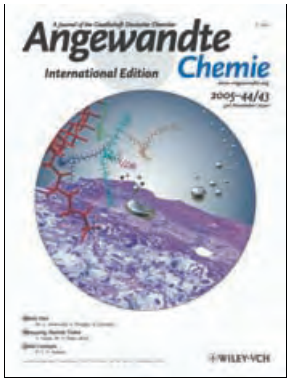
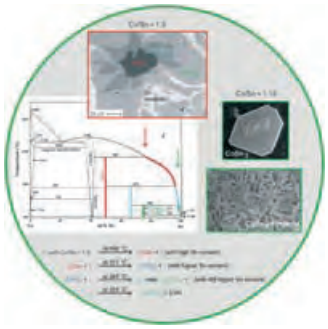
Cover Picture

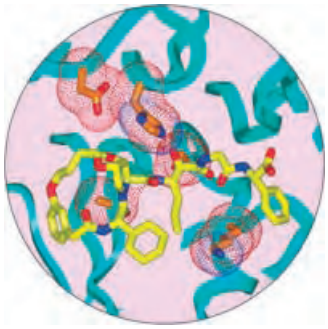


Justin M. Wiseman, Satu M. Puolitaival, Zoltán Takáts, R. Graham Cooks,* and Richard M. Caprioli*

Desorption electrospray ionization is applied to the mass spectrometric profiling of phospholipids. In their Communication on page 7094 ff., R. G. Cooks, R. M. Caprioli, and co-workers report the rapid analysis of untreated biological tissues, including the tumor region of liver tissue. The impact of charged liquid microdroplets on liver tissue in air and the release of lipids and other molecules as ions for analysis is illustrated in the cover picture (prepared by Z. Ouyang, J. Wiseman, and R. Shreve).



Solid-State Synthesis
A large number of new phases have been synthesized in recent years by using a metal flux. The advantages of employing liquid metals as solvents in the preparation of intermetallic compounds are presented by M. G. Kanatzidis et al. in their Review on page 6996 ff.



Hepatitis Virus Inhibitor
A proline-based macrocycle binds tightly with the Ala156 methyl group of hepatitis C virus (HCV) NS3 protease. In their Communication on page 7024 ff., K. X. Chen and co-workers show why the macrocycle is a potent HCV inhibitor.

Noncovalent Interactions
M. J. Krische and H. Gong show in their Communication on page 7069 ff. how aminopyrazolones, through interactions between their amide and amidine groups, can self-assemble into 1D architectures or aggregates to give macrocyclic quartets.

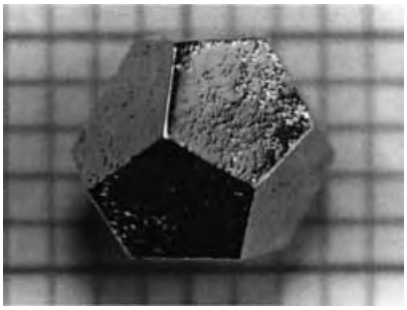
The Catalysis Gold Rush: New Claims

Reviews



In flux: Syntheses in metal fluxes have a huge potential for generating new intermetallic species, and in recent years many new phases, sometimes with very unusual compositions, have been prepared by this method. The advantages of this approach lie in the enhanced diffusion of the elements that are dissolved in the metal solvent and the lower reaction temperatures that can be employed.

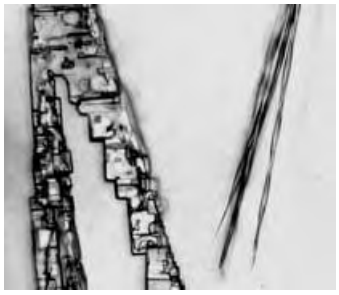
Combined forces: Theory and experiment are used together to determine the mechanism of primary amino acid catalyzed intermolecular aldol reactions. A six-membered chairlike structure is determined to be the transition state for the reaction between benzaldehyde and cyclohexanone catalyzed by (*S*)-alanine (see scheme), and a carboxylic acid catalyzed enamine mechanism is shown to be the most favorable reaction pathway.

