vapor pressure and reasonable thermal stability of the organic part (with respect to the conductivity, etc.), optimized viscosity, homogenous distribution of the inorganic and organic phases on the nanometer scale (no macroscopic phase separation), solvent-free processing, a reasonable chemical stability (electrochemical, redox, and hydrolytic stability) and improved processing properties with regard to fluidity requirements (films). The properties of the inorganic and organic species should be maintained in the composite, but eventually also new desired properties could be obtained. However, many of these basic demands are not matched yet by currently available materials. For instance, some of the delicate problems of water-based ion conductive nanocomposite membranes used in fuel cells are related to the nature of water in the membrane, differences in mechanical strength and the ductility as a function of the water content.[2,5] Also, water-based electrolytes are only operable at relative low temperatures, which represents a significant hurdle for fuel cell applications. The interest in non-aqueous electrolytes with low viscosity is therefore driven by the development of rechargeable batteries and fuel cells.[6] Ionic liquids (ILs; organic salts with melting points below 80 °C) have been identified as ideal materials to solve some of these shortcomings of water-based electrolytes because they combine high conductivity (both protic and aprotic ILs are known) with low viscosity and an extremely low vapor pressure.[7] It was recently reported that certain ILs even reach the conductivity and ionicity of water, and also have a sufficiently high ductility.[6,8] These properties make them promising candidates as electrolyte medium in fuel cell and solar cell devices.[9] While most of the developments in the field of ILs focused on optimizing the conductivity and vapor pressure, the generation of nanocomposites of ILs with inorganic species has been neglected up to now. As shown recently, certain ILs also act as a template to create highly ordered mesostructured oxidic materials.[10,11] Hence, these materials fulfill several of the aforementioned requirements for useful nanocomposites.

In the light of these recent developments, Giannelis and co-workers have reported a further important attempt to prepare the so far unavailable organic–inorganic nanocomposites with "liquid-like" behavior. They described a composite based on polyoxometalates (POMs).[12] POMs are composed of transition-metal-ion clusters in which the metal centers coordinate to oxygen atoms and have an octahedral coordination environment. POMs can form various shapes such as balls and wheels.[13] Solid POM protonic conductors are potentially interesting as electrolytes in fuel cells, however, this potential is limited by the sensitivity of their protonic conductivity, in particular towards humidity and higher temperatures. An elegant strategy to reduce the sensitivity substantially is shielding the surface of the POMs with suitable ionic organic molecules. Kurth et al. and Polarz et al. had already reported the formation of ordered, mesostructured aggregates of molybdenum-based POMs with ionic surfactants, which could even be imbedded in organic species.[14,15]

Giannelis and co-workers went a step further and obtained a solvent-free POM-containing liquid salt with zero vapor pressure, good thermal stability, high proton conductivity, and superionic behavior.[12] Selected poly(ethylene glycol) (PEG) containing quaternary ammonium cations were attached to POMs: in a simple procedure, a commercially available heteropolyacid POM such as $H_3PW_{12}O_{40}$ was treated with species such as $(CH_3)(C_{18}H_{37})N^+$-$[(CH_2CH_2O)_nH][(CH_2CH_2O)_mH]Cl^-$ ("S^+Cl^-"), leading to a partial exchange of surface protons of the POM (yield about 40%) to give $H_{3-x}S_xPW_{12}O_{40}$ ($x \approx 2$). This method takes advantage of the low viscosity and melting points of organic species such as S^+ (the coupling with PEG oligomers is an established technique to reduce the melting point and viscosity of organic salts[7]). This modified POM has a viscosity of 75 Pa s at room temperature, which drops to 0.5 Pa s at 120 °C. For comparison, water has a viscosity of approximately 10^{-3} Pa s and honey of 0.104 Pa s at room temperature, and the viscosity of ILs is usually significantly smaller than that of the "liquid" POMs (in general below 0.1 Pa s).[7a,8]

While still showing a high viscosity, this POM-based "inorganic liquid" show a reasonable conductivity over a broad temperature range, for example, 6×10^{-4} S cm^{-1} at 140 °C. Furthermore, in comparison to a corresponding solid potassium-substituted POM, the ionic conductivity of the liquid POM salt is extremely high, it exceeds that of the potassium-exchanged analogue by three orders of magnitude. This high conductivity has been attributed to superionic behavior.[12] Hence, the proton conductivity and the liquid-like character of this POM suggests applications in fuel cells or catalysis. Moreover, through the IL, the magnetic, electrochemical, and optical characteristics of POMs might be exploited in the field of organic chemistry.

Giannelis and co-workers also offer an approach towards the generation of inorganic liquid-like oxidic nanoparticles through surface functionalization by organosilanes (Figure 1).[16] In the first step, the surface of the silica nanoparticles is modified through condensation of surface silanol groups with a charged organosilane $(CH_3O)_3Si(CH_2)_3N^+$-$(CH_3)(C_{10}H_{21})_2Cl^-$. A solution of the organosilane in methanol was added to a suspension of silica particles in water, and the precipitate, which forms immediately, was aged at room temperature for 24 h. The nature of the counterion determines whether a salt is obtained that is liquid at room-temperature. While a simple chloride ion gives a typical solid salt, a subsequent ion exchange with a more complex PEG-containing sulfonate ion leads to the desired liquid salt. For this step, the chloride analogue was treated with a solution of $R(OCH_2CH_2)_7O$-$(CH_2)_3SO_3^-K^+$ ($R = C_{13-15}$ alkyl chain) in water at 70 °C for 24 h. A high organic content of around 75 wt.% was achieved and the material had a liquid-like ionic-conductivity temperature dependence and rheological performance ($G'' > G'$). In contrast, isostearate (50 wt.% organic content) and oleate (40 wt.% organic content) as counterions resulted in quite viscous gel-like materials at room temperature that only reached a low viscosity at temperatures above 120 °C. These results show the substantial dependence of the macroscopic properties on the chemical composition.

The liquid salt obtained from the silica nanoparticles was used to dissolve and polymerize pyrrole (Figure 2), thus demonstrating that such inorganic liquid salts can serve as a reaction medium in which interesting inorganic–organic composites with extra functionality can be generated.

Figure 1. Schematic representation of silica or γ-Fe_2O_3 nanoparticles linked to liquid organic salts; A^- poly(ethylene glycol) sulfonate ion.

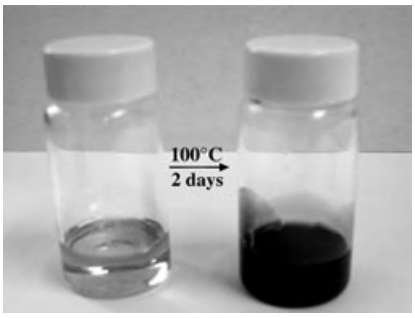

Figure 2. Liquid salt, based on silica nanoparticles, containing pyrrole before (left) and after (right) polymerization.

The preparation of liquid salts of maghemite (γ-Fe_2O_3) is a significant extension of the reported strategies for surface-functionalized iron oxide nanoparticles.[17] The synthesis is quite similar to the one used for the silica particles. The silane solution was added to a suspension of Fe_2O_3 in alkaline water (pH 10), giving the maghemite chloride salt. Then the desired sulfonate derivative was obtained through ion exchange with the PEG-containing sulfonate ion. Since the superparamagnetism of the nanoparticles remained unaffected through this procedure, a solvent-free, ionically conductive ferrofluid (a "magnetic liquid electrolyte") was obtained. Unlike the "SiO_2 liquids", the maghemite system showed a liquid-like behavior with only moderate viscosity at room temperature and flowed easily at 40 °C. For both types of inorganic nanoparticles, rheological properties can be expected to be improved by the suitable choice of the organic counterion. Further work has to focus on the improvement of the still low ion conductivity and high viscosity of the "inorganic liquids", which limit their application as electrolytes or reaction mediums.

Besides surface functionalization of nanoparticles through counterion exchange, other successful "nanochemical" approaches towards ferrofluids were described recently: Landfester et al. introduced straightforward and reliable strategies to obtain stable emulsions of magnetic iron oxide particles both in aqueous and non-aqueous media, with loadings up to 40%.[18] One advantage is that such emulsions have a much lower viscosity than the liquid salts, eventually improving their processing properties. However, the materi-

als introduced by Giannelis and co-workers for the first time show ionic conductivity in addition to the liquid and magnetic properties, which is difficult to achieve by emulsion strategies.

The "inorganic liquid salts" can be regarded as important examples of the potential of nanochemistry to create materials with completely new properties: the combination of the physical properties of inorganic species such as binary oxide nanoparticles or POMs with those of organic liquid salts generated a "chimera", showing properties, which before had not been considered to be compatible in one homogeneous material. Once again, organic liquid salts ("ionic liquids") have demonstrated their potential to significantly contribute to solutions for future technologies.[7,10] But perhaps it is not even necessary to establish a covalent linkage between the organic liquid salt and the nanoparticles: Recently, Antonietti and co-workers reported on a low-temperature synthesis of crystalline TiO_2 nanoparticles within ionic liquids of low viscosity.[11] Also in this case the inorganic species were well dispersed in the liquid organic salt, but without a covalent bond between the organic part and the inorganic particles. This concept and the approach of Giannelis and co-workers could be suitable general strategies in quite different areas such as batteries and solar cells: noteworthy was that the addition of certain liquid salt electrolytes significantly improved the stability of titania-based solar cells of the Grätzel-type.[9] A "vision" in this field is the use of dye-sensitized "TiO_2 liquids" to improve their processing properties and conversion rate of such solar cells.

The fabrication of "inorganic liquids" now presents a new conceptual methodology in materials chemistry: combining suitable nanoparticles and well-chosen ionic liquids opens new vistas towards a facile, rational strategy to create inorganic liquids with optimized conductive and rheological properties.

The protein tyrosine phosphatases (PTPs) constitute a family of closely related key regulatory enzymes that dephosphorylate phosphotyrosine residues in their protein substrates. Malfunctions in PTP activity are linked to various diseases, ranging from cancer to neurological disorders and diabetes. Consequently, PTPs have emerged as promising targets for therapeutic intervention in recent years. In this review, general aspects of PTPs and the development of small-molecule inhibitors of PTPs by both academic research groups and pharmaceutical companies are discussed. Different strategies have been successfully applied to identify potent and selective inhibitors. These studies constitute the basis for the future development of PTP inhibitors as drugs.

1. Introduction

Protein phosphorylation and dephosphorylation reactions are employed by living organisms for the regulation of innumerable cellular processes; aberrancies in protein phosphorylation contribute to the development of many human diseases such as cancer and diabetes.[1] Phosphorylation states are governed by protein kinases (PKs), which catalyze protein phosphorylation, and protein phosphatases (PPs), which are responsible for dephosphorylation (Scheme 1). Given this complementary relationship and the fact that PKs are established targets for drug discovery,[2] it is surprising that the development of small-molecule inhibitors of PPs has emerged only recently as a rapidly growing area of investigation in clinical biology and medicinal chemistry. Protein phosphatases have been classified by structure and substrate specificity into protein serine/threonine phosphatases (PSTPs) and protein tyrosine phosphatases (PTPs). Among the PPs, the development of small-molecule inhibitors of PTPs[3] has attracted considerable attention in both basic research and pharmaceutical investigations.[4] This development was undoubtedly triggered by the discovery that disruption of the *ptp1b* gene in mice confers resistance to obesity and increases insulin sensitivity without negative side effects (Section 5.2).[5] Moreover, the use of antibodies to modulate the activity of CD45, the first transmembrane phosphatase discovered, has been shown to prevent rejection of organ transplants and the formation of Alzheimer plaques in animal models.[6] In this review, we discuss the recent advances in the field of PTP inhibitor discovery with a focus on phosphatases that could be among the targets of the next drug generation. The inhibition of PSTPs has been investigated intensively, mainly through research in basic chemical biology. This topic has been discussed elsewhere[7] and is therefore not a subject in this review.

2. PTPs and Diseases

PTPs exert key regulatory functions, and thus it does not come as a surprise that the perturbation of PTP activity has been linked to various diseases (Table 1). On the one hand, mutations which inactivate PTPs have been correlated with genetic disorders like the lafora disease[8] and the autoimmune disease, systemic lupus erythematosus (SLE).[9] On the other hand, many PTPs act as tumor suppressors[10] and are mutated or underexpressed in diverse cancers.

More interestingly, some PTPs enhance disease which indicates that their inhibition could be of immense therapeutic interest. For example, the bisphosphonate alendronate (**1**, Section 7.2, Figure 5) is a drug used to treat osteoporosis. It inhibits PTP-ε, a phosphatase that plays a significant role in the development of osteoclasts, which are responsible for bone resorption.[11] It has been proposed that the main action of alendronate comes at least partially from its inhibitory activity toward PTP (alendronate is also thought to exert its action through the inhibition of enzymes of the mevalonate pathway). Many immune diseases and allergic reactions involve the receptor phosphatase CD45.[12] In cancer, the Cdc25 phosphatases enhance cell growth by stimulation of the cell cycle. The inhibition of Cdc25 could therefore be useful as a course of anticancer therapy.[13] Another interesting target that is currently under investigation by Incyte is the dual-specificity phosphatase MKP-1, which inactivates the JNK kinase and is overexpressed in various cancers.[14] Many PTPs are major players in the field of neurological disorders. The inhibition of CD45 is especially likely to be a successful approach toward therapeutic treatments for Alzheimer's disease.[15] Many bacteria like *Salmonella typhimurium* (the typhus pathogen) and *Yersinia pestis* (the plague pathogen) use their own phosphatases (such as YopH of *Yersinia*,[16] which blocks phagocytosis by macrophages), or the host-derived phosphatases (such as RPTP-β of *Helicobacter*)[17] to infect their hosts or escape from an immune response. PTP inhibition would thus constitute a valuable strategy against infectious diseases and bioterrorism. Another area which could benefit from PTP inhibitors is in the treatment of type 2 diabetes and obesity. In this respect, the phosphatase PTP1B is a particularly promising target[5] (Section 5.2).

Table 1 shows some PTPs which play a major role in the development of disease. Some of these phosphatases constitute potential therapeutic targets. This review summarizes the efforts which have been made in the development of small-molecule phosphatase inhibitors for new therapeutic strategies. Other strategies, such as antisense (ISIS is currently developing an antisense drug against PTP1B (ISIS 113715), which has entered phase II clinical trials for the treatment of type 2 diabetes) and antibody treatments, are not discussed herein.

3. PTPs and Dual-Specificity Phosphatases: General Classification

The PTP superfamily (107 human PTP genes have been identified) is divided into four categories according to the amino acid sequence of PTP catalytic domains (Figure 1).[46] The first category is made up of the type I cysteine-based PTPs, which share a characteristic motif of ≈250 residues. This highly conserved "PTP-domain" catalyzes the enzymatic reaction in which an active-site cysteine group plays a central role (Section 4). The classical PTPs (nonreceptor and receptor PTPs) that are specific for phosphotyrosine substrates are members of this class. Some receptor PTPs contain two PTP domains, although usually only one is active. The dual-specificity phosphatases (DSP) also belong to this first group of PTPs, but in contrast to the classical PTPs they catalyze the dephosphorylation of both tyrosine and serine/threonine residues of their protein substrates. The DSP family contains special types of tyrosine phosphatases, which are mentioned only briefly in this review; these include members of the myotubularin (MTM) family,[47b] the C-terminally prenylated PRL-type phosphatases,[47c] RNA triphosphatases,[47d] and PTEN-type phosphatases,[47e] which accept inositol phosphates as substrates.

The second PTP group is the class II cysteine-based PTPs. This type of phosphatase is especially common in bacteria, whereas only one gene (*lmptp*) has been found in humans. Class II PTPs are not discussed in this review.[47a]

Although they are also able to catalyze the dephosphorylation of both tyrosine and serine/threonine substrates, the

Herbert Waldmann, born in 1957, received his PhD in 1985 with Horst Kunz at the University of Mainz. After postdoctoral studies at Harvard University with George Whitesides and a lectureship at the University of Mainz, he accepted a professorship at the University of Bonn in 1991. In 1993 he moved to the University of Karlsruhe as full professor of organic chemistry. In 1999 he was appointed as Director at the Max Planck Institute of Molecular Physiology in Dortmund (Department of Chemical Biology) and as full professor of biochemistry at the University of Dortmund. His honors include the Friedrich Weygand Award, the Carl Duisberg Award, the Otto Bayer Award, the Steinhofer Award, and the Max Bergmann Medal.

Laurent Bialy, born in 1974 in Karlsruhe, studied chemistry between 1992 and 1998 in Karlsruhe. He finished his PhD in 2002 at the Max Planck Institute for Molecular Physiology and the University of Dortmund on the synthesis and biological evaluation of the phosphatase inhibitor cytostatin and its analogues. As a postdoc with Mark Bradley at the University of Southampton, he investigated applications of PNA–peptide conjugates and microarray technology to the field of combinatorial chemistry. He is the laureate of the International DSM Award, the Prize of the Chemical Society of Karlsruhe, and the Klaus Grohe Award for medicinal chemistry.

Table 1: Protein tyrosine phosphatases linked to various diseases.

Disease Class	PTPs Involved	Physiological Effect(s)
immune diseases, organ transplantation, inflammation	SHP-1	mutation causes moth-eaten phenotype;[18][a] negative regulator of allergic responses[19]
	CD45	inhibitors as potential drugs against xenograft rejection[6]
	PTP-ε	immune response[20]
cancer	PTEN[a]	tumor-suppressor gene[21]
	PTP-α	activates kinases Src/Fyn[22]
	Cdc25A, Cdc25B	stimulate cell cycle progression; oncogenic roles[13]
	FAP-1[a]	apoptosis induction[23]
	HePTP[a]	regulates ERK; changes in expression linked to hematopoietic malignancies[24]
	PRL-3	tumor metastasis[25]
	PTP1B	dephosphorylates and activates c-Src in human breast cancer cell lines[26]
	JSP-1	activates the MAPK JNK[27]
	SAP-1[a]	negatively regulates integrin signaling; downregulated in hepatocellular carcinoma[28]
	RPTP-β/PTP-ζ[a]	highly expressed in a glioblastoma cell line[29]
	SHP-2[a]	mutation causes juvenile myelomonocytic leukemia[30]
	SHP-1[a]	tumor suppressor by degradation of JAK kinases[31]
	PTP-χ[a]	frequently deleted in renal and lung cancers[32]
	CD45	correlates with proliferation rate of myeloma cells[33]
	PacP (prostatic acid phosphatase)[a]	decreased activity in prostate cancer cell lines[34]
	MKP-1	overexpressed in cancers[14]
neurological diseases and neuroprotection	Laforin[a]	mutation causes lafora progressive myoclonus epilepsy[8]
	LAR	downregulation prevents apoptosis, inhibition could be useful for nerve regeneration[35]
	PTP-σ	nerve regeneration is faster in PTP-σ knock-out mice[36]
	CD45	Alzheimer's disease[15]
	SHP-1	neuroprotection[37,38]
	SHP-2[a]	neuroprotection[39]
infectious diseases	*Yersinia* YopH	essential for virulence[16]
	Salmonella SptP	essential for virulence[16]
	SHP-1	leishmaniasis[40]
	SHP-2	activated by *Helicobacter pylori*[41]
	MPtpA, MPtpB	*Mycobacterium tuberculosis*[42]
	RPTP-α, RPTP-β/PTP-ζ	target of VacA from *Helicobacter pylori*[17]
diabetes	PTP1B	PTP1B knockout mice are resistant to diabetes[5]
	LAR	overexpression causes insulin resistance[43]
osteoporosis	PTP-ε	alendronate = inhibitor[11]
	GLEPP-1	renal receptor-like PTP, inactivation results in altered podocyte structure[44]
obesity	PTP1B	PTP1B knockout mice are resistant to obesity[5]
	SHP-2	negatively regulates leptin signaling which is important in obesity[45]

[a] Disease caused by inactive phosphatase; inhibition would therefore be counterproductive in these cases.

Cdc25 phosphatases form the third category of cysteine-based PTPs as class III enzymes. They are involved primarily in cell-cycle progression. Phosphatases based on aspartate instead of cysteine as a key catalytic residue form class IV of the PTPs; members of the haloacid dehalogenase (HAD) superfamily[47f] belong to this group, and are treated only briefly in this review.

PTPs are crucial for the regulation of cellular processes and therefore it is not surprising that PTPs themselves are highly regulated enzymes. Regulation mechanisms include gene expression, subcellular localization, alternative splicing, phosphorylation, and even reversible oxidation of the catalytic cysteine residue.[48]

4. Structure of the Catalytic PTP Domain and Mechanism of Enzymatic Catalysis[46]

The crystallographic structures of more than 20 PTPs have been solved and, together with mutagenesis experiments, have strongly contributed to our understanding of catalysis and substrate recognition.[49] PTPs are α/β proteins composed of β barrels flanked by α helices. The catalytic site is located in a groove at the protein surface which is deeper for classical PTPs (9 Å) than for DSPs (6 Å), a difference which explains the higher substrate selectivity of the classical PTPs. The characteristic motif $(H/V)C(X)_5R(S/T)$ and a

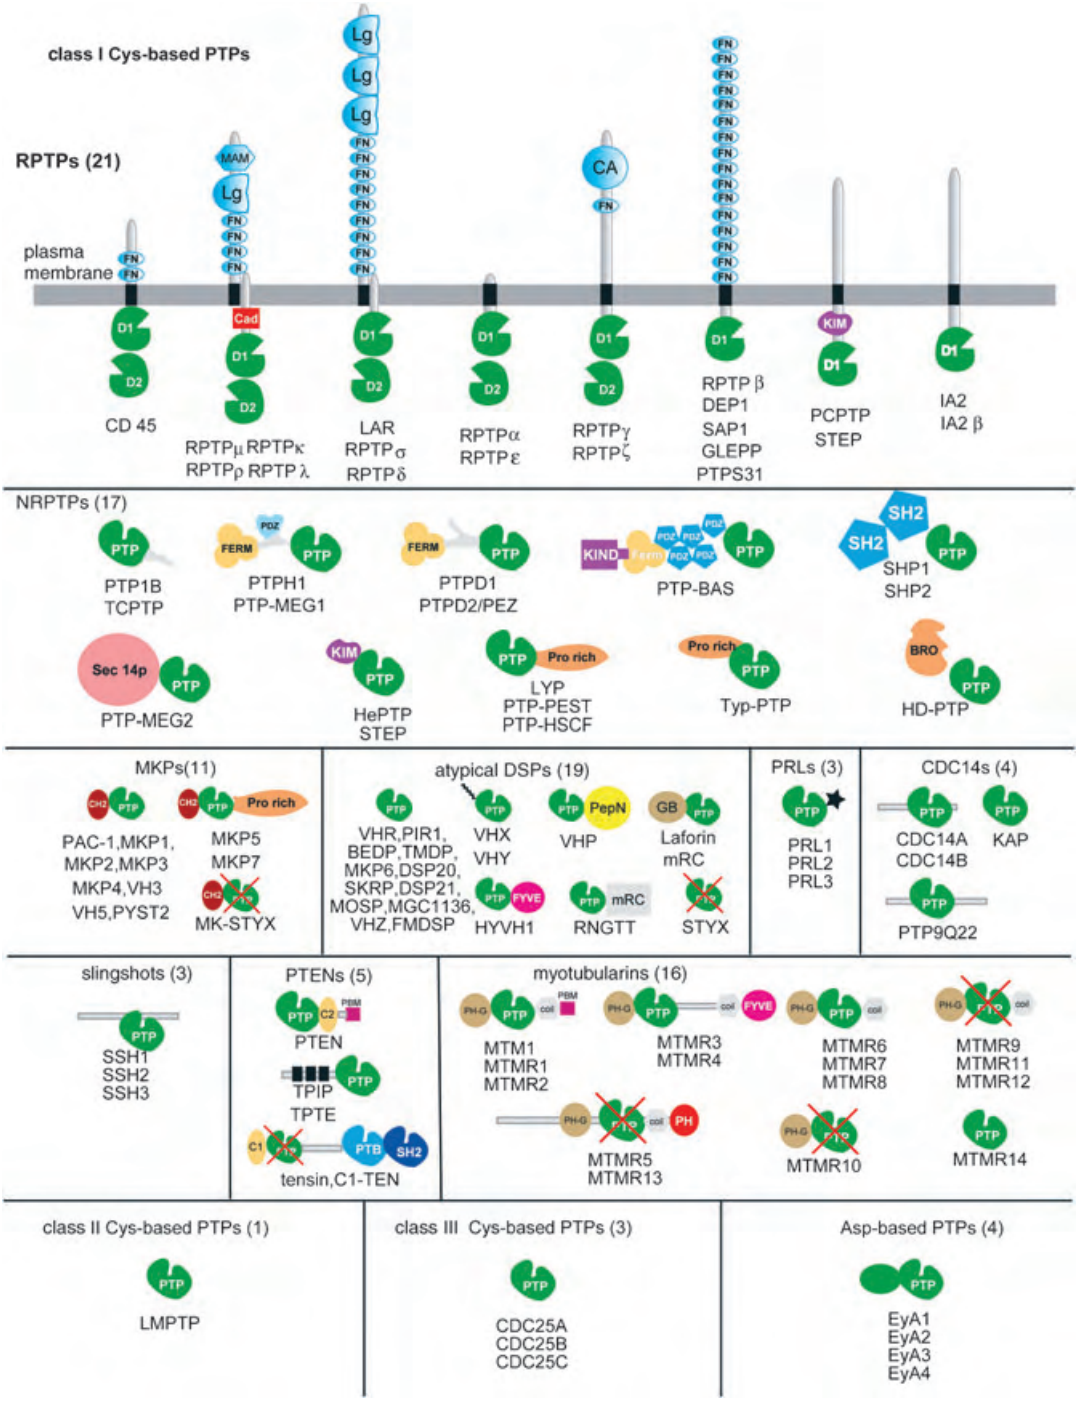

Figure 1. The PTPs are classified according to their overall composition and cellular localization (from Ref. [46b] with permission).

surface loop rich in acidic residues are further elements common to the PTP domain (Figure 2).[50]

The general mechanism is explained herein for PTP1B,[51] a phosphatase important in the insulin cascade (Section 5.2), whose mechanism is likely reflective of that for most PTPs.[46] The negatively charged phosphate substrate is stabilized by hydrogen bonds to residues of the phosphate-binding loop (P loop) and a highly conserved arginine group (Arg 221 of PTP1B; Figure 2). Furthermore, a nearby α-helix dipole stabilizes the phosphate. Upon substrate binding, the enzyme undergoes a conformational change that brings the WPD loop over the substrate-binding pocket and generates further stabilizing interactions, which are essential for substrate selectivity and catalytic activity. In the closed state, Asp 181 is positioned near the substrate and forms a hydrogen bond with the phenolic oxygen atom of phosphotyrosine. Furthermore, the phenyl ring of phosphotyrosine is sandwiched by and forms hydrophobic interactions with Tyr 46 and Phe 182.

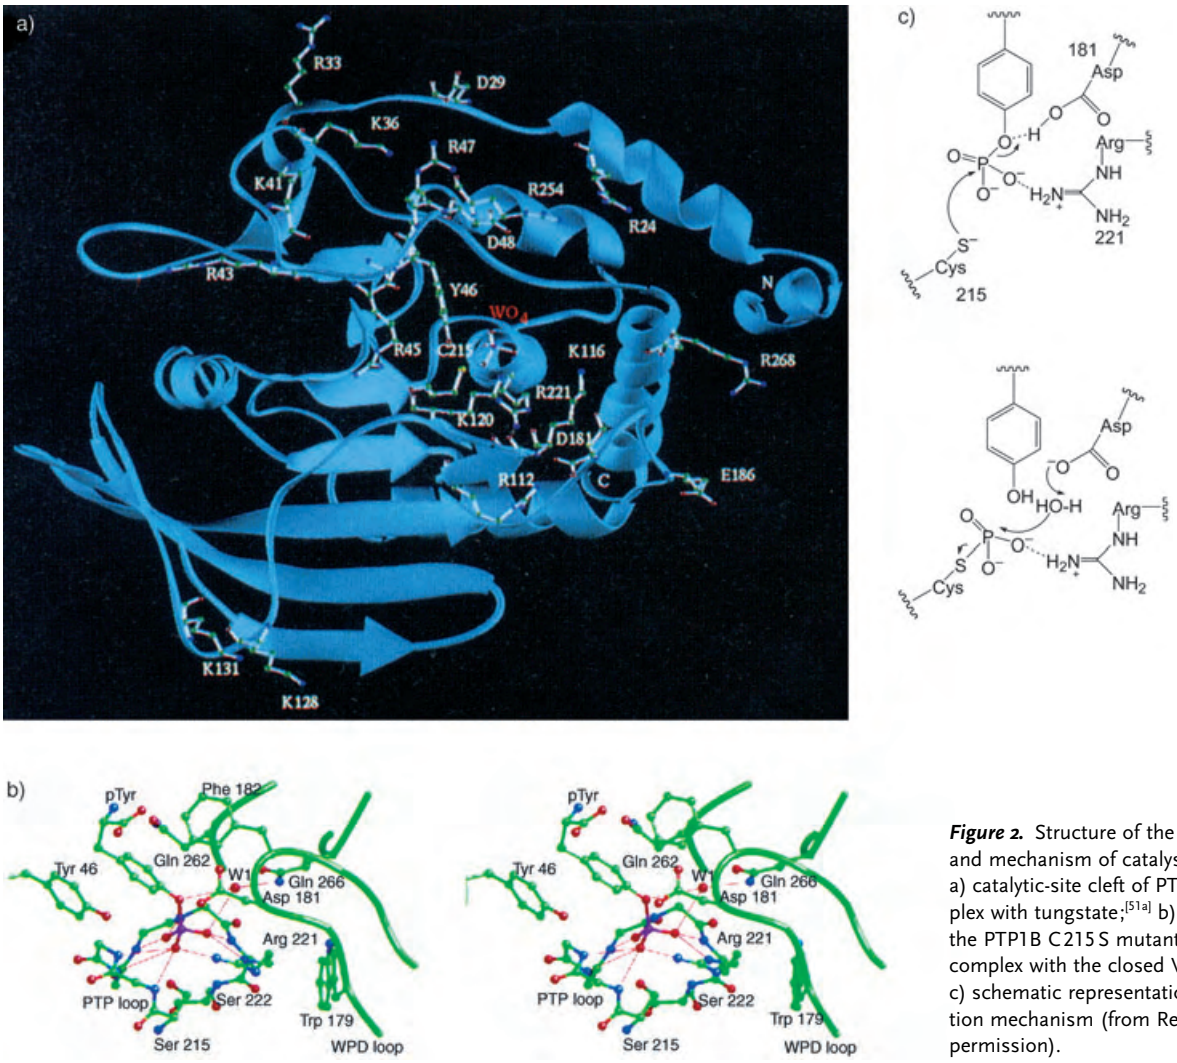

Figure 2. Structure of the catalytic site and mechanism of catalysis by PTP1B: a) catalytic-site cleft of PTP1B in complex with tungstate;[51a] b) stereo view of the PTP1B C215S mutant Tyr(P) in complex with the closed WPD loop;[51b] c) schematic representation of the reaction mechanism (from Ref. [51] with permission).

The central step of catalysis is a nucleophilic attack by a deprotonated cysteine residue (Cys215), which results in the formation of a covalent thiophosphoryl intermediate.[52] Mutational analysis has shown that substitution of the active-site cysteine totally abolishes enzymatic activity.[53] The active-site cysteine is particularly acidic in PTPs, as the thiolate anion is stabilized by several hydrogen bonds, one of which is formed with the proximal OH group of a conserved Ser/Thr moiety.[54] The geometry of the pentacoordinate intermediate is stabilized by ionic interactions with the positively charged Arg221.[55] The acidic Asp181 stabilizes the formation of a negative charge by protonation.[56] In a second step, the intermediate is attacked by a water molecule that is deprotonated by Asp181 (at this point in its basic form), thereby releasing the cysteine and regenerating the enzyme after dissociation of the product.[57] The conserved Ser/Thr group found proximal to the conserved Arg residue (Arg221) in the catalytic loop facilitates the hydrolysis of the enzyme-phosphoryl adduct, possibly through hydrogen-bond stabilization of a negative charge on the sulfur atom in the hydrolysis step of the phosphoryl-enzyme intermediate.[58]

5. Intracellular PTPs

5.1. SHP1 and SHP2

In addition to the PTP domain, the SHP phosphatases have a phosphotyrosine binding SH2 (SH2 = Src homology 2) domain of ≈100 amino acid residues, which is also present in many other signaling proteins.[59] SHP1 is mainly expressed in hematopoietic cells and exerts negative regulatory functions in signaling pathways of cytokine receptors, antigen receptors, and receptor tyrosine kinases.[60] SHP1 interacts with numerous growth factor receptors that have tyrosine kinase activity (such as the EGF receptor)[61] and cytokine receptors (like IL-R[62] and Epo-R[63]).[60] Dysfunction of SHP1 in lymphocytes has been correlated with cancers like lymphoma and leukemia;[64] SHP1 acts as tumor suppressor.[31] In contrast, SHP2 is ubiquitously expressed and exerts positive functions in receptor tyrosine kinase signaling.[65] It interacts with many signaling proteins through its SH2 domain, like the PDGF receptor,[66] the EGF receptor,[67] and IRS-1[68]. Both proteins contain two SH2 domains, of which the N-terminal domain

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

binds to the catalytic PTP domain, thereby acting in an autoinhibitory manner.[69] For example, binding of Epo-R to the N-terminal SH2 domain of SHP1 releases the catalytic PTP domain, thereby activating SHP1.[70] SHP1 and SHP2 could be valuable targets for the treatment of infectious diseases, as sodium stibogluconate, a known agent against leishmaniasis, has been found to inhibit SHP1 and SHP2.[40] SHP2 is involved in many biological pathways and has been correlated with clinical diseases such as the Noonan syndrome,[71] neutropenia,[72] diabetes,[73] and juvenile myelomonocytic leukemia.[30]

5.2. PTP1B

PTP1B was the first mammalian PTP to be purified and characterized.[74] In addition to the PTP catalytic domain, it contains a proline-rich sequence and an anchor domain which localizes the enzyme to the endoplasmic reticulum (ER). Following enzymatic cleavage from the anchor domain, the phosphatase can diffuse to its cytosolic substrates. PTP1B plays a key role in the insulin-dependent signaling cascade (Figure 3) and has attracted considerable attention as a possible target for the treatment of type 2 diabetes.

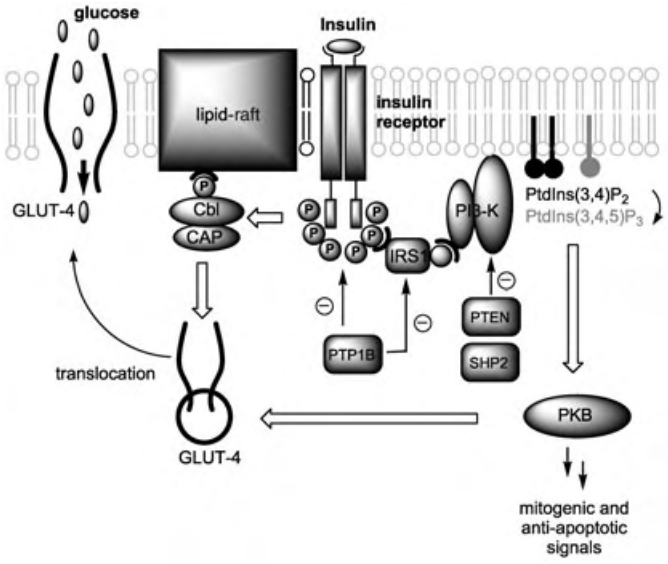

Figure 3. Schematic illustration of insulin-dependent signaling and relevant interactions with PTP1B; other phosphatases such as PTEN and SHP-2 have also been reported to exert functions in this pathway (adapted from Ref. [4] with permission).

Insulin is an anabolic peptide hormone which is secreted by the pancreatic β cells. It binds to the extracellular (α) domains of the dimeric insulin receptor (IR), which belongs to the family of receptor tyrosine kinases. Upon binding insulin, the IR undergoes autophosphorylation at tyrosine residues in the cytosolic (β) domains in a manner similar to other receptor tyrosine kinases.[75] In its phosphorylated state, the IR recruits and phosphorylates additional cytosolic molecules like the insulin receptor substrate 1, IRS-1. Phosphorylated IRS-1 is recognized by other SH2 domain-containing proteins, particularly the phosphatidylinositol 3 kinase (PI-3-K), which itself phosphorylates further substrates. By means of this cascade, insulin triggers numerous biological processes such as glycogen synthesis, fatty acid synthesis, protein synthesis and mitotic processes.[76] Of central importance is the translocation of the glucose transporter GLUT-4 from intracellular vesicles to the cell membrane which enables the cellular uptake of glucose from plasma.[77]

Type 2 diabetes, which accounts for 95% of all diabetes cases, is characterized by a deficient insulin cascade and is therefore also termed insulin resistance. PTP1B works as an insulin antagonist through the dephosphorylation and inactivation of the IR at Tyr 1150 and Tyr 1151. This has been shown by substrate trapping with an inactive C215S mutant[78] and kinetic as well as crystallographic data.[79] There are presumably additional substrates of PTP1B, with IRS-1 as a possible example.[80] The insulin antagonizing activity of PTP1B has been confirmed by many experiments. The most spectacular results were obtained from PTP1B knockout mice, in which the *ptp1b* gene has been deactivated.[5] PTP1B is not needed for embryonic development, so the mutation is not lethal. The animals showed hypersensitivity to insulin and resistance to obesity. No negative side effects of the mutation could be detected. These results have triggered intense efforts in pharmaceutical companies to identify PTP1B inhibitors as potential drugs against diabetes or obesity.[4]

In addition to its central role in the insulin cascade, PTP1B is involved in other important pathways. Of particular significance is its overexpression in human breast and ovarian cancers.[81] PTP1B dephosphorylates and thereby activates the kinase c-Src in human cancer cell lines.[26] Besides these activation functions, PTP1B also has negative-regulatory functions, for example in EGF receptor signaling[82] and integrin-mediated cell adhesion.[83] In light of these multiple functions, it comes as a surprise that PTP1B knockout mice do not show serious side effects.

5.3. Dual-Specificity Phosphatases[48]

DSPs contain the conserved active-site motif of the PTPs, $(H/V)C(X)_5R(S/T)$, but otherwise share little primary sequence identity. They accept a broader range of substrates and display catalytic activity against phosphotyrosine, phosphoserine, phosphothreonine, and even nonprotein substrates like phospholipids and RNA in vitro. The prototype of this family is VH-1, an enzyme identified in the *Vaccinia* virus.[84]

5.3.1. VHR

VHR is a human dual-specificity phosphatase.[85] It dephosphorylates and inactivates the extracellular regulated kinases (ERKs; members of the MAP kinase family).[86] The crystallographic structure of VHR has been disclosed and shows that the substrate-binding pocket is shallower than that

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

of PTP1B.[87] This difference could explain why DSPs can accommodate not only phosphotyrosine but also phosphoserine and phosphothreonine. Other members of the DSP family have been identified and show additional binding domains, like the Cdc25 homology (CH) domains which play an essential role in substrate binding and recognition. DSPs are found in the cytosol and in the nucleus and their expression is tissue-dependent.

The main role of VHR seems to be the dephosphorylation and inactivation of the MAP kinases in the activation loop TXY (in which both T and Y must be phosphorylated for enzymatic activity), which plays an essential role in signal transduction cascades.[48] Interestingly, different DSPs show a surprisingly high selectivity in the recognition of their substrates and contribute to the correct spatial and temporal regulation of MAP kinases.[48]

5.3.2. Cdc25 Phosphatases

This enzyme family is classified separately from the DSP family because they are different from other DSPs on the primary and tertiary structure levels. The Cdc25 phosphatases are present as three homologs in humans: A, B, and C.[88] They have attracted particular attention as regulators of the cell cycle, as they dephosphorylate the cyclin-dependent kinases.[89] Cdc25B has attracted considerable interest, as its overexpression has been correlated to the malignancy of tumors.[13] Thus, selective inhibitors of Cdc25B could be interesting candidates for anticancer drug development. Cdc25B activates the Cdc2–cyclin B complex in the cytoplasm (prior to its translocation to the nucleus) by dephosphorylating Cdc2 at Tyr 15, which is placed in close proximity to the ATP binding site of the enzyme.[90] The Cdc2–cyclin B complex phosphorylates and activates Cdc25C, which in turn dephosphorylates and activates nuclear Cdc2–cyclin B. The ensuing positive feedback mechanism triggers the transition from G2- to M-phase.[91]

The Cdc25A phosphatase is expressed in early G_1-phase and is responsible for the $G_1 \rightarrow S$ transition.[92] It is necessary for the activation of the cyclin E–Cdk2 complex, and is itself phosphorylated by this complex in a positive feedback loop similar to that described above for Cdc25C (for a more detailed discussion, see Ref. [93]). The inappropriate activation and/or amplification of Cdc25A and Cdc25B have been suggested to play an important role in various human cancers.[13] Several crystal structures have been published for the catalytic domains of Cdc25A and Cdc25B.[94]

5.4. Other Phosphatases

Other phosphatases have been described which exert quite diverse functions. Some of them accept phospholipids as substrates, like the phosphatase PTEN (a tumor suppressor) and myotubularin (MTM), which dephosphorylate specific inositol phosphates.[95] Members of the MTM family have been associated with human muscular and neurodegenerative diseases.[96] Another class of DSPs is formed by the enzymes Mce1 and BVP, which dephosphorylate RNA triphosphates.[97] Members of the haloacid dehalogenase (HAD) superfamily define a further protein tyrosine phosphatase class that is unrelated to the family of "classical" PTPs. It was shown recently that the nuclear transcription factor "Eyes absent", a HAD superfamily member, is a tyrosine phosphatase that hydrolyzes its substrates with a nucleophilic aspartic acid residue instead of a cysteine group, used by classical PTPs.[98] Another phosphatase type is exemplified by the prenylated enzyme PRL-3, which is overexpressed in metastatic tumors and might be an interesting therapeutic target for anticancer therapy.[25]

6. Receptor Protein Tyrosine Phosphatases (RPTPs)

Receptor PTPs contain an extracellular domain that consists of several structural motifs (immunoglobulin-like, fibronectin type, etc.), which are also found in other cell-adhesion molecules. This suggests a role for these PTPs in mediating cell–cell and cell–matrix interactions. Besides a single transmembrane domain, they contain intracellular domains, which are formed by one or two PTP domains (usually only one is catalytically active) and other noncatalytic domains involved in the regulation or subcellular localization of the enzymes. By structural and evolutionary analysis the RPTPs have been classified into eight distinct subfamilies, whereas the NRPTPs (nonreceptor PTPs) have been classified into nine subtypes[99] (Figure 1). Interestingly, there is a strong relationship between PTP domain sequence similarity and overall structural composition of the full-length proteins.[100]

The exact roles of the RPTPs have yet to be elucidated, and herein we discuss only some general features of this type of PTP, with particular emphasis on CD45, the first and best-characterized transmembrane phosphatase. It is present in hematopoietic cells and is essential for antigen receptor signaling in T cells and B cells.[12] CD45 is expressed in various isoforms that differ in their extracellular domains as a result of alternative exon splicing in the N-terminal region.[12] The variable, N-terminal extracellular domain consists of ≈ 200 amino acid residues and is heavily glycosylated. Therefore significant differences are present in the glycosylation patterns between different isoforms. The N-terminal region is followed by a cysteine-rich region, three fibronectin type 3 repeats, and a single transmembrane region (Figure 4). On the cytoplasmic side, the phosphatase is composed of two phosphatase subunits (D1 and D2). However, only the membrane-proximal domain D1 is responsible for phosphatase activity, whereas D2 is involved in protein–protein interactions and proper phosphatase folding. Expression of the different CD45 isoforms is cell-type specific and is also dependent on the state of differentiation of hematopoietic cells.[12]

Some extracellular ligands of RPTPs have been identified, such as the secreted protein galectin-1 (for CD45), which may have an inhibitory effect toward the phosphatase activity of CD45,[101] an extracellular matrix complex between laminin and nidogen (for LAR),[102] and the growth factor pleiotrophin, which appears to bind and inhibit PTP-ζ.[29]

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

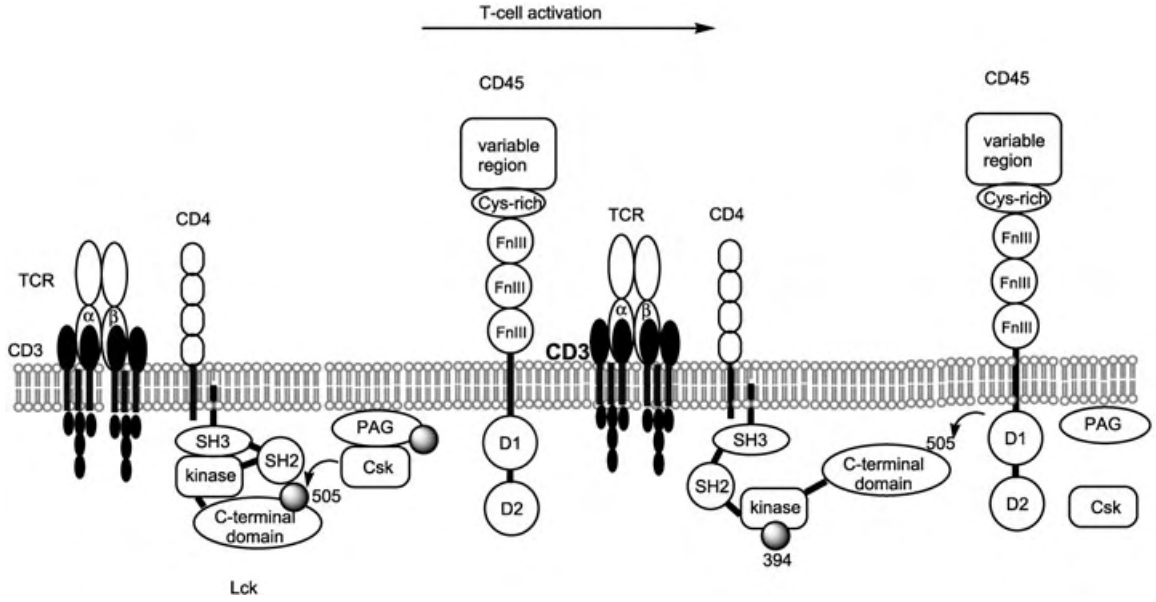

Figure 4. The role of CD45 in T-cell signaling.

RPTPs also seem to form homodimeric and heterodimeric complexes.[103] Importantly, the dimerization of RPTPs regulates their catalytic activity, which is reminiscent of the activation of receptor protein tyrosine kinases (RPTKs) by dimerization.[104] For example, it has been shown that for CD45, dimerization results in the inhibition of catalytic activity. The inhibitory wedge structure of one D1 domain (the membrane-proximal, catalytically active PTP domain) binds and inhibits the D1 domain of the second phosphatase.[105] Heterodimerization of RPTPs could play an important role in the cross-talk between different RPTP-mediated pathways.

In recent years, an increasing number of intracellular RPTP substrates have been identified, thus elucidating their physiological function. The first substrate type consists of the PTKs. For example, CD45 is critically involved in the activation of T cells. CD4 facilitates T-cell receptor (TCR) association with the kinase Lck (a Src-type kinase). By activating Lck through the dephosphorylation of an inhibitory residue (Tyr 505), CD45 plays a determining role in T-cell signaling (Figure 4). In the inactive form, Tyr 505 is kept in a phosphorylated state by the kinase Csk, which is associated through its SH2 domain with the transmembrane phosphoprotein, PAG (phosphoprotein associated with glycosphingolipid-enriched microdomains).[106] Upon cell activation, PAG is dephosphorylated and Csk is released into the cytosol, where it can no longer maintain the phosphorylated state of Lck Tyr 505. CD45 can associate with the SH2 domain and the N-terminal region of Lck. Upon dephosphorylation by CD45, Tyr 505 no longer binds to an intramolecular SH2 domain, causing a major conformational change in Lck. The accessible SH2 domain is free to bind substrate phosphoproteins. Moreover, the conformational change allows auto- and transphosphorylation of Lck Tyr 394, which displaces the activation loop and creates a more accessible catalytic cleft.[12] Interestingly, CD45 also has a negative function and dephosphorylates the same Tyr 394 residue, thus terminating Lck activity.[12]

CD45 has similar stimulatory activity toward other Src kinases, such as Lyn in B cells.[107] Besides these stimulatory activities, RPTPs can inhibit kinases such as Janus kinases,[12,108] and LAR through insulin receptor signaling.[109] RPTPs appear to be involved in various processes such as cell adhesion,[103] neuronal development,[110] and ion channel-mediated processes.[111] CD45 has gathered particular attention as its inhibition by antibodies blocks T-cell activation in vitro[112] and graft rejection in mice.[113] Thus, selective inhibitors of CD45 could find applications in the treatment of autoimmune disease and the treatment of transplant rejection. Decreased CD45 expression and/or activity has been discovered in SLE patients.[9] A point mutation in the CD45 gene (*ptprc*) has been associated with autoimmune diseases like multiple sclerosis[113] and autoimmune hepatitis.[114] Moreover, the modulation of CD45 activity by antibodies inhibits the formation of Alzheimer plaques.[15] The negative regulation of cytokine receptor signaling by CD45 could explain the loss of CD45 activity that has been observed in several cancers, such as leukemia.[115] CD45 has been correlated with the proliferation of myeloma cells and could therefore be a potential therapeutic target for the treatment of multiple myelomas.[33]

7. PTP Inhibitors

Below, we discuss the development of PTP inhibitors, which are classified according to type. Only those inhibitors were chosen that exhibit cellular activity which is not necessarily linked to phosphatase inhibition in vitro.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

7.1. Unspecific and Inorganic PTP Inhibitors

Vanadate-based compounds have been used as unspecific phosphatase inhibitors. They work by mimicking the phosphate group of the natural enzyme substrate. They have been shown to work as insulin mimetics and also exhibit antimetastatic activity.[116] Other mainly inorganic compounds, like nitric oxide and phenyl arsine oxide, are thought to exert their pharmacological effects by phosphatase inhibition,[117] although other enzymes are likely to be targets for these compounds as well; this severely limits their therapeutic usefulness.

7.2. Natural Products and Derivatives as PTP Inhibitors

Natural products have been a rich source of PTP inhibitors and a good starting point for the development of synthetic analogues. 4-Isoavenaciolide (**2**, Figure 5) was isolated from a fungal strain and identified as an irreversible inhibitor of VHR with an IC_{50} of 1.2 μM.[118] Some other phosphatases like Cdc25B, Laforin, and PTP1B were inhibited with similar potency, whereas CD45 and serine/threonine phosphatases like PP2A and PP1 were not inhibited. An investigation into the mechanism of inhibition showed that two inhibitor molecules covalently bind to two of the four cysteine residues of VHR, namely Cys124 in the active-site and Cys171 on the protein surface. The results were rationalized by the proposal of a hydrophobic cleft near the cysteine residue that is required for efficient binding.

The alkaloid nornuciferine (**3**) inhibits CD45 with an IC_{50} value of 5.3 μM. T-cell receptor-dependent production of IL-2 was inhibited, whereas other phosphatases like calcineurin (PP2B), alkaline phosphatase, and acid phosphatase were not inhibited.[119] Nornuciferine was also shown to be active against leishmaniasis.[120] and is thought to be the antidepressive component in the fruit of *Annona muricata*.[121] The total syntheses of nornuciferine and other natural products of this class have been described.[122]

The stevastelins (e.g. **4a–c**), an interesting class of depsipeptides, have been isolated as immunosuppressive agents from *Penicillium* spp. and inhibit T-cell proliferation.[123] It has been shown that these natural products act through inhibition of the dual-specificity phosphatase VHR and thus cell-cycle progression. A structure–activity relationship of this natural product class was established through the evaluation of a small subset of analogues. It was shown that the long alkyl side chain and the free hydroxy group of the threonine residue (type A stevastelins; **4c**) are required for activity against Jurkat cells. Derivatization of the hydroxy group either by sulfatation (**4a**) or phosphorylation (**4b**) abolished the in-vivo inhibitory activity of the compounds against Il-2 and Il-6-dependent gene expression in Jurkat cells. In contrast, the sulfated compounds (type A) showed good in-vitro inhibitory activity against VHR in the micromolar range, but not against the PTP CD45 and the PSTPs PP2A and PP2B. The desulfated compounds showed a decrease in PTP inhibition by one order of magnitude. These findings were rationalized by suggesting that the compounds may be threonine-phosphorylated or sulfated by cellular enzymes after cellular uptake of the uncharged (type B) compounds. The stevastelins constitute a novel, calcineurin-independent class of immunosuppressive agents and have therefore been the targets of several total syntheses.[124]

The tetronic acid derivative RK-682 (**5a**) was isolated from a *Streptomyces* strain and identified as a competitive inhibitor of the DSP VHR and CD45. It arrests the cell-cycle progression of mammalian cells in the G_1 phase.[125] The synthesis of derivatives and a subsequently derived structure–activity relationship revealed that the highly acidic 3-acyltetronic acid moiety functions as a phosphate mimic. [126] The hydrophobic side chain at C3 and the enolic hydroxy group at C4 were found to be important for VHR inhibition, whereas removal of the hydroxy group from the C5 arm did not interfere with inhibition. None of the compounds showed any activity against the PSTPs PP1, PP2A, or PP2C. Some derivatives showed inhibition of Cdc25B at the submicromo-

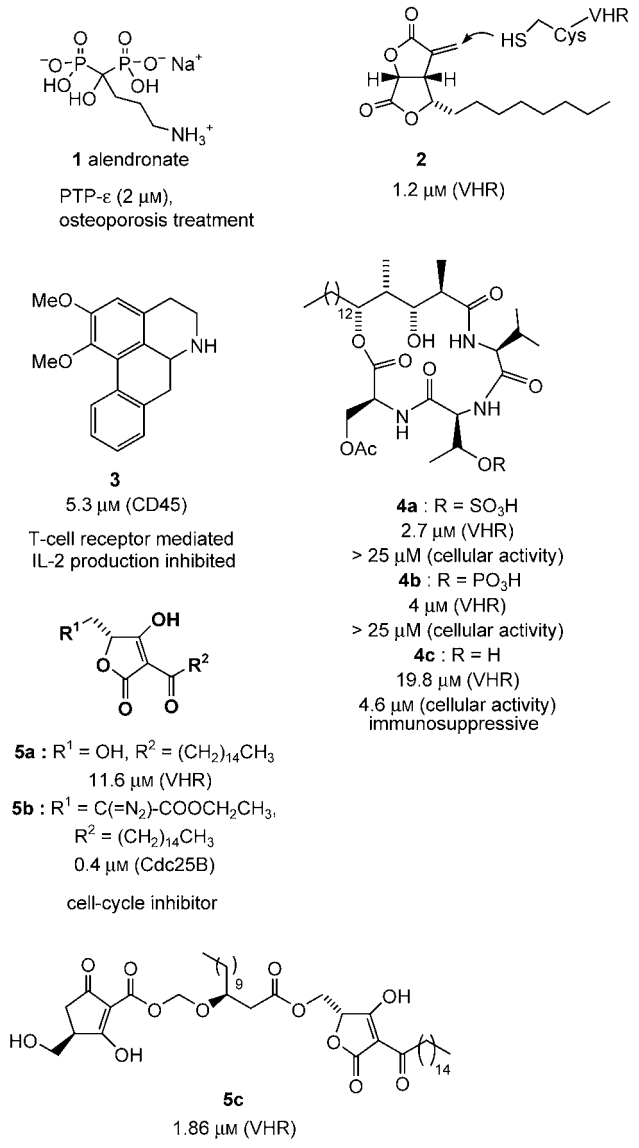

Figure 5. Natural-product-derived PTP inhibitors; the IC_{50} values are shown for all compounds unless mentioned otherwise.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

lar level and inhibition of VHR in the micromolar range. Interestingly, **5b** exhibited some selectivity toward Cdc25B ($IC_{50} = 0.4\ \mu M$) over VHR ($IC_{50} = 12.4\ \mu M$) and PTP-S2 ($IC_{50} > 100\ \mu M$), whereas the natural product **5a** showed the opposite trend in selectivity ($IC_{50} = 11.6\ \mu M$ (VHR) and $> 100\ \mu M$ (Cdc25B)).[127] This example clearly demonstrates how selectivity toward related enzymes can be tuned within a natural product library. Molecular modeling, the crystallographic structure of VHR, and a detailed kinetic analysis were used to propose a model in which the acyltetronic acid anion is a phosphate mimic with multiple hydrogen bonds to the active-site loop (Cys124–R130). A second molecule of tetronic acid is involved in the inhibition and interacts with Arg158.[128] Both C_3 alkyl side chains interact with the hydrophobic groove of the enzyme (Figure 6). Based on this

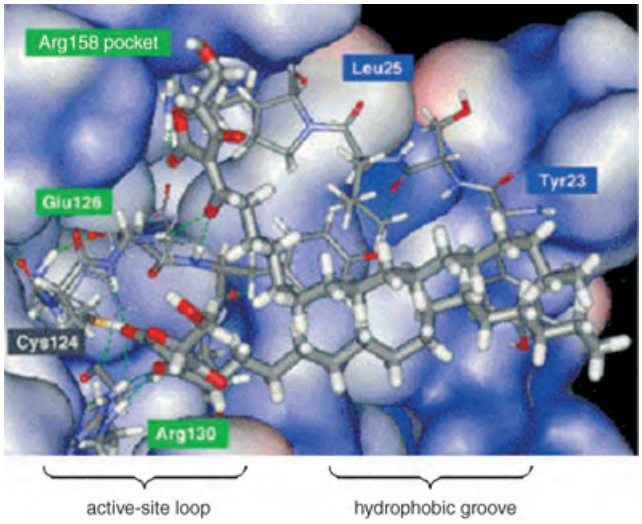

Figure 6. Binding of two molecules of **5a** to VHR (from Ref. [128] with permission).

model, a dimeric inhibitor **5c** was designed. This compound showed increased potency against VHR in comparison with the natural product ($IC_{50} = 1.83\ \mu M$). Interestingly, the arginine group (Arg158) involved in binding the second tetronic acid moiety is in a sequence region that is less conserved among various phosphatases. Therefore, this new type of dimeric inhibitor might constitute an excellent starting point for the generation of new, highly selective protein phosphatase inhibitors.

Another highly interesting natural product, dysidiolide (see the 6-epimer **6**), was isolated 1996 from the marine sponge *Dysidea etheria* (Figure 7).[129] Dysidiolide is a sesterterpene with a γ-hydroxybutenolide group and was identified as an inhibitor of Cdc25A ($IC_{50} = 9.4\ \mu M$). Other phosphatases like calcineurin, CD45, and LAR were not inhibited at this concentration. Moreover, dysidiolide inhibited growth of A-459 lung carcinoma cells and P388 murine leukemia cells at micromolar concentrations. However, whether dysidiolide works as a phosphatase inhibitor subsequently came into question. It was concluded that the inhibitory activity of isolated samples of the natural product could stem from an

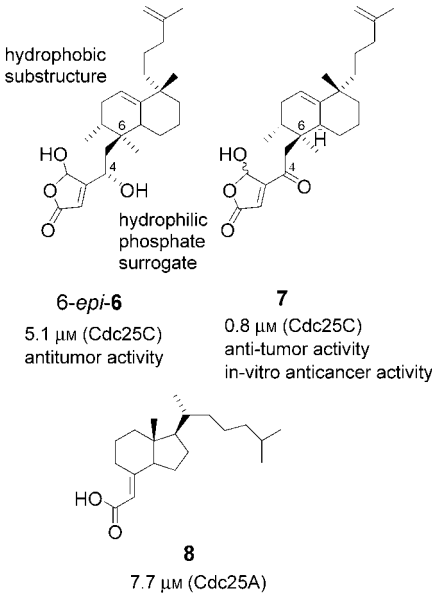

Figure 7. Inhibitors derived from dysidiolide; IC_{50} values are given.

unidentified impurity.[130] Several total syntheses[131] and the synthesis of simple analogues[132] of dysidiolide have been reported. Similar natural products with antitumor activity have been described.[133] Based on their total synthesis of dysidiolide, Shirai and co-workers synthesized a series of analogues of the natural product in solution.[134] This study showed that the bicyclic structure could not be replaced with a cyclohexane ring without destroying the activity. Variation of the stereochemistry at C4 and C6 did not interfere with activity. Clearly, the orientation of the hydroxybutenolide unit relative to the hydrophobic portion is not important. Indeed, some of the diastereomers showed even stronger inhibition of Cdc25A and B than the natural product itself.

In the context of a program in which natural products are used as biologically validated starting points for the development of compound libraries, the solid-phase synthesis of a small collection of dysidiolide analogues was reported. The library was screened against Cdc25C and various cancer cell lines, including the colon cancer cell line HCT116, the prostate cancer cell line PC3, and the breast cancer cell line MDA-MB231.[135] The key steps of the synthesis included an asymmetric Diels–Alder reaction for the construction of a bicyclic hydrophobic substructure and the singlet-oxygen-mediated oxidation of a furan ring to the γ-hydroxybutenolide group. A traceless linker that is cleaved by ring-closing metathesis was used for solid-phase attachment. By this strategy, inhibitors of Cdc25C that are more potent than 6-*epi*-dysidiolide ($IC_{50} = 5.1\ \mu M$), for example, the ketone **7** ($IC_{50} = 0.8\ \mu M$), were obtained (Figure 7). Anticancer activity was also observed at micromolar levels in vitro for these analogues, although the activity did not strictly parallel that of phosphatase inhibition.

In the initial report of the isolation and structure elucidation of dysidiolide, the hydroxybutenolide moiety was already proposed to be a nonionic phosphate surrogate, whereas the decalin scaffold bearing the alkyl side chain was

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

proposed to exert hydrophobic interactions with the enzyme. Based on this hypothesis, Shirai and co-workers described simplified analogues of the natural product which were synthesized from vitamin D_3 and which contained a carboxylic acid group instead of the hydroxybutenolide moiety. Among these compounds, **8** showed both Cdc25A inhibition and antitumor activity in the micromolar range, comparable to the natural product (Figure 7).[132a]

An interesting approach to the synthesis of micromolar inhibitors of similar structure has been described by Zalkow and co-workers (Figure 8). By silica-mediated pyrolysis of

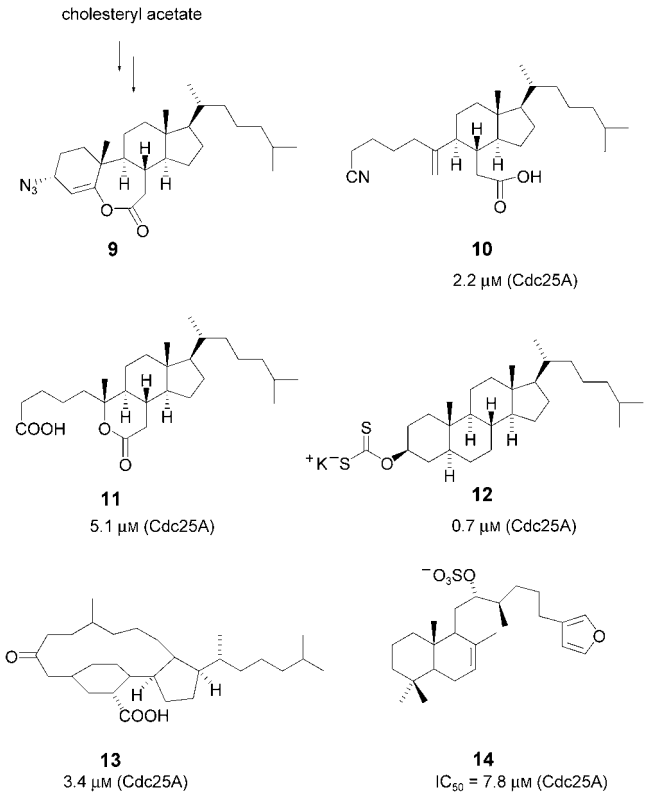

Figure 8. Cholesterol-derived PTP inhibitors **9**–**13** and the natural product, sulfircin (**14**); IC_{50} values are given.

azide **9**, itself readily synthesized from cholesteryl acetate, ten compounds were isolated and subjected to further chemical transformations, leading to a panel of analogues. Among them, nitrile **10** was identified as a reversible, noncompetitive inhibitor of Cdc25A, B and C ($IC_{50} = 2.2$, 8.3, 12.2 μM). The authors proposed that the cyano group may bind to an arginine residue located in a region distinct from the substrate binding site. Whereas CD45 was also inhibited by this compound, acid **11** and *O*-cholestanyl xanthate **12** were highly selective for Cdc25A (**11**: $IC_{50} = 5.1$ μM; **12**: 0.7 μM) relative to CD45 ($IC_{50} > 100$ μM).[132b] Interestingly, although most of the compounds showed inhibition of cancer cell lines in vitro, this did not necessarily correlate with the inhibition of phosphatase activity. Thus, simple steroidal derivatives like **12** functionalized with a phosphate surrogate chain, although excellent phosphatase inhibitors, were weaker inhibitors of tumor cell growth than more complex structures like **11**. The authors suggested that poor cellular uptake and metabolic degradation may be important factors in modulating the anticancer activity of these phosphatase inhibitors.

Researchers at Schering synthesized a series of micromolar inhibitors of Cdc25B, based on a rigid steroid-derived macrocyclic scaffold.[136] Among these, compound **13** is the most potent ($IC_{50} = 5.6$ μM). It is believed that the keto functionality serves as a phosphate mimic, and the carboxyl group binds to the side chains of either Arg544 or Arg482, which flank the binding site (Figure 8).

Another natural product, sulfircin (**14**, Figure 8), was isolated from a marine sponge[137] and exhibited an IC_{50} value of 7.8 μM against Cdc25A, although selectivity over other PTPs was poor. Analogues of this natural product have been synthesized, and the sulfate group can be replaced by a malonate group.[138]

Dnacin A1 and B1 (**15a** and **15b**, Figure 9), two naphthyridinomycin-type antibiotics with antitumor activity have

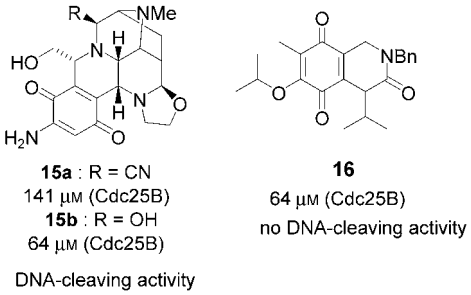

Figure 9. Dnacins A1 and B1 as well as a simplified analogue; IC_{50} values are given.

been isolated from *Actinomycetes* strains.[139] They are weak, noncompetitive inhibitors of Cdc25B ($IC_{50} = 141$ μM and 64 μM).[139] However, these natural products also showed the ability to cleave DNA through the generation of superoxide radicals. Recently, Wipf and co-workers synthesized analogues of the natural product (for example, **16**) which still showed PTP inhibition in the micromolar range, but no DNA-cleaving activity. They were thus able to "separate" the two biological mechanisms of this interesting class of compounds.[140] It was also shown that PTP1B and VHR were inhibited as well as Cdc25A and B. For two compounds, selectivity for Cdc25 and PTP1B over VHR was observed. The authors concluded that truncated analogues that lack the bridged piperidine moieties were good leads for the design of novel Cdc25 inhibitors without DNA-cleaving activity.

A new lead compound for the development of PTP inhibitors was derived from the antitumor 2-pyridone TMC-69.[141a–c] The synthesis of the hydrogenated enantiomers (17*S*)-**17** and (17*R*)-**17** (Figure 10) and their biological evaluation against a panel of phosphatases showed, in contrast to previous reports, that the structures are moderate (micromolar) inhibitors of PTP1B, VHR, and PP1 (a serine/threonine phosphatase), whereas Cdc25A is only weakly inhibited.[141d]

The natural product dephostatin **18a** was found to be a micromolar, competitive PTP inhibitor in *Streptomyces* sp-

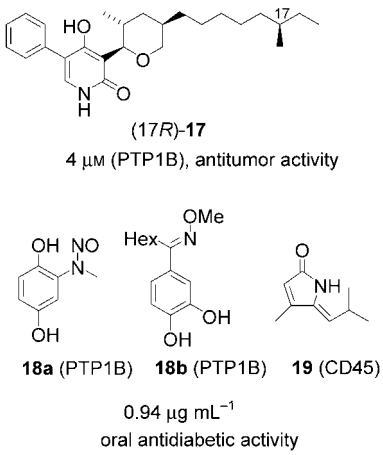

Figure 10. Analogues of the antitumor 2-pyridone TMC-69 are PTP inhibitors; IC_{50} values are given.

p.[142a,b] More selective and stable analogues without the potentially carcinogenic nitrosamino unit were later designed by molecular modeling. C–H π interactions of the alkyl side chain are thought to play an important role in the binding of these inhibitors, which essentially function as tyrosine mimics. The most potent inhibitor, compound **18b**, is a micromolar inhibitor of PTP1B ($IC_{50} = 0.94\ \mu g\,mL^{-1}$). These compounds also show moderate selectivity towards PTP1B and SHPTP-1 (30-fold over CD45 and >100-fold over LAR). More importantly, they show oral antidiabetic activity in mice by decreasing high blood glucose levels. No serious toxicity was observed.[142c]

In 1997, Alvi et al. isolated a natural product from the marine fungus *Corollospora pulchella* with inhibitory activity toward CD45: pulchellalactam (**19**).[143] This natural product contains 3-pyrrol-2-one as a core structure, and could constitute an interesting pharmacophore for the development of phosphatase inhibitors.

In a recent study, a range of glycolipids, among them glucolipsin A, cycloviracin B_1, caloporoside, woodrosin I, sophorolipid, tricolorin G, and analogues thereof were screened against phosphatases PTP1B and Cdc25A.[144] Most of the structures (some of which are shown in Figure 11; **20**–**22**) were identified as micromolar inhibitors of Cdc25A, whereas PTP1B was not inhibited. These results are surprising, as glycolipids had not been identified previously as phosphatase inhibitors. Analogues and synthetic precursors of the natural products roseophilin and the prodigiosins[145] were identified as inhibitors of Cdc25A, PTP1B, and VHR (**23a–c**; Figure 11). Whereas none of the compounds inhibited PP1, some micromolar inhibitors of phosphatases were identified, thus illustrating once more the utility of natural compounds as starting points for the identification of phosphatase inhibitors.[146]

7.3. Mechanism-Based Small-Molecule Inhibitors

Apart from inspiration from a rich pool of natural products, more rational approaches have been successful in

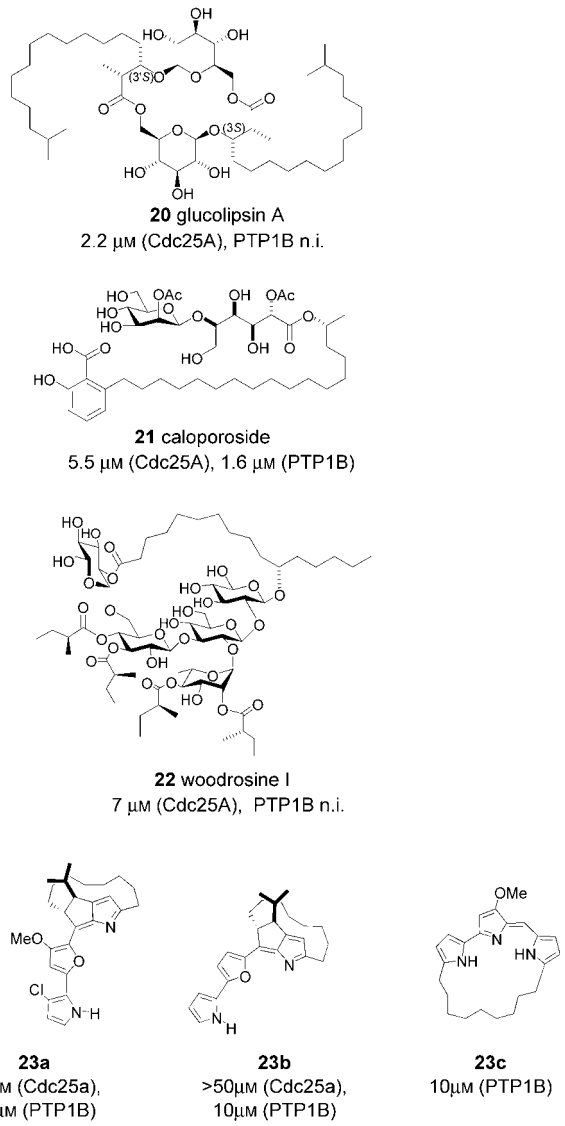

Figure 11. Structures of glycolipids and alkaloids identified as phosphatase inhibitors; IC_{50} values are given; (n.i. = no inhibition).

the development of PTP inhibitors, such as molecular modeling based on X-ray crystallographic structures of PTPs. Most of this work has focused on the development of competitive inhibitors that bear a nonhydrolyzable phosphotyrosine mimetic group.

7.3.1. Nonhydrolyzable Tyrosine Phosphate Mimetics

A rational concept for the design of competitive PTP inhibitors has been realized through the replacement of the phosphate portion of peptidic substrates with nonhydrolyzable phosphate mimetics. A range of simple anionic mimetic structures has been developed and successfully converted into PTP inhibitors. Thus, the phosphotyrosyl group has been replaced by sulfotyrosyl,[147a] thiophosphoryltyrosyl,[147b] *O*-dithiophosphoryltyrosyl,[147c] *O*-boranophosphoryltyrosyl,[147c] phosphonomethylphenylalanine (Pmp),[147d] *O*-malonyltyrosyl,[147e] fluoro *O*-malonyltyrosyl,[147f] and most successfully,

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

difluorophosphonomethylphenylalanine (F_2Pmp) groups.[147g] In the latter compound, the fluorine atoms form hydrogen bonds with N–H groups of PTP, which increases the binding affinity by several orders of magnitude.[147h]

Early inhibitor designs relied on peptidic structures as templates for the phosphotyrosine mimetic. For example, the hexapeptide Asp-Ala-Asp-Glu-F_2Pmp-Leu-NH_2 was developed by Burke et al., and has an IC_{50} of 0.2 μM for PTP1B.[147g] However, peptides are generally poor candidates for drug development, as they are susceptible to protease degradation and have poor permeability through the cell membrane. Interestingly, simple aromatic difluoromethylphosphonates have already shown weak PTP inhibition and even exert biological activity like promotion of neovascularization.[148] Biphenyl- and naphthyl-substituted compounds showed higher potency than phenyl derivatives, as hydrophobic interactions play a dominant role in the stabilization of inhibitor–enzyme interactions.[149]

The main drawback of double-negatively charged phosphotyrosine mimetics is their inherent lack of cell-membrane permeability.[150] Indeed, most of the compounds, despite their strong inhibition of phosphatases in vitro, are not biologically active in cell-based assays. Therefore, considerable efforts have been undertaken by academic groups and pharmaceutical companies to develop nonpeptidic, small-molecule PTP inhibitors (especially PTP1B inhibitors) with more "druglike" character and less negatively charged phosphotyrosine mimetic groups.[4] In the following section we discuss some of the inhibitors generated under this principle, with a focus on new developments.

Researchers at Merck Frosst developed a series of difluoromethylphosphonates substituted with a deoxybenzoin side chain which showed strong (nanomolar) PTP1B inhibition and, perhaps surprisingly, cellular activity. Moreover, compound **24** (Figure 12), with an *ortho*-bromo substituent on the phenyl ring, proved to be orally bioavailable and displayed glucose-lowering activity in rat models.[151] Unfortunately, only poor selectivity over the closely related phosphatase TCPTP was observed. The lack of information about the binding mode of these inhibitors impaired a further improvement in selectivity.

Moran et al. demonstrated that cinnamic acids (for example, **25a**; Figure 12) are potent inhibitors ($K_i = 79$ nM) of PTP1B.[152] Unfortunately, these structures are likely to covalently modify the enzymes, a feature which may be undesirable in drug development. Similar cinnamic aldehydes (such as **25b**) with a tripeptide moiety were later reported by Pei and co-workers that lead to micromolar inhibitors of PTP1B and the catalytic domain of SHP-1, whereas the dual-specificity phosphatase VHR showed only weak inhibition.[153] Surprisingly, **25b** acts as an activator of SHP-1 by binding to the inhibitory N-terminal SH2-domain of the enzyme.[154] NMR spectroscopic analysis of the mode of inhibition suggests that an enamine is formed reversibly between the aldehyde moiety and Arg221 of PTP1B.

Taylor and co-workers described the difluoromethylenesulfonic acid (F_2Smp) as a monoanionic phosphate surrogate and incorporated this moiety into peptides and compared it to other phosphate mimetics in the same peptidic template.[155]

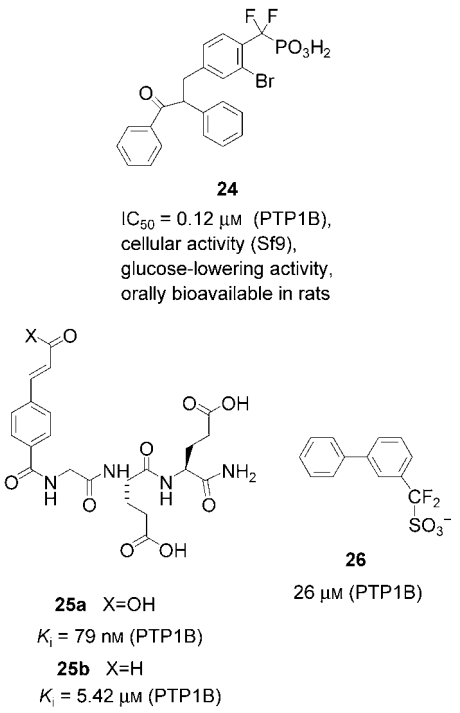

Figure 12. Cinnamic aldehydes, acids and difluoromethylenesulfonic acids as phosphotyrosyl mimetics.

This work showed that whereas F_2Smp is less potent than the bisanionic F_2Pmp, it performs similarly to other monoanionic surrogates. The same research group also synthesized a range of simple nonpeptidic aromatic derivatives with IC_{50} values toward PTP1B that range between 26 and 197 μM (for example, **26;** Figure 12).

Researchers at Pharmacia replaced the *O*-malonyltyrosine moiety (**27a**) by a more potent 2-carboxymethoxybenzoic acid group (**27b**; Figure 13). To overcome problems caused by poor cell-membrane permeability, one carboxylic acid moiety was replaced by a tetrazole unit as a carboxyl group bioisostere (**28**).[156] The resulting compound **29** showed PTP1B inhibition ($K_i = 2$ μM) and modest cellular activity (insulin-stimulated 2-deoxyglucose uptake by L6 myocytes). Another successful approach was in the use of the corresponding diester moiety **27c** as a prodrug. This compound is more cell-membrane permeable than the diacid, and can be cleaved in the cell by enzymes to release the active PTP inhibitor.[157] Replacement of the Boc group in **29** by arylalkanoyl groups yielded inhibitors (for example, **30**) with submicromolar K_i values against PTP1B and improved insulin-stimulated glucose transport by L6 myocytes at 100 μM. Moreover, the compounds showed selectivity over LAR and SHP-2.[158]

The binding modes of these inhibitors have been investigated by X-ray crystallographic analysis (Figure 14).[157] The peptide backbone adopts a β-strand conformation and forms hydrogen bonds with Asp48 and Arg 47 (PTP1B numbering). The two phenyl rings form hydrophobic interactions with the side chains of Tyr46, Val49, Ala217, Ile 219, Gln 262, and Phe 182. Interestingly, binding of the inhibitors by the enzyme results in closure of the WPD loop in a manner similar to

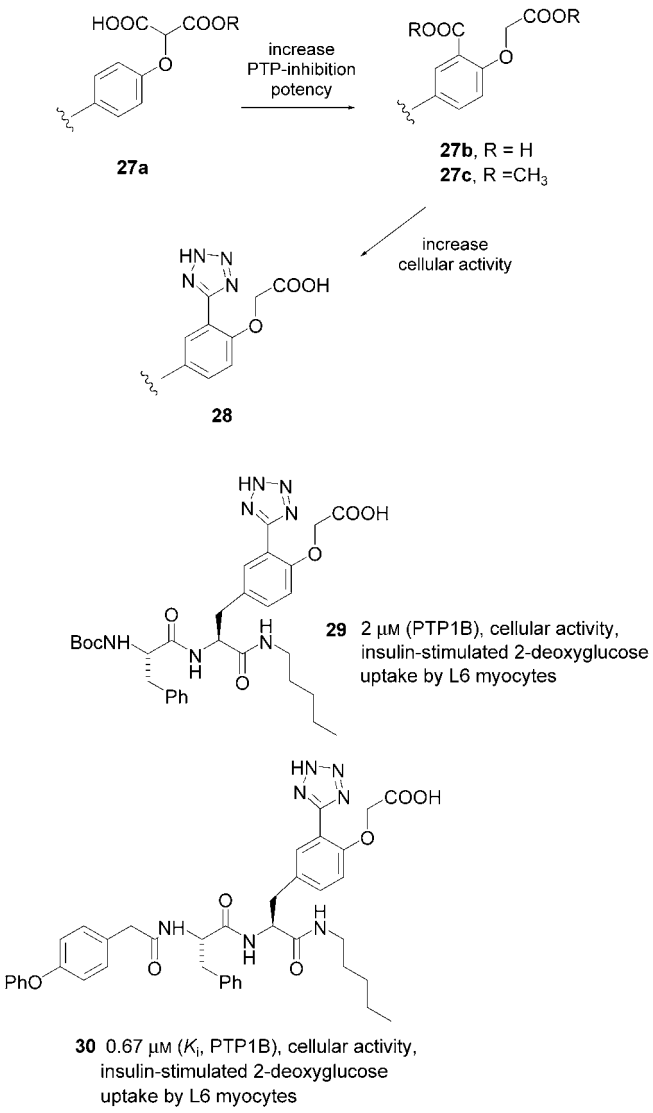

Figure 13. Improvement of PTP inhibition and cellular activity starting from *O*-malonyltyrosyl derivatives; the tetrazole group is a well-established carboxylic acid bioisostere; K_i values are given.

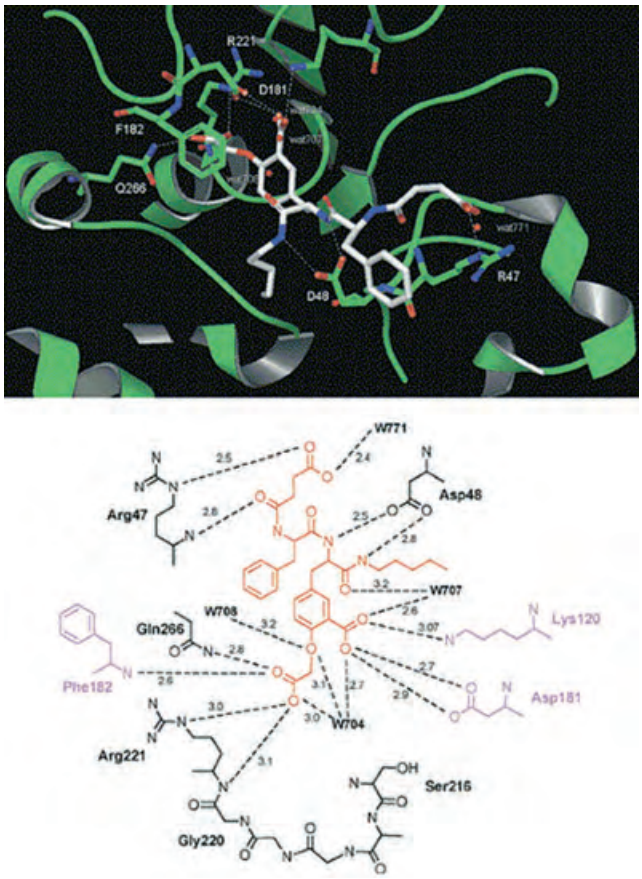

Figure 14. Binding mode of an inhibitor of type **27b** (white) to the active site of PTP1B (green); (W = water molecule; from Ref. [157] with permission).

substrate binding, as described earlier. Relative to the phosphate groups of substrates, the carboxylic groups are closer to the WPD loop and form hydrogen bonds with water molecules inside the active site as well as with amide groups.

Researchers at Novo Nordisk identified a similar structure, 2-(oxalylamino)benzoic acid (**31**) as a phosphotyrosine mimetic (Figure 15). Based on this structural element, analogues such as thiophene **32** were developed with submicromolar IC_{50} values for PTP1B and good oral bioavailability in rats.[159] The X-ray crystallographic structure of **32** in complex with PTP1B revealed that the oxalylamino carboxyl group forms hydrogen bonds with the main chain amide nitrogen atom of Gly220 and Arg221 and a salt bridge with the guanidinium side chain of Arg221. The other carboxyl group forms a salt bridge with Lys120. Upon binding of the inhibitor, the WPD loop is closed similarly to the binding mode of phosphotyrosine. In this conformation, Phe182 forms favorable aromatic–aromatic interactions with the thiophene ring of **32** while the tetrahydropyridine ring interacts with Ile219, Val49 and Tyr46. Another remarkable interaction is present between the nitrogen atom of the tetrahydropyridine ring and Asp48. The corresponding position in many other phosphatases such as SHP-1, PTP-α, and LAR is occupied by an Asn residue, which would exert a repulsive interaction with the same nitrogen atom, thereby contributing to the PTP selectivity of this class of inhibitors. To overcome the poor cellular uptake of such highly charged compounds, a prodrug approach (ethyl ester) was used, and these compounds showed cellular activity (enhancement of 2-deoxyglucose accumulation in C2C12 cells) in the high micromolar range (100 μM).

The same phosphotyrosine mimetic was used by researchers at Abbott for the development of nanomolar PTP1B inhibitors (Section 7.3.2).

Researchers at Molecumetics designed a phenylalanine derivative[160] based on earlier work by Ham et al.[161] When incorporated into a library containing triazolopyridazine β-strand templates, micromolar irreversible inhibitors of PTP1B were obtained (for example, **33**; Figure 15).

Researchers at Wyeth–Ayerst developed and optimized PTP-inhibitors with benzofuran or benzothiophene rings. The most potent inhibitors obtained showed IC_{50} values against PTP1B in the range of 20–50 nM, and some compounds

normalized plasma glucose levels at intraperitoneal doses of 1 mg kg^{-1}, with **34** as the best compound in vivo (Figure 16).[162] Furthermore the compound showed 10- to 100-fold selectivity for PTP1B over other PTPs. A model for the binding of this class of compounds has been developed based on X-ray crystallographic data. The carboxylic acid group binds to two water molecules that bridge the guanidine group of Arg221 (PTP1B), which normally binds the phosphate group of the substrate. Thus, this moiety acts as a phosphate mimetic in a broader sense. The biphenyl ring proximal to the carboxylic acid group is sandwiched between Tyr46 and Phe182, which resembles the binding of the phenyl ring of phosphotyrosine substrates. Other interactions that contribute to the high affinity of the inhibitor are mainly hydrophobic in nature. The second biphenyl ring binds the positively charged ammonium group of the Lys120 side chain, while the 2-benzyl-benzofuran/benzothiophene moiety interacts with the Lys116 side chain and the aromatic ring of Phe182.

In the same report, a similar compound with a salicylic acid moiety as the polar group was described (**35;** Figure 16). Interestingly, the mode of binding is quite different in this case, as determined by X-ray crystallographic analysis of this compound in complex with PTP1B. A molecule of **35** forms amide hydrogen bonds with Lys120 and Tyr46 and interacts with one H_2O molecule bridging Arg221, while the hydrophobic moieties point toward the opposite side relative to the case of inhibitor **34** (Figure 17). A similar compound, Ertiprotafib (PTP-112, **36**; Figure 16) was developed by

the occurrence of dose-limiting side effects.[4,63] Ertiprotafib has also been shown to be a PPAR modulator, and some of its biological effects may be linked to this activity.[63b]

A further phosphate mimetic, α-ketocarboxylic acid, was developed by Seto and co-workers.[164] When this mimetic was incorporated into peptides, weak inhibitors were obtained ($IC_{50} = 150$ μM toward *Yersinia* PTP). However, much higher affinities were obtained with dimeric structures like **37** (Figure 18).[165] (The use of dimeric phosphotyrosine mimetics

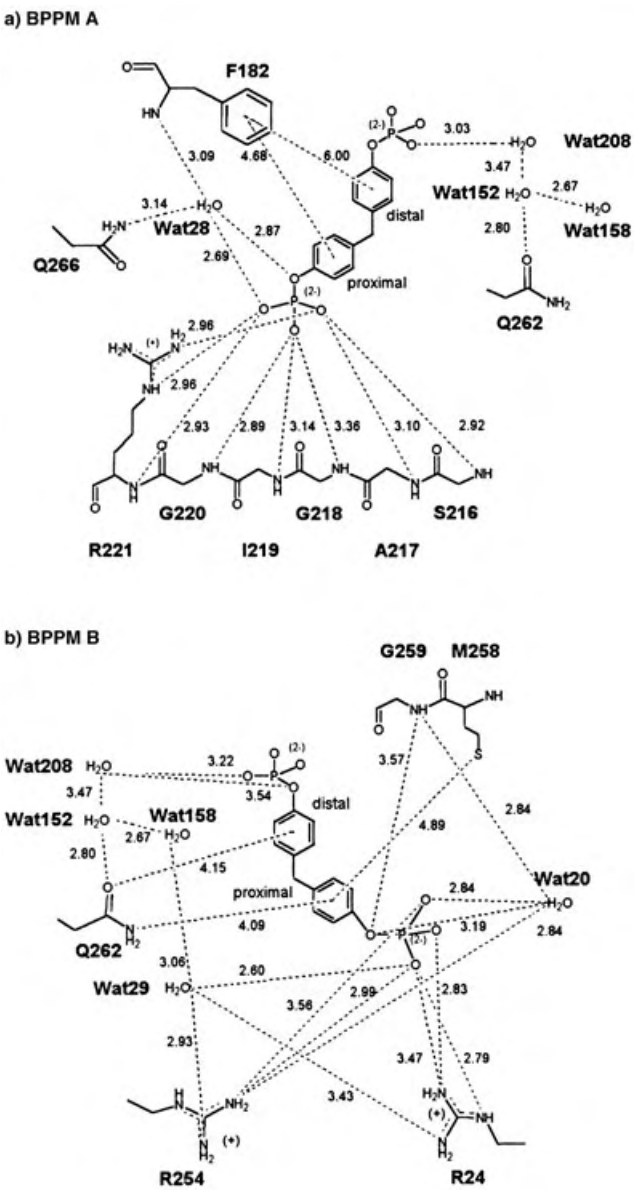
is discussed in greater detail in the following Section 7.3.2.) The same research group also showed that aryl-substituted squaric acids can serve as phosphotyrosine mimetics.[166] Among the compounds tested, the naphthyl-substituted squaric acid **38** showed the highest inhibition ($IC_{50} = 47$ μM against *Yersinia* PTP; Figure 18). Furthermore, a kinetic analysis revealed that the compounds act as reversible competitive inhibitors, thus confirming that they are phosphotyrosine mimetics.

7.3.2. ***Two-Site-Binders as Selective Inhibitors of PTP1B***

A major problem in finding selective inhibitors for PTPs is the high sequence homology of the catalytic site shared by the enzymes (up to 80% homology between TCPTP and PTP1B). In this respect the discovery by Zhang and co-workers[167] of a second, noncatalytic binding site on PTP1B in the vicinity of the active site which shows less homology among the phosphatases is of particular importance for the development of a new class of more selective inhibitors of PTP1B. By resolving the crystallographic structure of a catalytically inactive mutant (C215S) of PTP1B in complex with the small-molecule substrates bis(*para*-phosphophenyl)methane or phosphotyrosine, it was found that the substrates could bind the enzyme at two sites (Figure 19). In the catalytic site, the phosphotyrosine forms ionic interactions with Arg221, hydrogen bonds with the main-chain nitrogen atoms of Ser216–Arg221, and aromatic–aromatic contacts with Tyr46



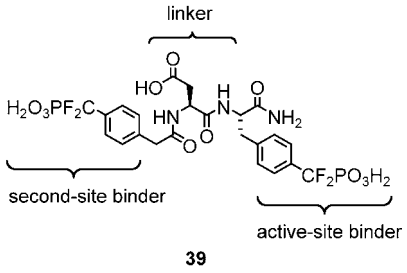


Figure 19. The PTP1B inhibitor BPPM can bind to the enzyme in two different modes, suggesting the presence of two aryl phosphate binding sites in PTP1B: the first mode (a) is similar to the binding of phosphotyrosine substrates, whereas the second mode (b) involves amino acids that are less conserved among phosphatases (from Ref. [167a] with permission).

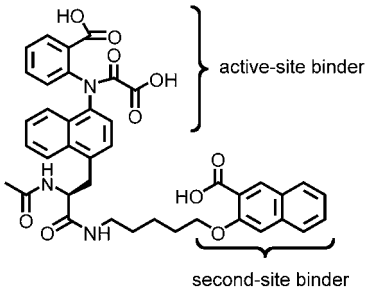
and Phe182. Unexpectedly, a second binding site in the vicinity of the catalytic site was found. In this site, phosphotyrosine forms ionic interactions with Arg24 and Arg254, polar interactions with Met258 and Gln262, and van der-Waals contacts with Ile219, Asp48 and Arg254.

This observation constitutes a new paradigm for ligand design, as the second aryl phosphate binding site is less conserved among phosphatases (apart from Arg254 and Gln262, which are present in all PTPs). Thus, a bidentate ligand that binds the two sites has a better chance to be more selective than a classical active-site binding compound. The authors later successfully applied this paradigm to the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

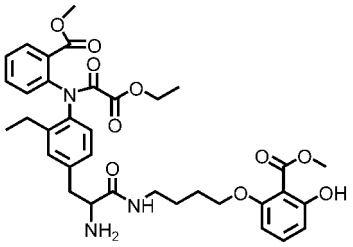
development of potent and remarkably selective PTP1B inhibitors.[167b] They first synthesized a 184-membered library of compounds with three distinct moieties: an invariable, active-site binding aryl phosphate group, an amino acid as linker (23 members) and a second-site binding fragment (8 compounds). The compounds were screened for binding to the inactive C215S mutant form of PTP1B. A further advantage to the use of this enzyme is that inhibitors emerging from these studies are less likely to act through irreversible alkylation or oxidation of the catalytically active cysteine group, a characteristic undesirable in drug development.[168] The most powerful binder was then converted into a nonhydrolyzable phosphate mimetic, the corresponding difluoromethylphosphonate, to give compound **39,** which gave a K_i value of 2.4 nM (Figure 20). Besides this remarkable

39



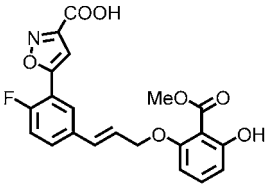
2.4 nM (K_i, PTP1B)

Figure 20. Two-site-binders: an alternative approach to the design of selective and potent PTP inhibitors.



potency, the compound showed excellent selectivity (in most cases by three orders of magnitude) over other intracellular PTPs, receptor-like PTPs, and DSPs. The selectivity against the most closely related TCPTP was tenfold. TCPTP is implicated in regulation of T-cell activation[169] and a mutation has been shown to be lethal for embryonic development in mice.[170] Therefore, from a therapeutic point of view, selectivity of PTP1B over TCPTP is highly desirable.

The exceptional potency and selectivity of compound **39** was later rationalized by the crystallographic structure of a similar compound in complex with PTP1B.[171] Whereas the active-site-targeting phenyldifluoromethylphosphonyl group bound the active site in the expected fashion, the authors found that the aspartic acid linker and the distal difluoromethylphosphonyl group developed interactions mainly with Lys41, Arg47 and Asp48. Other groups previously identified similar interactions by crystallization of a bisphosphonate inhibitor with PTP1B.[172] Thus the second phosphonate group binds near Arg47 rather than the previously identified secondary binding site.



Researchers at Abbott applied this concept to the development of nanomolar PTP1B inhibitors with good to excellent selectivities over other phosphatases.[173a] Their "linked-fragment approach" was based on a NMR spectroscopic screen for compounds that bind weakly to the active site as well as the second site. The investigation started with a 10000-membered library of compounds with ^{13}C-enriched PTP1B ("SAR by NMR"). Guided by X-ray crystallographic data from protein–ligand complexes and linkage of the identified fragments, compound **40** was designed (Figure 21), a 22 nM inhibitor of PTP1B. The diaryloxamic acid moiety binds to the active site, and the naphthoic acid

group binds the second site. Other phosphatases like LAR, SHP-2, and CD45 were inhibited at much higher concentrations (1–54 μM), whereas the compound was twofold less effective toward the most closely related phosphatase, TCPTP. By analysis of X-ray crystallographic data of the protein–inhibitor complex, the authors developed a model of inhibition for compound **40** (Figure 22). The oxamic acid moiety works as a phosphate mimetic and binds to the open form of the enzyme, where the Trp179–Ser187 loop retains a conformation similar to that of the unoccupied enzyme. The benzoic ring of the oxamic acid moiety makes hydrophobic contacts with Gln262, while the carboxylate interacts with Arg221. The naphthalene moiety makes hydrophobic interactions with Tyr46, while the adjacent C_4-diamido chain extends out of the active site to form hydrogen bonds with Asp48. The naphthoic acid group is placed in the second binding site, forming ionic interactions with Arg254 and Arg24; the naphthalene ring forms weak hydrophobic

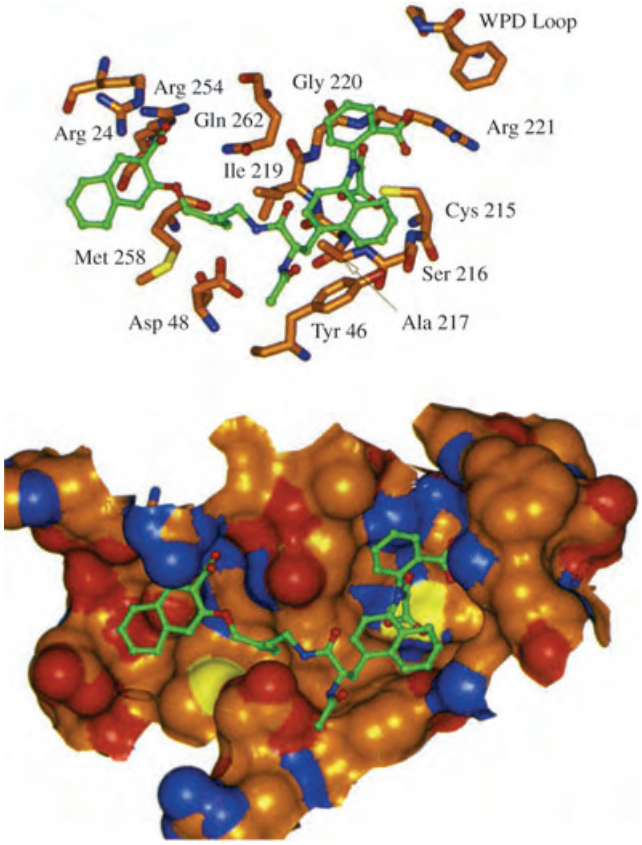

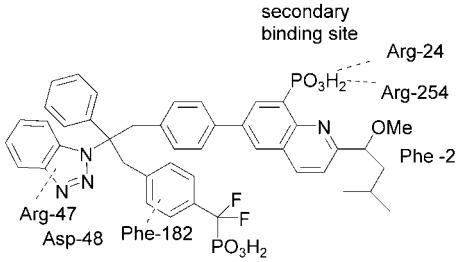

Figure 22. Inhibitor **40** bound to PTP1B (from Ref. [173a] with permission).

interactions with Met258. Although a good phosphatase inhibitor in vitro, compound **40** showed poor cellular membrane permeability as a result of its high polarity. To circumvent this problem, a prodrug approach was applied, leading to diester **41**, which showed increased insulin-induced PKB phosphorylation of FAO cells.[173b] In another approach, the same research group used NMR spectroscopic screening, but started from less polar compounds.[173c] From this study, compound **42** was produced in which the oxamic acid unit was replaced by isoxazole carboxylic acid. Compound **42** shows a K_i (PTP1B) value of 6.9 μM, a 30-fold selectivity preference over TCPTP, and no inhibition of other phosphatases (LAR, CD45, Cdc25, and SHP-2) up to 300 μM. It is therefore one of the most selective PTP1B inhibitors described to date. Moreover, **42** showed activity in the leptin pathway in COS-7 cells (for similar studies by Abbott see Ref. [173]).

Although it is a remarkable advance in the development of more potent inhibitors of PTPs, there has been some reservation concerning the utility of this concept to the development of truly selective PTP inhibitors, as some of the residues involved in the binding of the second aryl moiety (especially Arg47) are also present in phosphatases other than PTP1B, with particular regard to TCPTP.[172a]

Other amino acid residues like Phe52 and Ala27 (PTP1B) have also been targets of research at Merck Frosst, as the corresponding positions in TCPTP have different residues (Tyr and Ser, respectively). Based on X-ray crystallographic structural data, inhibitor **43** was developed (Figure 23) which employs a phenyldifluoromethylphosphonate group as a primary active-site binding motif, a benzotriazole group that interacts with Arg47 and Asp48, and a substituted quinoline moiety directed toward Phe52 and Ala27, tethered by a rigid

biphenyl linker to the rest of the molecule. The phosphonate moiety of the quinoline interacts with Arg24 and Arg254, the residues of the original secondary binding site as defined by Zhang,[167] whereas the methoxy and the isobutyl groups interact with Phe52 (Figure 24). Although a very potent

PTP1B inhibitor ($IC_{50} = 5$ nM) with cellular activity ($IC_{50} =$ 58 nM, compare with **24**; Figure 12), compound **43** was only moderately selective over TCPTP (sevenfold), again illustrating the difficulty in finding truly selective PTP1B inhibitors.[174]

7.3.3. *Quinones*

Many PTP inhibitors contain a quinone functionality, in which case one would intuitively expect the active-site cysteine residue to be oxidized, or to form covalent adducts with such compounds. However, the modes of inhibition of quinone-derived inhibitors sometimes differ from the expected scenarios.

In an interesting approach, Wipf and co-workers screened 10070 compounds of the National Cancer Institute (NCI) for inhibitors of Cdc25.[175] They identified 21 compounds with IC_{50} values less than 1 μM. Furthermore, they found that 75% of the hits were quinones; more than 40% were *para*-naphthoquinones, among them compound **44** (NSC95397, IC_{50}(Cdc25B) = 0.125 μM; Figure 25). This compound is

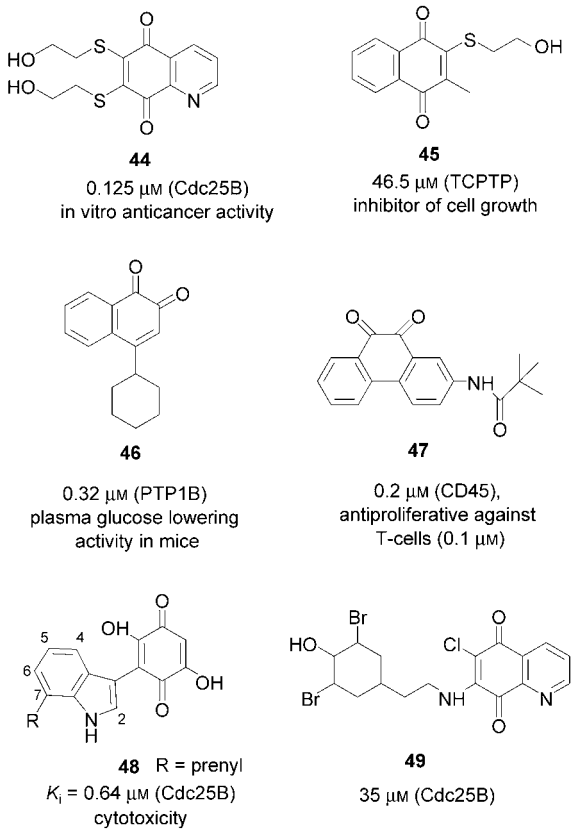

Figure 25. Quinone-derived PTP inhibitors; IC_{50} values are given.

closely related to naphthoquinone **45**, a vitamin K analogue which had been described before as an inhibitor.[176] The compounds show only moderate selectivity against other phosphatases like PTP1B and VHR. They inhibit irreversibly, have anticancer activity in vitro against one prostate and two breast cancer cell lines and induce cell-cycle arrest of tsFT210 cells at micromolar concentrations. With the known structure of Cdc25B, Wipf and co-workers proposed a binding mode of the naphthoquinone moiety at the surface of the enzyme in a secondary, sulfate-binding site located adjacent to the active site.[175,94b] In this model, the carbonyl oxygen atoms of the quinone form hydrogen bonds to two arginine residues: Arg482 and Arg544. The aromatic ring is bound by hydrophobic interactions with other amino acids (Arg479, Thr547, Tyr428, Phe543) in the interior of the pocket. To confirm their model, a set of analogues was synthesized. It was shown that the aromatic moiety and the *para*-quinone were needed for inhibition. Further substitution of the thiol side chains did not improve activity. This model also explains why so many *para*-quinone compounds of the NCI library do not inhibit Cdc25; the binding site is close enough to the catalytic cysteine group (Cys473) to allow covalent modification by the electrophilic quinone moiety.[177]

In a similar approach, Choi and co-workers identified the 1,2-naphthoquionone moiety as the pharmacophore for PTP1B.[178] They found that some substituted compounds like **46** showed remarkable activity against PTP1B (IC_{50} = 0.32 μM). Furthermore, a 10- to 60-fold selectivity over other phosphatases (like CD45, LAR, Yop, PP1, and Cdc25B) was demonstrated. The compounds lowered plasma glucose levels in mice.

A similar series of compounds, namely phenanthrenediones (for example, **47**; Figure 25) which showed cellular activity, was investigated by researchers at AstraZeneca.[179] The most effective compounds obtained inhibited CD45 in the single-digit micromolar range, whereas PTP1B was not inhibited at 30 μM. The compounds acted as reversible competitive inhibitors. Furthermore, some compounds inhibited the proteases cathepsin L and S, but not cathepsin B.

A difficult aspect in the search for inhibitors of dual-specifity phosphatases like Cdc25 is the open and shallow shape of the active site, which is directly linked to the low specificity of these enzymes towards their substrates. In this respect, the indolyldihydroxyquinone moiety has been described by Rudolph and co-workers as a promising lead for the development of reversible, competitive inhibitors of Cdc25 with submicromolar inhibition constants (**48**; Figure 25).[180] The substitution pattern of the indole moiety was varied systematically, showing that variation at positions 2 and 4 led to a significant decrease of potency, substitution at positions 1 and 5 had little effect, whereas modification at positions 6 and 7 led to stronger Cdc25 inhibition. All isoforms of Cdc25 (A, B, and C) were inhibited, while the activity of PTP1B was unaffected up to 50 μM. Although similar to previously described quinone-based phosphatase inhibitors (for example, NSC668394 (**49**); Figure 25), the authors demonstrated that the mode of inhibition was different (reversible and competitive). The finding that the quinone moiety does not covalently modify the enzyme was rationalized with the rather electron-rich nature of the quinone (two hydroxy groups, one indolyl group). To understand the mechanism of inhibition, several site-directed mutants and a C-terminally truncated variant of Cdc25B were tested. The authors showed that three amino acids, Glu474, Phe475 (which are part of the characteristic HCX_5R loop), and Arg482 as well as the C-terminal tail were important for the inhibition mode. Arg482 has been proposed before to bind other quinone-based Cdc25 inhibitors.[175] The C-terminal portion has been shown to play an essential role in the interaction with the natural substrate of Cdc25, the Cdk2–cyclin A complex.[181] It is interesting to note that the IC_{50}

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

values of the inhibitors determined with the natural substrate proved to be higher (albeit still in the micromolar range) than those determined with the commonly used artificial substrate 3-*O*-methylfluorescein phosphate. Cell toxicity of the inhibitors in vitro, possibly through apoptotic mechanisms, was demonstrated. Remarkably, no increase in phosphorylation of the Cdks was detected. The observed nonspecific binding of the inhibitors to serum albumin could be a problem for their future development as drug candidates.

7.3.4. Other Approaches

Starting from a pharmacophore model derived from natural product inhibitors of the serine/threonine phosphatase PP1,[182] a combinatorial approach was used to generate new inhibitors (for example, **50**; Figure 26) which are active toward PTPs and DSPs.[183] This is remarkable, as serine/threonine phosphatases are quite different from their PTP counterparts. The mechanism of inhibition remains unclear; a kinetic analysis has shown that they act as partially competitive, reversible inhibitors of Cdc25B, whereas they exhibit noncompetitive inhibition toward other phosphatases. The compounds inhibit tumor cell growth in culture. Hydrophobic interactions with the enzyme play an important role in inhibition, while both the carboxylic acid and the oxazole moieties form hydrogen-bond interactions. The cyclohexyldiamine linker confers conformational rigidity and thereby enhances the potency of the compounds.

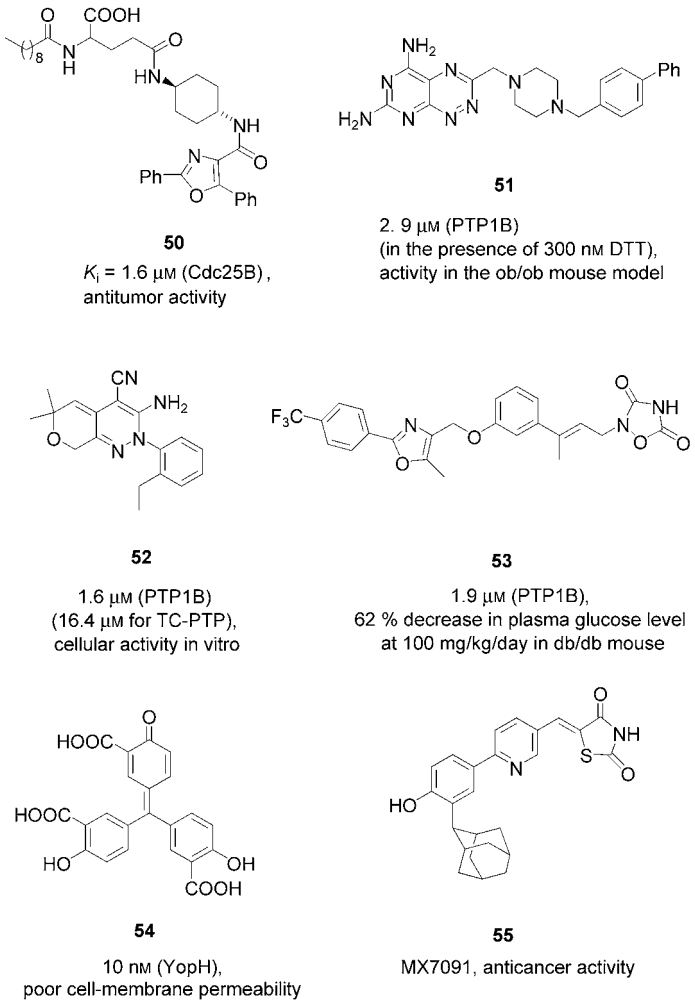

Figure 26. Further PTP inhibitors obtained from diverse approaches; IC_{50} values are given except for **50** and **55**.

PTPs contain a cysteine residue which is essential for catalytic activity. Oxidation of this cysteine inactivates the enzyme, a mechanism also relevant for the in-vivo regulation of enzymes, for example, in the early phases of the insulin signal-transduction cascade, in which a burst of intracellular hydrogen peroxide inhibits PTP1B upon insulin stimulation. As a result, the cascade is enhanced.[135] This process is reversible, as the resulting oxidation product is reduced by glutathione. A similar mechanism is probably responsible for the in-vitro inhibition of PTP1B by pyrimidotriazinediamine-based compounds (for example, **51**; Figure 26) developed at Roche, which show a reversible inhibition of the enzyme in the presence of DTT.[184] Although the compounds are active in vivo in the ob/ob mouse model at 30 mg kg^{-1}, they show little selectivity over other phosphatases such as LAR, PTP-α, and SHP-2.

Researchers at Biovitrum described another inhibitor type, the pyridazine analogues (for example, **52**; Figure 26).[185] They act as noncompetitive reversible inhibitors, with IC_{50} values in the low micromolar range. Therefore, they bind to a site different from the active site. Additional positive aspects include their high selectivity over TCPTP (20-fold in the case of some analogues) and their cell-membrane permeability. They exhibited oral bioavailability and increased insulin-stimulated phosphorylation of the insulin receptor.

Further small-molecule inhibitors of PTP were discovered more or less by chance. For example, researchers at Wyeth–Ayerst described azolidinone derivatives that have submicromolar IC_{50} values against PTP1B; some of these derivatives, like **53**, (Figure 26) normalized plasma glucose and insulin levels in diabetic mouse models.[186] However, the authors pointed out that the compounds may also act as agonists toward the peroxisome proliferator-activated receptor γ (PPAR-γ).

In an effort to identify agents that work against the plague, Zhang and co-workers identified a highly potent and selective inhibitor against the *Yersinia* phosphatase YopH (which is essential for virulence) by screening 720 commercially available carboxylic acids.[187] Aurintricarboxylic acid (**54**) inhibited YopH with an IC_{50} of 10 nM and 6–120-fold selectivity over other phosphatases, such as PTP1B (61 nM) and CD45 (250 nM). The compound also restored T-cell activity in YopH-transfected Jurkat cells, although electroporation was necessary to enable cellular uptake of the highly charged compound.

Incyte is currently developing inhibitors against the dual-specificity phosphatase MKP-1. MKP-1 inhibits apoptosis through the inactivation of the kinase JNK. One MKP-1 inhibitor, MX7091 (**55**; Figure 26) proved to be more effica-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

cious against solid tumors than paclitaxel in mice and exhibited synergistic effects when combined with cisplatin.[14]

8. Conclusions and Future Prospects

We have given an overview of the structure, functions and possible therapeutic relevance of selected PTPs. Today, the structures and catalytic mechanisms of several phosphatases are reasonably well-understood. Although major progress has been made toward an understanding of the involvement of PTPs in signal-transduction pathways, and in the development of diseases and infections, there is still a lot of work to be done in this field, as well as for the search for other PTPs and their biological relevance.

Ever since the discovery that the PTP1B knockout is not a lethal mutation in mice, but instead confers protection from obesity and improved insulin sensitivity, scientists in both academia and pharmaceutical industry have realized that the inhibition of PTPs may be a valuable tool for molecular biology research, as is the well-established case for the serine/threonine phosphatases. PTP inhibition could also be a possible source of valuable drugs against major diseases like diabetes and obesity. Moreover, the treatment of other diseases (infectious, autoimmune or neurological disorders, and cancer) is expected to profit from PTP inhibitor research. Although a few natural products have been identified as PTP inhibitors, the major strategy adopted today has been the design of small molecules based on nonhydrolyzable phosphotyrosine mimetics. Whereas very potent in-vitro PTP inhibitors have been identified, two major challenges characterize this field: increasing cell-membrane permeability through the design of noncharged (or less-charged) compounds, which is a prerequisite for activity in vivo, and the identification of truly selective inhibitors—a task quite difficult, regarding the highly conserved nature of the PTP active site. The finding of a second aryl phosphate binding site on PTP1B has been a major step in getting closer to achieving this goal. However, a further increase of selectivity over other phosphatases, which exert vital cellular functions (like the T-cell PTP) is required to decrease the risk of undesirable side-effects.

The aforementioned tasks appear to be within reach, given the progress already made in the development of PTP1B inhibitors and the power of modern medicinal chemistry research. In line with this notion, the phosphatases have already been considered by pharmaceutical researchers to make up a considerable part (4%) of the "druggable genome",[188] and an in-depth analysis of the genome revealed that there are 107 protein tyrosine phosphatases[189] which will most likely be the prime candidates for drug development. For several years, various phosphatases have been forming an integral part of the screening units of pharmaceutical companies, and an initial candidate has already been subjected to clinical trials (Section 7.3.1). Notably, in comparison with other target classes that belong to the "druggable genome", phosphatases are only beginning to move into the focus of pharmaceutical research, and today the field is clearly still in its infancy. However, given the crucial roles these enzymes play in innumerable biological processes, it appears almost certain that phosphatase inhibitors will be an integral part of the drugs of the next generation.

Communications

Molecular clusters formed by hydrogen bridges can be highly dynamic systems, as shown here for a fluoromethane–trifluoromethane molecular complex: The two subunits are not rigidly locked, but almost freely spin around their symmetry axes. For more information, see the Communication by W. Caminati et al. on the following pages.

Molecular Complexes

Weak CH···F Bridges and Internal Dynamics in the $CH_3F{\cdot}CHF_3$ Molecular Complex**

Walther Caminati, Juan C. López, José L. Alonso, and Jens-Uwe Grabow*

Herein, we report the effects of weak CH···F hydrogen bonds and dipole–dipole interaction energies on the conformation of the molecular complex fluoromethane–trifluoromethane and the internal dynamics of the two symmetric top subunits, which rotate almost freely with respect to each other.

The non-covalent interactions CH···F and CH···O, which play important roles in biological, atmospheric, and supramolecular chemistry, have been classified as weak hydrogen bonds (WHBs).[1] Studies on WHBs have been mainly performed by X-ray diffraction[2] and, to a lesser extent, by IR spectroscopy on solutions of rare gases.[3] The experimental data on WHB obtained from investigations in the solid or solution states are contaminated by other intermolecular interactions that take place in condensed phases and do not give information on the internal dynamics of the subunits held together by these interactions.

The few rotationally resolved investigations of molecular adducts in which the monomers are held together by CH···F and CH···O WHBs have shown the specificity and directionality of these interactions.[4–9] For example, the dimer of difluoromethane is stabilized only by CH···F bridges[4] and several theoretical investigations have been reported on this type of interaction.[10–12]

The heterodimer fluoromethane–trifluoromethane ($CH_3F{\cdot}CHF_3$) is also expected to contain only CH···F linkages, and an investigation of this dimer is of particular interest to assess the relative weights of the WHBs and dipole–dipole interaction energies. In Figure 1 two plausible conformations of $CH_3F{\cdot}CHF_3$ (A and B) are shown in which three WHBs stabilize the two subunits. In A the three hydrogen s orbitals in CH_3F can probably better overlap with the three fluorine p orbitals of the opposing molecule, but B has a more favorable electrostatic potential energy from the dipole–dipole interaction, with the two dipole moments almost antiparallel to each other. To elucidate the balance between these two stabilization mechanisms, we studied the rotational spectrum of $CH_3F{\cdot}CHF_3$ isolated in the interaction-free matrix of a supersonic jet by employing Fourier-transform microwave spectroscopy (see Experimental Section for details). We could assign only the spectrum of species B: 32, 12, and 11 rotational transitions (see Supporting Information) have been measured for the normal, $CH_3F{\cdot}^{13}CHF_3$, and $^{13}CH_3F{\cdot}CHF_3$ isotopomers, respectively. At an overall point group symmetry of C_s, the molecular complex has two inequivalent internal rotors of C_{3v} symmetry. By taking the feasible large amplitude motions into account within the permutation-inversion (PI) group theory formalism,[13] the appropriate molecular symmetry (MS) group will be G_{18} and the torsional wavefunctions can accordingly be symmetry-classified as A_1, E_1, E_2, E_3, and E_4.[14] All measured transitions were split into a non- and a doubly degenerate (designated A_1 and E_1, respectively) component line as a result of the internal rotation of the CHF_3 group around its symmetry axis. The three other components, E_2, E_3, and E_4, which arise from the internal rotation of the CH_3F group and the interaction between both groups, were not observed. For a very low tunneling barrier, the corresponding splittings are predicted to be very large and thus difficult to locate. The combined analysis of the rotational transition frequencies for the A_1 and E_1 states of the internal rotations of the CHF_3 group[15] yielded the spectroscopic constants shown in Table 1. The internal rotation parameters[16] included therein are: 1) I_α, the moment of inertia of the CHF_3 top, 2) $\measuredangle(a,i)$, the angle between the internal rotation axis of the CHF_3 top and the principal axis of inertia a of the complex, and 3) V_3, the barrier to internal rotation of the CHF_3 top. For the two less abundant isotopomers the results were similar; the larger standard errors are a result of the smaller experimental data set. The effective moment of inertia determined from the A_1–E_1 splitting pattern for an internal rotor (see Table 2) in

Table 1: Spectroscopic constants for adduct $CH_3F{\cdot}CHF_3$.[a]

Parameter	$CH_3F{\cdot}CHF_3$	$CH_3F{\cdot}^{13}CHF_3$	$^{13}CH_3F{\cdot}CHF_3$
A [MHz]	6451.696(2)	6456(5)	6440(2)
B [MHz]	1459.976(6)	1456.23(2)	1430.48(1)
C [MHz]	1413.440(6)	1410.10(2)	1386.47(1)
D_J [kHz]	2.740(3)	2.720(7)	2.668(3)
D_{JK} [kHz]	53.44(2)	52.2(5)	51.2(2)
D_K [kHz]	16.3(3)	16.3[b]	16.3[b]
d_J [kHz]	0.222(2)	0.219(5)	0.204(2)
d_K [kHz]	1.4(9)	1.4[b]	1.4[b]
I_α [u Å^2]	86.0(3)	89(3)	86(2)
$\measuredangle(a,i)$ [°][c]	51.4(1)	53(2)	50.6(8)
V_3 [kJ mol^{-1}]	0.840(5)	0.80(3)	0.88(2)
N[d]	64	24	22
σ [kHz][e]	3.2	4.1	1.5
P_{bb} [u Å^2]	44.865(1)[f]	44.82(4)	44.85(2)

[a] A_1 and E_1 states of the internal rotation; I^r representation of Watson's S-reduced Hamiltonian.[15]. Standard errors in parentheses are given in units of the last digit.[b] Parameters were fixed to those of the normal species. [c] $\measuredangle(a,i)$ is the angle between the inertial axes a and the internal rotation axis I; $\measuredangle(b,i)$ is the complement of $\measuredangle(a,i)$ at 90°, while $\measuredangle(c,i)$ is 90° from the symmetry axis. [d] Number of transition frequencies in the fit. [e] Root-mean-square deviation of the fit. [f] Smaller than the sum (46.17 u Å^2) of the P_{bb} values of isolated CHF_3 and CH_3F (44.62 and 1.55 u Å^2, respectively).

Table 2: Comparison of the internal rotation parameters for the CF_3 and CH_3 internal rotors of $CH_3F{\cdot}CHF_3$.

Internal rotor	CF_3	CH_3
I_α [u Å^2]	85.0	3.20
V_3 [kJ mol^{-1}]	0.840	0.36
s	67.92	2.5
Δ_{AE} [MHz][a]	2.6×10^{-1}	1.2×10^{5}
N_{levels}[b]	12	2

[a] Energy spacing between the A_1 and E_1 or E_2 sublevels, that is, $W(E_1)-W(A_1)$ and $W(E_2)-W(A_1)$, respectively, of the vibrational ground state. [b] Number of bound levels below the corresponding V_3 barrier.

$CH_3F{\cdot}CHF_3$ is only slightly smaller than the value of 89.23(2) u Å^2 for isolated CHF_3.[17] This result indicates that the motion responsible for the A_1–E_1 spectral separations is essentially the rotation of the CHF_3 group around an axis close to its C_3 symmetry axis.

The A_1–E_2 torsional splitting was deduced also for the internal rotation of the lighter CH_3F group. This splitting is related to the unexpectedly low value of the planar moment of inertia, P_{bb}, of the complex. The planar moments of inertia, defined as $P_{aa}=1/2\,(-I_{aa}+I_{bb}+I_{cc})$, and cyclic permutations give the extensions of the molecular system in the directions of the considered principal axis. For the $CH_3F{\cdot}CHF_3$ complex the value of P_{bb} should correspond to the sum of the values of P_{bb} for the two isolated symmetric tops (1.55 and 44.62 u Å^2),[17,18] that is, 46.17 u Å^2. This is the case, for example, for oxirane·CHF_3,[6] for which P_{bb} (63.86 u Å^2) is almost exactly the sum of the P_{aa} value of oxirane and the P_{bb} value of CHF_3 (19.43 and 44.62 u Å^2, respectively). In $CH_3F{\cdot}CHF_3$, P_{bb} is 44.69 u Å^2, which is lower by 1.48 u Å^2 than the sum value (46.17 u Å^2). Such an unusually low value of P_{bb} is indicative of an exceptionally low V_3 barrier to the internal rotation of the methyl group. In fact, rotational constants are effective quantities that include the "pseudo" contributions due to the internal rotation of the methyl group, according to Equation (1),[19] in which A_r, B_r, and C_r are the "rigid" rotational constants in the limit of the very high barrier; $W_{00}^{(n)}$ are Hersbach's barrier-dependent perturbation sums relative to the A sublevels of the ground state;[20] F is the reduced constant of the motion; $\rho_g=\lambda_g I_\alpha/I_g$.

$$\begin{aligned} A_{00} &= A_r + W_{00}^{(2)}\,F\,\rho_a^2 \\ B_{00} &= B_r \\ C_{00} &= C_r + W_{00}^{(2)}\,F\rho_c^2 \end{aligned} \qquad (1)$$

The experimentally determined value of P_{bb} is obtained at $V_3=30\ \mathrm{cm}^{-1}$. As the curve V_3 versus P_{bb} is very steep at that point, we can set an estimated error of $10\ \mathrm{cm}^{-1}$. The parameters relevant to the internal rotations of CH_3F and CHF_3 are compared in Table 2. Although the two V_3 barriers are relatively similar, the reduced barriers s, which contain both potential- and kinetic-energy factors, are very different from each other. Correspondingly, the A_1–E_1 and A_1–E_2 splittings, that is, the Δ_{AE} energy spacings between the A_1 and E_1 or E_2 sublevels, respectively, of the vibrational ground state, differ by six orders of magnitude.

For several molecular complexes, it has been possible to estimate the force constant (k_s) of the stretching motions between the two moieties that lead to dissociation, by using approximated Equation (2),[21] in which μ, R_{CM}, B, C, and D_J are the reduced mass, the distance between the monomer centers of mass, the rotational constants, and the first-order centrifugal distortion constant, respectively, of the adduct, and h is Planck's constant. However, in the case of $CH_3F{\cdot}CHF_3$, the effective parameter D_J contains contributions from one of the large amplitude motions, that is, the internal rotation of the CH_3F group. These contributions can be calculated with Equation (3).[22]

$$k_s = 16\,\pi^4\,(\mu\,R_{CM})^2\,[4\,B^4+4\,C^4-(B-C)^2(B+C)^2]/(h\,D_J) \qquad (2)$$

$$D_J = -1/2\,(\rho_b^4+\rho_c^4)\,W_{00}^{(4)}\,F \qquad (3)$$

The estimated correction (0.029 kHz) to the effective value in Table 1 is very small. Thus, by using the value of 2.711 kHz in Equation (2), a value $k_s=5.2\ \mathrm{N\,m^{-1}}$, which corresponds to a harmonic stretching frequency of $62\ \mathrm{cm}^{-1}$, was obtained. The dissociation energy (E_D) has been evaluated to be $5.3\ \mathrm{kJ\,mol^{-1}}$ by assuming a Lennard–Jones potential function and using the approximated equation[23] $E_D=1/72\,k_s R_{CM}^2$. Such a dissociation energy corresponds to a binding energy of $1.8\ \mathrm{kJ\,mol^{-1}}$ for each C–H···F linkage. This value is very similar to that found for the dimer of difluoromethane, which also displays three C–F···H–C interactions.[4]

If we assume the geometries of isolated CHF_3[17] and CH_3F[18] to remain unaltered in the adduct, we have sufficient experimental data to obtain a plausible r_0 structure, that is, to determine the three parameters r, α, and β shown in Figure 1. First, we calculated the rigid values of the rotational constants by applying the CH_3 corrections indicated in Equation (1) to the effectively determined rotational constants. Then we

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

fitted the nine available rotational constants to obtain the three parameters. In the fit, we allowed these parameters to change, with respect to the ab initio values, at "confidence intervals" of 0.01 Å for the bond distance and at 2° for the two angles, respectively, according to the diagnostic least-squares procedure described by Curl.[24] The three parameters, r, α, and β, are reported in Table 3, together with the derived distance of the other hydrogen bonds. The substitution coordinates[25] of the carbon atoms of the CH_3F and CHF_3 subunits (see Table 3 footnotes) allow the C–C distances, which are also listed in Table 3, to be determined.

Table 3: Relevant structural parameters of $CH_3F{\cdot}CHF_3$ (see Figure 1).

r_0 parameters	r_0[a]	r_s[b]	ab initio[c]
$r(F_{CH_3F}\cdots H_{CHF_3})$ [Å][a]	2.427(10)	–	2.405
α [°][a]	124.1(3)	–	122.3
β [°][a]	115.5(3)	–	109.9
$r(F_{CHF_3}\cdots H_{CH_3F})$ [Å][d]	3.052(15)	–	2.842
$r(C_{CH_3F}\cdots C_{CHF_3})$ [Å][d]	3.645	3.60(2)[e]	3.522

[a] $r(F_{CH_3F}\cdots H_{CHF_3})$, which coincides with r of Figure 1, α, and β are the fitted parameters. The remaining parameters have been derived from the obtained partial r_0 geometry. [b] From the substitution coordinates of CH_3F and CHF_3 carbon atoms. [c] Computed values at MP2/6-311++G(2df,2p) level. [d] Derived parameter. [e] C···C distance between the carbon atoms of CH_3F and CHF_3. From r_s coordinates of C_{CHF_3} [$|a|$ = 0.84(6); $|c|$ = 0.43(4) Å] and of C_{CH_3F} [$|a|$ = 2.619(7); $|c|$ = 0.57(3) Å]. $|b|$ is fixed to 0 because imaginary.

Ab initio computations at the MP2/6-311++G(2df,2p) level[26] at different points of the $CH_3F{\cdot}CHF_3$ potential-energy surface have been performed to investigate the conformational behavior of the dimer. Conformer B is predicted to be the global minimum. Some of the calculated structural parameters for this conformer are compared to the experimental values in Table 3. The counterpoise (CP)-corrected dissociation energy for this conformer is calculated to be 10.0 kJ mol^{-1}, which is higher than that determined from the centrifugal distortion. Conformer A is predicted to be also a stable minimum, some 714 cm^{-1} (619 cm^{-1} after CP corrections) higher in energy than species B.

Other plausible conformers shown in Figure 2 were also considered. However, at this level of theory these conformers are predicted to be transition configurations with one negative frequency. Figure 3 shows the calculated potential-energy curves that describe the internal rotation of CHF_3 and CH_3F around their local C_3 axes. As indicated, the measured V_3 values thus give the experimental energies of configurations C and D with respect to B. They are in good agreement with the ab initio values, although the results of ab initio calculations lead us to anticipate that the shape of the potential-energy surface is more complicated.

In summary, we have shown how rotational spectroscopy can supply detailed information on the chemical features of weak hydrogen bonds and provide insight on the internal dynamics of the unit constituents of molecular complexes with unrivaled precision. In the case of $CH_3F{\cdot}CHF_3$ studied here, the CH_3F moiety "sees" CHF_3 in a well-defined position, while the CHF_3 unit "sees" CH_3F as a "cone".

Experimental Section

Commercial samples of CH_3F (Aldrich) and CHF_3 (Linde gas) were used without further purification. The spectra of the isotopic ^{13}C-containing species were measured in natural abundance.

The rotational spectrum in the 6–18.5 GHz frequency region was measured using a coaxially oriented beam-resonator arrangement-(COBRA)-type[27] pulsed supersonic jet Fourier-transform microwave (FT-MW) spectrometer,[28] as described elsewhere[29] and recently updated with the FTMW++ set of programs.[30]

A gaseous mixture of CH_3F (1%) and CHF_3 (1%) in He at a total pressure of 2.0 bar was expanded through the solenoid valve (General Valve, Series 9, nozzle diameter 0.5 mm) into the Fabry–Pérot cavity. The spectral line positions were determined after Fourier transformation of the 8000-data-point time-domain signal, recorded at intervals of 100 ns. Each rotational transition is split by the Doppler effect as a result of the coaxial arrangement of the supersonic jet and resonator axes in the COBRA-FTMW spectrometer. The rest frequency is calculated as the arithmetic mean of the frequencies of the Doppler components. The estimated accuracy of frequency measurements is greater than 3 kHz. Lines separated by more than 7 kHz are resolvable.

Coordination Polymers

A Metal–Organic Framework with the Zeolite MTN Topology Containing Large Cages of Volume 2.5 nm^3 **

Qianrong Fang, Guangshan Zhu, Ming Xue, Jinyu Sun, Yen Wei, Shilun Qiu,* and Ruren Xu*

Metal–organic framework (MOF) coordination polymers have attracted tremendous attention because of their intriguing molecular topologies and their potentially useful ion-exchange, adsorption, catalytic, fluorescence, and magnetic properties.[1–7] By taking advantage of the well-defined coordination geometries of metal centers as nodes, the structures of various minerals, such as quartz diamond,[8,9] perovskite,[10] rutile,[11] PtS,[12,13] and feldspar,[14] with specific functionalities, have been artificially reproduced by replacing monoatomic anions (O^{2-}, S^{2-}) with polyatomic organic bridging ligands as linkers. To meet the increasing demand for large-pore frameworks that are suitable for catalyzing reactions of large molecules, successful synthetic strategies for the preparation of large-pore metal–organic polymers with a genuine zeolite topology are still a huge challenge.

The expansion and decoration of the topological networks of inorganic materials, which is an effective and powerful synthetic strategy, has been shown to produce a new generation of highly porous metal–organic polymers.[15,16] During the course of our work, Férey et al. described a novel metal–organic hybrid compound, $[Cr_3F(H_2O)_3O\{C_6H_3(CO_2)_3\}_2]\cdot n\,H_2O$ (MIL-100, $n \approx 28$),[17] with the zeolite MTN topology from Cr^{3+} ions and benzene-1,3,5-tricarboxylate, whose structure was determined by powder X-ray diffraction simulation. Our strategy for preparing such a metal–organic framework with large pores is based on expanding the zeolite topologies[18,19] by constructing metal–organic tetrahedral building blocks with four connections. In this work, we consider the hexamethylenetetramine (hmt) ligand to be the best candidate because it contains four coordinating N atoms, similar to the mode of the SiO_4 building block in zeolites. The cadmium ion was chosen as the bridge on account of the equatorial-plane locations of its trigonal-bipyramidal coordination geometry; these locations are easily coordinated by water molecules. Thus, a metal–organic tetrahedral building block TM_4 (T = tetrahedrally coordinated molecule; M = transition-metal ion), in which the M-T-M angles range from 108 to 120°, was constructed from an hmt molecule and four cadmium ions. We present herein a new metal–organic framework with zeolite topology constructed from this tetrahedral building block. The novel open-framework metal–organic polymer $[\{Cd(H_2O)_3\}_{34}(N_4C_6H_{12})_{17}]Cl_{68}\cdot 46\,H_2O\cdot 68\,DMF$ (**1**; DMF = *N*,*N*-dimethylformamide) possesses the zeolite MTN topology (MTN = zeolite socony mobil – thirty-nine) with two types of 5^{12} and 6^45^{12} cages. The 6^45^{12} cage has a volume of about 2522 Å^3 (a van der Waals sphere with a diameter of 16.8 Å would just fit inside the void). To the best of our knowledge, architectures with large cages have rarely been reported so far for metal–organic polymers (such as MOF-101[20] and MIL-100[17]).

Polymer **1** was synthesized under mild conditions. In a typical procedure, a mixture of $CdCl_2\cdot 2.5\,H_2O$ and hmt (10:1) was prepared in DMF/ethanol/H_2O (5:3:3) containing HCl, and then a solution of triethylamine in DMF was allowed to diffuse into the above mixture at room temperature to adjust the pH value of the solution. After standing for a month, colorless octahedron-shaped crystals of **1** were collected with a 67% yield based on cadmium. This complex is stable in air, soluble in water, methanol, and ethanol, slightly soluble in DMF, but insoluble in acetonitrile and nitromethane.

X-ray crystallographic analysis revealed that polymer **1**[21] consists of a 3D open framework with the zeolite MTN topology. Each cadmium ion is coordinated by two nitrogen atoms from two different hmt ligands and three coordinated water molecules (Figure 1). The hmt ligands adopt a tetrahe-

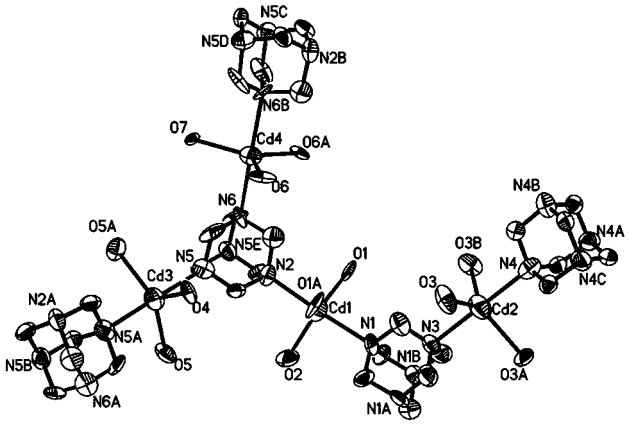

Figure 1. The coordination geometry of the cadmium ions in the asymmetric unit of polymer **1**. Thermal ellipsoids are shown at the 50% probability level. Selected bond lengths [Å] and angles [°]: Cd1–N1 2.455(8), Cd1–N2 2.385(7), Cd1–O1 2.445(4), Cd1–O2 2.466(7), Cd2–N3 2.468(13), Cd2–N4 2.421(16), Cd2–O3 2.459(6), Cd3–N5 2.440(6), Cd3–O4 2.485(5), Cd3–O5 2.419(5), Cd4–N6 2.513(8), Cd4–O6 2.453(4), Cd4–O7 2.448(7); N2-Cd1-N1 177.1(3), N2-Cd1-O1 90.12(13), O1-Cd1-N1 88.51(12), N2-Cd1-O2 90.2(3), N1-Cd1-O2 92.6(3), O1-Cd1-O2 118.36(13), N4-Cd2-N3 180.0(6), N4-Cd2-O3 89.64(17), N3-Cd2-O3 90.36(17), O5-Cd3-N5 92.50(17), N5-Cd3-O4 87.53(13), O5-Cd3-O4 114.69(15), O7-Cd4-N6 90.51(16), O6-Cd4-N6 89.74(8), O7-Cd4-O6 121.13(17).

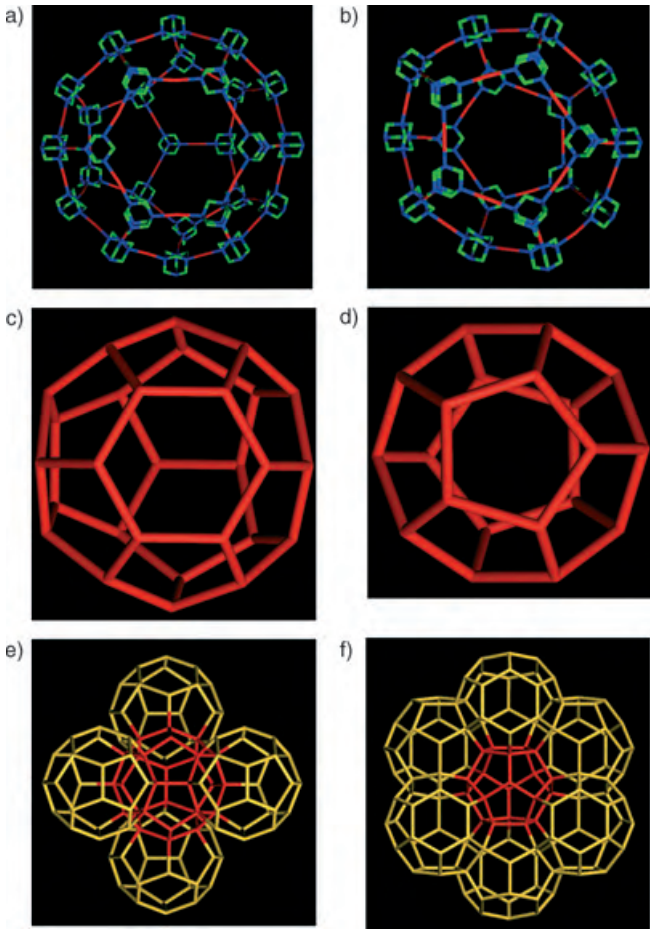

Figure 2. a) A large cage constructed from four six-membered rings (six {Cd_4(hmt)} tetrahedra) and twelve five-membered rings (five {Cd_4(hmt)} tetrahedra) and b) a small cage constructed from twelve five-membered rings (five {Cd_4(hmt)} tetrahedra) in the structure of polymer **1**. Cd red, N blue, C green; for clarity, the oxygen and hydrogen atoms are not shown. The topologies of the 6^45^{12} and 5^{12} cages are shown in (c) and (d), respectively. e) The 6^45^{12} cage in (c; red) sharing its four six-membered rings with four others (yellow). f) The 5^{12} cage in (d; red) sharing its six six-membered rings with six 6^45^{12} cages (c; yellow).

dral coordination geometry, with four different cadmium ions occupying the four coordination sites. The Cd–O lengths (2.419(5)–2.485(5) Å) are within the normal range,[22] and the Cd–N lengths (2.385(7)–2.513(8) Å) are close to those reported for other cadmium–nitrogen donor compounds.[23]

The framework of polymer **1** contains two kinds of cages composed of tetrahedral {Cd_4(hmt)} building blocks. The large 6^45^{12} cage (Figure 2a,c) consists of four six-membered rings (made of six tetrahedrally coordinated hmt molecules) of about 12.3×13.1 Å^2 (as measured between the centers of opposite atoms) and twelve five-membered rings of about 10.4×10.4 Å^2 in diameter. The small 5^{12} cage (Figure 2b,d) consists of twelve five-membered rings. Each 6^45^{12} cage in polymer **1** shares its six-membered rings with four neighboring 6^45^{12} cages (Figure 2e) and five-membered rings with twelve neighboring 5^{12} cages, while each 5^{12} cage in **1** shares its five-membered rings with six neighboring 6^45^{12} cages (Figure 2f) and six neighboring 5^{12} cages. In this way, all of these cages give rise to the 3D framework of polymer **1** with the MTN topology.[24] Figure 3 shows two kinds of windows for the five- and six-membered rings along the [110] direction. The same structure exists along five other directions (such as [101], [011], [$\bar{1}$10], 10$\bar{1}$], and [01$\bar{1}$]).

Unlike most zeolites, polymer **1** has a positively charged framework. The charge-balancing chlorine anions in the cages could not be directly located in the crystal structure analysis. However, inductively coupled plasma analysis[25] and mass-spectrometric analysis[26] indicated that the molar ratio of cadmium to chlorine is 1:2. In addition, elemental analysis[27] and thermal gravimetric analysis (TGA)[28] showed that each formula unit of polymer **1** includes about 46 guest H_2O and 68 DMF molecules. Anion exchange was carried out for the cationic framework[29–31] by substituting SCN^- for Cl^- in the cages. Typically, a 200-mg sample of the coordination polymer was treated at room temperature with 5 mL of DMF containing 3 M KSCN. After stirring for 20 min the product was filtered, washed with pure DMF, and then dried in air. The IR spectra of the exchanged product show new SCN^- bands (2075 cm^{-1}); the other signals of the IR spectrum and the powder XRD pattern remain virtually unchanged, which

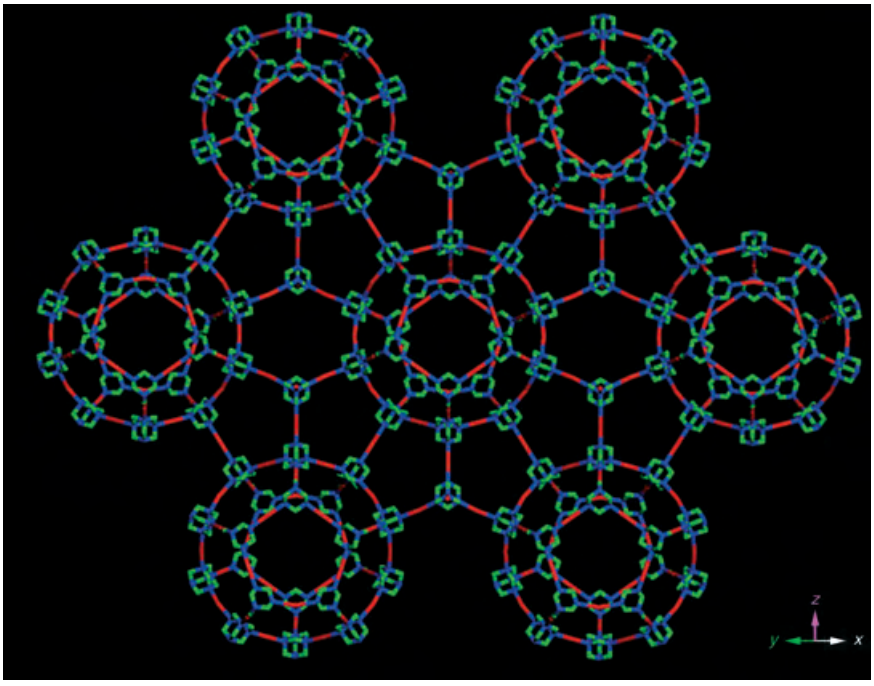

Figure 3. Infinite 3D coordination framework of polymer **1** viewed along the [110] direction. The windows of the six-membered rings (six {Cd_4(hmt)} tetrahedra) are about 12.3×13.1 Å^2 (measured between atom centers), and the windows of the five-membered rings (five {Cd_4(hmt)} tetrahedra) are about 10.4×10.4 Å^2 in this structure. Cd red, N blue, C green; for clarity, the oxygen and hydrogen atoms are not shown.

suggests that the skeleton is retained after anion exchange (see Supporting Information).

In conclusion, the novel 3D metal–organic framework polymer **1** with the zeolite MTN topology has been synthesized from the metal–organic tetrahedral building block TM_4. The framework of **1** greatly expands the original structure of MTN and possesses large cages with a volume of about 2522 Å^3. Other structures with zeolite or zeolite-like topologies and large cages should be obtainable by following a similar synthetic strategy. We believe that such metal–organic framework coordination polymers will come to be seen as a genuine third generation of zeolites that contain the same structures as traditional zeolites but offer several fundamental advantages, including ion-exchange, adsorption, and catalytic properties.

Experimental Section

1: $CdCl_2 \cdot 2.5\,H_2O$ (0.228 g, 0.1 mmol), HCl (0.1 mL, 2 M solution), hmt (0.014 g, 0.01 mmol), DMF (5 mL), ethanol (3 mL), and H_2O (3 mL) were placed in a 25-mL vial and stirred. After stirring in air for 1 h, the vial was placed in a 100-mL beaker containing a solution of triethylamine (0.1 mL) in DMF (8 mL), and then sealed and left for 30 days at room temperature. The resulting colorless octahedron-shaped crystals of **1** were collected (67% yield based on cadmium). The complex is stable in air, soluble in water, methanol, and ethanol, slightly soluble in DMF, but insoluble in acetonitrile and nitromethane. FTIR (KBr): $\tilde{\nu} = 3448$ (s), 2939 (w), 2360 (w), 1651 (s), 1466 (w), 1388 (w), 1242 (m), 1111 (w), 1011 (s), 818 (m), 694 (m), 579 (w) cm^{-1}.

[21] A colorless crystal of **1** ($0.30 \times 0.30 \times 0.28$ mm^3) was selected for X-ray structural analysis on a Bruker SMART CCD diffractometer at 298 K. The compound crystallized in the space group $Fd\bar{3}m$, cubic, $a = 48.9411(12)$ Å, $V = 117225(5)$ Å^3, $Z = 8$, $\lambda = 0.71073$ Å, $\rho_{calcd} = 1.185$ Mg m^{-3}, $\mu(Mo_{K\alpha}) = 1.558$ mm^{-1}, $F(000) = 40800$. A total of 108996 reflections were collected in the range $3.72 < \theta < 28.27$, of which 6526 were unique. The structure was solved and refined by full-matrix least-squares on F^2 (SHELXL-97; G. M. Sheldrick, SHELXL-97, program for X-ray crystal structure refinement, University of Göttingen, Göttingen, Germany). Non-hydrogen atoms were refined anisotropically. Hydrogen atoms were fixed at calculated positions and refined in a riding mode. Final $R1$ value 0.1891 (0.0799 after SQUEEZE) for 3121 independent reflections ($I > 2\sigma(I)$). The solvent-accessible volume was assessed using the PLATON software (A. L. Spek, *Acta Crystallogr., Sect. A* **1990**, *46*, C34) and the contribution of the chlorine anions and the disordered solvent to the diffraction pattern was subtracted from the observed data by the "SQUEEZE" method as implemented in PLATON (P. van der Sluis, A. L. Spek, *Acta Crystallogr., Sect. A* **1990**, *46*, 194). The SQUEEZE-bypass method referred to therein is widely used in crystallographic analysis of compounds containing substantial amounts of disordered solvent that cannot be located precisely from diffraction data. CCDC-253194 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

[28] TGA shows a weight loss of 5.24% during the first step (35–75°C), which corresponds to the loss of 46 guest water molecules (calcd: 5.10%). The weight loss of 11.18% during the second step (75–130°C) is attributed to the removal of 25 guest DMF molecules (calcd: 11.24%). The weight loss of 30.41% during the third step (140–245°C) is in accordance with the removal of 43 guest DMF molecules and 102 coordinated water molecules (calcd: 30.64%). (The IR spectrum of **1** displays bands at $\tilde{\nu}=$ 1651 and 2939 cm^{-1} because of $\nu_{C=O}$ and the asymmetric stretching vibration of the methyl group of the guest DMF molecules, respectively.) Decomposition of **1** began above 300°C.

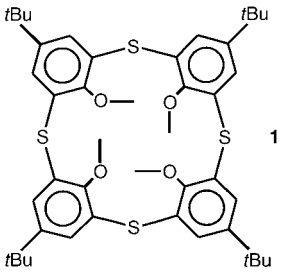
Water Transport



Diffusion of Water in a Nonporous Hydrophobic Crystal**

Praveen K. Thallapally, Gareth O. Lloyd, Jerry L. Atwood, and Leonard J. Barbour**

The transport of water molecules across cell membranes in biological systems is significantly enhanced by the presence of aquaporins,[1] proteins that associate as tetramers to form cylindrical transmembrane pores 2 to 3 nm long and about 0.3 nm wide at their narrowest point. Water travels through these channels at bulk diffusion rates,[2] presumably as single-file, hydrogen-bonded chains consisting, at any instant, of about seven to nine water molecules.[3] While interest in the transport properties of aquaporins has mainly focused on their selectivity for water over protons,[4] the influence of the channel size on water permeation has also received significant attention.[4f,5]

The shape, dimensions, and electrostatic profile of biological pores are considered to be the major determinants of their function. Intuitively, the simple notion of molecular transport through any matrix implies the presence of suitably sized channels defined and bounded by van der Waals surfaces. For example, molecular-scale hydrodynamics is only expected to occur if the narrowest site of the channel is at least wide enough to admit a single water molecule. Our own recent work with crystals composed of relatively small organic molecules has raised questions about the transport of small, mobile molecular species in solid media and we have shown that the conventional conception of crystal porosity may be flawed.[6] We have now extended our investigations of transport phenomena within seemingly nonporous crystals to include studies of water diffusion processes.

Crystals of pure 5,11,17,23-tetra-*tert*-butyl-25,26,27,28-tetramethoxy-2,8,14,20-tetrathiacalix[4]arene (**1**) were prepared

by sublimation at 240 °C under reduced pressure. Visual examination of the crystals revealed two different morphologies: primarily parallelepipeds (**1a**), interspersed with a relatively small number of square plates (**1b**). The structures of both crystal forms were elucidated by single-crystal X-ray diffraction analysis and found to be polymorphic variants of one another. In both cases the calixarene assumes the 1,3-alternate conformation, and the molecule is approximately box-shaped, with estimated dimensions of $10 \times 10 \times 14$ Å^3. The space group of polymorph **1a** is $C2/c$ and the molecules are arranged in two distinct orientations, each with the principal molecular axis canted at an angle of 83° with respect to the other. However, in the context of the present study, the structure of **1a** is of limited interest. The space group of polymorph **1b** is $P\bar{4}2_1m$ and the structure possesses two crystallographically unique molecules of **1** (Figure 1). One of the molecules ($\mathbf{1b_1}$) is situated on the intersection of the two mirror planes at (110) and (−110) while the other ($\mathbf{1b_2}$) straddles a position of $\bar{4}$ site symmetry at 0,0,0. All of the calixarene molecules in the crystal are aligned with their principal molecular axes parallel to [001] and the extended structure consists of columns of $\mathbf{1b_1}$ and $\mathbf{1b_2}$ stacked end-to-end along this direction. Although $\mathbf{1b_1}$ and $\mathbf{1b_2}$ have the same overall conformation, remarkably subtle yet ultimately critical metric differences exist between them.

It is useful to briefly discuss the shape of the 1,3-alternate conformation of **1** in relation to its potential as a host molecule. In the context of host–guest chemistry, calix[4]-arenes are usually of more interest when they incorporate phenolic rather than methoxy groups at the lower rim. A cyclic hydrogen-bonded arrangement of hydroxy groups enforces a truncated cone conformation, thus giving rise to

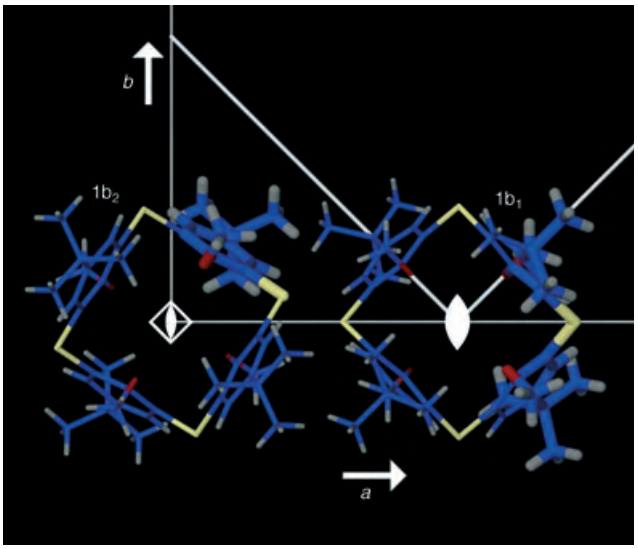

Figure 1. Perspective view of **1b** projected along [001]. The space group is $P\bar{4}2_1m$ (no. 113) with $a=b=19.494(2)$, $c=12.102(1)$ Å. Two crystallographically unique molecules are shown in capped-stick representation and the asymmetric unit in each case is indicated by thick bonds. As indicated, molecule $\mathbf{1b_1}$ resides on a 2*mm* axis while $\mathbf{1b_2}$ occupies a position of $\bar{4}$ site symmetry.

a molecular cleft large enough to accommodate small molecular moieties. Substitution of the phenolic protons usually causes distortion of the molecule to form the pinched cone, the 1,2-alternate, or the 1,3-alternate conformation. None of these substituted conformations result in the formation of a sizeable cleft, and the molecular host properties specifically associated with the cone conformation are generally forfeited.

Each pair of distal aromatic rings in the 1,3-alternate conformation of **1** forms a pincerlike arrangement. At each extremity of the molecule along its principal axis the "pincer" enfolds a small cleft with a narrow entrance guarded by two *para-tert*-butyl moieties. It is interesting to note that **1b** contains two crystallographically distinct molecules of **1**, with three of the four clefts unique. As a consequence of its $\bar{4}$ site symmetry, both clefts of $\mathbf{1b_2}$ are identical, and the dihedral angle between the distal rings is 26.0°. Two unique clefts are present in $\mathbf{1b_1}$ and the dihedral angles between their distal rings are 20.7° and 35.6°. This observation implies that one cleft is significantly larger than the other. The radius of the largest sphere capable of passing through the center of $\mathbf{1b_2}$ along its principal axis is 0.97 Å and the corresponding value for $\mathbf{1b_1}$ is 0.89 Å (note that the van der Waals radius of a hydrogen atom is often taken to be about 1.2 Å).

After collection of X-ray diffraction data, the crystal of **1b** was immersed in water for 8 h. Data were then recollected, and yielded structure **1c**. The space group of **1c** is also $P\bar{4}2_1m$ ($a=b=19.516(2)$, $c=12.096(1)$ Å) and structure solution reveals the same arrangement and relative conformations of the calixarene moietiess (correspondingly designated $\mathbf{1c_1}$ and $\mathbf{1c_2}$) as observed in **1b** (distal ring dihedral angles are 26.4° for $\mathbf{1c_2}$, and 20.2° and 35.0° for $\mathbf{1c_1}$). FT-IR analysis of carefully dried crystals, after similar treatment with water, indicated the presence of water molecules in **1c** and an overall calixarene:water ratio of 1:1 was determined by thermogravimetric analysis. In accordance with these results, least-squares refinement of **1c** yielded difference electron density peaks consistent with the presence of water oxygen atoms in the structure. Each of the two clefts of $\mathbf{1c_2}$ contains a water molecule at 50% site occupancy. The larger of the two clefts of $\mathbf{1c_1}$ contains one water molecule, while the smaller cleft remains unoccupied. A lower-symmetry structure of an inclusion complex of **1** with both water and dichloromethane has been previously published.[7]

The structure of **1b** is most likely dictated by complex packing considerations that do not favor a more symmetrical arrangement containing a single, unique conformation of **1**. Our experimental results show unequivocally that exposure of single crystals of **1b** to liquid water results in water molecules becoming lodged within some of the pincerlike clefts of the calixarenes. The water uptake is stoichiometric and the lattice structure remains otherwise unchanged. It appears that the three crystallographically different but similar molecular clefts exhibit remarkably subtle degrees of selectivity towards the guest water molecules. Figure 2 shows the two unique clefts of $\mathbf{1c_1}$ represented as Connolly[8] surfaces. The *tert*-butyl groups guarding the mouth of the smaller of the two clefts (Figure 2a) are rotated such that the cleft volume is maximized. Although the void is large enough to accommodate a water molecule, it remains unoccupied in **1c** (Figure 2c). The cleft at the other end of the calixarene

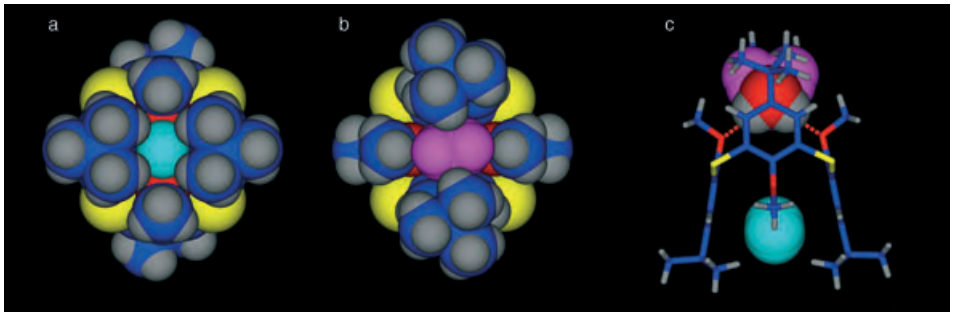

Figure 2. Molecule $\mathbf{1c_1}$ with its two clefts shown as Connolly surfaces. A probe radius of 1.4 Å was used to calculate the surfaces representing the voids. a) At one extremity of the host molecule, the unoccupied void (16.1 Å^3) is shown as a light blue surface. b) The fully occupied void (35.8 Å^3) at the other end of the molecule is shown as a purple surface. c) A side-view of **1** showing a section through the two cavity surfaces. The water molecule within the larger cavity is shown in van der Waals representation. Hydrogen bonds are indicated as dashed red lines.

(Figure 2b) is larger, as a result of the greater angle between its distal aromatic rings. The two *tert*-butyl groups at this end are each disordered over two distinct positions. Four combinations of positions of these groups relative to one another are possible, but only two are geometrically unique (the combination defining the maximal void space is shown in Figure 2). This cleft accommodates one water molecule which donates two hydrogen bonds (O···O = 2.998 Å) to the methoxy oxygen atoms at the base of the cleft (Figure 2c).

The two molecular clefts in $\mathbf{1c_2}$ (shown as Connolly surfaces in Figure 3) are equivalent in size and shape, and

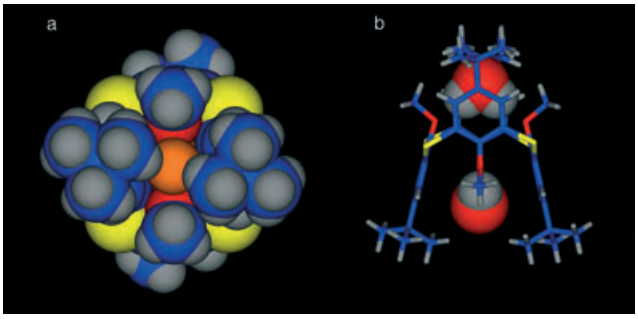

Figure 3. Connolly surfaces (orange) representing the two symmetry-related clefts (13.5 Å^3 each) in $\mathbf{1c_2}$. a) A view along the principal axis of the host molecule shows that the mouth of the cleft is guarded by two *tert*-butyl groups. b) A side-view of **1** showing two water molecules, each at 50% site occupancy, in space-filling representation.

each is barely large enough to accommodate a single molecule of water (ca. 19.7 Å^3) in a hydrogen-bonded environment (assuming that hydrogen bonding involves a small amount of van der Waals overlap of molecules). The *tert*-butyl groups do not appear to be disordered, and are positioned relative to one another so as to minimize the total void volume as well as the opening to the cleft. In the final crystallographic model, $\mathbf{1c_2}$ acts as host to only one water molecule that is disordered equally over the two possible sites. The water molecule donates two hydrogen bonds (O···O = 2.995 Å) to the calixarene methoxy oxygen atoms.

From our thermogravimetric and X-ray structural analyses we infer that any molecule of **1** only accommodates a maximum of one water molecule, even though there is enough space for two. Indeed, repeated soaking experiments lasting from eight hours to several days yielded consistent host:guest ratios of 1:1. The two distal *tert*-butyl groups at the mouth of each cleft are too close to one another to allow a water molecule to enter without conformational distortion of the calixarene. We believe that water uptake occurs through a complex mechanism involving rotation of the *tert*-butyl groups, with concomitant flexing of the host molecule whereby the distal aromatic rings lining the target cleft move apart. Such flexing most likely occurs as rotation about the C–S bonds of the thioether linkages. Thus the aromatic rings of the remaining cleft would be required to pinch closer together to compensate energetically for bond strain. Once a water molecule is admitted into the cleft, the host molecule can return to its original conformation. The water molecule now finds itself in a favorable environment where it is stabilized by two hydrogen bonds to symmetrically placed methoxy oxygen atoms. According to our assumption, the incorporation of a water molecule into one of the calixarene clefts inhibits uptake of water by the remaining cleft. The water molecule serves as a steric brace to the pinching motion that is required to open the opposite cleft of the host in order to capture a second water molecule. One of the voids of $\mathbf{1c_1}$ is significantly larger than the other and is also guarded by rotationally compliant *tert*-butyl groups. Hence, it is plausible that water uptake by this void is kinetically favored over that of the other, and the crystallographic model with a single water molecule at only one end of $\mathbf{1c_1}$ seems reasonable. Since both of the host cavities of $\mathbf{1c_2}$ are equivalent, we propose that a water site occupancy of 50% in each cavity implies that each molecule of **1** only captures one water molecule, but that the two cavities are equally favored.

Although we have discussed the possible mechanism by which water molecules enter the voids of isolated host molecules, careful scrutiny of the packing mode of the calixarene molecules reveals that the host framework is nonporous. This observation raises the intriguing question of how the water molecules diffuse through the lattice before becoming lodged within the calixarene cavities. Since structures **1b** and **1c** were determined using the same crystal, we can disregard the possibility of a water-inclusion process involving crystal dissolution and regrowth. Indeed, compound **1** is highly hydrophobic with no discernable water solubility, even in boiling water.

The calixarene molecules are stacked in columns parallel to [001]. Connolly surface plots (Figure 4a) reveal lattice voids (shown in green) embedded within bundles composed of four nearest-neighbor calixarene columns. These voids are isolated from one another by *tert*-butyl and methoxy methyl groups and do not merge to form channels. Assuming that the

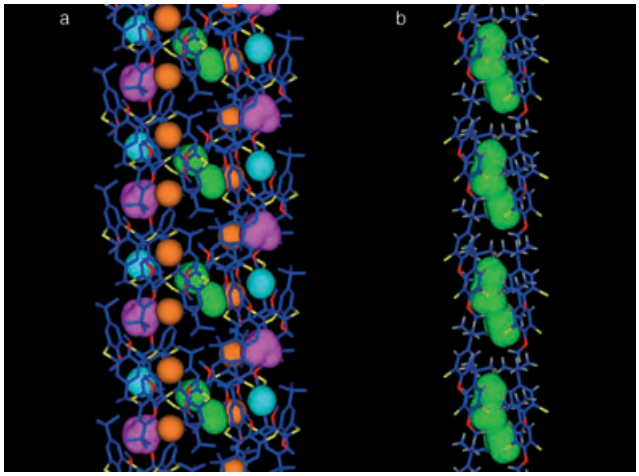

Figure 4. Four adjacent columns of **1** in **1c**, viewed perpendicular to [001]. a) The Connolly surfaces of the molecular clefts in **1** are shown in blue, purple, and orange (see Figures 2 and 3). The lattice voids between the calixarene atoms are shown in green (45.6 Å^3). Hydrogen atoms are omitted for clarity. b) The *tert*-butyl groups of **1** have been rotated to allow maximum extension of the lattice voids (91.4 Å^3) along [001]. Only the calixarene aromatic rings defining the lattice voids are shown.

tert-butyl groups can rotate in a concerted fashion during water uptake, it is possible to construct a model in which the lattice voids can be extended maximally towards one another along [001] (Figure 4b). However, there appears to be no set of orientations for the *tert*-butyl groups that allows the lattice voids to transform into channels. Therefore, no rational pathway can be traced whereby water molecules might be transported through the crystal lattice. Moreover, with the exception only of the location between the two methoxy oxygen atoms embedded within each calixarene cleft, the entire host framework presents a highly hydrophobic environment. In summary of the above, the molecular clefts of the host molecules constitute the only hydrophilic regions of the crystal structure, and there are no channels leading to these clefts.

The uptake of an individual water molecule can be simplified as a two-step process involving diffusion through the lattice, followed by complexation by the host molecule. While water molecules travel through the nonporous hydrophobic lattice with seemingly little concern for van der Waals surface constraints, they appear to be quite selective with regard to the size, shape, and electrostatic profile of their final resting places. Carbon nanotubes have been studied extensively as model systems for small hydrophobic channels by using molecular dynamics simulations.[4f–h,9] These studies indicate that water can be transported quite rapidly through such channels in single file. However, for diffusion to occur, it is generally understood that the channels must be of a suitable diameter (as defined by the van der Waals surfaces of the constituent atoms) to allow free passage of the water molecules. Indeed, this is taken to be a universal requirement for the diffusion of any substance through any matrix.[10]

The double-ended host molecule features two pincerlike clefts, each defining a void approximately the size of a single water molecule. Encapsulation of water at one extremity of the molecular receptor appears to inhibit guest inclusion at the other end. This observation is easily rationalized in terms of conformational flexibility of the host molecule during guest complexation, as well as by our comprehension of van der Waals interactions. However, conventional wisdom does not explain why water molecules display seemingly little regard for van der Waals constraints during the dynamic diffusion process: it is only when they finally come to rest that the water molecules appear to obey spatial restrictions imposed by van der Waals surface contacts. These findings have potentially important implications for both theoretical and experimental studies of water-transport phenomena, particularly across biological membranes.

Our results imply that the classical view of diffusion might be inappropriate when applied at the atomic scale. We have shown that water molecules have the ability to burrow through a rigid medium such as a crystal without the clear presence of suitable channels. It is our belief that the lattice and molecular voids in the structure of **1b** are essential to the diffusion process. Although these voids do not merge to form channels, they are situated relatively close to one another at the atomic scale. In such cases, it is perhaps possible for water molecules to exploit the voids as "stepping stones" to travel through the lattice. The water-transport mechanism would thus involve water molecules hopping between voids until a thermodynamically favorable location can be found. The implications of these findings are that, either crystals are not as rigid as generally presumed, or that van der Waals surfaces do not behave as classical barriers to small molecules in motion.

Protein Structures

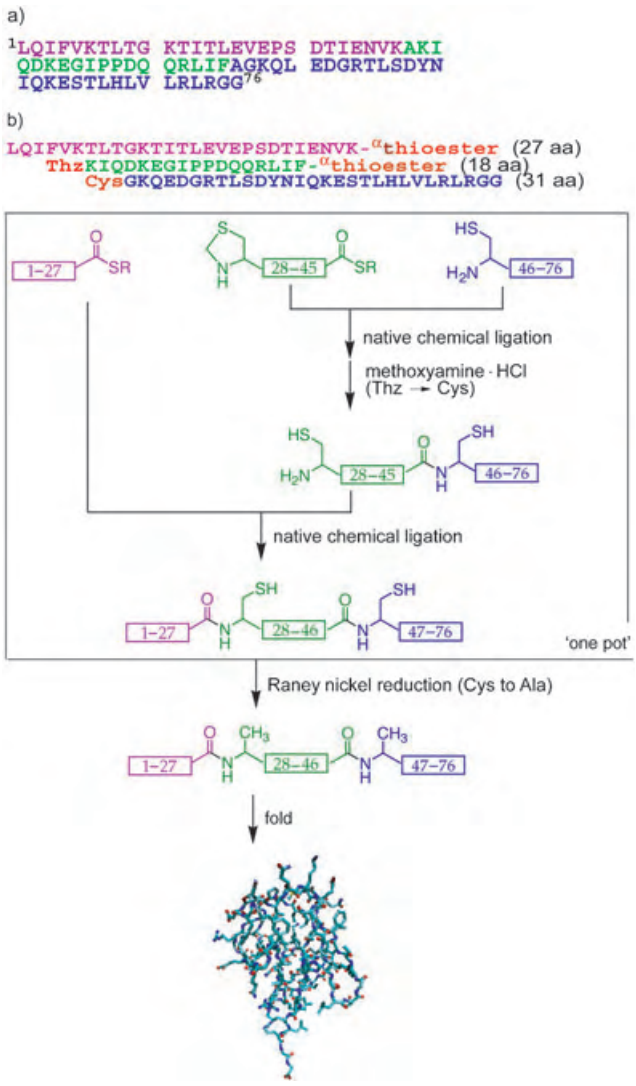
Total Chemical Synthesis and X-ray Crystal Structure of a Protein Diastereomer: [D-Gln35]Ubiquitin**

*Duhee Bang, George I. Makhatadze, Valentina Tereshko, Anthony A. Kossiakoff, and Stephen B. Kent**

Proteins found in nature contain polypeptide chains made up of L-amino acids and glycine. The sequence of amino acids in the polypeptide chain defines the folded tertiary structure of the protein molecule, and the protein owes its biological activity to that folded structure. Non-natural amino acids have been used to construct proteins that are not found in nature to investigate the role of amino acid chemical structure in the formation and stability of the folded protein molecule.[1] In particular, substitution of D-amino acid residues into the protein molecule has been explored for its effects on the binding of insulin to insulin receptors.[2] More recently, D-amino acid substitution has been proposed for enhancing protein stability,[3a] and the structure–function relationships in the K^+ ion channel selectivity filter have been explored by incorporation of a D-Ala residue in place of a Gly residue.[3b] However, despite their potential importance for investigating protein structure–function relationships, there is little detailed knowledge of how the incorporation of a D-amino acid residue affects the local and global conformations that define the folding, stability, and function of the protein molecule.

We set out to understand how a native protein would incorporate a D-amino acid residue into its overall architecture. To definitively explore the perturbation of the local and global conformation in a protein molecule that results from incorporation of D-amino acids, we synthesized and determined the X-ray crystal structure of the chemically engineered globular protein ubiquitin (76 amino acids) with a D-amino acid residue in place of the Gly35 residue in the C-cap region of an α helix. This residue was targeted because the conformation of the Gly35 residue ($\phi = 81°$, $\varphi = 5°$) in native ubiquitin[4] is only allowed for an L-amino acid in a left-handed α helix or for a D-amino acid residue. Herein, we report: 1) an efficient strategy for the total chemical synthesis of ubiquitin; 2) the direct observation of the conservation of amino acid configuration after protein desulfurization by Raney-nickel reduction (that is, L-Cys→L-Ala); 3) high-resolution crystal structures for native ubiquitin and for the ubiquitin protein diastereomer [D-Gln35]ubiquitin; and 4) a striking similarity between the molecular structures of native ubiquitin and the ubiquitin protein diastereomer. The significance of these results is also discussed.

Our research focuses on the investigation of protein folding and stability by using chemical techniques, so we set out to establish an efficient total chemical synthesis of the model protein ubiquitin and its various analogues.[5] We sought to use the recently developed one-pot ligation method[9] to covalently assemble three unprotected peptide segments. However, the ubiquitin molecule does not have the cysteine residues that are needed for native chemical ligation[10] (the amino acid sequence of ubiquitin is shown in Scheme 1a). We noted that human erythrocytic ubiquitin has two alanine residues, which are in positions 28 and 46 and so are suitably located for use as ligation sites (Swiss-Prot accession number P62988).[4] Thus, we adopted a protein-desulfurization strategy[11] that enables the use of native chemical ligation at Cys28 and cys46, after which the cysteine residues are converted into the native Ala28 and Ala46 residues. Our synthetic strategy is shown in Scheme 1b.



Data for the synthesis of native ubiquitin are shown in Figure 1. The C-terminal peptide and the peptide-$^{\alpha}$thioesters were prepared by solid-phase peptide synthesis by using manual stepwise Boc-chemistry (Boc = butoxycarbonyl) "in situ neutralization" protocols.[12] Several hundred milligrams of high-purity peptide were obtained by preparative reverse-phase HPLC from each 0.4-mmol-scale synthesis. The recovered peptide yields were approximately 30% for the (1–27)-$^{\alpha}$thioester and (Cys^{46}–76) peptides and approximately 45% for the (Thz^{28}–45)-$^{\alpha}$thioester (Thz = 1,3-thiazolidine-4-carboxo group) sequences, based on the starting aminoacyl resin. These three peptides were used as the substrates for the one-pot three-segment ligation on a tens-of-milligrams scale:

Scheme 1. a) Target amino acid sequence for human erythrocytic [Met 1 Leu]ubiquitin. b) Peptide segments and strategy used for the total chemical synthesis of ubiquitin.

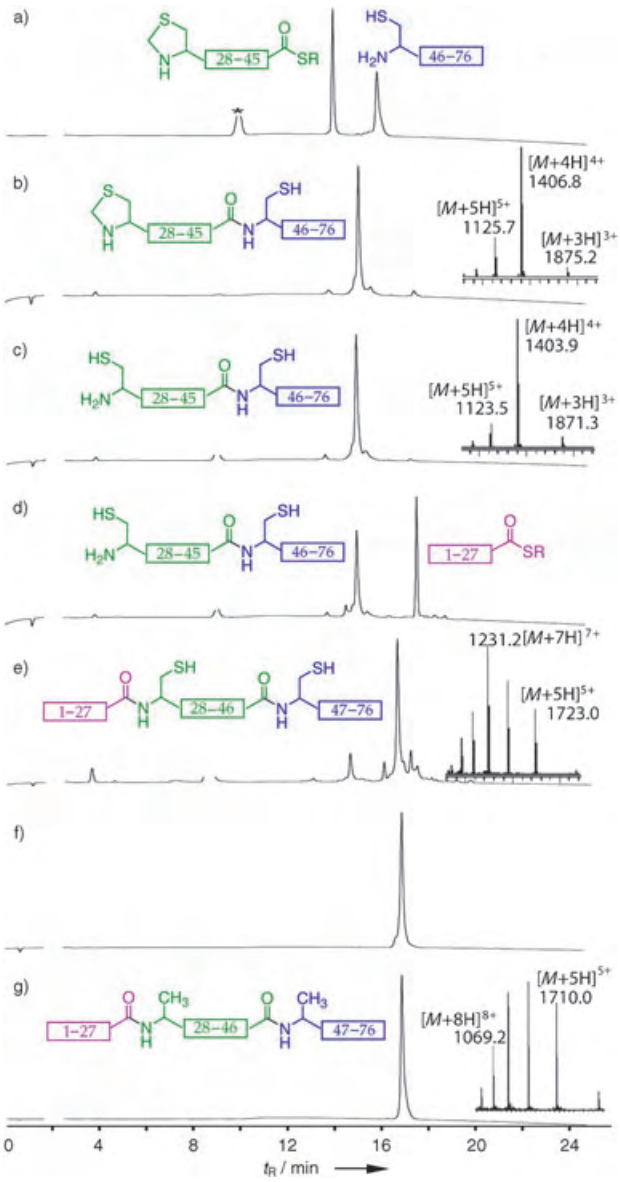

Figure 1. Data for the synthesis of native ubiquitin. Reactions were monitored by LC–MS. The UV profile at 214 nm is shown, together with ESIMS data (inset) corresponding to each major product. The chromatographic separations were performed using a linear gradient (10–50%) of buffer B in buffer A over 20 min (buffer A = 0.1% trifluoroacetic acid (TFA) in water; buffer B = 0.08% TFA in acetonitrile). a) $t = 0$ h, b) $t = 12$ h, c) $t = 16$ h, d) $t = 17$ h, e) $t = 40$ h, f) purified, and g) desulfurized and purified. Observed and calculated masses of the synthetic intermediates and final products were: b) observed mass (obs) 5623.1 ± 0.5 Da, calculated mass using average isotopes (calcd) 5623.4 Da; c) obs = 5611.6 ± 0.7 Da, calcd = 5611.4 Da; e) obs = 8610.2 ± 1.0 Da, calcd = 8610.9 Da; g) obs = 8546.0 ± 1.1 Da, calcd = 8546.8 Da.

the first ligation of the (Thz^{28}–45)-$^{\alpha}$thioester and (Cys^{46}–76) peptides was performed in phosphate buffer (100 mM, pH 6.8) containing guanidinium hydrochloride (6 M) and thiophenol (1% (v/v)) at a concentration of 3 mg mL^{-1} for each peptide (Figure 1a,b). Methoxyamine·hydrochloride (0.2 M) was added to convert the Thz peptide into the Cys peptide ligation product at pH 4.0 (Figure 1c). Readjustment of the solution to pH 6.8 was followed by addition of the third peptide segment, (1–27)-$^{\alpha}$thioester, to effect the second ligation (Figure 1d,e). The ligated full-length 76 residue polypeptide was purified by reverse-phase HPLC (Figure 1f) and lyophilized for the subsequent Raney-nickel desulfurization reaction.

Desulfurization with Raney nickel has been applied to proteins to convert cysteine residues into alanine residues.[13] No change in the absolute configuration at the α carbon atoms of the cysteine/alanine residues was observed in model studies on acylated cysteine.[14,15] Yan and Dawson used Raney-nickel reduction subsequent to native chemical ligation at Cys to extend the use of chemical ligation to the synthesis of proteins that do not contain Cys.[11] One disdavantage of the Raney-nickel reduction is that desulfurization not only affects the cysteine residues but also results in the demethylthiolation of the methionine side chain (although at a slower rate).[11] The first residue of ubiquitin

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

is a methionine, so for synthetic convenience, we replaced Met 1 in ubiquitin with Leu 1 (Scheme 1 a).[16]

We prepared the Raney nickel as described:[11] Nickel acetate (600 mg) was dissolved in distilled water (15 mL) and then sodium borohydride (100 mg) was added slowly. The black nickel precipitate was collected by filtration and then washed extensively with distilled water. We carried out the conversion of Cys 28 and Cys 46 into Ala 28 and Ala 46 in the synthetic polypeptide by adding the freshly prepared nickel precipitate to the peptide solution (ca. 20 mg of purified 76 amino acid polypeptide at a concentration of 3 mg of lyophilized peptide per 1 mL of 0.1 M phosphate buffer containing 6 M guanidinium hydrochloride). We observed that oxidized cysteine residues retarded the rate of the reaction (the same observation has been made previously[13]). We added TCEP (tris(2-carboxyethyl)phosphane hydrochloride; 10 mM) to our reaction mixture to insure that the two cysteine residues were fully reduced. The final pH value of the reaction mixture was 6.0. The Raney-nickel reduction was complete in 12 hours and a mass decrease of 64 Da was observed, as expected for the loss of two sulfur atoms (Figure 1 g).

Essentially identical results were obtained for the total chemical synthesis of the [D-Gln 35]ubiquitin protein molecule (Figure 2). The folded structure of chemically synthesized ubiquitin was confirmed by dissolution of the lyophilized polypeptide under native conditions and the procurement of circular dichroism spectra, which were consistent with the native protein structure (data not shown). The folded protein was obtained at the high concentrations necessary for crystallization by dissolution of the the synthetic polypeptide (20 mg mL^{-1}) in phosphate buffer containing guanidinium hydrochloride (6 M) and was then dialyzed against distilled water.

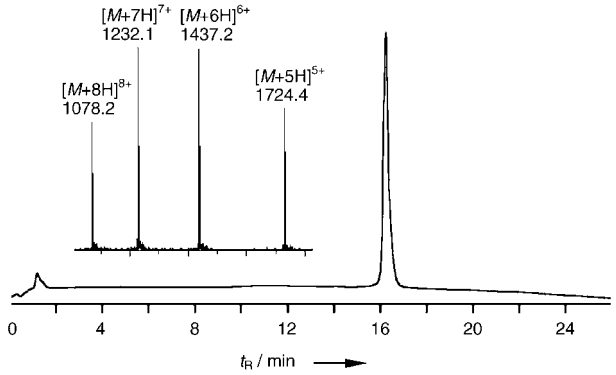

Figure 2. HPLC profile of purified [D-Gln 35]ubiquitin at 214 nm and ESIMS data (inset) corresponding to the product peak (observed mass = 8617.4 ± 0.5 Da; calculated mass = 8617.9 Da (average isotopes)).

We performed several syntheses of both the native ubiquitin and the [D-Gln 35]ubiquitin diastereomer to produce enough protein material for the screening of crystallization conditions and for the optimization of the growth of high-quality crystals. An average yield of recovered product of 36 % from the overall preparation of the full-length polypeptide containing Cys 28 and Cys 46 was obtained using the protocols described above (Figure 1 a–f). The yields of recovered product from the desulfurization reaction were 75 % on average (Figure 1 f–g). Ten- to twenty-milligram quantities of wild-type ubiquitin and its diastereomer were produced in each synthesis. The average synthetic yields were 27 % based on the peptides used. Therefore, excellent yields of high-quality protein constructs were obtained from the synthetic strategy reported herein, and furthermore we could apply this multisegment strategy to the ready synthesis of analogues. Thus, we could reuse the peptides (1–27)-$^{\alpha}$thioester and (Cys^{46}–76) and it was only necessary to remake the short [Gly 35D-Gln](Thz^{28}–45)-$^{\alpha}$thioester for the synthesis of the diastereomer analogue protein.

At first, we considered a protein NMR experiment to investigate the local and global structure of the ubiquitin diastereomer. However, we concluded that high-resolution crystallography would be better suited to explore even small configuration changes caused by the incorporation of D-Gln 35 into the protein molecule and to definitively show the local and global structural changes of a protein diastereomer compared to the wild-type protein molecule. Ubiquitin is reported to be difficult to crystallize.[4,17–19] Attempts to form ubiquitin crystals under the conditions used in the first successful crystallization[17] have since failed.[4,17–19] Instead, most of the crystals of sufficient quality for X-ray crystallographic studies have been produced by seeding with samples of the original crystal.

We carried out extensive screening of crystallization conditions for ubiquitin, but without seeding we were unable to obtain crystals. However, we were aware that solid-state NMR spectroscopy researchers were using ubiquitin nanocrystals to study protein structures.[20] The conditions reported for the production of ubiquitin nanocrystals used cadmium salts not usually included in commercially available crystal screening kits. By using cadmium salts in combination with the crystal screening kits, we were able to grow two different forms of ubiquitin crystals under different conditions. Subsequent rounds of optimization led to crystals of both the wild-type ubiquitin and its diastereomer that were of sufficient quality for X-ray crystallographic studies. Crystal formation could be reproducibly obtained by mixing ubiquitin solution (2 μL, 20 mg mL^{-1}) and $CdCl_2$ solution (2 μL, 50 mM), and poly(ethylene glycol) 2000 monomethyl ether (PEG MME; 20 %, *w*/*v*) in bis–tris buffer (bis(2-hydroxyethyl)iminotris(hydroxymethyl)methane; 0.1 M, pH 6.5).

X-ray diffraction data were collected using synchrotron radiation at the Advanced Photon Source at the Argonne National Laboratory. Cubic ($P4_332$) and orthorhombic ($P2_12_12_1$) space groups were identified for both the wild-type and diastereomer crystals. In particular, the orthorhombic crystals were highly ordered and diffracted well to 1.3 Å (a complete data set was obtained to only 1.5 Å because of the geometric limitations of the CCD detector). The structures of the native ubiquitin and the diastereomer protein were solved by the molecular replacement method, in which the ubiquitin structure PDB accession number 1UBQ was used as the test model.[21] Subsequent refinement procedures were carried out

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

using the CNS and refmac refinement packages (see the Supporting Information for data collection and refinement statistics for both native ubiquitin and [D-Gln35]ubiquitin).

The synthetic native ubiquitin protein had the same molecular structure as that previously reported.[4] The stereochemical configuration of the D-Gln35 residue was directly confirmed by the high-resolution electron-density map of the ubiquitin diastereomer, in which the side chain of D-Gln35 could be seen pointing in the opposite direction to that expected for the side chain of an L-Gln residue (Figure 3). Thus, the ubiquitin diastereomer can incorporate D-Gln35 into its overall fold without perturbing the global architecture of the protein molecule (Figure 4). Both Gly35 and D-Gln35 were in a left-handed conformation ($\phi = 80°$ for Gly35 and $\phi = 77°$ for Gln35; see the Supporting Information).

Comparison of the wild-type and diastereomer structures showed a striking similarity in both the local and global conformations (Figure 4). The root-mean-square difference (rmsd) value for the comparison of the Cα atoms at corresponding positions in the two protein structures was 0.39 Å, and the rmsd value for all corresponding main-chain atoms in the local region (from residue 31 to 37) near the D-Gln35 substitution was 0.24 Å (see the Supporting Information). These values are within the experimental variation expected for two proteins of identical structure at the resolution of the analysis. This striking similarity 1) validates the replacement of natural amino acid residues occupying left-handed conformations in native protein molecules by D-amino acids and 2) provides experimental support for the assumption that replacement of a Gly residue occupying a left-handed conformation by a D-amino acid does not alter the local and global conformations of the protein molecule.

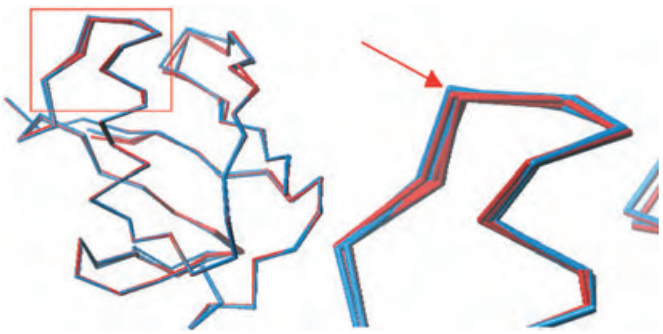

Figure 4. Superposition of the molecular structures of the three native and three [D-Gln35]ubiquitin protein molecules found in the unit cell for the two different proteins. Left: the backbone of Cα-atom traces of the two proteins are shown superimposed; [D-Gln35]ubiquitin (blue); native ubiquitin (red). Right: close up of nine residues near D-Gln35/Gly35 (arrow).

The conservation of the L configuration of Ala28 and Ala46 after the desulfurization reaction could be directly observed in the electron-density map of the synthetic proteins (Figure 5). The conservation of the L configuration during the Raney-nickel reduction further validates the synthetic strategy that Yan and Dawson devised to prepare cysteine-free proteins by using native chemical ligation followed by a desulfurization reaction.[11]

In summary, we have developed an efficient route to cysteine-free ubiquitin molecules by combining one-pot three-peptide-segment native chemical ligation[9] and protein desulfurization[11] for chemical protein synthesis to produce large quantities of high-quality protein materials for X-ray crystallographic studies. We have also verified a striking

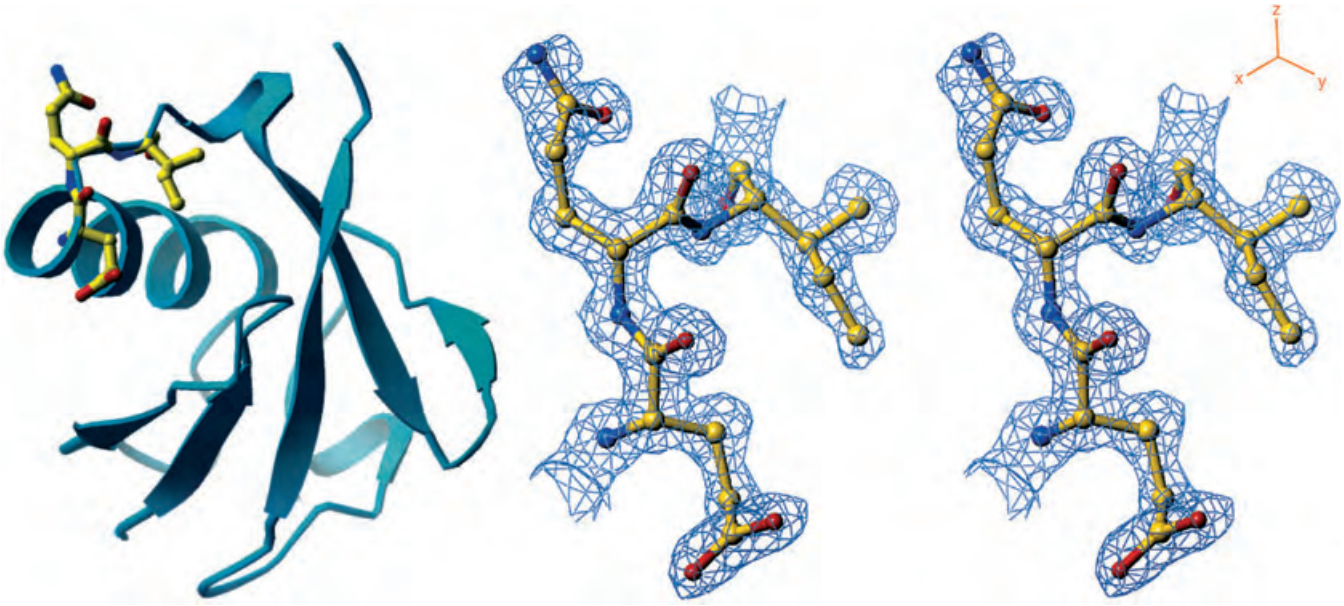

Figure 3. Left: structure of the [D-Gln35]ubiquitin diastereomer; the sequence Glu34–D-Gln35–Ile36 is highlighted in yellow. Right: stereoview of the local conformation near the D-Gln35 residue; the residues Glu34–D-Gln35–Ile36 are shown fitted to the $2F_o - F_c$ electron-density map contoured at 1σ. Figure 5. Stereoview showing Ala 46 fitted to the $2F_o-F_c$ electron-density map contoured at 1σ. The conservation of configuration in the desulfurization reaction (L-Cys→L-Ala) is apparent. Occupancy and thermal factor refinement indicated that the Cβ atoms showed full occupancy for the L conformation of the alanine side chain, within experimental uncertainty (<10%), with an accompanying low thermal factor ($B=3$ Å^2).

conservation of molecular structure between the folded conformations of a protein diastereomer and the corresponding wild-type protein by using high-resolution X-ray crystallography. This study provides experimental support that replacement of a native Gly residue that occupies a left-handed conformation by a D-amino acid does not significantly perturb the local or global conformations of a protein molecule. We are currently using the ubiquitin synthesis and crystallographic methods reported herein, in combination with other modern biophysical techniques, to systematically dissect the molecular basis of stability in this model protein.

Polyoxometalates

Triangular Geometrical and Magnetic Motifs Uniquely Linked on a Spherical Capsule Surface**

Achim Müller, Ana Maria Todea, Joris van Slageren, Martin Dressel, Hartmut Bögge, Marc Schmidtmann, Marshall Luban, Larry Engelhardt, and Mariana Rusu*

Dedicated to Professor Francis Sécheresse on the occasion of his 60th birthday

Polygons can be placed on spherical surfaces such that periodical structures of a cyclic nature result, while these can be considered as discrete models for two-dimensional (extended) structures. If we wish to construct a chemical structure on a spherical capsule surface in the same way, we have to remember that 1) pentagons are the basic units for sphere constructions, as is well known, for example, from virus structures, 2) they exist, for example, in the form of $\{(Mo^{VI})Mo^{VI}_5\}$ type units, and that 3) they occur in Keplerates of the type $\{(Mo^{VI})Mo^{VI}_5\}_{12}\{Linker\}_{30}$[1–5] (linker can be of the mononuclear M (M = metal center) or dinuclear type M_2; for the definition of Keplerates, see ref. [5b]). However, until now it was not possible to synthesize a spherical capsule surface directly by the addition of linkers to the pentagonal units that are available in a dynamic library.[1–5] It is significant that in the Keplerates the linkers describe generic Archimedean solids: in the case of dinuclear linkers M_2 a distorted truncated icosahedron, $\{M_2\}_{30}$, and in the case of mononuclear linkers the unique icosidodecahedron (Figure 1)[6] $\{M_{30}\}$, which has—geometrically speaking—linked M_3 triangles. Surprisingly the related consequences for chemistry have not been discussed until now. In the $\{M_{30}\}$ situation, there is a network of corner-shared triangles on the sphere surface, this can result unique magnetic properties as in the case of the "classical" Keplerate $\{(Mo^{VI})Mo^{VI}_5\}_{12}Fe^{III}_{30}$.[7,8] This is the first laboratory example of a "zero-dimensional" system that at low temperatures embodies characteristics of geometrical frustration/magnetic ordering[8b] which otherwise have only been observed in selected one-, two-, and three-dimensional lattice spin systems.[9] Herein we report on the spherical cluster **1a** where the twelve $\{(Mo^{VI})Mo^{VI}_5\}$ type units fix 30 d^1 V^{IV} linkers/centers with spin $S = 1/2$ in the form of an icosidodecahedron, and thus 1) demonstrating for the first time that the spherical capsule/Keplerate can be directly constructed from the mononuclear linkers and the appropriate molybdate library,[5c] 2) providing the chance to obtain new information regarding the unique molecular magnetism of the $\{M_{30}\}$ type network of linkers/triangles, and 3) clarifying the quantum effects of the spin $S = 1/2$ vanadyl linkers especially in connection with the two-dimensional $S = 1/2$ Kagomé lattice which contains linked triangles and exhibits unique magnetic properties.[9a]

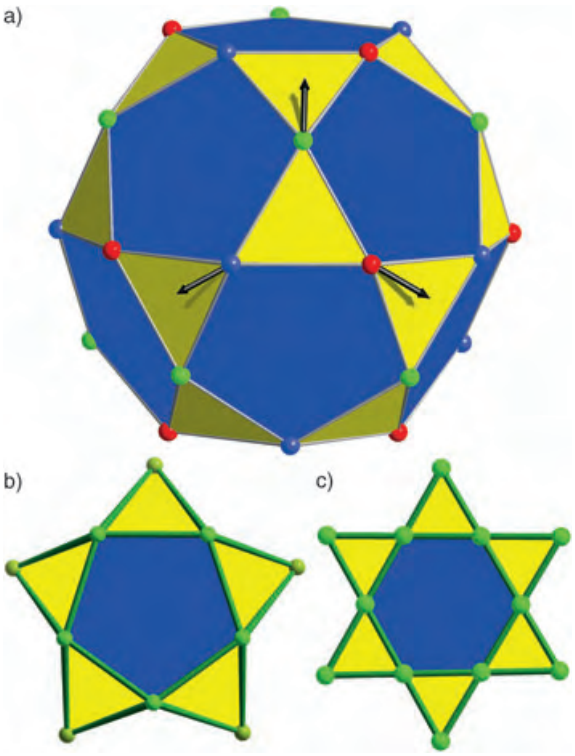

Figure 1. a) The M centers (small colored spheres) of the $\{(Mo^{VI})Mo^{VI}_5\}_{12}M_{30}$ type Keplerates (e.g., M = V^{IV}, Fe^{III}) describe the icosidodecahedron shown, which is unique among the icosahedral Archimedean solids as all edges are equivalent and all dihedral angles equal. Referring to the special situation of M = Fe^{III}, there are three groups ("sublattices") of 10 spins (colors: red, blue, green), with all spins of a sublattice pointing in the same direction, while nearest-neighbor spin vectors (three are highlighted) differ in angular orientation by 120°. Also shown: b) A fragment highlighting five linked triangles around a pentagon. c) A fragment of a planar Kagomé lattice with six linked triangles around a hexagon.

After adding vanadyl sulfate to an acidified molybdate solution, in the presence of K^+ ions, compound **1** precipitates after some time in high yield. (A simpler expression for the

cluster anion **1a** without referring to structural differences is given as well.)

$$Na_8K_{14}(VO)_2[\{(Mo^{VI})Mo^{VI}_5O_{21}(H_2O)_3\}_{10}\{(Mo^{VI})Mo^{VI}_5O_{21}(H_2O)_3(SO_4)\}_2\{V^{IV}O(H_2O)\}_{20}\{V^{IV}O\}_{10}(\{KSO_4\}_5)_2]\cdot \approx 150\,H_2O \quad \mathbf{1}$$

$$[K_{10} \subset \{(Mo^{VI})Mo^{VI}_5O_{21}(H_2O)_3(SO_4)\}_{12}\{(V^{IV}O)_{30}(H_2O)_{20}\}]^{26-} \quad \mathbf{1a}$$

Compound **1**, which crystallizes in the monoclinic space group *C*2/*c*, was characterized by elemental analysis, thermogravimetry (to determine the crystal water content), redox titrations (to determine the number of V^{IV} centers), spectroscopic methods (IR, Raman, UV/Vis), single-crystal X-ray structure analysis (including bond valence sum (BVS) calculations),[10] and susceptibility measurements (including related quantum Monte Carlo calculations).

The cluster anion **1a** of **1** is of the expected $(Pentagon)_{12}(Linker)_{30}$ type and is a slightly compressed sphere, while the heptacoordinate Mo^{VI} centers of the 12 pentagonal units correspondingly describe a slightly distorted icosahedron and the 30 V^{IV} centers—acting as linkers for the pentagonal $\{(Mo^{VI})Mo^{VI}_5\}$ type units—describe a (slightly distorted) icosidodecahedron (Figure 2; the V^{IV}–V^{IV} distances in the distorted Archimedean solid vary from 6.3 to 6.6 Å). The distortion is in agreement with the fact that 20 V^{IV} centers in the equatorial region have octahedral coordination and the two sets of five V^{IV} centers in the polar area have square-pyramidal coordination; the distances from the 10 equatorial V^{IV} units to the center of the cluster are a little shorter (10.3 Å) than the related distances of the other 20 V^{IV} units (10.6 Å). Ten of the twelve $[SO_4]^{2-}$ ligands are coordinated by three oxygen atoms to three adjacent Mo^{VI} centers of the $\{(Mo^{VI})Mo^{VI}_5\}$ groups such that two $\{KSO_4\}_5$ rings parallel to the equator result, with the K^+ ions (formally) bridging the $[SO_4]^{2-}$ ions (Figure 3). The other two sulfate groups are disordered and act as ligands to the two polar $\{(Mo^{VI})Mo^{VI}_5\}$ groups. The structure of **1a** comprising the twenty triangular and twelve pentagonal faces of the icosidodecahedron built up by 30 V^{IV} centers shows an interesting relation to the much less symmetrical cluster anion **2a** which has a non-complete spherical $\{V_3\}$ type net. In **2a**, a strongly distorted icosidodecahedron is described by 10 Mo^{VI} and 20 V^{IV} centers, while the equatorial $\{V_{20}\}$ belt—formed by 10 linked $\{V_3\}$ triangles—is identical to the related equatorial segment of **1a**.

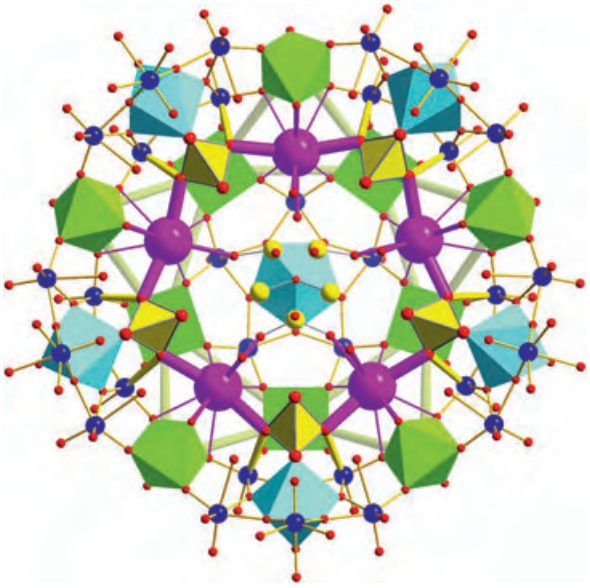

Figure 3. Combined polyhedral and ball-and-stick representation of a fragment of **1a** (view in direction of the C_5 axis) showing one of the two $\{KSO_4\}_5$ rings and the coordination of $\{SO_4\}$ groups to Mo centers as well as the disorder of one of the two sulfate groups (color code as in Figure 2, additional light blue pentagonal bipyramids: $\{MoO_7\}$).

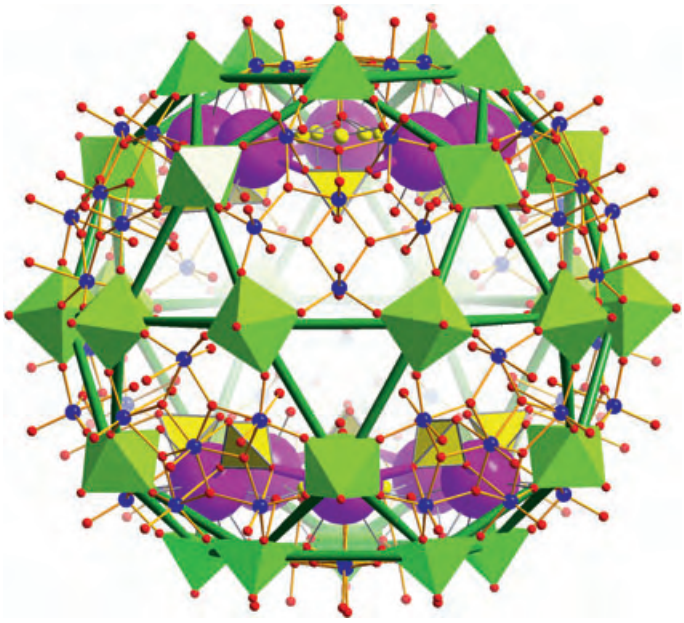

Figure 2. Combined polyhedral and ball-and-stick representation of the structure of **1a** showing the triangles and pentagons of the icosidodecahedron (green sticks), and additionally the basic $\{VO_5\}$ and $\{VO_6\}$ units as green polyhedra; as the interaction between the "lattice K^+" ions and the 20 pores is not homogeneous, this interaction was not considered here (blue Mo, red O, purple K, yellow tetrahedra: $\{SO_4\}$ groups; yellow spheres: disordered S atoms).

$$[\{Mo^{VI}O_3(H_2O)\}_{10}\{(Mo^{VI})Mo^{VI}_5O_{21}(H_2O)_3\}_{10}\{V^{IV}O(H_2O)\}_{20}(\{Mo^{VI}O_2(H_2O)_2\}_{5/2})_2(\{NaSO_4\}_5)_2]^{20-} \quad \mathbf{2a}$$[7d]

The presence of K^+ and $[SO_4]^{2-}$ ions in the reaction medium seems to be of fundamental importance for the structure formation, as the potassium cations of the two $\{KSO_4\}_5$ rings of **1a** attract the two negatively charged polar $\{(Mo^{VI})Mo^{VI}_5\}$ units thus causing the slight compression of the sphere. This distortion leads to an inclination of the adjacent $\{VO_5\}$ polyhedra and thus prevents an octahedral coordination of the 10 polar V^{IV} centers. The sixth (H_2O) ligand required for octahedral coordination would be too close to the $[SO_4]^{2-}$ ligands of the $\{KSO_4\}_5$ rings.

The investigations nicely show that $\{(Mo^{VI})Mo^{VI}_5\}$ type units are potentially available in a dynamic polymolybdate library; remarkably, they can be "used" in the present case as

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

virtual units in the presence of potential linkers. In aqueous solution at low pH values, the pentagonal structural unit occurs in the $[Mo^{VI}_{36}O_{112}(H_2O)_{16}]^{8-}$ ion,[11] which is the only(!) abundant species under those conditions. Correspondingly, **1a** is formed from that solution in the presence of VO^{2+} linkers by a "split-and-link" process with the $\{(Mo^{VI})Mo^{VI}_5\}$ unit being formed from the $\{Mo_{36}\}$ species after the addition of the linkers. The option to extend this to mixed-metal species such as $\{Mo^{V}_8V^{IV}_{22}\}$,[12] $\{Mo^{V}_4V^{IV}_{26}\}$, or $\{Fe^{III}_{22}V^{IV}_8\}$[13] will be reported elsewhere.

Turning to the magnetic properties, two circumstances are of pivotal importance for the possible occurrence of geometrical frustration in the type of system considered herein: First, the 30 mononuclear magnetic Keplerate linkers occupy the vertices of an icosidodecahedron, which may be pictured as 20 linked (corner sharing) triangles arranged around 12 pentagons and corresponds to an equidistant distribution of the spins on the surface of a spherical cluster; second, each magnetic center ("spin vector") interacts with its four nearest-neighbors by isotropic antiferromagnetic exchange as a consequence of the special geometry of the unique $\{M_{30}\}$ type quasi-regular solid (Figure 1). Analogous to what occurs for the Kagomé spin system (planar lattice of triangles framed around hexagons; Figure 1c),[9] the geometric frustration of the individual Keplerate can be achieved by the cooperative interactions among the full set of spin vectors. In the special case of the above mentioned $\{(Mo^{VI})Mo^{VI}_5\}_{12}Fe^{III}_{30}$, we may refer to it as a "classical" Keplerate (because of the relatively high spin, $S = 5/2$, of individual Fe^{III} centers) and the spin frustration/magnetic ordering may therefore be visualized in geometrical terms[8c] (Figure 1). The 30 spin vectors are composed of three groups ("sublattices") of 10 spins each; all spins of a given sublattice point in the same direction, and any pair of nearest-neighbor spin vectors differ in angular orientation by 120° (Figure 1).[8c] In **1a** we have replaced the Fe^{III} centers by VO^{2+} ions which have the much smaller spin of $S = 1/2$, that is, "quantum spins". In addition, in **1a** the 3d electrons are not "localized" at the vertices of the icosidodecahedron as is approximately the case in the $\{Fe^{III}_{30}\}$ Keplerate.[14] However, the spin frustration of these quantum spins can not be visualized in geometric terms. More generally the magnetism of the "quantum" Keplerate **1a** is expected to be significantly different from that of its classical counterpart $\{Fe_{30}\}$, and more properties are expected to emerge.

Our experimental susceptibility data versus T, recorded for an applied field of $H = 0.1$ T, and corrected for the d^1 centers of two VO^{2+} ions which are magnetically/structurally independent from the cluster skeleton **1a**, are shown in Figure 4.[15] These results show the strong antiferromagnetic coupling in **1a**, in contrast to the $\{(Mo^{VI})Mo^{VI}_5\}_{12}Fe^{III}_{30}$ case.[16] The behavior of $T\chi$ at low T is qualitatively what could be expected for a spin system having a ground state with $S = 0$ and with very strong exchange coupling. This situation can be explained by a strong delocalization of the 3d electrons which arises because the 3d V levels are comparable in energy with the LUMOs of the molybdate fragment system.[16] This is a completely different situation than the classical $\{Fe_{30}\}$ type Keplerate where the exchange interaction is very weak, and

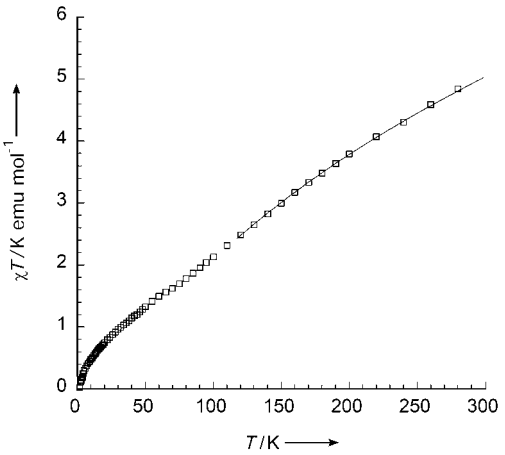

Figure 4. Magnetic susceptibility of $\{V_{30}\}$ versus temperature: Experimental data corrected for the two d^1/VO^{2+} centers (□);[15] quantum Monte Carlo results (solid curve).

therefore the room temperature value of $T\chi$ corresponds to 30 uncoupled $S = 5/2$ ions. The quantum Monte Carlo (QMC) method provides accurate values of susceptibility for the Heisenberg model of the $\{V_{30}\}$ system for $T > 0.5J/k_B$, and as seen in Figure 4, a very good fit to $T\chi$ is achieved for $T >$ 120 K for the choices $J/k_B = 245$ K and $g = 1.95$. Unfortunately, reliable results cannot be obtained for lower temperatures using the QMC method owing to the "sign problem" that occurs for spin systems with antiferromagnetic exchange based on lattice geometries where the classical counterpart exhibits spin frustration.

To summarize: We have demonstrated that it is possible to "use" pentagonal units as "building units" which play, geometrically speaking, the same role as the pentagonal units in other sphere-based constructions, such as spherical viruses, fullerenes, and geodesic domes; in our context they are used as a glue for trapping magnetic centers, such that triangles are linked to form an icosidodecahedron, that is, a part of a Keplerate. As the "quantum" Keplerate **1a** obtained is a new example of a frustrated magnetic system which shares a topological feature with the classical Keplerate $\{(Mo^{VI})Mo^{VI}_5\}_{12}Fe^{III}_{30}$ and the Kagomé-lattice antiferromagnet, its exploration is expected to provide a deeper understanding of basic aspects of magnetic frustration and the role played by the size of the intrinsic spin of the interacting magnetic ions. This study should also shed light on the parallel problem, and the focus of an intense effort, to characterize and understand the $S = 1/2$ Kagomé lattice, which is considered to have unique magnetic/electronic properties originating in the small value of S.[9] The behavior of the magnetization of the quantum Keplerate **1a** in high magnetic fields will be of key importance in studies aimed at elucidating the characteristics of its magnetic frustration.[17]

Experimental Section

A solution of $VOSO_4 \cdot 5H_2O$ (2.53 g, 10 mmol) in H_2O (35 mL) was added to a stirred solution of $Na_2MoO_4 \cdot 2H_2O$ (2.42 g, 10 mmol) in H_2SO_4 (0.5 M; 8 mL) in an conical flask. The resulting dark purple

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

mixture was stirred at room temperature for 30 min (flask closed with a rubber stopper) and then treated with KCl (0.65 g, 8.72 mmol). After additional stirring for 30 min the solution was stored in the flask which was closed with a rubber stopper. After 5 days, the purple-black rhombic crystals of **1** were collected by filtration, washed with cold water, and finally dried in air. Yield: 1 g; elemental analysis: calcd (%) for $Na_8K_{24}Mo_{72}V_{32}S_{12}O_{538}H_{412}$: Na 0.96, K 4.92, V 8.55, S 2.02; found: Na 1.0, K 5.1, V 8.5, S 2.1. IR (KBr pellet): $\tilde{\nu}=1622$ (m), ($\delta(H_2O)$) 1198 (w), 1130 (w), 1055 (w) ($\nu_{as}(SO_4)$ triplet), 964 (s) (ν(V=O)/ν(Mo=O)), 791 (vs), 631 (w), 575 (s), 449 (w) cm^{-1}; FT-Raman (solid; $\lambda_e=1064$ nm): $\tilde{\nu}=941$ (w, ν(V=O)/ν(Mo=O)), 872 (s, $A_{1g}O_{br}$ breathing) cm^{-1}; UV/Vis (in H_2O): $\lambda=510$ (vs), 689 (w), 845 (w) nm.

[2] a) In this context we should refer first to the fact that molybdenum oxide building units—abundant as virtual ingredients in a dynamic library in aqueous solution—display a unique type of flexibility and that the units can adjust their size and shape by a type of "split-and-link process" depending on the relevant boundary conditions.[1] (Pentagonal $\{(Mo^{VI})Mo^{VI}_5\}$ building blocks, for instance, occur in spherical capsules/Keplerates of the $\{Pentagon\}_{12}\{Linker\}_{30}$ type.[1–5]) The flexibility is nicely shown by the reaction of $[PMo_{12}O_{40}]^{3-}$ with Fe^{III} leading to a fragmentation of the Keggin ion while the fragments and the Fe^{III} ions form the (present type of) spherical system $\{(Mo^{VI})Mo^{VI}_5\}_{12}Fe^{III}_{30}$ which has the pentagonal units and encapsulated non-decomposed Keggin ions; see b) A. Müller, S. K. Das, H. Bögge, M. Schmidtmann, A. Botar, A. Patrut, *Chem. Commun.* **2001**, 657–658.

Rev.* **2001**, *222*, 193–218; c) The related direct synthetic conditions, simply based on addition of the finally appearing linker to the relative medium, are reported herein for the first time. Earlier Keplerate syntheses were more complex.

[6] The (quasi-regular) icosidodecahedron is a hybrid of the icosahedron and the dodecahedron and thus contains 20 trigonal and 12 pentagonal faces which intersect at each corner. Unlike the other related Archimedean solids, such as the $\{M_{60}\}$-type truncated icosahedron, it comprises not only equivalent vertices but also equivalent edges and equal dihedral angles (Figure 1); see a) M. O'Keeffe, B. G. Hyde, *Crystal Structures, I. Patterns and Symmetry*, Mineralogical Society of America, Washington, DC, **1996**; b) H. S. M. Coxeter, *Introduction to Geometry*, Wiley, New York, **1989**; c) H. S. M. Coxeter, *Regular Polytopes*, 3rd ed., Dover, New York, **1973**, in which we read (p. 18): "*A quasi-regular polyhedron (like the icosidodecahedron) is defined as having regular faces, while its vertex figures, though not regular, are cyclic and equiangular (i.e., inscriptible in circles and alternate-sided). It follows from this definition that the edges are all equal, say of length 2L, that the dihedral angles are all equal, and that the faces are of two kinds, each face of one kind being entirely surrounded by faces of the other kind.*"); d) A. [10] Crystal data for **1**: $H_{412}K_{24}Mo_{72}Na_8O_{538}S_{12}V_{32}$, $M_r=19068.10\ g\,mol^{-1}$, monoclinic, space group $C2/c$, $a=47.155(2)$, $b=42.5364(18)$, $c=26.5344(12)$ Å, $\beta=90.2510(10)°$, $V=53222(4)$ Å^3, $Z=4$, $\rho=2.380\ g\,cm^{-3}$, $\mu=2.530\ mm^{-1}$, $F(000)=36848$, crystal size $=0.30\times0.20\times0.02\ mm^3$. Crystals of **1** were removed from the mother liquor and immediately cooled to 183(2) K on a Bruker AXS SMART diffractometer (three circle goniometer with 1 K CCD detector, $Mo_{K\alpha}$ radiation, graphite monochromator; hemisphere data collection in ω at 0.3° scan width in three runs with 606, 435, and 230 frames ($\phi=0$, 88, and 180°) at a detector distance of 5 cm). A total of 158364 reflections ($1.50<\Theta<26.99°$) were collected of which 57718 reflections were unique ($R(\mathrm{int})=0.0612$). An empirical absorption correction using equivalent reflections was performed with the program SADABS. The structure was solved with the program SHELXS-97 and refined using SHELXL-97 to $R=0.0567$ for 40563 reflections with $I>2\sigma(I)$, $R=0.0916$ for all reflections; max/min residual electron density 3.456 and $-2.026\ e\,Å^{-3}$. (SHELXS/L, SADABS from G. M. Sheldrick, University of Göttingen **1997**; structure graphics with DIAMOND 2.1 from K. Brandenburg, *Crystal Impact GbR*, **2001**.) As usual the cations not bound to the capsule as well as the crystal water molecules could not be found completely due to disorder. As this is also the case for the $[VO(H_2O)_5]^{2+}$ centers, the H_2O ligand sphere was not considered in the formula. Further details on the crystal structure investigations may be obtained from the Fachinformationszentrum Karlsruhe, 76344 Eggenstein-Leopoldshafen, Germany (fax: (+49) 7247-808-666; e-mail: crysdata@fiz-karlsruhe.de), on quoting the depository number CSD-415055.

[14] In spite of these expected differences, there are some important features common to the two Keplerates, such as similar characteristics of the ground state and the low-lying excitation states, which arise because of their otherwise common geometrical structure and the existence of antiferromagnetic exchange between nearest-neighbor spins. As one example, the total spin quantum number of the ground state eigenvector for the "quantum" Keplerate **1** is expected to be $S=0$, as it is for the "classical" Keplerate $\{Fe_{30}\}$, and its direct manifestation would be in the vanishing of T_χ (proportional to $\langle S^2\rangle$), in the low-temperature regime; χ is the zero-field susceptibility.

[15] The raw M/H ($\equiv\chi$) data display a rapid rise on decreasing the temperature below 50 K that is very accurately simulated by a term proportional to $1/T$ (Curie behavior). This observation suggests the presence of additional non-interacting paramagnetic centers in the sample. In fact, fitting the low temperature data leads to a value of approximately 2 $S=1/2$ centers. These centers are considered to be the non-interacting VO^{2+} (d^1) ions. In large cluster systems like **1**, they can take the same place as the other diamagnetic cations, which are usually disordered in the large voids between the clusters and can therefore not be discovered by single-crystal structure analysis (see ref. [10]). On subtracting the contribution of these discrete paramagnetic centers, we obtain a corrected magnetization M' as well as the corrected susceptibility data, $T\chi \equiv T'/H$, shown in Figure 4. The Curie behavior of the paramagnetic centers shows that they do not interact with each other and with the $\{V_{30}\}$ cluster. The possibility that the finite $T\chi$ value at low temperatures is due to a non-zero spin ground state can be precluded. Regarding the presented $T\chi$ curve: As always there is uncertainty as to the appropriate choices for diamagnetic and temperature-independent paramagnetism (TIP) corrections. Additionally, because of the large voids between the clusters the VO^{2+} groups need not be present stoichiometrically in the compound; correspondingly, there is a very small error limit in the given/used number of two VO^{2+} groups which influences the correction of the raw magnetic data ($(VO)_{1.8}$ could, for example, correspond to $K_{14.4}$).

[16] The exchange coupling difference between the classical and quantum Keplerates discussed herein is analogous to that of the cluster pair with 6 V^{IV} and 6 Fe^{III} centers embedded in the $\{Mo_{57}\}$ type skeleton; see D. Gatteschi, R. Sessoli, W. Plass, A. Müller, E. Krickemeyer, J. Meyer, D. Sölter, P. Adler, *Inorg. Chem.* **1996**, *35*, 1926–1934.

[17] Note added in proof, April 27, 2005: Very recent measurements by H. Nojiri (Tohoku University) of M versus H at 0.5 K up to 27 Tesla, as well as ESR measurements at 190 GHz for several temperatures, show features which are fully consistent with our physical interpretation of a strong intracluster exchange constant and approximately two VO^{2+} ions per formula unit that are magnetically independent of the $\{V_{30}\}$ cluster. Full details will be published elsewhere.

Bioorganic Chemistry

Irreversible Inhibition of Metallo-β-lactamase (IMP-1) by 3-(3-Mercaptopropionylsulfanyl)-propionic Acid Pentafluorophenyl Ester**

Hiromasa Kurosaki, Yoshihiro Yamaguchi, Toshihiro Higashi, Kimitaka Soga, Satoshi Matsueda, Haruka Yumoto, Shogo Misumi, Yuriko Yamagata, Yoshichika Arakawa, and Masafumi Goto*

Pathogenic bacteria that produce metallo-β-lactamases (MBLs) are emerging as a new challenge to the medical community. These enzymes catalyze the hydrolysis of a wide spectrum of β-lactams, including carbapenems such as imipenem, some of which are coded in transferable plasmids.[1,2] Among the currently known MBLs, IMP-1, a member of subclass B1, which is encoded by the bla_{IMP} gene included in the integron structure,[2,3] rapidly spreads by facile horizontal gene transfer to other bacteria.[4] Moreover, many of the currently used serine β-lactamase inhibitors such as clavulanic acid, sulbactam, and tazobactam are ineffective against MBLs. Thus, the development of inhibitors of MBLs is important for the continuing application of such widely prescribed β-lactam antibiotics. Several such inhibitors have been reported to date;[5–11] for example, Payne et al. demonstrated[6] that mercaptoacetic acid, a hydrolysis product of mercaptoacetic acid thiol esters that are hydrolyzed by MBLs (β-lactamase II, CfiA, and CphA), binds irreversibly to the enzyme through formation of a disulfide bond with the active site cysteine residue under aerobic conditions, as evidenced

by both tryptic digestion and electrospray mass spectrometry studies.

Our ultimate goal was to develop an irreversible inhibitor of IMP-1. We report here on the design and inhibition properties of three-dimensional structure-based irreversible inhibitors of IMP-1, **1** and **2**, and the crystal structure of a covalently bound complex formed between the hydrolysis product of **2** and IMP-1.

1 **2**

The strategy for the irreversible inhibition of IMP-1 is shown in Scheme 1: The thiol group in **2** coordinates to one or

Scheme 1. Strategy for the irreversible inhibition of thiol compounds with a good leaving group.

two Zn^{II} ion(s) in the active site as an anchor. Lys224 (following BBL numbering[12]) is conserved in almost all MBLs of subclass B1. In the first IMP-1 structure reported (PDB code 1DD6),[7] Lys224 is located at a distance of about 6 Å from the two Zn^{II} ions. Lys224 is thought to be important for substrate binding[6,13] and may attack an activated ester, thus forming a covalently bound inhibitor–enzyme adduct that irreversibly inhibits the enzyme. At this point, water molecules, from the solvation shell surrounding Lys224, may act as acceptors of H^+ ions from the positively charged N^{ζ} group of Lys224.

The coupling reaction of one equivalent of 3-mercaptopropionic acid (MPA) and 1-hydroxy-1*H*-benzotriazole (HOBt) with pentafluorophenol in the presence of one equivalent of *N*,*N*′-dicyclohexylcarbodiimide (DCC) in ethyl acetate at 0 °C afforded **1**, a synthetic intermediate of **2**, in 15 % yield (see Supporting Information). The desired inhibitor **2** was prepared in 45 % yield by treating **1** with MPA in the presence of DCC in ethyl acetate at 0 °C (see Supporting Information).

The time-dependent inactivation of IMP-1 by **1** and **2** was determined by incubating various amounts of inhibitor with 10 nM IMP-1 in 50 mM tris-HCl/0.5 M NaCl buffer (pH 7.4, tris = tris(hydroxymethyl)aminomethane) at 15 °C (see Supporting Information). The inactivation of IMP-1 by **1** and **2** was both time and concentration dependent. Plots of the natural logarithm of the residual activity against incubation time were linear, thus suggesting that the observed rate of inactivation follows pseudo-first-order kinetics (Figure 1 a and b). The double reciprocal plots of these slopes (k_{obs}) versus concentration of **1** and **2** gave straight lines (Figure 1 c

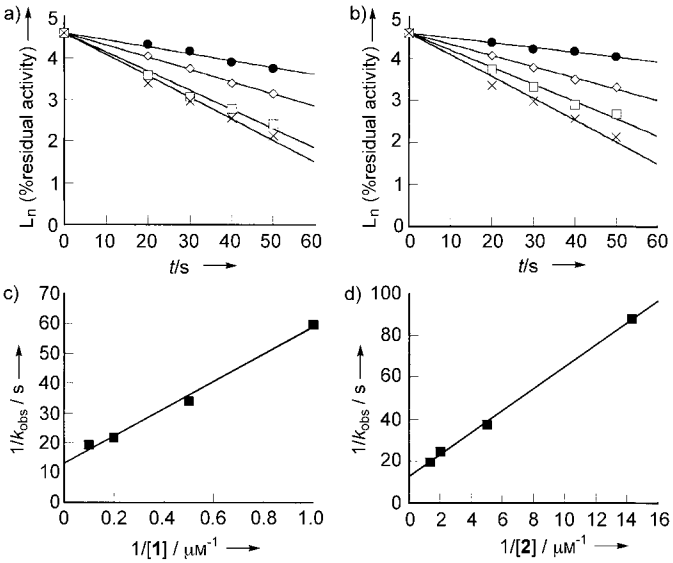

Figure 1. Time- and concentration-dependent inactivation of IMP-1 by **1** (a) and **2** (b) in 50 mM tris-HCl/0.5 M NaCl buffer (pH 7.4) at 15 °C. Inhibition concentrations: ●: 1 μM; ◇: 2 μM; □: 5 μM; and ×: 10 μM for **1**, and ●: 0.07 μM; ◇: 0.2 μM; □: 0.5 μM; and ×: 0.75 μM for **2**. Each point shown represents the mean of three experiments. Double reciprocal plots of k_{obs} versus concentration of **1** (c) and **2** (d).

and d). The regression line did not pass through the origin, but intercepted the positive *y*-axis, thus indicating the initial formation of a dissociable complex between IMP-1 and inhibitor before inactivation.[14] The k_{inact} and K_i values were calculated from these plots to be $0.076 \pm 0.002\ s^{-1}$ and 3.452 ± 0.030 μM for **1** and $0.080 \pm 0.002\ s^{-1}$ and 0.423 ± 0.013 μM for **2**. These results show that the second-order rate constant for inactivation (k_{inact}/K_i) with **2** increases by about ninefold over that with **1**.

To determine whether **1** or **2** inhibits IMP-1 irreversibly, 10 μM IMP-1 was incubated with 1 mM **1** or **2** at 0 °C for various periods of time (0–2 h) and the mixtures were then filtered through gel (Sephadex G-25) to separate the protein from the excess inhibitor (see Supporting Information). The activity of the resulting protein was measured using nitrocefin as the substrate. The control, without inhibitor, shows no loss of activity of IMP-1 after filtration through the gel. On the other hand, the inactivation of IMP-1 by **1** and **2** resulted in a nearly 100 % inhibition, clearly showing that both inhibitors inhibited IMP-1 very rapidly and irreversibly. Furthermore, the irreversibility of the binding of **1** and **2** was also confirmed by dialysis at 4 °C for 16 h (see Supporting Information): in neither of these cases was any activity recovered, thus verifying that **1** and **2** are irreversible inhibitors.

After the incubation of 100 μM **2** with 10 μM IMP-1 for 30 minutes and gel filtration, the sample was analyzed by MALDI-TOF mass spectrometry (see Supporting Information). The MALDI-TOF mass spectrum of the intact IMP-1

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

showed the parent signal at *m*/*z* 25113.2 while that treated with **2** showed a peak at *m*/*z* 25290.1 (see Supporting Information). The increase in mass of *m*/*z* 176.9 corresponds to the mass of $SCH_2CH_2COSCH_2CH_2CO$ (this unit is denoted **2**-P), which indicates that this moiety of **2** is covalently attached to IMP-1 in a ratio of 1:1.

To identify the site of amino acid attachment and to determine the three-dimensional structure, crystals of IMP-1 treated with **2** were prepared by the hanging-drop method and the molecular structure was determined (see Supporting Information). The structure of the inhibitor bound IMP-1 (**2**-P/IMP-1) at a resolution of 2.63 Å was refined to an *R*-factor value of 22.8 % and an R_{free} value of 24.3 % using 2.63- to 44.7-Å data.[15] There are two **2**-P/IMP-1 molecules, A and B, in the asymmetric unit. The two molecules are almost identical with a root-mean-square deviation of 0.31 Å when all C^{α} atoms between A and B are superimposed. The overall structure of each molecule adopts a αβ/βα sandwich structure as found in the native enzyme, the three-dimensional structure of which was not greatly perturbed by the inhibitor. The overall structure of molecule A is shown in Figure 2a.

The thiolate group in **2**-P bridges between the two Zn^{II} ions in the active site (distances Zn1···inhibitor(S), 2.2/2.2; Zn2···inhibitor(S), 2.3/2.5 Å in molecules A/B; Figure 2b). The geometry around Zn2 is changed from a trigonal bypyramid in the native structure to a distorted tetrahedral structure, as previously reported by Concha et al.[7] (angles (Asp120)$O^{\delta 2}$-Zn2-Cys221(S^{γ}), 101/101°; (Asp120)$O^{\delta 2}$-Zn2-His263($N^{\varepsilon 2}$), 99/104°; Asp120 $O^{\delta 2}$-Zn2-inhibitor(S), 122/112°; (Cys221)S^{γ}-Zn2-His263($N^{\varepsilon 2}$), 109/116°; (Cys221)S^{γ}-Zn2-inhibitor(S), 107/113°; (His263)$N^{\varepsilon 2}$-Zn2-inhibitor(S), 117/111° in molecules A/B.

The $2|F_o|-|F_c|$ electron density map clearly indicates the formation of a covalent amide bond between the ester and side chain N^{ζ} atom of Lys224 with the concomitant displacement of the pentafluorophenolate group, which is not seen in the electron density.

The carbonyl oxygen atom of the amide group formed between the inhibitor and IMP-1 forms a hydrogen bond with the main-chain nitrogen atom of Asn233 (ca. 3.1/3.3 Å in molecules A/B) while the carbonyl oxygen atom of the thioester group of the inhibitor is hydrogen bonded to the side chain nitrogen atom of Asn233 (ca. 3.0/3.5 Å in molecules A/B).

In summary, the synthesis of a covalent, irreversible inhibitor **2** of IMP-1 is described. An X-ray crystal structure of the inhibitor covalently bound to IMP-1 confirmed this strategy. These findings shed further light on the design of inhibitors based on the three-dimensional structure of MBLs related to IMP-1.

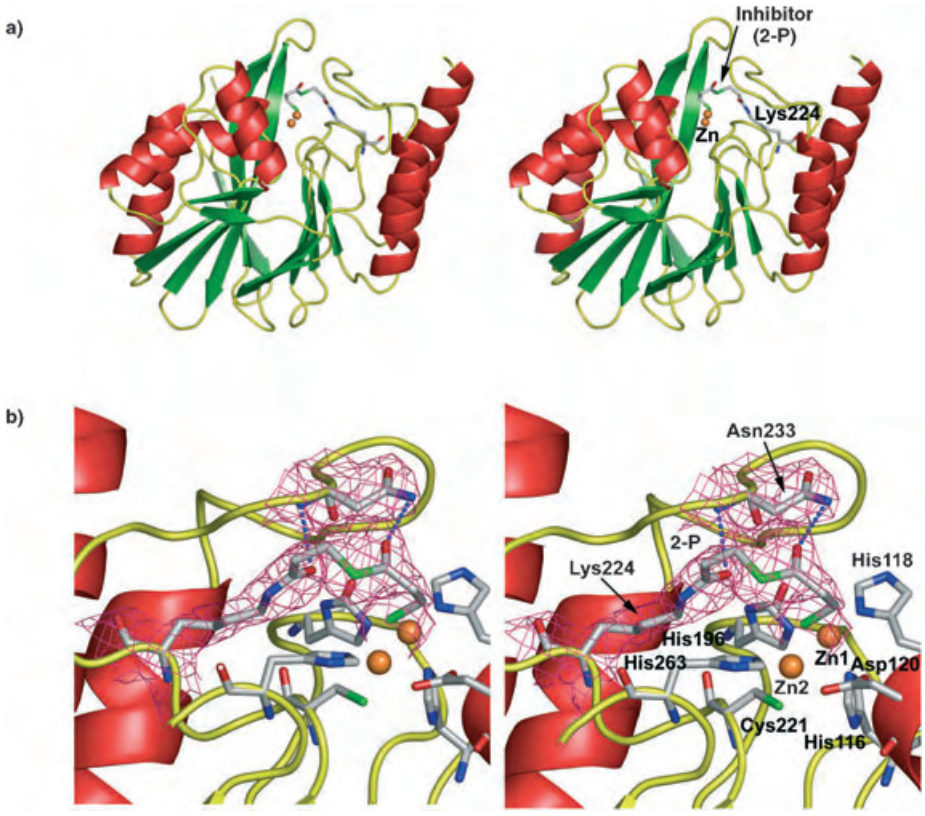

Figure 2. a) The overall structure of IMP-1 complexed with 2-P. α-Helices, β-strands, and loops are shown in red, green, and yellow, respectively. Zn^{2+} ions are represented as orange spheres. The inhibitor and Lys224 are displayed as sticks (C, N, O, and S atoms colored gray, blue, red, and green, respectively). b) The crystal structure of IMP-1 modified by **2**-P. The electron density of Asn233 as well as Lys224 and its covalently attached inhibitor molecule is shown countoured at 1.0σ in a $2|F_o|-|F_c|$ map. Hydrogen bonds are indicated by blue dashed lines.

Coordination Polymers

Self-Assembly of an Interlaced Triple-Stranded Molecular Braid with an Unprecedented Topology through Hydrogen-Bonding Interactions**

Xin-Jun Luan, Yao-Yu Wang, Dong-Sheng Li, Ping Liu, Huai-Ming Hu, Qi-Zhen Shi, and Shie-Ming Peng*

The current interest in the crystal engineering of coordination polymers[1] stems from their potential applications as materials[2] for molecular selection, ion exchange, and catalysis, as well as because of their intriguing variety of architectures and topologies. Many recent examples have illustrated that topological types unprecedented in inorganic compounds and in minerals can be observed within coordination polymer frameworks.[3] Particularly attractive is the finding of species with novel modes of supramolecular intertwining, such as helices, rotaxanes, catenanes, and knots,[4] which contribute more and more to our increasing knowledge of the self-assembly processes and the supramolecular self-organization of coordination polymers. The amount of predefined information can be reduced by incorporating a higher degree of flexibility into the building blocks, and more unpredictable structures can arise from identical metal–ligand combinations. For example, rigid polyfunctional ligands are well known to form grids,[5] brick-wall structures,[6] honeycombs,[7] diamondoid nets,[8] and other noteworthy species,[9] while long flexible polyfunctional ligands have shown the ability to produce unique interwoven extended structural motifs, such as polycatenanes,[10] polyrotaxanes,[11] double helices,[12] triple helices,[13] and other uncommon species.[14] Some of the interwoven structures may be predictable; however, structural control of metal–organic reactions (especially those involving flexible ligands) remains a great challenge, and unexpected structures with unprecedented topologies often result. Herein we report a fascinating interlaced triple-stranded braid based on a Cu^{II} complex with the highly flexible 1,3-bis(4-pyridyl)propane (bpp) ligand. To the best of our knowledge, this species presents a remarkable and unprecedented topology of a triple-stranded molecular braid which looks just like a hair plait. Moreover, it shows an interesting behavior in which the interlaced chains are self-recognized by hydrogen bonds between them.

Slow evaporation of the methanol/acetonitrile solvent from a solution of bpp and $[Cu_2(maa)_4{\cdot}2H_2O]$ (Hmaa = 2-methylacrylic acid) in a 2:1 stoichiometry led to crystals of $[Cu_4(bpp)_4(maa)_8(H_2O)_2]{\cdot}2H_2O$ (**1**).

The structure of **1** was determined unambiguously by X-ray crystallographic analysis.[15] This system crystallized in the centrosymmetric space group $P\bar{1}$, with three independent copper centers per asymmetric unit (Figure 1). Each Cu^{II} center has a different coordination environment: distorted square pyramid, ideal square-planar, and distorted octahedral geometries. Although it is well known that Cu^{II} ions can give rise to tetracoordinate, pentacoordinate, and hexacoordinate geometries, complexes in which the three coordination styles all exist hasn't been reported to date. The complex reported herein contains the three modes of coordination for Cu^{II} ions in the arrangement $(\text{-}Cu^5\text{-}Cu^6\text{-}Cu^5\text{-}Cu^4\text{-})_n$ (Cu^x, x = coordination number). In addition, the terminally coordinated maa anions exhibit a versatile coordination behavior and display different bonding modes with the copper cations: monodentate for Cu1 and Cu2 and chelating for Cu3. In the complex, bpp is employed as a bridging ligand for the construction of a one-dimensional chain along the *c* axis which has alternating helical sections (alternating right and left turns of the strand when looking down the "growth axis"). However, the single strand chain is not a helical structure, because the strand contains centers of inversion and does not have defined chirality. Interestingly, bpp can adopt different conformations with respect to the relative orientations of the CH_2 groups: the bpp ligand between Cu1 and Cu2 adopts a *trans– gauche* (TG) conformation, in which N···N is 8.684(2) Å, whereas the

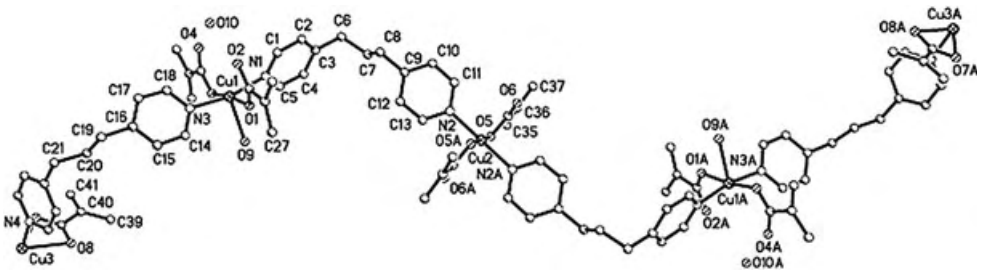

Figure 1. A view of the coordination environments at the three Cu^{II} centers in **1**. Selected bond lengths [Å]: Cu1-O1 1.918(2), Cu1-O3 1.920(2), Cu1-O9 2.329(2), Cu1-N1 2.027(2), Cu1-N3 2.026(3), Cu2-O5 1.991(2), Cu2-N2 1.995(3), Cu3-O7 2.111(3), Cu3-O8 2.361(3), Cu3-N4 1.985(2).

bpp ligand between Cu1 and Cu3 adopts a TT conformation, in which N···N is longer (9.375(2) Å). The chain in **1**, therefore, results from metal–ligand interactions coupled with various other factors and can be described as $(\text{-bpp}^{TT}\text{-Cu}^{5}\text{-bpp}^{TG}\text{-Cu}^{6}\text{-bpp}^{TG}\text{-Cu}^{5}\text{-bpp}^{TT}\text{-Cu}^{4}\text{-})_n$. The periodicity of the chain is 44.280(2) Å and contains four Cu^{II} centers per repeat unit.

The crystal structure of **1** shows the presence of a neutral interlaced triple-stranded braid, which is formed by the interweaving of three single-stranded chains with alternating helical parts that extend along the *c* axis (Figure 2). The repeat distance of the braid (14.760 Å) is 1/3 of the repeat distance of the single chain. Cu^{II} atoms are arranged in a line in the middle of the braid, and the distance between the adjacent Cu^{II} centers is 7.380 Å, which is half of the repeat distance of the braid. Discrete triple-stranded intertwining chains generally show a triple-helix topology in supramolecular chemistry.[13] In contrast, the structure of **1** can be described as a molecular braid with an unprecedented topology. To the best of our knowledge, this is the first example of a molecular braid which mimics perfectly a hair plait. Careful examination of the structure indicates that strong intermolecular hydrogen bonds of O9–H9A···O8 (2.764(1) Å) and O9–H9···O6 (2.800(2) Å) exist between the three independent chains in the braid (Figure 3). It is clear that two hydrogen atoms of one coordinated water molecule serve as the acceptors, while the two oxygen atoms of different coordinated maa anions serve as the donors in each self-recognition site. Self-recognition often operates between groups during the assembly of amino acid molecules in crystals, in the majority of cases, through the formation of hydrogen bonds. In the current complex, the molecular braid structure can be considered to be dependent on self-recognition between the three chains. That is, the hydrogen bonds,

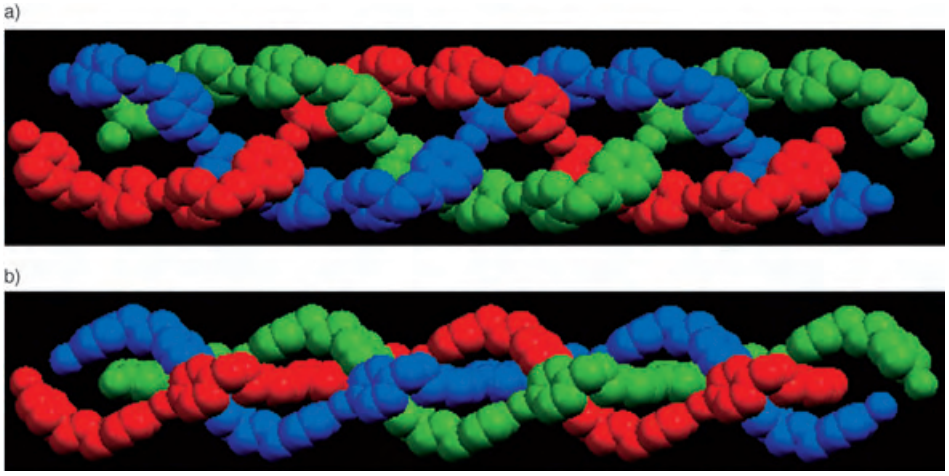

Figure 2. a) Top view of the interlaced triple-stranded braid of **1** and b) side view of **1**. The maa anions are omitted for clarity, and the triple-stranded chains are colored red, blue, and green.

through which the molecular braid is aligned exactly, operate between the three interwoven chains. Thus, the formation of the molecular braid in this case is expected to occur in two steps: initial construction of an infinite interwoven chain of ligated Cu^{II} ions, followed by hydrogen-bonding between the infinite chains. Thermogravimetric analysis (TGA) of the crystalline complexes **1** showed that after the loss of uncoordinated water molecules (2.0%) below 65°C, no weight loss occurred until approximately 235°C, which indicates the molecular braid is thermally stabile. Detailed analysis of the crystal structure also indicates that the main factor governing this phenomenon is not only the hydrogen bonds between the chains, as expected, but also by the braid framework, that is, by the interweaving of the single polymeric strands (which have alternating right and left turns looking down the "growth axis"). The rigidity of the braid framework means that the braids cannot approach one another sufficiently closely in the crystal; thus, the framework promotes the formation of an interlaced triple-stranded braid.

Another interesting structural feature of **1** is that there are many uncoordinated oxygen atoms that become arranged along the two sides on formation of the braid. In the process of self-assembly, uncoordinated oxygen atoms can act as hydrophilic sites and easily form hydrogen bonds with water molecules that approach the host (O10–H10A···O2 2.884(2) Å, O10–H10B···O4 2.798(1) Å; Figure 4). As a result, guest water molecules seem to cling to the surface of the braid.

In conclusion, the results demonstrate that an unusual complex comprising an interlaced triple-stranded braid is synthesized from the reaction of a Cu^{II} complex having a paddle-wheel structure with a flexible neutral organic ligand in the ratio of 1:2, which is different to the typical reaction route.[16] To the best of our knowledge, this complex–ligand combination represents a unique case in which the supramolecular assembly results in a molecular braid with an unprecedented topology. This example thus brings a new member to the family of suprastructures composed of identical units.

Experimental Section

$[Cu_2(maa)_4]\cdot 2H_2O$: Reaction of $[Cu_2(OH)_2CO_3]$ (2.211 g, 10 mmol) with 2-methylacrylic acid (3.442 g, 40 mmol) in methanol under reflux for 2 h afforded blue-green crystals of $[Cu_2(maa)_4\cdot 2H_2O$ in approximately 87% yield. Elemental analysis calcd (%) for $C_{16}H_{24}Cu_2O_{10}$: C 38.17, H 4.80; found: C 38.28, H 4.83. IR (KBr): $\tilde{\nu}$ = 2968, 2932, 1681, 1645, 1594, 1497, 1414, 1299, 1225, 1008, 951, 856, 826, 638, 445 cm^{-1}.

1: A solution of bpp (0.040 g, 0.200 mmol) in acetonitrile (10 mL) was added to a solution of $Cu_2(maa)_4\cdot 2H_2O$ (0.050 g, 0.100 mmol) in methanol (10 mL). The clear mixture was stirred for a few minutes and then allowed to evaporate at room temperature. Well-shaped blue needles of **1** appeared after several days. The crystalline product was filtered, washed with ethanol, and dried in air. Yield, 65%. Elemental analysis calcd for $C_{84}H_{104}Cu_4N_8O_{20}$: C 56.05, H 5.82, N 6.22; found: C 56.12, H 5.85, N 6.28. IR (KBr): $\tilde{\nu}$ = 3421, 2953, 1650, 1618, 1591, 1453, 1427, 1379, 1232, 939, 835, 810, 627, 523 cm^{-1}.

Helical Structures

A Modular Strategy to Artificial Double Helices**

Yoshie Tanaka, Hiroshi Katagiri, Yoshio Furusho, and Eiji Yashima**

The fascination of the structure, dynamics, and recognition properties of naturally occurring helical polymers, such as the α-helix of peptides and the double helix of DNA structures have prompted chemists to design and synthesize artificial helical polymers and oligomers.[1] Although a number of synthetic polymers and oligomers that fold into single-helical conformations have been reported, only a few structural motifs are available for constructing double-helical structures. The most widely used approach is the utilization of metal-directed self-assembly, in which ligand-containing strands form double-, triple-, or quadruple-helical complexes, that is, helicates;[2] the three-dimensional structures of helicates are determined by the geometry of the template metal ions. Hydrogen-bonding-driven self-assembly is another common approach to constructing supramolecular duplexes.[3] In most cases, however, their three-dimensional structures have been characterized as ladder- or zipperlike linear conformations. It was recently disclosed that some oligoamides give rise to double-helical assemblies by making use of interstrand hydrogen-bonding and aromatic–aromatic interactions.[4] Although the hydrogen-bonding interaction is a readily available and versatile tool for constructing supramolecular assemblies,[5] it is still difficult and challenging to design double helices with predictable structures.[4c] Herein, we describe the design and synthesis of hydrogen-bonding-driven double helices by a modular strategy in which intertwined supramolecular binary complexes are employed.

Our strategy is based on the crescent-shaped *m*-terphenyl derivatives (Figure 1). Crescent-shaped molecules, such as bipyridine and phenanthroline derivatives, have often been used to construct intertwined supramolecular complexes and

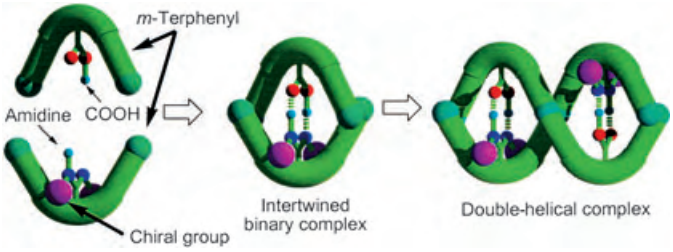

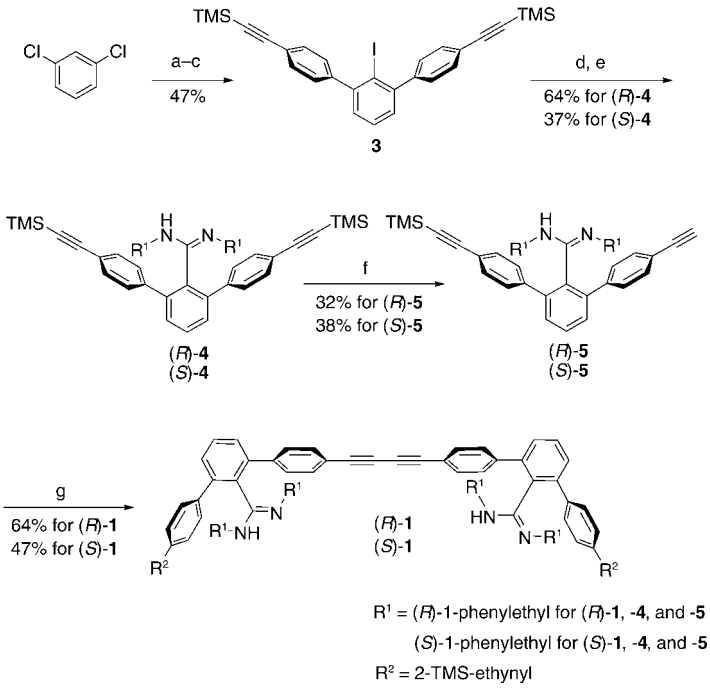

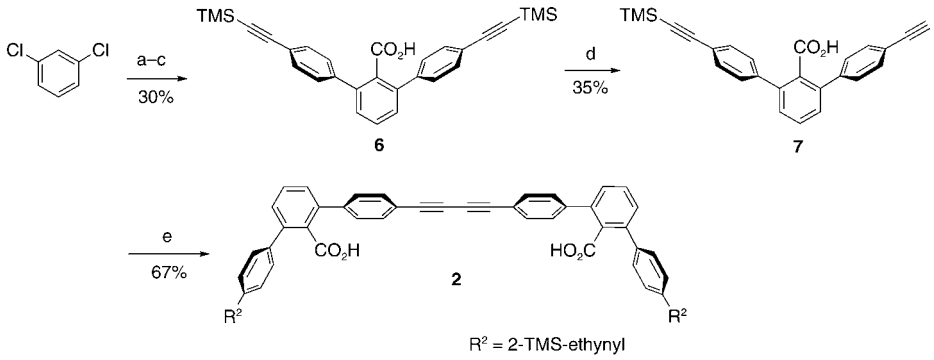

Figure 1. Schematic illustration of the modular strategy for the construction of artificial double-helical assemblies.

interlocked molecules.[6] We chose amidinium–carboxylate salt bridges as the supramolecular junction for the *m*-terphenyl derivatives because the charge-assisted hydrogen bonding between amidines and carboxylic acids is quite strong even in polar solvents and has a well-defined geometry.[7] Chiral groups were introduced onto the nitrogen atoms of the amidine moieties to control the chirality of the double helices. The formation of the salt bridge leads to a supramolecular binary complex, in which the two *m*-terphenyl derivatives are intertwined around the salt bridge (Figure 1). Connecting the intertwined complexes together should result in the formation of the double-helical structure.

The chiral diamidine (*R*)-**1** and its antipode (*S*)-**1** were prepared according to Scheme 1.[8] The iodide **3** was obtained by the Hart coupling of *m*-dichlorobenzene with 4-trimethylsilylethynylphenylmagnesium bromide followed by quenching with iodine.[9] Iodide **3** was lithiated and then treated with *N*,*N*′-bis[(*R*)-1-phenylethyl]carbodiimide[10a] to yield the amidine (*R*)-**4**.[11] (*R*)-**4** was treated with tetra-*n*-butylammonium fluoride (TBAF) to give the monosilane (*R*)-**5**, which was dimerized by oxidative coupling using the Sonogashira reagents to afford the diamidine (*R*)-**1**. The antipode (*S*)-**1** was synthesized in a similar manner except that *N*,*N*′-bis[(*S*)-1-phenylethyl]carbodiimide was used.[10b] Similarly, the dicarboxylic acid **2** was prepared according to Scheme 2. Carboxylic acid **6** was obtained by Hart coupling using CO_2 as the quencher. The monodesilylation of **6** was achieved by treatment with TBAF to yield the monosilane **7**, which was subsequently dimerized by oxidative coupling to afford **2**.

Complexation of the diamidine (*R*)-**1** with the dicarboxylic acid **2** was first investigated by ^1H NMR spectroscopy (Figure 2). The ^1H NMR spectrum of **1** in $CDCl_3$ was complicated at 25 °C, because of the presence of several conformers originating from the *E*–*Z* isomerism of the C=N double bonds and the restricted rotation about the C–C bond between the amidine and the *m*-terphenyl groups.[11] In contrast, the ^1H NMR spectrum of the complex (*R*)-**1**·**2** showed a simple spectrum, thus indicating the presence of only one isomer. This result is consistent with the formation of a salt bridge between (*R*)-**1** and **2**, through which the geometry around the amidine residues is fixed in the *E* configuration. The resonances of the NH protons (c′ and c″) were observed as two doublets at a low magnetic field of approximately $\delta = 13.5$ ppm, which is indicative of the formation of a salt bridge. The CH_3 protons of the amidine groups (d′ and e′) were also evident. The non-equivalency of these signals is attributed to the formation of a duplex between (*R*)-**1** and **2**, which was also supported by 2D NMR spectroscopic and electrospray ionization mass spectrometry (ESI-MS) studies.[8] The association constant of **1** and **2** at

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

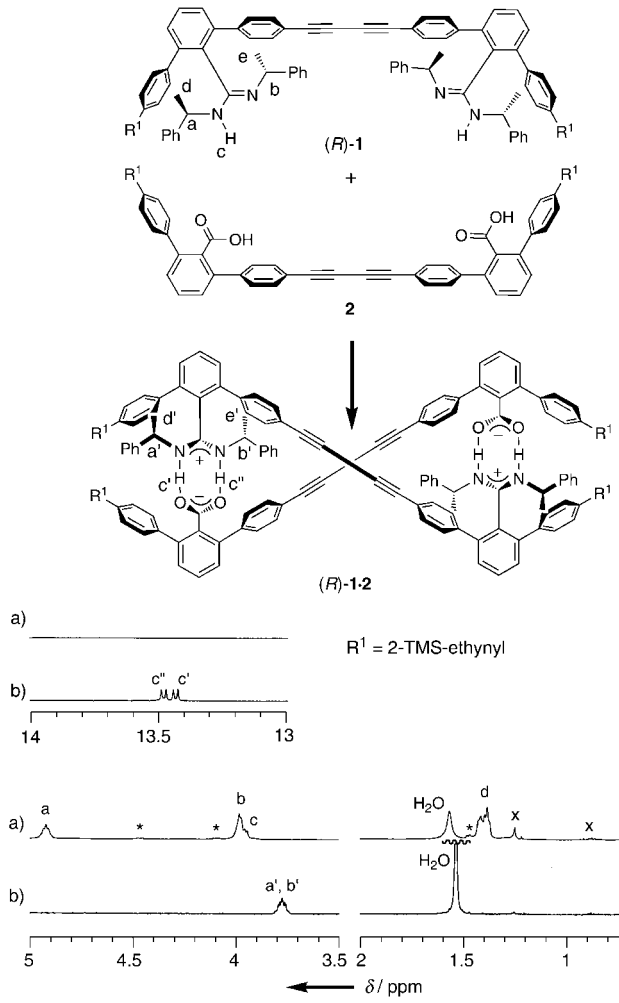

Figure 2. Partial ^{1}H NMR (500 MHz, $CDCl_3$, 25 °C) spectra of a) diamidine (*R*)-**1** (7.1 mM) and b) complex (*R*)-**1·2** (0.4 mM). The asterisks denote the signals for the corresponding *Z* isomer of (*R*)-**1**. "x" indicates impurities.

25 °C in $CDCl_3$ was estimated to be $>10^6\,M^{-1}$ by ^{1}H NMR spectroscopy.[8]

The X-ray structural analysis unambiguously revealed that the complex (*R*)-**1·2** adopted a right-handed double-helical structure in the solid state (Figure 3).[8,12] The amidine and carboxy groups formed two identical salt bridges with two hydrogen bonds for each and average N···O distances of 2.73 Å. The two amidinium–carboxylate salt bridges enabled the two strands to be held together. All the benzene rings of the *m*-terphenyl groups were chirally twisted clockwise by about 48–61°, and the two strands were wound up to form the right-handed double-helical structure.

Circular dichroism (CD) measurements were then performed to examine if the complexes (*R*)- and (*S*)-**1·2** maintained their single-handed double-helical structures in solution (Figure 4). Both enantiomers of **1·2** showed intense mirror-image CD signals between approximately 260 and

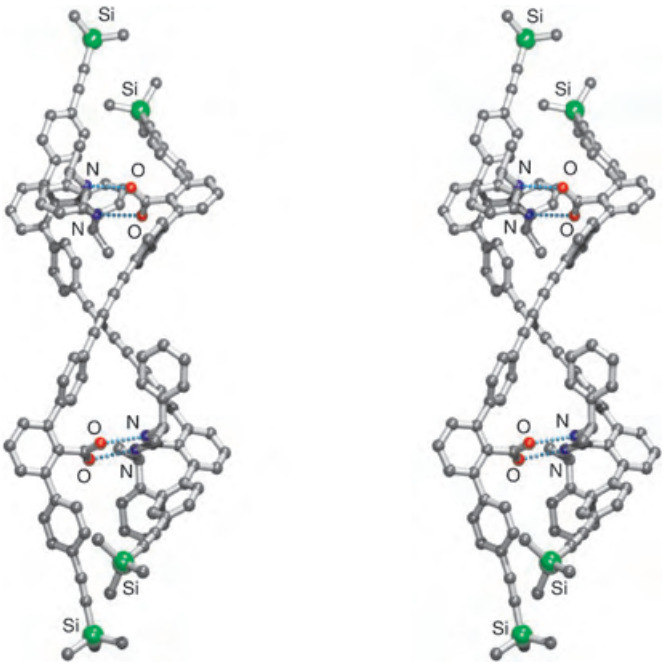

Figure 3. Stereoview of the crystal structure of (*R*)-**1·2**. The hydrogen atoms and included solvents are omitted for clarity. The intermolecular hydrogen bonds between N and O are shown by dashed lines.

370 nm in $CHCl_3$, whereas (*R*)- and (*S*)-**1** exhibited very weak Cotton effects in this region. The significant enhancement of the Cotton effects for the complexes **1·2**, especially in the absorption region of the diacetylene linkages (ca. 300–370 nm), indicates that the single-handed double-helical structures of (*R*)- and (*S*)-**1·2** are likely retained in $CHCl_3$. This presumption was supported by the variable-temperature ^{1}H NMR spectroscopic measurements of (*R*)-**1·2** in $CDCl_3$; no signals corresponding to the opposite diastereomeric left-handed double helix were observed, even at temperatures as low as −60 °C. Thus, (*R*)-**1·2** seems to adopt a predominantly right-handed double-helical structure, although the possibility that the inversion of the double helices is still fast on the NMR time scale even at −60 °C can not be ruled out.

It should be noted that (*R*)-**1·2** even exhibited intense Cotton effects in DMSO, although the intensities were reduced to 67 % of those in $CHCl_3$ (Figure 4). The ^{1}H NMR

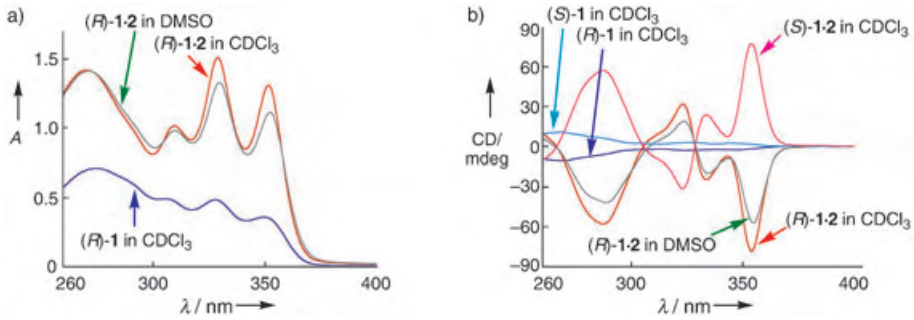

Figure 4. a) UV/Vis spectra (0.1 mM, 20 °C) of amidine (*R*)-**1** in $CDCl_3$ (blue), and complex (*R*)-**1·2** in $CDCl_3$ (red) and in DMSO (green). b) CD spectra (0.1 mM, 20 °C) of (*R*)-**1** (blue), (*S*)-**1** (light blue), (*R*)-**1·2** (red), and (*S*)-**1·2** (pink) in $CDCl_3$, and (*R*)-**1·2** in DMSO (green).

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

spectrum of **1·2** showed that 60% of the complex **1·2** retained its duplex structure, whereas the rest of **1·2** underwent dissociation into **1** and **2** in [D_6]DMSO (0.1 mM, 25 °C).[8] In sharp contrast, (*R*)-**4·6**, a simple model for (*R*)-**1·2**, showed a weak CD spectrum similar to that of (*R*)-**4** in DMSO.[8] In fact, it was shown by ^{1}H NMR spectroscopic analysis that **4·6** dissociated into **4** and **6** in [D_6]DMSO.[8] Consequently, the complexation of **1·2** was more stable than that of the simpler **4·6**.

In summary, we have successfully prepared the first artificial single-handed double helices through formation of salt bridges between chiral diamidines ((*R*)- and (*S*)-**1**) and the achiral dicarboxylic acid **2.** Both single-handed double helices are stable in the solid state as well as in solution. The modular strategy, we believe, can act as a new design rationale for the formation of hydrogen-bond-driven double helices in which the three-dimensional structures including the helix sense are predictable.

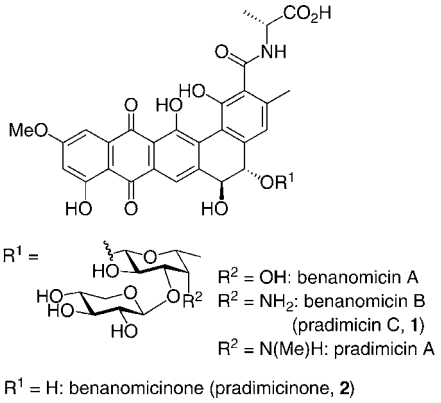
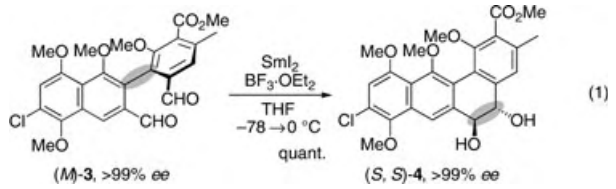
Total Synthesis



Regio- and Stereocontrolled Total Synthesis of Benanomicin B**

*Ken Ohmori, Minoru Tamiya, Mitsuru Kitamura, Hirohisa Kato, Mami Oorui, and Keisuke Suzuki**



In memory of Tsuguo Mizuochi

Benanomicin/pradimicin antibiotics (BPAs) constitute a class of natural products with a unique structure consisting of a benzo[*a*]naphthacene core, an amino acid, and a disaccharide.[1] Their potent antifungal and anti-HIV activity is attributed to the specific, Ca^{2+}-mediated binding of BPAs to the mannose-rich oligosaccharides presented on the fungi or virus surfaces.[2] Stimulated by these intriguing biological properties and structural novelty, we initiated a synthesis study of BPAs.

In a previous synthesis study we reported the stereoselective synthesis of the common aglycon benanomicinone (pradimicinone, **2**)[3] by exploiting the complete transfer of

the axial chirality into the central chiralities in the pinacol cyclization of biaryl dicarbaldehyde (*M*)-**3** into the *trans*-1,2-diol (*S*,*S*)-**4** [Eq. (1)].

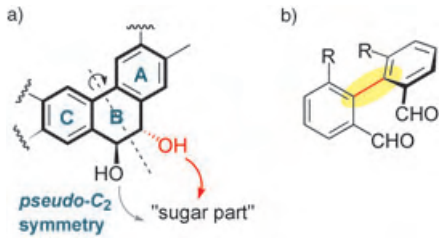
[**] We thank Meiji Seika Kaisha Ltd. for providing an authentic sample of benanomicins A and B. This work was partially supported by the 21st Century COE program (Tokyo Institute of Technology).

Two additional issues must be addressed en route to the fully controlled total synthesis (Figure 1): a) introduction of the sugar moiety into the aglycon in a regioselective manner, and b) stereoselective access to the chiral, nonracemic biaryl



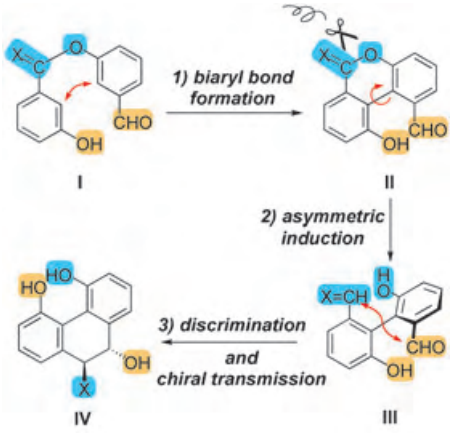


Figure 1. Tactical issues for the total synthesis of BPAs. a) regioselective introduction of the sugar moiety and b) stereocontrol of the axial chirality.

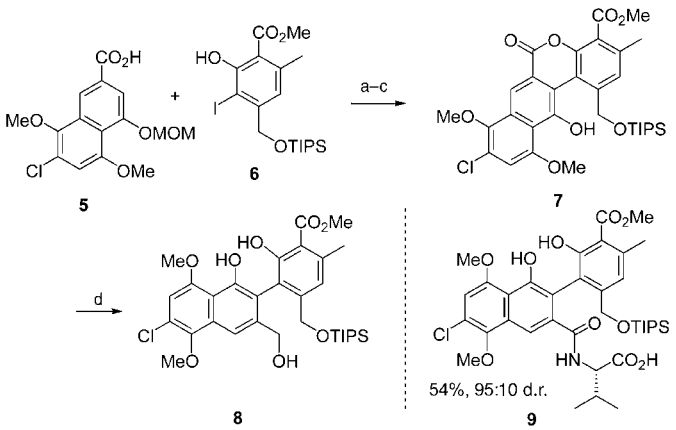
dicarbaldehyde (*M*)-**3**, as the key cyclization precursor. Conjugation of the disaccharide was an intriguing challenge, because of the local pseudo-C_2 symmetry of the 1,2-diol on the B ring. Although a subsidiary issue, the enantioselective synthesis of (*M*)-**3** was a serious bottleneck in the sequence of our synthesis. Herein, we describe clean solutions to these problems, which have culminated in the first total synthesis of benanomicin B (**1**).

Scheme 1 features three key points in our strategy; 1) construction of sterically encumbered biaryl structure **II**



Scheme 1. Overview of our synthesis strategy.

by formation of an internal C–C bond in the tethered derivative **I**; 2) The asymmetric cleavage of the C–O tether in **II** by employing a chiral agent to give the axially chiral biaryl **III**; and 3) Reconnection at two carbonyl groups to give the tricyclic product **IV**. A special requirement for the third stage was the capability of an axial-to-central chirality transfer with concomitant discrimination of the two oxy functions.

The first task was to prepare optically pure **8** as a key precursor for the pinacol cyclization (Scheme 2). We applied an asymmetric ring opening of biaryl lactones pioneered by Bringmann et al. for introducing the biaryl chirality.[4] The substrate for this purpose, the biaryl lactone **7**, was prepared

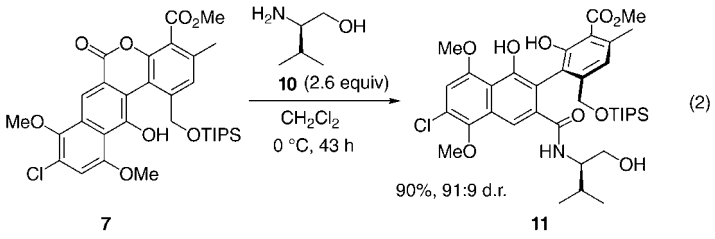
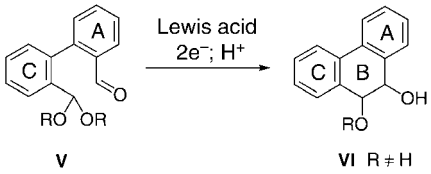


Scheme 2. Preparation and the ring-opening reaction of **7**. a) 2,4,6-trichlorobenzoyl chloride, Et_3N, DMAP, toluene, 25 °C, 20 min (99 %). b) CF_3CO_2H, CH_2Cl_2, 25 °C, 4 h (96 %). c) $Pd(OAc)_2$ (30 mol %), PPh_3 (60 mol %), $tBuCO_2Na$ (3 equiv), DMA, 110 °C, 20 min (60 %). d) L-valine (3.3 equiv), $NaBH_4$ (3.0 equiv), THF, (8 %, 2 % *ee*). DMAP = 4-*N*,*N*-dimethylaminopyridine, DMA = *N*,*N*-dimethylacetamide.

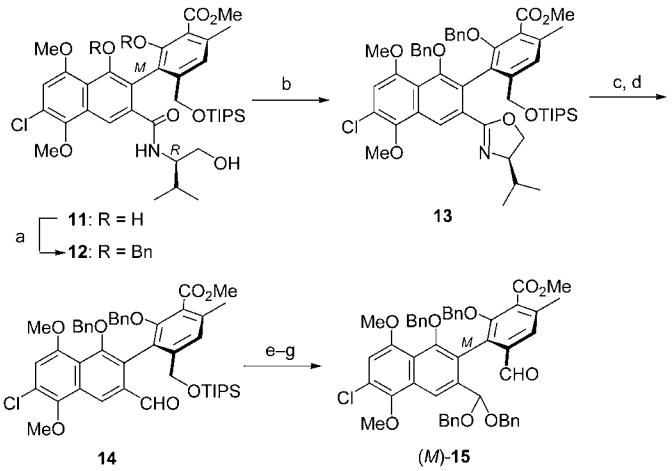
in high yield by the Yamaguchi esterification[5] of carboxylic acid **5**[3b] with phenol **6**[6] followed by the Pd-mediated cyclization.[3b,7]

Initial attempts were centered at the enantioselective reduction of **7** with $NaBH_4$ by using stoichiometric amounts of various chiral modifiers,[8–10] all of which resulted in disappointing enantioselectivities. Unexpectedly, however, we obtained an important hint when L-valine was employed: thus, although the reaction itself was not very effective (8 % yield and 2 % *ee*), a sizable amount of a highly polar by-product was noted, which was proved to be the amide **9**—the direct adduct of the amino acid. An important observation was that amide **9** was highly enriched in one of the diastereomers (90:10 d.r.).



Encouraged by this finding, we decided to pursue a diastereoselective ring-opening reaction, and optimization experiments showed that D-valinol (**10**) was an excellent chiral nucleophile, which afforded amide alcohol **11** in 90 % yield with 91:9 diastereoselectivity [Eq. (2)].[11] Purification of

(2)

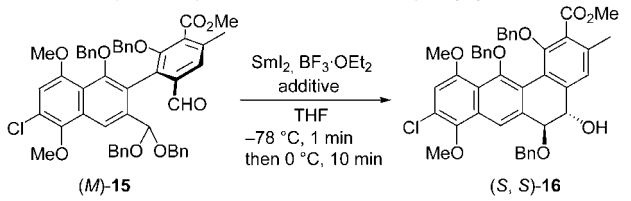


the major diastereomeric product by column chromatography (silica gel, hexane/EtOAc = 1/2) gave single crystals that were suitable for X-ray crystallographic analysis.[12] This analysis proved the compound had the requisite *M* configuration around the biaryl axis.

Now the stage was set for the pivotal stage: construction of the B-ring diol with discrimination of the two oxy functions, for which we planned the semipinacol cyclization of acetal-aldehyde **V** [Eq. (3)]. Activation of the acetal with Lewis acid followed by a net two-electron reduction would hopefully give the mono-masked diol **VI**.[13]

(3)

With this strategy in mind, we envisioned the acetal-aldehyde (*M*)-**15** as the key substrate, which was readily available from the lactone ring-opening product **11** (Scheme 3). After selective benzylation of two of the phenol



Scheme 3. a) BnBr, Cs_2CO_3, DMF, 0 °C → RT, 70 min (97 %). b) I_2, PPh_3, imidazole, CH_2Cl_2, 0 °C, 20 min (quant.). c) MeOTf, 2,6-di-*tert*-butylpyridine, CH_2Cl_2, RT, 1 h. d) L-Selectride, 0 °C, 20 min; SiO_2, RT, 17 h (96 % from **13**). e) BnOTMS, TMSOTf, toluene, −15 °C, 6 h. f) nBu_4NF, THF, 0 °C, 1 h. g) MnO_2, CH_2Cl_2, RT, 16 h (94 % from **14**). TIPS = triisopropylsilyl; Bn = benzyl, Tf = trifluoromethanesulfonyl, L-selectride = lithium tri-*sec*-butylborohydride, TMS = trimethylsilyl.

groups in **11**, the hydroxyamide moiety in the product **12** was converted into an oxazoline functionality by treatment with PPh_3 and I_2 to give **13** in high yield. After N-methylation of **13**, reduction and exposure to silica gel gave the corresponding aldehyde **14** cleanly in 96 % yield.[14] Conversion of **14** into the corresponding dibenzyl acetal[15] followed by detachment of the silyl group and oxidation afforded the enantiopure acetal-aldehyde (*M*)-**15** for the key cyclization.

The initial attempts at the semipinacol cyclization of (*M*)-**15** by using SmI_2 and $BF_3{\cdot}OEt_2$ suffered from not only modest yields, but also the lack of reproducibility (Table 1).[16] The yields widely fluctuated in the range 10–50 %, even by a slight change in reaction parameters (temperature, reaction time, amounts of reducing agent, and Lewis acid). After extensive effort, we finally found that the presence of a suitable proton source was the key to secure the reproducibility. A clean reaction occurred in the presence of H_2O to give semipinacol

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Table 1: Semipinacol cyclization of acetal-aldehyde (*M*)-**15**.[a]

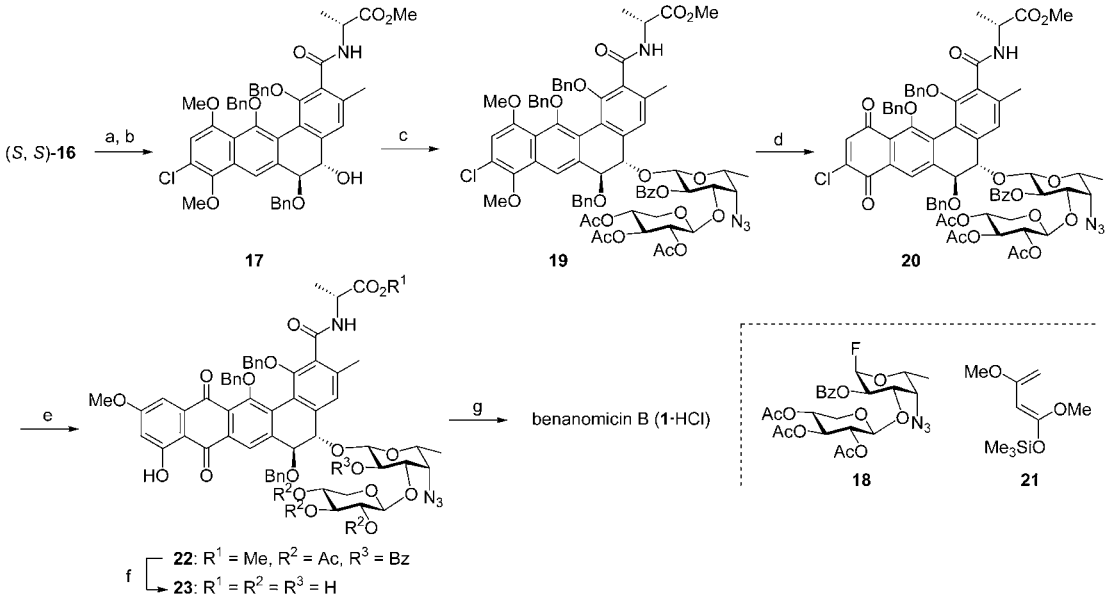
Entry	Additive[b]	Yield [%]	*trans*/*cis*	*ee* [%]
1	none	0–50	>99/<1	>99
2	H_2O	82	>99/<1	>99
3	MeOH	95	>99/<1	>99

[a] 2.5 equiv of SmI_2, 3.0 equiv of $BF_3{\cdot}OEt_2$. [b] 1.0 equiv.

16 in 82% yield; furthermore, methanol proved to be even more effective (95% yield). The reaction proceeded with stereochemical integrity, namely it was *trans*-selective and with complete chiral transmission, and (*M*)-**15** (>99% *ee*) was cleanly converted into (*S*,*S*)-**16** (>99% *ee*).[17]

Having finally overcome two major synthetic hurdles, the stage was set for the introduction of the amino acid and the sugar moieties (Scheme 4). Thus, tetracycle **16** was saponified, and condensed with D-alanine methyl ester by using the benzotriazole derivative BOP to give the corresponding amide **17** in excellent yield. The metallocene-based activator $[Cp_2HfCl_2]/2\,AgOTf$,[18] allowed the coupling of glycosyl fluoride **18**[19] with the acceptor **17** to give the β-glycoside **19** in 72% yield along with its α-anomer in 9% yield.

After oxidation of **19** by $Ce(NH_4)_2(NO_3)_6$ (CAN), the resulting chloroquinone **20** was subjected to a Diels–Alder reaction with siloxydiene **21**,[3b,20] from which pentacycle **22** was obtained in a fully regiocontrolled manner, thus completing the full carbon framework. Removal of the four acyl groups and hydrolysis of the methyl ester moiety in **22** was achieved by treatment with 1M NaOH to give **23**. Final hydrogenolysis of **23** in the presence of aqueous HCl gave benanomicin B hydrochloride (**1**·HCl), which was fully identical with an authentic sample.[21]



In conclusion, the first total synthesis of benanomicin B (**1**) was achieved based on a chiral transmission strategy. Stereoselective incorporation of valinol into lactone **7** effectively gave the axially chiral product **11**. The semipinacol cyclization of acetal-aldehyde (*M*)-**15** successfully provided the semiprotected *trans*-diol (*S*,*S*)-**16**, which allowed the selective introduction of the sugar moiety, thus enabling access to **1**.

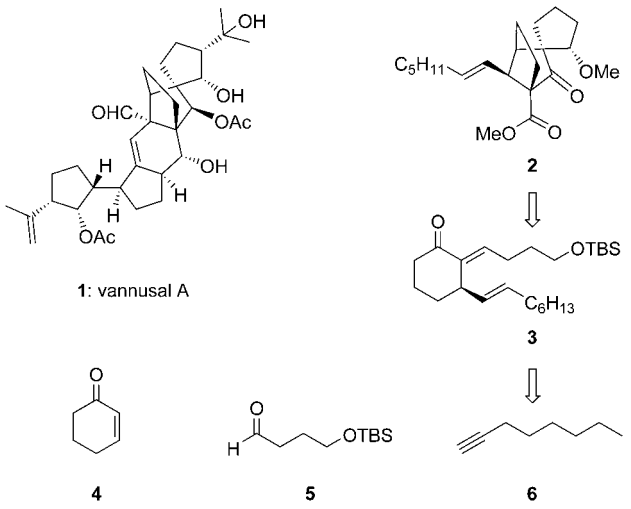
Multicomponent Reactions

A Catalytic Asymmetric Three-Component 1,4-Addition/Aldol Reaction: Enantioselective Synthesis of the Spirocyclic System of Vannusal A**



K. C. Nicolaou, Wenjun Tang, Philippe Dagneau, and Raffaella Faraoni*

The advantages of multicomponent reactions over the more common two-component processes have been widely demonstrated and reviewed.[1] Efficient asymmetric versions of such reactions offer even greater benefits to the art of chemical synthesis, as these can provide expedient access to polyfunctionalized molecules in enantioenriched form, starting from simple prochiral building blocks.[2,3] During a program directed towards the total synthesis of vannusal A (**1**, Scheme 1), an architecturally complex marine natural product isolated from the ciliate *Euplotes vannus*,[4] the key optically enriched spirocyclic intermediate **2** was required. This demand led us to the development of an asymmetric multicomponent reaction that combined α,β-unsaturated

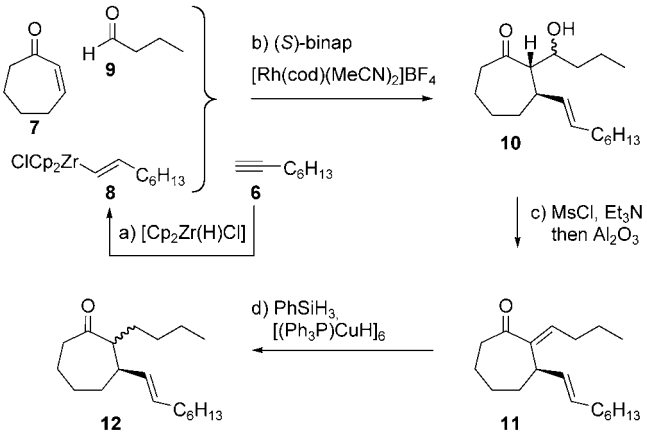
enones, aldehydes, and alkenyl zirconium species in the presence of a chiral rhodium catalyst to give enantioselective access to 2,3-disubstituted cycloalkanones. Herein we report this new synthetic technology and describe its application to the construction of enantioenriched building block **2**, which represents the spiro domain of vannusal A (**1**).

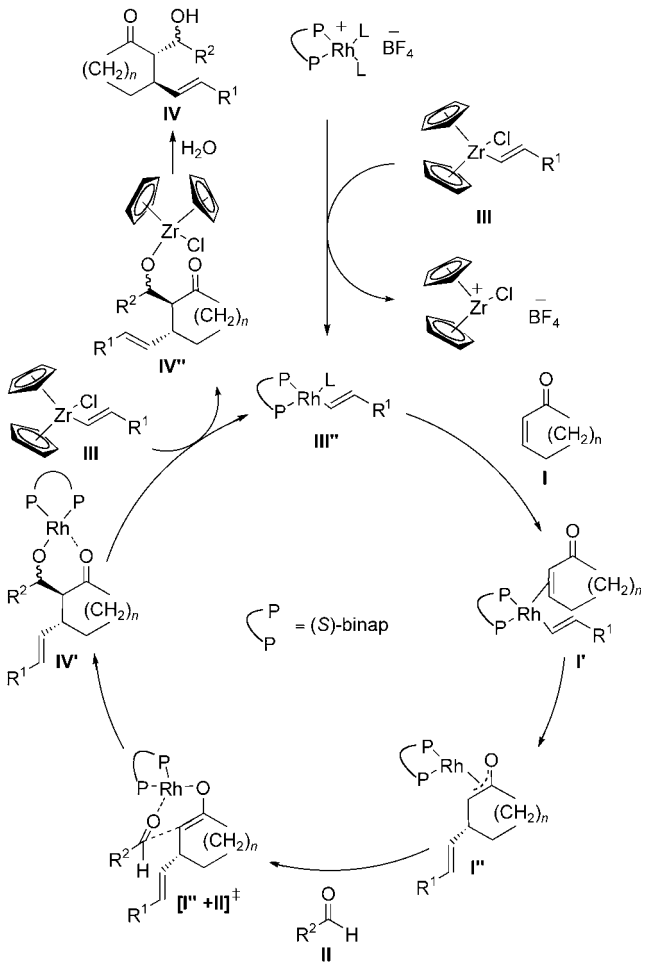


Scheme 2 shows the general strategy for the intended three-component (**I**, **II**, and **III**) catalytic asymmetric con-

Scheme 2. General scheme for the catalytic asymmetric three-component reaction (**I** + **II** + **III**→**IV**→**V**→**VI**).

struction of aldol-type compounds **IV**, α,β-unsaturated enones of type **V**, and 2,3-disubstituted cyclic ketones of type **VI**. This proposed multicomponent reaction was partially based on the pioneering work of Oi, Sato, and Inoue,[5] who demonstrated the efficient rhodium-catalyzed addition of alkenyl zirconium species to enones (under non-aqueous conditions) to afford 1,4-adducts. Furthermore, the elegant studies of the Hayashi group[6] on the catalytic cycle of the rhodium-catalyzed conjugate addition of *B*-aryl-9-BBN to a reactive vinyl ketone, which showed that a transient rhodium enolate can react with electrophiles, were key to this proposal. Both studies, however, stopped short of a three-component process capable of delivering enantiomerically enriched products as reported herein. According to our plan, a chiral rhodium complex was to act as a catalyst to induce the asymmetric 1,4-addition of zirconium species **III** to α,β-unsaturated ketone **I**. This should, in turn, furnish a rhodium enolate intermediate, whose trapping with aldehyde **II** was expected to lead first to aldol **IV** and thence to enone **V** and disubstituted cyclic ketones **VI** (by sequential elimination of water and reduction, respectively). It was, therefore, hoped that the products from this multicomponent reaction would include any one or more desired compounds **IV** to **VI** (Scheme 2).

This work was initiated with some considerable success, as demonstrated in Scheme 3 in the case of α,β-unsaturated



Scheme 3. Proof of principle of the catalytic asymmetric three-component reaction. Reagents and conditions: a) $[Cp_2Zr(H)Cl]$, THF, 30 min; b) **7** (1.2 equiv), **8** (1.2 equiv), **9** (1.0 equiv), $[Rh(cod)(MeCN)_2]BF_4$ (0.05 equiv), (*S*)-binap (0.06 equiv), THF, 25 °C, 12 h, 50% (**10**; ≈4:1 isomeric ratio); c) MsCl (3.0 equiv), Et_3N (6.0 equiv), 0→25 °C, 30 min; then Al_2O_3 (excess), 12 h, 95% (**11**, *E*:*Z*≈20:1, 98% *ee*); d) $PhSiH_3$ (1.5 equiv), $[(Ph_3P)CuH]_6$ (1 mol%), toluene, 25 °C, 6 h, 85% (*trans*/*cis*≈1:3). cod = cyclooctadiene, (*S*)-binap = (*S*)-(−)-2,2′-bis(diphenylphosphino)-1,1′-binaphthyl, Ms = methanesulfonyl.

cycloheptenone (**7**). Thus, mixing of **7** with the zirconium species **8** (derived from 1-octyne and $[Cp_2Zr(H)Cl]$)[7] and aldehyde **9** in the presence of $[Rh(cod)(MeCN)_2]BF_4$[5] and (*S*)-binap as the catalyst system in THF at 25 °C for 12 h led to the formation of **10** as a mixture of two diastereoisomers (≈4:1, 50% combined yield). This mixture was subjected to a standard mesylation/elimination sequence to produce enone **11** (*E*/*Z*≈20:1; Table 2) in 95% overall yield. Furthermore, and gratifyingly, the enantiopurity of this enone ($[\alpha]_D^{33}$ = +118.5 ($CHCl_3$, c = 1.0)) was found to be 98% *ee* by chiral HPLC (Chiralcel, OD-H). Finally, this enone **11** was reduced with $PhSiH_3$ in the presence of a catalytic amount of $[(Ph_3P)CuH]_6$[8] (1 mol%) to afford 2,3-disubstituted cycloheptanones **12** (*trans*/*cis*≈1:3; 85% combined yield).

With regards to a mechanism for this process, we envisage a similar catalytic cycle (see Scheme 4) to those previously proposed by the Oi and Inoue group[5] and the Hayashi group[6] to explain their enantioselective 1,4-addition of zirconium species, aryl boronic acids, or *B*-aryl-9-BBN

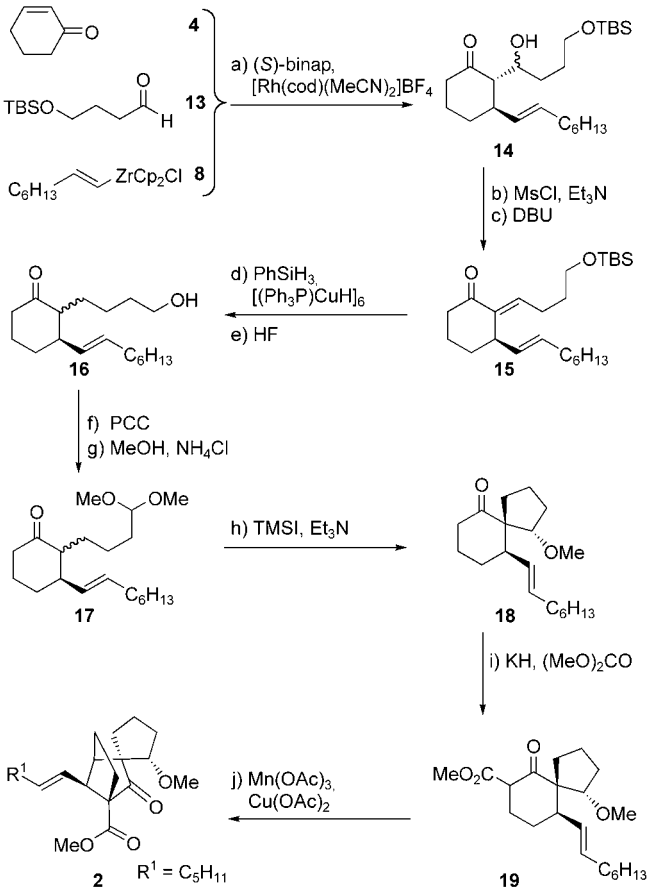
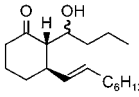
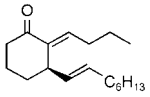


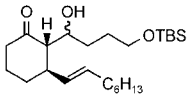
Scheme 4. Proposed mechanism for the asymmetric three-component, rhodium-catalyzed 1,4-addition/aldol reaction (**I** + **II** + **III**→**IV**). L = CH_3CN, cod (cycloocta-1,5-diene), or thf.

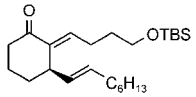
reagents to α,β-unsaturated enones. Thus, transmetalation of the alkenyl zirconium species **III** may lead to the rhodium alkenyl complex **III″**, which could react with cyclic enone **I** to form the π-coordination complex **I′**. Rearrangement of **I′**, upon transfer of the alkenyl group onto the 4-position of the enone, should lead to the rhodium enolate **I″**. This chiral enolate may then engage the aldehyde **II** in an aldol reaction, generating rhodium complex **IV′** through a six-membered-ring transition state [**I″** + **II**]‡. Transmetalation of **IV′** with another alkenyl zirconium species **III** could then lead to zirconium alkoxide **IV″** and regeneration of rhodium alkenyl complex **III″**. Hydrolysis of **IV″** provides aldol product **IV**. Both the chemoselectivity of the rhodium alkenyl species **III″** in differentiating between the conjugated ketone **I** and an aldehyde **II**, as well as the ability of the postulated transient rhodium enolate to engage the aldehyde component in an aldol reaction,[9,10] are crucial for the success of this process.

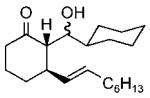
Next, we examined the generality and scope of the present enantioselective reaction. As demonstrated in Table 1, this process proceeded well with five- (Table 1, entries 7 and 8), six- (Table 1, entries 1–6), and seven-membered cyclic enones (Table 1, entries 9–11), as well as an acyclic ketone (Table 1, entry 12). Thus, a series of aldol products **IV** were obtained in good yields (30–62%) through the three-component 1,4-addition/aldol reaction. Good to excellent enantioselectivities (78–98% *ee*) were observed for the corresponding enones **V**. Various aliphatic aldehydes that carry linear or branched chains or ring systems at their α sites were employed successfully. It is noteworthy that benzaldehyde and trimethyl acetaldehyde did not prove to be suitable substrates for these reactions. The alkenyl zirconium species employed in these asymmetric processes were derived from terminal alkynes with different aliphatic or functionalized carbon chains.

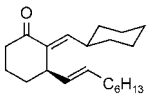


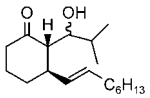


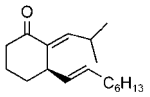


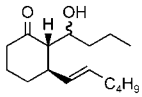


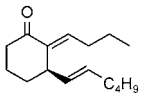


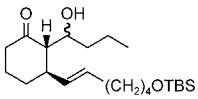


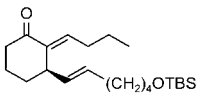


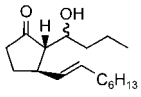


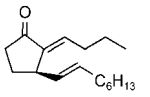


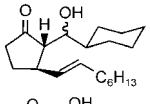


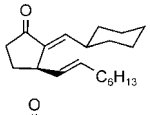


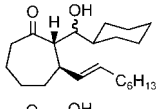


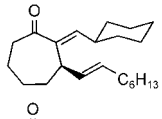


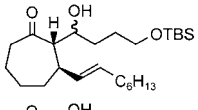


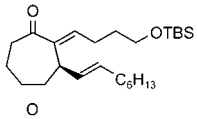


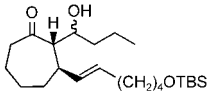


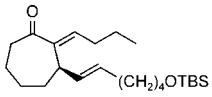


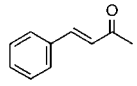


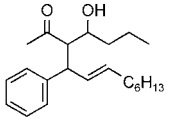


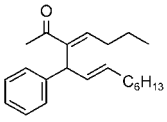












The developed technology was successfully applied to the synthesis of the spiro system **2** of vannusal A (**1**), as depicted in Scheme 5. Thus, enone **4**, alkenyl zirconium species **8** (generated in situ from 1-octyne and $[Cp_2Zr(H)Cl]$)[7] and aldehyde **13** were combined in the presence of $[Rh(cod)(MeCN)_2]BF_4$ (5 mol%) and (*S*)-binap (6 mol%) in THF at

Scheme 5. Construction of spirocyclic building block **2** of vannusal A. Reagents and conditions: a) $[Rh(cod)(MeCN)_2]BF_4$ (5 mol%), (*S*)-binap (6 mol%), THF, 25 °C, 12 h, 52%; b) MsCl (2.0 equiv), Et_3N (3.0 equiv), CH_2Cl_2, 25 °C, 30 min; c) DBU (2.0 equiv), THF, 25 °C, 2 h, (**15**, *E*:*Z* ≈ 13:1), 85% (over two steps); d) $PhSiH_3$ (1.5 equiv), $[(Ph_3P)CuH]_6$ (1 mol%), toluene, 25 °C, 6 h, (*trans*/*cis* ≈ 2:1); e) aqueous HF (48%;10 equiv), THF, 25 °C, 2 h, 79% (over two steps); f) PCC (1.5 equiv), CH_2Cl_2, 25 °C, 2 h, 91%; g) MeOH, NH_4Cl (0.01 equiv), reflux, 2 h, 98%; h) TMSI (1.5 equiv), Et_3N (1.2 equiv), CH_2Cl_2, 0 to 25 °C, 2 h, 50%; i) KH (5.0 equiv), $(MeO)_2CO$ (10 equiv), THF, reflux, 2 h; j) $Mn(OAc)_3$ (2.5 equiv), $Cu(OAc)_2$ (1.2 equiv), EtOH, reflux, 2 h, 68% (over two steps), (**2**, 96% *ee*). DBU = 1,8-diazabicyclo-[5.4.0]undec-7-ene, PCC = pyridinium chlorochromate, TMS = trimethylsilyl.

[a] Reactions were carried out at ambient temperature on a 1.0-mmol scale (aldehyde) in THF in the presence of catalytic amounts of $[Rh(cod)(MeCN)_2]BF_4$ and (*S*)-binap (see Experimental Section for more details). [b] Yields of isolated products. [c] Ratios were determined by ^{1}H NMR spectroscopy. The relative configurations were not determined. [d] The *E* enones were predominantly formed along with small amounts of the *Z* enones ($E/Z > 9:1$), unless otherwise specified. The absolute configurations of products in entries 1–11 were tentatively assigned by analogy with their corresponding 1,4-addition products.[5]. [e] Overall yield of mesylation–elimination (**IV**→**V**). [f] The *ee* values of the *E* enones were determined by chiral HPLC (chiralpak AD or chiralcel OD-H columns). [g] $E/Z \approx 3:1$. [h] $E/Z \approx 5:1$. [i] Four isomers by ^{1}H NMR spectroscopy.

25 °C. After 12 h of stirring, aldol product **14** was obtained (52% yield, ≈1.4:1 ratio of diastereomers). Mesylation of this mixture, followed by exposure of the resulting products to DBU, furnished enone **15** ($E/Z \approx 13:1$; Table 2) in 85% overall yield. The conjugated double bond within **15** was selectively reduced with $PhSiH_3$ in the presence of a catalytic amount of $[(Ph_3P)CuH]_6$[8] (1 mol%) which led, after desilylation, to disubstituted cyclohexanones **16** (*trans*/*cis* ≈ 2:1, 79% combined yield). From this point, the synthesis followed the sequence established previously on a similar, racemic, substrate.[11] Thus, oxidation of hydroxyketone **16** with PCC, followed by acetalization of the resulting aldehyde, led to **17** (90% yield). Treatment of this acetal **17** with TMSI in the presence of Et_3N gave methoxy spiroketone **18** (48% yield of the desired diastereoisomer; Table 2). Finally, carboxymethylation of the latter compound **18**, followed by exposure to the radical oxidation conditions of $Mn(OAc)_3$–$Cu(OAc)_2$, afforded the desired vannusal A key building block **2** (68%;

Table 2). Intermediate **2** ($[\alpha]_D^{33} = -1.0$ ($CHCl_3$, $c = 1.0$)) was thus obtained with 96% *ee*, as determined by chiral HPLC (Chiralcel OD-H).

The methodology presented herein represents a convenient entry into multifunctionalized and relatively complex building blocks, starting from comparatively simple and readily available starting materials. Its scope incorporates substituted acyclic as well as cyclic ketones. Good to excellent enantiomeric excess was attained in all cases studied. Application of this catalytic asymmetric three-component reaction to the construction of the spirocyclic domain of vannusal A powerfully demonstrates the applicability and versatility of this process. The total synthesis of this challenging triterpene **1** is well underway in our laboratories.

Experimental Section

General procedure: The alkyne (1.25 mmol, 1.25 equiv) was added to $[Cp_2Zr(H)Cl]$[12] (1.2 mmol; 1.2 equiv) in anhydrous THF (4 mL) under argon. The mixture was stirred at 25 °C for 30 min until it became homogeneous. In a separate flask, $[Rh(cod)(MeCN)_2]BF_4$ (0.05 mmol, 0.05 equiv) and (*S*)-binap (0.06 mmol, 0.06 equiv) were dissolved in anhydrous THF (4 mL) under argon and stirred at 25 °C for 30 min. The enone (1.2 mmol, 1.2 equiv) was then added to the resulting red catalyst solution, followed by the aldehyde (1.0 mmol; 1.0 equiv). The zirconium reagent was transferred to this solution through a cannula, and the resulting mixture was stirred at 25 °C for 12 h. The mixture was concentrated under reduced pressure, and the residue taken up in diethyl ether and directly filtered through a small pad of celite and then concentrated. The resultant crude mixture was purified by flash column chromatography (silica gel), with Et_2O/hexanes mixtures as eluant, to provide aldol products **IV** as colorless oils. Triethylamine (1.8 mmol, 6.0 equiv) and methanesulfonyl chloride (0.9 mmol, 3.0 equiv) were added to a stirred solution of the aldol product **IV** (0.3 mmol) in CH_2Cl_2 (4 mL) at 0 °C. The resulting mixture was allowed to warm to 25 °C within 30 min, and then basic alumina (2 g) was added (alternatively, DBU/THF could be employed for the elimination step). The mixture was then stirred vigorously at 25 °C for 12 h, filtered, and concentrated. The residue was purified by flash column chromatography (silica gel) with EtOAc/hexanes mixtures as eluant to provide enone product **V**.

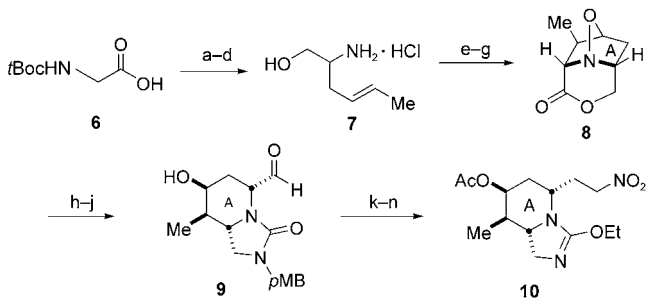
Natural Product Synthesis

Synthesis of the Putative Structure of 7-Deoxycylindrospermopsin: C7 Oxygenation Is Not Required for the Inhibition of Protein Synthesis**

*Ryan E. Looper, Maria T. C. Runnegar, and Robert M. Williams**

Cylindrospermopsin (**1**) and its naturally occurring epimer, 7-*epi*-cylindrospermopsin (**2**; Scheme 1), are attracting increasing attention as threats to public health.[1] These alkaloids are hepatotoxic metabolites of the cyanobacterium *Cylindrospermopsis raciborskii* and of three other types of cyanobacteria, and they pose a serious public-health problem when they occur in water supplies. Both **1** and **2** are potent inhibitors of protein synthesis both in vitro ($IC_{50} = 200$ and 480 nM, respectively) and in vivo ($IC_{50} = 1.28$ and 2.66 μM, respectively).[2] A number of researchers have shown that these compounds inhibit the translation of mRNA into protein.[2,3] Despite two decades of research, the exact mechanism of this inhibition remains unknown. Investigations into the removal of these toxins from water supplies have led to the isolation of both 5-chlorocylindrospermopsin (**3**) and cylindrospermic acid (**4**).[4] Both of these by-products were shown to be nontoxic by mouse bioassay. Furthermore, a related metabolite (**5**), described as 7-deoxycylindrospermopsin, has been isolated and shown to be nontoxic.[5] Interestingly, **5** is thought to exist as a mixture of tautomers (which are illustrated in Scheme 1), as its ^{1}H NMR spectrum lacked a signal for the vinylic proton on the uracil unit and the resonances were generally broad. These structure–activity relationships have led to conjecture about the steric and electronic requirements of the uracil unit and its role in the toxicity of these compounds.[1,4]

Our continuing interest in the synthesis of these intriguing natural products and elucidation of their mode of action led us to pursue the synthesis of 7-deoxycylindrospermopsin for several reasons:[6] First, the absorption maximum (λ_{max}) for **5** at 263 nm, which is consistent with the presence of a uracil unit and not the tautomers shown in Scheme 1.[7] Second, the configuration of C7 arises biosynthetically from the methyl group of an acetate unit;[8] thus, the synthesis of 7-deoxycylindrospermopsin would allow us to explore its intermediacy in the biogenesis of **1** and **2**. Last, the involvement of cytP450 oxidases in the toxicity of **1** suggests a possible oxidation event at C7,[9] thus potentially explaining the redundancy of the configuration of C7 and also implicating 7-deoxycylindrospermopsin as a potential toxin if it intercepted a common metabolic pathway.



Noting that the optical rotation of **5** has not been reported, we began by synthesizing it in a racemic fashion (Scheme 2). Diimide-mediated coupling of 3-buten-2-ol with *N*-Boc-glycine (**6**) afforded an allylic ester that underwent a smooth enolate Claisen rearrangement on treatment with 2.2 equivalents of NaHMDS.[10] Reduction of the acid and acidic removal of the Boc group gave crotyl glycinol salt **7** in good yield. Isourea **10** was obtained in nine further steps.[6b] A highlight of this sequence is the intramolecular dipolar cycloaddition to afford **8**, in which three contiguous stereogenic centers were constructed[6a] in ring A in a selectivity of approximately 10:1. An acid-mediated oxidation employing tetramethylpiperidine-1-oxyl allowed a selective oxidation of

Boc = *tert*-butoxycarbonyl.

the hydroxymethyl group, thus affording good yields of the sensitive ureido aldehyde **9**.[11]

Intrigued by the possibility of conducting a reductive guanidinylation sequence and simultaneously unmasking the uracil unit, we first synthesized the dibenzyloxypyrimidine aldehyde **12** (Scheme 3): A slightly modified procedure permitted the substitution of 2,4,6-tribromopyrimidine (**11**) with benzyl ether groups,[12] and formylation of the lithiated pyrimidine with dimethylformamide (DMF) afforded **12** in good yield. Treatment of **10** with **12** in the presence of acetic anhydride and excess cesium fluoride couples these two units directly and allows dehydration to occur in a single operation, thus affording **13** in 67% yield. This nitroalkene was produced as a single geometric isomer, which is presumed to be the *E* isomer from studies of the NOE interactions of the pyrimidine proton. Attempts to reduce the nitroalkene directly to the corresponding saturated amine led predominantly to hydrolysis of the presumed enamine intermediate.

To obviate this reactivity, sodium borohydride was employed to reduce **13** to the nitroalkane. Hydrogenolysis of this mixture reduced the nitroalkene, thus effecting reductive guanidinylation, and cleanly cleaved the benzyl ether groups to afford the uracil/guanidine compounds in an approximate 1:1 mixture of isomers. Brief exposure of this mixture to HCl facilitated the removal of the acetate group at C12 to give **14** and **15**. The configuration of **15** was ultimately determined by X-ray crystallographic analysis.[13] It should be noted that the guanidine moieties were obtained as trifluoroacetate salts after purification by HPLC. This method of purification has been used in all of the previous syntheses of **2**.[6b,14] The small amount of synthetic material produced did not allow this counterion to be detected by ^{13}C NMR spectroscopy, but it is presumed to accompany the non-zwitterionic guanidines purified by HPLC with trifluoroacetic acid (TFA) in the eluent.

The reductive guanidinylation sequence is sufficiently clean to effect the direct sulfonation of **14** and **15** at O12 to give sulfates **16** and **17** in a combined yield of 66% from **13** after a single purification by HPLC. In the ^1H NMR spectrum of **16**, the uracil proton at C5 is clearly evident at $\delta =$ 5.72 ppm, and the resonances are well defined and closely match those of **1**, except for the methylene protons at C7. In an attempt to reconcile these differences, this spectrum was compared with the spectrum that had led to the elucidation of the structure of **5**. However, it is clear that the natural material is a mixture of compounds, and it was not possible to conclude whether **16** was a minor component of that mixture.

Most significantly, our synthetic 7-deoxycylindrospermopsin (**16**) proved to be a potent inhibitor of protein synthesis in vitro, as measured in the rabbit reticulocyte lysate system.[9b] Protein synthesis was completely inhibited at 12 μM and partially inhibited at 500 nM. This effect on protein synthesis was also evaluated in whole cells (Table 1).[2] As seen, **16** completely inhibits protein synthesis at 10 μM, thus displaying a potency that is within an order of magnitude of natural **1**. Synthetic **16** also inhibits the synthesis of glutathione (GSH), in a similar fashion to **1**.[3,9a]

Table 1: Inhibition of protein synthesis in rat hepatocytes.

Compound	Conc. [μM][a]	Protein [%][b]	GSH [%][c]
1	0.20	58	100
	1.03	15	80
	1.55	7	60
16	2	64	100
	5	28	95
	10	8	45
17	40	73	100
	80	56	100

[a] Calculated from $\varepsilon = 4600\ mol^{-1}\ dm^3\ cm^{-1}$ at 263 nm. [b] Measured by the incorporation of [^{35}S]methionine into protein (given as % of control values). [c] Measured as nmol of GSH per mg of protein (given as % of control values).

Contrary to previously reported findings,[5] we found that a sample of natural 7-deoxycylindrospermopsin also inhibits protein synthesis with potency similar to the synthetic 7-deoxycylindrospermopsin (**16**). These two materials were shown by HPLC analysis to be identical, thus corroborating the natural occurrence of **16**.[15,16]

The synthesis detailed herein should cast doubt on the notion of uracil tautomers in the purported structure of 7-deoxycylindrospermopsin. It appears unlikely that an oxygenation event at C7 or C8 occurs in the metabolism of **1**, **2**, or **16** (to generate an enol ketone), as the C8 diastereomer **17** is two orders of magnitude less toxic. Compounds **14** and **16** have been labeled with $^{13}CH_3NO_2$ to investigate their intermediacy in the biosynthesis of **1** and **2**. These studies will be reported in due course.

Henry Reaction

Enantioselective Henry Reactions under Dual Lewis Acid/Amine Catalysis Using Chiral Amino Alcohol Ligands**

Claudio Palomo, Mikel Oiarbide, and Antonio Laso*

There is increasing interest in developing catalytic asymmetric C–C bond-forming processes.[1] In this endeavor the Henry reaction[2] is prominent because of the versatile chemistry of the nitro group.[3] Remarkably, however, while this reaction is closely related to the aldol addition reaction, it has been much less developed than the latter and only a few examples of efficient catalytic enantioselective Henry reactions are known to date.[4] The most outstanding examples include the use of metal-based bifunctional chiral catalysts, as reported by the groups of Shibasaki,[5] Trost,[6] and Evans,[7] which rely on concurrent activation of the aldehyde and the nitroalkane.[8,9] This concurrent activation in Henry reactions has also been

realized by the combined use of discrete Lewis acids and Brønsted bases as structurally independent entities.[10] While this approach allows the straightforward scrutiny of a wide range of Lewis acids and Brønsted bases during the optimization of the catalyst system, it is apparently troublesome because of the chemical incompatibility of Lewis acids and Brønsted bases[11] and the occurrence of a nonselective, base-initiated Henry side reaction.[12] Herein, we report that highly enantioselective direct Henry reactions can be triggered by a combination of a simple Zn^{II} salt, an amine base, and a chiral amino alcohol ligand.

On the basis of precedents in the literature, the combination of a metal triflate salt, a tertiary amine base, and a chiral amino alcohol ligand was initially selected.[13,14] Accordingly, the Henry reaction of nitromethane **2** with hydrocinnamaldehyde **1a** and benzaldehyde **1i** (see Table 3), as representative aliphatic and aromatic aldehydes, respectively, was examined in the presence of stoichiometric quantities of $Zn(OTf)_2$, diisopropylethylamine, and a series of commercially available chiral amino alcohol ligands[15,16] (**4**–**10**; Scheme 1). As the data collected in Table 1 show, (+)-*N*-methylephedrine ((+)-NME; **4**) was prominent in providing both nitroaldol products **3a** and **3i** in good yields and, most importantly, with 90% and 70% *ee*, respectively. When **5**, **8**, or **10** were employed as the ligand, the efficiency of the reaction was maintained although a decrease in enantioselectivity was observed, whereas the reactions of the two aldehydes in the presence of the related amino alcohol ligands **6**, **7**, and **9** were sluggish.

In subsequent experiments, it was found that substoichiometric quantities of the promoter system sufficed for the reaction between nitromethane (**2**) and **1a** (Table 2).[17] The

[a] Reactions conducted on a 1-mmol scale (**1**) in nitromethane (1 mL) for 15–16 h at −20°C. [b] Percentage values refer to the mole percentage (% mol) of the catalyst constituents with respect to the aldehyde. [c] Percentage conversion of the reaction. [d] Determined by HPLC.

threshold loading for satisfactory results was set at 30 mol% of metal salt, relative to the aldehyde, with lower loadings usually accompanied by a diminished selectivity (entries 6 and 7).[18] The optimum result (90% yield, 90% *ee*) was obtained by using $Zn(OTf)_2$, iPr_2EtN, and (+)-NME (**4**) in a percentage mole ratio of 30:30:45 (entry 2). Lowering the loading of (+)-NME to 30 mol% slightly diminished the selectivity (entry 1), whereas increasing the ligand loading above 45 mol% did not improve the result. The quantity of iPr_2EtN was crucial too. Lower loading or absence of iPr_2EtN (entries 3 and 4) led to diminished yields and *ee* values. Interestingly, the absence of iPr_2EtN could be partially compensated by increasing the quantity of the ligand (Table 2, entry 5) which is consistent with the amino alcohol ligand playing the double role of chiral inductor and base. Also, while a stoichiometric quantity of (+)-NME (**4**) alone promoted the reaction (entry 8), the product was obtained as a racemic mixture. Amongst the solvents examined, namely methylene chloride, toluene, diethyl ether, and tetrahydrofuran, all worked similarly well and lead to high enantioselectivities except for THF.

A representative selection of aldehydes **1** were evaluated under the optimized conditions and the results obtained are summarized in Table 3. The enantioselectivities obtained were above 90% for essentially all the aliphatic aldehydes explored and even for the branched or sterically hindered aldehydes, which gave values of up to 98% *ee*. Aromatic aldehydes were also tolerated with equal chemical efficiency although the enantioselectivities were comparatively moderate. Typically, the reactions were carried out at −20°C, but lower temperatures (−40°C, or even −60°C under stoichio-

[a] Reactions conducted on the 1-mmol scale (**1**) in dry nitromethane (1 mL) using $Zn(OTf)_2$ (30 mol%), iPr_2EtN (30 mol%), and (+)-NME (45 mol%), otherwise stated. [b] Isolated yields after chromatography. The numbers in parentheses refer to the percentage conversion. If not specified, conversions are >99%. [c] Determined by HPLC. [d] Using a 1:1 (v/v) mixture of nitromethane and CH_2Cl_2 as solvent, and a ratio of 1:1:1:1.5 of aldehyde/$Zn(OTf)_2$/iPr_2EtN/ligand.

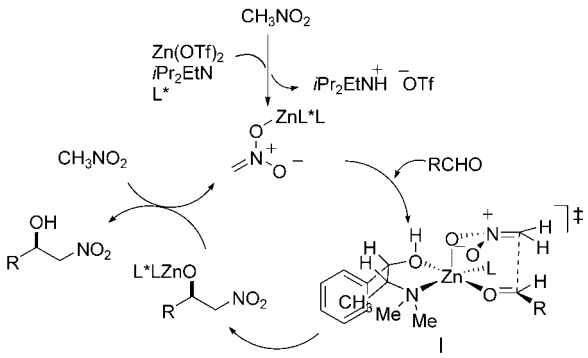

Figure 1. Proposed reaction pathway and transition state (I) for the catalytic Henry reaction. L* = (+)-NME (**4**).

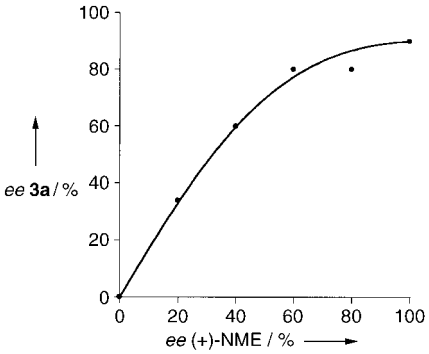

Figure 2. Positive nonlinear effect for the Henry reaction of nitromethane and hydrocinnamaldehyde under substoichiometric conditions.

metric conditions) could also be used effectively to enhance the enantioselectivity. Enals, however, constitute a limitation of the present Henry reaction as they were either recovered unconverted or led to a complex mixture of unidentifiable products. Of practical relevance, the source of chirality, (+)-NME (**4**), could be easily recovered in near-quantitative yield after the reaction by simple aqueous acid/base workup and reused (see Experimental Section).

While the present Henry reaction[19] is simple in execution and uses readily available reagents, the elucidation of its mechanism is appealing. The sense of the asymmetric induction imparted may be correctly predicted by transition model I (Figure 1), which is in accord with previously reported steric and electronic considerations.[7] However, the nonlinear effect observed for the substoichiometric reaction suggests a higher order molecularity of the catalytically active species. In this respect, the data collected in Figure 2 for the Henry reaction of nitromethane (**2**) with hydrocinnamaldehyde (**1a**) seem to fit well with Kagan's two-ligand model.[20] However, control experiments indicate that there is not an appreciable variation of the nonlinear magnitude measured at different values of catalyst loading, while the enantiomeric composition of the product remains essentially constant regardless of the level of conversion of the reaction.[21] Accordingly, it also appears that both the reservoir effect and the possible interaction of the catalytic species with the forming nitroaldol may be discarded as factors of the observed nonlinearity. Studies directed to clarify these mechanistic aspects as well as the extension of this Lewis acid–Brønsted base dual-activation strategy to other reactions is currently underway.

Experimental Section

In a typical procedure, diisopropylethylamine (1.04 mL, 6 mmol) was added to a suspension of $Zn(OTf)_2$ (2.18 g, 6 mmol) in CH_3NO_2 (**2**; 15 mL), and the slurry was stirred for 1 h at 25 °C. (1*S*,2*R*)-(+)-*N*-Methylephedrine (**4**; 1.61 g, 9 mmol) was then added, and the resulting yellow mixture was stirred for an additional 2 h at room temperature. After cooling the mixture to −20 °C a solution of trimethylacetaldehyde (**1g**; 2.17 mL, 20 mmol) in **2** (5 mL) was added by syringe, and the mixture was stirred at the same temperature for 17 h. The reaction was quenched with a saturated aqueous solution of NH_4Cl (20 mL), the mixture was extracted with Et_2O (3 × 20 mL), and the combined organic layer was washed with HCl (12 N; 2 × 10 mL) and saturated NH_4Cl (1 × 10 mL). The organic layer was dried with $MgSO_4$ and filtered, and the solvent was removed by evaporation. The crude product was purified by column chromatography to give (*R*)-3,3-dimethyl-1-nitrobutan-2-ol (**3g**) as the major product (2.3 g, 83% yield, 96% *ee*; Chiralcel OD, 98:2 hexane/*i*PrOH, 0.8 mL min^{-1}). *R* major t_r = 16.5 min, *S* minor t_r = 19 min; $[\alpha]_D^{25} = -37.2$ ($c = 1$, CH_2Cl_2).[22] To recover the chiral ligand from the aqueous phase, a solution of NaOH (20% w/v) was added dropwise to the aqueous phase, cooled in an ice bath, until pH 10. The mixture was extracted with CH_2Cl_2 (3 × 10 mL), and the organic layer was dried

over $MgSO_4$ and filtered, and the solvent was evaporated to afford chemically and optically pure (1*S*,2*R*)-*N*-methylephedrine (2.8 g, 97% recovered).

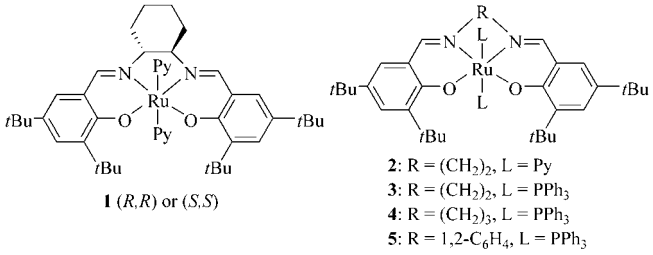
[22] By using (1*R*,2*S*)-(−)-*N*-methylephedrine as the ligand under otherwise identical reaction conditions, the corresponding (*S*)-nitroaldol was obtained (80% yield, 96% *ee*). $[\alpha]_D^{25} = +36.8$ ($c = 1$, CH_2Cl_2) ($[\alpha]_D^{25} = +29.39$ ($c = 3.39$, CH_2Cl_2), 93% *ee*).[7]



Asymmetric Catalysis

Axial Ligand Effects: Utilization of Chiral Sulfoxide Additives for the Induction of Asymmetry in (Salen)ruthenium(II) Olefin Cyclopropanation Catalysts**

*Jason A. Miller, Bradley A. Gross, Michael A. Zhuravel, Wiechang Jin, and SonBinh T. Nguyen**

The enantioselective synthesis of compounds containing the cyclopropyl fragment has recently received considerable attention, largely because of the frequent occurrence of cyclopropanes in natural products and their importance as valuable synthetic intermediates.[1–3] Although many methods have been developed, transition-metal-catalyzed asymmetric cyclopropanation has emerged as one of the most efficient routes for the formation of optically pure cyclopropanes.[1,4] However, the syntheses of the necessary chiral catalysts for this important transformation are often rather laborious. A general and facile method for the asymmetric synthesis of a cyclopropanation catalyst has yet to be developed.

Recently, we have focused on cultivating efficient methods for the development of asymmetric catalysts. We began by improving on our previously reported (salen)ruthenium(II) asymmetric cyclopropanation system. This catalyst system has been shown to be highly effective for the cyclopropanation of olefins with the carbene precursor ethyl diazoacetate (EDA).[5] However, although the use of chiral catalyst **1** (Scheme 1) has led to exceptional selectivity and high yields for the cyclopropanation of olefins with EDA, these results

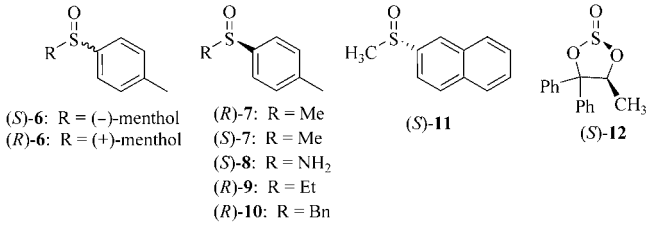
can not necessarily be extended to all olefin substrates. For some olefins, multiple catalysts containing different chiral diamine backbones must be examined before optimal results can be achieved. The synthesis of a series of chiral salen-based catalysts with differing backbones is both expensive and time consuming so an alternative approach is needed to expedite the screening of new olefins and diazo compounds for the cyclopropanation reaction.

Previous work in our group has demonstrated a significant ligand-accelerated catalysis effect for certain substrates through what is presumed to be axial ligand binding and further activation of the ruthenium carbene cyclopropanation intermediate (Scheme 2a).[6] We hypothesized that this could be used to our advantage and an optically pure Lewis base



Scheme 2. a) Ligand-accelerated catalysis in olefin cyclopropanation catalyzed by a (salen)ruthenium(II) complex. b) A chiral Lewis base **L*** ligated axially to an achiral (salen)ruthenium–carbene cyclopropanation intermediate could induce asymmetry.

could be used to bind axially to an achiral catalyst as an alternative to using the preformed chiral (salen)ruthenium(II) catalyst **1**. The Lewis base, if paired correctly with the catalyst (both electronically and sterically), should force an achiral salen ligand into an asymmetric conformation, thus transferring enantioselectivity to the cyclopropanation reaction occurring on the opposite axial face of the catalyst. This approach would allow the use of the inexpensive and readily synthesized achiral catalysts **2**–**5** and the facile screening of a nearly endless library of chiral Lewis bases **L*** that can function as ligands to the metal carbene intermediate (Scheme 2b). Related strategies were previously employed by Katsuki and co-workers with varying degrees of success for the (salen)manganese(III)-catalyzed asymmetric epoxidation of olefins through the application of chiral amines[7,8] and chiral pyridine *N*-oxides.[9] Walsh and co-workers also reported considerable enhancement in selectivity when chiral additives were used to convey asymmetry into an achiral titanium precatalyst for the addition of an ethyl nucleophile to aldehydes.[10–12] A recent review by Walsh et al. touched on the potential application of this novel and exciting approach to catalyst screening.[13]

Herein, we describe the first example of an asymmetric cyclopropanation mediated by a combination of achiral (salen)ruthenium(II) catalysts **2**–**5** and a catalytic amount of chiral sulfoxide additives (**6**–**12**; Scheme 3). Sulfoxides were chosen as a test class of chiral Lewis bases because they have

Scheme 3. Sulfoxide Lewis bases used as chiral additives for the cyclopropanation of olefins with achiral (salen)ruthenium(II) complexes.

been recently used as ligands in asymmetric catalysis.[14,15] Sulfoxide ruthenium(II) complexes are well known[12,16] and chiral sulfoxides have centers of asymmetry that are very close to the ruthenium center during coordination and should have a high probability of transmitting chirality to a flexible salen ligand.

We screened several chiral sulfoxides (**6**–**12**) individually as catalytic additives for the cyclopropanation of styrene with EDA catalyzed by the achiral catalyst **3** [Eq. (1); Table 1]. In

[a] Reaction conditions: EDA (0.5 mmol), styrene (2.5 mmol), **3** (1 mol%), **L*** (10 mol%), CH_2Cl_2 (5 mL), RT, 12 h. [b] Yield determined by GC analysis based on EDA with undecane as an internal standard. [c] Absolute configuration determined from chiral GC analysis versus known standards.

general, the addition of these chiral additives does not affect either the yield or diastereoselectivity of the reaction. Furthermore, reversing the chirality of the sulfoxide (that is, (*S*)-**6** versus (*R*)-**6** and (*S*)-**7** versus (*R*)-**7**) leads to opposite enantioselectivities, thus lending support to the supposition that the chirality of the product is a direct result of the Lewis base additive.

These preliminary results were quite promising. Even with a very low concentration of additive in solution (10 mol% relative to EDA), *ee* values of up to 57% were noted. These results suggested to us that (*R*)-(+)-methyl *p*-tolyl sulfoxide (*R*)-**7** was the best chiral additive for the cyclopropanation of styrene. This was somewhat surprising in light of the small size of the methyl substituent on (*R*)-**7** relative to the larger menthol substituents on additive **6**. The use of additives with amino ((*S*)-**8**), ethyl ((*R*)-**9**), and benzyl ((*R*)-**10**) substituents on the *p*-tolyl sulfoxide was also investigated to probe for the optimal steric environment; however, none of these compounds proved as successful as (*R*)-**7**. (*S*)-Methyl 2-naphthyl sulfoxide ((*S*)-**11**) was used to determine the effect of adding steric bulk to the other side of the sulfoxide. Surprisingly, this also yielded lower enantioselectivities than (*R*)-**7**. Additive (*R*)-**7** was, however, expected to produce higher enantioselectivities than the cyclic compound (*S*)-**12**, in which the cone angle of the chiral center is considerably smaller.

As we previously reported, the olefin cyclopropanation product can be readily separated from a reaction mixture containing solvent, catalyst, and excess olefin.[17] This same isolation strategy can also be applied in the current case when a chiral Lewis base is also present in solution. As a representative example, the optically enriched styrene cyclopropanation product produced in the presence of additive (*R*)-**7** could be isolated in excellent yield (94%). Further details on the isolation procedure can be found in the Experimental Section.

Additive (*R*)-**7** was then subjected to a range of reaction conditions and catalysts to optimize the enantioselectivity for the cyclopropanation of styrene (Table 2). The enantioselectivity of the reaction increased to nearly 70% with respect to the *cis* isomer when 50 mol% of (*R*)-**7** was used with **3** (Table 2, entry 5). The same increase was noted when the solvent amount was decreased and the amount of sulfoxide added was maintained at 10 mol% (Table 2, entries 6 and 7). Decreasing the temperature of the reaction also positively affected the *ee* value of the products; when the reaction temperature was lowered to −78 °C and the additive concentration increased, the *cis* and *trans* products were obtained in 93 and 87% *ee*, respectively (Table 2, entry 9). These promising results are amongst the highest *ee* values reported for asymmetric induction resulting from the action of a chiral additive on an achiral catalyst.

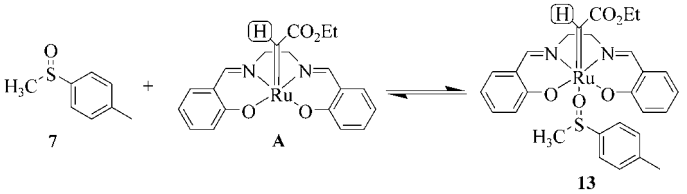
We propose that the mechanism of asymmetric induction for Equation (1) involves the axial coordination of the chiral sulfoxide to the ruthenium center as a key induction step in the reaction stereoselectivity (Scheme 4). Initial reaction of

Scheme 4. Proposed mechanism of asymmetric induction through a chiral additive.

EDA with the axial triphenylphosphane ligands of **3**–**5** causes the rapid formation of phosphorus ylides, which do not bind significantly to the metal center.[18] This leaves the axial positions of the catalyst open to coordination by the chiral sulfoxide. The chiral additive can then bind preferentially to one of the two chiral conformers of the achiral (salen)ruthenium complex,[7–9] thus effectively forcing the larger achiral salen ligand to adopt a preferred chiral conformation. Therefore, the asymmetry of the additive is transmitted/amplified to the opposite axial position where a ruthenium carbene can interact stereoselectively with an olefin to complete the cyclopropanation cycle. Balsells and Walsh termed this phenomenon *chiral environment amplification*.[12] The catalytic formation of cyclopropanes through this induced chiral environment, especially when coupled with ligand-accelerated catalysis (Scheme 2a), would afford an excess of one enantiomer, as expected from our work with preformed chiral (salen)ruthenium(II) complexes.[5] Catalyst **5**, with the rigid phenylene diamine backbone, yielded no enantioselectivity when chiral sulfoxide (*R*)-**7** was used as an additive (entry 4), which is consistent with our proposed mechanism.



Catalyst **4**, which contains the propylenediamine backbone, yields the same sense of chiral induction as the ethylenediamine analogue **3** in the presence of (*R*)-**7** (Table 2, entries 3 and 2), as could be predicted from the proposed mechanism in Scheme 4. It is also reassuring that the *cis*/*trans* ratio is very close to that when the reaction is carried out in the absence of a chiral additive (1:6.2).

The addition of either (*R*)-**7** or (*S*)-**7** to the cyclopropanation reaction of styrene with EDA using the chiral preformed catalyst **1** (*R*,*R* or *S*,*S*) results in no increase or decrease in the enantiomeric excess of the cyclopropane product compared to use of the chiral catalyst alone. These match/mismatch experiments suggest that the backbone of a chiral catalyst overrides the chirality of an additive and, therefore, plays a larger role in asymmetric induction.

The use of (*R*)-**7** and catalyst **2**, which contains pyridine axial ligands, together with led to lower optical enrichment of the product cyclopropanes compared to when **3**, which loses both PPh_3 moieties at the beginning of the catalytic cycle, was employed (see entries 1 and 2). This effect is most likely because of competition between the pyridine and the additive for the axial position of the catalyst. Pyridine binds strongly to the ruthenium(II) center,[5] so coordination of the chiral additive is hindered. Titration data suggest that this is indeed the case, as addition of increasing amounts of pyridine to a mixture of (*R*)-**7** and **3** leads to linearly decreasing enantiomeric excess.

Control experiments with either a chiral sulfoxide/EDA system or preformed sulfoxide ylides,[19] both with and without the (salen)ruthenium(II) catalyst **3**, confirm that the metal center is necessary for catalytic activity and that the reaction does not occur through a pathway that requires the formation of a sulfoxide ylide. These results are consistent with our proposed mechanism and fully support the idea of chiral induction by an axial ligand.

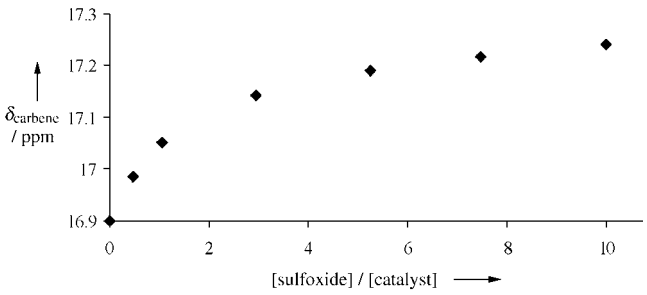
Further support for our proposed mechanism was obtained by examining the binding mode of the sulfoxide to **A** by NMR spectroscopy.[20] The changes in the chemical shift of the resonances for the α-methyl protons in **7** when it was alone in solution and when it was in solution with the carbene complex **A** were compared ($\delta = 2.07$ versus $\delta = 2.14$ ppm, respectively), thus indicating that **7** binds through the sulfoxide oxygen atom. This small change in chemical shift (< 0.1 ppm) is diagnostic of the oxygen-atom binding mode; binding through the sulfur atom produces a much larger change (> 1 ppm).[15] Furthermore, analysis of the carbene proton of the (salen)ruthenium carbene cyclopropanation intermediate allowed us to calculate the binding constant for the formation of the bound complex **13** [Eq. (2); salen *t*Bu

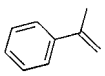
(2)

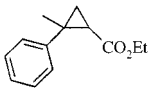
groups omitted for clarity]. Figure 1 shows that increasing concentrations of sulfoxide in solution leads to a downfield shift of the carbene proton. These data were used to calculate a binding constant of $K_{eq} = 129 \pm 6\ M^{-1}$ using WinEQNMR software.[21]

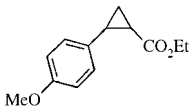
Although binding at the ruthenium center to the oxygen atom of the sulfoxide group is inferred by our spectroscopic observations (see above), it is possible that a Curtin–Hammett situation may occur in which the oxygen-bound complex is not necessarily the active species responsible for the excellent cyclopropanation enantioselectivities. That is,

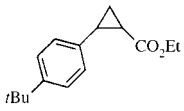
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

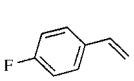


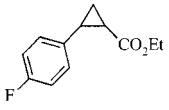


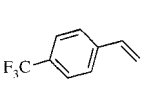












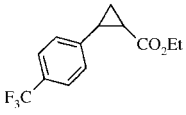


Figure 1. Changes in the chemical shift of the ruthenium carbene proton on addition of sulfoxide **7**.

the sulfur-bound carbene complex could be present in a minute quantity that cannot be observed by NMR spectroscopy but is primarily responsible for the asymmetric induction. Further mechanistic experiments are in progress to help elucidate this possibility and the results will be published at a later date.

We have also extended this sulfoxide-induced chiral amplification strategy to the cyclopropanation of other olefins (Table 3). Quite promising enantioselectivities were observed for these substrates despite having a limited library of chiral sulfoxides, such as **6**–**12**. As observed with styrene, diastereoselectivities remained similar both with and without the chiral additives. These exciting results prove that styrene is not a unique case and that this method is, in fact, applicable to other olefins. Interestingly, although additive (*R*)-**7** induces the greatest enantioselectivities for styrene and its *para*-substituted derivatives, it is not the best chiral Lewis base for all other substrates: methyl methacrylate gave the best results when (*R*)-benzyl *p*-tolyl sulfoxide (*R*)-**10** was utilized, whereas (α-methyl)styrene required the use of (*R*)-**6**. Table 3 shows representative results for these two substrates with some of the optimally performing sulfoxides. These results show that a combinatorial approach can be used to simultaneously screen the substrate and chiral additives for optimum selectivity and reaction conditions. As with styrene, the cyclopropanation products of the substrates listed in Table 3 can be readily isolated in yields closely matching those calculated by GC-calibration techniques.

In conclusion, we have found an efficient and facile method for the development of new (salen)ruthenium(II) catalysts for the asymmetric cyclopropanation of olefins. This exciting modular approach is amenable to parallel-screening optimization and has great potential advantages over traditional catalyst development and synthetic methods. We feel that this approach may also be extended to other types of catalysis where one metal coordination site is free during a reaction. The initial selectivities with this achiral catalyst/chiral Lewis base system are very promising and provide a solid proof-of-concept that chirality can be introduced into a complex cyclopropanation system through the addition of a simple optically active additive. Screening experiments with other classes of chiral additives is underway and optimization data will be reported in due course.

Table 3: Optimized results for the cyclopropanation of various olefins with EDA by using chiral sulfoxides to induce asymmetry into achiral catalyst **3**.[a]

Experimental Section

General procedure for the asymmetric cyclopropanation of olefins with EDA using (salen)ruthenium(II) complexes **1**–**5** and chiral sulfoxide additives **6**–**12**:[22] A mixture of achiral ruthenium catalyst (0.005 mmol), olefin (2.5 mmol), and sulfoxide (0.05 mmol for 10 mol% and 0.25 mmol for 50 mol%) in CH_2Cl_2 (2.5 mL) was placed in a 25-mL round-bottom flask under N_2 in a drybox. A three-times degassed CH_2Cl_2 (2.5 mL) solution of EDA (0.50 mmol) and undecane internal standard (0.50 mmol) was slowly added by a gas-tight syringe over a period of 20 min under N_2. After the addition was complete, the reaction mixture was allowed to stir for 12 h at room temperature. A sample of the solution was then passed through a short plug of silica gel (0.3 × 3 cm) to remove the catalyst and the plug was washed with CH_2Cl_2 (15 mL). The combined organic solutions were analyzed by using standard-phase GC for diasteroselectivity and either chiral-phase GC or HPLC for enantioselectivity.

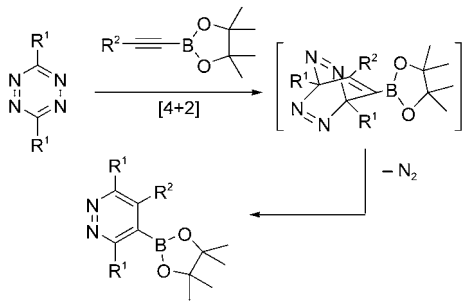
Synthetic Methods

Synthesis of Highly Substituted Pyridazines through Alkynyl Boronic Ester Cycloaddition Reactions**

*Matthew D. Helm, Jane E. Moore, Andrew Plant, and Joseph P. A. Harrity**

Aryl boronic acids and esters represent one of the most heavily used classes of synthetic intermediates in recent times.[1] The versatility of the C–B bond allows the organoboron species to be transformed into numerous new synthetic compounds through various functional group interconversions and C–C bond-forming reactions. In an effort to develop new strategies toward the synthesis of highly substituted and functionalized aromatic boronic esters, we have embarked on a program that endeavors to access these compounds through a series of benzannulation protocols. Specifically, we have prepared benzenoid-derived boronic esters through a chromium-mediated benzannulation reaction[2] and isoxazole boronic esters through a [3+2] cycloaddition.[3] More recently, we investigated the use of [4+2] cycloaddition reactions to broaden the scope of our approach. Previous studies in this area have demonstrated that alkynyl boronic esters, alkynyl dihaloboranes, and alkynyl dialkyl boranes can all function as dienophiles.[4] We report herein our efforts to exploit this strategy for the synthesis of pyridazine boronic esters.



The inverse-electron-demand Diels–Alder reaction of 3,6-disubstituted 1,2,4,5-tetrazines (developed by Carboni and Lindsey) is an effective method for the synthesis of highly substituted pyridazines and other aromatic systems.[5,6] We envisaged that employing alkynyl boronic esters in this reaction would allow the rapid assembly of highly substituted pyridazine boronic esters with potential control of the regiochemistry around the heteroaromatic ring (Scheme 1). Indeed, Seitz and Haenel gave three examples of cycloaddition reactions of ethynyl boronic esters with symmetrical tetrazines that provided the corresponding pyridazines in good yield.[7] The authors did not explore the use of more heavily substituted alkynyl boronic esters or investigate the regiochemistry of this reaction. Nonetheless, it is notable that, to the best of our knowledge, this report is the only

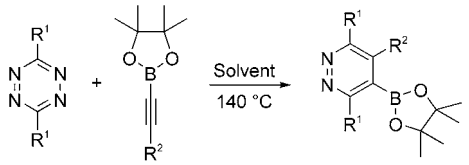

Scheme 1. Synthesis of pyridazine boronic esters through cycloaddition reactions of tetrazines.

documented method for the preparation of pyridazine boronic esters.

We began our studies by investigating the cycloaddition reactions of some substituted alkynyl boronic esters with the readily prepared symmetrical tetrazines **1** and **2**[8] (the results are summarized in Table 1). The preliminary results were encouraging, and we were pleased to find that the ester-substituted tetrazine **1** participated smoothly in the cycloaddition process at 140 °C to form the corresponding pyridazine boronic esters **9**–**12** in moderate to high yield. An interesting solvent effect was also observed, whereby the reactions proceeded more quickly and cleanly when conducted in nitrobenzene (Table 1, compare entries 1, 3, 5, and 7 with entries 2, 4, 6, and 8). Furthermore, the bis(3,5-dimethylpyrazol-1-yl) (DMPY) substituted tetrazine **2** furnished the corresponding heteroaromatic boronic esters **13**–**15** in high yield; moreover, these substrates were stable to chromatography on silica gel, whereas the purification of the ester-substituted boronic esters was more successful when florisil was used. Finally, the parent tetrazine **3** also participated in cycloaddition reactions with alkynes **5** and **7** to provide the simpler pyridazines **16** and **17** in good yield.

[a] TMS = trimethylsilane.

We next turned our attention to investigating the cycloaddition reactions of unsymmetrical tetrazines with a view to developing a regioselective method for preparing the corresponding pyridazine boronic esters. It has been reported that the DMPY group can be readily displaced with a variety of O- and N-containing nucleophiles,[9] and therefore **2** was employed as a common intermediate for the preparation of unsymmetrical tetrazines (Scheme 2). The treatment of **2** with ammonia followed by Boc_2O furnished a Boc-protected tetrazine **18**. Furthermore, oxazolidinone-substituted tetrazines **19** and **20** were readily prepared by addition of the appropriate amino alcohol followed by acylation with triphosgene.

Cycloaddition reactions with model alkynes were carried out under the conditions optimized in the earlier studies (Scheme 3). Accordingly, heating a solution of **18** and a phenyl-substituted alkynyl boronic ester in nitrobenzene resulted in smooth conversion into pyridazine **21**, which was isolated as the free amine[10] and, notably, as a single regioisomer. NOE interaction studies were used to determine the regiochemistry of this cycloaddition reaction, and it was

shown that the boronic ester is adjacent to the pyrazolyl ring. We extended this promising reaction to the oxazolidinone-substituted tetrazine **19** to afford **22** and **23** and were pleased that, once again, single regioisomers were isolated. Crystals of **22** suitable for X-ray crystallographic analysis were obtained, and it was confirmed that the boronic ester moiety was again incorporated adjacent to the pyrazole ring.[11] Finally, we extended the cycloaddition chemistry to the chiral oxazolidinone-substituted tetrazine **20** and synthesized chiral pyridazine boronic esters **24** and **25** with equally satisfying results.[12]

With a series of pyridazine boronic esters in hand, our final goal was to investigate functionalization reactions of the C–B bond. The primary objective was to establish the viability of these substrates for Suzuki cross-coupling reactions. It was anticipated that these reactions would require significant optimization as electron-deficient boronic acid derivatives are known to be prone to protodeboronation.[13] Also, the significant steric crowding around the boronate moiety in these compounds further suggested that they would be very challenging substrates. Accordingly, we initiated our studies by examining the cross-coupling of the parent pyridazine boronic ester **17** (Scheme 4). After significant optimization, we were pleased to find that **26** was successfully generated in high yield by employing the protocol of Netherton and Fu[14] for the Suzuki reaction. Pleasingly, these conditions could also be applied to the cross-coupling reaction of the hindered diester **9** to provide the coupled product **27** in 57% yield. Finally, the cross-coupling reaction of **14** with iodobenzene proved to be extremely difficult and resulted in the formation of a substantial quantity of protodeboronated material with a small amount of desired product. Nonetheless, the use of microwave irradiation allowed the desired product **28** to be isolated in 51% yield within a short reaction time.[15] Finally, we explored a simple oxidation of **14** to the 1*H*-pyridazin-4-one **29** and were pleased to find that this transformation proceeded smoothly and in high yield (Scheme 4).

In conclusion, we have reported that the cycloaddition of tetrazines with alkynyl boronic esters provides a direct and regioselective method for the synthesis of highly functionalized pyridazine boronic esters. We have also shown that these intermediates can undergo C–O and C–C bond-forming reactions; the latter transformation requires bulky and electron-rich phosphine ligands to promote catalytic cross-coupling over protodeboronation.

Natural Product Synthesis

Total Synthesis of Avrainvillamide (CJ-17,665) and Stephacidin B**

Phil S. Baran, Carlos A. Guerrero, Benjamin D. Hafensteiner, and Narendra B. Ambhaikar*

The stephacidins and related alkaloids are a distinctive class of bioactive prenylated indole alkaloids[1] isolated from various terrestrial and marine fungal sources.[2–4] Recently, we reported an enantioselective route to stephacidin A (**1**, Figure 1).[5] Although our synthesis permitted the assignment of relative configuration, the lack of an authentic sample and an optical rotation measurement left the absolute configuration of **1** a mystery.[7] The highest oxidized member in this family of natural products, avrainvillamide (**3**, first isolated by Fenical et al.),[2c,6] also posed some unanswered questions. Specifically, the unique oxidation pattern (3-alkylidene-3*H*-indole-1-oxide) present in **3** is the first of its sort in a natural product[2] and required new methodology for its installation. Although it appeared logical to target **3** through a natural progression of oxidative transformations from the parent stephacidin A (**1**), the execution of this plan was uncertain. For instance, the benzopyran subunit of **1** is susceptible to oxidation under many of the conditions used for the oxidation of amines to nitrones.[8] Herein, we present the following results: 1) a streamlined enantioselective synthesis of both antipodes of **1**, 2) the absolute configuration of this family of alkaloids, 3) the verification of the structure of avrainvillamide (CJ-17,665; (+)-**3**) through reisolation and total synthesis, 4) an approach to the chemoselective conversion of (+)-**1** into (+)-**3**, and 5) the spontaneous dimerization of (+)-**3** to stephacidin B ((−)-**2**).

Our first synthesis[5] of (−)-**1** could be shortened and rendered more amenable to scale-up by making the modifications as illustrated in Scheme 1. The superfluous protection and oxidation of the ester side chain was avoided by using proline derivative **6**,[9] which was able to undergo peptide coupling with **5**[5] without intramolecular cyclization to form a γ-lactam. This undesired cyclization could be avoided when amine **6** was immediately subjected to peptide coupling to furnish **7**. The yield of the key enolate coupling (**8** to **9**) was improved (61% yield along with 8% recovered starting materials), and the reproducibility of the thermal annulation (**10** to **1**) was enhanced by using sulfolane as solvent at a higher temperature (240 °C). By this route, (+)-**1** or (−)-**1** could be prepared in seven steps (12% overall yield) from readily available **5** and (*R*)- or (*S*)-**6**, respectively. Although one could make an educated guess regarding the absolute configuration of these natural products by comparison to the paraherquamides, brevianamides, and other bicyclo-[2.2.2]diazaoctane alkaloids,[1] we elected to use natural (*S*)-proline until this uncertainty was resolved.

On the basis of the assumption that **3** is produced in nature by oxidation of **1**, we collaborated with Professor Fenical et al. (Scripps Institution of Oceanography) to obtain a sample of natural **3** as the original isolated compound was no longer available. Our hope was that **3** could be reduced to **1** to ascertain its absolute configuration. Careful analysis of the crude extracts indicated the presence of not only avrainvillamide (**3**) but also stephacidin A (**1**). Stephacidin B (**2**) was not detected by LC-MS. With a natural sample of (+)-**1** in hand the issue of absolute configuration could be addressed.[10] As shown in Figure 2, comparison of the CD spectra of synthetic (−)-**1** and natural (+)-**1** revealed that the enantiomer had been synthesized previously in these laboratories. The use of (*R*)-proline to secure the enantiomer of amine **6** eventually led to the preparation of (+)-**1** with the correct absolute configuration (synthetic (+)-**1**: $[\alpha]_D = +68.5$ ($c = 0.35$, 1:1 CH_2Cl_2/MeOH); natural (+)-**1**: $[\alpha]_D = +61.5$ ($c = 0.26$, 1:1 CH_2Cl_2/MeOH).

[**] We are deeply grateful to Professor William Fenical (Scripps Institution of Oceanography) for his invaluable advice and support, and for generously providing samples of the crude extracts of *Aspergillus sp.* (CNC358). We are indebted to Professor Axel Zeeck, Dr. Jennifer Qian-Cutrone of BMS, and Pfizer for authentic samples of avrainvillamide, stephacidin B, and CJ-17,665, respectively. Ms. Sarah Siegel of the Kelly group is acknowledged for expertise in obtaining CD spectra. We thank Dr. D.-H. Huang and Dr. L. Pasternak for assistance with NMR spectroscopic studies, and Dr. G. Suizdak for assistance with mass spectrometry measurements. We thank Biotage for a generous donation of process vials that were used extensively during these studies. Financial support for this work was provided by The Scripps Research Institute, Eli Lilly & Co, GlaxoSmithKline, the Searle Scholarship fund, and the NIH (predoctoral fellowship to C.A.G.). CJ-17,665 is the name given to avrainvillamide isolated independently from a soil sample collected in Venezuela.

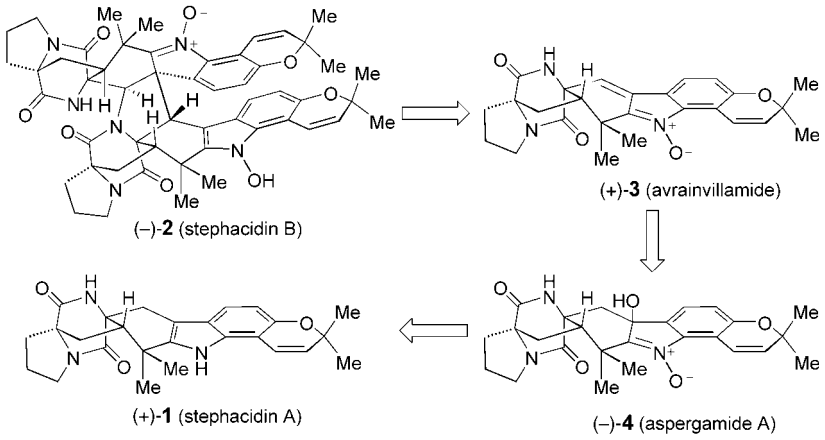

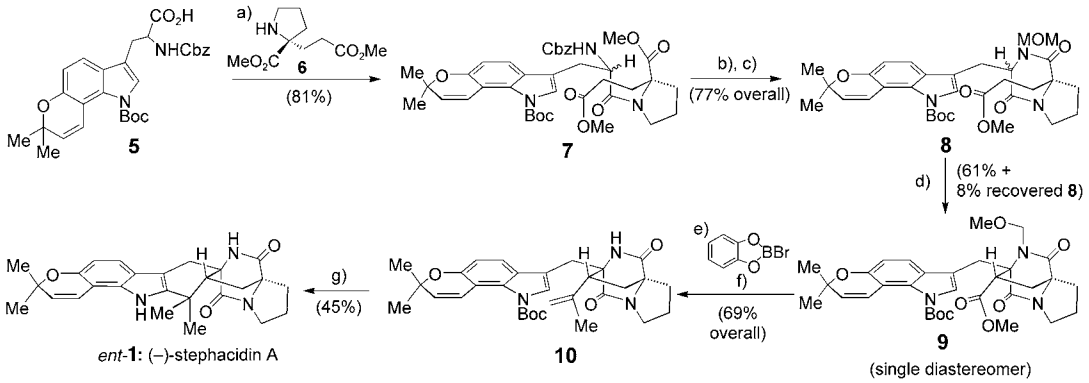

Figure 1. Structures of the stephacidins and related alkaloids along with their proposed[2,3] biogenetic relationships and absolute configuration.

With a shorter synthetic route and the absolute configuration of **1** determined, attention was turned to exploring its conversion into **3**. In the meantime, we had received a sample of aspergamide A (**4**) from Professor Axel Zeeck.[10] Surprisingly, analysis of the material indicated that it had transformed to (+)-**3** by dehydration (Scheme 2). We therefore targeted **4** as a logical precursor to **3**. In principle, the conversion of **1** into **3** could be carried out by chemoselective oxidation of the indole at C3 followed by conversion of the resulting C3-hydroxyindolenine into the corresponding nitrone. In the event, photooxidation with $^1O_2$[11] gave hydroxyindolenine **11** in good yield (Scheme 2). However, all attempts to carry out further oxidation to aspergamide A (**4**) met with failure. A variety of oxidants

that were screened to convert either **1** or **11** into either **3** or **4** were similarly unsuccessful. These shortcomings forced a reevaluation of our planned pathway to avrainvillamide.

In 1971, Somei put forth a provocative hypothesis for the role of 1-hydroxyindoles (tautomers of saturated indolic nitrones) in the biosynthesis and functionalization of indole alkaloids in nature.[12] These highly reactive species are susceptible to nucleophilic attack and dimerization, and undergo a variety of interesting rearrangements. These pioneering studies led us to hypothesize that perhaps such a species would be a viable precursor to **3**. As a proof of principle, model compound **12** was synthesized by a route that paralleled our synthesis of **1**.[13] As shown in Scheme 3, chemoselective reduction of the indole C2–C3 π bond with sodium cyanoborohydride in acetic acid (Gribble reduction)[14] gave indoline **13** (53% yield), poised for Somei oxidation.[12] Treatment of **13** with catalytic $Na_2WO_4{\cdot}2H_2O$ and excess H_2O_2 did not lead to appreciable amounts of the expected 1-hydroxyindole **14**. Instead, we were pleased to find that the major constituent in the crude reaction mixture was the bright yellow α,β-unsaturated nitrone **15** isolated in approximately 30% yield (unoptimized).

Scheme 3. Synthesis of simple avrainvillamide model **15** and the successful conversion of (+)-**1** into (+)-**3** and (−)-**2**. Reagents and conditions: a) $NaBH_3CN$ (10 equiv), AcOH, 25 °C, 12 h, 53%; b) $Na_2WO_4{\cdot}2H_2O$ (0.2 equiv), aq. 35% H_2O_2 (50 equiv), MeOH, H_2O, 25 °C, 6 h, ca. 30%; c) $NaBH_3CN$ (50 equiv), AcOH, 25 °C, 24 h, 93%; d) SeO_2 (0.25 equiv), 35% H_2O_2 (50 equiv), dioxane, 25 °C, 40 h, 27% **3** with 50% recovered **16**; e) Procedure A: Preparative TLC (SiO_2, EtOAc); Procedure B:[6] Et_3N (excess), CH_3CN, 25 °C, 1 h; Procedure C: DMSO, then solvent removal, approx. 2:1 mixture of **3** to **2**, purified by preparative TLC. PMB = *p*-methoxybenzyl; DMSO = dimethyl sulfoxide.

With a method in hand for the desired oxidative conversion, we turned our attention to stephacidin A (**1**) once again. Gribble reduction of synthetic (+)-**1** furnished indoline **16** (Scheme 3) in essentially quantitative yield as a separable but inconsequential mixture of diastereomers. This mixture was subjected to Somei oxidation, which unfortunately provided about 20% yield of (+)-**3** mixed with some inseparable impurities. Alternatively, indoline **16** could be treated with catalytic SeO_2[15] and excess H_2O_2 to provide pure (+)-**3** in 27% isolated yield along with 50% recovered **16** (spectroscopically identical to the samples obtained from Prof. Zeeck and Prof. Fenical and that reported by Myers;[6] synthetic (+)-**3**: $[\alpha]_D = +11$ ($c = 0.1$, $CHCl_3$); natural (+)-**3**: $[\alpha]_D = +10.6$ ($c = 0.17$, $CHCl_3$). We speculate that this cascade oxidation proceeds via the putative intermediate 1-hydroxyindole **17**, which is further oxidized directly to **3** or perhaps first to **4** (Figure 1) followed by loss of water to form (+)-**3**.

In accord with Herzon and Myers' observations in the unnatural series,[6] synthetic (+)-**3** underwent spontaneous dimerization to (−)-**2** under a variety of conditions, including exposure to silica gel (during preparative TLC), base (Et_3N),[6] or even simple evaporation from DMSO (synthetic (−)-**2** was spectroscopically identical to a sample obtained from BMS[2a] and to that reported by Myers;[6] optical rotation of synthetic (−)-**2**: $[\alpha]_D = -33$ ($c = 0.1$, $CDCl_3$); natural (−)-**2** (as received from BMS): $[\alpha]_D = -21.1$ ($c = 0.19$, $CDCl_3$); (+)-**2**:[6] $[\alpha]_D = +91$ ($c = 0.25$, CH_3CN)). The ease with which the dimerization took place actually hampered purification of **3**. Likewise, **2** underwent facile retrodimerization back to a mixture of **3** and **2** during chromatography. A final issue that needed to be addressed was the true identity of CJ-17,665[2d] as slight differences between synthetic **3** and the reported ^{1}H NMR spectra of CJ-17,665 were observed by both us and Herzon and Myers.[6] Comparison (LC-MS, TLC, NMR spectroscopy) with an authentic sample from Pfizer confirms that it is indeed **3**, and, perhaps not surprisingly, the sample contained approximately 20% of stephacidin B (**2**) as judged by ^{1}H NMR spectral analysis and LC-MS.[16] Interestingly, the sample from Pfizer was provided as a (yellow) solution in DMSO, whereas the sample from Professor Zeeck (see above) was a yellow–green powder and contained no stephacidin B (as judged by ^{1}H NMR spectroscopy), which implies that dimerization does not occur over time in the solid state.

The spontaneous (and reversible) dimerization of **3** to **2** is consistent with the known tendency of saturated indolic nitrones (a tautomeric form of a 1-hydroxyindole) to dimerize.[12] Taken together, these findings add further support for Somei's hypothesis regarding the potentially widespread significance of fleeting 1-hydroxyindoles in nature. The new selenium- and tungsten-based protocols reported herein to chemoselectively generate an unsaturated nitrone group from an easily accessible indoline should facilitate the synthesis of avrainvillamide and stephacidin mimics for biological explorations.[16]

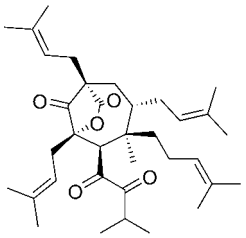
Ring Systems



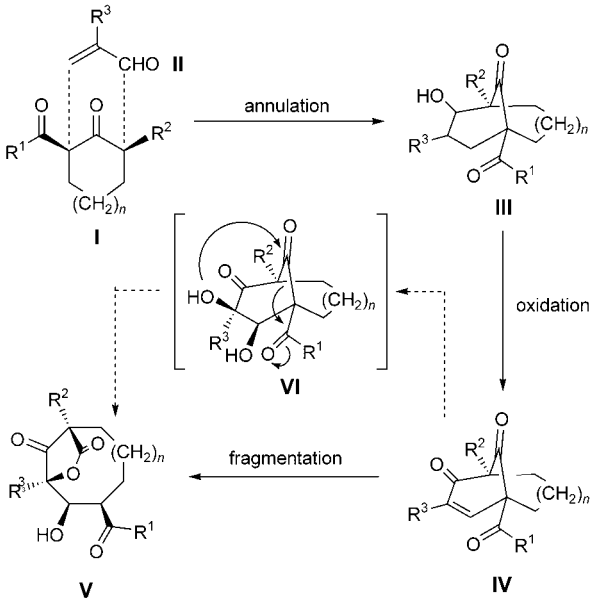
Construction of Highly Functionalized Medium-Sized Rings: Synthesis of Hyperforin and Perforatumone Model Systems**

K. C. Nicolaou, Giacomo E. A. Carenzi, and Valer Jeso*

Hyperforin[1] (**1**) and perforatumone[2] (**2**) are two secondary metabolites with unique molecular architectures and were

1: hyperforin

2: perforatumone



isolated from *Hypericum perforatum* (St. John's wort),[3] famous for its antidepressant properties. Despite their relatively small size, these structures constitute thorny synthetic challenges and remain to this day defiant to chemical synthesis.[4] As part of our efforts to develop synthetic routes to these and other natural and designed polyprenylated phloroglucinol derivatives, we sought a general method of entry into bridged medium-sized rings reminiscent of this class of compounds. Herein we report a novel synthetic sequence to such polyfunctional systems from simple cyclic ketones that involves a series of cascade reactions and delivers model systems of both hyperforin and perforatumone in a stereoselective manner.

Scheme 1 depicts the hypothetical strategy devised for reaching bridged medium (and potentially large)-sized rings of type **III**, **IV**, and **V** from simple building blocks such as disubstituted cyclic ketones **I** and α,β-unsaturated aldehydes **II**. Implementation of this strategy would require annulation of cyclic ketone **I** with the α,β-unsaturated aldehyde **II** to

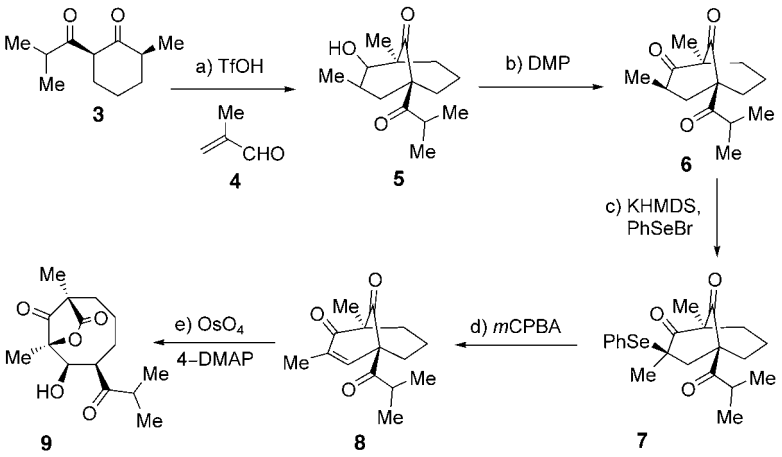

Scheme 1. General strategy for the construction of polyfunctional, bridged medium-sized rings **III**, **IV**, and **V**.

afford the bridged bicyclic system **III**, followed by oxidation of the latter compound to the α,β-unsaturated enone **IV**. Dihydroxylation and subsequent fragmentation of **IV** was expected to afford the ring-expanded product **V** via intermediate **VI**. Notably, besides the two-carbon expansion involved in the fragmentation reaction (**VI**→**V**), this process would concurrently form a new bridge, which being a lactone, can be conveniently disassembled to afford further multifunctional products. Noteworthy is also the choice of annulation partners **I** and **II** in which the fine-tuning of the reactivity of each compound at its two reactive ends was deemed crucial to the success of the anticipated cascade reaction to afford **III**. Favoring the proposed fragmentation was the proximity of the attending hydroxy group to the attached bridging carbonyl moiety, the closeness of its trajectory to the Bürgi–Dunitz angle,[5] and the strain released upon the event.

Delightfully, implementation of this plan with cyclohexanone derivative **3** and 2-methylacrolein (**4**) as starting materials proved successful (Scheme 2). Thus, mixing of diketone **3**[6] with acrolein **4** in CH_2Cl_2, followed by addition of TfOH[7] at −78 °C and slowly allowing the reaction mixture to reach ambient temperature, led to the formation of bicyclic hydroxy diketone **5** in 63% yield, presumably through: 1) initial activation (enolization) of the carbon atom between the two carbonyl groups of the cyclic diketone **3**, followed by 2) intermolecular 1,4-addition to the α,β-unsaturated aldehyde **4**, 3) protonation, and 4) intramolecular aldol reaction.[8] This annulation process is remarkable, not only for its efficiency, but also for its stereoselectivity: only two diastereomers of **5** (≈2:1) were obtained. Four diastereomers could plausibly be formed in this reaction, but the stereochemistry of the observed two was neither determined nor of consequence as both stereocenters were destroyed in the subsequent steps (see below). Continuing with the sequence (Scheme 1), the hydroxy group within the bicyclic product **5** (mixture of two compounds) was oxidized with DMP (81%) to afford tricarbonyl compound **6** (single compound), whose regioselective unsaturation (to afford enone **8** (Scheme 2)) proceeded smoothly through phenylselenide **7** (produced by sequential exposure to KHMDS and PhSeBr, 71%) by oxidation to the corresponding selenoxide with *m*CPBA (98%). Finally, stereoselective dihydroxylation of enone **8** from the *exo* face (OsO_4/4-DMAP) led conveniently to the targeted product **9** (Scheme 2; Table 3) in 68% yield, presumably through fragmentation[9] of the dihydroxy tricarbonyl compound corresponding to **VI** (Scheme 1) whose existence is apparently transient (not detected by TLC). While the resemblance of structures **5**–**8** to that of hyperforin (**1**) is obvious, the architecture of fragmentation product **9** contains one extra carbon in its medium-sized ring compared with that of perforatumone (**2**). Nevertheless, this sequence proved quite useful in synthesizing several other polyfunctional ring systems, including a bridged seven-membered ring corresponding to **2** (i.e. compound **25**, Table 2, Figure 1[10]).

The success of this process encouraged us to explore its optimization, generality, and scope. Table 1 lists the results of a number of experiments carried out to optimize the initial annulation procedure. Besides TfOH, a number of Lewis acids such as $Bi(OTf)_3$,[11] TMSOTf, $Sn(OTf)_2$, $Y(OTf)_3$, and AgOTf performed well, although it is not clear whether they act through the generation of TfOH. Optimizations for this step were also carried out for the five-membered (compound **10**, Table 2) and seven-membered rings (compound **11**, Table 2), as shown in Table 1. From these results we conclude

Scheme 2. Synthesis of polyfunctional ring systems. Reagents and conditions: a) TfOH (0.3 equiv), CH_2Cl_2, −78→25 °C, 1.5 h, 63%; b) DMP (1.5 equiv), py, CH_2Cl_2, 25 °C, 81%; c) KHMDS (1.15 equiv), THF, −41 °C, 2 h; then PhSeBr (1.4 equiv), −41 °C, 15 min, 71%; d) *m*CPBA (2.0 equiv), CH_2Cl_2, −10→0 °C, 30 min, 98%; e) OsO_4 (1.1 equiv), 4-DMAP (1.1 equiv), *t*BuOH/H_2O (1:1), 25 °C, 1 h, 68%. Tf = trifluoromethanesulfonyl; DMP = Dess–Martin periodinane; py = pyridine; KHMDS = potassium bis(trimethylsilyl)amide; *m*CPBA = *m*-chloroperbenzoic acid, 4-DMAP = 4-dimethylaminopyridine.

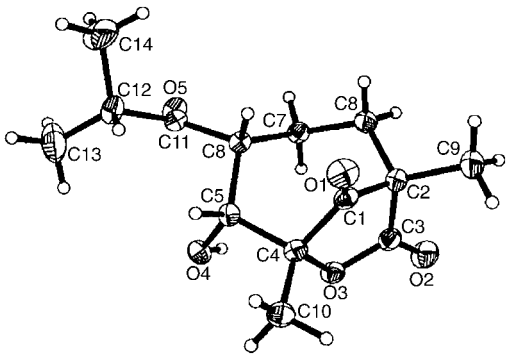

Figure 1. ORTEP drawing of **25** drawn at the 30% probability level.

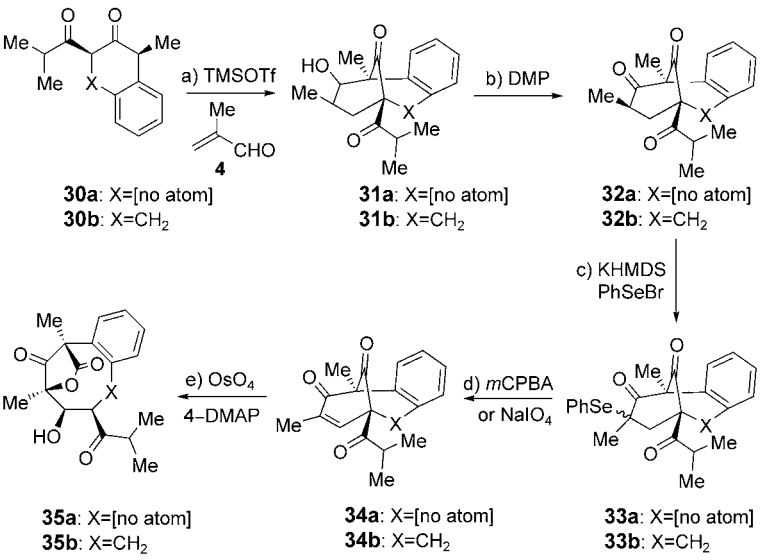
that the best catalysts for this reaction can be found from the collection of TfOH, TMSOTf, and the triflate salts of Bi, Sn, Y, and Ag.

As shown in Table 2, the five- to ten-membered ring disubstituted ketones (**10**, **3**, **11**–**14**) entered and completed the sequence to the final lactone-bridged fragmentation products (**25**, **9**, **26**–**29**, respectively) via the corresponding intermediate compounds (**15**, **5**, **16**–**19**, and **20**, **8**, **21**–**24**) in varying yields. Thus, while the five- to eight-membered ring ketones performed well and yielded the seven- to ten-membered ring systems (Table 2, entries 1–4), the larger-ring ketones behaved erratically both in the initial (annulation) and in the final (fragmentation) steps to afford the expected products in low yields (Table 2, entries 5 and 6). The higher flexibility of the larger-ring substrates may be responsible for the poor performance of these ring-forming and -rupturing reactions, a hypothesis that was supported by the refusal of an open-chain disubstituted ketone (i.e. 2,4,6-trimethylheptan-3,5-dione) to enter the initial productive step (i.e. the annulation step).



As a further demonstration of the generality of the developed synthesis of polyfunctional medium-sized rings, we attempted the construction of the fully substituted seven- and eight-membered bridged ring systems **31a,b**–**35a,b** (Scheme 3). Each carbon atom of these benzenoid fused ring systems is uniquely substituted, making them both synthetically challenging and potentially useful as biological probes. Thus, the substituted diketones **30a** and **30b** upon reaction with methyl acrolein (**4**) under the influence of TMSOTf, formed the annulated products **31a** (41%) and **31b** (31%), respectively. The latter compounds were then oxidized with DMP to the corresponding triketones **32a** (60%) and **32b** (61%), which were subjected to the phenylselenenylation/oxidation procedure to afford enones **34a** (74%) and **34b** (56%) via **33a** and **33b**. Finally, exposure of **34** to the OsO_4/4-DMAP conditions led directly to the targeted products **35a** (38%; Table 3) and **35b** (31%) through the postulated dihydroxylation/fragmentation cascade (yields unoptimized).

The described synthetic technology offers rapid and convenient build-up of molecular complexity from simple and readily available starting materials. Its application to the synthesis of natural and designed molecules containing medium-sized rings (seven- to ten-membered) appears particularly attractive and should be forthcoming.