Homochirality

A. Bassan, W. Zou, E. Reyes, F. Himo,*
A. Córdova* ——— **7028 – 7032**

The Origin of Stereoselectivity in Primary Amino Acid Catalyzed Intermolecular Aldol Reactions



At long last, the crystal structure of the metastable form of benzamide, whose existence has been known of for over 170 years, has finally been solved by using a combination of in situ crystallization, high-speed synchrotron X-ray powder diffraction, and global-optimization methods of structure determination (see picture).

Crystallography

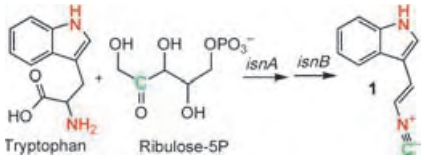
Biosynthesis

S. F. Brady,* J. Clardy ——— **7045 – 7048**

Systematic Investigation of the *Escherichia coli* Metabolome for the Biosynthetic Origin of an Isocyanide Carbon Atom

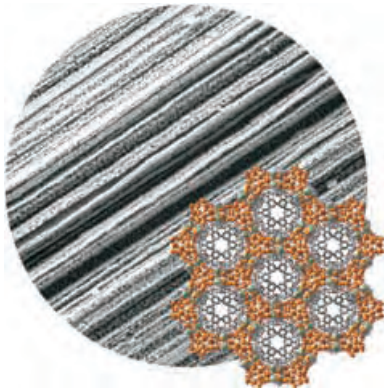


Feeding studies were conducted in which *E. coli* metabolism was controlled through the systematic use of strains that carry mutations in primary metabolic pathways, thus allowing the origin of the isocyanide carbon atom in antibiotic **1** to be determined. This carbon atom was shown to be derived from the C2 atom of ribulose-5P, or a tautomerically equivalent sugar (see scheme; *isnA* and *isnB* are the genes responsible for the biosynthetic pathway of **1**).

Hybrid Materials

W. Schmitt,* J. P. Hill, S. Malik, C. A. Volkert, I. Ichinose, C. E. Anson, A. K. Powell* ——— **7048 – 7053**

Thermolysis of a Hybrid Organic–Inorganic Supramolecular Coordination Assembly: Templating the Formation of Nanostructured Fibrous Materials and Carbon-Based Microcapsules

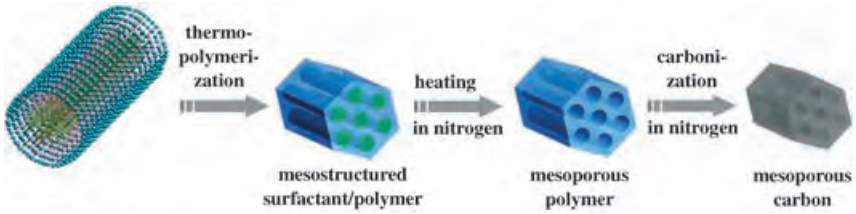


Burning a honeycomb: An exceptional hybrid organic–inorganic coordination assembly with an extended 3D structure that contains vast separated organic and inorganic regions has been prepared (see picture of its supramolecular structure and a scanning electron micrograph image). This hybrid is used as a template in thermolysis reactions to yield nano- and microsized products whose properties are determined by those of the precursor compounds.

Mesoporous Polymers

Y. Meng, D. Gu, F. Q. Zhang, Y. F. Shi, H. F. Yang, Z. Li, C. Z. Yu, B. Tu, D. Y. Zhao* ——— **7053 – 7059**

Ordered Mesoporous Polymers and Homologous Carbon Frameworks: Amphiphilic Surfactant Templating and Direct Transformation



Ultrahigh stability (> 1400 °C) is found for the highly ordered mesoporous polymers and carbon frameworks synthesized from polymerization of phenol and formaldehyde around triblock copolymer templates. Calcination and carbonization lead to removal of the templates and formation of hexagonal and cubic carbon mesostructures with large uniform pores and surface areas (see schematic diagram).

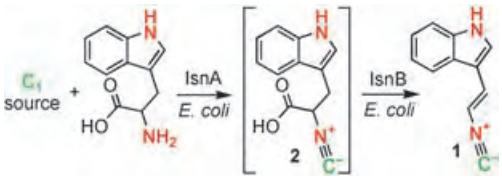
Crystal Engineering

K. Sada,* K. Inoue, T. Tanaka, A. Epergyes, A. Tanaka, N. Tohnai, A. Matsumoto, M. Miyata* ——— **7059 – 7062**

Multicomponent Organic Alloys Based on Organic Layered Crystals

Random layer: Multicomponent organic solid solutions were obtained by treating equimolar mixtures of two or more aliphatic carboxylic acids with 1-naphthylmethylamine (NMA; see scheme). The single sharp XRD peaks of the crystalline products indicate specific pairing of alkyl groups between the NMA layers to form mixed crystals rather than eutectic mixtures of the components.

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

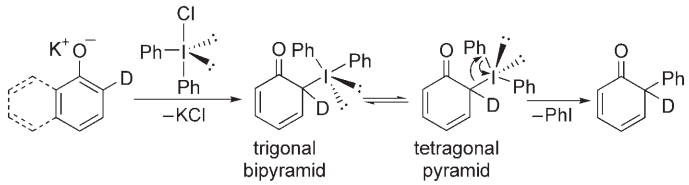


One gene, *isnA*, encodes the enzyme that converts the precursor amine functionality of tryptophan into the isocyanide moiety. The isolation and characterization of the isocyanide-containing environmental-DNA-derived antibiotic **1**, its biosynthetic genes (*isnA* and *isnB*), and the general outline of the biosynthesis of **1** via intermediate **2** are presented (see scheme).

Biosynthesis

S. F. Brady,* J. Clardy ——— **7063 – 7065**

Cloning and Heterologous Expression of Isocyanide Biosynthetic Genes from Environmental DNA



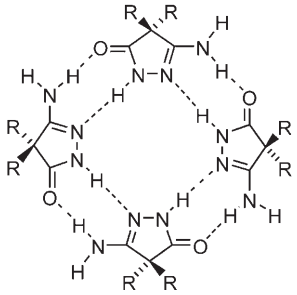
Dearomatization: Treatment of phenols and naphthols substituted at the *ortho* position by a small electron-donating group D with chlorodiphenyl-λ^3-iodane leads to their regioselective *ortho* phenylation to give cyclohexa-2,4-dienone derivatives (see scheme). The mechanism of this reaction involves a nonradical direct coupling of the ligands.

Regioselective Reactions

A. Ozanne-Beaudenon, S. Quideau* ——— **7065 – 7069**

Regioselective Hypervalent-Iodine(III)-Mediated Dearomatizing Phenylation of Phenols through Direct Ligand Coupling

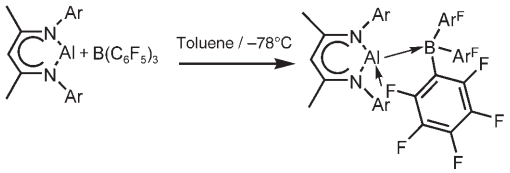
The fab four: Aminopyrazolones which incorporate two ditopic hydrogen-bond donor–acceptor pairs of amide and amidine functional groups can self-assemble through formation of four hydrogen bonds. Single-crystal X-ray diffraction analysis reveals that homomeric aggregation (amide–amide, amidine–amidine) affords 1D architectures while heteromeric aggregation (amide–amidine) generates macrocyclic quartets (see picture).



Self-Assembly

H. Gong, M. J. Krische* ——— **7069 – 7071**

Hydrogen-Bond-Mediated Self-Assembly of Aminopyrazolones: Macrocyclic Quartets—Single and Stacked One-Dimensional Motifs



Some elements go both ways: The reaction of [LAl] (L = HC(CMeNAr)$_2$, Ar = 2,6-*i*Pr$_2$C$_6$H$_3$) with BAr$^F_3$ (Ar^F = C$_6$F$_5$) yields [LAlBAr$^F_3$] (see scheme). Crystallographic studies and ab initio calculations show the formation of an Al–F bond, which shows the aluminum center having both Lewis base and Lewis acid character.