Table 1: Optimization of annulation conditions (**I** + **II**→**III**)[a]

Entry	Substrate	Solvent	Equiv	*t* [h]	Product	Yield [%][b]

Natural Product Synthesis

Total Synthesis of Cavicularin and Riccardin C: Addressing the Synthesis of an Arene That Adopts a Boat Configuration**

David C. Harrowven, Timothy Woodcock, and Peter D. Howes*

From a structural perspective cavicularin (**1**), from the liverwort *Cavicularia densa*,[1] is one of the most unusual natural products to have been isolated in the last decade. It comprises a macrocyclic core that contains dibenzyl and dihydrophenanthrene units conjoined by a biaryl bond and an ether linkage. This core imparts such strain on the system that one of the arenes, ring A, adopts a boatlike configuration and is twisted out of the plane by some 15° in the solid state. Herein, we describe the first total synthesis of cavicularin (**1**), in which a radical-induced transannular ring contraction features as a key step (Scheme 1).

Scheme 1. Synthetic strategy to cavicularin (**1**).

In planning the synthesis of cavicularin, we identified two problems that required special consideration: one was the obvious kinetic barrier to closure of the strained macrocycle;

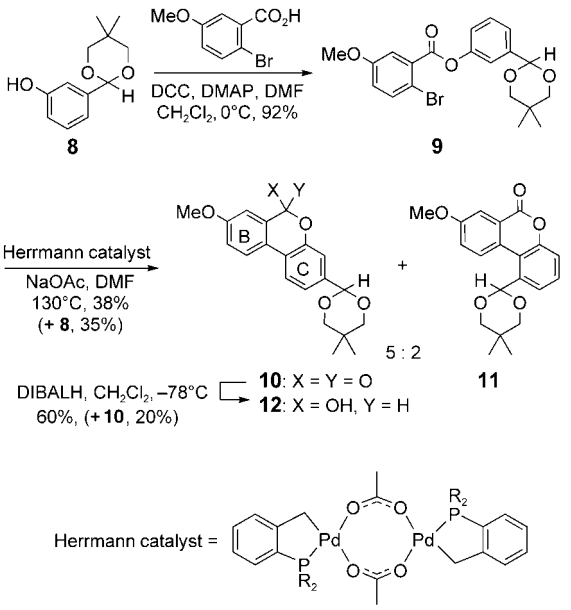
the other was a thermodynamic constraint imposed by the need to distort arene A. We felt that both of these problems could be resolved by employing a radical-induced, transannular ring-contraction strategy, such as **2**→**3** (Scheme 1).[2] In particular, by employing a larger and less-strained macrocycle as a precursor the kinetic burden would be transferred to the ring-contraction step, in which the close proximity of the aryl radical intermediate to arene D offered good prospects for a favorable outcome. It also seemed likely that cyclization could proceed without significant distortion of arene A. Indeed, that would occur in the second phase of the reaction with the collapse of **3** to cavicularin trimethyl ether, with the thermodynamic cost of bending the arene compensated by the rearomatization of arene D.[3,4]



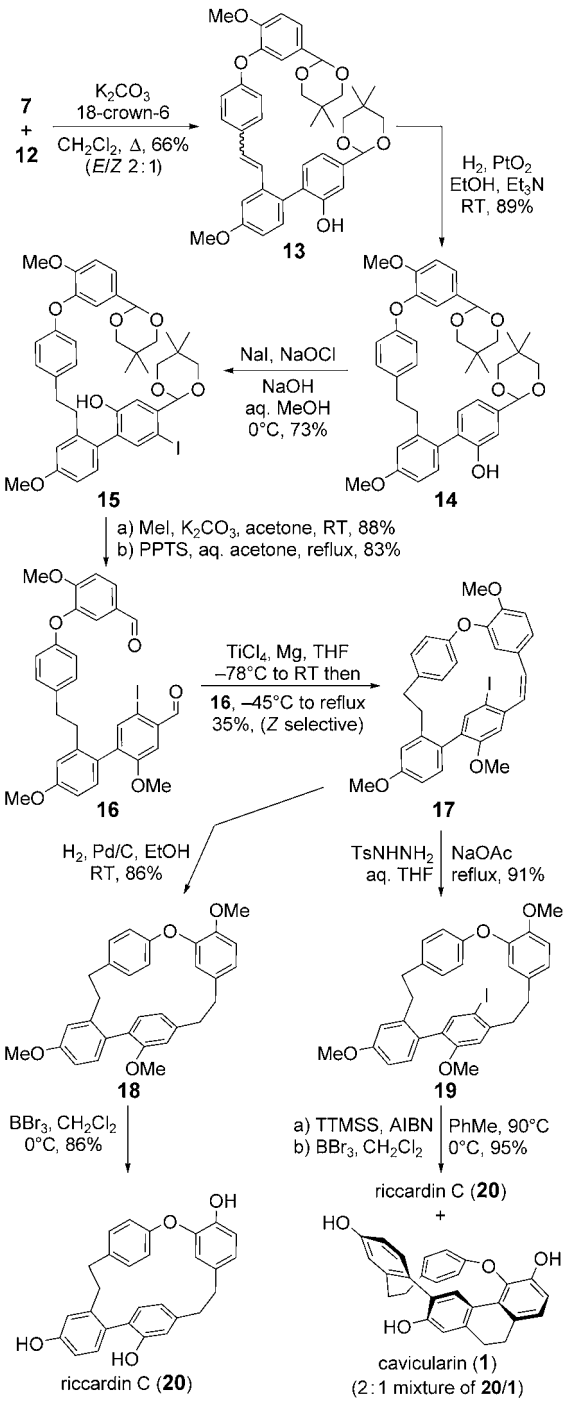
Our synthesis began with the protection of isovanillin as its dioxolane acetal **4**. Union of **4** with 4-fluorobenzaldehyde then gave diaryl ether **5**,[6] which was reduced with sodium borohydride to the corresponding alcohol. Bromination with CBr_4/PPh_3 additionally unmasked the latent aldehyde function to give **6**, which, on sequential treatment with PPh_3 and neopentyl glycol, led to the suitably functionalized AD ring system **7** (Scheme 2).

Scheme 2. Synthesis of the AD ring biaryl ether **7**. DMF = *N*,*N*-dimethylformamide, PPTS = pyridinium *p*-toluenesulfonate.

Construction of the BC ring system began with the protection of 3-hydroxybenzaldehyde as its neopentyl glycol acetal **8**. Coupling of **8** and 2-bromo-5-methoxybenzoic acid in the presence of DCC then gave ester **9**, which, on heating in the presence of the Herrmann catalyst, underwent cyclization to benzo[*c*]chromen-6-ones **10** and **11** (Scheme 3).[6] Though low-yielding, the rapidity with which this sequence led to the BC ring system of cavicularin (**1**) offered practical advantages over the alternative routes investigated. Most notably, reduction of **10** with DIBALH provided lactol **12**, which was appropriately functionalized for union with **7** and primed to facilitate regioselective iodination of arene C at a later stage.

The coupling of phosphonium salt **7** and lactol **12** by using standard Wittig protocols proved troublesome at first. However, through the simple expedient of adding 18-crown-6 to the reaction mixture, stilbene **13** was formed in 66% yield as a mixture of *E* and *Z* isomers in 2:1 ratio.[7] Next, reduction of the alkene gave phenol **14**, which was selectively iodinated under basic conditions to give tetraarene **15**.[8] Protection of

Scheme 3. Synthesis of the BC ring system. DCC = dicyclohexylcarbodiimide, DMAP = 4-dimethylaminopyridine, DIBALH = diisobutylaluminum hydride, R = *o*-tolyl.



the phenol group as its methyl ether and removal of the acetal functions then provided dialdehyde **16**, which underwent macrocyclization on treatment with low-valent titanium to yield (*Z*)-**17** (Scheme 4).[9]

We were now in a position to address the synthesis of riccardin C (**20**) and cavicularin (**1**). Catalytic hydrogenation of **17** using palladium on carbon simultaneously effected hydrogenolysis of the aryl iodide to give riccardin C trimethyl ether (**18**). Deprotection of the phenolic groups with boron tribromide then gave riccardin C (**20**) in 86% yield.[10,11] Reduction of the alkene in **17** also proceeded smoothly to give **19** without concomitant reduction of the aryl iodide.[12] A solution of macrocycle **19** in toluene was then heated at 90 °C with TTMSS and AIBN to induce homolysis of the carbon–iodine bond.[13] This procedure gave an inseparable mixture of riccardin C trimethyl ether (**18**) and cavicularin trimethyl ether in 2:1 ratio. Exposure of the mixture to boron tribromide provided riccardin C (**20**) and cavicularin (**1**), which were readily separated by column chromatography. Pleasingly, data recorded on our synthetic samples matched those reported for the natural products.[1,10,11]

In summary, we have completed the first total synthesis of cavicularin (**1**), a cyclic dibenzyldihydrophenanthrene ether from *Cavicularia densa*, in which one of the arenes is under such strain that it is forced to adopt a boat configuration. The key step involved the addition of an aryl radical intermediate to a proximal arene to facilitate a transannular ring contraction with concomitant bending of aromatic ring A (Scheme 1). The macrocyclic precursor **19** was also transformed into riccardin C (**20**) to complete the shortest synthesis of this natural product described to date.[11]

Bioorganic Chemistry

An Artificial Riboflavin Receptor Prepared by a Template Analogue Imprinting Strategy**

Panagiotis Manesiotis, Andrew J. Hall, Julien Courtois, Knut Irgum, and Börje Sellergren**

Molecular imprinting has resulted in a range of robust polymer-based receptors that are being considered for use in a variety of applications based on molecular recognition.[1] The technique entails polymerization of mono- and polyfunctional monomers in the presence of a template, whose subsequent removal leaves sites that can be reoccupied by the template or a closely related compound. These synthetic receptors are distinguished by their robustness and ease of synthesis, but they also have drawbacks, notably their poor water compatibility and, with notable exceptions,[2–5] the lack of strategies for imprinting water-soluble target molecules. One approach towards overcoming the latter is to use a non-aqueous imprinting protocol, in which lipophilic templates representing a close structural analogue or substructure of the target are employed.[6,7] Here, a solvent/porogen is chosen such that the intrinsically weak monomer–template interactions based, for example, on hydrogen bonding, electrostatics, or charge transfer, are stabilized. Thus, the use of solvents with low polarity and hydrogen bonding strength is generally favored. Although polymers prepared by this route have displayed selective binding of their targets under aqueous conditions, the effects were typically too weak to be of practical value. Following this approach, we report here on molecularly imprinted polymers (MIPs) that recognize their targets (riboflavin) effectively under such conditions (Figure 1). Careful fine-tuning of the synthesis conditions with respect to the choice of template and cross-linking monomer proved critical and resulted in a polymer which strongly and selectively bound riboflavin in water-rich media similar to those found in common alcoholic beverages.[8]

For the design of the polymers, we first turned our attention to the functional monomer. The flavin ring system contains an imide functionality which contains an acceptor-donor-acceptor (ADA) array of hydrogen-bonding sites capable of interacting with receptors containing a complimentary DAD array. Representative of such molecules are 2,6-bisamidopyridines, whose ability to bind to imide functionalities has been widely studied.[9] Accordingly, we chose 2,6-bis(acrylamido)pyridine (BAAPy) as our functional monomer (Scheme 1).[10,11]

With regards the choice of template, we focused on flavin and riboflavin derivatives having high solubility in typical imprinting solvents, in this case chloroform (Scheme 1), initially attempting to use N(10)-alkylflavins.[12] However, the solubility of these compounds in chloroform was found to be too low (ca. 16 mM for **1** and only ca. 6 mM for **2**) for a conventional template/monomer molar ratio to be used. As expected, polymers prepared using these analogues as templates exhibited low imprinting factors and capacities (see below). Riboflavin tetraesters performed better in this regard, their solubility in chloroform being far greater than that of the N(10)-alkylflavins described above (RfAc: 0.2 M, RfPr: 0.6 M, RfBu: 0.8 M). Furthermore, the use of these tetraesters of various sizes allowed the investigation of other effects of the templating process, for example, size-exclusion phenomena. A ^{1}H NMR titration was performed in $CDCl_3$ using **1** as the guest and BAAPy as the host to check the likely effects of these pairings of template(s) and functional monomer. The raw data were fitted by nonlinear regression to a 1:1 binding isotherm and an association constant of $K_a = 570 \pm 35\ M^{-1}$ was extracted.[13] This value is in accordance with association constants obtained previously with similar systems,[14] and implies that the major part of the template is complexed prior to polymerization. The magnitude of the K_a value, along with the observed complexation-induced shifts of protons in the NMR spectra of both the host and guest, support the presence of a three-point hydrogen-bonded complex as depicted in Figure 1.

The use of the riboflavin esters as templates leads to MIPs[15] that exhibit extremely strong retention of their respective templates (Figure 2). Indeed, modification of the mobile phase with acetic acid was necessary to reduce the retentions to a workable time frame. Anticipating that the primary electrostatic driving force causing this retention was the three-point hydrogen-bond array, we also challenged the RfAc-imprinted and control polymers with the *N*-methylated template analogue **6**. We observed total suppression of the retention on both the imprinted and control polymers, thus providing proof that the complexation mode observed in solution is also preserved in the polymer. Furthermore, evidence of size-exclusion effects is seen in the different polymers. Thus, P(RfAc) retains its template to a greater extent than the other analytes, while the retentions of RfAc and RfPr on P(RfPr) are very similar. This result suggests that the polymeric binding site formed around RfAc is able to exclude the larger analytes, while the polymeric binding sites formed around RfPr appear to still offer a "good fit" for the smaller analyte. The larger analyte RfBu is less strongly retained on both these polymers. However, the retention of

Scheme 1. The monomersand templates investigated in the study.

RfBu is strongest on P(RfBu), perhaps indicating that, while the binding sites formed in these polymers are large enough to accommodate RfAc and RfPr, there is a lessening of secondary interactions provided by the polymeric matrix, as the templated cavity is now too large for these smaller analytes. This view is further supported by the much lower retentions of the other smaller analytes (BU and **3**–**5**) on all polymers. The large imprinting factors arise from two effects, namely the pronounced retention of the riboflavin analytes on the MIPs coupled with low retention on the control, non-imprinted polymer P(N). This observation suggests that the binding sites provided by the functional monomer units in P(N) are located in areas of the polymeric matrix that cannot be accessed by the larger tetraester analytes. This assumption is again supported by the comparatively stronger retentions of the smaller analogue analytes on P(N).

Insights into the affinities and abundance of these sites were obtained by frontal analysis (low concentration range, 0–1 mM) and batch partitioning experiments (higher concentration range, 0–20 mM). In the low concentration range (Figure 3 a) the isotherms could be excellently fitted to a Freundlich multiple site model (Figure 3 a inset). This model has been shown to describe well the binding behavior of several MIPs in the low concentration range and indicates a heterogeneous distribution of binding sites within this interval.[16,17] The isotherms obtained in the higher concentration interval (Figure 3 b) display a sigmoidal-type saturation behavior, the origin of which is currently unclear.

As suggested from the earlier chromatographic results, binding to the non-imprinted polymer is confirmed to be weak. The isotherms of the imprinted polymers also agree with the relative retentions observed in the chromatographic investigation. Thus, P(RfAc) shows the highest binding capacity, exceeding that of P(N) by more than 30 $\mu mol\,g^{-1}$

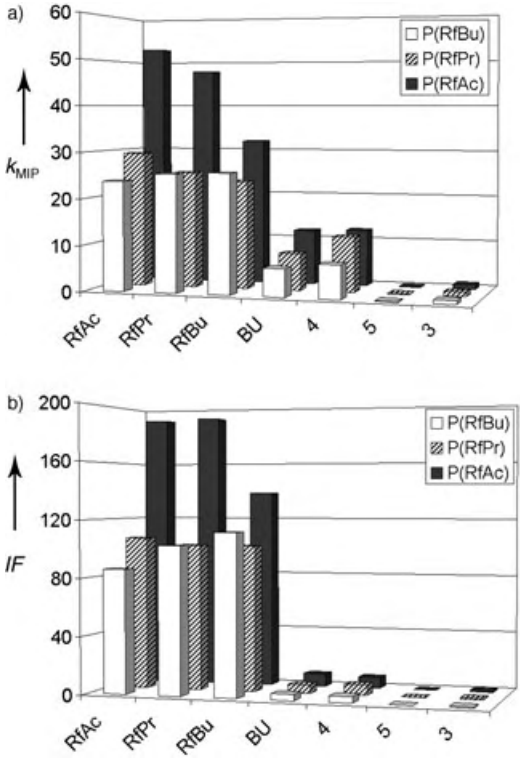

Figure 2. a) Retention factors (k) and b) imprinting factors (IF) obtained in the chromatographic evaluation of the riboflavin tetraester imprinted polymers (P(RfAc), P(RfPr), P(RfBu)) and a control, non-imprinted, polymer (P(N)) using acetonitrile/acetic acid (99/1 v/v) as the mobile phase. k and IF are defined as follows: $k=(t-t_0)/t_0$; $IF=k_{MIP}/k_{NIP}$; where t = retention time of the solute; t_0 = retention time of a nonretained void marker; $k_{MIP}(k_{NIP})$ = retention factors for a given solute using the imprinted (or non-imprinted) polymer as stationary phase.

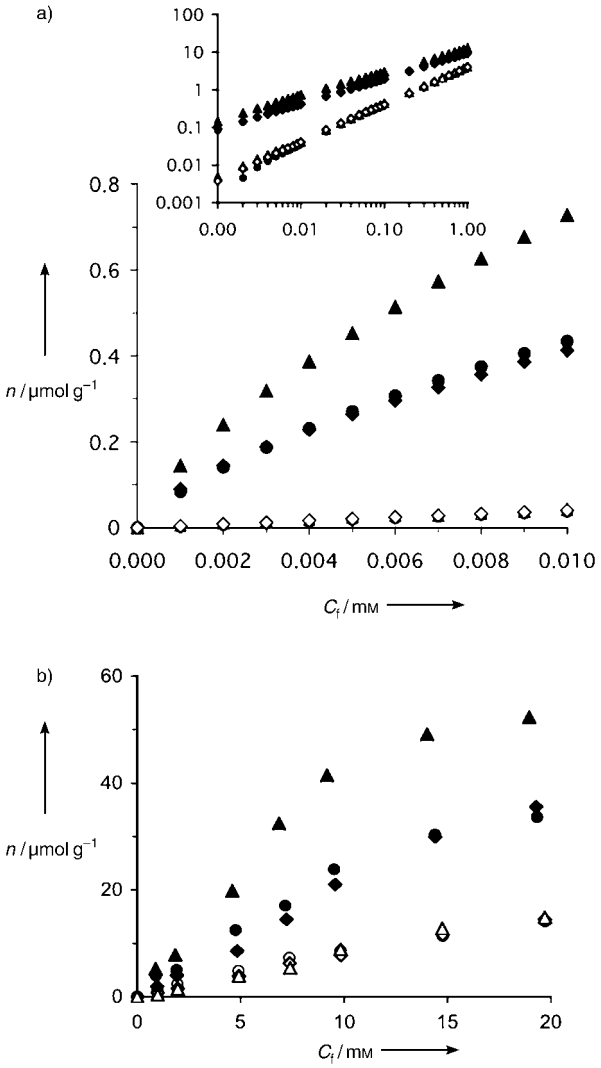

Figure 3. Binding isotherms of riboflavin tetraesters (RfAc: triangles, RfPr: circles, RfBu: diamonds) on their respective complementary polymers (P(RfAc), P(RfPr), P(RfBu): filled symbols) and on a control non-imprinted polymer (P(N); open symbols) as determined a) by frontal analysis using the staircase method or b) by a batch partitioning experiment in acetonitrile/acetic acid (99/1 v/v). In (b) the polymers (10 mg) were equilibrated for 24 h with solutions (0.5 mL) containing different concentrations of the riboflavin tetraesters.

at saturation. The binding curves of P(RfPr) and P(RfBu) exhibit similar shapes, but with lower binding of the templates. Thus, the reason for the stronger retention of RfAc on its complementary polymer appears to be a consequence of a larger number of sites rather than the presence of sites of higher affinity. Nevertheless, high-energy binding sites are clearly present. Thus, at a free concentration (C_f) of 1 μM, P(RfAc) adsorbed 0.15 μmol RfAc g^{-1} polymer with negligible nonspecific adsorption, thus indicating the presence of sites with $K_a > 10^6\,M^{-1}$.

The primary goal of our study was the recognition of riboflavin in aqueous-based media. To this end, the above polymers were tested, again in the chromatographic mode, for their ability to retain Rf under such conditions (Figure 4).

Retention of Rf by **P1** is weak and only minimally different from the retention of Rf by the control P(N). Thus, although **P1** is able to recognize its template over analogous molecules in organic media, **1** is a poor template for the preparation of MIPs that exhibit Rf recognition in aqueous media. For the MIPs prepared using the riboflavin esters as templates, much stronger retentions of Rf are observed, with P(RfAc), P(RfPr), and P(RfBu) all capable of retaining Rf to a much greater extent than either P(N) or **P1**. The relative retention of Rf on these polymers agrees with their relative binding capacities for their own templates (Figure 3). Thus, P(RfAc) emerges as the MIP best able to retain Rf under the conditions tested, which implies that the binding sites formed around this tetraester offer a good fit for the ribose chain of Rf as well.

These encouraging results were somewhat offset by the performance of the polymers in pure water or water containing small amounts of additives. In this case, nonspecific, hydrophobically driven binding dominated the retention, thus leading to much lower imprinting factors. To suppress this contribution, the polar cross-linking monomer pentaerythritol triacrylate (PETRA) was used in place of EDMA. The corresponding polymer (P(RfAc)′) retained Rf strongly, with a retention almost two times higher than P(RfAc). Furthermore, the retention displayed by the control polymer (P(N)′) was lower than that of the corresponding EDMA-based

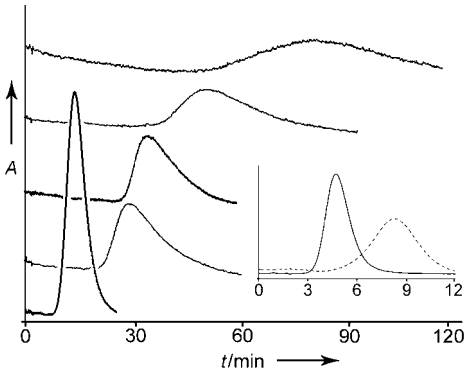

Figure 4. Elution profiles of riboflavin (10 µl of a 1 mM solution) injected on columns packed with from bottom to top (main figure): P**1**, P(RfBu), P(RfPr), P(RfAc), and P(RfAc)′. The inset shows the elution profiles of riboflavin on columns packed with P(N) (dashed line) and P(N)′ (solid line). Mobile phase = water/acetonitrile/ethanol (85.5/10/4.5 v/v/v).

control P(N) (see inset in Figure 4). Thus, it appears that the hydroxy groups of the cross-linking monomer create both a more hydrophilic backbone with lower affinity for nonpolar compounds and provide additional stabilizing interactions in the imprinted sites, presumably through hydrogen bonds to the ester function of RfAc. Frontal analysis on this polymer confirmed these findings. Thus P(RfAc)′ bound roughly two times more template at a given solution concentration than P(RfAc) and displayed more uniform high-affinity sites.

P(RfAc)′ was then subjected to a thermodynamic investigation using isothermal titration microcalorimetry (ITC). This technique has proven extremely versatile for the thermodynamic characterization of receptor–ligand interactions,[18] including an imprinted system,[19] and is based on the measurement of the heat changes occurring upon titration of a receptor (or a ligand) with its binding partner. The addition of a dilute solution of Rf to a suspension of the polymer particles ($0.9\,mg\,mL^{-1}$) in a beverage-mimicking solution (water/formic acid/ethanol: 90.6/4.7/4.7 (v/v/v)) led to exothermic heat pulses, thus indicating noncovalent interactions between the titrant and the suspended polymer particles. The heat generated per addition was calculated by integrating the heat pulses and thereafter plotted against the total concentration of Rf in the cell (Figure 5 a). Within this small concentration interval, limited by the analyte solubility, the heat generated per addition was constant, with no evidence of saturation. Nevertheless, clear differences between the polymers were observed. Interaction of Rf with the imprinted polymer was exothermic, exceeding that with the nonimprinted polymer by more than $1.3\,kcal\,mol^{-1}$, with the latter signal coinciding with the background signal obtained by addition of riboflavin in the absence of polymer.

The presence of highly discriminating imprinted sites was further supported by the absence of any such effect when the control analyte uridine was added. Uridine, which contains both the imide and ribose substructures, could be expected to cross-react with sites designed to bind riboflavin. However, the signal observed when this analyte was added to the different polymers did not differ from the blank runs.

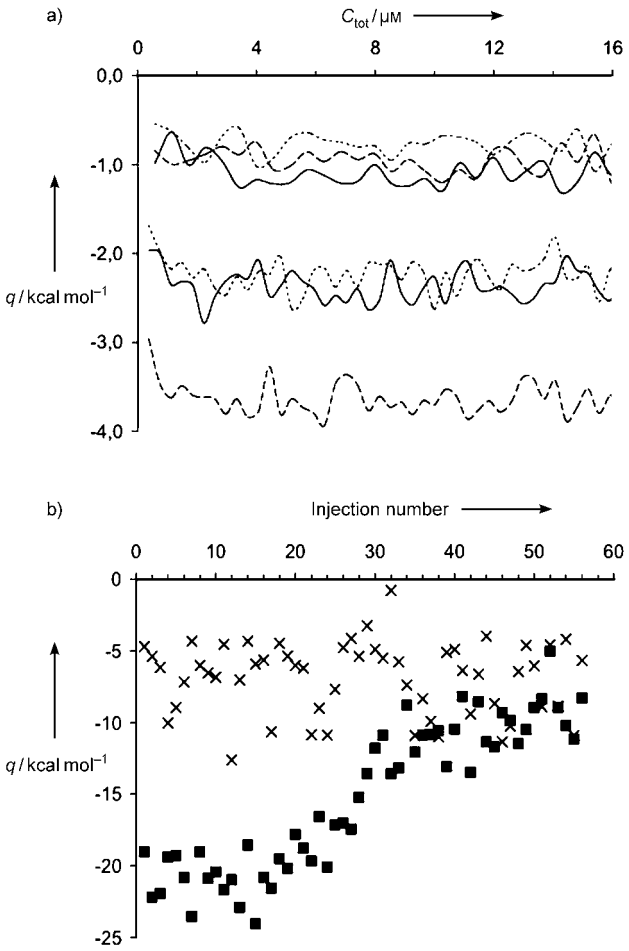

Figure 5. ITC titration profiles showing in a) the energy released (q) versus the total concentration of the titrant in the cell (C_{tot}) for the titration of P(RfAc)′ (dashed lines), P(N)′ (solid lines), or blank (dotted lines) with Rf (lower three profiles) or U (upper three profiles) in water/ethanol/formic acid: 90.6/4.7/4.7 (v/v/v), and b) the energy released versus the injection number for the titration of solutions of Rf (■) or U (X) (1 µM in 50 mM aqueous sodium phosphate buffer pH 7) by RfBP.

Unfortunately, the limited solubility of riboflavin meant that only a fraction of the binding sites could be investigated in these experiments. Thus, none of the thermodynamic quantities typically furnished by this type of experiment could be estimated. However, the presence of a specific exotherm at a low total concentration of analyte (<400 nM) implies that binding sites with affinities $>10^6\,M^{-1}$ are present. The absence of saturation effects further indicates that the sites within this population are relatively uniform.

Finally, we compared the imprinted receptor with its biological counterpart—riboflavin binding protein (RfBP). This protein was titrated by the classical technique in two different solvent systems. Pronounced exothermic heat pulses were observed under neutral conditions, with saturation clearly occurring close to a receptor:ligand stoichiometry of 1:1. Analysis of the saturation curve provided a binding constant of $9.0(\pm0.5)\times10^5\,M^{-1}$ (four independent measurements), with an associated enthalpy of $9.4(\pm0.1)\,kcal\,mol^{-1}$. Similar to the situation with the imprinted receptor, no signal

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

was observed when the control analyte uridine was used as the titrant. A different picture emerged when the protein was assessed in the beverage-mimicking solution used to evaluate the imprinted polymer. A pronounced exotherm was observed under these conditions upon each addition, with no apparent binding-related signals, which implies that the protein denatures under conditions where the imprinted polymer retains its ability to bind the target. Notably, this occurs in a solvent system which resembles that found in common alcoholic beverages.[8]

We are currenttly investigating means to further enhance the affinity of the polymers for riboflavin and to suppress the nonspecific binding occurring in pure water.

Platinum–Gallium Compounds

One-Step Synthesis of a Platinum(0)–Gallium(III) Chrysene Complex**

*Mikhail Gorlov, Andreas Fischer, and Lars Kloo**

Recent investigations of gallium(III) halide–aromatic solvent systems with respect to platinum-group metal halides have shown them to be very efficient reducing media.[1,2] Another attractive feature of gallium(III) halides is their aptitude to abstract halide ions from other metal halides, which facilitates metal–metal bond formation. Taking advantage of these properties, we have prepared and crystallographically characterized a series of dipalladium(I) and diplatinum(I) complexes $[M_2(\eta^6\text{-arene})_2(GaX_4)_2]$ (arene = benzene, its alkylated derivatives, or naphthalene; $X = Cl^-$ or Br^-).[1,2]

The reactions of $GaCl_3$ with $PtCl_2$ and polycyclic aromatic hydrocarbons (PAH), such as anthracene, tetracene, or pentacene, turned out to be complicated, probably because of the interaction between the strong Lewis acid $GaCl_3$ and the PAHs; only dark oily products have so far been obtained from these systems. In spite of this, the reaction of platinum(II) and gallium(III) chlorides in the presence of chrysene in 1,2,4-trichlorobenzene leads to the formation of a dark violet solution, from which red crystals can be isolated within a few weeks. An X-ray single-crystal structure determination revealed that the crystalline product is the Pt–Ga compound **1**.[3] The formation of this complex can be described schematically with Equation (1).

$$2\,PtCl_2 + 12\,GaCl_3 + 4\,\text{chrysene} \xrightarrow{+4e^-} [Pt_2Ga_2Cl_2(\mu\text{-}Cl)_2(\text{chrysene})_4](Ga_3Cl_{10})_2 + 4GaCl_4^- \quad (1)$$

The main structural feature of compound **1** is a centrosymmetric $(PtGaCl_2)_2$ unit, where each Pt center is coordinated by two chrysene molecules (Figure 1). This structural unit can be derived from the structure of Ga_2Cl_6 by replacing one terminal Cl substituent on each Ga atom by the Pt-containing group. The geometry is thus that of two edge-sharing tetrahedra. The Ga–Cl bond lengths are 213.6 pm for the terminal Cl substituents and 230.0 and 240.5 pm for the two bridging Cl substituents. They are thus of the same order of magnitude as in Ga_2Cl_6, and are much shorter than would be expected for gallium(I), thus suggesting a +3 oxidation state for Ga. The Ga–Pt distance (233.6 pm) is similar to Ga–Pt bond lengths in related compounds.[4–8] The overall charge

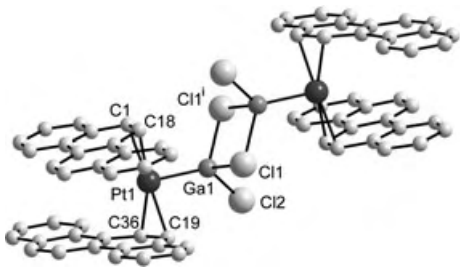

Figure 1. Structure of the cation $[Pt_2Ga_2Cl_2(\mu\text{-}Cl)_2(chrysene)_4]^{2+}$. Selected bond lengths [pm]: Pt1–Ga1 233.6(2), Pt1–C1 222(2), Pt1–C18 221(2), Pt1–C19 223(2), Pt1–C36 219.4(14), Ga1–Cl2 213.6(4), Ga1–Cl1 240.5(4), Ga1–Cl1^{i} 230.0(4). Symmetry operation: I: $2-x$, $1-y$, $1-z$.

of +2 of this unit is unequivocally determined by the fact that there are two $[Ga_3Cl_{10}]^-$ anions present in the structure. The formal oxidation state of Pt in this structure is thus zero.

Each platinum atom is connected to two planar chrysene molecules. The Pt–C bond lengths in **1** (219.4–223.2 pm) are comparable to those in a diplatinum(I) naphthalene complex (219.9–225.8 pm),[1] but they are shorter than those in some other platinum(II) complexes containing arene ligands (for example, 233–234 pm in the 9,10-dihydro-9,10-ethenoanthracene complex).[9]

It should be emphasized that the isolation of compound **1** demonstrates the diversity of reaction routes based on platinum or palladium halides in combination with aluminum or gallium halides in arene-based media. Indeed, only compounds with a dimetallic M_2^{2+} (M = Pd, Pt) core have so far been isolated from these systems.[1,2,10] In the only platinum complex isolated from related systems the platinum center is coordinated by naphthalene. In spite of that, the chrysene complex **1** has a unique structure. The shortest distance between the benzene rings of adjacent chrysene ligands is 358.8 pm, which may indicate a π–π interaction between the chrysene ligands, possibly providing additional stability to **1**.

The crystal packing of **1** is shown in Figure 2. Organic layers of coordinated chrysene molecules are separated by inorganic layers composed of gallium and chlorine atoms, which belong to the central part of the cation and the $[Ga_3Cl_{10}]^-$ anions. The shortest distance between chrysene ligands of adjacent molecules is 360 pm.

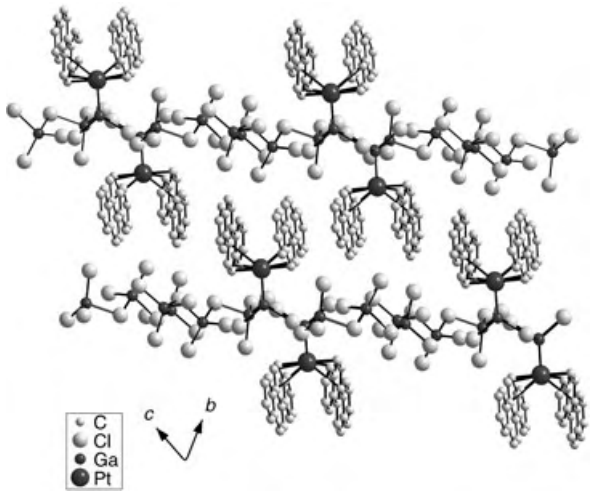

Figure 2. View of the crystal packing of **1**.

Compound **1** is the first platinum–chrysene compound whose structure has been confirmed by X-ray diffraction.[3] It should be noted that among platinum-group metals only ruthenium–chrysene compounds have been described previously.[11–13] In contrast to these compounds, which have an η^6-type coordination, the chrysene in **1** is coordinated in an η^2-mode. Moreover, in the case of the ruthenium complexes exterior ring(s) of chrysene are bound to the metal atom(s), while in **1** the inner ring is coordinated to platinum.

Another remarkable feature of **1** is the presence of a direct platinum–gallium bond whose length is 233.6(2) pm. The platinum–gallium distance is comparable to those in platinum(0)–gallium(I) complexes described in the literature.[4–8] This is remarkable, since electron bookkeeping based on the structure of **1** (vide supra) suggests a platinum(0)–gallium(III) interaction, which means two electrons less on the metal centers available for covalent interaction. In spite of this essentially the same Pt–Ga separation is observed.

To get some further insight into the oxidation states of the atoms involved, X-ray photoelectron spectroscopy (XPS) data were collected for **1**. The binding energies (BE) for **1** are presented in Table 1. Charge-transfer to the ligands has an important impact, and the binding energy of the Pt4f(7/2) electrons in **1** more resembles that of a formal oxidation state of +2 [for example, the BEs of Pt4f(7/2) in $K_2[Pt^{II}Cl_4]$ and $[Pt^0(PPh_3)_4]$ are 73.4 and 71.6 eV, respectively].[14] Thus, the XPS results do not provide the clear-cut information about formal oxidation states hoped for.

Table 1: The XPS data of **1**.

	Line C1s	Pt4f(7/2)	Cl2p(3/2)	Ga2p(3/2)	Ga3d
BE [eV]	284.7 285.6	72.9	199.7 200.4	1120.0	22.2

To shed some further light on the formal oxidation states of the metal centers in **1**, quantum chemical calculations were performed for a series of model compounds. $[(C_6H_6)_2Pt–Ga_2Cl_5]^+$ was chosen as a simplified model of **1** as it essentially represents the cation in **1** terminated by an extra chloride ion, instead of a second $(C_6H_6)_2Pt$ entity, and chrysene molecules replaced by more simple η^2-coordinated benzene molecules. The Natural Bond Order (NBO) charge of platinum in the geometrically optimized model was calculated to be +0.27 at the B3LYP level. This is larger than that found in the isolated, neutral $(C_6H_6)_2Pt$ entity (+0.14) but significantly smaller than that in a formal platinum(II) compound such as $[PtCl_4]^{2-}$ (+0.48). The corresponding $[(C_6H_6)_2Pt]^{2+}$ unit, which thus contains two electrons less, displays a Pt charge of +0.73. The corresponding NBO charge of the gallium atom directly connected to platinum is +1.04 and of the one furthest away

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

+1.17. Both values are close to those found in compounds with formal gallium(III) (viz. +1.12 in $[GaCl_4]^-$). These results confirm the assignment of both gallium atoms in **1** as gallium(III). The optimized Pt–Ga distance obtained is 241.8 pm, which is slightly longer than the experimentally obtained. The closest Pt–C distances range from 228 to 232 pm.

Susceptibility measurements of **1** show the compound to be diamagnetic, thus ruling out a qualitative electron transfer from platinum to the chrysene ligands to give a formal platinum(II) center and anionic arene ligands. Logically, therefore, the platinum centers must be formally assigned as platinum(0).

The bonding situation in known compounds with a platinum(0)–gallium(I) interaction closely resembles that in $[Ni(CO)_4]$. The platinum(0) center is surrounded by neutral phosphine and/or cyclopentadienylgallium(I) entities in a quasi-tetrahedral fashion,[4–8] and the bonding can be described in terms of a perturbed T_d symmetry involving both σ- and π-bonding.[15–17] In a series of such compounds, quantum chemical calculations have been used to assign the NBO charge on Pt to about −0.6. Gallium typically displays an NBO charge from +0.5 to +0.7, substantially lower than in the model of **1**.

The bonding situation in **1** is clearly different, and the platinum(0)–gallium(III) interaction is best described as dative, similar to that between Cl^- and gallium(III), and the similar Pt–Ga separation observed must be simply a coincidence.

The presence of hydride ligands bound to platinum and/or gallium atoms can also formally be proposed. However, neither chemical, structural, or spectroscopic, nor theoretical results give any support to the presence of hydride ligands in **1**.[18] As a bonus, it should be noted that the title compound contains the first example of a structurally characterized decachlorotrigallate anion, whose existence has only been shown by spectroscopic techniques until now.[19]

The nature of the reducing agent in this system is not clear, although two possibilities can be proposed. First of all, chrysene can be oxidized by gallium(III) chloride (presumable products are chlorinated chrysenes and/or products of chrysene polymerization) and thereby chrysene may act as the reductant. However, the Pt:Ga:chrysene molar ratio is 1:2:1, which means that no excess of chrysene was used. The solvent, 1,2,4-trichlorobenzene, can also be chlorinated, but, as noted earlier,[1] chlorinated benzene–$GaCl_3$ systems are inert with respect to the reduction of platinum-group metal chlorides.

The reactions between $PtBr_2$ and $GaBr_3$, $PtCl_2$ and $AlCl_3$, and $PtBr_2$ and $AlBr_3$ in the presence of chrysene in 1,2-dichlorobenzene were also studied. In spite of the formation of deeply colored solutions, no crystals could be isolated. Attempts to obtain the analogous palladium compounds were unsuccessful, both in the gallium and aluminum halide systems.

In conclusion, this work describes the one-step synthesis of a platinum(0)–gallium(III) compound from readily available $PtCl_2$. The complex, with two Pt–Ga bonds, contains platinum chrysene units and Ga_3Cl_{10} groups, the latter of which have been crystallographically confirmed for the first time.

Experimental Section

General: $GaCl_3$ (Aldrich, 99.99%), $GaBr_3$ (Alfa Aesar, 99.999%), $PtCl_2$ (Aldrich, 99.9+%), $PtBr_2$ (Alfa Aesar, 99.9%) $AlCl_3$ (Alfa Aesar, 99.985%), $AlBr_3$ (Alfa Aesar, 99.998%), $PdCl_2$ (Alfa Aesar, 99.999%), $PdBr_2$ (Aldrich, 99%), and chrysene (Aldrich, 98%) were used as received. 1,2,4-Trichlorobenzene (Aldrich, 99%) and 1,2-dichlorobenzene (Fluka Chemika, ≥99%) were dried over molecular sieves. All experiments were performed in a glove box under an inert atmosphere of deoxygenated and dried nitrogen (< 1 ppm H_2O and O_2).

XPS spectra were recorded with a Kratos Axis Ultra electron spectrometer fitted with a monochromatic $Al_{K\alpha}$ source operating at 180 W. The BE scale was referenced to the C 1s line of *p*-quaterphenyl (284.7 eV). The uncertainty in the BE values is ±0.1 eV, and ±10% in atomic ratios. Processing of the spectra was accomplished with Kratos software. Special care (glove bag) was taken during transfer of the air-sensitive samples for analysis by ensuring a dry nitrogen atmosphere. The samples were pre-cooled and XPS analyses were carried out at liquid-nitrogen temperature.

NMR spectra were obtained on a Bruker AMX 500 MHz spectrometer. The spectra were recorded at 300 K in 1,2,4-trichlorobenzene solution under an inert atmosphere.

1: 1,2,4-Trichlorobenzene was added to a solid mixture of $PtCl_2$ (30 mg, 0.113 mmol), $GaCl_3$ (40 mg, 0.226 mmol), and chrysene (26 mg, 0.113 mmol). The mixture was stirred for 15 min. A red crystalline product was obtained after 4–5 weeks. Crystals of **1** are unstable: 2–3 weeks after their formation most of the crystals had decomposed, even in the dark and when in contact with the mother liquor.

Quantum chemical calculations were performed at the Hartree–Fock and hybrid density functional level (B3LYP) using the Gaussian 98 program package.[20] Basis sets for H, C, and Cl were of 6-31G quality supplemented with additional diffuse and polarization functions. Valence basis sets for Ga and Pt were fully noncontracted of (7s6p6d) and (8s7p6d1f) quality, respectively. Quasi-relativistic effective core potentials replaced 18 and 60 electrons for Ga and Pt, respectively.[21] Natural Bond Order populations were evaluated using the integrated Gaussian NBO version 3.1.

[18] From a chemistry point of view, the co-existence of gallium(III) and a hydride in the cation of **1** is highly unlikely. Both the Lewis acidity and reduction propensity of gallium(III) would most likely lead to direct reaction. The X-ray structure analysis supplied no indications of the presence of hydride ligands in **1**. A solution of **1** in 1,2,4-trichlorobenzene shows no hydrides in the negative chemical-shift region in the ^{1}H NMR spectrum. In addition, the introduction of hydrides into the theoretical model to give $[(C_6H_6)_2Pt(H_2)Ga_2Cl_5]^+$, with a formal platinum(II)and hydrides initially placed as bridging atoms along the Pt–Ga bond (which is the structurally most elusive position), gave rise to an extraction of one hydride by the $[Ga_2Cl_5]^+$ entity to give a neutral Ga_2Cl_5H molecule that is well separated from platinum, thus highlighting the expected Lewis acidity of gallium(III).

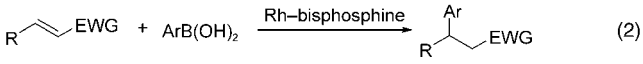
Asymmetric Catalysis



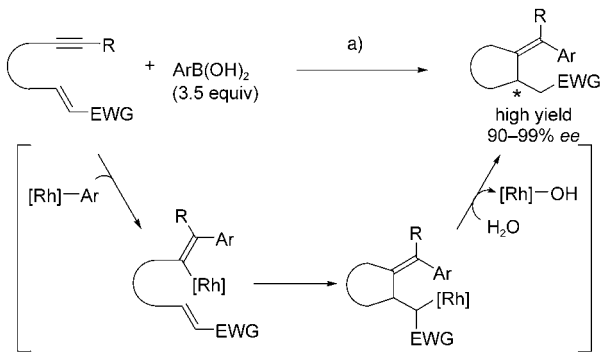
Highly Chemo- and Enantioselective Arylative Cyclization of Alkyne-Tethered Electron-Deficient Olefins Catalyzed by Rhodium Complexes with Chiral Dienes**

*Ryo Shintani, Akihiro Tsurusaki, Kazuhiro Okamoto, and Tamio Hayashi**

Multiple carbon–carbon bond-forming reactions catalyzed by transition metals are a powerful method for the construction of structurally complex molecules in a convergent manner from relatively simple precursors.[1] Compounds that bear two or more electrophilic sites at appropriate positions are potentially useful for the preparation of complex cyclic materials by sequential addition and cyclization of nucleophiles in a cascade manner.[2,3] However, if these electrophilic sites are all reactive toward the incoming nucleophile, chemoselectivity of the initial nucleophilic attack becomes an important issue. In this context, alkyne-tethered electron-deficient olefins should be an interesting class of substrates, as both internal alkynes[4] and electron-deficient olefins[5] are good electrophiles in a rhodium–bisphosphine-catalyzed addition of aryl boronic acids [Eq. (1) and Eq. (2); EWG = electron-withdrawing group]. Herein, we describe how a rhodium–diene catalyst, rather than a rhodium–bisphosphine catalyst, can effectively catalyze an arylative cyclization of alkyne-tethered electron-deficient olefins with high chemoselectivity, and that high enantioselectivity can also be attained by the use of chiral diene ligands in this process (Scheme 1).

(1)

(2)



In an initial investigation, we employed alkyne-tethered enoate **1a** as a model substrate in combination with $PhB(OH)_2$ to examine the effect of the ligand in the presence of 6 mol% rhodium (Table 1). Although the reaction proceeds smoothly when (*S*)-binap is used as a ligand, a mixture

Scheme 1. a) [{RhCl(C_2H_4)$_2$}$_2$] (6 mol% Rh), (*S*,*S*)-Bn-bod* (6.5 mol%), KOH (0.3 equiv), dioxane/H_2O (10:1), 60°C, 4 h.

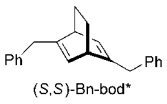

Table 1: Rhodium-catalyzed asymmetric arylative cyclization of model substrate **1a**: effect of the ligand.[a]

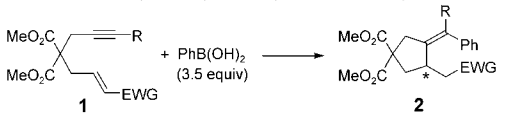
1a

	Yield [%]		
	2a	**3a**	**4a**
(*S*)-binap	23 (95% *ee*)	22	45
dppf	3	9	32
(*S*,*S*)-Bn-bod*	83 (99% *ee*)	5	5
cod	72	3	8

[a] Conditions: [{RhCl(C_2H_4)$_2$}$_2$] (6 mol% Rh), ligand (6.5 mol%), KOH (0.3 equiv), dioxane/H_2O (10:1), 60°C, 4 h. (*S*)-binap = 2,2′-bis(diphenylphosphino)-1,1′-binaphthyl, dppf = 1,1′-bis(diphenylphosphino)ferrocene, cod = cycloocta-1,5-diene.



(*S*,*S*)-Bn-bod*

of three different phenylated products (**2a**, **3a**,[6] and **4a**) are obtained rather nonselectively (23, 22, and 45% yields, respectively). The use of other bisphosphine ligands such as dppf leads to somewhat lower reactivity (51% conversion), which tends to give 1,4-adduct **4a** as the major product. In contrast, the use of chiral diene ligand (*S*,*S*)-Bn-bod*[2f,7] dramatically changes the course of the reaction and preferentially leads to product **2a**, which is obtained in 83% yield and with 99% *ee* (compare with 95% *ee* when (*S*)-binap is used), with a small amount of **3a** and **4a** (5% yield for each) also formed. The employment of other diene ligands such as cod also provides compound **2a** as the major product.

Under these conditions with Rh(*S*,*S*)-Bn-bod* as a catalyst, several alkyne-tethered electron-deficient olefins can be successfully used as shown in Table 2. Thus, not only methyl or ethyl esters (entries 1–3) but also phenyl ketone (entry 4) can be employed as an electron-withdrawing group

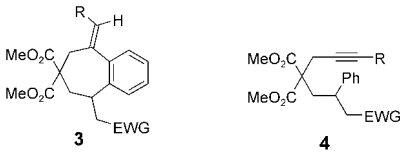


Table 2: Rhodium-catalyzed arylative cyclization: scope of substrate **1**.[a]

1 **2**

Entry	Substrate	R; EWG	Yield [%][b]	*ee* [%][c]	$[\alpha]_D^{20}$ (in $CHCl_3$)

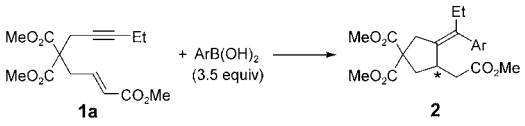
2	**1b**	Me; CO_2Me	86	99	−67.0 (*c* = 0.97)
3	**1c**	Et; CO_2Et	89	99	−73.5 (*c* = 1.02)
4	**1d**	Et; COPh	87	90	−90.2 (*c* = 1.45)

[a] Conditions: [{RhCl(C_2H_4)$_2$}$_2$] (6 mol% Rh), (*S*,*S*)-Bn-bod* (6.5 mol%), KOH (0.3 equiv), dioxane/H_2O (10:1), 60°C, 4 h. [b] Contaminated with up to 10% of **3** and **4** (≈1:1) in all cases. [c] *ee* values were determined by HPLC on a chiralpak AD-H column.

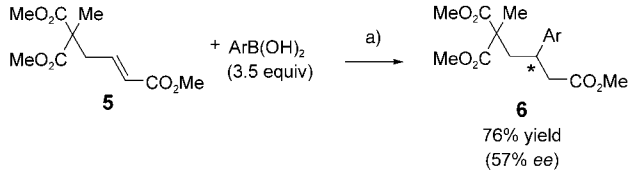


3 **4**

on the olefin to furnish five-membered carbocycles with high chemo- and enantioselectivities (90–99% *ee*).

With respect to the scope of the nucleophilic component, sterically and electronically diverse arrays of aryl boronic acids can be used under the same conditions to afford the five-membered products uniformly with high chemoselectivity and with excellent enantioselectivity (Table 3; 97–99% *ee*).

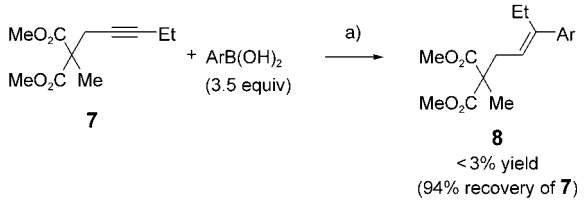
Table 3: Rhodium-catalyzed asymmetric arylative cyclization: scope of the aryl boronic acid.[a]



1a **2**

Entry	Ar	Yield [%][b]	*ee* [%][c]	$[\alpha]_D^{20}$ (in $CHCl_3$)
1	Ph	93	99	−65.8 (*c* = 0.97)
2	4-MeC_6H_4	87	99	−87.7 (*c* = 1.11)
3	4-$MeOC_6H_4$	86	99	−90.9 (*c* = 1.14)
4	4-FC_6H_4	88	97	−72.5 (*c* = 1.28)
5	3-ClC_6H_4	84	99	−77.4 (*c* = 1.29)
6	3,5-$Me_2C_6H_3$	83	99	−63.5 (*c* = 1.07)
7	2-naphthyl	80	98	−82.8 (*c* = 0.94)

[a] Conditions: [{RhCl(C_2H_4)$_2$}$_2$] (6 mol% Rh), (*S*,*S*)-Bn-bod* (6.5 mol%), KOH (0.3 equiv), dioxane/H_2O (10:1), 60°C, 4 h. [b] Contaminated with 7–11% of **3**/**4** (≈1:1) in all cases. [c] *ee* values were determined by HPLC on a Chiralpak AD-H column.



To gain insight into the origin of the difference in chemoselectivity between rhodium–bisphosphine and rhodium–diene catalysts in these arylative cyclization reactions, we conducted the following experiments. Reaction of α,β-enoate **5** with an aryl boronic acid (Ar = 3,5-$Me_2C_6H_3$) in the presence of 6 mol% Rh–(*S*)-binap produced the corresponding 1,4-adduct **6** in 76% yield (Scheme 2). In contrast, the use of alkyne **7** as a substrate under Rh–(*S*)-binap catalysis resulted in 94% recovery of **7** with almost no formation of

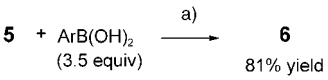
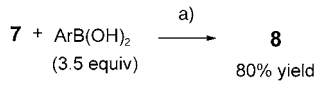


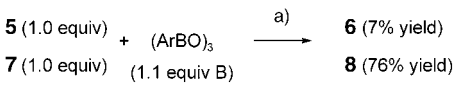
Scheme 2. a) [{RhCl(C_2H_4)$_2$}$_2$] (6 mol% Rh), (*S*)-binap (6.5 mol%), KOH (0.3 equiv), dioxane/H_2O (10:1), 60°C, 4 h.

arylated product **8** (Scheme 3). Compared to these results, both α,β-enoate **5** and alkyne **7** reacted with the aryl boronic acid (Ar = 3,5-$Me_2C_6H_3$) in the presence of 6 mol% Rh–cod



Scheme 3. a) [{RhCl(C_2H_4)$_2$}$_2$] (6 mol% Rh), (*S*)-binap (6.5 mol%), KOH (0.3 equiv), dioxane/H_2O (10:1), 60°C, 4 h.

catalyst to furnish the corresponding arylated products **6** and **8** in over 80% yield (Scheme 4 and Scheme 5). To distinguish the reactivity between the two, we conducted a competition



Scheme 4. a) [{RhCl(cod)}$_2$] (6 mol% Rh), KOH (0.3 equiv), dioxane/H_2O (10:1), 60°C, 4 h.

Scheme 5. a) [{RhCl(cod)}$_2$] (6 mol% Rh), KOH (0.3 equiv), dioxane/H_2O (10:1), 60°C, 4 h.

experiment using a 1:1 mixture of **5** and **7** with 1.1 equivalents of aryl boron species (Ar = 3,5-$Me_2C_6H_3$) in the presence of 6 mol% Rh–cod (Scheme 6). Under these conditions, α,β-enoate **5** was recovered in 90% yield and alkyne **7** was completely comsumed to give product **8** in 76% yield. These results indicate that a Rh–bisphosphine catalyzes the 1,4-addition of α,β-enoates more effectively than the arylation of alkynes, and that a Rh–diene catalyst displays higher activity

Scheme 6. a) [{RhCl(cod)}$_2$] (6 mol% Rh), KOH (0.3 equiv), dioxane/H_2O (10:1), 60°C, 4 h.

in the arylation of alkynes than in the 1,4-addition of α,β-enoates. This conclusion should partially explain the observed high chemoselectivity in the arylative cyclization of **1** with a rhodium–diene catalyst.[8]

In summary, we have developed a rhodium-catalyzed arylative cyclization of alkyne-tethered electron-deficient olefins with aryl boronic acids, and high chemo- and enantioselectivities have been observed by the use of a chiral diene ligand. We hope to further develop chiral diene ligands and their application to various transition-metal-catalyzed asymmetric processes.

Experimental Section

Procedure for Table 1: An aqueous solution of KOH (0.3 M in H_2O; 0.2 mL, 60 μmol) was added to a solution of [{RhCl(C_2H_4)$_2$}$_2$] (2.3 mg, 12 μmol Rh) and ligand (13 μmol) in 1,4-dioxane (1.0 mL), and the mixture was stirred for 5 min at room temperature. $PhB(OH)_2$ (85.4 mg, 0.70 mmol) and **1a** (59.3 mg, 0.20 mmol) were then added along with additional 1,4-dioxane (1.0 mL), and the resulting solution was stirred for 4 h at 60°C. The reaction mixture was directly passed through a pad of silica gel with Et_2O, and the solvent was removed under vacuum. The residue was purified by preparative TLC (silica gel) with a mixture of Et_2O/hexane (1:1) as eluent.

With (*S*)-binap as ligand, a mixture of **2a**, **3a**, and **4a** (26:24:50, as determined by ^{1}H NMR spectroscopy) was obtained as a pale yellow oil (67.7 mg, 90% combined yield). The *ee* value for **2a** was determined on a Daicel Chiralpak AD-H column with hexane/2-propanol (90:10) and a flow rate of 0.3 mL min^{-1}. Retention times: 29.8 min ((+)-enantiomer) and 33.5 min ((−)-enantiomer, 95% *ee*).

With (*S*,*S*)-Bn-bod* as ligand, a mixture of **2a**, **3a**, and **4a** (90:5:5, as determined by ^{1}H NMR spectroscopy) was obtained as a yellow oil (69.5 mg, 93% combined yield). **2a**: 99% *ee*; $[\alpha]_D^{20} = -65.8$ ($c = 0.97$, $CHCl_3$).

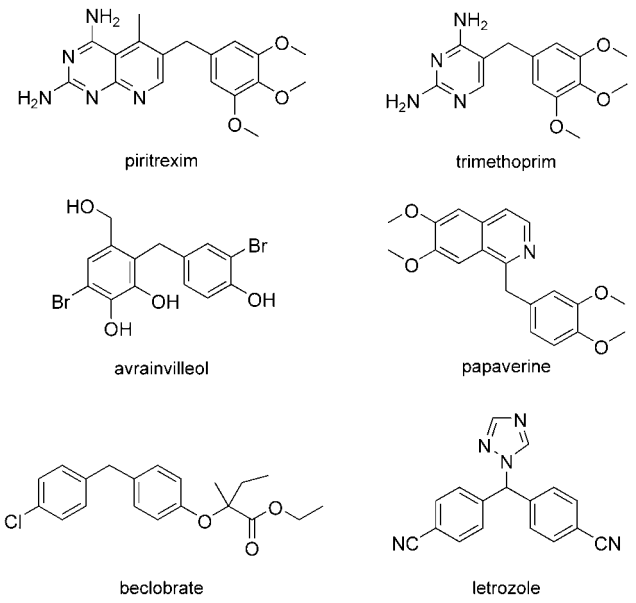
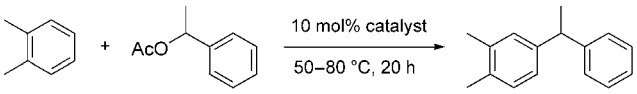
Arene Functionalization



An Efficient and General Iron-Catalyzed Arylation of Benzyl Alcohols and Benzyl Carboxylates**



*Irina Iovel, Kristin Mertins, Jette Kischel, Alexander Zapf, and Matthias Beller**

Dedicated to Professor Dirk Walther on the occasion of his 65th birthday

Functionalized arenes and heteroarenes are of outstanding importance as pharmaceuticals, agrochemicals, fine and bulk chemicals. Hence, the development of environmentally benign C–C coupling reactions of arenes is an important topic of organometallic chemistry and catalysis. Elegant examples of direct C–H transformations of arenes[1] include the addition of olefins to acetophenones (Murai reaction)[2] and aromatic imines,[3] novel additions of olefins to electron-rich arenes[4] and heterocycles,[5] the addition of aromatics to alkynes,[6] the carbonylation of heterocycles,[7] and the cyclization of arene–alkyne substrates[8] as well as the C-arylation of heteroarenes.[9] In addition, recently significant progress has been seen in Friedel–Crafts-like alkylations[10] in which the use of lanthanide and actinide triflates[11] as well as heterogeneous catalysts[12] is especially noteworthy. Very recently we demonstrated that also various late-transition-metal salts, such as $IrCl_3$, $RhCl_3$, or H_2PtCl_6, are capable of catalyzing the addition of benzyl acetates to arenes and heteroarenes with high yield and selectivity under ambient conditions.[13,14] The resulting diarylmethane motif is an integral part of a number of biologically active compounds and pharmaceuticals such as piritrexim, trimethoprim, avrainvilleol, papaverine, beclobrate, or letrozole. In addition, diarylmethanes are utilized for the preparation of fluorenyl-based electroactive and photoactive oligomers and polymers.[15]

Although the selectivity of our recently developed procedure is often good to very good, to date a significant amount (5–10 mol%) of an expensive late-transition-metal catalyst has to be applied. Thus, we are interested in alternative, more practical catalyst systems, which can be used in the synthesis of all types of diarylmethanes. In looking for new and improved catalysts the reaction of *o*-xylene and 1-phenylethyl acetate was studied as a model reaction. The performance of different Brønsted acids and transition-metal salts was compared without additional solvent at 50–80 °C (Scheme 1). With regard to the catalyst, our attention focused in this study mainly on inexpensive and relatively nontoxic metal salts based on Fe, Cu, Co, Zn, and Mn. Table 1 shows a summary of the results.

Scheme 1. Reaction of *o*-xylene with 1-phenylethyl acetate.

Table 1: Reaction of *o*-xylene with 1-phenylethyl acetate (Scheme 1).[a]

Entry	Catalyst	Conversion [%]	Yield of **1** [%] (Regioselectivity[b])
1	HCl	5	0

While in the presence of catalytic amounts (10 mol%) of various Brønsted acids (HCl, HOAc, *p*-toluenesulfonic acid) no or only low yields (<2%) of the product 1-(3,4-dimethylphenyl)-1-phenylethane (**1**) are obtained (Table 1, entries 1–3), iron(III) salts proved to be excellent catalysts for the test reaction (Table 1, entries 13–15).[16] The best results (>99% of **1**) are obtained in the presence of $FeCl_3$ (Table 1, entries 13, 14). Advantageously, even hydrated $FeCl_3$ can be used under mild conditions (50°C) and the reaction is not sensitive towards air or moisture. Although screening reactions have been run for convenience for 20 h, it is noteworthy that the reaction with $FeCl_3$ is finished within 1 h at 80°C. With other metal salts a significant difference between the conversion and the yield of **1** is observed in some cases. In these reactions, side-reactions of 1-phenylethyl acetate, such as elimination of acetic acid to give styrene that then undergoes oligomerization and polymerization, took place.

We were interested in the reactivity of different arenes and heteroarenes (Table 2). However, only the most active and selective catalyst ($FeCl_3$) was tested. As expected a variety of electron-rich aromatics, such as toluene, anisole, 1,4-dimethoxybenzene, 1-methylnaphthalene, 1,3-dimethylnaphthalene, 2-naphthol (all >99% yield), and 1,4-xylene (97%), gave the corresponding products in excellent yields. In addition, heteroarenes, such as 2-methylthiophene, 2,5-dimethylthiophene (>99%), 2,5-dimethylfuran (87%), and 2-acetylfuran (92%), react very well.

Even non-activated substrates, for example, benzene (50%) and functionalized starting materials, such as 4-bromophenol (86%), 2- and 4-chloroanisole (>99%), 2-

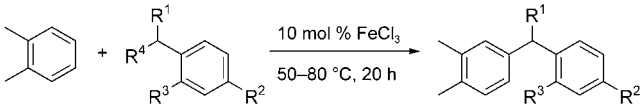
bromoanisole (97%), 2-iodoanisole (88%), and also 2-methoxybenzaldehyde (93%) and methyl 4-methoxybenzoate (>99%), gave the corresponding products highly selectively. Note that this reaction catalyzed by $FeCl_3$ is one of the few successful Friedel–Crafts alkylations which work well also with non-activated arenes, and entry 15 (Table 2) constitutes one of the rare cases of a selective Friedel–Crafts reaction in the presence of an aldehyde group.



The scope and limitation of the benzylation reagent are shown in Table 3 in more detail: as well as 1-phenylethyl acetate, also benzyl alcohol, benzyl acetate, benzyl chloride, benzyl methyl carbonate, 1-phenylethanol, 1,1-diphenylmethanol, 4-chlorobenzyl acetate, 2,4-dichloro- and 2,4-difluorobenzyl alcohol react with *o*-xylene in the presence of $FeCl_3$ at 80°C (Table 3, entries 1–10). In all cases the corresponding products are obtained in good to excellent yields (96 to >99%). To our surprise there is basically no difference between the reaction of benzyl acetate and benzyl alcohol, although in the latter case stoichiometric amounts of water are produced which are expected to deactivate the catalyst.

Applying 4-methoxybenzyl acetate, 2-(hydroxymethyl)-thiophene, or 5-(hydroxymethyl)-2-furfural the desired products are observed in somewhat lower yields (66, 61, and 37%, respectively) owing to "self-arylation" of the benzylating reagent (Table 3, entries 11–13). In general, the regioselectivity of the reaction is good to excellent (89 to >99%). However, in a few cases applying halogen derivatives and heterocyclic reagents the regioselectivity is somewhat lower (62–75%). From a standpoint of general applicability it is interesting to note that the method allows for the use of benzyl alcohols or acetates which are functionalized in the benzylic position (Scheme 2). Hence, easily available aromatic cyanohydrins can be arylated despite the decreased stability of the intermediate carbocation (Table 3, entry 14). To our knowledge this is the first example of such an arylation reaction. Another example for a functionalized substrate is ethyl 3-phenyl-3-hydroxypropanoate, which yields the corresponding 3,3-diarylpropanoate in 98% yield (Table 3, entry 15).

Table 3: Variation of the benzylating agent in the reaction with o-xylene (Scheme 2).[a]

Scheme 2. Reaction of *o*-xylene with different benzylating reagents.

In summary, we have developed a general method for the arylation of benzyl carboxylates and benzyl alcohols. Using iron catalysts[17] an easy and practical synthesis of many kinds of diarylmethanes and arylheteroarylmethanes is possible. Typically reactions proceed under mild conditions (50–80°C, without strong acid or base) and it is not necessary to exclude air or moisture. Of special importance is the tolerance of a wide variety of functional groups, such as CHO, CO_2R, I, Br, Cl, F, OH, OMe, as well as the thiophene and furan derivatives, which is a rare feature of Friedel–Crafts-type chemistry. Using benzyl alcohols this arylation method is a state-of-the-art green route to diarylmethanes, because water is the only side-product in this transformation.

Experimental Section

General: All reactions were carried out without any special precautions against air. ^1H and ^{13}C NMR spectra were recorded on a Bruker ARX 400 spectrometer. Chemical shifts (δ) are given in ppm and refer to the residual solvent as the internal standard. Gas chromatography was performed on a Hewlett Packard HP 6890 chromatograph with a HP5 column. Mass spectra were recorded on an AMD 402/3

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

mass spectrometer. Chemicals and solvents were purchased from Fluka or Aldrich and used as received.

Benzylation of *o*-xylene: In a pressure tube, 1-phenylethyl acetate (0.5 mmol) and catalyst (10 mol%, 0.05 mmol) were dissolved in *o*-xylene (5 mL). Then hexadecane or decane (50 μL) was added as internal GC standard. After stirring for 20 h at 80 °C aliquots were taken from the reaction mixture and subjected to GC analysis for determination of yield and conversion. For isolation of the products the reaction was quenched with water. The water phase was extracted with dichloromethane. The combined organic layers were dried over $MgSO_4$ and the solvents were distilled off. The product was purified by silica gel column chromatography (70–230 mesh, *n*-heptane/ethyl acetate (50:1)).

^{1}H NMR (400 MHz, $CDCl_3$, 25 °C): $\delta = 1.5$ (d, ^3J(H,H) = 7.2 Hz, 3H; $CHCH_3$), 2.1 (s, 6H; $2ArCH_3$), 4.0 (q, ^3J(H,H) = 7.2 Hz, 1H; CH), 6.9–7.2 ppm (m, 8H; CH aromat.); ^{13}C NMR (101 MHz, $CDCl_3$, 25 °C): $\delta = 18.3$, 18.8, 20.9, 43.2, 123.8, 124.8, 126.5, 127.3, 127.9, 128.6, 133.1, 135.4, 142.8, 145.6 ppm; MS (70 eV): *m*/*z* (%): 210 (40) [M^+], 195 (100) [$C_{15}H_{15}^+$], 91 (10) [$C_7H_7^+$].

Analysis of X-ray Data

Cluster Disorder and Ordering Principles in Al-Stabilized "LaI"**

*Oliver Oeckler, Thomas Weber, Lorenz Kienle, Hansjürgen Mattausch, and Arndt Simon**

Diffuse X-ray scattering is frequently dismissed in conventional structure analyses. However, it contains valuable information in many respects, particularly concerning the chemical constitution of a crystal. Most investigations on diffuse scattering so far have been restricted to qualitative discussions, trial-and-error simulations, and analytical Fourier calculations.[1] The quantitative measurement of the continuous intensity distribution in reciprocal space has become routinely feasible with the advent of area detectors. As computing power is still a bottleneck for complex numerical methods, quantitative structure refinement against diffuse data has been performed in only a few investigations.[2] Such refinements will become more and more accessible in the future. Here we present a case where only the refinement against diffuse scattering data led to detailed insight into the chemical nature of a compound.

Some time ago the preparation and structure of LaI was described in this journal.[3] It crystallizes in the hexagonal NiAs structure type. Now we have found a phase with the approximate composition $(La_{1-x}Al_x)I$ ($x < 0.15$) for which on the basis of sharp Bragg reflections a NaCl-type structure ($a =$ 6.323 Å) can be refined down to $R \approx 5\,\%$.[4] In spite of the convincing value, this structural characterization is incomplete and even misleading. A correct structural model can be derived only by taking into account the pronounced diffuse scattering that shows up as sections of hollow spheres in Figure 1.

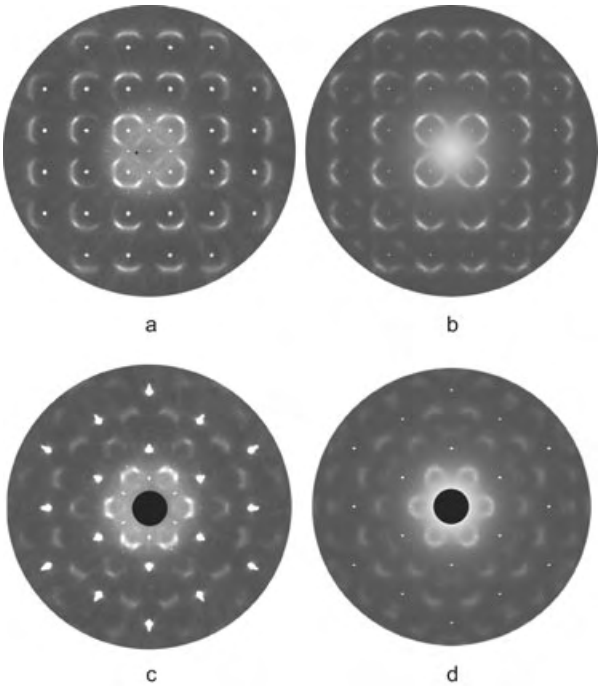

Figure 1. Experimental (a, c) and calculated (b, d) X-ray diffraction patterns for $La_{\approx 0.7}I_{1-x}Al_x$ ($x \approx 0.14$); first layer perpendicular [100] (a, b) and zero layer perpendicular [111] (c, d). The calculated images are based on the best refinement result.

A hint to the correct interpretation of the diffraction data comes from the extended cluster chemistry of the rare-earth metals.[5] Their metal-rich halides are composed of discrete or condensed clusters, and the M_6X_{12}-type cluster stabilized by an endohedral atom Z is frequently observed. The $M_6X_{12}Z$ entity can be viewed as a section of the rock-salt structure.[6] Hence, one way of addressing the disorder problem is to start from a hypothetical NaCl-type LaI, in which some iodine atoms are replaced by endohedral atoms Z = Al, and the La atoms that are not part of the La_6Al units are removed. If we assume the presence of such $La_6I_{12}Al$ clusters[7] in the title compound, the occurrence of structured and narrow diffuse scattering indicates their nonrandom distribution, which is quite common with metal-rich cluster compounds of lanthanoids and other elements.[8]

Some conclusions can be drawn from the qualitative analysis of the diffuse intensity. Generally speaking, the presence of spheres and their location only around odd Bragg reflections can be interpreted as due to some spherical modulation[9] characterized by the complementary behavior of cation and anion sites, and the higher intensity on the large-

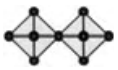
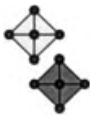
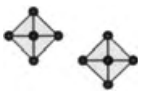
angle side indicates lattice distortions due to a "size effect",[10] where a smaller structural motif (e.g. a cluster) is a stronger scatterer than a larger structural motif. However, from these and other possible qualitative considerations no reliable statements can be made concerning the kind of chemical entities, their interconnection, and their nonrandom arrangement. Here we demonstrate a quantitative structure solution by a new, very efficient evolutionary algorithm.[2a,11]

The first important step is the modeling of the disorder with a realistic atom arrangement using as few parameters as possible, because diffuse data contain limited information and precision in comparison to Bragg data. A (defect-)NaCl-type structure can be derived starting from a *fcc* lattice of I atoms by statistically substituting a variable number of atoms (11–15%) by La_6Al units to create a set of 80 different structures, each defined by a specific set of parameters. In Monte Carlo (MC) calculations we used a set of 13 parameters, including "interaction energies" for edge- and corner-sharing octahedrons and all possible relative cluster positions up to a distance of 13.4 Å. Furthermore, the cluster concentration and local relaxation around vacancies and interstitial atoms are parameters of the disorder model obtained by "energy minimization" with respect to the specific parameter set.







The pixelwise comparison of the scattering intensities calculated for these model structures with observed intensities is quantified by an *R*-factor for each structure ("individual"). Then the next generation of structures strictly related to the specific parents, and hence comprising the same number of individuals as the starting set, is created by admixing a certain percentage of another parent's parameter set, and those members of the new generation are dismissed whose structures lead to an inferior fit with the experimental data. In a later generation the calculation converges to a set of statistically identical structures which optimally represents the experimental scattering pattern. This final structure model is analyzed in terms of the structural features actually present.[12]

Figure 2 illustrates that the final structure model exhibits a uniform cluster distribution in contrast to the random arrangement for the refined cluster concentration x. This refinement yields $x = 0.136$ and the chemical formula $La_{0.69}I_{0.86}Al_{0.14}$, which is confirmed by chemical analyses. The deviation of La and I atoms from the ideal NaCl-type positions as refined from diffuse data is in good agreement with the corresponding numbers derived from Bragg data;[13] however, now the displacements can be interpreted directly in terms of a contraction of the clusters. The cluster geometry is in very good agreement with that of $La_6I_{12}Al$ or related clusters in other compounds.[7]

Based on this result, a reasonable interpretation of Bragg data can be obtained, too, in a constrained refinement[14] assuming one anion site with x Al and $(1-x)$ I and implying La_6Al octahedrons by placing $6x$ La on the cation site. In accordance with the result from diffuse data, x amounts to 0.110(1). However, information on the interconnection of clusters can *only* be derived from the final structure model.

From Table 1 we conclude that edge- or corner-sharing octahedrons are very unfavorable in this compound as their frequency amounts to 49% and 31%, respectively, of the random arrangement. Double octahedrons have been frequently observed in other systems;[5a,d] however, the present disordered NaCl-type matrix obviously cannot adjust to the high degree of strain induced by the contraction due to metal–metal bonding in such an entity. Configurations that do not allow complete relaxation are observed less frequently, and the tendency to avoid local strain is evident from the most favorable relative cluster position in which the centers are on opposite corners in the [111] direction of the NaCl cell as shown in Figure 3. Short La–I contacts are avoided (3.16 Å in the average NaCl structure instead of 3.28–3.40 Å in comparable compounds) both by contraction of the La_6 unit as well as by displacement of the I atoms towards the void.

Table 1: Comparison of relative cluster positions (characterized by lattice vectors corresponding to a NaCl unit cell) for a) random cluster distribution with $x = 0.136$ before MC calculation and b) the final model crystal. The frequencies of intercluster arrangements are denoted n_i for (a) and n_f for (b).

Relative cluster positions		n_i	n_f	n_f/n_i

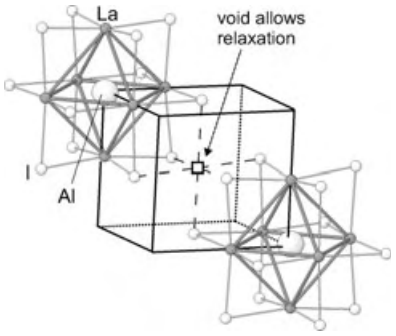

Figure 3. Pair of clusters in the relative position [111] of the average NaCl cell (cell dimensions are outlined). Short La–I distances can be avoided by both cluster contraction and displacement of I atoms towards the void.

Additional evidence for the preference of this relative cluster orientation has also been obtained from high-resolution electron microscopy (HRTEM) studies.[15] Images taken along the zone axis [111] (Figure 4) show the disordered

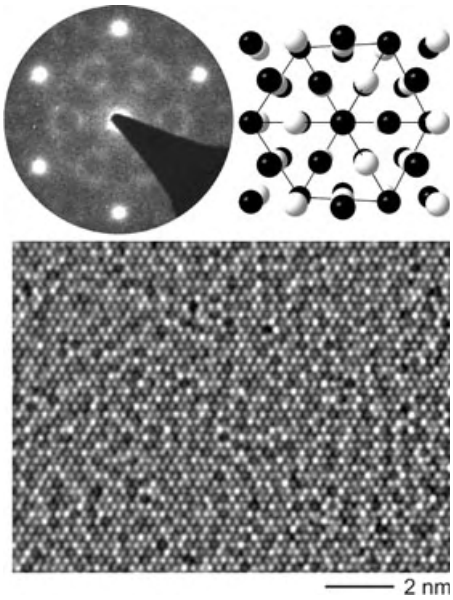

Figure 4. Electron diffraction pattern (top, left) and HRTEM image (bottom) of disordered crystal along the zone axis [111]. The hexagonal arrangement of dots results from the average symmetry of the structure along [111]. The bright and dark contrasts of the experimental image can be correlated with the projection of the real structure (top, right). Simulated images ($\Delta f = -65$) indicate that bright dots correspond to rows of the heavy atoms La and I, while dark dots indicate a sequence of these atoms replaced by Al and voids.

structure as light spots for rows of La and I, and dark spots for rows in which Al and voids alternate statistically. Prolonged exposure to the electron beam as well as long annealing times does not remove the disorder. Based on our investigations we explain this behavior as a consequence of the impossibility of the title compound to order in small unit cells with high symmetry.

However, allowing for slight compositional variations, ordered variants of this structure are sometimes observed in electron diffraction patterns (cf. Figure 5) which show the diffuse scattering to develop into superstructure reflections.

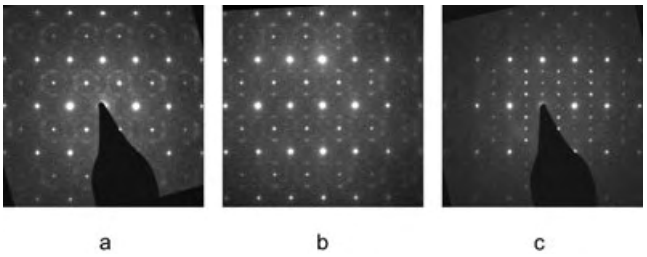

Figure 5. Electron diffraction patterns (zone axis [110]) of several crystals in one sample of the approximate composition $La_{\approx 0.7}I_{1-x}Al_x$ ($x \approx 0.14$). a) The most frequently observed pattern, corresponding to X-ray single-crystal diffraction, b) a crystallite with partial ordering, c) an ordered crystallite with a distinct superstructure.

All reasonable refinements from X-ray Bragg data[16] lead to structure models in which a certain degree of disorder remains; however, a body centering of ordered clusters in a $2\boldsymbol{a}2\boldsymbol{b}2\boldsymbol{c}$ NaCl-type cell is a feature common to all models. This partial ordering corresponds exactly to the preferred cluster arrangement in the disordered structure of the title compound.

Summing up, the title compound and its disorder can be well understood. The cluster distribution is far from a statistically random function. The *uniform* (not *random*) distribution avoids short intercluster distances which leads to an approximately harmonic radial distribution function of intercluster vectors that is reflected in the diffuse spheres. The preferred relative cluster arrangement (Figure 2) allows a unique possibility to avoid short distances in a dense packing by contraction of both Ln_6 units around endohedral Al atoms and of I_6 octahedrons around voids.

Finally, we point out that our investigation, though addressing a special system, is quite relevant to the extended structural chemistry of NaCl-type transition-metal oxides, nitrides, and carbides. They form ordered cluster structures in a few instances, for example, NbO[17] and TiO,[6a,18] and frequently show diffuse scattering effects due to local order and long-range disorder.[19]

Experimental Section

Single crystals of $La_{\approx 0.7}I_{1-x}Al_x$ ($x \approx 0.14$) were first obtained from La, LaI_3, and Al in different reactions (e.g. the nominal composition $La_3Al_2I_2$) during a systematic investigation of the La/I/Al system. EDX analyses (Tescan scanning electron microscope, Oxford EDX detector) of several crystals confirmed the given composition. The best method for obtaining pure samples was by heating a stoichiometric mixture of La, LaI_3, and AlI_3 in a tantalum ampule at 875 °C for 7 days. These samples are single phase according to X-ray powder diagrams (Stoe STADI P diffractometer, $Mo_{K\alpha}$ radiation). Since the starting materials as well as the product are very moisture sensitive, all manipulations must be carried out in a glove box or by Schlenk techniques under purified argon atmosphere. [7] Compounds are well characterized with Al-centering trigonal Ln_6 prisms (H. Mattausch, O. Oeckler, C. Zheng, A. Simon, *Z. Anorg. Allg. Chem.* **2001**, *627*, 1523). Octahedral clusters have been observed in comparable compounds, e.g. boride halides,[5a,c] and a few Al-containing octahedral clusters are known as well.

[8] Other disordered cluster compounds have been discussed, cf. for example: J. Köhler, G. Svensson, A. Simon, *Angew. Chem.* **1992**, *104*, 1463; *Angew. Chem. Int. Ed. Engl.* **1992**, *31*, 1437; O. Oeckler, L. Kienle, H. Mattausch, A. Simon, *Angew. Chem.* **2002**, *114*, 4431; *Angew. Chem. Int. Ed.* **2002**, *41*, 4257. In the latter case, a reasonable structural model was not evident from the averaged structure, but a "semiquantitative" analysis of diffuse diffraction data was successful.

[10] T. R. Welberry, *J. Appl. Crystallogr.* **1986**, *19*, 382.

[11] This algorithm mimics the principles of Darwinism (for a detailed overview, cf. Z. Michalewicz, *Genetic Algorithms + Data Structures = Evolution Programs*, Springer, Berlin, **1996**). It starts from a "population" of diverse structure models, each one characterized by its "genes", that is, a set of parameters defining a model crystal as the "phenotype". Its "fitness" corresponds to the crystallographic *R* factor based on all individual pixels of the diffraction image and not only on a set of Bragg intensities. A new generation is created from the parent population by recombination and variation ("mutation") of the parameters ("genes"). Here, we used so-called differential evolution (K. Price, R. Storn, *Dr Dobb's J.* **1997**, April issue, 18; R. Storn, K. Prince, *J. Global Optimization* **1997**, *11*, 341; and ref. [2a]) replacing parents by "fitter" children (models with better *R* factors) and discarding "unfit" members of each new generation.

[12] Refinement of the disordered structure based on diffuse data: Measurement of diffuse data: Huber four-circle goniometer, MAR345 image-plate detector, $Ag_{K\alpha}$ ($\lambda = 0.56086$ Å), graphite monochromator, $2\vartheta_{max} = 45°$, beam normal to oscillation axis and normal to detector, 492 frames, $\Delta\phi = 0.5°$/frame, reconstruction of undistorted reciprocal layers with XCAVATE (M. A. Estermann, W. Steurer, *Phase Transitions* **1998**, *67*, 165). Monte Carlo model: An initial model structure containing a random distribution of clusters was modified by swapping cluster and noncluster positions. The energy difference between the old and the new configuration was calculated based on the model parameters, and the new configuration was accepted with a probability following a Boltzmann distribution. Finally, local relaxations around vacancies and interstitial atoms were applied. Neither the cluster interaction nor the total energy can be interpreted as actual energy values, and the parameters of the structure model cannot be directly analyzed. All "interactions" are simply abstract parameters, but the result of the corresponding MC simulation bears physical significance. The model parameters were refined in analogy to T. Weber, H.-B. Bürgi, *Acta Crystallogr. Sect. A* **2002**, *58*, 526 with $f_m = f_r = 0.6$. The number of lots was subsequently increased after no improvement was found during one generation. The final results are based on 125 lots, $R(\text{final}) = 0.09$ (based on F^2).

[13] Atom shifts from Bragg data are just a mean displacement ("octahedral" split position) from the atom positions of the NaCl type: 0.25(1) Å for La and 0.22(1) Å for I. They can be compared only approximately with the results from diffuse data, which model the actual situation more clearly: an "attractive force" between Al and La yields a refined La–Al distance of 2.8 Å. A "repulsive force" between La and I (avoiding short contacts) leads to an average distance of 3.3 Å for the inner and 3.5 Å for the outer ligands. The root-mean-square displacements as obtained from the Monte Carlo modeling were 0.40 Å for La and 0.19 Å for *I* (based on diffuse data only).

[14] Refinement of the average structure of $La_{\approx 0.7}I_{1-x}Al_x$ ($x \approx 0.14$): Enraf Nonius CAD4 four-circle diffractometer, $Mo_{K\alpha}$ ($\lambda = 0.70173$ Å), $2\vartheta_{max} = 70°$, crystal dimensions $0.11 \times 0.09 \times 0.08$ mm^3, cubic, space group $Fm\bar{3}m$ (No. 225), $a = 6.323(1)$ Å, $V = 252.80(7)$ Å^3, $Z = 4$, calcd density $\rho = 5.44$ g cm^{-3}, $\mu(Mo_{K\alpha}) = 21.7$ mm^{-1}, 590 measured reflections, 48 independent ($R_{int} = 0.055$), least-squares refinement based on F^2 (G. M. Sheldrick, SHELXL-97, Program for the Refinement of Crystal Structures, Universität Göttingen, Göttingen (Germany), **1997**); *R* values [all data/data with $I > 2\sigma(I)$]: $R_1 = 0.033/0.029$, $wR_2 = 0.068/0.066$, GooF = 1.14 for 41 observed reflections [$I > 2\sigma(I)$] and 6 parameters. Further details on the crystal structure investigations may be obtained from the Fachinformationszentrum Karlsruhe, 76344 Eggenstein-Leopoldshafen, Germany (fax: (+49) 7247-808-666; e-mail: crysdata@fiz-karlsruhe.de), on quoting the depository number CSD-391280.

[15] HRTEM along several zone axes was performed with a Philips CM30 ST electron microscope (300 kV, LaB_6 cathode, Gatan multiscan CCD camera). The multislice formalism (P. A. Stadelmann, *Ultramicroscopy* **1987**, *21*, 131–146) was used for image simulations.

[16] A quantitative analysis of the diffuse data from crystals with partial long-range ordering could not be performed due to moderate crystal quality and very weak diffuse intensity as well as limited computational resources. As it is common for many partially ordered cubic structures, the space group assignment (including possible twinning) remains ambiguous in this case.

DNA–Peptide Complexes

Single-Molecule Experiments in Synthetic Biology: An Approach to the Affinity Ranking of DNA-Binding Peptides**

Rainer Eckel, Sven David Wilking, Anke Becker, Norbert Sewald, Robert Ros, and Dario Anselmetti**

Gene expression in eukaryotes is controlled at the transcriptional level by the specific binding of transcription factors to defined DNA sequences. In this way, cell growth, differentiation, and development are regulated. The possibility to influence and control cell metabolism through modified synthetic transcription factors[1–4] offers fascinating prospects for molecular cell biology in the framework of biomimetics and synthetic biology.[5,6] The design and synthesis of biologically active artificial enzymes and new protein-based materials can be investigated by the combination of bioorganic bottom-up synthesis and single-molecule affinity nanotechnology. With this approach important questions can be addressed, such as the extent to which a single recognition helix contributes to the specific binding of a complete protein to DNA, the effect that a single amino acid point mutation has upon biological specificity and affinity, and the minimal peptide sequence length to ensure binding specificity. This approach would also aid in the design of artificial proteins that contain a purely synthetic helix-turn-helix (HTH) binding motif.

In this context, it is of considerable interest to elucidate the DNA-binding specificity of synthetic peptides with a primary sequence akin to the binding domain of a transcription factor. We studied a 20-residue peptide that represents the native sequence of a binding epitope of the transcription activator PhoB (*E. coli*) and three single point mutants of this peptide.

PhoB is a transcription activator which, after phosphorylation by PhoR, binds to the phosphate box in the promoter region of the phosphate regulon *pho* and activates the expression of genes involved in phosphate metabolism.[7–9] The protein[9] consists of a regulatory phosphorylation domain in the N-terminal region (PhoB 1–127) and a DNA-binding domain in the C-terminal region (PhoB 128–229). Deletion experiments showed that PhoB 139–229 binds to double-stranded DNA and recognizes the sequence TGTCA. The NMR solution structure of the regulatory domain and the DNA-binding domain (PhoB126–229),[10] as well as the X-ray crystal structure of the complex with DNA have been reported (Figure 1a).[11] Structurally, the DNA-binding domain of PhoB belongs to the family of *winged* helix-turn-helix proteins with the topology β^1-β^2-β^3-β^4-α^1-β^5-α^2-α^3-β^6-β^7, in which the rigid turn is replaced by a loop. This family is characterized by an N-terminal four-stranded β sheet (β^1-β^2-β^3-β^4), one α helix (α^1) connected through a short β sheet (β^5) to another α helix (α^2), followed by a third α helix (α^3) and a β hairpin (β^6-β^7). The DNA-recognizing helix α^3, is amphiphilic and is connected to α^2 by a loop.[12] The β hairpin (β^6-turn-β^7) is often called the *recognition wing*.[13]

The single amino acid residues of DNA-binding peptides and proteins contribute differently to affinity and specificity. Whereas cationic side chains (Lys, Arg) often form sequence-independent ionic interactions with the phosphate backbone, the sequence information of the DNA is read through hydrogen bonds and van der Waals interactions with the peptide. Binding of the recognition helix α^3 of PhoB takes place in the DNA major groove.[11] Arg201 interacts through a hydrogen bond with the carbonyl oxygen atom of a guanine base while Arg193, His198, Arg200, and Arg203 form salt bridges with phosphate groups. Furthermore, van der Waals contacts with Thr194 and Val197 are involved in specific recognition. Arg219 in the *recognition wing* is bound to deoxyribose moieties through hydrogen bonds.

In the work reported herein, the contribution that single amino acid residues in the DNA-binding helix α^3 contribute to intermolecular affinity was investigated on the single-molecule level. We synthesized peptides in which the amino acid residues that interact with the DNA phosphate backbone in the X-ray crystal structure through salt bridges were individually exchanged by alanine (Table 1). The synthesized peptides comprised the native sequence PhoB(190–209) as well as the point-mutated peptides PhoB(190–209) R193A, PhoB(190–209) H198A and PhoB(190–209) R203A. Accord-

[a] k_{off}: dissociation rate constant for the peptide–DNA complex; x_β: molecular reaction length.

ing to CD spectroscopy measurements, all peptides exhibit an α-helical structure. N-terminal functionalized fragments of the PhoB helix α^3 were synthesized on the solid phase with 2-chlorotritylresin preloaded with a suitable linker according to the Fmoc/*t*Bu protection scheme.[14] The peptides were purified by HPLC with acetonitrile/water/TFA gradients. The interaction of the synthesized peptides with the corresponding DNA was investigated with AFM force spectroscopy.

A broad affinity range for specific molecular recognition between single binding partners from 10^{-5} M[15] to 10^{-15} M[16,17] can be investigated with single-molecule force spectroscopy. The deflection of a micro-fabricated force sensor (cantilever) is used to detect forces in the pico-Newton range. The AFM principle permits investigation of molecular binding forces under physiological conditions, and AFM force spectroscopy has found applications in the study of a variety of specific biological receptor–ligand interactions[16–22] as well as in supramolecular host–guest systems.[15] The direct investigation of specific, native protein–DNA interactions has been reported recently.[23–25]

In our studies reported herein, we applied AFM single-molecule force spectroscopy to study the specific binding between the peptides listed in Table 1 and the DNA target sequence. Each peptide was covalently immobilized to an amino-functionalized mica surface in a directed manner with the short C-terminal linker 1,8-diamino-3,6-dioxaoctane and the cross-linker BS^3 (bis(sulfosuccinimidyl)suberate; Figure 1b). This immobilization prevents unfolding of the peptide caused by physisorption on the surface. PCR-amplified genomic DNA containing the 600-bp PhoB binding motif from *E. coli* was chosen as the binding partner, and was bound to an AFM tip with a bifunctional polyethylene glycol (PEG) linker (molar mass: 3400 g mol^{-1}, corresponding to an average length of 30 nm).[26] The application of the PEG linker serves various purposes. First, it adds steric flexibility to the system and ensures that dissociation occurs far from the surface. Second, the linker facilitates the distinction between single and multiple dissociation events, and decreases non-specific adhesion. Third, the elastic stretching of the linker ensures a gradual increase in force until the point of bond rupture, and allows precise measurement of the molecular elasticity of the complex (Figure 1c). As the elasticity is determined for each rupture event individually, variations in the entropic portion of the rupture peaks are included and do not affect the statistical interpretation.

Compilation of the rupture forces to histograms and statistical analysis of the resulting force distribution yields the most probable dissociation forces at a given retract velocity. Each histogram represents the analysis of 2000 force curves; the binding probabilities given in the figures (Figure 2 and Supporting Information) refer to the ratio of rupture events divided by the total number of force curves recorded (for example, 300 binding events out of 2000 force curves results in a binding probability of 15%). The maximum of the force distribution was taken as the most probable dissociation force.

Competition experiments were performed to determine if binding between the peptides and the DNA target sequence occurs specifically. For each mutant, a series of force spectroscopy experiments in standard buffer solution (100 mM Na_2HPO_4, 50 mM NaCl, pH 7.4) was followed by a series of experiments with an excess of free binding partner (peptide or DNA) as competitor in solution. This was followed by washing the sample with standard buffer and then performing another series of experiments in standard buffer. Figure 2 shows the results of the competition for the native peptide: part (a) shows the force distribution in standard buffer solution, with a total binding probability of ≈33%; part (b) shows the competition with free peptide in

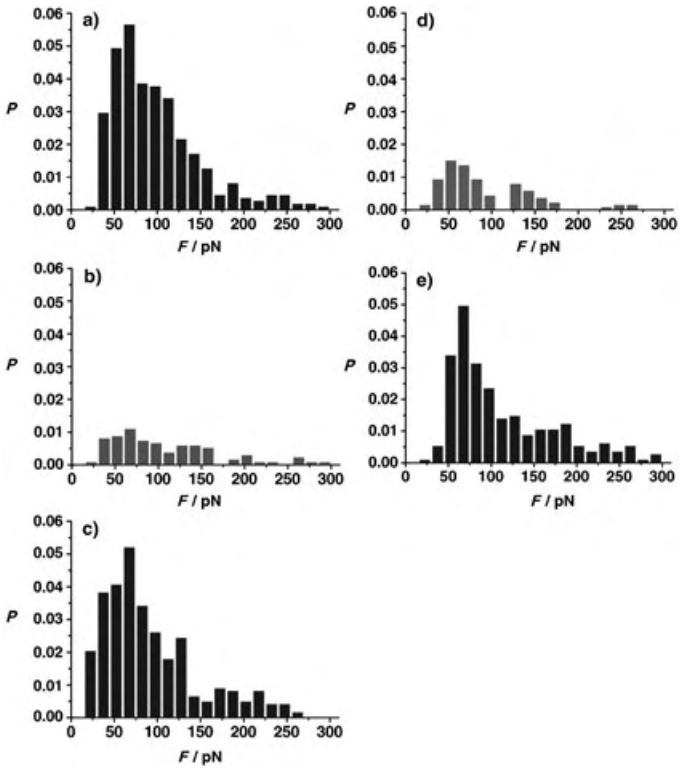

Figure 2. Competition experiments with the native peptide sequence: a) force spectroscopy experiment in standard buffer solution (100 mM NaH_2PO_4, 50 mM NaCl, pH 7.4) without competitor; b) experiment in buffer solution with an excess of free peptide as competitor; c) experiment after washing with standard buffer solution; d) experiment in buffer solution with excess of free DNA as competitor; e) as in c).

buffer solution, in which a significant decrease in total binding probability is apparent; part (c) illustrates how the original binding probability and activity of the interaction is restored after washing the sample in standard buffer; part (d) shows the analogous competition experiment with excess free DNA in buffer solution, and part (e) illustrates the reactivation of the interaction. In additional control experiments with EBNA DNA fragments, which lack the PhoB binding sequence, no binding was observed at all (data not shown; EBNA = Epstein–Barr virus nuclear antigen). These results clearly prove that the binding of the peptide with the native sequence takes place specifically at the binding sequence on the DNA.

The same conclusion applies to the results of the competition experiments performed with the peptide mutants R193A and H198A. Again, competition was successful both with free peptide and with free DNA as competitor (Supporting Information). For H198A, however, the total binding probability was distinctly lower than those of the native peptide and the mutant R193A. In contrast, binding experiments with the mutant R203A yielded very few binding events, rendering statistical analysis impossible. In summary, there is evidence that the native sequence and the mutants R193A and H198A specifically recognize the PhoB target sequence. As it was doubted recently that short peptide sequences with only one α helix are capable of specific DNA binding,[1] our results are quite remarkable given that the 20-residue peptides represent a rather small epitope from the binding domain of the protein.

Dynamic force spectroscopy experiments were performed with the native sequence and the mutants R193A and H198A to obtain information on the dissociation kinetics and energy landscapes. In force-induced thermally driven dissociation of a metastable molecular complex,[27–29] the measured dissociation forces depend on the temporal force evolution on the complex, commonly referred to as the loading rate. It is given as the product of the molecular elasticity and the retract velocity of the cantilever. In our experiments, the molecular elasticity was determined by fitting the last 20 data points prior to bond rupture in the force–distance curve. The retract velocity was varied in the range of 10–6000 nm s^{-1}.

The results of the dynamic experiments are shown in Figure 3. The dissociation forces (derived from analysis of the

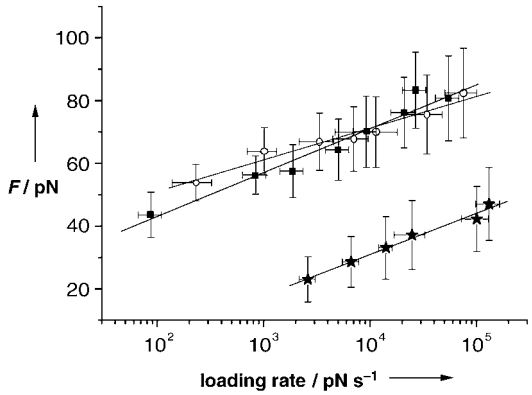

Figure 3. Dynamic force spectroscopy: ■ = native sequence; ○ = R193A; ⋆ = H198A.

respective force histograms) are plotted logarithmically against the loading rate. The linear fit of the data provides two important parameters. First, extrapolation to zero external force $F = 0$ gives the thermal off-rate k_{off}. For the native sequence, the thermal off-rate amounts to $k_{off} = (3.1 \pm 2.1)\ s^{-1}$ (Table 1), which corresponds to a time constant (lifetime) for complex dissociation of $\tau = (320 \pm 220)$ ms. The complex between DNA and the mutant R193A, interestingly, dissociates more slowly, with $k_{off} = (0.071 \pm 0.053)\ s^{-1}$, indicating a longer complex lifetime of $\tau = (14.1 \pm 10.5)$ s. In contrast, the mutant H198A exhibits a considerably higher off-rate: $k_{off} = (49.5 \pm 21.2)\ s^{-1}$, corresponding to a shorter lifetime of $\tau = (20 \pm 8)$ ms. This is not surprising, as in mutant H198A the basic residue His 198 from the native sequence was replaced by alanine. Hence, the charge-controlled contribution to the binding of the peptide with DNA should be decreased. Surprisingly, the mutant R193A, in which Arg 193 was replaced by an alanine, exhibits a lower off-rate and consequently, a longer complex lifetime than the native peptide sequence. This result can presumably be attributed to an enhanced α-helical conformation of the peptide in solution, a finding which will be examined more closely in future experiments. In comparison with recent single-molecule experiments with complete transcription-activating proteins bearing a HTH DNA-binding motif,

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

which exhibit lower dissociation rates (2×10^{-4} to $1.3\times10^{-2}\,s^{-1}$)[23] and lifetimes (100–1000 s), this interesting fact indicates the presence and importance of cooperative binding effects—an issue which must be addressed in the future as well.

The affinity of a ligand to its receptor, represented in the case of a 1:1 kinetics by the dissociation equilibrium constant $K_D = k_{off}/k_{on}$, is governed by the dissociation rate k_{off}.[22] Assuming diffusion-controlled association with a typical on-rate constant of $k_{on} = 10^5\,M^{-1}s^{-1}$ [24,30–32] for the binding of a peptide to the target DNA, equilibrium constants of $K_D = 3\times10^{-6}\,M$ (native sequence), $K_D = 7\times10^{-8}\,M$ (mutant R193A), and $K_D = 5\times10^{-5}\,M$ (mutant H198A) can be estimated. According to $\Delta G° = RT\ln K_D$, the corresponding Gibbs′ free energy differences of complex formation can be estimated to $\Delta G° = -31\,kJ\,mol^{-1}$ (native sequence), $\Delta G° = -41\,kJ\,mol^{-1}$ (mutant R193A), and $\Delta G° = -25\,kJ\,mol^{-1}$ (mutant H198A).

From the inverse slope of the linear fit to the data (Figure 3), a molecular reaction length x_β can be obtained as a second parameter, which amounts to values of 6.8 ± 1.2 Å for the native peptide and 7.2 ± 3.5 Å for the mutant H198A (Table 1). However, for peptide R193A, which exhibits the longest complex lifetime, a larger value of $x_\beta = 9.3\pm2.6$ Å is found. This is consistent with the previous results, as it indicates that the final activation barrier is located late along the reaction coordinate. This suggests the possibility for the complex to re-associate (assuming microscopic reversibility) over a larger distance along the reaction coordinate, which corresponds to a longer lifetime of the complex.

In summary, the specific interaction of synthetic peptides that comprise only the recognition helix of a transcription activator with DNA could be investigated for the first time at the single-molecule level. The molecular binding forces observed for single peptide–DNA complexes upon induced dissociation were analyzed quantitatively with AFM force spectroscopy. Competition experiments have proven the specific binding of two peptide mutants to DNA. The results of dynamic force spectroscopy experiments indicate a dependence of the binding forces on external load, which is consistent with thermally driven dissociation. These experiments yield values for the dissociation rates of the corresponding complexes, which allow a direct affinity ranking of synthetic peptides with single point mutations. Furthermore, our results indicate the importance of peptide length, cooperative binding effects, and the contribution of single point mutations to the specific binding of (synthetic) peptides to DNA. These results prove the potential of combining chemical synthesis strategies for biomimetics (synthetic biology) with the high sensitivity of AFM single-molecule force spectroscopy to investigate, quantify, and control the mechanisms and properties of molecular recognition processes (molecular nanotechnology).

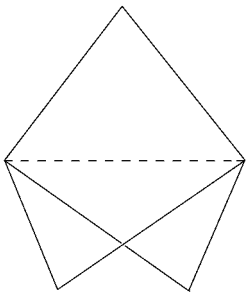
Propellanes

Electron Density and Bonding at Inverted Carbon Atoms: An Experimental Study of a [1.1.1]Propellane Derivative**

*Marc Messerschmidt, Stephan Scheins, Lutz Grubert, Michael Pätzel, Günter Szeimies, Carsten Paulmann, and Peter Luger**

The most exciting problem in the chemistry of small-ring propellanes is the nature of the central bond that connects the two "inverted" bridgehead carbon atoms common to the three "wings" of the cage structure (see Figure 1). For several



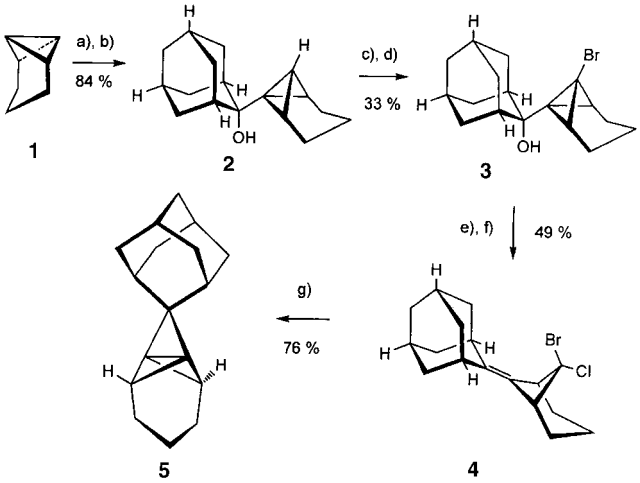


Figure 1. Structure of [1.1.1]propellane. The dashed line connects the inverted carbon atoms.

[1.1.1]propellanes, the X-ray structures showed distances of 1.59 (±0.01) Å[1] between these atoms—only slightly longer than the standard C–C bond length in saturated hydrocarbons.

The results of intensive theoretical work devoted to the question of covalent bonding seem to converge to the conclusion that the inverted carbon atoms are covalently bonded; this is supported by the existence of a bond critical point.[2] On the other hand, the electron deformation density is not accumulated in this region,[3] which was, however, regarded by Wiberg et al. *"as an artefact of the promolecule density distribution and not as a reflection of the relative properties of the two charge distributions of interest"* (quotation from ref. [2]). An experimental investigation of the electron density of two [1.1.1]propellane derivatives agreed qualitatively with the theoretical results.[4] Since no quantitative topological analysis was applied, a conclusion on the existence of a bond critical point could not been drawn from the experiments. Therefore, it was necessary to readdress the issue of electron density in [1.1.1]propellanes, and we present here quantitative results of a synchrotron experiment carried out with propellane **5** (Scheme 1).

Propellane **5** was prepared in four steps from tricycloheptane **1**[6] (Scheme 1). After metalation of **1** with butyllithium, the resulting lithium species was treated with adamantan-2-one to afford the tertiary alcohol **2**. The substitution of the second bridgehead hydrogen atom by bromine was achieved by twofold lithiation of **2** followed by reaction with tosyl bromide. Reaction of **3** with the dimethyl sulfide/*N*-chlorosuccinimide reagent furnished the olefin **4** bearing a geminal halogen moiety. The key step of the synthesis is the intramolecular addition of the carbene, [5] generated by treatment of **4** with methyllithium, to the C–C double bond, to afford the target propellane **5** in 10% overall yield.

Scheme 1. a) BuLi (0.8 equiv Et_2O), 0 °C→RT, 72 h, b) adamantan-2-one (0.9 equiv in Et_2O), 0 °C→RT; c) BuLi (2.25 equiv in Et_2O), 0 °C→RT, 72 h, d) *para*-toluenesulfonyl bromide (0.55 equiv), RT; e) Me_2S (1.0 equiv in CH_2Cl_2), NCS (1.0 equiv in CH_2Cl_2), −25 °C→RT; f) chromatography, silica gel, hexane; g) MeLi (1.25 equiv in Et_2O), −25 °C→RT.

Single crystals of **5** were obtained from a cold pentane solution at 258 K. The rather small crystals, which did not diffract sufficiently in the outer regions of reciprocal space with our laboratory setup, made it necessary to collect high-resolution data at a synchrotron beam line.[7] Propellane **5** crystallizes in the space group *Pmmn* and is situated at an *mm2* site of symmetry in the crystal; this results in nine independent carbon atoms (Figure 2). This symmetry is possible only with a 1:1 disorder for one methylene group (C1/C1a, see Figure 2).[8]

For comparison of the experimentally obtained electron density with the theoretical, ab initio calculations, which

initially were performed by Wiberg et al.[2] with HF methods, were now completed at the density functional B3LYP level of theory.[9]

The deformation densities visualize the difference between the multipol model and a promolecule that consists of neutral spherical atoms. Therefore, it is open whether they reproduce properly the charge accumulation in strained systems, as was already pointed out in Wiberg's statement cited above.[2] For the two experimentally independent wings of the propellane cage of **5** the static deformation densities are shown in Figure 3 along with the corresponding densities derived from theory. The features of the two experimental maps show some differences, which can be caused by the different crystal environments or by the fact that the C3-containing map displays a region close to the disordered part of the molecule. Nevertheless, the major features are comparable. The bonding densities on the wings have maxima clearly outside the direct internuclear vectors, showing the so-called banana bonds that are typically found in very strained ring systems.[10,11] The second common feature is the absence of density accumulation in the region between the inverted carbon atoms, as is also shown in the theoretical distribution (Figure 3, right).

Regardless of whether the deformation density is an artefact of the promolecule distribution, the Laplacian $\nabla^2\rho(\boldsymbol{r})$, which is directly obtained from the total electron density, should provide more reliable and detailed information on the bonding situation. As shown in Figure 4, the bonds on the wings have saddle-shaped regions with a clear charge accumulation over the whole bond, as is characteristic for covalent bonds. In contrast, the central bond through the cage shows, in good agreement with theory, no charge accumulation at the center.

Quantitative results were obtained from the bond critical points (bcps), all of which were found in the experimental density of **5** and characterized using Bader's theory of "Atoms in Molecules".[12] They are summarized in Table 1, where also, for comparison, corresponding topological data are given for the cage of a [1.1.1]bicyclopentane derivative, of which the experimental electron density was described earlier.[11] There is a relationship between the two types of cages, in that formally the addition of two substituents to the propellane bridgehead atoms breaks the bond in question and yields the corresponding bicyclopentane molecule, where the intracage distance increases to 1.8–1.9 Å.[1]

As shown in Table 1 the bonds in the wings are described by experiment and theory as covalent. The experimental

densities on the bond critical points fall roughly in the range also found for the six wing bonds in the [1.1.1]bicyclopentane derivative, although these bonds are slightly shorter in **5**. In total, the agreement for the wing bonds is reasonable for the two compounds; both ρ_{bcp} and $\nabla^2\rho_{bcp}$, and experimental and theoretical descriptions are all in good agreement as well.

Of major interest is the central bond through the cage. While for the bicyclopentane only a cage critical point (ccp) could be located inside the cage, a bond critical point is found unambiguously also in the experimental electron density of the propellane **5**. For the much shorter contact between the bridgehead atoms, the bcp has nearly twice the density of the bicyclopentane ccp, which is in good agreement with theoretical calculations. The Laplacian at this bond critical point is positive, as is seen normally for noncovalent interactions. Its higher value in the experiment indicates that the experimental bond path has a stronger curvature than the theoretical.

By using an exponential relation introduced by Bader et al.,[13] a bond order n can be derived from the electron density at the bond critical point. For C4–C4a and the experimental value $\rho_{bcp} = 1.31(3)\ e\,Å^{-3}$ we obtained a bond order of $n = 0.71$, which is in line with $n = 0.73$ determined by Wiberg et al.[2] in earlier theoretical studies and comparable to $n = 0.69(1)$ recently reported for the lengthened bond in the cyclopropane ring of a barbaralane derivative.[14] It should, however, be noted that the determination of bond orders smaller than one is uncertain because the extrapolation to zero bond order is not well defined. The existence of a bond path is further supported by the location of ring critical points (rcps) in the two crystallographically independent wings of **5** with densities found very close to theoretical values (see Table 1). Such ring critical points were not located in the bicyclopentane cage.

This study shows that a high-resolution data set could be obtained even from otherwise weakly diffracting crystals thanks to the use of very intense synchrotron primary radiation. This data set served as the experimental basis for the determination of the electron density of the [1.1.1]propellane **5** and its topological analysis. Although a small part of the molecule was affected by disorder, all expected topological descriptors in terms of critical points could be located and a general good agreement was seen between experiment and theory. In contrast to a related [1.1.1]bicyclopentane derivative,[11] a bond critical point was found between the bridgehead atoms in **5**. This bond is unusual according to topological analysis: it has a bond path with a bond critical point of significant density, as is characteristic for a covalent bond, but no charge accumulation is evident at the bond critical point where the Laplacian is positive. These findings, confirming small-ring propellanes as a unique class of hydrocarbons, have been obtained for the first time by quantitative topological results derived from experimental electron density distribution.

Experimental Section

2: The solvent was removed from a solution of butyllithium (50 mL, 1.6 M in hexane, 80 mmol) under reduced pressure and under nitrogen. The residue was dissolved in about the same volume of Et_2O. To this first solution was added a solution of **1** (9.4 g, 100 mmol) in Et_2O (100 mL) at 0 °C within 30 min. The reaction solution was allowed to warm to room temperature and was stirred for further 72 h. Then the reaction mixture was cooled to 0 °C, and adamantan-2-one (11.25 g, 75 mmol) dissolved in Et_2O (100 mL) was added dropwise. After stirring for 5 h the mixture was hydrolyzed with 1 M NaOH. The ether phase was washed twice with 1 M NaOH, the organic layer was dried ($MgSO_4$), and the solvent was removed under reduced pressure. The solid residue was dissolved in diisopropyl ether. Recrystallization at −10 °C afforded **2** (16.5 g, 84 %) as colorless crystals. M.p. 122–124 °C (diisopropyl ether). ^{1}H NMR (600 MHz, $CDCl_3$, TMS): $\delta = 2.45$ (m, 2H, H-6′ and H-2′), 2.19 (m, 2H, H-4a and H-9a), 2.11 (m, 2H, H-8a and H-10a), 1.88 (m, 1H, H-5), 1.81 (m, 1H, H-7), 1.74 (m, 7H, H-1, 3, 6, 8b, 10b and H-7′), 1.58 (m, 2H, H-4b and H-9b), 1.42 (m, 1H, H-3a′), 1.38 (m, 4H, H-3b′, 4′, 5b′), 1.31 (m, 1H, H-5a′), 1.03 ppm (s, 1H, OH); ^{13}C NMR (75 MHz, $CDCl_3$, TMS): $\delta = 73.9$ (C-2), 39.5 (2C, C-2′ and C-6′), 38.1 (C-6), 38.0 (2C, C-1 and C-3), 34.9 (2C, C-8 and C-10), 33.0 (2C, C-4 and C-9), 27.5 (C-5), 27.1 C-7), 26.7 (C-1′), 20.8 (C-4′), 19.9 (2C, C-3′ and C-5′) 13.5 ppm (C-7′).

3: Carbinol **2** (5.76 g, 40 mmol) in Et_2O (100 mL) was added dropwise with stirring at 0 °C to butyllithium (56 mL, 1.6 M in Et_2O, 90 mmol). Stirring was continued for 72 h at room temperature. The reaction mixture was again cooled in an ice bath, charged with 4-toluenesulfonyl bromide (11.75 g, 50 mmol) in small portions, stirred for 5 h at room temperature, and then hydrolyzed with 1 N NaOH in an ice bath. The layers were separated, the aqueous part extracted three times with Et_2O, and the combined ether layers dried with $MgSO_4$. After filtration and removal of the solvents and volatile products under reduced pressure (5×10^{-5} Torr) and elevated bath temperature (up to 80 °C), the solid residue was dissolved in Et_2O. Recrystallization at −10 °C afforded **3** (2.5 g, 33 %) as colorless crystals. M.p. 77–78 °C (Et_2O). MS (CI) m/z (%): 322//324 (0.5) [$M^{+\bullet}$], 243 (23) [$M-Br^{+\bullet}$], 171//173 (6) [$M-Ad\text{-}OH^{+}$], 162 (58), 151 (42), 91 (100), 79 (64), 77 (45), 67 (35), 55 (40), 41 (55), 39 (33); ^{1}H NMR (300 MHz, $CDCl_3$, TMS): $\delta = 2.85$ (m, 2H, H-6′ and H-2′), 2.28 (m, 2H, H-4a and H-9a), 1.99 (m, 2H, H-8a and H-10a), 1.88 (s 1H, OH), 1.82 (m, 4H, H-1, 3, 5, 7), 1.72 (m, 4H, H-6, 8b, 10b), 1.57 (m, 2H, H-4b and H-9b), 1.54 (m, 2H, H-3a′ and H-5a′), 1.38 ppm (m, 4H, H-3b′, 4′, 5b′); ^{13}C NMR (75 MHz, $CDCl_3$, TMS): $\delta = 75.8$ (C-2), 46.6 (2C, C-2′ and C-6′), 38.4 (2C, C-1 and C-3), 38.0 (C-6), 34.6 (2C, C-8 and C-10), 33.0 (C-7′), 32.6 (2C, C-4 and C-9), 27.9 (C-1′), 27.3 (C-5), 27.0 (C-7), 19.9 (C-4′), 19.0 ppm (2C, C-3′ and C-5′).

4: *N*-Chlorosuccinimide (2.4 g, 0.018 mol) and dimethyl sulfide (1.32 mL, 0.018 mol) were mixed at 0 °C in dichloromethane (75 mL). The milky suspension was cooled to −25 °C, and a solution of **3** (4.83 g, 0.015 mol) in 25 mL dichloromethane was added dropwise with stirring. The bath temperature was increased to 25 °C, and stirring was continued for 4 h. The dichloromethane solution was extracted three times with 1 M NaOH and twice with brine, dried with $MgSO_4$, and filtered, and the solvent was removed under reduced pressure. The volatile products were removed in vacuo (10^{-5} Torr, 40 °C). The residue was purified by chromatography (silica gel, *n*-hexane) The solvent was removed and the target compound **4** (2.5 g, 49 %) was obtained as colorless crystals. M.p. 55 °C (*n*-hexane). MS (CI) m/z (%): 340/342/344 (3/4/1) [$M^{+\bullet}$], 213 (100), 131 (16), 91 (36), ^{1}H NMR (600 MHz, $CDCl_3$, TMS): $\delta = 3.39$ (d, 2H, H-1′ and H-5′), 2.53 (s, br, 2H, H-1 and H-3), 2.30 (m 2H, H-2′ and H-4′) 1.93 (m, 2H, H-5 and H-7) 2.85 (m 10H, H-2′, 4′, 4, 6, 8, 9, 10), 1.71 (d, br., 2H, H-4 and H-9) 1.63 (m, 1H, H-3′), 1.45 ppm (m, 1H, H-3′); ^{13}C NMR (75 MHz, $CDCl_3$, TMS): $\delta = 140.2$ (C-6′), 121,4 (C-2), 70.9 (C-7′), 59.1 (2C, C-1′ and C-5′) 39.2 (2C, C-4 and C-9), 38.3 (2C, C-8 and C-10), 37.1 (C-6), 33.9 (2C, C-1 and C-3), 29.6 (2C, C-2′ and C-4′) 28.3 (2C, C-5 and C-7), 14.7 ppm (C-3′).

5: Methyllithium in Et_2O (6.1 mL, 1.5 M, 9.1 mmol MeLi) was diluted at 0 °C with Et_2O (10 mL) and cooled down to −25 °C. This solution was stirred and a solution of dihalide **4** (2.5 g, 7.25 mmol) in Et_2O (40 mL) was added dropwise. The mixture was allowed to warm

to room temperature and kept at this temperature for 5 h. The reaction mixture was cooled in an ice bath, then 2 N NaOH (5 mL) was added with stirring. After separation of the phases, the organic layer was extracted twice with water and dried with $MgSO_4$. Removal of the solvent afforded a crystalline residue. Recrystallization yielded **5** (1.25 g, 76 %) as colorless needles. M.p. 81–83 °C (*n*-pentane at −10 °C). ^{1}H NMR (600 MHz, $CDCl_3$, TMS): $\delta = 3.25$ (s, 2H, H-2′ and H-6′), 1.70 (br s, 2H, H-1 and H-3), 1.57 (br s, 2H, H-5 and H-7), 1.55 (br s, 4H, H-4, 8, 9, 10), 1.45 (m, 6H, H-4, 8, 9, 10 and H-6), 1.34 (m, 4H, H-3′ and H-5′), 0.96 ppm (m, 2H, H-4′); ^{13}C NMR (75 MHz, $CDCl_3$, TMS): $\delta = 102.2$ (C-8′=C-2), 80.8 (2C, C-2′ and C-6′), 40.0 (4C, C-4, 8, 9, 10), 39.1 (C-6), 29.2 (2C, C-5 and C-7), 28.7 (2C, C-1 and C-3), 22.3 (2C, C-3′ and C-5′), 20.8 (C-4′), 20.2 ppm (2C, C-1′ and C-7′).

[7] Crystal structure analysis of **5**, $C_{17}H_{22}$, at 100 K: Crystal size $0.4 \times 0.2 \times 0.1$ mm^3, orthorhombic, *Pmmn*, $a = 6.706(1)$, $b = 7.332(1)$, $c = 12.521(2)$ Å, $V = 608.99(14)$ Å^3, $\rho_{calcd} = 1.240$ g cm^{-3}, $\sin\theta/\lambda_{max} = 1.18$ Å^{-1}. The structure was solved by direct methods and at first spherically refined using full matrix least squares methods (SHELXTL).[20] The synchrotron experiments were carried out at beamline F1 (κ-axis geometry) at Desy/Hasylab. A Bruker CCD area detector and Oxford Cryosystem N_2 gas stream device were used. The measurement strategy was determined with ASTRO,[15] the measurement was controlled with SMART,[15] and the integration and correction of the data was done with SAINT[15] and SORTAV.[16] Si double-crystal monochromator, $\lambda = 0.5600$ Å, $T = 100$ K, 26569 reflections measured, 4087 unique ($R_{int} = 4.4$ %), 2371 reflections with ($I > 3\sigma(I)$) were included in multipole refinements which were carried out then based on the formalism of Hansen and Coppens[17] with the program system XD.[18] Hexadecapoles were used for the heavy atoms and dipoles for the H atoms. Atomic site symmetry was applied according to corresponding special positions in the crystal structure. The disorder was considered by a 1:1 population. After convergence $R(F) = 3.56$ % for 217 parameters, $Rw(F) = 3.47$ %, min./max. residual density: −0.23/0.28 e Å^{-3}. The topological analysis, derivation of electronic properties, and graphical visualization (Figures 3 and 4) were also done with XD. CCDC 257891 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.
[8] Attempts to solve and refine the structure in the corresponding acentric space group $Pmn2_1$ confirmed the disorder, although it is not forced by the symmetry of this space group.
[9] To predict the influence of the substituents on the propellane cage, several calculations at HF and B3LYP level of theory were performed with the basis set 6-311G**.[21] All calculations resulted in an almost D_{3h}-symmetric propellane cage and showed no significant influence of the substituents on the interesting bond features of the propellane cage. Therefore results of the unsubstituted propellane were used for all further comparisons. These are in line with earlier calculations,[2] except for minor quantitative differences in the bond topological descriptors. The partitioning procedure which uses the zero-flux surfaces of $\nabla\rho(\boldsymbol{r})$ to obtain atomic properties was applied to the theoretical density of propellane[22] derived from the above-mentioned calculation. It yielded practically zero charges for all atoms and volumes of 13.5 Å^3 and 10.1 Å^3 for the bridgehead and the wing carbon atoms, respectively.

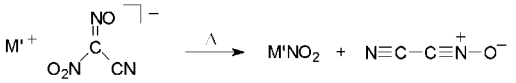
Stable Methanides

Nitro(nitroso)cyanomethanides**

Harald Brand, Peter Mayer, Axel Schulz, and Jan J. Weigand*

Methanide anions of the type $[HCR^1R^2]^-$ and $[CR^1R^2R^3]^-$ ($R^{1,2,3}$ = CN, NO, NO_2 and all possible permutations of $R^{1,2,3}$) can be considered to be resonance-stabilized, nonlinear pseudohalides.[1] The term pseudohalogen/pseudohalide was first introduced by Birckenbach in 1925 and applied to linear species such as CN/CN^-, CNO/CNO^-, N_3/N_3^-, OCN/OCN^-, and SCN/SCN^-.[2] In the same year Grimm developed the hydride displacement law,[3] according to which the pseudo-elements CH_3, NH_2, and OH have properties similar to those of fluorine; for example, they form singly charged anions. Successive substitution of the hydrogen atoms in CH_3 (CH_3^-) and NH_2 (NH_2^-) by electron-withdrawing groups in resonance with π bonds, such as CN, NO, and NO_2, leads to the class of resonance-stabilized, nonlinear pseudohalogens (pseudohalides).[4] Prominent examples of methanides are di- and tricyanomethanides,[5,6] di- and trinitromethanides,[7,8] dinitrosomethanide,[9] and the mixed substituted species such as nitrosodicyanomethanide $[(ON)C(CN)_2]^-$ and nitrodicyanomethanide $[(O_2N)C(CN)_2]^-$.[10] Nitro(nitroso)cyanomethanide, a methanide with three different characteristic groups, is not known yet. Here we wish to report the synthesis and full characterization of the alkali-metal and tetramethylammonium salts of nitro(nitroso)cyanomethanide, a simple new class of salts with surprising thermal stability.

Nitro(nitroso)cyanomethanides (NNCM) were synthesized readily in a two-step reaction (Scheme 1). First, nitroacetonitrile was nitrosated with sodium nitrite in water to give the metastable cyanomethylnitrolic acid (**1**), which was extracted with diethyl ether. Then an anhydrous ether solution of **1** was treated with a solution of M′OR (M′ = alkali metal, NR_4; R = H, alkyl) in 2-propanol, resulting in a red precipitate of M′NNCM. The beautiful red alkali-metal NNCM salts were purified easily by recrystallization from methanol (yield 50–60%).



Scheme 1. Synthesis of nitro(nitroso)cyanomethanide salts (M′ = alkali metal, NR_4; R = H, alkyl).

Metastable cyanomethylnitrolic acid and its red color in basic water solution have already been observed by Steinkopf.[11] Moreover, he postulated the existence of the silver salt of **1**. The intermediate formation of the silver salt was also postulated by Pillai and Boyer in the reaction of ICH_2CN with $AgNO_2$, which finally gave $NC{-}CH_2{-}O{-}N{=}C(NO_2)CN$ as the only isolable product.[12]

Crystals of LiNNCM and NaNNCM are very hygroscopic (they deliquesce within seconds), while crystals of KNNCM and CsNNCM can be handled without inert gas for some minutes. Interestingly, the red color of the NNCM salts darkens the heavier the alkali-metal counterion is: LiNNCM exhibits a bright orange-red color while CsNNCM displays a purple color.

Similar to the alkali-metal dinitrosomethanide salts,[9] pure dry alkali-metal NNCM salts are stable at ambient temperature, are heat and shock sensitive, and decompose slowly in polar solvents releasing N_2O gas (detected by ^{14}N NMR experiments). To determine the gases formed when M′NNCM explodes, combined IR and HRMS pyrolysis experiments were carried out. The only gaseous products observed were NC–CNO, N_2O, CO_2, NO, and CO. An intriguing feature of NNCM salts is the liberation of cyanogen *N*-oxide (NC–CNO)[13] upon gentle heating (e.g. KNNCM: $80\,^\circ C < T < T_{onset}$) and the formation of $M'NO_2$ in the solid state as well as in solution (Scheme 2).[14] Differential scanning calorimetry (DSC) experiments revealed that M′NNCM salts (M′ = K, Cs, NMe_4) undergo exothermic decomposition. For example, for the explosion of KNNCM: $\Delta H = -37.25\ kcal\,mol^{-1}$; onset of decomposition: 101.7 °C ($\beta = 5\,^\circ C\,min^{-1}$) in a temperature range of 90–117 °C; estimated activation energy of ca. 31.9(±0.5) $kcal\,mol^{-1}$.[15] We assume that the presence of a π system delocalized over the entire anion accounts for the remarkable kinetic stability of NNCM salts (see below). Nitro-, nitrosodicyanomethanide, and dinitrosomethanide salts possess a higher thermal stability than M′NNCM salts.[9,10] It is interesting to note that we were able to detect the NNCM anion in a FAB^- mass spectrometry experiment that was carried out with crystals of KNNCM.

Scheme 2. Decomposition of M′NNCM (M′ = alkali metal) upon gentle heating.

^{14}N NMR spectra of the NNCM anion in DMSO solution display three resonances in the ranges typical for C–NO (265 ppm, cf. 332 ppm $[HC(NO)_2]^-$),[9] $C{-}NO_2$ (−15 ppm, cf. −25 ppm $H_2C(NO_2)_2$),[16] and C–CN species (−107 ppm, cf. −105 ppm $[C(NO)(CN)_2]^-$).[16] The ^{13}C NMR spectrum shows

singlet resonances at 149.6 ppm (*C*-CN, cf. 150.3 ppm $[C(NO_2)_3]^-$)[17] and 119.5 ppm (C-*C*N, cf. 117.2 ppm $[C(NO_2)(CN)_2]^-$).[10] The characteristic frequencies of the NO (1380–1400 cm^{-1}), NO_2 (1490–1510 cm^{-1}), and CN (2210–2230 cm^{-1}) groups can be detected in the Raman and IR spectra of all M′NNCM salts (M′ = alkali metal, Me_4N).[18a]

KNNCM crystallizes in beautiful red rods in the monoclinic space group $P2_1/c$ with four units per cell.[19] The structure consists of an infinite three-dimensional network of repeating $K[C(NO_2)(NO)(CN)]$ units. Each anion is bonded to six potassium cations and vice versa (Figure 1). Specifically,

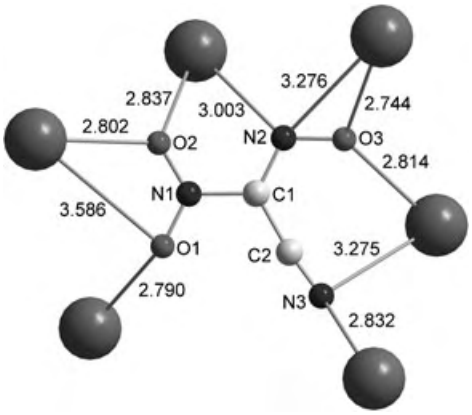

Figure 1. Coordination environment of NNCM in KNNCM; bond lengths [Å]: C1–N1 1.418(3), C1–N2 1.323(3), C1–C2 1.422(4), C2–N3 1.138(3), N1–O1 1.233(3), N1–O2 1.236(3), N2–O3 1.273(3); angles [°]: C1-C2-N3 173.2(3), C1-N1-O1 117.5(2), C1-N1-O2 119.7(2), C1-N2-O3 115.6(2), N1-C1-N2 117.4(2), N1-C1-C2 117.7(2), N2-C1-C2 124.9(2).

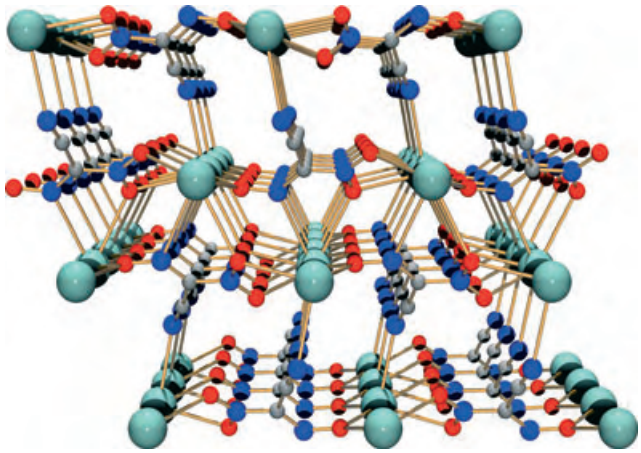
the oxygen atoms of the nitro group are bonded to three potassium centers with K–O distances of 2.790(2) to 3.586(2) Å, while the oxygen atom of the NO group is attached to two potassium centers (d(K–O) = 2.814(2) and 2.744(2) Å). Additionally, two K–N interactions are found for the N atom of the NO group (3.003(2) and 3.276(2) Å). The nitrogen atom of the CN group coordinates to two neighboring potassium centers with K–N distances of 2.832(2) and 3.275(3) Å. Hence, as shown in Figure 1, each potassium center is surrounded by four nitrogen and five oxygen atoms. The potassium coordination sphere consists of six NNCM ligands which leads to the interesting three-dimensional network arrangement of the ions (Figure 2). A view along the *a* axis reveals stacked chains of K^+ and $NNCM^-$ ions.[18b,c]

As depicted in Figure 1, the NNCM anion is nearly planar[20] (sum of angles at C1 = 359.9°) like most of the known NO-, NO_2-, and CN-substituted methanide anions (except trinitromethanide, in which the balance between resonance stabilization and steric repulsion results in the torsion of one NO_2 group out of the plane).[8a,21] Inspection of the conformational space at the B3LYP/aug-cc-pvTZ level yielded two different planar structures of the NNCM ion: a *cis* isomer (as shown in Figure 1, O3 in *cis* position to C2) and a *trans* arrangement. In agreement with the experiment our calculations indicated that the *cis* form is the most stable isomer (ΔE^{tot}(*cis*–*trans*) = +4.6 kcal mol^{-1}). As expected, all



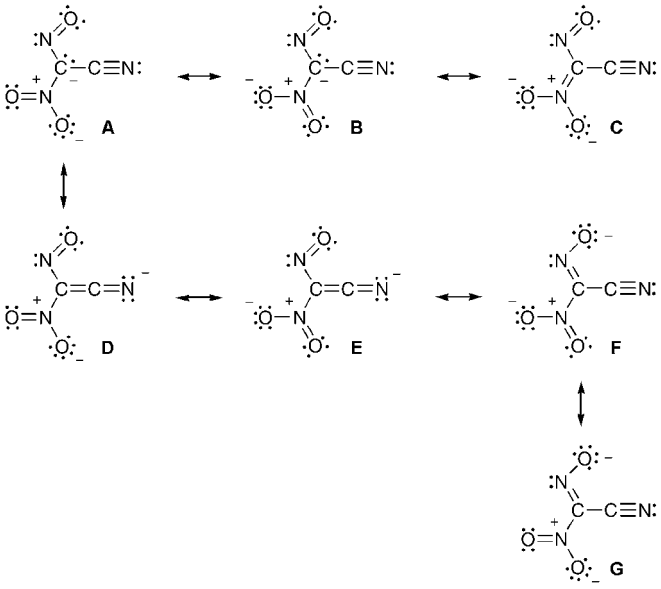


Figure 2. Packing diagram of KNNCM (view along 100).

N–O bonds (KNNCM: 1.233(3), 1.236(3), and 1.273(3) Å) are significantly shorter than the C1–N1, C1–N2, and C1–C2 bonds (KNNCM: 1.418(3), 1.323(3), and 1.422(4) Å).[18c] This is comparable to the situation found in the structure of dinitrosomethanide[9] and the nitroso- and nitrodicyanomethanides.[10] The $C–N_{nitroso}$ bond is significantly shorter than the $C–N_{nitro}$ bond, indicating a stronger π interaction along the $C–N_{nitroso}–O$ moiety. These short C–N bonds together with the planarity indicate that the π bonds are delocalized over the whole anionic species.

MO[18d] and natural bond orbital (NBO)[22] calculations of the NNCM ion support the existence of a 10π-electron, eight-center bond (Scheme 3 and Figure 3).[23] According to NBO analysis **A** and **B** in Scheme 3, are the energetically preferred Lewis representations. Investigation of the intramolecular donor–acceptor interactions utilizing the NBO partitioning scheme clearly indicates a highly delocalized 10π-system

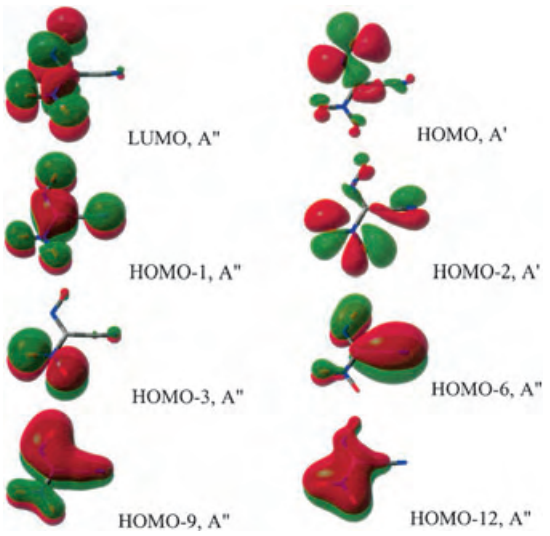

Figure 3. Selected molecular orbitals (B3LYP/aug-cc-pvTZ) of *cis* NNCM (the five occupied π MOs are those with A″ symmetry).

corresponding to the resonance structures **A**–**G**. The calculated natural atomic orbital population (NAO) net charges are $q(O) = -0.459$ (O1), -0.430 (O2), -0.464 (O3); $q(N) =$ 0.475 (N1), 0.022 (N2), -0.382 (N3); $q(C) = -0.025$ (C1), 0.263 *e* (C2). This indicates that the negative charge is found mainly on the three O atoms and the N atom of the CN group.

The UV/Vis spectra of the red solutions of NNCM alkali-metal salts in methanol exhibit one very strong characteristic $\pi \rightarrow \pi^*$ and one weak $n \rightarrow \pi^*$ electronic transition at roughly 328 and 489 nm, respectively, which could be assigned on the basis of TD-B3LYP calculations (Figure 3).[18d] The red color arises from the weak $n \rightarrow \pi^*$ HOMO–LUMO electronic transition in the anion. The HOMO describes a lone pair that lies in the anion plane. A closer inspection of the orbital coefficients of the HOMO shows rather large coefficients for the nitroso group; hence, it can be concluded that the nitroso group is mainly responsible for the red color.

In conclusion, we present here an easy, high-yielding synthetic procedure and first full characterization of alkali-metal and tetramethylammonium salts of nitro-(nitroso)cyanomethanides. The presence of a π system delocalized over the entire anion accounts for the remarkable thermal stability of alkali-metal NNCM salts, and the NNCM anion can be regarded as a nonlinear, resonance-stabilized pseudohalide. Because of the three different functional groups, NNCM salts may have great synthetic potential, for example, as a source for NC–CNO release in situ.[14b]

Experimental Section

Caution: Although ammonium and alkali-metal NNCM salts are kinetically stable compounds, they are nonetheless high-energy materials and appropriate safety precautions should be taken, especially when these compounds are prepared on a larger scale (see the Supporting Information).

Synthesis of KNNCM:[24] A solution of H_2SO_4 (100%; 1.10 g, 11.2 mmol) in water (3 mL) was added dropwise to a stirred solution of nitroacetonitrile (1.80 g, 20.9 mmol)[25] and sodium nitrite (1.50 g, 21.7 mmol) in water (30 mL) at 0 °C. The reaction mixture was stirred at 0 °C for 30 min, and then **1** was extracted with diethyl ether (4 × 25 mL). The combined extracts were dried over anhydrous calcium chloride, filtered, and cooled to 0 °C with stirring. A solution of KO*t*Bu (1.40 g, 12.5 mmol) in 2-propanol (10 mL) was added dropwise, resulting in a red precipitate, which was recrystallized from methanol to give red crystals (rods) of KNNCM (1.82 g, 11.9 mmol, 57%). M.p. 105 °C (decomp.), Raman (200 mW, 25 °C, 100 scans):[18a] $\tilde{\nu}(I_{rel}) = 2225$ (4), 1501 (3), 1400 (7), 1344 (10), 1258 (2), 1214 (9), 848 (2), 834 (2), 806 (1), 777 (1), 570 (0.5), 537 (1), 489 (0.3), 258 (1), 180 (2), 154 cm^{-1} (1); UV/Vis (methanol):[18d] $\lambda_{max}(\varepsilon) = 489$ (60), 328 (11055), 245 nm (5493 $cm^{-2}mmol^{-1}$); ^{13}C NMR ([D$_6$]DMSO, 101 MHz, 25 °C): $\delta = 119.5$ (s, C-*C*N), 149.6 ppm (s, *C*-CN); ^{14}N NMR ([D$_6$]DMSO, 28.9 MHz, 25 °C): $\delta = -107$ (s, $\Delta\nu^{1/2} = 240$ Hz, C-C*N*), -15 (s, $\Delta\nu^{1/2} = 80$ Hz, C-*N*O$_2$), 265 ppm (s, $\Delta\nu^{1/2} = 320$ Hz, C-*N*O); MS (FAB$^-$, xenon, 6 keV, *m*NBA matrix): 267 [NNCM + NBA]$^-$, 114 [NNCM]$^-$; MS (EI, 70 eV, >5%, explosion gases); *m*/*z* (%): 68 (6) [NCCNO]$^+$, 52 (28) [(CN)$_2$]$^+$, 44 (100) [CO$_2$]$^+$ and [N$_2$O]$^+$, 32 (8) [O$_2$]$^+$, 30 (41) [NO]$^+$, 28 (30) [CO]$^+$, 27 (6) [HCN]$^+$; Elemental analysis for $KC_2N_3O_3$ (153.139) calcd C 15.69, N 27.44; found C 16.16, N 26.24.

Dedicated to *Professor Herbert W. Roesky on the occasion of his 70th Birthday*

Recently we have started to study the synthesis and structural analysis of copper complexes containing heavier elements of Group 15.[1] Despite the extensive amount of work that has been carried out in the area of transition-metal complexes of heavier Group 15 elements, there are only a few accounts of antimony- or bismuth-containing copper complexes.[2] Most

of these complexes are adducts of copper(I) salts with tertiary stibanes or bismuthines ER_3 (E = Sb, Bi; R = aryl or alkyl) as terminal ligands.[3] The first copper(I) antimonide complex $[\{Mes_2SbCu(PMe_3)_2\}_2]$ (Mes = 2,4,6-trimethylphenyl) was prepared by the metathesis reaction of Mes_2SbLi with CuCl.[4] Our approach to the syntheses of copper(I) antimonides reported herein involves the reaction of $Sb(SiMe_3)_3$ with copper(I) salts in the presence of tertiary phosphines (see Scheme 1).[1] By this approach we have already synthesized the copper–antimony clusters $[Cu_{10}(Sb_3)_2(SbSiMe_3)_2(dppm)_6]$, $[Cu_{17}Sb_8(dppm)_7]$, and $[Cu_{20}Sb_{10}(PCy_3)_8]$ (dppm = 1,2-bis-(diphenylphosphino)methane, Cy = cyclohexyl).[1a,c] The different ratio of Cu:Sb present in complexes **2** and **3** suggests copper atoms in the oxidation states 0, +I, or +II. UV/Vis studies and magnetic measurements on these type of compounds, however, did not confirm the presence of metal centers in various oxidation states and instead showed that these compounds are best described as phosphine-stabilized molecular copper–antimony alloys. On our way towards the selective synthesis of molecular alloys and the correlation of their properties with those of CuSb phases which have similar Cu:Sb ratios, we report herein the structure of an intermediate copper–antimony cluster and the two largest molecular CuSb alloys belonging to this class of compounds.[5] The structures of the complexes were established by X-ray crystallography and the results assessed with structures obtained from DFT studies.

The reaction of CuOAc with $Sb(SiMe_3)_3$ in the presence of P*i*Pr$_3$ produced $[Cu_{12}(SbSiMe_3)_6(PiPr_3)_6]$ (**1**, Scheme 1).[19] In the solid state **1** consists of a distorted centrosymmetric octahedral arrangement of six $\{SbSiMe_3\}$ units. The copper atoms Cu(2,3,6) and their symmetry equivalents are each coordinated by one phosphorus atom of a P*i*Pr$_3$ ligand and two antimony atoms from an edge of the distorted Sb_6 octahedron (Figure 1 a; Cu–P 2.227(2)–2.253(3), nonbonding Sb···Sb distances are ca. 4.0–4.8 Å). The remaining copper

Scheme 1. Synthesis of Cu–Sb clusters **1**–**3** (X = O*t*Bu, OAc).

atoms Cu(1,4,5) and their symmetry equivalents are located on the faces of the Sb_6 octahedron and are coordinated by three Sb atoms. All the copper atoms have distorted trigonal-planar coordination environments. A remarkable feature of **1** is that trimethylsilyl groups are still present despite the stoichiometric supply of starting materials (CuOAc:Sb-$(SiMe_3)_3$ = 3:1). An explanation for this observation could be the presence of bulky *i*Pr$_3$P ligands which prevent **1** from further reactions with CuOAc. Compound **1** can be described as a "classical" Cu–Sb complex where charges can formally be assigned to give twelve Cu^+ centers and six $[SbSiMe_3]^{2-}$ ligands. Similar short Cu···Cu distances such as those in **1** (ca. 2.4 Å) were also observed in a range of other copper(I) complexes.[6] Sb–Cu bond lengths of approximately 2.5 Å are characteristic and are similar to distances observed in other Cu–Sb complexes.[1] Inspired by the structural diversity of copper clusters bridged by Group 16 elements, the reaction conditions(R groups of tertiary phosphines, anions of the Cu^I salts, and solvents), were modified. Particular synthetic targets were larger CuSb clusters which could be regarded as molecular representatives of the various crystallographically characterized CuSb intermetallic phases.[5] The reactions of PMe_3 with one equivalent of CuO*t*Bu and then with $Sb(SiMe_3)_3$ produced black crystals of the copper–antimony clusters $[Cu_{40}Sb_{12}(PMe_3)_{20}]$ (**2**) (Figure 1 b) and a complex which has the approximate composition $[Cu_{40}Sb_{21}(PMe_3)_{16}]$

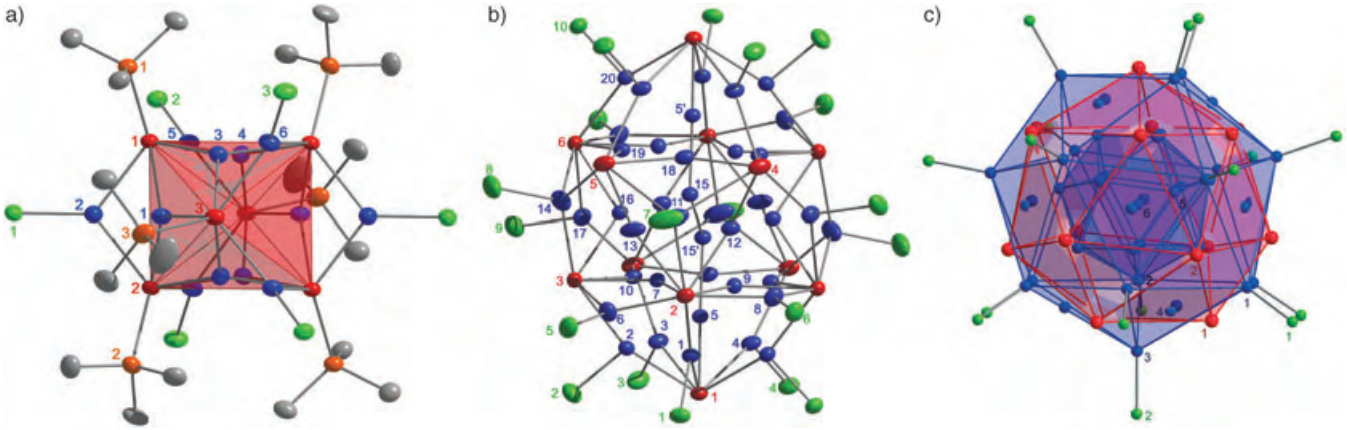

Figure 1. a) Molecular structure of **1** (Sb red, Cu blue, P green, Si orange). *i*Pr groups have been omitted for clarity; thermal ellipsoids set at 50% probability. Selected ranges of bond lengths [Å]: Cu–Sb: 2.600(1) for Sb1-Cu2 to 2.778(1) for Sb3-Cu1, Sb–Si: 2.537(2) for Sb3-Si3 to 2.547(2) for Sb2-Si2, shortest Cu-Cu distances 2.381(2) for Cu1-Cu4a to 2.541(2) for Cu1-Cu2, Cu-P: 2.228(2) for Cu5-P2 to 2.253(2) for Cu6-P3. B) Molecular structure of **2** (Sb red, Cu blue, P green). Methyl groups have been omitted for clarity; thermal ellipsoids set at 50% probability. Selected ranges of bond lengths [Å]: Cu–Sb: 2.454(1) for Sb1-Cu5 to 3.162(2) for Sb4-Cu11, shortest Cu–Cu distances 2.316(2) for Cu15–Cu15′ to 2.923(2) for Cu3-Cu4, Cu–P: 2.220(2) for Cu11-P7 to 2.265(2) for Cu3-P3. c) Polyhedral representation of **3** (Sb red, Cu blue, P green; C and H atoms have been omitted for clarity). Selected ranges of bond lengths [Å]: Cu–Sb: 2.5798(8) for Sb1-Cu4′ to 2.922(1) for Sb1-Cu2, Cu···Cu distances 2.442(2)–2.923(2), Cu–P: 2.186(4) for Cu1-P1 and 2.188(8) for Cu3-P2.

(**2a**). Crystals of **2** and **2a** can be separated manually under perfluoroether oil but decompose once placed under vacuum as a result of the loss of lattice-bound solvent. For these reasons a characterization of **2** was only possible by X-ray crystallography.[19]

The solid-state structure of **2** consists of a distorted Sb_{12} icosahedron (nonbonding Sb···Sb distances ca. 5 Å). The twenty copper atoms located on the cluster surface are all coordinated to phosphorus atoms of PMe_3 ligands and bridge the edges or cap Sb_3 faces of the icosahedral Sb_{12} unit. The copper atoms not coordinated by PMe_3 ligands are located inside the cluster. They bridge edges of the icosahedron and the atoms Cu(5), Cu(15), and their symmetry equivalents form a Cu_4 chain inside the cluster. The Cu···Cu distance of 2.316(2) Å between Cu(15) and Cu(15′) is to our knowledge the shortest Cu–Cu distance observed to date in a molecular complex and is close to the distance observed in Cu_2(g) 2.2 Å.[7] The Sb–Cu bond lengths in **2** (2.453(1)–3.162(2) Å) are characteristic for Cu–Sb complexes and are in the range of distances observed in Cu_2Sb alloy.[8] Further experiments to elucidate the electronic structure and in particular the oxidation-state of the copper atoms involved were hindered by the unselective formation of **2** which makes it impossible to prepare larger amounts of pure **2** as it can not be separated from the byproducts. Since the composition of **2** is non-stoichiometric with four excess electrons, density functional theory (DFT) calculations[9,10] were carried out to investigate its electronic structure. The results show typical semiconductor features: the occupied valence band and the empty conduction band are separated by a band gap of about 1.5 eV,[11] whereas orbital energies within these bands differ by typically 0.1 eV. A similar situation was observed in clusters of the composition $[Cu_{26}Te_{12}(PEt_2Ph)_{12}]$, $[Cu_{32}As_{10}(dppm)_8]$.[12] In agreement with the small difference in electronegativities of Cu and Sb (Pauling scale: Cu 1.6, Sb 1.9), a valence band composed of 5p(Sb) and (4s)Cu orbitals is formed, which accommodates the four excess electrons. An "ionic" model of **2** which could consist of Cu^+ and Sb^{3-} ions and Cu^0 is inappropriate. A structural model of **2a** was also investigated using DFT methods and the results showed that the solution we obtained in the space group $F23$ was wrong. The DFT analysis was necessary because highly symmetric structures of large Cu–Sb clusters can sometimes not be determined reliably by X-ray crystallographic methods alone. This is due to the intrinsic problem that a crystal structure represents the arrangement of atoms averaged over a lot of molecules. For large clusters containing more than 60 metal atoms this means that metal atom positions in different cluster molecules can sometimes be occupied by Cu or Sb atoms. To gain further insight into this problem we have performed similar reactions of CuOAc and $Sb(SiMe_3)_3$ in the presence of phosphines and the reaction with PEt_2Me gave rise to another cluster containing the same number of metal atoms as **2a**. Black crystals were obtained from this reaction in addition to an amorphous black precipitate. The X-ray analyses has shown that the structure can be solved in the cubic space group $F\bar{4}3m$.[19] The cluster has the composition $[Cu_{45}Sb_{16}(PEt_2Me)_{16}]$ (**3**) and consists of two metal shells (see Figure 1c).

The atom Cu(6) is in the center of **3** and is surrounded by a regular arrangement of 16 Cu atoms forming a slightly distorted Frank–Kasper polyhedron (Cu(6)···Cu 2.629(2) and 2.771(1) Å). Sixteen Cu atoms of the outer shell have a tetrahedral coordination environment and each one is bonded to a P atom of a PEt_2Me ligand and three Sb atoms. These Cu atoms and the outer Sb atoms are located on the corners of another Frank–Kasper polyhedron (with nonbonding Cu···Cu distances of ca. 4.1–4.9 Å; Sb···Sb ca. 3.5 and 4.5 Å). Each of the remaining twelve surface Cu atoms is coordinated trigonally planar by three Sb atoms and is located in the center of the Sb_3 faces of the Sb_{16} shell. These outer three-coordinate Cu atoms are also located in the center of a trigonal face of the polyhedron formed by the sixteen $\{Cu(PEt_2Me)\}$ units. The organic groups of the phosphine ligands prevent the coordination of additional phosphine ligands to the three-coordinate Cu atoms.[13] Having solved the structure of **3** we were unable to unequivocally identify the atom type in the center of the cluster (herein refined as Cu(6)) by crystallographic methods alone. Other analytical tools, such as elemental analysis and mass spectrometric methods, also failed to give us clear evidence. Again the accuracy of the X-ray structure determination was assessed by DFT methods. Calculations for the isomorphous cluster cores $[Cu_{40}Sb_{21}]$ (**2a**), $[Cu_{41}Sb_{20}]$, $[Cu_{44}Sb_{17}]$, and $[Cu_{45}Sb_{16}]$ with PMe_3 ligands in molecular symmetry T were performed.[14] Figure 2 shows the deviation between measured and calculated bond lengths in **3**.

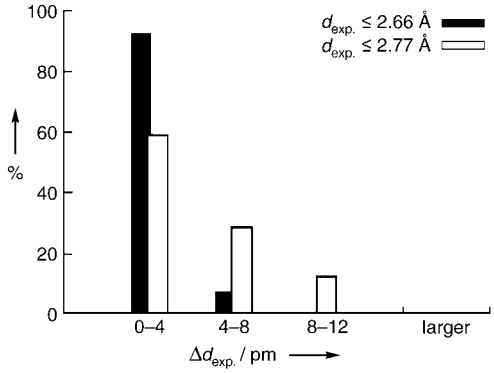

Figure 2. Deviations of selected calculated from experimentally determined metal···metal distances (d_{exp}) in **3**.

This deviation is most meaningful for short and strong bonds which are those described best by theory. $[Cu_{45}Sb_{16}L_{16}]$ ($L = PMe_3$) gives a perfect match: short bonds (≤ 2.66 Å) deviate by only up to 0.08 Å, and the deviation is less than 0.04 Å in over 90% of cases. Even for a larger cutoff, bonds ≤ 2.77 Å, which includes relatively weak bonds there are no discrepancies larger than 0.12 Å. All the calculated cluster cores contain 61 metal atoms stabilized by phosphine ligands, but for Cu:Sb $\neq$ 45:16 they show unacceptably large deviations from X-ray results and can be reliably excluded.[15] The electronic structure of **3** shows remarkable features. The odd numbers of electrons leads to an open-shell structure with a singly occupied tHOMO in molecular symmetry T resulting

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

in a ^{2}T state that will undergo a (slight) Jahn–Teller distortion. The high-lying HOMO, $\varepsilon_{HOMO} = -1.902$ eV, and a band gap of 0.85 eV between HOMO and HOMO-1 indicate that **3** is a strong reducing agent.[16]

In addition to the synthesis of the molecular CuSb alloys **2** and **3**, which are nonclassical compounds in a sense that they cannot be described by localized charges, calculations of the largest CuSb clusters have shown that DFT calculations can assist in the correct assignment of atom types in highly symmetric crystal structures. It can be assumed that the synthesis of even larger CuSb alloy complexes does not simply proceed via elimination of volatile trimethylsilyl-containing leaving groups but instead via aggregates similar to **3** which could act as reducing agents in reactions with other metal cations present in solution.

Experimental Section

All operations were carried out in an atmosphere of purified Argon. THF was heated under reflux over potassium and freshly distilled. Hexane and diethyl ether were dried over $LiAlH_4$. PMe_3, $Sb(SiMe_3)_3$, CuO*t*Bu, and CuOAc were prepared according to published procedures.[17]

1: CuOAc (0.27 g, 2.20 mmol) was dissolved in Et_2O (9 mL) and P*i*Pr$_3$ (0.83 mL, 4.04 mmol) was added. The dark yellow solution was cooled to −78 °C and $Sb(SiMe_3)_3$ (2.4 mL, 0.73 mmol; 0.31 M in hexane) was added and solution then stored at −78 °C for 12 h. The reaction was then allowed to warm to −40 °C and stored for one week. Dark brown crystals of **1** were isolated (0.15 g, 31 %), which decomposed at room temperature.

2: PMe_3 (0.36 mL, 4.00 mmol) was added to CuO*t*Bu (0.27 g, 2.00 mmol) in THF (5 mL). The yellow solution was briefly heated to reflux and then allowed to cool to room temperature. At −78 °C $Sb(SiMe_3)_3$ (3.9 mL; 0.66 mmol; 0.17 M in hexane) was then added. After storage at −40 °C for two weeks the mixture was then stored at room temperature for another two weeks producing black crystals of **2** (eight molecules of THF as lattice-bound solvent) (ca. 0.10 g, 33 %), which decomposed at room temperature.

3: A solution of CuOAc (0.25 g, 2.00 mmol) in THF (8 mL) and $PMeEt_2$ (0.52 mL, 4.00 mmol) was cooled to −78 °C and $Sb(SiMe_3)_3$ (2.0 mL, 2.00 mmol; 1 M in hexane) was added. The reaction was stored at −78 °C for 12 h, allowed to warm to −40 °C, and stored for two weeks. Black crystals of **3** were isolated (ca. 0.08 g, 28 %), which decomposed at room temperature.

X-ray Crystallographic Study: Data were collected on a Stoe IPDS II diffractometer using graphite-monochromated $Mo_{K\alpha}$ radiation ($\lambda = 0.71073$ Å). The structures were solved by direct methods and refined by full-matrix least-squares on F^2 (all data) using the SHELXTL program package.[18,19] Hydrogen atoms were placed in calculated positions, non-hydrogen atoms were assigned anisotropic thermal parameters, atoms of lattice-bound solvent molecules were refined with isotropic thermal parameters. To identify further possible by-products, unit cell dimensions of crystals from different samples were repeatedly determined and in each case **1**–**3** were the only products we were able to characterize. CCDC 263819–263821 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

A reversible spin transition occurs when a single laser pulse (8 ns) is applied in the hysteresis loop (black curve) of the spin-crossover complex [Fe(pyrazine){Pt(CN)$_4$}] (structure shown). This bi-directional, photoinduced spin switching occurs at room temperature over a wide region of bistability and involves magnetization as well as color changes (low spin: red; high spin: yellow). More details on this phenomenon are given in the Communication by A. Bousseksou and co-workers on page 4069 ff.

Kinetic Resolution
The development of kinetic resolution from its initial discovery and its fascinating course through historical milestones to current techniques is retraced by E. Vedejs and M. Jure in their Review on page 3974 ff.

Materials Science
The design and synthesis of nanotubular mesoporous platinum by an epitaxial casting method using nanoporous gold membrane molds is described by J. Erlebacher and co-workers in their Communication on page 4002 ff.

Stereoselective Mannich Reactions
In two independent studies, B. Westermann and C. Neuhaus as well as D. Enders et al. describe on page 4077 ff. and page 4079 ff. an (*S*)-proline-catalyzed three-component Mannich reaction to form protected amino sugars.

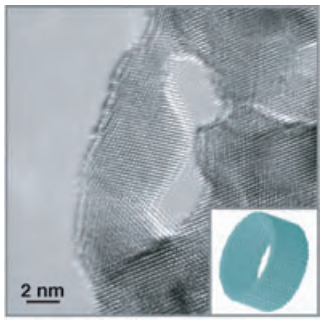
Enzyme Mechanisms for Triterpene Cyclization: New Pieces of the Puzzle

Cationic polycyclization cascades: The stereoselective transformations of linear polyolefins to give cyclic triterpenes (see scheme) have fueled half a century of intense research. Structures of triterpene cyclases complexed with the substrate analogue 2-azasqualene and the reaction product lanosterol provide new insights into the elegant mechanisms of these enyzmes.

Reviews



Among the numerous synthetic methods for the preparation of chiral products with high enantiomeric excess, kinetic resolution is the oldest. It is unique, as it has been applied to practically every type of chiral substrate, and can be combined with any method of enantioselective synthesis. The scheme shows an example of dynamic kinetic resolution through the enantioselective catalytic hydration of an equilibrated racemic β-ketoester.

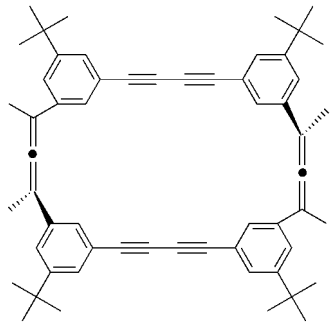
High enantioselectivities (up to 94% *ee*) were attained in the Michael addition of a variety of α,β-unsaturated imides **1** and malononitrile (**2**) catalyzed by bifunctional thiourea **4**. The pyrrolidinone moiety of **1** plays a key role in the reaction. The reaction provides access to a variety of Michael adducts **3** (see scheme; R = aryl and alkyl groups).

Natural Product Synthesis

D. Muri, N. Lohse-Fraefel, E. M. Carreira* ——— 4036 – 4038



Total Synthesis of Erythronolide A by Mg^{II}-Mediated Cycloadditions of Nitrile Oxides

erythronolide A

A cycloaddition comes of age: The focal points of a stereoselective total synthesis of erythronolide A (see structure) are two Mg^{II}-mediated cycloadditions of nitrile oxides. Of broader significance, the strategy not only facilitates the synthesis of specific polyketide targets (i.e. natural products) but also opens up new possibilities for the preparation of non-natural analogues.

A cyclophane with allene and acetylene bridges has been prepared as a single enantiomer. This acetylenic allenophane (see structure) was synthesized by a series of palladium- and copper-mediated coupling reactions. The allene bridge was derived from the ring opening of a chiral epoxy alkyne, which was prepared by a Sharpless asymmetric epoxidation of an allylic alcohol.

Asymmetric Synthesis

Awarded...

K. Nakanishi Awarded Gold Nagoya Medal 2005

Koji Nakanishi, Centennial Professor of Chemistry at Columbia University, will receive the Gold Nagoya Medal 2005 in November. Since 1995, this annual award has been given to organic chemists who have made original and significant contributions to their field. During the award ceremony at the University of Nagoya, he will discuss ginkgolides and bilobalide, about which he and K. Strømgaard co-authored a Review in *Angewandte Chemie* last year.[1]

K. Nakanishi

Nakanishi has 60 years of chemistry research behind him! He received his BSc in Chemistry in 1947 at the University of Nagoya. He spent the following two years working with Professor L. Fieser at Harvard University. Afterward, he returned to the University of Nagoya, where he completed his PhD in 1954 with Professor Y. Hirata. He spent the following years there as an assistant professor until 1958, when he accepted a full professorship in chemistry at Tokyo Kyoiku University. His next position was held between 1963 and 1969 at Tohoku University in Sendai. He has been a faculty member at Columbia University in New York since 1969. His research involves the isolation as well as structural and bioorganic studies of bioactive compounds, retinal proteins, ligand–neuroreceptor interactions, and the development of spectroscopic methods. Nakanishi is an editorial board member for several journals and is editor-in-chief of *The Chemical Record*, issued by a series of Japanese chemical societies.

M. Suginome Receives Silver Nagoya Medal 2005

Michinori Suginome, professor of chemistry at Kyoto University, will be awarded with the Silver Nagoya Medal 2005 in November. The silver medal has been presented each year since 1999 to young Japanese scientists whose research has had a major influence on the field of synthetic organic chemistry. Professor Suginome is being recognized for his contributions to synthetic organic chemistry through work with boron and silicon compounds in combination with catalysts to develop new synthetic methods toward biologically relevant molecules.

M. Suginome

Suginome studied chemistry at the University of Kyoto, where he received his PhD in 1993 under the direction of Professor Y. Ito. In the same year, he accepted an assistant professorship at the University of Kyoto. He visited the Massachusetts Institute of Technology between 1998 and 1999 to conduct research with Professor G. Fu. He was promoted to associate professor in 2002 and to full professor in 2004 at the University of Kyoto. His research interests include organometallic chemistry as well as organic synthesis and polymer synthesis. His work in the synthesis of α,β-unsaturated β-boryl nitriles by palladium-catalyzed cyanoboranation of alkynes appears in this year's volume of *Angewandte Chemie*.[2]

M. Shibasaki Receives Japan Academy Prize

Masakatsu Shibasaki, professor of chemistry at the University of Tokyo, will be awarded with the Japan Academy Prize in a ceremony in the presence of the Emperor and Empress of Japan on June 13th. The prize is accompanied by an endowment of one million yen. He is being recognized for his lifetime achievement in the creation of new asymmetric catalysts and their application toward the efficient synthesis of medicinal compounds.

Professor Shibasaki received his PhD from the University of Tokyo in 1974 under the direction of Professor Shun-ichi Yamada before conducting postdoctoral research with Professor E. J. Corey at Harvard University. In 1997 he returned to Japan and joined Teikyo University as an associate professor. In 1983 he moved to Sagami Chemical Research Center as a group leader, and in 1986 accepted a professorship at Hokkaido University until 1991. He then returned to the University of Tokyo, where he holds his current position. Shibasaki's research interests include asymmetric catalysis and the asymmetric synthesis and medicinal chemistry of biologically active compounds. His report in *Angewandte Chemie* describes the design and application of chirally economical, non-C_2-symmetric linked-binol derivatives with readily tunable properties.[3] Shibasaki is a member of the editorial board of *Chemistry—A European Journal*.

Cross-Coupling Reactions

Couplings with Monoorganotin Compounds: A "Radical" Twist from the Original Stille Reaction

*Antonio M. Echavarren**

Keywords:
cross-coupling · nickel · palladium · reaction mechanisms · stannanes

The Stille cross-coupling reaction of tetraorganostannanes R_4Sn' with organic electrophiles is one of the most reliable methods for the selective formation of carbon–carbon bonds,[1] in particular C_{sp^2}–C_{sp^2} bonds.[2–4] However, this method suffers the disadvantage that only one of the four groups at tin is transferred to the organic electrophile. Also, the triorganotin halide R_3SnX that forms stoichiometrically as a byproduct is toxic and, on occasions, its separation from the desired product can be rather difficult.

Recent developments in cross-coupling methodology allow Stille reactions to be performed under milder conditions.[2,3] This is more clearly seen by comparing the best current methods for the coupling of aryl bromides with Stille's original procedure published in 1987 (Table 1).[5] Fu and co-workers discovered that palladium complexes $[Pd_2(dba)_3]/PtBu_3$ or $[Pd(PtBu_3)_2]$, that bear bulky phosphane groups, are excellent catalysts for the coupling of aryl bromides at room temperature.[6] Verkade and co-workers developed related conditions for the Stille coupling reaction by using proazaphosphatranes as P ligands.[7] Concurrently, Baldwin and co-workers found a synergetic effect of fluoride anion and Cu^I ions that allowed the coupling of aryl bromides to be carried out under mild conditions.[8] For the coupling of aryl chlorides, the least reactive of the common aryl electrophiles,[9] relatively harsh conditions are still required.

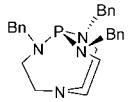

Table 1: Comparison of some of the best methods for Stille couplings with aryl bromides and chlorides.[a]

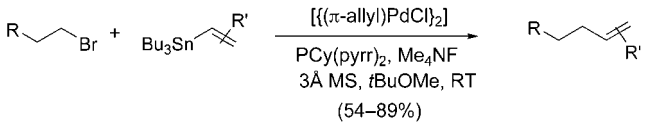
X = Cl, Br

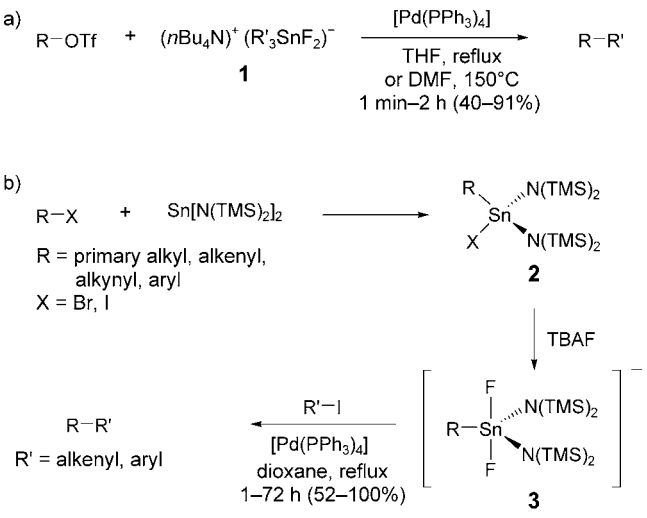


Method	Ar–Br	Ar–Cl
Stille[5]	$[Pd(PPh_3)_4]$ (2%), toluene, 110°C	–
Fu[6]	$[Pd_2(dba)_3]$ (0.5–1.5%), $PtBu_3$ (1.1–3.3%),[b] toluene or NMP, RT, (CsF, 2.2 equiv for R = Ar)	as for Ar–Br, but in dioxane at 100°C with CsF (2.2 equiv)
Verkade[7]	$[Pd_2(dba)_3]$ (1.5%), L[c] (3%), CsF (2.2 equiv), THF, RT	as for Ar–Br, but in dioxane at 110°C
Baldwin[8]	$PdCl_2$ (2%), $PtBu_3$ (4%), CuI (4%), CsF (2 equiv), DMF, 45°C	as for Ar–Br, but at 100°C

[a] Bn = benzyl, dba = dibenzylideneacetone, NMP = *N*-methylpyrrolidone, DMF = *N*,*N*-dimethylformamide.
[b] $[Pd(PtBu_3)_2]$ could also be used as catalyst.

[c] L = 

Part of the success of these new methods for the coupling of ordinary aryl chlorides relies on the use of fluoride anion to enhance the reactivity of the stannane. Fu and co-workers found that activation by fluoride anion is also crucial in the coupling of stannanes with primary alkyl bromides that bear β-hydrogen atoms (Scheme 1).[10] This result represented a significant development in this area.[11,12] Fluoride ion probably gives rise to pentacoordinated species with enhanced reactivity in the transmetalation step, as demonstrated by García Martínez et al. using hypervalent difluorostannate reagents **1**, which are easily prepared by reaction of triorganostannyl fluorides (Scheme 2).[13]



Fouquet et al. reported that monoalkylstannanes **2**, prepared in situ from RX and Lappert's stannylene $Sn[(Me_3Si)_2N]_2$, are activated by tetrabutylammonium fluoride (TBAF) to form reagents **3**, which react with alkenyl or aryl iodides (Scheme 2).[14] The accelerating effect of fluoride ion in the Stille coupling reaction had been discovered earlier using TBAF by Fugami et al.[15] Significantly, selective aryl transfer was attained in the palladium-

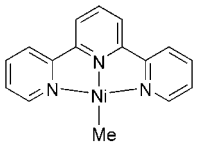
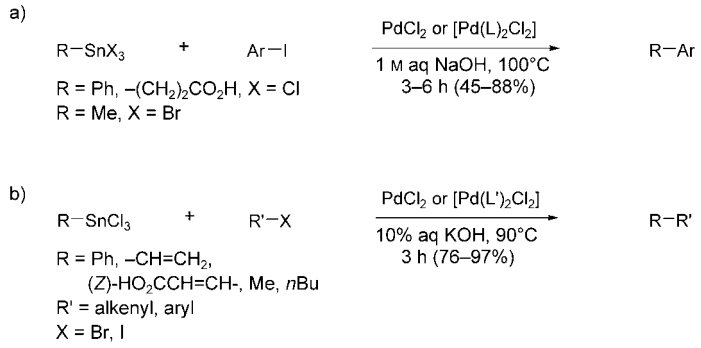
Scheme 2. a) See ref. [13]; Tf = trifluoromethanesulfonyl. b) See ref. [14]; TMS = trimethylsilyl.

catalyzed reaction between di-*n*-butyl-*p*-tolylstannyl chloride and *p*-iodoanisole to give 4-methoxy-4′-methylbiphenyl. Recently, Thiele and Mitchell reported palladium-catalyzed alkenyl transfers from an alkenyldi-*n*-butylstannyl chloride or bromide in the presence of excess TBAF, although the yields of product were only low to moderate.[16]



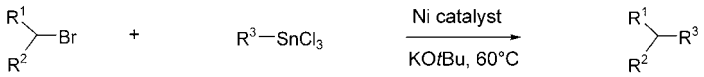
Bumagin and co-workers[17] and Collum and co-workers[18] succeeded in performing Stille reactions with monoorganotin compounds $RSnX_3$ (Scheme 3). These couplings were performed under basic conditions in aqueous solutions at 90–100 °C with $PdCl_2$ or, preferentially, with palladium complexes of water-soluble phosphanes.[19]

As part of a study on the cross-coupling of alkyl halides, the groups of Knochel[20] and Fu[21] found that nickel catalysts were particularly effective in this context.[22] This led Fu et al. recently to develop a coupling of secondary alkyl bromides with monoorganostannanes $RSnCl_3$ that drastically departs from conventional Stille reactions (Scheme 4).[23] In this case, activation of the stannane is carried out with KO*t*Bu. The byproducts of the reaction are nontoxic inorganic tin species that can be easily removed. This and related methods are significant steps forward in synthetic methodology.



Nickel-catalyzed couplings with different Ar–M reagents are compared in Table 2.[22] Although the Suzuki-type coupling (entry 1) proceeds with only 4 mol% catalyst,[21b] reaction with the stannane (entry 3) uses a catalyst formed from bipyridine and $NiCl_2$,[23] a less sensitive and much cheaper source of nickel than $[Ni(cod)_2]$.

Another distinct advantage of this coupling is the ready availability of monoorganostannanes $RSnCl_3$ by redistribution of commercially available tetraorganostannanes such as **4** and **5** with $SnCl_4$ (Scheme 5).[23]



As shown in the coupling of cholesteryl iodide **6**, retention of configuration was observed to give **7** (Scheme 5). It remains to be seen if the C-3 epimer of **6**, with an axial leaving group, would also react with retention of configuration. Importantly, note that the Suzuki and Hiyama couplings of *exo*- (**8**) and *endo*-2-bromonorbornene (**9**) give selectively the *exo*-coupled product **10** (Scheme 6).[21b,c] These and other results[23] point to a radical mechanism for the oxidative addition step involving Ni^I species, which is supported by the recent finding that Ni^I complex **11** is the

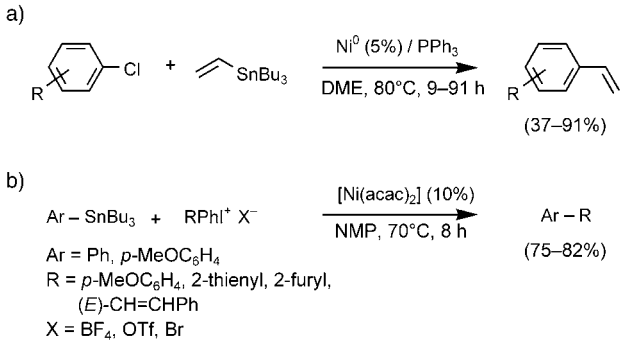
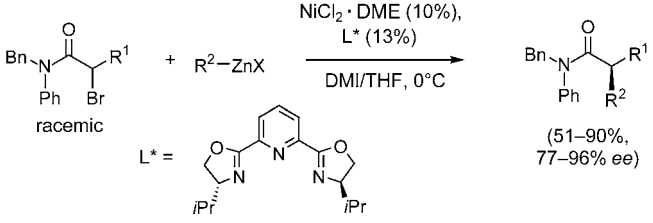


Scheme 6. [Ni] = Ni catalyst.



active catalyst in the coupling of *n*-pentylzinc bromide with alkyl bromides and iodides.[24]

Nickel catalysts in Stille-type couplings had already been used by Shirakawa et al. for the synthesis of styrenes from aryl chlorides (Scheme 7 a).[25,26] The reactive Ni^0 catalyst, presumably $[Ni(PPh_3)_4]$, was prepared from $[Ni(acac)_2]$ (acac = acetylacetonate) and PPh_3 in the presence of iBu_2AlH as reductant. Aryl bromides also react with alkenyl-, allyl-, and alkynylstannanes in the presence of this catalyst. Stannanes are also able to reduce Ni^{II} in situ as shown in the coupling of hypervalent iodonium salts with aryltri-*n*-butyltin (Scheme 7 b).[27] Aryl–aryl couplings have also been reported for arylboronic acids in the presence of nickel catalysts.[28]

The original Stille protocols can hardly be recognized in the Ni-catalyzed reaction of monoorganotin compounds.[23] This coupling raises intriguing mechanistic questions and paves the way to the development of asymmetric couplings of secondary alkyl halides by using chiral ligands. Indeed, recently Fisher and Fu have successfully reported asymmetric Ni-catalyzed Negishi couplings of α-bromoamides (Scheme 8).[29] New procedures for the formation of C_{sp^2}–C_{sp^2} and C_{sp^2}–C_{sp^3} bonds can also be foreseen by using nickel catalysts and monoorganotins $RSnX_3$ or related reagents.

Cyclizations

Enzyme Mechanisms for Triterpene Cyclization: New Pieces of the Puzzle**

*K. Ulrich Wendt**

Keywords:
bioorganic chemistry · enzyme catalysis · steroids · structural biology · terpenes

The remarkable stereoselective cyclizations of 2,3-oxidosqualene (**1**) and squalene (**2**) to give polycyclic triterpenes have fascinated bioorganic chemists for over half a century.[1–3] These reactions are catalyzed by related enyzmes, the squalene cyclases and 2,3-oxidosqualene cyclases, which occur in a wide variety of microorganisms and in higher eukaryotes. Different active-site geometries of these enzymes give rise to structurally diverse polycyclic triterpenes that serve as precursors of hopanoids and steroids.[2] Consequently, the 2,3-oxidosqualene cyclases have been investigated as potential targets for anticholestermic and antifungal therapies.[4]

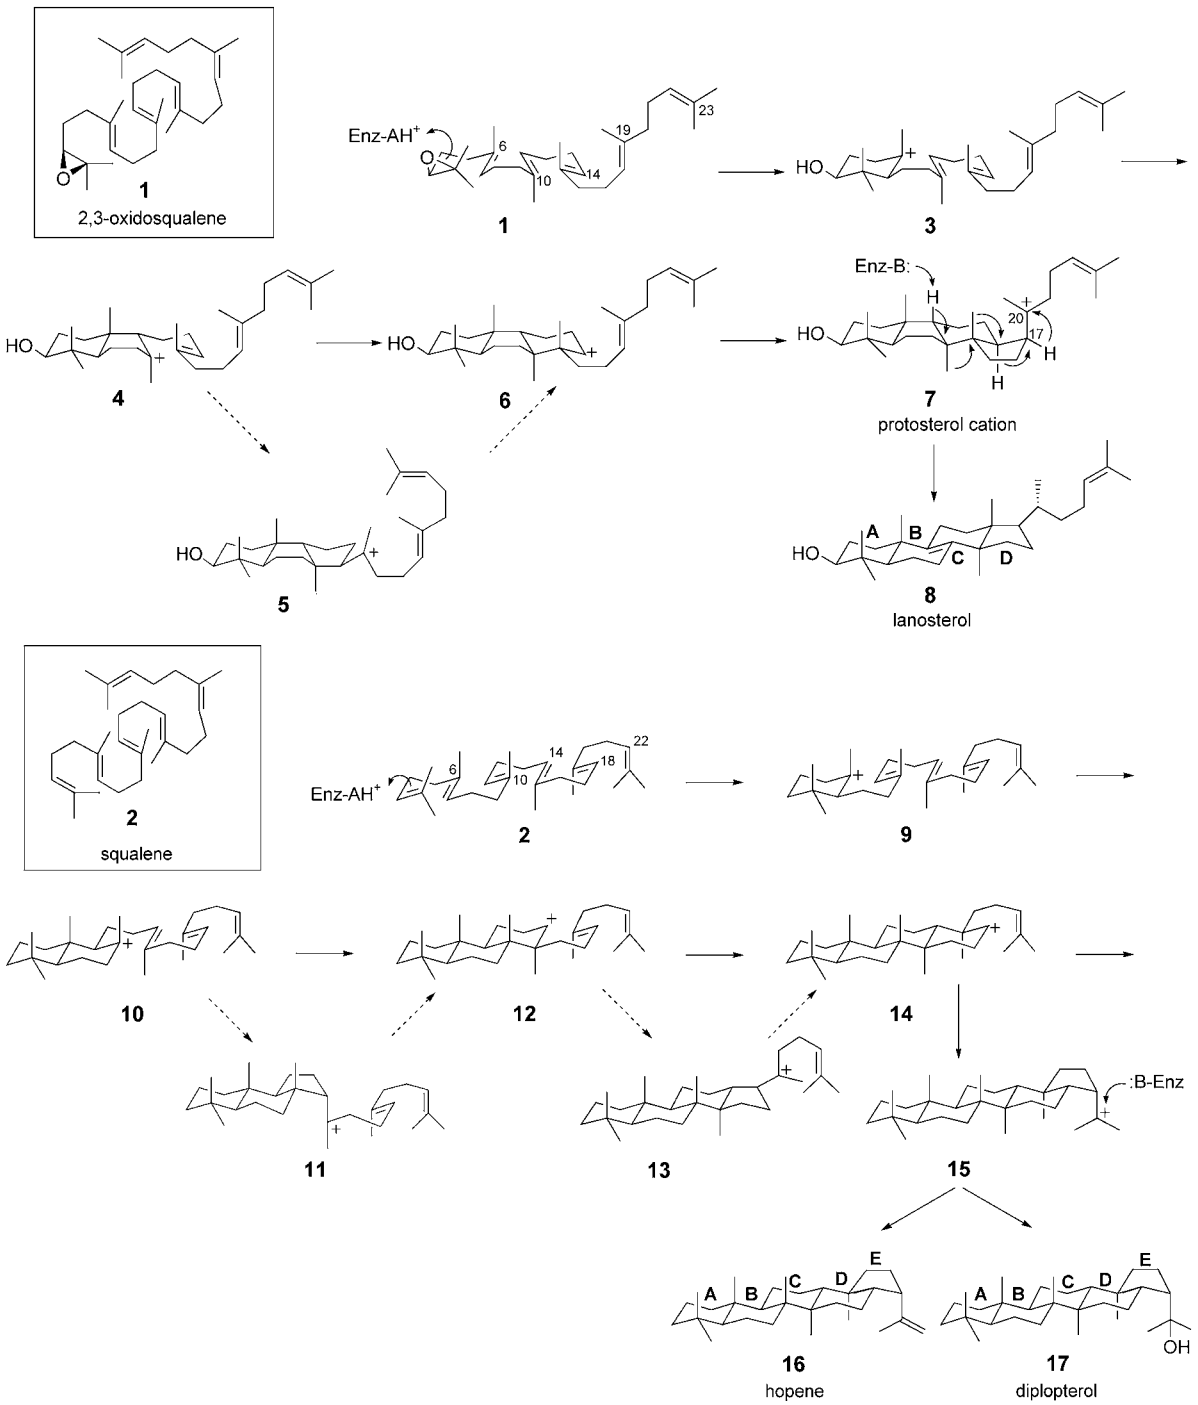
Detailed studies with nonnatural substrates have established the overall pathways of the enzymatic reactions (Scheme 1) involving: 1) binding of the polyolefinic substrate in a folded conformation, 2) initiation of the reaction by protonation of a double bond (squalene) or an epoxide (2,3-oxidosqualene), 3) ring formation, 4) in some cases skeletal rearrangement by 1,2-methyl and -hydride shifts (e.g. 2,3-oxidosqualene–lanosterol cyclase; OSC), and 5) termination by deprotonation or addition of water.[1–3]

Crystal structures of the monotopic membrane protein squalene–hopene cyclase (SHC) have provided a three-dimensional framework, which together with a wealth of bioorganic and mutational data, yielded the first biomolecular mechanism for enzymatic triterpene cyclization.[3,5] In brief, the structures show how the hydrophobic substrates are channeled from the membrane interior into a buried active-site cavity, where the reaction is initiated through protonation by an acidified aspartic acid residue ($Asp376^{SHC}$/$Asp455^{OSC}$).[5,6] During subsequent ring formation, the cation proceeds away from the catalytic acid, and the intermediates are shielded by the aromatic residues that line the active-site cavity with their π-electron-rich faces.[7] Deprotonation of the terminal cation has been shown to occur through polarized water (SHC) or a basic residue such as $His232^{OSC}$.[3]

Key questions around these complex reactions have remained unanswered: How is the energetically unfavorable chair–boat–chair conformation of the substrate induced in OSC? To what extend is ring formation concerted with the initial protonation step? Do C-ring formation (OSC and SHC) and D-ring formation (SHC) proceed through Markovnikov additions to intermediates **5**, **11**, and **13**, or does the reaction proceed along other pathways? What is the catalytic base in OSC?