Aluminum Complexes

Z. Yang, X. Ma, R. B. Oswald, H. W. Roesky,* H. Zhu, C. Schulzke, K. Starke, M. Baldus, H.-G. Schmidt, M. Noltemeyer ——— **7072 – 7074**

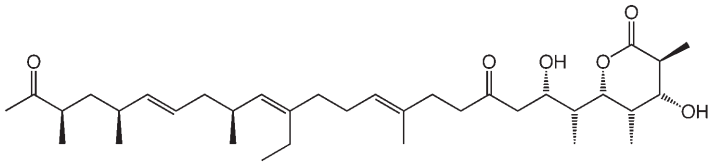
Biosynthesis

A. Bhatt, C. B. W. Stark, B. M. Harvey, A. R. Gallimore, Y. A. Demydchuk, J. B. Spencer, J. Staunton, P. F. Leadlay* ——— **7075 – 7078**

Accumulation of an *E*,*E*,*E*-Triene by the Monensin-Producing Polyketide Synthase when Oxidative Cyclization is Blocked

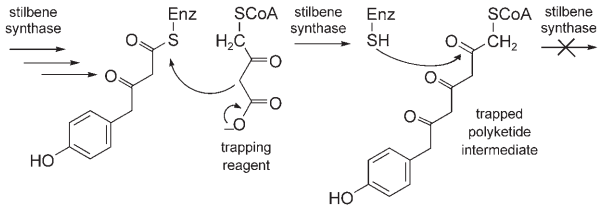


Evidence for the intermediate in the polyether biosynthesis of the ionophore antibiotic monensin A has been obtained. A tridecaketide *E*,*E*,*E*-triene (see formula) has been isolated by using mutant strains of *Streptomyces cinnamonensis*. Characterization of this intermediate allows the likely biosynthetic route to monensin to be discriminated.

Enzyme Reaction Mechanisms

D. Spiteller, C. L. Waterman, J. B. Spencer* ——— **7079 – 7082**

A Method for Trapping Intermediates of Polyketide Biosynthesis with a Nonhydrolyzable Malonyl-Coenzyme A Analogue

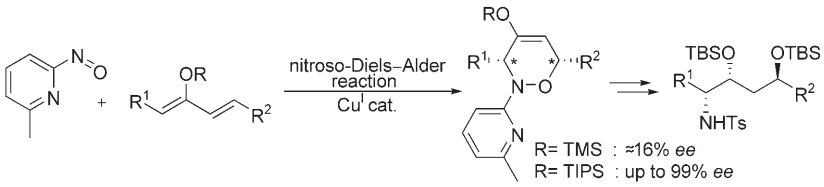


Trapped in the middle: To investigate the mechanistic details of polyketide biosynthesis, intermediates are trapped by a nonhydrolyzable malonyl-coenzyme A analogue that reacts with a growing polyketide chain formed by a stilbene synthase. As the reverse transesterification reaction is not possible, the polyketide intermediates accumulate attached to the analogue (see scheme; Enz = enzyme, CoA = coenzyme A).

Diels–Alder Reactions

Y. Yamamoto, H. Yamamoto* ——— **7082 – 7085**

Catalytic Asymmetric Nitroso-Diels–Alder Reaction with Acyclic Dienes

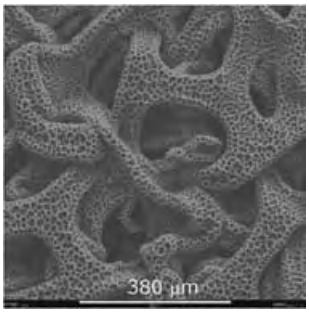


Bigger, bulkier, better: Catalytic asymmetric nitroso-Diels–Alder reactions of nitrosopyridines with silyloxydienes lead to adducts with excellent enantioselectivities (see scheme). The bulk of the silyl group (TMS = trimethylsilyl, TIPS = triisopropylsilyl) forces the diene to adopt an *s-cis* configuration in favor of the typical concerted [4+2] cycloaddition. The Diels–Alder adducts can then be converted into protected amino alcohols.

Composite Films

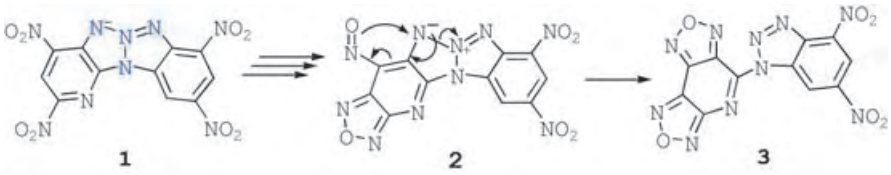
Y. Yu, C.-H. Chen,* J.-L. Shui, S. Xie ——— **7085 – 7089**

Nickel-Foam-Supported Reticular CoO–Li_2O Composite Anode Materials for Lithium Ion Batteries



Although considered to be the inactive component, Li_2O plays three important roles in the carbon-free CoO–Li_2O composite films (see SEM image) that have now been prepared: It prohibits CoO particle growth during synthesis, it oxidizes Co^{2+} to Co^{3+}, and it acts as a structural buffer. The composite films, supported on a conducting nickel-foam substrate, were prepared by the electrostatic spray deposition technique. They display large initial discharge capacities and low first-cycle capacity losses.

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Off with a bang: The thermally stable high-energy **1** was prepared in a more efficient synthetic route. An unexpected ring scission of the tetraazapentalene T-shaped isomer **1** (distinctive nitrogen atom arrangement indicated in blue) occurs through an intramolecular electron rearrangement activated by highly-reactive ψ-dinitroso substituents of intermediate **2** to give **3**.

Explosives

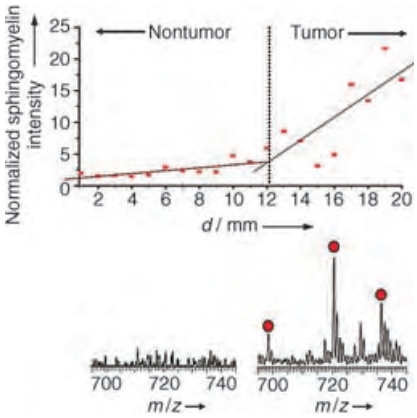
Tetraazapentalene Chemistry: Unexpected Intramolecular Electron Rearrangement Induced by Highly Reactive ψ-Dinitroso Substituents

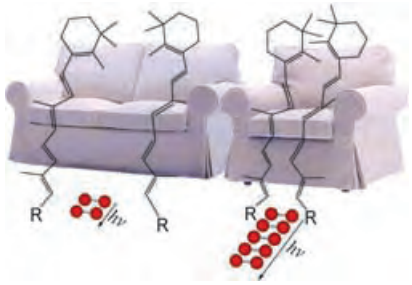


Direct chemical profiling of biological tissues, including metastatic human-liver adenocarcinoma, was carried out by using mass spectrometry under ambient conditions. Desorption electrospray ionization revealed enhanced signals from sphingolipids and increased unsaturation levels of the phospholipids in the tumor region of the tissue (see picture).

Phospholipids

J. M. Wiseman, S. M. Puolitaival, Z. Takáts, R. G. Cooks,* R. M. Caprioli* _____ **7094 – 7097**

Mass Spectrometric Profiling of Intact Biological Tissue by Using Desorption Electrospray Ionization



Up close and personal: Intimate retinoid polyenes, shown on the right chair, were found to react readily with oxygen (shown in red) to give the polyoxygenated species. On the other hand, when the polyenes are separated, shown on the left sofa, the oxidation is limited.

Superoxidation

I. Washington, S. Jockusch, Y. Itagaki, N. J. Turro,* K. Nakanishi* _ **7097 – 7100**

Superoxidation of Bisretinoids

Five are too many: It is known experimentally that $[(Cp')_2Zr(N_2)Zr(Cp')_2]$ ($Cp' = C_5H_{5-n}Me_n$) with $n = 4$ activates N_2 for hydrogenation, but the complex with $n = 5$ does not. This difference in reactivity arises from the N_2 coordination mode (see scheme): For $n = 0$–4, N_2 is side-on coordinated—the most suitable mode for hydrogenation—whereas for $n = 5$, N_2 is end-on coordinated owing to steric repulsion between five Me groups.