Recent findings provide two important additional snapshots of the triterpene polycyclization cascades. Reinert et al. have determined the structure of SHC in complex with the substrate mimic 2-azasqualene, providing a view on the meandering conformation of the substrate prior to the initial protonation step (Figure 1).[8] Thoma et al. have succeeded in determining the long-awaited structure of human OSC in complex with the reaction product lanosterol (Figure 1).[9] In this article the contributions of these studies are highlighted along the principal steps of the enzymatic reaction.

Initiation



Since epoxides are more readily protonated than alkenes, one would expect that the catalytic acid of OSC need not be as acidic as that of SHC. In SHC, the catalytic acid $Asp376^{SHC}$ faces the substrate with its more acidic *anti* proton.[3,10] $Asp376^{SHC}$ is hydrogen-bonded to $His451^{SHC}$, a residue that is likely to carry a positive charge prior to the proton transfer and thus acidifies $Asp376^{SHC}$ (Figure 1). A negative countercharge on the hydrogen-bonded pair $Asp374^{SHC}$:$Asp377^{SHC}$ (2.6 Å distance) resides in an appropriate position to stabilize the C2 and C6 cations (squalene numbering). Three hydrogen bonds connect $Asp376^{SHC}$ with the bulk solvent such that reprotonation can occur while the cyclizing cation migrates away from the catalytic acid.[5]

The structure determined by Thoma et al. confirms $Asp455^{OSC}$ as the catalytic acid of OSC (Figure 1).[9,11] As predicted for this structure, $Asp455^{OSC}$ is not polarized by a positively charged histidine, and consequently the countercharged $Asp377^{SHC}$:$Asp374^{SHC}$ pair is missing as well.[3,5,9] Surprisingly, $Asp455^{OSC}$ is hydrogen-bonded to two cysteine residues, and it directs its less acidic *syn* proton toward the active-site cavity.[9,10] As in SHC, reprotonation can

Scheme 1. Overall mechanisms for reactions catalyzed by 2,3-oxidosqualene–lanosterol cyclase (OSC, top) and squalene–hopene cyclase (SHC, bottom).

occur through a chain of rigidly held water molecules that connect $Asp455^{OSC}$ with the bulk solvent. Overall, the Brønsted acidity of the OSC catalytic acid appears to be lower than that of SHC, potentially in order to enable the enzyme to discriminate between the olefin and epoxide sides of its natural substrate.

Ring Formation

The complex structure of OSC with lanosterol suggests how the energetically unfavorable boat conformation of the B-ring is induced. Thoma et al. suggest that in the otherwise highly conserved "upper" part of the active site, $Tyr98^{OSC}$ (Leu36 in SHC) is well positioned to induce this conformation by pushing the methyl group at C10 of 2,3-oxidosqualene below the molecular plane (Figure 2).[9]

For OSC, temporal overlap between the initial protonation step and A- and potentially B-ring cyclization has been inferred from nonenzymatic data and substrate-analogue studies and is sup-

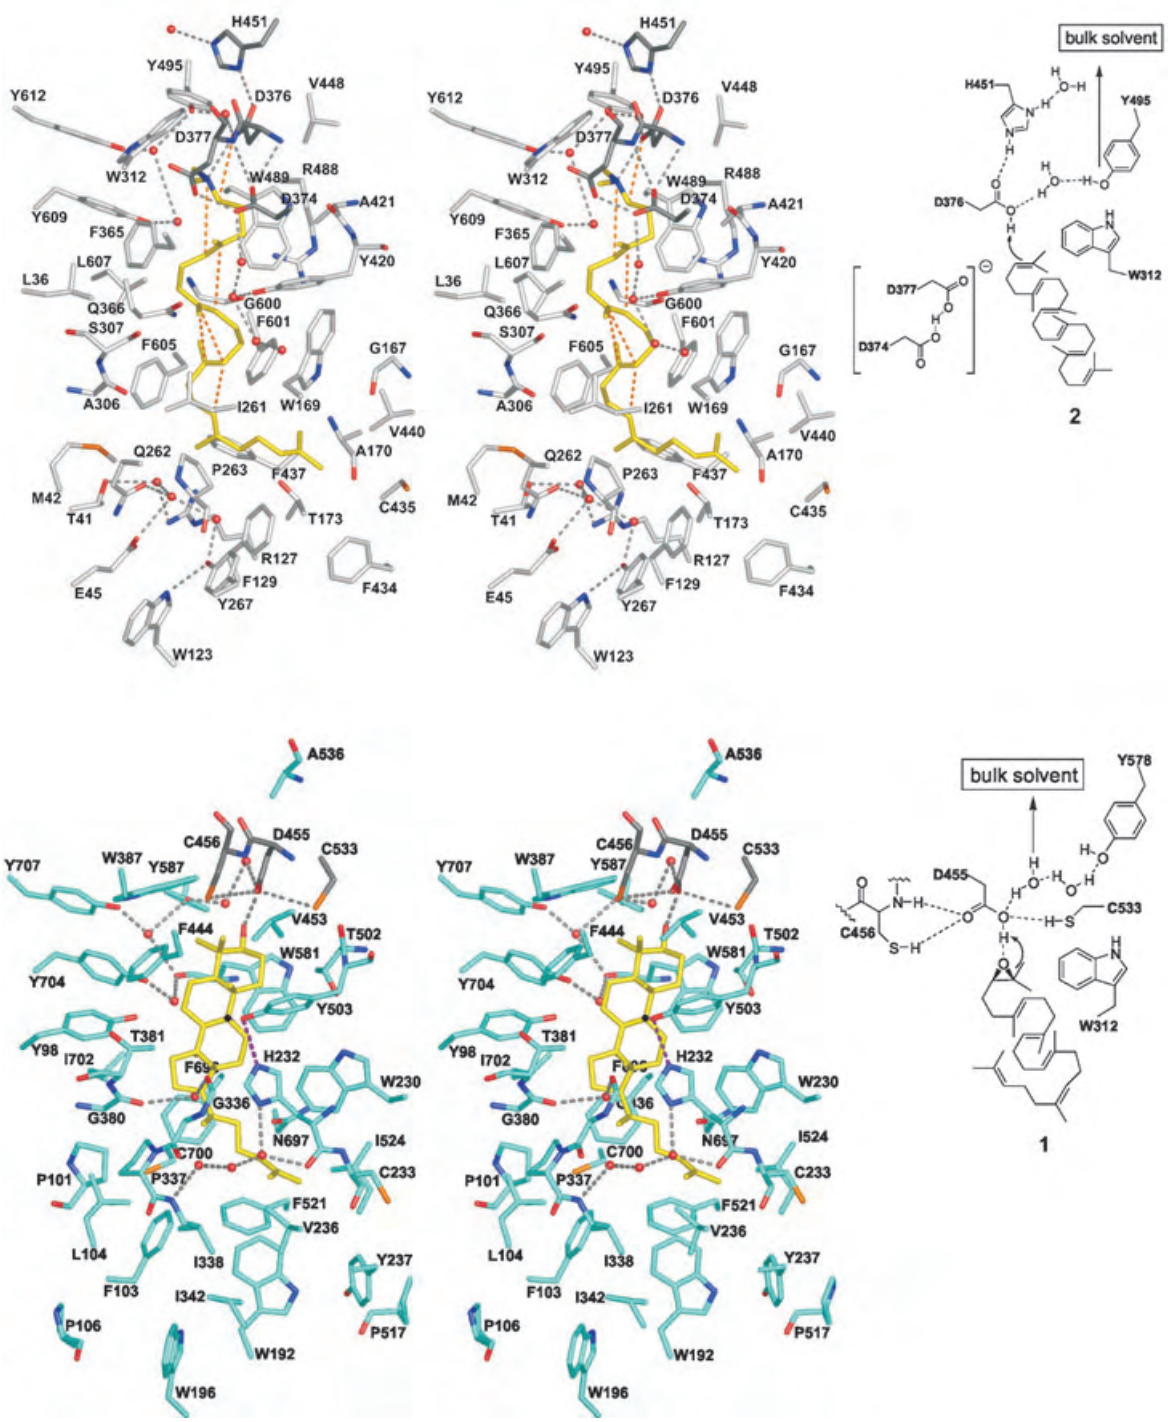

Figure 1. Active sites (stereoview in left and middle panels), and schemes of the initiation sites (right panels). Upper stereoview: *A. acidocaldarius* SHC (gray) with 2-azasqualene (yellow; PDB entry 1ump).[8] Highlighted are polar residues around the catalytic acid $Asp376^{SHC}$ (dark gray), structural water molecules (red spheres), and polar interactions (gray dashes). Trajectories for the first four ring-formation steps are indicated according to Reinert et al. (orange dashes).[8] Lower stereoview: *H. sapiens* OSC (turquoise) with lanosterol (yellow; PDB entry 1w6k).[9] Polar residues around catalytic acid $Asp455^{OSC}$, polar interactions, and structural water are shown as above. The $His232^{OSC}$:$Tyr503^{OSC}$ catalytic base dyad (purple dash) is proposed to accept a proton from C9 of the lanosterol cation (black dot).[9]

ported by computational results.[12–14] Computational studies have suggested an analogous mechanism for SHC.[15] The SHC complex with the substrate mimic 2-azasqualene shows a conformation in which the first four isoprene units orient themselves in a way such that only small displacements are required for the formation of a 6-6-6- or 6-6-5-tricycle (Figure 1).[8] For D-ring formation, a productive approach of the C18–C19 double bond towards C14 requires rotation around the C17–C18 bond and is therefore unlikely to occur in concert with the initial protonation step. The

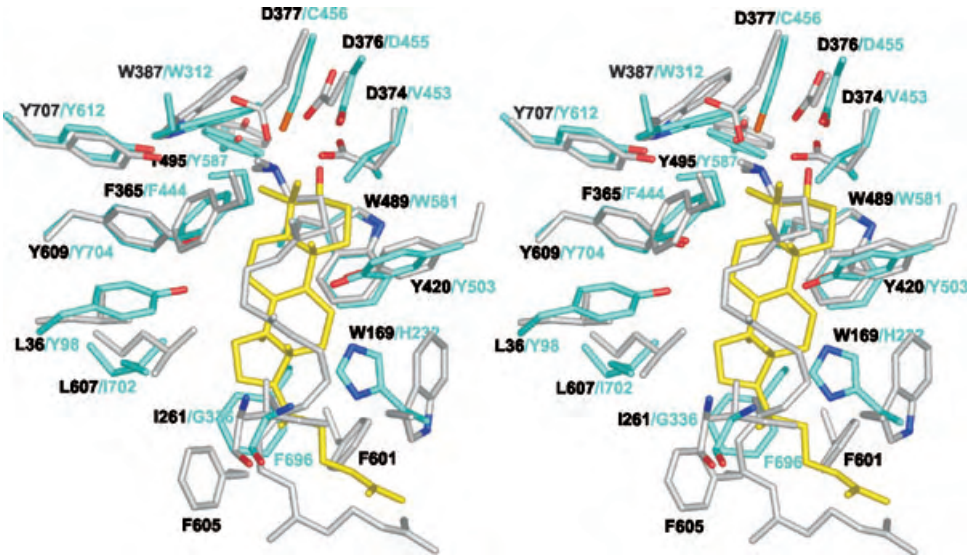

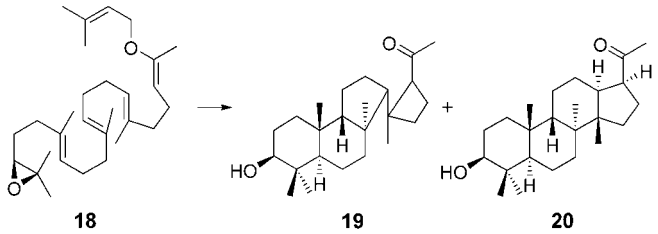

Figure 2. Stereoview of the superposition of selected residues of *H. sapiens* OSC (turquoise, turquoise labels) with lanosterol (yellow) and *A. acidocaldarius* SHC with 2-azasqualene (gray, black labels).[8,9]

observed conformation of 2-azasqualene appears to favor Markovnikov-type closure to a 6-6-6-5-tetracycle.[8] Furthermore, Reinert et al. show that the E ring is not prefolded in 2-azasqualene. They argue convincingly that the approach of the C22–C23 double bond to C18 involves a significant reorientation of the substrate, which has a considerable activation barrier, and they conclude that the cascade pauses at the 6-6-6-5-cation **13**.[8] This pause would provide time for side reactions to occur and thereby corresponds well to the observation of various 6-6-6-5 side products in the reaction of SHC with the natural substrate squalene.[8,16]

The concept of a Markovnikov-type C-ring closure with subsequent ring expansion was initially suggested by Corey et al. and was based on the finding that cyclization of 20-oxaoxidosqualene (**18**) with *S. cerevisiae* OSC yields the 6-6-5 fused-ring product **19** in addition to the expected 6-6-6-5 product **20** (Scheme 2).[17] Observations of numerous partially cyclized 6-6-5 and 6-6-6-5 side products arising from site-directed mutagenesis and substrate-analogue studies have been considered to support the relevance of cations **5**, **11**, and **13** for the mechanisms of SHC and OSC.[3] In contrast, the corresponding 6-6-6 products arising from cations **6** (OSC) and **12** (SHC) have not been trapped,[3] and 6-6-6-6 side products arising from cation **14** have been isolated in only trace amounts.[18] Based on these observations one could assume that **6**, **12**, and **14** may not be stable species in the reaction pathway. However, the isolation of side products arising from aborted cyclizations provides no conclusive evidence for the true reaction pathway of the enzyme.

Scheme 2. Products arising from the cyclization of 20-oxaoxidosqualene (**18**) catalyzed by *S. cerevisiae* OSC.[17]

Based on molecular dynamics simulations, Gao et al. recently suggested the 6-6 cation **10** as the only reaction intermediate of SHC with a significant lifetime. Intermediate **10** would react to **15** via a single transition state.[15] This proposal appears to be in contrast with that of Reinert et al., who suggest rapid formation of the 6-6-6-5 intermediate **13**, followed by first a slow conformational rearrangement of the remaining noncyclized substrate and subsequent concerted D-ring expansion and E-ring formation.[8] Resolving this dilemma will likely require knowledge of the conformation of the noncyclized isoprene chain in structures of SHC with analogues of intermediates **10**–**13**.

For OSC, Thoma et al. show that $His\,232^{OSC}$ and $Phe\,696^{OSC}$ are well positioned for π–cation interactions with the C20-protosteryl cation **7** as well as with a charge on C14 (2,3-oxidosqualene numbering), which would arise in a potential intermediate **6** (Figure 1).[9] As shown for SHC, the detailed understanding of C-ring formation in OSC would benefit from complex structures with 2-azasqualene and with analogues of intermediates **4**–**6**. As expected, $Phe\,605^{SHC}$, which has been shown to be critical for E-ring formation by SHC, is nonconserved in OSC, where only four rings are formed (Figure 2).[3]

In contrast to squalene cyclases, OSCs exhibit a conserved deletion of $Gly\,600^{SHC}$.[19] It has been shown that the corresponding $\Delta Gly\,601^{SHC}$ mutant of *A. acidocaldarius* SHC transforms (3*S*)-2,3-oxidosqualene into a mixture of

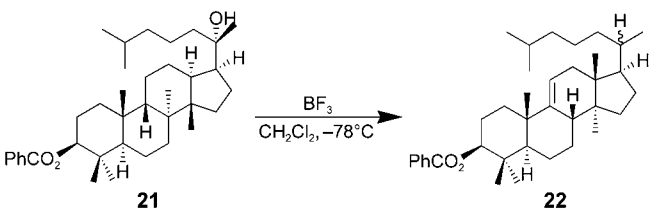
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

mono- and tricyclic fused-ring products but is inactive towards (3*R*)-2,3-oxidosqualene and the natural product squalene.[20] In view of the available crystal structures, this result cannot be explained and requires further investigation.

Rearrangement, Elimination, and Product Release

In SHC, the reaction is terminated by a polarized water molecule X[5] that deprotonates the hopenyl cation **15** to give hopene (**16**) or adds to diplopterol (**17**). The water molecule X has not been observed in any SHC structures.[8] Based on molecular dynamics simulations Reinert et al. suggest that the cyclizing squalene contracts from both sides towards its center. The resulting position of the hopenyl cation **15** allowed the definition of a putative position for water X in proximity to a defined water network around Glu45^{SHC}.[5,8]

In the active site of OSC the C20-lanosterol cation **7** is rearranged and then deprotonated at C9 (lanosterol numbering; Scheme 1 and Figure 1). Thoma et al. propose that a gradient in the π-electron density of different active-site regions is the driving force for the rearrangement from **7** to **8**. However, the nonenzymatic reaction of **21** generates 24,25-dihydroparkeol benzoate (**22**, Scheme 3).[21] This observation suggests that rearrangement from **7** to **8** requires only minimal assistance from the enzyme. Therefore, the appropriate positioning of the catalytic base may be a more relevant determinant for the rearrangement than the π-electron gradient of the active site. Thoma et al. confirm that His232^{OSC} is the only basic residue in proximity to the termination site,[3,11] and they demonstrate that His232^{OSC} forms a hydrogen bond with the Tyr503^{OSC} hydroxy group, which is in a better position to accept the proton from C9 of the lanosterol cation than His232^{OCS} itself (Figure 1).[9] The assignment of His232^{OSC}:Tyr503^{OSC} as the catalytic base dyad of OSC is supported by additional data: 1) The essential character of the corresponding His234 of the *S. cerevisiae* OSC[11] and 2) the finding that the Tyr510Ala mutant of *S. cerevisiae* forms parkeol (**23**), [22] a product that corresponds to that of the nonenzymatic rearrangement of **21** to **22**.[22]



23

The release of the bulky reaction products from the hydrophobic active site back to the membrane is an intriguing feature of the triterpene cyclases. For SHC it has been suggested that a loop region that lines the channel connecting the active site with the membrane interior is likely to be mobile enough to open for product passage.[5,8] Inspection of the OSC structure shows that the related regions are mobile as well, so that a similar mechanism can be expected for both enzymes.

Outlook

Key features of the mechanisms of enzymatic triterpene cyclization have been clarified by a combination of bioorganic chemistry, structural biology, and mutational analyses. A more detailed experimental analysis of these complex mechanisms is currently hampered by the fact that even small steric changes of the enzyme or substrate can alter the conformation and positioning of the cyclizing polyolefin chain in such manner that the reaction pathway is influenced distant from the site of mutation.[3,19] Clarification of the exact reaction trajectories and delineation of the steric and electronic contributions of individual active-site residues therefore requires structures of native and mutated cyclases in complex with substrate and transition-state analogues.

HUMBOLDT-UNIVERSITÄT ZU BERLIN

The Faculty of Mathematics and Natural Sciences I, Institute of Chemistry at Humboldt-Universität zu Berlin announces the position of a

Full Professor (W3)
"Organic Chemistry and Functional Materials".
to commence on or after October 1st, 2006.

Applicants should have an outstanding record of achievement in important areas of synthetic organic chemistry as applied to functional materials. A research focus on organic chemistry of polymers, conjugated systems, catalytic, sensory or biosensory materials is desired. The research activities of the candidate should complement research areas in the institute of chemistry. The ideal candidate has a record of close collaborations. She/he will be expected to further the scientific exchange with research institutes within and outside Humboldt-Universität and with high tech companies at the science park Berlin-Adlershof and in the greater Berlin area. The candidate will be involved in the teaching of students covering the entire field of organic chemistry.
Applicants must meet the requirements for a university professor as stipulated in § 100 BerlHG.

Humboldt-Universität is an equal opportunity employer, committed to the advancement of individuals without regard to ethnicity, religion, sex, age, disability or any other protected status.

Applications with necessary documents should be sent to Dekan der Mathematisch-Naturwissenschaftlichen Fakultät I, Humboldt-Universität zu Berlin, **code number PR/013/05**, 12489 Berlin, Newtonstr. 14, not later than 30.09. 2005.

The Walden memorial at the Technical University in Riga is pictured in the frontispiece to mark the recent centennial of the Walden inversion. This is a rare public monument to key events from the first era of exploration in stereocontrolled synthesis, and may be the only such monument to use the language of organic chemistry expressed at the molecular level. The reaction of racemic substrates with chiral nucleophiles is one of many methods currently known to achieve kinetic resolution, a phenomenon that ranks as the oldest and most general approach for the synthesis of highly enantioenriched substances. The first nonenzymatic kinetic resolutions as well as the original forms of the Walden inversion were studied in the 1890s. All of these investigations were conducted within the first generation following the demonstration that carbon is tetrahedral, and provided abundant evidence that the principles and importance of enantiocontrolled syntheses were understood. However, a reliable, rapid technique to quantify results and guide the optimization process was still lacking. Many decades passed before this problem was solved by the advent of HPLC and GLPC assays on chiral supports, which stimulated explosive growth in the synthesis of nonracemic substances by kinetic resolution. The Walden monument is accessible to passers-by for hands-on inspection as well as for contemplation and learning. In a similar way, kinetic resolution is experimentally accessible and can be thought-provoking at several levels. We follow the story of kinetic resolution from the early discoveries through fascinating historical milestones and conceptual developments, and close with a focus on modern techniques that maximize efficiency.

1. Introduction

Among the numerous synthetic methods that are capable of producing chiral substances with high enantiomeric excess (*ee*) values, kinetic resolution (KR) has the distinction of being the oldest (for its historical development, see Section 2). KR is also unique among the available methodologies because it allows the preparation of samples that are enantiomerically pure, well beyond the assay limits of modern analytical techniques. This feature has stimulated academic interest as well as speculation about possible connections with the origin of enantiomerically pure natural substances (Section 3). A third distinction is that KR can be applied to virtually every class of chiral substrates and can be used in combination with all methods of enantioselective synthesis.

With so many possibilities, the topic of KR must be reviewed selectively. Herein, we expand on some aspects of the comprehensive review from 1987 by Kagan and Fiaud[1] to emphasize developments that have improved the efficiency of KR, to comment briefly on interesting new examples, and to make connections with historical origins for key techniques and concepts. Because more than 50 specialized reviews have appeared since 1987,[2,3] we mention some topics very briefly and bypass enzymatic KR techniques almost entirely. The latter field has been the subject of many recent reviews,[3] and is mentioned only where needed for the purpose of comparison. Even with these limitations in scope, the subject remains large (>400 papers on nonenzymatic KR since 1987). The reader is referred to specialized reviews to appreciate the breadth of some important topics mentioned in specific context below.

The definition of KR according to the 1996 IUPAC recommendation follows: "The achievement of partial or complete resolution by virtue of unequal rates of reaction of the enantiomers in a racemate with a chiral agent (reagent, catalyst, solvent, etc.)".[4] We prefer this wording over older definitions[1,5] because it does not focus on the recovery of unreacted substrate and therefore fits better with recent variations that feature total conversion into products, such as dynamic kinetic resolution (DKR; Section 4).

In the simplest cases of KR, the substrate enantiomers interact with a chiral reagent or catalyst to generate two diastereomeric transition states. The free energies of these competing transition states define the rate constants for conversion of the fast-reacting and slow-reacting enantiomers, and the ratio k_{fast}/k_{slow} (equal to k_{rel} or the enantioselectivity s) controls the product distribution. As discussed later, additional factors are important for cases in which the preparative focus is on the isolation of products (DKR, PKR).

It is convenient to relate the variables in simple KR experiments with Equation (1) (based on *ee* of the recovered substrate) or, for cases in which the product is also chiral, with Equation (2) (based on *ee*′ of the product).

$$s = \frac{\ln[(1-C)(1-ee)]}{\ln[(1-C)(1+ee)]} \quad (1)$$

$$s = \frac{\ln[1-C(1+ee\prime)]}{\ln[1-C(1-ee')]} \quad (2)$$

Equation (2), when applicable, can be used to check for self-consistency and to calculate an accurate value for conversion (C), as values of *ee* and *ee*′ can usually be measured easily and with high precision, whereas the precise determination of C is relatively difficult. The derivation and history of this treatment can be found in reviews by Kagan and Fiaud[1] and (in the case of enzymatic KR) by Sih and Wu,[3a] together with graphical representations of enantiomeric purity as a function of s and C. For the present purposes, the numerical summary of *ee* or *ee*′ as a function of selected values of conversion and enantioselectivity is sufficient (Tables 1 and 2).

Although Equation (1) is widely used, caution is appropriate because the equation assumes simple first-order kinetics for the substrate, and the absence of nonlinear effects involving the catalyst. Jacobsen and co-workers have noted cases of KR with organometallic catalysts in which this expression is not obeyed.[2q] We recommend measuring s at two or more conversion values to test the kinetic assumptions. If s is found to vary with conversion, then Equation (1) does not apply, and the data must be expressed in terms of material recovery and *ee*. If this is necessary, then care should be taken to measure and report the ratio of products and starting materials so that comparisons and evaluation of results are easier.

Table 1: Conversion C and theoretical yield limits for *ee* values of 90, 95, and 99% in the unconverted substrates in kinetic resolution as a function of enantioselectivity s [Eq. (1) and Eq. (2)].

2. History of Kinetic Resolution

This story has been told many times, but it is worth repeating. In 1858, Pasteur observed that fermentation of racemic ammonium tartrate with *Penicillium glaucum* selectively destroys the dextrorotatory isomer.[6] The structural basis for this phenomenon was not yet known, but Pasteur understood that the reactive and unreactive isomers were related as mirror image forms of each other. By 1890, Fischer had observed several other enzymatic resolutions in the carbohydrate series, and had correctly deduced that the

Edwin Vedejs earned his BS degree in chemistry from the University of Michigan in 1962, and his PhD from the University of Wisconsin in 1966, under the direction of H. Muxfeldt. After a year of postdoctoral research with E. J. Corey, he returned to Wisconsin in 1967 to accept a faculty position. In 1999, he moved to the University of Michigan where he is currently the Moses Gomberg Professor of Chemistry. His research interests are in main group element chemistry and the mechanistic and conceptual aspects of organic synthesis and stereochemistry.

Mara Jure received her engineering diploma in 1986 and her PhD in 1990 from the Riga Polytechnical Institute (Latvia), where she began her academic career. She later worked as research associate in the group of Edwin Vedejs at the University of Wisconsin, Madison. Since 2001, she has been a professor of chemical technology of biologically active compounds at the Riga Technical University. Her current research interests concern heterocyclic chemistry.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

natural *d*-hexoses are consumed upon fermentation with brewer's yeast, whereas the *l* enantiomers remain unchanged.[7][*] This work was part of Fischer's monumental studies that defined relative and absolute configuration of monosaccharides, and the stereochemical issues were already described in perfect detail.

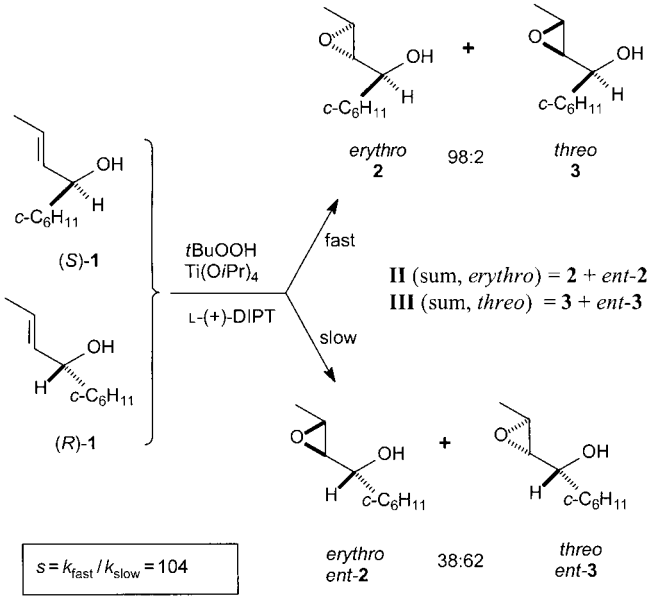
Fischer's fermentation experiments probably included the first examples in which a racemic, synthetic substance was converted into a single enantiomer with $>99\,\%$ *ee* by using KR. This supposition assumes total conversion of the more reactive *d* sugar into fermentation products as well as total enantioselectivity, as seems likely in the hexose experiments. Fischer understood the implications, but he may not have shared the current fascination with $>90\,\%$ *ee*, and did not quantify the optical purity of residual *l* sugars in typical experiments beyond showing that the optical rotation is opposite in sign relative to that of the *d* sugar.

The first example of the KR phenomenon with nonenzymatic reagents was reported a few years later. Marckwald and McKenzie observed enantioselective esterification of racemic mandelic acid by (−)-menthol upon heating the reactants,[8] and were able to recover a small amount of the less-reactive *l*-mandelic acid in pure form after multiple crystallizations. They also explained the relative reactivity issues responsible for the observed optical enrichment. Shortly thereafter, Dakin published the first examples of KR by using a lipase catalyst (in the hydrolysis of racemic ethyl mandelate with crude pig liver lipase).[9] This work is noteworthy because, as clearly demonstrated with polarimetry, the product *ee* depends on conversion (25 % *ee* at 5 % conversion; 5 % *ee* at 94 % conversion). Whereas the earlier reports by Pasteur and Fischer could have been taken to imply that natural catalysts accept only a single enantiomer, the results by Dakin showed that enzymes are not perfectly enantioselective, and that relative reactivity issues and percent conversion must be taken into account.

Subsequent reports by Fajans and Bredig revealed that the relationship between reaction rates, enantioselectivity ($s = k_{fast}/k_{slow}$), enantiomeric purity of reactants and products, and conversion in KR experiments was understood by 1910.[10] Fajans also reported the first examples of *catalytic* nonenzymatic KR (in the decarboxylation of camphor-3-carboxylic acid in the presence of chiral alkaloids; $s = 1.1$–1.5). His kinetic treatment would have shown that the *ee* value of unconverted substrate continuously increases as the conversion approaches 100 %, but only the product of decarboxylation (camphor) was assayed (with polarimetry).

3. Kinetic Resolution and Highly Enriched Chiral Substances

The possibility that nonenzymatic KR might allow the preparation of enantiomerically pure chiral substances may have been fully understood after the first enzymatic experiments, but it was not discussed explicitly until a report by Kuhn and Knopf appeared in 1930.[11] This paper was not at all concerned with synthesis applications. Instead, it focused on the origin of enantiomerically pure natural products. Kuhn and Knopf showed that the photodecomposition of 2-azido-*N*,*N*-dimethylpropionamide by circularly polarized light (CPL) results in optically active recovered starting material ($\approx 0.5\,\%$ *ee*). This form of KR occurs because the enantiomers differ in their absorption coefficients for CPL, which results in differing rates of photodecomposition. A single data point corresponding to 30–40 % conversion was measured, but the discussion included a derivation of kinetic expressions and relevant commentary to show that the optical activity of recovered starting material would continuously increase with an increase in conversion.



In one hypothetical scenario, the authors used kinetic equations to argue that even a small difference in absorption coefficients resulting in 1 % *ee* for the unreacted substrate at $\approx 60\,\%$ recovery would produce 10 % *ee* at 0.67 % recovery, or 76 % *ee* at $5 \times 10^{-20}\,\%$ recovery! The same principle is evident in Table 1, although the limits for enantioselectivity are set higher, and the percent conversions are lower. If yield is not a concern, then $>99\,\%$ *ee* can be easily achieved with KR. It is this feature that intrigued Kuhn and Knopf because they recognized that CPL is a natural phenomenon, and that it might induce formation of an enantiomerically pure substance under conditions of exceptionally high conversion. Subsequent studies by Kagan and co-workers demonstrated KR in the photodecomposition of racemic camphor by CPL, and reported a more substantial 20 % *ee* at 1 % recovery of the substrate.[12] The previous findings with 2-azido-*N*,*N*-dimethylpropionamide were confirmed, and the increase in *ee* with conversion was shown to correspond to the original mathematical model.

A milestone in the use of KR for the preparation of highly enantioenriched substances came in 1981 when Sharpless and co-workers reported KR experiments with racemic allylic alcohol substrates and the diisopropyl tartrate/*tert*-butylhydroperoxide (TBHP)/Ti(O*i*Pr)$_4$ reagent.[13] One of the best examples is shown in the conversion of (*R*,*S*)-**1** into the *erythro* and *threo* products **II** (**2** + *ent*-**2**) and **III** (**3** + *ent*-**3**), respectively (Scheme 1). Because the enantioselectivity was quite high ($s = 104$) the problem was no longer in the recovery of trace residual substrate for assay. Instead, the problem was to find an assay method sufficient to measure *ee* values in excess of 96 % for recovered (*S*)-**1**, not to mention the 99.99999999999 % *ee* calculated for a related example (2-methylhept-1-en-3-ol at 60 % conversion, $s = 138$) according to the relationship established by Equation (1). The problem of assay precision in the range of 96–99.9 % *ee* would soon be solved with the development and broad availability of chiral supports (not "chiral chromatography"!) for HPLC and GPLC assays. The problem of confirming 13 significant figures in the larger number can be entrusted to the mathematical approach in view of the proven predictive value of Equation (1).

The principles were understood long before the Sharpless study, and Horeau had described the mathematical basis as

[*] The stereochemical descriptors *d* and *l* for right- and left-handed compounds, respectively, are considered antiquated and are used herein for historical reasons. Recommended descriptors for the respective directions of optical rotation are (+) and (−).

Scheme 1. Kinetic resolution of the allyl alcohol (*R*,*S*)-**1** as reported by Sharpless and co-workers.[13]

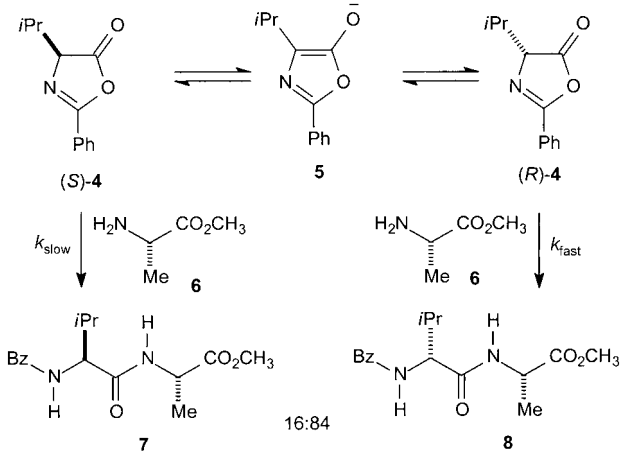
well as an example of KR to prepare samples with $>99.9\%$ *ee* by 1975.[14] However, the Sharpless paper certainly awakened the synthetic chemistry community to the preparative potential of nonenzymatic KR. Within several years, explosive growth in the field was evident, as summarized in several reviews.[1,2a–d] More recent studies have greatly expanded the scope of nonenzymatic KR and have added conceptual developments as well as technology for rapid-throughput screening. All of this would probably have impressed the pioneering researchers in the field, yet they would have understood the concepts, because most of the fundamentals of KR were known by 1910. It has taken time to develop these concepts to the current level of utility, and progress in the field has been closely tied to the advent of sensitive assay methodology for enantiomeric excess.

4. Improved Efficiency in Kinetic Resolutions

If the racemic substrate is simple or inexpensive, and the theoretical limit of 50% yield for KR is not a serious problem, good results can be obtained even with relatively modest values of *s*. Table 1 shows that $>40\%$ recovery of substrate with 95% *ee* is possible with $s=20$ or higher. If substrate recovery is the objective, then there is little to be gained by optimizing catalysts for higher *s* values, as may be observed by comparing the entries for $s=20$ (42% yield limit) with those for which $s=60$ (48% yield limit).

The situation is quite different for cases in which the recovery of enantioenriched product is also important, and the objective is to recover both enriched enantiomers with high efficiency (combined yield of 90% or more). Table 2 shows that product enrichment to the level of 95% *ee*′ requires that $s=50$ or above. However, $s=50$ is not good enough for efficient recovery because the *ee*′ value drops rapidly as conversion approaches or exceeds 50%.

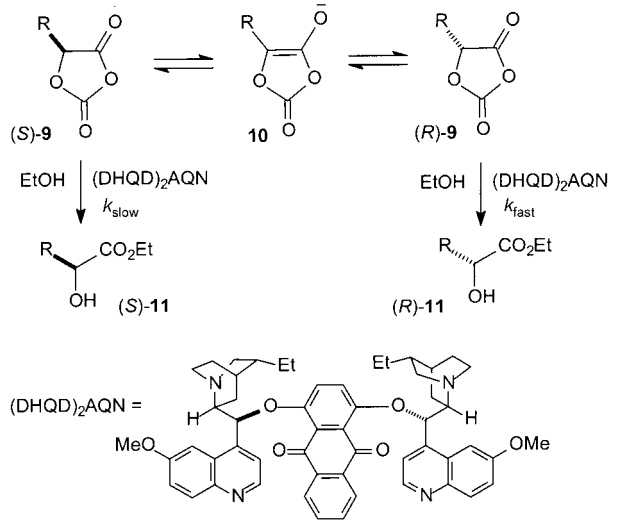
For typical KR experiments in which the kinetic assumptions for Equations (1) and (2) are satisfied, the values of *ee* (substrate) and *ee*′ (product) become equal at 50% conversion. The column for $C=50\%$ in Table 2 can therefore be used to evaluate the enantioselectivity *s* needed if highly efficient recovery of both enantiomers is desired. If the goal of a simple KR experiment is to obtain both enantiomers in 95% *ee* or more, then it would be necessary to have $s=200$ or higher. Although such levels of enantioselectivity are known for some of the best nonenzymatic methods, they are not yet routine. Fortunately, there are alternative approaches that allow efficient recovery of material, as discussed in Sections 4.1–4.3.



4.1. Dynamic Kinetic Resolution (DKR)

The theoretical limit of 50% yield for the simplest versions of KR has stimulated the search for more efficient procedures. Dynamic kinetic resolution (DKR) is the most important of these techniques. In DKR,[2e–m] the enantiomers of a racemic substrate are induced to equilibrate at a rate that is faster than that of the slow-reacting enantiomer in reaction with the chiral reagent (Curtin–Hammet kinetics). If the enantioselectivity *s* (k_{fast}/k_{slow}) is sufficient, then isolation of a highly enriched nonracemic product is possible with a theoretical yield of 100% based on the racemic substrate. This is an advantage over simple KR in which the realistic expectation for recovery is often 40% or less, owing to losses incurred during the separation of products from starting materials.[13] A second advantage of considerable importance is that the levels of enantioselectivity required for DKR are lower than those needed for KR for similar efficiency in material recovery. The key difference with DKR is that there is no decay in product *ee* as percent conversion increases, in contrast to KR. This means that even a modest *s* value of 20 allows the preparation of product with $>90\%$ *ee* and $>90\%$ recovery. On the other hand, DKR does not permit the same degree of enrichment as does KR because there is no conversion-dependent increase in substrate *ee*.

4.1.1. DKR by Enolization



Possibly the first clear example of DKR appears in a 1966 study by Weygand et al.,[14] involving the reaction of racemic azlactones with chiral amino esters to form dipeptides (Scheme 2). The best example is shown, in which (*R*,*S*)-**4** and methyl alaninate (**6**) afford dipeptide **8** as the major product. Similar transformations were probably encountered much earlier in attempts to prepare peptides from activated *N*-acylamino acids, but Weygand's report is distinct because it demonstrates the mechanistic and preparative aspects of what is now recognized as DKR. A typical Curtin–Hammett kinetics scheme was shown, illustrating the interconversion of enantiomeric azlactones via enolate **5**. The diastereomeric ratios for the peptide products **7** and **8** (d.r. $\approx$ 1:5) require at least partial racemization, and demonstrate that DKR had occurred.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Scheme 2. One of the first examples of DKR by Weygand et al. [14] Treatment of the azlactone (*R*,*S*)-**4** with alanine methyl ester (**6**) gives dipeptide **8** as the major product.

Several recent studies have exploited the same facile interconversion of azlactone enantiomers in DKR by using nonenzymatic chiral reagents or catalysts.[15] Furthermore, highly effective enzymatic adaptations that involve azlactone cleavage have been reported.[16] As discussed in the review literature,[3l] the concept has also been applied by using one or more enzymatic catalysts to obtain highly enantioselective ring cleavage of racemic hydantoins under conditions in which enolization is facile. In a related nonenzymatic application, Tang and Deng found that the commercially available cinchona derivative $(DHQD)_2AQN$ (which is also used in enantioselective Sharpless osmylation) is an effective catalyst for the enolization and ethanolysis of 5-substituted 1,3-dioxolan-2,4-diones (*R*,*S*)-**9** (Scheme 3).[17] The reaction works well for several cases in which the substituent R is aryl (Table 3, entries 1–3), but the 2-chloro derivative (Table 3, entry 4) gives lower enantioselectivity for (*R*)-**11** if the reaction is allowed to go to completion. For this example, the enantioselectivity is higher in the early stages of the reaction, which indicates that the interconversion of enantiomers (*S*)-**9** and (*R*)-**9** via enolate **10** is not rapid enough to satisfy the conditions for efficient DKR. For cases in which R = benzyl or *n*-butyl (Table 3, entries 5 and 6) enolization becomes so slow that the reactions proceed as simple kinetic resolutions. Fortunately, the enantioselectivities are quite high, allowing the recovery of unreacted (*S*)-**9** as well as the product (*R*-**11**) with $>90\,\%$ *ee*. The transition from KR to DKR occurs as the substituent R is changed from alkyl to aryl and reflects the relative ease of enolization.

Scheme 3. Nonenzymatic DKR with the use of the cinchona derivative $(DHQD)_2AQN$ reported by Tang and Deng (see Table 3).[17]

Table 3: DKR of 5-aryl-1,3-dioxolane-2,4-diones (see Scheme 3).

6	*n*-C_4H_9	36	−78	46[b]	92

[a] KR conditions, unconverted **9** ≈39%, 95% *ee*, $s=133$. [b] KR conditions, unconverted **9** 36%, 95% *ee*, $s=57$.

To our knowledge, the first use of the term "dynamic kinetic resolution" appears in the title of the classic 1989 work by Noyori et al.[18] This paper describes the catalytic enantioselective hydrogenation of equilibrating racemic β-keto esters **12** and *ent*-**12** to afford the *syn* alcohol **13** in very high *ee*, together with a trace of the *anti* diastereomer **14** (Scheme 4, Table 4). This work has been reviewed[2e,f,l] and modified for applications by other groups.[19–21] Scheme 4 illustrates an impressive recent example of the efficiency of this method which allows the simultaneous control of absolute configuration as well as *syn* stereochemistry of two adjacent stereocenters with yields of 95% or more. The method also works with cyclic keto esters and lactones,[2f,18] and even with enolizable 2-substituted cyclohexanones.[21] The optimized example of the conversion of *rac*-**15** into **16** is shown in Scheme 4,[21a] but the previously reported hydrogenation of 2-isopropylcyclohexanone is also highly enantioselective.[21b]

In another example of DKR involving enolization to interconvert ketone enantiomers, Jurkauskas and Buchwald were able to hydrogenate 3,5-disubstituted racemic cyclopent-2-enones *rac*-**18** to highly enriched (89–95% *ee*) cyclopentanones **19** by using poly(methylhydrosiloxane) (PMHS) and a chiral catalyst consisting of *p*-tol-binap/CuCl in the presence of sodium *tert*-butoxide (Scheme 5).[22] The reaction proceeds with yields of 90% or more, and with $>90\,\%$ selectivity for the *syn*-disubstituted products (Table 5). If the *tert*-butanol additive is omitted, interconversion via the enolate is no longer fast enough to allow DKR, and the reaction proceeds as a simple KR process with $s=25$–52. Selectivities of this magnitude are sufficient for the recovery of unreacted **18** with $>90\,\%$ *ee* at ≈45% recovery (Table 1). By comparison, the conditions that promote DKR allow $>90\,\%$ recovery and comparable enantioselectivity.[23]

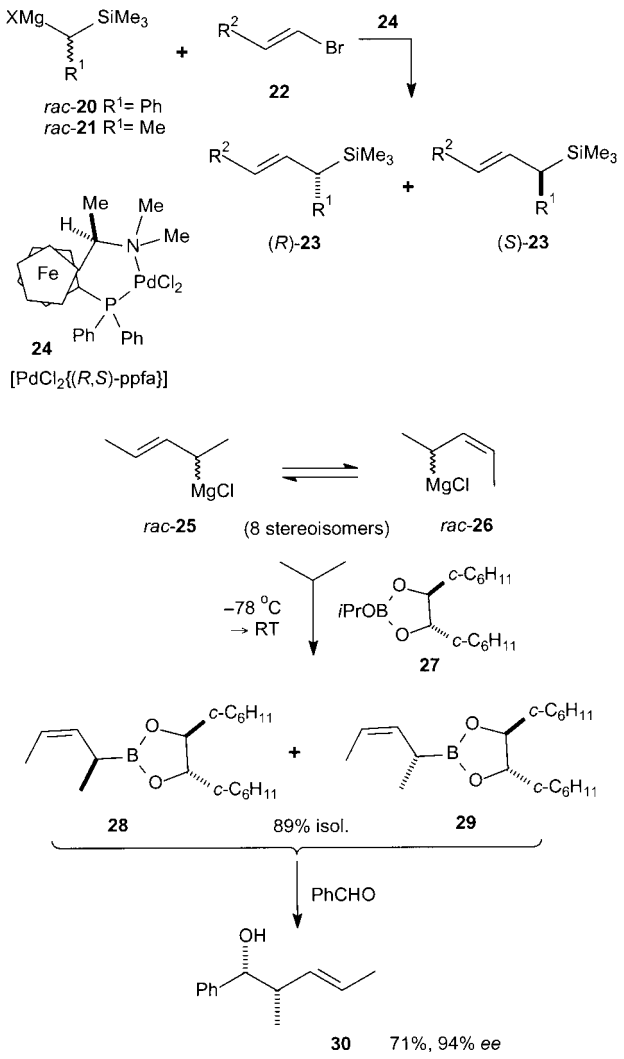
4.1.2. ***DKR Involving Carbon–Metal Bond Equilibration***

A large and diverse category of DKR applications is the reversible thermal inversion of configuration at a stereogenic, metal-substituted carbon atom as a way to interconvert enantiomers. The 1989 report by Noyori et al. cited possible examples of this phenomenon that involve equilibration at a secondary carbon–metal (C–M) bond.



Many examples of simple KR have been reported with C–M substrates.[24–30] One of the first reports described the nickel-catalyzed coupling of 2-butylmagnesium bromide with chlorobenzene in the presence of a chiral phosphine ligand to give 2-phenylbutane in 52% yield and 17.5% *ee*.[24a] If the secondary Grignard reagent is capable of inversion of configuration at the C–Mg bond, then the conditions for DKR might be satisfied. However, the relatively low yield and *ee* might also be the result of simple KR if the reaction was not taken to completion. Subsequent studies by other researchers increased the yield and enantioselectivity in related palladium-catalyzed coupling reactions of the more easily inverted benzylic Grignard reagents by using the optimized catalyst **24**.[25] The principle is illustrated in Scheme 6 and Table 6 with silylated Grignard reagents *rac*-**20** and *rac*-**21**.[25c]

For cases in which the C–Mg bond is benzylic (Table 6, entries 1 and 2), interconversion of the enantiomers is easy and DKR conditions are largely maintained. This is shown by the relatively small decrease in *ee* as the excess of *rac*-**20** over the halide **22** is decreased (compare entries 1 and 2 in Table 6). The trimethylsilylethyl Grignard reagent *rac*-**21** (Table 6, entry 3) works especially well and affords **23** with excellent *ee* if employed in excess. As shown in entry 4, DKR conditions are no longer satisfied by using a deficiency of *rac*-**21**. This observation is consistent with the greater configurational stability of **21** (methyl-substituted) over the phenyl-substituted Grignard reagent **20**, and suggests that with a deficiency of *rac*-**21** a simple KR pathway is taken.

Scheme 6 also shows an interesting example of an allylic Grignard reagent in which equilibrating *Z* and *E* isomers as well as enantiomers (**25** and **26**) are intercepted by a stoichiometric amount of a chiral borate **27**. In keeping with earlier precedents of double-bond geometry, the reaction affords isolable (*Z*)-(1-methyl-2-butenyl)boronic esters **28** and **29** with a remarkable diastereoselectivity of 97:3. The product ratio was inferred from an analysis of enantiomeric excess of the product of benzaldehyde trapping **30** (94% *ee*).[24e] On the basis of the product ratio, the facile interconversion between all possible stereoisomers must be facile to maintain DKR conditions.

A variety of organolithium reagents undergo inversion of configuration at or below room temperature,[26] and are therefore potentially useful in DKR applications. As might be expected with the relatively reactive benzyllithium **31**, reaction with the chiral electrophile (*S*)-**32** occurs with modest selectivity to give an unassigned ratio of 63:37 for the formation **33** and **34** (Scheme 7).[27a,b] If the enantiomers of **31** were stable to interconversion under the reaction conditions, then the product ratio would have to be 1:1, the same as the enantiomeric ratio (this is one variation of the

Hoffmann test for configurational stability).[27c] As the ratio of **33** to **34** is not 1:1, at least some degree of benzyllithium interconversion must occur, and electrophilic trapping takes place with at least partial DKR. However, DKR is by no means assured in other organolithium trapping experiments, and there are a number of mechanistic possibilities to consider.

4.1.3. *DKR versus Dynamic Thermodynamic Resolution (DTR) of Carbon–Metal Bonds*

Numerous reactions of heteroatom-stabilized organolithium species involve potentially interconverting carbon–lithium bonds, and some of the most useful examples are encountered in reactions conducted in the presence of sparteine or other chiral complexing agents.[28,29] A recent review by Beak et al. evaluates the mechanistic alternatives.[29] In a representative case, sparteine forms a coordination complex with the racemic organolithium species **36** under equilibrium conditions (−25 °C) to generate diastereomers **37** and **38** in solution (Scheme 8). If the solution is cooled to

Scheme 8. Silylation of **37** + **38** in the presence of sparteine (see Table 7); TMS = trimethylsilyl, Piv = pivaloyl.

−78 °C and treated with 0.1 equiv of TMSCl, then products (*R*)-**39** and (*S*)-**39** are formed in a ratio of 91:9 (Table 7, entry 1). If this ratio were the result of ideal DKR conditions, then the precursors **37** and **38** would have to be in rapid equilibrium, and the product ratio would be unaffected by the stoichiometry of TMSCl. However, the corresponding experiment with excess TMSCl afforded a much lower ratio of products (Table 7, entry 2). Furthermore, addition of sparteine at −25 °C prior to silylation at −78 °C with 0.1 equiv of TMSCl gives an exceptionally high *R*/*S* product ratio of 99:1 (Table 7, entry 3). These results indicate that **37** does not

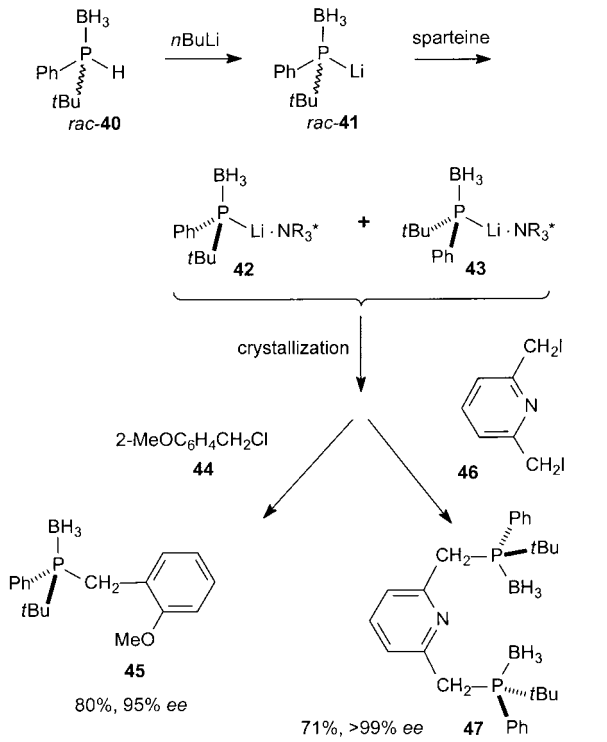
Table 7: Silylation of **37**+**38** in the presence of sparteine (see Scheme 8).

Entry	Equiv TMSCl	T_1 [°C]	T_2 [°C]	(*R*)-**39**/(*S*)-**39**	*ee* [%]
1	0.1	−78	−78	91:9	82
2	2.3	−78	−78	56:44	12
3	0.1	−25	−78	99:1	98
4	2.1	−25	−78	92:8	84



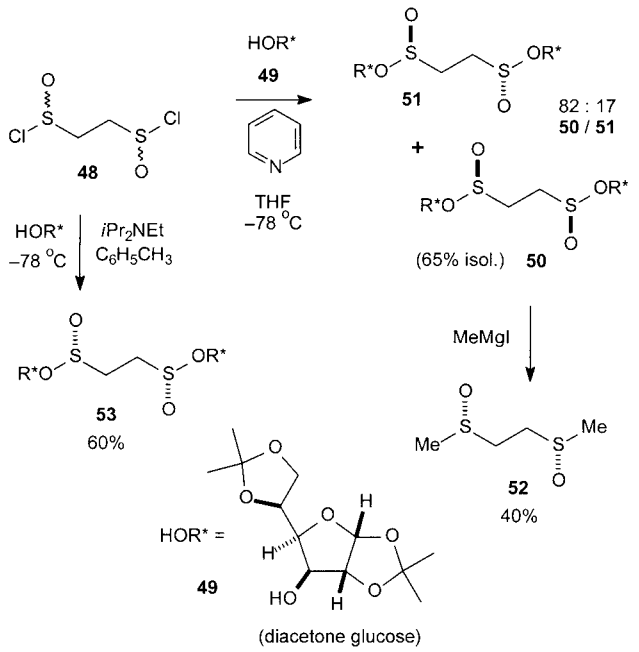
interconvert with **38** at −78 °C, and that the major diastereomer **37** is also the more reactive isomer. Entry 4 of Table 7 describes an experiment in which equilibration with sparteine at −25 °C is followed by the addition of excess TMSCl at −78 °C. In this case, both **37** and **38** must be completely consumed. As **37** and **38** do not interconvert at −78 °C, the ratio of (*R*)-**39**/(*S*)-**39** reflects the thermodynamic ratio of **37** and **38** established by the preceding equilibration at −25 °C. Thus, none of the four experiments involves dominant DKR.

Beak et al. classified the scenario of entry 4 in Table 7 as a dynamic thermodynamic resolution (DTR).[29] This is defined as a two stage process: 1) a thermodynamic ratio of reactive intermediates is established by equilibration of diastereomers; 2) a subsequent reaction is conducted at a lower temperature where the equilibrium is frozen out, resulting in chiral products.

In principle, the DTR phenomenon is possible in a variety of organometallic environments in which an equilibrating pair of enantiomers is modified for further reaction by complexation with an enantiomerically pure ligand. This concept has considerable potential for the control of configuration at labile carbon–metal bonds, as underscored in a recent study of 2-lithiopyrrolidines by Coldham et al.[28f] However, DTR is distinct from DKR, so the reader is referred to the review by Beak et al. for further examples.[29]

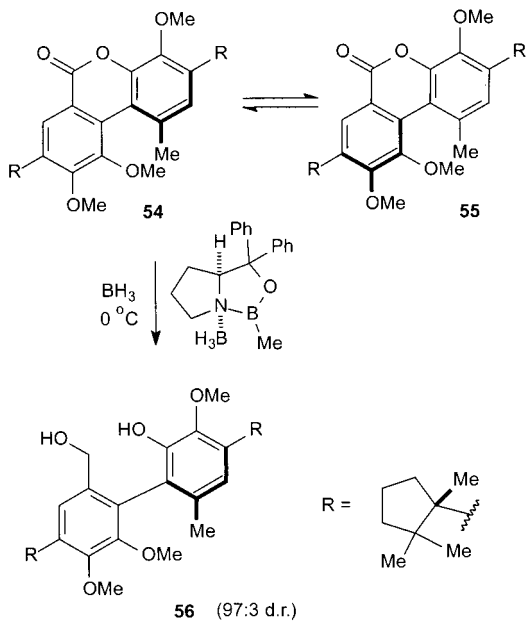
In the first stage of DTR, diastereomeric species interconvert through inversion of configuration at one of the asymmetric atoms. If the process occurs in solution, then the first stage is referred to as an "asymmetric transformation of the first kind".[30] The more interesting variation occurs if one of the isomers crystallizes from solution. In this situation, events are controlled by the thermodynamics of phase equilibrium. The more stable crystal lattice can be formed exclusively because two equilibrating solid phases with different stabilities cannot be present simultaneously unless the temperature happens to match the critical temperature for a phase transition.[31,32] Eliel et al. define this striking phenomenon as a crystallization-induced asymmetric transformation, also known previously as an "asymmetric transformation of the second kind".[30]

A more recent case in which DKR and DTR are possible in principle was reported by Wolfe and Livinghouse.[33] The conversion of the phosphine–borane complex *rac*-**40** into the chiral phosphine **45** (95 % *ee*) was carried out by deprotonation, treatment of *rac*-**41** with sparteine,[33] equilibration of the resulting mixture of diastereomers **42** and **43**, and alkylation with the benzylic halide **44** (Scheme 9). High *ee* values were only observed upon warming the mixture of **42** and **43** to 25 °C, and stirring the resulting suspension for one hour,



Scheme 9. Example of DKR as a likely consequence of DTR as reported by Wolfe and Livinghouse.[33]

followed by cooling to −78 °C prior to alkylation. If the sample was not warmed above 0 °C, the *ee* value of **45** was not more than 35 %. Therefore, the product ratio cannot be controlled solely by the differences in relative reactivity between rapidly interconverting **42** and **43** (commensurate with DKR). The result is consistent with a DTR interpretation, and may involve crystallization-induced asymmetric transformation in the first stage if the formation of a suspension ("voluminous precipitate") results from the crystallization of **42**. A similar sequence with the difunctional halide **46** in the alkylation step gave the interesting diphosphine **47** in >99 % *ee* (Scheme 9). The higher *ee* reflects an upgrade resulting from the formation of separable diastereomers as minor by-products in the alkylation step.



4.1.4. DKR with S(O)Cl and P(O)Cl Derivatives

Equilibration of configuration at sulfinyl sulfur or phosphinyl phosphorus atoms can also be used in DKR experiments.[34a,b] The most impressive example is shown in Scheme 10: the difunctional bis(sulfinyl chloride) **48** in reaction with the chiral alcohol diacetone glucose (**49**) (HOR*).[34a] Thus, a mixture of enantiomers and diastereomers of **48** is treated with **49** in the presence of pyridine to afford a mixture of diastereomeric bis(sulfinates) **50** and **51** in a ratio of 82:17, with the remaining 1 % as a third isomer **53**. Crystallization affords pure **50**, and Grignard displacement occurs with inversion to produce the interesting C_2-symmetric bis(sulfoxide) **52** in moderate yield. Evidently, the isomers of **48** are in equilibrium at −78 °C, and formation of **50** is favored kinetically. If the first step in the sequence is modified by the

Scheme 10. DKR of a mixture of enantiomers and diastereomers of bis(sulfinyl chloride) **48** with the chiral alcohol diacetone glucose (**49**).

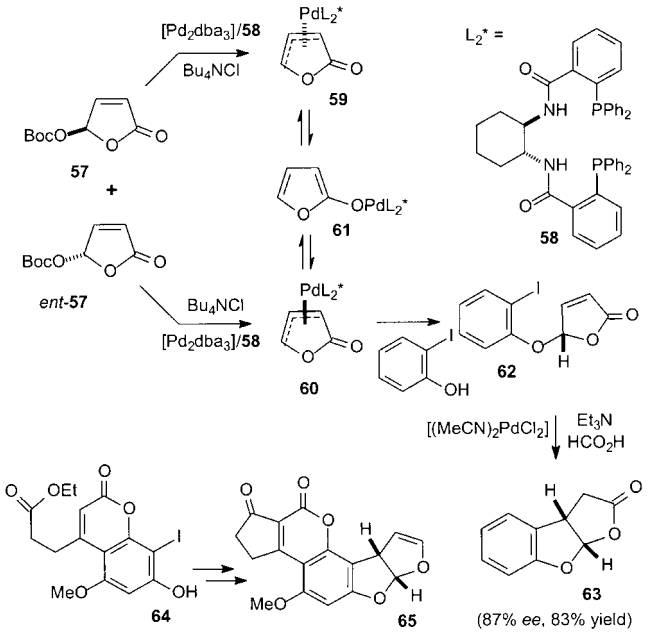
Scheme 11. DKR of enantiomeric atropisomers as reported by Bringmann, et al.[35a]

replacement of pyridine with the Hünig base, and the solvent is changed to toluene, then the kinetic selectivity is inverted; **53** becomes the dominant product. In this manner, either enantiomeric series of C_2-symmetric bis(sulfoxides) is accessible.

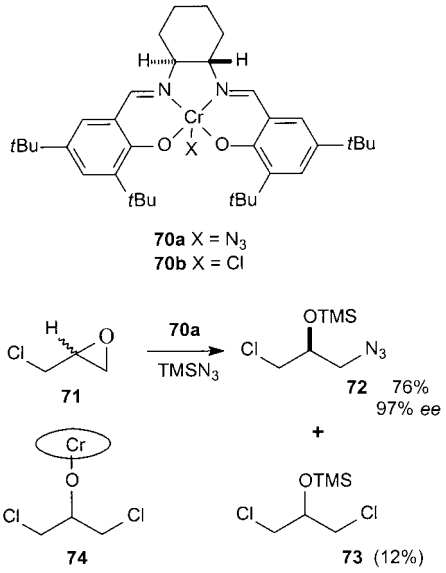
The same methodology also works with simple sulfinyl chlorides, and provides a route to unsymmetrical chiral sulfoxides.[34a] A conceptually similar DKR approach has been used to prepare chiral phosphites, aminophosphines, and phosphines.[34b–e] These methods are attractive alternatives to simple KR of sulfur- or phosphorus-containing substrates.[34f,g]

4.1.5. DKR with Atropisomers

In principle, DKR is possible if interconverting, enantiomeric atropisomers are treated with enantioselective reagents.[35] The concept is illustrated in Scheme 11,[35a] although it is not technically a case of DKR because the process involves equilibrating diastereomers **54** and **55** (note that chirality is present in the remote substituent R). The recognition process occurs far from the chiral substituent, and involves the selective reduction of the lactone carbonyl group of isomer **54** by diborane with a chiral oxazaborolidinone catalyst. After the constraint imposed by the lactone ring is removed, the atropisomers interconvert much more slowly, and **56** is isolated with excellent diastereomeric purity (97:3 d.r.). Structure **56** is an intermediate in the synthesis of mastigophorene A by Bringmann et al.[35a]

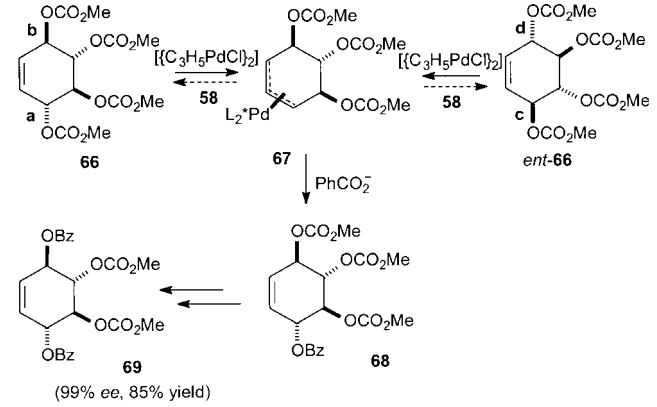


4.1.6. DKR with Transition-Metal Intermediates



Catalytic cycles that are capable of converting both enantiomers of a racemic substrate into a common intermediate have been recognized which provide additional opportunities for DKR. Simple KR via π-allyl intermediates is well-known,[36] but recent investigations have encountered cases in which DKR is also possible if allylpalladium intermediates are generated catalytically from allylic carbonates (Scheme 12).[37,38] Thus, treatment of the racemic butenolide **57** with $[Pd_2dba_3]$ in the presence of the chiral ligand **58** under carefully optimized conditions results in the reversible formation of diastereomeric π-allylpalladium intermediates **59** and **60**.[37a,b] If a Cl^- ion source is included in the system, then **59** and **60** interconvert via the "enolate complex" **61**, and DKR becomes possible. If the experiment is conducted in the presence of *o*-iodophenol, the intermediate **60** is intercepted selectively, and **62** is formed in 83% yield (87% *ee*). Subsequent reductive Heck cyclization to **63** was also demonstrated, and the analogous sequence from **64** was used by Trost and Toste in an elegant synthesis of aflatoxin B (**65**).[37a,b]

One further example of palladium-mediated DKR illustrates an unusual pathway for the conversion of both enantiomers of a complex racemic substrate into a common intermediate.[38a] The treatment of racemic tetracarboxylate **66** (an ester of *rac*-conduritol B) with a palladium source, a soluble benzoate salt, and the chiral ligand **58** results in a remarkable conversion into the bis(benzoate) **69** (85% yield, >99% *ee*; Scheme 12). Selective oxidative insertion of palladium into bond **a** in preference to bond **b** initiates the events leading from **66** to **67**. However, the same intermediate can also be formed from *ent*-**66** by selective insertion into bond **d** in preference to bond **c**. This provides an efficient pathway to **68** and ultimately to **69** from either enantiomer of the starting compound **66**.



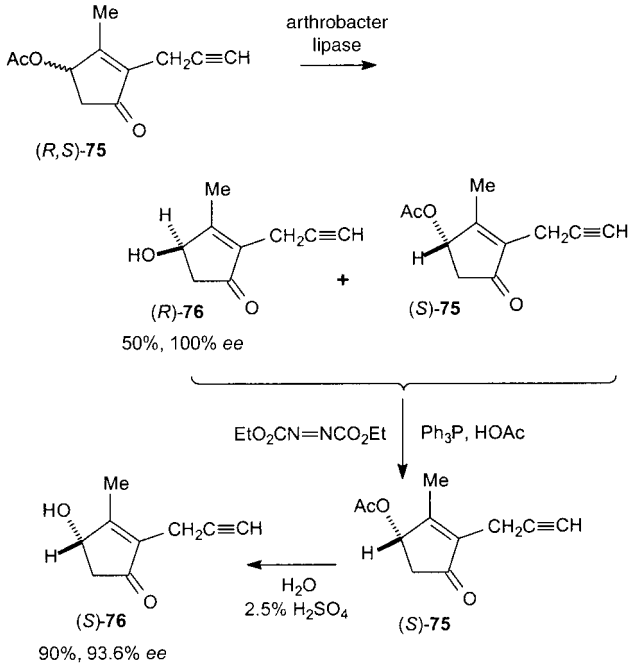
Another approach to the generation of a common intermediate from a racemic mixture through organometallic catalysis is described by Schaus and Jacobsen (Scheme 13).[39]

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Scheme 13. DKR through the production of a common intermediate from a racemic mixture by organometallic catalysis. [39]

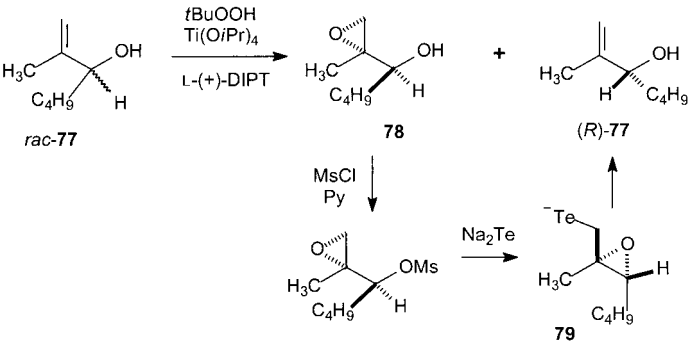
Scheme 12. Palladium-mediated DKR through catalytic production of allylpalladium intermediates; Boc = *tert*-butoxycarbonyl, dba = dibenzylideneacetone, Bz = benzoyl.

The intent was to evaluate catalyst **70a** for the conversion of epichlorohydrin **71** into **72** with trimethylsilyl azide under conditions expected to allow simple KR. However, the recovered epichlorohydrin did not show the expected enrichment of *ee*, apparently the result of competing racemization under the reaction conditions. This observation suggested a DKR application, and an optimized experiment was developed with controlled addition of the azide to provide **72** in 76% yield (97% *ee*). The formation of a common intermediate **74** was proposed to explain racemization of **71** during the DKR process, as well as formation of the by-product **73** through interaction of a modified catalyst **70b** with the starting epichlorohydrin.

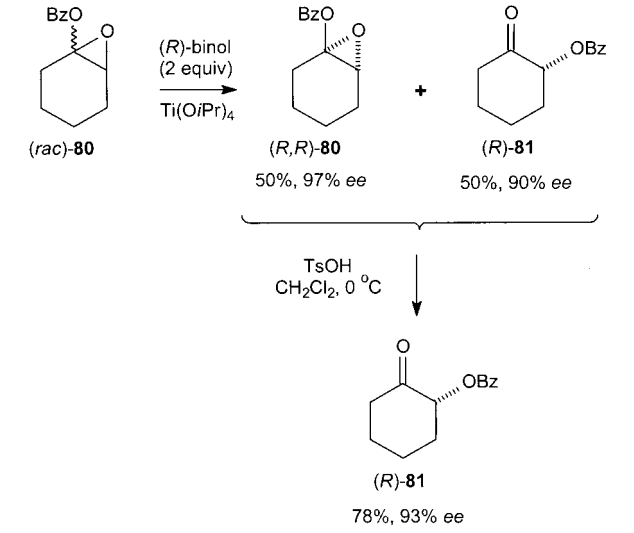


A variety of other methods for the interconversion of enantiomers of labile substrates have been exploited for DKR,[2g,i,40] and some have been used in combination with enzymatic catalysis. Some of the best examples feature equilibrating racemic cyanohydrins and racemic heterobenzylic alcohols as substrates for DKR in the presence of lipase acyl-transfer catalysts, a topic that has been described extensively in the review literature.[3a–j] Some of the most recent work in this area emphasizes the simultaneous use of enzymatic catalysts and transition-metal racemization catalysts; specialized reviews on this topic are also available.[2j,m]

4.2. Kinetic Resolution with Subsequent Enantioconvergent Processing of Intermediates or Products



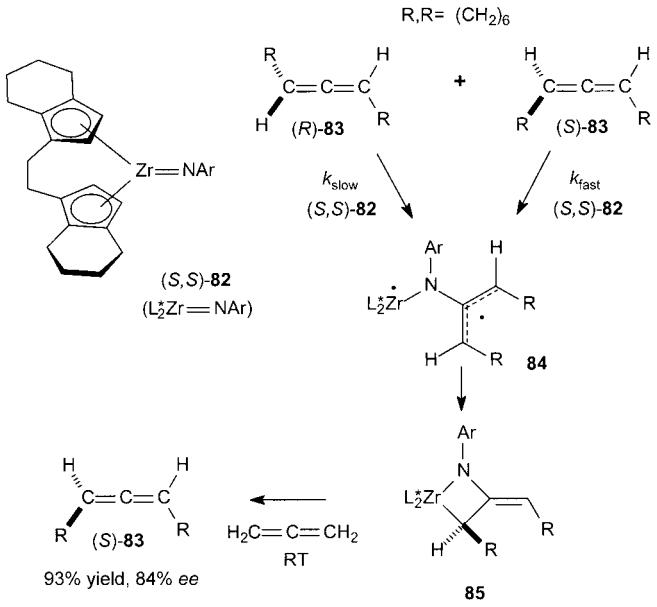
A racemic substrate can be efficiently converted into a single enantiomer if simple KR is combined with the stereospecific conversion of one enantiomer into a product derived from the other. Early experiments to demonstrate enantioconvergent processing relied on lipase-mediated KR to afford a mixture of a secondary alcohol and the enantiomeric secondary ester.[3p,41] Simple Mitsunobu esterification was then used as the enantioconvergent step to transform the alcohol into the ester by inversion of configuration. One of the best examples is shown in Scheme 14.[41a] Through the lipase-catalyzed hydrolysis of racemic ester (*R*,*S*)-**75**, a mixture of alcohol (*R*)-**76** and acetate ester (*S*)-**75** was obtained with perfect selectivity. After the mixture was subjected to Mitsunobu conditions, a single product consisting of (*S*)-**75** was isolated. Ester hydrolysis with dilute acid then produced the alcohol (*S*)-**76** in 90% overall yield and 93.6% *ee*. Evidently, the Mitsunobu inversion from (*R*)-**76** to (*S*)-**75** occurs with ≈97% stereospecificity. In principle, the same enantioconvergent approach can be used with a variety of secondary alcohols, and several simpler examples have been demonstrated.[41b]



Among the few cases in which nonenzymatic catalysts were used for enantioconvergence is a study by Discordia and Dittmer (Scheme 15).[42] Standard Sharpless epoxidation KR was performed to convert *rac*-**77** into a mixture of epoxide **78**

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Scheme 14. KR by lipase-catalyzed hydrolysis of a racemic ester and subsequent enantioconvergent transformation. [41a]



Scheme 15. Enantioconvergent transformations with nonenzymatic catalysts as reported by Discordia and Dittmer (top)[42] and Shi and co-workers (bottom);[43] Py = pyridine, Ms = methanesulfonyl, Ts = *p*-toluenesulfonyl.

and the slow-reacting alcohol (*R*)-**77**. After isolation of **78**, treatment with methanesulfonyl chloride followed by reaction with a telluride ion source resulted in a sequence of intermolecular and intramolecular displacement steps to afford the transient epoxide **79** with inversion of configuration. Subsequent 1,2-elimination by an unknown mechanism then converted **79** into (*R*)-**77**, identical to the slow-reacting enantiomer from the initial Sharpless KR (88% combined yield, 94% *ee*).

An intriguing report by Shi et al. illustrates another epoxidation approach (Scheme 15) that results in enantioconvergence.[43] A racemic mixture of epoxides **80** was prepared by the epoxidation of cyclohexenyl benzoate. Upon treatment of the racemic epoxide with a chiral Lewis acid generated from (*R*)-binol and titanium tetra(isopropoxide), the (*S*,*S*)-epoxide was selectively converted into α-benzoyloxycyclohexanone (*R*)-**81**. The reaction proceeds by simple KR that occurs with inversion of configuration and with excellent enantioselectivity ($s > 100$). The product mixture was then treated with toluenesulfonic acid to convert the slow-reacting epoxide (*R*,*R*)-**80** into (*R*)-**81** with retention of configuration (78% overall yield, 93% *ee*). Thus, enantioconvergence was achieved in the first stage (rearrangement of (*S*,*S*)-**80** to (*R*)-**81**), whereas structural convergence was effected in the second stage. Several other examples of this two-stage process were reported by Shi and co-workers.[43]

Another case in which enantioconvergence occurs at the stage of a reactive intermediate was reported by Bergman and co-workers. Kinetic resolution of chiral allenes can be effected with the chiral zirconium imido complex **82** (Scheme 16).[44] However, for 1,2-cyclononadiene **83**, both the fast-reacting and slow-reacting enantiomers eventually afford the same major product **85**, apparently via the diradical intermediate **84**. Upon treatment of **85** with excess allene at room temperature,

Scheme 16. Enantioconvergence at the stage of a reactive intermediate in the kinetic resolution of a chiral allene. [44]

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the 1,2-cyclononadiene is displaced and is recovered in 93% overall yield and with 84% *ee*.

The above case is conceptually related to some of the DKR experiments mentioned in Section 4.1.6.[37,38] For example, the formation of a single allylpalladium complex **67** from either enantiomer **66** or *ent*-**66** was described in Scheme 12. If conversion into **67** is reversible, as suggested in a generalized reaction Scheme by the authors,[38a] then the experiment involves DKR by the conventional definition. However, if conditions were found under which **67** is formed irreversibly from both **66** and *ent*-**66**, it would still be possible to obtain a single product in high yield and high *ee*. In this case, the experiment would be an example of enantioconvergence, and not DKR.

By similar logic, the example illustrated in Scheme 16 might involve DKR if **84** were formed reversibly from (*R*)-**83** and (*S*)-**83**. However, this possibility is ruled out because unreacted 1,2-cyclononadiene did not racemize under the reaction conditions. Therefore, the process appears to be enantioconvergent, and does not involve DKR. In view of the potential for efficient processing of both enantiomers of a substrate, the prospect of future reports of further examples of this phenomenon is exciting.

4.3. Divergent Reactions on a Racemic Mixture and Parallel Kinetic Resolution

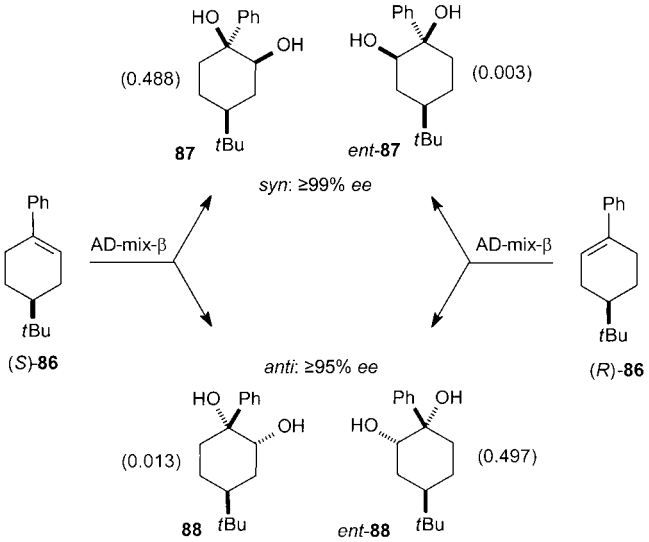
Efficient recovery of highly enantioenriched products starting from a racemic mixture is possible if each substrate enantiomer can be selectively converted into a distinct, easily separated product. Generally accepted terminology for such reactions has not yet reached the consensus stage,[2ee,45–47] although relevant examples that involve a single chiral reagent had been recognized many years ago.[45] Herein, we use Kagan's recent classification of this potentially diverse family of transformations as "divergent reactions on a racemic mixture" (divergent RRM).[46b] This terminology applies broadly to a number of possible scenarios, some of which involve a component of kinetic resolution, whereas others do not.

By 1967, Guetté and Horeau had already demonstrated that reaction of racemic ketones with a chiral hydride donor affords alcohol diastereomers with significant *ee* values.[45] The results were correlated by using material balance relationships for the case in which the chiral substrate is completely converted into two products. Subsequent papers by Kagan extended the mathematical treatment to a broader range of divergent RRM scenarios (partial conversion, more than two products).[46] Furthermore, Kagan recognized that the Sharpless epoxidation of **1**, already mentioned in a different historical context (Scheme 1), is an example of divergent RRM because the reaction affords diastereomeric *erythro* and *threo* epoxides.

Sharpless and co-workers had shown that the minor *threo* diastereomer **III** (**3** + *ent*-**3**) is formed in an enantiomeric ratio of 24:1 (92% *ee* favoring *ent*-**3**) if the reaction of racemic alcohol **1** (= **I**) is allowed to proceed to completion.[13] The *ee* value of products **II** from racemic **1** was not reported, but may be inferred as 44% *ee* if the product enantiomeric ratios of Scheme 1, deduced from the reactions of pure enantiomers (*R*)-**1** and (*S*)-**1**, also apply to the reaction of racemic **1**. Further insight can be obtained by applying the mathematical model of Horeau to the reaction of the racemic alcohol **1** [Eq. (3)].

given : $\mathbf{II} = \mathbf{2} + \textit{ent}\text{-}\mathbf{2} = \textit{erythro}$ diastereomer;
$\mathbf{III} = \mathbf{3} + \textit{ent}\text{-}\mathbf{3} = \textit{threo}$ diastereomer

from Scheme 1 : $(R,S)\text{-}\mathbf{1} \rightarrow \mathbf{II} + \mathbf{III}$



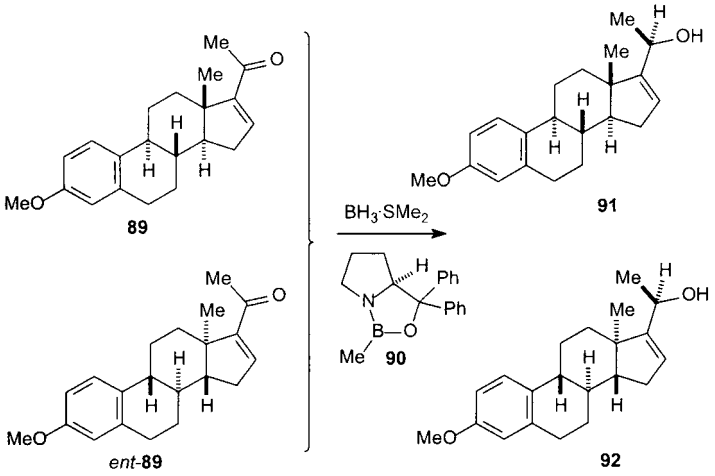
Horeau equation : $x_{\mathbf{II}}(ee_{\mathbf{II}}) + x_{\mathbf{III}}(ee_{\mathbf{III}}) = 0$ (3)

The terms $x_{\mathbf{II}}$ and $x_{\mathbf{III}}$ refer to the mole fractions of diastereomers **II** and **III**, and $ee_{\mathbf{II}}$ and $ee_{\mathbf{III}}$ represent their respective enantiomeric purities (Horeau's derivation uses *ee* values as decimals with opposite signs for cases in which the major enantiomers have opposite absolute configurations). From the measured value of $ee_{\mathbf{III}}$ for **III** (92%), it is possible to calculate the value of $ee_{\mathbf{II}}$ if the mole fractions of **II** and **III** are known (that is, from the diastereomeric ratio). This data was not reported for the reaction of racemic **1**, but may be inferred from Scheme 1 as $x_{\mathbf{II}} = 68\%$ and $x_{\mathbf{III}} = 32\%$. The predicted value of $ee_{\mathbf{II}}$ from Equation 3 is 44%, the same as inferred above from the product ratios shown in Scheme 1. Thus, Equation (3) may be used to check for self-consistency in diastereomeric and enantiomeric ratio data.

Equation (3) requires the major product, **II**, in a divergent RRM process to have the lower *ee* value. This is a consequence of the material balance relationship, and a lower degree of reagent control (for example, 38:62 in the path from enantiomer (*R*)-**1** to the products *ent*-**2** and *ent*-**3**, Scheme 1). On the other hand, Equation (3) predicts that both products can be formed with high *ee* and high yield if both enantiomers react with high reagent control (high diastereoselectivity), as discussed in the following examples. We classify these reactions as stereodivergent RRM to indicate that individual enantiomers may react with different levels of diastereoselectivity.

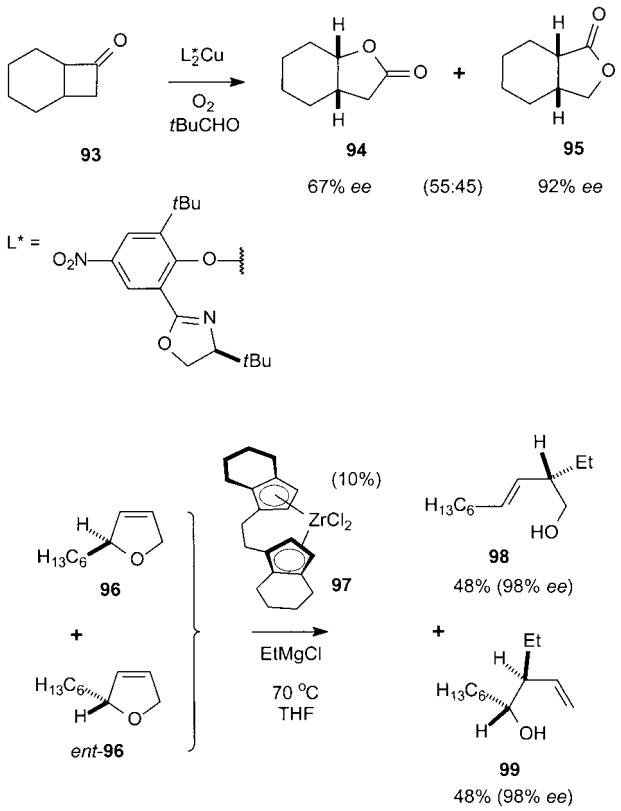
Examples of efficient stereodivergent RRM are known under Sharpless osmylation conditions,[48] one of which is summarized in Scheme 17. The racemic cyclohexene **86** was treated with the commercially available Sharpless osmylation reagent (AD mix β) to give separable diastereomers **87** ($\geq$99% *ee*) and **88** ($\geq$95% *ee*) in 82% combined yield.[48g] The Horeau relationship [Eq. (3)] allows calculation of the detailed product ratios from the conservative *ee* limits (taken as 99% *ee* and 95% *ee*, respectively) and the mole-fraction relationship (sum of **87** + *ent*-**87** + **88** + *ent*-**88** = 1). The predicted mole fractions (Scheme 17, in parentheses) show that the osmylation occurs with excellent reagent control. The major product from each enantiomeric alkene corresponds to osmylation of the pro-*R* face of the phenyl-substituted carbon. The directing influence of the *tert*-butyl substituent is relatively small, as shown by the calculated diastereomeric ratio of (*R*)-**86** (37.5:1 *syn*/*anti*) in comparison with that of (*S*)-**86** (1:166 *syn*/*anti*). Assuming that conventional purification would separate the diastereomers efficiently, the result would

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 17. Stereodivergent RRM in the osmylation of racemic cyclohexene **86** with AD mix β.

be to enrich the enantiomers to a level of $\geq 95\%$ *ee* with a theoretical recovery limit equal to the overall yield (82%).



The ideal situation for stereodivergent RRM is to have total reagent control. In this case, the asymmetric carbons in the racemic substrate would have no influence on the diastereomeric ratio and would serve only to enable the separation of product diastereomers. Scheme 18 illustrates an example of enantiofacially controlled ketone reduction in which the efficiency may have reached the ideal limit.[49] The reduction of racemic **89** with dimethylsulfide borane and the oxazaborolidine catalyst **90** affords a 1:1 mixture of diastereomers **91** (>99% *ee*) and **92** (>99% *ee*) in 95% combined yield after chromatographic separation. The same phenomenon had been encountered earlier with racemic ketones under enzymatic reduction conditions,[50a–j] or by the use of nonenzymatic hydride donors in the presence of chiral additives, although the level of enantiofacial control in the latter examples was usually lower.[45,50k–o] For the example in Scheme 18, the highly selective reduction allows the preparation of both enantiomeric steroids by using a simple technique to separate the product diastereomers and thus the enantiomers as well.

In principle, stereodivergent RRM is possible in a variety of addition reactions in which an sp^2-hybridized carbon atom is converted into an asymmetric carbon atom. A relevant study has appeared involving the hetero-Diels–Alder reaction of racemic enals and achiral enol ethers. Highly selective stereodivergent RRM was observed, resulting in the synthesis of diastereomeric dihydropyrans with good *ee* by using a chiral chromium Lewis acid catalyst (Chavez and Jacobsen).[51]

The Horeau relationship [Eq. (3)] also applies to a reaction category that we classify as regiodivergent RRM. The only new feature is that product separation depends on the formation of a distinct regioisomer from each substrate enantiomer. Early reports of this phenomenon involved a variety of enzymatic oxidations,[52] including a number of highly efficient Baeyer–Villiger reactions.[52j–n] Synthetic catalysts for analogous Baeyer–Villiger oxidations are now available,[53] as illustrated for the conversion of racemic **93** into a separable mixture of the regioisomers **94** and **95** (Scheme 19).[53a]

Scheme 18. Separation of both enantiomers of a steroid **89** and *ent*-**89** by stereodivergent RRM (highly selective reduction).

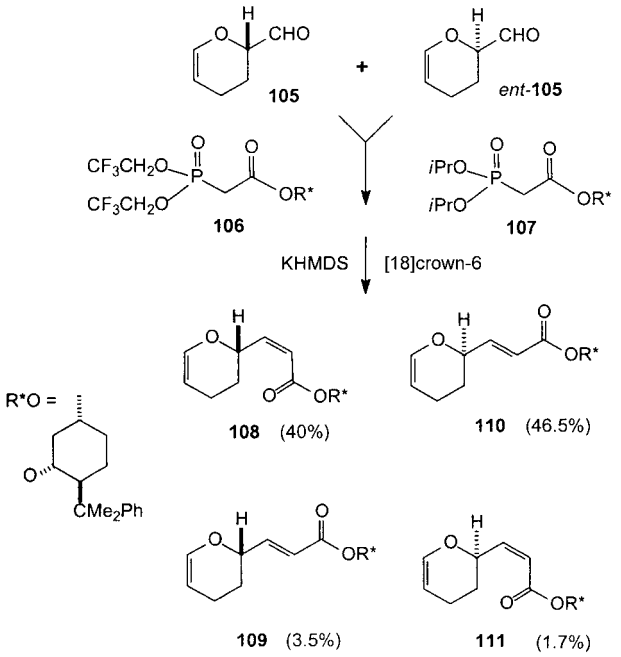
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Other interesting examples of regiodivergent RRM have been reported recently,[54–58] including regioselective C–O bond cleavage,[54] Sharpless epoxidations,[55] transition-metal-catalyzed diazo insertions and cyclopropanations,[56] and a rhodium-catalyzed ynal cyclization in which one enantiomer affords a cyclopentenone product while the other produces the isomeric alkylidenecyclobutanone.[57] In one of the most impressive examples, the ring opening of racemic dihydrofuran **96** by a Grignard reagent in the presence of the chiral zirconocene catalyst **97** was carried out with near-perfect control, as shown in Scheme 19.[58] Excellent recovery and selectivity (96% yield of separated isomers **98** and **99**, each with 98% *ee*) were observed, resulting from dominant reagent control.

The examples of stereodivergent and regiodivergent RRM discussed above feature a single reagent that reacts in a different way with each enantiomer. This difference is the basis for enantiodivergence. If reagent control is sufficiently high and the products can be separated, then the process allows efficient separation of enantiomers. Although the experimental setup resembles that of simple KR (a chiral reagent is used to modify a racemic mixture), there is a crucial difference: in divergent RRM, the reaction is taken to completion. If this were done in a simple KR situation in which the divergence of enantiomers to give distinct products is not possible, the product would be racemic. Simple KR may or may not take place as divergent RRM experiments are performed, but KR has nothing to do with the desired outcome in RRM using a single chiral reagent because the relative reactivities of the enantiomers are unimportant.

Parallel kinetic resolution (PKR) is a variation of divergent RRM in which two complementary chiral reagents are employed for selective modification of a racemic substrate to afford distinct products.[47] The experiment consists of two simple KR reactions conducted "in parallel", in contrast to divergent RRM with a single reagent. In PKR, the relative reactivities of enantiomers are very important, and the two chiral reagents are chosen so that each substrate enantiomer reacts at a similar rate. Under these conditions, the enantiomeric ratio of the unreacted substrate remains close to 1:1 regardless of conversion, and product *ee* reflects the inherent enantioselectivities of each reagent. In these respects, PKR resembles DKR.

The first example of a preparative PKR experiment is shown in Scheme 20 with quasienantiomeric pyridinium carboxylates **100** and **101** as the chiral reagents.[47] The reagents were selected for their similar reactivities and complementary enantioselectivities in simple KR experiments (**100**, $s = 42$, selective for (*S*)-**102**; **101**, $s = 41$, selective for (*R*)-**102**). The chiral R group (fenchyl) in reagent **101** plays no role other than to provide steric bulk as needed to match the reactivity of **100**. For the PKR experiment, **100** and **101** were mixed and allowed to react with *rac*-**102**. The quasienantiomeric esters **103** (e.r. 94.5:5.5 *S*/*R*) and **104** (d.r. 97.5:2.5 **104**/*epi*-**104**) were obtained as the major products in >95% combined yield. Reductive cleavage of the trichlorobutyl protecting group from **103** allowed easy product and enantiomer separation to a level of 89% *ee* or more, and with a substantial improvement in recovery of enantioenriched products (>95%) over simple KR.



Scheme 20. Preparative PKR using chiral reagents with complementary enantioselectivities.[47]

Brooks et al. may have encountered an earlier example of the two-reagent process in the reduction of a racemic ketone with bakers' yeast. In this case, two different enzymes were involved in enantiomer discrimination, although one of the products in their experiment was achiral.[59a] The optimum conditions required for conducting two parallel, complementary enantioselective reactions were not discussed in this report. However, another early study by Preston not only discussed the principles, but also conducted relevant experiments with two complementary chiral reagents.[59b] These were probably the first attempts designed specifically to achieve PKR (termed "simultaneous kinetic resolution" by Preston), but evidence for PKR was largely based on NMR spectroscopic analysis because the product mixtures could not be separated.

An intriguing study of reagent selectivity has been reported in connection with another example of PKR (Scheme 21).[60] In this case, differing phosphonate alkoxy groups in the phenmenthyl-derived reagents **106** and **107** allowed complementary selectivity for individual enantiomers of the substrate **105**. Evidently, the phosphorous-bound alkoxy groups invert reagent enantioselectivity and *E*/*Z* selectivity, which results in divergent processing of the substrate enantiomers (enantiodivergence) to afford diastereomers **108–111**. Even if the chiral auxiliary OR* were removed, separation of *E* and *Z* isomers would still provide a

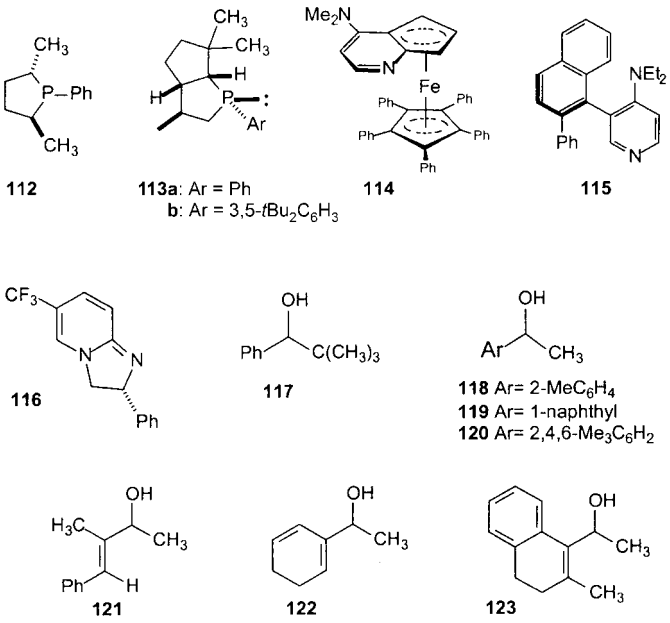
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Scheme 21. An example of complementary selectivity with reagents **106** and **107** for the individual enantiomers of a substrate.[60]

basis for the separation of enantiomers because of the high diastereomeric ratios of *Z* isomers (**108** > **111**) and *E* isomers (**110** > **109**). The authors also report other highly selective variations of PKR with different chiral auxiliaries on each substrate enantiomer[60a] and enantioconvergent processing via allylpalladium intermediates to give one dominant product with enhanced efficiency.

All of the two-reagent divergent RRM (PKR) applications require the compatibility of both reagents as well as similar reaction rates and enantioselectivities for optimum results. These requirements are easier to satisfy by using two stoichiometric chiral reagents,[47,59–63] although a doubly catalytic example of PKR has also been reported.[63] In contrast, the single reagent version (divergent RRM) is easier to perform in the catalytic mode if the necessary level of reagent control is achieved, and if a structural basis for enantiodivergence is present.

As shown above, PKR experiments can be stereodivergent, regiodivergent, or structurally divergent in other ways, provided that a distinct modification is made to each enantiomer that allows conventional separation.[47,59a,60–63] The Horeau relationship [Eq. (3)] still applies because it is based on material balance, yet PKR experiments involve a kinetically distinct situation[64] from the single-reagent version (divergent RRM). In the literature, PKR terminology has often been used to describe divergent RRM, but we recommend that PKR be reserved for the two-reagent experiment as a special case of divergent RRM.[45] As already noted, single reagent divergent RRM does not depend on the existence of any KR component, whereas the two-reagent version (PKR) requires two simultaneous enantiocomplementary KR reactions.



5. Kinetic Resolution of Important Functional Group Categories

5.1. Alcohols

As the most versatile class of substrates for synthesis applications, alcohols have received the most attention in the context of KR. A number of examples have already been encountered in connection with the techniques for improving efficiency, especially in the context of DKR with the Noyori hydrogenation methodology. Furthermore, KR with enantioconvergent processing of products is easily applied to secondary alcohol-containing structures because there are good methods available to invert alcohol group configuration, such as the Mitsunobu reaction as mentioned earlier. Recent developments in the preparation of alcohol derivatives with nonenzymatic KR is therefore discussed in detail herein, with an emphasis on catalytic methods.[2u–y]

5.1.1. KR of Alcohols with Chiral Nucleophiles as Catalysts

Major advances have been made in the development of chiral synthetic catalysts for acyl transfer through the activation of anhydrides. Studies in this area can be traced to the experiments of Wegler in the 1930s in which alkaloids were used to mediate enantioselective acylations with acetyl chloride and acetic anhydride, and to subsequent work with stoichiometric acyl-transfer agents.[65] The first example of KR of alcohols with $s > 10$ under nonenzymatic catalytic conditions was reported in 1996 in which the chiral phosphine **112** (Scheme 22) was used to activate *m*-chlorobenzoic anhydride.[66] Since that time, rapid progress has been made with other chiral nucleophiles, including structures **113**–**116**.[67–72] Hindered secondary benzylic and allylic alcohols

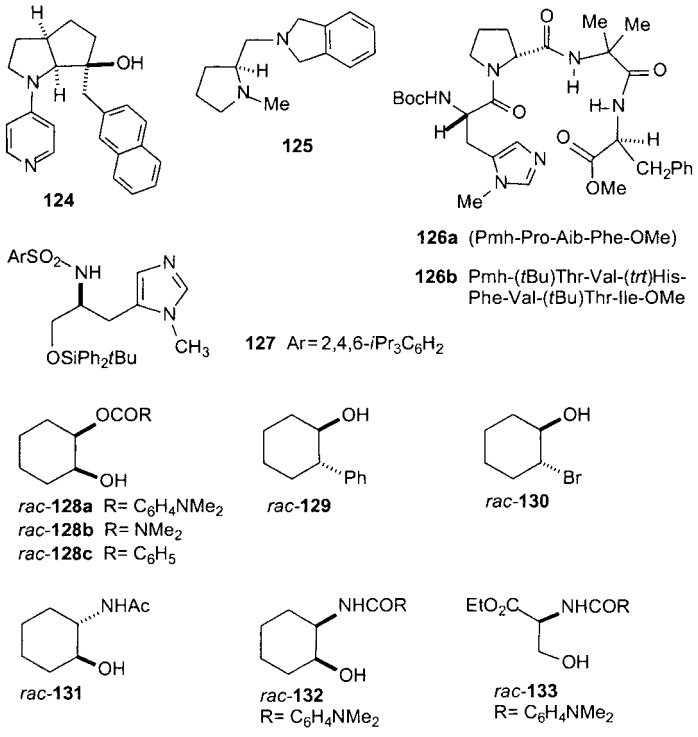
Scheme 22. Catalysts **112**–**116** for the kinetic resolution of alcohols **117**–**123** under nonenzymatic conditions (see Table 8).

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

are excellent substrates, provided that the hydroxy group and double bond are not constrained within a ring (Table 8).

Nucleophilic catalysts **124**–**127** (Scheme 23) have been shown to activate anhydrides for the kinetic resolution of several 2-substituted cycloalkanols, 1,2-diol monoesters, and 2-amido alcohols with impressive enantioselectivity (Table 9; tertiary amine additives are required for good catalyst turnover, but are not specified in the table).[73–78] Lower selectivity was observed with a primary alcohol **133** (s = 6.8),[73b] but promising results have been obtained with analogous tertiary alcohols.[75f] These examples suggest that nonenzymatic catalysts may soon be capable of competing with lipases in terms of substrate generality. The peptide-based catalysts reported by Miller and co-workers are especially promising in this regard.[75] The first-generation tetrapeptide catalyst **126a** was initially optimized for functional-group recognition in the acetamido alcohol *rac*-**131** (s = 28),[75a] but the more recent octapeptide **126b** is highly selective in the KR of other substrates, including benzylic alcohols **117** (s = 30), **119** (s > 50), and the 2-phenylcyclohexanol *rac*-**129** (s > 50),[75c] whereas related octapeptides distinguish between the enantiomers of *rac*-**131** with s = 50–51.[75b] Several other chiral DMAP derivatives are known that have been used to catalyze O-acylation, but the selectivities are lower.[77,78]

An enantioselective acylation and KR of alcohols has been demonstrated with a polymer-supported amine catalyst in combination with the soluble reagents benzoyl chloride/triethylamine.[79] Furthermore, polymeric reagents have been employed to help separate unreacted substrate from the product of lipase-catalyzed KR.[80] Phase isolation is also important in the doubly catalytic PKR experiment discussed earlier.[63] Catalytic PKR relies on an insoluble, polymer-supported mixed anhydride that is selectively activated as an acyl donor with the soluble phosphine catalyst *ent*-**113b** while an insoluble lipase catalyst activates the soluble vinyl pivalate as the lipase-activated acyl donor.[63] Phase isolation of the mixed anhydride and the lipase allows two enantiocomplementary esterifications to be conducted simultaneously without harm to either catalyst.



A different approach to solubility-based product separation uses lipase-catalyzed acylation with fluorinated acyl donors, followed by extraction with fluorine-containing solvents.[81] Alternatively, lipase-catalyzed saponification of a racemic fluorinated ester can be conducted under triphasic conditions in a U-tube such that the product alcohol collects in one methanolic phase.[82] The unreacted ester remains in the fluorinated solvent phase during lipase hydrolysis, and is then saponified by contact with aqueous hydroxide in a second methanol layer. This technique allows separation and recovery of each enantiomeric alcohol (89% *ee* or more) without chromatography or solvent extraction. Similar experiments with nonenzymatic acylation catalysts should

be possible, and deserve evaluation for preparative applications. Enantioselective acylation with chiral Lewis acid catalysts is another topic for which further exploration may be worthwhile.[83]

5.1.2. Oxidative KR of Alcohols

There has been considerable interest in kinetic resolutions that are based on the oxidation of a chiral secondary alcohol to a prochiral ketone, as the (achiral) product of the reaction can usually be recycled to the racemic starting material by simple hydride reduction. In principle, product recycling allows improved material recovery and greater efficiency. The first broadly applicable method for this purpose was developed by Noyori and co-workers under catalytic hydride transfer conditions similar to those used for the asymmetric hydrogenation of ketones. The methodology works well with benzylic alcohols, as is the case in the conversion of *rac*-**134** into (*R*)-**134** with the chiral ruthenium catalyst **135** to abstract hydride in the presence of acetone as the ultimate stoichiometric hydride acceptor (Scheme 24).[84] This reaction is essentially the reverse of the Noyori hydrogenation of ketones, a transformation that employs the same catalyst in the presence of isopropanol as the stoichiometric hydride donor.

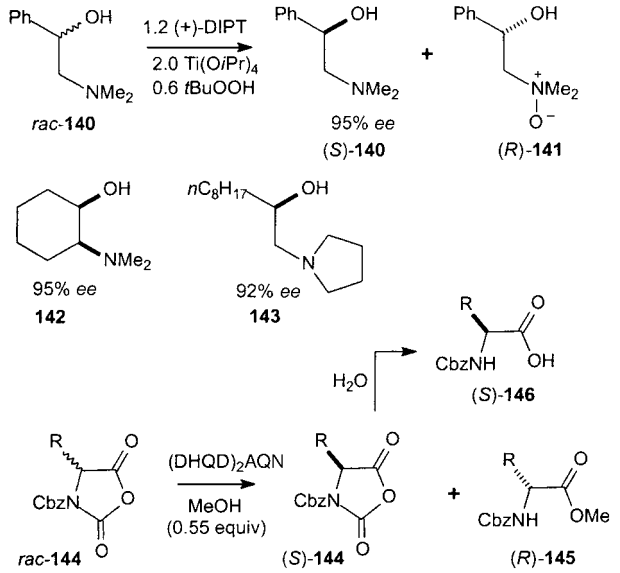
Scheme 24. Examples of kinetic resolution in the oxidation of chiral secondary alcohols to prochiral ketones; nbd = norbornadiene.

The same conditions are effective with allylic alcohols, and allow the kinetic resolution of *rac*-**136**. The reaction proceeds with exceptional selectivity to give highly enriched alcohol **136** (> 99% *ee*, 49% yield) as well as ketone **137** (94% *ee*, 49% yield).[85] As ketone **137** is chiral, simple hydride reduction would not be applicable for the purposes of improving efficiency through product recycling, in contrast to the tetralone case discussed above. On the other hand, one can imagine methodology that might allow the enantioconvergent transformation of **137** into **136**. Even higher selectivities ($s > 360$) have been reported for the oxidative KR of substituted 1-phenylethanols with modified ruthenium catalysts,[86] but the corresponding acetophenone hydrogenations are also highly enantioselective and would be preferred for efficient preparation of the alcohols.

Conceptually related oxidative KR methods have been developed with palladium catalysis in the presence of sparteine as a chiral ligand.[87] Selectivities are generally lower than with the ruthenium catalysts ($s = 47$ in the best case from *rac*-**138**; $s = 24$ or less in most other reported examples with Pd or other metals and ligands).[88] The use of oxygen as the oxidant with hydrocarbon solvents raises some safety issues that would need attention as the technology is developed.

Another reaction type involving oxidative KR has been encountered in the metal-catalyzed decomposition of racemic hydroperoxides.[89] Catalyzed Baeyer–Villiger reactions of cyclic ketones might also be placed in this category, although oxidation occurs at the carbonyl carbon atom to produce a lactone product.[53]

5.1.3. KR by Mitsunobu Reaction of Alcohols



Several recent studies have described the KR of alcohols through nucleophilic substitution that results from azodicarboxylate activation with chiral phosphines,[90] or use of an achiral phosphine in combination with ketopinic acid as a chiral nucleophile.[91] The latter approach requires a stoichiometric quantity of ketopinic acid, whereas the former involves conversion of one equivalent of the chiral phosphine into the phosphine oxide. The ketopinic acid method can be used under DKR conditions with several benzylic alcohol substrates, resulting in the formation of a single ester product with > 95% *de*. Apparently, racemization occurs by ionization of the alkoxyphosphonium salt intermediate in the Mitsunobu sequence.[91] In principle, this might allow increased efficiency, but both of the reported Mitsunobu KR variants have the disadvantage of using stoichiometric chiral reagents.

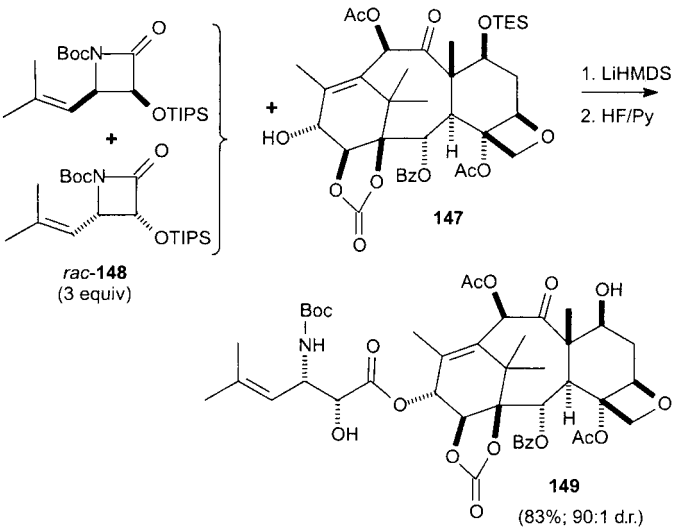
5.2. Amines

Nonenzymatic methodology for the KR of amines and their derivatives is much less developed than that of the KR of alcohols. Indeed, the earliest catalytic example, the oxidative KR of β-hydroxy-*N*,*N*-dialkylamines described by Sharpless

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

and co-workers, is still among the best applications.[92,93] Several specific examples, **140**–**143**, are shown in Scheme 25. A few other cases have already been mentioned in which nitrogen-containing molecules have been used in some of the

Scheme 25. Examples of nonenzymatic methods for the KR of amine derivatives (see Table 10); cbz = benzyloxycarbonyl.



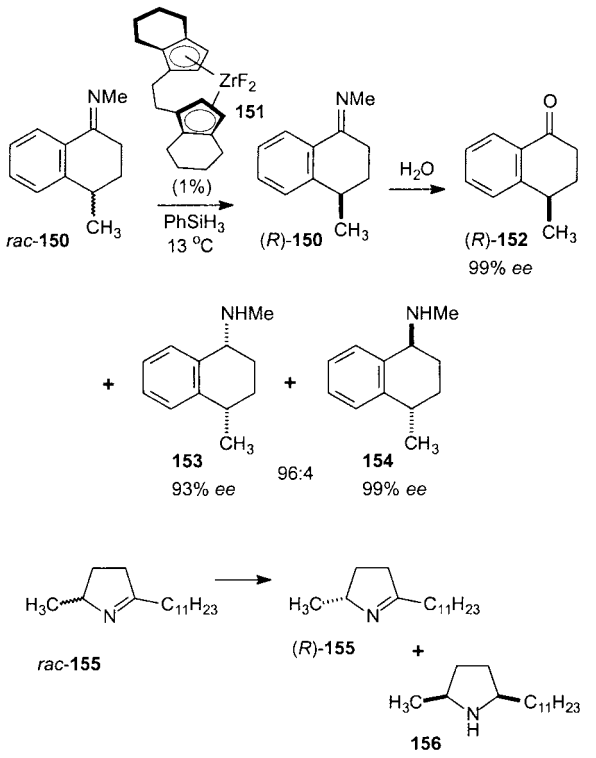
techniques for efficient KR, but in these cases the nitrogen substituent serves as a spectator group (see Schemes 2 and 4). A related example of this type is the catalytic methanolysis of oxazolidinediones described by Deng and co-workers (illustrated in the reaction of *rac*-**144** to (*S*)-**144**; Table 10).[94] With

Table 10: KR of oxazolidinediones **144**

Entry	R	*t* [h]	*T* [°C]	*s*
1	C_6H_5	16	−78	170
2	$CH_3(CH_2)_5$	37	−60	78
3	$C_6H_5CH_2$	17	−60	114
4	$BnOCH_2$	72	−78	69

some substrates, this method is selective enough to produce both the product (*R*)-**145** and the unreacted (*S*)-**144** in high *ee*. Because (*S*)-**144** is easily hydrolyzed to (*S*)-**146**, both enantiomers of the amino acid can be obtained with >90% *ee*. In the case of the aryl derivatives (for example, **144** with R = phenyl), a similar experiment can be performed under DKR conditions at room temperature to afford the ester in 91% yield and 90% *ee*).[94b] Several other interesting methods for the KR of nitrogen-containing compounds are known under catalytic[95,96] or stoichiometric[97] conditions in which issues of scope and efficiency remain to be explored.

One of the most remarkable stoichiometric KR examples of a nitrogen-containing substrate was described by Ojima and co-workers (Scheme 26). Enantiopure baccatin analogues such as **147** act as the resolving agents for a racemic chiral β-lactam **148** (threefold excess) to afford **149** (taxoid



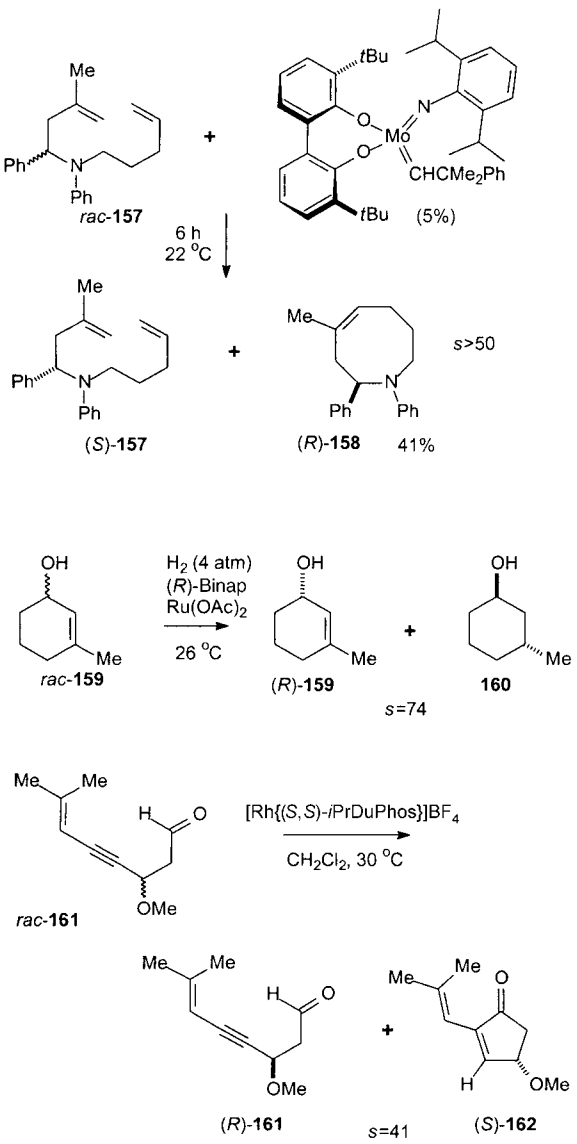
Scheme 26. Stoichiometric KR of an azetidine derivative as reported by Ojima and co-workers;[98] TIPS = triisopropylsilyl, TES = triethylsilyl.

series) with a diastereomeric ratio of 90:1 in favor of the isomer shown.[98] The efficiency of KR in this example is so high that the racemic β-lactam **148** can be used for preparative amide-bond formation without significant loss of the more complex reactant **147**.

Potentially valuable catalytic KR methodology that relies directly on the nitrogen substituent is highlighted by examples of aziridine carbonylation[95] and N-acylation,[96] as well as KR methods that use racemic imines as substrates.[99–101] Some useful examples involving imine hydrogenation are shown in Scheme 27. Yun and Buchwald demonstrated the reduction of imine *rac*-**150** with the chiral precatalyst [Zr(ebthi)] **151** and phenylsilane as the stoichiometric reducing agent. Aqueous workup gave the ketone **152** (>99% *ee*) and two isomeric amines **153** and **154**, both with high *ee*.[100] The two saturated amine products are the result of a stereoselective reduction involving the more reactive enantiomer, whereas **152** is formed by hydrolysis of the less reactive enantiomer (*R*)-**150** resulting from simple KR with $s = 61$. The Buchwald group has also shown that reductive KR is possible with cyclic imines, as in the reaction of *rac*-**155** to afford (*R*)-**155** (>95% *ee*, 41% yield) and **156** (>95% *ee*, 41% yield) with a similar catalytic system.[101]

5.3. Alkenes

Alkenes continue to play a central role as substrates for KR. This subject is discussed briefly because nearly all of the most important applications have been extensively reviewed.[2a–d,o–q] A number of examples have already been mentioned in the context of stereodivergent or regiodivergent RRM, for example, the Sharpless KR of allylic alcohols and osmylations. More recently, epoxidation methodology for the KR of simple alkenes has become available with chiral dioxiranes[102a] and the Jacobsen epoxidation catalyst.[102b]

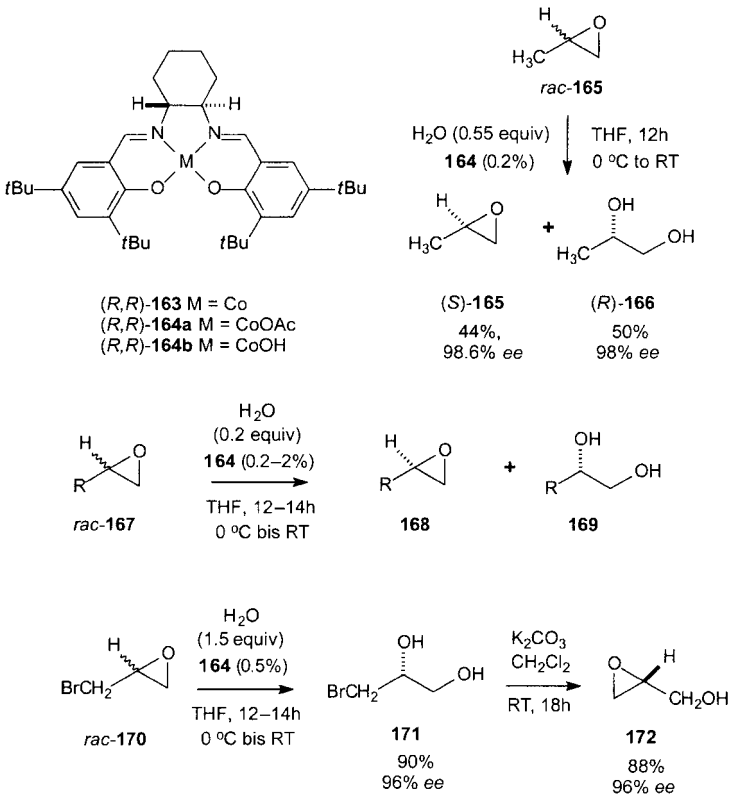


Scheme 27. Reductive KR of imines as reported by Buchwald and coworkers.[100,101]

Epoxidation methodology for the KR of allenes has also appeared.[102c]

Transition-metal-catalyzed alkene KR methodology continues to attract the most attention, and excellent reviews are available.[2o,q,z] The zirconium-catalyzed carbomagnesation of allylic ethers has already been mentioned in the context of DKR (Scheme 19), and simple KR examples are also known.[103] Other interesting examples of metal-catalyzed KR applications include the ring-closing metathesis of dienes (**157** to **158**; Scheme 28),[104] the catalytic hydrogenation of chiral allylic alcohols[105a,b] and unsaturated esters,[105c,d] and the zirconium-catalyzed polymerization of chiral alkenes.[106] Among the examples of hydrogenation, the best allylic alcohol case is shown in Scheme 28 (**159** to **160**).[105b] The substrate *rac*-**159** is a constrained, cyclic allylic alcohol with which the Sharpless epoxidation KR method is not effective, but with which the ruthenium-catalyzed hydrogenation occurs with excellent enantioselectivity ($s = 74$) and, in principle, allows recovery of highly enriched (*R*)-**159** near the 50%-yield limit.

KR based on the catalytic internal cyclization of functionalized alkynes has been reported most recently,[107] for example, the hydroacylation of unsaturated aldehydes (**161**→**162**; Scheme 28).[107b] In an intriguing variation of this process with a related substrate, Tanaka and Fu observed that a similar rhodium catalyst containing the tol-binap ligand allows conversion of one enantiomeric ynal into an alkylidene cyclobutanone while the other enantiomer affords the cyclopentenone as usual.[57] As mentioned in Section 4.3, this example can be classified as an unusual case of regiodivergent RRM. A related KR process that involves internal cyclo-



Scheme 28. Examples of kinetic resolution of olefins.

isomerization of oxygen-tethered enynes has also been reported. A chiral rhodium catalyst was used to convert allyl propargyl ethers into highly enantioenriched 4-alkylidene-3-alkenyltetrahydrofurans.[107c] More familiar reactions of chiral alkenes have also been used in KR processes, including thermal cycloadditions[108] and photoinitiated reactions in the presence of chiral additives.[109]

5.4. Epoxides

The Jacobsen methodology for enantioselective epoxide ring opening by nucleophiles is the most important recent development in nonenzymatic KR,[2q,r,t,110,111] especially the hydrolytic ring opening of epoxides (HKR; Scheme 29).[2q,r,110j] An example of the HKR process is illustrated by the conversion of propylene oxide (*rac*-**165**) into a mixture of (*S*)-**165** (44% yield, 98.6% *ee*) and propylene glycol (*R*)-**166**

Scheme 29. Examples of enantioselective epoxide ring-opening reactions with applications in hydrolytic KR (see Table 11).

(50% yield, 98% *ee*) with 0.55 equiv water and the cobalt(III) catalyst **164a** (0.2%).[110j] Both enantiomers of the precatalyst **163** are commercially available, and the conversion into **164a** is easily performed by air oxidation in the presence of acetic acid. Among the advantages of the HKR process are its broad applicability over a range of simple as well as functionalized terminal epoxides, high enantioselectivity, and low catalyst loading. A number of applications of this methodology have already appeared from other research groups.[111]

High enantiomeric purity for the product (*R*)-**166** as well as for the recovered epoxide (*S*)-**165** reflects a remarkably high enantioselectivity $s = 500$.[110j] Most of the other terminal epoxide examples summarized under the generalized structure **167** react with somewhat lower selectivity (Table 11). However, the *s* values are still high enough to permit preparation of diol products **169** with >95% *ee* if epoxide conversion is in the range of 15–20%. The extent of hydrolytic ring opening is controlled by limiting the amount of added water to 0.2 equiv. Recent studies have shown that the consistently high enantioselectivity of the Jacobsen HKR process is the result of an unusual mechanism in which **164a** or **164b** serves as a Lewis acid to activate the epoxide while **164b** is responsible for the nucleophilic cleavage step.[110m] Thus, **164b** functions as a precatalyst as well as a cocatalyst.

Table 11: Hydrolytic epoxide ring opening of *rac*-**167** (see Scheme 29).

R	*s*	R	*s*	R	*s*
CH_3	500	CH_2Cl	190	CO_2CH_3	120
*n*Bu	310	CF_3	620	$COCH_3$	81
CH_2Ph	96	CH_2OTBS	250	C_6H_5	130
c-C_6H_{11}	630	$(CH_2)_2OBn$	82	$CH{=}CH_2$	120
*t*Bu	76	CH_2CO_2Et	130	$CCSiMe_2tBu$	420

An interesting HKR result is observed with *rac*-**170** (Scheme 29), a case in which enantioselectivity is not especially high ($s = 49$).[110j] However, the epoxide substrate undergoes racemization under the reaction conditions to make DKR possible. Thus, treatment of *rac*-**170** with 1.5 equiv water in the presence of catalyst **164** (0.5%) affords the diol **171** in 90% yield (96% *ee*). Further reaction with potassium carbonate affords glycidol **172** in excellent yield and enantiomeric purity. Other interesting KR applications of the Jacobsen catalyst include the catalyzed cleavage of epoxides by other nucleophiles such as azide and phenoxide.[2t]

Several other methods for the KR of epoxides are known. They are not competitive with the Jacobsen procedure for terminal epoxides, but the methodology can be used for 1,2-disubstituted epoxides with which the Jacobsen catalyst is less reactive. Reports of this include epoxide ring opening induced by chiral organometallic agents,[112a–c] and conversion of epoxides into allylic alcohols by elimination in the presence of chiral metal amides.[112d–g] The kinetic resolution of epoxides with a Jacobsen-type salen chromium catalyst and indole as nucleophile has also been reported.[111i]

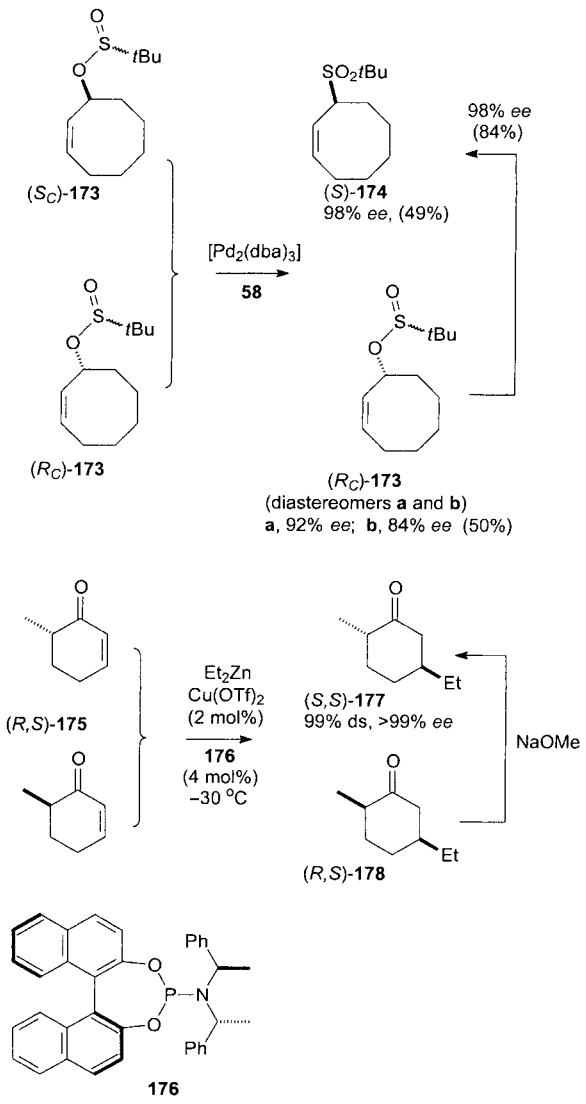
5.5. Miscellaneous Functional Group Categories

This Section contains a brief overview of the relevant literature citations for the various KR methodologies organized by functional group class: aldehydes (Horner–Emmons olefination,[60] hydroacylation[107]); allylic alcohols (Sharpless epoxidation);[13,55] allylic carboxylates (palladium-catalyzed substitution);[36–38] allylic ethers (carbometallation);[58] alkenes (osmylations);[48,49] atropisomers;[35] azlactone cleavage;[14–16] 1,3-dioxolan-2,4-dione cleavage;[17] enones (hydrogenation,[22] cuprate addition[23e]); Grignard reagents;[24a–f,25] halides (palladium-catalyzed amine coupling);[113] ketones (aldol reaction,[23a] Baeyer–Villiger oxidation,[53] Horner–Emmons olefination,[23b] enolization,[23c] organozinc addition,[23d] reduction,[23f,50,51] Noyori hydrogenation[18–21]); lactones;[28e] organolithium reagents;[28,29] phosphorus compounds;[33,34b–e] and sulfur compounds.[34a,c]

6. Data Treatment and Assay Methods

Recent advances in this area are beyond the scope of this review, and are mentioned only in brief outline to provide some leading references. Mathematical treatments have appeared that focus on DKR,[114] sequential KR (two stages of KR conducted in sequence to improve enantiomeric purity),[115] catalytic KR with enantiomerically impure catalyst,[116] nonlinear effects in KR,[116b–d] and KR involving *meso*/*d,l* isomer mixtures.[117] Access to programs that perform the simple KR calculations of Equation (1) and Equation (2) is now possible through the Internet,[118] and a program for

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



calculating enantioselectivities *s* and plotting *ee* as a function of conversion is available in a free downloadable version.[119]

A variety of assay techniques designed for high-throughput screening have been applied to KR experiments, including methods based on mass spectroscopy[120] and fluorimetry.[121] Techniques have also been reported that speed up the measurement of enantiomeric excess for large numbers of samples.[122] A method for the evaluation of the KR potential of racemic catalysts has also been described.[123]

7. Current State and Perspectives of Nonenzymatic KR

Several KR and DKR techniques have become important for the synthesis of enantiomerically enriched substances on the preparative scale, including the Sharpless epoxidation of allylic alcohols,[13] the Noyori hydrogenation of enolizable ketones,[18] and the Jacobsen hydrolytic cleavage of terminal epoxides.[2q,r,t] Numerous other KR techniques of fundamental interest have served as a proving ground for conceptual advances in enantioselective synthesis. Much of the work to improve KR efficiency can be viewed in this context, and this has been the focus of the current review.

Some of the preparative applications of simple KR will eventually be replaced by advances in enantioselective synthesis methodology with chiral catalysts and achiral substrates, procedures that are not subject to the 50%-yield limit. This limit does not apply to DKR, but neither does the possibility of improving substrate *ee* with conversion. This is the unique advantage of KR, even for modest levels of enantioselectivity *s*. At the current stage of development, almost any chiral substance can be prepared with exceptional levels of enrichment (>99% *ee*) with KR, if yields in the range of 30–40% are acceptable. As the nonenzymatic KR methodologies become more selective and more versatile, new ways will be found to improve efficiency.

Scheme 30. Examples in which kinetic resolution is combined with an equilibration step for the conversion of both enantiomers into a single product.

Addendum (December 8, 2004)

A number of interesting developments in kinetic resolution have been reported since the bulk of this manuscript was written. Many of these have been covered by the insertion of relevant references according to conceptual or functional group categories, but two selected examples of unusual interest are described in Scheme 30. In both cases, kinetic resolution is combined with an equilibration step for the conversion of both enantiomers into a single product. In the first example from racemic **173** (a mixture of two sulfinate diastereomers and enantiomers), Gais and co-workers demonstrated the rearrangement of an allylic sulfinate into the sulfone (*S*)-**174** with the remarkably high 98% *ee* for the apparent product of simple KR.[124] The unusual sequence is initiated with a palladium catalyst in the presence of the Trost chiral diphosphine **58**, and affords the slow-reacting enantiomer (R_C)-**173** together with the original sulfur diastereomers (S_S and R_S, labeled **a** and **b**, respectively), but both with significant enantiomeric enrichment (92% *ee* and 84% *ee*). With a higher loading of both the palladium source and chiral ligand **58**, however, complete conversion was observed and gave only the sulfone (*S*)-**174**, again with 98% *ee*. This result requires some form of deracemization and equilibration at the sulfur and carbon atoms on the way to products, and was attributed to the formation of ion pair intermediates.

In the second example of Scheme 30, Alexakis and co-workers reported an intriguing 1,4-addition process from racemic enone **175** in which stereodivergent RRM occurs in the first stage to afford the diastereomers (*S*,*S*)-**177** and (*R*,*S*)-**178**.[125] The diastereomer mixture was then treated with NaOMe to equilibrate the enolizable α-carbon, resulting in the conversion of the *cis* diastereomer **178** into the *trans* diastereomer **177**. Because this process does not alter configuration at the β′ carbon atom, the net result is an enantioconvergent process in which (*R*,*S*)-**175** is converted into (*S*,*S*)-**177** with excellent *ee*.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Both of the examples in Scheme 30 were selected to underscore the principal message of this account. Many of the recent extensions and modifications of simple KR are academically fascinating, but not always practical. On the other hand, the investigation of simple KR phenomena has resulted in permutations such as DKR or stereodivergent RRM. As shown by the examples of Scheme 30, these adaptations can be exceptionally efficient.

[30] a) See Ref. [5], pp. 1192–1193 for the definitions; b) The terminology of DTR does not distinguish between the process in solution (asymmetric transformation of the first kind) and the very different heterogeneous experiment in which crystallization of the labile intermediate is responsible for the high selectivity. Important information may be difficult to find in the literature unless authors continue to use the older asymmetric transformation terminology as appropriate for the first stages of DTR.

[38] a) B. M. Trost, D. E. Patterson, E. J. Hembre, *J. Am. Chem. Soc.* **1999**, *121*, 10834 – 10835; For related conduritol examples, see B. M. Trost, D. E. Patterson, E. J. Hembre, *Chem. Eur. J.* **2001**, *7*, 3768 – 3775; b) The key events of Scheme 12 were described with modified terminology, and were referred to as dynamic kinetic asymmetric transformations, or DYKAT. A personal communication from Prof. Trost provides the following definition: "*Dynamic kinetic asymmetric transformation is the preferential formation of one enantiomer of a product in a chemical transformation arising from both enantiomers of a racemic starting material that is structurally different from the starting material.*" This definition of DYKAT has the same meaning as generally accepted for DKR, but is more accurate in the sense that "resolution" is usually defined to imply the recovery of resolved, unreacted substrate.

Chem.* **1987**, *52*, 2244 – 2248; This paper reports an enzymatic version of the product-divergent PKR experiment, although one of the products is achiral; b) S. C. Preston, *Asymmetric Synthesis via Iron Acyl Complexes*, PhD Dissertation, Oxford University, **1989**; Preston lists the following points among the criteria for "simultaneous resolution": 1) [reagents] X and Y must display high degrees of chirality discrimination of opposite sense in their reactions with the substrate enantiomers *R* and *S*. 2) The two reactions must have similar rate coefficients (i.e., $k_R = k_S$). 3) The reactions must proceed in the same vessel without detrimental mutual effects. 4) [products] A and B must be readily separable.

[60] a) T. M. Pedersen, J. F. Jensen, R. E. Humble, T. Rein, D. Tanner, K. Bodmann, O. Reiser, *Org. Lett.* **2000**, *2*, 535 – 538; b) T. M. Pedersen, E. L. Hansen, J. Kane, T. Rein, P. Helquist, P.-O. Norrby, D. Tanner, *J. Am. Chem. Soc.* **2001**, *123*, 9738 – 9742.

[61] The equivalent of a two-reagent PKR process has been achieved by using a single, unsymmetrical imide that selectively transfers one of two different acyl groups to enantiomeric amines: A. G. Al-Sehemi, R. S. Atkinson, C. K. Meades, *Chem. Commun.* **2001**, 2684 – 2685; A. G. Al-Sehemi, R. S. Atkinson, J. Fawcett, *J. Chem. Soc. Perkin Trans. 1* **2002**, 257 – 274.

[62] PKR with quasienantiomeric nitrones for the [2+3] cycloaddition to a racemic enol ether: a) K. M. Pietrusiewitz, W. Holody, M. Koprowski, S. Cicchi, A. Goti, A. Brandi, *Phosphorus Sulfur Silicon Relat. Elem.* **1999**, *144–146*, 389 – 392; F. Cardona, S. Valenza, A. Goti, A. Brandi, *Eur. J. Org. Chem.* **1999**, 1319 – 1332; PKR using quasienantiomeric *N*-lithioamides for Michael addition to a racemic enoate: b) S. G. Davies, D. Diez, M. M. El Hammouni, A. C. Garner, N. M. Garrido, M. J. C. Long, R. M. Morrison, A. D. Smith, M. J. Sweet, J. M. Withey, *Chem. Commun.* **2003**, 2410 – 2411; PKR in the reaction of a racemic cyclopropene carboxylate with quasienantiomeric *N*-lithiooxazolidinones: c) L.-a. Liao, F. Zhang, O. Dmitrenko, R. D. Bach, J. M. Fox, *J. Am. Chem. Soc.* **2004**, *126*, 4490 – 4491.

Materials Science

Epitaxial Casting of Nanotubular Mesoporous Platinum**

*Yi Ding, Anant Mathur, Mingwei Chen, and Jonah Erlebacher**

Mesoporous precious metals (pore size 2–50 nm), especially platinum, are particularly sought after because of their immense technological importance in, for example, catalysis,[1] sensing,[2] and actuation.[3] A common approach to the fabrication of these materials is the replication of porous alumina[4] or liquid-crystal templates.[5,6] Templating generally offers a high degree of control over the pore size as well as microstructure periodicity, but most techniques in this class result in materials with one-dimensional porosity, such as an array of tubes. This characteristic is desirable for some optoelectronic applications, but for applications such as sensing or catalysis, materials with open porosity extending in all dimensions are favored to allow unlimited transport of the molecules of the medium;[1] in fact, the most useful materials often exhibit bicontinuous microstructures in which both the void space and the scaffold are completely interconnected, with the scaffold imparting mechanical stability and electrical pathways to catalytically active sites. Two important classes of bicontinuous mesoporous materials are aerogels[1] and nanoporous metals made by dealloying.[7]

Here we report the design and fabrication of nanotubular mesoporous platinum (NMP), a new material that can be described as a network of platinum nanotubes with diameters of about 15 nm and walls 1 nm thick that interconnect to form an open, doubly bicontinuous structure that may possess the highest surface area to volume ratio known (or possible) for a macroscopic sample of metal. NMP possesses a higher order of geometric complexity than most known porous materials in that the walls separate two distinct void spaces, one with predominantly negative curvature, the other with predominantly positive curvature. As such, the material exhibits interesting capillary behavior, and we envision application in nanofluidic systems as well as in ultrahigh surface area catalysis. Intriguingly, NMP exhibits structural characteristics of a macroscopic metal, in the sense that grains of micrometer size or larger are typical and that the nanotubular network within each grain exists as a single crystal with characteristic dimensions several orders of magnitude smaller.

The nanotubular mesoporous platinum is formed by epitaxial casting[8] using nanoporous gold (NPG) membrane molds. Our typical starting material is comprised of free-standing NPG membranes 100 nm thick for which the in-plane grain size is on the order of micrometers, but in principle this fabrication method is not limited to any particular size and shape of sample. NPG is a three-dimensional bicontinuous mesoporous metal with a tunable ligament size on the order 10–100 nm.[7] The crystallographic coherence of NPG extends to the scale of the grains of the Au/Ag alloy. In this sense, NPG is markedly different from most other nanoporous materials that are essentially controlled aggregates of nanoparticles.[9] Epitaxial casting is a new casting method in which an epitaxial skin of a second material coats a mold that is subsequently dissolved away. In previous work, we discovered that platinum could be grown epitaxially onto NPG by an electroless plating process,[10] which resulted in a composite core–shell nanoporous structure. More specifically, we found that a coating of Pt with an average thickness of about 1 nm took the form of a conformal coating of uniformly sized epitaxial islands on the NPG substrate. Past studies of Pt films on planar gold[11] exhibited a heteroepitaxial growth mode where initial layer-by-layer growth was followed by accommodation of misfit strain (4% in Pt/Au system) through injection of misfit dislocations (MD) at the interface. The critical thickness for injection of MDs was typically 1 nm. The presence of coherent islands with no MDs in the present case suggested that the approximately 5-nm radius of curvature allowed out-of-plane relaxation to occur by islanding, a characteristic feature of the Stranski–Krastanov growth mode. The presence of large epitaxial strains was confirmed during the course of this study by the behavior of the material after annealing at a moderate temperature (300 °C for 30 minutes), during which it was observed that the islands smoothed out to form a uniform coating with injection of misfit dislocations at the Pt/Au interface. At this point of processing, surprisingly, we found that we could completely dissolve the gold away in aqueous gold etchant (KI: 10 wt%, I_2: 5 wt%) to leave the 1-nm-thick Pt shell, still single crystalline within individual grains and retaining the bicontinuous void space of the original NPG but adding a second, tubular void region where the gold had been prior to etching.

Figure 1b shows a representative scanning electron microscopy (SEM) image of NMP. The average diameter of the tubular ligaments is about 15 nm, which is consistent with the ligament size of the NPG template (Figure 1a). Tube openings (see inset to Figure 1c) are frequently seen at the sample edges, and the shell thickness of the tubes is estimated to be around 1–2 nm. This thickness may be adjusted by varying the amount of platinum plated onto the NPG mold. A 1-nm-thick shell is only 4–6 atoms thick, which is smaller than the diameter of typical Pt nanoparticles by more than a factor

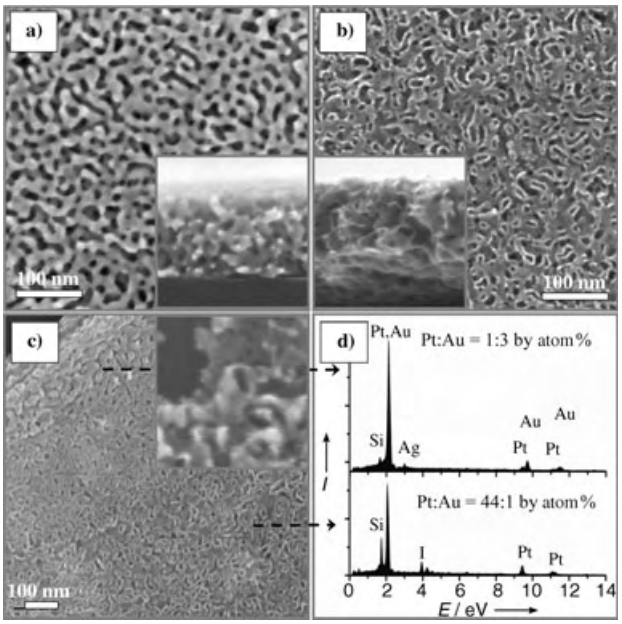

Figure 1. a) Plan-view and cross-section (inset) SEM images of NPG. b) Plan-view and cross-section (inset) SEM images of NMP. c) SEM image of a Pt-coated NPG sample within which gold has been only partially removed; the inset shows a tube opening of NMP. d) EDS analysis indicates a gradual structure transition from Pt/NPG to NMP. The NPG mode was made by dealloying white gold leaf in nitric acid for 10 minutes. The NPG surface was coated with platinum by electroless plating. Typical plating time is on the order of minutes, and thicker platinum layers may be formed with longer plating times. Experimental details have been reported in Ref. [10]. SEM images were acquired on a JEOL JSM-6700F SEM, equipped with a EDAX Genesis 4000 microanalysis system, under an accelerating voltage of 20 kV.

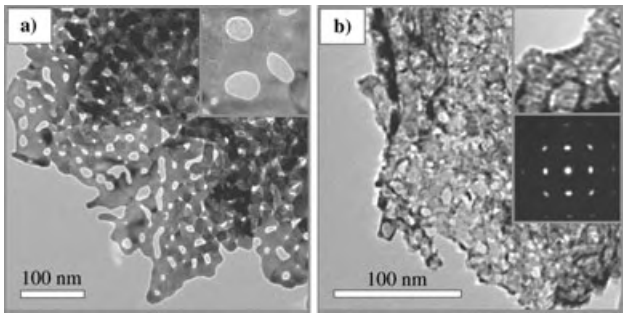

Figure 2. Bright-field TEM images of: a) NPG and b) NMP. The insets in (a) and (b) show three-way junctions of solid and tubular ligaments, and the electron-diffraction pattern shown as a lower inset in (b) indicates that NMP is a single crystal over a scale that is orders of magnitude greater than the pore size.

of two.[12,13] Note that all the tube edges of the structure show brighter contrast, a characteristic feature of tubular morphologies when observed by SEM. Figure 1c shows a Pt-coated NPG sample within which gold has been only partially removed. In this image, a gradual structure change from Pt/NPG to NMP can be clearly seen. Energy dispersive spectroscopy analysis (EDS) confirms this change. A Pt/Au ratio of 1:3 is found in the Pt/NPG region (Figure 1d), while the gold concentration is on the order of the detection limit of the instrument (ca. 1 atom%) in the NMP area and indicative of the nearly complete removal of the gold backbone.[14] If it is assumed that Pt/NPG has the idealized structure of coaxial cylinders with a diameter of 15 nm, one can calculate the shell thickness of the platinum layer to be about 1.1 nm (4 atomic layers), which is consistent with the SEM observation. We have also performed a virtual experiment (computer simulation) of coating a simulated NPG structure made by using literature methods[7], and then removing the porous gold substrate. The simulated morphology shows the original porous channels and hollow ligaments, and is remarkably similar to the experimental morphology (see the Supporting Information).

Complementary structural information is given by transmission electron microscopy (TEM) images and selected-area electron diffraction patterns (Figure 2). NPG and NMP appear as very complicated morphologies under TEM because of a 3D to 2D projection of highly interconnected wires (for NPG) and tubes (for NMP). The insets of Figure 2 show areas of three-way junctions of solid and tubular ligaments. NMP shows darker edges along the edges of its tubular ligaments than nanoporous gold. These darker edges correspond to electron attenuation by wall features parallel to the electron beam. As mentioned above, the epitaxial relationship between Pt and the NPG substrate mold suggests that large (approximately micrometer) grains of NMP are retained upon etching away the gold. The selected-area electron diffraction pattern shows this is indeed the case, as illustrated in the inset of Figure 2b, which shows a single-crystal square lattice recorded from a $\langle 001 \rangle$ zone axis of face-centered cubic (fcc) Pt. The stretched diffraction spots indicate minor lattice distortion possibly resulting from surface stresses or simply sample preparation.[3,15] Further characterization of epitaxial casting leading to NMP formation is given by high-resolution electron microscopy (HREM) images. The micrograph in Figure 3a clearly shows the epitaxial relationship between the annealed Pt overlayer and the NPG substrate. EDS analysis using an electron beam of about 1 nm shows that the bright area with a thickness of 5–8 atomic layers is a platinum skin. After removing the Au backbone, the Pt nanotubules with thin shells and nanosized holes can be clearly seen in HREM images. Figure 3b shows an example of this tubular structure, where a tubule appears to slightly tilt out of the plane as shown schematically in the insert in Figure 3b. The internal diameter of the tubule is around 10 nm, close to the ligament size of NPG. One side of the tubule was imaged along a $\langle 111 \rangle$ orientation of fcc Pt. The thickness of the sheet was estimated by simulating the atomic image, and the best match between the HREM and simulated images was obtained at a sample thickness of about 2 nm, which is consistent with the thickness of tubular shells observed in the cross-sectional image (Figure 3a). The HREM images also clarify the geometry of the tubular ligaments which are seen not to be single-valued in surface curvature; instead, they are more like hyperboloids of revolution for which each point is a saddle, thus possessing both positive and negative principal curvatures.

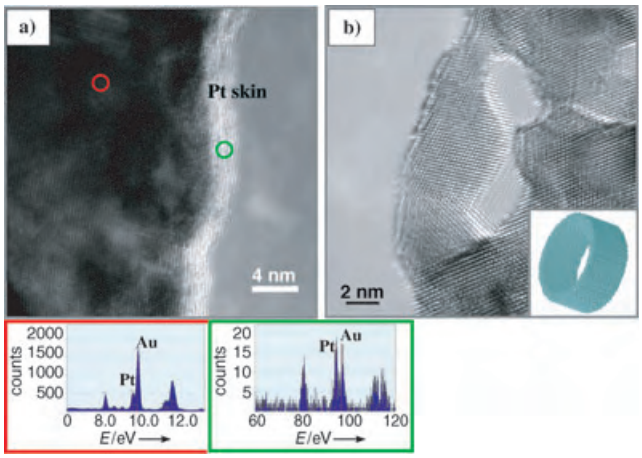

Figure 3. HREM images of Pt/NPG and NMP. a) A uniform skin of heteroepitaxial Pt on nanoporous gold was made by platinum deposition followed by thermal annealing at 300 °C for 30 minutes. The bright area with a thickness of 5–8 atomic layers is the platinum skin, as demonstrated by EDS analysis. The observation of gold in the shell region arises from sample drifting during imaging. b) Side-view of a tube opening of NMP. Lattice distortion and dislocations are observed. The inset is an atomistic model consistent with the projection of the tube opening shown in (b). TEM analysis was performed on a 300 kV, field-emission Philips CM300FEG in the Electron Microscopy Center at Johns Hopkins University.

Since NMP has atomically thin tube walls it has a very high surface area and total surface free energy. This situation imparts an intrinsic metastability to the material which could potentially lead to morphological coarsening, a problem akin to the sintering problems plaguing nanoparticle-based catalysts. The likely mechanism for such coarsening in NMP at moderate temperatures is surface diffusion, for which the characteristic coarsening time t depends on the characteristic length scale l of the structure material according to the relationship $t \approx l^4$; [16] thus, NMP with $l \approx 1$ nm should coarsen 10^{12} times faster than 1-μm-sized solid platinum grains should sinter. We do know, however, that platinum surface self-diffusivities are three to four orders of magnitude slower than gold,[17] and NPG does coarsen at room temperature, particularly in certain electrolytic environments.[18] To examine this stability problem for nanotubular mesoporous platinum we studied the morphological stability of NMP by annealing it at elevated temperatures (see the Supporting Information). It was found that NMP is stable at 125 °C for at least 24 h. At 150 °C, the tube walls start to deform, and eventually evolve into Pt nanoparticles (Pt-NPG, in contrast, is stable at these temperatures). This behavior indicates that NMP may be useful for catalytic reactions at moderate temperatures, such as in a H_2/O_2 fuel cell.

The thermal stability of NMP is also interesting from the standpoint of fundamental thermodynamics. It has been predicted that the melting point of small particles is suppressed relative to that of bulk particles.[19] We estimate for Pt that a suppression of the melting point below 300 °C requires a radius of curvature less than approximately 1 nm. The principal curvatures of the network are greater than this (ca. 7–10 nm), so we expect NMP to be stable with regards to this instability. However, small pinholes in the tubular network may occasionally open up which may locally melt and then resolidify when the mass of the melted regions increases to the point that the solid is again thermodynamically stable. In this context, it is interesting to note the similarity of the NMP sample annealed at 300 °C to a network of solidified droplets.

The whole network and each individual tubular segment in NMP are essentially one crystallographic lattice. This characteristic feaure enhances the mechanical rigidity of the material, and one may be able to use this interconnected 3D channel structure as a model system with which to study nano-/microfluidic transport phenomena or confined reactions on the nanoscale.[20] To further develop this concept, we have made a platinum–palladium bicontinuous mesoporous composite structure by refilling the tubes of NMP[21] with palladium chloride. Samples were made by touching the edge of a sample of NMP with a drop of concentrated $PdCl_2$ solution. Strong capillary forces drove the liquid into the tube channels, an effect that caused a change in the appearance that was visible to the naked eye, and then the samples were subsequently dried and imaged by SEM. Figure 4 shows the structure of such a sample at the filled/

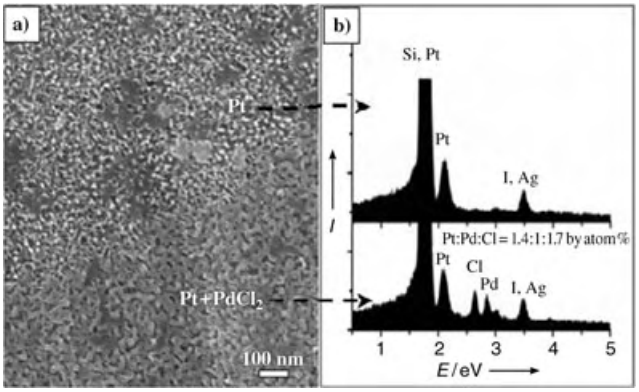

Figure 4. a) SEM image of NMP that has been partially filled with $PdCl_2$. b) EDS analysis showing the difference in pore composition between unfilled and refilled regions.

unfilled boundary. The area with $PdCl_2$ looks very similar to the morphology of unetched Pt/NPG, that is, the edge contrast arising from the tubular morphology disappears and the region in the upper section of the micrograph is clearly unfilled. Compositional analysis from both areas (Figure 4b) supports this view. It is interesting to find that liquid transport occurs preferentially through tubes rather than pores, possibly because of the much stronger capillary forces of tubes, which have very high negative curvature.

The surprising mechanical stability imparted by the nanostructure of NMP enables it to be produced in macroscopic quantities (membrane samples on the order of one square centimeter are routinely made). This feature should enable its easy integration into technologies for catalysis, nano-/microfluidic transport, as well as supplying a new

Chiroptical Probes

A Cationic Zinc Porphyrin as a Chiroptical Probe for Z-DNA**

Milan Balaz, Massimo De Napoli, Andrea E. Holmes, Angela Mammana, Koji Nakanishi, Nina Berova, and Roberto Purrello**

DNA is a polymorphic polymer that can adopt a variety of secondary structures ranging from the canonical right-handed B form to the left-handed Z conformation.[1] The latter conformation is less common than the right-handed B-DNA because under physiological conditions Z-DNA has a higher energy.[2–4] Although the biological role of Z-DNA still remains to be clarified, it has recently been inferred that certain classes of proteins bind to it both tightly and specifically.[5–8]

The different handedness of the two DNA forms is reported in the spectral region below 300 nm of circular dichroism (CD) spectra. B-DNA is characterized by a complex positive band centered at 274 nm and a negative Cotton effect at 253 nm, while Z-DNA exhibits a negative Cotton effect at 293 nm and a positive Cotton effect at 263 nm. Determination and sensing of Z-DNA based on these spectral differences, however, can be hampered by the concomitant presence of the two forms of DNA and/or other biomolecules such as proteins that make the region below 300 nm in the CD spectra difficult to analyze. To solve this problem, it is desirable to design chiroptical probes that discriminate between the B and Z structures and absorb above 300 nm, a region that is free from interferences, to provide characteristic induced circular dichroism (ICD) signals.

Recognition of B- and Z-DNA has been achieved by using the Δ or Λ enantiomers, respectively, of chiral complexes of transition metals (Fe, Ru, and Rh).[9,10] Recently, it has been reported that the enantiomeric pairs of daunorubicin or helicene display structural selectivity in binding to B- or Z-DNA.[11] However, none of these systems can be used as chiroptical probes because recognition of the Z or B forms is not reflected in unique spectroscopic features, such as new CD bands, which unequivocally show the detection event.

Porphyrins and their metallo-derivatives are very attractive molecules because of their unique spectroscopic and geometric properties. They have been covalently linked to specific chiral sequences, and their CD spectral properties have been used to resolve complicated stereochemical issues[12–15] as well as monitor polynucleotide dynamics.[16] Also, the noncovalent interactions of cationic or anionic water-soluble achiral porphyrins with chiral templates have been exploited to build supramolecular species to detect and/or amplify the handedness of the matrix.[17,18] Achiral cationic porphyrins are indeed good candidates as noncovalent probes for right- and left-handed DNA.[19] Up to now, cationic porphyrins and metalloporphyrins have been used as reporters of different sequences of DNA bases,[20–22] but have never been employed for recognizing the handedness of a DNA helix.

Circular dichroism spectroscopy has been very useful for distinguishing the three main DNA-binding modes of porphyrins: intercalation (negative CD), outside groove binding (positive CD), and outside stacking (bisignate CD).[20,21] However, few studies have been performed on the interactions of cationic porphyrins with Z-DNA because the intercalation of porphyrins reverts the helix back to the B form.[23] The latter data suggest that pentacoordinated cationic metalloporphyrins, such as the zinc(II) derivative of *meso*-tetrakis(4-*N*-methylpyridyl)porphyrin (ZnT4, **1**; Figure 1), should be an ideal chiroptical probe for Z-DNA because the axially coordinated water molecule hinders intercalation[24–28] and prevents the Z-to-B transition.

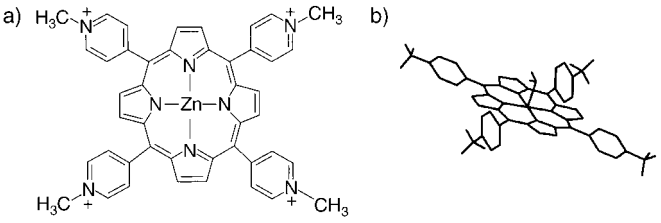

Figure 1. a) Chemical structure of zinc(II) porphyrin **1** and b) its 3D structure which shows the axially coordinated water molecule.

In our study we used poly(dG-dC)$_2$ (poly(deoxyguanylic-deoxycytidylic) acid; average base length 960), as this alternating purine–pyrimidine sequence favors the Z conformation. The B-to-Z transition can be induced in vitro by molar concentrations of NaCl, millimolar concentrations of multivalent cations such as $Co(NH_3)_6^{3+}$, or micromolar concentrations of protonated spermine.[29,30] Among these, spermine seems to be the most appropriate choice as this tetraamine, which is fully protonated at pH 7, is ubiquitous in cells and other biological systems.[31]

With B-DNA (Figure 2, blue line) only a small ICD signal is detectable in the visible region, while with Z-DNA (Figure 2, red line) a very intense bisignate curve, with $\Delta\varepsilon = -154\,M^{-1}cm^{-1}$ at $\lambda = 449$ nm and $\Delta\varepsilon = +87\,M^{-1}cm^{-1}$ at $\lambda = 433$ nm, is observed even at concentrations as low as 1 μM of **1**. The ICD spectra remain remarkably different at concentrations of **1** ranging from 1 to 8 μM (see Supporting Information) which thus shows that ZnT4 (**1**) can be highly diagnostic of the different DNA structures. The region below 300 nm in the CD spectra suggests changes in the Z-DNA helix upon interactions with **1** which become more apparent with increasing concentrations of porphyrin.

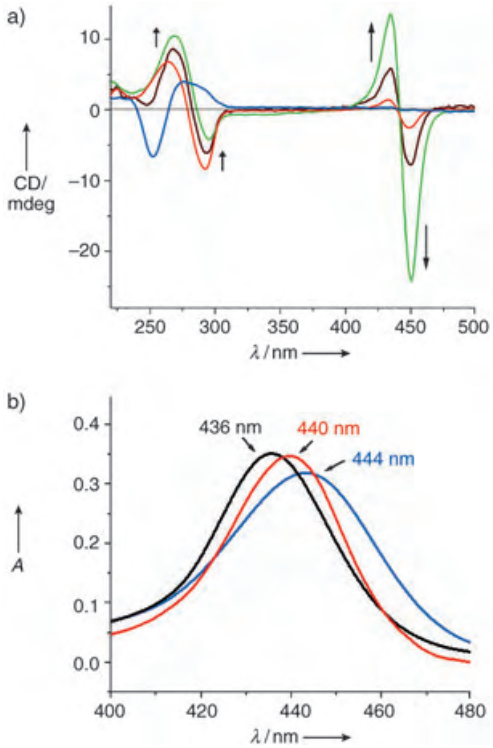

Figure 2. a) Circular dichroism (CD) spectra of Z-DNA (50 μM) in the presence of **1** (1 μM (red), 4 μM (brown), and 8 μM (green)), and B-DNA (50 μM) in the presence of **1** (1 μM; blue). b) Variation of the Soret band in the UV/Vis spectra of unbound **1** (black), **1**+Z-DNA (red), and **1**+B-DNA (blue).

So far,[21,32] observation of a ICD bisignate signal has been related to the aggregation of porphyrins. However, absorption data of ZnT4 (**1**) in the presence of Z-DNA (Figure 2b) does not support porphyrin aggregation, which should lead to quite extensive hypochromicity and broadening of the Soret band. None of these changes are observed upon binding of **1** to Z-DNA. To understand the origin of the bisignate signal we also performed fluorescence measurements, as porphyrin aggregation usually leads to severe quenching of the fluorescent emission. While the fluorescence of ZnT4 (**1**) is quenched upon complexation with B-DNA, it is only marginally affected in the presence of the Z form (Figure 3). In particular, the emission of **1** at $\lambda = 633$ nm is blue-shifted to 622 nm and quenched slightly upon binding to Z-DNA, while the intensity of the band at 670 nm increases by about 10%. This behavior clearly indicates the absence of close π–π interactions. The increase in fluorescence of **1** upon binding to Z-DNA suggests that the porphyrins lose some vibrational freedom as a result of a tighter interaction with Z-DNA than that found with B-DNA.

While the presence of the bisignate signal implies electronic communication between the porphyrin chromo-

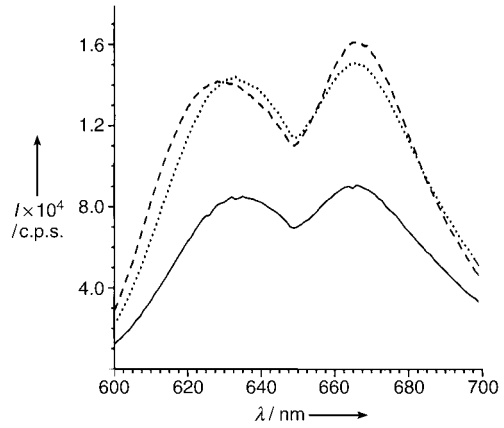

Figure 3. Fluorescence spectra (*I*/counts per second) of **1** unbound (••••), in the presence of Z-DNA (50 μM; -----), and in the presence of B-DNA (50 μM; ——).

phores (Figure 2), this is not inferred from either the absorption or fluorescence spectra (Figure 2b and Figure 3, respectively).

To better understand the binding modes, resonance light scattering (RLS) measurements were performed.[33] One advantage of RLS compared with other scattering techniques is that it provides information on the coupling between the transition dipole moments of interacting chromophores. RLS data provided a clear difference in the interactions of **1** with B- and Z-DNA (Figure 4). The RLS spectrum for the system

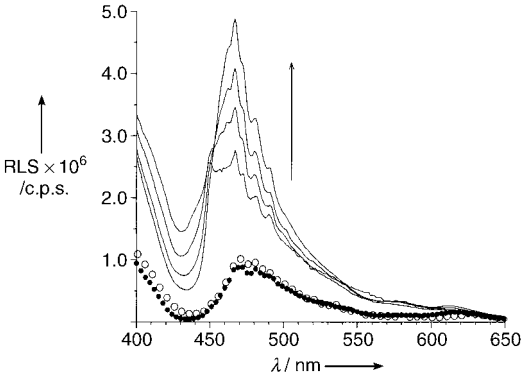

Figure 4. Resonance light scattering (RLS/counts per second) spectra of unbound **1** (2 μM; ○), **1** (2–8 μM) in the presence of B-DNA (50 μM; ●), and **1** (2, 4, 6, and 8 μM) in the presence of Z-DNA (50 μM; ——).

1·B-DNA is superimposable on that of free ZnT4 (**1**) at the same concentration, and its intensity did not change upon changing the concentration of **1**. In contrast, the intensity of the RLS spectrum of **1** in the presence of Z-DNA (**1**·Z-DNA) was higher than that of unbound **1** at the same concentration and increases with increasing concentrations of **1** (Figure 4). Therefore, in agreement with ICD data, RLS indicates that the porphyrins ZnT4 (**1**) are electronically coupled on Z-DNA but not on B-DNA.

Thus the CD, absorption, fluorescence, and RLS spectra show a profound difference in the binding modes of **1** with the two forms of DNA, B and Z . ICD and RLS data reveal that the porphyrin probes are dispersed disorderly on B-DNA and, therefore, not involved in interporphyrin coupling. In contrast, the structure of Z-DNA induces an ordered distribution of **1** which allows electronic coupling between porphyrin molecules that are not in close π–π contact (according to fluorescence measurements).

The different modes of interporphyrin coupling observed with B- or Z-DNA suggests that interaction of ZnT4 (**1**) with Z-DNA involves an additional binding site. Moreover, it is quite unlikely that only the different geometry of the phosphate backbone of the two DNA forms might cause such a different distribution of the porphyrin molecules. Inspection of the structure of Z-DNA reveals that the alternate *anti* and *syn* conformation of nucleobases leads to exposure of guanine atoms N7 and C8, which are both shielded in the B form.[1,3] In Z-DNA, nitrogen atom N7 is available for coordination with transition-metal ions, as shown previously by IR,[34,35] and therefore can provide a site for axial coordination with the central zinc atom of **1**. This hypothesis is corroborated by recent fluorescence studies which reported that the interactions of a cationic zinc(II) porphyrin with polynucleotides caused a blue shift in the emission of the porphyrin despite the red shift in the absorption Soret band,[28,36] similar to what is observed here in the emission of **1**·Z-DNA. The "anomalous" shift of the emission maximum of the porphyrin was interpreted in that case as arising from a change in the binding with respect to the fifth ligand, that is, upon changing from a molecule of water to DNA. The change in the fifth ligand around the Zn(II) ion may also be the case here for **1**·Z-DNA, with substitution of the axial water molecule in ZnT4 (**1**) by guanine N7 of Z-DNA.

Compelling evidence for the occurrence of this binding event came from a competition experiment. Figure 5 shows the decrease in ICD in the Soret region of **1**·Z-DNA and the partial restoration of the original CD features of unbound Z-DNA upon addition of micromolar concentrations of Ni^{II} ions to a solution of the DNA–porphyrin complex. This behavior can be explained by the complexation of Ni^{II} ions to site N7 in Z-DNA and the simultaneous release of porphyrins **1**, together with the strains related to their binding as shown

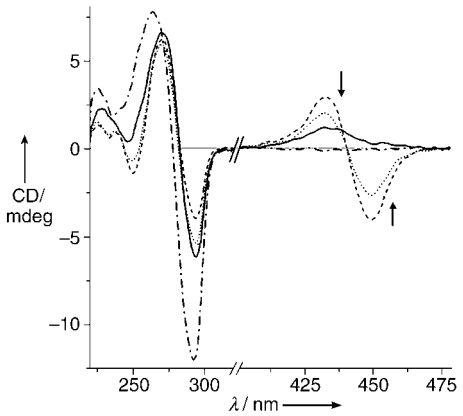

Figure 5. CD spectra of Z-DNA (–•–•), complex **1**·Z-DNA (-----), and **1**·Z-DNA after the addition of $NiCl_2$ (5 μM (••••) and 46 μM (——)).

by the decrease of the ICD of **1** and the partial restoration of the CD spectrum of Z-DNA in Figure 5. A possible model of the **1**·Z-DNA complex is shown schematically in Figure 6b.

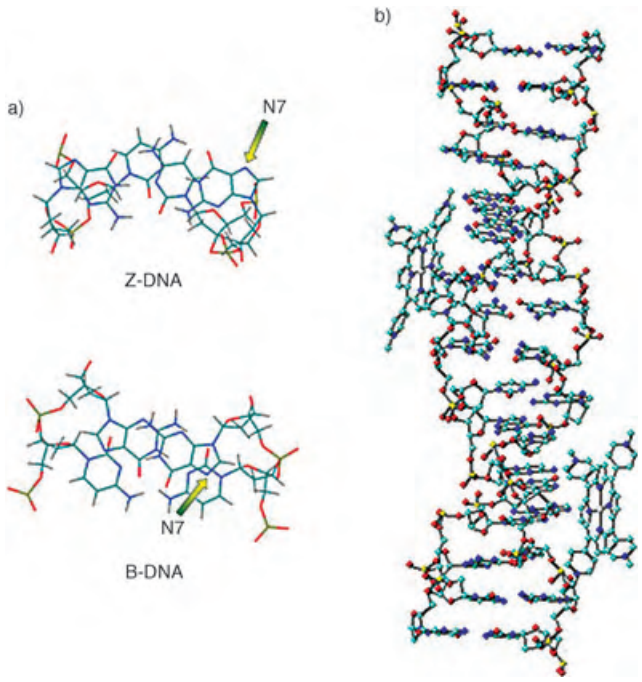

Figure 6. a) Stacking diagram demonstrating the overlap of successive bases (CpG = cytidine-phosphate–guanosine) along the helices of Z- and B-DNA (the arrows point to guanine N7 to highlight their different environments in the two forms), and b) schematic of the proposed structure of the complex **1**·Z-DNA.

In conclusion we have shown that cationic zinc porphyrin **1** is a promising chiroptical probe, which operates at micromolar concentrations, for the structure of left-handed Z-DNA. By application of different spectroscopic techniques, we have proposed the possible origin for a clear-cut discrimination between B- and Z-DNA in the presence of zinc porphyrin **1**. We have clarified the interaction of **1** with left-handed Z-DNA which in turn has led us to propose a structure for the complex **1**·Z-DNA. Studies aimed to better understand the interaction between Z-DNA and porphyrin molecules as well as the design of new porphyrin derivatives with improved discrimination abilities are underway.

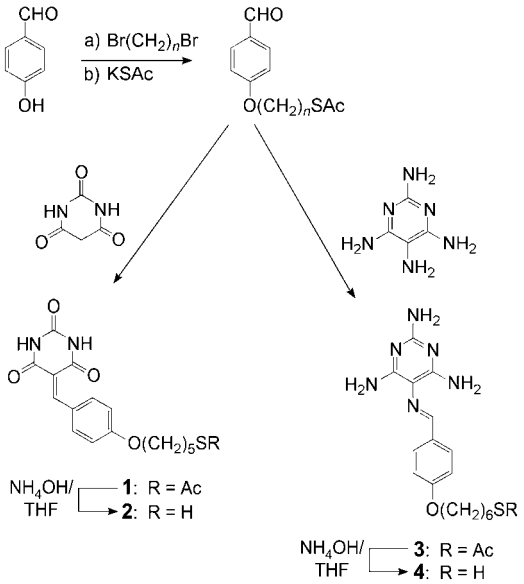
Nanotechnology



Hydrogen-Bonded CdS Nanoparticle Assemblies on Electrodes for Photoelectrochemical Applications**

Ronan Baron, Chih-Hao Huang, Dario M. Bassani, Avital Onopriyenko, Maya Zayats, and Itamar Willner**

The organization of functional semiconductor nanoparticles on surfaces has been extensively examined in recent years,[1] and the use of organized semiconductor nanoparticle systems for photoelectrochemical applications has attracted specific research efforts.[2] For example, core–shell nanoparticle systems were reported to behave as organized matrices that assist charge separation and enhance photocurrent generation when deposited on electrodes.[3] Similarly, the electropolymerization of CdS semiconductor nanoparticles in conductive bis-aniline films proved to result in an organized system that facilitated the charge separation of electron–hole pairs, generated upon photoexcitation of the semiconductor nanoparticles, and the transport of conduction-band electrons to the electrode and led to improved photocurrents.[4] The deposition of layered semiconductor nanoparticles on surfaces by using electrostatic interactions[5] or covalent bonds[6] has been described. Likewise, the assembly of semiconductor nanoparticles on electrode supports by using molecular[7] or supramolecular[8] cross-linkers and hybrid layered metal nanoparticle/semiconductor nanoparticle assemblies[9a] or carbon nanotube/semiconductor nanoparticle systems[9b] were studied. The relationship between structure and photoelectrochemical function in these nanostructures was characterized, and the assembly of these hybrid systems proved to be an effective means to improve the generation of photocurrents by assisting charge separation.

In other organized systems, hydrogen-bonded interactions are an important motif in the generation of supramolecular structures.[10] However, the use of hydrogen bonds to assemble nanoparticle structures has been less explored. The aggregation of silver nanoparticles[11] or gold nanoparticles[12] by interparticle hydrogen bonds of the capping monolayers was reported. Also, modified gold nanoparticles that form hydrogen-bonded host–guest complexes have been synthesized[13] and applied to the development of an electrochemical sensor for phosphate.[13b] To date, the use of hydrogen bonds to fabricate layered nanoparticle structures on surfaces is little explored, but the formation of a multilayer of gold nanoparticles, modified by carboxylic acids, using polyvinylpyridine as the cross-linker in a layer-by-layer deposition process was examined.[14] However, the assembly of functional hydrogen-bonded layered nanoparticle structures on surfaces is unknown. Herein, we report the assembly of cadmium sulfide nanoparticles and gold nanoparticle/cadmium sulfide nanoparticle hybrids on gold surfaces through complementary barbiturate–triaminodiazine hydrogen-bonded interactions and the application of the systems for the generation of photocurrents.

The thioacetyl-protected barbiturate **1** and its complementary hydrogen-bonding aminopyrimidine partner **3** (Scheme 1) were used to modify the CdS or Au nanoparticles.

Scheme 1. Synthesis and structures of barbiturate compounds **1** and **2** as well as their triaminodiazine complements **3** and **4**. $n = 5$ for **1** and **2**; $n = 6$ for **3** and **4**.

The capped nanoparticles were then organized on surfaces by using complementary hydrogen bonds as the driving force. The CdS nanoparticles (4–5 nm diameter) were prepared according to reported methods,[15] and the resulting nanoparticles were treated in a solution of heptane/THF with the thiol derivatives **2** or **4**. The average loading of the CdS nanoparticles with **2** or **4** was determined spectroscopically by monitoring the absorption spectra of the CdS nanoparticles in solution before and after thiol modification. The subtraction of the respective absorbance spectra led to the net absorbance of the capping reagents associated with the CdS nanoparticles.

From the absorbance value at $\lambda = 270$ nm of a solution of known concentration of the CdS nanoparticles (the extinction coefficient (ε) of 4–5-nm CdS nanoparticles is $7 \times 10^5\,\text{M}^{-1}\,\text{cm}^{-1}$),[16] we estimate the average loading of **2** and **4** to be 172 and 190 units per particle, respectively.

Figure 1 depicts the methods to assemble the hydrogen-bonded CdS nanoparticles on gold electrodes. The systems were assembled on Au/quartz piezoelectric crystals to enable

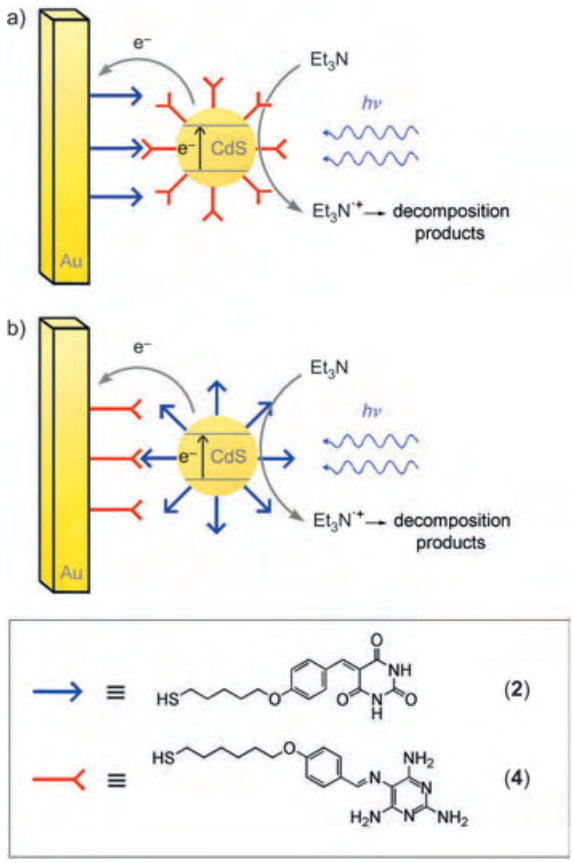

Figure 1. Schematic presentation of hydrogen-bonded CdS nanoparticle assemblies in which a) **2** is bound to the gold electrode and **4** is bound to the CdS nanoparticles, and b) **4** is bound to the electrode and **2** is associated with the CdS nanoparticles.

the characterization of the loading of the different components on the surfaces by microgravimetric quartz-crystal-microbalance (QCM) analyses. In one configuration, Figure 1 a, the thiolated barbiturate **2** was linked to the Au/quartz surface. From the frequency change (Δf), its surface coverage was calculated to be 6.6×10^{-10} mole cm^{-2}. The monolayer-modified surface was then treated with the **4**-functionalized CdS nanoparticles in dry THF. From the frequency change ($\Delta f = -420$ Hz in air), we estimate the surface coverage of the CdS nanoparticles to be 3.1×10^{12} particles cm^{-2} (note, the calculation took into account the loading of the CdS nanoparticles with **4**). Thus, presumably, about 32 monolayer units participate in the hydrogen-bonded association of a CdS nanoparticle to the surface. Further support that the CdS nanoparticles are linked to the electrode by hydrogen bonds was obtained by FT-IR experiments. For the monolayer of thiolated barbiturate **2** on the gold-coated glass, a broad band at $\tilde{\nu} = 3250$ cm^{-1} for the N-H group and three sharp bands at $\tilde{\nu} = 1747$, 1716, and 1687 cm^{-1} for the three different carbonyl functionalities were observed. These bands are consistent with the reported values of IR peaks for barbiturate derivatives.[17] A drop of a solution that contained the CdS nanoparticles capped with the thiolated triaminodiazine **4** was dried on the gold surface, and the residue revealed a broad band at $\tilde{\nu} = 3255$ cm^{-1} (N-H) and an intense band at 1574 cm^{-1} (C=N). For the hydrogen-bonded assembly in which the **4**-capped CdS nanoparticles are linked to the **2**-functionalized gold surface, two bands at $\tilde{\nu} = 3262$ and 3031 cm^{-1} were observed. The appearance of a wide band at $\tilde{\nu} = 3031$ cm^{-1} was previously attributed to the hydrogen-bonded N–H bond between the aminoazine and barbiturate carbonyl functionalities.[18] Similarly, the three sharp bands of the carbonyl group of the barbiturate monolayer are reduced to two bands and shifted to $\tilde{\nu} = 1702$ and 1698 cm^{-1} upon formation of the hydrogen-bonded assembly with the **4**-capped CdS nanoparticles. These shifts are in good agreement with the reported IR bands of hydrogen-bonded assemblies between barbiturate and triaminodiazine derivatives.[17]

In the second configuration of the hydrogen-bonded CdS nanoparticles, as depicted in Figure 1 b, **4** was assembled on the Au/quartz crystal with a surface coverage of 6.4×10^{-10} mole cm^{-2}. The **2**-functionalized CdS nanoparticles were then bound through hydrogen bonds to the surface with a surface coverage of 3.3×10^{12} particles cm^{-2}. The formation of this hydrogen-bonded CdS nanoparticle assembly was also supported by FTIR measurements. Similar to the spectral changes discussed in detail above for system a, analogous shifts for system b were observed. New stretching frequencies for the hydrogen-bonded carbonyl group at $\tilde{\nu} =$ 1700 and 1705 cm^{-1} as well as the non-bonded carbonyl functionalities associated with the particles at $\tilde{\nu} = 1730$, 1716, and 1683 cm^{-1} are the most indicative bands for the formation of the hydrogen-bonded system. A new, less intense band at $\tilde{\nu} = 3035$ cm^{-1}, which corresponds to the hydrogen-bonded N–H bond to the barbiturate carbonyl functions that cap the CdS nanoparticles, was also observed.

The resulting surfaces were also characterized by absorption spectroscopy. Figure 2 a shows the absorption spectrum of the gold surface functionalized with CdS nanoparticles, generated by the association of the **4**-modified CdS nanoparticles with the **2**-functionalized surface. Figure 2 b shows the photocurrent action spectrum of the electrodes modified with CdS nanoparticles, prepared according to system a (Figure 1 a). The photocurrents were recorded in anhydrous THF in the presence of triethylamine (Et_3N) as the electron donor and tetra-*n*-butylammonium hexafluorophosphate as the electrolyte. The photocurrent action spectrum follows the absorbance pattern of the CdS nanoparticles. Furthermore, control experiments indicated that in the absence of either the electron donor or the CdS nanoparticles, no photocurrent was generated in the system. Figure 2 c shows the effect of the applied potential on the magnitude of the resulting photocurrent. As the applied potential is negatively shifted, the photocurrent decreases and is completely blocked at about −0.5 V (vs SCE). These results allow us to define the

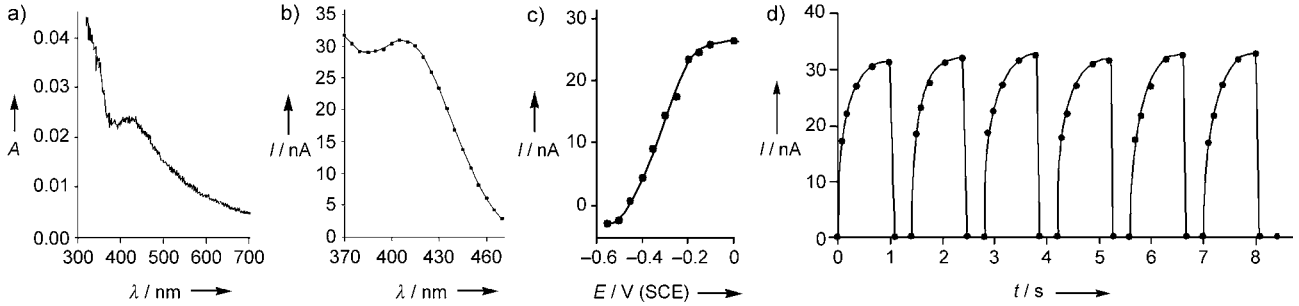

Figure 2. a) Absorbance spectrum of the CdS nanoparticle layer on a gold-coated glass support prepared according to Figure 1 a; b) photocurrent action spectrum corresponding to the CdS nanoparticle assembly shown in Figure 1 a; c) photocurrent recorded as a function of the applied potential at $\lambda = 410$ nm (SCE = standard calomel electrode); d) light-induced "ON" and "OFF" states of switchable photocurrents generated upon irradiation of the functionalized electrode at $\lambda = 410$ nm. All data were recorded in THF solutions containing triethylamine (2×10^{-2} M) and tetra-*n*-butylammonium hexafluorophosphate (0.1 M).

mechanism for the generation of photocurrents in the system. Upon photoexcitation of the CdS nanoparticles, an electron–hole pair is generated in the nanoparticles. The transfer of conduction-band electrons to the electrode followed by the oxidation of the electron donor by valence-band holes leads to the formation of the steady-state photocurrent. Biasing the electrode potential at −0.5 V (vs SCE) blocks the transfer of conduction-band electrons to the electrode which prohibits the generation of photocurrents. By knowing the absorbance features of the CdS nanoparticle interface, the efficiency of light to electrical-energy conversion was calculated to be 0.5%. The functionalized electrode revealed reasonable stability. Figure 2 d shows the cyclic "ON" and "OFF" formation of light-induced photocurrents in the system. The electrode was stable for at least 3 days upon storage in the dark under dry conditions, whilst less than 10% decrease in the photocurrents were observed after immersion for 5 hours in the THF/electrolyte solution.

Further support that the CdS nanoparticle interface is stabilized by hydrogen-bonding interactions was obtained by examining the effect on the resulting photocurrent of the addition of 10% water to the THF/electrolyte solution (Figure 3). As the time interval after the addition of H_2O becomes longer, the resulting photocurrent decreases. Simultaneous QCM analyses indicated that the addition of H_2O to the CdS nanoparticle modified Au/quartz surface resulted in the dissociation of CdS nanoparticles from the electrode support. Interestingly, however, we did not notice desorbtion of the photoactive interface within 10 minutes after the addition of 2% H_2O to the THF/electrolyte solution. Increasing the concentration of H_2O enhanced the dissociation rate of the CdS nanoparticles. The relative stability of the CdS nanoparticle interface is therefore attributed to the multipoint hydrogen-bonded association of the nanoparticles to the monolayer which results in the synergetic binding of the nanoparticles to the surface.

The photocurrent action spectrum observed for the system described in Figure 1 b is depicted in the Supporting Information. The efficiency of conversion of light to electrical energy in this system was estimated to be about 0.4%. This electrode reveals similar properties and functions to the electrode configuration outlined in Figure 1 a. The addition of

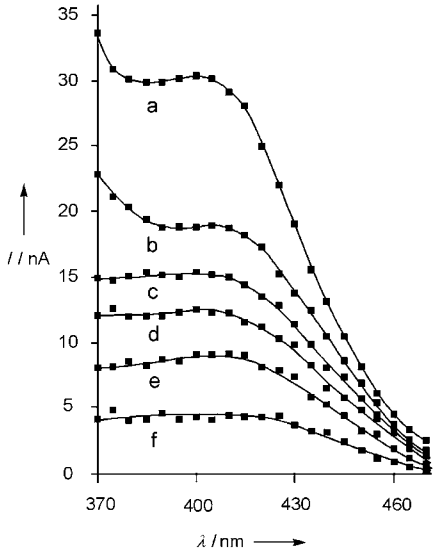

Figure 3. Effect of added water on the photocurrent spectra generated by the CdS nanoparticle assembly shown in Figure 1 a. Data recorded in THF solutions containing triethylamine (2×10^{-2} M) and tetra-*n*-butylammonium hexafluorophosphate (0.1 M). Photocurrent spectra were recorded a) before and (b–f) after the addition of 10% water to the solution in THF: b) 4 min, c) 8 min, d) 12 min, e) 16 min, and f) 20 min.

10% of H_2O to this system similarly resulted in the time-dependent degradation of the hydrogen-bonded interface and decrease of the photocurrent.

In light of previous observations that employed layered gold nanoparticle/CdS nanoparticle hybrid systems for the enhanced generation of photocurrents,[9a] we decided to use hydrogen bonds as a means to construct gold nanoparticle/CdS nanoparticle composites (Figure 4). Citrate-stabilized gold nanoparticles[19] (12 ± 1 nm) were linked by a thiolated monolayer to a Au/quartz surface and a semitransparent (Au film thickness ≈ 50 nm) gold-coated glass slide. Then a monolayer of **4** was assembled on the gold nanoparticles, with an average loading of 5.8×10^3 molecules of **4** per particle determined by QCM measurements. CdS nanoparticles functionalized with **2** were then linked through hydrogen bonds to the gold nanoparticles. QCM measurements of the

parallel assembly of the layered nanoparticle system on a Au/quartz piezoelectric crystal indicated that the surface coverage of the base dithiol monolayer was 8×10^{-10} mole cm^{-2} and the surface coverage of the gold nanoparticles and the CdS nanoparticles corresponded to 7.0×10^{10} and 2.6×10^{12} particles cm^{-2}, respectively.

Figure 5a, curve 1, shows the absorption spectrum of the primary layer of gold nanoparticles on the gold surface. The characteristic plasmon absorbance is clearly visible at $\lambda=$ 520 nm. From the values of the absorbance and the extinction

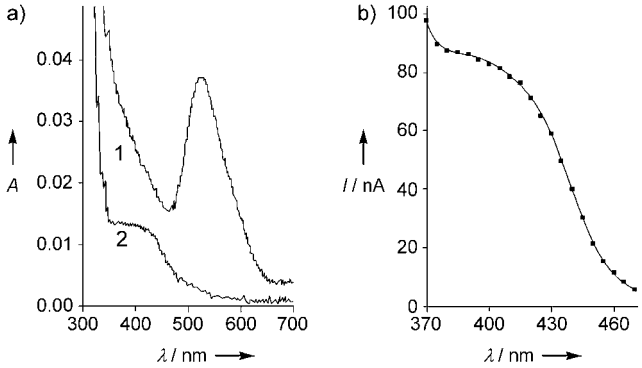

Figure 5. a) Absorbance spectra on a gold-coated glass support of 1) the gold nanoparticle layer and 2) the gold nanoparticle/CdS nanoparticle assembly shown in Figure 4. b) Photocurrent action spectrum corresponding to the gold nanoparticle/CdS nanoparticle assembly. Data recorded in THF solutions containing triethylamine (2×10^{-2} M) and tetra-*n*-butylammonium hexafluorophosphate (0.1 M).

coefficient of 12-nm gold nanoparticles ($\varepsilon=3\times10^{8}$ M^{-1} cm^{-1}),[20] the surface coverage of the gold nanoparticles was estimated to be 6.9×10^{10} particles cm^{-2}, in excellent agreement with the QCM measurements. Figure 5a, curve 2, shows the corrected absorption spectrum of the system after linking the **2**-functionalized CdS nanoparticles to the surface, with the background absorbance of the primary gold nanoparticles subtracted from the spectrum of the composite. The absorbance spectrum of the CdS nanoparticles is clearly identified and exhibits a characteristic shoulder at $\lambda=420$ nm.