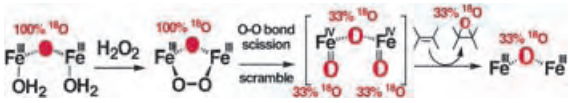
A Diiron Center Stabilized by a Bis-TPA Ligand as a Model of Soluble Methane Monooxygenase: Predominant Alkene Epoxidation with H_2O_2

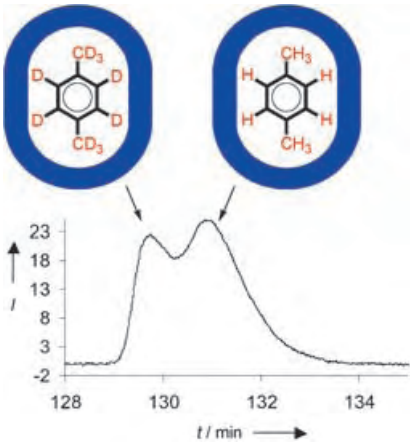


Double act: The diiron(II) complex $[Fe_2(6\text{-HPA})(O)(OH_2)_2](ClO_4)_4$ (**1**) catalyzes alkene epoxidation with H_2O_2 via a peroxodiiron complex. Detailed isotope-labeling experiments with μ-^{18}O-**1** reveal incorporation of both oxo- and peroxo-derived oxygen atoms into the epoxide reaction product (see scheme; 6-HPA = 1,2-bis[2-{bis(2-pyridylmethyl)-aminomethyl}-6-pyridyl]ethane).

Host–Guest Systems

Y. Liu, R. Warmuth* ——— **7107 – 7110**

A "Through-Shell" Binding Isotope Effect



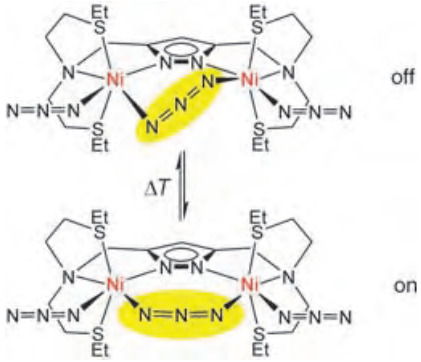
Small, but very significant: Partial separation of two hemicarceplexes which differed only in the degree of guest deuteration could be achieved by normal-phase chromatography (see picture). The difference in retention time arises from a variation in the interaction between the hemicarceplex and the silica surface as a consequence of a 0.005-Å difference in the C–H and C–D bond lengths of the guest molecules.

Magnetic Compounds

G. Leibeling, S. Demeshko, S. Dechert, F. Meyer* ——— **7111 – 7114**

Hysteretic Magnetic Bistability Based on a Molecular Azide Switch

Like a molecular toggle switch, the bridging azide ion in a highly preorganized dinickel(II) complex turns strong antiferromagnetic coupling on or off (see picture). Single crystals of the compound stay intact over the entire temperature range studied and feature hysteretic bistability not far from ambient temperature.



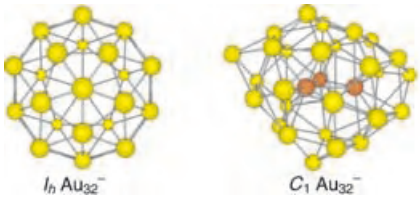
Synthetic Methods

V. Gandon, D. Leboeuf, S. Amslinger, K. P. C. Vollhardt, M. Malacria, C. Aubert* ——— **7114 – 7118**

Chemo-, Regio-, and Stereoselective Cobalt-Mediated [2+2+2] Cycloaddition of Alkynyl Boronates to Alkenes: 1,3- and 1,4-Diboryl-1,3-cyclohexadienes

Diborylated compounds are obtained by means of CpCo-mediated cocyclization of alkynyl(pinacol)boronic esters to alkenes followed by oxidative demetalation (see scheme). This strategy for the rapid and efficient construction of highly functionalized 1,3-cyclohexadienes and arenes is compatible with various substrates.