Photocurrents from the electrode functionalized with the gold nanoparticle/CdS nanoparticle array were then measured. Figure 5b shows the photocurrent action spectrum of the system. The results are compared to the related hydrogen-bonded CdS nanoparticle assembly that lacks the gold nanoparticles (Figure 1b). The depicted photocurrent action spectra were normalized to exhibit identical surface coverage of the CdS nanoparticles. The photocurrent observed in the gold nanoparticle/CdS nanoparticle composite system is approximately 2.6-fold enhanced relative to the system that lacks the gold nanoparticles. The enhanced photocurrent in the gold nanoparticle/CdS nanoparticle composite system is attributed to the charge separation of the electron–hole pair that is generated upon the photochemical excitation of the CdS nanoparticles; that is, the transfer of the conduction-band electrons to the gold nanoparticles spatially separates the electron–hole pair, thus leading to the retardation of the electron–hole recombination. This delay facilitates the effective scavenging of the valence-band holes by the electron donor as well as the transfer of the electrons trapped by the gold nanoparticles to the electrode, processes that lead to the enhanced generation of photocurrents. There is a substantial difference between the hydrogen-bonded bulk gold surface/CdS nanoparticle configurations (Figure 1a and b) and the hydrogen-bonded gold nanoparticle/CdS nanoparticle array (Figure 4) in facilitating charge separation. A comparison of the surface coverage of molecular components on the functionalized gold nanoparticles or the CdS nanoparticles with the surface coverage by **2**, **4**, or propanedithiol on the bulk gold surfaces indicates that the surface coverage of the bulk gold support is 50- to 100-fold higher than the loadings of the particles. This result implies that the CdS nanoparticles which are linked to the electrode exist in a rigid configuration, whereas structural flexibility exists within the gold nanoparticle/CdS nanoparticle array. This flexibility facilitates the quenching of the conduction-band electrons and enhances charge separation. Furthermore, note that the schematic configuration depicted in Figure 4 is a simplified configuration. The CdS nanoparticles as well as the gold nanoparticles exhibit irregular surface roughness. As a result, the nanoparticles may exist at a substantially closer distance than that dictated by the hydrogen-bonded complex which would facilitate the interparticle charge transport. The special separation of the electron and hole in two different particles then retards the recombination reactions and enhances the photocurrent.

The addition of water to the composite gold nanoparticle/CdS nanoparticle system resulted in the dissociation of the CdS nanoparticles, as observed from microgravimetric QCM measurements, absorption spectra, and photocurrent measurements (see Figure 6). These results imply that the CdS nanoparticles are linked to the gold nanoparticles by complementary hydrogen bonds that are dissociated by water, whereas the gold nanoparticles themselves are tightly bound to the gold support by the dithiol bridging monolayer.

In conclusion, the present study has employed complementary hydrogen bonds to fabricate metal and semiconductor nanoparticle arrays on surfaces and has demonstrated the functional use of the resulting nanostructures for the generation of photocurrents. Although the results may have a limited impact for energy conversion owing to the low photocurrent values, the study highlights fundamental effects

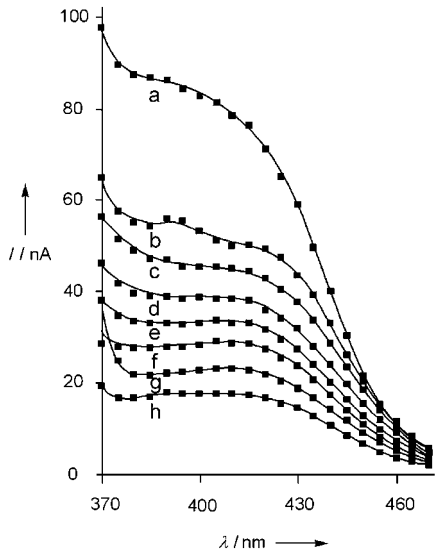

Figure 6. Effect of added water on the photocurrent spectra generated by the gold nanoparticle/CdS nanoparticle assembly shown in Figure 4. Data were recorded in THF solutions containing triethylamine (2×10^{-2} M) and tetra-*n*-butylammonium hexafluorophosphate (0.1 M). Photocurrent spectra were recorded a) before and (b–f) after the addition of 10% water to the solution in THF: b) 4 min, c) 8 min, d) 12 min, e) 16 min, f) 20 min, g) 24 min, and h) 28 min.

of hydrogen-bonded complexes on charge transport at semiconductor nanoparticle/electrode interfaces. The fact that the presented systems are in a monolayer/bilayer nanoparticle configuration suggests, however, that by tailoring hydrogen-bonded composites of higher complexity the resulting photocurrents could be further enhanced.

Experimental Section

Photocurrent experiments were performed using a homebuilt instrument described previously.[7] All spectra were recorded under argon on solutions in THF (0.1M) that contained triethylamine (Et_3N; 2×10^{-2} M) as a sacrificial electron donor and tetra-*n*-butylammonium hexafluorophosphate (0.1M) as electrolyte. The electrodes used were piezoelectric Au/quartz crystals, which allowed us to determine the surface coverage as well as record the photocurrent. The photocurrent spectra were normalized by using the surface coverage of CdS nanoparticles on the piezoelectric crystals.

Absorbance spectra and quantum efficiencies were measured using glass slides coated with a 3-nm layer of chromium and a 50-nm layer of gold (Analytical-μ Systems, Germany). The absorbance spectra were obtained after subtraction of the background absorbance of the gold coating. The quantum efficiency was calculated by determining the light intensity absorbed by the CdS nanoparticle systems and the photocurrent intensities generated by the respective electrodes. The intensity of the light absorbed by the CdS nanoparticle layered system was determined by monitoring the intensity of the light transmitted through the gold-coated glass and the light reflected from the coated surface, and then subtracting the respective values for the transmitted/reflected light for the gold surface modified with CdS nanoparticles. To determine the intensity of absorbed light in the gold nanoparticle/CdS nanoparticle system, the intensity of the transmitted/reflected light in the gold nanoparticle/CdS nanoparticle system was substracted from the intensities of the transmitted/reflected light from the gold surface modified with gold nanoparticles.

Preparation of the CdS nanoparticle assemblies: (The characterization of compounds **1** and **3** is detailed in the Supporting Information.) The acetyl protecting groups in compounds **1** and **3** were removed by hydrolysis under basic conditions in THF by the addition of approximately 10 mg of NH_4OH. CdS nanoparticles, which were prepared according to the reported methods,[15] were capped by mixing solutions of CdS nanoparticles (4 mL) with a solution of **1** or **3** (5×10^{-3} M) in THF (2 mL). The mixture was stirred overnight, then pyridine (0.5 mL) was added, and the resulting particles were collected by centrifugation, washed with THF (×3), and dissolved in THF (2 mL). This solution of nanoparticles was then used to assemble the functionalized electrodes.

The electrode configurations shown in Figure 1a and b were prepared by the following procedure: Au/quartz-crystal electrodes and gold-plated glass electrodes were cleaned in boiling ethanol prior to modification. The electrodes were then modified with either **2** or **4** (5×10^{-3} M overnight in THF) and then immersed for 30 min in the solution of the CdS nanoparticles in THF that were capped with the complementary compound. After each modification step, the electrodes were washed with THF (×3).

For the configuration presented in Figure 4, the electrodes were modified with a propanedithiol monolayer (10^{-2} M, overnight in methanol) and then immersed overnight in an aqueous solution of citrate-stabilized gold nanoparticles. The electrodes were then modified by the procedure described above for the configuration of Figure 1b.

FT-IR spectra were obtained using a Bruker Equinox 55 instrument. The measurements were made directly on gold-coated glass slides in the dry phase under argon, and 1000 scans were averaged for each curve.

The estimation of the number of hydrogen bonds between the CdS nanoparticles and the complementary base monolayer associated with the gold support was based on some rough geometrical approximations. By knowing the average particle diameter, the footprint area of the particles with the monolayer was calculated. By knowing the total loading of the CdS nanoparticles with **2** or **4** (the surface coverage of the gold surface is substantially higher than the coverage of the particles), we were able to estimate the number of hydrogen bonds between the nanoparticles and the surface by also assuming that all the units associated with the footprint area form the hydrogen bonds with the surface.

Donor–Acceptor Systems

A Rigid Neutral Molecule Involving TTF and TCNQ Moieties with Intrinsic Charge- and Electron-Transfer Properties that Depend on the Polarity of the Solvent**

Evgeny Tsiperman, James Y. Becker, Vladimir Khodorkovsky,* Alex Shames, and Lev Shapiro*

Since the discovery[1] of the first organic metal in 1973, much attention has been devoted to the investigation of TTF, its derivatives, and analogues as electron-donor components for many charge-transfer (CT) complexes and ion-radical salts.[2] A proposed model of a unimolecular rectifier[3] involving TTF and TCNQ moieties linked covalently through a rigid saturated spacer has stimulated intensive studies in this direction. A concept involving a number of donor and acceptor units incorporated in a single molecule was later developed[4] that would enable the properties related to molecular organic conductors to be controlled. So far, the realization of this notion has been limited to linking moderate acceptors to TTF derivatives and weak donors to TCNQ fragments,[5] while the incorporation of TTF and TCNQ moieties in a single molecule has proved to be an elusive goal.[6]

In 2003, Bryce and co-workers published[7] a synthesis of a TTF-σ-TCNQ molecule containing a nonconjugated flexible spacer. This compound is expected to exhibit a high degree of intramolecular CT in both solution and the solid state. However, while its IR data are consistent with a degree of charge transfer of about 0.85 in the solid state, only less than 1% biradicals were observed by EPR and UV/Vis/NIR spectroscopy. Also, the redox potentials shifted by only 20 mV with respect to those of the individual donor and acceptor components, thus indicating only a small degree of donor–acceptor interaction. Furthermore the authors' claim of a thermally induced electron transfer in their system, which was based on temperature-dependent EPR measurements, is somewhat misleading. Their calculated HOMO/LUMO gap (0.17–0.75 eV) and measured energy of the CT transition (0.75 eV, red edge 0.45 eV) are much higher than the energy

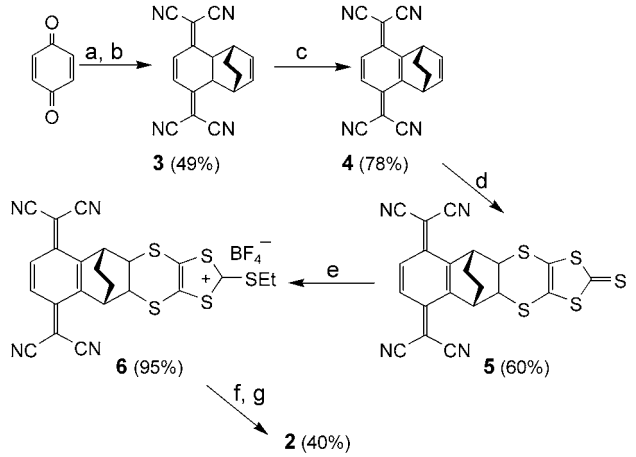
[**] V.K. was on leave at the Université de la Mediterranée, UMR CNRS 6114, 13288 Marseille 09 (France) during the preparation of this manuscript. TTF = tetrathiafulvalene; TCNQ = tetracyanoquinodimethane.

 DOI: 10.1002/anie.200500812 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



at room temperature (0.025 eV), and therefore, thermal ion-radical generation should be totally excluded. In our view, the discrepancies could stem from the flexible nature of the spacer used allowing several conformations, thus leading to difficulties in the interpretation of the observed results. Consequently, it would be more adequate to study TCNQ–TTF systems involving rigid spacers.

Recently[8] we reported the synthesis of compound **1** containing a TTF moiety covalently linked to *p*-benzoquinone through a rigid saturated spacer with a bent structure

that allows an intrinsic through-space charge transfer. Herein, we describe the synthesis, electrochemistry, and spectroscopic results of the rigid TCNQ-σ-TTF-σ-TCNQ derivative **2**. The synthesis was based on the known TCNQ derivative **4** (Scheme 1),[9] which was prepared by a novel procedure, since the reported oxidation was not reproducible in our hands. Intermediate **5** exhibited CT properties as a result of intramolecular through-space interactions between the TCNQ and trithiocarbonate moieties. The combination of zinc dust and bromine in dry acetonitrile[10] was utilized for the self-coupling of 2-ethylthio-1,3-dithiolium salt **6** to obtain

Scheme 1. Synthesis of TCNQ-σ-TTF-σ-TCNQ system **2**: a) PBQ (19 mmol), cyclohexadiene (60 mmol), EtOH (10 mL), b) $TiCl_4$/pyridine (80 mmol/100 mmol), malononitrile (55 mmol), CH_2Cl_2 (450 mL); c) **3** (1.8 mmol), MnO_2 (10–20 mmol), toluene (40 mL); d) **4** (1,4 mmol), 1,3-dithiole-2,4,5-trithione (1.4 mmol), thiophene (20 mL); e) **5** (0.8 mmol), $(EtO)_3CH/BF_3{\cdot}Et_2O$ (5 mmol/3 mmol), CH_2Cl_2 (40 mL); f) **6** (0.8 mmol), Zn/Br_2 (8 mmol/6 mmol), dry CH_3CN (20 mL); g) DDQ (3.5 mmol), dry CH_3CN (20 mL). PBQ = *para*-benzoquinone, DDQ = 2,3-dichloro-5,6-dicyano-1,4-benzoquinone.

a reduced form of **2**. Oxidation of the TCNQ moieties with DDQ in boiling acetonitrile afforded the final product **2**, as a greenish brown powder.

The UV/Vis/NIR spectrum of **2** in CH_2Cl_2 (Figure 1) shows a broad absorption band centered at about 1330 nm ($\varepsilon \approx 750 \pm 40\ cm^{-1}M^{-1}$). The extinction coefficient is concentration and temperature independent and the spectrum

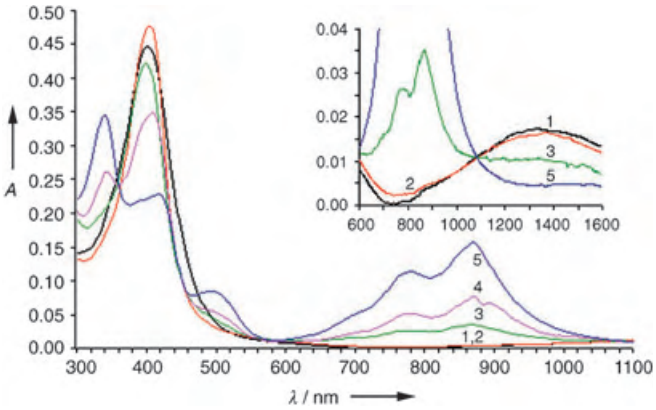


Figure 1. Absorption spectra of **2** in toluene (black, line 1), CH_2Cl_2 (red, line 2), CH_3CN (green, line 3), CH_2Cl_2 + DMF (magenta, line 4), and DMF (blue, line 5).

remains unchanged upon irradiation. The spectrum in toluene is essentially the same, with a similar minimum at about 750 nm. No radicals have been detected by EPR spectroscopy in either solvent. Therefore, the band at approximately 1330 nm can be attributed to an intramolecular CT transition from the TTF to the TCNQ moieties. In comparison, the cation radical and the dianion diradical of **2**[11] exhibit the expected absorption bands between 650 and 1050 nm, centered at about 850 nm, that are characteristic of these species.[12]

The cyclic voltammogram of **2** (Figure 2) in dichloromethane exhibits two $2e^-$ reversible reduction waves at $E^{1/2}_{red1} = 0.14$ V and $E^{1/2}_{red2} = -0.39$ V, which represent the consecutive reduction steps of the two identical TCNQ moieties

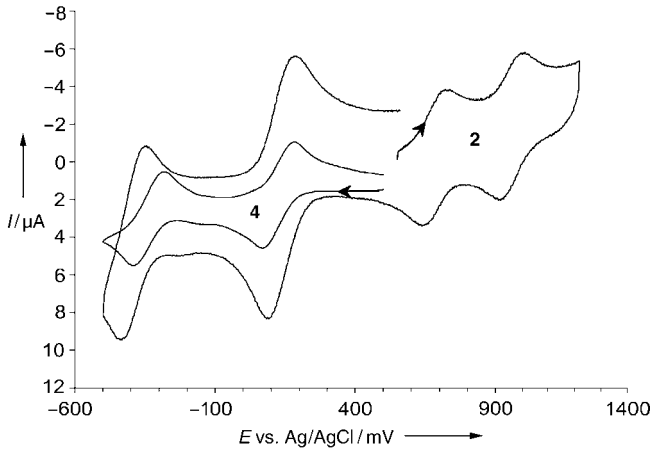

Figure 2. Cyclic voltammograms of **2** and **4** in CH_2Cl_2; 0.1 M $TBA^+PF_6^-$, on glassy carbon electrode versus Ag/AgCl; scan rate 100 $mV s^{-1}$. TBA = tetrabutylammonium.

(**4** shows (Figure 2) $E^{1/2}_{red1} = 0.10$ V, $E^{1/2}_{red2} = -0.34$ V), and two reversible $1e^-$ oxidation waves at $E^{1/2}_{ox1} = 0.69$ V and $E^{1/2}_{ox2} = 0.96$ V, for the oxidation of the TTF fragment. As can be seen by comparing the oxidation of **2** with that of BEDT-TTF (bis(ethylenedithio)tetrathiafulvalene; $E^{1/2}_{ox1} = 0.48$ V, $E^{1/2}_{ox2} = 0.90$ V), the two waves are shifted by about 200 and 60 mV, respectively. These shifts indicate a relatively high degree of CT between the TTF and one (or both) of the TCNQ fragments, thus causing the TTF moiety to be partially charged, and therefore, more difficult to oxidize. The positive shift of the first reduction potential of **2** with respect to that of **4**, which was observed under various experimental conditions, is not fully understood yet.

A significant degree of CT in solid **2** was also observed by IR spectroscopic analysis, with the band corresponding to the cyano groups shifted to a smaller wave number with respect to the similar band in **4** and **5**. On the basis of the well-studied and widely used correlation between the degree of CT and the stretching frequency of the CN groups in TCNQ,[13] we estimated the degree of CT in solid **2** to be of about 0.2. This estimation is based on the absorption bands of the CN groups in the IR spectra of **2** (2206 cm^{-1}), **5** (2213 cm^{-1}), and their corresponding lithium salts (2175 cm^{-1} for both). It is noteworthy that our result is consistent with the absence of signals in the EPR spectrum of solid **2**.

Thus, both in the solid state and relatively nonpolar solvents, derivative **2** exists as an intramolecular CT complex with a degree of CT about 0.2. However, **2** undergo gradual changes in its properties when the polarity of the is solvent increased. For example, the shape of the UV/Vis/NIR spectrum changes completely in DMF solution (Figure 1): the broad NIR absorption band disappears and a strong band centered at 850 nm appears. The spectrum becomes similar to the superimposed spectra of the cation radical and dianion biradical of **2**. The solution also shows a strong EPR signal with $g = 2.0055$, which is an average of the g-factors of the corresponding cation and anion radicals. According to a simulation we performed, the signal is split by four equivalent hydrogen atoms (Figure 3). Both ion radicals and CT complexes can be observed in less-polar solvents or mixtures of solvents (Figure 1).

In summary, a strategy has been developed for preparing a novel system involving TTF and TCNQ moieties covalently linked through rigid saturated spacers. We have shown the first example of a rigid unimolecular system of type TCNQ-σ-TTF-σ-TCNQ that is capable of both through-space intramolecular charge and electron transfer, depending on the polarity of the surroundings. The strong dependence of the ground-state electronic structure on the polarity of solvents, which is a unique and unprecedented case of solvatochromism, can be useful for imaging since the more polar zones will contain larger amounts of ion radicals. The observed polarizing effect in the solid state was not sufficiently strong to give rise to ion radicals, but subtle changes in molecular structure could bring about drastic changes in molecular packing that may lead to different degrees of charge transfer.

Phase Transitions

An Onion Phase in Salt-Free Zero-Charged Catanionic Surfactant Solutions**

Aixin Song, Shuli Dong, Xiangfeng Jia, Jingcheng Hao, Weimin Liu,* and Tianbo Liu*

Mixtures of cationic and anionic (catanionic) single-chain surfactants can readily form bilayers in aqueous solutions,[1] in which uni- and multilamellar onion phases (the so-called vesicle phase) are often observed to be in equilibrium.[2] Since vesicles represent simple model systems for biological membranes and have practical applications (for example, for controlled drug or DNA release),[3] investigations of vesicle phases are of considerable interest in different areas, including surfactants, materials, and life sciences. Recently, two new self-assembled structures of controlled size (nanodisks and regular hollow icosahedra) were observed in dilute catanionic surfactants with H^+ and OH^- counterions by Zemb and coworkers.[4–6] Such so-called "true" catanionic systems, with a nonswelling but finite uptake of water, and with a spacing of the same order as described in the current study were studied and documented by Jokela et al.[7] It was also later established by Rand, Parsegian, and Leiken[8] that the lamellar phase at maximum swelling of salt-free catanionic systems with a zero osmotic pressure, that is, the repulsive hydration interaction is compensated by van der Waals force at that point. The molar ratio r of the anionic to cationic components controls the structural surface charge and, hence, controls the long-range repulsive interaction independently of the weight volume fraction (ϕ), which in turn controls the average colloid–colloid distance. The salt-free catanionic systems can be represented in a ternary phase diagram whose two independent variables are ϕ and r.[6]

Herein we report, for the first time to our knowledge, the discovery of a "true", salt-free concentrated catanionic uni- and multilamellar onion phase that differs from the catanionic surfactant systems with excess salt that are formed by the combination of the counterions, as evident from our freeze-fracture transmission electron microscopy (FF-TEM) observations and small-angle X-ray scattering (SAXS) measurements. This molecular catanionic couple comprises the longest hydrocarbon chains described to date, so it was essential to determine if the carbon chains were in a frozen (gel) or liquid state. The size of the unilamellar vesicles ranges from about 20 to 700 nm and that of the large onions are several micrometers. The interlamellar spacing between the bilayers of onions is about 35 nm, thus suggesting rather compact packing of the bilayers. The high osmotic pressure sustains the highly stable colloidal suspension of the catanionic onion phase. The observations of the onion phase may prove valuable and stimulating to fellow specialists, not least as "true" catanionic surfactant systems do not seem to be exhaustively investigated yet.

The "true" salt-free catanionic vesicle phase was obtained by mixing aqueous solutions of trimethyltetradecylammonium hydroxide (TTAOH) and oleic acid (OA; see Figure 3). The stock solution of TTAOH (pH 12–13) was prepared from the commercial bromide form (TTABr) by anion exchange with a strong base at 40 °C until no bromide ions could be detected by precipitation with $AgNO_3$ in excess HNO_3. The resulting ion exchange with hydroxide ions was $>99\,\%$ (as determined from the detection limit of Br^- ions (Br^- sensitivity)).[9] The critical micelle concentration (cmc) of TTAOH was determined by surface tension measurements to be 1.8 mmol L^{-1}. The phase behavior on mixing 100 mM TTAOH with increasing concentrations of OA (up to 200 mM) was studied (not shown here). OA can dissolve in the aqueous solution containing TTAOH micelles. A single transparent, low viscous solution, which is the L_1 phase (spherical micelle phase), is evident at $c_{OA} = 0$–49.5 mM. The single transparent but viscous L_1 phase (rodlike micelles) is obtained between $c_{OA} = 49.5$ and about 62.5 mM; the viscosity of the samples in this region is much higher, which is evident since the surface of the L_1 phase could not be inclined on tilting the sample tube. A macroscopic phase separation into a birefringent Lα phase on top of the viscous L_1 phase at the bottom of the

tube occurs between 62.5 and approximately 90 mM. From $c_{OA} = 90$ to about 180 mM, a very stable, slightly turbid, bluish, and viscoelastic solution is seen. When $c_{OA} > 180$ mM, this birefringent Lα phase again separates into a two-phase emulsion/viscous layer. The upper phase is an emulsion phase and the lower phase contains the oleic acid component.

The birefringent Lα phase consists of both uni- and multilamellar vesicles, as shown in Figure 1 for two typical samples of TTAOH/OA by means of FF-TEM. The features of the vesicular structures in the two samples are apparent; uni- and multilamellar vesicles can both be seen throughout the samples. The diameters of the unilamellar vesicles, which range from about 20 to over 700 nm, are similar to those formed by single-tailed catanionic surfactants[10] and natural lipids such as lecithine.[11] The vesicles are completely dispersed in solutions and do not tend to associate with each other. Very large multilamellar vesicles with diameters of more than 3 μm can also be seen. The interlamellar spacing between the bilayers is rather small, in the range of about (36 ± 2) nm (Figure 1c), thus suggesting quite compact packing of the bilayers. An important feature is evident in Figure 1a and b: the multilamellar onion phase in the system containing excess cationic component (namely with positive charges; $r_{TTAOH}/r_{OA} = 100{:}94$) has less bilayers than those of ones with zero charges (at $r_{TTAOH}/r_{OA} = 100{:}100$), thus suggesting that the imbalance in the molar ratio of cationic and anionic surfactants does not favor the formation of multilamellar "onions" with quite a compact packing of bilayers.

Small-angle X-ray scattering (SAXS) measurements were carried out on one sample with the birefringent, viscoelastic Lα phase (containing 100 mmol L^{-1} TTAOH and 100 mmol L^{-1} OA), and clearly revealed the formation of lamellar aggregate structures (Figure 2). Three scattering peaks at $q = 0.18$, 0.36, and 0.54 nm^{-1} were observed. The relative peak positions $q_1{:}q_2{:}q_3$ are 1:2:3, which is typical for a Bragg scattering pattern from a one-dimensional lamellar structure (corresponding to the 001, 002, and 003 planes). The interlayer distance d $(= 2\pi/q_{max})$ was determined to be around 35 nm (Figure 3), which is completely consistent with the value obtained from the FF-TEM images. Such a lamellar structure has been commonly observed in mixtures of polyelectrolyte/surfactant complexes[12] and cationic/anionic

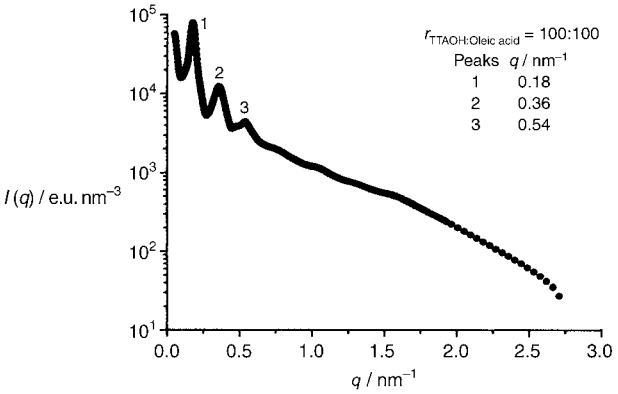

Figure 2. A SAXS profile of one Lα phase in the sample prepared from 100 mmol L^{-1} TTAOH/100 mmol L^{-1} OA. The scattering peaks for the TTAOH/OA mixture can be indexed to a lamellar structure.

surfactant systems[13] with excess salts; very few observations have been reported of such an onion-phase structure in salt-free catanionic systems. The observation of an onion phase in the salt-free catanionic surfactant system should open up new studies on such catanionic systems, and shed new light on the "true", salt-free catanionic onion phase. Meanwhile, the viscoelastic onion phase which contains no dispersed materials will find many applications where such salt-free viscoelastic phases are required with the morphology (spherical core-shell structure) obtained with our catanionic mixtures, for example, in producing mesoporous materials, to orient solubilized molecules, as well as in pharmaceuticals. The SAXS measurements clearly show that the bilayers of vesicles with zero charge have large spacing. This situation arises since electrostatic effects add to the hydration force to compensate for the attractive force and produce low osmotic pressure, probably about 1000 Pa—as reported by Meister et al.[14]

Electrostatic and hydrophobic interactions are responsible for the formation of aggregates in all catanionic surfactant systems investigated in the literature. These catanionic surfactant systems contain dissociated small electrolytes from the counterions of both the anionic and cationic surfactants, which lead to some exclusive properties. For example, the mixed solutions have high ionic strength between the aggregates, electrostatic repulsions are screened,

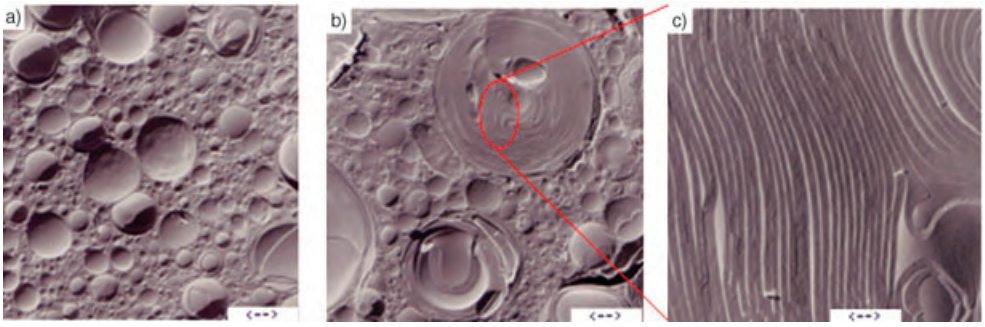

Figure 1. FF-TEM images of two samples: a) 94 mmol L^{-1} OA in 100 mmol L^{-1} TTAOH micellar solution, the scale bar corresponds to 0.350 μm, and b) 100 mmol L^{-1} OA in 100 mmol L^{-1} TTAOH micellar solution, the scale bar corresponds to 0.583 μm. c) Magnification of the multilamellar vesicles to determine the interlamellar spacing between two adjacent bilayers; the scale bar corresponds to 0.14 μm. The sample was frozen from room temperature in liquid propane cooled by liquid N_2: for further details see reference [2].

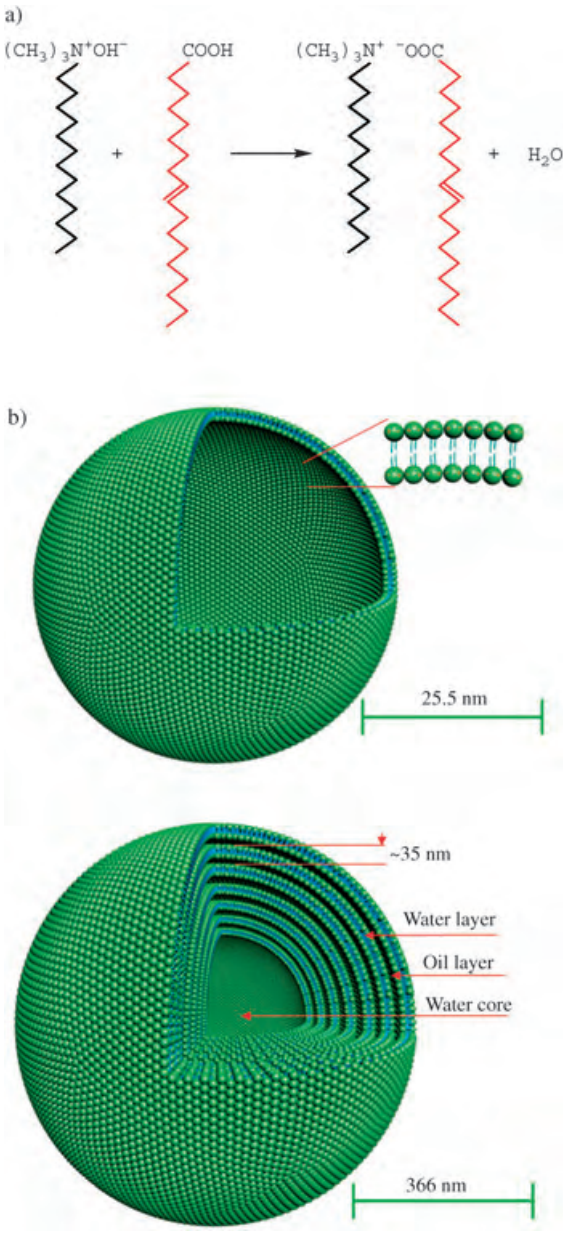

Figure 3. a) Formation of the salt-free catanionic surfactants. b) Models of unilamellar vesicle (top) with 25.5-nm radius and multilamellar vesicles (below) with 366-nm radius. The analysis of experimental data is shown for the multilamellar vesicles. The hydrophobic double-chain hydrocarbons are shown as blue rods and the hydrophilic-charged cationic-anionic groups as green spheres. A sector in each model has been cut out to enhance the visibility. Seven bilayers comprise the multilamellar onion phase.

and osmotic pressure of aggregates is <100 Pa. Moreover, when mixing cationic and anionic surfactants in solutions, the strong reduction in area per head group resulting from ion pairing induces lamellar structures. Thus vesicles, flexible cylinders, as well as flat lamellae can be prepared and observed.[10,13]

In the current study, a low osmotic pressure is produced by unscreened electrostatic repulsion, which sustains the highly stable colloidal suspension, the "onion phase". However, it is quite different from the excess-salt catanionic surfactants, because solid surfactant precipitates do not form in the salt-free systems at relatively high surfactant concentrations (100 mmol L^{-1}, or 3–5 wt% surfactants) and a 1:1 cationic/anionic surfactant ratio (zero charge). Thus, the observation of an onion phase in the current study constitutes a salt-free concentrated catanionic surfactant system with the longest hydrocarbon chains having an unsaturated bond to date. Such a well-defined salt-free onion-phase system should be much more useful than the excess-salt catanionic surfactant systems, because of the interactions and effects controlling the assembly of the surfactants and/or the formation of different new surfactant phases, the more theoretically predictable behavior, and the fact that solid surfactant precipitates do not form at a 1:1 cationic and anionic surfactant ratio.

Experimental Section

Materials**:** Trimethyltetradecylammonium bromide (TTABr) was purchased from Acros Organics, New Jersey, USA and recrystallized three times from the mixed solvent of diethyl ether/ethanol. The TTAOH stock solution was prepared from the TTABr solution (120 mM) by anion exchange with a strong base (Ion exchanger III, Merck) at 40 °C. Bromide ions could not be detected by $AgNO_3$ in the TTAOH stock solution ($Ag^+ + Br^- \rightarrow AgBr\downarrow$), so the ion exchange with hydroxide is $>99\%$.[9] The critical micelle concentration (cmc) of TTAOH (0.0018 mol L^{-1}) was determined by using surface tension measurements. Oleic acid (OA) was obtained from Shanghai Chemical Co. with ionic impurities of sodium (0.1% molar fraction) and calcium (0.05% molar fraction). The fatty acids are quasi-insoluble in water, however, they can be mixed with TTAOH solution to provide clear solutions by heating to 40 °C.

Methods: The phase diagram of 100 mM TTAOH with the variable oleic acid concentrations was established by observing the solutions in test tubes at 25.0 ± 0.1 °C. The samples were homogenized by mixing and heating to about 40 °C for a few minutes, and then the hot solutions were cooled to room temperature with permanent shaking during cooling. The solutions were allowed to equilibrate for at least four weeks at 25.0 ± 0.1 °C and did not contain any trace of insoluble materials. All the experiments described were done at 25 ± 0.1 °C unless specified otherwise.

The microstructure of the samples with birefringence between the polarizers was examined by freeze-fracture transmission electron microscopy (FF-TEM). A small amount of sample (ca. 4 μL) was placed on a 0.1-mm thick copper disk covered with a second copper disk. The copper sandwich with the sample was frozen by plunging it into liquid propane which had been cooled by liquid nitrogen. A freeze-fracture apparatus (Balzer BAF 400, Germany) was used at a temperature of −140 °C for fracturing and replication. Pt/C was deposited at an angle of 45°. The replicas were examined with a Zeiss CEM 902 transmission electron microscope operated at 80 kV.

SAXS measurements were carried out at room temperature on a modified Kratky compact camera. The evacuated camera was mounted on a sealed X-ray tube equipped with a copper target. The scattering intensities were measured with a linear position-sensitive, gas-filled detector (Mbraun, Germany) by monitoring the scattering curves in the q range ($q = 4\pi/\lambda \sin\theta/2$, where θ is the scattering angle and λ is the wavelength of radiation). The sample solutions were injected into a 1 mm diameter quartz capillary mounted in a steel cuvette. The data collection time for each scattering curve amounted to about 15 h.

Dipoles in Crystal Engineering

Molecular Tectonics: Porous Cleavable Networks Constructed by Dipole-Directed Stacking of Hydrogen-Bonded Sheets**

*Nadia Malek, Thierry Maris, Marie-Ève Perron, and James D. Wuest**

An exciting challenge in contemporary science is learning how to make ordered molecular materials with predetermined structures and properties. The effort to reach this goal continues to yield new knowledge of both fundamental and practical value. Of particular interest are ordered molecular materials produced spontaneously by methods of self-assembly, such as crystallization. Although detailed predictions of the structure of molecular crystals remain unreliable,[1] crystal engineering provides increasingly effective strategies for identifying compounds predisposed to crystallize in particular ways.[2] One such strategy, which has been called molecular tectonics,[3,4] relies on special compounds that participate in multiple directional interactions. Such compounds, called tectons from the Greek word for builder, are programmed to associate and to form networks in which each molecule is placed in a predictable position with respect to its neighbors. Herein, we show how two different directional forces, hydrogen bonding and dipole-dipole interactions,[5] can be used in potent combination to engineer molecular networks with predictable cleavage and high porosity.[6]

Tetrahedral tectons **1** with peripheral sites of association (●) are predisposed to form three-dimensional four-connected networks, whereas trigonal analogues **2** favor sheets (Figure 1). In the first case, the entire three-dimensional structure is programmed by the tectons and maintained by strong interactions in all directions; in the second case, however, the ultimate structure must result from the stacking or interpenetration of sheets,[7] governed by forces that are not normally subject to rational control. Examples of structural polytypism resulting from subtle variations in the stacking of sheets are numerous in chemistry and include the diverse phases of graphite,[8] sheet silicates in which the layers have different offsets,[9] and various hydrogen-bonded molecular sheets.[10] For many applications, polytypism is undesirable because it makes full structural predictions unreliable, even when the positions of all the atoms in individual sheets are well established.

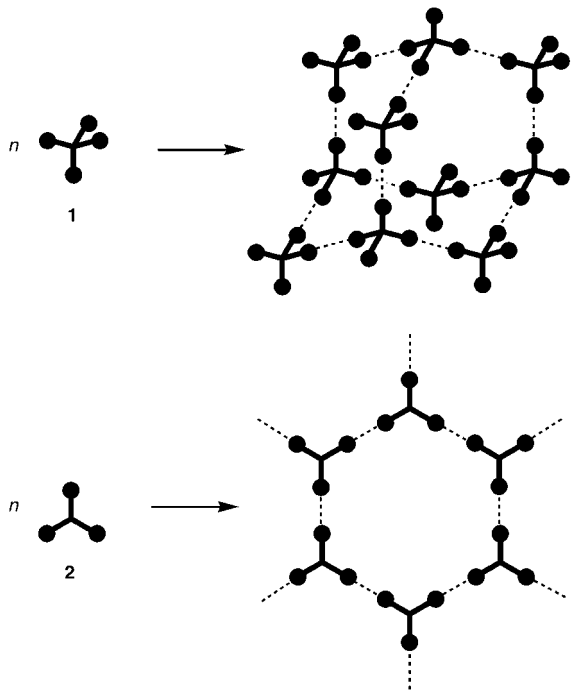

Figure 1. Representations of the hypothetical three-dimensional network built from tetrahedral tecton **1** and the two-dimensional network formed by trigonal tecton **2**.

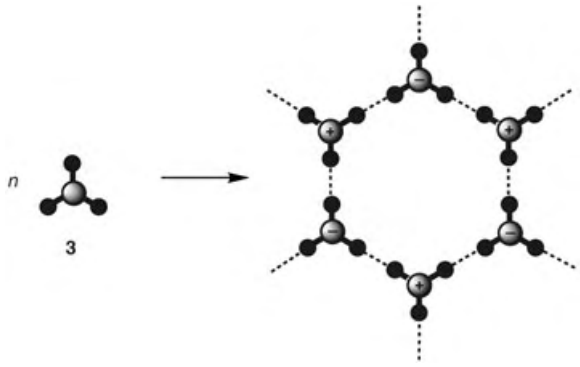
A potentially effective element of control can be introduced by incorporating a dipole at each trigonal center to create tecton **3** (Figure 2). Assembly directed cooperatively



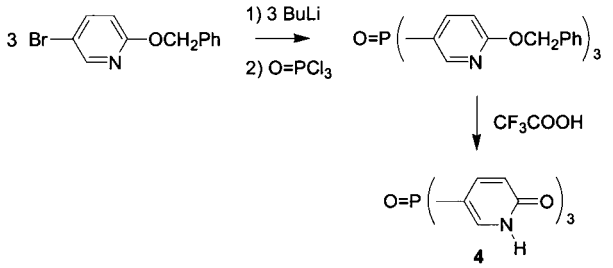


Figure 2. Hypothetical sheet resulting from trigonal tecton **3** with a dipolar core (white circle) showing the expected antiparallel alignment of adjacent dipoles (represented by inscribing + and − in the cores).

by the normal association of the sticky sites (●) and by antiparallel orientation of neighboring dipoles should produce the sheet shown in Figure 2. Such sheets are then predisposed to create a hexagonal three-dimensional array by stacking in registry, directed by the formation of head-to-tail columns of dipoles that lie perpendicular to the sheets. An encouraging precedent for the dipole-directed assembly of sheets is provided by the structure of the most stable polymorph of phosphorus pentoxide.[11] In this structure, PO_4 tetrahedra share three corners to form covalently bonded sheets composed of 12-membered rings. Adjacent P=O bonds are oriented perpendicularly toward opposite faces of each sheet, and their alignment suggests that dipolar interactions control the stacking of the sheets.

The feasibility of using dipoles to direct the stacking of hydrogen-bonded molecular sheets was tested by studying phosphine oxide **4** (Scheme 1). Three pyridinone groups are

Scheme 1. Synthesis of phosphine oxide **4**.

incorporated in compound **4** to ensure strong intermolecular hydrogen bonding through a reliable supramolecular synthon,[12–14] and the P=O bond introduces a large and unambiguous dipole, which is approximately 4.5 D in triphenylphosphine oxide.[15] Compound **4** was prepared in 89% overall yield from 5-bromo-2-(phenylmethoxy)pyridine[16] by the route summarized in Scheme 1. Crystallization was achieved by allowing hexane to diffuse into solutions of compound **4** in either CH_3COOH or CH_3CH_2COOH. Both crystallizations produced hexagonal prisms of composition **4**·3 RCOOH, as determined by X-ray crystallography, thermogravimetry, and ^{1}H NMR spectroscopy of dissolved samples. X-ray diffraction established that crystals grown under both conditions belong to the trigonal space group $P\bar{3}$ and are isomorphous, so only views of the structure containing CH_3COOH are shown (Figures 3 and 4).

The structure produced by crystallizing tecton **4** can be interpreted as a direct consequence of the combined effects of hydrogen bonding and dipolar interactions. Characteristic intermolecular hydrogen bonding of the three pyridinone groups defines a porous sheet composed of cyclic hexamers (Figure 3). It is noteworthy that hydrogen bonding of carboxylic acid solvents with compound **4** does not prevent normal association of its pyridinone groups. Since the P atom is approximately tetrahedral (∢O-P-C 112.08(11)° in crystals grown from CH_3COOH/hexane), the pyridinone groups do not diverge from the core in a single plane, and the resulting sheet is corrugated (Figure 4). Each cyclic hexamer has a chair conformation with the P=O dipoles oriented axially, and adjacent dipoles are antiparallel and directed toward opposite faces of the sheet. Like other triarylphosphine oxides,[17–19] compound **4** adopts a chiral conformation in the crystalline state, and molecules with dipoles oriented in one direction are enantiomers of those with dipoles aligned in the opposite direction. The intertectonic distance between the P atoms of neighboring hydrogen-bonded molecules is 11.82 Å, and the pores in individual sheets are approximately 15.1 Å in diameter.[20]

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

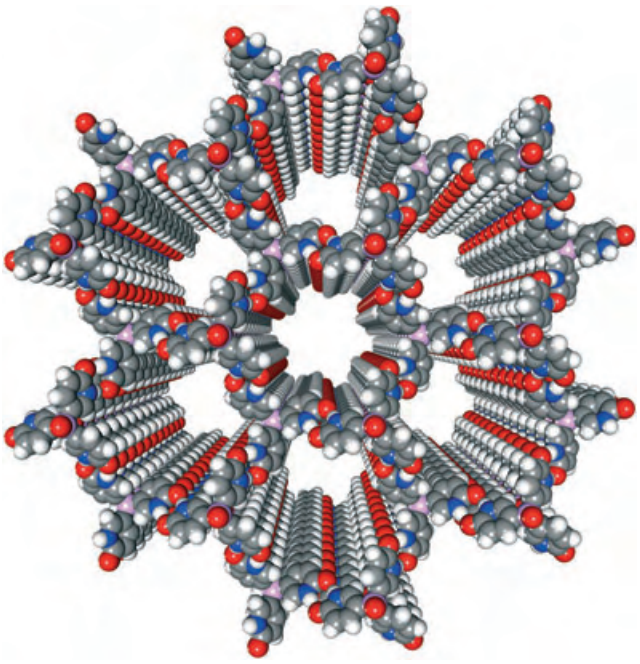

Figure 3. Perspective view along the *c* axis of the network constructed by crystallizing phosphine oxide **4** from CH_3COOH/hexane. Guests are omitted, and atoms are shown as spheres of van der Waals radii to reveal the cross-sections of the channels. Atoms of hydrogen are shown in white, carbon in gray, nitrogen in blue, oxygen in red, and phosphorus in pink.

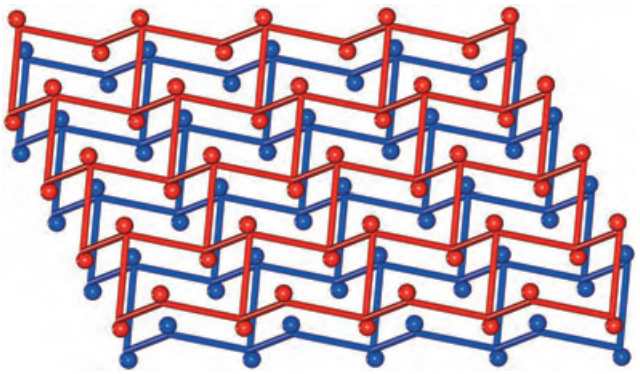

Figure 4. Representation of the dipole-directed stacking of corrugated sheets observed in crystals of phosphine oxide **4** grown from CH_3COOH/hexane, as viewed with the *c* axis approximately vertical. Two adjacent sheets are shown, one in red and the other in blue, and P=O dipoles are represented by lobes of the same color. The sheets are defined by lines joining the central phosphorus atom of each tecton to the centers of the three hydrogen-bonded neighbors.

As planned, the sheets then stack in registry in a way that appears to be directed by head-to-tail alignment of P=O dipoles in adjacent layers (Figure 4). In the resulting structure, the average intertectonic distance between the closest P atoms of neighboring sheets is 5.39 Å. As a result of the registry the pores in each sheet are aligned with those in adjacent sheets, thereby creating impressive parallel channels that run perpendicular to the sheets and contain partially ordered molecules of CH_3COOH and CH_3CH_2COOH. Approximately 50% of the volume of the crystals of compound **4** is available for including guests.[21,22] This degree of porosity is impressive but somewhat smaller than that of the very best three-dimensional molecular networks,[23] perhaps because tecton **4** favors association in two dimensions to form sheets that can then pack closely. However, the channels are among the largest ever observed in molecular crystals. It is instructive to compare the network constructed from compound **4** with those of crystalline inorganic analogues that have similar parallel channels and have been cited repeatedly as benchmarks in the field of microporous materials. In particular, gross structural features of the network built from tecton **4** (porosity 50%, 15-Å channels) resemble those of the synthetic aluminophosphate VPI-5 (porosity 43%, 13-Å channels)[24] and the natural Fe^{III} phosphate cacoxenite (porosity 49%, 17-Å channels).[25,26] These analogies underscore the potential of engineering porous networks from purely molecular precursors. Moreover, the network derived from compound **4** was built by design and can be assembled at 25 °C as large single crystals with a structure that can be solved by straightforward X-ray diffraction, unlike VPI-5, cacoxenite, and many related inorganic and metal–organic materials.[26]

The behavior of compound **4** differs significantly from that of structurally similar molecules lacking the same capacity to take part in directional interactions. For example, compound **4** yields isomorphous structures when crystallized from either CH_3COOH/hexane or CH_3CH_2COOH/hexane, whereas triphenylphosphine oxide crystallizes under different conditions as multiple polymorphs.[17,18] Some of these polymorphs do not incorporate the head-to-tail alignment of P=O dipoles observed in crystals of compound **4**, which suggests that the contribution of dipolar interactions to the overall lattice energy is important but not dominant. In addition, compound **4** forms a highly porous network, whereas all known polymorphs of triphenylphosphine oxide are close-packed, and enclathration of guests is not observed.[17,18,27] Together, these comparisons show how the behavior of tectons differs markedly from that of models lacking oriented arrays of sticky sites, and they confirm that tectonic association normally reduces opportunities for polymorphism and favors the formation of networks that are not close-packed.

In the open network constructed from phosphine oxide **4**, each tecton forms a total of six hydrogen bonds with its three neighbors in the same sheet, and it participates in attractive dipole–dipole interactions with the two closest neighbors in adjacent sheets. In contrast, included guests are weakly bound to the network and are located in large channels that in principle offer easy escape from the network. As observed in other porous molecular networks held together by multiple hydrogen bonds, crystals of compound **4** are permeable, and guests can be exchanged in single crystals without loss of crystallinity. For example, crystals of composition $\mathbf{4}\cdot 3\,CH_3COOH$ and approximate dimensions $0.5\times0.5\times2.0\ mm^3$ were suspended in CH_2=CHCOOH/hexane at 25 °C for 3 days.[28] The recovered sample remained transparent and morphologically unchanged. Furthermore, it continued to diffract and to show uniform extinction between crossed polarizers. Analysis of dissolved samples by ^1H NMR spec-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

troscopy confirmed that CH_3COOH had been replaced completely to give new crystals of composition **4**·3 CH_2=CHCOOH. The quality of the exchanged crystals was high enough to allow their structure to be solved by single-crystal X-ray diffraction. The exchanged crystals proved to be isomorphous, with unit cell parameters essentially identical to those of the initial crystals (±4%). The close similarity of the structures of crystals containing CH_3COOH, CH_3CH_2COOH, or CH_2=CHCOOH suggests that the network built from tecton **4** is resistant to deformation.[12]

The three-dimensional architecture generated by crystallizing compound **4** consists of sheets held together by a high density of strong hydrogen bonds, stacked in the perpendicular direction by a lower density of weaker dipolar interactions. As a result, we reasoned that the mechanical properties of the crystals would be highly anisotropic. In particular, we expected cleavage of the crystals to show marked directional preferences, perhaps similar to those observed in micas and other lamellar inorganic materials, and we hoped to be able to make thin sections by cleaving crystals perpendicular to the axes of the channels. Unlike sections cleaved from lamellar inorganic materials, which are typically dense and nonporous,[29] those split from crystals of compound **4** are expected to be selectively permeable and to have well-defined pores of nanometric dimensions.

Indexation of hexagonal prisms of compound **4** grown from CH_3COOH established that the long axis of the crystals corresponds to the crystallographic *c* axis, so the channels run from one end of the prisms to the other. Stress was induced in the crystals by removing them from their mother liquors and exposing them to air, thereby initiating slow loss of included guests. Close examination of a typical stressed crystal (Figure 5) reveals multiple planes of fracture, all lying perpendicular to the *c* axis. This fractographic analysis[30] confirmed that the crystals are mechanically fragile and susceptible to preferential basal cleavage between adjacent hydrogen-bonded sheets, as expected. Moreover, pressing gently on crystals with a microscalpel held perpendicular to the length of the prism readily cleaved sections as thin as 30 μm, such as the one shown in Figure 5. The prism faces in ideal prisms free of defects should not show significant permeability; instead, guests should enter or exit only at the terminations, then reach the core by diffusion.[31] In real crystals, however, fractures may provide additional surfaces for the exchange of guests. In a prism with *N* complete basal fractures of the type observed, the surface available for exchange will in principle be multiplied by a factor of $2N+2$, and the rate of exchange will increase accordingly. Similar phenomena may account in part for the high rate of exchange observed in other permeable molecular crystals.

Together, these observations underscore the potential of molecular tectonics as a strategy for the purposeful construction of ordered materials with new properties, and they show how carefully selected combinations of directional forces can be used to engineer crystals with particular anisotropic features.

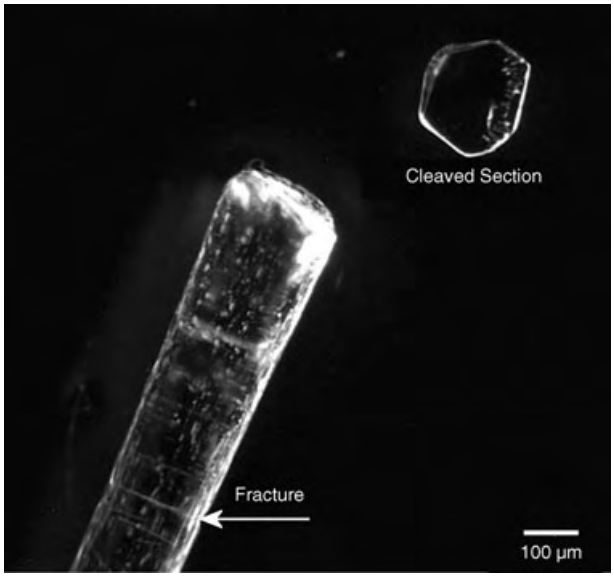

Figure 5. Optical micrograph showing 1) an intact single crystal of phosphine oxide **4** (lower left) grown from CH_3COOH/hexane, then stressed by partial evaporation of guests to induce the formation of basal fractures and 2) a thin section (upper right) cleaved from the same single crystal.

Experimental Section

For experimental details, see reference [32]. X-ray crystal structural analyses:[33] Data were collected at 223 K using a Bruker SMART 2000 CCD diffractometer with $Cu_{K\alpha}$ radiation ($\lambda = 1.54178$ Å). Intensities were integrated using SAINT[34] and corrected for absorption and other effects using SADABS.[35] Structures were solved and refined using the SHELX suite of programs.[36]

Crystal data for tecton **4**·3 CH_3COOH: crystal size $0.40 \times 0.15 \times 0.15\ mm^3$, trigonal, space group $P\bar{3}$, $a = b = 16.9535(8)$, $c = 5.2396(3)$ Å, $V = 1304.21(11)$ Å^3, $Z = 2$. Least-squares refinement of 137 parameters using 73 restraints for 1404 reflections with $I > 2\sigma(I)$ out of 1659 reflections gave residual factors $R_1 = 0.0772$, w$R_2 = 0.2660$, and GOF = 1.086.

Crystal data for tecton **4**·3 CH_3CH_2COOH: crystal size $0.40 \times 0.40 \times 0.20\ mm^3$, trigonal, space group $P\bar{3}$, $a = b = 17.1474(4)$, $c = 5.3885(2)$ Å, $V = 1372.13(7)$ Å^3, $Z = 2$. Least-squares refinement of 117 parameters using 2 restraints for 1403 reflections with $I > 2\sigma(I)$ out of 1691 reflections led to residual factors $R_1 = 0.0682$, w$R_2 = 0.1984$, and GOF = 1.071.

Crystal data for tecton **4**·3 CH_2=CHCOOH: crystal size $0.60 \times 0.25 \times 0.25\ mm^3$, trigonal, space group $P\bar{3}$, $a = b = 17.4823(8)$, $c = 5.0683(8)$ Å, $V = 1341.5(2)$ Å^3, $Z = 2$. Least-squares refinement of 115 parameters using 30 restraints for 699 reflections with $I > 2\sigma(I)$ out of 1211 reflections gave residual factors $R_1 = 0.0956$, w$R_2 = 0.2542$, and GOF = 1.031.

[20] The dimensions of a channel in a particular direction correspond to those of an imaginary cylinder that could be passed through the hypothetical open network in the given direction in contact with the van der Waals surface. Such values are inherently conservative because 1) they measure the cross-section at the most narrow constriction, and 2) they systematically underestimate the sizes of channels that are not uniform and linear.

[21] The percentage of volume accessible to guests was estimated by the PLATON program.[22] PLATON calculates the accessible volume by allowing a spherical probe of variable radius to roll over the internal van der Waals surface of the crystal structure. PLATON uses a default value of 1.20 Å for the radius of the probe, which is an appropriate model for small guests such as water. The van der Waals radii used to define surfaces for these calculations are as follows: C: 1.70 Å, H: 1.20 Å, N: 1.55 Å, O: 1.52 Å, and P: 1.80 Å. If V is the volume of the unit cell and V_g is the guest-accessible volume as calculated by PLATON, then the porosity P in % is given by 100 V_g/V.

Zintl Anions

[(Ni-Ni-Ni)@(Ge$_9$)$_2$]$^{4-}$: A Linear Triatomic Nickel Filament Enclosed in a Dimer of Nine-Atom Germanium Clusters**

*Jose M. Goicoechea and Slavi C. Sevov**

The chemistry of nine-atom deltahedral Zintl anions of Group 14 has advanced greatly in recent years. Redox reactions of these clusters have led to dimers, trimers, tetramers, and infinite chains of germanium clusters such as [Ge$_9$-Ge$_9$]$^{6-}$,[1] [Ge$_9$=Ge$_9$=Ge$_9$]$^{6-}$,[2] [Ge$_9$=Ge$_9$=Ge$_9$=Ge$_9$]$^{8-}$,[3,4] $_\infty$[-(Ge$_9$)$^{2-}$-],[5,6] and $_\infty$[-(HgGe$_9$)$^{2-}$-].[7] Similar redox reactions combined with nucleophilic addition of various anions have produced, for the first time, substituted clusters such as [Ge$_9$-SnPh$_3$]$^{3-}$, [Ph$_3$Sn-Ge$_9$-SnPh$_3$]$^{2-}$, [Ph$_2$Sb-Ge$_9$-SbPh$_2$]$^{2-}$, and [Ph$_3$Sn-Ge$_9$-Ge$_9$-SnPh$_3$]$^{3-}$.[8–10] Also, it has been known for quite some time that ligand-exchange reactions with organometallic compounds can add a transition-metal vertex to the cluster and form species such as [Sn$_9$M(CO)$_3$]$^{4-}$ for M = Cr, Mo, W.[11–13] More recent experiments with [Pt(PPh$_3$)$_4$], [Ni(CO)$_2$(PPh$_3$)$_2$], and [Ni(cod)$_2$] (cod = 1,5-cyclooctadiene) have shown that the nine-atom cluster can accommodate a central transition-metal atom to form [Ni@(Ge$_9$Ni-PPh$_3$)]$^{2-}$,[14] [Ni@(Sn$_9$Ni-CO)]$^{2-}$, and [Pt@(Sn$_9$Pt-PPh$_3$)]$^{2-}$.[15] Note that these species also contain a ligated transition-metal atom in the form of {Ni-PPh$_3$}, {Ni-CO}, or {Pt-PPh$_3$} fragments as a vertex of the cluster and are thus ten-atom clusters. Similar reactions involving Pb$_9$ clusters resulted in cluster enlargement and formation of the first ligand-free, transition-metal centered deltahedral clusters [Ni@Pb$_{10}$]$^{2-}$ and [Pt@Pb$_{12}$]$^{2-}$ with the shapes of a bicapped square antiprism and an icosahedron, respectively.[16,17] Also, a reaction of the As$_7^{3-}$ ions with [Ni(cod)$_2$] leads to a large cluster of 20 arsenic atoms around an arsenic-centered {Ni$_{12}$} core.[18]

Herein we report the synthesis and characterization of a ligand-free anion that contains a linear trimer of nickel enclosed inside two nine-atom germanium clusters, [(Ni-Ni-Ni)@(Ge$_9$)$_2$]$^{4-}$ (**1**; Figure 1). This compound is the first ligand-free deltahedral formation of Group 14 with more than one transition-metal atom inside. The anion was structurally characterized in the species [K(2,2,2-crypt)]$_4$[Ni$_3$@(Ge$_9$)$_2$]·2tol (2,2,2-crypt = 4,7,13,16,21,24-hexaoxa-1,10-diazabicyclo-[8.8.8]hexacosane, tol = toluene) made in a high yield by a reaction of an ethylenediamine(en) solution of K$_4$Ge$_9$ with a threefold excess of [Ni(cod)$_2$].

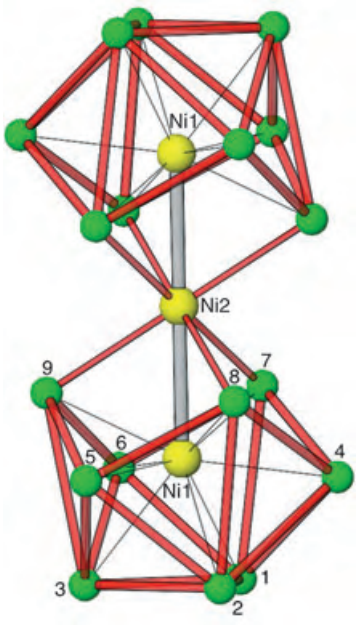

Figure 1. The anion **1**. Ge: green. The Ni–Ni bond length is 2.395(1) Å. Ni2 is at an inversion center and is octahedrally coordinated by germanium with distances [Å] from Ni2 to: Ge7 2.529(1), Ge8 2.540(1), Ge9 2.505(1) Å, and angles in the range 86.09(4)–93.91(4)°. Each Ge$_9$ cluster is a tricapped (atoms 4, 5, 6) trigonal prism (triangular bases of atoms 1-2-3 and 7-8-9) in which one of the triangular bases (7-8-9) has been opened by insertion of the nickel trimer. Distances [Å] from Ni1 to: Ge1 2.475, Ge2 2.487, Ge3 2.510, Ge4 2.446, Ge5 2.456, Ge6 2.453, Ge7 2.338, Ge8 2.340, Ge9 2.362. Other distances [Å]: Ge1-Ge7 3.016, Ge2-Ge8 3.052, Ge3-Ge9 3.061, Ge1-Ge2 2.654, Ge1-Ge3 2.634, Ge1-Ge4 2.726, Ge1-Ge6 2.749, Ge2-Ge3 2.640, Ge2-Ge4 2.712, Ge2-Ge5 2.713, Ge3-Ge5 2.724, Ge3-Ge6 2.738, Ge4-Ge7 2.662, Ge4-Ge8 2.621, Ge5-Ge8 2.653, Ge5-Ge9 2.604, Ge6-Ge7 2.621, Ge6-Ge9 2.612. (The standard deviations for all distances are 1 or 2×10^{-3} Å.).

The two end atoms of the nickel trimer center the two nine-atom germanium clusters while the central nickel atom is positioned at an inversion center and plays the role of a tenth (shared) vertex for each cluster. A closer look at the nine-atom germanium clusters reveals that, similar to many empty clusters, they can be described as distorted tricapped trigonal prisms (Figure 1). Typically, the distortion in empty clusters is expressed in elongation of one, two, or all three of the vertical prismatic edges 1-7, 2-8, and 3-9. The nickel-centered clusters in **1** show the same distortion, all three edges being significantly longer, 3.061(2), 3.052(2), and 3.016(2) Å, than the remaining Ge–Ge distances, 2.604(1)–2.749(2) Å. However, the clusters in **1** are additionally distorted by the opening of one of the triangular bases of the prisms, the base made of atoms 7-8-9. This distortion is clearly caused by the insertion of the additional nickel atom, Ni2, as a vertex of the two nine-atom germanium clusters (Figure 1) and results in two nickel-centered ten-atom clusters made of one nickel and nine germanium atoms, {Ni@Ge$_9$Ni}. The two clusters form a dimer by sharing the nickel vertex, and the formula of **1** can be

written as $[(Ni@Ge_9)Ni(Ni@Ge_9)]^{4-}$. Interestingly, the corresponding monomer, $[Ni@(Ge_9Ni\text{-}PPh_3)]^{2-}$ (**2**),[14] also exists, as mentioned above, and has exactly the same shape (as does $[Pt@(Sn_9Pt\text{-}PPh_3)]^{2-}$) as the {Ni@$Ge_9$Ni} unit of **1**.[15] The only difference is that the outer nickel atom in **2** is ligated (Figure 2b). The monomer, in turn, can be viewed as being

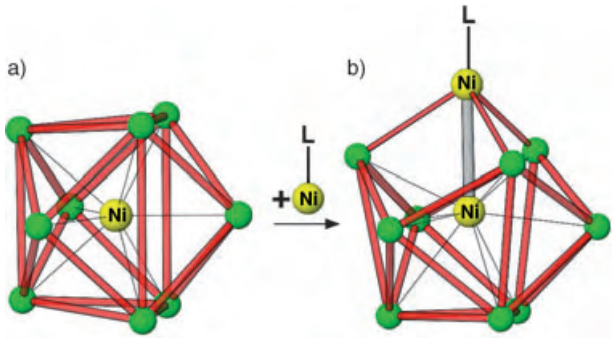

Figure 2. a) The centered nine-atom germanium cluster $[Ni@Ge_9]^{3-}$ (**3**) with the shape of elongated tricapped trigonal prism characterized in $[K(2,2,2\text{-crypt})]_6[Ni@Ge_9]_2\cdot 3en$. b) The $[Ni@Ge_9Ni\text{-}PPh_3]^{2-}$ (**2**) ion can be viewed as being made from $[Ni@Ge_9]^{3-}$ by insertion of an Ni–L fragment and opening of one of the bases of the trigonal prism.

made by insertion of a Ni–L (L = ligand) fragment along the pseudo threefold axis of a hypothetical nickel-centered $[Ni@Ge_9]$ tricapped trigonal prism and opening of the corresponding triangular base (Figure 2). We searched for these hypothetical species by carrying out reactions of Ge_9 clusters (K_4Ge_9 dissolved in ethylenediamine) with smaller excesses of $[Ni(cod)_2]$. These reactions were successful and produced a crystalline compound, $[K(2,2,2\text{-crypt})]_6[Ni@Ge_9]_2\cdot 3en$, that contained the anticipated nickel-centered clusters $[Ni@Ge_9]^{3-}$ (**3**; Figure 2a). The structure determination of this compound was somewhat problematic owing to its extremely large unit cell, the presence of two crystallographically different $[Ni@Ge_9]^{3-}$ clusters per cell, and the observed disorder in some of the germanium atoms of the clusters. Nevertheless, it is clear that the clusters are nickel-centered tricapped trigonal prisms elongated along the three vertical prismatic edges (edge distances within 3.089–3.560 Å). Thus, the existence of these clusters completes the series of species in the formation of **1**, that is, $[Ge_9]\rightarrow[Ni@Ge_9]\rightarrow[Ni@Ge_9NiL]\rightarrow[(Ni@Ge_9)Ni(Ni@Ge_9)]$.

The three nickel atoms of **1** form a linear trimer, a filament that is "protected" by the two germanium clusters. The Ni–Ni distance of 2.395(1) Å compares very well with bonding distances in nickel dimers, trimers, and larger clusters. For example, the distances in the triangular $[(\mu^3\text{-}NtBu)(NiCp)_3]$ (Cp = C_5H_5),[19] $(\mu^3\text{-}CO)_2(NiCp^*)_3$ (Cp* = C_5Me_5),[20] and $(\mu^3\text{-}CS)_2(NiCpMe)_3$ (CpMe = C_5H_4Me)[21] are in the range 2.335–2.442 Å. These distances are 2.419 and 2.428 Å in the octahedral $[(NiCp)_6]^+$ ion,[22] and the distance in the dimeric $[(NiCpMe)_2(\mu\text{-}CO)_2]$ is 2.390 Å.[23] The Ni–Ni distance in the monomeric cluster $[Ni@(Ge_9Ni\text{-}PPh_3)]^{2-}$ is also very similar, 2.361 Å.[14] The only other linear trimer of metal atoms that are part of fused clusters happens to be a ruthenium trimer in $[(Cp^*RuB_4H_{10})Ru(Cp^*RuB_4H_{10})]$.[24] Each cluster in this case is a pentagonal pyramid with a {Cp*Ru} moiety at its apex and a shared ruthenium atom in the base (the clusters are shared in a transoid fashion giving linear Ru-Ru-Ru). Furthermore, as with **2**, the corresponding monomeric cluster $[Cp^*RuB_4H_{10}Ru\text{-}Cp^*]$ is also known.[25]

The charge of 4− of **1** can be understood as the sum of the charges of $[Ni@(Ge_9Ni\text{-}L)]^{2-}$ and $[Ni@Ge_9]^{2-}$. The latter formally replaces the ligand L in the former, that is, $[Ni@(Ge_9Ni\text{-}L)]^{2-} + [Ni@Ge_9]^{2-}\rightarrow[(Ni@Ge_9)Ni(Ni@Ge_9)]^{4-} + L$. Note that the Ni–L fragment does not provide cluster-bonding electrons and, therefore, $[Ni@Ge_9Ni\text{-}L]^{2-}$ and $[Ni@Ge_9]^{2-}$ have the same numbers of such electrons, 20, despite the different numbers of vertices. This situation makes $[Ni@Ge_9Ni\text{-}L]^{2-}$, as well as each half of **1**, *hypo*-electronic because a deltahedron with 10 vertices should have $2n+2 = 22$ ($n = 10$) cluster-bonding electrons according to Wade's rules.[26] The reason for the deviation is clearly the shape of the cluster which differs greatly from the shape expected for a 10-atom deltahedron (a bicapped square antiprism). The same unusual shape and electron count was also observed for 10-atom indium clusters centered by Ni, Pd, or Pt, $[M@In_{10}]^{10-}$.[27] The relation between the shape and the electron count was explained in molecular orbital terms for these clusters. In short, the central d^{10} atom does not bring additional cluster-bonding electrons but provides central orbitals for overlap with the cluster orbitals and, therefore, improves the bonding within the cluster. A nine-atom deltahedron with the shape of a tricapped trigonal prism (20 cluster-bonding electrons) has a LUMO that is bonding within the triangular bases of the prism but is antibonding between them. Therefore, elongation of the prismatic edges (those between the triangular bases) reduces the antibonding character of the orbital while opening of a triangular base reduces its bonding character. Thus, the position of this orbital, and therefore its occupancy, depends very strongly on which of these distortions prevails in each particular case. Note that the addition of a tenth vertex along the threefold axis of the prism to cap one of the bases does not change the electronic requirements. The orbital in question is empty for $[M@In_{10}]^{10-}$, $[Ni@Ge_9Ni\text{-}L]^{2-}$, and the two halves of **1**, while it is occupied by a single electron in $[Ni@Ge_9]^{3-}$ (and many examples of $[Ge_9]^{3-}$).[28] Furthermore, as for empty nine-atom germanium clusters,[9,10] centered clusters with different charges may be in equilibria between themselves and solvated electrons. This situation would provide $[Ni@Ge_9]^{2-}$ ions in the solution in addition to $[Ni@Ge_9]^{3-}$.

The new ions $[(Ni@Ge_9)Ni(Ni@Ge_9)]^{4-}$ are intact in solution, that is, they do not form simply upon crystallization. This was demonstrated by electrospray mass spectroscopy of a dimethylformamide (DMF) solution of $[K(2,2,2\text{-crypt})]_4[Ni_3@(Ge_9)_2]\cdot 2tol$. The spectrum, acquired in negative-ion mode, shows clearly the signal for the dianion $[Ni_3@(Ge_9)_2]^{2-}$ with an isotope distribution matching perfectly the calculated one (Figure 3). The new compound is EPR silent (crystalline sample at room temperature), which indicates that the nickel centers have a Ni^0, d^{10} configuration.

Experimental Section

All manipulations were carried out under an inert atmosphere using standard Schlenk-line and/or glovebox techniques. Ethylenediamine (Acros, 99%) was distilled over sodium metal, collected and redistilled over K_4Sn_9 and/or K_4Pb_9 intermetallics. The K_4Ge_9 precursor was synthesized from a stoichiometric mixture of the elements (K: 99+%, Strem; Ge: 99.999%, Alfa-Aesar) heated at 900°C for 2 days in sealed niobium containers jacketed in evacuated fused-silica ampoules. 2,2,2-crypt (Acros, 98%) and $[Ni(cod)_2]$ (Strem, 98+%) were used as received after they had been carefully dried under vacuum. Electrospray mass-spectra were recorded from DMF solutions (10–20 μM) of $[K(2,2,2\text{-crypt})]_4\mathbf{1}\cdot 2\,tol$ on a Micromass Quattro-LC triple quadrupole mass spectrometer (125°C source temperature, 150°C desolvation temperature, 3 kV capillary voltage, and 25 V cone voltage).

$[K(2,2,2\text{-crypt})]_4[Ni_3@(Ge_9)_2]\cdot 2\,tol$: K_4Ge_9 (78 mg, 0.096 mmol) and 2,2,2-crypt (145 mg, 0.384 mmol) were dissolved in ethylenediamine (2 mL) in a test tube inside a glovebox yielding an intensely red solution. $[Ni(cod)_2]$ (82 mg, 0.298 mmol) was added to this solution, and the mixture was allowed to stir for 3 h yielding a dark reddish brown suspension. The suspension was filtered, and the resulting dark brown filtrate was layered with toluene and left undisturbed. It yielded dark greenish brown plates of $[K(2,2,2\text{-crypt})]_4[Ni_3@(Ge_9)_2]\cdot 2\,tol$ after 2–3 days (ca. 65%).

$[K(2,2,2\text{-crypt})]_6[Ni@Ge_9]_2\cdot 3\,en$: K_4Ge_9 (84 mg, 0.104 mmol) and 2,2,2-crypt (117 mg, 0.310 mmol) were dissolved in ethylenediamine (2 mL) yielding a bright red solution. $[Ni(cod)_2]$ (64 mg, 0.232 mmol) was added to this solution, and the mixture was allowed to stir for 2 h. The resulting dark red–brown solution was filtered. The filtrate was collected and layered with toluene, and left undisturbed to allow for crystallization. The solution afforded large bright red blocks of $[K(2,2,2\text{-crypt})]_6[Ni@Ge_9]_2\cdot 3\,en$ after 2–3 days.

Data sets were collected on a Bruker APEX diffractometer with a CCD area detector at 100 K with $Mo_{K\alpha}$ radiation. The crystals were selected under Paratone-N oil, mounted on fibers, and positioned in the cold stream of the diffractometer. The structures were solved and refined (on F^2) with the aid of the SHELXTL V5.1 package.[29] Crystal data for $[K(2,2,2\text{-crypt})]_4[Ni_3@(Ge_9)_2]\cdot 2\,tol$: monoclinic, $P2_1/n$, $a=14.439(2)$, $b=28.830(4)$, and $c=16.563(2)$ Å, $\beta=115.716(3)°$, $V=6211.9(1)$ Å^3, $R1=0.0735$ for the observed data. Crystal data for $[K(2,2,2\text{-crypt})]_6[Ni@Ge_9]_2\cdot 3\,en$: monoclinic, $P2_1/n$, $a=14.744(1)$, $b=21.437(1)$, and $c=53.575(4)$ Å, $\beta=93.459(2)°$, $V=16\,903(2)$ Å^3, $R1=0.0932$ for the observed data. CCDC-263116 for $[K(2,2,2\text{-crypt})]_4[Ni_3@(Ge_9)_2]\cdot 2\,tol$ and CCDC-263117 for $[K(2,2,2\text{-crypt})]_6[Ni@Ge_9]_2\cdot 3\,en$ contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Enzyme Engineering

The Heme Monooxygenase Cytochrome $P450_{cam}$ Can Be Engineered to Oxidize Ethane to Ethanol**

Feng Xu, Stephen G. Bell, Jaka Lednik, Andrew Insley, Zihe Rao, and Luet-Lok Wong**

The selective catalytic oxidation of alkanes to alcohols under ambient conditions is a great scientific challenge and is of potential industrial and economic importance. Heterogeneous catalysts require elevated temperatures and pressures, and further oxidation to aldehydes and carbon dioxide is prevalent. Although biological catalysts are attractive because they operate under mild conditions, the only enzymes capable of oxidizing ethane and methane are the copper and non-heme iron methane monooxygenases.[1–5] Of the other classes of monooxygenases, the heme-dependent cytochrome P450 enzymes, which use two electrons from NAD(P)H to activate oxygen and generate a ferryl intermediate $[(Por)^{+}Fe^{IV}=O]$ to attack C–H bonds, are known to oxidize a wide range of organic molecules, but not ethane and methane (Por = porphyrin).[6,7] We have explored the engineering of $P450_{cam}$ from *Pseudomonas putida* [8] for alkane oxidation.[9,10] The approach of varying the $P450_{cam}$ active-site volume to fit a non-natural substrate was first used by Loida and Sligar for ethylbenzene oxidation.[11,12] We have used bulky amino acid substitutions in the $P450_{cam}$ active site to promote the binding and oxidation of gaseous alkanes. The mutants showed fast and efficient *n*-butane oxidation, but propane oxidation activity was modest, and no ethane oxidation was observed.[10] This approach of decreasing the active-site volume has been combined with directed evolution to engineer $P450_{BM\text{-}3}$ from *Bacillus megaterium* to oxidize propane with a turnover rate of 54 min^{-1}.[13] Herein, we report the engineering of $P450_{cam}$ to provide the first example of ethane oxidation by a P450 enzyme.

The most active $P450_{cam}$ mutant for propane oxidation reported previously was the F87W/Y96F/T101L/L1244M/V247L mutant (the EB mutant).[10] We determined the crystal structure of the substrate-free form of the precursor mutant F87W/Y96F/V247L to a resolution of 2.1 Å to provide insight into the effects of the mutations.[14] The active-site structure is shown in Figure 1. The most interesting feature is that there

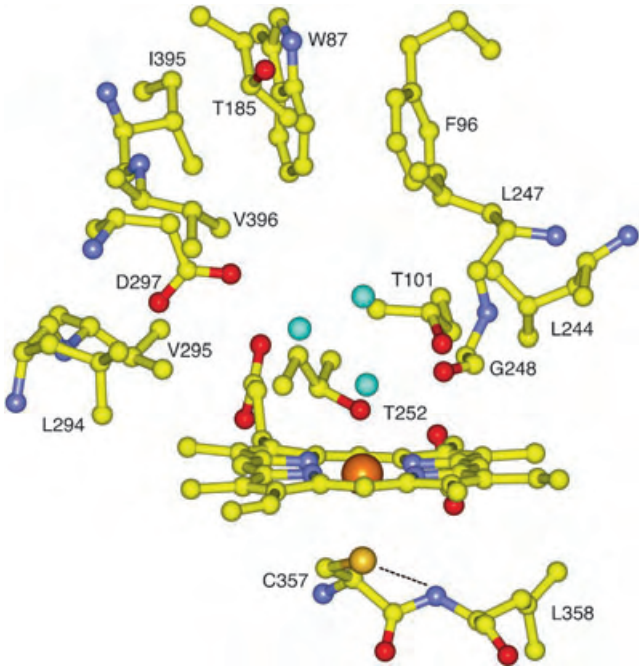

Figure 1. The active-site structure of the substrate-free form of the F87W/Y96F/V247L mutant of $P450_{cam}$ highlighting the cluster of three water molecules (light blue) in the substrate pocket and the hydrogen bond between the thiolato side chain of C357 and the main-chain amide of L358.

are only three water molecules in the active site, compared with six in the wild-type enzyme structure.[15] This probably results from the decreased active site volume, and is consistent with the increased activity of the mutant for the oxidation of small molecules such as propane. In the work discussed herein, we introduced additional mutations to the EB mutant to further decrease the size of the substrate-binding pocket. We examined the structure (Figure 1) for cavities within the active site that could bind a small molecule such as ethane away from the heme iron center. Mutations were then introduced to close such cavities. The $P450_{cam}$ active site is highly irregular in shape, and cavities were found between L294 and T252, L247 and G248, and in the A296–D297 region. The cavity between the W87, L247, and V396 side chains at the top of the active site is covered by T185. Therefore, the mutations L294M, G248A, and T185M were introduced to force ethane to bind closer to the heme iron center.

Morishima and co-workers recently reported the interesting effects of the L358P mutation.[16,17] The main-chain amide of L358 forms a hydrogen bond to the thiolato side chain of C357, thus modulating the donor strength of this heme-

 DOI: 10.1002/anie.200462630 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

proximal ligand.[18] The L358P mutation removes this hydrogen bond and alters the reduction potential of the heme, but it also promotes the oxidation of non-natural substrates.[16] We therefore investigated the effect of this mutation on alkane oxidation. While this work was in progress, the crystal structure of the L358P mutant was reported.[17] Among the interesting structural changes, it was found that the heme was pushed into the substrate pocket towards the substrate; a general tightening of the pocket was also observed. These changes may promote the binding of non-natural substrates that do not fit as well into the pocket as does camphor.

As none of the previous $P450_{cam}$ mutants oxidized ethane, we first examined the propane oxidation activity of the new mutants;[19] those with the highest activity were then tested for ethane oxidation. The results are given in Table 1. All the mutants showed $>90\%$ high-spin heme content upon propane binding (data not shown). The L294M mutation increased the NADH oxidation rate for propane by 50% relative to the EB mutant, but decreased the coupling efficiency (product yield based on NADH consumed). Overall, the propane oxidation rate was slightly increased. Interestingly, the EB/L294M mutant gave readily detectable amounts of propan-1-ol, whereas all previous $P450_{cam}$ mutants gave propan-2-ol exclusively. Hence the L294M mutation decreased the mobility of propane within the active site such that the higher intrinsic reactivity of secondary C–H bonds in the radical mechanism no longer dominated over that of the larger number of the less reactive, primary C–H bonds. The T185M mutation significantly increased the coupling, resulting in another increase in the propane oxidation activity. The L358P mutation increased both the activity and coupling, in agreement with previous reports on the effects of this mutation on the oxidation of non-natural substrates. Adding the G248A mutation increased both the activity and coupling further. The fast propane oxidation rate ($500\ min^{-1}$) and excellent coupling (86%) of the EB/L294M/T185M/L1358P/G248A mutant indicated good fit between the engineered $P450_{cam}$ active site and propane.

The EB/L294M/T185M/L1358P/G248A mutant was examined for ethane oxidation. The heme shifted to $>85\%$ high spin in the presence of ethane (Figure 2). We were surprised that the NADH oxidation activity ($741\ min^{-1}$)[20] was higher than that for propane. GC analysis showed that ethane was oxidized to ethanol (no ethanal was formed) at a rate of $78.2\ min^{-1}$, which corresponds to 10.5% coupling (Figure 3).[21] There was more peroxide uncoupling (40%) than observed with propane (15%). Therefore, the oxidase uncoupling pathway accounted for $\approx 50\%$ of the NADH consumed in ethane oxidation. This pathway becomes significant if the ethane substrate is bound too far away from the ferryl oxygen atom for rapid substrate oxidation,[12] such that two-electron reduction of the ferryl to the ferric state competes with substrate oxidation. The drop in coupling from propane (86%) to ethane (10%) is surprisingly large, indicating the stringent requirement of the active site architecture to localize ethane close to the heme iron center. It also explains why the other mutants did not show readily detectable ethane oxidation activity.

The EB/L294M/T185M/L1358P/G248A mutant also had the interesting property of being $\approx 45\%$ high spin even in the absence of substrate (Figure 2), whereas all other mutants

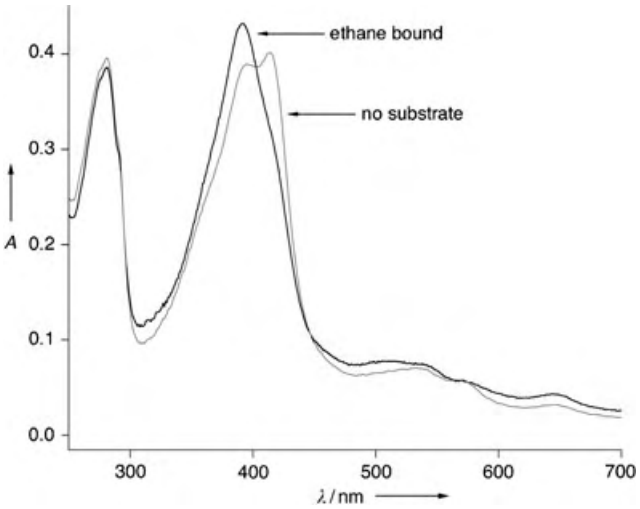

Figure 2. The Soret region of the electronic spectrum of the EB/L294M/T185M/L1358P/G248A mutant of $P450_{cam}$ showing the partial high-spin heme nature of the mutant in the absence of substrate and the $>85\%$ high-spin heme content upon binding of ethane.

Table 1: Propane and ethane oxidation activity of $P450_{cam}$ mutants.[a]

$P450_{cam}$ enzyme	Propane				Ethane			
	NADH rate	product rate[b]	coupling [%][c]	H_2O_2 [%]	NADH rate	product rate[b]	coupling [%][c]	H_2O_2 [%]
F87W/Y96F/T101L/V247L/L1244M[d] (EB mutant)	266	176 (<2%)	66.2	25.0	<20	–	–	–
EB/L294M	414	193 (5.8%)	46.8	38.0	<20	–	–	–

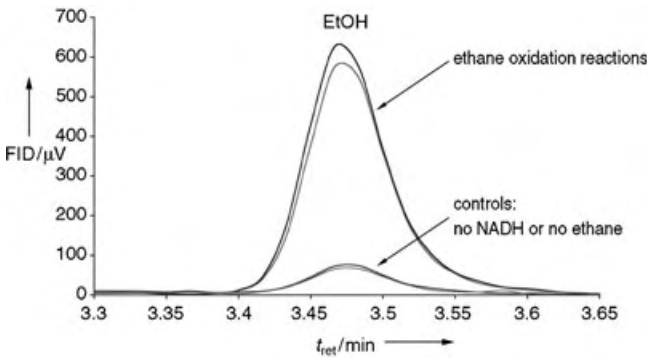

Figure 3. GC analysis of ethane oxidation assays with the EB/L294M/T185M/L1358P/G248A mutant. The controls with no ethane or no NADH added show the residual background peak from ethanol (< 1 μM) present in the water used to prepare the buffers. The apparent difference in the ethanol product peak areas for two separate incubations was corrected by the ratio to the pentan-1-ol internal standard peak. t_{ret} = retention time.

were low spin. The six-water cluster in substrate-free $P450_{cam}$ has strong hydrogen bonding, and the heme-bound water ligand is likely to have significant hydroxide ion character. Raag and Poulos noted the importance of hydrogen bonding to the heme ligand water: wild-type $P450_{cam}$ with non-natural substrates bound could have a six-coordinate heme, yet the iron center was high spin. Therefore, the presence of this sixth ligand on its own was not sufficient to bring the heme to a low-spin state.[22] Model compound studies have also shown that the P450 heme group is low spin if the axial water ligand is hydrogen bonded to other groups, but is high spin if there is no such hydrogen bonding.[23] The axial water ligand in the F87W/Y96F/V247L mutant is hydrogen bonded to two other waters, and the heme is low spin. As the EB/L294M/T185M/L1358P/G248A mutant contains five additional bulky substitutions within the active site, it is very likely that the three-water cluster observed in the F87W/Y96F/V247L mutant would be perturbed significantly, leaving only two or even one water molecule in the active site. Fewer active site water molecules and weakened hydrogen bonding allows ethane to bind more readily, and in this case, to induce a heme-group shift to > 90% high spin and a fast NADH turnover rate. Hence the EB/L294M/T185M/L1358P/G248A mutant has not only the interesting property of ethane oxidation, but its active site water structure could provide new insight into the origin of the heme spin state equilibrium in P450 enzymes.

In summary, we have engineered a cytochrome P450 enzyme to oxidize ethane to ethanol by decreasing the active site volume with bulky substitutions, and by altering the hydrogen bonding to the proximal ligand by the L358P mutation first reported by Morishima.[16,17] The high spin heme content of the EB/L294M/T185M/L1358P/G248A mutant in the absence of substrate suggests that it may also be a useful platform for structure–function studies of P450 enzymes. Finally, the high NADH oxidation rate of this mutant with ethane suggests that, as we had shown for *n*-butane and propane, fast ethane oxidation will be possible once the uncoupling pathways are suppressed by localizing ethane close to the ferryl oxygen atom.

[14] We had reported earlier that one molecule in the *P*1 asymmetric unit in the X-ray crystal structure of the F87W/Y96F/V247L mutant complexed with 1,3,5-trichlorobenzene had low substrate occupancy, and that the density above the heme could be modeled with three water molecules, but their locations could not be refined (X. Chen, A. Christopher, J. P. Jones, S. G. Bell, Q. Guo, F. Xu, Z. Rao, L. L. Wong, *J. Biol. Chem.* **2002**, *277*, 37519). The structure of the substrate-free form of the mutant was therefore determined. Procedures for crystallization of the mutant at 291 K by the hanging drop vapor diffusion method and data collection and refinement were as reported previously. Crystals of the F87W/Y96F/V247L mutant belonged to the space group $P2_1$, with unit-cell dimensions: $a = 66.8$ Å, $b = 62.1$ Å, $c = 94.9$ Å, $\alpha = 90°$, $\beta = 90.5°$, $\gamma = 90°$. A total of 236028 reflections were measured, with R_{merge} of 7.6% for 45978 unique reflections and 99.9% completeness (50–2.1 Å). Data were collected to 100% completeness in the highest resolution shell. The structure was solved by molecular replacement based on the crystal structure of wild-type $P450_{cam}$ (PDB code: 2CPP), but with the camphor removed. After initial refinement, the difference Fourier map for both molecules in the unit cell showed well-defined triangle-shaped electron density above the heme group that was modeled by three water molecules. The final refinement parameters were $R_{work} = 19.1\%$ and $R_{free} = 24.3\%$. Full details will be published elsewhere.

[19] General methods for mutagenesis, enzyme expression and purification, activity and GC analysis for propane were carried out as described previously.[10]
[20] The ethane oxidation assays required extra precautions. Ethanol was present in varying concentrations in most components of an activity assay, even in the ultra pure water obtained from water purification systems. Only water containing <500 nM ethanol (GC) were used for buffer preparation. Buffer solutions were then analyzed by GC to ensure that there was no ethanol in the chemicals used. Commercial NADH contains ethanol as a stabilizer. This ethanol was removed by washing with diisopropyl ether: 0.5-mL aliquots of a NADH solution (20 mg mL^{-1}) were mixed with 2 mL diisopropyl ether, vortexed and then centrifuged at 3000 rpm for 5 min. The organic layer was removed, and the wash repeated a further four times. The resulting solution of NADH was analyzed by GC to determine the ethanol concentration, and then lyophilized. This procedure gave <1 μM ethanol background in the reaction mixtures. NADH turnover incubations were carried out at 30 °C in 4-mL capacity cuvettes equipped with screw caps and Teflon septum seals. Incubation mixtures contained Tris (50 mM, pH 7.4), KCl (200 mM), $P450_{cam}$ (1 μM), putidaredoxin (16 μM), and putidaredoxin reductase (1 μM). In a typical reaction, the volume of buffer required to take the final volume to 2.5 mL was $\approx$1.6 mL. Half of this required volume of buffer was saturated with ethane, and the other half was a buffer solution saturated with oxygen. A sample was taken (the no-NADH control), and the cuvette sealed with a Teflon-backed screw cap. The mixtures were equilibrated at 30 °C for 2 min, and the reaction was initiated by the addition of NADH through a hypodermic syringe needle pushed through the Teflon septum. NADH was added as a stock solution (20 mg mL^{-1}) in Tris (50 mM, pH 7.4) to $\approx$200 μM (final A_{340} $\approx$1.2), and the absorbance at $\lambda = 340$ nm was monitored. The rate of NADH consumption was calculated from the slope of the time-course plot by using $\varepsilon_{340} = 6.22$ mM^{-1} cm^{-1}. A total of five experiments were carried out for each mutant tested. For each mutant, a control incubation with no substrate was also carried out to ensure that the ethane contained no ethanol.
[21] A 90-μL aliquot of a reaction mixture or control was added to a 10-μL aliquot of an aqueous solution of pentan-1-ol (200 μM) as internal standard. A 2-μL aliquot of each mixture was injected directly onto the SPB-1 GC column (0.5 mm × 60 m). The column temperature was held at 40 °C for 4 min and then increased at 5 °C min^{-1} to 100 °C. The retention times were: ethanol, 3.50 min; propan-2-ol, 4.80 min; propan-1-ol, 6.50 min; pentan-1-ol, 16.0 min. The concentration of product in a reaction mixture was determined by calibrating the FID response to the product.[10] Peroxide uncoupling was determined by a standard horseradish peroxidase/phenol/4-aminoantipyrine assay.

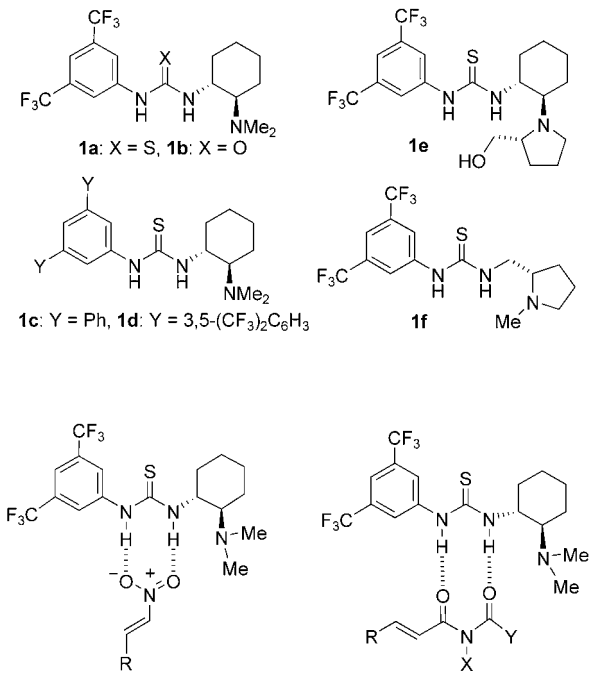
Organocatalysis

Enantioselective Michael Addition to α,β-Unsaturated Imides Catalyzed by a Bifunctional Organocatalyst**

*Yasutaka Hoashi, Tomotaka Okino, and Yoshiji Takemoto**

The catalytic asymmetric formation of a carbon–carbon bond represents one of the most challenging fields in organic chemistry. A number of asymmetric Michael additions to α,β-unsaturated carbonyl acceptors catalyzed by chiral catalysts have been reported.[1] However, the acceptors employed in the asymmetric Michael additions of 1,3-dicarbonyl compounds generally have been restricted to enones[2–4] and nitroalkenes.[5] Similarly, although organocatalysts that bear chiral secondary amine groups have been shown to be efficient catalysts for the Michael reaction with such acceptors,[6] their applications to α,β-unsaturated acid derivatives seems to be difficult. Therefore, the development of general and highly enantioselective versions of the reactions of α,β-unsaturated acid derivatives still remains a challenging goal. Quite recently, two groups achieved the initial breakthroughs on these problems. The Jacobsen and Kanemasa groups independently reported the highly enantioselective metal-catalyzed Michael additions of malononitrile, which is equivalent to a 1,3-dicarbonyl compound, to α,β-unsaturated imides.[7,8] However, there have been no reports of such asymmetric Michael addition without any metal catalysts. Herein, we report the first enantioselective Michael reactions of malononitrile to acyclic α,β-unsaturated imides in the presence of a chiral organocatalyst.



Although we recently reported that the bifunctional-thiourea-catalyzed Michael reaction of 1,3-dicarbonyl compounds to nitroalkenes proceeded with high enantioselectivity (up to 93% *ee*),[9] the same reaction of other nucleophiles such as malononitrile to nitroalkenes gave the corresponding product with low enantioselectivity. To extend the synthetic utility of the bifunctional thiourea **1a** in the asymmetric reaction, we undertook the screening of proper Michael acceptors other than nitroalkenes to react with malononitrile. For the purpose, α,β-unsaturated imides seem to have an ideal structure to form hydrogen bonds with the thiourea catalyst **1a** as shown in Scheme 1.[10,11]

Scheme 1. Hydrogen-bond interaction with thiourea **1a**.

We first investigated the Michael addition of malononitrile (**2**) to several types of α,β-unsaturated acid derivatives **3a**–**g** (Table 1). The reaction of **2** (2 equiv) with a solution of imides **3** in toluene (0.5 M) was carried out at room temperature in the presence of **1a** (10 mol%). Although the conjugate addition of **2** with amide **3a** gave no desired product, the same reaction with *N*-acyl-1,3-oxazolidinone **3b**[10e] was completed after 96 h to give the Michael adduct **4b** in 89% yield (Table 1, entries 1 and 2). The enantiopurity of **4b** was revealed to be 83% ee by means of HPLC analysis. In the hope of enhancing the hydrogen-bonding interaction with thiourea **1a**, we employed *N*-acyl-1,3-imidazolidinone **3c**, which bears a cyclic urea moiety, as a Michael acceptor, but both the yield of **4c** and enantioselectivity were poorer (59%, 81% *ee*; Table 1, entry 3). In contrast with **3c**, *N*-acylpyrrolidinone **3d** was revealed to be a good acceptor of **2**, providing the corresponding product **4d** in 93% yield with the best enantioselectivity (87% *ee*) (Table 1, entry 4). Use of *N*-acylpiperidinone **3e** and acyclic imide **3f** for the Michael addition reaction resulted in a significant decrease in both chemical yield and enantioselectivity (Table 1, entries 5 and 6). On the other hand, the conjugate addition of **2** with imide **3g** proceeded smoothly, but the enantioselectivity (84% *ee*) was somewhat lower than that with **3d** (Table 1, entry 7). Notably, the same reaction with **3d** under dilute conditions (0.1 M solution in toluene) improved the stereoselectivity up to 93% *ee*.

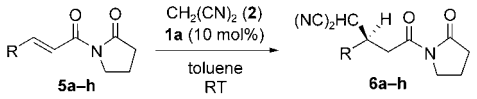
Table 1: Enantioselective Michael addition of malononitrile **2** with α,β-unsaturated acid derivatives **3a**–**g**.[a]

Entry	Substrate (R)	Product	*t* [h]	Yield [%][b]	*ee* [%][c]
1	**3a**	**4a**	48	0	–
2	**3b**	**4b**	96	89	83
3	**3c**	**4c**	120	59	81
4	**3d**	**4d**	60	93	87
5	**3e**	**4e**	140	42	59
6	**3f**	**4f**	216	27	56
7	**3g**	**4g**	8	94	84

[a] The reaction was conducted with **1a** (10 mol%), **2** (2 equiv), and **3a**–**g** in toluene (0.5 M). [b] Yield of isolated product. [c] The *ee* values were determined by HPLC analysis of **4a**–**g** with a chiral column.

Encouraged by the excellent results obtained with *N*-acylpyrrolidinone **3d** and thiourea **1a**, we explored the effectiveness of a bifunctional urea **1b** and other bifunctional thioureas **1c**–**f** for the Michael addition (Table 2). The reaction of **2** with **3d** in the presence of urea **1b** gave a similar result, affording the desired product **4d** in somewhat lower yield (78%, 87% *ee*; Table 2, entry 1). However, the introduction of phenyl and 3,5-bis(trifluoromethyl)phenyl groups on the aromatic ring of **1a** as well as modification of its dimethylamino group led to significant decrease in reaction rate and enantioselectivity (Table 2, entries 2–4). Furthermore, the (*N*-methylpyrrolidin-2-yl)methyl derivative **1f** was not catalytically active in the Michael reaction and resulted in a low yield of **4d**. These results demonstrated that the original thiourea **1a** was the best choice as a chiral organocatalyst.

Table 2: Enantioselective Michael addition of **2** and imide **3d** in the presence of several bifunctional thioureas **1a**–**f**.



Entry	**1**	*t* [h]	Yield [%][a]	*ee* [%][b]

2	**c**	120	66	60 (*R*)
3	**d**	120	78	69 (*R*)
4	**e**	120	61	48 (*R*)
5	**f**	120	13	3 (*S*)

[a] Yield of isolated product. [b] Determined by HPLC analysis of **4d** with a chiral column.

Having established the optimal reaction conditions for the enantioselective Michael reaction of malononitrile (**2**), we next screened a series of analogues **5a**–**h**, which bear various β substituents. As illustrated in Table 3, imides **5a**–**h** underwent conjugate addition of **2** in the presence of catalyst **1a** in high yields and enantioselecivities, which were almost independent of the β substituents in terms of steric hindrance and electronic properties. The reaction with aryl-substituted

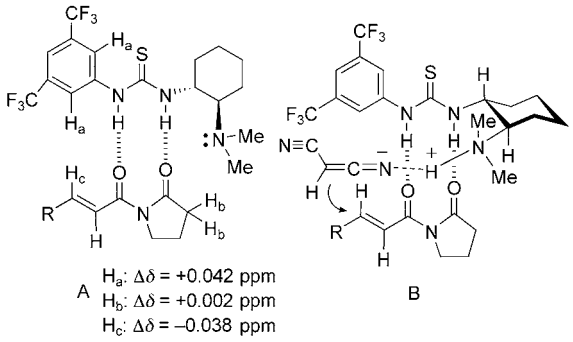
8	**h** (*t*Bu)	168	**h**	78	92

[a] The values in parentheses were obtained from reactions carried out in a 0.1 M solution. [b] Yield of isolated products, after chromatography, of reactions carried out in a 0.5 M solution. [c] Determined by chiral HPLC analysis.

imides **5a–c** proceeded with high enantioselectivity to furnish the addition adducts **6a–c**, while the rate of the reaction was somewhat lower for **5c** (R = *p*-methoxyphenyl) owing to the electron-rich substrate (Table 2, entries 1–3). Similarly, imides **5d–e** bearing 1-naphthyl and furyl groups as the β substituent underwent clean reaction as well, and gave the corresponding adducts **6d–e** with 85–88% *ee* (Table 2, entries 4–5). In contrast to the previously reported Michael addition with nitroalkenes,[9] the present reaction of **2** with imides **5f–h**, which bear alkyl groups as the β substituent, occurred smoothly to afford the desired products **6f–h** in good yields with high enantioselectivities similar to those of **5a–e**. The highest enantioselectivity (92% *ee*) was obtained under the standard conditions in the case of *tert*-butyl derivative **5h**. Furthermore, it is noteworthy that when the reactions were carried out in a 0.1M solution, the all the corresponding products were obtained with higher enantioselectivities (> 93% *ee*).



The absolute configuration of the Michael adduct **6b** was determined by the transformation of **6b** into a known compound **7**[7b] (Scheme 2). Treatment of **6b** with a catalytic

Scheme 2. Transformation of Michael adduct **6b** to methyl ester **7**.

amount of $Er(OTf)_3$ in methanol provided methyl ester **7** ($[\alpha]_D^{24} = +22$; $c = 0.70$, CH_3CN) in 89% yield. By comparing $[\alpha]_D$ value with that of an authentic sample ($[\alpha]_D^{24} = +19$; $c = 1.0$, CH_3CN),[7b] the absolute configuration of **6b** was determined to be *R*, and those of the other adducts **6a** and **6c–h** were also assumed to be *R* based on this result.

The formation of a substrate–catalyst complex **1a**·**3d** (**A**; R = Ph) was supported by ^1H NMR spectroscopic experiments (1:1 mixture of **1a** and **3d** in [D_8]toluene), as shown in Scheme 3. From these results, we propose a ternary complex

Scheme 3. ^1H NMR spectroscopic experiments of a substrate–catalyst complex **A** and proposed transition state **B** for the Michael reaction with **1a**.

B of catalyst **1a**, malononitrile (**2**), and imide **5** as a plausible transition state in which **5** and the anion of **2** coordinate to the thiourea moiety and the tertiary amine group of **1a**, respectively, through hydrogen-bonding interactions. The predominant production of *R* adducts is reasonably explained by this transition-state model.

In summary, we have developed the first highly enantioselective organocatalytic Michael reaction of malononitrile (**2**) with α,β-unsaturated imides **5a–h** in the presence of a bifunctional thiourea **1a**. The pyrrolidinone moiety of α,β-unsaturated imides is demonstrated to play a key role in the thiourea-catalyzed Michael reaction. The reaction is applicable to a variety of α,β-unsaturated imides that bear aryl and alkyl groups as a β substituent, and high enantioselectivities are attained. Unfortunately, the Michael addition of other carbon nucleophiles such as malonates and β-ketoesters with **4d** gave no desired products owing to their low reactivities. Further investigations into the mechanism and synthetic application are underway and will be reported in due course.

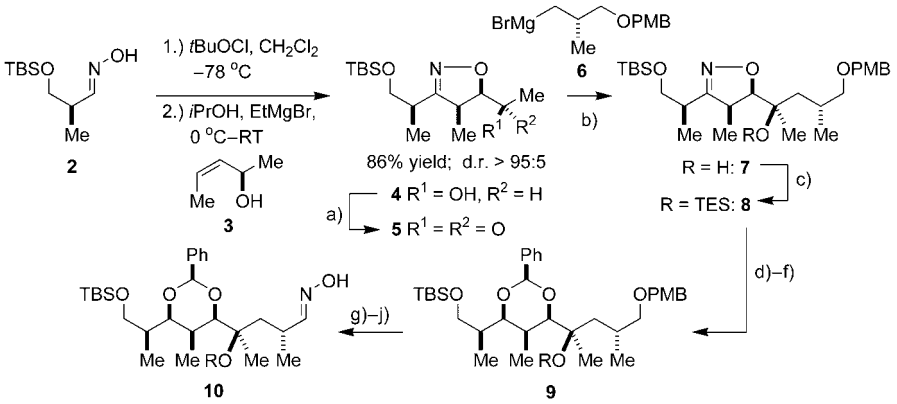
Natural Product Synthesis

Total Synthesis of Erythronolide A by Mg^{II}-Mediated Cycloadditions of Nitrile Oxides**



*Dieter Muri, Nina Lohse-Fraefel, and Erick M. Carreira**

Since its discovery in 1952,[1] erythromycin A has captured the imagination of research groups all over the world. The total syntheses of erythromycin A and its related derivatives (erythronolide A, erythromycin B, erythronolide B, (9*S*)-dihydroerythronolide A, 6-deoxyerythronolide B, 9,12-anhydroerythronolide A) have become benchmarks for the study of new methodologies in polyketide synthesis.[2–4] We have recently reported a general approach for the synthesis of polyketide building blocks by means of Kanemasa's Mg^{II}-mediated cycloadditions of nitrile oxides to allylic alcohols.[5] The nature of this approach allows the modular preparation of the entire spectrum of functionality and stereochemical permutations found in polyketide-derived structures. In this communication, we demonstrate the power and generality of this cycloaddition in the context of the total synthesis of erythronolide A (**1**). Erythronolide A was completed in 21 linear steps from the readily available oxime **2**.[5a] Of additional importance, we demonstrate the potential of the strategy to provide access to nonnatural analogues (ketolides) of this important agent.

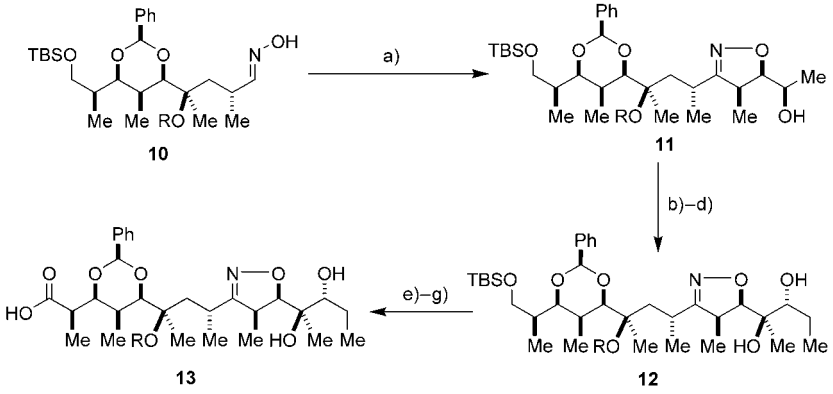
1

The synthesis commences with the cycloaddition of oxime **2** to allylic alcohol **3**; the former is available in three steps from (*S*)-methyl-3-hydroxyisobutyrate (Roche ester)[6] and the latter in two steps by Noyori reduction of propargylic ketone and semihydrogenation over the Lindlar catalyst.[7] Oxime **2** was treated with *t*BuOCl (−78 °C), which, after addition to a solution of *i*PrOH, EtMgBr, and **3**, provided isoxazoline **4** in 86 % yield on a 35-mmol scale and with a diastereomeric ratio of >95:5 as determined by ^{1}H NMR spectroscopy (Scheme 1). Oxidation of the secondary hydroxy group in **4** under conditions described by Ley et al. [8] and treatment with Grignard reagent **6**[9] afforded tertiary alcohol **7** in 64 % yield

Scheme 1. Conditions: a) TPAP, NMO, CH_2Cl_2, RT, 1.5 h, 82 %; b) **6**, THF, −78 °C, 1 h, 64 %, (d.r. > 98:2); c) TESOTf, 2,6-lutidine, CH_2Cl_2, 0 °C, 1 h, 93 %; d) Raney Ni (W2), $B(OH)_3$, H_2, $MeOH/H_2O$, RT, 2 h, 89 %; e) $Zn(BH_4)_2$, CH_2Cl_2, −30 °C, 2.5 h, 60 % (d.r. > 95:5); f) $PhCH(OMe)_2$, CSA (10 mol %), toluene, 50 mbar, RT, 1.5 h, 87 %; g) DDQ, pH 7 buffer, CH_2Cl_2, 0 °C, 2 h, 85 %; h) TEMPO (15 mol %), NaOCl, KBr (10 mol %), pH 8.6 buffer, CH_2Cl_2, 0 °C, 10 min; j) $H_2NOH{\cdot}HCl$, pyridine, EtOH, RT, 20 min, 85 % (over 2 steps). CSA = camphorsulfonic acid, DDQ = 2,3-dichloro-5,6-dicyanobenzoquinone, NMO = *N*-methylmorpholine *N*-oxide, PMB = *para*-methoxybenzyl, TBS = *tert*-butyldimethylsilyl, TEMPO = 2,2,6,6-tetramethyl-1-piperidinyloxyl, TESOTf = triethylsilyl trifluoromethanesulfonate, TPAP = tetrapropylammonium perruthenate.

(98:2 d.r., ^{1}H NMR). The tertiary hydroxy group was protected as triethylsilyl ether (93 % yield). Reductive cleavage of the N–O bond (Raney Ni, $B(OH)_3$, 93 % yield),[10] *syn* reduction of the ensuing hydroxy ketone ($Zn(BH_4)_2$, 60 % yield),[11] and protection of the isolated 1,3-diol provided **9** (87 % yield) as a single diastereomer (^{1}H NMR). Adduct **9** was converted to oxime **10** by a short three-step sequence of reactions in 72 % overall yield.

With oxime **10** in hand, we were ready for the second cycloaddition of a nitrile oxide. We were pleased to observe that this highly functionalized nitrile oxide smoothly underwent Mg^{II}-mediated 1,3-dipolar cycloaddition with allylic alcohol **3** under our standard reaction conditions (Scheme 2).[6] Isoxazoline **11** was obtained in excellent yield (86 %) as a single diastereomer as determined by ^{1}H NMR spectroscopy. The nitrile oxide derived from **10** represents one of the most complex substrates used in dipolar cycloaddition reactions and attests to the versatility of the cycloaddition strategy for the synthesis of polyketides.



Oxidation of the secondary hydroxy group in **11** with TEMPO/NaOCl provided the corresponding ketone in 93 % yield, which was subjected to Wittig olefination[12] ($PrPPh_3Br$ and *t*BuLi) to give a trisubstituted olefin in 78 % yield and 33:1 *Z*/*E* ratio. Dihydroxylation of this olefin with $(DHQD)_2PHAL/K_2OsO_4{\cdot}2H_2O$ (4 mol %) furnished the 1,2-diol **12** in 81 % yield and 96:4 d.r.[13,14] Selective deprotection of the primary *tert*-butyldimethylsilyl ether over the tertiary triethylsilyl ether could be accomplished with HF·pyridine/pyridine (1:3).[15] Chemoselective two-step oxi-

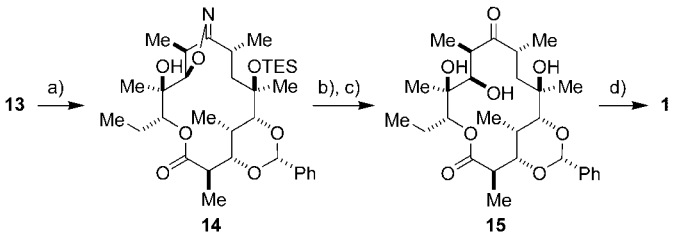
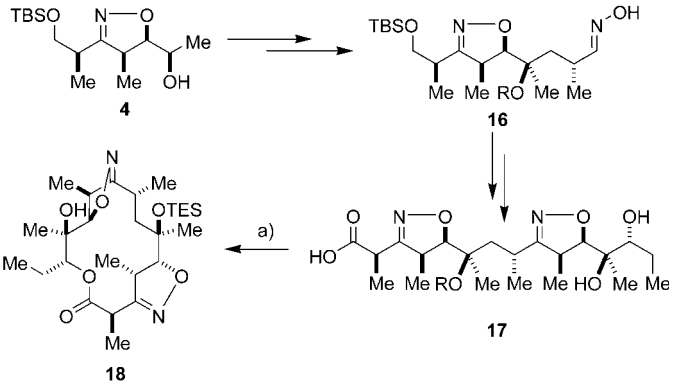


Scheme 2. Conditions: a) i) *t*BuOCl, CH_2Cl_2, −78 °C, 1.5 h, ii) *i*PrOH, EtMgBr, **3**, CH_2Cl_2, 0 °C→RT, 86%, (d.r. > 99:1); b) TEMPO (15 mol%), NaOCl, KBr (10 mol%), pH 8.6 buffer, CH_2Cl_2, 0 °C, 1 h, 93%; c) $PrPPh_3Br$, *t*BuLi, THF, −78 °C→RT, 15 h, 78%, (*Z*:*E* 33:1); d) $(DHQD)_2PHAL$ (20 mol%), $K_3[Fe(CN)_6]$, $MeSO_3NH_2$, K_2CO_3, $K_2OsO_4{\cdot}2H_2O$, *t*BuOH/H_2O, 0 °C, 2.5 h, 81% (d.r. 96:4); e) HF·py:py (1:3), 0 °C, 3 h, 80%; f) TEMPO (15 mol%), NaOCl, KBr (10 mol%), pH 8.6 buffer, CH_2Cl_2, 0 °C, 30 min; g) $NaClO_2$, 2-methyl-2-butene, pH 3.8 buffer, *t*BuOH, 0 °C, 30 min, 83% (over 2 steps). py = pyridine, $(DHQD)_2PHAL$ = dihydroquinidine phthalazine ligand. R = TES.

dation (TEMPO/NaOCl, $NaClO_2$, 83% yield) completed the synthesis of erythronolide A seco acid **13**.



At the outset of this project, it was far from certain whether the cyclization could be successfully executed with the isoxazoline carboxylic acid **13**. The classic work of Woodward on the total synthesis of erythromycin A underscores the sensitivity of related macrolactonizations of carboxylic acids to the constellation of protecting groups.[16] On the basis of modeling, we hypothesized that an isoxazoline bridging C9–C11 would lead to a favorable conformation of **13** and facilitate macrolactonization. Indeed, following a modified Yamaguchi protocol,[17] the desired macrolactone was isolated in 78% yield without detection of any other cyclization by-products (Scheme 3). Deprotection of the triethylsilyl ether and subsequent N–O bond cleavage (Raney-Ni, AcOH) provided **15** in 93% yield, thus completing the formal total synthesis of erythronolide A. Treatment of **15** with $Pd(OAc)_2$ for 6 h under an atmosphere of H_2 produced erythronolide A. Its ^1H and ^{13}C NMR spectra as well as melting point and optical rotation are identical with those of naturally derived erythronolide A.[18]

An important aspect of this cycloaddition strategy would be the ability to access nonnatural polyketides. This approach

Scheme 3. Conditions: a) i)2,4,6-$Cl_3C_6H_2COCl$, NEt_3, THF, 0 °C, 30 min; ii) DMAP, toluene, 50 °C, 4 h, 78%; b) HF·NEt_3, NEt_3, CH_3CN, RT, 64 h, > 99%; c) Raney-Ni (W2), AcOH, H_2, EtOH, RT, 20 min, 93%; d) $Pd(OAc)_2$, MeOH, H_2, RT, 6 h, 40%. DMAP = 4-*N*,*N*-dimethylaminopyridine.

would extend the methodology beyond an aldol-equivalent strategy to one that could provide unusual analogues not directly accessible either through genetic engineering or traditional synthetic methods. A number of erythromycin analogues investigated in the pharmaceutical industry are heterocyclic derivatives (bridging C9–C11, for example) prepared from the natural product.[19] We thus became interested in the generation of nonnatural analogues such as **18** (Scheme 4). In a similar reaction sequence as described above, isoxazoline **4** could easily be converted to oxime **16** and subsequently to carboxylic acid **17**. Under modified Yamaguchi conditions, we obtained macrolactone **18** in 60% yield. Since the nitrile oxide and allylic alcohol partners can be varied readily, this strategy enables an approach to a plethora of

Scheme 4. Conditions: a) i) 2,4,6-$Cl_3C_6H_2COCl$, NEt_3, THF, 0 °C, 30 min; ii) DMAP, toluene, 50 °C, 4 h, 60%.

derivatives that may exhibit useful properties and allow the development of new antibiotics against multiresistant bacterial strains.

In summary, we have reported a stereoselective total synthesis of erythronolide A, whose focal points are two Mg^{II}-mediated cycloadditions of nitrile oxides, making this the shortest synthesis of erythronolide A to date: 21 linear steps, 4% overall yield. These accomplishments establish this methodology as a powerful tool for the synthesis of polyketide natural products. The isoxazoline serves as a robust protecting group for β-hydroxyketones that can be cleaved at a late stage of the synthesis within a densely functionalized structure. Moreover, the isoxazoline proved suitable for the delicate macrolactonization of erythronolide A seco acid **13**. Of broader significance, the strategy, beyond its use as an aldol equivalent process, opens up new possibilities for the preparation of nonnatural analogues.

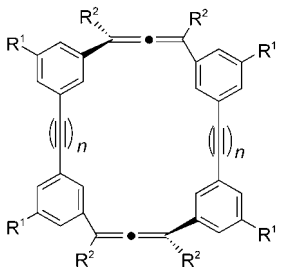
Asymmetric Synthesis

Acetylenic Allenophanes: An Asymmetric Synthesis of a Bis(alleno)-bis(butadiynyl)-*meta*-cyclophane**

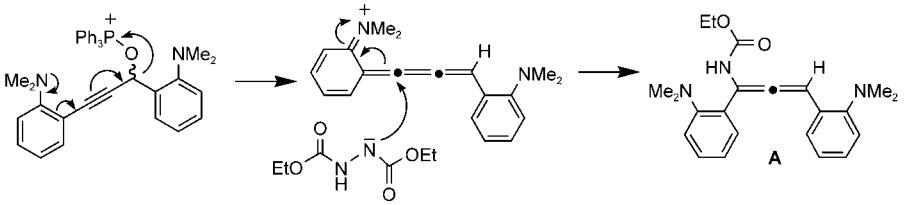


*Matthew D. Clay and Alex G. Fallis**

We have an ongoing interest in the design and synthesis of novel cyclophanes, many of which contain a twisted conformation that imparts helical chirality[1] to the assembled molecule.[2] This helical chirality is a consequence of the number, type, and combination of unsaturated linkages present in these molecules. The synthesis and design of cyclophanes[3] and cage compounds with high carbon content in novel shapes and supramolecular geometries[4] continues to be a topic of current interest.

Allenes are a unique family of organic molecules because of their diverse chemistry, axial chirality, and synthetic versatility,[5] and so investigations into allene-containing natural products and their total syntheses continue to increase.[6] Furthermore, medical applications for these compounds include employing them as inactivators of monoamine oxidase.[7]

In contrast, cyclophanes that have only allene bridges (termed allenophanes)[8] have received little attention and the only reported example was prepared as a mixture of diastereomers.[8] A related family of cyclophanes comprises structures that contain both allene and acetylene bridges. These acetylenic allenophanes should also possess interesting properties. Herein, we report the first asymmetric synthesis of an acetylenic allenophane that contains two allene bridges. This compound appears to be the first cyclophane of this general class.



The general structure of an acetylenic allenophane is depicted in Scheme 1. The R^1 substituents aid solubility: the absence of similar groups in the previously prepared allenophane[8] limited its solubility and prevented a full investigation into its properties. The R^2 substituents may be hydrogen atoms or alkyl groups, depending on the method selected to synthesize the allene moiety. The number of acetylene bridges may also be varied.

Scheme 1. An acetylenic allenophane.

We devised a strategy to an acetylenic allenophane related to **16** based on the dimerization of desilylated **15** (see Scheme 4). We[9a] and others[9b] observed previously that the separation of the alkyne termini dictates whether the intra- or intermolecular product dominates. Molecular modeling studies have strongly suggested that the intermolecular product is favored when the termini separation is greater than 7 Å.[9c] In the case of **15**, the calculated alkyne separation of 8.87 Å[10] indicated that the intramolecular product **16** should be preferred.

We initially examined the allene preparation used by Myers and Zheng for the synthesis of an allenophane in which R^2 groups are hydrogen atoms (Scheme 1).[11] This asymmetric method had the advantage that the allene precursor, a secondary propargyl alcohol, was readily available through the addition of an acetylide to an aldehyde.[12] Initially, *ortho*-amino substituents at the aryl ring were chosen to aid solubility, but this idea had to be abandoned because electron donation from the lone pair of electrons on the nitrogen atom in the *ortho*-amino substituent leads to the formation of cumulene-type intermediates during allene formation (Scheme 2), and so *tert*-butyl groups were selected instead.

Scheme 2. Proposed mechanism for the formation of allene **A** because of *ortho*-amino aryl substituents.

Unfortunately, the procedure of Myers and Zheng afforded a disappointing yield of 18%.

An attractive alternative for the generation of asymmetric allenes employs an S_N2' addition of an organocuprate to a propargyl acetate.[13] This method allows fully substituted allenes to be synthesized, but requires the asymmetric synthesis of a tertiary propargyl alcohol. Reported methods for the preparation of this species are limited to examples that utilize the asymmetric addition of a zinc acetylide to a ketone[14] or the asymmetric addition of an alkyl zinc to a ketone.[15] Unfortunately, the asymmetric addition of dimethylzinc to the ketone precusor of **13** failed (see Scheme 4).

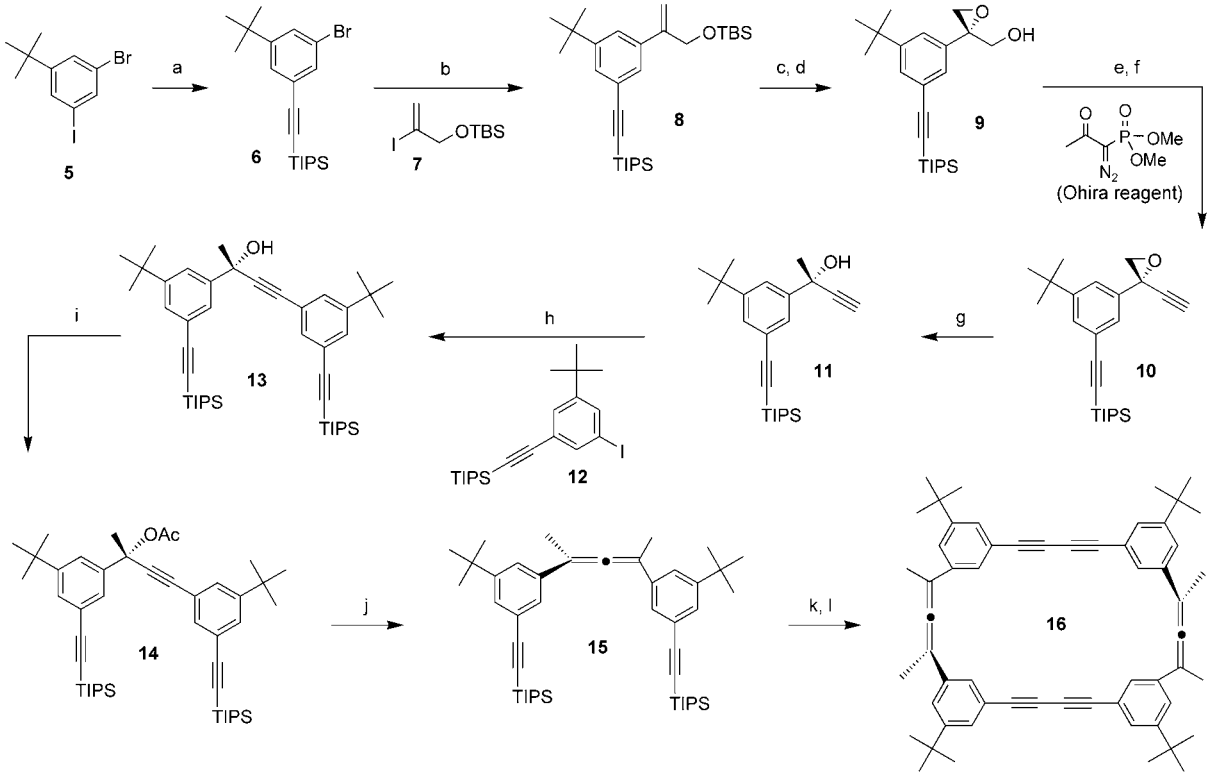
Similarly, the combination of the zinc acetylide to the appropriate acetophenone to generate **13** directly was also unsuccessful. This failure was likely due to the steric encumbrance of the *tert*-butyl solubilizing groups as well as the inherent poor electrophilicity of the ketones employed. Consequently, a new strategy was developed to construct these tertiary propargyl alcohols.

We designed a method in which the requisite stereogenic centers could be installed by using a Sharpless asymmetric epoxidation (Scheme 3). Oxidation of epoxy alcohol **2** should



Scheme 3. An asymmetric synthetic route to tertiary propargyl alcohols.

afford the desired aldehyde **3**, which upon exposure to the reagent developed by Ohira[16] would give an epoxy alkyne that could undergo ring opening with a suitable hydride reagent to yield the desired tertiary propargyl alcohol **4**. The synthetic pathway that was developed is given in Scheme 4.

A Sonogashira coupling between 1-bromo-3-iodo-5-*tert*-butylbenzene (**5**)[17] and (triisopropylsilyl)acetylene smoothly generated aryl bromide **6** in 99% yield. A lithium–halogen exchange followed by quenching of the resulting anion with zinc bromide generated an organozinc intermediate, which was coupled with vinyl iodide **7**[18] to generate the *tert*-butyldimethylsilyl (TBS) ether **8**, also in 99% yield. Selective cleavage of the TBS group followed by Sharpless asymmetric epoxidation of the allylic alcohol provided the allylic epoxy alcohol **9** in 93% yield (88% *ee*).[19] Initially, the ring opening of **9** was examined with various aluminum hydride reagents. In each case, the epoxide was cleaved readily, however, despite a literature precedent[20] the resulting diol was partially racemized. This occurred presumably through a Payne rearrangement[21] of the epoxy alcohol. Therefore, the ring opening of the epoxide was postponed until a later stage in the synthesis.

Oxidation of **9** with the Dess–Martin periodinane gave an aldehyde in 89% yield, which was subsequently converted into a terminal alkyne with the Ohira reagent (93%). The epoxide in **10** was opened cleanly on exposure to L-selectride to provide tertiary propargyl alcohol **11**, and no lowering of enantiomeric excess was detected (HPLC analysis). This sequence for the conversion of an epoxide into a tertiary

propargyl alcohol was easily completed within one day in an overall yield of 73%. A Sonogashira reaction between **11** and aryl iodide **12** (prepared through a lithium–halogen exchange of **6** followed by quenching with iodine) generated the propargyl alcohol **13** in 51% yield. A modification of the standard Sonogashira coupling conditions failed to increase the yield.[22]

Acetylization of **13** with acetic anhydride gave acetate **14** in 85% yield. As anticipated, (*S*)-allene **15** was formed through the addition of **14** to the organocuprate generated from a mixture of CH_3MgBr, LiBr, and CuI (74% yield). Removal of the triisopropylsilyl groups with TBAF generated the terminal bisalkyne **15** in 98% yield with 83% *ee*. This indicated that there was minimal racemization during generation of the allene. The slow addition of (*S*)-**15** to a solution of $Cu(OAc)_2$ in pyridine and diethyl ether afforded the desired (*S*,*S*)-acetylenic allenophane **16** in 40% yield. The desilylation–dimerization sequence could also be conducted in a one-pot procedure, but the isolation of **16** was more difficult because of the presence of several highly fluorescent impurities. Unfortunately, crystals of **16** suitable for X-ray crystallographic studies could not be obtained; however, molecular modeling studies revealed the unique conformation of this cyclophane:[23] Figure 1 a illustrates the chirality of **16**, whereas Figure 1 b reveals its helical nature.

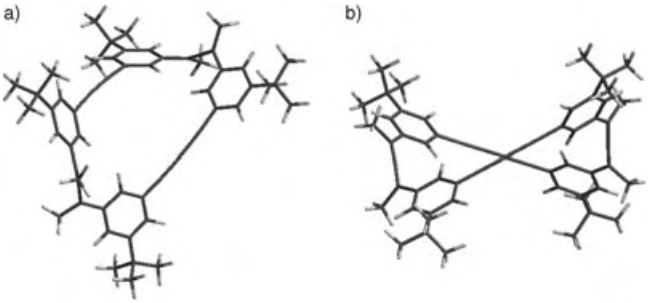

Figure 1. Molecular models of **16**: a) stereochemical configuration and b) helical arrangement.

The UV/Vis absorption and circular dichroism (CD) spectra of **16** in a solution of chloroform were recorded and are illustrated in Figures 2 and 3, respectively. There are very few reported examples of UV/Vis and CD spectra of cyclic

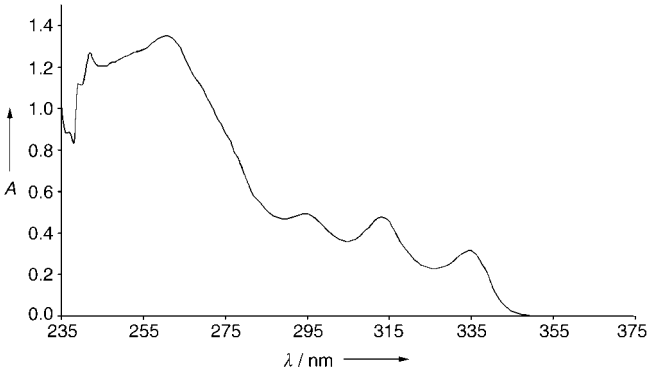

Figure 2. UV/Vis absorption spectrum of **16**.

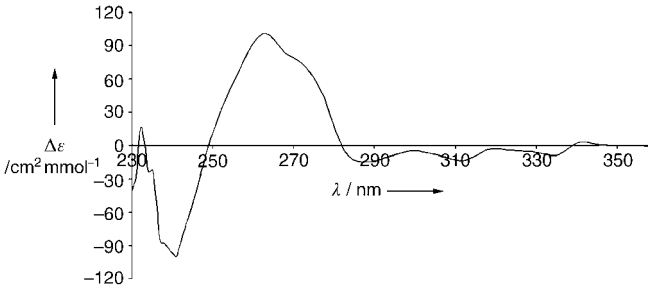

Figure 3. CD spectrum of **16**.

allenes with which to compare the spectra of our acetylenic allenophane.[24] Nevertheless, the typical "fingerprint" pattern for acetylenes with bands at 295, 313, and 335 nm is apparent in the UV/Vis spectrum. Major signals at 263 and 270 (sh) nm were observed in the CD spectrum that may have arisen from the through-space interactions of the phenyl rings.

In conclusion, a novel single-enantiomer acetylenic allenophane **16** has been synthesized by a series of palladium- and copper-mediated coupling reactions. A new protocol was developed that allowed the stereochemistry of the allene to be controlled by the use of a Sharpless asymmetric epoxidation and a tertiary α-hydroxyethyne intermediate. We are currently investigating the scope and synthetic utility of this reaction sequence for other targets.

Homogeneous Catalysis

Ru-Catalyzed Anti-Markovnikov Addition of Amides to Alkynes: A Regio- and Stereoselective Synthesis of Enamides**

Lukas J. Gooßen, Jan E. Rauhaus, and Guojun Deng*

The enamide group is an important substructure that is often found in natural products[1] and synthetic drugs that have, amongst others, sedative,[2] cytotoxic,[3] or anti-inflammatory[4] properties. Moreover, they are versatile synthetic intermediates that can serve as substrates for polymerizations,[5] [4+2] cycloadditions,[6,7] cross-coupling reactions,[8] Heck olefinations,[9] halogenations,[8] enantioselective additions,[10] or asymmetric hydrogenations.[11] However, a regio- and stereoselective construction of enamide substructures is not at all trivial. Traditional syntheses—for example, from carbonyl compounds and amides[12] or from hydroxylamines and acetic anhydride[13]—require harsh conditions and yield mixtures of *E*/*Z* products. Metal-catalyzed coupling reactions of vinyl halides,[14] vinyl triflates,[15] or vinyl ethers[16] proceed under milder conditions but suffer from the limited availability of these substrates.

In our opinion, a catalytic addition of amides to alkynes would be an ideal synthetic entry to enamides, since it would use readily available starting materials and be inherently atom-economic (Scheme 1). Related addition reactions of carboxylates,[17] water,[18] and amines[19] are well-established.[20] However, to the best of our knowledge, there is only one reported protocol in the literature for a catalytic hydroamidation reaction of terminal alkynes:[21] Watanabe et al. found that in the presence of Ru_3CO_{12}/trialkylphosphane catalysts, a very limited range of formanilides and acetanilides can be added to 1-hexyne, albeit at extremely high temperatures (180 °C) and under pressure.[22] Clearly, much more effective catalyst systems are required to allow an application of this reaction in organic synthesis.

To identify a catalyst system for the desired hydroamidation reaction, we chose the reaction of 1-hexyne (**1a**) with 2-pyrrolidinone (**2a**) as a model system and investigated the catalytic activity of several ruthenium complexes under various conditions (Scheme 2, Table 1). As anticipated, no

enamide products were observed in the presence of the literature systems[21c,22] at ambient pressure and a temperature of only 100 °C (entries 1 and 2). In contrast, several other ruthenium sources, although inactive themselves (entries 2–5), displayed noticeable catalytic activity when combined with tri-*n*-butylphosphane (entries 6–10). In all cases, the anti-Markovnikov products **4a** and **5a** were formed regioselectively. However, a significant stereoselectivity ($E/Z > 10{:}1$) was observed only for 1,5-cyclooctadienebis(2-methallyl)ruthenium [Ru(methallyl)$_2$(cod)]; with all other ruthenium sources, **4a** and **5a** were formed in almost equal amounts. The reaction of [Ru(methallyl)$_2$(cod)] with monodentate phosphanes leads to the formation of isolable bis(2-methallyl)bis(phosphane)ruthenium(II) complexes, which show the same reactivity as the mixtures prepared in situ (entry 16).

Among all the ligands investigated, tri-*n*-butylphosphane gave the highest *E* selectivity in combination with [Ru(methallyl)$_2$(cod)] (entries 10–15). Triarylphosphanes were less effective, and use of the chelating phosphane bis(dicyclohexylphosphanyl)methane ($Cy_2PCH_2PCy_2$) even led to a reversal of the stereoselectivity in favor of the *Z* product (entry 12).

As in our recently disclosed protocol for the anti-Markovnikov addition of carboxylic acids to alkynes,[17c] the addition of pyridine derivatives (2 equiv with respect to ruthenium) strongly enhanced the catalyst performance; other additives had no beneficial effects (entries 17–22). 4-(*N*,*N*-Dimethylamino)pyridine (DMAP), in particular, led to a significant increase in both the activity and the stereoselectivity of the [Ru(methallyl)$_2$(cod)]/P*n*Bu$_3$ catalyst system, and allowed the synthesis of **4a** in almost quantitative yield with an *E*/*Z* selectivity of 28:1 (entry 22). Gratifyingly,

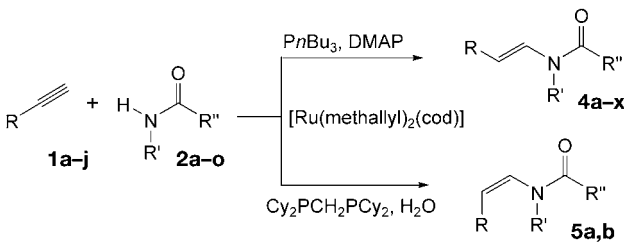
[a] Conditions: pyrrolidinone (1.0 mmol), 1-hexyne (2.0 mmol), ruthenium source (0.02 mmol), ligand (0.06 mmol; or 0.03 mmol for chelating ligands), additive (0.04 mmol), toluene (3 mL), 100 °C, 15 h. The yields and selectivities were determined by GC using *n*-tetradecane as the internal standard. Abbreviations: acac = acetylacetonate; Np = naphthyl; DABCO = 1,4-diazabicyclo[2.2.2]octane. [b] nd = not determined. [c] 0.5 mmol H_2O; [d] The reaction vessel was briefly purged with air. [e] 1.2 mmol 1-hexyne. [f] 8-mmol H_2O.

the presence of air and moisture had only a minor influence on the yields and selectivities of this optimized reaction protocol (entries 22, 24, and 25).

Since *Z* enamides are of similar synthetic importance but particularly hard to synthesize,[23] we next set out to identify a complementary *Z*-selective hydroamidation catalyst. Starting with the [Ru(methallyl)$_2$(cod)]/$Cy_2PCH_2PCy_2$ system, which had already shown some *Z* selectivity (entry 12), we again studied the influence of additives. Interestingly, this catalyst was completely inhibited by the addition of DMAP (entry 23), while other bases and additives had only a minor influence on the reaction outcome. Only the addition of small quantities of water increased both its activity and *Z* selectivity, such that **5a** also became accessible in excellent yield (99 %, $Z/E = 5{:}1$; entries 27 and 28).



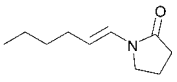
To make up for losses due to oligomerization and evaporation, the alkyne is best used in a slight excess of at least 1.2 equivalents (entries 22 and 26).

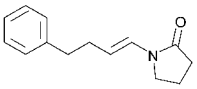
Currently, we can only speculate about the exact reaction mechanism; more in-depth investigations are underway. The *Z*-selective protocol is likely to follow the mechanism

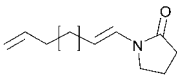
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

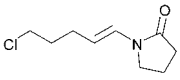
proposed for the addition of carboxylic acids to alkynes,[17] but it is difficult to pinpoint the origin of the reversal of selectivity when adding monodentate phosphanes and DMAP. A conceivable mechanism for the *E*-selective protocol might involve oxidative addition of the N–H bond to the ruthenium, followed by insertion of the alkyne into the resultant metal–nitrogen bond, and reductive elimination of the enamide product. On the other hand, the two mechanisms may mainly differ in concerted against stepwise addition of the nucleophile and the proton.[17a,b]

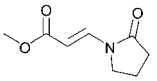
To investigate the scope of this new hydroamidation protocol, we applied it to the addition of a broad variety of nitrogen nucleophiles to several terminal alkynes (Scheme 3).

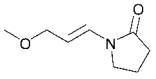


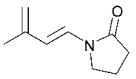


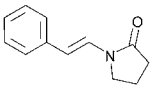


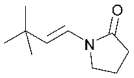


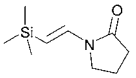


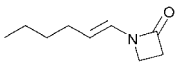


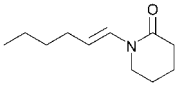


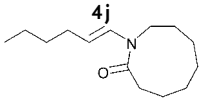


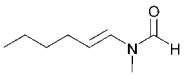


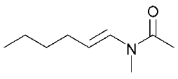


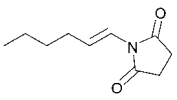


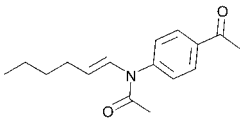


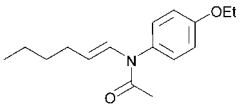


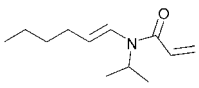


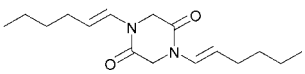


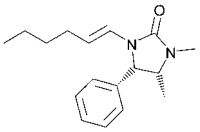


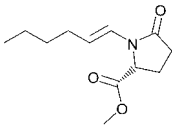


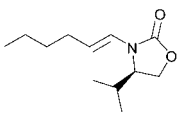


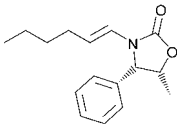












Scheme 3. Addition of N–H compounds to terminal alkynes.

Table 2 demonstrates the impressive scope of the *E*-selective reaction. Various alkynes were successfully converted into enamides, among them phenylacetylene, acetylenecarboxylic esters, trimethylsilylacetylene, and even conjugated enynes. The trimethylsilyl-enamides obtained should be attractive substrates for further coupling reactions, and the dienamides for hetero-Diels–Alder reactions.

Besides lactams, various secondary amides, anilides, ureas, bislactams, carbamates, and even chiral auxiliaries for subsequent cycloaddition reactions[7] can be used as the N–H-

Table 2: Substrate scope of the hydroamidation reaction (Scheme 3).[a]

coupling partner. The reaction proceeds smoothly even in the presence of sensitive functional groups such as esters, ethers, ketones, halides, or silanes. For most substrates, the *E* products were obtained in an isomeric ratio greater than 20:1, and only imides gave only moderate yields and selectivities; primary amides could not be converted.

The *Z*-selective protocol was also successfully applied to selected substrates (Table 2, first row). Although this protocol does not yet reach the selectivity of its *E*-selective counterpart, the examples **5a** and **5b** demonstrate that the stereoselectivity of the reaction can indeed be inverted by modifying the ligand system.

In summary, a ruthenium-catalyzed reaction has been developed that allows, for the first time, the anti-Markovnikov addition of secondary amides, anilides, lactams, ureas, bislactams, and carbamates to terminal alkynes. Two complementary protocols have been identified that provide stereoselective synthetic entries to either the *E* or the *Z* isomers. Due to the mild reaction conditions, the excellent availability of the starting materials, and the ideal atom economy, this new transformation is well-suited for applications in synthetic organic chemistry and drug discovery.

Experimental Section

4a: An oven-dried flask was charged with [Ru(methallyl)$_2$(cod)] (6.4 mg, 0.02 mmol) and DMAP (4.99 mg, 0.04 mmol), and flushed with argon. Subsequently, P*n*Bu$_3$ (15 μL, 0.06 mmol), 2-pyrrolidinone (**2a**; 85.1 mg, 1 mmol), 1-hexyne (**1a**; 229 μL, 2.0 mmol), and dry toluene (3.0 mL) were added with a syringe. The resulting green solution was stirred for 15 h at 100 °C, then poured into an aqueous $NaHCO_3$ solution (30 mL). The resulting mixture was extracted repeatedly with 20 mL portions of ethyl acetate, the combined organic layers were washed with water and brine, dried with $MgSO_4$, and filtered, and the volatiles were removed in vacuo. The residue was purified by column chromatography (SiO_2, ethyl acetate/hexanes 3:1) to yield **4a** (158.9 mg, 95 % yield, 97 % isomeric purity) as a colorless oil.

^{1}H NMR (300.1 MHz, $CDCl_3$): $\delta = 6.86$ (d, $^3J = 14.7$ Hz, 1H), 4.92 (dt, $^3J = 14.7$ Hz, 7.2 Hz, 1H), 3.48 (t, $^3J = 7.2$ Hz, 2H), 2.46 (t, $^3J = 8.1$ Hz, 2H), 2.01–2.14 (m, 4H), 1.24–1.39 (m, 4H), 0.88 ppm (t, $^3J = 7.2$ Hz, 3H); ^{13}C NMR (75.5 MHz, $CDCl_3$): $\delta = 172.2$, 123.6, 112.5, 45.3, 32.3, 31.3, 29.7, 22.1, 17.4, 13.9 ppm; MS (EI, 70 eV): *m*/*z* (%): 167 (20), 124 (100) $[M]^+$, 86 (23), 69 (12), 41 (21); HRMS (EI): calcd for $C_{10}H_{17}NO$: 167.131014; found: 167.130871.

The experiments in Table 2 were carried out analogously. All products were purified by column chromatography and characterized by NMR spectroscopy and standard/high-resolution mass spectrometry.

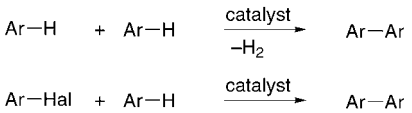
C–H Activation



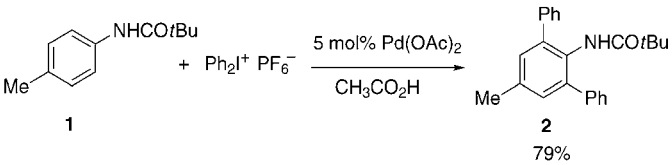
Anilide *ortho*-Arylation by Using C–H Activation Methodology**

Olafs Daugulis and Vladimir G. Zaitsev*

With few exceptions, the current methodology for biaryl formation utilizes functionalization on both components of the coupling process (Scheme 1).[1] Ideally, one would like to

Both coupling components must be functionalized.
Current investigations use substrates where Hal = Cl.

C–H Activation - one or no functionalized coupling components - use of the C–H bond as a functional group



Scheme 1. C–X bond activation versus C–H bond activation.

selectively and efficiently couple two C–H bonds to give the corresponding product (Scheme 1). From a thermodynamic point of view, however, this latter process is quite often unfavorable (for example, the coupling of benzene to give biphenyl and hydrogen is unfavorable by 13.8 kJ mol^{-1}).[2] Given the potentially large number of C–H bonds in both reactants, it is also problematic to achieve the desired regioselectivity of coupling.

The R–X coupling with R–H is viable, but this variation has not been extensively investigated. Phenols and heterocycles have been *ortho*-arylated with aryl bromides through Pd^0–Pd^{II} catalytic cycles.[3] Benzanilides have been *ortho*-arylated on the benzoyl moiety under similar conditions.[4] Simple arenes may be arylated with aryl iodides under Ir catalysis, and *ortho*-arylation of aromatic ketones and imines by using Ru catalysis has been shown.[5] A few other examples of coupling reactions between Ar–H and Ar–Hal have been reported, mostly proceeding through a Pd^0–Pd^{II} catalytic cycle.[6]

Tremont, Liebeskind and co-workers have shown that anilide and aromatic imine coupling with alkyl iodides is promoted by Pd^{II}.[7] This alkylation is mechanistically distinct from the processes described above since it proceeds either through a σ-bond methathesis pathway or a Pd^{II}–Pd^{IV} couple.[7a] Inspired by this work, we have investigated the Pd-catalyzed arylation of arenes containing *ortho*-directing groups, in the hope of developing a general method for arene *ortho*-arylation under C–H activation conditions. We report herein the Pd-catalyzed *ortho*-arylation of anilides. 2,6-Diarylanilines are useful for the synthesis of ligands employed in Brookhart-type transition-metal-catalyzed polymerizations and currently are synthesized only from highly functionalized starting materials.[8]

The screening reactions were performed with respect to the arylating agent and the solvent. Reaction of 4-methylpivalanilide (**1**) with 4-methylphenyldiazonium tetrafluoroborate gave only minor amounts of coupling product under the tested conditions in a variety of solvents. Arylation of **1** with the commercially available $Ph_2I^+PF_6^-$ was successful in acetic acid and allowed the isolation of the diphenylated product **2** in 79% yield (Scheme 2; Table 1, entry 12).[9]

1 **2** 79%

Scheme 2. Amide arylation with iodonium salts.

Unfortunately, diphenyliodonium salts are the only ones commercially available, thus limiting the scope of this reaction. In addition, these salts are very expensive and have to be used in excess for complete conversion into the product.

We were pleased to find out that the combination of aryl iodides and AgOAc is effective in catalytically arylating the anilides by using palladium acetate. The reaction proceeds well in acetic acid, but the fastest rates were observed in trifluoroacetic acid and thus further investigations were carried out in this solvent.

A number of anilides could be arylated by using this methodology (Table 1). Generally, the pivaloyl derivatives gave the cleanest reactions; however, acetamides (entry 11) are also compatible with the reaction conditions. In this case more optimization is needed due to a competitive side reaction.[10] The reaction is highly tolerant with respect to substituents on the anilide: any halogenes, including iodine (entries 4, 9), are tolerated. The reaction is also compatible with bromo substituents on the aryl iodide (entries 2, 5). This allows construction of scaffolds that could be functionalized further by using conventional Pd^0 coupling processes. Ester groups are also tolerated (entries 7, 8). The use of *meta*-substituted anilides results in the selective addition of one aryl

Table 1: Iodoarene coupling with amides[a]

Entry	Amide FG	Ar	Product	Yield [%]
1	H	C_6H_5		91
2	4-Br	3-Br-C_6H_4		95
3	H	4-Me-C_6H_4		95
4	4-I	4-Me-C_6H_4		92
5	H	3-Br-C_6H_4		55
6	H	4-MeO-C_6H_4		67
7	4-Me	3-MeO_2C-C_6H_4		85
8	4-Me	4-MeO_2C-C_6H_4		96
9	3-I	C_6H_5		83
10	[b]	4-Me-C_6H_4		62
11	[c]	C_6H_5		76
12	4-Me	[d]		79

[a] Substrate (1 equiv), ArI (2–9 equiv), AgOAc (1 equiv per coupled Ar), $Pd(OAc)_2$ (0.2–5 mol%). In entries 1–10 and 12 R = *t*Bu, in entry 11 R = Me. Yields are given for isolated products. See the Experimental Section and Supporting Information for details. [b] 1-Naphthyl-*N*-pivalamide. [c] 2-Methylacetanilide. [d] $Ph_2I^+PF_6^-$ was used instead of ArI, with CH_3CO_2H as the solvent, and no AgOAc was added.

group (entry 9). High turnover numbers have been achieved: Entry 3 was run with 0.2 mol% Pd and complete conversion (according to GC) was observed, a result indicating a turnover number of 1000. This is a remarkably high turnover number for a C–H activation process.[11]

At this point only a speculative discussion about the reaction mechanism is possible. Qualitatively, the reactions are faster for ArI containing electron-donating groups, a result which sets this process apart from the conventional Pd-catalyzed couplings.[12] As expected for an electrophilic C–H activation process, the reactions are faster for anilides possessing donor substituents.[13] It has been shown that diaryliodonium trifluoromethanesulfonates can transfer Ar^+ to nitrogen-ligated Pd^{II}, thereby leading to the formation of unstable Pd^{IV} species that decompose through reductive elimination pathways.[14] This finding of Canty and co-workers may be relevant to the mechanism of this arylation procedure; however, at this point a σ-bond metathesis pathway can not be ruled out.

Finally, we include a note regarding the use of silver salts in this coupling process: the silver acetate price per mole is about twice that of the price of cesium carbonate, a base widely used for Pd-catalyzed coupling reactions. However, in many cases several equivalents of Cs_2CO_3 are used for the reactions, as opposed to the one equivalent of AgOAc per introduced aryl group for this method.

In conclusion, we have developed a new anilide arylation process based on C–H activation. The method is highly tolerant to functional groups and allows the presence of any halogens on the anilide moiety and bromo substituents on the aryl iodide. Up to 1000 turnovers have been demonstrated for this reaction. Recently, we have verified that the reaction developed here is quite general and allows for the arylation of other arenes containing *ortho*-directing groups. 2-Arylpyridines and imines derived from substituted benzaldehydes can be arylated using this methodology. The results of these latter investigations will be published separately.

Experimental Section

General considerations: The coupling reactions were performed without special precautions in 2-dram screw-cap vials. Flash chromatography was performed by using 60-Å silica gel (Sorbent Technologies) or acidic, Brockmann I, aluminum oxide (Aldrich). GC analyses were performed on a Shimadzu GC-2010 chromatograph equipped with a Restek column (Rtx-5, 15 m, 0.25 mm inner diameter). The ^1H and ^{13}C NMR spectra were recorded on a GE QE-300 spectrometer by using the residual solvent peak as a reference. IR spectra were obtained by using a ThermoNicolet Avatar 370 FT-IR instrument. Melting points were measured on a Mel-Temp apparatus and are uncorrected. Elemental analyses were performed by Atlantic Microlab Inc. of Norcross, GA.

2,6-Di(4-methylphenyl)pivalanilide (Table 1, entry 3): A solution of pivalanilide (0.53 g, 3.0 mmol), 4-iodotoluene (3.30 g, 15.0 mmol), palladium acetate (1.3 mg, 0.006 mmol), and silver acetate (1.00 g, 6.0 mmol) in trifluoroacetic acid (TFA; 2 mL) in a 2-dram screw-cap vial was heated at 90 °C for 3 days. At that point, the conversion was observed by GC analysis to be >99%. During this time, a dark-yellow precipitate was formed and the supernatant became clear dark red. The reaction mixture was diluted with toluene (30 mL), the solution was decanted, and the precipitate was washed with toluene (2 × 5 mL). The combined organic solutions were evaporated under reduced pressure and the residue was purified by flash chromatography on silica gel (toluene, then dichloromethane/toluene (1:1)) to give the product as a white solid (1.02 g, 95%): m.p. 239–240 °C

(pentane); $R_f = 0.35$ (dichloromethane/pentane (1:1)); ^{1}H NMR ($CDCl_3$): $\delta = 0.87$ (s, 9H), 2.37 (s, 6H), 6.74 (br s, 1H), 7.17 (d, $J =$ 7.8 Hz, 4H), 7.25 (d, $J = 7.8$ Hz, 4H), 7.25–7.40 ppm (m, 3H); ^{13}C NMR ($CDCl_3$): $\delta = 21.2$, 27.1, 38.7, 127.1, 128.6, 128.7, 129.5, 131.6, 136.7, 136.8, 140.6, 176.3 ppm; FT-IR: $\tilde{\nu} = 1642$ (C=O), 3250 cm^{-1} (N–H); elemental analysis: calcd (%) for $C_{25}H_{27}NO$: C 83.99, H 7.61, N 3.92; found: C 83.47, H 7.64, N 4.00.

Silver iodide (1.37 g, 5.82 mmol) obtained after drying the precipitate in vacuo and in the dark dissolved completely in 28–30% ammonia (100 mL).

2,6-Di(3′-bromophenyl)-4-bromopivalanilide (Table 1, entry 2): A solution of 3-bromoiodobenzene (130 μL, 1.0 mmol), 4-bromopivalanilide[15] (64 mg, 0.25 mmol), palladium acetate (1.5 mg, 0.007 mmol), and silver acetate (87 mg, 0.5 mmol) in TFA (0.5 mL) was heated at 120 °C for 2 h. Workup as above followed by purification by flash chromatography (toluene, then dichloromethane) afforded the product as an off-white solid (135 mg, 95%): m.p. 206–207 °C (colorless crystals, from pentane); $R_f = 0.35$ (dichloromethane/pentane (1:2)); ^{1}H NMR ($CDCl_3$): $\delta = 0.90$ (s, 9H), 6.66 (br s, 1H), 7.20–7.30 (m, 4H), 7.40–7.55 ppm (m, 6H); ^{13}C NMR ($CDCl_3$): $\delta = 27.1$, 38.9, 121.0, 122.0, 127.5, 129.9, 130.8, 130.9, 131.5, 132.6, 140.1, 141.4, 176.7 ppm; FT-IR: $\tilde{\nu} = 1639$ (C=O), 3280 cm^{-1} (N–H); elemental analysis: calcd (%) for $C_{23}H_{20}Br_3NO$: C 48.80, H 3.56, N 2.47; found: C 48.91, H 3.48, N 2.54.

Polyoxometalates

Molecular Recognition of Basic Fibroblast Growth Factor by Polyoxometalates**

*Qiang Wu, Ju Wang, Ling Zhang, An Hong, and Jinsong Ren**

The inhibition of angiogenesis-promoting factors such as fibroblast growth factor is considered to be a potential treatment for cancers, and has become an active area of research pursued with intense interest.[1] Two major targets of pharmacologic therapies are vascular endothelial growth factor (VEGF) and basic fibroblast growth factor (bFGF). bFGF is a globular single-chain heparin-binding polypeptide synthesized by different cell types. The 3D structure of the 18-kDa bFGF has been recently elucidated by X-ray crystallography.[2] bFGF consists entirely of β-sheet structure, which includes a threefold repeat of a four-stranded antiparallel β

meander. It has been detected in a wide variety of normal and malignant tissues and is known to play key roles in the development, growth, and disease states in almost every organ system.[3] Ligands that recognize and bind bFGF may disrupt its interaction with endothelial cell-surface receptors such as heparan sulfate proteoglycans (HSPGs) and fibroblast growth factor receptors (FGFRs), and would represent a new class of potential therapeutic agent.

Much effort is underway in the development of drugs that inhibit bFGF-induced angiogenesis. The potential use of exogenous heparin analogues as inhibitors of angiogenesis, such as suramin,[4] pentosan polysulfate (PPS),[5] sulfonated derivatives of distamycin A,[6] and carboxylated compounds[7] have become the focus of several research groups. Suramin and PPS[8] have been evaluated in patients with various tumors, including Kaposi's sarcoma (KS), yet very large doses of these compounds are required to show activity, and their efficacy is limited by anticoagulant side effects. However, minor structural changes to suramin have resulted in a significant decrease in toxicity without loss of activity.[9]

This result was clear incentive for the design of novel compounds with high efficacy and low toxicity. Early transition metal oxygen anion clusters (polyoxometalates, or POMs) were explored as a different class of therapeutic agent. Unlike the flexible organic polysulfonated polyanionic heparin-based compounds, POMs are inorganic polyoxygen polyanions with fairly rigid cagelike structures.[10] POMs have been attractive for their promising antiviral, antitumor activities for more than a decade.[11] Based on cell-culture assays, enzymatic activities in vitro, and molecular modeling studies, POMs have regained considerable interest in recent years as a result of their remarkable interactions with HIV-1 reverse transcriptase (RT) and HIV-1 protease (P), as demonstrated by Hill, Pope, and co-workers.[12,13] Recently, it was reported that the POM $K_5SiCoW_{11}O_{39}$ could affect the mitogenic activity of bFGF,[14] yet little is known about the POM–bFGF interaction. Herein, we describe the recognition and binding of several POMs to bFGF. These POMs represent promising leads for the design of new compounds that might recognize bFGF, and which may represent potentially new avenues for the design and synthesis of new types of inhibitors of tumor angiogenesis.

Three representative POMs, the Keggin ($K_6SiNiW_{11}O_{39}$), the Wells–Dawson (α-$K_8P_2NiW_{17}O_{61}(H_2O)$), and the trivacant Keggin-derived sandwich ($K_{10}P_2Zn_4(H_2O)_2W_{18}O_{68}$) structures were selected for the present study. These ligands, whose basic anion backbones are illustrated in Figure 1, are hydrolytically stable under physiological conditions and vary in size and charge. The Keggin structure is ≈ 11.5 Å in diameter with six negative charges, the Wells–Dawson structure is $\approx 11.5 \times 15$ Å with eight negative charges, and the Keggin-derived sandwich structure is $\approx 11.5 \times 18.0$ Å with ten negative charges. The direct interaction between bFGF and POMs was first demonstrated by fluorescence, ultraviolet absorption, and circular dichroism measurements. bFGF was excited at 275 nm and its fluorescence was monitored at 303 nm in phosphate-buffered saline (PBS), pH 7.4 at 20 °C. The fluorescence intensity of bFGF was strongly quenched with an increase in the amount of POM. The titration reached

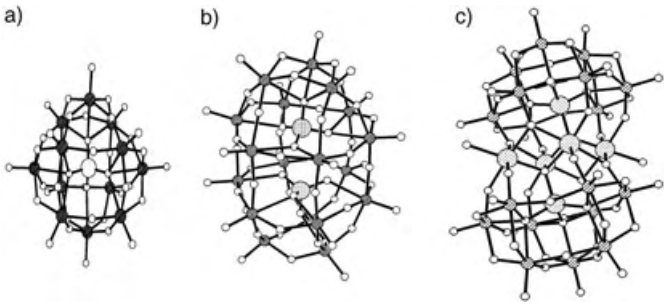

Figure 1. Basic anion backbone drawings of the three polyoxometalates: a) the Keggin structure, $[SiNiW_{11}O_{39}]^{6-}$; b) the Wells–Dawson structure, $[P_2NiW_{17}O_{61}(H_2O)]^{8-}$; and c) the trivacant Keggin-derived sandwich structure, $[P_2Zn_4(H_2O)_2W_{18}O_{68}]^{10-}$.

a clear end point at a molar ratio of 1:1 for all compounds, which permitted a direct measurement of the interaction stoichiometry. Nonlinear least-squares fits of the data yielded apparent binding constants (K_{app}) of 3.0, 5.0, and $5.7 \times 10^6\,M^{-1}$ for the Keggin-, the Wells-Dawson-, and the sandwich-type POMs, respectively.

A number of heparin analogues that bind bFGF have various effects on the thermal stability of bFGF. Heparin and sucrose octasulfate, for example, enhance the stability of bFGF to thermal denaturation.[15] Conversely, sulfonated distamycin A derivatives destabilize the protein.[6] To determine the effect of POMs on the thermal stability of bFGF, we used temperature-dependent circular dichroism (CD) at various wavelengths to investigate the melting of the complex. Under the ionic-strength conditions described herein, bFGF alone has a thermal melting temperature (T_m) of 59 °C. Figure 2 shows that upon addition of POM at a molar ratio of 1:1, bFGF was stabilized by 9, 12, and 20 °C for the Keggin, Wells–Dawson and sandwich structures, respectively. The results of the CD experiments demonstrate that the conformation of bFGF underwent a dramatic change in the presence of POMs which manifests mainly in a decrease in the band intensity at 204 nm (Figure 3). In comparison, Wells–

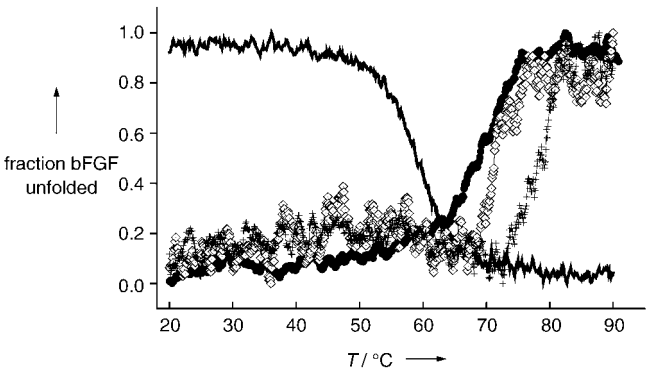

Figure 2. CD melting profiles of bFGF in the absence (——) and presence of Keggin (●), Wells–Dawson (◇), and Keggin-derived sandwich (+) compounds; POM/protein ratio = 1:1, and [bFGF] = 5 μM; solution conditions: NaCl (150 mM), PBS buffer (20 mM, pH 7.4); spectra were measured at $\lambda = 203$ or 229 nm and the temperature was raised in increments of 1 °C min^{-1} from 20 to 90 °C.

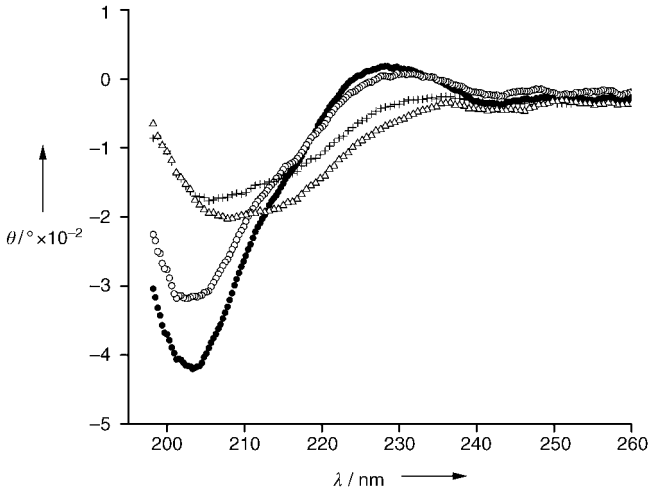

Figure 3. CD spectra of bFGF acquired at 20°C in the absence (●) and presence of Keggin (○), Wells–Dawson (△), and Keggin-derived sandwich (+) compounds. All experimental conditions and concentrations were the same as those described for Figure 2. The spectra were recorded as an average of three scans from 195 to 260 nm.

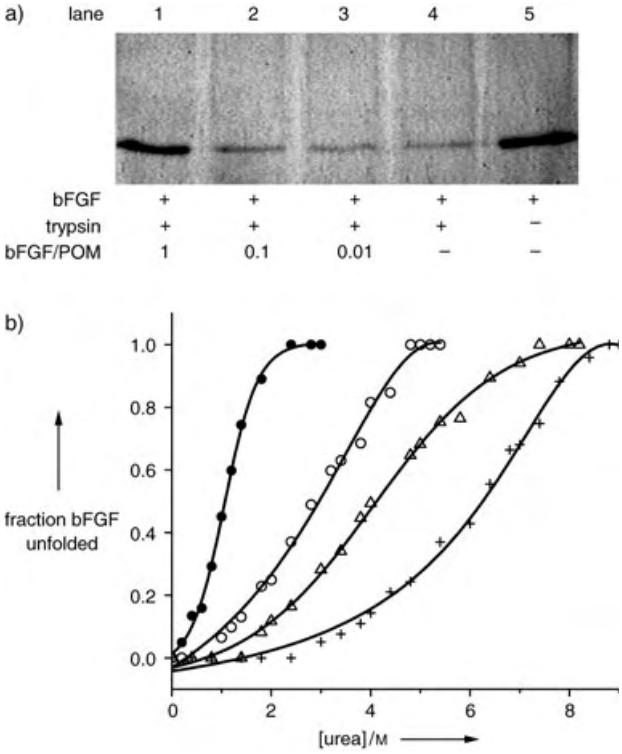

Figure 4. a) SDS-PAGE analysis of the effect of POMs on tryptic digests of bFGF: bFGF (10 μL, 4.8 μM) was incubated at 37°C for 3 h with trypsin (1 μg in 1 μL of 0.1 N HCl) in the absence or presence of increasing concentrations of the Keggin-type POMs. At the end of the reaction, all samples were supplemented with SDS-PAGE reducing sample buffer, heated at 100°C for 2 min, and subjected to SDS-PAGE (15%), after which the gels were stained with Coomassie blue. b) Fluorescence profiles of urea-induced bFGF denaturation in the absence (●) and presence of equimolar Keggin (○), Wells–Dawson (+), and Keggin-derived sandwich (△) compounds. All samples were incubated at 4°C for 48–72 h prior to analysis to ensure equilibrium had been established. The fluorescence data were collected at 20°C with a bFGF concentration of 1 μM and were presented as the fraction of unfolded bFGF. These experiments were performed in 100 mM PBS buffer, pH 7.0.

Dawson and sandwich-type POMs exerted a much more significant effect on bFGF with an approximate twofold loss in the CD signal and a marked red-shift of the minimum band. The direct interaction of POMs with bFGF was confirmed by their ability to protect bFGF from trypsin digestion; all compounds protected bFGF from protelytic cleavage. Figure 4a shows a digestion experiment with bFGF in the absence and presence of Keggin-type POMs. This protective effect was dose-dependent, and complete inhibition was observed at molar ratio of 1:1. Similar observations have been reported for the interaction of bFGF with heparin and its analogues.[16] To our knowledge, this is the first example of an enzyme or protein stabilized by a POM compound.

The binding of POMs to bFGF induced conformational changes, affected the whole structure of the protein, and had a stabilizing effect relative to free protein; all this was further verified by the effect of POMs on urea-mediated denaturation of bFGF. In the absence of POMs, the midpoint of urea-induced unfolding was observed at a urea concentration of 1.0 M (Figure 4b). Upon the addition of POMs at a molar ratio of 1:1, the unfolding transition of bFGF shifted to notably higher urea concentrations. The large shift in the transition midpoint suggests that POMs bind tightly to bFGF, which strongly supports the binding studies and thermal denaturation experiments discussed above. It should be noted that the degree of POM-based stabilization is highly dependent on the structure of the POM compound employed. The fluorescence titration, CD, and thermal unfolding studies demonstrated the varied effects of the different POM structures.

It was reported that the ability of heparin and its analogues to stabilize aFGF (acidic fibroblast growth factor) against denaturation in urea was diminished if the number of charges on these compounds was decreased.[17] In contrast to this trend, the Wells–Dawson-type POM has fewer charges than the sandwich-type POM, but exhibited the strongest stabilization of bFGF against urea-mediated unfolding. Previous studies have shown that the size, charge, and composition of POMs may all be interrelated in the inhibition of viral absorption/fusion and the inhibition of viral polymerase activity in a cell- or kinetics-based assay.[18] Modeling studies of POMs with HIV-1 P and HIV-1 RT determined that POMs exhibit reasonable steric fits in the substrate binding sites of these enzymes.[12,13]

Our results support these previous reports, and suggest that the structure of POMs might play a key role in the recognition and binding to bFGF. The POM compound $K_8ZnNiW_{11}O_{39}$ was generated through substitution of the central Si atom of the Keggin structure with Zn. It maintains the size of the smaller Keggin-type POM, but contains the same number of charges as the Wells–Dawson structure. Thermal denaturation and CD conformation studies indicate that it elicits similar effects upon the binding of bFGF as does the Keggin structure (data not shown). Whereas the exact mode of binding is not yet clear, the potential structure

relevance is unambiguous. One issue that needs to be addressed is the stability of the Keggin and Wells–Dawson anions in dilute aqueous solution. Although it is not easy to quantify the stability of these compounds experimentally, an approximate calculation can be made.[19] At the most commonly used concentration of 5 μM employed for the experiments reported herein, the Keggin anion remains intact, and the Wells–Dawson structure could experience a Ni cation loss of ≈30%. Both anionic compounds could lose a certain amount of the Ni cation upon further dilution. As a consequence, the lacunary anions might also react in a manner similar to that of the Ni derivatives. Further studies are therefore required to elucidate this point as well as the structural basis for the molecular recognition of bFGF by the compounds discussed herein, but these issues are beyond the scope of this brief communication.

The identification of the specific bFGF binding site of POMs is essential for the understanding of their biological function. Unlike heparin and its analogues, POMs are fairly rigid, cagelike structures coated with oxygen atoms bearing partial negative charges; the binding modes of POMs may therefore be different from the organic polyanions. For example, the Hill and co-workers recently demonstrated that POMs function not by binding to the active site of HIV-1 P, but by binding to a cationic pocket of lysine residues on the outer surface of the flaps that cover the active site.[13] This led us to explore the binding site of POMs on bFGF; the cationic heparin-binding cleft of bFGF was decided as a good candidate target site.[20] Competition assays were first used to verify that the putative POM binding site on bFGF is at or near the cationic pocket of the previously described heparin-binding site. The fluorescent polyanion suramin, a polysulfonated naphthylurea compound, is a common chaotropic agent. It is known to inhibit a large number of important enzymes[21] and to block the activity of several growth factors, one of which is bFGF.[22] A comprehensive analysis of the interaction of suramin with the growth factor has shown that suramin caused nonspecific and irreversible protein aggregation with a stoichiometry that depends on drug concentration. Furthermore, suramin was found to bind at or near the heparin binding site of bFGF, and the fluorescence intensity was strongly enhanced upon binding bFGF.[23] The addition of POMs to the bFGF–suramin complex resulted in a progressive decrease of suramin fluorescence intensity (Supporting Information), which suggests that POMs can displace the drug from the bFGF. This observation implies that both suramin and POMs compete for the same binding site.

We subsequently constructed the C78S–C96S double mutant of bFGF and studied its interaction with POMs. Fluorescence titration studies showed that POMs also form a 1:1 stoichiometric complex with the mutant bFGF with similar affinities. The apparent binding constants of the POM–mutant bFGF complexes were found to be three to fivefold less than the corresponding complexes with wild-type bFGF. At a 1:1 molar ratio, the POMs showed no effect on the thermal denaturation profiles of the mutant bFGF, except for a slight increase in T_m (2 °C) for the sandwich-type complex. Although the change of local microenvironment could not be ruled out with the substitution of cysteine by serine residues, the overall conformation of the mutant bFGF was identical to that of the wild-type as monitored by CD studies and X-ray crystallography.[6] CD data showed that the Wells–Dawson and sandwich structures caused a compatible conformational change of mutant bFGF, whereas the Keggin-type showed no effect (data not shown). These results indicate that the replacement of Cys 78 and Cys 96 considerably affects the interaction of the protein with POMs. Among the four cysteine residues in bFGF, Cys 34 is completely buried and Cys 101 is partly buried within the folded peptide chain. Only Cys 78 and Cys 96 can be modified by thiolation or carboxymethylation.[13,24] Under nondenaturing conditions with the 5,5′-dithiobis(2-nitrobenzoic acid) (DTNB) method,[25] direct thiol titration studies revealed two free SH groups in the absence of POMs, and one free SH group in the presence of POMs, which indicates that POMs bind near one of the two, and subsequently prevent the protein from the thiol-mediated disulfide exchange reaction with the DTNB reagent. Cysteines 78 and 96 are located on opposing surfaces of the protein, and Cys 96 is known to be in the vicinity of the cationic pocket of the heparin binding site.[6,20] The competition study, the cysteine mutation data, and the thiol titration studies all strongly suggest that POMs bind in the vicinity of the heparin binding region of bFGF, whereas the exact binding site awaits high-resolution structural analysis of bFGF–POM complexes.

The design of synthetic molecules that can bind to a protein and block biologically important protein–protein interactions remains a major challenge. The results of the experiments described herein have identified a new structural family of bFGF-binding ligands. The unique structure of POMs may play a key role in the recognition and binding to the protein. The development of POMs as selective FGF binders may be limited, as many derivatives have little or no hydrolytic stability at physiologically relevant pH values and some POMs exhibit toxicity. However, the versatility of the POM compounds render them attractive, because many of the properties that dictate their utility, including elemental composition, structure, charge density, redox potential, acidity, and solubility can be controlled synthetically to varying degrees. Furthermore, a number of new POMs with hydrolytic stability at physiologically relevant pH values have been synthesized recently, and the toxicity problems exhibited by some POMs are considerably smaller or nonexistent in the second generation of POM-based chemotherapeutic agents. The data reported herein show promise for the development of new types of selective binders of fibroblast growth factors. Although we have just begun to address the issue of antiangiogenic activity, preliminary studies of POMs have shown an inhibition effect similar to that caused by heparin; further investigations of these points are currently underway.

Sapphyrins

A Benzodipyrrole-Derived Sapphyrin**

*Pradeepta K Panda, Young-Jin Kang, and Chang-Hee Lee**

The discovery of expanded porphyrins has broadened the scope of porphyrin-related research. Since the first report of expanded porphyrins, namely a pentapyrrolic aromatic macrocycle referred to as sapphyrin,[1] various other oligopyrrole macrocycles including pentaphyrins, hexaphyrins, and rubyrins have been synthesized and characterized.[2] However, sapphyrins remain among the best studied of all the expanded porphyrins. For instance, they have been studied as hosts for anions[3,4] and as potential photosensitizers for photodynamic therapy,[5] and owing to their unique electronic features, which are exhibited in their narrow absorption bands, sapphyrins have also attracted interest as possible nonlinear optical materials. The synthesis and anion-binding properties of sapphyrins have been reviewed recently.[6] The most common synthesis of sapphyrins is the so-called 3+2 approach reported by Broadhurst et al.,[1] and this approach has successfully been employed to obtain a range of alkyl- and *meso*-substituted sapphyrins.[7–12] A less common but equally attractive approach is the so-called 4+1 approach, which relies on the use of a tetrapyrrolic precursor and formylpyrroles.[8,13,14] Despite these and other efforts, there has apparently been no report of a sapphyrin that imposes intrinsic conformational restriction on its pentapyrrolic core. In this light, we report here the synthesis and spectroscopic properties of what we believe is the first benzodipyrrole-derived sapphyrin system, **1**. As the corresponding benzo-extended sapphyrins[15] were found to exhibit red-shifted absorption bands, it was considered likely that the use of a benzodipyrrole unit such as **3** would provide another means of fine-tuning the electronic properties of sapphyrins.

Sapphyrin **1** was synthesized through a typical 3+2 condensation from the key precursors, diformylbenzodipyrrole derivative **5** and tripyrromethane dicarboxylic acid **6**. As shown in Scheme 1, 3,6-diformylbenzodipyyrole **3** was

Scheme 1. Synthesis of sapphyrin **1**. DMF = *N*,*N*-dimethylformamide, TsOH = *p*-toluenesulfonic acid.

obtained by a Vilsmeier–Haack reaction of benzodipyrrole (**2**),[16] which upon reduction with $LiAlH_4$ yielded 3,6-dimethylbenzodipyrrole (**4**). A further Vilsmeier–Haack reaction of this intermediate afforded the required dialdehyde **5** in 72% yield. Tripyrromethane dicarboxylic acid **6** was synthesized easily according to a reported procedure.[17] Acid-catalyzed condensation of benzodipyrrole derivative **5** and tripyrromethane dicarboxylic acid **6** followed by air oxidation provided the desired fused sapphyrin **1** in 18% yield. A higher yield was expected as a result of the conformational restriction imposed by the fused dipyrrole moiety, but the isolated yield of **1** was rather low. Intermediate **5** proved to be less reactive than simple dipyrroles, and this lack of reactivity is thought to account, in part, for the low isolated yield of the sapphyrin product.[18] Sapphyrin **1** was characterized by standard spectroscopic methods, as well as single-crystal X-ray diffraction studies. The salt $\mathbf{1}\cdot 2H^+2OTs$ (OTs = *p*-

$CH_3C_6H_4SO_3^-$ (tosylate)) was easily obtained by shaking a solution of **1** in dichloromethane with aqueous *p*-toluenesulfonic acid.

The ^{1}H NMR spectrum of the free-base sapphyrin **1** revealed three broadened signals at $\delta = -0.87$, -1.30, and -2.46 ppm for the inner NH protons which indicates that inner NH protons reside unsymmetrically as shown in Scheme 1. On the other hand, the ditosylate salt **1**·2 H$^+$2 OTs showed distinctive resonances at $\delta = -3.65$, -3.78, and -4.79 ppm, with a respective ratio of integration of 2:1:2, which indicates C_{2v} symmetry for the diprotonated salt. The signals for the aromatic protons of *p*-toluenesulfonic acid appear as broad singlets at $\delta = 5.44$ and 2.59 ppm and indicate a strong diamagnetic influence from the sapphyrin.

Diffraction-grade crystals of **1**·2 H$^+$2 OTs were obtained by the slow diffusion of hexane into a solution of the salt in chloroform. X-ray crystal structure analysis revealed the presence of one molecule of chloroform in the unit cell[19] and also showed that the oxygen atoms on one of the tosylate groups (upper) were disordered. As shown in Figure 1, the two oxygen atoms on the upper tosylate group are bound to three pyrrolic NH groups, with O–N distances of 2.830 (O1–N2), 2.932 (O1–N3), and 2.962 Å (O2–N5), while only a single oxygen atom (O1′) from the lower tosylate group is bound to the three NH groups at N1, N2, and N4 with respective O–N distances of 2.881, 2.927, and 2.838 Å. Presumably as a result of these interactions with the anions and possible steric congestion between the five inner N–H groups, the pyrrole ring that bears N5 is tilted upward relative to the mean plane of the macrocycle. This behavior is most unusual for a β-alkyl-substituted sapphyrin.

The pyrrole–tosylate N–O distances range from 2.838 to 2.962 Å and are well within the range expected for effective hydrogen-bonding interactions. Further analysis of the 3D packing structure indicated that two tosylate groups are located between two sapphyrin molecules. The two tosylate anions lie slip-stacked one above the other in an antiparallel manner with the sulfonate groups pointing outwards to minimize electronic repulsion between them (see Figure 2). The distance between the uppermost hydrogen atom (H50) of the methyl group of the lower tosylate group and carbon atom C49 at the 4-position of the benzene ring in the upper tosylate is 2.941 Å.

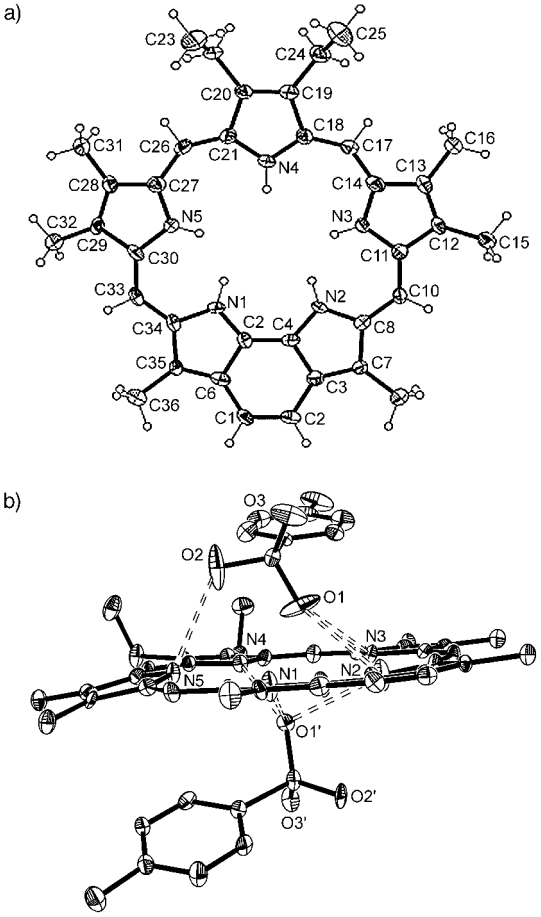

Figure 1. ORTEP views of the sapphyrin di-*p*-toluenesulfonic acid salt, **1**·2 H$^+$2 OTs$^-$. a) Top view with the tosylate groups omitted for clarity, and b) side view showing the unsymmetrical nature of the hydrogen-bonding interactions between the two anions and the protonated macrocycle.

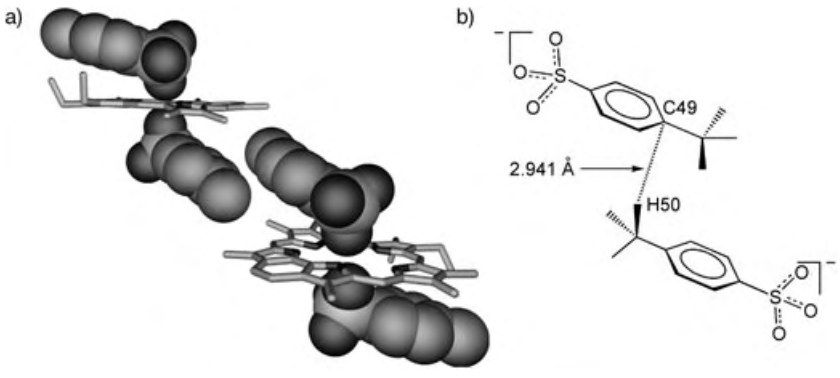

Figure 2. a) Arrangement of two diprotonated sapphyrin molecules (stick representations; C light gray, N dark gray) and their respective tosylate anions (space-filling representation; sulfonate oxygen atoms are shaded darker than S and C atoms) within the crystal structure. b) The two tosylate anions located between the two sapphyrins are packed antiparallel, with a distance of 2.941 Å separating atom C49 (*C*–C) of one OTs moiety and H50 (tolyl H_2C–*H*) of the other.