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

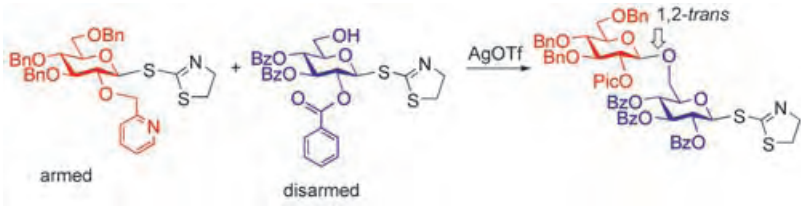


A heart of gold: The structure of the Au_{32}^- cluster has been elucidated by comparison of the results from photoelectron spectroscopy with those from theoretical calculations. Although DFT calculations suggest a high-symmetry hollow-cage structure (I_h, left) to be the lowest in energy at 0 K, the spectrum calculated for a low-symmetry (C_1, right) distorted cage containing three Au atoms inside agrees best with the experimental results.

Gold Clusters

M. Ji, X. Gu, X. Li, X. G. Gong,* J. Li,* L.-S. Wang* ——— **7119 – 7123**

Experimental and Theoretical Investigation of the Electronic and Geometrical Structures of the Au_{32} Cluster



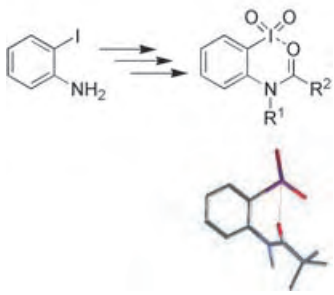
Armed and dangerous: A new armed–disarmed glycosylation strategy (see picture) allows chemoselective introduction of a 1,2-*trans* glycosidic linkage prior to other linkages through the use of a 2-*O*-picolyl moiety. This neighbouring group is capable of efficient participation through a six-membered intermediate while retaining the glycosyl donor in the armed state. Bn = benzyl, Bz = benzoyl, Tf = trifluoromethanesulfonyl, Pic = picolyl.

Selective Glycosylations

J. T. Smoot, P. Pornsuriyasak, A. V. Demchenko* ——— **7123 – 7126**

Development of an Arming Participating Group for Stereoselective Glycosylation and Chemoselective Oligosaccharide Synthesis

A pseudo-benziodoxazine structure with intramolecular secondary I···O bonding, as shown by X-ray analysis, is seen in a series of *N*-(2-iodylphenyl)acylamides prepared from 2-iodoaniline (see scheme). These compounds contain a six-membered pseudocyclic scaffold about an iodine(v) center and are able to oxidize either alcohols or sulfides, with the reactivity depending largely on the substitution pattern on the amide group adjacent to the iodyl moiety.



Synthetic Methods

U. Ladziata, A. Y. Koposov, K. Y. Lo, J. Willging, V. N. Nemykin,* V. V. Zhdankin* ——— **7127 – 7131**

Synthesis, Structure, and Chemoselective Reactivity of *N*-(2-Iodylphenyl)acylamides: Hypervalent Iodine Reagents Bearing a Pseudo-Six-Membered Ring Scaffold

A small number of isolated Au^{3+} ions (0.02 Au^{3+}/nm^2) heterogenized on a zirconia surface from a cheap inorganic source ($HAuCl_4$) is able to grant high catalytic activity for the selective hydrogenation of 1,3-butadiene (see picture). The catalytic turnover and mass activity rates of the Au^{3+} ions are respectively one and two orders of magnitude higher than those of metallic gold nanoparticles.