The absorption spectra of free-base **1** and its ditosylate salt **1**·2 H$^+$2 OTs are shown in Figure 3. Sapphyrin **1** shows a Soret-like band at 466 nm, whereas the Soret-like band is slightly red-shifted and appears at 469 nm in the salt **1**·2 H$^+$2 OTs. The bands are also red-shifted relative to the values of 457 and 456 nm reported for decaalkylsapphyrin and its diprotonated form, respectively.[20] The strongest absorbing Q-band in free-base form **1** appears at 727 nm, whereas for the salt **1**·2 H$^+$2 OTs the major Q-band at 703 nm is accompanied by a weaker band at 748 nm. The Q-bands are also significantly red-shifted relative to those of decaalkylsapphyrin.[14a] The Q-bands for **1** and its diprotonated salt are relatively less intense than those for other diprotonated

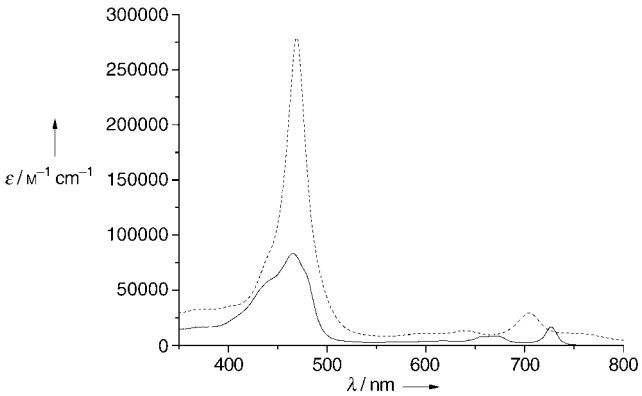

Figure 3. UV/Vis spectra of sapphyrin **1** (——; 1.99×10^{-5} M in $CHCl_3$ with 1% Et_3N) and **1**·2 H^+2 OTs^- (-----; 6.79×10^{-5} M in $CHCl_3$).

sapphyrin species. The absorption spectrum of the dichloride salt of **1**, which was obtained by Sessler's method,[18,20] was compared directly with the spectra of some benzo-extended sapphyrins.[15] From the results obtained (data not shown), it appears that incorporation of the benzene ring directly into the sapphyrin, as in **1**, has a stronger effect on the electronic properties of the molecule than in benzo-extended analogues by extension of the overall π-electron conjugation (aromaticity) through the use of the diene part of the fused benzene unit.

In conclusion, we have introduced a new member to the family of extended porphyrins, a pyrrole-fused sapphyrin. The diprotonated benzodipyrrole-bridged sapphyrin **1** is slightly buckled presumably from a combination of conformational restriction about the fused benzodipyrrole moiety and through steric interactions between the five inner amine groups. Currently, we are exploring further extensions of this theme, for instance, by targeting the replacement of the dipyrrole moiety with other aromatic and heteroaromatic subunits.

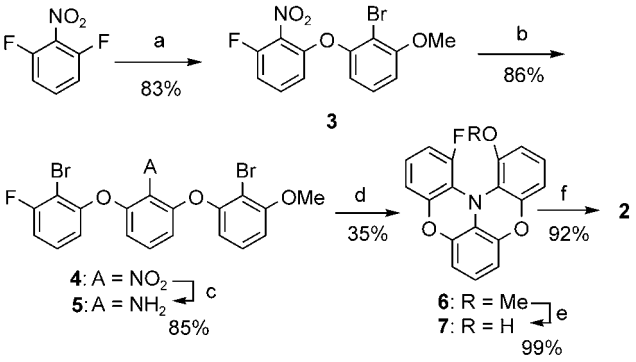
Heterocyclic Chemistry

2,2′:6′,2″:6″,6-Trioxytriphenylamine: Synthesis and Properties of the Radical Cation and Neutral Species**



*Masato Kuratsu, Masatoshi Kozaki, and Keiji Okada**

A planar stable triphenylamine radical cation is a fascinating π-electron system that is potentially applicable to electronic and magnetic materials. Hellwinkel and co-workers synthesized an interesting compound **1**,[1] from which the radical cation **1**$^{\bullet+}$ was generated in concentrated sulfuric acid[1a] or by oxidation with lead tetraacetate in trifluoroacetic acid.[1c] The triphenylamine framework of **1**$^{\bullet+}$ is most likely planar. The dimethylmethylene bridges contribute to its stabilization; however, they disrupt the CT-type intermolecular interaction that is crucial for the construction of electronic and magnetic materials. To overcome this disadvantage and to improve stability, we designed a synthetic route to the new oxygen-bridged analogue **2**.[2,3] Quite recently, Livant and co-workers described a product fraction showing a molecular ion of $m/z =$ 287 in the thermolysis of tris(2,6-dimethoxyphenyl)amine. They assumed the structure **2** for the MS peak. However, the compound showed no NMR spectroscopic signal.[4] Herein, we report the preparation, structures, and properties of the neutral **2** and the radical cation **2**$^{\bullet+}$.

1 **2**

The synthesis of **2** is outlined in Scheme 1. Sequential aromatic nucleophilic substitution reactions of 2,6-difluoronitrobenzene with 2-bromo-3-methoxyphenolate and then with 2-bromo-3-fluorophenolate gave **4** (71% yield in two steps). The reduction of **4** proceeded selectively in the presence of *p*-bromophenol (10 equiv) to avoid a competing reduction of aromatic bromide. Intramolecular cyclization of **5** was performed under Pd^0-mediated cross-coupling reaction conditions[5] to afford **6** in 35% yield. Treatment of **6** with BBr_3 gave **7** in good yield. Intramolecular nucleophilic

Scheme 1. Reaction conditions: a) 2-bromo-3-methoxyphenol, NaH/DMSO, 130°C; b) 2-bromo-3-fluorophenol, NaH/DMSO, 130°C; c) hydrazine hydrate, Pd/C, *p*-bromophenol/ethanol, reflux; d) NaO*t*Bu, [Pd(dba)$_2$], P(*t*Bu)$_3$/toluene, reflux; e) BBr_3/CH_2Cl_2, −78°C→room temperature; f) K_2CO_3/DMF, room temperature. dba = *trans*,*trans*-dibenzylideneacetone.

substitution of **7** in DMF with K_2CO_3 as a base proceeded efficiently under remarkably mild conditions to give the desired compound **2** in good yield. Compound **2** had a reversible oxidation wave at +0.59 V versus SCE in DMF (SCE = saturated calomel electrode). The chemical oxidation of **2** was performed by using tris(*p*-bromophenyl)aminium hexafluorophosphate as an oxidant in methylene chloride. The salt **2**$^{\bullet+}\cdot PF_6^-$ can be recrystallized from acetonitrile/diethyl ether.

Figure 1 shows the molecular structures determined by X-ray crystallographic analysis of **2** and **2**$^{\bullet+}$.[6] The neutral compound **2** has a shallow bowl structure, whereas the radical

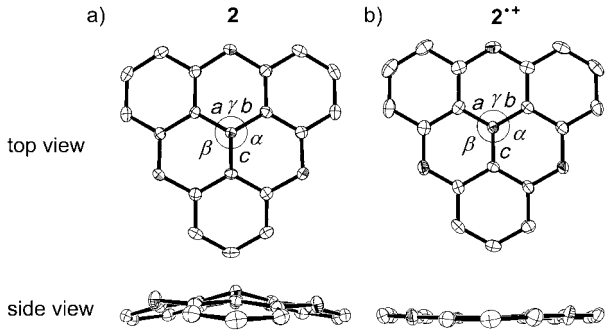


Figure 1. Molecular structures of **2** and **2**$^{\bullet+}$ drawn at 50% ellipsoid level; hydrogen atoms are removed for clarity. Selected bond lengths [Å] and angles [°]. a) For **2** measured at 123 K: $a = 1.408(2)$, $b = 1.403(3)$, $c = 1.412(3)$; $\alpha = 115.3(2)$, $\beta = 115.6(2)$, $\gamma = 115.7(2)$. b) For **2**$^{\bullet+}$ measured at 113 K: $a = 1.376(3)$, $b = 1.377(3)$, $c = 1.378(3)$; $\alpha = 120.1(2)$, $\beta = 119.9(2)$, $\gamma = 120.0(2)$.

cation **2**$^{\bullet+}$ has a planar structure. The C–N bond lengths become shorter and the C-N-C bond angles approach 120° in the radical cation **2**$^{\bullet+}$. The bond-length difference is in qualitative accordance with the HOMO shape of **2**; that is, the C–N and C–O bonds have an antibonding nature in the HOMO.

Triphenylamine radical cations without *para* substituents are generally unstable because of the large spin densities of

the *para* positions.[7] For $\mathbf{2}^{\bullet+}$, neither dimerization tendency in the crystal structure nor oxygenation under aerated conditions in solution was observed. The spin delocalization in a whole molecule involving the oxygen atoms (phenoxazine radical cation structure) contributes to the stability of $\mathbf{2}^{\bullet+}$. The radical cation $\mathbf{2}^{\bullet+}$ exhibited a well-resolved EPR spectrum. The hyperfine coupling constants for $\mathbf{2}^{\bullet+}$ ($g = 2.0031$, $a_N = 0.90$, $a_{H_p} = 0.26$, and $a_{H_m} = 0.06$ mT) in butyronitrile at room temperature were slightly smaller than those for $\mathbf{1}^{\bullet+}$ ($g = 2.0027$, $a_N = 0.95$, $a_{H_p} = 0.30$, and $a_{H_m} = 0.07$ mT).[1c] The smaller spin density values for $\mathbf{2}^{\bullet+}$ are clearly related to the positive spin density of the oxygen atoms. The calculated spin-density map and values are shown in Figure 2.[8]

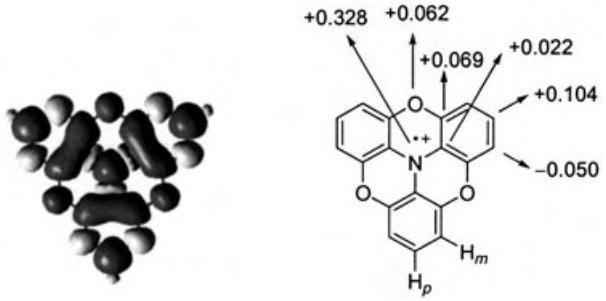

Figure 2. The spin-density map (black: positive spin, white: negative spin) and values (UB3LYP/6-31G*) for $\mathbf{2}^{\bullet+}$.

The radical cation $\mathbf{2}^{\bullet+}$ had broad absorptions in the visible region ($\lambda = 709$ and 785 nm, Figure 3). These absorptions can be related to the electronic transitions from the occupied

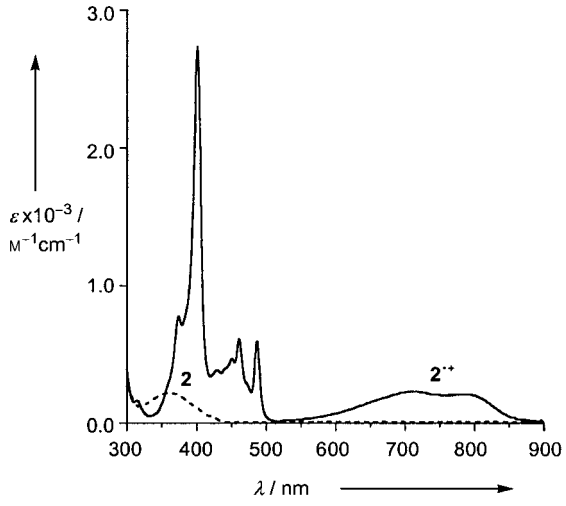

Figure 3. UV/Vis absorptions of **2** (-----) and $\mathbf{2}^{\bullet+}$ (——) in dichloromethane.

MOs delocalized on the outer electron-rich trioxytris(1,3-phenylene) moieties to the delocalized unoccupied orbital involving the nitrogen cation. The theoretical calculation (TD-DFT/6-31G*) roughly reproduced this situation ($\lambda_{calcd} = 729$ nm as a degenerate transition with the main contribution ($\approx 90\,\%$) of HOMO-1(β), HOMO(β)→LUMO(β) (oscillator strength of 0.01 in both cases); Figure 4).[8,9] The observed absorptions with a rather broad slope in the region of 500–700 nm can be attributed to vibrational fine structure of the degenerate band. The peak separation of 1370 cm^{-1} is close to that observed for the 10-phenylphenoxazine radical cation (1270 cm^{-1}).

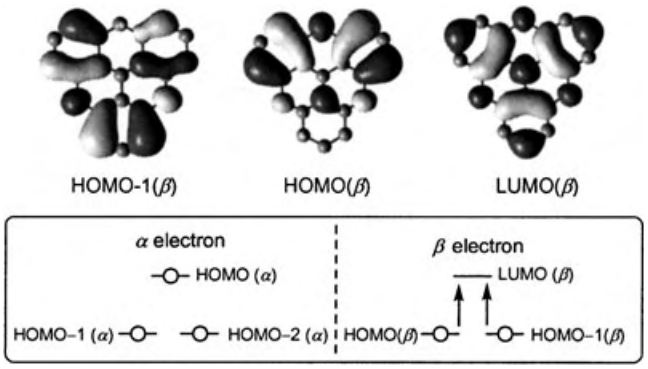

Figure 4. MOs and the energy diagram (UHF) of $\mathbf{2}^{\bullet+}$.

These studies clearly establish that 1) the neutral compound **2** is a good electron donor with a shallow bowl structure and 2) the radical cation $\mathbf{2}^{\bullet+}$ is a highly stable planar species. Moreover, the neutral compound **2** can form stable CT complexes with several electron acceptors, suggesting applicability to electronic and magnetic materials. We are particularly interested in forthcoming projects to follow up this work. The introduction of stable radicals at the *para* positions followed by the formation of CT complexes with electron acceptors would provide a magnetic CT-salt material.[10] Furthermore, the small geometrical change between the neutral and radical cation states may allow photostimulated phase transition to the photoconductive state $\mathbf{2}_2^{\bullet+}$.[11] The preparation of such materials is in progress.

Experimental Section

The synthesis of compounds **2**–**7** and the EPR spectrum for $\mathbf{2}^{\bullet+}$ with its simulation are described in the Supporting Information.

$\mathbf{2}^{\bullet+}\cdot PF_6^-$: Compound **2** (25.0 mg, 0.0870 mmol) was dissolved in dichloromethane (20 mL). A solution of tris(*p*-bromophenyl)aminium hexafluorophosphate (54.8 mg, 0.0874 mmol in CH_2Cl_2 (10 mL)) was added dropwise at room temperature with stirring in a glove box. After 30 min, the solvent was evaporated under vacuum and the crude product was recrystallized from acetonitrile/diethyl ether to give $\mathbf{2}^{\bullet+}$ as deep green plates (29.4 mg, 78 %); m.p. $\approx 278.0\,^{\circ}C$ (decomp). MS: *m*/*z* (%): FAB^+ (*m*-NBA) 287 (100) [$C_{18}H_9NO_3^+$], FAB^- (*m*-NBA) 145 (100) [PF_6^-]. Elemental analysis calcd (%) for $\mathbf{2}^{\bullet+}\cdot PF_6^-$ ($C_{18}H_9F_6NO_3P$): C 50.02, H 2.10, N 3.24; found: C 50.12, H 2.00, N 3.21.

Tumor Imaging Agents

A Labeled Neutral Endopeptidase Inhibitor as a Potential Tool for Tumor Diagnosis and Prognosis**

Olivier Raguin, Marie-Claude Fournié-Zaluski, Anthony Romieu, André Pèlegrin, François Chatelet, Didier Pélaprat, Jacques Barbet, Bernard P. Roques, and Anne Gruaz-Guyon**

Scintigraphy with labeled somatostatin analogues and positron-emission tomography (PET) with ^{18}F-labeled 2-deoxy-2-fluoro-D-glucose (^{18}F-FDG) have greatly improved the diagnosis and staging of numerous tumors with somatostatin-receptor-subtype overexpression or active glucose metabolism, respectively. This entailed the development of numerous radiolabeled peptides that target other receptors overexpressed by tumors that do not accumulate somatostatin analogues or ^{18}F-FDG.[1,2] Proteolytic enzymes expressed on many cancer cells are also potential targets for radiopharmaceuticals. Recently ^{18}F- or ^{11}C-labeled inhibitors of metalloproteinase-2 (MMP-2), which is expressed in a variety of malignant tumors, have been proposed for use in PET.[3,4]

Neutral endopeptidase (NEP, CD10, CALLA, enkephalinase, neprylisin, EC 3.4.24.11) is a membrane-bound zinc metallopeptidase that interrupts cell signaling by degradation

of numerous physiologically active peptides.[5,6] NEP is expressed in a large variety of tissues including the brain, kidney, and lung,[7] but it is also overexpressed in various types of hematological tumors, particularly acute lymphoblastic leukemia[8] and some lymphomas, as well as in solid tumors such as melanoma,[9] colonic, pancreatic, and prostatic adenocarcinomas.[10] Presence, or absence, of NEP expression has been proposed as a prognostic indicator, depending on the tumor type.[11–17] In addition, lack of NEP expression in a prostatic carcinoma may predict decreased androgen sensitivity and a poorer response to hormonal deprivation therapy.[18,19] A noninvasive scintigraphic technique imaging tumor-cell accumulation of a labeled NEP inhibitor could be an interesting diagnosis and/or prognosis tool.

Structure–activity relationship studies of NEP inhibitors,[6] site-directed mutagenesis experiments,[6,20,21] and crystallographic studies of enzyme–inhibitor complexes further elucidated the interactions that stabilize substrates or inhibitors in the NEP active site. Potent inhibition of NEP is obtained with compounds containing a strong zinc ligand as a phosphinic group, a hydrophobic moiety interacting with the S'_1 subsite of the enzyme,[22] hydrogen-bonding donor and acceptor groups for binding with Asn542 and Arg717, and a carboxylate function for Arg102 recognition (Scheme 1).

Scheme 1. Model of NEP active-site recognition by the phosphinic inhibitors AR58 and AR60 proposed from the crystallographic data reported by Oefner et al.[24]

Based on these findings, we designed novel compounds with a biphenylmethyl group and an aspartic acid unit to interact with the S'_1 and S'_2 subsites, respectively, and a benzyl moiety bearing a phosphinyl group as zinc ligand (Scheme 1). A 6-aminohexanoic acid was introduced as a spacer and its carboxylate moiety was coupled to a dipeptide amide Tyr-Lys-NH_2, with the tyrosine residue allowing labeling with iodine isotopes. The chelating agent diethylenetriaminepentaacetic acid (DTPA) was introduced on the ε NH_2 group of the lysine to allow labeling with metal radioisotopes. The peptide part of the molecule was synthesized by solid-phase methods and the phosphinic moiety, prepared independently by liquid-phase synthesis, was incorporated onto the peptidyl resin by a classical coupling step (Scheme 2, see the Supporting Information).

Scheme 2. Synthesis of the NEP inhibitor AR58. a) Bis(trimethylsilyl)-acetamide, 70°C; b) BOP, DIEA, NMP, solid-phase peptide synthesis then cleavage from the MBHA resin and final deprotection of the side chains of the amino acid residues (*tert*-butyl ether: Tyr, *tert*-butyl ester: Asp, *N-tert*-butoxycarbonyl: Lys) by trifluoroacetic acid to form R^1 and the desired product. BOP = 1-benzotriazolyloxytris(dimethylamino)-phosphonium hexafluorophosphate, DIEA = diisopropylethylamine, NMP = *N*-methyl-pyrrolidone, MBHA = 4-methyl-benzhydrylamine.

As the phosphinic moiety was synthesized as a mixture of enantiomers, the inhibitor was obtained as a mixture of two stereoisomers, which were separated by C18 reversed-phase HPLC. The first eluted isomer exhibited the best inhibitory potency: AR58-1 had an inhibition constant of $K_i = (3.6 \pm 0.1) \times 10^{-8}$ M, versus $K_i = (6.7 \pm 0.4) \times 10^{-7}$ M for the second eluted isomer (AR58-2).

High specific activities were obtained by labeling the DTPA-substituted derivative of AR58-1, referred to as AR60, with ^{111}In ((191 ± 20) MBq nmol^{-1}). The AR60 equilibrium binding-affinity constant ($(1.1 \pm 0.1) \times 10^8$ M^{-1}) was determined by competition binding experiments (Figure 1) on a human Burkitt lymphoma cell line (Ramos cells), in which NEP expression was confirmed by fluorescence-activated cell sorter (FACS) analysis (see the Supporting Information). This result suggests that coupling to DTPA does not significantly lower affinity. The number of NEP binding sites per Ramos cell (2.6×10^4–5.7×10^4) was in the same range as that already determined from equilibrium binding experiments of ^{125}I-labeled anti-CD10 antibody (2.1×10^4–7.5×10^4).[23]

A significant specific binding of ^{111}In-labeled AR60 to tissues of the kidneys (mainly the cortical zone), lungs, liver, and small intestine, but not of muscle, heart, stomach (not shown), and colon, was demonstrated by in vitro autoradiography studies (Figure 2), in agreement with NEP expression already described in these organs.[7] This labeled inhibitor

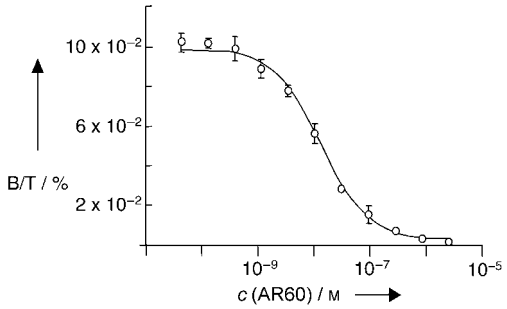

Figure 1. Typical competition binding curve between ^{111}In-labeled and unlabeled AR60. Trace amounts of ^{111}In-labeled AR60 were incubated with Ramos cells in the presence of increasing concentrations of AR60 saturated with nonradioactive indium. (The curve was generated by computer simulation with the Equilibrium Expert software.[25]) The fraction of radioactivity associated to the cells (bound/total (B/T) in %) was counted. The mean values from triplicate determinations are plotted. Bars give standard deviation values except those that were smaller than the points as plotted.

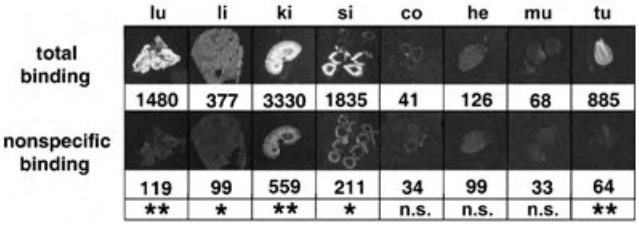

Figure 2. Autoradiogram of ^{111}In-AR60 binding to tissue sections (lu = lungs, li = liver, sp = spleen, ki = kidneys, si = small intestine, co = colon, he = heart, mu = muscle) from healthy BALB/c mice and intravenous grafts of Ramos cells to SCID mice (tu = tumor). Top: total binding. Bottom: nonspecific binding evaluated on adjacent sections in the presence of an excess (10^{-6} M) of AR58-1. Binding quantification, expressed in arbitrary activity units per surface unit, is indicated on each image. The Student t test was used to evaluate the significance of the results (*: statistical probability value $p < 0.05$; **: $p < 0.01$; n.s.: not significant).

bound specifically to sections of Ramos cell grafts to SCID mice.

We then investigated the in vivo biodistribution of ^{111}In-AR60 three and six hours after intravenous injection to healthy BALB/c mice (Figure 3). A fast blood clearance of ^{111}In-AR60 was observed, as assessed by the low residual blood radioactivity six hours after injection. Activity uptake was observed primarily in the kidneys and to a lesser extent in the lungs, liver, and colon. Since about 92% of the colon activity was associated with the stools, activity uptake in this organ was related to biliary excretion of ^{111}In-AR60. A low activity accumulation of < 1% of the injected dose per gram was observed in other organs six hours after injection. ^{111}In-AR60 stability in vivo was high since more than 70% was recovered intact in the serum 1 h after injection.

Coinjection of ^{111}In-AR60 (10 pmol) and a large excess of unlabeled Thiorphan (790 nmol), a specific NEP inhibitor, considerably reduced organ activity in the lungs, adrenal tissues, and kidneys, a result indicating uptake specificity in these organs (mean D values ± (standard error of the mean; s.e.m.) in the absence versus in the presence of thiorphan as

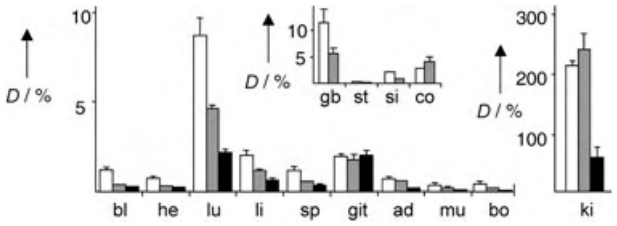

Figure 3. Biodistribution studies of ^{111}In-AR60 in healthy BALB/c mice. Mice were sacrificed, after an intravenous injection of only ^{111}In-AR60 (10 pmol in 150 μL of phosphate-buffered saline (PBS)) at 3 h (white bars) or 6 h (gray bars) or at 6 h in the presence of excess thiorphan (790 nmol, black bars). Tissue radioactivity is expressed as the percentage of injected dose per g of tissue (D, mean value ± standard error of the mean (s.e.m.), number of animals: 5 at 3 h, 4 at 6 h). Injected doses were corrected by subtraction of noninjected and subcutaneously injected material. Additional abbreviations to Figure 2: bl = blood, sp = spleen, git = gastrointestinal tract, ad = adrenal tissues, bo = bone, gb = gall bladder, st = stomach.

well as the p values: lungs: 4.60 ± 0.93 versus 2.17 ± 0.31, $p < 0.05$; adrenal tissues: 0.60 ± 0.08 versus 0.21 ± 0.03, $p < 0.01$; kidneys: 234 ± 56 versus 56 ± 33, $p < 0.01$;). Liver labeling was low and no significant difference was observed in the presence of thiorphan. These results are consistent with the rapid decrease of liver activity and the absence of gut activity through uptake of a tritiated NEP inhibitor, facts which suggest that several tissues are inaccessible to intravenously injected inhibitors thanks to the presence of functional barriers.[7]

^{111}In-AR60 uptake in tumors evaluated in SCID mice intravenously grafted with Ramos human Burkitt lymphoma cells was high ((10.3 ± 2.4) D, with a range of 21.8–3.5 D, 4.5 h after injection). Since in this model disseminated tumor-cell grafts occur in different organs, normal tissue uptakes were evaluated in healthy SCID mice. Tumor to normal tissue uptake ratios were high for the brain (144 ± 30, not shown), heart, stomach, blood, adrenal tissues, liver, spleen, and small intestine. Lower targeting contrasts were obtained for other organs, with values of around 3 for the colon, muscle, and bone, 1.4 ± 0.3 for the lungs, and 0.06 ± 0.01 for the kidneys (Figure 4).

Since the tumor to normal tissue uptake ratio is the key for isotopic tumor imaging, ^{111}In-AR60 should provide good contrast images except for tumors located on or near organs with high NEP expression, such as the kidneys and lungs. In

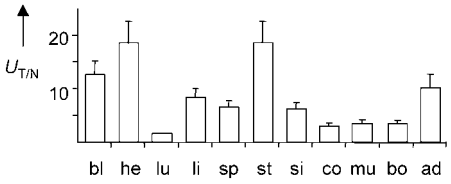

Figure 4. Tumor to normal tissue uptake ratios $U_{T/N}$ of ^{111}In-AR60 in SCID mice intravenously grafted with Ramos cells. Four animals were given ^{111}In-AR60 (10 pmol in 150 μL of PBS) by intravenous injection. Blood, organs, and tumor masses were collected and counted for radioactivity 4.5 h later. Tumor involvement of macroscopically suspect specimens was confirmed by histological analysis. Injected doses were corrected for losses as described in the legend to Figure 3. Since the graft is disseminated, results are expressed as the ratio between tumor uptake (10 samples) and mean organ uptake in nongrafted mice (mean value of $U_{T/N}$ ± (s.e.m.)).

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

some organs of tumor-bearing mice, with no macroscopic tumor involvement, activity uptake was greater than the mean uptake of corresponding organs of nongrafted mice. Histological analysis revealed tumor involvement in four of these samples, two brain samples with values of 0.78 and 0.57 *D* versus (0.07 ± 0.03) *D* in ungrafted mice and two adrenal tissue samples with values of 1.91 and 9.33 *D* versus (1.07 ± 0.39) *D* in ungrafted mice. These results further demonstrated the specificity of tumor uptake of ^{111}In-AR60.

In conclusion, the fast plasma clearance, the elevated tumor labeling, and the low nonspecific uptake of ^{111}In-labeled NEP ligand AR60 in normal organs provide high uptake ratios between tumor and normal organs except for the kidneys and lungs, which express high NEP levels. Noninvasive scintigraphic imaging of NEP expression with this compound may be a potential tool for the diagnosis and/or prognosis of different tumor types.

Drug Design

Polymer Therapeutics Designed for a Combination Therapy of Hormone-Dependent Cancer**

María J. Vicent, Francesca Greco, Robert I. Nicholson, Alison Paul, Peter C Griffiths, and Ruth Duncan**

Over the last decade, polymer therapeutics have emerged as first-generation nanomedicines.[1] The term polymer therapeutics was coined to include water-soluble polymers that are polymeric drugs,[2] hybrid polymer–drug[1,3] and polymer–protein conjugates,[4] polymeric micelles that contain cova-

lently bound drug,[5] and multicomponent polyplexes used as nonviral vectors[6] to deliver genes and proteins into the cytosolic compartment of the cell. Of particular relevance to this study are those polymer–drug conjugates now finding acceptance as a new class of antitumor agents.[1,3,6] Polymer conjugates have distinct advantages over conventional chemotherapy. These include 1) passive tumor targeting owing to the enhanced permeability and retention (EPR) effect, a phenomenon that arises from the hyperpermeability of angiogenic tumor blood vessels,[7] 2) lower toxicity of bound drug,[8] and 3) after cellular uptake by the endocytic route, the potential to bypass mechanisms of drug resistance, including p-glycoprotein-mediated multidrug resistance (MDR).[9] So far, only conjugates derived from polyethyleneglycol (PEG),[10] polyglutamic acid (PGA),[11] polysaccharides,[12] and *N*-(2-hydroxypropyl)methacrylamide (HPMA) copolymer conjugates[13] have progressed to clinical trials. The HPMA copolymer–doxorubicin (Dox) conjugate PK1 (also named FCE28068) was the first synthetic polymer conjugate to enter Phase I trials in 1994.[8] Since then, HPMA copolymer conjugates with established chemotherapy drugs (such as taxol, platinates, or camptothecins)[6,13] and two gamma-camera imaging agents derived from HPMA copolymer have also progressed to clinical testing. Conjugates are now being synthesized to contain experimental drugs[14] and drugs directed towards new therapeutic targets (e.g. antiangiogenic HPMA copolymer–TNP470[15]). Further developments in this field include chemotherapy with two-step polymer–drug combinations (e.g. polymer-directed enzyme prodrug therapy (PDEPT)[16]).

The aim of this study was to design a polymer conjugate that would for the first time combine endocrine therapy and chemotherapy with the hope of eliciting improved antitumor activity in breast cancer. Arrival of the selective oestrogen receptor antagonist tamoxifen led to a 28% reduction in mortality of breast cancer patients at 5 years.[17] Even so, the prognosis for patients with metastatic breast cancer is still poor, the survival rate at 5 years being $<20\%$. The mixed antagonist/agonist activity of tamoxifen and the acquired resistance that can develop over time limit its therapeutic potential.[18] To circumvent this problem, there has been growing interest in the use of aromatase inhibitors. They prevent estrogen biosynthesis by inhibiting P450 aromatase present in normal tissue and in breast-cancer cells of postmenopausal women (77% of the new cases of breast cancer diagnosed each year).[19] Recent clinical trials in these patients showed that the aromatase inhibitors letrozole and anastrozole were more effective in treating estrogen receptor positive breast cancer than tamoxifen.[20]

In our case, we hypothesized that the combination of endocrine therapy and chemotherapy by simultaneous attachment to the same polymer would bring significant advantages. The combination could be administered as a single dose; benefits would be the manufacture of a single conjugate and improved patient compliance. After EPR-mediated targeting, the arrival of both pendant drugs within the tumor cells at the same time is guaranteed. It also provides the opportunity to tailor polymer–drug linkers to impart different rates of drug release for each compound, thus allowing agents to act synergistically. As HPMA copolymer–Dox has already shown activity in chemotherapy refractory breast-cancer patients[8] and this polymer has proven clinical safety, HPMA was chosen as the polymeric carrier (**1** and **5**), and the anthracycline antibiotic Dox (**3**) (widely used as a first-line treatment for breast cancer) was selected as the model chemotherapeutic. The first-generation aromatase inhibitor, aminoglutethimide (AGM; **2**), was chosen as the endocrine model.

A library of conjugates **6**–**11** was synthesized to contain Dox, AGM, or both drugs attached to the same polymeric chain (Scheme 1, Table 1, Supporting Information). HPMA copolymer intermediates ($M_w \approx 20\,000$–$25\,000\ g\,mol^{-1}$; $M_w/M_n = 1.3$–1.5) were used that contained either the tetrapeptide linker Gly–Phe–Leu–Gly (known to be cleaved by lysosomal thiol-dependent protease cathepsin B to release Dox)[6,13] or a Gly–Gly linker (known to be nondegradable and as such to provide a reference control for biological experiments). First, conjugates were prepared by aminolysis of polymeric intermediates in which the C-terminus of the

ND = not determined.

peptide side-chains were esterified with *p*-nitrophenol.[21] The lower reactivity of the aromatic amine of AGM, however, favored the use of DCC-mediated coupling. The improved yield of conjugation was particularly noticeable when AGM was bound to the polymeric precursor containing pendant side chains (10 mol%) (Table 1). FTIR and NMR spectroscopy confirmed the identity of the product, and NOE measurements verified the covalent binding of AGM (see Supporting Information). These observations were consistent with previous NOESY and TOCSY experiments, which established the structure of HPMA copolymer–Dox.[22]

Accurate characterization of the bioactive content of any polymer–drug conjugate destined for biological or clinical testing is essential. It is well known that the extinction coefficient of a bound drug can change significantly upon conjugation.[23] In this instance, measurement of the total and free Dox was straightforward, and a validated HPLC method was used.[24] For example, the Dox content of conjugate **9′** was 7.2% w/w (free Dox < 0.8% w/w total drug) (Table 1). The AGM content was more difficult to determine. Values were obtained either by UV/Vis spectroscopy with an *N*-Gly-AGM (**13**) derivative as standard or by an indirect HPLC method established to quantify residual AGM left after reaction (Table 1 and Supporting Information). Overall, the AGM content of the conjugates was in the range 3.1–10.4% w/w (free AGM content < 1.2% w/w total AGM) and in conjugate **9′** it was 5.4% w/w (Table 1). The molecular weight of the conjugates was in the range $M_w \approx 25\,000$–$30\,000\ g\,mol^{-1}$.

It has been postulated that polymer–drug conjugates exist in solution as unimolecular micelles and that conformation is influenced by drug loading. At present, however, there is almost no direct physical evidence to support this hypothesis.[25] We have recently demonstrated the value of small-angle neutron scattering (SANS) in providing insight into the solution conformation of polymer therapeutics, particularly in relation to the pH-triggered conformational change of endosomolytic polymers.[26] SANS was used in this case for the first time to define conjugate structure in solution (Table 1 and Supporting Information). The Gaussian coil model for polymer conformation showed the best fit to the raw scattering data. Whereas HPMA copolymer–GFLG–Dox (**10**) and HPMA copolymer–GFLG–AGM (5 mol%) (**6′**) conjugates prepared from the same polymeric intermediate had similar Rg (radius of gyration) values (7.7 and 7.9 nm, respectively; truly nano-sized medicines), an increase in the side-chain content to 10 mol% led to an increase in Rg to 16.5 nm for the AGM conjugate **7′**, but only to 12.5 nm for the Dox conjugate (**11**). Interestingly the HPMA copolymer–GFLG–AGM–Dox conjugate **9′** also displayed an Rg value of 12.8 nm. This might be explained by the tendency of Dox to display π–π stacking, thus leading to the formation of more-compact unimolecular micelles. It is clear that polymer–drug conjugate conformation is affected by both the drug loading and chemical nature of the drug.

Effective functioning of polymer–drug conjugates relies on 1) the stability of the polymer–drug linker in the circulatory system and, after arrival in the tumor tissue and cellular uptake by endocytosis, 2) lysosomal enzyme cleavage of the linker to release the active drug. All the HPMA copolymer conjugates were completely stable in buffer alone, as was the HPMA copolymer–GG–AGM (**8′**) in the presence of isolated rat liver lysosomal enzymes (Figure 1c and Supporting Information). However, in the presence of lysosomal enzymes, Dox and AGM were released from conjugates containing the Gly–Phe–Leu–Gly linker. The drug-release profile displayed marked differences depending on conjugate composition. For conjugates **10** and **11**, Dox release began immediately after addition of enzyme (Figure 1b) and was linear with time; it was apparent that the lower the Dox loading (cf. **10** and **11**) the greater the drug release after 5 h (see Supporting Information). This is in agreement with the solution conformation predicted by SANS (Table 1). Enzyme accessibility would be limited by a more compact coil structure. AGM release (conjugates **6** and **7**) also showed dependence on drug loading with a lower initial release for the highest loading (**7**) (Figure 1a). After 30 min, however, AGM liberation from **7** accelerated and release from **6** started to plateau (see supplementary information for comparison at 5 h).

When incubated with lysosomal enzymes, the conjugate containing both AGM and Dox as the combination (**9′**)

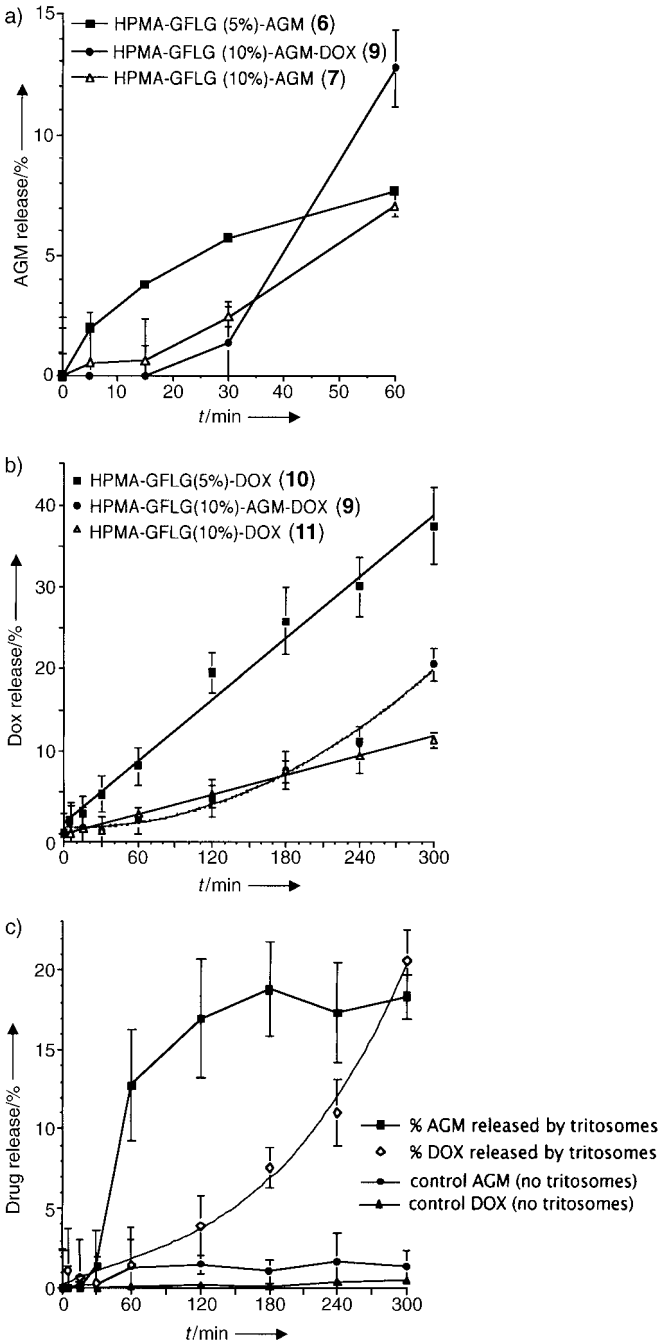

Figure 1. Liberation of Dox or AGM from HPMA copolymer conjugates during incubation with rat liver lysosomal enzymes (tritosomes). Release of a) AGM, b) Dox, and c) Dox and AGM from the HPMA copolymer–GFLG–AGM–Dox conjugate (**9′**). In all cases, drug release is expressed as a percentage of the total drug bound, and data represent the mean ± SEM ($n=4$). In specific cases, the release of drug in the absence of enzymes (control) is also shown.

displayed different profiles of drug liberation (Figure 1c) in comparison with that seen for the single-drug-pendant conjugates (at both 5 and 10 mol % loading). Both Dox and AGM release show a marked lag phase with little release over the first 30 min. However, after this time, AGM release was enhanced relative to **6** and **7**, and the Dox release rate was initially slower but then returned to that seen for **10**. The dynamic and complex geometry of this unimolecular micelle structure determines enzyme access leading to these complex release kinetics. To investigate how the release profile would translate into cytotoxicity, a human estrogen-dependent breast-cancer cell line MCF-7 and the aromatase-transfected derivative MCF-7ca were used (Figure 2 and Supporting Information). As expected, as a result of its slow rate of cellular uptake by endocytosis and the relatively prolonged duration needed for drug liberation, HPMA copolymer–GFLG–Dox (**10**) was much less active than free Dox (**3**). For example, their IC_{50} values against the MCF-7 cell line were >150 μM and 0.74 μM Dox-equivalents, respectively. Neither the HPMA copolymer–GFLG–AGM (**6′**), nor individual mixtures of drug conjugates bearing AGM (**6′**) or Dox (**10**) caused an elevation in cytotoxicity in either cell line MCF-7 or MCF-7ca (see Supporting Information).

In contrast, when AGM and DOX were covalently linked to the same polymeric backbone, that is, in conjugate **9′**, the in vitro cytotoxicity was significantly greater than seen for **10**, **3**, or **6′** against MCF-7 cells. The enhanced cytotoxicity of **9′** was even more evident for the aromatase expressing MCF-7ca cells (see Figure 2 and Supporting Information). The IC_{50} values obtained for MCF-7ca cells incubated with **3**, **6′**, or **9′** were 5238 μM, >1377 μM, and 40.9 μM AGM-equivalents, respectively. Conjugate **9′** displayed approximately tenfold enhancement in cytoxicity in the aromatase cell line, irrespective of whether the data are expressed in terms of Dox- or AGM-equivalents Although it is necessary to understand the precise molecular mechanism of action of these novel conjugates better, it has been reported that aromatase inhibitors can also promote apoptosis, so they may potentiate Dox cytotoxicity in this way.[19]

To conclude, the HPMA copolymer–GFLG–AGM–Dox conjugate (**9**) is the first polymer therapeutic to combine chemotherapy and endocrine therapy. The fact that AGM and Dox can act synergistically to produced markedly enhanced cytotoxicity in vitro relative to that of the HPMA copolymer–GFLG–Dox conjugate (**10**) (PK1), which has already shown activity in breast-cancer patients clinically, underlines the potential importance of this polymer–drug combination. It should be emphasized that mixtures of polymer conjugates containing only AGM or only Dox did not show synergistic benefit. The studies reported confirm cellular uptake of conjugate by endocytosis (verified by flow cytometry as shown in Figure 2b and in the Supporting Information), and also demonstrate the requirement of lysosomal thiol-dependent protease degradation of the polymer–drug linker to liberate drug and thus promote cytotoxicity. All the components (HPMA copolymers, Dox and AGM) are well established clinically, so further preclinical studies are warranted to establish the antitumor potential of this novel anticancer strategy in vivo. The observation that HPMA copolymer conjugates displayed lower hemolytic activity (10 % release at 1 h; $p<0.001$) than Dox (**3**) (92 % hemoglobin release at 1 h) (see Supporting Information) establishes the suitability for intravenous administration. Tailoring of the linker structure and drug loading within this novel nano-sized medicine (Rg in solution of 12.8 nm) may further optimize the drug-release

Supported Catalysts

A Collaborative Effect between Gold and a Support Induces the Selective Oxidation of Alcohols**

Alberto Abad, Patricia Concepción, Avelino Corma, and Hermenegildo García*

The selective oxidation of alcohols is one of the most challenging reactions in green chemistry.[1–4] An ideal green oxidation process should involve a highly active and selective recyclable catalyst that is able to work at atmospheric pressure in the presence of oxygen and the absence of solvents and bases.[5] Stoichiometric oxidations using transition metal compounds or sulfoxides (Swern oxidation) are still commonly used, despite the formation of a large amount of undesirable products. Several homogeneous Pd-, Cu-, or Ru-based catalysts are able to perform the selective oxidation of alcohols, but they require the use of organic solvents or high oxygen pressure.[6–11]

From the point of view of heterogeneous catalysis, probably the best system has been reported recently by Kaneda et al.,[12] where a palladium-containing apatite is able to oxidize alcohols at atmospheric oxygen pressure even in the absence of solvents. Mizuno et al.[13,14] have described a ruthenium-containing solid catalyst that is able to selectively produce carbonyl compounds from alcohols in the presence of oxygen at atmospheric pressure. Other solid catalysts based on hydrotalcites,[15] apatites and mixed oxides,[16] or supported Pt and Pd[17,18] have also been studied.

Small-crystal-size gold supported on inorganic oxides or active carbon has recently attracted considerable attention since these catalysts are able to promote the selective oxidation of alcohols.[19–25] Taking into account that inorganic oxides contain some sites that are able to oxidize alcohols stoichiometrically, it appeared to us that a new concept of catalyst could be put forward if these stoichiometric sites can be converted into catalytic sites by introducing a solid co-catalyst that facilitates the reoxidation of the intermediate metal hydrides to water and the original inorganic oxide. To prove this concept we selected cerium oxide, which contains stoichiometric oxidation sites of alcohols, and cationic gold, which is a metal that transfers hydrides reversibly.

In particular, the combination[26] of small-crystal-size gold (2–5 nm) and nanocrystalline ceria ($\approx$5 nm) turned out to give a highly active, selective, and recyclable catalyst for the oxidation of alcohols into aldehydes and ketones with high turnover numbers (TON) and frequencies (TOF) using oxygen at atmospheric pressure as oxidant in the absence of solvent and base.

Pure, nanocrystalline cerium oxide contains sites that are able to perform the oxidation of alcohols in a stoichiometric manner. Indeed, when IR experiments were carried out in situ by adsorbing 2-propanol on nanocrystalline cerium oxide (see Supporting Information), two IR bands associated with cerium alkoxide appeared; the growth of a band attributable to cerium hydride, was also observed. The appearance of a carbonyl band indicates that acetone was formed at the same time as the cerium hydride. Upon subsequent introduction of O_2 into the IR cell at room temperature, the band due to cerium hydride remained unaltered and the formation of water was not observed. These experiments show that cerium oxide alone is able to perform one reaction cycle, but the reduced cerium is stable in the presence of physisorbed O_2 and the catalytic cycle is not closed.

When gold nanoparticles were deposited onto the nanocrystalline cerium oxide (see Supporting Information for the detailed preparation procedure), the XPS spectrum of the Au 4f7/2 core level shows three bands (see Supporting Information), which correspond to Au^{3+}, Au^{+}, and Au^{0}.[27] The presence of cationic gold was also confirmed by the IR band of adsorbed CO (see Supporting Information).[28] These results can be rationalized by assuming that the gold nanoparticles formed on the $Au\subset CeO_2$ catalyst (see HRTEM images in the Supporting Information) interact with the nanometric ceria surface, which stabilizes the positive oxidation states of gold[26,29,30] by creating Ce^{3+} and oxygen-deficient sites in the ceria.

When the anaerobic oxidation of 2-propanol on $Au\subset CeO_2$ was monitored in situ by IR spectroscopy (see Supporting Information) in the same way as with pure nanocrystalline CeO_2, the IR bands of the cerium alkoxide

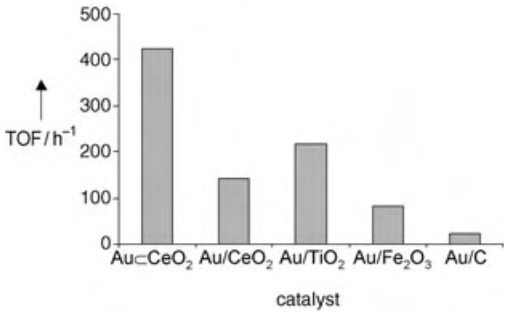
and hydride were again observed, and acetone was also formed. However, when O_2 was subsequently introduced the metal hydride disappeared and water was formed, contrary to what occurred with CeO_2. At this point the cerium oxide is therefore ready to perform another catalytic cycle.

After these spectroscopic studies, Au⊂CeO_2 was tested as a solid catalyst for the selective aerobic oxidation of a large variety of alcohols. The reactions were performed in a magnetically stirred, glass batch reactor in the absence of solvent and base at 80 °C, with O_2 at atmospheric pressure. In other cases the oxidations were also performed in basic water (see Supporting Information for experimental details). High conversions and selectivities were obtained with short reaction times (Table 1).

The benefit of using nanoparticles of CeO_2 as a support for the gold becomes obvious when comparing the activity (TOF) of Au⊂CeO_2 with the activities of Au supported on conventional CeO_2 (Au/CeO_2), Au/carbon (Au/C) (see Supporting Information for experimental details of the preparation), Au/TiO_2, and Au/Fe_2O_3 (these two last catalysts were supplied by the International Gold Council; Figure 1).[31] Note that Au⊂CeO_2 is active for the oxidation of alcohols in the absence of solvent and base, conditions under which most other supported gold catalysts are inefficient.[5] For instance, Au/C does not catalyze oxidation reactions in the absence of base and water.

Secondary alcohols can be oxidized with essentially complete conversion and high selectivities on Au⊂CeO_2 in the absence of solvent, and benzylic or allylic alcohols are selectively oxidized to the corresponding unsaturated aldehydes, although longer reaction times are required. Aliphatic primary alcohols are more reluctant to undergo oxidation in the absence of solvent. Notably, they give predominantly the corresponding ester with high selectivity, accompanied by lesser amounts of the aldehyde. We have found that esters are directly formed via the hemiacetal, which is detectable by ^{1}H NMR spectroscopy,



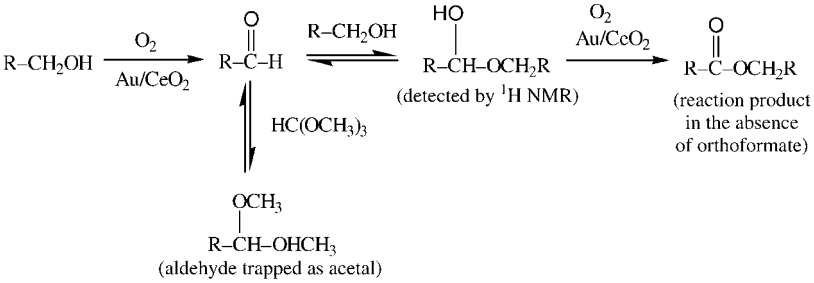


Figure 1. Turnover frequencies for the oxidation of 3-octanol, given as the ratio of moles of 3-octanone per mole of Au per hour, measured at $t = 10$ min (see Table 1 for reaction conditions).

as indicated in Scheme 1. Indeed, we have seen that the introduction of trimethyl orthoformate, which acts as a scavenger for aldehydes, into the reaction mixture gives the dimethyl acetal of the aldehyde with very high selectivity and completely inhibits the formation of the ester. Note that Au⊂CeO_2 is also very active for the oxidation of alcohols in basic aqueous solution. In this case pH plays an important role, with the TOF decreasing upon lowering the pH. In basic aqueous solution, the oxidation of primary alcohols gives the carboxylic acids rather than the esters.

Scheme 1. Reaction route proposed for the formation of esters in the oxidation of primary alcohols.

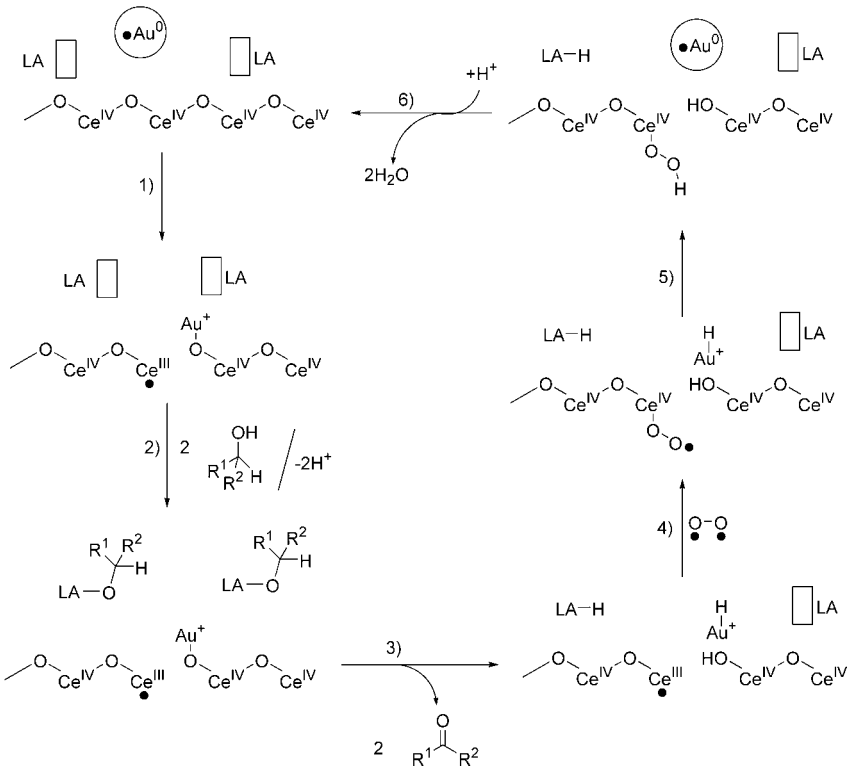

Table 1: Aerobic alcohol oxidation catalyzed by Au⊂CeO_2.[a]

Entry	Substrate	t [h]	Conversion [%]	Product	Selectivity [%]

On the basis of the Au⊂CeO_2 characterization and IR study, a reasonable mechanism for the catalytic reaction is depicted in Scheme 2. According to this mechanism, the interaction between gold and ceria will give rise to an important population of positively charged gold and Ce^{3+} species (detectable by XPS; step 1). The alcohol or the corresponding alkoxide will then react with the Lewis acid sites of Au⊂CeO_2 to give a metal alkoxide (step 2), which subsequently undergoes a rapid hydride transfer from C–H to Ce^{3+} and Au^+ to give the ketone and Ce–H (indicated as LA–H in Scheme 2) and Au–H (as observed by IR spectroscopy; step 3). Upon admission of oxygen into the system and coordination to the oxygen-deficient sites of ceria, formation of cerium-coordinated superoxide (Ce–OO•) species occurs (step 4).[32] These superoxide species evolve into cerium hydroperoxide by hydrogen abstraction from Au–H (step 5), and are responsible for the formation, after reduction of Ce^{IV}, of the initial Au^+ species. The absence of gold would render this step impossible and lead to a depletion of Ce^{III}. This mechanism is compatible with the lack of influence of an excess of TEMPO in the reaction (see footnote [e] in Table 1), since TEMPO is not able to quench oxygen-centered radicals.

Scheme 2. Proposed mechanism for the oxidation of alcohols in the presence of Au⊂CeO_2 as the catalyst. LA = Lewis acid.

Kaneda et al. have reported recently that Pd supported on hydroxyapatite is the most active solid catalyst, with a turnover number of 236000 and a TOF of 9800 h^{-1}.[12] We have been able to reproduce these results. Under the reported conditions our catalyst gives a TOF of 12500 h^{-1} for the conversion of 1-phenylethanol into acetophenone at 160 °C, with greater than 99 % selectivity for the desired product. The catalyst is fully recyclable after filtering and washing (NaOH 0.5 M), with a TON of 250000 after three recycles. This shows that gold, which was previously believed to be of little catalytic interest, can become an interesting oxidation catalyst when combined with the right support.

In conclusion, we have shown that gold nanoparticles transform nanocrystalline cerium oxide from a stoichiometric oxidant into a catalytic material for the selective oxidation of primary and secondary alcohols to aldehydes and ketones in the presence of oxygen at atmospheric pressure, with high TOFs and selectivities observed. This catalyst makes the process interesting from both an economic and environmental point of view.

Spin Crossover

One Shot Laser Pulse Induced Reversible Spin Transition in the Spin-Crossover Complex $[Fe(C_4H_4N_2)\{Pt(CN)_4\}]$ at Room Temperature**

*Sébastien Bonhommeau, Gábor Molnár, Ana Galet, Antoine Zwick, José-Antonio Real, John J. McGarvey, and Azzedine Bousseksou**

The use of light is one of the most promising ways to reversibly control various physical properties of organic and metal-organic compounds and opens up the possibility for the generation of new information storage devices.[1,2] Among these materials, iron(II) spin-crossover complexes are particularly interesting as they are known to exhibit a light-induced low-spin (LS) to high-spin (HS) transition.[3] However, this light-induced excited spin state trapping (LIESST) phenomenon is only efficient at cryogenic temperatures (typically below 50 K) because at higher temperatures the photo-induced HS state relaxes rapidly to the ground state. This is a serious limitation for the development of optical switches based on spin-crossover materials.

A possible approach to overcome this problem consists of working within the thermal hysteresis loop, in which the metastable HS or LS states have "infinite" lifetimes.[4] Such hysteresis phenomena have been found in many spin-crossover solids and can be related to long-range elastic interactions between the spin-state-changing molecules.[5] It should be emphasized that the hysteresis loop can be fine-tuned by chemical methods to situate it around room temperature.[6] The first light-induced LS→HS transition in the hysteresis region was recently observed by means of optical reflectivity when an 8-ns laser pulse was applied at 170 K to $[Fe(pm\text{-}bia)_2(NCS)_2]$ (pm-bia = *N*-2′-pyridylmethylene-4-aminobiphenyl), but the reverse phenomenon could not be detected.[2a] Herein, we report spectroscopic evidence for a bi-directional, light-induced spin transition at room temperature in $[Fe(pyrazine)\{Pt(CN)_4\}]$ (Figure 1) by applying a one-shot laser pulse of irradiation.

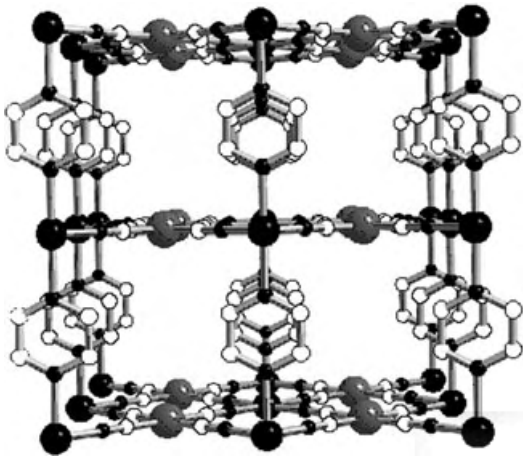

Figure 1. Schematic structure of $[Fe(pyrazine)\{Pt(CN)_4\}]$.

The synthesis of a hydrated form of the above-mentioned compound has been reported elsewhere.[7] Subsequent research has demonstrated that the spin-crossover behavior of this hydrated form ($[Fe(pyrazine)\{Pt(CN)_4\}]\cdot n H_2O$; $n \approx 2$–3) depends dramatically on the water content. Thermogravimetric analysis revealed that heating the sample at 420 K for 30 minutes is necessary to remove the water of crystallization. The dehydrated form $[Fe(pyrazine)\{Pt(CN)_4\}]$ exhibits "improved" spin-crossover behavior in that the transition becomes complete and is centered at room temperature. Moreover, the hysteresis loop becomes wider, square-shaped, and reproducible over several cycles. This compound preserves its spin state (HS or LS) for several months if it is kept in a dry atmosphere at room temperature (295 K).

Figure 2 shows the temperature dependence of the $\chi_M T$ value (χ_M is the molar magnetic susceptibility) for

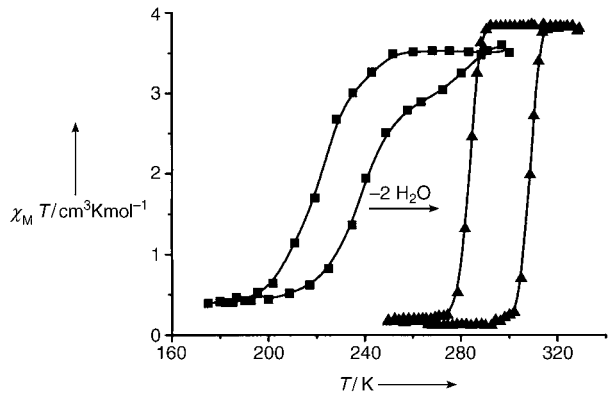

Figure 2. Graph of $\chi_M T$ versus T for [Fe(pyrazine){Pt(CN)$_4$}] in the cooling and heating modes before and after thermal treatment at 430 K.

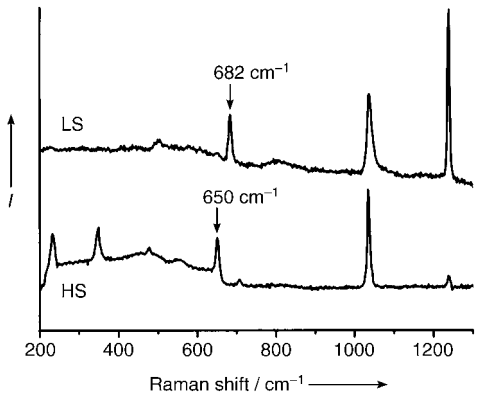

Figure 3. Raman spectra of [Fe(pyrazine){Pt(CN)$_4$}] in the HS and the LS states recorded in the 200–1300 cm^{-1} frequency range at 295 K and 265 K, respectively. Selected Raman marker bands are shown at 650 cm^{-1} (HS) and 682 cm^{-1} (LS). The intensity I on the y axis is given in arbitrary units.

[Fe(pyrazine){Pt(CN)$_4$}] before and after heating to 430 K. This figure demonstrates the dramatic improvement in the spin-crossover characteristics following the thermal dehydration treatment described earlier. The value of $\chi_M T$ for the dehydrated form at 330 K is 3.81 cm^3 K mol^{-1}; this value is consistent with the iron(II) ion being in the HS state ($S = 2$). Upon cooling the sample, the value of $\chi_M T$ remains constant down to about 292 K but then undergoes a sharp decrease that is characteristic of a first-order spin transition. The $\chi_M T$ value drops to 0.16 cm^3 K mol^{-1} at around 270 K, thus indicating that the spin transition is virtually complete. The heating mode reveals the occurrence of a thermal hysteresis with a hysteresis loop that is 24 K wide. The change in the spin state was also confirmed by Mössbauer spectroscopy. The Mössbauer spectrum recorded at 300 K (in the cooling mode) consists of a single doublet with quadrupole splitting (1.159(5) mm s^{-1}) and isomer shift (1.047(3) mm s^{-1}) values typical of Fe^{II} ions in the HS state. A new doublet appears at 80 K with smaller quadrupole splitting (0.306(4) mm s^{-1}) and lower isomer shift (0.439(2) mm s^{-1}) values, as expected for the LS state ($S = 0$) of Fe^{II} ions. The change in the spin state is also accompanied by a marked color change: pale orange for the HS state and deep red for the LS state.

Raman spectra of [Fe(pyrazine){Pt(CN)$_4$}] in the pure HS and LS states were recorded between 200 and 1300 cm^{-1} (Figure 3). In agreement with our previous observations on this family of complexes,[8] the Raman spectra are markedly different, which is in line with the change in the spin state, and several "marker bands" can be chosen to follow the spin transition. For example, peaks around 349 and 233 cm^{-1} (assigned to Pt-CN bending and Fe-N stretching modes, respectively) are associated with the HS state and the feature at 1238 cm^{-1} exhibits a significant increase in intensity in going from the HS to the LS state. However, the most relevant "marker band" near 650 cm^{-1}, previously assigned to an in-plane bending mode of the pyrazine ring,[8] is fairly intense in both spin states and exhibits a well-resolved frequency shift from 650 cm^{-1} (HS) to 682 cm^{-1} (LS).

A pulsed Nd:YAG laser enables the application of 8 ns pulses ($\lambda = 532$ nm) with pulse energies of about 1 mJ at the sample (spot size = 0.4 mm^2) in the ascending and descending branches of the hysteresis loop. Figure 4 exhibits the proportion of HS iron(II) ions before and after the one-shot laser pulse irradiation, as evaluated from the intensities of the Raman peaks. Raman spectra recorded in the 620–720 cm^{-1} frequency range before and after the application of the pulses are also presented in the insets of Figure 4. These spectra, as well as the color change observed just after excitation with light, prove clearly that a single laser pulse ensures both a LS→HS and a HS→LS transition, depending on the position in the hysteresis loop. Thermal effects arising from laser irradiation (either pump or probe beams) must be carefully checked for these light-induced changes to be fully interpreted. In any case, however, laser heating can induce only the LS→HS transition. Therefore, the observed light-induced HS→LS transition proves irrefutably that a simple heating effect cannot play any role here.

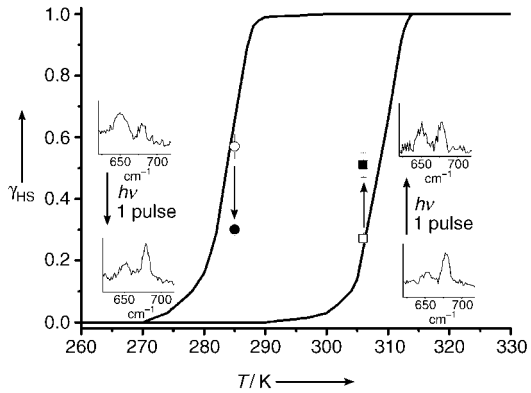

Figure 4. Proportion of HS iron(II) ions before and after a one-shot laser pulse of irradiation on the ascending and descending branches of the hysteresis loop of [Fe(pyrazine){Pt(CN)$_4$}]. The insets show the Raman spectra recorded before and after irradiation.

The observed change in the spin state appears to be incomplete: only around 20% of the iron ions are apparently converted from one state to the other in the single-pulse experiment. However, the absorption spectra of the compound indicate that the penetration depths of the pump laser (532 nm) and the probe laser (785 nm) are rather different.[9]

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

In fact, the latter probes a volume that is larger than that irradiated by the green pulse. In other words, the ratio of the Raman peak intensities underestimates the real photoconversion efficiency and can therefore be used only to confirm the change in the spin state and to compare the relative efficiency of the laser pulses as a function of the number of pulses, pulse energy, etc. It should be noted that we could not obtain any useful Raman spectra using a green (514.5 nm) continuous wave laser because of laser heating effects.

A one-shot excitation triggers at least a partial spin conversion. We have therefore studied the effect of applying additional laser pulses and found that while the second pulse increases the spin conversion (to ca. 40% HS), subsequent pulses do not have any measurable additional effect on the HS/LS ratio. The conversion efficiency was also studied at different points around the wide hysteresis loop of [Fe(pyrazine){Pt(CN)$_4$}] which correspond to distinct stability regions for the LS and the HS states (Figure 5). The HS state

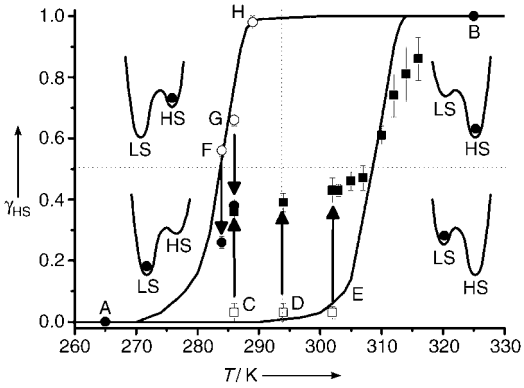

Figure 5. Proportion of HS iron(II) ions before and after irradiation with 10 laser pulses on points A–H of the hysteresis loop of [Fe(pyrazine){Pt(CN)$_4$}]. Points obtained by heating following irradiation at point E are also presented. Schematic diagrams of the free energy with minima corresponding to the LS and HS states at the respective temperatures are drawn in each part of the graph delimited by the two dotted lines. The intensity *I* on the *y* axis is given in arbitrary units.

is the ground state at high temperatures (point B) while the LS state becomes the stable form at low temperatures (points A and C). At points E and D (F, G, and H) the system is in the metastable LS (HS) state. Raman spectra were collected at each point before and after the application of 10 successive laser pulses. The Raman signals at points C, D, and E (Figure 6, points C, D, and E) for the irradiated region clearly demonstrate the appearance of the HS state following the pulsed irradiation, while at points F and G (Figure 6, points F and G) the fraction of the LS state increases. In contrast, we could not observe any irradiation effects at points A, B, and H (Figure 6, point H). As far as points A and B are concerned, this observation is clearly related to the fact that they are situated outside the hysteresis region. On the other hand, the absence of any effect at point H is probably related to the lower optical density of the HS state (relative to the LS form)[10] and the different energy barriers (compared to points F and G).

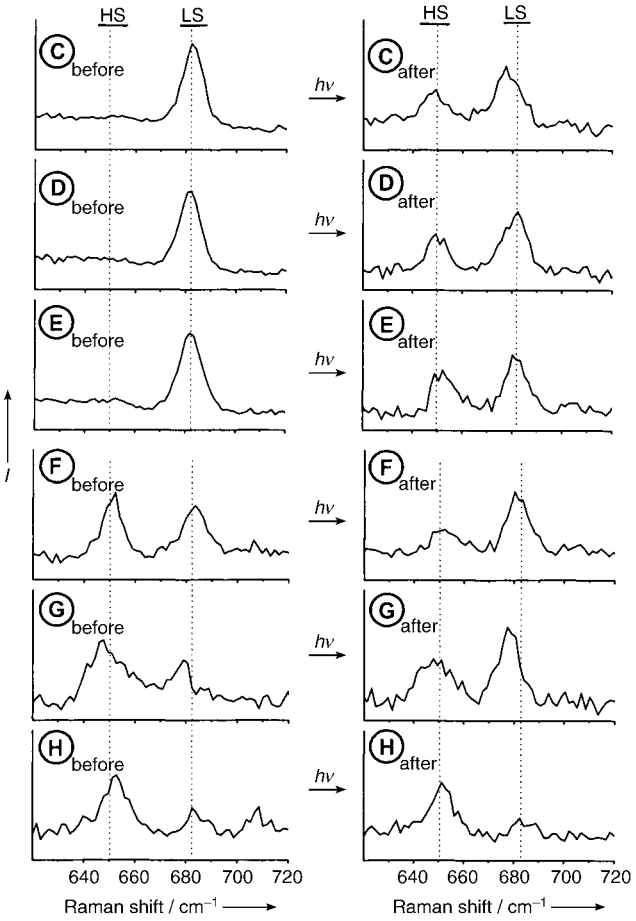

Figure 6. Selected Raman spectra of [Fe(pyrazine){Pt(CN)$_4$}] at points C–H on the hysteresis loop. These Raman spectra were recorded before and after 10 successive laser pulses.

The HS fractions, evaluated before and after an irradiation sequence of 10 pulses, are shown in Figure 5. First of all it should be noted that—within the experimental limits of accuracy—the same final state (ca. 40% HS) was reached from points C, D, and E, thus also confirming the absence of significant heating effects in the LS→HS transition. It appears also that the HS→LS transition can be obtained only in the descending branch (from an initial HS fraction of 0.7) of the hysteresis, which is in contrast with the findings for the LS→HS transition which was observed even in the stability domain for the LS state (point C). Figure 5 also shows data obtained by heating the sample following irradiation at point E. The photoinduced fraction of the HS state does not change within the hysteresis loop. With further heating it follows a similar evolution to that determined by magnetic measurements. This result reveals also that the intensities of the Raman peaks give a fairly reasonable approximation for the HS fraction in the zone irradiated by the laser pulses.

In considering the mechanism of the observed pulsed-laser-induced change in the spin state, we refer to the general concept of photoinduced phase transitions.[1a,b] The phase transition between the two spin states cannot occur thermally in the hysteresis region, because of the existence of a free

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

energy barrier. However, photoexcitation may induce local transformation of the microscopic state of the system. The photoexcited species relaxes rapidly to the initial state when there is a weak excitation density. On the other hand, if the photoexcitation density exceeds a threshold it can lead to the formation of a nucleus of the second phase, which is stabilized by the lattice distortions accompanying the change in the spin state. Such photoinduced phase transitions are always cooperative and highly nonlinear phenomena, because the efficiency is not simply proportional to the total absorbed energy, and a threshold effect on the light intensity exists.

An interesting feature of the photoswitching phenomena observed in [Fe(pyrazine){Pt(CN)$_4$}] is that both the LS→HS and the HS→LS transitions can be triggered by the same irradiation wavelength. Such an unusual effect has also been reported by Liu et al.[2c] for a Prussian blue analogue. These authors took the observation as evidence for the so-called "domino effect": namely that the generation of a small amount of HS (LS) excited species in the LS (HS) lattice initiates the complete transformation of this latter into the second phase. We believe, however, that the effect can be explained more readily by the simple fact that the optical absorption bands of the HS and LS forms overlap at 532 nm. Since the color of the sample is very different in the two spin states, one can anticipate that there exists an excitation photon energy, which induces the LS→HS or the HS→LS transition selectively in this compound.

In conclusion, we have demonstrated by a spectroscopic method that a bi-directional, photoinduced spin transition can be brought about when applying a nanosecond laser pulse to [Fe(pyrazine){Pt(CN)$_4$}]. This phenomenon can be interpreted as a photoinduced structural-phase transformation. Since this transition occurs around room temperature over a wide range of bistability and involves magnetization and color changes as well, it opens up interesting perspectives for applications in memory devices and optical switches. A more detailed study of the dependence of the photoconversion efficiency on the excitation wavelength and pulse energy, as well as a dynamic study, are, however, necessary to find the optimal working conditions as well as to probe more thoroughly the physical mechanisms involved.

Experimental Section

Variable-temperature magnetic susceptibility measurements were carried out between 300 and 1.8 K on the polycrystalline sample (20 mg) using a Quantum Design MPMS2 SQUID magnetometer operated at 0.5 T. The magnetometer was calibrated with $(NH_4)_2Mn(SO_4)_2{\cdot}12H_2O$. Experimental susceptibilities were corrected for diamagnetism of the constituent atoms by the use of Pascal's constants.

A Spectra Physics Nd/YAG, model GCR3, pulsed laser operating at 532 nm was used to irradiate the polycrystalline sample with pulses of 8 ns duration. CW Raman spectra were collected from the irradiated region in a backscattering geometry before and after applying the laser pulse. Raman scattering was excited at 785 nm by means of a Ti-sapphire laser (Spectra Physics, model 3900S) pumped by an Ar^+ laser (Spectra Physics, model 2060A). The Rayleigh scattering was removed by a holographic notch filter and Raman spectra were recorded with a thermoelectrically cooled CCD detector (Andor Technology, Model DV430-FI) coupled to a Jobin–Yvon spectrograph (model HR640) equipped with a grating containing 300 grooves per mm. The spectral resolution at a slit width of 100 μm was around 7 cm^{-1}. Raman spectra were recorded between 200 and 1300 cm^{-1} with acquisition times of about 3 min. A cylindrical lens was inserted in the beam pathway to reduce the incident power density of the pump and probe beams, which traversed the same optical path close to the sample. CW beam power at the sample was then fixed at 5 mW on a spot size of about 0.4 mm^2, while the energy of each laser pulse on the sample was 1 mJ at the same spot. Under these conditions the experiments could be repeated many times on the same sample without degrading it. The sample temperature was controlled using a Linkam THMS600 liquid-nitrogen cryostage.

[9] Unfortunately, we were unable to grow crystals to carry out optical density measurements and therefore the penetration depths could not be determined precisely. In practice, the "Raman sampling depth" and the "photoexcitation depth" should be compared. The latter depends not only on the absorption coefficient of the sample, but also on many other parameters such as the threshold photoexcitation density for the phase transition, while the former is determined by the collection optics, in addition to the sample's own optical properties (for example, diffuse scattering). Any quantitative analysis would be feasible only for a very thin film of the sample. To obtain an approximate idea at least of the beam penetration at different wavelengths we have carried out diffuse reflectance measurements on the HS and LS states at 295 K using an integration sphere and a teflon reference sample. These show that the optical density of the LS state at 532 nm is about twice

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

that in the HS state, while at 785 nm it is 2 times (6 times) smaller than at 532 nm for the HS (LS) state.

[10] The key quantity here is the excitation photon density but its calculation requires the assumption that the total photon flux of the 532 nm pulse is absorbed uniformly within the sample. For our relatively thick and diffuse scattering samples this assumption would be invalid.

Electron Transfer in Peptides

Multistep Electron Transfer in Oligopeptides: Direct Observation of Radical Cation Intermediates**

Bernd Giese, Matthias Napp, Olivier Jacques, Hassen Boudebous, Alexander M. Taylor, and Jakob Wirz*

For the transport of electrons or electron holes over long distances, nature often uses DNA double strands or proteins. With DNA, experiments[1] and calculations[2] have clearly shown that these processes can occur by a hopping mechanism, where the charge transport takes place in a multistep reaction.[3] Purines act as carriers of positive charge[4] ("electron-hole transport"), and pyrimidines are carriers of negative charge[5] ("excess-electron transport"). A similar hopping model was also applied to explain long-distance charge transport through proteins.[6] Hopping is especially favored if the amino acids carry side chains that can be easily oxidized (tyrosine, tryptophan, and histidine). For instance, a multistep electron-hole transport cascade involving three tryptophan units was proposed for the photoactivation process in the enzyme photolyase.[6a] Presumably, not only tryptophan but also tyrosine and histidine are involved in the mechanism of radical initiation in ribonucleotide reductase, where an electron hole is transported over a distance of 35 Å.[6e] In these systems, transient intermediates occurring in the multistep charge transport have not yet been detected, and it is not clear whether the electron transfer is best described as proceeding through space or through the peptide bonds.[7]

In order to examine electron-hole transport in peptides, we synthesized the series of model systems **1a–d** bearing three different redox sites, that is, a modified tetrahydrofuran as a charge-injection system,[8] 2,4,6-trimethoxyphenylalanine[9] as an intermediate charge carrier, and tyrosine as a final electron donor. An oligoproline spacer of variable length ($n = 0, 1, 3, 5$) was chosen to separate the tyrosine residue from the 2,4,6-trimethoxyphenylalanine moiety. As is known from related studies of electron-hole transfer in DNA, irradiation of the pivaloylated tetrahydrofuran unit in compounds like **1a–d** will generate the dihydrofuranosyl radical cations, **2a–d**, through Norrish α cleavage and subsequent β elimination of the phosphate leaving group.[10] These radical cations have

Scheme 1. Mechanism for the photolysis of **1a–d** and the subsequent electron-transfer reactions.

strong oxidizing properties[11] and can oxidize the neighboring 2,4,6-trimethoxyphenylalanine side chain (Scheme 1).[12]

Compounds **1a–d** were dissolved in acetonitrile/water (3:1) and irradiated with 308-nm pulses from a XeCl excimer laser,[13] which allowed selective excitation of the pivaloyl chromophore. The transient absorption spectra observed after a delay of 50 ns with respect to the laser pulse indicated the presence of radical cations **3a–d** with an absorption maximum at 550 nm (Figure 1a shows the spectrum for system **1c** as a typical example).[14,15] This signal decayed

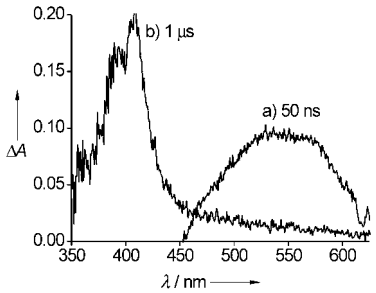

Figure 1. Transient absorption spectra observed after a delay of a) 50 ns and b) 1 μs with respect to the irradiation of **1c** in degassed acetonitrile/water (3:1) at a concentration of 8 mM.

within 1 μs and was replaced by the characteristic signal of the tyrosyl radical with a maximum absorbance at 410 nm (Figure 1b).[16]

Kinetic traces of the absorbance decay at 550 nm and of the growth observed at 410 nm obeyed the first-order rate law well, and the rate constants determined by least-squares fitting at the two wavelengths were the same within the limits of error. A typical example is shown in Figure 2.

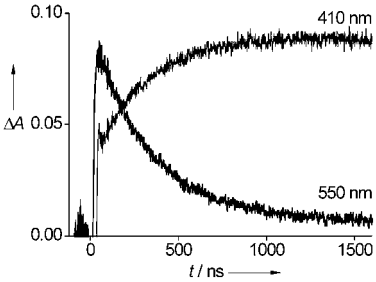

Figure 2. Kinetic traces of the transient absorptions at 410 and 550 nm for **1c** (7 mM) in degassed acetonitrile/water (3:1). The decay rate constant at 550 nm is $3.1(\pm0.2)\times10^6\ s^{-1}$ and the absorbance growth constant at 410 nm is $3.5(\pm0.3)\times10^6\ s^{-1}$.

However, the rate constants observed with model peptides **1a–d** increased linearly with the concentration of these compounds. This pointed to competition of intra- and intermolecular electron transfer. The slopes of these plots correspond to the intermolecular rate contributions k_{inter}, and the values so obtained ($k_{inter}\approx4\times10^8\ M^{-1}s^{-1}$) agree well with the rate constants of diffusion expected for compounds of this size. The intramolecular contributions, namely the rate constants k_{intra}, for electron transfer from the tyrosine side chain to the 2,4,6-trimethoxyphenylalanine radical cation moiety (**3a–d**→**4a–d**) were determined from the intercepts (Table 1).[17]

The rate constants k_{intra} (Table 1) decrease by a factor of only about two when the spacer between the aromatic redox centers is elongated by addition of two proline units (compare **1b** with **1c** and **1c** with **1d**). For an electron transfer through the peptide bonds one would expect a rate decrease of about 500 for two additional proline units.[18] This indicates that the electron transfer does not proceed by a through-bond mechanism. We attribute the small influence of additional proline spacers upon the k_{intra} value to the conformational flexibility of the aromatic amino acids.[19] The rate does increase considerably when the proline spacer is absent, as in **1a**, where the aromatic side chains are in close contact with each other.

Table 1: Rate constants for intramolecular (k_{intra}) and intermolecular (k_{inter}) electron transfer, determined from the intercepts and slopes of rate-versus-concentration plots. The number of proline units between the aromatic side chains is given by n, and σ_l is the length of the through-bond pathway, based on the number of covalent bonds between the aromatic redox centers.[6f]

	n	k_{intra} [s^{-1}]	k_{inter} [$M^{-1}s^{-1}$]	σ_l [Å]
1a	0	$8.6(\pm0.6)\times10^6$	$\leq5\times10^8$	9.8
1b	1	$1.1(\pm0.1)\times10^6$	$4.3(\pm0.4)\times10^8$	14.0
1c	3	$5.1(\pm0.3)\times10^5$	$3.0(\pm0.1)\times10^8$	22.4
1d	5	$2.8(\pm0.3)\times10^5$	$3.2(\pm0.1)\times10^8$	30.8

The radical cation of 1,3,5-trimethoxybenzene[12] should not be capable of oxidizing phenol to the phenol radical cation (oxidation potential $E_{ox}(PhOH/PhOH^{\bullet+})=1.50$ V versus a NHE).[20] But oxidation of phenol to the phenoxy radical in aqueous solution (pH 7) has a much lower potential of $E_{ox}(PhOH/PhO^{\bullet})=0.86$ V versus a NHE.[21] Thus, oxidation of tyrosine in the systems **3a–d** can easily occur, if the electron transfer is coupled with proton transfer to the solvent. We measured a kinetic deuterium isotope effect k_H/k_D of 1.8(±0.2).[22] This value is in good agreement with the isotope effect of 2.0–2.5 for the oxidation of tyrosine by a ruthenium–tris(bipyridine) complex in aqueous media, where a proton-coupled electron transfer occurs.[23]

In summary, electron-hole transport in peptide radical cations **3a–d** occurs by a hopping mechanism between the aromatic side chains of the amino acids, which is similar to the long-distance hole transport through DNA.[1–4]

[11] When 2,3-dihydrofuran is used as a simple model system, the reduction potentials of radical cations like **2a–d** are estimated to be larger than 1.27 V versus a normal hydrogen electrode (NHE): K. Bernhard, J. Geimer, M. Canle-Lopez, J. Reynisson, D. Beckert, R. Gleiter, S. Steenken, *Chem. Eur. J.* **2001**, *7*, 4640.

[12] The half-wave oxidation potential of 1,3,5-trimethoxybenzene is 1.25 V versus a NHE: A. Zweig, W. G. Hodgson, W. H. Jura, *J. Am. Chem. Soc.* **1964**, *86*, 4124.

[13] Solutions of **1a–d** (0.3–8 mM) were degassed in a quartz cell of 4.5-cm path length and irradiated with laser pulses (Lambda-Physik COMPex 205, $\lambda = 308$ nm, pulse width of 25 ns, 100–150 mJ per pulse) at RT (22–24 °C). An iStar 720 ICCD camera (Andor) was used for the detection of transient absorption spectra. Transient kinetics were recorded with a 1P28 photomultiplier (Hamamatsu). For a detailed description, see: a) J. Wirz, *Pure Appl. Chem.* **1984**, *56*, 1289; b) E. Leyva, M. S. Platz, G. Persy, J. Wirz, *J. Am. Chem. Soc.* **1986**, *108*, 3783; c) S. Gerber, J. Wirz, *EPA Newsl.* **1989**, *36*, 19.

[14] P. O'Neill, S. Steenken, D. Schulte-Frohlinde, *J. Phys. Chem.* **1975**, *79*, 2773.

[15] The transient absorption spectrum recorded after oxidation of *N*-acetyl-2,4,6-trimethoxyphenylalanine methyl ester (**5**) by photosensitized electron transfer with 1,4-dicyanonaphthalene as a sensitizer and biphenyl as a codonor is similar to the spectrum shown in Figure 1a (see the Supporting Information). Furthermore, a compound with the pivaloylated tetrahydrofuran unit directly connected to *N*-acetyl-2,4,6-trimethoxyphenylalanine was synthesized (**6**). Laser flash photolysis of this compound again gave a spectrum that was practically identical to the one shown in Figure 1a (see the Supporting Information).

[16] K. M. Bansal, R. W. Fessenden, *Radiat. Res.* **1976**, *67*, 1.

[17] The irradiations were carried out at concentrations of 0.3–8 mM, which provided k_{intra} values from the intercepts of rate-versus-concentration plots with a standard error of about 10% (see the Supporting Information). The decay of the radical cation of 2,4,6-trimethoxyphenylalanine in the absence of tyrosine was much slower (dissociation constant $k_d = 1.1 \cdot 10^4\ s^{-1}$) than the intramolecular electron-transfer reaction **3a–d**→**4a–d** ($k_{intra} = 0.28 \times 10^6$–$8.6 \times 10^6\ s^{-1}$). These intramolecular rates are 10–100 times faster than the observed electron-transfer rates between a tryptophan radical cation and tyrosine.[7a,b] This is in accord with the higher oxidation potential (E_{ox}) of trimethoxyphenylalanine[12] compared to tryptophan ($E_{ox} = 1.02$ V versus a NHE).[21]

[18] By addition of two proline units, the length of the through-bond pathway (σ_l, 1.4 Å times the number of covalent bonds in the effective path) is increased by 8.4 Å. With a distance-decay constant of $\beta = 0.73\ Å^{-1}$, the k_{intra} value is expected to drop by a factor of about 500: D. R. Casimiro, L. L. Wong, J. L. Colon, T. E. Zewert, J. H. Richard, I.-J. Chang, J. R. Winkler, H. B. Gray, *J. Am. Chem. Soc.* **1993**, *115*, 1485.

[19] By using ^{1}H-NOESY experiments in [D_3]acetonitrile, conformation studies of **1c** were performed. The proline spacer adopts the all-*trans* conformation in about 80%. Subsequent molecular-modeling analysis (with the MakroModel 7.2 program) of compounds **1a–d** in a fixed all-*trans* conformation revealed that, due to the conformational flexibility of the aromatic side chains, different distances exist between the redox centers.

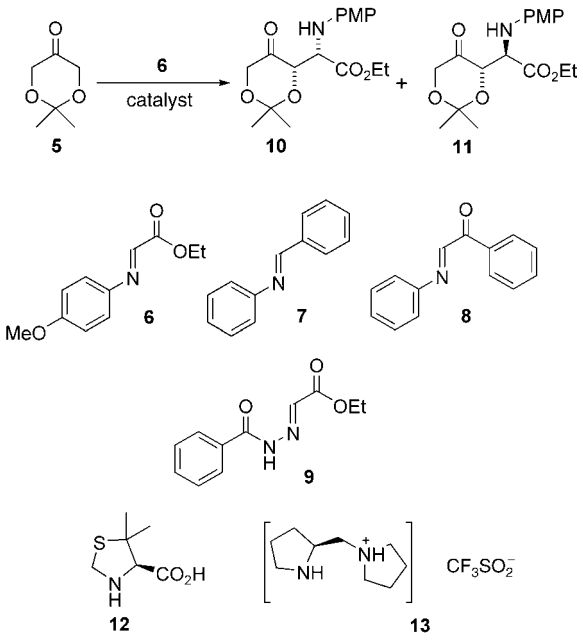
Organocatalysis

Dihydroxyacetone in Amino Acid Catalyzed Mannich-Type Reactions**

Bernhard Westermann and Christiane Neuhaus*

After lying in obscurity for more than 40 years, proline-catalyzed carbonyl reactions have been studied intensively in recent years.[1] Although Martens and co-workers pointed out the enormous potential of these reactions in a Review in 1982, they did not attract significant interest until the studies of List, Barbas, MacMillan, Jørgensen, and others were published.[2] Proline-catalyzed reactions could possibly explain the origin of prebiotic aldol and Mannich products and thus the stereoselective synthesis of carbohydrates. During glycolysis and gluconeogenesis, an aldolase-catalyzed aldol reaction of two C_3 building blocks, 3-glyceraldehyde phosphate (GAP), and dihydroxyacetone phosphate (DHAP) takes place (Scheme 1).[3]



Scheme 1. Dihydroxyacetone and phosphorylated derivatives in aldol and Mannich reactions.

Despite the enormous number of publications dealing with organocatalytic carbonyl reactions, only a few examples can be found in which dihydroxyacetone (DHA, **1**) was used as the C_3 methylene compound in aldol reactions towards carbohydrate precursors.[4,5] Mannich and Mannich-type reactions of DHA are, to the best of our knowledge, unknown.[6] These reactions would offer a very simple approach to azasugar and aminosugar derivatives, which are of considerable biological interest owing to their glycosidase-inhibiting and aminoglycoside-mimicking properties.[7] As a multistep sequence is generally required in the synthesis of these compounds, a simple approach is highly desirable.

Herein we report the use of protected dihydroxyacetone and various imines in Mannich reactions. In this context, we present 2,2,2-trifluoroethanol (TFE) as a highly suitable solvent and describe the application of microwave irradiation to accelerate organocatalytic reactions.[8]

In contrast to hydroxyacetone no reaction could be observed with DHA (**1**) under the conditions provided by List and by Cordova and co-workers (L-proline (30 mol%), DMSO, room temperature).[9] Therefore, we used phosphate-protected dihydroxyacetone derivatives **2** and **3** in preliminary reactions.[10] Unfortunately, no reaction occurred between imine **6** and the methylene compound (Schemes 1 and 2).[11] Subsequently, we used the acetonide **5** of dihydroxyacetone which can easily be synthesized in large amounts in two steps. Acetonide **5** was previous employed in diastereo- and enantioselective aldol reactions as a DHA equivalent.[12] Besides the distinct reactivity, we assumed that a very compact, bicyclic transition state would result with this cyclic ketone, thus leading to high diastereoselectivities.

In the first experiment it could be shown that the desired products **10** (*syn*) und **11** (*anti*) were formed by using protected DHA **5** and imine **6** in the presence of racemic proline (30 mol%) (Scheme 2; Table 1, entry 1 (91:9 d.r.)). Further experiments with L-proline led to identical diastereomeric ratios; the enantioselectivity (82% *ee*) was satisfying.[13] Whereas solvents such as acetonitrile, toluene, and ionic liquids (Table 1, entries 4–6) did not result in notable improvements in stereoselectivites, very polar solvents such as formamide and TFE led to excellent diastereo- and enantioselectivities (Table 1, entries 7, 8). The use of TFE

Scheme 2. Catalyzed Mannich reactions. The reaction conditions are given in Table 1; PMP = *p*-methoxyphenyl.

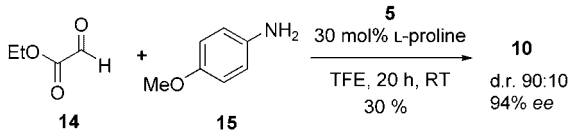
[a] $BMIMBF_4$ = 1-butyl-3-methylimidazolium tetrafluoroborate; TFE = 2,2,2-trifluoroethanol. [b] Yields of isolated products. [c] d.r. determined by GC–MS. [d] *ee* determined by HPLC (Chiralcel OD-H); n.d.: not determined.



allowed the isolation of the product in 72% yield with reproducible diastereoselectivity (97:3 d.r.) and enantioselectivity (99% *ee*). A slight decrease in the selectivities (95:5 d.r. and 96/95% *ee* (Table 1, entries 9, 10) was observed in TFE/H_2O solvent mixtures (95:5; 90:10). To decrease the amount of proline, we ran further experiments in TFE with decreasing concentrations of catalyst (Table 1, entries 11–13). We proved that the amount of catalyst could be decreased significantly. Only at 5 mol% of L-proline did the stereoselectivity decrease quite drastically. Temperature effects were not observed (Table 1, entries 14, 15).

Other proline-derived catalysts proved to be unsuitable. L-5,5-Dimethylthiazolidine-4-carboxylic acid (DMTC; **12**) resulted in poor selectivities. No reaction occurred in the presence of (*S*)-1-(2-pyrrolidinylmethyl)pyrroline triflate (**13**) (Table 1, entries 16, 17). Disappointingly, imines **7** and **8** and hydrazone **9**[14] did not react with **5**.

One disadvantage of many proline-catalyzed reactions is the long reaction time. We therefore tried to accelerate the reaction under the action of microwaves. The results of the microwave-assisted organocatalytic Mannich reactions are listed in Table 2. Consistent with the previously observed results, TFE was once again the solvent of choice. After only 10 min **10** was obtained in 72% yield with high diastereo- (90:10 d.r.) and enantioselectivities (95% *ee*). A decrease in the irradiating power led to a lower yield, although the selectivities remained the same. The use of DMSO or formamide as solvent led to a significant decrease in the yield and diastereoselectivity.[15]

The Mannich-type reaction could also be carried out as a three-component process (Scheme 3). The reaction of glyoxylate **14**, *p*-anisidine (**15**), and **5** yielded **10** in 30% yield with selectivities comparable with those of the two-component reaction.

The relative configuration of all the products was determined by NMR spectroscopy. The *syn* conformation of the main diastereomer can be concluded based on the ^3J coupling constant (CHO-CHN) of 2.3 Hz and on NOE interactions.[16] This is consistent with results from other Mannich-type reactions. Therefore, it is possible to assume the same transition state proposed by Cordova.[6]

Scheme 3. Three-component reaction to **10**.

In conclusion nitrogen-containing carbohydrate derivatives were obtained with very good stereoselectivities from DHA derivatives. Furthermore it is possible to improve existing protocols (shorter reaction times, less catalyst) by using 2,2,2-trifluoroethanol as solvent and microwave-assisted procedure.[17]

Amino Sugars

Asymmetric Synthesis of Selectively Protected Amino Sugars and Derivatives by a Direct Organocatalytic Mannich Reaction**

Dieter Enders, Christoph Grondal, Marianna Vrettou, and Gerhard Raabe*

In the classic Mannich reaction the corresponding β-aminocarbonyl compounds are formed from formaldehyde, an amine, and an enolizable carbonyl component.[1] These so-called Mannich bases have found broad applications as synthetic building blocks,[2] most importantly in the preparation of natural products and biologically active compounds.[3] The main disadvantage of the classic Mannich reaction has been the lack of stereocontrol and the formation of by-products. As a result, the development of more selective and particularly diastereo- and enantioselective protocols for this important C–C bond-forming reaction has been of substantial interest. In 1985 our research group, in cooperation with Steglich et al., disclosed for the first time a procedure for a stereoselective Mannich reaction, by which enamines together with acyliminoacetates could be transformed into diastereo- and enantiomerically pure α-amino-γ-keto esters.[4] Later on we developed a first practical procedure for the regio- and enantioselective α-aminomethylation of ketones with the assistance of a directing silyl group at the α-position to the carbonyl group.[5]

Interest in catalytic asymmetric variants of the Mannich reaction has grown considerably in recent years. The application of both metal-containing and metal-free catalysts has led to a breakthrough in accomplishing diastereo- and enantioselective Mannich reactions.[6] Although very low loadings of sophisticated chiral metal-based catalysts can be employed and lead to excellent yields as well as diastereo- and enantioselectivities,[7] more generous loadings of readily available metal-free organocatalysts are often preferentially used.

Special notice should be taken of the proline-catalyzed three-component Mannich reaction developed by List et al.[8] In this highly developed organocatalytic method, enolizable aldehydes and ketones are treated with in situ generated imines to afford the corresponding Mannich products with good to excellent stereoselectivities.[9] Barbas and his co-workers independently used this strategy for the direct

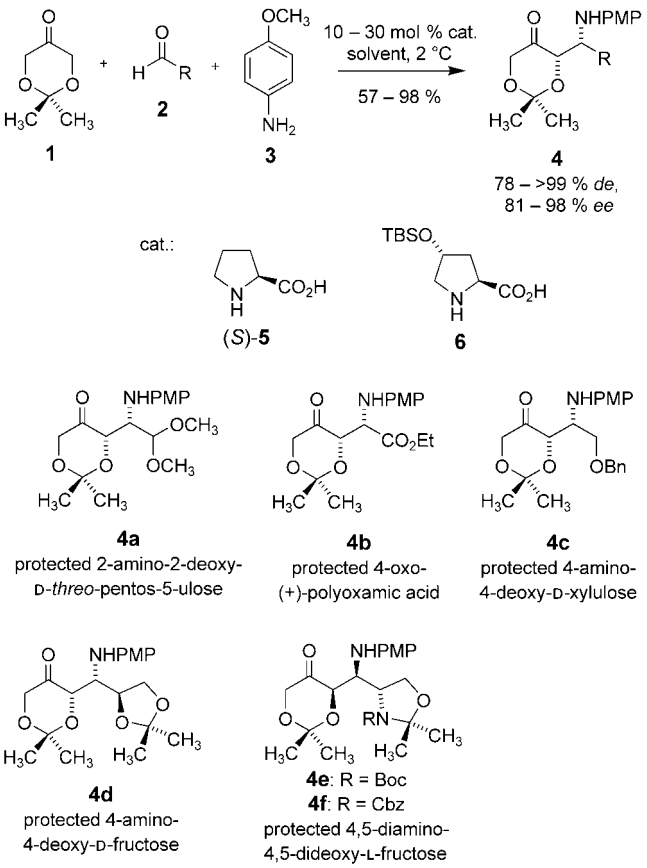
asymmetric synthesis of α-amino acids by employing preformed iminoglyoxylates.[10]



Recently, we reported a direct, organocatalytic de novo synthesis of carbohydrates. Starting from the dihydroxyacetone equivalent 2,2-dimethyl-1,3-dioxan-5-one (**1**),[11] various protected carbohydrates and amino sugars could be assembled in one step by a highly diastereo- and enantioselective proline-catalyzed aldol reaction.[12]

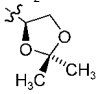
Carbohydrates are of great significance because of their diverse biological activities and application as synthetic building blocks and chiral auxiliaries.[13] Amino sugars are a class of carbohydrates, in which one or more hydroxy functions are replaced by amino groups. They are found as parts of glycoproteins, glycolipids, aminoglycosides, and many biologically active secondary metabolites containing free, methylated, or acetylated amino group.[14] The substitution of a hydroxy function by an amino group may alter the properties of the sugar significantly, for example, its hydrogen bonding properties, solubility, and charge. Consequently, amino sugars play important physiological roles in many glycoconjugates and are of interest for the development of new drugs.[15] There are numerous approaches for the synthesis of amino sugars. Most of them are based on naturally occurring carbohydrates and involve several protecting group manipulations as well as oxidation–reduction steps.[16] Alternatively, a linear synthetic sequence is used, but generally many reaction steps are required.[17]

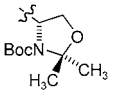
Based on our organocatalytic $[C_3+C_x]$ concept for the direct synthesis of carbohydrates, we report here the successful development of a diastereo- and enantioselective Mannich variant that paves the way to selectively protected amino sugars and their derivatives.[18a] Initially, the (*S*)-proline-catalyzed three-component Mannich reaction of **1** with dimethoxyacetaldehyde (**2a**) and *para*-anisidine (**3**), as the amine component, was achieved. Thus, in the presence of 30 mol% proline in DMF at 2°C we obtained the Mannich product **4a** in 91% yield and excellent stereoselectivities (>99% *de*, 98% *ee* determined by HPLC; see Scheme 1). After recrystallization from heptane/2-propanol (9:1) **4a** could be obtained in practically diastereo- and enantiomerically pure form. Analogous conditions employed for the α-branched aldehydes **2d–g** and aldehyde **2b** also led to very good yields and selectivities; however, in the case of **2g** slightly superior results were obtained when acetonitrile and catalyst **6** were used (see Table 1). In contrast to the results of Barbas et al. aldehyde **2b** could also be used in the three-component reaction without prior isolation of the iminoglyoxylate.[18b]

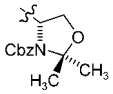
In the case of linear aldehydes such as **2c** and the aromatic aldehydes **2h** and **2i** the results obtained under the above reaction conditions were not as good. Following extensive optimization of the reaction conditions we were able to verify the following general tendencies for these reactions.

1) The optimal reaction temperature was found to be between 2°C and ambient temperature. Apart from the expected decrease of the reaction rate at lower temperatures, we also observed a decline in the diastereo- and enantioselectivity, which may point to an isoinversion effect.[19]

Scheme 1. Organocatalytic asymmetric three-component Mannich reaction of dioxanone **1** with different aldehydes **2** and the amine **3**. R groups are defined in Table 1. PMP = *para*-methoxyphenyl, TBS = *tert*-butyldimethylsilyl, Bn = benzyl, Boc = *tert*-butoxycarbonyl, Cbz = benzyloxycarbonyl.







2) The addition of 1–10 equivalents of water led to an increase of the stereoselectivity independent of the solvent employed, although depending on the solvent, a decrease in the reaction reate could be observed.
3) The use of catalyst **6** generally led to an enhancement of the reaction rate, due to its superior solubility properties, and also the stereoselectivity subject to the solvent.
4) When catalyst **6** is employed, the addition of water has again a positive effect on the stereoselectivity.

In the case of the (*S*)-proline-catalyzed reaction of **2c**, we found that *N*-methylpyrrolidinone (NMP) accompanied by the addition of 3 equiv of water yielded the best results (94% yield, 60% *de*, 82% *ee*). Substitution of proline and NMP by catalyst **6** and acetonitrile, respectively, accompanied by the addition of 5 equiv of water afforded **4c** in 77% yield and greatly improved the selectivities (88% *de*, 96% *ee*). Similar observations were made in the case of aromatic aldehydes **2h** and **2i**.

In our initial report of the proline-catalyzed aldol reaction of **1**, we were able to show that in the case of NBoc- or NCbz-protected, (*S*)-configured enantiomerically pure Garner aldehydes **2e** and **f** (*S*)-proline is the appropriate catalyst. Analogous investigations of the Mannich reactions showed

[f] Based on the *ee* value of the corresponding aldehyde **2**.

that when (*S*)-proline is used, only traces of the desired products could be isolated, whereas the (*R*)-proline-catalyzed reaction provided the Mannich products in good yields and virtually stereoisomerically pure (**4e**: 67%, ≤96% *de*, ≤96% *ee*; **4f**: 63%, 96% *de*, 96% *ee*). These results may support the suggestion that the proline-catalyzed Mannich reaction could facilitate kinetic resolutions of **1** with sterically demanding α-substituted aldehydes. Accordingly, (*R*)-proline should be the appropriate catalyst in the case of (*S*)-configurated, α-substituted aldehydes and (*S*)-proline for the application of (*R*)-configurated, α-substituted aldehydes. This was corroborated by the Mannich reaction of **1** with **2d** and **2g** and with (*S*)-proline as the catalyst (Table 1). As is evident from Scheme 1, the Mannich products **4a**–**f** constitute different selectively protected amino sugars and their derivatives, which could either be transformed to the corresponding amino sugars or used as synthetic building blocks, for example, **4a**. This organocatalysis can also be carried out smoothly on a multigram scale without any adverse effects on the yield and stereoselectivity (89% yield, ≤96% *de*, ≤96% *ee*), as exemplified by the reaction of **1** with **2a** and **3** to give **4a**.

The *syn* configuration of the Mannich products **4** was confirmed both by NOE measurements and an X-ray crystal structural analysis[20] on **4a** (Figure 1). These results are consistent with the transition-state model proposed by List et al. for the proline-catalyzed Mannich reaction. The stated absolute configurations are consistent with this model (Figure 2).

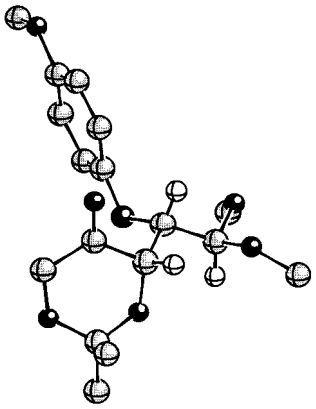

Figure 1. Crystal structure of **4a**.[20]

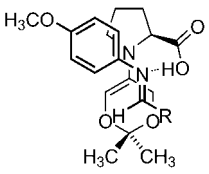

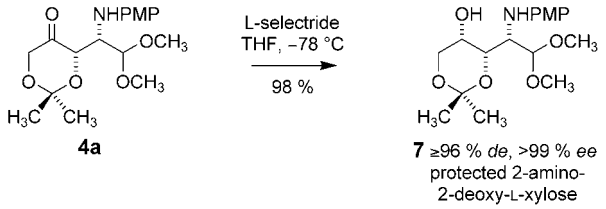

Figure 2. Transition-state model proposed by List et al.

The Mannich products **4** described here could be transformed into the corresponding β-amino alcohols by reduction of the keto function, which was successfully demonstrated in the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

case of **4a**. Thus, the reduction of **4a** with L-selectride proceeded at −78 °C with high stereocontrol to yield the all-*syn*-configured β-amino alcohol **7**, which in its protected form belongs to the class of the biologically very important 2-amino-2-deoxy sugars (Scheme 2).[17c,21] Furthermore, the polyoxamic acids are directly available from **4b** by reduction of the keto function.[22] They are integral parts of the polyoxines and also occur in isolated form in nature, and have attracted interest due to their biological activity.[23]

Scheme 2. Diastereoselective reduction of **4a** to **7** with L-selectride.

The efficient asymmetric catalytic method we have described here starting from simple and commercially available compounds provides a viable alternative to the conventional, relatively elaborate, and less flexible methods for the synthesis of amino sugars. Our protocol facilitates the synthesis of different amino pentoses and hexoses with high diversity in only one to two steps.

Experimental Section

Unless otherwise stated, all chemicals are commercially available and were used without further purification with the exception of aldehyde **2g**[24] and catalyst **6**.[25] All new compounds were fully characterized (IR, NMR, MS, elemental analysis, optical rotation, melting point).

4a: In a 100-mL round-bottomed flask a 60 % aqueous solution of **2a** (2.6 g, 15 mmol) was dissolved together with **3** (2.04 g, 16.5 mmol) and (*S*)-proline (519 mg, 4.5 mmol) in DMF (55 mL) at 2 °C. The solution was stirred for 30 min before **1** (2 g, 15 mmol) was added, and the mixture was stored for 5 days at 2 °C. The reaction was quenched with pH 7 buffer (50 mL) and the mixture stirred for 15 min at ambient temperature. After extraction of the aqueous phase with ethyl acetate (3 × 75 mL), the combined organic layers were dried over Na_2SO_4, concentrated, and purified by column chromatography using silica gel (diethyl ether/pentane, 1:2). The product **4a** (4.53 g, 89 %) was obtained as a pale yellow solid, which was recrystallized from heptane/2-propanol (9:1) to afford colorless crystals. Enzyme Catalysis

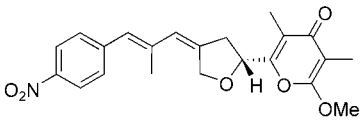
Sequential Enzymatic Oxidation of Aminoarenes to Nitroarenes via Hydroxylamines**

*Robert Winkler and Christian Hertweck**



Aromatic nitro groups are relatively rare structural elements in natural products, but are found in diverse types of natural products, most of which are endowed with important biological properties. Prominent examples of bacterial nitroaryl metabolites include the potent antibiotic chloramphenicol (**1**),[1] the antifungal agent pyrrolnitrin (**2**),[2] and the cytostatic, *p*-nitrobenzoate-derived polyketide aureothin (**3**).[3,4] The nitrophenanthrene derivative aristolochic acid C (**4**) is the causative agent for "Chinese herbs nephropathy"[5] and 2-

nitrophenol (**5**) is a well-studied component of the aggregation–attachment pheromone of ticks. The fungal nitroaryl compound stephanosporin (**6**) is the precursor of 2-chloro-4-nitrophenol.[6] Important examples of natural nonaromatic nitro compounds are nitropropionic acid[7] and the bacterial signal metabolite hormaomycin.[8,9]

Surprisingly, the biosynthesis of aromatic nitro groups is understood only to a small extent. One possible pathway involves aromatic substitution of nitro groups, as is the case for the unusual nitro alkaloid 1-nitroaknadinine (**7**) from *Stephania sutchuenensis*, which occurs simultaneously with the non-nitrated alkaloid. The proposed biosynthetic nitration step was mimicked in vitro with HNO_3.[10] More recently, it was reported that a NO synthase (NOS) takes part in the nitration of the diketopiperazine thaxtomin (**8**), a phytotoxin produced by the plant pathogen *Streptomyces turgidiscabies*.[11] Additional studies revealed that tryptophan is regioselectively nitrated by a complex of *Deinococcus radiodurans* NOS and Trp–tRNA synthetase.[12]

Despite these important findings, it appears that biosynthesis of the vast majority of aromatic nitro compounds proceeds by an alternate route: the enzymatic oxidation of primary amines.[1,13–15] In their studies with ^{18}O labeling and ^{15}N NMR spectroscopy, Baxter and co-workers revealed that both oxygen atoms of the fungal metabolite nitropropionate are derived from molecular oxygen.[7,16]

Conceivably, *N*-oxygenation could proceed in three steps via hydroxylamine and nitroso intermediates (Scheme 1), or both oxygen atoms could be introduced simultaneously by a

Scheme 1. Proposed biosynthetic pathway from PABA to PNBA via *p*-hydroxylaminobenzoate (PHABA).

dioxygenase, yet no direct evidence for either hypothesis has been given. The only existing studies on enzymatic nitro group formation have been carried out with haloperoxidases. These are not genuine N-oxygenases; they catalyze the oxidation of amino groups only under very specific, non-natural in-vitro conditions through the formation of reactive peroxo species, with excess H_2O_2 and/or in the absence of halide ions.[17–19] Furthermore, haloperoxidases such as CPO-P are not naturally involved in the biosynthesis of nitro compounds, as has been revealed by the analysis genes responsible for pyrrolnitrin biosynthesis.[13,20]

We recently cloned the N-oxygenase gene *aurF* from the gene cluster encoding aureothin biosynthesis in *Streptomyces thioluteus*.[21] Inactivation and complementation studies revealed that AurF plays a crucial role in the formation of the novel polyketide synthase starter unit *p*-nitrobenzoate (PNBA) from *p*-aminobenzoate (PABA),[14] and that the involvement of the cytochrome P_{450} monooxygenase AurH in *N*-oxygenation can be ruled out.[22] Furthermore, *aurF*-deficient null mutant permitted mutasynthesis of the aureothin derivative, aureonitrile.[23] Aside of PrnD from the pyrrolnitrin pathway in *Pseudomonas pyrrocinia*,[13] AurF is only the second known N-oxygenase involved in the biosynthesis of a nitro-group-containing metabolite. Whereas PrnD shows a clear Rieske motif, AurF appears to represent a novel type of oxygenase, as it does not share any of the known conserved oxidoreductase motifs (such as those for cofactor binding, for example).

A PABA-to-PNBA oxidation assay with AurF appeared as an ideal model system for gaining a deeper insight into nitro group formation. Although the expression of AurF was successful, all attempts to promote an in-vitro oxygenation failed, probably the result of a missing and yet unknown cofactor. It was reported earlier that cell-free extracts of *S. thioluteus* are unable to carry out *N*-oxygenation.[24] For this reason, *aurF* was expressed in the heterologous host *S. lividans*, and the oxygenation was performed as a whole-cell assay. Comparison of the whole-cell activities of recombinant and wild-type strains[24] implies that the heterologously produced AurF exhibits a slightly lower conversion rate, albeit in the same order of magnitude as that of the native enzyme. However, as all attempts at genetic manipulation of the wild-type *S. thioluteus* have failed, this functional vector–host system represents a valuable and flexible model system. A host strain of *S. lividans* containing the empty vector and phosphate buffer were used as negative controls in all experiments.

The putative PABA-derived hydroxylamine and nitroso arene intermediates are known to be highly reactive and unstable compounds. Therefore, the rapid and manipulation-free isolation and analysis of the corresponding benzoates from aqueous solution was a challenge. To avoid the extraction of labile intermediates, an at-line detection method was established analogously to a protocol for the analysis of acylated anilines from human whole blood.[25] The supernatant of centrifuged samples (1 mL) was loaded directly onto a RESOURCE RPC-18 column and eluted with a gradient of aqueous Na_2HPO_4-buffered acetonitrile/methanol. The method was thoroughly validated, and a very low detection limit (signal/noise ratio 3:1) for PABA (0.4 $\mu g\,mL^{-1}$) and PNBA (0.6 $\mu g\,mL^{-1}$) was detected with UV/Vis spectroscopy at $\lambda = 280$ nm. With this setup, the course of the oxygenation reaction (PNBA formation and PABA consumption) was observed. First, the *N*-oxygenation reaction was relatively slow (> 12 h to reach completion). Second, LC analyses revealed the simultaneous formation of an intermediate with PNBA production. Its shorter retention time relative to PABA and the UV/Vis spectrum suggested that this intermediate could be *p*-hydroxylaminobenzoic acid (PHABA; Figure 1).

Comparison with an authentic PHABA reference, prepared from PNBA with zinc and ammonium chloride in aqueous NaOH solution,[26] unequivocally confirmed this

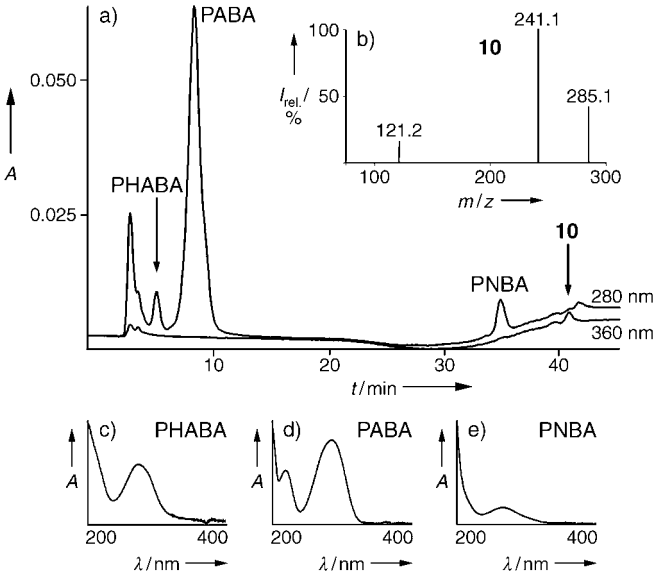

Figure 1. a) Chromatogram of PABA oxidation assay after 5 h; insets: b) MS–MS data for **10**; UV/Vis spectra for c) PHABA; d) PABA; e) PNBA.

finding. Moreover, synthetic PHABA was readily transformed into PNBA when administered to the AurF-producing strain, whereas the control strain was not capable of this transformation. This result shows that not only the first monooxygenation step, but also the second oxygen transfer is catalyzed by AurF. In fact, PNBA formed from exogenously supplied PHABA is produced approximately fivefold faster than it is formed from PABA (Figure 2). This result provides

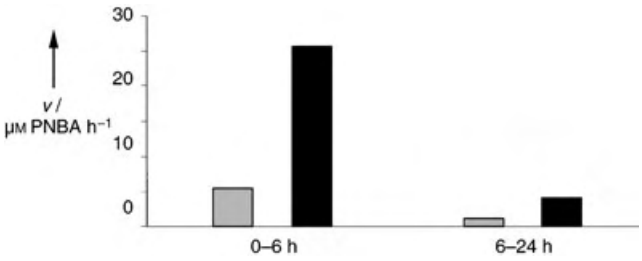

Figure 2. Rate of PNBA formation v with PABA or PHABA as substrates; ■ PNBA from PABA, ■ PNBA from PHABA.

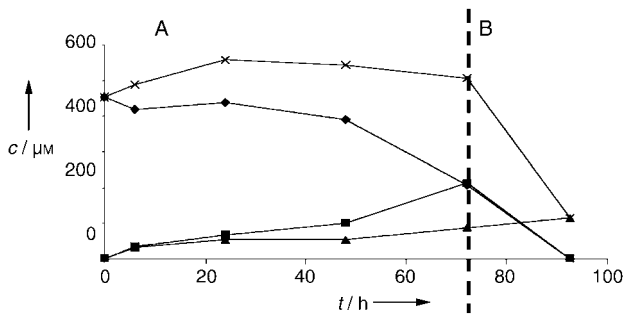
the strongest evidence that PHABA is indeed a true intermediate in nitro group formation and that the N-oxygenation catalyzed by AurF occurs in a stepwise manner. Furthermore, the first oxygenation reaction to hydroxylamine appears to be the rate-limiting step for the overall reaction in vivo.

To gain deeper insight into the course and stoichiometry of the *N*-oxygenation reaction, the fates of PABA, PHABA, and PNBA were monitored by LC (Figure 3). Under starvation conditions (A), the biotransformation of PABA to PNBA clearly predominates. The concentrations of both hydroxylamine and PNBA increase while the concentration of PABA decreases; the sum of all three remains constant. After three



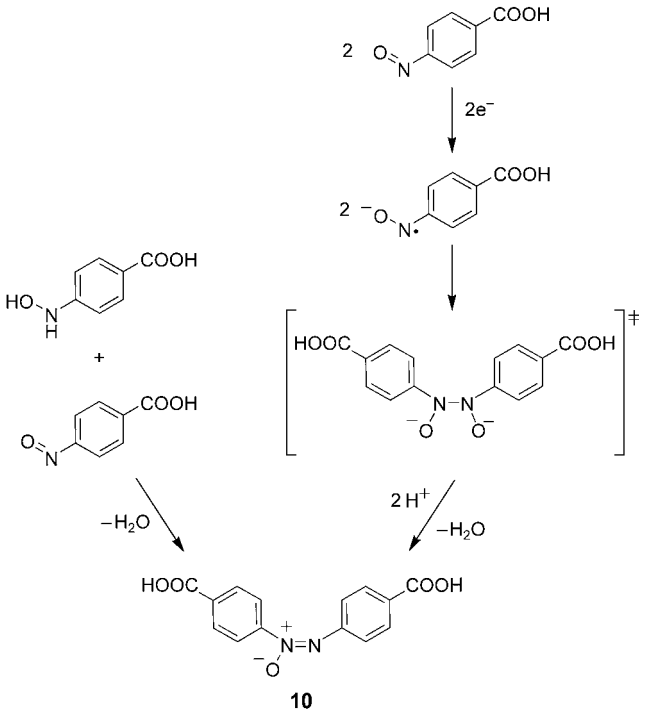


Figure 3. Stoichiometry of the *N*-oxygenation reaction. Time-dependent concentrations of PABA, PHABA, and PNBA under A) starvation conditions (secondary metabolism predominates) and B) growth (primary metabolism predominates); ◆ PABA, ■ PHABA, ▲ PNBA, × sum.

days, however, before all exogenously supplied PABA is converted into PNBA, cell lysis with concomitant release of new substrates initiates the continuation of cell division and growth. At this stage (B), primary metabolism sets in with predominant consumption of PABA for the biosynthesis of folic acid. This finding is in full accord with our earlier observation that feeding PABA to a growing culture (log phase) results in a significant decrease in the transformation of PABA into PNBA.[27] Moreover, the same phenomenon, the initiation of near-complete PABA consumption after three days, was observed in a control experiment with the strain lacking the *aurF* gene. Contrary to this, the formation of PNBA is detectable in cells expressing *aurF* even without supplemented PABA, which indicates that PABA is withdrawn from primary metabolism. Crosstalk between primary and secondary metabolism takes place as a result of the dual role of PABA as precursor for the polyketide synthase starter unit PNBA as well as for folic acid. Furthermore, the course and exact stoichiometry of the reaction under starvation conditions strongly support the key role of PHABA in nitro group formation.

Despite the high sensitivity of the analytical method, the proposed nitroso intermediate **9** (see Scheme 1), which resulted from the subsequent oxygen transfer to PHABA, could not be detected in the medium. The absence of a free nitroso intermediate in the reaction mixture may be rationalized by the rapid and possibly spontaneous turnover to the nitro compound. However, at $\lambda = 360$ nm it was possible to identify small amounts of another metabolite that derived from administered PABA and PHABA, respectively, which implies the intermediacy of a nitroso compound. MSn analyses and comparison with a synthetic sample proved that this novel metabolite is identical to azoxybenzol-4,4′-dicarboxylic acid (**10**). According to a number of mechanistic investigations, azoxybenzene derivatives are formed by the condensation of hydroxylamines with nitroso compounds, or by the dimerization of nitrosobenzenes (Scheme 2).[17,28,29] In both cases, nitroso benzoate intermediates are involved. However, it was also possible to observe the nonenzymatic formation of **10** from synthetic PHABA in phosphate buffer which seems to result from a spontaneous oxidation of PHABA under aerobic conditions. Nonetheless, the kinetic data clearly show that AurF also promotes the oxidation of

Scheme 2. Formation of azoxy compound **10** from PHABA.

PHABA to PNBA. Interestingly, **10** was previously identified as a metabolite of the insect parasitic zygomycete *Entomophthora virulenta*.[30,31] The detection of **10** as a by-product in PABA oxidation thus not only supports the existence of PHABA, but also provides the first model for the biosynthesis of this unusual fungal azoxy metabolite.

Many speculations have been made on the biosynthesis of nitro compounds from amines,[15] yet until now, no hard evidence has been reported. Through the extraction-free at-line detection of PHABA, and by successful transformation of synthetic PHABA to PNBA, we provide herein the first direct evidence for a stepwise oxidation of aromatic amines to nitro groups via *p*-hydroxylamine as a key intermediate. Our results clearly demonstrate that AurF is a monooxygenase, which not only catalyzes the formation of hydroxylamine, but also the subsequent oxidation to the aromatic nitro group, presumably through the same catalytic mechanism (Scheme 1). Thus, regarding the intermediates, the sequential N-oxygenation by AurF represents the reverse of the stepwise enzymatic reduction of nitroaromatic compounds, as in the case of biodegradation of TNT.[32]

Experimental Section

Strains and cultivation: For heterologous expression, *aurF* was amplified by PCR from cosmid pHJ48, cloned into the expression vector pWHM4* downstream of the constitutive ermE* promoter. The resulting plasmid, pRW01, was introduced into *Streptomyces lividans* ZX1. A strain containing only the plasmid, but not the AurF-encoding insert, *S. lividans* ZX1/pWHM4*, was used as control. Both strains were stored as glycerol cell banks at −80 °C. A cell bank volume of 1 mL was used to inoculate 100 mL soy 2G medium (soy flour (15 g L^{-1}), glucose (15 g L^{-1}), NaCl (5 g L^{-1}), $CaCO_3$ (1 g L^{-1}), KH_2PO_4 (0.3 g L^{-1}), pH adjusted to 6.9 prior to sterilization) containing thiostrepton (25 μg mL^{-1}). Growth proceeded for 3 days at 28 °C in a 500-mL Erlenmeyer flask on a rotary shaker at 180 rpm. Seed culture (10 mL) was grown in 1-L Erlenmeyer flasks containing 250 mL Bö 6 (glucose (20 g L^{-1}), oatmeal (20 g L^{-1}), yeast extract (3 g L^{-1}), NaCl (3 g L^{-1}), $CaCO_3$ (3 g L^{-1}), $FeSO_4 \cdot 7H_2O$ (0.57 g L^{-1}), $MnCl_2 \cdot 4H_2O$ (0.6 g L^{-1})) containing thiostrepton (25 μg mL^{-1}) for 4 days at 28 °C on a rotary shaker at 180 rpm.

The deduced amino acid sequence of AurF has been deposited under accession number CAE 02601 at EMBL/GenBank.

N-Oxygenation assay: Culture broth of *S. lividans* ZX1/pRW01 was filtered through MN640 filter paper, and portions of wet cell mass (20 g) were resuspended in 500-mL Erlenmeyer flasks with 100 mL PBS ($Na_2HPO_4 \cdot 2H_20$ (1.44 g L^{-1}), KH_2PO_4 (0.24 g L^{-1}), NaCl (8.00 g L^{-1}), KCl (0.20 g L^{-1})), pH 7. After shaking for 15 min on a rotary shaker at 28 °C and 180 rpm, blank samples were taken, and substrates were added from a stock solution ($\approx$20 mg mL^{-1}) in methanol to yield a final concentration of 0.07 mg mL^{-1}. The enzymatic reaction was measured "at-line" by chromatographic determination of PABA, PHABA, and PNBA from 1-mL samples. Additional samples were frozen at −20 °C for later analysis.

LC Measurement of PABA, PHABA, PNBA: LC analysis was performed on an ÄKTAexplorer system equipped with a RESOURCE RPC-18 column (3 mL, Amersham Biosciences). Samples (1 mL) were centrifuged for 1 min at 12500 rcf and the supernatant was subsequently injected into a 100-μL sample loop through a 0.22-μm PES syringe filter. The chromatography method starts with 5 CV eluent A (CV = column volume), followed by a gradient of 5 CV from 0 to 100 % eluent B, and finally 5 CV eluent B, each with a flow rate of 2 mL min^{-1}. Eluent A consists of acetonitrile (12 % *v*/*v*) in Na_2HPO_4 (10 mM), pH 3; eluent B is methanol. This methanol gradient is essential for the elution of PNBA, and also permits the detection of more hydrophobic compounds. UV/Vis absorption was monitored at $\lambda = 280$, 325, and 360 nm. These detection wavelengths are based on results from previous UV/Vis scans of possible substrates and products. Peaks were identified and quantified by comparison with external reference standards. Peak fractionation was used to isolate 4,4-diazoxybenzoate for MS–MS analysis.

Crystal Engineering

Crystalline, Porous Microspheres Made from Amino Acids by Using Polymer-Induced Liquid Precursor Phases**

Sebastian Wohlrab, Helmut Cölfen, and Markus Antonietti*

Control of the crystallization processes is one of the most important techniques in applied colloid chemistry. With a controlled preparation of crystallites of defined size, the kinetic aspects of solubility (e.g. of pharmaceuticals), crystal superstructures, texture-controlled flow properties, filling degrees, and mechanical properties can be influenced. A high reproducibility of the chosen procedure is necessary to ensure the quality of industrial products.

As nucleation and growth are very sensitive processes, crystallization is usually controlled by addition of nucleation agents, stabilizers, or other ternary components. The use of special cosolvents,[1] low molecular additives, surfactants, and functional polymers is regularly reported (for recent reviews, see refs. [2–4]). Recent progress in the field of morphosynthesis indicates that there are non-classical pathways of crystallization via colloidal intermediates and subsequent mesoscale transformation.[3,5–7] In this process, crystalline structures are constructed by assembly and/or transformation from larger units (instead of by the addition of single molecules). Both Addadi et al.[8] and Cölfen and Mann[3] reviewed independently the role of amorphous nanoparticles in bio- and biomimetic mineralization. The experimental verification and role of similar intermediates in the size-directed formation of $CaCO_3$ particles is a question of industrial relevance.[9,10] Taden et al. analyzed a model system based on dye nanodroplets and found extraordinarily ordered dye crystals formed by mesoscale transformation.[7] Such colloidal intermediates are a manifestation of the Ostwald rule of stages, which describes structural growth in the practically relevant kinetic control limit.[11]

High-concentration liquid intermediates seem to be especially promising for rapid crystallization leading to objects with a controlled outer shape. Gower et al. were the first to describe the fine droplets of a polymer-induced liquid precursor phase (PILP) for a $CaCO_3$/polypeptide system,[12,13] the subsequent crystallization of which leads to bent, corrugated, and curved crystal superstructures. A special feature of

the PILP phases is that they allow easy morphosynthesis of novel, biorelevant mineral structures through the shaping of a liquid on the micrometer scale so that crystallization occurs without requiring mass transport over longer distances.[14,15]

Herein we extend this approach to polar organic molecules by studying the formation of PILP phases consisting of charged amino acids and oppositely charged polyelectrolytes in ethanol/water mixtures. While addition of ethanol to an aqueous solution of the pure amino acid leads to well shaped single crystals, stable PILP microdroplets are formed spontaneously by adding an oppositely charged polyelectrolyte to the starting solution. These precursor phases can subsequently be crystallized to build novel crystalline porous microspheres of the component amino acids.

The method presented herein is an addition to the available approaches for the preparation of porous microspheres, such as solvothermal methods,[16] sol–gel methods,[17] preparation in commercially available microspherical silica gels,[18] the use of microemulsion droplets as liquid templates to prepare hollow inorganic microspheres,[16,19–21] and dynamic emulsification of oil droplets containing metal oxide precursors which through a reaction at the oil–water interface give porous star-shaped shells.[22]

Amino acids are practically insoluble in organic media, so their aqueous solutions undergo fast crystallization upon addition of a water-miscible organic solvent.[23] The charged amino acids employed, glutamic acid, aspartic acid, lysine, and histidine, crystallize according to this general scheme. Figure 1a shows the result of a default experiment with D,L-glutamic acid, and is representative for the other amino acids. Irregular elongated crystals with a size of 50 to 400 μm are obtained. As a result of the very fast precipitation process, no defined crystal faces or well-shaped edges are formed, although the macroscopic facetted crystal implies a single-crystalline nature.

A completely different behavior is obtained by addition of different amounts of branched polyethyleneimine (PEI, $M_w = 600\ g\,mol^{-1}$) corresponding to polymer:amino acid mass ratios of approximately 2:1, 1:1, 1:2, and 1:10 to the D,L-glutamic acid starting solution. The addition of ethanol results in turbidity, but no precipitation of crystals. Light microscopy investigations indicate the formation of amorphous liquid droplets (Figure 1b), similar to the PILP phases reported by Gower.[12–15]

Owing to their size and the small refractive index differences to the surrounding solvent, the existence of a PILP-phase is sometimes hard to observe. Anionic or cationic dyes, which interact with the polymers in the PILP phase, can be used for staining, such as the anionic dye amaranth for the PILP of D,L-glutamic acid and polyethyleneimine. Amaranth is highly soluble in ethanol and in water, but in the charged PILP-phase it acts as an ionophile leading to high extraction rates.

The process is illustrated in Figure 2. A 0.01 wt% amaranth solution in ethanol (I, red solution) is added to a D,L-glutamic acid solution (II, $10\ g\,L^{-1}$, clear solution) with 1 wt% PEI_{600}. A turbid pink emulsion is formed, and microscopy reveals liquidlike red droplets in a transparent medium. Centrifugation (3500 rpm for 30 min) of the emulsion results in a phase-separated binary system, where the dyed PILP forms a liquid viscous phase at the bottom (Figure 2c). This phase is very viscous as demonstrated in Figure 2d and subsequent crystallization leads to an imprint

of the centrifuge tube, the opposite side of the crystal has a microporous appearance (see Supporting Information). This experiment clearly demonstrates the existence of a liquid amino acid and polymer-rich phase in chemical equilibrium with its environment.

The droplets consist of amino acid bound to the polymer with a certain amount of water, while a surface excess of the charged polymers stabilizes the droplets. FTIR and ^{1}H NMR spectroscopic analyses qualitatively revealed a high amount of protonated PEI in the D,L-glutamic acid PILPs but through quantitative ^{1}H NMR spectroscopic analysis it was not possible to determine the exact concentration (data not shown). According to the altered ^{1}H NMR chemical shifts for all D,L-glutamic acid signals, the entire D,L-glutamic acid in the PILP interacts with PEI, thus indicating electrostatic as well as hydrogen-bonding interactions exist. This result was also supported by the FTIR data and pH dependent experiments (data not shown). For all polymer/amino acid pairs at different mass ratios, investigations indicate the formation of PILPs in the range of 1 to 5 μm. The PILPs have a long time stability (several months), but vanish immediately when the surrounding ethanol is evaporated. Experimental parameters, such as mode of mixing, stirring (at 0, 400, 1200 rpm), or ageing, had no influence on the particle size distribution.

To investigate the interacting forces and in particular the influence of charge, the zeta potentials of pure D,L-glutamic acid crystals where measured. Additionally, PEI_{600} was added to the crystals in a crystal:polymer ratio of 1:1 to give a reference value for polymer-coated colloids. While crystals of D,L-glutamic acid show a negative zeta potential of around −19 mV, crystals with adsorbed PEI have a positive potential of around 27 mV (Figure 3).

All PILPs made of D,L-glutamic acid and PEI_{600} gave a positive zeta potential of around 18 mV, indicating that the droplets are indeed electrostatically stabilized by an outer excess layer of adsorbed PEI. This finding also reflects the high PEI amount in the PILPs found by FTIR and ^{1}H NMR spectroscopy.

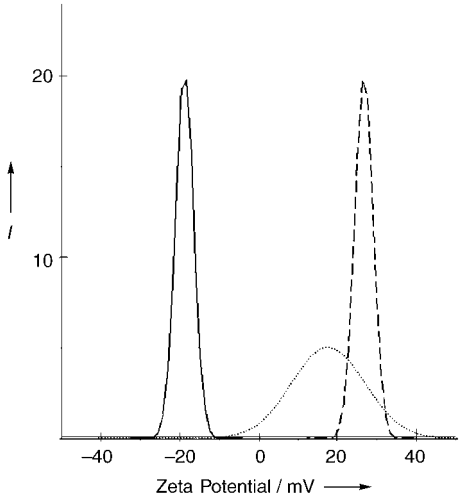

Figure 3. Zeta potentials for different particles: pure D,L-glutamic acid crystals (——); D,L-glutamic acid crystals plus PEI_{600} (– – –); positive zeta potential of a PILP made of D,L-glutamic acid and PEI_{600} (••••).

The three other polyelectrolyte/amino acid pairs examined also show comparable PILP formation. For the basic amino acids L-lysine and L-histidine, polyacrylic acid, PAA_{2000} ($M_w = 2000\ g\,mol^{-1}$), was employed to form the PILPs. Crystallization does not occur in any of the systems containing a low amount of amino acid and a high amount of polymer. A charge-coupled complex between the polyelectrolyte and the amino acid counterions is presumably inhibited from crystallizing, very similar to many structures formed by ionic self assembly.[24]

To promote crystallization from the PILPs, the amino acid concentration and thus the driving force towards crystallization has to be increased, while keeping the polymer concentration at the former level. The high amino acid concentrations of 10 wt% can only be realized by dissolving the amino acid at 60 °C, the PILPs formed at this temperature are then slowly cooled to room temperature to drive crystallization. As shown by light and polarized-light microscopy, the PILP is still liquid directly after cooling. However, after 1 h crystallization is underway for all amino acid/polymer pairs and concentrations, and within 24 h, the vast majority of droplets have crystallized, but a certain amount of PILP droplets are still present. After one week the crystallization process is completed. The resulting crystalline superstructures are spherical and have diameters between 10–100 μm.

The final crystalline structures are therefore much larger than the primary droplets. It is meanwhile a quite common observation that the colloidal stability is lowered throughout the crystallization process, and that the first-formed structures grow by attraction and aggregation of the primary amorphous species.[3,7] Figure 4a shows the light-microscopy image of the so-formed spherical crystal superstructures of D,L-glutamic acid. The typical spherical shape is a superstructure made of primary nanocrystals which in polarization microscopy results in the so called "Brewster cross" (Figure 4b).[25] This result indicates at a perfect radial alignment of the nanocrystals.

Scanning electron microscopy (SEM) investigations reveal that the spherical superstructure is porous, with the primary nanocrystals having a platelet like appearance with a diameter of 200 nm and thickness of 10–20 nm (Figure 4c and d). As D,L-glutamic acid usually crystallizes as needles, this shape speaks for a morphology control provided by the cationic polyelectrolyte, which stabilizes a distinct face. A double hydrophilic block copolymer was recently reported to exert a similar influence on the crystallization of D,L-alanine.[26] To learn more about the microparticle composition, we performed FTIR experiments, these indicated a negligible amount of PEI in the D,L-glutamic acid microcrystals (data not shown). These results were confirmed by ^{1}H NMR spectroscopy data (data not shown) which revealed a low amount of protonated PEI around the ^{1}H NMR detection limit in the microparticles. Wide-angle X-ray scattering (WAXS) revealed domain sizes of D,L-glutamic acid monohydrate > 100 nm for all directions except along the [232] axis which was found to be 20 nm in agreement with the nanoplate thickness in Figure 4d. The formation of these exposed and initially negatively charged (Cerius^2 calculation, not shown) nanoplatelet (232) faces maybe the result of face-selective polymer adsorption. This idea is supported by

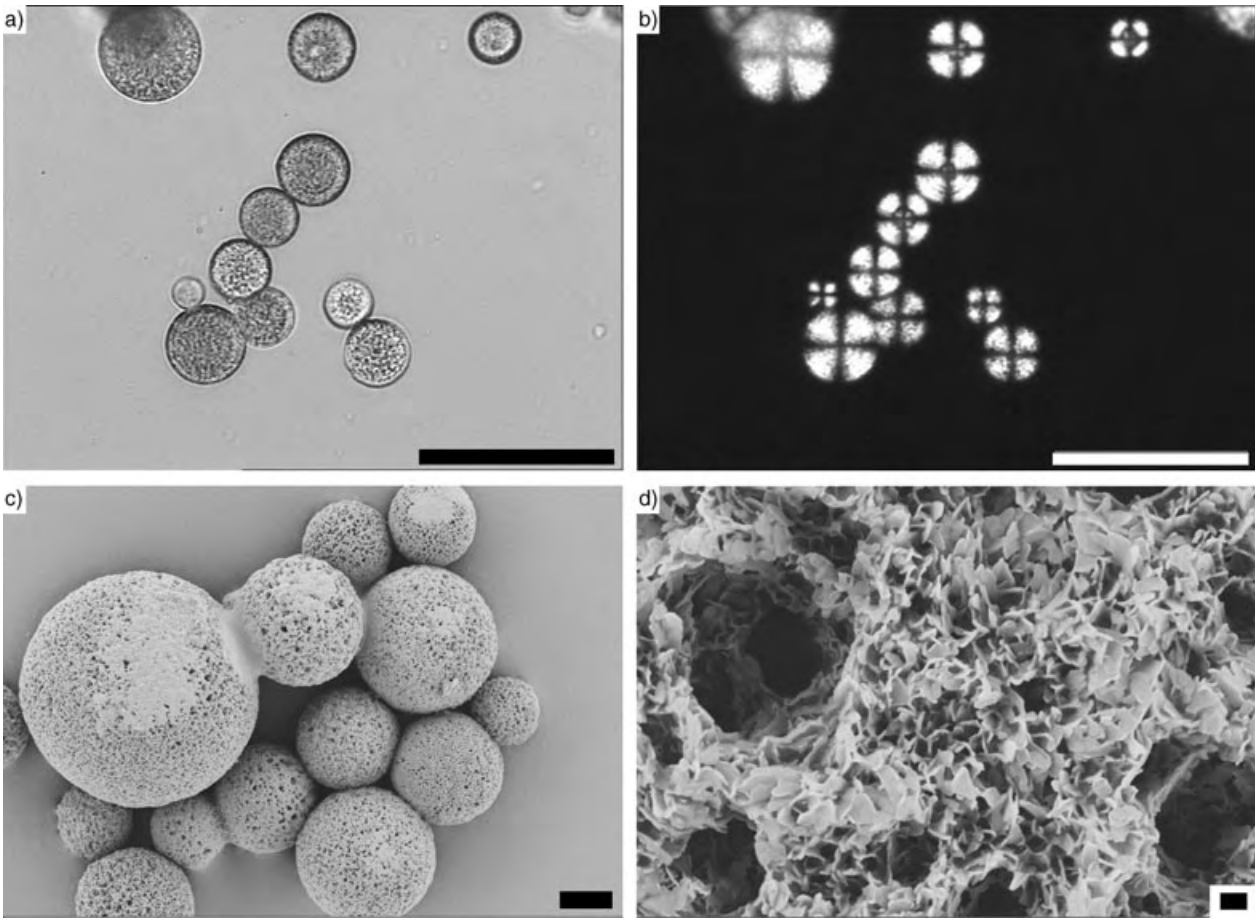

Figure 4. D,L-glutamic acid crystals through growth from a concentrated PILP precursor phase. The PILP formation was induced by adding 10 mL ethanol to 1 mL of a saturated solution (at 60 °C) of D,L-glutamic acid in the presence of 1 wt% PEI ($M_w = 600\ g\,mol^{-1}$), a) light microscopy, b) polarized light microscopy, c) SEM overview of some crystalline superstructures indicating porosity, d) SEM image with a higher magnification to resolve the pore architecture and the construction principle of the spheres. Scale bars: a,b) 100 μm, c) 10 μm, d) 200 nm.

^{1}H NMR spectroscopy which revealed a notable portion of D,L-glutamic acid with a different chemical shift to the pure crystal. This difference was also found in the PILP and indicates interaction with cationic PEI (data not shown).

The porous character is a memory of the excess water and polyelectrolyte in the parent PILP droplets. Therefore it is important to dry the crystals at 50 °C under vacuum to ensure a water-free product. The porosity is then determined by nitrogen sorption experiments using the BET method. For the samples prepared with polymer concentrations of ≤ 1 wt%, a BET-surface area of approximately 13 $m^2\,g^{-1}$ is found which is independent of the initial PILP droplet size. An estimate of the surface area based on the SEM images would result in slightly higher values and suggests the possibility that parts of the structural core are not accessible. BET measurements for L-lysine particles reveal a specific surface of 17 $m^2\,g^{-1}$, very similar to the value for the D,L-glutamic acid.

In the case of the basic amino acids, crystallization again leads to spherical aggregates of smaller crystals (Figure 5). In this case, we have chosen to use the chiral L-enantiomorphs. Again they show a completely different growth pattern to that of the corresponding pure solutions (default experiments shown in the insets of Figure 5), that is, the added polyacrylic acid also modifies the morphology of the primary nanocrystals. Flat crystals, with a thickness of around 50 nm (L-histidine) and about 30 nm (L-lysine), come together to form porous spherical particles with high surface areas. The platelets however have larger lateral extensions than in the D,L-glutamic acid case, resulting in a snowball-like morphology of the final crystalline superstructures. Again, it is interesting to see that the crystals are—whenever possible—radially aligned, so that the distance between the platelets can be seen.

The aspartic acid is effectively blocked from crystallization by the PEI coordination even at elevated concentrations, this is because of its low solubility in water (4 $g\,L^{-1}$ at 20 °C compared to 10 $g\,L^{-1}$ for D,L-glutamic acid at 20 °C), thus other conditions have to be explored for this system.

In conclusion, precipitation of charged amino acids in the presence of oppositely charged polyelectrolytes leads in all the examined cases to rather unusual colloidal structures, the resulting liquid droplets are made of the corresponding amino acid complexes in water. At lower supersaturations these supramolecular "water-in-ethanol" emulsions are stable against crystallization and Ostwald ripening for several months. This prolonged stability against crystallization is

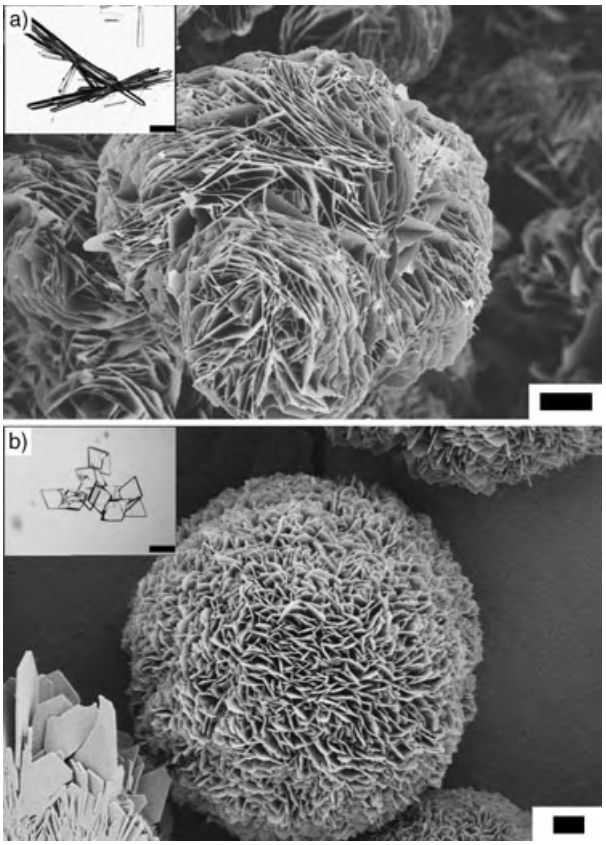

Figure 5. SEM images of a) L-histidine (scale bar 20 μm), b) L-lysine (scale bar 3 μm) crystal superstructures formed through growth from their PILPs. Insets: light micrographs of the default experiments of the as-prepared crystals precipitated without polymer (scale bars 250 μm).

most likely a result of the organic molecule crystals used which have a lower lattice energy than the inorganic ionic crystals investigated previously.[13–15] A kinetic effect can not be ruled out. By increasing the amino acid concentration, it is possible to use this polymer-induced liquid precursor state as a basis for crystallization. After some days, spherical, porous crystal superstructures with 10–100 μm diameter and a radial alignment of the primary nanocrystals are obtained. If the crystallization is repeated in 0.1N HCl or 0.1N NaOH, the electrostatic influence of the polymer on the resulting structures can be revealed. Although PILPs were obtained in every case, porous microcrystals were only obtained at acidic to neutral pH values for the acidic D,L-glutamic acid, and neutral to basic pH values for the basic L-histidine and L-lysine.

The described crystallization can also be understood as a special case of the crystallization by "drowning-out", "salting out", or "solventing out".[27] During protein crystallization similar effects can be observed when "liquid protein" phases are built.[28] While this effect is undesirable during protein crystallization, application of such precursors for crystal morphogenesis is very promising. Since the crystallization proceeds by the Ostwald rule of stages, including a liquid precursor step, the drowning-out process now becomes more attractive for crystal engineering. By using liquid intermediates for further crystallization, it is possible to direct the crystallization into desired morphologies or crystalline coatings,[13] as well as into micro- and nanostructures made of polar organic molecules. The particles have in addition an appropriate size, shape, and porosity for chromatographic applications, where beads made of the enantio-pure amino acids are especially promising.

Experimental Section

All polymers and amino acids were purchased from Aldrich (purity: 99% for D,L-glutamic acid, 98% for L-histidine and D,L-aspartic acid, and >97% for L-lysine), and used without further purification. Double distilled water was used for the preparation of the solutions. As the precipitation agent, HPLC grade ethanol (Merck) was used.

PILP formation: The oppositely charged polymer (0.1, 0.5, 1.0, and 2.0 wt% with respect to the water amount) was added to a solution of the amino acid (1 mL, 1 wt%; or in case of a lower solubility product, the saturated solution) at 20°C in double distilled water. Branched polyethyleneimine (PEI_{600}; $M_w = 600\ g\,mol^{-1}$) was used as the oppositely charged polymer for the negatively charged amino acids D,L-glutamic acid (isoelectric point (IEP) = pH 4.20) and D,L-aspartic acid (IEP = pH 4.25). Polyacrylic acid (PAA_{2000}; $M_w = 2000\ g\,mol^{-1}$) was employed to form PILPs of the positively charged amino acids L-lysine (IEP = pH 8.88) and L-histidine (IEP = pH 6.78). Ethanol (10 mL) was added to this mixture with stirring. The developed PILP phases could be observed by light microscopy as droplets with a diameter of 1–5 μm, depending on mechanical agitation. These low-concentration PILPs are stable for at least 6 months, both against crystallization and colloidal agglomeration.

Crystallization from the PILPs: To stimulate crystallization from the PILPs, the concentration of amino acid has to be increased, which was done by elevating the temperature to 60°C. The oppositely charged polymers (0.1, 0.5, 1.0, and 2.0 wt%) were added to the solution of the amino acid (1 mL of a 10 wt% solution, or in case of a lower solubility, the saturated solution) in double distilled water. Ethanol (10 mL) was added with stirring and the solution was allowed to cool to room temperature. Liquid PILP droplets could be observed, that crystallized within 24 h as indicated by light microscopy. The crystals were isolated from the fluid and washed three times with ethanol, then dried at 50°C under vacuum.

Light microscopy, polarized light microscopy, and high-resolution scanning electron microscopy (HRSEM) were applied to all samples. Light microscopy in solution establishes that the SEM micrographs show real structures and not drying artifacts resulting from the sample preparation. The SEM measurements were performed on a LEO 1550 GEMINI. Light microscopy images were taken in solution with an Olympus BX50 microscope. BET isotherms were measured with a Micromeretics Tristar 3000. Zeta potentials were measured with a Zetasizer HS3000 (Malvern), which determines the zeta potential from the speed of the particle movement in an electric field. Crystal and PILP containing dispersions in ethanol with and without PEI_{600} were investigated according to the conditions of the crystallization experiment.

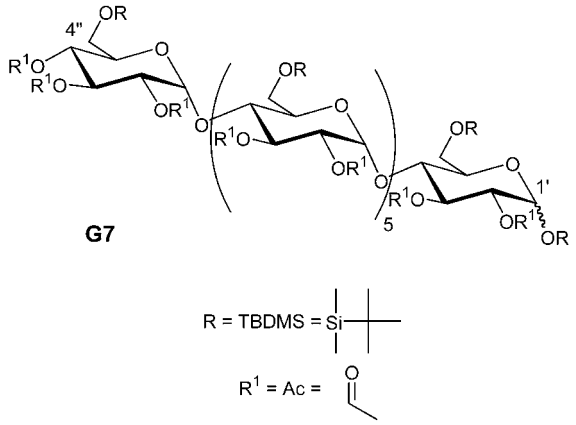
Enantiomer Separation

Modified Linear Dextrins ("Acyclodextrins") as New Chiral Selectors for the Gas-Chromatographic Separation of Enantiomers**

*Giuseppe Sicoli, Zhengjin Jiang, Laszlo Jicsinsky, and Volker Schurig**

In memory of József Szejtli

Cyclodextrins (CDs) modified by alkylation, acylation, and silylation represent versatile chiral stationary phases (CSPs) for the gas-chromatographic separation of enantiomers.[1] Typically, they are dissolved in semipolar polysiloxanes[2a] or linked chemically to polydimethylsiloxane (Chirasil-Dex).[2b] The mechanism of enantiomer recognition is still not well understood, and the role of the CD cavity is unclear in cases were enantioselectivity is low, as it is in most reported cases ($\alpha < 1.1$).[1a] We therefore conjectured that the existence of a cavity may not be a prerequisite to chirality recognition in cyclodextrins. This has now been borne out by employing linear dextrins ("acyclodextrins") as a new generation of carbohydrate-based chiral selectors for the gas-chromatographic separation of enantiomers.



Despite the well-known propensity of cyclodextrins to include various organic compounds in their cavities,[3] it seems plausible to consider the ability of modified linear oligosaccharides as selectors for enantioselective chromatography since helical conformations may act as "semicavities" and suitable functionalities may be present. Previously, per-*n*-pentylated amylose[4a] and amylose tris(*n*-butylcarbamate)[4b] were employed for chiral separations by GC, albeit with limited enantioselectivity. Moreover, the ability of native acyclic α-1,4-linked dextrin (i.e. maltoheptaose) to form molecular complexes and its use for chiral separation by capillary zone electrophoresis has been demonstrated,[5a] for example, for racemic 1,12-dimethylbenzo[*c*]phenanthrene-5,8-dicarboxylic acid.[5b] Even with modified cyclodextrins, NMR studies in solution have shown that interactions of the outer surface play an important role in the chiral-recognition process.[6]

Herein, we compare the enantioselectivity of the versatile cyclic chiral selector heptakis(2,3-di-*O*-acetyl-6-*O*-*tert*-butyldimethylsilyl)-β-cyclodextrin (**CD7**)[7] with that of the acyclic dextrin counterpart heptakis[(1′-*O*,6-*O*)-*tert*-butyldimethylsilyl-(2,3-di-*O*,4″-*O*)-acetyl)]-maltoheptaose (**G7**, G = glucose), which was for the first time subjected to a two-step derivatization procedure that is well established for cyclic oligosaccharides.[8] Thus, maltoheptaose was first etherified with *tert*-butyldimethylsilyl chloride (TBDMSCl) at the primary hydroxy sites and then esterified with acetic anhydride at the secondary hydroxy sites. Spectroscopic evidence indicated that the derivatization of the terminal 1′,4″-hydroxy groups mainly leads to the 1′-*O*-TBDMS/4″-*O*-acetyl derivative. The linear selector **G7** was dissolved in the polysiloxane PS86, and a fused-silica capillary column (20 m × 0.25 mm i.d.) was coated according to the static method.[2a]

The new selector is capable of separating derivatized α-amino acid enantiomers. Thus, the racemic *N*-trifluoroacetyl-*O*-*methyl* esters of α-amino acids could be separated on both **CD7** and on the analogous linear dextrin counterpart **G7** with optimized temperature programming (Figure 1). Under isothermal conditions (Table 1) cyclic **CD7** exhibits a higher enantioseparation factor α than acyclic **G7**. The retention factors *k*′ of the enantiomers are quite different for **CD7** and **G7**, and the elution order is reversed for *tert*-butyl leucine and norvaline (Table 1). In all separations, D enantiomers are eluted after L enantiomers. More intriguing differences are observed for the separation of the racemic *N*-trifluoroacetyl-*O*-*ethyl* esters of α-amino acids (Table 2). Whereas the enantioselectivity is higher for alanine (Ala) on cyclic **CD7** than on acyclic **G7**, only the two diastereomers of isoleucine (IsoLeu) are separated on cyclic **CD7**. However, they are further resolved into enantiomers on acyclic **G7** (Figure 2a). Norvaline (Norval, Figure 2b) and serine (Ser, Figure 2c) can be separated on acyclic **G7** but not on cyclic **CD7**. Further differences in the retention factor *k*′ and enantioseparation factor α are evident from Table 2.

The role of molecular inclusion cannot be ignored in examples of extreme enantioselectivities that vary with the size of the cavity. For example, the unusually high enantioseparation factor of $\alpha = 4.08$ was observed for racemic 2-(fluoromethoxy)-3-methoxy-1,1,1,3,3-pentafluoropropane

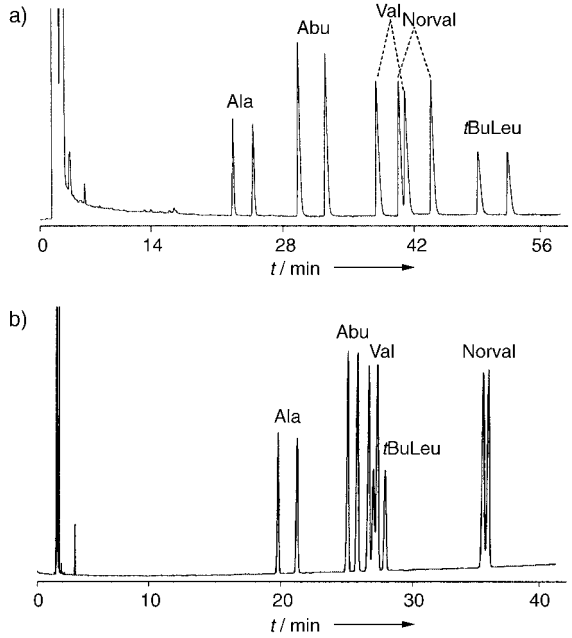

Figure 1. Gas-chromatographic separation of racemic *N*-trifluoroacetyl-*O*-methyl esters of α-amino acids on **CD7** (a) and on **G7** (b); in each case the dextrin is 20% (w/w) in PS86. Figure 2. Gas-chromatographic separation of racemic *N*-trifluoroacetyl-*O*-ethyl esters of α-amino acids on **CD7** (left) and on **G7** (right); in each case the dextrin is 20% (w/w) in PS86. Columns: 20 m × 0.25 mm i.d. fused-silica capillary, film thickness 0.25 μm. For other experimental conditions, see Table 2.

("compound B", a decomposition product of the narcotic sevoflurane) on **CD7** (Figure 3a). The separation factor drops to $\alpha = 2.70$ for the γ-cyclodextrin analogue **CD8** and to $\alpha = 1$ (no enantiomeric discrimination) for the α-cyclodextrin analogue **CD6** (Table 3). Surprisingly, the separation of "compound B" occurs also on **G7**, although with reduced enantioselectivity (Figure 3b). Whereas a remarkable difference of enantioselectivity is observed for **CD7** and **CD8**, no such difference is discerned for **G7** and **G8** (Table 3). More interestingly, enantioselectivity is displayed by acyclic **G7** and **G8** but not by cyclic **CD6** (Table 3).

In conclusion, derivatized linear dextrins ("acyclodextrins") represent a new class of carbohydrate-based selectors for gas-chromatographic separation of enantiomers. Comparisons between **G7** and **CD7** indicate that acyclodextrins are useful for investigations of the role of molecular inclusion. Besides *N*-trifluoracetyl amino acid esters, other racemates such as lactones, alcohols, diols, and amides are also amenable to enantiomeric separation by **G7**. Current trials are concerned with the influence on the number of glucose entities in the linear dextrins for enantiorecognition.

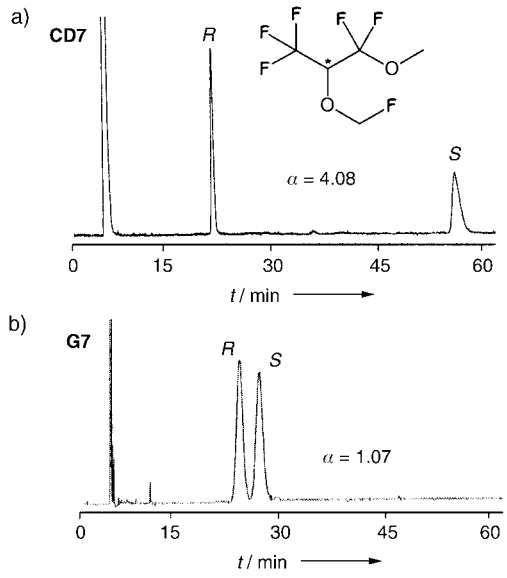

Figure 3. Gas-chromatographic separation of racemic 2-(fluoromethoxy)-3-methoxy-1,1,1,3,3-pentafluoropropane ("compound B") on **CD7** (a) and on **G7** (b); in each case the dextrin is 20% (w/w) in PS86. Columns: 20 m × 0.25 mm i.d. fused-silica capillary, film thickness 0.25 μm. Carrier gas: 0.3 bar; oven temperature: 30 °C.

Table 3: Enantioseparation factor α of "compound B" on modified cyclic and acyclic dextrins.[a,b]

CSP	CD6	CD7	CD8	G7	G8
α	1.00	4.08	2.70	1.07	1.06

[a] In each case the dextrin is 20% (w/w) in PS86. [b] Columns: 20 m × 0.25 mm i.d. fused-silica capillary, film thickness 0.25 μm, carrier gas 0.3 bar hydrogen, oven temperature 30 °C.

Experimental Section

Gas-chromatographic experiments were carried out on an HP 5890 gas chromatograph equipped with a flame ionization detector operated at 250 °C. The carrier gas was hydrogen (99.996%) (Messer-Griesheim, Frankfurt, Germany), which was used without further purification. The splitting ratio at the injector (held at 220 °C) was set to 1:100. Retention times were determined using a Shimadzu C-R6A data processor (Kyoto, Japan). *tert*-Butyldimethylsilyl chloride (TBDMSCl) and acetic anhydride were purchased from Aldrich.

Heptakis[(1′-*O*,6-*O*)-*tert*-butyldimethylsilyl]-maltoheptaose: Dry maltoheptaose (1 g, 0.87 mmol) was dissolved with vigorous stirring in anhydrous pyridine (15 mL). The solution was cooled in an ice bath, and a solution of TBDMSCl (1.6 g, 10.6 mmol) in anhydrous pyridine (20 mL) was then added dropwise over 4 h. Cooling was continued a further 2 h before the solution was allowed to warm to room temperature. After a further 12 h at RT, the solvent was removed under reduced pressure to give a white solid, which was taken up in CH_2Cl_2 (30 mL). The CH_2Cl_2 phase was washed with an aqueous solution of $KHSO_4$ (20 mL, 1M) to remove any residual pyridine and then with saturated aqueous NaCl solution. The CH_2Cl_2 layer was recovered and concentrated to dryness. Yield: 1.61 g (85%). The product was used without further purification. A mixture of three silylated linear dextrins was present (with 7 (M^1), 8 (M^2), and 9 (M^3)

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tert-butyldimethylsilyl substituents), as confirmed by mass-spectrometric analysis (ESI-MS): *m*/*z* 993 $[M_1+2Na]^{2+}$, 1056 $[M_2+2Na]^{2+}$, 1113 $[M_3+2Na]^{2+}$. From the elemental analysis it is evident that the main species (95%) is the linear oligosaccharide as its octa-*tert*-butyldimethylsilyl ether. Elemental analysis (%) calculated for $C_{90}H_{184}O_{36}Si_8$: C 52.29, H 8.97; found: C 52.20, H 9.35.

Heptakis[(1′-*O*,6-*O*)-*tert*-butyldimethylsilyl-(2,3-di-*O*,4″-*O*)-acetyl]-maltoheptaose (**G7**): Crude heptakis[(1′-*O*, 6-*O*)-*tert*-butyldimethylsilyl]-maltoheptaose (1.5 g) were dissolved in anhydrous pyridine (20 mL) and acetic anhydride (18 mL). The solution was stirred for 5 h at 100 °C and then concentrated. The remainder of the solvents were removed by coevaporation with toluene. Column chromatography of the residue eluting with toluene/ethanol (95:5 v/v) afforded amorphous **G7**. After acetylation of the hydroxy groups at the 2- and 3-positions, the structure of the mixed acetyl/TBDMS selector was elucidated by ^1H and ^{13}C NMR spectroscopy. The main species (95%) of the mixture showed a terminal silyl ether group on the reducing terminus C1 and a terminal acetyl ester group on the nonreducing terminus C4. ESI-MS: *m*/*z*: 1365 $[M+2Na]^{2+}$ (main species). Elemental analysis (%) calculated for $C_{120}H_{214}O_{51}Si_8$: C 53.43, H 8.00; found: C 53.35, H 8.17.

Catalyst Recycling

"Catalyst-on-a-Tape"—Teflon: A New Delivery and Recovery Method for Homogeneous Fluorous Catalysts**

*Long V. Dinh and J. A. Gladysz**

There are intense efforts to develop new or improved strategies for recovering homogeneous molecular catalysts.[1] Many of these approaches are bi- or multiphasic in nature, and one particularly innovative method involves catalysts that are derivatized with $(CH_2)_m(CF_2)_{n-1}CF_3$ ($(CH_2)_mR_{fn}$) moieties or fluorous "ponytails".[2,3] The initial applications of this now-familiar technique utilized perfluoroalkane solvents for recovery. However, the relatively high costs of such fluorous solvents, and other factors, pose limitations for industrial applications.

Second-generation methods eliminated the fluorous solvent by exploiting the temperature-dependent solubilities of fluorous catalysts in common organic solvents.[4,5] Appropriately designed fluorous molecules are soluble only at elevated temperatures, and essentially insoluble at low temperatures. Such a thermomorphic character allows homogeneous catalysis at the high-temperature limit, and catalyst recovery by a simple liquid/solid-phase separation at the low-temperature limit. The presence of an insoluble fluorous support can be beneficial, for example, when small quantities are involved. Initial efforts have involved Teflon shavings[4] and fluorous silica gel.[6–8]

We sought to expand the range of catalysts and fluorous supports that could be applied in such methods, and report herein a surprisingly effective procedure involving common commercial Teflon tape. This approach provides not only a convenient means of catalyst recovery, but also of catalyst delivery. From an engineering standpoint, tapes offer a variety of unique attributes, and it is reasonable to extrapolate that meshes and/or reactor parts, such as liners or stirring assemblies, could be fabricated with similar properties.

As a test reaction, we selected the ketone hydrosilylation shown in Figure 1, which in earlier work was catalyzed by the fluorous rhodium complexes **1**-R_{f6} and **1**-R_{f8} in a liquid/liquid biphase system comprising an organic and a fluorous solvent.[9] The red-orange compounds **1**-R_{f6} and **1**-R_{f8} have very little or no solubility in organic solvents at room temperature.[10] However, their solubilities increase markedly with

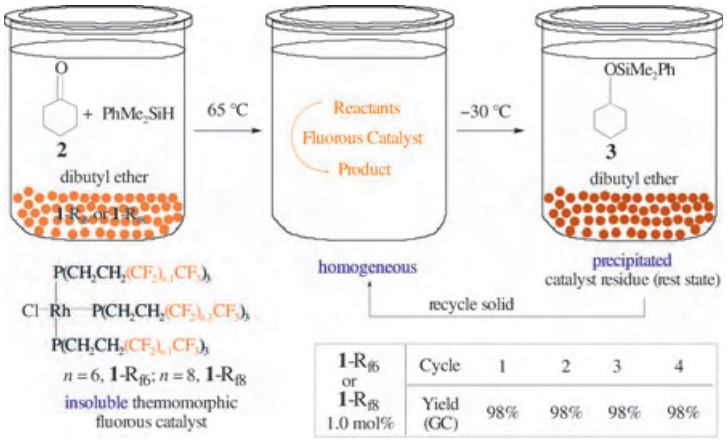

Figure 1. Recycling of a thermomorphic fluorous rhodium hydrosilylation catalyst by liquid/solid phase separation.

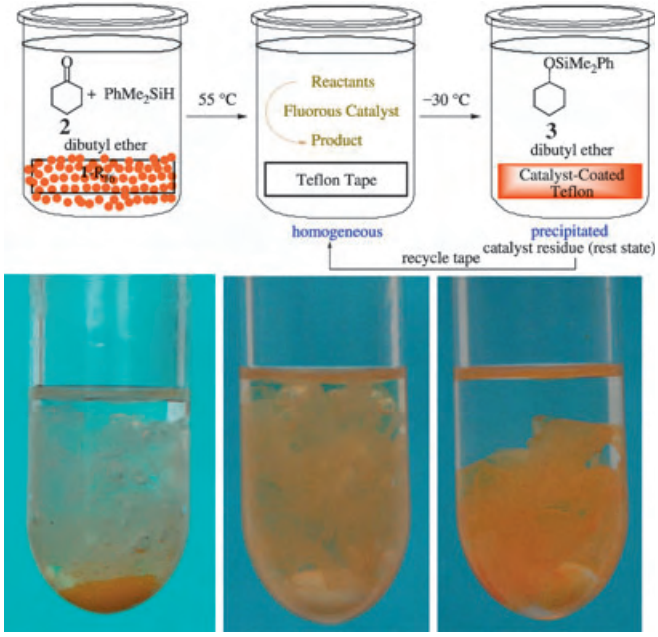

Figure 2. Recycling of a thermomorphic fluorous rhodium hydrosilylation catalyst using Teflon tape.

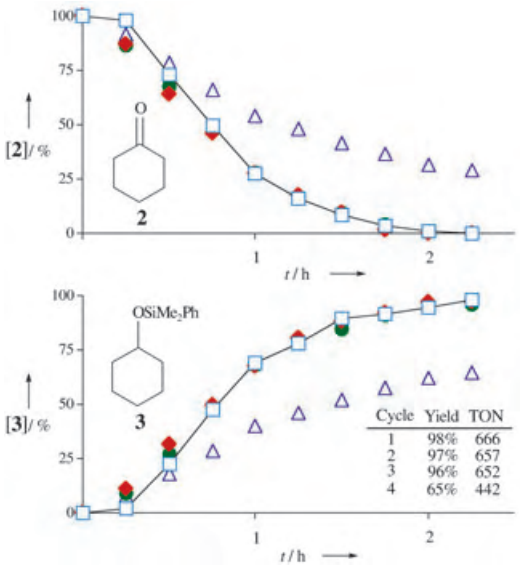

Figure 3. Reaction profile for four cycles under the conditions given in Figure 2: □ Cycle 1 ◆ Cycle 2 ● Cycle 3 △ Cycle 4. Top: decrease (%) in **2** with time, bottom: increase (%) in **3** with time. TON = turnover number.

temperature. Several features make this catalyst system a particularly challenging test for recovery by precipitation. For example, a variety of rest states are possible (e.g., various {Rh(H)(SiR_3)} or {Rh(OR′)(SiR_3)} species), each with unique solubility properties.[11] Also, the first cycle exhibits an induction period,[9] indicating some fundamental alteration of the catalyst precursor.

The solvent dibutyl ether was selected due to its extended liquid range (b.p. 142 °C). A solution of cyclohexanone (**2**; 0.53 M), $PhMe_2SiH$ (1.2 equiv), and a GC standard was treated with **1**-R_{f6} (1 mol %), and warmed to 65 °C, achieving homogeneous conditions.[12] After 8 h, the mixture was cooled to room temperature. GC analysis showed a 98 % yield of the silyl ether **3**. A brown-red catalyst residue slowly precipitated over several hours, and no color remained in the product-containing supernatant solution. To speed up this process, samples were transferred to a freezer (−30 °C); the supernatant solutions were then removed by syringe. The residue was washed twice with cold dibutyl ether and charged with fresh reactants. The cycle was repeated three additional times, each giving a 98 % yield of **3**.

Supports were sought that would facilitate the recovery of lower catalyst loadings. Thus, a similar sequence was conducted with **1**-R_{f6} (0.15 mol %), but in the presence of Teflon tape (thickness/width 0.0075/12 mm). For this system, homogeneous conditions could be achieved at 55 °C. Photographs of a typical sequence are shown in Figure 2. The white tape became lightly colored during the reaction, and orange-red when the sample was cooled. Enthalpic interactions between perfluoroalkyl segments are very small. Hence, it is noteworthy that the catalyst rest-state phase separates onto the tape, as opposed to giving a second solid phase. Interestingly, the Teflon stirring bar remained white.

GC analysis as above indicated a 97 % yield of **3**. In an identical reaction the concentrations of **2** and **3** were assayed at 15 min intervals over four cycles. Data are summarized in Figure 3. As in earlier work,[9] the first cycle exhibited an induction period. Retention of activity was excellent in the second and third cycles, but there was substantial loss in the fourth. In view of the similar rates of the first three cycles, this loss of activity can be attributed to catalyst deactivation, as opposed to leaching or some intrinsic problem with the recycling method.

Leaching was probed in two ways. First, the dibutyl ether supernatants from the first three cycles of the experiments shown in Figure 3 were combined, a fluorine-containing standard added, and a ^{19}F NMR spectrum recorded. The chemical shifts of the $-(CF_2)_5CF_3$ signals are independent of the remote substituent, and integration indicated a "total pony-tail leaching" corresponding to 11.4 % of the phosphine

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ligands of **1**-R_{f6}. Since the active and resting states of the catalyst probably involve only two phosphine ligands, some extraction is not surprising. Second, the supernatant from the first cycle was analyzed for rhodium by AAS-ICP (atom absorption spectrometry with inductively coupled plasma). An average of three determinations indicated leaching corresponding to 0.57% of the original charge. The second cycle gave a value of 5.3%.

One procedural refinement would be to precoat the catalyst on the Teflon tape. When coating is uniform, this would allow low loadings to be delivered by length as opposed to mass measurements. Accordingly, two $50 \times 12 \times 0.0075$ mm strips of tape were added to a solution of **1**-R_{f6} (0.013 g, 0.0039 mmol) in $CF_3C_6F_{11}$ (1.0 mL). The solvent was removed under an inert gas stream to give a yellowish catalyst-coated tape. This tape was applied in a three-cycle sequence and gave yield results similar to those in Figure 3. Photographs are supplied in the Supporting Information.

When catalysts are recycled as solid residues, it is important to exclude impurities that may "piggyback", such as metal particles, as the active species. This situation was probed in two ways. First, the tape was removed after a first cycle, rinsed with cold dibutyl ether, and transferred to a new vessel. A second charge of **2** and dibutyl ether was added, but not the $PhMe_2SiH$. The sample was warmed to 55°C, the now-off-white tape "fished out", and $PhMe_2SiH$ added. The rate profile was similar to the first cycle (ca. 20% slower at higher conversions), consistent with predominant homogeneous catalysis by desorbed fluorous species. Second, the second cycle of a sequence was conducted in the presence of elemental mercury (Hg:Rh 500:1), which inhibits catalysis by metal particles.[13] However, the rate profile was the same as a sequence in the absence of mercury (see Supporting Information).

Hydrosilylations of 2-octanone, acetophenone, and benzophenone to the corresponding ethers have been conducted under identical conditions. As summarized in the Supporting Information, similar results are obtained, albeit with up to 20% activity loss in the third cycle. The basis for this somewhat diminished performance is under study and further details will be provided in a full paper.

In summary, the above data constitute, to our knowledge, the first catalyst recycling method involving common Teflon tape. Attractive interactions between the fluorous domains of the catalyst and the tape are clearly operative. However, other forms of Teflon—such as used to coat stir bars—are ineffective, and additional work is needed to identify the optimum morphologies.[14] There are also tantalizing possibilities with other fluoropolymers, as well as for fabricating reactors or components thereof that could efficiently release and recapture thermomorphic fluorous catalysts as a function of temperature. Furthermore, precoated "catalyst-on-a-tape" systems offer many advantages for delivery alone, such as the introduction of low loadings without recourse to a balance or the tedious preparation of standard solutions. Finally, the slightly different solubility profiles of **1**-R_{f6} and **1**-R_{f8}[12] nicely illustrate how physical properties of fluorous compounds can be engineered to optimally fit a particular application or reaction condition.

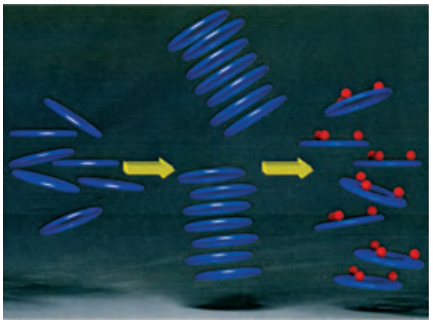
WILEY-VCH

1998/1506_gu

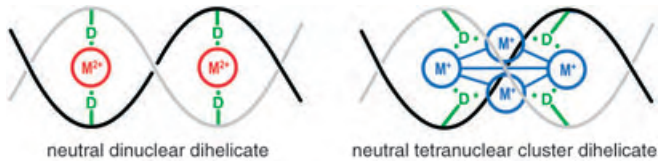


Globular configuration: a microporous coordination polymer based on a dodecanuclear copper(I) cluster (picture: C black, Cu red, N blue, S yellow) as a twelve-connected node, was synthesized by a simultaneous redox, sulfurization, and self-assembly reaction under solvothermal conditions. The synthesis provides a model reaction to simulate the transformation of inorganic sulfur into organic sulfur.

Topological Networks

D. Li,* T. Wu, X.-P. Zhou, R. Zhou, X.-C. Huang ——— **4175 – 4178**

Twelve-Connected Net with Face-Centered Cubic Topology: A Coordination Polymer Based on $[Cu_{12}(\mu_4\text{-}SCH_3)_6]^{6+}$ Clusters and CN^- Linkers



Fluorescence switching: Multimetallic fluorescent macrocycles aggregate into supramolecular assemblies on changing the solvent from THF to CH_2Cl_2. Coordinating bases (e.g., pyridine) cause deaggregation of these assemblies and result in a large enhancement of the fluorescence (see schematic representation of the organization of the macrocycles in THF (left), in CH_2Cl_2 (middle), and after addition of pyridine (right)).

Supramolecular Chemistry

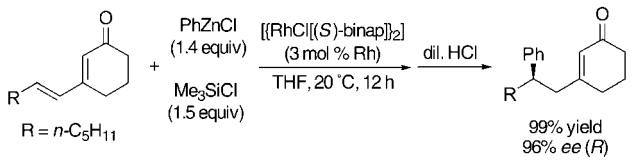
Carbohydrate Chemistry

S. Hanashima, S. Manabe, Y. Ito* ——— 4218 – 4224

Divergent Synthesis of Sialylated Glycan Chains: Combined Use of Polymer Support, Resin Capture–Release, and Chemoenzymatic Strategies

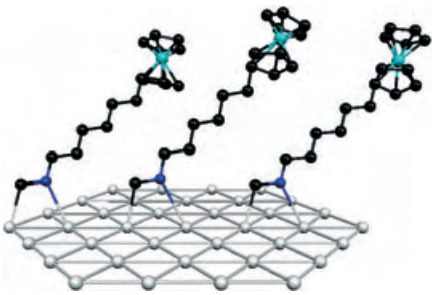


Carbo loading! The synthesis of α(2,3)- or α(2,6)-sialylated biantennary glycans is possible with a new approach. The common precursor **1** was synthesized with a soluble polymer support strategy (a) in combination with a resin capture–release protocol. Hexasaccharide **1** can then be diverged to various polysaccharides by enzymatic glycosylation (b). Bn = benzyl, TBS = *tert*-butyldimethylsilyl.

Asymmetric Catalysis

T. Hayashi,* S. Yamamoto, N. Tokunaga ——— 4224 – 4227

Rhodium-Catalyzed Asymmetric 1,6-Addition of Aryl Zinc Reagents to Dienones

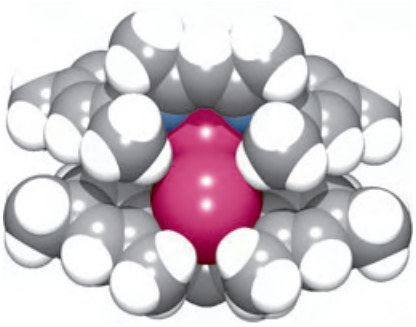


A highly enantioselective methodology allows the preparation of α,β-unsaturated ketones that contain a new stereogenic center at the C5 position. This approach is realized through the title reaction in the presence of chlorotrimethylsilane as a Lewis acid and a rhodium/(*S*)-binap complex as the catalyst followed by acidic hydrolysis (see scheme). binap = 2,2′-bis(diphenylphosphanyl)-1,1′-binaphthyl.

Molecular Devices

Y. Lee, G. M. Morales, L. Yu* ——— 4228 – 4231

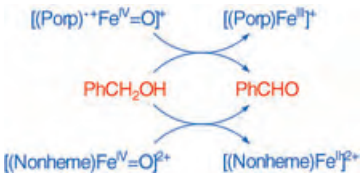
Self-Assembled Monolayers of Isocyanides on Nickel Electrodes



Alligator clip on a nickel electrode: Monolayers of ferrocenyl-terminated isocyanides are strongly chemisorbed on nickel surfaces (see picture). The nickel–isocyanide interaction has a parallel binding mode, and the monolayers have higher thermal stability in boiling ethanol than thiol monolayers on gold. The nickel–isocyanide monolayers could be useful in molecular electronics.

Metal–Metal Interactions

M. S. Hill,* P. B. Hitchcock, R. Pongtavornpinyo ——— 4231 – 4235

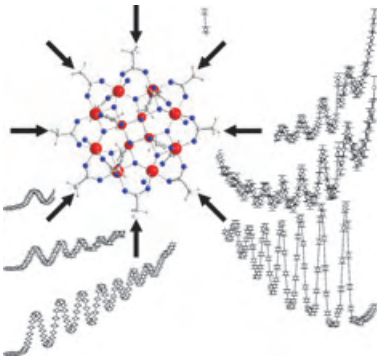


Dimerization of Indanediyl Fragments: An Alkene Analogue for Group 13?

A β-diketiminate complex of indium, $[In\{N(2,4,6\text{-}Me_3C_6H_2)C(Me)\}_2CH]$, dimerizes in the solid state (see space-filling model) to provide an indium species that is formally isoelectronic to the historically significant bis(stannane)diyls. A direct In–In bond is formed yielding a centrosymmetric dimer that possesses approximate C_{2h} symmetry with a mutual *trans*-bent orientation of the N-chelating ligands.

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

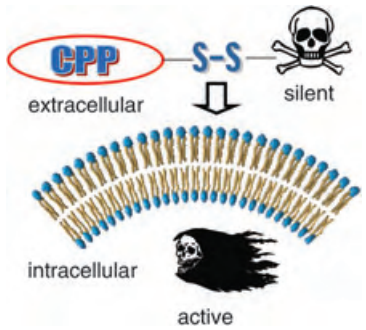
Iron-mediated oxidation: High-valent iron(IV)–oxo complexes of heme and nonheme ligands are generated in situ and are used in mechanistic studies of alcohol oxidation (see scheme). It is proposed that the oxidation of alcohols occurs by an α-CH hydrogen atom abstraction followed by electron transfer. Porp = porphyrin.



Reaction Mechanisms

N. Y. Oh, Y. Suh, M. J. Park, M. S. Seo, J. Kim,* W. Nam* ——— **4235 – 4239**

Mechanistic Insight into Alcohol Oxidation by High-Valent Iron–Oxo Complexes of Heme and Nonheme Ligands



The pressure-dependence of the zero-field splitting of the $S = 10$ ground state of the single-molecule magnet Mn_{12}-acetate was studied by inelastic neutron scattering (INS) at hydrostatic pressures up to 12 kbar (see picture). The anisotropy increases with increasing pressure, and a pressure-dependent minority species of Mn_{12}-acetate was observed. The increased anisotropy arises from increases in the single-ion anisotropy of the Mn^{3+} building blocks.

Single-Molecule Magnets

A. Sieber, R. Bircher, O. Waldmann, G. Carver, G. Chaboussant, H. Mutka, H.-U. Güdel* ——— **4239 – 4242**

Effect of Pressure on the Magnetic Anisotropy in the Single-Molecule Magnet Mn_{12}-Acetate: An Inelastic Neutron Scattering Study

Ricin, diphtheria toxin, and other cytotoxic proteins are two-component systems which contain a carrier protein that biochemically silences the activity of the appended "warhead" protein until it is delivered into the cell. A cell-penetrating peptide (CPP) has been used in an analogous fashion (see picture) to suppress the activity of a PTP1B inhibitor that becomes activated by cleavage of the disulfide bridge upon cellular entry.

Drug Delivery

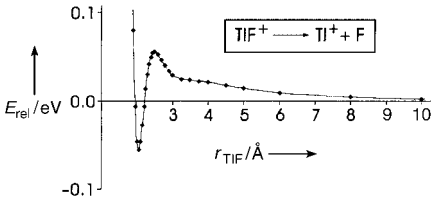
Metal Nitrides

P. Kroll,* T. Schröter, M. Peters _____ 4249 – 4254

Prediction of Novel Phases of Tantalum(V) Nitride and Tungsten(VI) Nitride That Can Be Synthesized under High Pressure and High Temperature

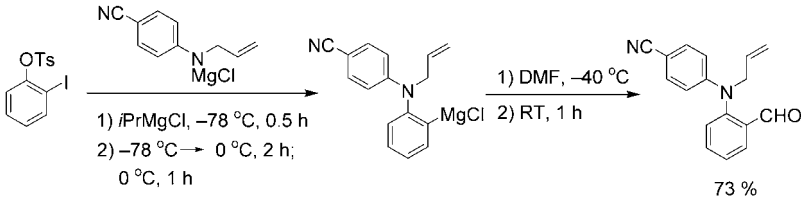


A combination of quantum-chemical and thermochemical calculations leads to the prediction of novel polymorphs of Ta_3N_5 and WN_2. Based on thermochemical data the fugacity of nitrogen at very high pressures is estimated which facilitates a detailed assessment of the synthesis conditions. The modifications of Ta_3N_5-II and WN_2-II have metal centers the are eight- and nine-fold coordinate (see picture: red W, green N).

Gas-Phase Reactions

D. Schröder,* C. van Wüllen,* H. Schwarz, T. M. Klapötke _____ 4254 – 4257

Stability of Gaseous Thallium Monofluoride as TlF^0, TlF^+, and TlF^{2+}

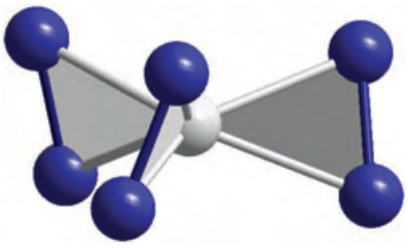


Probing a shallow minimum with a sledgehammer can be said to characterize the present experimental studies, which reveal the existence of thallium fluoride in three different charge states. High-level theory provides a quantitative description of the redox energetics of $TlF^{0/+/2+}$ (see picture: potential curve for TlF^+).

Arene Functionalization

W. Lin, I. Sapountzis, P. Knochel* _____ 4258 – 4261

Preparation of Functionalized Aryl Magnesium Reagents by the Addition of Magnesium Aryl Thiolates and Amides to Arynes



Reactive arynes, which are readily generated by the reaction of *ortho*-iodoarylsulfonates with *i*PrMgCl, undergo the smooth addition of various magnesium nucleophiles like magnesium thiolates, selenides, and amides. In all cases the resulting functionalized aryl magnesium species can be trapped by an electrophile leading to highly functionalized aromatic compounds (see scheme).

Oxygen-Rich Compounds

G. Stößer, H. Schnöckel* _____ 4261 – 4264

The Molecules AlO_2, $Al(O_2)_2$, and $Al(O_2)_3$: Experimental and Quantum-Chemical Investigations on the Oxidation of Aluminum Atoms

On the route to alumina, oxygen-rich oxides such as $Al(O_2)_3$ (see picture) are detected spectroscopically during the stepwise oxidation of aluminum atoms and confirmed structurally by quantum-chemical calculations.

MASAKATSU SHIBASAKI and YOSHINORI YAMAMOTO, (eds.)

Multimetallic Catalysts in Organic Synthesis

The reference comprehensively covers this hot topic presenting the information hitherto scattered throughout smaller reviews or single book chapters to provide an introduction to this rapidly expanding field.
In ten chapters, the international team of expert authors treats asymmetric syntheses, new transformations, and organometallic reactions using homo- and hetero-bimetallic catalysts. Written for advanced researchers, this very timely publication is of significant benefit to organic and organometallic chemists in both academia and industry.

Molecular Motors

Molecular Motors: Synthetic DNA-Based Walkers Inspired by Kinesin**

*T. Ross Kelly**

Keywords:
bioorganic chemistry · DNA · molecular devices · nanotechnology

The field of molecular devices has stimulated much research during the last two decades.[1] Over the past several years, increasing attention has focused on the construction of synthetic molecular motors, and both rotary and linear motors have been observed with "organic"[2–9] and DNA-based[10–16] systems. Biology is rich with molecular motors (flagella, muscles, cilia, etc.),[17] and until 2004 only biology provided examples of processive molecular motors in which a motor molecule moves across a surface. Kinesin is the prototypical processive biological motor,[18] although others such as DNA polymerases also exist. Fueled by ATP, kinesin "walks" along a microtubule as illustrated by the cartoons in Figure 1. A key feature of the kinesin system is that the direction of movement is controlled. The challenge of controlling directionality is perhaps best illustrated by considering the situation halfway between Figure 1b and 1c: If the kinesin is attached by only the turquoise-colored foot, and the nearest binding sites for a pink foot are identical (one to the left, to give Figure 1a, and one to the right, to give Figure 1d), how is unidirectional movement accomplished? Nature has clearly found a solution with kinesin, but to solve the issue of directionality in a synthetic device is probably the most challenging part of the problem. Four papers published in 2004[19–22] provide the first steps toward meeting this challenge. All of these use DNA-based systems.

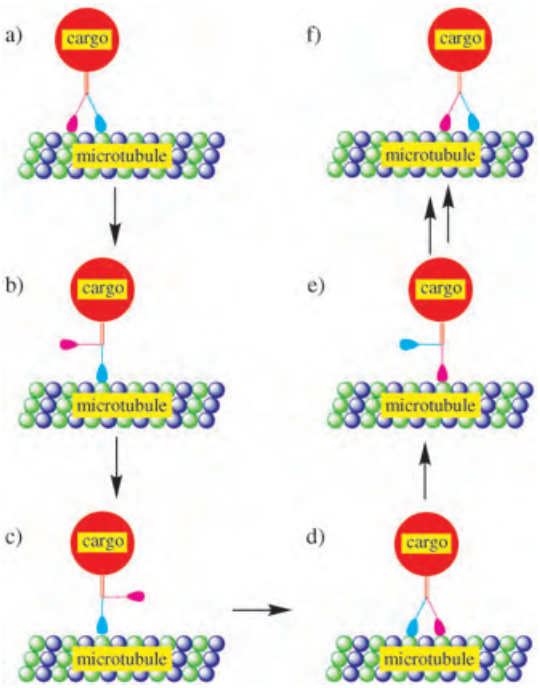

Figure 1. Schematic representation of kinesin (carrying cargo) "walking" along a microtubule.

The specifics of the four reports vary, but in essence the association/dissociation processes are driven by the hybridization of complementary single strands of DNA to form double helices, sometimes with the simultaneous cleavage of a second double helix. The second law of thermodynamics requires the expenditure of energy to achieve unidirectional motion.[23] All four systems utilize chemical energy to accomplish movement; the first three are powered by the free energy released during the course of base-pairing and double-helix formation, while the fourth is impelled primarily by the energetics of ATP hydrolysis.

Progress in this area of molecular motors was first reported by Sherman and Seeman.[19] Their concept is illustrated in Figure 2 and consists of several all-DNA components including a "footpath" (dark blue), two "legs" (brown, connected to each other by three flexible linkers) that bear single-stranded "feet" (foot 1 (F1) pink, foot 2 (F2) orange), and "footholds" (FH) A (turquoise) and B (green). Both *movement* and *standing still* are achieved by using two families of single-stranded DNA fuel strands designated as "unset" and "set" strands. Set strands join single-stranded segments by hybridizing with them, but can be removed by the addition of unset strands for which they have greater affinity. A foot attaches to a foothold when a set strand that is complementary to both is added to the solution. Complementary strand sections are shown in Figure 2 with the same color. Thus, when the pink and turquoise set strand labeled "SS 1A" is present as in Figure 2a, it connects foot 1 of the biped to foothold A as shown.

Each set strand has an eight-base overhang or "toehold" that is not complementary to any of the feet or footholds (it is colored gray in Figure 2a). The toehold allows the set strand to be

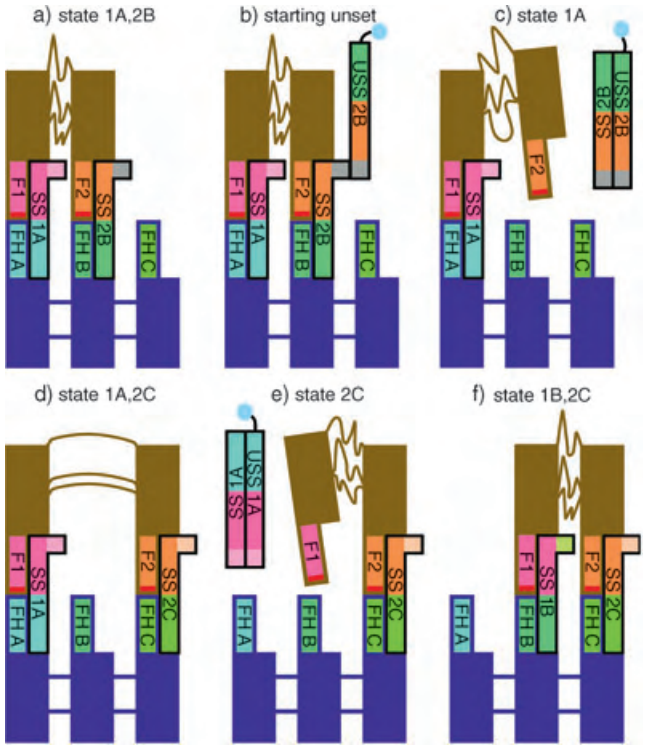

Figure 2. Conceptual representation of the operation of the Sherman–Seeman[19] biped walking device (see text for details). Matching colors indicate complementary sequences between strands; SS = set strand, USS = unset strand, F = foot, and FH = foothold. Panels (b) and (c) depict unset strand 2B first attaching to the toehold section of set strand 2B (drawn in gray) and then removing it to set foot 2 free. The set/unset complex in panel (c) can, if desired, then be removed by complexing the biotin group (depicted as a light blue circle) with streptavidin-coated magnetic beads. (Reproduced with permission of the authors.)

removed by the unset strand (Figure 2b, c). The sequences of each foot, foothold, and toehold are represented in the cartoons by unique colors. Detailed sequences are provided in Figure 3.

Figure 2a shows state 1A,2B of the system: In this state, foot 1 is set to foothold A, and foot 2 is set to foothold B. The biped is initially prepared in this state. For the biped to take a step, foot 2 first needs to be released from foothold B, as shown in Figure 2b and c. To start, unset strand 2B is introduced into the solution. It binds to the toehold of set strand 2B (Figure 2b) and subsequent branch migration results in the complete hybridization of set strand 2B with unset strand 2B. The resulting state shown in Figure 2c leaves foot 2 connected to the footpath only indirectly through the flexible linkers to foot 1 and set strand 1A. Once foot 2 has been freed from foothold B, it is free to be set back down either on foothold B, which would return the system to state 1A,2B, or on foothold C, which would move the system to state 1A,2C, as shown in Figure 2d. Note that the flexible linkers need to extend across foothold B to reach from foothold A to foothold C. Starting with state 1A,2C (Figure 2d) similar unset and set operations can be used to move foot 1 from foothold A to foothold B to bring the system to state 1B,2C, as shown in Figure 2f. The total distance traveled by the biped relative to the footpath during this step is approximately the 2-nm width of one DNA helical domain.

At present the range of the Sherman–Seeman walker is limited to one or two steps. Notably, it moves in a so-called inchworm fashion, with one foot always trailing the other. Until recently, it was not known if kinesin itself locomotes by an inchworm or hand-over-hand (foot-over-foot) mode. The inchworm motif has now been disproven[18] for kinesin (but not for inchworms).

Shin and Pierce[20] have taken Sherman and Seeman's work a step further by demonstrating a processive bipedal DNA nanomotor that moves by advancing the trailing foot to the lead at each step, as shown in Figure 4. As noted in the introduction, directionality is a crucial issue and especially difficult if only two feet and two kinds of footholds are used. The Shin–Pierce system uses two

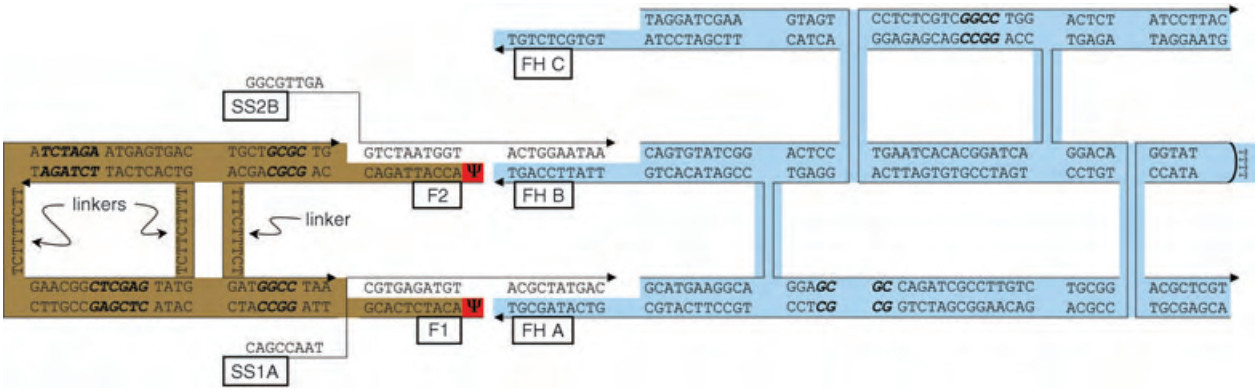

Figure 3. DNA base sequence corresponding to Figure 2a rotated 90° counterclockwise relative to Figure 2a, with SS = set strand, F = foot, and FH = foothold. (Reproduced with permission of the authors.)

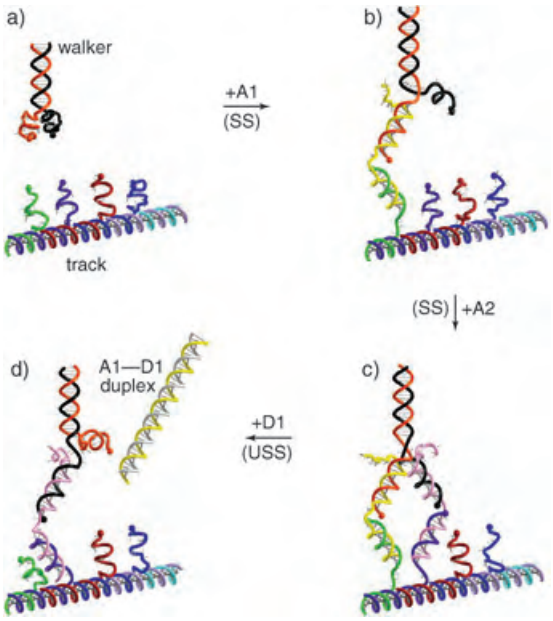

Figure 4. Schematic of the locomotion of the Shin–Pierce walker[20] (see text for details). The diagrams depict a) unbound walker, b) walker attached to branch 1, c) walker attached to branches 1 and 2, and d) walker released from branch 1 to yield DNA duplex waste. A and D denote attachment (set, SS) and detachment (unset, USS) strands, respectively. (Reproduced with permission of the authors.)

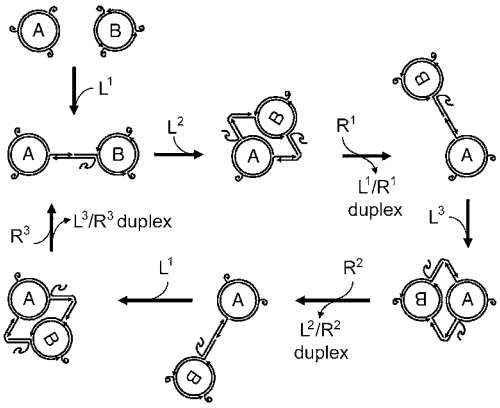

Figure 5. Rolling around a circle (or two meshed gears) following the design of Tian and Mao.[21] L = linker (set) strands, R = removal (unset) strands. (Figure courtesy of C. Mao.)

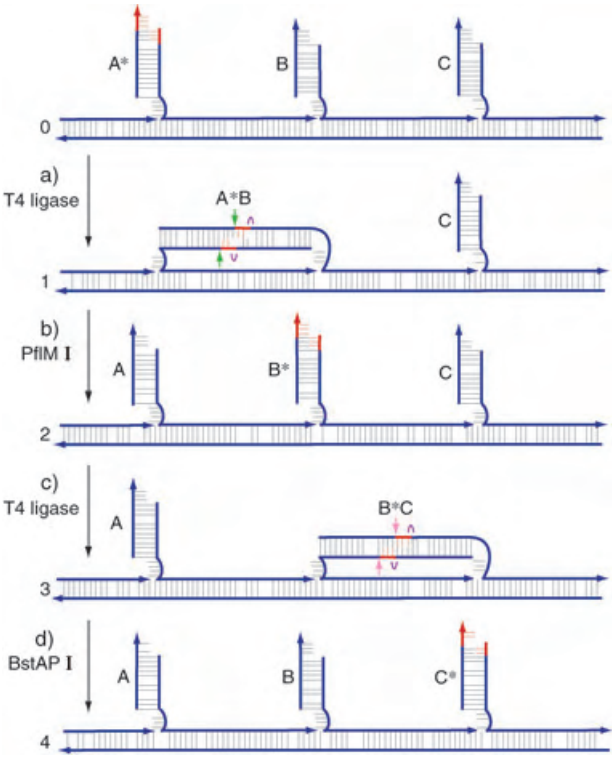

Figure 6. Operation of the device by Yan, Turberfield, Reif, and co-workers[22] (see text for details). The green and pink arrows indicate the sites of restriction; the purple ∩/∪ symbols show where ligation occurs. (Reproduced with permission of the authors.)

feet and four footholds and succeeds in efficiently achieving directionality. Their system comprises four components: a walker, a track, attachment fuel (i.e. "set") strands (A), and detachment (i.e. "unset") strands (D). The walker consists of two partially complementary oligonucleotides, with two single-stranded legs (feet) joined by a double-stranded helix. The track, which is constructed of six oligonucleotides, has four protruding single-stranded branches (footholds) separated by 15-base-pair scaffold helices. Neighboring branches run in opposite directions, so spacings of 1.5 helical turns place all branches on the same side of the track at approximately 5 nm apart (Figure 4a).

As shown in Figure 4, the walker strides along a track under the external control of A and D strands. An A set strand (yellow in the first instance) specifically anchors the orange leg of the walker to the green branch (foothold) by forming double helices with the corresponding leg and foothold. Single-stranded hinges adjacent to either end of these helices provide flexibility for adopting different conformations that depend on the fuel species that are present. When both legs are bound to the track, the trailing leg is released (Figure 4, c→d) by using a D unset strand that nucleates with the perfectly complementary A1 strand at a 10-base overhang (toehold) and then undergoes a strand-displacement reaction to produce duplex waste and to free the walker leg for the next step. Although Figure 4 does not show it, by appropriate additions of A and D strands, the walker is able to traverse the track from one end to the other and back, with full directional control.

A conceptually similar approach, except that movement is around a circular track, was reported by Tian and Mao[21] and is summarized in Figure 5.

A third strategy was recently described by Yan, Turberfield, Reif, and co-workers.[22] In this case, the walker, a six-nucleotide fragment colored red and indicated by * in Figure 6, moves along a DNA track, but it is more like a bucket being passed along a bucket brigade (or a crowd surfer being transported across a mosh pit). Here too, the process is unidirectional, but instead of using set and unset strands, T4 ligase accomplishes the set function and creates, at the same time, a recognition site for restriction endonucleases (PflM I, BstAP I)

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

that subsequently operate in place of unset strands.

As shown in Figure 6, the self-assembled track contains three anchorages at which the walker (the red six-nucleotide fragment) can be bound. Each anchorage consists of a double-stranded segment with a three-nucleotide single-strand overhang ("sticky end"). At each step the ligand is ligated (e.g. 0→1) to the next anchorage, then cut (1→2) from the previous one by the restriction endonuclease. Each ligation creates a new restriction site, and each cut destroys the previous restriction site. The motion of the walker is unidirectional: the product of ligation between two neighboring anchorages can only be cleaved such that the walker moves onto the downstream anchorage (A*B and B*C can only be cut such that the walker is left attached to B and C, respectively). In effect, the system burns its bridges behind it as the six-nucleotide bundle tumbles down the track. Two idling steps are possible: B* can be religated to A and regenerated by restriction with PflM I; similarly, C* can be religated to B and regenerated with BstAP I. However, these idling steps neither reverse nor block the overall unidirectional motion of the walker. Once B* has been ligated to C, the walker can never return to A. It should be possible to extend the motion of the walker beyond three anchorages.

The sequence of events in Figure 6, unlike those discussed in the context of Figures 2–5, is said to be "autonomous," because once the walker (A*), the track (with its anchorages), and the three enzymes (T4 ligase and the restriction endonucleases PflM I and BstAP I) are mixed at the beginning, all the events (0→4) in Figure 6 occur without further external intervention.

The four papers highlighted above offer ingenious responses to a challenging design problem. Much remains to be done before a practical synthetic solution to transporting cargo across surfaces is achieved. But, as Confucius reputedly said, a journey of a thousand miles begins with a single step. With the walkers described above, the journey has begun.

The development of small-molecule modulators of protein–protein interactions is a formidable goal, albeit one that possesses significant potential for the discovery of novel therapeutics. Despite the daunting challenges, a variety of examples exists for the inhibition of two large protein partners with low-molecular-weight ligands. This review discusses the strategies for targeting protein–protein interactions and the state of the art in the rational design of molecules that mimic the structures and functions of their natural targets.

5. Synthetic Inhibitors of Protein–Protein Interactions from Rational Design 4150
6. Summary and Outlook 4156

1. Introduction

The pharmaceutical industry is largely built on the skills of organic chemists—with occasional assistance from Nature—in the identification of small molecules (MW < 750 Da) that inhibit a given target (proteins, DNA, etc.) but that also retain optimized pharmacokinetic and oral absorption properties. The completion of the human genome sequence is clearly a landmark achievement which, in theory, should reveal all the targets available for drug development. In the spirit of Herbert Hoover ("*a chicken in every pot and a car in every garage*"), Stuart Schreiber has thrown out the challenge "*… to identify a small-molecule partner for every gene product*".[1]

There is little doubt that the enterprise of designing small molecules to fit enzyme active sites has been remarkably successful. The problem of identifying enzyme inhibitors is simplified by the nature of enzyme active sites. Most often the catalytic domain is made up of multiple recognition sites that are contained within a well-defined cleft or cavity, shielded from solvent to some extent. As the dominant interactions in an enzyme active site include hydrogen bonding, salt bridges, and electrostatic forces, "druglike" molecules that contain various hydrophilic motifs and hydrogen-bond donors and receptors often work well. Furthermore, native substrates can provide effective templates for inhibitor design. Finally, biological assays for the potency of enzyme inhibitors are generally straightforward, as they are based on the modification of enzyme activity.

In contrast, the development of small-molecule modulators of protein–protein interactions has been widely regarded as a formidable goal, albeit one that possesses significant potential for the discovery of novel therapeutics. Approaches for the disruption of protein–protein interactions are limited by the following key aspects: 1) natural proteinaceous ligands do not provide direct links to the design of small molecules, and the key interacting residues are often unclear; 2) large interfacial areas, typically $\approx 1600\ \text{Å}^2$ of buried surface (around 170 atoms) are involved in forming protein–protein interfaces, which poses a serious challenge for any small molecule to be competitive; 3) the binding regions of protein partners are often noncontiguous and thus cannot be mimicked by simple synthetic peptides; 4) selectivity in targeting an individual protein is difficult, as many protein–protein interfaces are relatively featureless; 5) few "druglike" small molecules have been identified from library screening as effective disruptors of protein–protein interactions; and 6) biological assays cannot necessarily follow enzyme activity, and in many cases activity must be detected through more challenging techniques that monitor binding directly (for example, calorimetry or surface plasmon resonance).

Despite these daunting challenges, there is a variety of examples of the inhibition of two large protein partners with low-molecular-weight ligands. A number of recent reviews have addressed this topic,[2–8] so our goal herein is to provide an overview of the strategies for targeting protein–protein interactions and the state of the art in the rational design of mimetics that reproduce the structures and functions of their natural targets.

2. Key Features of Protein–Protein Associations Relevant to Inhibitor Design

2.1. "Hot Spots" of Binding Energy

In a milestone analysis by Clackson and Wells, the binding energy of the complex between human growth hormone (hGH) and the extracellular domain of its first-bound receptor (hGHbp) could be ascribed to a small and complementary set of interfacial residues.[9] This suggested that the critical domain of one protein partner might be mimicked by relatively simple small molecules. The technique of alanine scanning (in which the interfacial residues are mutated to alanine systematically to determine the change in binding free energy) was used to detect which residues constituted the key binding region (or functional epitope, which also became known as the "hot spot"). Cunningham and Wells found that eight out of 31 side chains on the binding surface of hGH

 DOI: 10.1002/anie.200461786 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

accounted for approximately 85% of the binding energy, whereas half of the residues make no substantial contributions to the interaction.[10] On the side of hGHbp, Trp 104 and Trp 69 dominated the binding interface with each contributing over -4.5 kcal mol^{-1} in binding energy to the total energy of the hGH–hGHbp complex formation of -12.3 kcal mol^{-1} (Figure 1).

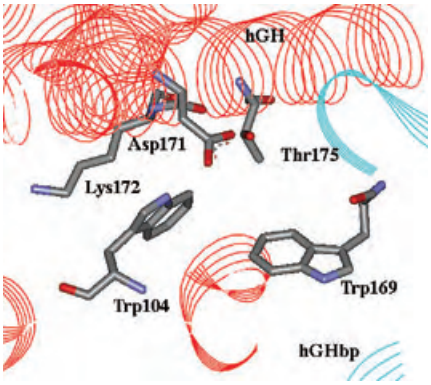

Figure 1. The hGH/hGHbp interface (key binding residues are shown in stick representation).

Extensive work has been done since then to further underpin the concept of hot spots in protein–protein interactions.[11] Bogan and Thorn examined 2325 alanine mutants for which changes in the free energy of binding have been measured, and showed that the energetic contributions of the individual side chains did not correlate with their buried surfaces.[12] In several cases, a set of energetically unimportant contacts surrounded the hot spot, and appeared to occlude bulk-solvent access in the manner of an O-ring. Certain amino acid residues, particularly tryptophan (21%), arginine (13%), and tyrosine (12%) appear more frequently in hot spots (that is, they contribute more than 2 kcal mol^{-1} to a given binding interaction) than others such as leucine, methionine, serine, threonine, and valine, each of which account for less than 3% of all hot-spot residues.[13] Tryptophan, arginine, and tyrosine residues are also found more frequently in the protein interfaces, with 3.91, 2.47, and 2.29-fold enrichment in hot-spot areas, respectively. An enrichment of tyrosine and tryptophan and a discrimination against valine, isoleucine, and leucine have also been reported in antibody complementarity-determining region (CDR) sequences.[14] Padlan proposed that the enrichment of these aromatic amino acid residues is a result of their contribution to the binding energy through hydrophobic effects without a large entropic penalty, as they have fewer rotatable bonds.

Recent developments in bioinformatics have provided insight into the analysis of protein–protein interfaces and have helped the detection of hot spots. A wealth of data on alanine mutations in various protein–protein complexes is available and has assisted in the design of small molecules to modulate their interactions.[15] Alternatives for the detection of hot-spot regions include computational tools that generate combinatorial libraries of functional epitopes and identify recurring sets of residues in the epitope.[16] By this method the spatial arrangement of key structural motifs at protein–protein interfaces has been efficiently detected. Ben-Tal and co-workers have developed an algorithm (Rate4Site; http://consurf.tau.ac.il) for the identification of functional interfaces based on the evolutionary relations among homologous proteins reflected in phylogenetic trees.[17] By using the tree topology and branch lengths corresponding to the evolutionary relationships between two proteins, the method accurately predicted a homodimer interface of a hypothetical protein Mj0577 that was also confirmed under X-ray crystallographic analysis.

2.2. Enthalpy, Entropy, and Heat Capacity

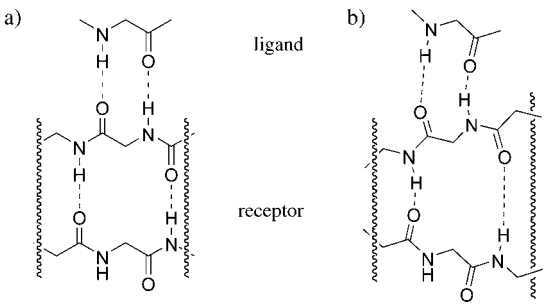
In an excellent in-depth review, Stites addressed the thermodynamic aspects of protein–protein association and the relative importance of enthalpy, entropy, and heat-capacity effects in stabilizing complex formation.[7] The most important parameter is the association constant, which is determined by the free-energy difference (ΔG) between the associated and unassociated states of the proteins. This determines the concentration at which the protein complex is formed in significant quantity.

Hang Yin is currently a postdoctoral associate with Prof. William F. DeGrado at the University of Pennsylvania School of Medicine. In 2004, he completed his PhD with Prof. Andrew D. Hamilton at Yale University from research in synthetic agents as α-helical mimetics that target protein–protein interactions. Prior to that, he completed his BS degree in Chemistry at Peking University.

Andrew D. Hamilton is currently the Provost, Benjamin Silliman Professor of Chemistry, and Professor of Molecular Biophysics and Biochemistry at Yale University. He received his undergraduate education at the University of Exeter. In 1974, he moved to the University of British Columbia, and then to Cambridge University where he received his PhD in 1980 for work on porphyrin chemistry with Prof. Sir Alan Battersby. After postdoctoral research with Prof. Jean-Marie Lehn, he was appointed to an Assistant Professorship in Chemistry at Princeton University. In 1988, he moved to the University of Pittsburgh, where in 1992 he became Professor of Chemistry, and in 1994, Chair of the Chemistry Department. In 1997, he moved to his present position at Yale University.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

It is widely accepted that the hydrophobic effect dominates the change in heat capacity (ΔC_p) for protein folding and binding.[18] However, Stites pointed out that there is no clear correlation between ΔH or ΔS and the values of ΔG and ΔC_p, despite the previous assertion that protein–protein interactions are driven by either enthalpic or entropic processes.[19] He also concluded that hydrophobic interactions generally provide the key driving force for protein–protein complex formation. Other alternatives, such as electrostatic effects, can also play an important role in protein association in certain cases.[20] The amount of polar and nonpolar surface buried in a protein–protein interaction does not often correlate well with its ΔC_p value.[21] A possible explanation for this is the large number of buried water molecules at the interface; water of this type may have a lower heat capacity than bulk solvent and is probably responsible for the large change in ΔC_p for many protein–protein interactions.



Cochran has argued that despite the large interacting surfaces and high binding energies of protein association, small molecular antagonists can be identified that have competitive binding affinities.[6] The driving force for disruption derives either from enthalpy-favored protein stabilization or entropy-favored ligand exchange.

2.3. Positively and Negatively Cooperative Interactions

Williams et al. proposed that the thermodynamic parameters for protein–protein associations have more complex origins.[22] They analyzed the cooperativity of protein–ligand interactions and suggested that the binding energy can derive in part from changes occurring within the receptor proteins.[22–25] These findings have implications for protein–protein interactions, as the binding between two proteins is not simply a function of the properties of the interacting surface regions; it is also a function of how these interactions modify the internal structure of the protein.

A binding event is defined as positively cooperative with respect to a second interaction if its affinity is increased in the presence of that second interaction. Conversely, a binding event is negatively cooperative if its affinity is decreased in the presence of that second interaction (Scheme 1). The general expectation for a positively cooperative binding event is the tightening of protein structure with a resulting gain in enthalpy and loss in entropy. An example is the formation of the biotin–streptavidin complex ($\Delta H = -134\ \mathrm{kJ\,mol^{-1}}$ and $T\Delta S = -57\ \mathrm{kJ\,mol^{-1}}$ at 25 °C).[26] During a positively cooperative binding event, the ligand decreases the dynamic motion of the residues with which it interacts directly. As noncovalent bonding is opposed by the kinetic energy of motion, these residues, in turn, form more stable bonds with adjacent residues. This effect propagates and results in a more efficient packing of the whole protein.[24]

In negatively cooperative ligand binding the interacting partners become more dynamic, with an associated loss in enthalpy and gain in entropy.[25] Williams et al. showed that O_2 binds to hemoglobin in a negatively cooperative manner.[24] The optimal binding of O_2 is incompatible with the geometry present in the tense (T) state. Analogous to Scheme 1b, the ligand distorts the structure of the receptor, which forces a loosening of the hemoglobin tetramer through breakage of inter-subunit salt bridges, and converts the protein to the relaxed (R) state.[27]

Scheme 1. Structural models for a) positive and b) negative cooperativity; the lower pair of hydrogen bonds is within a protein receptor and the upper pair of hydrogen bonds is formed upon the binding of a peptide ligand.

3. Strategies for the Recognition of Protein Exterior Surfaces

Each protein has a unique exterior surface composed of charged, hydrophobic, and hydrophilic domains. Protein surfaces are critical in mediating protein–ligand and protein–protein interactions in a variety of biological processes, such as cell proliferation, growth, and differentiation. Therefore, synthetic molecules that match both the electrostatic and structural features of the protein target are expected to bind to the exterior surface and disrupt protein–protein interactions. Such possibilities could offer an innovative and systematic approach to regulating biological processes.[28]

3.1. Recognition of Protein Surfaces: Biological Strategies

3.1.1. Artificial Antibodies

Many uses of antibodies in chemistry and medicine require a single defined molecular specificity in the form of monoclonal antibodies (MAbs).[29] Earlier efforts have been focused on the humanization of antibodies derived from rodent MAbs to overcome the problems of immunogenicity and inefficient secondary immune function that frequently beset clinical use.[30] Humanized antibodies are created by transplanting the CDR loops from the rodent to the human antibody constant regions. The functional antibody fragments are then secreted from *E. coli*.[31]

Monoclonal antibodies that block the interaction between interleukin 2 (IL-2) and its receptor (IL-2R) represent a successful example of targeting protein–protein interactions in immunotherapy.[32] Mouse antibodies against IL-2R (anti-Tac) have been used to inhibit graft-versus-host disease (GVHD) and to suppress autoimmune disorders in rodents.[33,34] In clinical trials, anti-Tac has ameliorated steroid-resistant GVHD. Jones et al. humanized anti-Tac by combining the CDR from rodent antibodies with constant

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

and framework regions from human antibodies, thus minimizing xenogenic elements.[35] Queen et al. and Junghans et al. produced a humanized version of anti-Tac that retains the murine CDR along with virtually all of the remainder of the molecule from human immunoglobulin G1κ (IgG1κ).[36]

Some strategies have been employed to improve the efficacy of immunotherapy. One is through the modification of a natural toxin to kill cells that express the MAb-recognized antigen. Lorberboum-Galski et al. deleted the cell-recognition domain I of the single-chain *Pseudomonas* exotoxin (PE) to create the modified toxin PE40.[37] The chimeric protein IL-2–PE40 was able to inhibit protein synthesis in tumor cell lines that express IL-2R, leading to cell death. However, large protein toxins are immunogenic and provide only a narrow therapeutic window before the host develops antitoxin antibodies. Radiolabeled MAbs were developed as alternative immunoconjugates for the delivery of cytotoxic agents to target cells.[38] Waldmann used ^{90}Yb-labeled anti-Tac antibodies to treat patients with adult T-cell leukemia (ATL); 11 of 17 treated patients underwent a partial (9) or complete (2) remission.[33] Thus, the anti-Tac antibody armed with a radionuclide provides an effective therapy for leukemias expressing IL-2R.

3.1.2. Miniature Proteins

Despite the success of protein engineering in the generation of functional antibody fragments, alternative smaller and more compact protein frameworks are still desirable for several reasons:[39] 1) higher theoretical affinities can be expected for structured proteins because of the smaller loss in entropy upon binding;[40] 2) the interpretation of the interaction at the interface is simplified if the overall structure of the parent protein is preserved; 3) a higher proteolytic stability can be expected for a folded protein than a random peptide, making it more suitable for recombinant production; 4) a constrained scaffold has the potential to effectively present hydrophobic residues which might be buried in a peptide format; 5) the binding activity of a domain rather than a peptide is more likely to be maintained when produced by fusion to a different protein or domain.

Rather than designing such presentation scaffolds de novo, many groups have recruited naturally existing proteins or domains for further engineering. To date, a number of native or engineered protein scaffolds, such as β barrels,[41] α-helix bundles,[42] and zinc-finger motifs,[43] have been used to construct artificial binding molecules.

Schepartz and co-workers have developed a general solution called "protein grafting", in which the functional epitope is grafted into a rigid miniature protein scaffold. This method, often used in combination with molecular evolution, can be used to identify miniature proteins with high affinity and specificity for protein and nucleic acid targets.[44] A recent application of this approach was in the identification of high-affinity ligands for the KIX domain of the transcriptional coactivator protein (CBP).[45] The complex between the CBP KIX domain and the kinase-inducible activation domain (KID) of the transcription factor CREB represents a challenging target, as the KID-binding cleft on the surface of the KIX domain is shallow and is more reminiscent of a solvent-exposed protein surface than a typical α-helix-binding groove.[46] Hydrophobic interactions contribute significantly to the free energy of KID^{P}–KIX complex formation; the side chains at *i*, *i*+3, *i*+4, and *i*+7 positions (Tyr 134, Ile 137, Leu 138, and Leu 141, respectively) on the same face of the helical region of the CREB KID domain interact with the surface of KIX. These key residues were grafted onto the solvent-exposed α-helical face of the small yet stable protein, avian pancreatic polypeptide (aPP).[47] The resulting phosphopeptide PPKID4^{P} (G**PSQPTYP**GDDAPVRRLS^{P}F-FYILLDLYLDAPGVC, S^{P} = phosphoserine), containing the additional functional epitope (shown in bold), exhibited high affinity ($K_d = 562 \pm 41$ nM). The grafted protein also showed a higher preference for CBP KIX than for carbonic anhydrase (CA; $K_d = 106 \pm 12$ μM), which also binds hydrophobic ligands, and calmodulin (CaM; $K_d = 52 \pm 12$ μM), whose native ligand, smooth muscle myosin light-chain kinase (smMLCK) also adopts an α-helical conformation with the key binding residues at the *i*, *i*+3, *i*+7 positions (Trp800, Thr803, and Val807, respectively).[48–50]

Vita and co-workers reported the rational design of miniature proteins that reproduce the CDR2-like region of CD4, which interacts with the envelope protein of HIV-1.[51–53] This strategy is based on the scorpion charybdotoxin as a scaffold.[54,55] Charybdotoxin is a compact protein (37 amino acids) composed of an antiparallel triple-stranded β sheet and a short α helix, stabilized by three disulfide bonds in the interior core (Figure 2b).[56,57] Such geometry is adopted by all known scorpion toxins,[56,58] regardless of size, amino acid sequence, or function (blockage of K^+, Na^+, or Cl^- ion channels, etc.),[59] which indicates that this motif readily permits sequence adoption. As this scorpion toxin contains most of the structural elements commonly found in protein

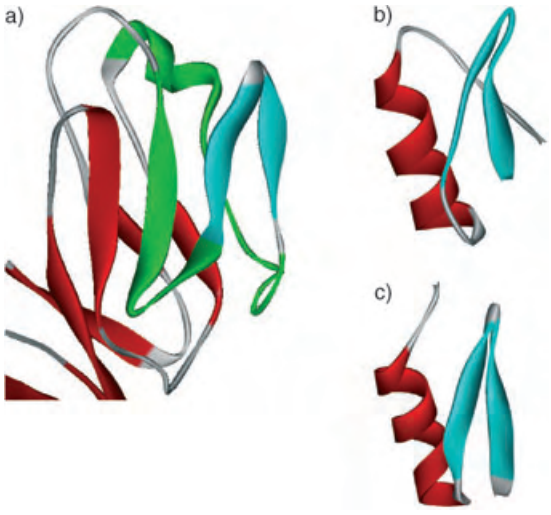


Figure 2. Structural comparison between a) CD4 and b) scorpion charybdotoxin and c) scyllatoxin. The region of residues 25–64 of CD4 (green) binds gp120. The CDR2-like loop of residues 36–47 (cyan) was transferred to charybdotoxin or scyllatoxin, each of which contain a solvent-exposed β hairpin loop (also shown in cyan), structurally similar to the CDR2-like loop.

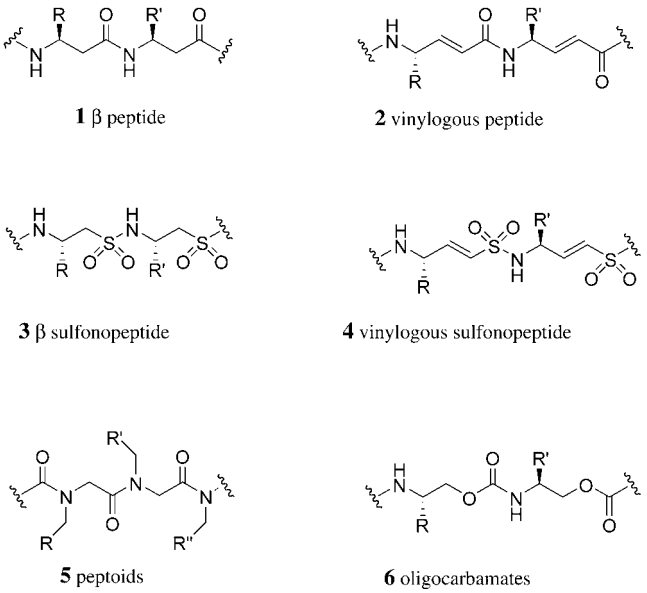
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

structure (α helix, β sheet, β turn, and loops), it is an attractive scaffold for protein grafting on which functional amino acid sequences can be incorporated. The cell-surface protein CD4 binds to the envelope glycoprotein gp120, which plays important roles in determining HIV virus tropism and cell infection.[60] A protruding β hairpin, the CDR2-like loop of CD4 (Figure 2a), is centered on the CD4–gp120 interface to form an antiparallel β sheet with the β15 strand of gp120.[61] The chimeric miniature protein, CD4M, based on the charybdotoxin scaffold (Figure 2b) yet with the key amino acid residues of CD4, inhibited the binding of gp120 to CD4 with an IC_{50} value of 20 μM.[55]



With scyllatoxin, another scorpion toxin scaffold, Vita et al. observed additional miniature proteins as potent inhibitors of the CD4–gp120 interaction.[52] Scyllatoxin (Figure 2c) is a 31-residue protein with a double-stranded β sheet (residues 18–29) that is structurally similar to the CDR2-like loop of CD4.[52] It is slightly shorter than charybdotoxin and has no N-terminal β strand. It has a shorter loop joining the helix to the first β strand, which allows full access of the β hairpin of the toxin to a large-molecule probe and makes it a better host structure for the CDR2-like loop of CD4. A chimeric protein based on the scyllatoxin scaffold, CD4M9, showed improved potency in disrupting the CD4–gp120 interaction with an IC_{50} value of 0.4 μM, 100-fold higher than that of native CD4. In a later report, the interacting face of CD4M9 was optimized to produce a potent miniature CD4 (CD4M33, $IC_{50} = 4.0$ nM) with genuine CD4-like properties. CD4M33 also exhibited strong antiviral activity in blocking HIV-1 cell–cell fusions at low nanomolar concentrations.[53]

3.1.3. Functional Oligonucleotides

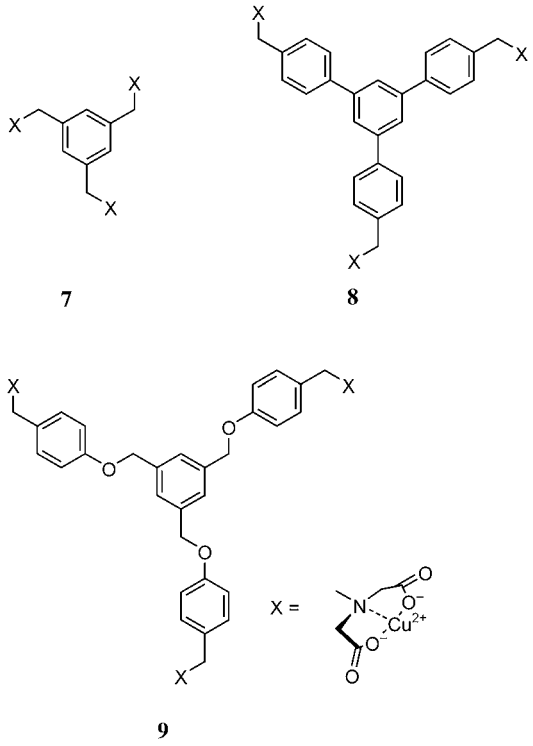
Analogous to peptide libraries, the generation and selection of oligonucleotides (aptamers) that bind specific ligands has been widely used for the development of pharmaceutical reagents and diagnostic assays.[62] Since the systematic evolution of ligands by exponential enrichment (SELEX) method was first reported in 1990,[63] numerous modifications of this technology have greatly expanded its potential.[64] Modified nucleotides have been introduced into selection experiments, resulting in the isolation of aptamers that are surprisingly stable in vivo. For example, nuclease-resistant nucleic acid ligands with high potency ($K_i = 100$ pM) for vascular endothelial growth factor (VEGF) were identified from RNA aptamer libraries.[65] Anti-HIV reverse transcriptase (HIV-RT) aptamers selected from a single-stranded DNA pool bound to the enzyme with K_i values as low as 1 nM.[66] Both RNA and modified RNA aptamers selected to bind basic fibroblast growth factor (bFGF) can successfully inhibit bFGF binding to cell-surface receptors at concentrations as low as 1 nM.[67] The antithrombin single-stranded DNA aptamers can block blood clotting in vivo.[68] The folding patterns of these selected aptamers are surprisingly diverse, and contain secondary structure elements such as G-quartets, stem-loops and pseudoknots.[69]

3.1.4. Unnatural Biopolymers

The intrinsic susceptibility of peptides and nucleotides to enzyme degradation makes alternative well-folded scaffolds desirable. Thus, peptide-like or nucleotide-like biopolymers, such as β peptides, β sulfonopeptides, peptoids, oligocarbamates and PNA, have been under intense investigation (Scheme 2).[70] For example, Seebach and co-workers

Scheme 2. Unnatural biopolymers with properties that are similar to peptides.

reported a small cyclo-β-tetrapeptide that mimics the natural hormone somatostatin and displays biological activity and micromolar affinity for human receptors.[71] Schreiber and co-workers examined the conformational properties of small vinylogous peptides.[72] Gennari et al. examined the folding of oligosulfonamides (β-sulfonopeptides and vinylogous sulfonopeptides).[73] Peptoids, one of the first unnatural oligomers developed for pharmaceutical and combinatorial applications, were found to adopt conformations in water when chiral side chains were appended onto amide nitrogens.[74] A family of oligocarbamates were reported by Schultz and co-workers to bind MAb 20D6.3 with IC_{50} values between 60 and 180 nM, although their structural preferences were not clear.[75]



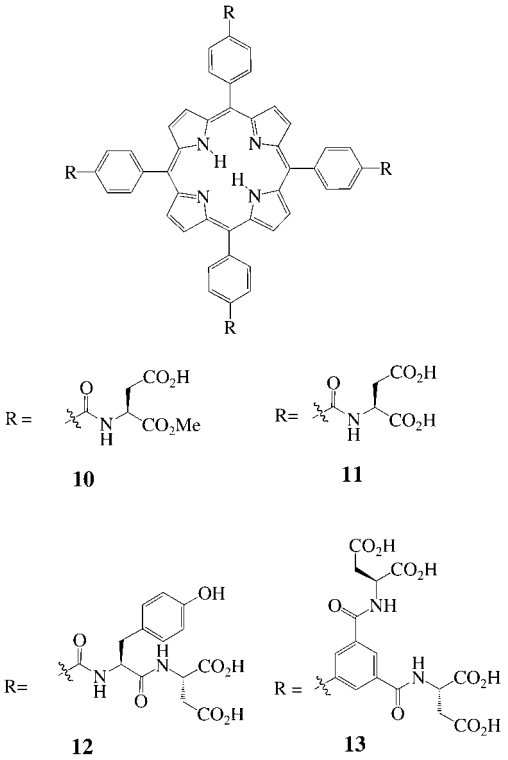
3.2. Recognition of Protein Surfaces: Chemical Strategies

3.2.1. Recognition of the Surface of Carbonic Anhydrase by Cu^{II} Complexes

The surface of a protein offers an array of charged, polar, aliphatic and aromatic groups that can be targeted by surface-recognition agents. For example, the imidazole group of histidine is a potential target site, as it coordinates strongly to transition metals. Mallik and co-workers described the design, synthesis, and protein-binding properties of molecules that contain three Cu^{2+}–iminodiacetate arms (Cu^{2+}-IDA) sepa-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

rated by aromatic linkers (Scheme 3).[48] The potential advantage of this strategy is that the metal–ligand interactions are stronger in water than other noncovalent forces, and thus complementary interactions can lead to tight and selective



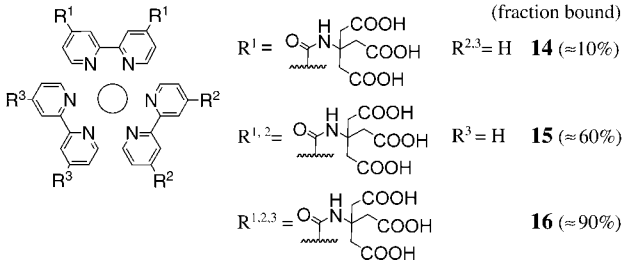
Scheme 3. Cu^{2+}-IDA-containing molecules that target the surface of carbonic anhydrase.

binding. Compound **8** was observed to bind to bovine erythrocyte carbonic anhydrase (CA), a protein with six surface histidine residues and a binding constant (K_a) of $3 \times 10^5\,M^{-1}$. With the copper cation removed, the ligand portion of **8** alone did not bind CA. Compound **7**, with a shorter spacer between the Cu^{2+}–IDA arms, and **9**, which is more flexible, both showed weaker binding to CA (**7**: $K_a = 7.5 \times 10^4\,M^{-1}$; **9**: $K_a = 3.3 \times 10^4\,M^{-1}$). Interestingly, the weaker binding of **7** is primarily due to a less-favorable ΔH, which suggests a poorer geometric fit between **7** and the histidine groups of CA. The more flexible **9** has a more favorable enthalpic contribution than **8**, yet a significantly larger unfavorable entropy term ($-T\Delta S$) which leads to weaker overall binding. Furthermore, **8** preferably binds CA over chicken egg albumin, which also contains six surface histidine residues but with a different spatial orientation. (Compounds **7** and **9** were much less selective in this regard.) These findings indicate the importance of geometric accessibility and preorganization of the copper arms relative to the target histidine groups for high binding affinity and selectivity.

3.2.2. *Surface Recognition of Cytochrome c*

Cytochrome c (Cytc) from horse heart is an electron-transport protein with a high isoelectric point (pI 10).[76] The exposed surface of the heme edge is surrounded by a series of cationic residues which constitute a distinct binding domain for various protein partners, such as cytochrome oxidase and cytochrome c reductase. These interactions are highly sensitive to modifications of the surface lysine residues, which indicates a strong dependence on electrostatic interactions.[77] Jain and Hamilton demonstrated that this surface can be recognized by receptors designed with tetraphenylporphyrin (TPP) as a scaffold bearing various amino acid and peptide derivatives on its periphery (Scheme 4).[78]

Scheme 4. TPP derivatives for the recognition of the exterior surface of cytochrome c.



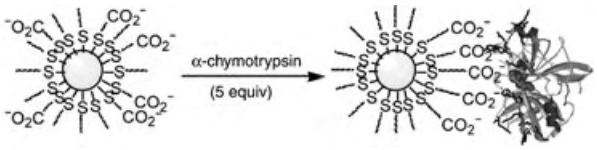
A convenient fluorescence-quenching assay permitted facile measurement of the dissociation constants of a range of derivatives. Porphyrin **12**, with a Tyr–Asp dipeptide residue on each phenyl ring, bound tightly to Cytc with a K_d value of 20 nM. Comparison of K_d values for a series of TPP derivatives showed that affinity is significantly increased through the addition of anionic residues to the porphyrin core, as octaanionic **11** showed an approximate sixfold increase in affinity ($K_d = 160$ nM) over tetraanionic **10** ($K_d =$ 900 nM). Thermodynamic parameters for **11** and the ionic-strength-dependence data of the binding interaction of **11** and **12** are similar to those of cytochrome c peroxidase, a native Cytc partner, which suggests that the molecular surfaces of **11** and **12** may mimic part of the binding domain of Cytc peroxidase. Tetrabiphenylporphyrin-based receptor **13**, which has a larger hydrophobic core and 16 charges on its periphery, exhibited the strongest affinity with a K_d value of 0.67 nM.[79] Compound **13** showed good selectivity in binding to Cytc in comparison with the closely related protein cytochrome c_{551}

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

($K_d = 180$ nM) and ferredoxin ($K_d = 17$ μM), which suggests that complementary charge and size are required for strong binding.

The effects of TPP derivatives on protein folding were also studied. The thermal denaturation profile of Cytc in the presence and absence of the TPP-based receptors at pH 7.4 was traced with circular dichroism (CD) spectroscopy. The melting point (T_m) of Cytc dropped from 85 °C to 64 °C in the presence of receptor **12**. The copper porphyrin dimer of **12** also induced the unfolding of Cytc with 2:1 stoichiometry under physiologically relevant conditions and accelerated its rate of proteolytic degradation.[80]

Hamachi and co-workers employed a related design concept for the recognition of Cytc.[81] A $[Ru(bpy)_3]$ complex with carboxylate groups on its periphery was shown to form a complex with Cytc selectively over myoglobin, horseradish peroxidase, and cytochrome b_{562}. This approach offers the advantage of the templating function of metal, with which molecular assembly can be carried out in a stepwise ligation of the individual bipyridine units. With this synthetic strategy, a series of unsymmetrically substituted receptors were prepared; compound **16** (Scheme 5), the most symmetrical



Scheme 5. $[Ru(bpy)_3]$ complexes that recognize the surface of cytochrome c.

compound, showed the strongest binding. However, investigation of the photoreduction of Cytc catalyzed by these complexes showed **15** to be the most efficient catalyst. This effect was attributed to a balance between the binding of the Ru complexes and accessibility to the sacrificial reducing agent.

3.2.3. Inhibition of Chymotrypsin with Nanoparticle Receptors

Rotello and co-workers developed mixed-monolayer-protected gold clusters (MMPCs) functionalized with terminal anionic groups for recognition of the positively charged surface of α chymotrypsin (ChT) (Scheme 6).[82] They found that the enzyme was inhibited by a two-step mechanism that comprised a fast, reversible inhibition step followed by a slower, irreversible process. The interaction was shown to be very efficient with a K_i^{app} value of 10.4 ± 1.3 nM and a stoichiometry of five protein molecules to one MMPC. This process was selective for ChT in comparison with elastase, β galactosidase, and cellular retinoic binding protein, demonstrating the effectiveness of the designed electrostatic interactions. Dynamic light scattering (DLS) data showed that the inhibition proceeds without MMPC aggregation. Furthermore, the minimum at 202 nm in the CD spectrum (a result of high β-sheet content) underwent a time-dependent increase and a shift to lower wavelength, indicating a conformational change toward random coil and a loss of native secondary structure.

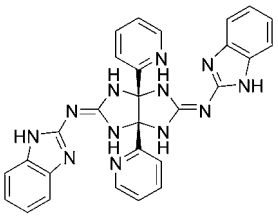
Scheme 6. Recognition of the surface of α chymotrypsin by a nanoparticle receptor.

In a subsequent publication, the authors demonstrated with DLS that the addition of cationic surfactants results in the release of ChT from the surface of the anionic gold nanoparticles.[83] In an effort to retain the native structure upon protein binding, the same group incorporated oligo(ethylene glycol) (OEG) groups onto the monolayer-protected nanoparticles.[84] CD and fluorescence anisotropy measurements indicated that the protein regained a high degree of structural integrity. ChT was also released under elevated ionic strength with full enzymatic activity, suggesting a complete restoration of the native structure.

These examples demonstrate that molecules designed to recognize protein surfaces can also dramatically affect the native conformation of the target protein. Much work remains to evaluate the mechanisms of these processes and to establish if they are medicinally viable. Similarly, it should be possible to identify molecules that enhance protein folding through stabilization of the native state.

4. Synthetic Modulators of Protein–Protein Interactions from Chemical Libraries

On the basis of bioinformatics analysis, there are predicted to be ≈6500 promising targets—receptors, enzymes, and ion channels—for the design of novel pharmaceutical agents.[85] This number increases dramatically, however, if protein–protein interactions are also considered as drug targets. The key is to find strategies that will effectively and reliably lead to molecules with acceptable pharmacokinetic properties that disrupt protein–protein contacts. High-throughput data-generation techniques, including microarray analysis, combinatorial chemical library preparation, and computational (in silico) screening methods have become essential in the search for protein–protein disruptors. If structural information on a certain target is not available, then screening is arguably the most efficient method to search for synthetic antagonists of protein–protein interactions as drug candidates.



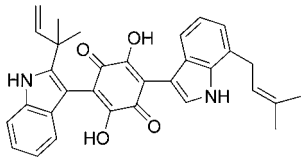
4.1. Agonists of Protein–Protein Interactions

4.1.1. Small Nonpeptide Mimetics of G-CSF

The granulocyte colony-stimulating factor (G-CSF) is a polypeptide growth factor that regulates the production of

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

neutrophilic granulocytes, which serve as the foundation for host defense systems.[86] When G-CSF binds to its receptor (G-CSFr), it triggers receptor homodimerization, which results in the activation of protein tyrosine kinases JAK1 and JAK2.[87,88] The JAK kinases then phosphorylate receptor-associated proteins, such as the signal transduction and activators of transcription (STAT) proteins, thereby regulating transcription.[87,89] Compound **17** (Scheme 7) was identified from a high-throughput cell-based screen as an agonist of the G-CSF protein with 30% efficacy in a luciferase assay.[90] Like G-CSF, **17** caused tyrosine phosphorylation of both JAK1 and JAK2 as well as of G-CSFr, but not the interleukin-3 (IL-3) receptor, indicating specific recognition of the target. Both G-CSF and **17** induced tyrosine phosphorylation of STAT3 and STAT5. The time course for STAT activation in response to **17** is similar to that to G-CSF.



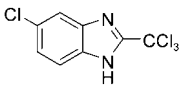
17 SB 247464

Scheme 7. The G-CSFr agonist **17** (SB 247464).

Further studies showed that **17** stimulates primary murine bone marrow cells to form granulocytic colonies and elevates peripheral blood neutrophil counts in mice. The collective data demonstrated that **17** acts as a mimetic of G-CSF to activate G-CSF receptors by targeting a different domain of G-CSFr.

4.1.2. An Agonist of Insulin Receptor Tyrosine Kinase with Antidiabetic Activity in Vivo

A natural product, L-783,281 (**18**; Scheme 8), from a fungal extract was identified as an agonist of the human insulin receptor tyrosine kinase (IRTK).[91] The development of orally active small-molecule mimetics of insulin is a major challenge in medicinal chemistry. Insulin binds to the extracellular α subunits of its receptor and causes conformational changes that lead to the stimulation of tyrosine kinase activity and autophosphorylation of the membrane-spanning β units.[92] Compound **18** was selected from a 50000-compound library including synthetic compounds and natural products. Compound **18** induced 50% of the maximal effect of insulin on IRTK activity at low concentration (3–6 μM). The in vivo efficacy of **18** was tested in mice, and elicited a significant decrease in blood glucose levels.



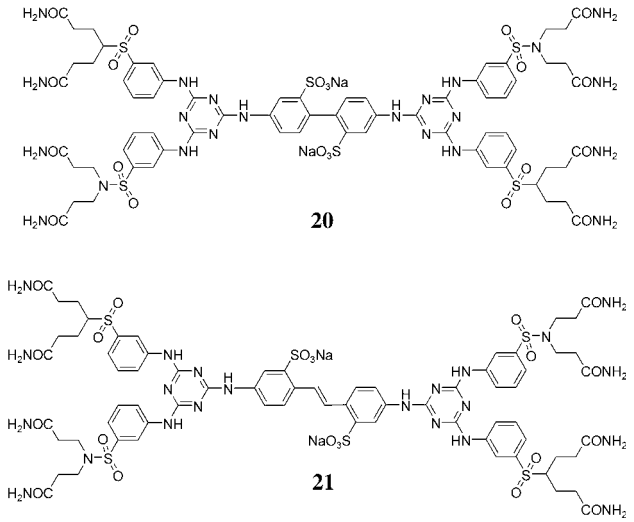
18 L-783,281

Scheme 8. Insulin mimetic **18** (L-783,281) that induces activation of IRTK.

4.1.3. Small-Molecule Switches for the hGH–hGHbp Interaction

Schultz and co-workers reported the regulation of human growth hormone (hGH) and the extracellular domain of the hGH receptor (hGHbp) through a two-step process.[93] First, two residues, Thr175 of hGH and Trp104 of hGHbp were mutated to glycine, creating a cavity on the hGH–hGHbp interface. In the second step, a library of small molecules was screened; compound E8 (**19**, Scheme 9) was identified as a ligand that complements the defective interface. The binding affinity of E8 was quantified with surface plasmon resonance. The binding affinity of the mutant hormone for the mutant receptor increased by more than 1000-fold in the presence of 100 μM E8 relative to the control in the absence of E8. JAK2 phosphorylation assays showed that the mitogenic signaling pathway through the hGH receptor is stimulated only in the presence of the mutant hormone and 50 μM E8. Dose-dependent proliferation of IL-3-dependent promyeloid cells (FDC-P1) further confirmed that E8 gates mitogenic signaling through the mutant hGH–hGHbp complex ($EC_{50} = 10$ nM). The combined results indicated that E8 not only mediates binding of the mutant hormone but also switches on the signal transduction pathway.

19 E8



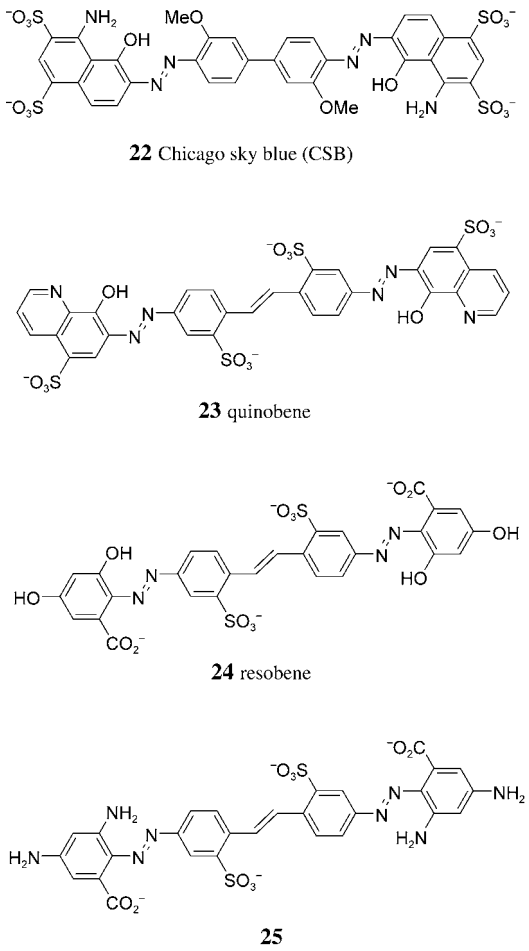
Scheme 9. The ligand **19** (E8) complements the defective hGH–hGHbp interface in the complex of Thr175 Gly hGH and Trp104 Gly hGHbp.

4.2. Inhibitors Identified from Solution- and Solid-Phase Screening

4.2.1. Bistriazine Derivatives that Disrupt Multimer Assembly of RS Virus Fusion Protein

Human respiratory syncytial virus (RSV) is one of the leading causes of lower respiratory tract infection in children and infants and is an important cause of community-acquired respiratory infection among hospitalized adults.[94] The 70K viral fusion glycoprotein (F) of human RSV forms homotetramers and mediates viral fusion.[95] By screening a 20000-compound library with a whole-cell-based assay, a group from Wyeth–Ayerst Research identified a series bistriazine derivatives with biphenyl **20** or stilbene **21** linkers (Scheme 10) that disrupt viral fusion.[96] These inhibitors target RSV(F), which functions in an oligomeric state on the virion surface. In particular, the bistriazine inhibitors selectively block the assembly of the fusion protein F without affecting other surface glycoproteins. The disruption involves destabilization of the bioactive multimeric state of the F protein and a decrease in its fusion capacity. Compound **20** binds tightly to

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



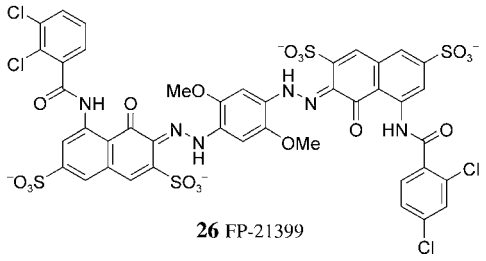
Scheme 10. Bistriazine compounds that inhibit the multimer assembly of RS virus fusion proteins.

F protein with an IC_{50} value of 0.15 μM, and **21** with an even more potent IC_{50} value of 0.05 μM.

Structure–activity relationship studies of these bistriazine derivatives indicated the importance of the negatively charged core and the rigidity around the central unit. One proposal was that the inhibitor interacts with F protein through multivalent hydrogen bonds to terminal amide groups. The authors also took advantage of the intrinsic fluorescence of **20** and **21** to show that the inhibitors bind directly to the F protein. Several of these agents are currently undergoing clinical trials as potential prophylactic drugs against RSV.[97]

4.2.2. *Bisazobenzene and Bisazonaphthalene Derivatives as Anti-HIV-1 Agents through the Disruption of Gp120–CD4 Fusion*

The treatment of human immunodeficiency virus type 1 (HIV-1) remains an area of great interest in clinical research. The third variable domain (V3 loop) of the HIV-1 gp120 exterior envelope glycoprotein interacts with the β-chemokine receptors CCR3 and CCR5, which in turn facilitates viral infection.[98] The active sites of coreceptors CXCR4 and CCR5 are exposed upon binding of CD4 to gp120, which results in virus/coreceptor binding and subsequent fusion of the viral particle with the cell. The processes of viral attachment and virus–cell fusion are critical therapeutic targets. This has been established by the recent success of the T-20 peptide of Trimeris, which itself, however, has been an impetus for the discovery of nonpeptide antagonists.[99] In an antiviral drug screen conducted by the National Cancer Institute (NCI), Chicago Sky Blue (CSB; **22;** Scheme 11), a naphthalene sulfonic acid dye, was identified as an active inhibitor of HIV activity through the disruption of the gp120–CD4 interaction.[100] Although this compound was active in vitro ($IC_{50} = 4.8$ μM), the azobenzidine core was metabolized to carcinogenic aromatic amines, preventing continued development.



Scheme 11. Bisazobenzene- and bisazonaphthalene-based synthetic inhibitors of the gp120–CD4 interaction.

Further screening of CSB analogues resulted in the identification of compounds such as **23**–**25** (Scheme 11), in which the biphenyl core was replaced with stilbene to avoid degradation.[101] Compounds **23** (quinobene) and **24** (resobene) showed moderate disruption of the gp120–CD4 interaction with IC_{50} values of 1.3 μM and 1.4 μM, respectively, whereas **25** was markedly less potent ($IC_{50} = 31$ μM). As the molecular target of these compounds was unknown in the early phase of the study, more recent experiments have shown that resobene (**24**) interacts with the V3 domain of gp120 rather than binding to CD4. The principal neutralizing domain of the V3 loop is rich in hydrophobic and cationic residues, and it is likely that the correct orientation and composition of anionic and electron-rich heteroatoms in conjunction with the aromatic character of these compounds is important for V3 binding. Resobene, which possesses the best pharmacological profile, has been suggested as a possible topical microbicide in preventing HIV transmission.[102]

An independent screening effort by Lexigen led to the discovery of FP-21399 (**26**; Scheme 12) as a disruptor of the interaction between gp120 and antibodies directed against the V3 loop.[103] FP-21399 inhibits gp120-mediated spreading of T-cell-topic strains and interacts in a specific manner with the HIV-1 gp120–gp41 complex during virus entry.[104] Ono and

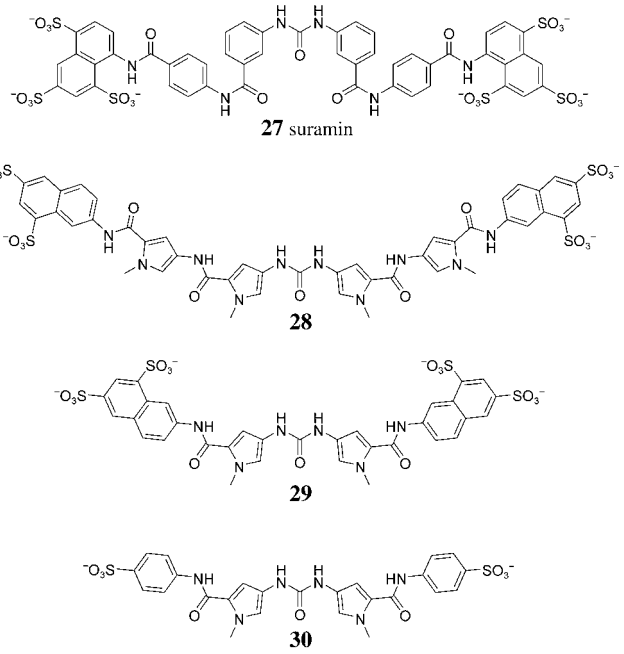
26 FP-21399



Scheme 12. FP-21399.

co-workers showed that FP-21399 mediates membrane fusion at concentrations as low as 1 $\mu g\,mL^{-1}$. Animal studies showed that FP-21399 decreases the infected population of mice from 71 % (control) to 21–13 % at a dosage of 10–50 $mg\,kg^{-1}$. FP-21399 is currently under phase-II clinical trials as a potential anti-HIV drug that operates through the disruption of viral fusion.[105] These approaches towards molecules that bock HIV viral fusion have provided excellent examples of the identification of synthetic ligands from a chemical library that disrupt protein–protein interactions.

4.2.3. Bisnaphthalene Sulfonates and Cationic Porphyrins as Anti-FGF Agents

Fibroblast growth factors (FGF) have been detected in a variety of cell types and are implicated in the progress of cell differentiation and development, including mitosis and angiogenesis. There are at least 19 members in the FGF family; among them, FGF-1 (acidic FGF) and FGF-2 (basic FGF) are regarded as the most important growth factors that bind to heparin sulfate proteoglycans.[106] X-ray crystallographic studies showed that FGF-2 proteins take up a β-trefoil structure with a central cavity ringed by hydrophobic residues that are conserved in all FGF family proteins.[107,108] Mutagenesis studies on FGF-2, supported by X-ray crystallography, have identified separate functional domains for heparin and receptor binding (Figure 3).[107,109]

Suramin (**27**; Scheme 13) a prototype growth factor antagonist, was found to disrupt the interaction between FGF-2 and FGFR (FGF protein receptor) in various cell lines. However, the development of suramin into a viable drug has been hampered by its high toxicity and lack of selectivity. For example, Takano et al. showed that the administration of suramin leads to tumor enhancement, possibly due to its immunosuppressive activity.[110] Gagliardi et al. conducted a detailed structure–activity relationship of 70 oligo-anionic analogues of suramin by measuring the ability of each to inhibit angiogenesis in a chick egg chorioallantoic membrane (CAM) assay.[111] Of the 70 analogues, compound **30** (Scheme 13) had antiangiogenic activities similar to suramin, and an additional seven compounds showed significantly stronger potency than suramin. All of the seven analogues were based on the naphthalenetrisulfonic acid scaffold and contained urea groups. The authors concluded that the presence of the naphthalene sulfonate groups and the correct number of rigid spacers between them is crucial for maintaining activity. Based on such observations, Manetti et al. attempted to optimize the pharmacological profile of suramin without compromising its affinity by synthesizing heterocyclic suramin analogues such as compound **28**.[112] In comparison with **27**, the congeners generally have a lower number of sulfonic groups either on the α- or β-aminonaphthalene moieties to modulate the binding to plasma proteins, whereas the benzene rings are replaced by pyrrole and pyrazole. These compounds possess better toxicity profiles than suramin and are more promising anti-FGF agents. Structure–activity relationship studies showed that compound **29**, which lacks a pyrrole spacer on either side, and **30**, in which the naphthalene sulfonate groups are missing, were less active than **28**. One of the low-energy conformations of **28**, obtained by molecular modeling, is a crescent shape in which all NH groups are directed toward the same face. A model of this conformation interacting with the FGF surface showed excellent electrostatic and geometric complementarity, cor-

relating well with structure–activity relationships observed experimentally. Further biophysical characterization by Zamai and co-workers with fluorescence anisotropy partially validated this model by confirming a 1:1 stoichiometry for the binding of **28** to FGF ($K_d = 0.127$ μM).[113] The interaction was reversible through the addition of heparin which suggests that **28** binds to the heparin-binding domain of FGF, as was suggested in the modeled structure. Moreover, single and double lysine mutants K128Q ($K_d = 1.23$ μM) and K128Q-K138Q ($K_d = 5.12$ μM) showed much weaker binding, which indicates the importance of the cationic side chains in complex formation.

Yayon and co-workers reported the disruption of the FGF-2–FGFR interaction with synthetic compounds based on a porphyrin scaffold (Scheme 14).[114] The cationic tetra-(methylpyridinium)porphyrin (TMPP) **31** was initially iden-

31 TMPP **32** P1016

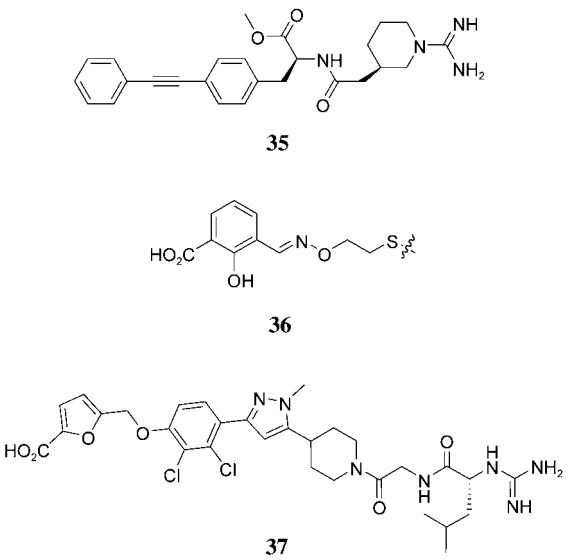
33 P1020 **34** P1021

Scheme 14. FGF inhibitors based on the TMPP scaffold.

tified from high-throughput screening. Further studies indicated that TMPP is able to block the binding of ^{125}I-labeled FGF to FGFR with an IC_{50} value of 1 μM. TMPP also showed some affinity for VEGF and was able to block its interaction with VEGFR ($IC_{50} = 10$ μM). Furthermore EGF, which is not a heparin-binding or heparin-dependent growth factor, was not inhibited in binding to its receptor tyrosine kinase by TMPP. This selectivity suggests that interfering with heparin binding might play a key role in the inhibitory effect of TMPP.

Several analogues of **31** were prepared and similarly measured for their ability to disrupt the FGF-2–FGFR complex. Interestingly, the unsymmetrical compound **32**, in which the charged *N*-methylpyridinium group was replaced with a neutral *N*-pentafluorophenyl group, showed a 50-fold higher potency in vitro ($IC_{50} = 20$ nM) than TMPP. Compound **33**, with an *N*-methyl-3-pyridinium modification, is 10-fold less active than TMPP, indicating that the position of the charges is important. As compound **32**, in contrast to TMPP (**31**), was completely inactive in vivo in the suppression of the metastasis of Lewis lung carcinoma, other derivatives with high efficacy in vivo and in vitro were sought. Compound **34**, a corrole derivative with three positive charges as in **32** and with the same side chains as in **33**, seemed to be the most balanced agent. The in vitro activity of **34** was 10-fold higher ($IC_{50} = 100$ nM) than that of TMPP, and the corresponding in vivo activity was also improved. Compound **34** inhibited tumor metastasis at a concentration fivefold lower than that of TMPP.

The exact mechanism of inhibition is unclear at this stage. Beyond the demonstration of disrupting the heparin–FGF-2–FGFR ternary complex, there has been no further characterization of the direct binding of **34** with FGF-2 or FGFR. In light of the binding capacity of oligo-anionic compounds such as suramin and its analogues, it is unlikely that these cationic porphyrins bind to FGF at the same site; this would potentially leave other molecular surfaces involved in the bioactive ternary complex available as therapeutic targets.



4.2.4. Inhibitors of the IL-2–IL-2Rα Interaction

The development of a synthetic antagonist for IL-2 binding to the α subunit of its receptor (IL-2Rα) is an interesting example of the combination of rational design, library screening, and sheer good fortune. IL-2 triggers T-cell proliferation by recognition of a heterotrimeric (α, β, and γ subunits) receptor complex on the T-cell surface.[32] X-ray crystallographic analysis showed that IL-2 is a four-helix bundle, and site-directed mutagenesis identified residues in the AB loop (K35, K38, T41, F42, K43, and Y45) and in the B helix (E61 and L72) as critical for the formation of the IL-2–IL-2Rα complex.[115] Previous studies have shown that monoclonal antibodies against IL-2R (anti-Tac) are effective immunosuppressive agents[32,116] which emphasizes the potential advantage of low-molecular-weight ligands that are able to disrupt the binding of IL-2 to IL-2Rα.

Research at Hoffmann–LaRoche reported that the synthetic inhibitor **35** (Scheme 15) was able to disrupt the IL-2–IL-2Rα interaction.[117] Compound **35** was designed to mimic the R38–F42 region of IL-2 through an acylphenylalanine group to emulate residues R38 and F42 in their contact with the IL-2Rα receptor. Compound **35** and its enantiomer were prepared and evaluated with a scintillation proximity competitive binding assay. A moderate affinity of **35** to disrupt the IL-2–IL-2Rα complex was observed ($IC_{50} = 3$ μM at pH 7.4), whereas the opposite enantiomer was inactive. In comparison, IL-2 gave an IC_{50} value of 13 nM. However, ^{15}N-HSQC NMR experiments showed that **35** actually inhibits the IL-2–IL-2Rα association by binding to IL-2 instead of IL-2Rα.[118] Nonetheless, **35** exemplifies a designed low-molecular-weight compound that mimics a discontinuous protein surface epitope, and represents the first well-characterized nonpeptide inhibitor of a cytokine–cytokine-receptor interaction.

A research group from Sunesis recently reported small-molecule IL-2 inhibitors with improved potency.[119] Their

Scheme 15. Synthetic antagonists of the formation of the IL-2–IL-2Rα complex.

approach involved the identification of synthetic fragments with modest affinity for protein surfaces by using a novel "tether" technique (Figure 4).[120] This method involves link-

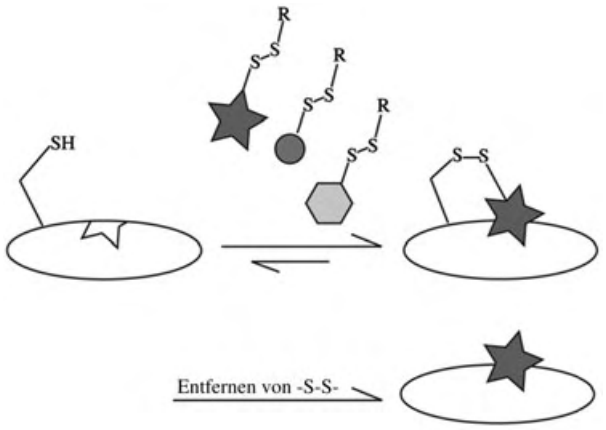

Figure 4. Principle of the "tether" method for the detection of lead compounds that recognize a specific site on the protein surface.

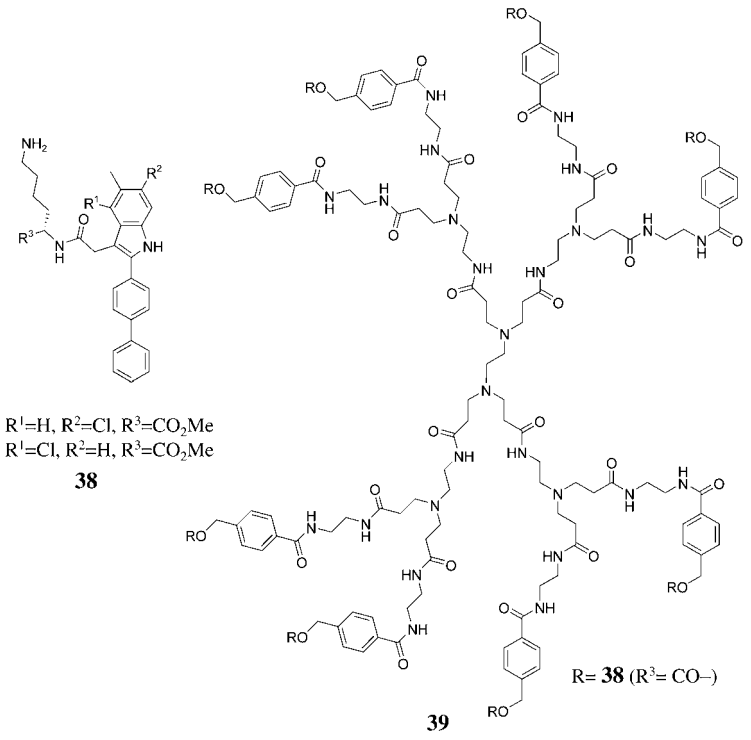
ing a library of thiol-functionalized fragments with cysteine-containing or modified proteins under reducing conditions. The resulting equilibrium exchange process favors fragments that make contact with the protein surface in addition to the disulfide bond. The identity of the favored and thus enriched fragment can then be determined by mass spectrometry. This method allows not only the screening of large fragment libraries, but also the probing of different regions of the protein by changing the location of the cysteine groups. Two or more fragments that bind to different regions of the protein with modest affinity can then be potentially linked to form a tight-binding inhibitor.

Braisted and co-workers applied the tether method to screen a library for IL-2 inhibitors. A series of fragments, such as **36**, were detected as hits by the mutant proteins.[119] Statistical analysis of these fragments indicated that the mutants Y31C and L72C preferentially select for small aromatic carboxylic acids. A focus set of 20 compounds then was prepared with the addition of carboxylic acid analogues to **36**. Eight of the 20 compounds inhibited IL-2–IL-2Rα binding at submicromolar concentrations, showing 5 to 50-fold improvement in potency over the lead. Analogue **37** showed the strongest binding with an IC_{50} value of 60 nM. A stoichiometry of 1:1 for **37** binding to IL-2 was confirmed by surface plasmon resonance (SPR). Further studies showed both **35** and **37** bind to a "hot spot" region on IL-2,[121] which is revealed through a conformational change that, in turn, is initiated upon binding of the small-molecule ligand. This study demonstrates how screening of a guided library is a useful alternative to structure-based, rational design in the search for inhibitors of protein–protein interactions. The structure-based design relies on X-ray crystallographic or NMR solution structures to identify rigid, well-defined pockets, whereas the fragment-assembly methods have advantages in targeting protein surfaces with adaptable or dynamic regions.

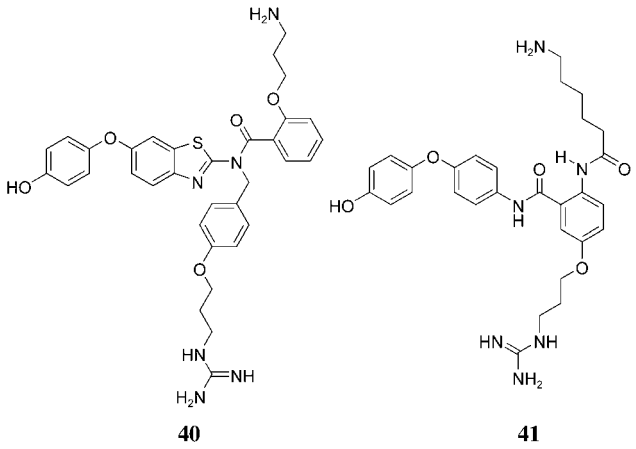
4.2.5. An Antagonist of the EPO–EPOR Interaction that Induces EPOR Dimerization



Erythropoietin (EPO) binds EPO receptors (EPOR) on red blood cells and regulates the proliferation and differentiation of erythroid progenitor cells.[122] Upon EPO binding, EPOR dimerizes, which in turn triggers a variety of biological responses. The original purpose of the work reported by Qureshi et al. was to use small molecules to mimic the functional EPO protein and to induce EPOR dimerization. Instead, an antagonist of the EPO–EPOR interaction was identified through a preliminary screen of the Merck chemical library (compound **38**; present as two regioisomers; Scheme 16).[123] The ability of **38** to block the EPO–EPOR interaction was detected with a radiolabeling/binding assay, and an IC_{50} value of 59.5 ± 1.1 μM was determined.

A branched compound, **39**, with eight units of **38**, was more potent ($IC_{50} = 4.4 \pm 1.9$ μM) and induced EPOR dimerization. In analogy to natural EPO, **39** was able to activate a STAT-dependent luciferase reporter gene in BAF cells expressing human EPOR. It also supported the proliferation of EPOR-expressed tumor cell lines and differentiated human progenitor cells into colonies or erythrocytic lineage. These results demonstrate that **38** is a weak antagonist of the EPO–EPOR interaction, whereas compound **39**, with several identical binding domains, may act as an activator of EPOR.

4.2.6 A Low-Molecular-Weight Modulator of the N-Type Calcium Channel



The N-type calcium channel is a critical protein for the process of neurotransmitter release in the central and peripheral nervous system.[124] The protein subunit assembly within the calcium channel is essential to its biological function, and previous work has shown that calcium channel activity can be mediated by modulation of the interaction

among its subunits.[125] Computational modeling was used to design mimetics of the discontinuous three-residue pharmacophore of ω-conotoxin GVIA, a native ligand of voltage-gated N-type calcium channels.[126] Benzothiazole derivative **40** (Scheme 17) was selected to mimic the K2 and Y13 C^{α}–C^{β}

Scheme 17. Inhibitors of the N-type calcium channel.

bond vector based on the computational modeling prediction. Further optimization of the design led to anthranilamide **41** with more conformational flexibility. Moderate affinities for functional blocking of the N-type calcium channel were observed (**40**, $IC_{50} = 98\ \mu M$; **41**, $IC_{50} = 68\ \mu M$).

4.2.7. Allosteric Inhibitors of iNOS Dimerization

The mammalian nitric oxide synthase (NOS) isoforms are homodimeric proteins that catalyze NADPH-dependent oxidation of L-arginine to nitric oxide (NO) and L-citrulline.[127] Crystallographic structures of the three NOS isoforms (eNOS, nNOS, and iNOS) have revealed that they share a catalytic heme domain that is highly conserved in the immediate vicinity of the heme active site.[128] As the NOS isoforms are only active as homodimers,[129] synthetic agents that disrupt the dimerization of the subunits would have broad therapeutic potential in iNOS-mediated pathologies.

A research group from Berlex Bioscience reported highly potent and selective pyrimidine-imidazole-based inhibitors identified from a screen of an 8649-compound library prepared on a solid-phase support in three combinatorial steps.[130] A cell-based iNOS activity assay was conducted to measure the production of the NO· radical species, and identified 53 compounds as preliminary leads, accounting for 0.6% of the library. The binding mode of one of the most potent compounds **42** ($K_i = 2.2$ nM) was further characterized by X-ray crystallography (Figure 5). The crystal structure reveals

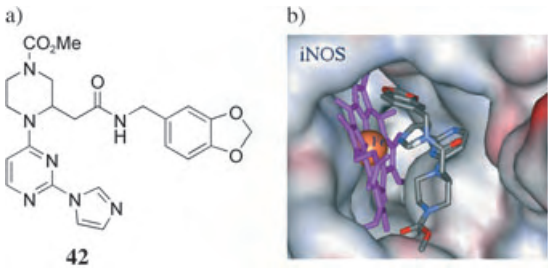

Figure 5. a) Pyrimidine-imidazole-based Inhibitor of iNOS; b) Crystal structure of the inhibitor–iNOS complex shows that **42** coordinates with the heme.

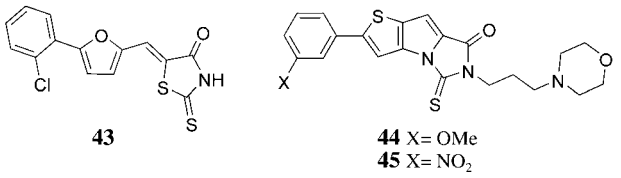
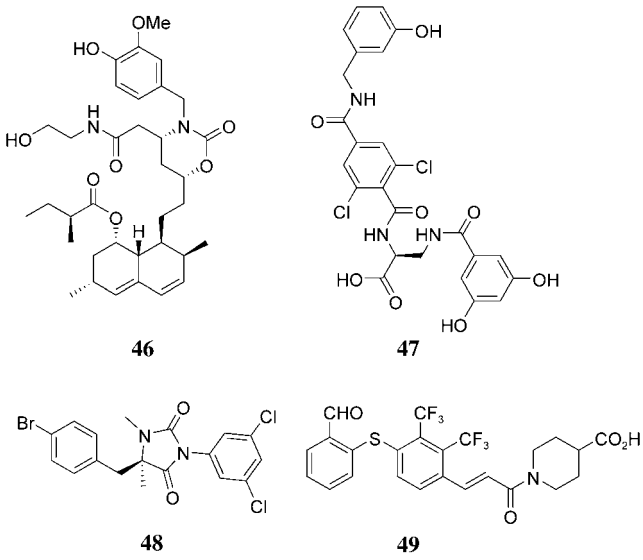


that **42** occupies the arginine-binding site of the iNOS oxygenase domain and directly coordinates to the heme. Helix 7a (not shown) of iNOS, as well as the critical arginine-binding residue Glu 371, are displaced upon the binding of **42**, and the induced disorder disturbs the interface of the dimer, thus inhibiting the dimerization through an allosteric effect. This study represents a relatively rare case in which the inhibitory mode of a low-molecular-weight ligand of protein–protein interactions was fully characterized, shedding light on the design of small-molecule antagonists.

4.2.8. Photochemically Enhanced Inhibitors of the TNF-α–TNFRc1 Interaction



A research group from DuPont reported a group of photochemically enhanced low-molecular-weight inhibitors of tumor necrosis factor alpha (TNF-α),[131] a pleiotropic

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

cytokine involved in inflammation.[132] A preliminary screen identified **43** (Scheme 18) as a lead with moderate potency in disrupting the binding of TNF-α to its native receptor TNFRc1 ($IC_{50} = 2.9$ μM). Structure–activity relationship studies showed that replacement of the internal heterocyclic sulfur atom improves binding, and the optimized compounds **44** and **45** showed IC_{50} values of 50 nM and 270 nM, respectively. More interestingly, **43** exhibited an impressive 2000-fold selectivity in blocking the TNF-α–TNFRc1 interaction over that with the other receptor TNFRc2. Compound **44** had an IC_{50} value of 600 nM for inhibiting the TNF-induced phosphorylation of Iκ-B in Ramos cells and was not cytotoxic at concentrations up to 100 μM. An X-ray crystal structure showed that **45** covalently binds to the backbone nitrogen atom of A62 of TNFRc1, suggesting it functions by blocking interactions between the exposed Tyr-containing β turn of the native ligands and the region near A62 of TNFRc1. A key feature of these rhodamine thiocarbonyl-based TNF-α inhibitors is that they are light dependent, as it appears that **45** binds reversibly in the dark and irreversibly upon irradiation. The authors proposed a mechanism in which the inhibitors bind reversibly to TNRFc1 with weak affinity and then covalently modify the receptors through a photochemical reaction.

Scheme 18. Photochemically enhanced TNF-α inhibitors.

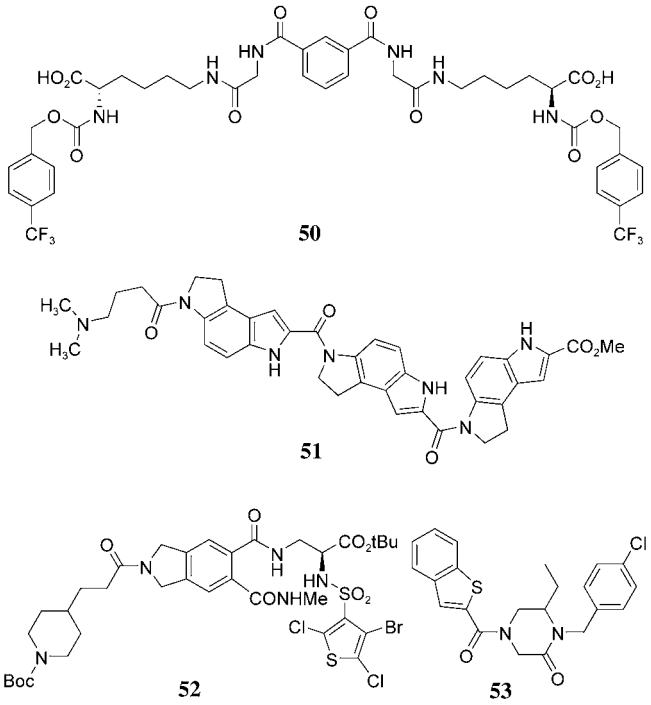
Entry	Source	Affinity in Vitro	Inhibition of Cell Adhesion	I domain binding
46[235,245]	Novartis	$IC_{50} = 40$ nM	$IC_{50} = 0.4$ μM	+
47[235]	Genentech	$IC_{50} = 20$ nM		–
48[246]	Boehringer Ingelheim	$K_d = 26$ nM	$IC_{50} = 2.6$ μM	+
49[247]	Abbott Laboratories	$IC_{50} = 5$ nM	$IC_{50} = 0.1$ nM	+

4.2.9. *Inhibitors of the ICAM-1–LFA-1 Interaction*

Integrins make up a large family of cell-surface receptor proteins that mediate the mechanical and chemical signals of the extracellular matrix (ECM) by signaling through the cell membrane.[133] Many integrin signals converge on cell-cycle regulation and modulate such cellular processes as proliferation and differentiation. Functional integrins are heterodimeric proteins consisting of two transmembrane glycoprotein subunits, α and β, that share homology and noncovalently interact with each other. Each α/β combination has its own binding specificity and signaling properties.

The interaction between leukocyte-function-associated antigen-1 (LFA-1) and intracellular adhesion molecule-1 (ICAM-1) has drawn considerable attention owing to its essential role in the regulation of immune and inflammatory responses.[134] LFA-1 forms a complex with ICAM-1 by inserting into the I domain between β sheets 2 and 3 of a seven-bladed putative β-propeller region on the α_L subunit.[135] Recently, several research groups have reported low-molecular-weight inhibitors of ICAM-1–LFA-1 interactions from screening efforts (see Scheme 19 and Table 1).

4.2.10. *Mediators of the Cell-Signaling Pathway from Solution-Phase Combinatorial Libraries*



The solution-phase preparation of combinatorial libraries developed in the research group of Boger has had an important impact on the study of low-molecular-weight modulators of cellular signaling through the inhibition, promotion, and mimicking of protein–protein interactions.[3] The advantage of solution-phase synthesis of combinatorial libraries is that significantly larger quantities can be prepared than is possible with solid-phase techniques. This allows the repeated use of library members without the need for resynthesis. The simplicity of the chemistry makes it applicable to a wide range of library designs. Boger et al. selected several targets in signal transduction pathways, wherein protein–protein interactions play key roles at distinct stages for modulating cellular signaling.[3] Table 2 summarizes the targets, screening methods, and compounds detected with their effectiveness in inhibition (see also Scheme 20). More extensive discussions are available elsewhere.[2–4]

4.2.11. *Antagonists of MDM2 that Induce p53 Accumulation*

p53 is a transcription factor found in a mutated state in approximately 50% of human tumors.[136] The overexpression

Table 2: Synthetic mediators of cell signaling pathways identified from screening solution-phase combinatorial libraries (see Scheme 20).

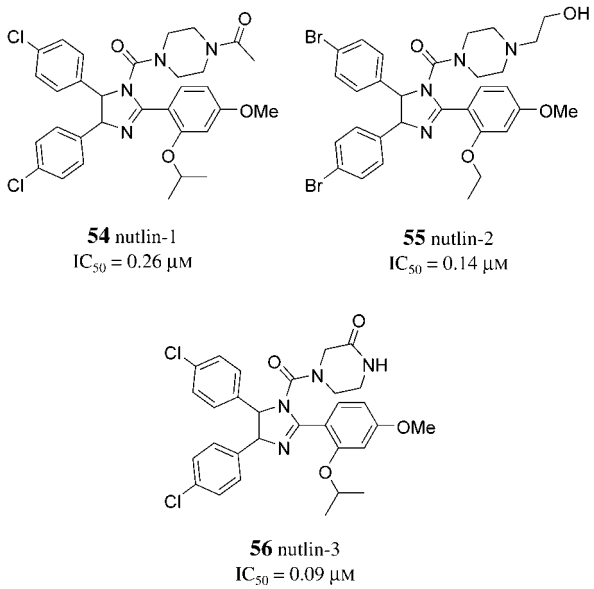

Scheme 20. Mediators of cell-signaling pathways.

of wild-type p53 induces a large number of downstream genes that lead to cell-cycle arrest or apoptosis. In unstressed normal cells, p53 is present at very low levels, resulting from its rapid degradation through the ubiquitin-dependent proteasome pathway. A research group at Pfizer identified small molecules that stabilize p53 by inhibiting its ubiquitination which thus induce apoptosis of human cancer cells.[137]

The oncoprotein mouse double minute 2 (MDM2) regulates p53 turnover by promoting its ubiquitination.[138] The overexpression of MDM2 abolishes the ability of p53 to induce cell-cycle arrest and apoptosis.[139] In about 40–60% of human osteogenic sarcomas and about 30% of soft-tissue sarcomas, MDM2 is overexpressed, implicating its involvement in the development of these tumors.[140] Therefore, the overexpression of MDM2 plays a key role in the tolerance of wild-type p53, making it an attractive target for the development of potential antitumor agents. Recently, several approaches were taken to modulate the p53–MDM2 interaction. Chen et al. showed that inhibition of MDM2 expression by antisense oligonucleotides resulted in the activation of p53, leading to growth arrest or apoptosis.[141] Blaydes et al. inhibited the binding of p53 to MDM2 through microinjection of the 3G5 anti-MDM2 antibody; this led to activated cellular p53 function.[142] García-Echeverría et al. reported that a hexapeptide representing residues 18–23 of p53 is the minimum-binding epitope for HDM2 (the human analogue of MDM2) recognition. The hexapeptide blocked HDM2 interaction with p53 with an IC_{50} value of 700 μM. A 13-residue peptide from the region of residues 16–28 of p53 displayed even more potent binding (IC_{50} = 8.7 μM).[143] Robinson and co-workers recently reported a group of α-helical mimetics based on a β-hairpin scaffold as antagonists of p53–MDM2 binding.[144] These studies provide a proof-of-concept for the activation of p53 by targeting MDM2, but the various oligonucleotides, antibodies, and polypeptides are not suitable for studies in vivo, emphasizing the need for small-molecule inhibitors.

A research group at Roche has recently reported a series of low-molecular-weight antagonists of MDM2 that cause the accumulation of p53 in cellular assays.[145] Three *cis*-imidazoline analogues **54**–**56** (Nutlins; Scheme 21) were identified in

Scheme 21. *cis*-Imidazoline-based MDM2 inhibitors.

a preliminary screen by using surface plasmon resonance (IC_{50} = 90–260 nM). The binding modes of these inhibitors were determined by X-ray crystallography. The imidazoline scaffold reproduces features of the helical backbone of the p53 peptide and directs the side chains to the pockets on MDM2 that are normally occupied by residues Phe19, Trp23, and Leu26 of p53 (Figure 6). The halogen atoms on the phenyl groups filled the Trp23 pocket and enhanced binding, consistent with a previous result that the p53 peptide with a 6-Cl-Trp23 mutant showed stronger affinity for MDM2.[146]

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

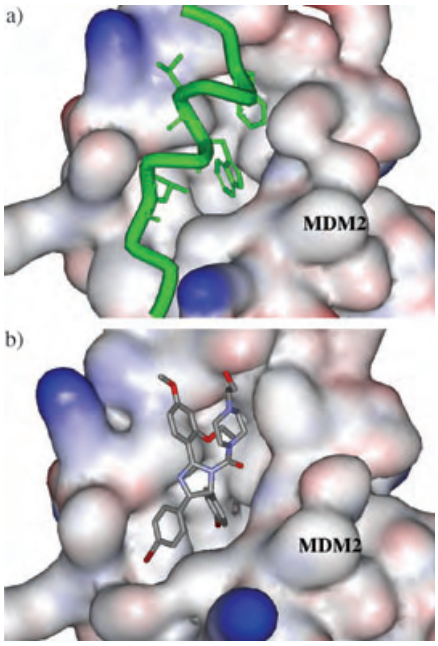

Figure 6. X-ray crystallographic structures of a) the p53–MDM2 complex; b) the **55**–MDM2 complex.

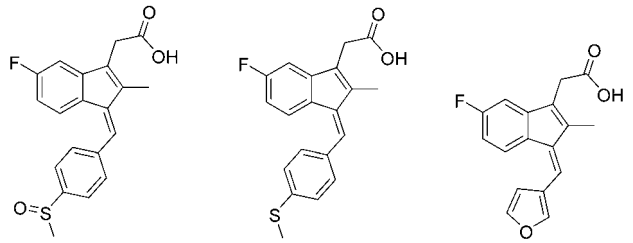


Nutlin-1 (**54**) induced the accumulation of p53 as well as the downstream cyclin-dependent kinase inhibitor $p21^{waf1/Cip1}$ and MDM2 in HCT116 and RKO tumor cells. For cells in which p53 is mutated or deleted, no accumulation of MDM2 or p21 was detected despite the high basal levels of p53. These results indicate that wild-type p53 accumulates in cells treated with **54**, leading to an elevation in the levels of MDM2 and p21 proteins in a manner that is consistent with activation by the p53 pathway. An alternative possibility that the imidazoline derivatives induce p53 accumulation by means of DNA damage was ruled out, as the phosphorylation of serine residues normally caused by DNA-damaging reagents was not observed. Further investigation showed that **56** induced apoptosis in cancer cells with wild-type p53. Animal studies demonstrate that **56** is effective in decreasing tumor volume in nude mice (200 mg kg^{-1} twice a day) over a 20-day period with tolerable toxicity.

As the most recent examples of small-molecule inhibitors of the p53–HDM2 interaction, Hamilton and co-workers reported terphenyl-based helical mimics of p53 that target the HDM2 protein.[147] Issaeva et al. reported a small molecule, RITA (reaction of p53 and induction of tumor cell apoptosis), that binds to p53 and induces its accumulation in tumor cells by disrupting the p53–HDM2 interaction.[148]

4.2.12. *Inhibitors of the Ras–Raf Interaction*

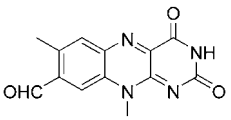
There has been considerable interest in the identification of small-molecule agents that modulate the activity of the Ras family of GTPases, as these proteins play a vital role in growth-factor-activated cell proliferation, differentiation, and survival.[149] The signaling pathway that passes through Raf (a downstream effector of Ras), mitogen-activated protein kinase kinase (MEK), and extracellular signal-regulated kinase (ERK) is necessary for Ras-regulated cellular proliferation.[150]

Müller, Waldmann, and co-workers identified a series of synthetic compounds from a cell-based assay that were able to disrupt the Ras–Raf interaction.[151] The Müller research group had previously reported that the metabolite **58** of the nonsteroidal anti-inflammatory drug (NSAID) sulindac (**57**) (Scheme 22) is able to interfere with the Ras pathway,

57 Sulindac **58** **59**

Scheme 22. Structures of sulindac and its analogues that disrupt Ras–Raf binding.

although its molecular target has yet to be identified.[152] Phenotype-based screening of a library containing 188 sulindac analogues, prepared by solid-phase synthesis, generated 23 lead compounds. All of these derivatives had the ability to induce reversion of the transformed phenotype of the Madine–Darby canine kidney (MDCK)-F3 cells and to induce apoptosis. Four compounds were shown to disrupt the Ras–Raf interaction. The most active compound **59** blocked the Ras–Raf interaction with an IC_{50} value of 30 μM in vitro and an IC_{50} value of 10 μM in the cellular cytotoxicity assay.



An alternative approach for the identification of small-molecule inhibitors of Ras–Raf-1 binding was reported by Tamanoi and co-workers,[153] with a previously developed dual-bait two-hybrid system.[154] A library of 73400 compounds was screened for the ability to block the interaction of DBD-H-Ras and full-length AD-Raf-1 expressed in SKY54 cells. From this, 3009 compounds were found to have a growth-inhibitory effect. From these leads, 708 compounds induced a phenotype of decreased growth and β-galactosidase activity with some degree of selectivity for H-Ras–Raf-1, versus the negative control on plates. Further evaluation allowed the selection of 38 compounds that showed a clear decrease in β-galactosidase activity at 30 μM in SKY54 cells expressing DBD-H-Ras and AD-Raf-1. A serum response element (SRE)-luciferase assay was used as a secondary screen to determine the ability of the 38 compounds to inhibit the Ras-induced transcriptional activation through SRE and AP-1 sites from the c-fos promoter.[155] MCP1 ($C_{29}H_{27}ClN_2O_3$; M_r 487; structure not available), which has an excellent profile in the primary two-hybrid assay, showed robust dose response in CHO cells and the ability to inhibit H-Ras (V-12)-induced AP-1 activation in HEK293 cells. An alternative mechanism by which the MCP compounds indirectly disrupt Ras–Raf by inhibition of Hsp90 and destabilization of the structurally fragile Raf-1 was ruled out,[156] because MCP1 did not decrease the level of endogenous Raf-1 upon 40 h incubation

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

in HT1080 cells. MCP1 also inhibited Ras-induced Raf-1 activation in HEK293 cells, Raf-1 and MPK1 activities in HT1080 fibrosarcoma cells, and epidermal growth factor-induced Raf-1 activation in A549 lung carcinoma cells.

4.2.13. *An Antagonist of Nerve Growth Factor*

A research group at Hoffmann–LaRoche reported a low-molecular-weight antagonist of nerve growth factor (NGF) with good selectivity.[157] NGF is a homodimer protein that binds to two neurotrophin ligands with different domains: $p75^{NTR}$, a nonselective receptor of the tumor necrosis factor (TNF) superfamily, and $p140^{Trk}$ (TrkA), a tyrosine kinase receptor that mediates the trophic effects of NGF.[158] In cells that express both NGF receptors, TrkA activity is modulated by $p75^{NTR}$.[159] If cells lack TrkA expression, $p75^{NTR}$ triggers apoptosis by binding to NGF.[160] Niederhauser et al. have reported that Ro 08-2750 (**60**; Scheme 23) selectively inhibits the binding of NGF to $p75^{NTR}$ over TrkA.[157] The inhibitory potency of Ro 08-2750 was determined in a cell-based competition assay with radiolabeled NGF protein. Compound **60** is effective in blocking the NGF interaction with $p75^{NTR}$ with an IC_{50} value in the lower micromolar region. Furthermore, 10-nM Ro 08-2750 completely rescued cells from NGF-induced apoptosis, indicating that the inhibitor disrupts the formation of the NGF–$p75^{NTR}$ complex, whereas no toxic effect was observed. The authors proposed that Ro 08-2750 causes a conformational change in NGF over time, as the inhibition is time-dependent. However, Arkin and Wells argued that the dependence could be the result of covalent binding; therefore, further clarification of the inhibitory mechanism is necessary.[8]

60 Ro 08-2750

Scheme 23. The NGF inhibitor Ro 08-2750.

4.2.14. *Antagonists of the Immune Regulatory Protein B7.1*

Erbe et al. reported low-molecular-weight compounds that inhibit the binding of CD28 and CTLA4 to human B7.1,[161] a T-cell surface protein that plays a critical role in the activation of native T cells.[162] Signaling through CD28 augments the T-cell response, whereas CTLA4 signaling attenuates it.[163] The crystal structure of the B7.1–CTLA4 complex revealed that CTLA4 dimers and B7.1 dimers pack in a periodic arrangement (Figure 7a).[164] Figure 7b shows that the ^{99}MYPPPY^{104} loop of CTLA4 is buried in a shallow depression of the B7.1 surface, indicating a high degree of shape complementarity. Two compounds, **61** ($IC_{50} = 30$ nM) and **62** ($IC_{50} = 60$ nM), were identified as inhibitors of the B7.1–CD28 interaction in high-throughput screening assays (Scheme 24). These two compounds bind to the same site within the N-terminal domain of human B7.1, which is not present in the homologous protein B7.2 or mouse B7.1. This imparts high selectivity of the inhibition of human B7.1 over its analogues. Structure–activity relationship studies identified a dihydrodipyrazolopyridinone derivative **63** as the most potent inhibitor for the B7.1–CD28 interaction ($IC_{50} = 4$ nM).[165]

4.2.15. *A Photoaffinity-Labeled Inhibitor of the RSV Fusion Protein*

The transient hexameric helical bundle involved in viral entry into cells is an important target that has been the focus of many recent studies. Although small-molecule inhibitors of the HIV gp41 glycoprotein and other viral fusion proteins have been ardently sought,[166,167] no well-characterized inhibitors of that type have been found. A research group from Bristol-Myers Squibb recently used photoaffinity labeling to determine the binding site of a previously reported inhibitor, **64**, on the respiratory syncytial virus (RSV) fusion protein (Scheme 25).[168] A photolabeled analogue, **65**, was found to attach to Tyr 198 in the hydrophobic cavity on the N-terminal heptad repeat (HR-N) trimer of the RSV fusion machinery. Molecular dynamics (MD) simulations were then employed to predict the orientation of **65** within the binding cleft. The photoaffinity labeling method provides a general means to study the binding modes for inhibitors that target protein–protein interfaces.

4.3. Computer-Aided Screening for Low-Molecular-Weight Inhibitors of Protein–Protein Interactions

Major advances in high-throughput screening technologies in recent years have made it possible to assay up to 100 000 compounds a day. Such screens could be made even more efficient if the size of the target pool were decreased. Screening compound libraries in silico beforehand can decrease the number of compounds actually synthesized and tested. The operations can be categorized as diversity- and structure-based designs. Diversity-based designs are used to select a focused library from a larger library while maintaining the diverse character of the full-range library.[169] A variety of computational methods based on compound similarity clustering, gridlike partitioning of chemical space, and the application of genetic algorithms are used in screening large libraries to generate focused libraries.[170] Whereas diversity-based design is the method of choice if no structural information is available, structure-based methods use prior information of the target structure to assist the design and selection of the leads with 3D complementarity to the target binding site and provide a higher hit rate than the diversity design.[171] Although in-silico screening technology has been used in many studies to aid the discovery of new enzyme inhibitors for indications such as AIDS and parasitic infections, the use of this technology to search for inhibitors of protein–protein interactions remains a largely underexplored area.[172] Some progress has been made in the establishment of computer-aided screening and design as a general approach to search for inhibitors of protein–protein interactions.[173,174]

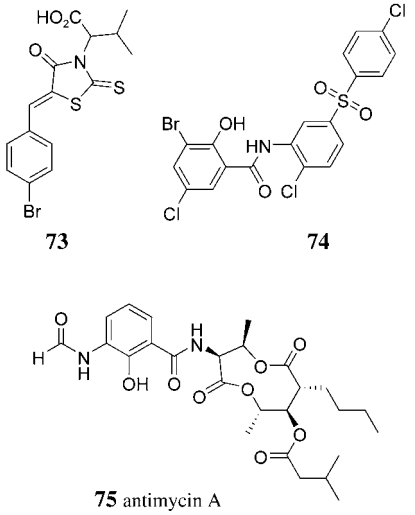
4.3.1. Inhibitors of Antiapoptotic Bcl-2 Proteins

Proteins in the Bcl-2 family play a critical role in determining the fate of a cell through the process of apoptosis.[175] Many oncogenic mutations, particularly those of p53, result in defects in DNA-damage-induced apoptosis through a Bcl-2-dependent mechanism.[176] Furthermore, the overexpression of Bcl-2 can inhibit the potency of many currently available anticancer drugs by blocking the apoptotic pathway.[177] Therefore, agents that directly mimic the death-promoting BH3 domain of the pro-apoptotic subfamily of Bcl-2 proteins are of potential therapeutic value.[178]

Several research groups have used in-silico screening to assist in the search for low-molecular-weight inhibitors of Bcl-2 and Bcl-x_L (Scheme 26 and Table 3).[179] Huang and co-workers presented one of the first approaches in computer-

Scheme 26. Inhibitors of Bcl-2 (Bcl-x_L) from virtual library screening.

Table 3: Inhibitors of Bcl-2 (Bcl-x_L) discovered with in silico screening techniques (see Scheme 26).



Compound	Target	IC_{50} [μM]	Docking Program	Library (Size)	Size of Focused Library
66[180]	Bcl-2	9	DOCK 3.5	MDL/ACD 3D (193 833)	28
67[181]	Bcl-2	1.6 ± 0.1	DOCK	NCI (208 876)	35
68[181]	Bcl-2	7.7 ± 4.5			
69[181]	Bcl-2	10.4 ± 1.2			
70[181]	Bcl-2	5.8 ± 2.2

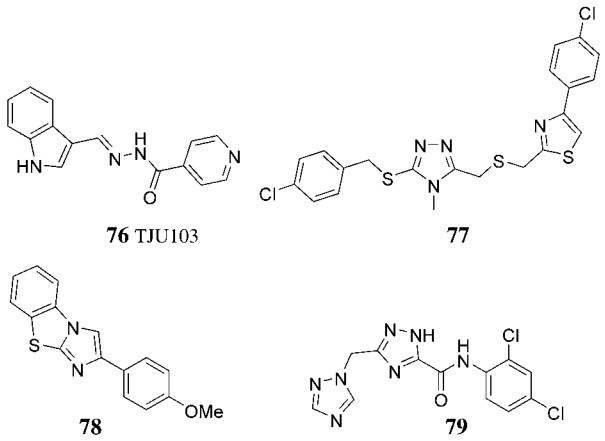
aided screening to narrow a large commercial library into a focused target group.[180] A 3D structure of the Bcl-2 protein derived from the NMR solution structure of the Bcl-x_L–Bak complex was used as the virtual target for 193 833 compounds from the MDL/ACD 3D database (Molecular Design). The computational docking experiments with DOCK 3.5 were carried out on 1000 compounds selected by their scoring function in shape complementarity, which relates to the attractive van der Waals energy. A filter of the preliminary candidates generated 53 compounds, of which 28 were chosen for synthesis and testing, reflecting a wide chemical diversity.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Compound **66** showed moderate potency in disrupting the Bcl-2–Bak dimerization ($IC_{50} = 9\ \mu M$) and was able to induce apoptosis in HL-60 cells by caspase activation. Compound **66** represents the first reported antagonist of the Bcl-2–Bak complex identified with de-novo computer-aided design. In a similar fashion, Enyedy et al. identified five synthetic compounds (**67**–**71**) that disrupt the interaction between Bcl-2 (Bcl-x_L) and the Bak peptide with IC_{50} values at the low μM level.[181] Lugovskoy et al. combined the structural and computational approaches to preselect 93 compounds that possess good spatial agreement with a previous lead by using structural interface mapping and exhaustive computational interaction analysis techniques.[182] Analogue **72** was selected from the virtual screening and showed a similar affinity to that of the initial lead compound.

In addition to the in-silico approach, traditional screening methods have also been employed to identify inhibitors of Bcl-2 (Bcl-x_L) proteins. Detgerev et al. screened a commercial library (ChemBridge) of 16320 compounds and identified three compounds that disrupt the Bcl-x_L–Bak interaction (Scheme 27) with IC_{50} values in the low μM range.[183] A ^{15}N-



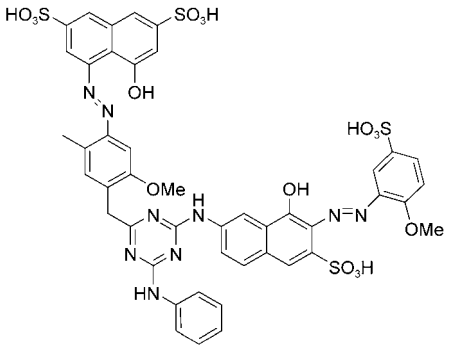
Scheme 27. Inhibitors of Bcl-x_L from wet screening.

HSQC NMR analysis showed that the synthetic inhibitors target the hydrophobic cleft where the BH3 domain binds on the surface of Bcl-x_L, and this was further confirmed with a NOESY experiment, which indicated direct contact between **73** and the residues Tyr65 and Phe107. Compound **73** was able to induce apoptosis in JK cells with overexpressed Bcl-x_L, suggesting the potential therapeutic application of **73** as an antitumor agent.

Antimycin A (**75**; Scheme 27), an inhibitor of mitochondrial electron transfer, was found to antagonize Bak binding to Bcl-x_L and to induce mitochondrial swelling.[2,179,184]

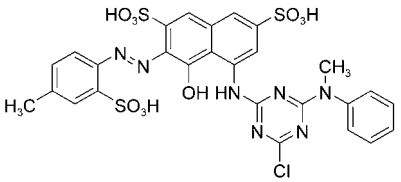
4.3.2. *Nonpeptide CD4 Inhibitors*

Protein–protein interactions among the proteins of the immunoglobulin superfamily (IgSF) play an important role in the mediation of cell-surface recognition.[185] The glycoprotein CD4 is expressed on the surface of helper T cells and functions as a coreceptor for stabilizing the interactions of T-cell receptors with antigens presented by the MHC class II molecule expressed on antigen-presenting cells.[186] CD4 binds to nonpolymorphic regions of the MHC class II β2 domain,[187] resulting in the co-oligomerization of CD4, MHC class II, and the T-cell receptor to initiate signaling in T cells. Huang and co-workers used computer-based screening to search a commercially available library of 150000 small organic compounds with the program DOCK 3.5.[173] After two rounds of virtual screening, 41 compounds were selected and tested in human mixed lymphocyte reactions. From the large library, four compounds were found to have inhibitory effects on alloreactive T-cell proliferation (Scheme 28). Among them, TJU103 (**76**) was the most promising lead for prolonging the median survival time of allograft mice to 52 days (in comparison with 20 days for the untreated control group).



Scheme 28. CD4 inhibitors from in-silico screening.

4.3.3. *Disruptors of the Hexameric Helical Bundle of gp41*



Debnath and co-workers improved the structure-based virtual screening with the DOCK suite of programs,[188] by using a force-field scoring method instead of shape-based scoring. This approach takes into account the interactions between the surrounding charged groups of the targeted hydrophobic cleft and the ionic groups in the potential inhibitors, thus improving the reliability of the docking results. The method was employed in the search for compounds that target the core region of gp41 of the HIV-1 virus. This has become an attractive target in light of the limitations in the use of inhibitors toward HIV-1 reverse transcriptase (HIV-1 RT) and HIV-1 protease.[189] A database of 20000 small organic molecules was screened, and the 200 top-scoring compounds were selected for inspection with visualization techniques for direct ranking.[190] Sixteen compounds from the screening process were prepared; their ability to disrupt the hexameric helical bundle formed through the gp41 N36–C34 complex was tested in vitro using an ELISA assay. Of these

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

compounds, **80** and **81** (Scheme 29) showed potent activity with IC_{50} values of 0.73 μg mL^{-1} and 3.18 μg mL^{-1}, respectively. Assays of the active compounds in vivo demonstrated that both **80** and **81** inhibit HIV-1-mediated cell fusion and the cytopathic effect (CPE). The validation of the in-silico screening method was confirmed, as **80** and **81** were ranked first and third in the computational scoring and showed the most potent activity in the assay.

5. Synthetic Inhibitors of Protein–Protein Interactions from Rational Design

Information from biology can aid the design of synthetic molecules with features that structurally and functionally mimic the complementarity-determining region (CDR) of targeted proteins. With the assistance of X-ray crystallography, NMR spectroscopy, and computational simulation, chemists can manipulate biological processes with small synthetic agents through the recognition of protein surfaces or the disruption of protein–protein interactions. For example, by using NMR-based screening, Hajduk et al. determined that certain motifs (e.g. biphenyls) are more likely to be used as a template for the discovery and design of therapeutics with high affinity and specificity for a broad range of protein targets.[191] Many designed inhibitors also have very rigid structures to prevent hydrophobic collapse. Although this theoretical and empirical insight facilitates rational design, the engineering of small molecules to target particular protein–protein interactions remains a major challenge.

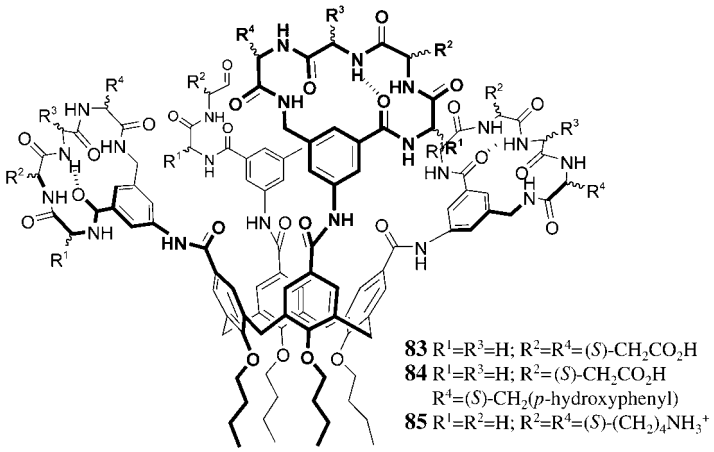
5.1. Rational Design of Synthetic Inhibitors that Recognize the Exterior Surfaces of Proteins

5.1.1. A Synthetic Inhibitor that Mimics the Complementarity-Determining Region of MAb 87.92.6

Through structural information and computational modeling, Saragovi et al. pioneered the design of small-molecule antagonists of protein–protein interactions.[192] Their target was the monoclonal antibody MAb 87.92.6, which recognizes the reovirus type 3 cellular receptor (Reo3R). Previous work had shown that cyclic peptide analogues of the second CDR of MAb 87.92.6 successfully block the interaction of MAb 87.92.6 and Reo3R.[193] However, the proteinaceous nature of the peptide analogues prevented further development as a result of their poor solubility, limited blood-brain barrier permeability, and susceptibility to proteolysis. For this reason the 87.1-mimetic **82** (Scheme 30) was designed and synthesized to mimic the second CDR of MAb 87.92.6. This synthetic inhibitor showed good solubility in water, making it permeable to the blood-brain barrier. Binding assays showed that immobilized **82** specifically binds to MAb 9BG5 (a native partner of MAb 87.92.6) with a 14-fold stronger affinity than the negative control. Compound **82** can competitively block the binding of MAb 9BG5 to VLSH, a dimeric peptide derived from the second CDR of MAb 87.92.6, in a dose-dependent fashion. Cellular studies demonstrated that **82** inhibits concanavalin A (Con A)-induced T-cell proliferation of splenocytes in a dose-dependent manner, as did the VLA5 peptide and the intact MAb 87.92.6. On the other hand, the peptide analogue and a CD4 mimetic (a reverse-turn mimetic derived from residues 41–54 of human CD4) were inactive in the same assay system. These data suggested that **82** inhibits cell proliferation by mediating the Reo3R receptor.

82 87.1-mimetic

Scheme 30. Structure of 87.1-mimetic as mimetic of the complementarity-determining region of monoclonal antibody 87.92.6.



5.1.2. Calix[4]arene-Based Inhibitors of PDGF and Cytochrome c

Calix[4]arene has been widely used in supramolecular chemistry as a result of its well-defined shape and ease of synthesis.[194] Sebti and Hamilton reported the use of calix[4]-arene derivatives as synthetic reagents for the recognition of protein surfaces.[195] The basis of this design was threefold: 1) the relatively large binding area (> 400 Å^2) of calix[4]arene provided a promising scaffold for mimicking the interacting region of an antibody–antigen interface; 2) modular design and stepwise functionalization of the upper rim of calix[4]-arene facilitates efficient diversity-oriented synthesis of inhibitors; 3) the flexibility of the calix[4]arene scaffold facilitates the recognition of a dynamic surface in an "induced-fit" mechanism.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

There are four positions on the upper rim of calix[4]arenes that can be used to attach different recognition domains. Varying both the nature and the symmetry of the substituents on the rim can be used to increase the diversity of the family. As protein surfaces are intrinsically unsymmetrical, the ability to prepare inhibitors with a complementary and unsymmetrical distribution of charge and hydrophobicity should greatly improve their selectivity.

Platelet-derived growth factor (PDGF) is a potent inducer of growth and motility such as cell proliferation, angiogenesis, wound healing, and chemotaxis.[196] PDGF binds to its cell-surface receptor, PDGFR, resulting in dimerization, receptor autophosphorylation, and recruitment of tumor cells.[197] Overexpression of PDGFR is observed in many carcinomas, and some cancer patients have high serum levels of PDGF.[198] These elevated levels of PDGFR in cancer patients also correlate with poor response to chemotherapy and shorter survival times. Hamilton and co-workers studied the surface recognition of PDGF by synthetic agents that are able to disrupt its interaction with PDGFR and thereby elicit antitumor and anti-angiogenesis effects.[199] PDGF-BB is a homodimer of two proteins that consist of two β strands with three intramolecular disulfide bridges. The three surface loops connecting the strands are clustered at one end of the elongated dimer upon dimerization. Mutational analyses indicates that the key binding regions are in these loop regions. These regions are rich in cationic and hydrophobic residues; the recognition strategy based on hydrophobic and electrostatic complementarity could be applied to this domain. Molecules **83–85** (Scheme 31), in which multiple

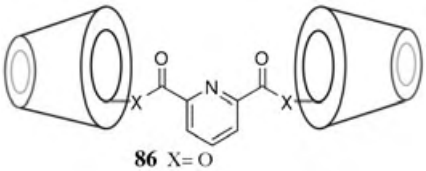
Scheme 31. Artificial inhibitors based on functionalized calix[4]arene derivatives.

recognition elements are projected on the same face of a calix[4]arene scaffold, were evaluated as antagonists against PDGF-induced PDGFR autophosphorylation and MAP kinase activation in NIH3T3 cells. These assays identified a strong dependence on the loop sequence projected by the calix[4]arene core to obtain high inhibitory activity. Cationic derivative **85** ($IC_{50}=50\ \mu M$) had only modest potency, whereas all anionic derivatives, including **83**, were moderately active ($IC_{50}<10\ \mu M$). The inhibitory effect was strongest for **84**, a derivative containing a Gly-Asp-Gly-Tyr cyclic peptide sequence, with a remarkably low IC_{50} value of 250 nM. Compound **84** directly interacts with PDGF as shown by gel-shift analysis, suggesting that inhibition was likely a result of **84** binding directly to PDGF. Compound **84** was also able to displace ^{125}I-PDGF from PDGFR in a dose-dependent manner, indicating that its binding led to the disruption of the PDGF–PDGFR interaction. Cell-based studies showed that **84** possesses potent antitumor and anti-angiogenic properties against human tumors in nude mice and it is currently being evaluated in further biological studies.



Another application of calix[4]arene **83** in the disruption of protein–protein interactions was reported by Wei and co-workers.[200] Synthetic receptor **83** was found to block cytochrome c (Cytc) binding to cytochrome c peroxidase (CytcP) in a fluorescence titration assay. Compound **83** replaced CytcP to efficiently form a Cytc–**83** complex in a binding ratio of 1:1 and with a K_a value of $10^8\ M^{-1}$. Further investigation also showed that the complex of Cytc–Apaf-1, a critical intermediate in the apoptosis pathway,[201] could be disrupted upon the addition of **83** at an antagonist/complex ratio of about 200:1.

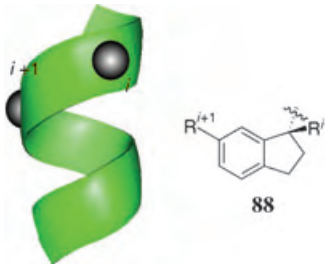
5.1.3. *β-Cyclodextrin Dimers as Disruptors of Lactate Dehydrogenase and Citrate Synthase Aggregates*

Breslow and co-workers reported that β-cyclodextrin (CD) dimers can selectively inhibit the assembly of individual protein subunits into multiprotein aggregates, such as the formation of citrate synthase (CS) dimers and L-lactate dehydrogenase (LDH) tetramers.[202] Protein interfaces of this type often contain defined hydrophobic patches. The disruption strategy was therefore to construct cyclodextrin dimers separated by appropriate spacers. Cyclodextrins had previously been shown to form tight complexes with hydrophobic side chains of polypeptides and were therefore expected to block protein assembly by interacting with the hydrophobic side chains in the interfacial regions.[203]

Eleven CD dimers with a variety of linkers and CD-cavity orientations were designed and synthesized. The ability of these analogues to disrupt protein multimerization were assayed by monitoring enzyme activity. Of a group of enzymes tested, only CS and LDH were vulnerable to inhibition, whereas sorbitol dehydrogenase, adenosine deaminase, D-galactose dehydrogenase and phosphohexose isomerase were not affected at CD dimer concentrations as high as 480 μM. Compounds with β or α cyclodextrin groups oriented with their cavities facing away from the spacer core were inactive, and neither were the compounds with ether linkages separating the cyclodextrin groups. However, compounds **86** and **87**, in which β-cyclodextrin dimers are respectively separated by either pyridyl diesters or diamides, selectively disrupted the aggregation of LDH ($IC_{50}=140\ \mu M$) and CS ($IC_{50}=30\ \mu M$) (scheme 32). As a negative control, the authors showed that β cyclodextrin and pyridine dicarboxylate alone were not active, indicating the special requirement of a correctly spaced β-cyclodextrin dimer for the disruption

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

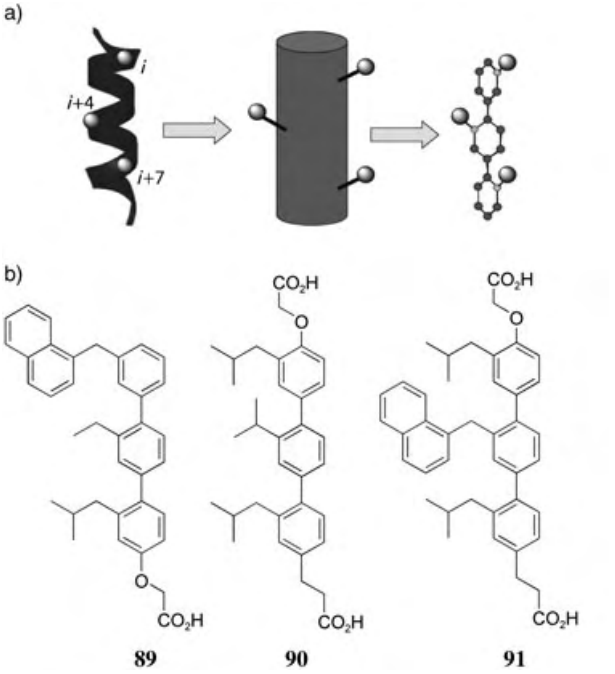
Scheme 32. Cyclodextrin dimers as inhibitors of protein subunit aggregation.



of LDH and CS. Although the exact origin of protein selectivity and the precise mode of disruption is still unclear, there are several aromatic side chains on the surface of LDH and CS where the cyclodextrin dimers could potentially bind.

5.2. Low-Molecular-Weight Agents as Structural and Functional Mimetics of Protein Secondary Structures

A logical progression from the use of constrained peptides as inhibitors of protein–protein interactions is to use easily accessible synthetic molecules to mimic the surfaces of constrained peptides. Such approaches offer the advantage of improved biostability, lower molecular weight, and in some cases better bioavailability. Synthetic molecules that adopt various well-defined secondary structures are well-documented;[72,73,75,204] the focus of this section is on low-molecular-weight compounds that disrupt protein–protein interactions by mimicking the structural features of different protein secondary structures.



5.2.1. α-Helix Mimetics

Several synthetic mimetics of α-helical surface binding domains have been reported. The pioneering work of Horwell et al. showed that 1,6-disubstituted indanes **88** present functionality in a similar spatial arrangement to the *i* and *i*+1 residues of an α helix (Scheme 33).[205] Derivatives with large hydrophobic peptide side chains (Phe-Phe and Trp-Phe) were found to bind to the tachykinin receptors NK1, NK2, and NK3 with micromolar affinities. These mimetics do not cover a large enough surface to sufficiently represent an α-helical mimetic. However, they demonstrate nicely the potential of using nonpeptide scaffolds to present critical recognition functionality in a suitable spatial orientation for binding to a target protein.

Scheme 33. The indane template that mimics the *i* and *i*+1 positions of an α helix.

Hamilton and co-workers recently reported that a terphenyl scaffold could reasonably mimic the surface of an α-helical peptide in which the 3,2′,2″-substituents on the phenyl rings present functionality in a spatial orientation that mimics the *i*, *i*+3(4) and *i*+7 residues on an α helix (Scheme 34a).

Scheme 34. a) Rational design of terphenyl-based α-helical mimetics; b) terphenyl-based inhibitors.

This strategy was first employed in the design of an inhibitor of the interaction between calmodulin (CaM) and small muscle myosin light chain kinase (smMLCK).[49] Mutational studies on the sequence of a 20-mer fragment from smMLCK revealed critical roles for residues Trp 800, Thr 803, and Val 807. A helical peptide derived from the plasma membrane calcium pump protein C20W that binds to the same region of CaM as smMLCK also indicates a critical role for hydrophobic residues at these positions. For synthetic simplicity, indole was changed to naphthalene for the tryptophan side chain, and the threonine hydroxy group was removed, leading to a designed ligand **89** (Scheme 34b). The binding of **89** to CaM was demonstrated with affinity chromatography. This ligand also inhibited the CaM-mediated activation of 3′,5′-phosphodiesterase (PDE), which is believed to bind CaM at the same site employed by smMLCK. Terphenyl **89** competed with smMLCK peptide with an IC_{50} value of 9 nM.

It was shown subsequently that appropriately designed terphenyl scaffolds can disrupt the assembly of the hexameric gp41 core that leads to HIV-1 viral particle fusion with host cells.[167] Terphenyl derivatives can be designed to mimic the hydrophobic functionality at the *i*, *i*+4 and *i*+7 residues of the α-helical heptad repeat regions of the C- and N-terminal peptides. These synthetic helix mimetics disrupt the binding of the C-terminal peptides to the trimeric N-terminal core and prevent HIV-1 entry into host cells. Derivative **90** was found

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

to disrupt a model system composed of two peptides (N36 and C34) from the N- and C-heptad repeat regions which form a stable six-helix bundle analogous to the gp41 core (Figure 8). Circular dichroism (CD) spectroscopy demonstrated that the

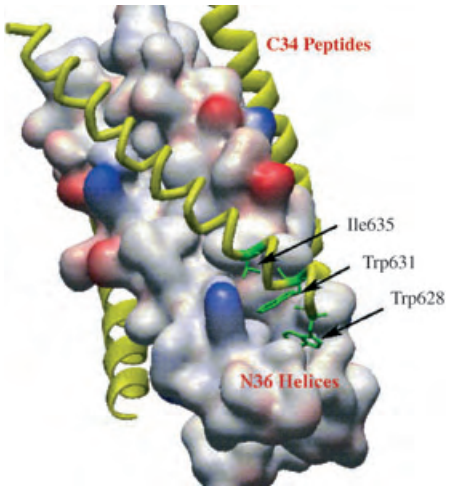


Figure 8. Crystal Structure of the gp41 fusion active center C34 (residues 628–661, represented as helical tubes) in complex with N36 (residues 546–581) The complex arises by inserting the side chains of Trp 628, Trp 631 and Ile 635 into a hydrophobic cleft on the protein surface.

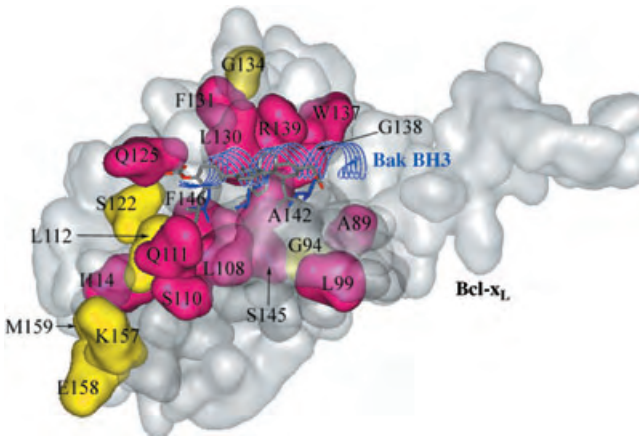
C34 peptide forms a random coil on its own in solution while the N36 peptide forms concentration-dependent aggregates. Titration of compound **90** into a PBS-buffered solution of this model system resulted in a decrease of the CD signal at 222 and 208 nm, corresponding to a decrease in helicity of the hexameric bundle; the decrease saturates at three equivalents of terphenyl. The T_m value of the N36 core in the presence of excess **90** is significantly lower than that of the gp41 core, and resembles that of the N36 region alone, which suggests that the terphenyl competes for the C34 binding site. The electrostatic and hydrophobic features of **90** were found to be critical for this behavior, as terphenyls with positively charged groups and no alkyl substituents had little effect on the behavior of the gp41 core as monitored by CD. An ELISA experiment with an antibody that binds to the N36–C34 helix bundle, but not the individual peptides, demonstrated that **90** disrupted the formation of the hexameric bundle with an IC_{50} value of $13.18 \pm 2.54\ \mu g\,mL^{-1}$ whereas a dye-transfer fusion assay indicated that **90** inhibited HIV-1-mediated cell–cell fusion with an IC_{50} value of $15.70 \pm 1.30\ \mu g\,mL^{-1}$.

This α-helix mimetic strategy was used for the design of an inhibitor of the anti-apoptotic protein Bcl-x_L.[206] A current strategy for inhibiting Bcl-x_L function is to block the Bak-recognition site on Bcl-x_L, thereby disrupting the protein–protein contact. A Bcl-x_L–Bak complex structure determined by NMR spectroscopy shows that a helical region of Bak (residues 72–87, $K_d = 340$ nM) binds to a hydrophobic cleft on the surface of Bcl-x_L.[207] Furthermore, the crucial residues for binding were shown by alanine scanning to be Val 74, Leu 78, Ile 81, and Ile 85, which project from the *i*, *i*+4, *i*+7 and *i*+11 positions along one face of the helix (Figure 9). A series of terphenyl derivatives were prepared with different sequences and substitution patterns on the 3,2′,2″-positions, and fluorescence polarization was employed to monitor their interactions with the target protein. The assay demonstrated that



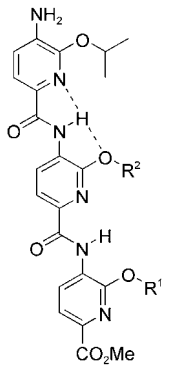


Figure 9. Results of the ^{15}N-HSQC experiment with ^{15}N-lalbeled Bcl-x_L. The residues that show chemical-shift changes in the presence of **91** (green) are highlighted. The most probable conformation of inhibitor **91**, predicted from a computational docking simulation, has been superimposed on the helical Bak BH3 domain (blue) for comparison.

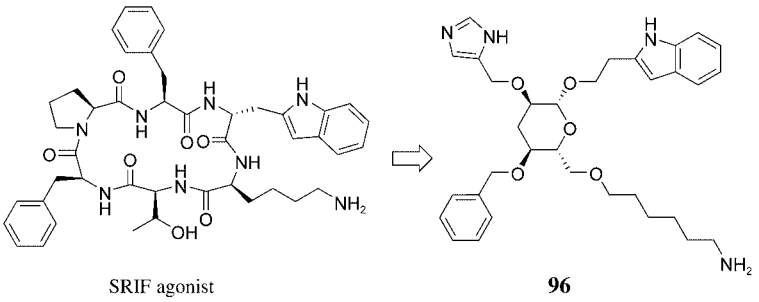
terphenyl **91** with two carboxylates and the substituent sequence isobutyl, 1-naphthylmethylene, isobutyl was a potent inhibitor ($K_i = 114$ nM). The specificity was confirmed by scrambling the sequence of the three key substituents, which produced a 30-fold decrease in K_i. Similarly, the removal of the two carboxylate groups or their replacement by positively charged groups led to a loss of activity. HSQC NMR experiments with **91** indicated that these terphenyl derivatives target the hydrophobic cleft on the surface of Bcl-x_L known to interact with Bak.

An alternative design for mimicking the binding surface of α helices based on an oligo-amide foldamer was subsequently elaborated by Hamilton and co-workers.[208] The anticipated foldamer conformation is depicted in Scheme 35 and results from the constraint of intramolecular hydrogen bonds between the amide hydrogen atoms and the pyridine nitrogen atoms, in addition to the disfavored interaction that would occur between the amide carbonyl group and the nitrogen atom of the pyridine in an alternative conformation. Further conformational biasing is induced by a hydrogen bond between the amide -NH group and the oxygen atom of the alkoxy binding functionality. The intramolecularly hydrogen-bonded conformation was confirmed in the solid state by crystallography, which further revealed that the alkoxy side chains were tilted at 45° to maximize interaction of the lone pair on the oxygen atom



92 $R^1 = R^2 = i$Pr
93 $R^1 = i$Pr; R^2 = Bn
94 $R^1 = R^2$ = Bn

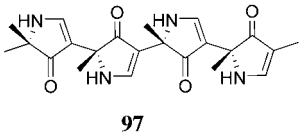
with the amide -NH group. The foldamer was tested as a proteomimetic antagonist of Bak to disrupt its interaction with Bcl-x_L. The in vitro assay identified three inhibitors of the interaction, **92–94**, with K_i values of 2.3, 9.8, and 1.6 μM, respectively, whereas the foldamers with trisbenzyloxy and trismethoxy groups demonstrated weaker activities and a requirement for some size matching and sequence specificity between the protein and the mimetic.

Scheme 37. β-D-Glucose-based nonpeptide peptidomimetics of somatostatin (SRIF).

Most recently, Hamilton and co-workers reported a group of novel synthetic helical mimetics based on a terephthalamide scaffold.[209] The backbone of the terphenyl was reduced to a much simpler terephthalamide, as in **95** (Scheme 36), while the spatial arrangement of the projected side chains was maintained. The flanking phenyl rings of the terphenyl backbone were replaced by two functionalized carboxamide groups, which retain the planar geometry of the phenyl rings, due to the restricted rotation of the amide bonds. The intramolecular hydrogen bond between the amide -NH and the alkoxy oxygen atom of **95** ensures that the 2-isopropoxy group and the upper isobutyl side chain are positioned on the same side of the terephthalamide group. A fluorescence polarization assay was once again used to monitor release of the fluorescently labeled Bak peptide from Bcl-x_L and sub-micromolar affinities were observed ($K_i = 0.78$ μM). Treatment of human HEK293 cells with the terephthalamide derivatives resulted in disruption of the Bcl-x_L–Bak interaction in whole cells. HSQC experiments with ^{15}N-labeled Bcl-x_L suggested that terephthalamide and the Bak BH3 peptide target the same area on the Bcl-x_L exterior surface, confirming that terephthalamide is a successful alternative scaffold to terphenyl as an α-helical mimetic.



Scheme 36. Terephthalamide-based α-helical mimetic.

5.2.2. *β-Turn Mimetics*

Hirschmann, Smith, and co-workers have made many important contributions to the development of nonpeptide peptidomimetics. For example, they reported a mimetic of the cyclic peptide somatostatin (SRIF) with a D-glucose scaffold, **96** (Scheme 37).[210] Carbohydrates represent an attractive approach to mimicking β turns, as they impose an appropriate projection of several side chains and are relatively rigid. The shape and substitution pattern of D-glucose was found to best present the Trp, Lys, and Phe side chains. A radiolabeling/binding assay showed that **96** completely displaced ^{125}I-CGP23996 from the SRIF receptor on membranes from cerebral cortex, pituitary, and AtT-20 cells with an IC_{50} value of 1.9 μM.

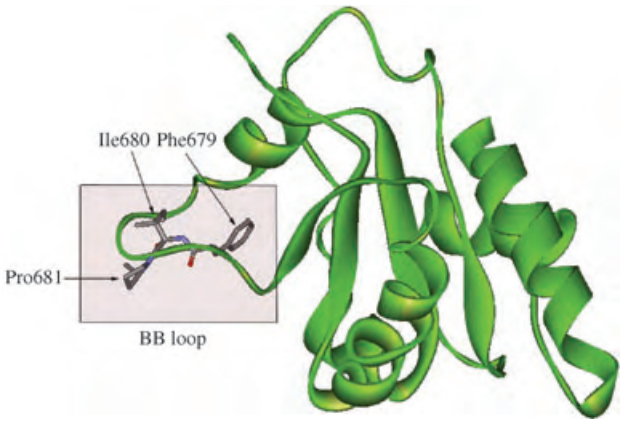
Further peptidomimetic approaches of this type include β-D-glucose-based mimetics for somatostatin (SRIF)[211] and antagonists for substance P (NK-1),[212] pyrrolinone-based renin inhibitors,[213] HIV-1 protease inhibitors,[214,215] pyrrolinone-based matrix metalloprotease inhibitors,[216] competent nonpeptide hybrid ligands for the human class II MHC protein HLA-DR1,[217] and azepine-based cryptophycin mimetics.[218]

Smith, Hirschmann, and co-workers elaborated a pyrrolinone-based mimetic of the β-strand/β-sheet and/or β-turn conformations of peptides[215,217,219] in which all of the key recognition features (side chains and hydrogen-bond donors/acceptors) are faithfully represented within a low-molecular-weight nonpeptide analogue based on pyrrolinone **97** (Scheme 38). This design has been applied to the development of antagonists of HIV-1 protease and more recently to mimics of MHC class II protein substrate.[214,217]

Scheme 38. Polypyrrolinone-based β-turn peptidomimetics.

Rebek and colleagues reported a low-molecular-weight β-loop mimetic that disrupts the interaction between the type I interleukin-1 receptor (IL-1RI) and the adapter protein MyD88.[220] The IL-1R superfamily and the Toll-like receptor (TLR), which share a conserved Toll/IL-1R/resistance (TIR) domain,[221] are critical to both innate and adaptive immunity for host defense.[222] IL-1 monomers act as proinflammatory mediators through dimerization and recruitment of the putative adapter protein MyD88, which also contains a TIR domain,[223,224] through homotypic binding of the TIR domain between IL-1RI and MyD88.[224,225] Xu et al. previously determined the crystal structure of the TIR domains of human TLR1 and TLR2 (Figure 10) and elucidated the structural basis of the TIR–TIR interaction between IL-1RI and MyD88.[226] The protruding BB loop was proposed to be critical for complex formation, as mutations at almost every position in this region led to a significant decrease in the signaling activity of the receptors.

Rebek and co-workers prepared an analogue of the central three-residue sequence of the BB loop **98** which mimics the (F/Y)-(V/L/I)-(P/G) residues (Scheme 39) and studied its ability to disrupt the IL-1RI–MyD88 interaction. Compound **98** attenuated the IL-1β-mediated activation of



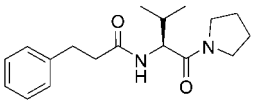


Figure 10. Crystal structure of the TIR domain with the BB loop bracketed.

98

Scheme 39. Low-molecular-weight mimetic **98** of the BB loop.

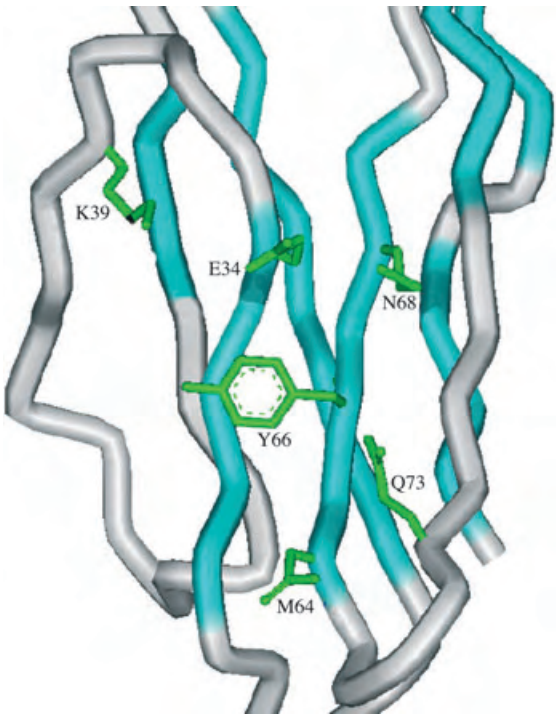
p38 MAP kinase at micromolar concentrations. Sandwich ELISA assays demonstrated that **98** prevents IL-1β-mediated IL-1RI–MyD88 association in EL4 cells. The specificity of **98** to disrupt the association of IL-1RI and MyD88 was confirmed by the fact that **98** did not affect other members of the Toll receptor superfamily (TLR1–10).

5.2.3. *β-Strand/β-Sheet Mimetics*

The β strand is a linear or saw-toothed peptide structural element that can form β sheets, which account for over 30% of all protein secondary structure. In the last decade, small-molecule β-strand/β-sheet mimetics and their applications, as in the development of protease inhibitors,[227] have been reported.[228] However, the examples of synthetic agents that mimic β strands and β sheets and disrupt large protein–protein interactions are still scarce.

Integrins are a receptor protein family involved in a variety of cellular functions such as wound healing, cell differentiation, homing of tumor cells, and apoptosis. Functional integrins are heterodimeric aggregates consisting of α- and β-transmembrane glycoprotein subunits that are non-covalently bound and share homology. Corbett et al. identified potent and selective $\alpha_v\beta_3$-integrin antagonists from screening a library prepared by solid-phase synthesis.[229] Nicolaou and co-workers applied scaffold **96** to mimic the cyclopeptide cRGDFV sequence that inhibits integrin–ligand interactions.[230]

ICAM proteins 1, 2, and 3 interact with LFA-1 (the integrin $\alpha_L\beta_2$, CD11a/CD18) and mediate the adhesion, extravasation, migration, and proliferation of lymphocytes.[231] An epitope consisting of the amino acids Glu34, Lys39, Met64, Tyr66, Asn68, and Gln73, located on the opposite side of an antiparallel β-sheet within the first domain of ICAM-1, was identified as essential for its interaction with LFA-1 (Figure 11).[232]



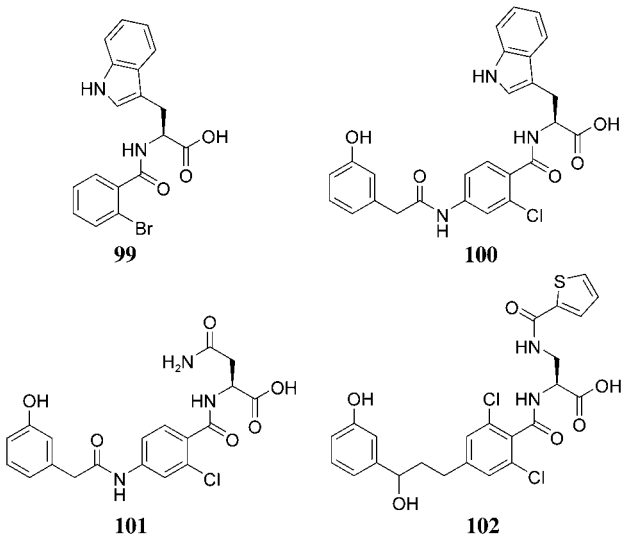


Figure 11. The discontinuous binding epitope of ICAM-1 (shown in green).

One of the greatest challenges in the design of small-molecule proteomimetics for the inhibition of protein–protein interactions is that the interacting units are often widely spread. To transfer all of the interacting functionality of a target protein to a designed synthetic compound remains a major challenge. A research group at Genentech presented an elegant approach in which the native ligand of the targeted receptor is used as the lead and small-molecule antagonists are identified through chemical diversity exploration.[233] Kistrin, a disintegrin protein containing an RGD sequence, was found to disrupt the LFA-1 and ICAM-1 interaction in vitro by mimicking the critical interacting residues from ICAM-1. The peptide sequence H_2N-CGY$^{(m)}$DMPC-COOH (Y$^{(m)}$ = *meta*-tyrosine), which has a similar potency for the disruption of the ICAM-1–LFA-1 interaction, was selected as a lead in the design of synthetic inhibitors.

Compound **100** (Scheme 40), from a related program with an IC_{50} value of 1.6 μM, was modified with a *meta*-phenol group to mimic the Y$^{(m)}$ residue in the peptide lead and gave a 30-fold improvement in the ELISA assay. Compound **100** was then subdivided into five modules and modifications were made within each module for further optimization. This exploration of chemical diversity generated **101**, which represents a minimal display of the epitope with high potency (IC_{50} = 3.7 nM), and **102**, one of the best combinations of the molecular modules (IC_{50} = 1.4 nM). An MLR assay showed that compound **102** antagonizes ICAM-1 by binding LFA-1

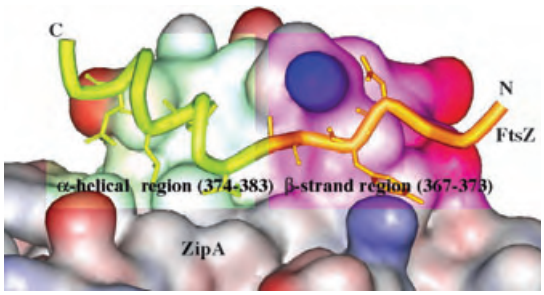
Scheme 40. Synthetic inhibitors that disrupt the LFA-1–ICAM-1 interaction.

and mediates lymphocyte proliferation and adhesion in vitro. Compounds **99–102** emerged from consideration of the discontinuous ICAM-1 epitope with five residues spanning three different β-strands across the face of a protein, through the lead compound kistrin and consequently the H_2N-CGY$^{(m)}$DMPC-COOH peptide. However, there has been ongoing debate about whether these compounds indeed function as ICAM-1 mimetics.[234] Springer and co-workers argued that this group of compounds are not ICAM-1 mimetics as they do not bind either to the α_L or α_M I domain as ICAM-1 does, but perturb binding of MAb to the β_2 I-like domain that does not participate directly in binding ICAM-1.[234,235]

FtsZ, a homologue of eukaryotic tubulins, is an essential component of the septal rings that mediate cell division in Gram-negative bacteria.[236] Z-interacting protein A (ZipA) is a 36.4-kDa membrane-anchored protein that is recruited to the septal ring at a very early stage of the cell-division cycle by the formation of a complex with FtsZ. Some cell division can be interrupted by disruption of the ZipA–FtsZ interaction; this protein–protein interface has become a possible target for the development of new antibiotics. X-ray crystallography and NMR spectroscopic analyses revealed that FtsZ binds to a broad and predominantly hydrophobic surface area on the solvent-exposed side of a β sheet on ZipA (Figure 12).[237] Upon binding, the 17-residue FtsZ peptide (^{367}KEPDYLDI-PAFLRKQAD^{383}) adopts an extended β-strand conformation in the region of residues 367–373 followed by an α-helical domain from positions 374 to 383. Direct interatomic contacts are made between 11 ZipA amino acid residues and seven FtsZ residues in the span between residues 370 and 381.

A group at Wyeth Research recently reported the design of small-molecule inhibitors of ZipA–FtsZ interactions based on key residues of the protein–protein interface.[238] Compounds **103–105** (Scheme 41) showed only weak inhibition in the fluorescence polarization assays ($IC_{50} = 1.17$, 2.06, and 2.75 mM, respectively).[239] X-ray crystallographic analysis showed that **103** and **104** essentially recognize the same



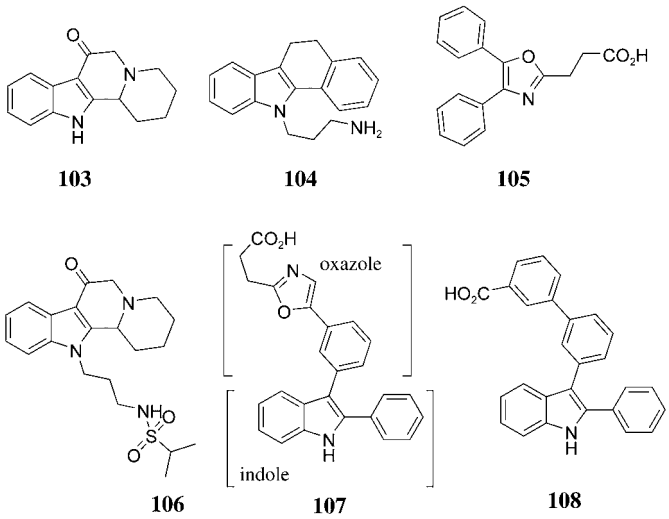


Figure 12. The ZipA–FtsZ interface (residues 367–383). FtsZ peptide (tube representation) binds to a hydrophobic pocket on the ZipA surface as an extended β strand (residues 367–373) followed by an α helix (residues 374–383).

Scheme 41. Synthetic inhibitors that disrupt the ZipA–FtsZ interaction.

binding site, whereas **105** and **106** occupy a distinct region on the surface of ZipA. The indole rings in **103** and **104** recognize the lipophilic pocket, whereas **105** binds to a hydrophilic region. Based on the structural information provided by the lead, the chimeric molecule **107**, which combines the structural features of both the indole and oxazole motifs, was designed. The most potent inhibitor **108**, an analogue of the chimera (Scheme 41), gave an IC_{50} value of 192 μM to disrupt ZipA-FtsZ binding. The target site of the inhibitors was confirmed by 2D ^{15}N-HSQC experiments.

6. Summary and Outlook

Recent examples of synthetic agents that disrupt protein–protein interactions have been reviewed. Most of these agents were identified from the screening of chemical libraries or from structure-based rational design. In the next a few years, emerging techniques have the potential to revolutionize the approach and to provide more efficient means for compound library preparation and evaluation. With a range of combinatorial synthetic methods, libraries containing many thou-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

sands of compounds can be readily prepared for screening.[3,4] Applications of mass spectrometry, NMR spectroscopy, and nanotechnology in high-throughput screening have greatly enhanced our ability to identify small molecules that disrupt protein–protein interactions.[240] Novel techniques such as the "tether" method (Section 4.2.4) make it possible to identify lead compounds with only weak to modest potency.[120] These compounds then offer the possibility of fragment reassembly, leading to highly potent inhibitors. Benkovic and co-workers recently reported a novel methodology of genetic selection to identify small-molecule antagonists of protein–protein interactions by using whole cells as reporters, thus bypassing the inherent limitation of in vitro analysis.[241]

Synthetic agents identified from high-throughput screening serve as valuable leads for structure–activity relationship (SAR) studies aimed toward higher potency or retention of binding affinity with improved bioavailability. Pharmacophore models derived from SAR are then required to be confirmed with further binding mode studies. The integration of biology into chemistry with strategies such as phenotype screening, have expanded our intellectual horizon.[151] As biological molecules often act on multiple targets simultaneously (for example, Danial et al. recently reported that Bcl-2 family proteins also play roles in metabolic pathways aside of apoptosis),[242] it seems likely that our model of single targets for highly selective small molecules may be outmoded. Akin to the way in which people have been practicing herbal medicine over millennia, modern scientists now are beginning to identify active compounds in living organisms prior to the identification of their targets.

Rational approaches, on the other hand, involve the design and synthesis of molecules that deliberately incorporate functional groups in a complementary manner to that of protein targets. The design of these mimetics is based on the features presented on protein surfaces, such as clusters of hydrophobic groups, electrostatic domains, and metal-coordinating groups. The selectivity and generality of inhibitors developed by this strategy in the context of numerous other protein targets remains to be determined. Protein surface recognition is greatly complicated by the high degeneracy of the exterior functionalities presented by different proteins. Most rational designs described herein have attempted to assign geometric, electrostatic, and hydrophobic complementarity requirements for recognition. In some cases, this evaluation was extended to the measurement of target selectivity through indirect (in vivo toxicity) or limited (selectivity among a small set of related proteins) techniques. These efforts are important initial steps toward improved affinity and selectivity. Computer-aided rational design is a very promising approach in the search for synthetic agents that target protein–protein interfaces. Enhanced selectivity remains the major challenge in the design of molecules that target protein exterior surfaces. However, as our understanding of surface mobility and functionality increases, coupled with more accurate computational analysis, designs will improve in potency and selectivity.

Large organic molecules ($MW > 750$ Da) are generally problematic as viable drug candidates.[199,243] The disadvantage of large molecules is primarily ascribed to their deviation from Lipinski's rules.[244] However, these agents may be particularly valuable for cases in which protein surfaces do not possess clear binding sites that may allow high affinity association with small molecules. For some proteins in which "epitope transfer" to small molecules is challenging, large synthetic agents may offer a pharmacological proof-of-principle that can be potentially minimized or modified to a viable drug candidate. This seems especially likely for cases in which the compounds are originally designed to allow facile structural modifications. Some large molecules have already been evaluated under clinical trials to have limited toxicity and moderate pharmacological profiles, indicating that a large size may not always be disadvantageous. It is also encouraging that other large molecules like antibodies and peptides have all yielded successful drugs. Polymers and nanoparticles represent other promising fields that can produce synthetic agents that modulate protein–protein interactions.

Without question, the use of synthetic agents to disrupt protein–protein interactions will increase over the next decade. After all, the opportunities provided to chemists by Nature are almost limitless.

We thank the National Institutes of Health (GM35208 and GM69850) for financial support of the work described in this review that was carried out in our laboratories.

Conducting Materials

A Neutral Mixed-Valent Conducting Polymer Formed by Electron Transfer between Metal d and Ligand π Orbitals**

Minoru Mitsumi, Hidekazu Goto, Shunsuke Umebayashi, Yoshiki Ozawa, Mototada Kobayashi, Toshihiko Yokoyama, Hisaaki Tanaka, Shin-ichi Kuroda, and Koshiro Toriumi**

Recently, conducting systems that consist of a single-component molecule have attracted much attention.[1–3] These studies should develop basic technology for molecular electronic devices. Kobayashi and co-workers reported that a crystal of $[Ni(tmdt)_2]_\infty$ (tmdt = trimethylenetetrathiafulvalenedithiolate) is a single-component molecular metal with a 3D π band, which was designed on the basis of a very small HOMO–LUMO gap and crossing bands formed by the HOMO and LUMO.[1] On the other hand, many directly bonded infinite M–M chain compounds have been prepared, but a single-component molecular conductor with a metal-containing backbone has yet to be reported.[4,5]

When building such a material by the bottom-up method, frontier-orbital engineering is very important for obtaining the desired physical properties and/or functionalities. Redox-active dioxolene derivatives can create redox isomers of benzoquinone (BQ), semiquinonate ($SQ^{\bullet-}$), and catecholate (cat^{2-}) by two sequential one-electron transfers. Several transition-metal complexes that contain these dioxolene ligands have very close energy levels between the frontier orbitals of the metal d and dioxolene ligand π orbitals, and intramolecular electron transfer occurs between the metal and the ligand in a thermal equilibrium known as valence tautomerism.[6] On the other hand, the rhodium(I) semiquinonato complex $[Rh(3,6\text{-dbsq})(CO)_2]_\infty$ (3,6-dbsq = 3,6-di-*tert*-butyl-1,2-benzosemiquinonate) was reported to form a linear-chain structure with a direct Rh–Rh interaction.[7] Although this compound does not show valence tautomerism, the energy levels of the electron-rich rhodium(I) core and the electron-deficient semiquinonato ligand are considered to be relatively close. If the energy level of the ligand $\pi^*(SQ^{\bullet-})$ orbital can be adjusted to be close to or the same as the energy level of the 1D d band, which is comprised of metal d_{z^2} orbitals, a rhodium(I,II) semiquinonato/catecholato mixed-valent state would be achieved by intramolecular electron transfer between metal and ligand (Figure 1). This approach

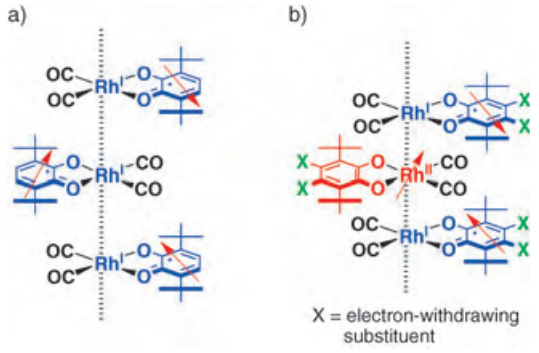

Figure 1. a) Stacking of $\{Rh^+\text{-}SQ^{\bullet-}\}$ units in $[Rh(3,6\text{-dbsq})(CO)_2]_\infty$. b) Mixed stack of $\{Rh^+\text{-}SQ^{\bullet-}\}$ and $\{Rh^{2+}\text{-}cat^{2-}\}$ units.

may be a fundamental methodology for the development of novel neutral mixed-valent conducting polymers with metal-containing backbones based on metal complexes. Recently, we successfully controlled the energy level of the frontier orbitals in the metal complex by chemically modifying the ligand. Electron transfer was realized between metals and ligands, and a mixed-valent state of the directly bonded infinite M–M chain was ascertained.

Herein, we report the synthesis, crystal structure, and electronic properties of the novel linear-chain mixed-valent rhodium(I,II) semiquinonato/catecholato complex $[Rh(3,6\text{-dbdiox-4,5-}Cl_2)(CO)_2]_\infty$ (**1**), in which 3,6-dbdiox-4,5-Cl_2 indicates the 3,6-di-*tert*-butyl-4,5-dichloro-1,2-benzosemiquinonate (3,6-dbsq-4,5-$Cl_2^{\bullet-}$) or 3,6-di-*tert*-butyl-4,5-dichlorocatecholate (3,6-dbcat-4,5-Cl_2^{2-}) state. This compound is the first example of a neutral mixed-valent conducting polymer with a metal-containing backbone in which the mixed-valent state is formed by electron transfer between metal d and ligand π* orbitals.

Black needle crystals of **1** were obtained by a redox reaction of $[Rh_4(CO)_{12}]$ with 3,6-di-*tert*-butyl-4,5-dichloro-1,2-benzoquinone[8] in *n*-pentane.[9]

The X-ray photoelectron spectrum (XPS) of **1** exhibits broad Rh $3d_{5/2}$ and $3d_{3/2}$ signals compared to the spectrum of the rhodium(I) complex $[Rh(3,6\text{-dbsq})(CO)_2]_\infty$. The signals of **1** are well resolved into Rh^+ $3d_{5/2,3/2}$ and Rh^{2+} $3d_{5/2,3/2}$ doublets (Figure 2), which clearly reveal that **1** exists in the mixed-valent state composed of Rh^+ and Rh^{2+} on the rapid XPS timescale (ca. 10^{-17} s).[10] Furthermore, the intensity ratios of the Rh^+ $3d_{5/2}$/Rh^{2+} $3d_{5/2}$ and Rh^+ $3d_{3/2}$/Rh^{2+} $3d_{3/2}$ doublets are 2:1(±0.1). This suggests that the formal oxidation state of

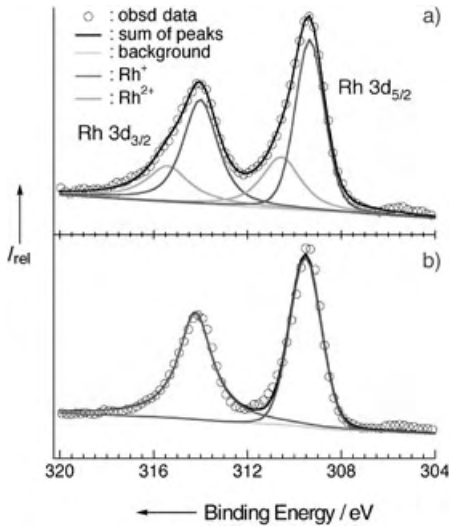

Figure 2. Rh $3d_{5/2}$ and Rh $3d_{3/2}$ core-level spectra for a) **1** and b) [Rh(3,6-dbsq)$(CO)_2]_\infty$. obsd = observed

rhodium is approximately $Rh^{1.33+}$ and the [Rh^{I}(3,6-dbsq-4,5-Cl_2)$(CO)_2$]/[Rh^{II}(3,6-dbcat-4,5-Cl_2)$(CO)_2$] ratio is nearly 2:1.

X-ray crystal structure analysis of **1** was performed at 302 and 56 K with synchrotron radiation (see the Experimental Section). Compound **1** crystallizes in the monoclinic space group *C*2/*c* at both temperatures. It consists solely of neutral linear chains of [Rh(3,6-dbdiox-4,5-Cl_2)$(CO)_2$] molecules, which form trimeric units in the linear chain at 302 K (Figure 3a). The Rh–Rh distances in the trimers (2.8685(2) and 2.8629(2) Å) are about 0.03 Å shorter than the Rh–Rh distances between them (2.8942(3) and 2.8984(3) Å). These Rh–Rh distances are approximately 0.4 Å shorter than those of Rh^+ complex [Rh(3,6-dbsq)$(CO)_2]_\infty$ (3.252(4) and 3.304(5) Å)[7] and are similar to those of $Rh^{1.5+}$ complex [{Rh$(MeCN)_4$}$(BF_4)_{1.5}]_\infty$ (2.8442(8) and 2.9277(8) Å).[12] The formation of the trimer is consistent with the formal oxidation state of $Rh^{1.33+}$ estimated from the XPS spectrum. The structural data also strongly suggests that **1** has a rhodium(I,II) mixed-valent state. The overlap of the complex molecules can be classified into two modes (Figure 3b), in which the dioxolene ligands do not directly overlap. These overlap modes alternate in the linear chain. At 56 K, the trimers in the linear chain are dimerized by shortening the Rh1–Rh1* bond to form hexameric units (Figure 4). The Rh–Rh distances in

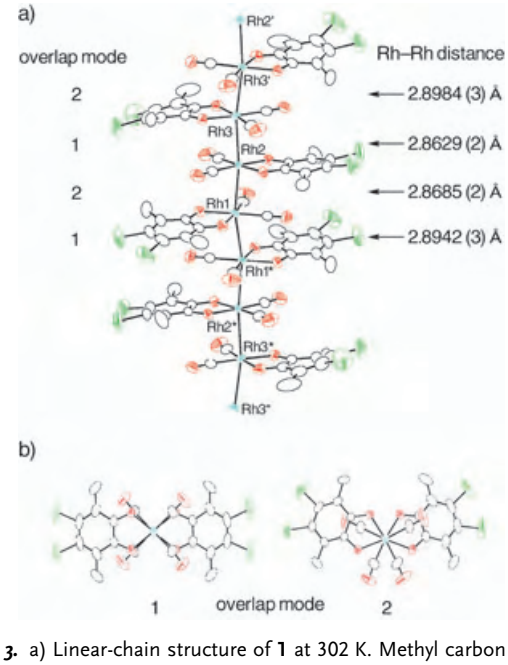

Figure 3. a) Linear-chain structure of **1** at 302 K. Methyl carbon atoms of the *t*Bu groups are omitted for clarity. b) Two overlap modes of the complex molecules.

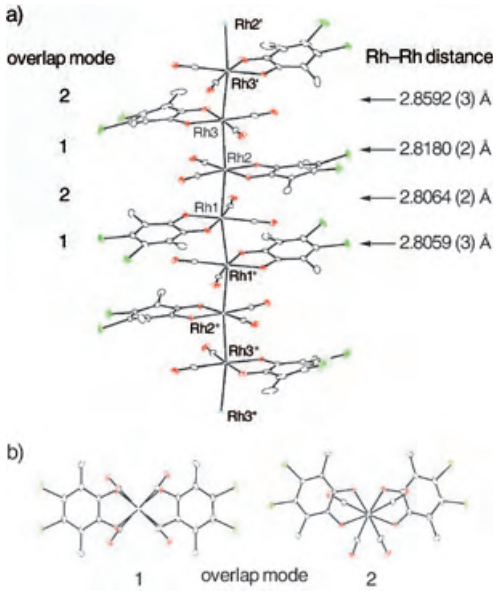

Figure 4. a) Linear chain structure of **1** at 56 K. Methyl carbon atoms of the *t*Bu groups are omitted for clarity. b) Two overlap modes of the complex molecules.

the hexamer are 2.8059(3)–2.8180(2) Å, while the Rh–Rh distance between hexamers is 2.8592(3) Å. The observed dimerization of trimers in the 1D chain originates from Peierls distortion associated with the pairing of unpaired electrons in the d_{z^2} orbitals of Rh^{2+} ions.[13] In the crystal structures at 302 and 56 K, no notable conformational change is observed. The C–C and C–O bond lengths of each dioxolene ligand exist in the boundary region of the semiquinonate and catecholate forms, respectively. These structural features indicate that the dioxolene ligands are either charge-localized and structurally disordered or charge-delocalized. Therefore, it is impossible to determine the oxidation state of each dioxolene ligand from the C–C and C–O bond lengths.

Figure 5 shows electronic absorption spectra of **1** in the solid state and in solution with CH_2Cl_2, and those of [Rh(3,6-dbsq)$(CO)_2]_\infty$ are shown for reference. In the solid state, [Rh(3,6-dbsq)$(CO)_2]_\infty$ shows a relatively intense absorption at 6700 cm^{-1}, which is assigned to the absorption associated with the band structure formed by d_{z^2} orbitals along the linear chain.[7] The dominant feature of the absorption spectrum of **1** in the solid state is an intense, broad absorption band that extends from 15000 cm^{-1} to the IR region. This broad

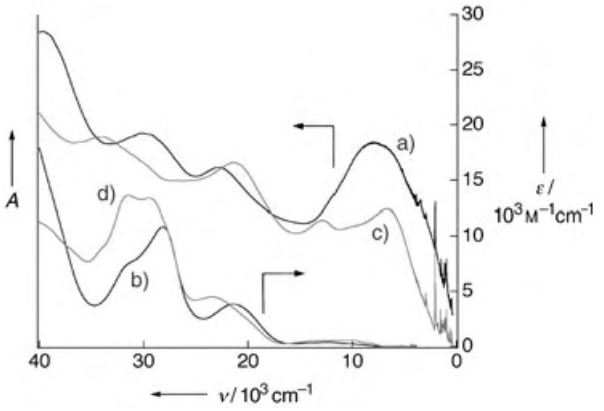

Figure 5. Electronic absorption spectra of **1** in the solid state (KBr pellet) (a) and in solution with CH_2Cl_2 (b) and of $[Rh(3,6\text{-dbsq})(CO)_2]_\infty$ in the solid state (KBr pellet) (c) and in solution with CH_2Cl_2 (d).

absorption band probably consists of several overlapping bands, including the intervalence charge-transfer transitions of $Rh^{2+}\leftarrow Rh^{+}$ and/or $\pi^*(SQ^{\bullet-})\leftarrow\pi^*(Cat^{2-})$[14] along with the absorption associated with the band structure formed by d_{z^2} orbitals, as observed in $[Rh(3,6\text{-dbsq})(CO)_2]_\infty$. On the other hand, the absorption spectrum of a solution of **1** in CH_2Cl_2 is quite similar to that observed for $[Rh(3,6\text{-dbsq})(CO)_2]_\infty$ in the same solvent, and this indicates that **1** exists as a discrete rhodium(I) semiquinonato complex in solution with CH_2Cl_2.

Single-crystal electrical resistivity ρ of **1** along the 1D chain direction was measured in the temperature range 80–300 K by a four-probe technique (Figure 6). Compound **1** shows significant electrical conductivity ($\sigma = 17$–$34\ S\,cm^{-1}$) at room temperature in spite of its neutral molecular character. This high electrical conductivity also clearly demonstrates that the rhodium atoms in **1** are in the mixed-valent state. The temperature dependence of the electrical conductivity confirms semiconducting behavior, and the activation energies E_a in the high- and low-temperature regions are 114 meV (300–179 K) and 64.4 meV (154–80 K), respectively. The increase in resistivity with decreasing temperature is attributable to dimerization of the trimers. The resistivity of **1** shows significant hysteresis in the temperature range of 161–275 K, but the origin of the hysteresis is unclear.

The effective magnetic moment μ_{eff} of **1** at 300 K is 1.61 μ_B, which is smaller than the theoretical value of 1.73 μ_B for a paramagnetic isolated spin of $S = 1/2$ (see the Supporting Information).[15] The μ_{eff} value gradually decreases down to 208 K, shows a rounded hump around 208–172 K, and then decreases to 1.22 μ_B at 5.0 K. This value is slightly smaller than that of 1.41 μ_B expected when two Rh^{2+} spins become a spin singlet and only four semiquinonato spins exist as magnetically isolated spins in a hexamer unit. The Weiss constants θ, based on the equation $\chi_M = C/(T-\theta)$, are −59 K (300–208 K) and −21.6 K (176–52 K), which suggest an antiferromagnetic interaction between the unpaired spins. This complicated magnetic behavior is attributed to either a Rh^{2+} ion or a semiquinonato ligand in the rhodium complex unit with a spin of $S = 1/2$.

The electronic structure of **1** can be estimated from these experimental results as follows: At room temperature, the 1D

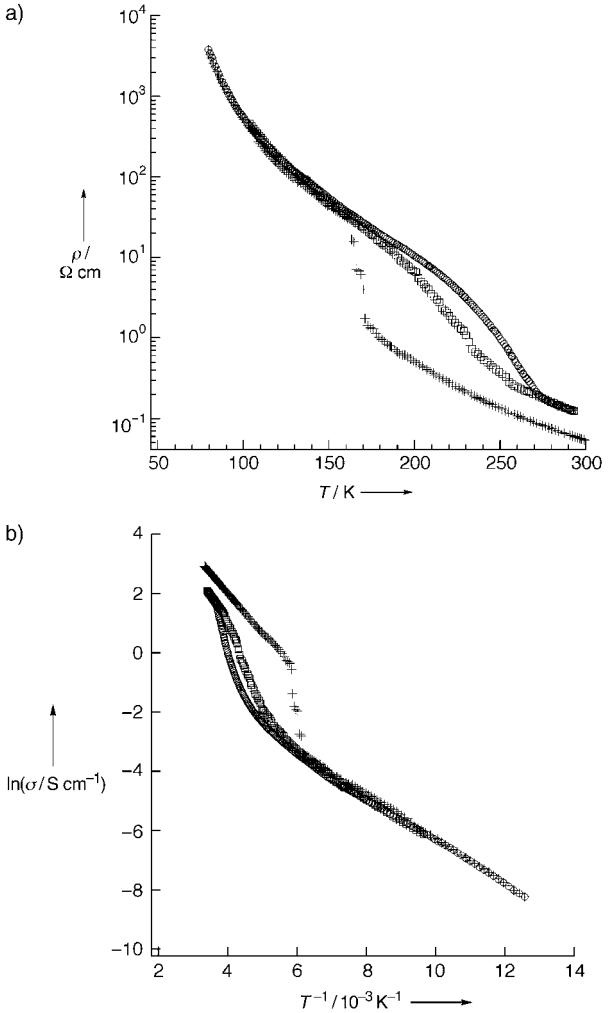

Figure 6. a) Temperature dependence of electrical resistivity ρ of **1** measured along the 1D chain direction: 1st cooling (+), 1st heating (○), 2nd cooling (□). b) Temperature dependence of electrical conductivity σ of **1**.

band formed by the d_{z^2} orbitals of **1** has one unpaired electron per trimer and exhibits significant conductivity. As the temperature is lowered, the trimers dimerize and the unpaired electrons pair, which lowers the conductivity.

In conclusion, we have reported the first neutral linear-chain mixed-valent rhodium(I,II) semiquinonato/catecholato complex **1**, in which the mixed-valent state is realized by electron transfer between metal d and semiquinonate π^* orbitals. This compound exhibits high conductivity (17–34 $S\,cm^{-1}$) at room temperature in spite of its being a neutral molecule. Tuning of the energy levels between the metal d and ligand π orbitals would be expected to facilitate the control of electron transfer between metal and ligand by external factors, such as light, heat, and/or pressure. Therefore, this research offers opportunities for the development of novel neutral conducting polymers based on metal complexes in which the solid-state properties could be changed by metal–ligand electron transfer induced by such external fields. Further investigations are currently underway to produce a variety of the mixed-valent rhodium(I,II) semiquinonato/catecholato compounds by using frontier-orbital control.

Experimental Section

1 was prepared by a procedure similar to a literature method.[9] $[Rh_4(CO)_{12}]$ (54 mg, 0.072 mmol) and 3,6-di-*tert*-butyl-4,5-dichloro-1,2-benzoquinone[8] (96 mg, 0.33 mmol) were dissolved in *n*-pentane at 35 °C. After slowly cooling to −5 °C, black needle crystals of **1** separated from the solution. These crystals were collected by filtration and washed with *n*-pentane: yield 75 mg (58 %). Elemental analysis (%) calcd for $C_{16}H_{18}Cl_2O_4Rh$: C 42.88, H 4.05, Cl 15.82; found: C 42.68, H 3.97, Cl 15.64; UV/Vis/NIR (KBr pellet): λ_{max} = 251, 334, 439, 1270 nm; UV/Vis/NIR (CH_2Cl_2): λ_{max} (ε_M) = 317 (sh, 7460), 356 (10800), 468 (3830), 818 (378), 990 (sh, 238), 1160 nm (sh, 119).

X-ray crystallography for **1**: A single crystal was mounted on a carbon fiber attached to a closed-cycle helium cryostat. Data were collected at 302 and 56 K, under vacuum to measure reflection intensity accurately by reducing air-scattering background, with synchrotron radiation (20.03 keV (λ = 0.6188 Å) at 302 K and 21.99 keV (λ = 0.5638 Å) at 56 K) and a MAC Science low-temperature vacuum X-ray camera equipped with an imaging plate (IP) area detector in the BL02B1 beamline at SPring-8. The frames were indexed and the reflections integrated with DENZO and subsequently scaled with SCALEPACK.[16a] An empirical correction for absorption anisotropy was applied to all intensity data by using PLATON-MULABS.[16b] The structure was solved by direct methods (SIR97)[17a] and refined by full-matrix least-squares techniques on F^2 (SHELXL-97).[17b] All non-hydrogen atoms were anisotropically refined, while all hydrogen atoms were placed at their idealized positions but not refined. All calculations were performed with the teXsan crystallographic software package.[17c]

Crystal data for **1** at 302 K: $C_{16}H_{18}Cl_2O_4Rh$, M_r = 448.13, black needles, 0.330 × 0.065 × 0.020 mm, monoclinic, space group *C*2/*c*, *a* = 31.696(1), *b* = 11.142(1), *c* = 34.317(1) Å, β = 116.030(1)°, *V* = 10890.0(11) Å^3, *Z* = 24, ρ_{calcd} = 1.640 g cm^{-3}, *F*(000) = 5400, μ(0.6188 Å) = 0.803 mm^{-1}, $2\theta_{max}$ = 52.46°. 15811 reflections were measured, of which 10533 were unique (R_{int} = 0.0399). *wR*2 = 0.1001, *S* = 0.921 (all data), *R*1 = 0.0363 (10533 reflections with $I > 2\sigma(I)$), 622 parameters, min./max. residual electron density −1.080/0.821 e A^{-3}, min./max. transmission 0.94227/0.95022.

Crystal data for **1** at 56 K: $C_{16}H_{18}Cl_2O_4Rh$, M_r = 448.13, black needles, 0.300 × 0.075 × 0.045 mm, monoclinic, space group *C*2/*c*, *a* = 31.644(1), *b* = 10.990(1), *c* = 33.683(1) Å, β = 116.373(1)°, *V* = 10494.7(11) Å^3, *Z* = 24, ρ_{calcd} = 1.702 g cm^{-3}, *F*(000) = 5400, μ(0.5638 Å) = 0.632 mm^{-1}, $2\theta_{max}$ = 60.46°. 28574 reflections were measured, of which 22583 were unique (R_{int} = 0.0312). *wR*2 = 0.1282, *S* = 1.056 (all data), *R*1 = 0.0473 (22583 reflections with $I > 2\sigma(I)$), 622 parameters, min./max. residual electron density −2.640/5.151 e A^{-3}, min./max. transmission 0.91585/0.97378. CCDC-267426 and -267427 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

XPS data were obtained on a VG ESCALAB 220i-XL spectrometer equipped with nonmonochromatized $Mg_{K\alpha}$ radiation (1253.6 eV). The carbon 1s binding energy (284.6 eV) was used to calibrate the binding energy. Curve-fitting analysis was performed with the iterative least-squares computer program XPSPEAK41 by using a combination of Gaussian and Lorentzian line shapes. Direct-current electrical conductivity measurements were made on several single crystals of **1** by using a four-probe technique. Magnetic susceptibility of **1** was measured with a Quantum Design MPMS-5SH SQUID magnetometer.

Cesium Oxide Nanoparticles

Preparation and Structural Characterization of Stable Cs_2O Closed-Cage Structures**

*Ana Albu-Yaron, Talmon Arad, Ronit Popovitz-Biro, Maya Bar-Sadan, Yehiam Prior, Martin Jansen, and Reshef Tenne**

Films of cesium oxides with a Cs to O ratio of about 2:1 (in addition to Ag) and approximately monolayer dimensions are widely utilized, for example, on the surface of S-1 photocathodes,[1] negative electron affinity (NEA) devices,[2] and also discharge lamps, television cameras, and lasers. These films reduce the work function of the electrode and thereby increase the electron emission current and long-wavelength response of these devices.[1,2] Particular emphasis has been placed on the study of $Cs_{1+x}O$ for applications in catalytic converters[3,4] and optical fibers. The structure of these surface layers deposited on photoemissive and NEA devices has proved difficult to resolve and interpret, partly due to the thinness of the film and the pronounced instability of Cs_2O. Furthermore, as these films are highly reactive and thin, they are damaged or destroyed by short exposure to low vacuum. This stringent vacuum requirement increases the difficulty and expense of their manufacture and handling and prevents applications that require periodic atmospheric exposure. Enhancing the stability of these films is a long-standing goal.

The complex Cs–O phase diagram[5] has been investigated in the past. Although the synthesis of various oxides of cesium was reported already in the early 1900s, the actual structural characterization of Cs_2O and Cs_3O was described only 50 years later.[6,7] Cs_2O crystallizes in the 3R anti-$CdCl_2$ structure (PDF #09-0104)[8a,b] and is the only known binary alkali metal oxide with a layered structure. This suggests that a much more stable Cs_2O configuration should exist. Kinetic stabilization could be achieved by forming a closed-cage fullerene-like (*IF*) structure, which is the subject of the present report. These structures do not expose the highly reactive (*hk*0) prismatic faces, as the strong and reactive bonds of the cesium and oxygen atoms at the edges of the layers are canceled out by the inherently closed nature, and only rather weak interactions between adjacent Cs-O-Cs triple layers across the van der Waals gap actually occur. Moreover, *IF* including nanotubes[9] of various other layered compounds, such as WS_2[10,11] and BN,[12] were shown to have unusual mechanical, optical, and electronic properties that arise mainly from their highly curved surfaces, shape, and size. The extensive potential of WS_2 *IF* as superior solid lubricants[13] and impact-resistant materials[14] has already been confirmed.

Here we report the synthesis of closed-cage (fullerene-like *IF*) Cs_2O nanoparticles and their structural characterization by HRTEM. We attempted the synthesis using a variant of laser ablation in a rather unusual setup (Figure 1 a).

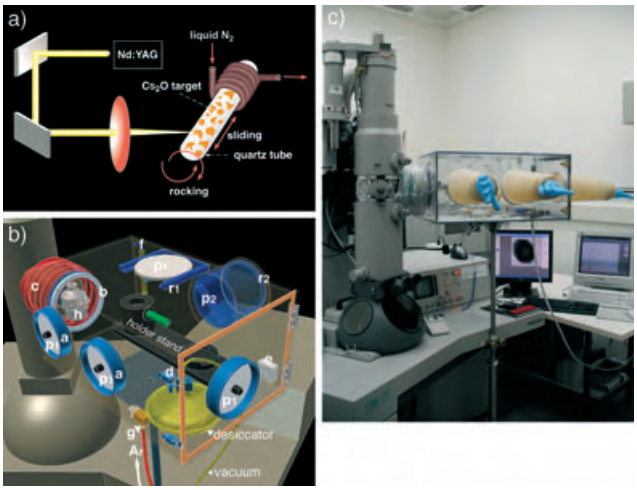

Figure 1. a) Experimental setup for laser ablation. b) Schematic of the environmental chamber. c) Image of the CM120 TEM with the environmental chamber attached to the CompuStage entry.

Moreover, a homebuilt argon-purged environmental chamber (Figure 1 b,c), tightly attached to the entry of the transmission electron microscope (TEM), has been designed and developed to overcome the tremendous experimental difficulties in manipulating Cs_2O. The synthesized nanoparticles exhibit remarkable stability not only under the electron beam of the microscope but also, to a certain extent, even when exposed temporarily to air, and this makes them potentially useful in developing new photoemissive and NEA devices.

3R-Cs_2O powder[15] (Figure 2) served as a precursor in the present work. Subsequent laser ablation of the powder while sealed in evacuated quartz ampoules led to the desired closed-cage nanoparticles of Cs_2O. Unfortunately, the production yields of the fullerene-like Cs_2O structures were too low to permit XRD characterization so far. Figure 3 a and b show two examples of closed-cage nested nanoparticles of Cs_2O typically observed in the laser-ablated material. While that shown in Figure 3 a is faceted, the layers of the *IF*-Cs_2O nanoparticles shown in Figure 3 b are evenly folded to form quasi-spherical, closed nanoparticles. Here, each fringe represents a molecular sheet of Cs_2O. The interlayer distance

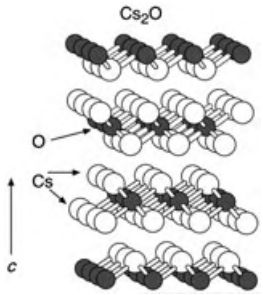

Figure 2. The structure of the Cs_2O precursor.

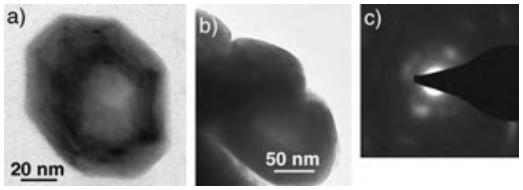

Figure 3. TEM images of typical closed-cage nested *IF*-Cs_2O nanoparticles obtained by laser ablation of 3R-Cs_2O powder precursor: a) faceted Cs_2O *IF* nanoparticle of approximately 70–90 nm in size, b) quasi-spherical *IF* nanoparticles of approximately 70–140 nm in diameter. All particles have at least 30 layers. c) SAED pattern of the nanoparticle in (a). Here reflections from both (00l) and (*hk*0) planes can be seen.

between the Cs_2O fringes is 6.35 Å. The faceted nanoparticle in Figure 3a is about 70–90 nm in size, while the quasi-spherical nanoparticles shown in Figure 3b are about 70–140 nm in diameter and consist of at least 30 layers. Although the nanoparticle cores appear quite dark, the somewhat brighter contrast suggests that they are hollow in the center. The folded and closed nature of both nanoparticles was verified by tilting experiments. Selected-area electron diffraction (SAED) from the nanoparticle in Figure 3a, which is shown in Figure 3c, exhibits the reflections of both (00l) and the hexagonal pattern of the (*hk*0) planes at any tilt angle and confirms the closed nature[10,11] of *IF*-CsO_2. Energy dispersive X-ray analysis (EDS) showed that only cesium and oxygen were present in the nanoparticle with an approximate 2:1 ratio.

Figure 4a shows an enlarged view of part of the faceted polyhedral Cs_2O nanoparticle shown in Figure 3a. A computer simulation of the magnified image is overlaid on the lattice image in Figure 4b. Note the good agreement between the simulated and experimentally observed image. A line profile of the framed area in Figure 4a, shown in Figure 4c, confirms the interlayer spacing of 6.37 Å, which agrees very well with the value of $^1/_3\,c$ of Cs_2O. The fast Fourier transform (FFT) of the framed region in Figure 4a is shown in Figure 4d, and the distance calculated therefrom (6.35 Å) also agrees with $^1/_3\,c$ of Cs_2O. The *IF*-Cs_2O nanoparticles were found to be very stable under the electron beam of the TEM, while TEM analysis of the surrounding amorphous or platelet bulk Cs_2O starting material, also present in these samples, was particularly difficult due to their instability and outgassing

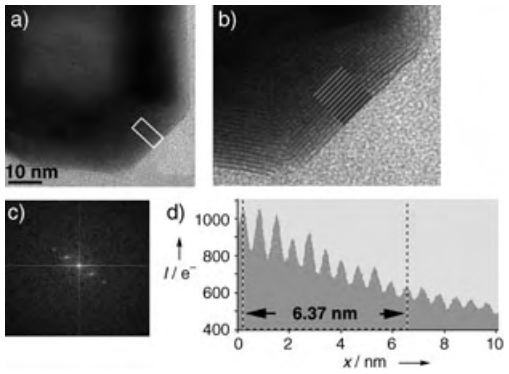

Figure 4. a) An enlarged view of part of a faceted Cs_2O nanoparticle. b) Higher magnification of the *IF*-Cs_2O nanoparticle displayed in a) with a computer simulation of the image overlaid on the lattice image. Note the good agreement between the simulated and experimentally observed images. c) FFT of the framed area in (a). d) Line profile of the framed area in (a) showing an interlayer spacing of 6.37 Å.

under the electron beam. More strikingly, when the grid bearing the specimen was taken out and reinserted into the TEM after a few minutes in the ambient atmosphere, almost no damage occurred to the inspected fullerene-like Cs_2O *IF* nanoparticles, while the surrounding Cs_2O material had deteriorated rapidly.

Subsequent HRTEM experiments on a grid transferred from the TEM and analyzed after roughly 1 h in the ambient laboratory atmosphere (Figure 5a), revealed that the pristine Cs_2O nanoparticle with fullerene-like structure was only partially damaged. The overall shape of this fullerene-like

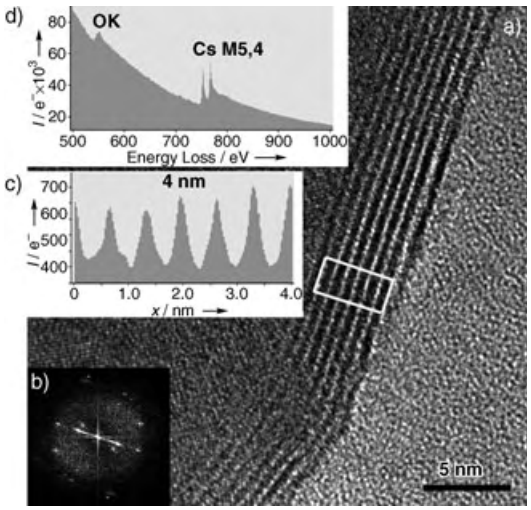

Figure 5. Higher magnification image of a faceted *IF*-Cs_2O nanoparticle, analyzed first in the CM120 TEM and then transferred to the HRTEM following about 1 h of exposure to ambient atmosphere. a) Region of the nanoparticle exhibiting reduced number of layers as compared to the 30 or more layers of a typical pristine nanoparticle (see Figures 3 and 4). The layer spacings, obtained from the respective FFT in (b) and the line profile in (c) from the framed areas in (a) is 6.8 Å in this part. The EELS spectrum in (d) exhibits only Cs and O in a ratio of less than 2:1.

nanoparticle changed from a faceted structure, like in Figure 3a, to a more spherical topology; starting from the kinks between the facets, exfoliation and amorphization of the outer molecular Cs_2O sheets took place and advanced progressively inwards. Careful inspection of this nanoparticle revealed that the number of perfectly closed molecular layers decreased from about 30 to 8, and most of the Cs_2O layers (ca. 20) were only partially ruptured. The interlayer distance increased from about 6.4 Å in the pristine nanoparticle to 6.8 Å (Figure 5b,c) and in some places even to 8.5 Å (not shown), likely due to intercalation of water. In general, however, the inner layers of the *IF*-Cs_2O nanoparticles were found to be undamaged and exhibited smaller expansion.

Electron energy loss spectroscopy (EELS) and imaging with the Gatan imaging filter (GIF) revealed only Cs and O (excess oxygen; Figure 5d), while GIF analysis of the surrounding amorphous material (not shown), revealed Cs, O, and C. These results, together with the above TEM observations, imply that the amorphous and platelet materials on the grid react vigorously with ambient CO_2 to form cesium carbonate, while the *IF* nanoparticles react slowly with water, which could be possibly removed by mild heat treatment or prolonged evacuation in the HRTEM column. In keeping with previous observations on alkali-metal-doped WS_2 and MoS_2 nanoparticles,[16] water uptake into the van der Waals gap between the layers is common in layered compounds. Furthermore, in analogy to intercalated *IF*-WS_2,[16] evidence for some time-dependent recovery of the damaged nanoparticles, accompanied by rounding of its initial polyhedral shape, was observed after a few days in the high vacuum of the HRTEM. The partially recovered Cs_2O layers were less faceted than the original ones. These observations indicate that, in contrast to the presently used cesium oxide films in photocathodes, which are irreversibly damaged under low vacuum, the *IF* nanoparticles, if damaged, could possibly be recovered by mild heating under vacuum.

The presence of the closed Cs-O-Cs hexagonal planes in the *IF*-Cs_2O structures clearly enhances the stability of the material in ambient atmosphere. The inert van der Waals surface of the closed nanoparticles presents a diffusion barrier to the intercalation process, which leads to a sequential and therefore slower hydrolytic attack on the layers in these structures. In contrast, the existence of dangling bonds at the prismatic edges on the periphery of the Cs_2O quasi-two-dimensional planar structures explains the high reactivity of amorphous or platelet powder. Therefore, the formation of closed-cage *IF*-Cs_2O nanostructures induces kinetic stabilization of the material and accounts for its intrinsically low reactivity.

The synthesis of *IF*-Cs_2O has led to a new member of the fullerene-like family of otherwise extremely unstable but important materials. The unprecedented relative stability of the *IF*-Cs_2O nanoparticles synthesized here, both under the electron beam and in air, is very encouraging and suggests that once larger amounts of pure *IF* nanoparticles have been synthesized and fully characterized, their beneficial effect on lowering the work function and photoemission from various surfaces could be directly evaluated and fully exploited in NEA, photoemissive, and other devices. The action of other metals, such as silver and bismuth, that are known to enhance the quantum yield of photocathodes may in fact be related to their possible catalytic effect in the synthesis of *IF*-Cs_2O nanoparticles. Theoretical work is underway to elucidate the electronic structure of these nanoparticles. Previous studies on various semiconducting nanotubes[17,18] indicated that while quantum-size effects are of lesser importance in closed-cage nanostructures, folding of the molecular sheets reduces the energy gap and makes the nanotubes more conductive, and this could favorably affect their thermionic and photoemission.

Experimental Section

The 3R-Cs_2O powder precursor in the present work was synthesized by reaction of measured amounts of cesium metal and oxygen at 180 °C for 3 d.[15] The product was subsequently sealed in evacuated quartz ampoules. The orange-tinted powder was characterized by XRD and Raman spectroscopy.[8a,b] The Raman peak at $\tilde{\nu} = 103\ cm^{-1}$ can be assigned to the A_{1g} mode.[8a]

Cs_2O powder precursor in a vacuum-sealed quartz ampoule was ablated with a pulsed Nd:YAG laser; the beam was manually scanned so as to impinge on a new position. Cooling with liquid N_2 vapor was performed through a copper tube in the form of a helical coil, which wrapped part of the ampoule surface. Figure 1a shows the experimental arrangement. During ablation, a deeply colored powder accumulated on the walls of the cooled side of the quartz ampoule.

Further manipulations were performed in a specially designed and built environmental cell attached as a matching counterpart to the CompuStage entry of the TEM, operating under a flow of Ar of purity > 99.99 % and without any modification of the microscope or of the sample holder; it allowed safe preparation, mounting, handling, and introduction into the microscope of the specimen grid without exposure to the ambient atmosphere. Figure 1b shows a schematic of the environmental chamber; Figure 1c is an overview of the installation of the chamber attached to the CM120 TEM column. The quartz ampoule was broken inside the chamber, and a small amount of the laser-ablated material transferred onto a gold grid for mounting into the TEM. The environmental chamber was operated with both the room-temperature and the cryo holders of the CM120 TEM. A completely different system, which only excludes air during insertion of the grid into the microscope, has been previously reported.[19]

The following microscopes were used: a TEM-Philips CM120 (120 kV) with EDS system (EDAX Phoenix) and a field-emission gun high-resolution TEM (HRTEM) model FEI Tecnai F-30 (300 kV). A Gatan imaging filter (GIF) was used for for electron energy loss spectroscopy (EELS) and for elemental mapping. Fast Fourier transform (FFT) of the high-resolution images was obtained by Digital Micrograph software (Gatan). The computer simulation was performed with the software MacTempas. The following parameters were used for the simulation: thickness 35 nm; defocus of −30 nm.

Pharmacophore Mapping

The INPHARMA Method: Protein-Mediated Interligand NOEs for Pharmacophore Mapping**

Víctor M. Sánchez-Pedregal, Marcel Reese, Jens Meiler, Marcel J. J. Blommers, Christian Griesinger, and Teresa Carlomagno**

In structure-based drug design, the relative orientation of two competitive ligands A and B in the receptor binding pocket plays a central role in the design of high-affinity drug candidates from weakly bound lead compounds. In this communication we report on the observation of interligand spin-diffusion-mediated transferred-NOE data, which have the potential to be used for the determination of the relative orientation of two competitive ligands in the receptor binding pocket. In many cases, the orientation of one ligand in the binding pocket is known, for example, from crystallography or fluorescence resonance energy transfer (FRET) data. In these cases it is desirable to develop a methodology that allows the determination of a unique binding mode and pharmacophore model for a second competitive ligand. We anticipate that the interligand transferred NOEs described here could provide the experimental basis for a methodology that is applicable to any combination of ligands weakly bound to a common receptor.

The conformation of a ligand in the binding pocket of a macromolecular receptor can be accessed by NMR spectroscopy in solution by two approaches. If the molecular weight of the complex is of the order of 50 kDa or smaller and $^{13}C/^{15}N$-labeled receptor can be produced in vitro, a detailed three-dimensional picture of the ligand and of its interactions with the receptor binding pocket can be obtained with standard NMR spectroscopy methods.[1] However, in other cases the macromolecular receptor is too large for NMR studies in solution or it cannot be synthesized in vitro to introduce NMR-active isotopes. In these instances, NMR spectroscopy

can be applied to determine the receptor-bound conformation of the ligand, provided the rate constant for the dissociation of the complex (k_{off}) is much larger than the relaxation constants of the ligand in the complex and the difference between the resonance frequencies of the free and bound ligand forms (a fast-exchange regime). Under this condition, which implies a dissociation constant (K_d) value in the low micromolar to millimolar range, information on the ligand structure is derived from transferred NOEs (tr-NOE)[2] and transferred cross-correlated relaxation rates (tr-CCRR).[3,4] The determination of the receptor-bound conformation of the ligand leaves open the question of its orientation in the receptor binding pocket.

The relative orientation of two competitive ligands weakly bound to a common receptor could be determined by the simple and novel approach that we propose here. A NOESY spectrum of a mixture of the two ligands in the presence of the common receptor is recorded. Under the fast-exchange condition described above, and provided that the two ligands A and B bind competitively to the macromolecular receptor T, intermolecular tr-NOE peaks between the two ligands A and B can be observed in the NOESY spectrum. A NOE peak between a proton H_A of ligand A and a proton H_B of ligand B in the presence of the receptor T originates from spin diffusion involving a proton H_T of the receptor. During the NOESY mixing time, ligand A binds to receptor T and H_A transfers its magnetization to H_T (Figure 1). The complex AT

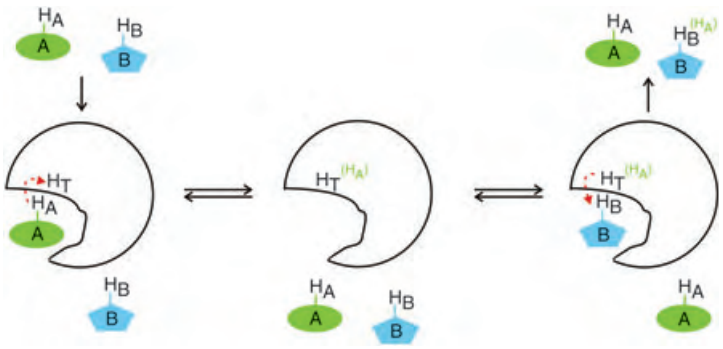

Figure 1. Schematic representation of the principle of the interligand NOEs observed between two competitive ligands A (in green) and B (in blue), which bind consecutively to the same target receptor T. For details see text.

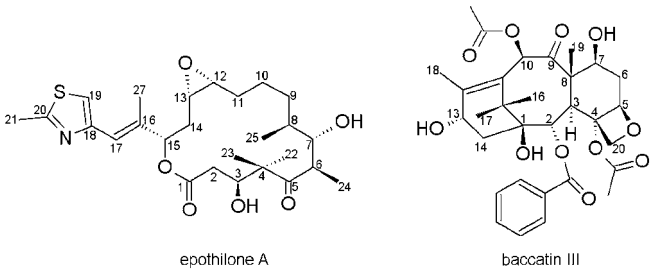
then dissociates and ligand B binds to receptor T. The magnetization of H_A, which had been transferred to H_T, can now be transferred to H_B; this results in an intermolecular peak H_A–H_B. Clearly, this peak can only exist if both H_A and H_B are close to H_T in the AT and BT complexes, respectively. Therefore, a number of such intermolecular NOE peaks will describe the relative orientation of the two ligands in the receptor binding pocket. Such interligand NOEs have never been observed so far and should not be mistaken for the interligand NOEs that occur for two ligands binding simultaneously in adjacent or partially overlapping binding pockets.[5] Here, the two ligands A and B are never either close in space or bound to the protein simultaneously; instead, the two ligands bind to the protein competitively and consecutively and the observed NOEs are a consequence of spin diffusion mediated by the protons of the protein.



If the orientation of ligand A in the binding pocket of receptor T is known, the possible binding modes of ligand B, resulting from docking calculations, could be ranked by evaluating their compatibility with the experimental interligand NOEs. The expected H_A–H_B intermolecular NOEs could be computed for each orientation of ligand B in the BT complex and compared with the experimental ones. The structures that give rise to intermolecular NOEs in good agreement with the experimental ones would be retained, while the others would be rejected. Work along these lines is currently being carried out in our laboratory to develop a computer program for the evaluation of interligand NOEs by using the full-relaxation-matrix approach.[6] A qualitative interpretation of the interligand NOEs, based on the simplified model shown in Figure 1, should not be attempted, as spin diffusion among protein protons can generate intermolecular NOEs between ligands that are in contact with nonneighboring sites of the protein binding pocket. The interligand NOEs should be interpreted exclusively with the help of theoretical calculations by using the full-relaxation-matrix approach. We call this approach INPHARMA (interligand NOE for pharmacophore mapping).

Herein, we show for the first time that such interligand NOEs can be observed. Our system is a mixture of the protein tubulin and two of its ligands. Tubulin is the target of several drugs that interfere either positively or negatively with the tubulin polymerization process. Disturbing microtubule dynamics and, therefore, the cell-division process represents one of the major therapeutic strategies against human solid tumors. Among the small organic molecules that promote tubulin polymerization, paclitaxel is routinely used in hospitals to treat mammalian and ovarian carcinomas. Epothilone and discodermolide,[7] which compete with paclitaxel for the same binding pocket,[8] are more potent than paclitaxel in the promotion of tubulin polymerization and will most likely enter the pharmaceutical market in the next decade. Two low-resolution structures of Zn-induced tubulin sheets stabilized by paclitaxel and epothilone, respectively, have become available by electron crystallography.[9,10]

Recently, thanks to a combination of tr-NOE and tr-CCRR data, we determined the structure of epothilone A (Epo A) weakly bound to soluble tubulin.[11] The tubulin-bound structure of Epo A determined by NMR spectroscopy[11] is not in agreement with the tubulin-bound conformation of Epo A determined by electron crystallography,[10] a fact suggesting that the binding mode of epothilone to tubulin can be dependent on the protein state. Therefore, it is relevant to investigate the binding mode of Epo A to soluble tubulin, namely in conditions that are as close as possible to the physiological ones.

We applied the INPHARMA method to a mixture of epothilone A and baccatin III[12] in the presence of tubulin. The complex Epo A–tubulin is only transiently formed during the mixing time of a NOESY experiment and tr-NOEs can be observed for a 100:1 mixture of Epo A and tubulin, thereby

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

making the system suitable for application of the INPHARMA method (epothilone A = ligand B; tubulin = target T). A model of the complex of tubulin with paclitaxel is available by electron crystallography. Unfortunately, paclitaxel is poorly soluble in water and therefore not suitable for NMR studies in solution. However, the precursor of paclitaxel, baccatin III, which lacks the C13 side chain, is water soluble, binds to tubulin in a transiently formed complex, and delivers tr-NOEs. Thus, although the biological activity of baccatin III is lower than that of paclitaxel, we chose baccatin III as ligand A for our experiments. To confirm that baccatin binds in the same pocket as paclitaxel, namely, that it competes with epothilone for the taxane-binding pocket, we evaluated the change in the tr-NOE rates of baccatin in the presence of tubulin upon addition of epothilone. For a concentration ratio of epothilone A/baccatin of 0.67:1, the tr-NOE rates of baccatin decrease to 60 % of their original value, a result confirming that the two ligands compete for the same binding pocket with a similar K_d value.

We recorded NOESY experiments at different mixing times (20, 40, 70, 100, and 200 ms) for a mixture of epothilone A (0.6 mM), baccatin III (0.6 mM), and tubulin (12 μM) in D_2O. Intermolecular NOE cross-peaks between the aromatic protons of baccatin III and several methyl groups of Epo A are clearly observable in the section of the NOESY spectrum recorded at a mixing time of 70 ms and shown in Figure 2.

19 intermolecular NOE peaks can already be observed in the NOESY spectrum with a mixing time of 40 ms. The build-up curves of the intensities of six of these NOE peaks (Figure 3) show the characteristic damped-parabolic shape for spin-diffusion-mediated NOEs. Additional intermolecular NOEs become visible after 100 ms or at higher mixing times. As a control, we recorded a NOESY spectrum of the mixture of Epo A and baccatin III in the absence of tubulin with a mixing time of 400 ms; this spectrum showed no intermolecular NOEs. Thus, we can conclude that the intermolecular NOEs between Epo A and baccatin III, observed in presence of tubulin, are mediated by protons of tubulin. We are in the process of developing a full-relaxation-matrix analysis of the observed interligand NOEs to determine the binding mode of epothilone to soluble tubulin, with the assumption that baccatin III binds tubulin with the same pharmacophore as paclitaxel.

Herein, we have reported the first observation of protein-mediated NOEs between two ligands that bind competitively and consecutively to the same target molecule. The inter-

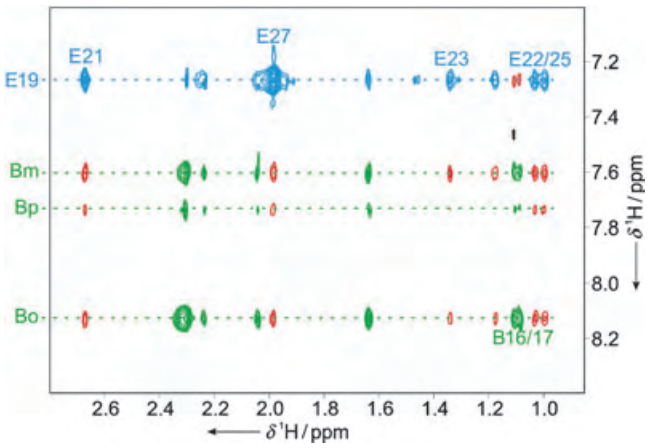


Figure 2. NOESY spectrum of a mixture of tubulin, epothilone A, and baccatin III with concentrations of 12 μM, 0.6 mM, and 0.6 mM, respectively. The spectrum was acquired on a 900-MHz spectrometer equipped with a cryoprobe with a mixing time of 70 ms. The blue and green peaks are intramolecular transferred NOE peaks of epothilone A and baccatin III, respectively. The red peaks represent the interligand transferred NOEs mediated by the protein protons. The numbering of the atoms corresponds to that shown in the compound structures for epothilone A (E) and baccatin III (B). Bm, Bo, and Bp indicate the protons in the *meta*, *ortho*, and *para* positions of the benzene ring of baccatin III, respectively.

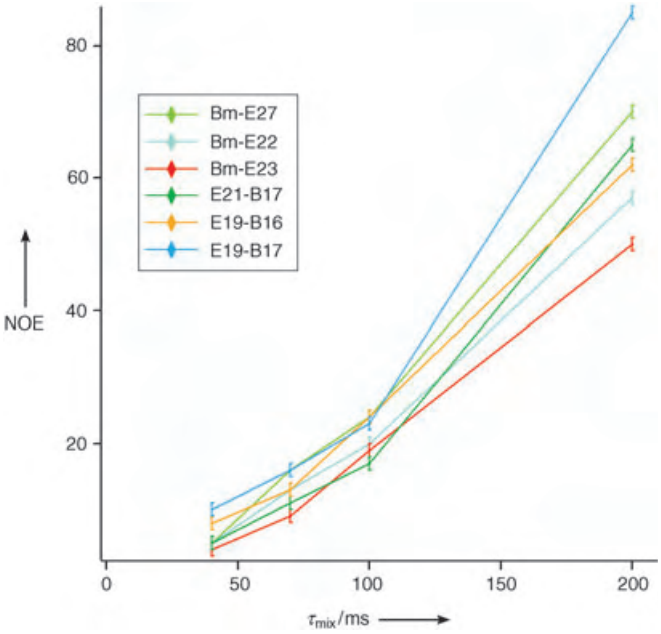

Figure 3. Build-up curves of 6 out of the 19 most intense interligand tr-NOE cross-peaks. The typical damped-parabolic behavior can be observed for all peaks, thereby confirming that the interligand NOEs arise from spin diffusion mediated by the protein protons.

ligand NOEs observed by us should not be confused with the interligand NOEs already reported in the literature,[13] where the two ligands bind simultaneously to the target. Our INPHARMA methodology could be used to distinguish among different binding modes of a ligand to a macro-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

molecular target, if the binding mode of a second competitive ligand is known. This novel approach should be particularly attractive for the pharmaceutical industry, where there is a strong need for the rapid determination of the binding epitope of different ligands to a common target.

Topological Networks

Twelve-Connected Net with Face-Centered Cubic Topology: A Coordination Polymer Based on $[Cu_{12}(\mu_4\text{-}SCH_3)_6]^{6+}$ Clusters and CN^- Linkers**

Dan Li, Tao Wu, Xiao-Ping Zhou, Rui Zhou, and Xiao-Chun Huang*

In recent years, the analysis of topological networks of metal–organic coordination polymers has been a topical area of research in crystal engineering, not only as an important tool for simplifying complicated supramolecular coordination polymers, but also in the rational design of some functional materials with unique properties.[1–3] Considerable effort has been invested in the characterization and design of such coordination polymers.[4] O'Keeffe et al. identified five regular nets, one quasiregular net, and fourteen semiregular three-periodic nets by transitivity *pqrs*.[5] Of these nets, the face-centered cubic net (fcu) is the only quasiregular net with transitivity 1112, which exhibits the highest coordination number (12). It has been suggested that among the numerous topological nets, the most important and plausible targets for designed synthesis are those with "simple, high-symmetry" structures.[6] Although many coordination polymers with different topological networks containing 3~8-connected nodes are known,[7] synthetically prepared examples of higher connected and higher symmetry nets, such as fcu, have not been reported to date.

Significant interest has also arisen in organic and coordination chemistry for the design and synthesis of novel coordination polymers with ligands generated in situ.[8] We have previously reported[9] the reaction of CuSCN with acetonitrile and methanol under solvothermal conditions, which yielded a novel 3D polymeric photoluminescent complex, $\{[Cu(\mu_3\text{-}SCH_3)_2(CN)]_2[Cu_{10}(\mu_3\text{-}SCH_3)_4(\mu_4\text{-}SCH_3)_2]\}_n$, in which the methyl mercaptide is generated in situ. The complex contains dodecanuclear copper(I) clusters, which can be rationalized in terms of an α-Po simple cubic net (pcu), by defining the decanuclear copper cluster $[Cu_{10}(\mu_3\text{-}SCH_3)_4(\mu_4\text{-}SCH_3)_2]$ as a node and $[Cu(\mu_3\text{-}SCH_3)_2(CN)]$ as a

linker. In our ongoing research, we have found that the complex can also be obtained by reaction of $Cu(NO_3)_2 \cdot 3H_2O$ or $Cu(CH_3COO)_2 \cdot 2H_2O$ and NaSCN in the presence of acetonitrile and methanol under the same solvothermal conditions (140 °C). Interestingly, when the reaction temperature was increased to 160 °C, a very different product, namely, $[Cu_{12}(\mu_4\text{-}SCH_3)_6(CN)_6]_n \cdot 2H_2O$ (**1**), was obtained in low yield. This compound is very stable in air at ambient temperature, and relatively insoluble in common solvents.

X-ray single-crystal analysis[10] revealed that the crystal structure of **1** is composed of a 3D neutral microporous framework based on the highly symmetrical, spherical dodecanuclear copper(I) cluster $[Cu_{12}(\mu_4\text{-}SCH_3)_6]^{6+}$ connected by CN^- ligands and guest water molecules, with space group $Fm\bar{3}m$. The basic spherical unit (Figure 1) contains a centrosymmetric Cu_{12} cubo-octahedron, involving a regular octahedron of sulfur atoms with each edge bridged by a CuX unit (X = C or N) from the CN^- ligand. All methyl groups point outwards. Three mutually perpendicular, coplanar, eight-membered Cu_4S_4 rings intersect at the sulfur atoms to generate an globular configuration. Each Cu^I center lies in a planar and trigonal coordination sphere and binds to two bridging μ_4-SCH_3 ligands and to one N or C atom of the CN^- ligand (S–Cu 2.2284(17), Cu–X 1.889(15), C–N 1.17(3) Å, S-Cu-S 127.1(2), S-Cu-X 116.44(12)°). The coordination environment of all the sulfur atoms in μ_4 bridging mode is a square-pyramidal $CSCu_4$ unit, with one carbon atom at the apex and four copper atoms in the equatorial plane. The C–S bond lengths are all 1.81(2) Å, similar to those in other mercaptanes.[11] While μ_2- and μ_3-thiolate bridging modes are relatively common, symmetric μ_4-thiolates remain scarce.[11] Three adjacent Cu^I atoms bridged by three sulfur atoms form an equilateral triangle with a Cu···Cu distance of 2.987(2) Å that indicates a weak Cu···Cu interaction. The corresponding bond angles and lengths are equal, and thus an ideal 32-face polyhedron results: eight equilateral triangles and 24 isosceles triangles (see Supporting Information).

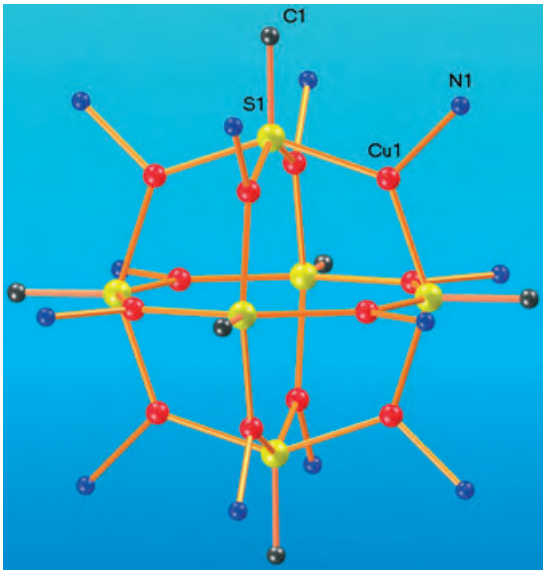

Figure 1. Structure of the basic globular $Cu_{12}(SCH_3)_6(CN)_6$ unit with a center of symmetry at the center of the S_6 cage; hydrogen atoms are omitted for clarity.

A polymer $[Cu_{13}Cl_{13}(SCH_2CH_2NH_3)_6 \cdot H_2O]_n$ containing $(Cu_{12}S_6)$ clusters with a similar globular configuration has been previously reported[11a] in which the corresponding bond angles and lengths in each cluster are non-equivalent, for example, Cu–S bond lengths range from 2.221 to 2.300 Å. In this complex, $^-SCH_2CH_2NH_3^+$ is a neutral ligand, and the clusters act as 4-connected nodes linked by CuCl subunits and chloride ions to form a 2D framework. In contrast, each $[Cu_{12}(\mu_4\text{-}SCH_3)_6]^{6+}$ unit in complex **1**, which has higher symmetry, is connected to twelve adjacent clusters by twelve cyanide ions to give a 3D microporous supramolecular framework (Figure 2). Approximately 20.3 % of the crystal volume is occupied by free water molecules with a volume of about 748.1 $Å^3$ in each cell unit.

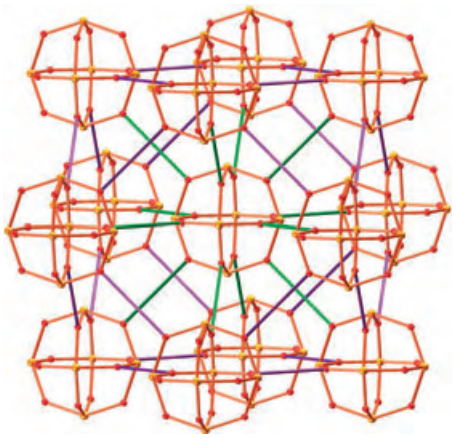

Figure 2. The site of each $Cu_{12}S_6$ cluster in the cell unit.

The 3D framework can be rationalized as a face-centered cubic net (fcu) with Schläfli symbol $(3^{24}4^{36}5^6)$ by assigning the dodecanuclear copper(I) cluster $[Cu_{12}(\mu_4\text{-}SCH_3)_6]^{6+}$ as a node and the CN^- ligand as a linker (Figure 3), in accordance with the quasiregular net structure defined by O'Keeffe. In each

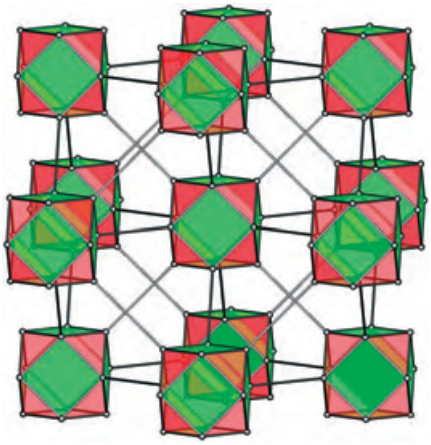

Figure 3. The 3D, 12-connected augmented fcu topological network.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

cell unit, the central node or the center of the central cluster is located at (0.5, 0.5, 0.5), and the other adjacent twelve nodes are located at the center of each edge of the cube, respectively (Figure 2). Eight water molecules occupy the center of the tetrahedron. The distance from the center of each spherical unit to adjacent units is $a/\sqrt{2}$ (10.918 Å), and each spherical unit resides at a crystallographic inversion center. To the best of our knowledge, this is the first fcu topological network observed in coordination polymers, and represents the highest connected topology of any known coordination network.

Thermogravimetric analysis of **1** showed that the structural skeleton remains stable up to 190 °C (see Supporting Information). Initial loss of guest water molecules is followed by the abrupt loss of organic components (CH_3 and CN) from 190 to 275 °C (found weight loss 21.9%, calcd 22.8%; see Supporting Information).

Another interesting feature of **1** is the in situ generation of SCH_3^- and CN^- ligands. We have previously shown that the sulfur atom in SCH_3^- originates from SCN^- and the methyl group from methanol rather than acetonitrile.[9] In an attempt to understand the mechanism for the transformation of inorganic sulfur into organic sulfur, we identified the following experimental phenomena: 1) the colorless residual solution has a characteristically pungent smell and quickly becomes green after the reactor is opened to air; this indicates reduction of Cu^{2+} to Cu^+ and production of CH_3SH or H_2S in the reactions; 2) yellow α-CuSCN single crystals and yellow S_8 single crystals were found in the residual solid in two analogous reactions.[12] Even though it cannot be found in the present reactions, we assume that H_2S acts indirectly as the sulfurization reagent, which is generated by the reaction of S with H_2O, and which can then react with CH_3OH to form SCH_3^-. Possibly, S from the decomposition of SCN^- and CuSCN from redox reaction of Cu^{2+} and SCN^- are two important intermediates in the present reactions. Moreover, it is likely that the frameworks of the two complexes were determined by the reaction temperature. The precise mechanism and the effect of the temperature on the reactions warrant further investigation.

In conclusion, a novel microporous polymer containing a face-centered cubic (fcu) topological network with the highest connectivity, based on a dodecanuclear copper(I) cluster as a twelve-connected node, was synthesized by a simultaneous redox, sulfurization, and self-assembly reaction under solvothermal conditions. The concept of using a cluster as a building block to construct high-connectivity networks is therefore feasible, and the reactions confirm the transformation of inorganic into organic sulfur. The result provides a new avenue for designing and generating new solid-state materials based on networks of high-coordinate nodes linked by bridging ligands.

Experimental Section

1: A mixture of $Cu(NO_3)_2{\cdot}3H_2O$ (0.241 g, 1.0 mmol), NaSCN (0.081 g, 1.0 mmol), methanol (5.0 mL), and acetonitrile (5.0 mL) was stirred for 1 min in air, then transferred and sealed in a 25 mL teflon-lined reactor, which was heated in an oven to 160 °C for 72 h and then cooled to room temperature at a rate of 5 °C h^{-1}. Yellow cubic crystals were obtained in 4.5% yield based on $Cu(NO_3)_2{\cdot}3H_2O$.

Elemental analysis (%) calcd for **1** ($C_{12}H_{22}Cu_{12}N_6O_2S_6$): H 1.79, C 11.65, N 6.79%; found: H 1.82, C 11.59, N 6.82%; IR (KBr, cm^{-1}): 2920s, 2825w, 2127s, 1418m, 1305m, 957s, 689w, 645m, 463w.

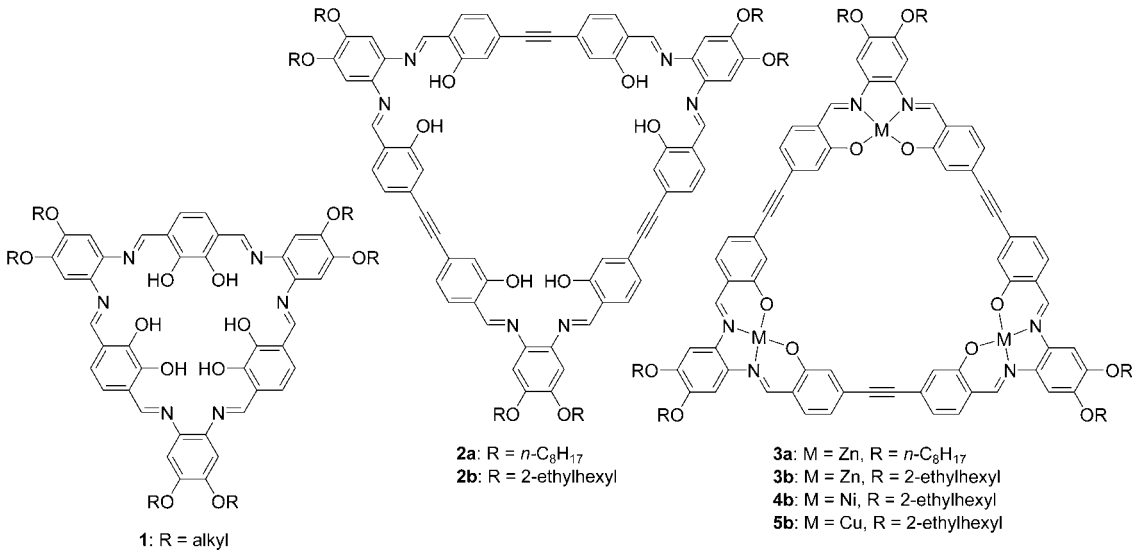
Supramolecular Chemistry

Supramolecular Assembly and Coordination-Assisted Deaggregation of Multimetallic Macrocycles**

*Cecily Tsz Lui Ma and Mark J. MacLachlan**

One of the most important objectives in supramolecular chemistry is the self-assembly of molecular building blocks into well-defined architectures.[1] The remarkable functions of self-assembled structures in biological systems has resulted in considerable effort being devoted to the development of new materials that employ this concept. Examples include catalysts,[2] organic nanotubes,[3] supramolecular polymers,[4] and chemical sensors.[5]

Aggregation of rigid, shape-persistent macrocycles has become a topic of growing interest.[6] Conjugated phenylacetylene macrocycles (PAMs), for example, show solvent- and concentration-dependent aggregation that is mediated by π–π interactions between the macrocycles and leads to nanotubular assemblies.[7] Such aggregation, however, is usually weak and depends strongly on the substituents of the macrocycles for organization.[8] Stronger forces, such as hydrogen-bonding interactions, have been used to aggregate cyclic D,L-peptides and urea macrocycles.[9] In these systems, solvents containing hydrogen-bond donors or acceptors may decrease aggregation.[10] The use of coordination chemistry to assemble shape-persistent macrocycles is an underdeveloped area.



We recently reported the synthesis of small macrocycles **1** containing Schiff bases with the intention of studying their self-assembly.[11] However, these macrocycles have only a very small cavity in the center and would not yield significant porosity if stacked. A larger, conjugated macrocycle **2a** containing Schiff bases (Scheme 1) is readily prepared in high yield without the use of a template.[12,13] This macrocycle may react with transition-metal salts to form trimetalated macrocycles, in which the metals are incorporated into the tetradentate (N_2O_2) binding sites. Herein, we report our findings on the surprising aggregation behavior of these large, shape-persistent metallomacrocycles in solution. The metal center plays an important role in mediating the assembly of the macrocycles. Furthermore, we demonstrate coordination-assisted deaggregation of the metallomacrocycles, a mechanism that may form the basis of new chemical sensors.

Scheme 1. Conjugated macrocycles **1**–**5**.

Metalation of **2a** with Zn^{II} salts afforded metallomacrocycle **3a**. Macrocycles with branched 2-ethylhexyloxy substituents **2b**–**5b** were also prepared to give enhanced solubility. MALDI-TOF mass-spectrometric analysis of metallomacrocycles **3**–**5** verified their composition. In addition to the molecular ion, signals corresponding to the protonated dimer were also observed. In the case of **3a**, significant aggregation was observed, as signals for ions of up to $[(\mathbf{3a})_9]^+$ were present in the spectrum (see the Supporting Information). The intensity of the signal that arose from the aggregates was very large only in the case of **3a**.

^{1}H NMR spectroscopic analysis of **3a** showed that it aggregates in solution. In [D$_8$]THF, sharp signals are displayed, all of which can be assigned to the macrocycle, including the imine resonance at $\delta = 8.85$ ppm. The resonances broaden as the ratio of CD_2Cl_2/[D$_8$]THF is increased such that the aromatic groups are no longer visible (Figure 1). This effect is attributed to a significant decrease in the T_2 relaxation time, caused by the formation of large aggregates.[14] Well-defined oligomeric structures (e.g., dimers) would be expected to give rise to sharp signals, but our results indicate that larger aggregates are present. The resonances associated with the macrocycle are completely diminished in CD_2Cl_2, whereas those for the alkoxy side groups are broad. Broadening has been observed in the aggregation of PAMs in highly polar solvents.[6c,15] For comparison, **2** and the monometalated compound **6** do not aggregate at similar concentrations in THF or CH_2Cl_2.

Self-association can have a large effect on the optical properties of macrocycles in solution. To investigate further the aggregation behavior of the macrocycles, we undertook UV/Vis and fluorescence spectroscopic studies of macrocycles **3**–**5** in mixtures of CH_2Cl_2/THF of different compositions at constant concentration (Figure 2a,b). Metallomacrocycles **4b** (M = Ni^{II}) and **5b** (M = Cu^{II}) both show UV/Vis spectra with several well-defined absorption features. Moreover, there is virtually no difference between the spectra recorded in THF and in CH_2Cl_2. The spectra of zinc macrocycles **3a** and **3b** in THF appear to be very similar to those of macrocycles **4b** and **5b**, with several distinct features observed. However, as the ratio of CH_2Cl_2/THF increases, the UV/Vis spectra for **3a** and **3b** undergo a dramatic change that leads to broad, featureless absorption spectra in CH_2Cl_2.

Metallomacrocycle **3a** is fluorescent in THF ($\phi = 0.86\,\%$), with signals at 558 and 596 nm (Figure 2b). The signals are red-shifted and diminish in intensity on changing the solvent from THF to CH_2Cl_2, thus leading to a broad emission for **3a** in CH_2Cl_2 that is similar to that arising from an excited-state complex (excimer) and that shows no vibrational fine structure. Metallomacrocycle **3b** with peripheral 2-ethylhexyloxy substituents behaves similarly to **3a**, which has unbranched alkyl substituents.

The optical properties for **3a** were examined in a range of solvents with varying dielectric constants (Figure 2c). In a coordinating solvent (e.g., THF, dimethyl sulfoxide (DMSO),

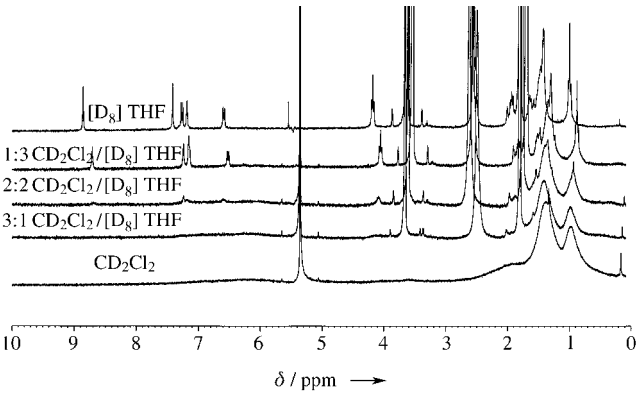

Figure 1. ^{1}H NMR spectra of **3a** in various mixtures of CD_2Cl_2/[D$_8$]THF ([**3a**] = ca. 6×10^{-4} M for all of the spectra).

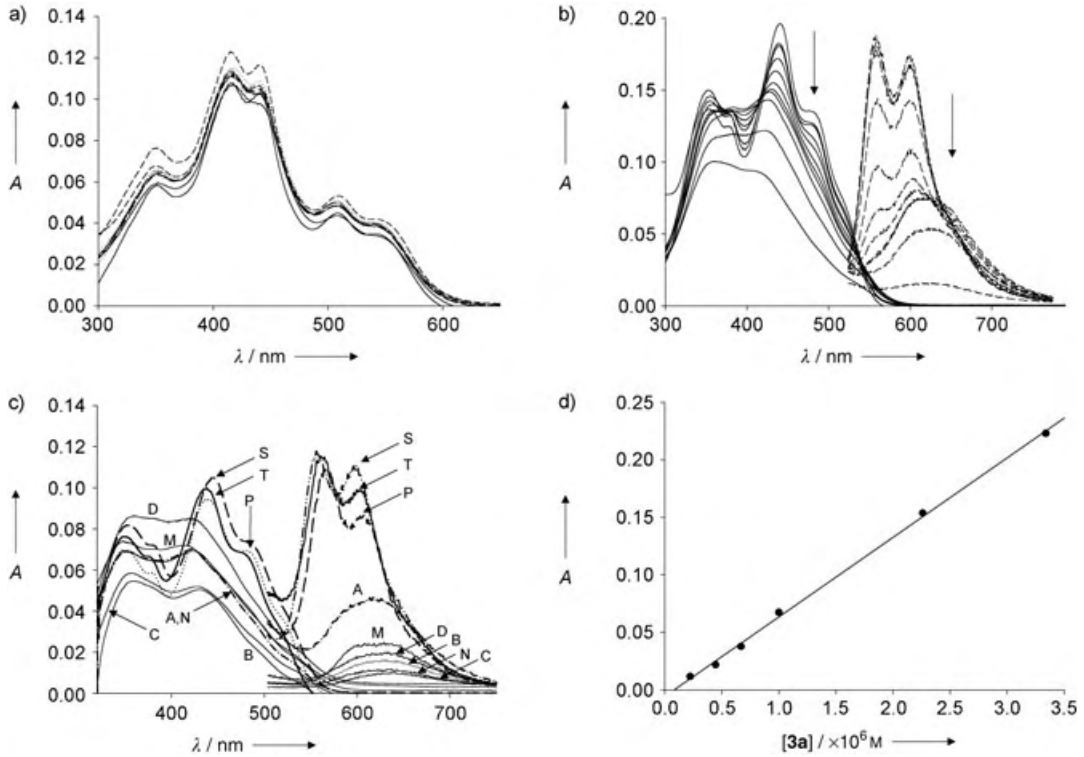

Figure 2. a) UV/Vis spectra of **4b** in various mixtures of CH_2Cl_2/THF (1:0–0:1 in 10% increments); [**4b**] = 9.0×10^{-7} M. b) UV/Vis and fluorescence spectra of **3a** in CH_2Cl_2/THF with the same solvent compositions; the arrows indicate the direction of the increasing CH_2Cl_2/THF ratio. c) UV/Vis and fluorescence spectra of **3a** in various solvents (T: THF, S: DMSO, P: pyridine, A: acetone, B: benzene, D: dichloromethane, M: methanol, C: cyclohexane, N: acetonitrile). d) Graph of absorbance (*A*) at 380 nm as a function of concentration (M) of **3a**.

and pyridine), the absorption spectrum shows well-defined features and the macrocycle fluoresces with two signals near to approximately 560 and 600 nm. In a weakly or noncoordinating solvent (e.g., acetone, methanol, dichloromethane, benzene, acetonitrile, and cyclohexane), the absorption spectrum is broad and nearly featureless and the emission spectrum is broad and red-shifted. The broad absorption spectra and the lack of any dependence on the dielectric constant corroborate the notion that the aggregation is a ground-state effect, and not because of excimers.

These results indicate that **3a** is aggregated at concentrations as low as 10^{-6} or 10^{-7} M in most noncoordinating solvents. Furthermore, a plot of absorbance versus concentration is linear with little concentration dependence on the aggregation (Figure 2d). A reliable equilibrium constant from the system could not be extracted, but it is estimated that K_{assoc} must be greater than 10^7.[16] Given that the macrocycle is electron rich, we were surprised that π–π interactions between the macrocycles would be significant at low concentration in a solvent such as CH_2Cl_2, in which **3a** is soluble.[8] Since **3a** aggregates in MeOH, it is unlikely that hydrogen-bonding interactions are an important factor for assembly. It is also surprising that **3a** aggregates in benzene, in which π–π interactions with the solvent are expected to compete with π–π interactions of the macrocycle, thus suppressing assembly. Moreover, if π–π interactions were solely responsible for the assembly, macrocycles containing Schiff bases and Cu^{II} and Ni^{II} centers are anticipated to be flat with square-planar geometry at the metal and would show a stronger tendency than Zn^{II} macrocycles to aggregate. These results suggest that the aggregation of the macrocycles involve a further interaction, namely, a Zn···O interaction between the macrocycles to maintain a coordination number of five at the Zn^{II} center. The fifth coordination site is occupied by a solvent molecule in coordinating solvents, but the coordination of phenolic oxygen atoms to the zinc centers is involved in the assembly. The coordination of phenolic oxygen atoms to metal centers in salen-type zinc complexes has been observed in the solid state.[17]

The addition of the paramagnetic Cu^{II} metallomacrocycle **5b** to a solution of the Zn^{II} metallomacrocycle **3b** in CH_2Cl_2 led to only a small degree of fluorescence quenching, but did not disrupt the aggregated state of **3b**, as observed by fluorescence and UV/Vis spectroscopies. This outcome indicates that **3b** prefers to interact with other macrocycles of the same type rather than forming dimers with **5b**, which further supports a Zn···O interaction between the macrocycles. If **5b** interacted with the aggregates of **3b**, the paramagnetic Cu^{II} centers would be expected to quench the fluorescence of the zinc metallomacrocycles.

In contrast to the negligible effects of nonpolar solvents on aggregation, coordinating solvents, such as THF and pyridine, readily interrupted the aggregation of **3a** and **3b**. To prove that coordination was the important interaction, **3a** was treated with pyridine and lutidine (Figure 3a,b). UV/Vis and fluorescence spectroscopic analysis showed that **3a** deaggre-

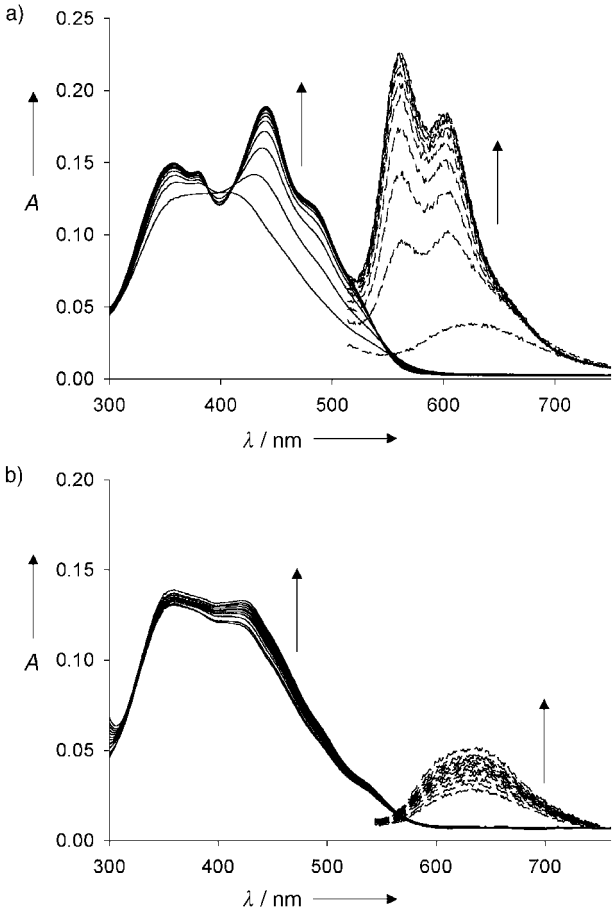

Figure 3. UV/Vis and fluorescence spectra of **3a** titrated with a) pyridine (3.6×10^{-3}–0.020 M; step size: 1.81×10^{-3} M) and b) lutidine (1.26×10^{-3}–0.014 M; step size: 1.26×10^{-3} M; [**3a**] = 1.8×10^{-6} M). The arrows indicate the direction of the increasing concentration of the base.

gates with the addition of pyridine. With lutidine, however, which is more basic but unable to coordinate to the metal centers, the macrocycle remained aggregated.[18] The absence of an isosbestic point in the titration of **3a** with pyridine is consistent with multiple metal centers being coordinated.

The aggregation behavior of **3a** and **3b** is illustrated in Figure 4. The molecules are not aggregated in THF but on changing the solvent to CH_2Cl_2 or benzene aggregate into supramolecular assemblies. We do not know for certain whether the assemblies are tubular, but it seems likely since the aggregation is dominant even at a concentration of 10^{-7} M. Although other possibilities cannot be ruled out, a tubular assembly would maximize interactions between the macrocycles. Addition of a molecule that can coordinate to the macrocycles results in deaggregation and replenished luminescence. These assemblies may serve as the basis of a new model for chemically sensing coordinating bases, in which the mechanism involves deaggregation of the supramolecular assembly.

To test this mechanism as the basis of a chemical sensor, we titrated the macrocycle assembly of **3a** in CH_2Cl_2 with quinuclidine. The fluorescence increased rapidly after

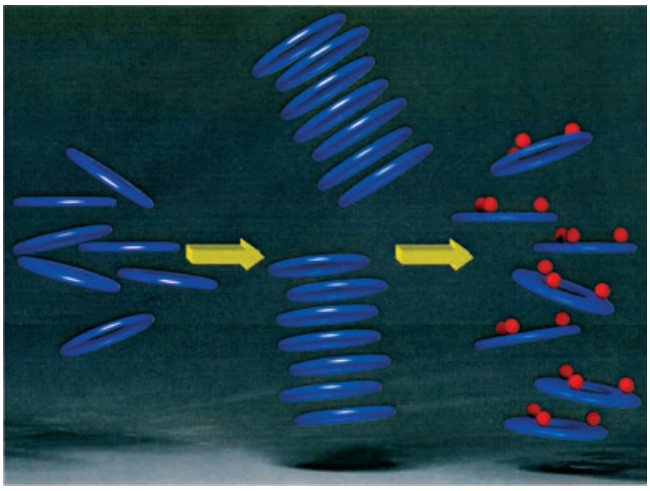

Figure 4. Illustration of aggregation and coordination-assisted deaggregation of multimetallic macrocycles. Left: macrocycles (blue) in THF. Middle: macrocycles aggregated when in CH_2Cl_2. Right: macrocyclic assemblies deaggregate after treatment with a coordinating ligand (red spheres).

30 equivalents of quinuclidine were added, with a total fluorescence increase of 100% at 575 nm. The deaggregation was confirmed by ^{1}H NMR spectroscopic analysis. Although the ^{1}H NMR spectrum of **3a** in CD_2Cl_2 is broadened by aggregation, the spectrum displays the sharp signals expected for **3a** on addition of only three–six equivalents of quinuclidine. Thus, the deaggregation of the macrocyclic assemblies generates a turn-on signal for sensing coordinating bases, such as quinuclidine. This approach is a new method of chemical sensing that may be exploited for sensing molecules of biological relevance.

In summary, we have observed the strong aggregation of metallomacrocycles containing Schiff bases in solution that appears to be facilitated by Zn···O interactions between the macrocycles. The optical and fluorescent properties of the macrocyclic assemblies undergo significant changes when treated with coordinating bases that cause deaggregation of the supramolecular assemblies. These results suggest a new chemical method for control over the assembly of nanostructures from shape-persistent macrocycles. Future work will involve the use of bidentate ligands (e.g., 1,4-pyrazine) to form supramolecular nanotubes.

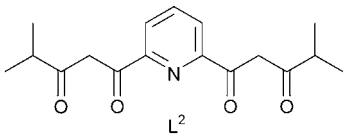
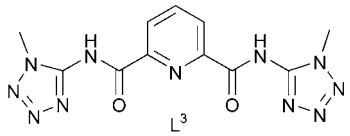
Supramolecular Chemistry



Route to Cluster Helicates**

Manuel R. Bermejo, Ana M. González-Noya, Rosa M. Pedrido, María J. Romero, and Miguel Vázquez*



Most supramolecular helicates contain either two or three metal centers, whereas those with four or more remain relatively uncommon.[1,2] Strategies for the construction of metallohelicates with high nuclearity use long organic ligand strands or guest molecules as templating agents, and thus some linear[3] and circular helicates[4] have been reported. In contrast, there are very few examples of discrete multimetallic helicates in which the metal centers are disposed in a polyhedral mode: the pentatopic ligand L^1 forms a quadruply

L^1

L^2

L^3

stranded helicate[5] $[Ag_{10}L^1_4]^{10+}$, and related ligands L^2 and L^3 form bis(triple-helical) metal complexes with six ligand strands wrapped around the $[M_8O_2]^{12+}$ metaloxo clusters ($M = Zn^{II}$, Cd^{II}, and Mn^{II}).[6] These helicates are complex

polystranded architectures that do not display metal–metal interactions.

Helicates are being used in the construction of novel materials, devices, and machines with programmed properties and functions, such as luminescence,[7] DNA binding,[8] chirality,[9] magnetic exchange,[3,10] anion binding,[11] metal-ion translocation,[12] or electrochemical structural rearrangement.[13] However, all these possible applications could undergo remarkable development if the extremely important biological, physical, and chemical properties of cluster compounds were considered.[14] Unfortunately, there are no efficient synthetic routes to "cluster helicates".

Herein, we report the first strategy to construct cluster compounds with a helical arrangement of ligands around the central metal core, that is, "cluster helicates". In particular, we describe the use of a ligand that potentially has a dianionic and helicand character and is equipped with two soft donor atoms, which allow the helicate assembly to be controlled through selection of the oxidation state of the metal centers. We therefore designed bis(4-ethyl-3-thiosemicarbazone)-2,6-diacetylpyridine (H_2L) as such a ligand (int = internal, term = terminal), which contains two soft sulfur donor atoms so that it would be an effective moiety to support the self-assembly of metal(II) dinuclear dihelicate complexes.[15] We recently reported the anion-binding properties of this ligand, and its application to the selective colorimetric recognition of fluoride anions in organic solvents.[16]

H_2L

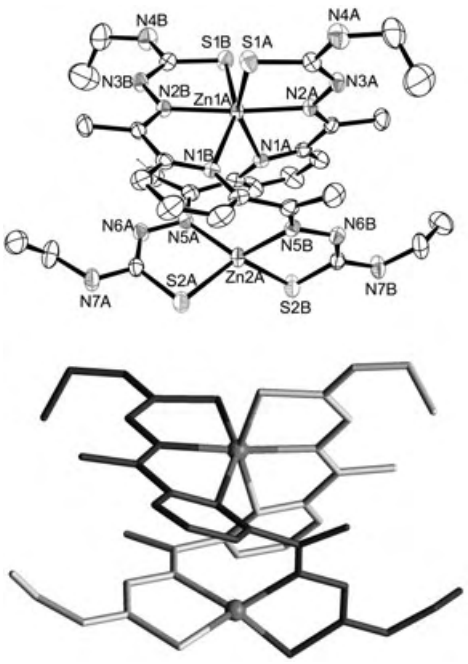

Figure 1. Top: Molecular structure of dihelicate complex $[Zn_2(L)_2]$ (**1**), with the two strands of L labeled as A and B. Thermal ellipsoids are drawn at the 40% probability level, carbon atoms are shown as unshaded ellipsoids, and hydrogen atoms have been omitted for clarity. Bottom: Ball-and-stick representation of **1**, with the two strands of L highlighted in light gray (A) and dark gray (B).

The next step in the study was the preparation of metal(II) dinuclear dihelicate derivatives containing H_2L. Our experience with this class of complex and the absence of hard donor atoms in the main body of H_2L led us to use Cu^{II} and Zn^{II} ions to prepare these complexes. Electrochemical oxidation[17] of a zinc plate in a conducting solution of H_2L in acetonitrile afforded a yellow solution, from which a pale yellow solid precipitated on concentration. The ESI mass spectrum and elemental analysis of this material are consistent with the formation of the neutral dimeric species $[Zn_2(L)_2]$, which arises from the double deprotonation of H_2L in the electrochemical cell. This complex was also characterized by IR spectroscopy (see Supporting Information).

Recrystallization of this yellow precipitate from acetonitrile by slow evaporation afforded pale yellow crystals of complex **1**, from which its molecular structure was determined by X-ray crystallography (Figure 1).[18,19] Its structure reveals the formation of the common [6+4] double-stranded dihelicate $[Zn_2(L)_2]$ (**1**). A racemic mixture of both enantiomers is observed in the unit cell. One Zn^{II} center is tetracoordinated in a tetrahedral mode by two imine nitrogen atoms and two thiolate sulfur atoms from two different ligands. The other Zn^{II} ion is hexacoordinated in a distorted octahedral mode by two pyridine nitrogen atoms, two imine nitrogen atoms, and two thiolate sulfur atoms. This coordination is achieved by symmetrical intertwining of the two ligand strands along the helical axis (Zn···Zn: 4.26 Å). This behavior is quite similar to that found by us in a zinc(II) dinuclear dihelicate complex containing a similar thiosemicarbazone ligand.[15]

The copper(II) derivative was obtained by treatment of H_2L with copper(II) perchlorate in hot acetonitrile. A dark brown solid was isolated and identified as the discrete complex $[Cu_2(L)_2]\cdot 2\,CH_3CN$ (**2**), which was characterized by elemental analysis, IR spectroscopy, ESI mass spectrometry, and magnetic moment measurements (see Supporting Information). Unfortunately, it was impossible to obtain single crystals suitable for X-ray diffraction studies. However, it is expected that **2** has a double-helical arrangement of ligands around the metal centers as it is structurally analogous to **1**.

Once the ability of H_2L to form dinuclear dihelicate complexes with Cu^{II} and Zn^{II} centers was established, we explored the possibility of increasing the nuclearity of these dinuclear dihelicates to obtain neutral dihelical species with a stoichiometry of M_4L_2 by substitution of the divalent metal centers by metal(I) ions (Figure 2).

It is known that all pure substances fulfill the principle of electroneutrality, and as H_2L has a tendency to form metal complexes in its doubly deprotonated form, two dianionic ligand units can be coordinated by four metal(I) ions to form a neutral $[M_4L_2]$ complex. We believe that the presence of the coordinatively versatile thiolate donor atoms in H_2L is

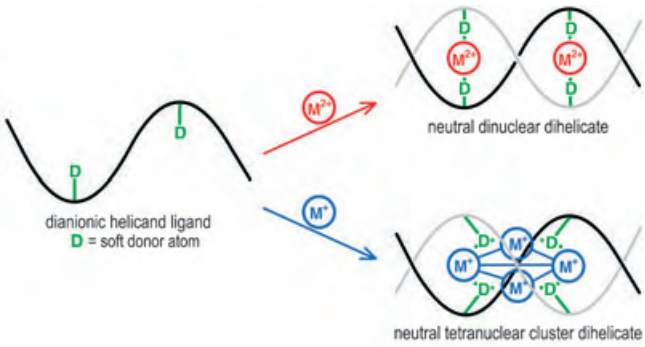

Figure 2. Schematic representation of our synthetic approach to the assembly of "cluster helicates": The substitution of divalent metal centers by metal(I) ions and the use of a dianionic and helicand ligand that contains two soft donor atoms, which can act both as terminal or bridging coordination points depending of the hardness/softness of the metal centers they bind, are the factors that make stabilization of this novel supramolecular motif possible.

essential in satisfying the coordination requirements of the four metal(I) ions and then in stabilizing the $[M_4L_2]$ cluster. Furthermore, these thiolate atoms can act either as terminal or bridging coordination points depending on the degree of hardness/softness of the metal centers to which they bind: as the hardness of the metal ion increases, the tendency of the thiolate sulfur atom to act as a μ_1 donor increases. Therefore, monothiolate ligands that act as μ_2 or μ_3 bridges between soft acids are very common in transition-metal chemistry.[20] Moreover, the ability of thiourea sulfur atoms to act as bridges between either Cu^I or Ag^I ions in the formation of high-nuclearity $[M_6L_6]$ cluster complexes has been recently reported by Dilworth and co-workers.[21] Finally, if two L^{2-} units can stabilize a neutral $[M_4L_2]$ complex, we expect that this $[M_4L_2]$ complex will have a double-helical microarchitecture, since H_2L can form dihelicates. Therefore, we expect H_2L, which potentially has dianionic and helicand character, to be a good building block for the construction of tetranuclear cluster dihelicates.

Treatment of H_2L with $[Cu(CH_3CN)_4]PF_6$ in hot acetonitrile and recrystallization of the resulting brown solid from acetonitrile afforded single crystals of $[Cu_4(L)_2]\cdot 4\,CH_3CN$ (**3**), which were studied by X-ray diffraction.[22] This complex was further characterized by IR spectroscopy and ESI mass spectrometry (see Supporting Information). In the ESI mass spectrum, a base peak corresponding to $[Cu_4(L)_2+H]^+$ was observed, thus confirming that the [4+2] complex is the main species in solution.

ORTEP and ball-and-stick representations of the structure of **3** are shown in Figure 3 (selected bond angles and distances are given in the Supporting Information). The structure comprises four Cu^I ions and two doubly deprotonated thiosemicarbazone ligands and is solvated with four molecules of acetonitrile. Each Cu^I center occupies a three-coordinate distorted trigonal environment, in which they are bound by two thiolate sulfur atoms from different ligands and one imine nitrogen atom. Thus, both ligands act as bis-bidentate N_2S_2 donors. The pyridine nitrogen atoms of the two

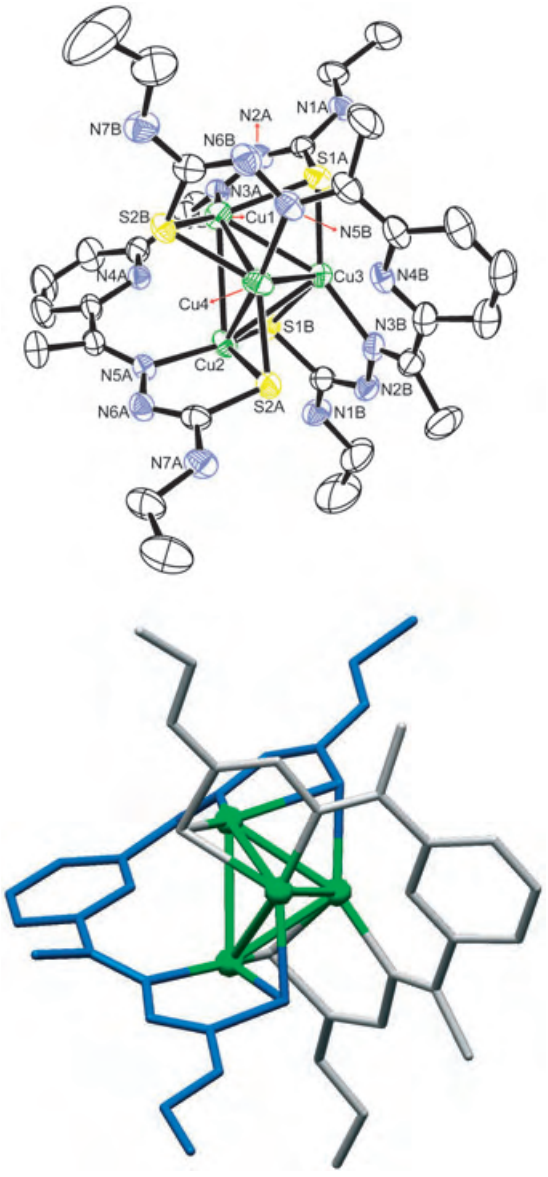

Figure 3. Top: Molecular structure of the neutral tetranuclear cluster helicate complex $[Cu_4(L)_2]\cdot 4\,CH_3CN$ (**3**), with the two strands of L labeled as A and B. Thermal ellipsoids are drawn at the 40% probability level, carbon atoms are shown as unshaded ellipsoids, and hydrogen atoms and solvent molecules have been omitted for clarity. Bottom: Ball-and-stick representation of **3**, with the two strands of L colored in blue (A) and gray (B), and the Cu_4 core shown in green.

L^{2-} units remain uncoordinated. The distortion from an ideal trigonal geometry at all the Cu^I centers is shown by the angles between the nitrogen, copper, and sulfur atoms, which range from 83.95° to 146.73° (see Supporting Information).

The four metal centers form a $\{Cu_4S_4\}$ central core, with each thiolate sulfur atom bridging two Cu^I ions. The two ligands span the tetrahedral core of metal centers and intertwine to give a double-helix structure. A racemic mixture of both enantiomers is observed in the unit cell. The double deprotonation of the ligand on coordination is evident from the observed bond lengths in the cluster (see Supporting

Information). The C_{thio}–S_{thio} bond lengths increased from 1.656–1.668 Å in H_2L to 1.764–1.771 Å in **3** while the N_{int}–C_{thio} bond lengths decreased from 1.367–1.368 Å to 1.282–1.294 Å, thus indicating that the N_{int}=C_{thio}–S_{thio} resonance form predominates in the complex. This assumption is confirmed by the C_{thio}–N_{term} bond lengths in **3** (1.346–1.366 Å), as they indicate the single nature of the bonds.

The four Cu^I ions in this unique neutral dihelicate are located in the vertex of a distorted tetrahedron. This distortion is clearly revealed by the Cu···Cu distances. Interestingly, the distances between the "bridged" Cu^I ions are shorter (2.672–2.706 Å) than those between the "unbridged" Cu^I ions (2.881–2.883 Å). Currently, there is extended controversy over the existence of Cu···Cu interactions in Cu^I cores, such as those found in the present case.[23] The distances between the metal centers are close to the sum of the van der Waals radii for two copper atoms (2.80 Å)[24] and are in agreement with the proposed existence of Cu···Cu interactions.[25] These interactions would mean that the coordination number of the Cu^I ions in **3** should increase from 3 to 6.

To confirm our approach to the preparation of cluster dihelicates, we synthesized another metal(I) derivative using this ligand. Electrochemical oxidation of a silver plate in a conducting solution of H_2L in acetonitrile yielded a yellow solution from which a yellow solid precipitated upon concentration. Recrystallization of this solid from dimethyl sulfoxide (DMSO) afforded single crystals of $[Ag_4(L)_2]\cdot 4\,DMSO$ (**4**), which were characterized by X-ray diffraction.[26] This complex was also characterized by IR spectroscopy and ESI mass spectrometry (see Supporting Information): the ESI mass spectrum showed a base signal corresponding to $[Ag_4(L)_2 + H]^+$, thus confirming the presence of **4** in solution.

ORTEP and ball-and-stick representations of **4** are shown in Figure 4 (selected bond angles and distances are given in the Supporting Information). The asymmetric unit of this complex comprises two doubly deprotonated ligands, four Ag^I ions, and four unbound DMSO molecules. The Ag^I complex has a similar connectivity to the Cu^I analogue **3**, with the two ligands wrapped around the tetranuclear central Ag^I core to give a double-stranded helical structure. The trigonal coordination geometries of the four metal centers are very distorted, as illustrated by the range of angles between the N, S, and Ag atoms (75.94°–157.45°). Moreover, the C_{thio}–S_{thio} bond lengths are in the range of 1.754–1.774 Å, the N_{int}–C_{thio} bond lengths lie in the range 1.267–1.321 Å, and the C_{thio}–N_{term} bond lengths lie in the range 1.302–1.382 Å, thus indicating a less regular geometry in this complex relative to the Cu^I analogue. Both left- and right-handed helicates are present in the unit cell at 50% occupancy.

The four Ag^I ions form a distorted tetrahedron (Figure 5). The intermetallic Ag···Ag distances range from 2.909 to 3.086 Å between the sulfur-bridged Ag^I ions and from 3.219 to 3.235 Å between the unbridged Ag^I ions. All these distances are significantly shorter than the sum of the van der Waals radii for two silver atoms (van der Waals radius for Ag = 3.44 Å)[24] and may suggest the existence of metal–metal interactions.[27] The possible existence of these interactions implies that the coordination number of the Ag^I ions in **4**

should increase from 3 to 6, which is unusual for this metal ion.

To our knowledge, complexes **3** and **4** are the first examples of double-stranded helicates in which the helical axis is composed of a polyhedron of metal ions. Moreover, there are few reports of structurally characterized copper(I) thiosemicarbazone complexes[21,28] and, surprisingly, the structure of only one silver(I) thiosemicarbazone complex has been determined,[21] although the stoichiometries of these coordination compounds were first reported in the early 1980s.[29]

In conclusion, we have prepared dinuclear dihelicates and tetranuclear cluster dihelicates and demonstrated that self-assembly of their building blocks can be controlled. This control can be achieved by using a dianionic helicand ligand that is equipped with two soft donor atoms and by selection of the oxidation state of the metal centers. We believe that this synthetic approach could provide new perspectives on the preparation of complex, stable, and reproducible metallosupramolecular architectures with high nuclearity and programmed properties. Our synthetic approach to the preparation of "cluster helicates" seems to be extendable to other systems, as our ongoing research has produced new examples of metal(I) tetranuclear cluster dihelicate complexes using different bis(thiosemicarbazone) ligands.

Hybrid Compounds

Supramolecular Coordination Assemblies of Dinuclear Fe^{III} Complexes**

Wolfgang Schmitt, Jonathan P. Hill, M. Paula Juanico, Andrea Caneschi, Ferdinando Costantino, Christopher E. Anson, and Annie K. Powell**

Dedicated to Professor Rüdiger Kniep on the occasion of his 60th birthday

Construction of 3D architectures as well as molecular recognition processes are regarded as key aspects of modern supramolecular chemistry.[1] The ability to produce hierarchically ordered structures by the self-assembly of oligomeric subunits is of importance for potential applications.[2] This self-assembly requires a detailed knowledge of the competing structure-directing forces present within the reaction systems. Furthermore, it requires the ability to tune these interactions by consideration of steric restrictions and the nature and specific affinities of the chemical components.

Hybrid organic–inorganic coordination assemblies represent a distinct class of supramolecular compound whose preparation is currently a very active area in chemical and materials research.[3] Hybrid organic–inorganic materials present a means for customizing physical and chemical properties by reducing dimensionality and by influencing the devolution pattern of classical inorganic materials within their crystal structures. One strategy for the synthesis of such

structures makes use of rigid organic complexing agents. By using metal atoms, oligonuclear complexes or clusters, and organic components with distinct morphologies as building blocks it is hoped to control the self-assembly process.[4] Using this approach it is not only possible to reconstruct classical inorganic structures but also to overcome the geometrical limitations of the classical aluminosilicates resulting in materials with unprecedented porosity. Construction of multidimensional M-O-M frameworks has been demonstrated to produce materials supporting cooperative effects in their inorganic regions and can also lead to improved thermal stability.[5] Careful selection of metal ions and ligands and consideration of their preferred coordination modes and geometries allows the construction of crystalline architectures containing 1D, 2D, and 3D M-O-M frameworks and a systematic investigation of their chemophysical properties.[5,6]

Herein we describe a concept for synthesis of hybrid organic–inorganic compounds where the shape and functionality of aromatic ligands determine the dimensions and architecture of the inorganic regions of the resulting hybrid materials. Our work emphasizes the structure-directing effects of iminodiacetic acid substituted phenols and similar naphthol derivatives (Scheme 1). These multidentate complexing agents contain hydrophilic and hydrophobic moieties

Scheme 1. The protonated organic ligands obtained by Mannich reaction on the appropriate phenol or naphthol; R = CH_2COOH.

and react with Fe^{III} salts to give dinuclear complexes where the transition-metal ions are doubly bridged by combinations of hydroxo-, oxo-, and carbonate groups. The resulting complexes, which form through hydrolysis reactions in the presence of specific amounts of water, can be described by the general formulae $[Fe_2(\mu\text{-}OH)(\mu\text{-}CO_3)L_2]^{3-}$, $[Fe_2(\mu\text{-}O)(\mu\text{-}CO_3)L_2]^{4-/6-}$, or $[Fe_2(\mu\text{-}CO_3)_2L_2]^{4-}$. The fixation of atmospheric CO_2 by transition-metal ions is now well-established.[7] Alkali counterions are bound to the negatively charged Fe^{III} complexes through the carboxylate groups and other O-donors. They are further linked to each other by water molecules forming supramolecular coordination assemblies. The hydrophilic/hydrophobic character of the reaction systems favors the formation of cross-linked structures in which self-assembling processes organize vast areas of different polarities.

The hydrolysis reactions in the presence of the tetradentate ligand tBu_2hda led to the crystallization of **1**.

$K_3[Fe_2(\mu\text{-}OH)(\mu\text{-}CO_3)(tBu_2hda)_2]\cdot 3H_2O\cdot EtOH$ **1**

The long Fe–O bond lengths of 2.002(3) and 2.007(4) Å to the bridging oxygen atom confirm the identity of this bridging ligand as a hydroxo group; the hydrogen atom could be located and refined in the crystal structure. This compound forms a two dimensional lamellar structure with potassium ions in the *ab* plane connected to the dinuclear Fe^{III} complexes above and below this plane while the organic residues of the Fe^{III} complexes point in the direction of the crystallographic *c* axis. In this direction the 2D layers bind to each other through weak induced dipole interactions forming organic regions approximately 11.5 Å thick. Similarly in **2**, the ligand hnida stabilizes a layered structure with organic and inorganic layers parallel to the crystallographic *bc* plane.

$K_4[Fe_2(\mu\text{-}O)(\mu\text{-}CO_3)(hnida)_2]\cdot 6H_2O\cdot 2EtOH$ **2**

The Fe^{III} centers of the dinuclear complex in **2** are doubly bridged by a carbonate anion and an oxo ligand, which has significantly shorter bonds (both 1.81 Å) to the Fe^{III} centers than the corresponding hydroxo group in **1**. This oxygen also coordinates to two K^+ ions resulting in a distorted tetrahedral $Fe_2(\mu_4\text{-}O)K_2$ geometry. Figure 1 shows the dinuclear Fe^{III} subunits in **1** and **2** and the layered arrangements of hydrophobic and hydrophilic moieties. It is noteworthy that in **2** the dinuclear subunit straddles the hydrophilic layer while in **1** both organic ligand moieties of a given $[Fe_2(\mu\text{-}OH)(\mu\text{-}CO_3)(tBu_2hda)_2]^{3-}$ unit are accommodated in the same hydrophobic layer.

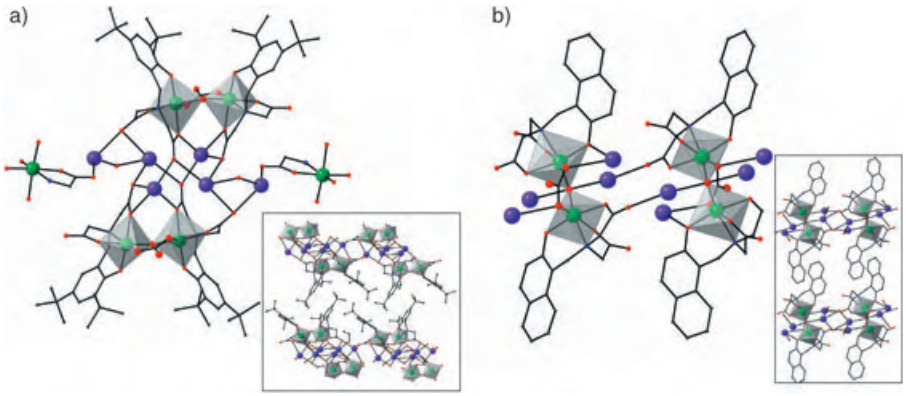

Figure 1. a) Layered arrangement of dinuclear Fe^{III} complexes in **1**. Inset: section of the structure of **1** viewed along the crystallographic *a*-axis. b) Structure of **2** illustrating the straddling of the hydrophilic layer by the dinuclear subunit. Inset: section of the structure of **2** viewed along the crystallographic *a*-axis. Hydrogen atoms and solvent molecules are omitted for clarity; Fe green, O red, N blue, K purple, C dark gray; coordination polyhedra of the Fe centers are shown in gray.

Modification of the tBu$_2$hda ligand by substitution of the *tert*-butyl groups with α,α-dimethylbenzyl groups increases the hydrophobicity of the complexing agent. The compound **3** crystallizes from aqueous systems containing the bc$_2$hda ligand, and dipole–dipole and dipole–cation interactions favor a layered structure similar to **1**. However, **3** has the additional feature of a π-bound potassium ion which is trapped within the hydrophobic part made up of the α,α-dimethylbenzyl groups (Figure 2).[8] This motif is attracting

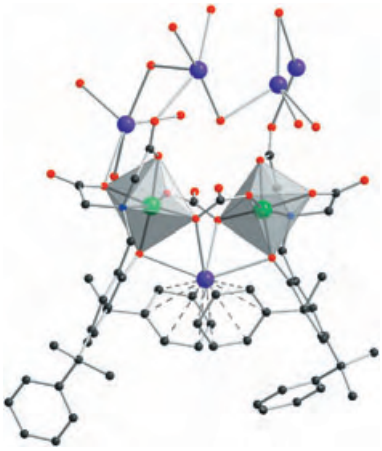

Figure 2. Coordination geometry of the Fe^{III} centers and the cation–π binding of potassium ions in complex **3**. Color code: Fe green, O red, N blue, K purple, C dark gray. Hydrogen atoms and solvent molecules are omitted for clarity.

interest because of its importance in protein dynamics although the near absence of structural evidence has made it difficult to visualize cation–π interactions involving alkali metal cations.[9]

$K_3[Fe_2(\mu\text{-}CO_3)_2(bc_2hda)_2] \cdot 3\,H_2O \cdot EtOH$ **3**

The π-binding of the potassium cation in **3** prompted us to consider further alterations to the ligand. Thus, we chose to introduce carboxylate or sulfonate groups, either of which can be placed at various positions on the ligand. We considered that these functional groups would influence the inorganic structural motif of the coordination assemblies and could create 2D or 3D networks. Introduction of a carboxy group at the 3-position of the naphthyl ring of (2-hydroxynaphthyl)-methylene iminodiacetic acid (hnida) gives the chnida ligand, which stabilizes another novel structural motif. In the resulting compound **4**, the dinuclear Fe^{III} complexes are arranged so that the polar oxo, carbonate, and carboxylate groups together with the water-bridged K$^+$ ions build a honeycomb structure containing channels running parallel to the crystallographic *c*-axis. Each dinuclear unit penetrates a honeycomb wall with the Fe···Fe axis approximately perpendicular to the *c* axis, whereas the naphthalene moieties of the two ligands project into adjacent channels of the lattice, where the naphthalene mean planes make angles of 40.7 and 51.4° to the *c* axis.

$K_6[Fe_2(\mu\text{-}O)(\mu\text{-}CO_3)(chnida)_2] \cdot 13.5\,H_2O$ **4**

The resulting hydrophobic channels are approximately 14 Å in diameter. In the chnida ligand, the carboxy group is positioned adjacent to the phenolic OH group maximizing the amphiphilicity of the ligand. As before, this enables complexes with this ligand to pack into a structure where hydrophobic and hydrophilic regions are segregated. However, in the structure of **4** it is almost as though the bilayer arrangement seen for **1**–**3** has been rolled up, leading to channels which contain the naphthyl residues (Figure 3 a).

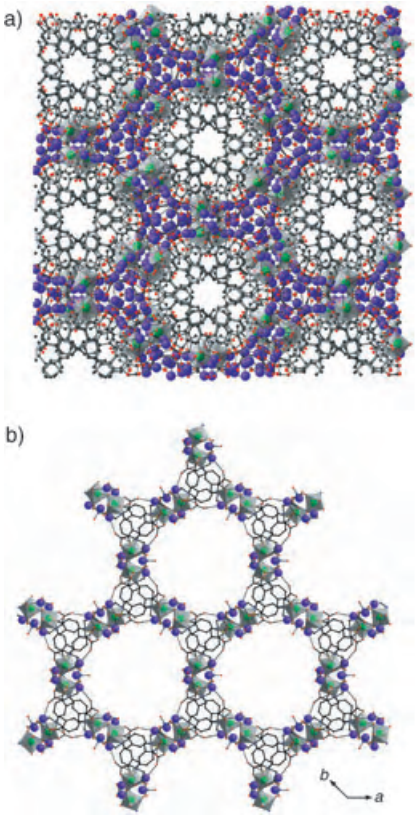

Figure 3. a) Honeycomb structural motif in **4**. Inorganic and organic parts form parallel nanosized channels which run along the crystallographic *c*-axis and which are filled with naphthyl moieties (view in [001] direction). b) Open framework structure in **5** viewed along the crystallographic *c*-axis. Hydrogen atoms, solvent molecules, and one disordered K$^+$ counterion are omitted for clarity; Fe green, O red, N blue, K purple, C dark gray.

This structure is the direct consequence of the introduction of the carboxy group adjacent to the phenolic OH group. This carboxy group does not coordinate to Fe^{III} ions but interacts only with the potassium counterions.

In addition to the single-crystal X-ray structure analysis, we performed high resolution transmission electron microscopy (HRTEM) on powdered samples of **4** to characterize the extended structure of the compound further. Although crystals of **4** are very sensitive to electron-beam-induced damage it was possible to observe areas displaying the expected honeycomb pattern, in good agreement with the crystal structure determination (Figure 4).

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

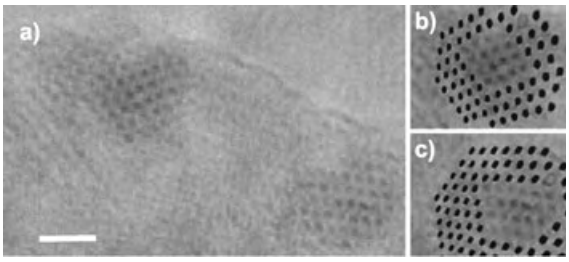

Figure 4. a) TEM image of **4** distinguishing the organic (dark) and inorganic (light) areas (scale bar 10 nm). b), c) Overlay of organic regions of the (110) plane of crystal structure on TEM image. Dot array was generated from the *hkl* file and adjusted for perspective.

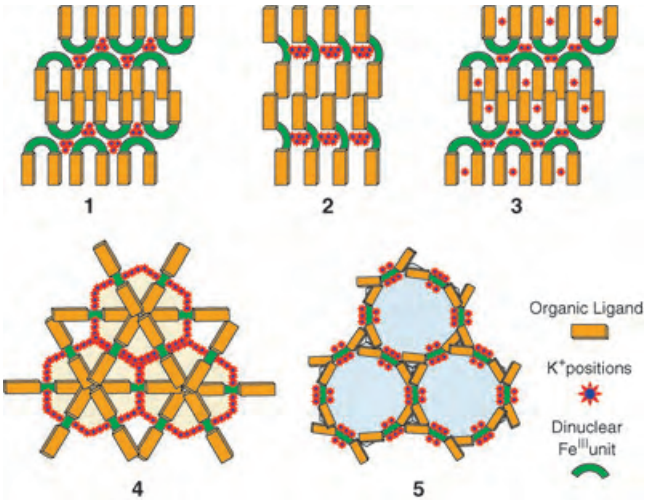
To encourage the formation of materials containing pores or empty channels where the organic ligand is incorporated into an extended framework structure, we introduced a sulfonic acid group in the position *para* to the phenolic hydroxy group of the hda ligand so that the dinuclear unit could pillar between hydrophilic regions of supramolecular structures. This strategy yielded **5** in which five of the potassium cations are strongly bound by the oxo, carbonate, and carboxylate groups around the Fe_2 unit. Each ligand sulfonate group binds to the K^+ counterions of a neighboring dinuclear complex. In the resulting coordination assembly, the dinuclear complexes and K^+ ions form the walls of an open framework honeycomb motif, where the Fe_2 units are aligned within, rather than through the walls, as was found for **4**.



$K_6[Fe_2(\mu\text{-}O)(\mu\text{-}CO_3)(SO_3hda)_2]\cdot 11\,H_2O\cdot 9\,MeOH$ **5**

The aromatic rings of the dinuclear subunits are stacked about the threefold screw (3_2) axes which coincide with the vertices of this hexagonal structure (Figure 3b). The open framework structure has channels with cross-sectional diameter of approximately 9 Å, which contain water, methanol, and the disordered sixth potassium ion. Recently, other hybrid coordination assemblies have attracted interest as new catalytic materials[5e,10] or separation media.[2d,11] Compound **5** is a good example of the application of our concept in the synthesis of closely related compounds and it seems reasonable to expect the tailoring of channel geometry by variation of the dimensions and functionality of the ligand.

Magnetic susceptibility studies show that the dinuclear Fe^{III} units in these compounds are, as expected, fairly strongly antiferromagnetically coupled, presumably with the coupling transmitted through the μ-oxo bridge.[12] As an example, for compound **5** the room temperature χT value is 1.25 $cm^3\,K\,mol^{-1}$ per dinuclear unit (for two uncoupled Fe^{III} ions the value is $\chi T_{theor} = 8.75\ cm^3\,K\,mol^{-1}$) and decreases steeply on lowering the temperature. It then remains constant, but not zero, between 35 and 5 K as a result of the presence of a small amount of paramagnetic impurity (confirmed by magnetization experiments). The data can be reproduced quantitatively using a van Vleck law for a dimer of coupled $S = 5/2$ ions with the best fit for $J = -173 \pm 2\ cm^{-1}$ and allowing for the presence of less than 3% paramagnetic impurity (for full details see the Supporting Information).

The thermogravimetric analyses (TGA) reveal that the coordination assemblies decompose by initial solvent loss (below 150 °C) followed by degradation of the organic ligand at temperatures between 250 and 350 °C. The loss of the structural integrity is accompanied by the formation of potassium oxide and iron oxides. Weight losses at higher temperatures can be attributed to the solid-state reactions of this mixture forming different phases of potassium iron oxides. A detailed account of thermolysis and pyrolysis of the complexes and the structure of the decomposition products will be reported elsewhere. However, it is noteworthy that in the case of **1** we were able to identify $KFeO_2$ and the K-β-ferrite $K_xFe_{22}O_{34}$ ($x = 2$–4)[13] as the main products using X-ray diffraction (XRD) analysis of samples thermolyzed at different, increasing temperatures. $KFeO_2$ and $K_xFe_{22}O_{34}$ ($x = 2$–4) are the only thermodynamically stable ternary compounds in the K_2O-Fe_2O_3 system and usually form by reaction of Fe_2O_3 or Fe_3O_4 with K_2CO_3 or K_2O.[14] Recent work has suggested that the active state of the industrially used Fe_2O_3 dehydrogenation catalyst for the production of styrene from ethylbenzene consists of the $KFeO_2$ and $K_xFe_{22}O_{34}$ ($x = 2$–4) oxides.[15] Since the production of styrene is one of the most important industrial processes and reaches a production level of 20×10^6 tons/year,[16] nanostructured materials containing these oxides are of industrial interest.

In summary, our studies demonstrate that hydroxybenzyl iminodiacetic acid ligands can be used to prepare an unprecedented type of hybrid organic–inorganic network by self-assembly of the dinuclear doubly bridged Fe^{III} subunits and their potassium counterions, resulting in a variety of 3D architectures which are summarized in Scheme 2. The structure of the inorganic hydrophilic zone is strongly influenced by the shape and functionality of the organic ligand providing a means of controlling different motifs of supramolecular coordination assemblies. Selection of the ligand structure and polarity can result in crystalline materials where the packing of hydrophilic and hydrophobic portions differs from a simple bilayer arrangement. This approach has allowed formation of a dense hexagonal array (using the chnida ligand) and a

Scheme 2. Pictograms of structural motifs in the supramolecular coordination networks.

hexagonal open-framework structure containing cylindrical voids (using the SO_3hda ligand). Thermal decomposition of these and similar aggregates, which contain distinct areas of polarity and structure, can lead to unusual oxides whose structures and compositions depend on those of the precursor compound. In particular, we are seeking to prepare nanostructured mixed transition metal oxides whose properties may depart from those prepared by other techniques.

Experimental Section

All ligands were prepared by Mannich reaction between the appropriate phenol or naphthol, iminodiacetic acid and aqueous formaldehyde.[17]

1: Complex **1** was prepared by the reaction of Na_2tBu_2hda (0.198 g, 0.5 mmol) with $Fe(NO_3)_3{\cdot}9H_2O$ (0.202, 0.5 mmol) in a mixture of methanol (20 mL) and ethanol (95%; 30 mL) and subsequent slow addition of (2 M; 1 mL KOH) to the stirred reaction mixture. Blue-purple crystals of **1** were grown by slow evaporation of the ethanol solution. Yield: 72% based on $Fe(NO_3)_3{\cdot}9H_2O$. Elemental analysis (%) calcd for $C_{41}Fe_2H_{63}K_3N_2O_{17}$, which corresponds to the crystallographically determined formula minus one water: C 45.39, H 5.85, N 2.58; found: C 45.66, H 6.41, N 2.83. FTIR: $\tilde{\nu}$ = 3679 (m), 3435 (s, br), 2955 (s), 2868 (w), 2814 (w), 1631 (vs), 1471 (m), 1440 (w), 1413 (w), 1375 (s), 1329 (m), 1308 (m), 1263 (m), 1243 (m), 1207 (m), 1171 (m), 1125 (m), 1085 (w), 1036 (s), 1008 (w), 980 (w), 961 (w), 916 (m) 892 (w), 875 (m) cm^{-1}.

2: Complex **2** was prepared by the reaction of hnida (0.08 g, 0.28 mmol) with $FeCl_3{\cdot}6H_2O$ (0.135 g, 0.5 mmol) in ethanol (95%, 30 mL) in the presence of potassium hydrogen carbonate (0.63 g, 6.3 mmol). Water (3 mL) was then added to assist the dissolution of the potassium hydrogen carbonate. Red-purple crystals of **2** were grown by slow evaporation of the solvent. Yield: 32% based on hnida. Elemental analysis (%) calcd for $C_{35}Fe_2H_{48}K_4N_2O_{22}$: C 37.64, H 4.33, N 2.51; found: C 37.31, H 4.22, N 2.57. FTIR: $\tilde{\nu}$ = 3557 (w), 3417 (s, br), 2967 (w), 2918 (w), 1598 (vs), 1507 (m), 1484 (m), 1460 (s), 1430 (m), 1398 (s), 1363 (s), 1309 (m), 1289 (sh), 1275 (s), 1243 (w), 1224 (w), 1174 (w), 1162 (w), 1144 (w), 1120 (w), 1099 (w), 1071 (m), 1046 (m), 1021 (m), 980 (w), 969 (w), 919 (m), 899 (w), 876 (w), 858 (m), 827 (m), 783 (w), 737 (s), 646 (m), 556 (m), 503 (m), 484 (m) cm^{-1}.

3: Complex **3** was prepared as reported previously.[8]

4: Complex **4** was prepared by the reaction of chnida (0.08 g, 0.24 mmol) with $FeCl_3{\cdot}6H_2O$ (0.135 g, 0.5 mmol) in a mixture of methanol (30 mL) and ethanol (95%; 20 mL) and subsequent slow addition of KOH (2 M; 2 mL) to the stirred reaction mixture. Red crystals of **4** were grown by slow evaporation of the solution. Yield: 36% based on chnida. FTIR: $\tilde{\nu}$ = 3412 (s), 3070 (sh), 2924 (w), 1621 (vs), 1597 (sh), 1558 (sh), 1500 (m), 1447 (m), 1428 (w), 1395 (s), 1365 (sh), 1291 (w), 1272 (m), 1210 (m), 1173 (w), 1154 (w), 1125 (w), 1097 (m), 1049 (w), 1024 (w), 978 (m), 930 (w), 906 (m), 862 (m), 815 (m), 743 (s) cm^{-1}.

5: Complex **5** was prepared by the dissolving of SO_3hda (0.08 g, 0.24 mmol) with $FeCl_3{\cdot}6H_2O$ (0.135 g, 0.5 mmol) in methanol (30 mL) and ethanol (95%; 20 mL) and subsequent slow addition of KOH (2 M; 2 mL) to the stirred reaction mixture. Red-brown crystals of **5** were grown by slow evaporation of the ethanol solution. Yield: 10–20% based on SO_3hda. FTIR: $\tilde{\nu}$ = 3475(br), 2576(m), 1610(s), 1480(s), 1385(s), 1295(s), 1213(s), 1183(s), 1132(s), 1104(s), 1034(s), 977(w), 934(w), 861(w), 794(w), 746(w) cm^{-1}.

Crystallographic data: Data measured on a STOE IPDS diffractometer for **1** and **2** or on a Bruker SMART Apex diffractometer for **4** and **5** at 200 K using graphite-monochromated $Mo_{K\alpha}$ radiation. The structure of **3** has been reported by us previously.[8] Structure solution by direct methods and full-matrix refinement against F^2 (all data) using SHELXTL.[18] Non-hydrogen atoms refined with anisotropic temperature factors apart from some disordered solvent molecules. The hydroxo hydrogen atom in **1** was located and refined, all organic ligand hydrogen atoms were placed in calculated positions. CCDC 262829–262832 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

1: $C_{41}H_{65}Fe_2K_3N_2O_{18}$, 1102.95 $g\,mol^{-1}$, purple-blue block 0.3 × 0.25 × 0.2 mm, T = 200 K, triclinic, $P\bar{1}$, a = 9.7594(8), b = 13.8993(11), c = 18.7162(16) Å, α = 97.662(10)°, β = 100.012(10)°, γ = 93.350(9)°, V = 2469.2(4) $Å^3$, Z = 2, $F(000)$ = 1156, ρ_{calcd} = 1.483 $Mg\,m^{-3}$, $\mu(Mo_{K\alpha})$ = 0.913 mm^{-1}, 16248 reflections measured ($2\theta_{max}$ = 52.0°), of which 9003 unique (R_{int} = 0.0897). 314 parameters, wR_2 = 0.1474, S = 0.921 (all data), R_1 (3984 data with $I > 2\sigma(I)$) = 0.0606.

2: $C_{35}H_{48}Fe_2K_4N_2O_{22}$, 1116.85 $g\,mol^{-1}$, purple block 0.25 × 0.2 × 0.15 mm, T = 200 K, triclinic, $P\bar{1}$, a = 8.6793(7), b = 15.1432(11), c = 17.9198(15) Å, α = 88.492(9), β = 76.093(9), γ = 74.962(9)°, V = 2206.3(3) $Å^3$, Z = 2, $F(000)$ = 1152, ρ_{calcd} = 1.681 $Mg\,m^{-3}$, $\mu(Mo_{K\alpha})$ = 1.121 mm^{-1}, 14611 reflections measured ($2\theta_{max}$ = 52.3°) of which 8112 unique (R_{int} = 0.0279). 625 parameters, wR_2 = 0.1202, S = 0.975 (all data), R_1 (5298 data with $I > 2\sigma(I)$) = 0.0690.

4: $C_{33}H_{49}Fe_2K_6N_2O_{31.5}$, 1324.04 $g\,mol^{-1}$, red cuboctahedron 0.2 × 0.2 × 0.2 mm, T = 200 K, rhombohedral, $R\bar{3}c$, a = 35.3692(10), c = 43.3010(18) Å, V = 46911(3) $Å^3$, Z = 36, $F(000)$ = 2444, ρ_{calcd} = 1.687 $Mg\,m^{-3}$, $\mu(Mo_{K\alpha})$ = 1.132 mm^{-1}, 63861 reflections measured ($2\theta_{max}$ = 52.0°) of which 10213 unique (R_{int} = 0.0798). 741 parameters, wR_2 = 0.4287, S = 1.348 (all data), R_1 (5085 with $I > 2\sigma(I)$) = 0.1294. Several crystals were investigated, and all gave a well-defined rhombohedral cell with systematic absences for $\bar{R}3c$. Structure solution readily gave the Fe_2 dinuclear complex and one or two of the K^+ counterions. However, refinement invariably resulted in high temperature factors for the atoms of the dinuclear unit, and indicated that all but one of the K^+ ions, and all the framework and lattice waters, were badly disordered, resulting in the high R-factors. Twinned refinement[19] in appropriate lower-symmetry rhombohedral or C-centered monoclinic space groups did not improve matters, and the problem is clearly one of disorder rather than (pseudo-)merohedral twinning. The final structure obtained, however, clearly establishes the formulation and the nature of the packing.

5: $C_{32}H_{76}Fe_2K_6N_2O_{40}S_2$, 1539.37 $g\,mol^{-1}$, red-brown prismatic needle 0.40 × 0.18 × 0.18 mm, T = 200 K, trigonal, space group $P3_221$, a = 20.8830(6), c = 12.4648(6) Å, V = 4707.6(3) $Å^3$, Z = 3, $F(000)$ = 2400, ρ_{calcd} = 1.629 $Mg\,m^{-3}$, $\mu(Mo_{K\alpha})$ = 1.026 mm^{-1}, 23724 reflections measured, of which 7108 unique (R_{int} = 0.0440). 332 parameters, wR_2 = 0.1551, S = 1.001 (all data), R_1 = 0.0561 (6232 data with $I > 2\sigma(I)$). One K^+ counterion was 50:50 disordered against a water molecule. One lattice MeOH molecule per asymmetric unit (two per dimer) could be located and refined, but the residual volume is consistent with an overall formulation with seven MeOH per dinuclear unit. Loss of these solvent molecules is facile on removal of crystals from the mother liquor.

Magnetism: The magnetic susceptibility of a polycrystalline powder of **5** was measured between 2 and 300 K with applied magnetic fields of 0.1 and 1 T using a Cryogenic S600 SQUID magnetometer. Data were corrected for the magnetism of the sample holder which was determined separately in the same temperature range and field, and the underlying diamagnetism of the sample was estimated from Pascal's constants. Magnetization measurements were performed on the same sample at 2.7 K with field up to 6.0 T.

Thermogravimetric analysis was performed under flowing N_2 and in a temperature range of 25–1000 °C using Rigaku ThermoPlus TG 8120 or Netzsch STA 409C instruments.

TEM studies were carried out on a JEOL FX2000. The sample was ground to a powder and placed on copper mesh for TEM analysis

[13] All potassium β-ferrite $K_xFe_{22}O_{34}$ ($x = 2$–4) structures are hexagonal and are composed of spinel blocks separated by layers of potassium ions. Depending on the potassium ion content (x), variation in the packing of the spinel units gives a different lattice constant c (23.8 or 35.9 Å with $a = b = 5.9$ Å). In this case the best simulation of the XRD pattern are obtained with $c = 35.9$ Å confirming $x = 4$.[12a]

Directed Evolution

Expanding the Range of Substrate Acceptance of Enzymes: Combinatorial Active-Site Saturation Test**

Manfred T. Reetz, Marco Bocola, José Daniel Carballeira, Dongxing Zha, and Andreas Vogel*

Directed evolution of proteins has emerged as a powerful tool to enhance the stability, activity, and selectivity of enzymes.[1] It involves the proper combination of random gene mutagenesis, expression of thousands of mutant enzymes, and high-

throughput screening.[2] Since structural and mechanistic information is not necessary, the process is fundamentally different from so-called rational design based on site-specific mutagenesis.[3] We have previously applied directed evolution to the creation of enantioselective lipases,[4] epoxide hydrolases,[5] and monooxygenases,[6] and other groups have contributed in this field as well.[1,7] The combination of rational design and random mutagenesis at defined positions in the form of focused libraries[1] has also been employed with the aim of enhancing ligand binding,[8] increasing catalytic activity,[1,9] or influencing enantioselectivity.[4b,10]

A major limitation in exploiting enzymes as catalysts in synthetic organic chemistry is the often encountered limited degree of substrate acceptance.[11] Especially in industrial applications, "methods are desired that have a broad substrate spectrum".[11a] In addition to the use of libraries focusing on a predefined region[1,9] of an enzyme, directed evolution through such standard techniques as the error-prone polymerase chain reaction (epPCR), saturation mutagenesis, and/or DNA shuffling can in principle be employed to solve this problem,[1] and successful cases with regard to nonaccepted substrates have been reported.[1,9,12]

Herein, we describe a method for expanding the scope of substrate acceptance of a given enzyme with the aim of including a wide range of structurally different compounds. Two straightforward steps are required: the design and the generation of relatively small focused libraries of enzyme mutants produced by randomization at several sets of two spatially close amino acid positions around the active site. The choice of two amino acids which are spatially close to one another allows for potential synergistic conformational effects arising from side-chain orientations, an unpredictable phenomenon which cannot be brought about by single-site saturation mutagenesis.[13] The optimal choice of the respective pairs of amino acids is guided by the 3D structure of the wild-type (WT) enzyme with a bound substrate. Geometric inspection allows the definition of sites at which the side chains of the individual amino acids in each pair point toward the binding site of the WT enzyme. On the basis of the secondary structure of an enzyme,[14] it is clear that, for a given pair of spatially as close as possible amino acids in which the side chains point in the direction of the binding site, the following geometric relation pertains: If one member of the pair occurs in the protein sequence at position n, then the second one is found at a sequence of (n+1) in a loop, (n+2) in a β sheet, (n+3) in a 3_{10} helix, and (n+4) in an α helix (Figure 1).[15]

Complete randomization at each pair is then performed in a process that we call the combinatorial active-site saturation test (CAST). Our strategy constitutes a practical compromise between conventional saturation mutagenesis at single sites and simultaneous randomization at multiple sites by using large cassettes. It ensures an appreciable degree of structural diversity and therefore a reasonable chance of finding useful catalysts arising from the $20^2 = 400$ theoretically different mutants in each library, a number which corresponds to $32^2 = 1024$ different codons when using NNK degeneracy (N: any nucleotide; K: G or T).[1] This is in contrast to the limited structural variation of the 20 expected single mutants

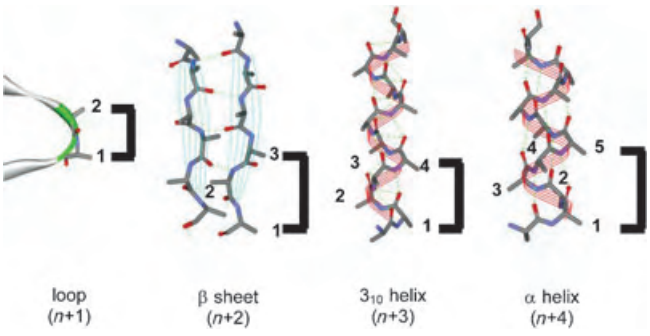

Figure 1. Structural guides in designing libraries of mutant enzymes for CASTing according to the secondary structure of proteins.

(32 codons) in the case of randomization at only single sites,[1,16] a value which may limit the probability of discovering hits. The second important feature of the CAST approach is the limited screening effort. To achieve 95% probability of mutant coverage in the case of randomization at two amino acid positions, about 3000 clones need to be screened (oversampling).[17] In contrast, a focused cassette involving simultaneous randomization at four amino acid sites,[4b] for example, produces theoretically a library of 160000 different mutants, a number requiring $32^4 = 1048576$ codons. This would require a huge screening effort comprising $> 3 \times 10^6$ clones for 95% coverage.[17] Although screening only a small fraction of such a focused library can actually lead to the discovery of positive hits,[4b,10a,10c] the overall process entails uncertainty with respect to the statistical possibility of missing positive mutants.

In a model study, we applied CASTing to expand the substrate acceptance of the lipase from *Pseudomonas aeruginosa*[18] as a catalyst in the hydrolysis of carboxylic acid esters.[4,19] In doing this, one can focus either on the carboxylic acid part or on the alcohol part of the ester (or both). The WT enzyme catalyzes the hydrolysis of triglycerides or fatty acid esters such as palmitic acid *p*-nitrophenyl ester but not of more sterically demanding substrates; not even benzoic acid esters are accepted. Since this constitutes a particularly difficult problem, we focused CASTing on this part of the enzyme. The lipase consists of 285 amino acids, with Ser 82 being the site at which the rate-determining formation of the intermediate oxyanion occurs.[18]

Upon applying the above guidelines (Figure 1) to the crystal structure of the lipase from *Pseudomonas aeruginosa*, solved by Dijkstra et al. in 2000[20] and partially reproduced in Figure 2, the following amino acid pairs were defined: Met 16/Leu 17, Leu 118/Ile 121, Leu 131/Val 135, Leu 159/Leu 162, and Leu 231/Val 232. Five libraries, A–E, respectively, were then created separately by complete saturation, that is, simultaneous radomization at each pair.

About 3000 bacterial colonies from each of the five libraries were harvested on agar plates by a colony picker and deposited in the deep wells of microtiter plates containing Luria–Bertani broth. Following growth of the bacteria and expression of the enzyme, aliquot portions of the lipase-containing supernatants were used to catalyze the hydrolysis of a set of 11 structurally different esters **1**–**11**. In all cases the

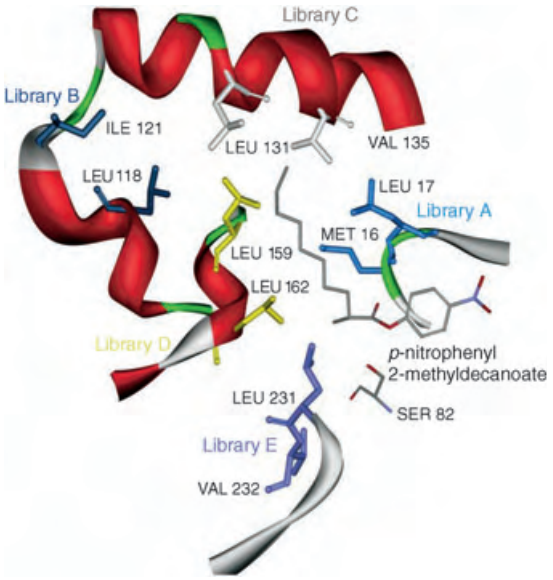

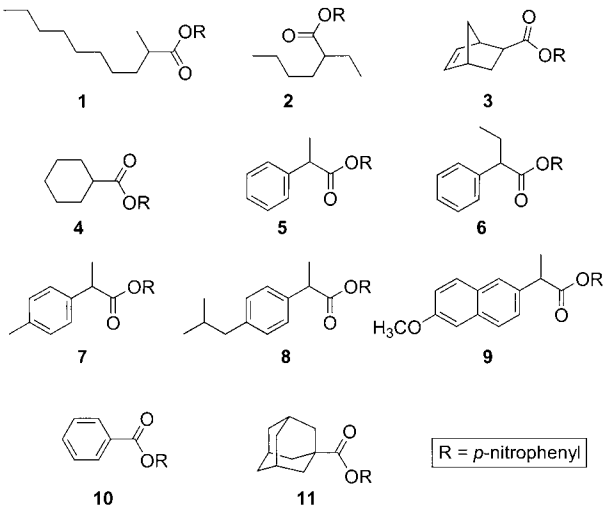

Figure 2. CASTing of the lipase from *Pseudomonas aeruginosa* leading to the construction of five libraries of mutants (A–E) produced by simultaneous randomization at two amino acid sites. (For illustrative purposes, the binding of substrate **1** is shown.)

p-nitrophenyl ester was chosen because the hydrolysis would liberate *p*-nitrophenol which can be monitored easily by UV/Vis spectroscopy.[2,4] A standard UV/Vis plate reader was used to record each reaction rate as measured by the time-resolved appearance of the *p*-nitrophenolate absorption peak at 405 nm (8 min per 96- or 384-well microtiter plate). Parts of the data were checked by GC, and the agreement was found to be excellent. The overall effort in studying the required 165 000 reactions (5 libraries × 3000 clones × 11 substrates) is actually limited, because the process of gene mutagenesis, gene expression, and harvesting of mutants needs to be performed only once.

The results of this multisubstrate screening are remarkable in several respects. Only a part of the data is shown here. Mutants were identified that catalyze the hydrolysis of substrates **1**–**11**; these substrates are either not accepted at all by the WT enzyme or the mutants were found to be considerably more active than the WT enzyme. Figure 3 summarizes the relative reaction rates of WT- and mutant-catalyzed hydrolyses.[21] The eight most important hits (mutants ACA5, A16D8, A2D3, D1A12, D1B10, D1C4, D1F8, and D1E1) originate from libraries A or D, with the latter providing the majority of improved mutants.

The data show that for each substrate, **1**–**11**, one or more mutants were found which lead to a pronounced increase in hydrolysis rate. This means that broad substrate acceptance

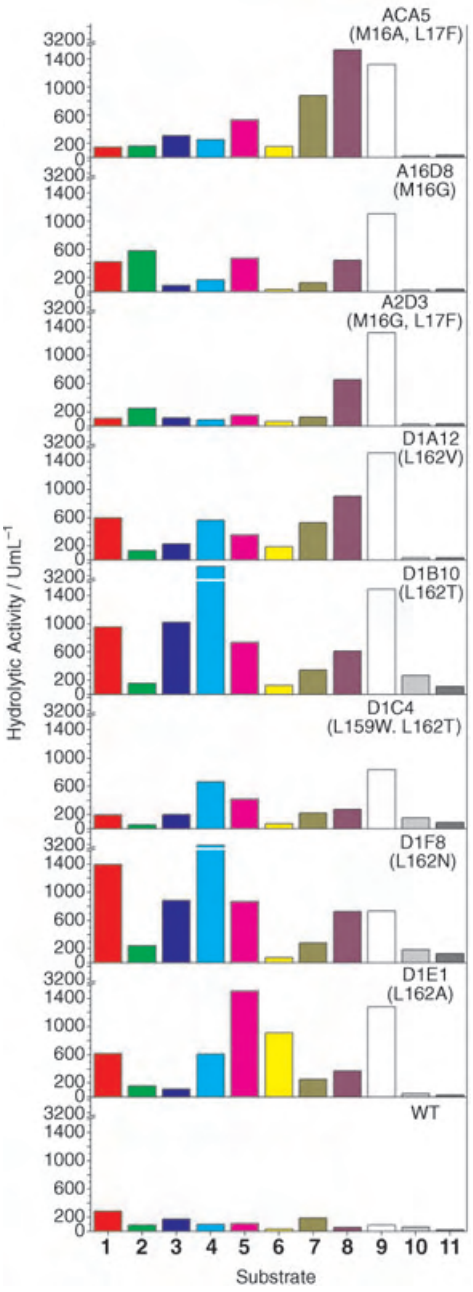

Figure 3. Substrate profiles of lipase variants produced by CASTing. Hydrolytic activities of selected mutants and the WT enzyme were measured photometrically in a continuous assay by following the absorbance at 405 nm for 8 min in a microtiter plate.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

has been achieved. Even such bulky substrates as the Naproxen ester **9** are hydrolyzed rapidly, in this case by at least six different mutants. In contrast, the lipase from *Candida rugosa* shows much lower low activity as do other commercial lipases.[22] The adamantyl carboxylic acid ester **11** is a special case. It is not accepted by the WT enzyme, a result that contrasts with the catalytic effect of mutants D1B10, D1C4, and D1F8, which lead to clearly detectable, although low, turnover. In this case further improvement is necessary.

The eight mutants identified by the screening process were sequenced.[23] Again, the results are remarkable. Firstly, in three cases the mutants are characterized by two amino acid substitutions, whereas in five cases single mutations are involved (Table 1). Some of the largest effects are observed in

Table 1: Active mutants of the lipase from *Pseudomonas aeruginosa* created by CASTing.

Mutant	Library[a]	Mutations
ACA5	A	Met16Ala, Leu17Phe
A16D8	A	Met16Gly
A2D3	A	Met16Gly, Leu17Phe
D1A12	D	Leu162Val
D1B10	D	Leu162Thr
D1C4	D	Leu159Trp, Leu162Thr
D1F8	D	Leu162Asn
D1E1	D	Leu162Ala

[a] Library A: simultaneous randomization at Met16 and Leu17; Library D: simultaneous randomization at Leu159 and Leu162; see Figure 2.

the double mutants, which would not have been discovered by conventional saturation mutagenesis. Moreover, the simple expectation that the introduction of a sterically smaller amino acid creates more space for a bulky substrate to fit properly is not fulfilled in all cases, a fact making a detailed interpretation of such subtle effects difficult at this time. The mutation Leu17Phe, which occurs in two different mutants, is an example. It is also interesting to note that amino acid 162 is a particularly sensitive hot spot (Table 1), in line with the results of earlier directed-evolution studies.[4] We conclude that CASTing is a practical first step in a directed-evolution project with the aim of expanding the range of substrate acceptance. Further improvements can be envisioned in an evolutionary sense by recasting, by combining the mutations of two hits, or by applying the usual mutagenesis methods, such as epPCR or DNA shuffling, which cover the whole gene.[1]

Finally, we note that several of the substrates are chiral, which means that kinetic resolution of the racemates is relevant. Although we have not (yet) performed systematic studies regarding this point, it appears that CASTing can indeed be used to evolve enantioselectivity as well, which is not surprising. For example, mutant D1A12 catalyzes the hydrolytic kinetic resolution of ester **6** with a selectivity factor of $E = 20 \pm 5$ and mutant ACA5 performs the same reaction with $E = 25 \pm 5$, both in favor of the *S* substrate. The WT enzyme does not accept this substrate to any appreciable extent, which means that enantioselectivity could not be measured reliably.

In summary, a practical method (CAST) for solving the long-standing problem of wide substrate acceptance of enzymes has been developed. CASTing combines the features of rational design and combinatorial amino acid randomization at focused sites. It is different from previous focused libraries[1,9] in that a complete set of pairs of amino acids around the bound substrate is considered. This enables the systematic creation of relatively small libraries of mutants, the screening of which by currently available assays leads to positive hits and consequently to the identification of the critical regions around the active site that are crucial for substrate acceptance. We believe that the method can also be considered when attempting to improve the catalytic profile of enzymes in general, for example, in the enhancement of activity and perhaps stability, as well as regio- and stereoselectivity. It is also relevant when attempting to convert a given enzyme into a different type of catalyst.[12] Therefore, CASTing may well constitute a useful alternative to the usual epPCR as the initial step in directed-evolution studies.

[15] These guidelines are derived from ideal secondary structural units. If in a given case the latter are not ideal, as, for example, in a kinked helix, then additional positions need to be considered. In the case of a kinked helix, for example, it may be a sequentially neighboring amino acid (n+1). It is mandatory to include such structural aspects when designing combinatorial active-site saturation test libraries, that is, the shape of the binding pocket serves as a guide.

[19] We thank K.-E. Jaeger for providing the lipase-expression system.[18]

[20] M. Nardini, D. A. Lang, K. Liebeton, K.-E. Jaeger, B. W. Dijkstra, *J. Biol. Chem.* **2000**, *275*, 31219 – 31225.

[21] Because of the instability of the lipase from *Pseudomonas aeruginosa*,[18] it was not possible to purify mutants and to perform detailed kinetic studies. A previous kinetic study was performed by using the supernatants and assuming similar amounts of enzyme expressed and secreted (M. T. Reetz, S. Wilensek, unpublished results; see also: M. T. Reetz, *Tetrahedron* **2002**, *58*, 6595 – 6602). To lend support to this assumption, we measured the lipase activity towards the "natural" compound palmitic acid *p*-nitrophenyl ester as a reference substrate. All of the mutants of the present study showed similar activities towards this reference substrate but slightly lower activities relative to the WT enzyme. Therefore, the low activities of the WT enzyme towards the different substrates in Figure 3 are not because of a lower expression rate. This was confirmed by sodium dodecylsulfate PAGE analysis. This means that the profiles of the mutants reflect inherent activity enhancements.

[22] A comparative study encompassing various substrates and lipases is underway, as are CASTing experiments on commercially available lipases that have higher thermal stability than the lipase from *Pseudomonas aeruginosa*.

[23] None of the variants contain additional mutations because of the PCR.

Fractal Iron Oxide

Single-Crystal Dendritic Micro-Pines of Magnetic α-Fe_2O_3: Large-Scale Synthesis, Formation Mechanism, and Properties**

Minhua Cao, Tianfu Liu, Song Gao, Genban Sun, Xinglong Wu, Changwen Hu, and Zhong Lin Wang**

Hierarchical self-assembly of nanoscale building blocks (nanoclusters, nanowires, nanobelts, and nanotubes) is a technique for building functional electronic and photonic nanodevices.[1,2] Fractal structures are common in nature across all length scales, from self-assembled molecules, to the shapes of coastlines, to the distribution of galaxies, and even to the 3D shapes of clouds. On the nanoscale, dendritic fractals are one type of hyperbranched structure which are generally formed by hierarchical self-assembly under non-equilibrium conditions.[3,4] Investigation of hierarchically self-assembled fractal patterns in chemical systems has shown that the distinct size, shape, and chemical functionality of such structures make them promising candidates for the design and fabrication of new functional nanomaterials,[5] but it is challenging to develop simple and novel synthetic approaches for building hierarchically self-assembled fractal architectures of various systems.

Magnetic nanomaterials have been the subject of increasing interest due to their physical properties and technological applications.[6–8] In the past few years, research has focused primarily on zero- and one-dimensional (1D) magnetic nanomaterials such as magnetic metals, alloys, and metal oxides and has led to substantial advances including the assembly of 2D or 3D superlattices from spherical nanoparticles or nanorods.[9–14] However, to the best of our knowledge, the hierarchical self-assembly of magnetic nanomaterials has not been reported. Here we present the spontaneous, large-scale, hierarchical self-assembly of dendritic nanostructures of magnetic Fe_2O_3 (so-called micro-pine structure). The α-Fe_2O_3 micron-pine dendrites were synthesized by hydrothermal reaction of $K_3[Fe(CN)_6]$ in aqueous solution at suitable temperatures. The method is based on the weak dissociation of $[Fe(CN)_6]^{3-}$ ions under hydrothermal conditions. The resulting structures display exquisite fractal features, which morphologically resemble a type of pine tree. The structure was formed as a result of fast growth along six crystallographically equivalent directions, and this process is different from the reported formation mechanism of general fractal structures. The magnetic properties of the nanostructure show a lower Morin transition temperature of 216 K. The reported structures could have important applications in biomedical science and magnetism.

The micro-pines were synthesized on a large scale and in high purity. Figure 1 shows typical SEM images of α-Fe_2O_3 micro-pine dendrites obtained with a $K_3[Fe(CN)_6]$ concentration of 0.015 M at 140 °C. The low-magnification image in Figure 1a shows that the product consists almost entirely of such dendritic structures, and this indicates the high yield and good uniformity achieved with this approach. The high-magnification images in Figure 1b and c show the morphology of a single dendrite in two opposite directions. They reveal a clear and well-defined dendritic fractal structure with a pronounced trunk consisting of corrugations and highly ordered branches distributed on both sides of the trunk. Figure 1d shows striking periodic corrugated structures on the trunk of a single dendrite. The lengths of the dendrite trunks are 3–5 μm, and those of the branch trunk range from 50 nm to 1.5 μm. Note that the protrusion direction of the dendrite trunk and those of the branches are opposite, as is clearly shown by the SEM images (Figure 1b and c), and all dendrites have similar structure. The micro-pine dendrites were shown by powder XRD (Figure 1e) to consist of pure α-Fe_2O_3 phase (hematite), which has a rhombohedral structure with lattice parameters of $a = 0.50355$ and $c = 1.3747$ nm. The XRD peaks are labeled by using the three- and four-index systems, as for hexagonal nanostructure. The four-index system facilitates the discussion below.

The phase composition is further supported by the room-temperature Mössbauer spectrum (Figure 1f), which shows a single sextet with an isomeric shift of 0.44 mm s^{-1}, a quadrupole splitting of -0.23 mm s^{-1}, and a hyperfine field of 516.8 KOe and thus provides clear evidence for the presence of α-Fe_2O_3 rather than γ-Fe_2O_3 or Fe_3O_4.[15] Moreover, the results of many experiments show that this approach has excellent reproducibility, and the resulting structures are

highly stable, without morphological or compositional change over several months when stored in air.

The dendrite micro-pines have a single-crystalline structure. Figure 2a shows a TEM image of a micro-pine. The TEM observations revealed that the micro-pine dendrites occasionally show a sixfold-symmetric structure (Figure 2b), like a snowflake. Further structural characterization of the dendrite was carried out by high-resolution TEM (HRTEM). Figure 2c–g show HRTEM images taken from the areas labeled c–g in Figure 2a; they respectively show the lattice structures at the tip of the dendrite, the trunk of the dendrite, the tip of the dendrite branch, the trunk of the dendrite branch, and the junction between the trunk of the dendrite and that of the dendrite branch. They all show clear lattice fringes that indicate single-crystallinity of the entire dendrite structure. The lattice spacing of 2.5177 Å between adjacent lattice planes in each of these images corresponds to the distance between two $\{11\bar{2}0\}$ crystal planes. The selected-area electron diffraction (SAED) pattern (Figure 2g) taken from the entire dendrite clearly shows a single-crystalline structure. The diffraction pattern indicates that the dendrite is oriented along [0001] with the three branches along $[10\bar{1}0]$ (or [100]), $[1\bar{1}00]$ (or $[1\bar{1}0]$), and $[0\bar{1}10]$ (or $[0\bar{1}0]$) (Figure 2a). Thus, the sixfold-symmetric structure shown in Figure 2b is a result of growth along $\pm[10\bar{1}0]$, $\pm[1\bar{1}00]$, and $\pm[0\bar{1}10]$.

The reaction temperature and the concentration of $K_3[Fe(CN)_6]$ significantly affect the morphology of the product. For example, when the temperature was increased from 140 to 200 °C while keeping the concentration of $K_3[Fe(CN)_6]$ constant at 0.015 M, the morphology of the sample changed continuously from hyperbranched dendrites at 140 °C (Figure 3a) to slightly branched dendrites at 170 °C (Figure 3b), and finally nanorod-branched dendrites at 200 °C (Figure 3c), somewhat similar to ZnO nanowire comb structures.[16] The reaction temperature must be higher than 140 °C, otherwise the reaction is very slow. When the concentration of $K_3[Fe(CN)_6]$ was varied between 0.005 and 0.025 M while maintaining a constant reaction temperature of 140 °C, α-Fe_2O_3 micro-pine dendrites such as that shown in Figure 2a were the major product. However, on gradually increasing the concentration of $K_3[Fe(CN)_6]$ while maintaining the reaction temperature at 140 °C, a continuous transition from thin to thick nanorod-branched dendrites was observed. Figure 3d–f show TEM images of samples that were synthesized at concentrations of $K_3[Fe(CN)_6]$ of 0.04, 0.06, and 0.1 M, respectively. The higher the concentration of $K_3[Fe(CN)_6]$, the thicker the nanorod branches of the dendrites. These results suggest that it is possible to control and tune the shape of α-Fe_2O_3 dendritic nanostructures by controlling the kinetic parameters of the reaction process, that is, temperature and concentration.

The formation of the dendrites could be explained by the model proposed in Figure 4. From the crystal structure, $\langle 10\bar{1}0 \rangle$ are six equivalent directions. For reasons of spatial confine-

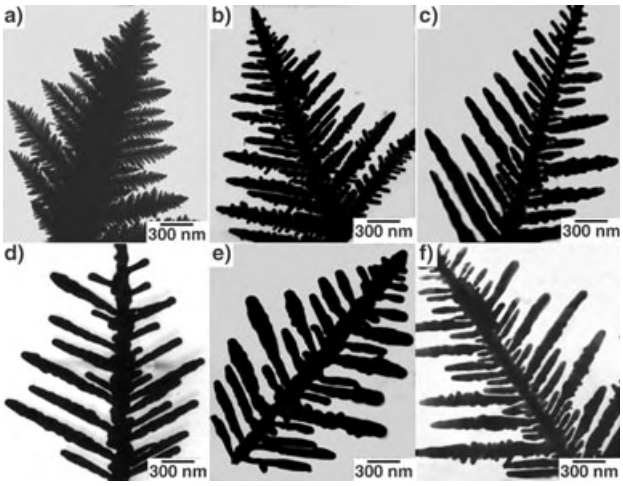

Figure 3. Evolution of crystal shape under different reaction conditions. a–c) TEM images of α-Fe_2O_3 dendrites obtained with a concentration of $K_3[Fe(CN)_6]$ of 0.01 M and reaction temperatures of 140, 170, and 200 °C, respectively. d–f) TEM images of α-Fe_2O_3 dendrites obtained at a reaction temperature of 140 °C and concentrations of $K_3[Fe(CN)_6]$ of 0.04, 0.06, and 0.1 M, respectively.

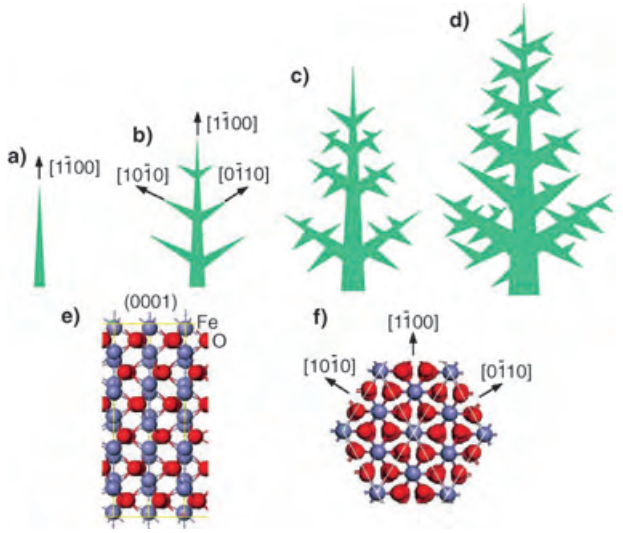

Figure 4. Proposed formation process of the micro-pine dendrite structure by fast growth along the six crystallographically equivalent directions $\langle 10\bar{1}0\rangle$.

ment, one of the directions, for example, $[1\bar{1}00]$, initiates fast growth, and formation of a needle is possible if the growth along $[1\bar{1}00]$ is much faster than along the other directions (Figure 4a). Subsequent growth along the other two crystallographically equivalent directions, $[10\bar{1}0]$ and $[0\bar{1}10]$, leads to the formation of main and possibly symmetric branches on both sides (Figure 4b). As growth continues, each side branch can initiate growth along $\pm[0\bar{1}10]$ and $\pm[10\bar{1}0]$ to form minibranches (Figure 4c). With further growth, all of the branches become thicker and finally interconnected (Figure 4d), and form the micro-pine dendrite structure observed in Figure 1. If growth is symmetric along the six crystallographically equivalent directions $\langle 10\bar{1}0\rangle$, a sixfold-symmetric "snowflake" structure would be formed (see Figure 2b).

To understand the reasons why the six $\langle 10\bar{1}0\rangle$ directions are the directions of fastest growth, we start from the crystal structure of hematite. Figure 4e shows a projection of the crystal structure along $[2\bar{1}\bar{1}0]$, which is parallel to the *c* plane. It is apparent that the Fe^{3+} and O^{2-} ions are arranged alternatively parallel to the *c* plane, which is thus terminated with either Fe^{3+} or O^{2-} and has a net ionic charge on the surface (so-called polar surface). Therefore, during synthesis in solution, the *c* plane will be immediately covered by adsorbing molecules to neutralize the ionic charges, which also terminate growth along [0001]. Therefore, the possible structure is a platelet parallel to the (0001) plane. On the other hand, the six crystallographically equivalent planes $\{2\bar{1}\bar{1}0\}/\{10\bar{1}0\}$ are neutral surfaces and are the most typical low-energy facets for a hexagonal crystal lattice (Figure 4f). Growth parallel to the *c* plane tends to enlarge the surfaces of $\{2\bar{1}\bar{1}0\}/\{10\bar{1}0\}$ and leads to the formation of side branches that are dominated by $\{2\bar{1}\bar{1}0\}$ and $\{10\bar{1}0\}$ surfaces.

The magnetic behavior of α-Fe_2O_3 dendritic micro-pines, which is of importance for practical applications, was investigated for the sample obtained with a $K_3[Fe(CN)_6]$ concentration of 0.015 M at 140 °C (Figure 1). The variable-temperature (5–300 K) magnetic susceptibility (Figure 5a) displays the characteristic behavior for α-Fe_2O_3 but with a lower

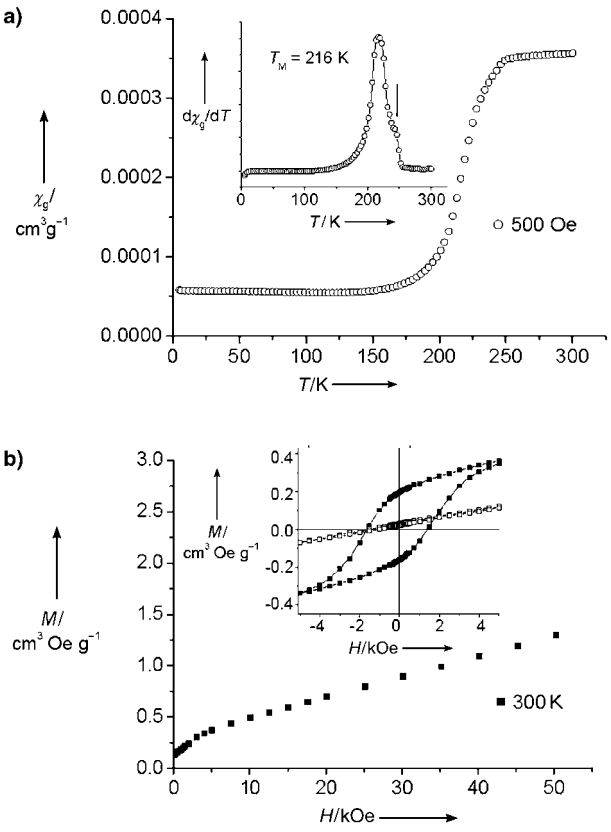

Figure 5. Magnetic measurements for the sample prepared with a $K_3[Fe(CN)_6]$ concentration of 0.015 M at 140 °C. a) Temperature dependence of magnetic susceptibility. b) Field dependence of magnetization at 5 (□) and 300 K (■).

Morin transition temperature T_M of 216 K, which is determined by the sharp peak in the $d\chi_g/dT$ curve. Normally bulk hematite has the Morin transition from the low-temperature antiferromagnetic phase to a weakly ferromagnetic phase at 260 K, and it was documented that annealing led to an increase in T_M for small-sized hematite.[17] The decrease in T_M here may result from some lattice strain and defects in the dendrites obtained by low-temperature hydrothermal synthesis. Superparamagnetic phenomena were not found for the sample, since the sizes of the branch trunk are rather large (50 nm to 1.5 μm) compared to the single-domain size of hematite. The shoulder around 243 K in the $d\chi_g/dT$ curve may indicate the presence of a larger trunk with higher T_M. The field dependence of the magnetization at 300 and 5 K (Figure 5b) confirm the antiferromagnetic state at low temperature and weak ferromagnetism above T_M. The coercive force at 300 K of 1510 Oe is larger than that of 1080 Oe for spherical hematite with a diameter of 160 nm, which might be due to the shape anisotropy of the dendrites.[17]

We recently employed a soft-templating route for fabricating well-crystallized 1D nanostructures based on self-assembly of surfactants and inorganic precursors.[18–20] However, the disadvantage of this method is that the presence of the surfactants can easily result in the formation of byproducts, which may limit their applications. In the present study, we emphasize the role of the $K_3[Fe(CN)_6]$ complex as a single precursor in the synthesis of nanomaterials. $K_3[Fe(CN)_6]$ plays a crucial role in the formation of dendritic fractal structures; if other iron sources such as $FeCl_3$, $Fe(NO_3)_3$, and $Fe_2(SO_4)_3$, are used, even under the same reaction conditions, only particles are observed instead of micro-pine dendrites. $[Fe(CN)_6]^{3-}$ ions are very stable ($K_s = 1.0 \times 10^{42}$) in aqueous solution at room temperature, and almost no free Fe^{3+} ions can be detected. However, in our case, we believe that α-Fe_2O_3 formation proceeds through three steps [Eq. (1)] under the hydrothermal conditions: first, $[Fe(CN)_6]^{3-}$ ions dissociate slowly into Fe^{3+} ions; second, the Fe^{3+} ions are subsequently hydrolyzed in aqueous solution to form FeOOH or $Fe(OH)_3$; and finally, the resulting FeOOH or $Fe(OH)_3$ decompose into α-Fe_2O_3. This growth process might be determined by the first step because of the weak dissociation tendency of $[Fe(CN)_6]^{3-}$ ions [Eq. (1)].

$$[Fe(CN)_6]^{3-} \rightleftharpoons Fe^{3+} \rightarrow FeOOH/Fe(OH)_3 \rightarrow \alpha\text{-}Fe_2O_3 \quad (1)$$

Dendritic fractals of several materials have been found and investigated.[21–27] It is generally accepted that fractal aggregation arises in situations far from thermodynamic equilibrium where high driving forces lead to the generation of rough crystallites and random association.[24] In the past few years the model known as diffusion-limited aggregation (DLA) has been successfully developed to interpret this ramified growth of different systems controlled by diffusive processes.[28] In our system, the formation of micro-pine dendrites of α-Fe_2O_3 is a new growth process in which fast growth along six crystallographically equivalent directions forms single-crystal dendrites or snowflakelike structures.

We have described a distinct type of hierarchical α-Fe_2O_3 micro-pine dendrite. Formation of such structures requires a suitable iron complex precursor that slowly dissociates to yield Fe^{3+} ions under the hydrothermal conditions. Our experimental method also provides a simple and facile route for the preparation of α-Fe_2O_3 nanostructures, which could have important applications in biomedical science due to the biodegradability of iron oxide. It could also be a general approach for the large-scale, high-purity growth of dendritic fractal structures of a wide range of materials.

Experimental Section

α-Fe_2O_3 micro-pine dendrites were synthesized by hydrothermal reaction of $K_3[Fe(CN)_6]$ in aqueous solutions at suitable temperatures. In a typical synthesis, $K_3[Fe(CN)_6]$ was dissolved in distilled water to form a clear solution of a certain concentration, which was placed in a Teflon-sealed autoclave and maintained at a given temperature for 2 d. The red product was isolated by centrifugation, repeatedly washed with distilled water and absolute ethanol, and dried at 50 °C in air. The concentration of $K_3[Fe(CN)_6]$ was varied in the range from 0.005 to 0.1 M, and the reaction temperature from 140 to 200 °C.

X-ray diffraction (XRD) was performed on a Japan Rigaku D/max γA X-ray diffractometer with graphite-monochromatized $Cu_{K\alpha}$ radiation ($\lambda = 0.154178$ nm). A JEOL JEM-2010F transmission electron microscope operating at 200 kV accelerating voltage was used for TEM (transmission electron microscopy) analysis. Scanning electron microscopy (SEM) was performed with an Amray 1910FE microscope. The Mössbauer spectrum was recorded on a conventional Mössbauer spectrometer with a room-temperature ^{57}Co source (Rh matrix) in transmission geometry. Magnetic measurements were performed on a Quantum Design MPMS-XL5 SQUID magnetometer.

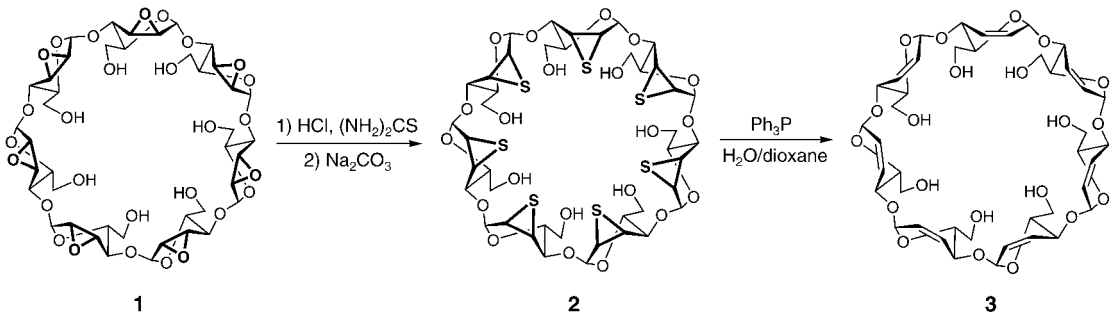
Non-Natural Cyclodextrins

Synthesis of a Cycloallin Derivative from β-Cyclodextrin: Heptakis(2,3-dideoxy-2,3-epithio)-β-cycloallin**

*Makoto Fukudome, Tomonori Shiratani, Stefan Immel, Yasuyoshi Nogami, De-Qi Yuan, and Kahee Fujita**



Macrocyclic molecules that comprise several subunits in a circular array exhibit novel functions that are otherwise not observed in the individual units. Many host molecules that consist of several identical functional subunits, such as cyclodextrins, cyclophanes, and their related natural and artificial macrocycles, have been prepared by enzymatic or synthetic methods and have developed the concept of artificial molecular recognition and catalysis.[1] Cyclodextrins, in particular, have been the leading compounds from the initial stage of this research. Despite extensive studies on the functionalization of cyclodextrins for diverse purposes such as the development of artificial receptors and enzymes, their modification has been limited mostly to their primary hydroxy groups while secondary sites have received much less attention.[2] Moreover, successful studies on complete modifications at the secondary sites are rare as the modifications on 2-OH or 3-OH do not proceed selectively and are accompanied inevitably by products of either over- or under-modification. Only per(3,6-anhydro)-[3] and per(2-*O*-tosyl)-cyclodextrins,[4] per(2,3-anhydro)-cyclomannins **1** (see Scheme 1),[4,5] cycloaltrins,[6] per(3-amino-3-deoxy)-β-cycloaltrin,[7] and per(3-deoxy)-cyclomannins[8] are available by the selective modifications of cyclodextrins at the present time. However, to the best of our knowledge, the preparation of a cycloallin family has not been studied as yet.

Here, we report the first successful one-pot preparation of a novel type of cycloallin derivative, **2**, from cyclomannin derivative **1**, which itself is obtained in three steps from β-cyclodextrin (Scheme 1). The synthesis is as simple as heating an aqueous acidic solution of **1** at 90 °C for 30 min followed by stirring at room temperature under alkaline conditions. It is quite astonishing that these simple reaction conditions not only ensure a complete conversion of the seven epoxide

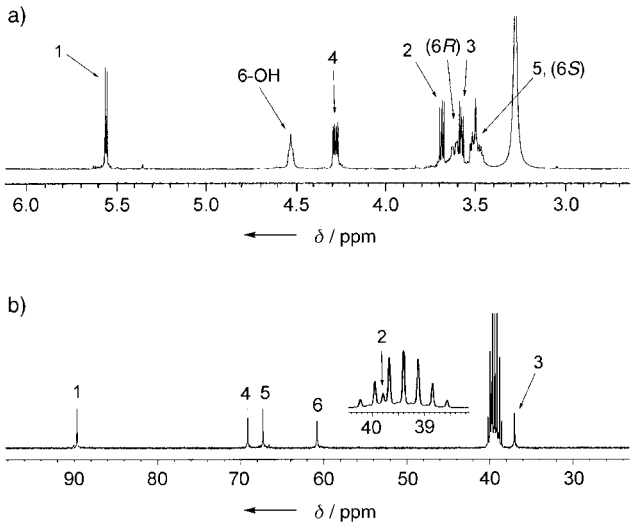
Scheme 1. Preparation of **2** from a cyclodextrin and its conversion into olefin **3**.

residues to episulfides but also guarantee the inversion of configuration at all the subunits, as revealed by the structural analysis of **2**.

The assignment of the NMR signals of **2** (Figure 1) relied on ^{1}H,^{1}H and ^{1}H,^{13}C COSY NMR spectra and indicates that **2** consists of 2,3-dideoxy-2,3-epithioallopyranose units. The



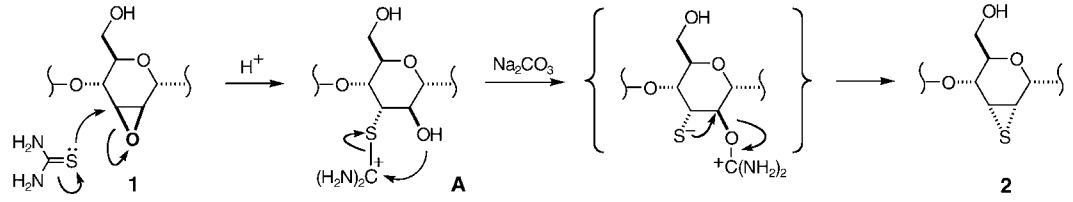


Figure 1. a) ^{1}H and b) ^{13}C NMR spectra of **2** measured in [D_6]DMSO.

remarkable upfield shifts of signals for both C-2 and C-3 ($\Delta\delta_{C2} = 8.9$ ppm and $\Delta\delta_{C3} = 16.1$ ppm relative to the corresponding signals for **1** suggest the replacement of all the oxygen atoms of the epoxide by sulfur substituents. The time-of-flight (TOF) mass spectrum of **2** showed a parent-ion peak for $[M+Na^+]$ at $m/z = 1143$, which is consistent with the molecular ion of **2** and strongly supports the above structural assignment.

The large coupling constant $J_{1,2} = 5.0$ Hz implies that the epithio groups are of allo-type rather than manno-type, after previous reports that $J_{1,2} = 4.4$ and 0 Hz for methyl 2,3-dideoxy-2,3-epithio-4,6-di-*O*-methyl-α-D-alloside or -mannoside, respectively.[9] Moreover, when the chemical shifts of C-2 and C-3 are compared with the corresponding values for mono-alloepoxy-β-cyclodextrin, the upfield shifts of $\Delta\delta_{C2} = 17.4$ ppm and $\Delta\delta_{C3} = 16.1$ ppm are similar in magnitude. However, such similarity in the upfield shifts is not observed in comparison with mono-mannoepoxy-β-cyclodextrin, $\Delta\delta_{C2} = 10.3$ ppm and $\Delta\delta_{C3} = 17.9$ ppm, which again supports the proposed allo structure of **2**. Thus, compound **2** is assigned as per(2,3-dideoxy-2,3-epithio)-β-cycloallin. The coupling constant $J_{4,5} = 8.9$ Hz indicates that the 2,3-anhydro-2,3-epithioalloses have an $^OH_5$ conformation[10] rather than the ^5H_O conformation, and the structure of **2** is expected to be as shown in Scheme 1.

A plausible mechanism for the transformation of **1** to **2** is depicted in Scheme 2. On the basis of the known reaction behavior of mannoepoxide rings in cyclodextrins,[2] the conversion of **1** into **2** is believed to be initiated by the nucleophilic ring opening of epoxide residues with thiourea as the nucleophile. Under basic conditions, transfer of $(NH_2)_2C^+$ from 3-S to 2-O and subsequent intramolecular substitution of 2-$OC^+(NH_2)_2$ by 3-S^- take place to generate the episulfide residues. Formation of thioureidoaltropyranoside residues was confirmed by monitoring the progress of the reaction by TLC (silica gel, *n*PrOH/EtOAc/H_2O = 7:7:5 by volume). The appearance of a new spot with a retention factor $R_f \approx 0$ was noted which is much lower than the R_f values for both **1** ($R_f = 0.7$) and the final product **2** ($R_f = 0.6$). The thioureidoaltropyranosides seem to be stable under acidic conditions until all the epoxide residues are transformed, and TOF-MS analysis of the reaction mixture clearly demonstrated a base peak at $m/z = 1540$, which is consistent with $[M-7]$ of perthioureido intermediate **A**. As soon as the reaction mixture was basified

Scheme 2. Plausible reaction mechanism for the formation of **2**.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

at room temperature, TLC analysis of the mixture revealed that the spot with $R_f = 0.6$ became more intense while that at $R_f = 0$ disappeared completely.

Molecular modeling studies were carried out to elucidate the 3D structure of **2** which is of pivotal importance in molecular design and recognition. As shown in Figure 2, all of the 2,3-epithioalloside units adopt $^{O}H_5$ conformations with Cremer–Pople ring-puckering parameters $Q = 0.504(5)$ Å, $\nu = 51.0(3)°$, and $\phi = 338(1)°$. The "straitjacket" effect of the 2,3-epithio rings enforces mean values of about 0.2° for the torsion angle about C1-C2-C3-C4 by forcing the pyranoside rings into this rigid conformation. Almost identical pyranoside geometries were also found in the solid-state structures of methyl 2,3-anhydro-4,6-bis(*O*-*p*-bromobenzyl)-α-D-mannopyranoside and its allo isomer[11] as well as per-2,3-anhydro-α-cyclomannin.[12]

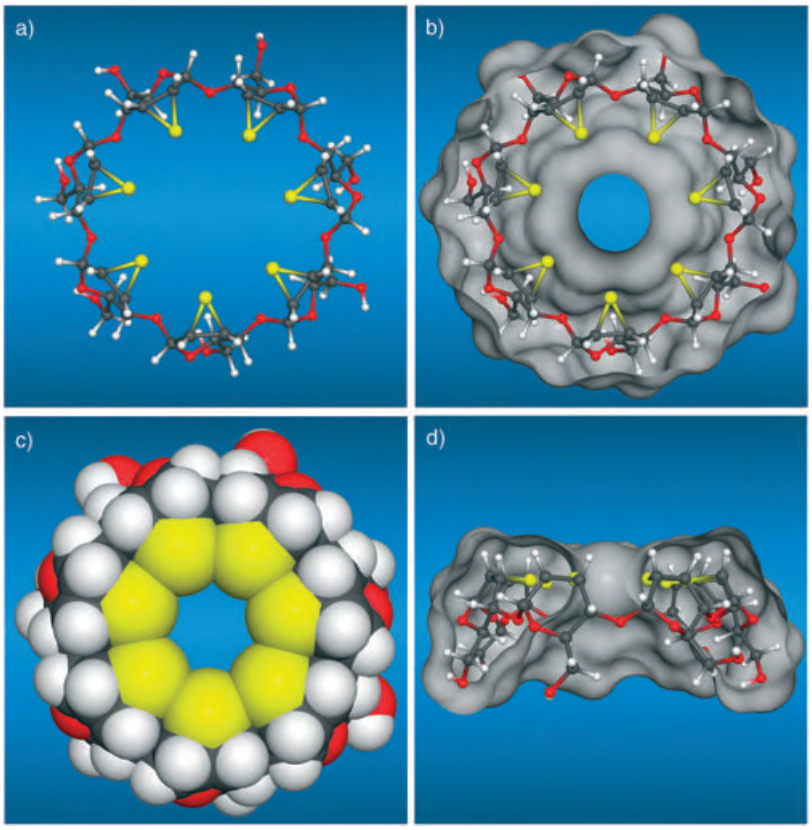

Figure 2. Molecular models of **2** displaying the arrangement of the inward pointing sulfur atoms and the reversed cavity shape of the macrocycle. (Left column (a, c): ball-and-stick and CPK-type models; right column (b, d): half-opened contact surface representations with models superimposed).

Corey–Pauling–Koltun (CPK) models and contact surface[13] representations reveal that the epithioalloside units of **2** are arranged to form a cavity whose shape is reversed from that of cyclodextrins; that is, the side on which the primary 6-OH groups reside is much wider than the other side (top side). The epithio rings are situated on the top side, parallel to the mean ring plane of the molecule, with the sulfur atoms pointing inwards and forming a circle with a radius of 3.7 Å (based on the atom positions). This arrangement of sulfur atoms substantially narrows the top side of the aperture to an inner width of about 3 Å only (diameter of the surface opening).

The unique 3D structure of **2** is of particular interest in molecular recognition. Furthermore, its seven episulfide rings make it a promising candidate for molecular recognition as well as further functionalization. As an example, thiirane **2** was converted quantitatively into the corresponding olefin species **3** simply by heating an alkaline solution of **2** in the presence of triphenylphosphine for a couple of hours. The TOF mass spectrum of **3** showed a parent-ion peak for $[M+Na^+]$ at $m/z = 919$. Seven different carbon atoms and eight different hydrogen atoms were recognized in the ^{13}C and ^{1}H NMR spectra, respectively, of **3**, consistent with C_7 symmetry. The large downfield shifts of resonances for atoms C-2 ($\delta = 127.0$ ppm), C-3 ($\delta = 130.0$ ppm), H-2 ($\delta = 5.76$ ppm), and H-3 ($\delta = 5.86$ ppm) suggest an olefinic structure.[2a]

In summary, we have reported the first successful synthesis of an epithio-β-cycloallin, which is an important intermediate in the functionalization of cyclodextrins and may equally serve as an artificial host molecule for molecular recognition.

Experimental Section

2: A solution of HCl (0.1M, 2 mL) containing **1** (29 mg, 0.029 mmol) and thiourea (720 mg, 9.3 mmol) was stirred at 90 °C for 30 min and then cooled down with a cold water bath. Sodium carbonate (28 mg, 0.26 mmol) and CH_3CN (0.9 mL) were added, and the solution was stirred at room temperature for 4 h. The solution was neutralized with HCl (1M), then diluted with 20% aq. EtOH (120 mL), and filtered through a cellulose acetate membrane (3 μm). The filtrate was purified by chromatography on a Lobar column (RP 18, size B) using initially an eluent of 20% aq. EtOH (500 mL) and then a gradient from 30% to 70% aq. EtOH (500 mL for each) to give **2** (18 mg, 56%); m.p.: 210 °C; $[\alpha]_D^{23} = +175.9$ ($c = 0.0433$ in 50% aq. ethanol); ^{1}H NMR (500 MHz, [D$_6$]DMSO, 35 °C, TMS): $\delta = 5.56$ (d, ^3J(H,H) = 5.0 Hz, 7H; H1), 4.54 (t, ^3J(H,H) = ca. 6.0 Hz, 7H; 6-OH), 4.28 (dd, ^3J(H,H) = 4.4, 8.9 Hz, 7H; H4), 3.69 (dd, ^3J(H,H) = 5.0, 6.6 Hz, 7H; H2), 3.62 (dd, ^3J(H,H) = ca. 5.5, ca. 10.5 Hz, 7H; 6R-H), 3.58 (dd, ^3J(H,H) = ca. 4.6, ca. 6.6 Hz, 7H; H3), 3.53–3.47 ppm (m, 14H; H5 and 6S-H); ^{13}C NMR (125 MHz, [D$_6$]DMSO, 35 °C, TMS): $\delta = 89.8$ (C1), 69.3 (C4), 67.4 (C5), 60.9 (C6), 39.8 (C2), 37.0 ppm (C3); TOF MS: $m/z = 1143$ $[M+Na^+]$.

3: Thiirane (**2**; 38 mg), sodium bicarbonate (8 mg), and triphenylphosphine (290 mg) were dissolved in aqueous dioxane (80% by volume, 3 mL), and the resultant solution was stirred at 95 °C for 170 min. After evaporation of the solvent, the residue was dissolved in water (70 mL), filtered through a membrane, and purified by chromatographey on a Lobar column (RP 18, size B) with a gradient elution from 40% to 80% aq. CH_3OH (500 mL for each) to give **3** (30 mg, 98%); m.p.: 188 °C; $[\alpha]_D^{25} = +105.5$ ($c = 0.133$ in 75% aq. methanol); ^{1}H NMR (500 MHz, [D$_6$]DMSO, 35 °C, TMS): $\delta = 5.86$ (dd, ^3J(H,H) = 1.4, 10.0 Hz, 7H; H3), 5.76 (ddd, ^3J(H,H) = 1.6, 3.0,

Drug Development

Highly Enantioselective Catalytic Fluorination and Chlorination Reactions of Carbonyl Compounds Capable of Two-Point Binding**

Norio Shibata, Junji Kohno, Kazumi Takai, Takehisa Ishimaru, Shuichi Nakamura, Takeshi Toru,* and Shuji Kanemasa*

The enantioselective electrophilic halogenation of carbonyl compounds represents one of the best established strategies for the construction of chiral C–X bonds in organic chemistry.[1] The resulting chiral halo compounds, especially fluorine-containing chiral organic molecules, are very fascinating in the field of medicinal chemistry.[2] The unique hydrophobic, space-filling, and electronic properties of a fluorine atom can make substrates with C–F bonds useful candidates for drug development. Next to fluorination, enantioselective chlorination is also an important topic with regard to some aspects of pharmaceuticals.[3] Although recent rapid advances in the methodology of enantioselective halogenations have made great contributions in these fields,[4–6] more efficient and more flexible methods are required. In this paper we describe highly enantioselective fluorination and chlorination reactions of carbonyl compounds that are capable of two-point binding. Both of the halogenations are catalyzed by the catalyst dbfox-Ph/Ni^{II} with very high enantioselectivity up to 99% *ee*. Furthermore, we also present the first significant examples of asymmetric amplification in enantioselective halogenations starting with the catalyst at 45% enantiopurity to afford the halogenated compounds with significantly increased *ee* values of $>90\%$.

We initiated the study of asymmetric fluorination reaction of β-keto esters **1a–g**, since α-fluorinated β-keto esters such as telithromycin have attractive antibiotic activity.[7] Recently, we found that chiral Cu^{II} and Ni^{II} complexes of phenyl-bis(oxazoline) (box-Ph) effectively catalyze the enantioselec-

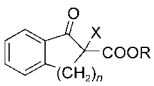
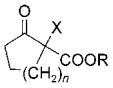
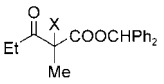
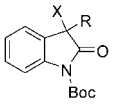
dbfox-Ph

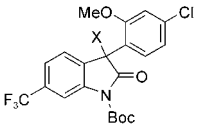
tive fluorination of β-keto esters with *N*-fluorobenzenesulfonimide (NFSI); however, the enantioselectivity was not high enough.[6d] In previous works by one of us, the dbfox-Ph ligand was highly effective in asymmetric Diels–Alder and Michael addition reactions.[8] Thus we turned to this ligand to improve the fluorination reaction. A solution of **1a** in CH_2Cl_2 was treated with 1.2 equiv of NFSI in the presence of a catalytic amount of dbfox-Ph/$Ni(ClO_4)_2{\cdot}6H_2O$ at room temperature to afford the α-fluoro compound **2a** in high yield with an extremely high enantioselectivity (Scheme 1; Table 1, entry 1, 99% *ee*). The ester **1a** proved to be the ideal yardstick to measure our results, as it has been studied by many investigators under a variety of conditions for enantioselective fluorinations.[4–6]

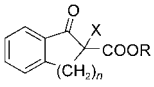












Scheme 1. Enantioselective halogenations of substrates capable of two-point binding using dbfox-Ph/Ni^{II} with NFSI or CF_3SO_2Cl.

The scope of the fluorination of a series of β-keto esters **1b–g** was investigated; we found that the dbfox-Ph/Ni^{II} catalyst exhibits excellent enantioselectivity as well (Table 1, entries 2–7). In most cases, our fluorination was more enantioselective than the reported procedures owing to the remarkable control of the enantioface of enolates by the dbfox-Ph/Ni^{II} complex.[9] It is notable that catalyst loading can be reduced to 2 mol% without loss of enantioselectivity (entries 1 and 11).

To demonstrate the further synthetic utility of this dbfox-Ph/Ni^{II} fluorination system, we tested other substrates capable of two-point binding. Pharmaceutically important fluorooxindoles[10] **2h–j** were selected as target molecules. Although we reported the enantioselective synthesis of fluorooxindoles using a combination of cinchona alkaloids and Selectfluor,[6c] no catalytic enantioselective method has been described. Under similar reaction conditions, a significant degree of enantioselectivity has been obtained irrespective of the substrates used (Table 1, entries 8–10). It is noted that fluorooxindole **2j** was converted into MaxiPost,[6c,10] an effective opener of maxi-K channels, by cleavage of the Boc group. This is the first example of a catalytic enantioselective preparation of MaxiPost.

[a] Reaction conditions: A solution of **1** (1.0 equiv), NFSI (1.2 equiv), dbfox-Ph (0.11 equiv), and $Ni(ClO_4)_2{\cdot}6H_2O$ (0.1 equiv) in CH_2Cl_2 was stirred in the presence of 4-Å molecular sieves at room temperature unless otherwise noted. Enantiomeric excess was determined by chiral HPLC analysis. See the Supporting Information for details. Abbreviations: L-Men = L-menthyl, Ad = 1-adamantyl. [b] The reaction was carried out at 0°C. [c] $Ni(OAc)_2{\cdot}4H_2O$ (0.1 equiv) was used instead of $Ni(ClO_4)_2{\cdot}6H_2O$. [d] Enantiomeric excess was determined after cleavage of the Boc group. [e] dbfox-Ph (0.02 equiv) and $Ni(ClO_4)_2{\cdot}6H_2O$ (0.02 equiv) were used.

Highly enantioselective chlorinations of ketones, acid halides, and aldehydes have been reported; however, asymmetric chlorination of β-keto esters has relatively low enantioselectivity.[5] In addition, no enantioselective syntheses of α-chlorooxindoles, which are potentially important in medicinal chemistry, have been reported.[11] We were pleased to find that our dbfox-Ph/Ni^{II} system was also effective for the asymmetric chlorination of a series of substrates including β-keto esters **1a–d** and oxindoles **1i** and **1j** (Table 2). The substrates were chlorinated smoothly with CF_3SO_2Cl under our optimized conditions to produce **3a–d, 3i**, and **3j** with high enantioselectivity. Chlorooxindole **3j** can be converted to BMS225113, a pharmaceutically important chlorooxindole.[11] It is highly noted that CF_3SO_2Cl as a chlorinating agent is essential to achieve high enantioselectivity, since *N*-chlorosuccimide (NCS) under the same conditions provided poorer results (entry 2 vs entry 3).

7[c]	**1j**	–	**3j**	17	93	60

[a] Reaction conditions: **1** (1.0 equiv), CF_3SO_2Cl (1.2 equiv), dbfox-Ph (0.11 equiv), and $Ni(ClO_4)_2 \cdot 6H_2O$ (0.1 equiv) were stirred in CH_2Cl_2 in the presence of 4-Å molecular sieves at room temperature unless otherwise noted. Enantioselectivity was determined by chiral HPLC analysis. See the Supporting Information for details. [b] NCS was used instead of CF_3SO_2Cl. [c] $Ni(OAc)_2 \cdot 4H_2O$ was used instead of $Ni(ClO_4)_2 \cdot 6H_2O$. *t*BuOMe was used as a solvent. [d] Conversion yield.

We finally examined experiments of chiral amplification[12,13] in the halogenations on our systems. Fluorinations of **1a** with NFSI were carried out in the presence of $Ni(ClO_4)_2 \cdot 6H_2O$ and dbfox-Ph, enantiopurities of which were varied from 11% to 60%. Figure 1 shows the relationship

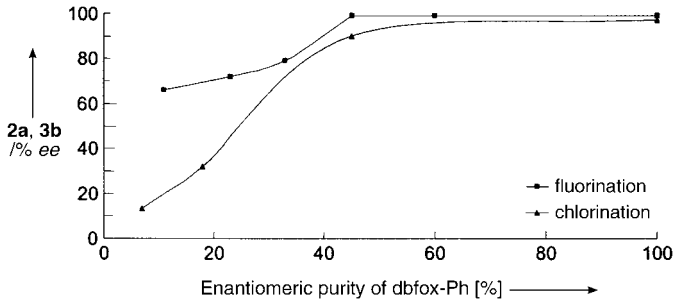

Figure 1. Chiral amplification in the halogenations of **1a**,**b** with NFSI or CF_3SO_2Cl catalyzed by dbfox-Ph/$Ni(ClO_4)_2 \cdot 6H_2O$.

between the enantiomeric purity of the dbfox-Ph ligand used and the enantioselectivity observed for **2a** when the molar ratio of dbfox-Ph to $Ni(ClO_4)_2 \cdot 6H_2O$ was 1.1:1 and the catalyst loading was 10 mol%. When the dbfox-Ph ligand had *ee* values of 45% and 11%, **2a** was obtained with 99% and 66% *ee*, respectively. A similar positive nonlinear effect of chiral amplification was also observed in the chlorination of **1b** with CF_3SO_2Cl under the same conditions, and dbfox-Ph with >45% enantiopurity was required to obtain the enantioenriched products **3b** with >90% *ee*.

In conclusion, the catalytic enantioselective fluorination and chlorination reactions of carbonyl compounds structurally capable of two-point binding were achieved with extremely high enantioselectivity by the use of the dbfox-Ph[14]/Ni^{II} complex. In addition, this system led to not only the first catalytic enantioselective synthesis of MaxiPost and BMS225113, but also the first observation of asymmetric amplification in halogenation reactions of β-keto esters.[13] We assumed octahedral complexes coordinated with a water molecule for **1a**/dbfox-Ph/Ni^{II}, **1j**/ dbfox -Ph/Ni^{II} optimized using MM2 in the light of the X-ray structure of the dbfox-Ph/Ni^{II} complex (Figure 2).[8] In these complexes, one of the faces

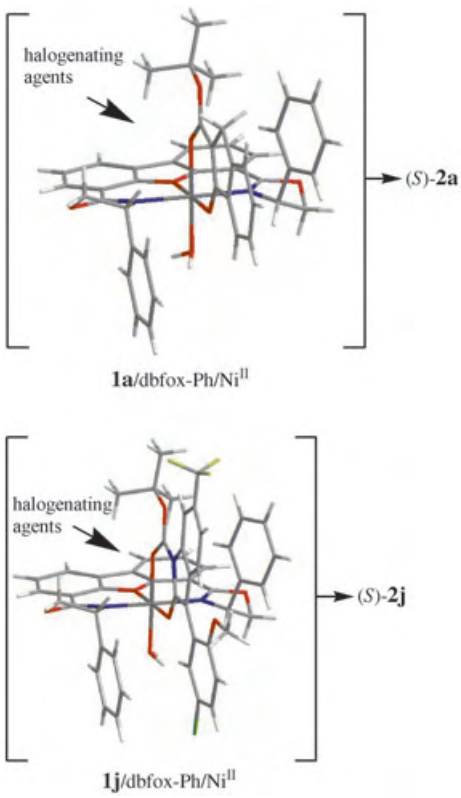

Figure 2. Optimized structures of the complexes of **1a**/dbfox-Ph/Ni^{II} and **1j**/dbfox-Ph/Ni^{II}.

is covered so efficiently that the halogenating agents approach from the *Si* face of the substrates. The details are now under investigation.

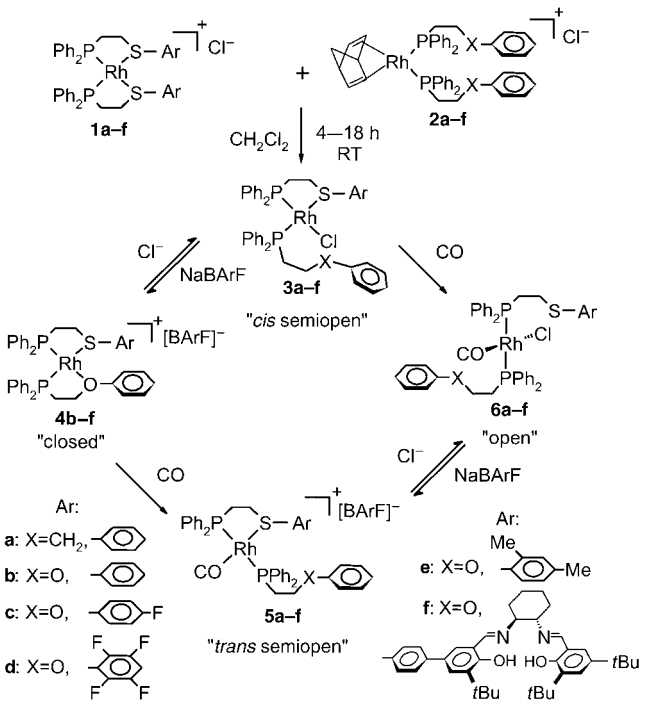
Coordination Chemistry

Heteroligated Rh^I Tweezer Complexes**

*Aaron M. Brown, Maxim V. Ovchinnikov, and Chad A. Mirkin**

The unique combination of the coordination geometry of transition-metal centers with the structural and geometric properties of organic ligands provides the basis for the synthesis and design of metallosupramolecular complexes[1] and metal–organic frameworks.[2] Indeed, the ability to incorporate multiple types of building blocks (namely, metal centers and ligands) into metallosupramolecular structures is a key requirement for the rational tailoring of their structural and electronic properties. Currently, the impetus for this research is shifting away from the synthesis of structurally complex and aesthetically pleasing structures towards the preparation of functional metallosupramolecular entities with preprogrammed catalytic and molecular-sensing properties.[3] We have previously demonstrated that tweezer-type salen-containing (salen = *N*,*N*′-bis(salicylidene)cyclohexyldiamine) complexes have improved catalytic rates and selectivities relative to the corresponding bimetallic macrocyclic analogues.[3b,c] These results motivated us to develop a general synthesis of "heteroligated" tweezer-type complexes.

Recently, we reported a novel halide-induced ligand-rearrangement process that was observed in multimetallic Rh^I metallomacrocycles and which results in the formation of two- and three-dimensional complexes that contain heteroligated coordination environments.[4] Herein, we report a general high-yielding methodology for the preparation and postsynthetic modification of heteroligated monometallic Rh^I tweezer-type complexes (Scheme 1). This methodology is based on a unique reaction that allows the preparation of condensed complexes **4b–f** which contain two distinct phosphine-substituted ligands or heteroligated systems that can undergo stepwise substitution reactions with Cl^- ions and/or CO to result in four unique geometries with respect to the orientation of each S- or O-appended aromatic group.



The neutral heteroligated "semiopen" tweezer complexes **3a–f** were synthesized in one step from stoichiometric amounts of the corresponding hemilabile ligands $Ph_2P(CH_2)_2SAr$ (Ar = aryl), $Ph_2P(CH_2)_2XC_6H_5$ (X = O, CH_2), and $[\{RhCl(nbd)\}_2]$ (nbd = norbornadiene) in CH_2Cl_2. Initially, the kinetic products **1a–f,** which have *cis*-thioether and *cis*-phosphine ligands around a Rh^I center, and **2a–f**, which have nbd and *cis*-phosphine ligands around a Rh^I center, are

Scheme 1. Synthesis of the heteroligated Rh^{I} tweezer complexes **3a–f**, and the stepwise synthesis of closed complexes **4b–f**, neutral *cis* semiopen complexes **3a–f**, cationic *trans* semiopen complexes **5a–f**, and open tweezer complexes **6a–f**. BArF = $B[3,5\text{-}(CF_3)_2C_6H_3]_4^-$

formed, but convert over 18 h into the semiopen neutral complexes **3a–f** (Scheme 1). Elemental analysis, ^{1}H, ^{19}F, and ^{31}P NMR spectroscopic, and ESIMS data are in full agreement with the proposed formulations. For example, complex **3b** exhibits highly diagnostic resonances in its $^{31}P\{^{1}H\}$ NMR spectrum at $\delta = 73.61$ ppm (dd, J(Rh-P) = 185 Hz, J(P-P) = 41 Hz), which corresponds to the P center of the η^2-P,S chelating ligand, and $\delta = 30.1$ ppm (dd, J(Rh-P) = 168 Hz, J(P-P) = 41 Hz), which corresponds to the P center of the η^1-P,O ligand.[4,5] Further evidence for the formation of these neutral complexes was obtained from a single-crystal X-ray study of complex **3e** (Figure 1).[6] The Rh^{I} center in **3e** exhibits a square-planar geometry with Cl1-Rh1-P2 and Cl1-Rh1-S1 angles of 87.8 and 86.8°, respectively.

The rate of these conversions was also studied by ^{31}P NMR spectroscopy at 25 °C in CD_2Cl_2, and the corresponding half-lives of the reactions were measured (**3a**: $t_{1/2}$ = 180 min, **3b**: 95 min, **3c**: 65 min, **3d**: 40 min, **3e**: 152 min, **3f**: 95 min; 20 mM [{RhCl(nbd)}$_2$]). These rates appear to be inversely proportional to the electron density of the aryl groups tethered to the S atom: As the electron density of the aryl subsitutent in the P,S ligand decreases, the Rh–S bonds in **1** weaken and the rate of the formation of **3** increases. This trend in the reaction rates reflects the increase in the strength of the Rh–S bond as a function of the increase in electron density of the aromatic group appended to the S atom.

The reversible abstraction of Cl^- ions from **3b–f** with one equivalent of NaBArF results in the clean formation of condensed cationic complexes **4b–f** in which the Rh^{I} center coordinates to the O atom. All the data obtained are

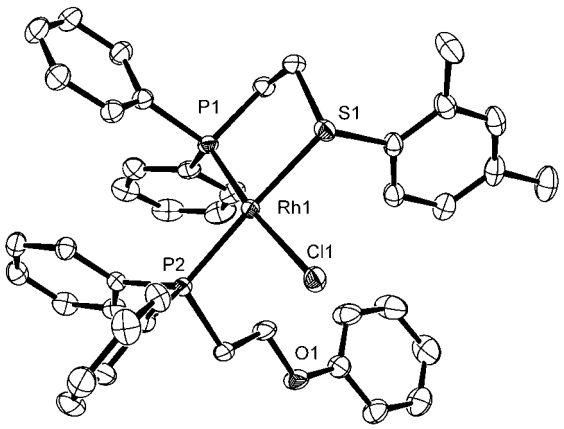

Figure 1. ORTEP diagram of **3e** ($C_{42}H_{42}ClOP_2RhS$) with thermal ellipsoids set at 50% probability. Hydrogen atoms and solvent molecules have been omitted for clarity.[6]

consistent with the proposed formulations. For example, complex **4b** exhibits highly diagnostic resonances in its $^{31}P\{^{1}H\}$ NMR spectrum at $\delta = 73.5$ ppm (dd, J(Rh-P) = 200 Hz, J(P-P) = 41 Hz) and $\delta = 51.8$ ppm (dd, J(Rh-P) = 168 Hz, J(P-P) = 41 Hz), which are characteristic of P centers in a coordination environment in which a Rh^{I} center has *cis*-phosphine, *cis*-thioether, and ether ligands. Furthermore, a signal at m/z 731.2 is observed in its ESIMS spectra that corresponds to a $[C_{40}H_{38}P_2S_2Rh]^+$ ion. Complexes **4b–f** react with stoichiometric quantities of benzyltriethyl ammonium chloride in CH_2Cl_2 to regenerate the corresponding chloride-ligated semiopen complexes **3b–f**. Abstraction of the Cl^- ion from **3a** results in a mixture of products because there is no O atom to which the Rh^{I} center can coordinate. However, the addition of one equivalent of benzyltriethylammonium chloride in solution or excess CO to **4a** in CH_2Cl_2 results in the formation of complexes **3a** or **5a**, respectively.

The addition of CO to complexes **4b–f** selectively cleaves the Rh–O bond and results in the formation of cationic semiopen tweezer-type complexes **5b–f**, in which the P atoms are *trans* to one another. Again, all the data collected are consistent with the proposed formulations. For example, semiopen complex **5b** exhibits resonances in its $^{31}P\{^{1}H\}$ NMR spectrum at $\delta = 63.1$ ppm (dd, J(Rh-P) = 116 Hz, J(P-P) = 268 Hz), which corresponds to a P center coordinated to a Rh^{I} center with phosphine and thioether ligands, and $\delta =$ 19.2 ppm (dd, J(Rh-P) = 121 Hz, J(P-P) = 268 Hz), which corresponds to a P center coordinated to a Rh^{I} center with phosphine and CO ligands. Alternatively, complexes **5a–f** may also be synthesized from complexes **6a–f** and stoichiometric quantities of NaBArF in diethyl ether. In this case, the lack of an O atom in **6a** does not affect the abstraction of the Cl^- ion and results in the clean formation of **5a**.

The neutral open complexes **6a–f** are synthesized from **5a–f** and stoichiometric quantities of benzyltriethylammonium chloride in CH_2Cl_2. Alternatively, the addition of CO to complexes **3a–f** cleaves the Rh–S bonds and results in the fully open tweezers **6a–f** in which the phosphines are *trans* to one another, thus resulting in further separation of the phosphine substituents. Each of these complexes exhibits

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

overlapping doublets of doublets in their $^{31}P\{^1H\}$ NMR spectra at approximately $\delta = 24$ ppm, which corresponds to two inequivalent phosphines.

The Cl^- ion is an integral component in these transformations. For example, the independently synthesized intermediate Rh^I complexes **1b** and **2b** were stirred together for 18 hours and the semiopen complex **3b** was formed. However, this reaction was repeated with the BF_4^- salt instead of the chloride salt and resulted in no ligand rearrangement, as determined by ^{31}P NMR spectroscopy.

The interconversion between complexes **3**–**6** allows the spatial separation between the aryl groups and the overall flexibility of these complexes to be systematically controlled (Scheme 1). The synthetic approach described herein is amenable to the inclusion of a variety of aromatic groups, including free-base salen functionalities, as demonstrated in **3f**–**6f**. With this approach, we now have the ability to synthesize designer catalytic intramolecular systems, which could be used to incorporate a catalytic functionality into one arm of a tweezer and add a separate cocatalyst, activator, or enantioselectivity-influencing agent on the other arm, with a precise control over spatial separation and flexibility. These types of structures are becoming important as allosteric catalysts[3b,c] and sensors,[3a] and the ability to modulate their properties through this type of chemistry will help researchers to finetune the reactivity of these complexes.

Asymmetric Catalysis

Achiral Ligands Dramatically Enhance Rate and Enantioselectivity in the Rh/Phosphoramidite-Catalyzed Hydrogenation of α,β-Disubstituted Unsaturated Acids**

Rob Hoen, Jeroen A. F. Boogers, Heiko Bernsmann, Adriaan J. Minnaard, Auke Meetsma, Theodora D. Tiemersma-Wegman, André H. M. de Vries, Johannes G. de Vries,* and Ben L. Feringa**

In 2000, three research groups demonstrated that the widely held view that chiral bidentate ligands are necessary to achieve high enantioselectivity in rhodium-catalyzed hydrogenations needs revision. Monodentate phosphonites,[1a] phosphites[1b] and phosphoramidites[1c] proved to be highly versatile ligands for this important transformation and afforded excellent enantioselectivities for a broad range of substrates.

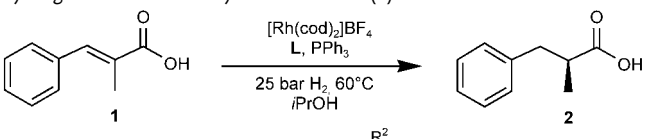
Recently it has been shown that mixtures of chiral monodentate ligands improve the enantioselectivity and reactivity in several cases.[2] This new strategy has been employed in rhodium-catalyzed asymmetric hydrogenations[2,3] and in rhodium-catalyzed additions of boronic acid.[4] By using this mixed-ligand approach and exploiting the fact that the structure of monodentate ligands can be varied easily enables a large number of different catalytic complexes to be screened for a variety of reactions. Reetz and co-workers have also introduced a variation of this mixed-ligand approach using a combination of chiral and achiral ligands.[3a] So far, however, beneficial influences observed for mixed-ligand systems are limited to a mixture of two chiral monodentate ligands.

Herein, we report a mixed-ligand approach in which a combination of a chiral monodentate phosphoramidite and an achiral monodentate phosphine ligand gives for the first time drastic improvement resulting in high, and in some cases unprecedented, enantioselectivities compared to known bidentate ligands and (combinations of) chiral monodentate ligands in the rhodium-catalyzed hydrogenation of disubstituted acrylic acids.

Our efforts focused on chiral dihydrocinnamic acid derivatives, which are key intermediates in the synthesis of several bioactive compounds, including renin inhibitors,[5] γ-secretase inhibitors,[6] enkephalinase inhibitors,[7] endothelin receptor antagonists,[8] and opioid antagonists.[9]



An initial screening of several mixtures of monodentate phosphoramidites and other phosphorus ligands in the rhodium-catalyzed asymmetric hydrogenation of α-methylcinnamic acid (**1**) showed that the heterocombination of a chiral phosphoramidite with an achiral triphenylphosphine gave a dramatic increase in conversion and in enantioselectivity, compared to the corresponding homocomplexes (Table 1).