Nobel Prizes 2005

Chemistry

The Nobel Prize in Chemistry is shared equally by Yves Chauvin (Institut Français du Pétrole, near Paris, France), Robert H. Grubbs (California Insitute of Technology, Pasadena, USA), and Richard R. Schrock (Massachusetts Institute of Technology, Cambridge, USA) for the development of the metathesis method in organic synthesis. While metathesis is now a well understood, many-flavored reaction with numerous industry-strength applications,[1] this was not the case when Chauvin started his investigations of its mechanism—many years after it had first been observed. In fact, he was put on the right track by publications in 1964 by Nobel laureates G. Natta (1963) and E. O. Fischer[2] (1973) as well as Banks and Bailey. Chauvin's groundbreaking paper on the mechanism appeared in 1971 and paved the way for the research of Grubbs and Schrock.[3]

Y. Chauvin

R. H. Grubbs

R. R. Schrock

Both Grubbs and Schrock have made outstanding contributions to the field of organometallic chemistry directed towards organic and polymer synthesis. Grubbs is famous for the development of a range of ruthenium-containing catalysts for olefin metathesis;[4] Schrock's name is associated with tungsten alkylidene complexes and ring-opening-metathesis polymerization.[5] Grubbs received his PhD in 1968 at Columbia University in New York under the direction of R. Breslow. In 1968 and 1969 he worked as a postdoc in the research group of J. P. Collman (Stanford University), and then as assistant and associate professor at Michigan State University in East Lansing. Since 1978 he has held a position as professor at the California Institute of Technology in Pasadena. He is the editor of the 2003 *Handbook of Metathesis* published by Wiley-VCH. Schrock earned his PhD in 1971 at Harvard University with J. A. Osborn. He subsequently worked for a year at Cambridge University (UK), and for three years at DuPont de Nemours. He has been active at the Massachusetts Institute of Technology since 1975, and as professor since 1980. Both Grubbs and Schrock serve on the boards of *Advanced Synthesis & Catalysis* and the *Journal of Polymer Science Part A: Polymer Chemistry*. Individually, they have received numerous awards, but only one jointly: In September this year, they received the German Chemical Society's prestigious August Wilhelm von Hofmann Medal. Chauvin worked at the Institut Français du Pétrole, an independent research, industrial development, and training institute, until his retirement about 10 years ago; he is still an honorary director there. His research encompassed organometallic chemistry and catalysis, as well as ionic liquids and polymers. He is a corresponding member of the French Academy of Sciences and recently contributed an introductory chapter to the handbook *Multiphase Homogeneous Catalysis* (Cornils et al. (Eds.), Wiley-VCH, 2005). Chauvin was surprized to have received the prize: "I am a bit embarrassed. I have enjoyed a quiet life until now. My American colleagues have demonstrated that my 35-year-old research was actually important. I owe the prize to them."

Physiology or Medicine

This year's laureates have indeed contributed to solving a common problem: Barry J. Marshall (QEII Medical Centre, University of Western Australia) and J. Robin Warren (formerly at the Royal Perth Hospital, Australia) were recognized for their research on the bacterium *Helicobacter pylori* and identifying its role in gastritis and peptic ulcer disease.

Physics

The Nobel Prize in Physics was awarded with one half to Roy J. Glauber (Harvard University, USA) for his contribution to the quantum theory of optical coherence and jointly to John L. Hall (National Institute of Standards and University of Colorado, Boulder, USA), and Theodor W. Hänsch (Universität München and Max Planck Institute of Quantum Optics, Germany) for their contributions to the development of laser-based precision spectroscopy, including the optical frequency comb technique. Their work made it possible to measure frequencies with an accuracy of fifteen digits, which is useful for high-precision clocks, satellite navigation, and telecommunications.

This year, the prizes are worth 1.3 million US Dollars each. They are presented traditionally by the King of Sweden on December 10, the anniversary of Alfred Nobel's death.

Wrapping Peptide Tubes: Merging Biological Self-Assembly and Polymer Synthesis**

*Marco A. Balbo Block and Stefan Hecht**

Keywords:
bionanotechnology · hybrid materials · peptides · polymers · self-assembly

Transmembrane channels and pores are among Nature's most admirable devices, especially with regard to their almost perfect selectivity, speed, and gating of transport processes. Their modular architectural design is often based on bundles of α-helices, best exemplified by the potassium channel,[1] but alternative structures such as barrel proteins and β-helices have also evolved as illustrated by the gramicidin A channel.[2] In addition to modifying existing biological pores,[3] a wide variety of tubular structures based on synthetic backbones has been prepared.[4] In particular, peptide-based tubular systems have received significant attention, and herein we highlight both general design concepts and major recent advances in this rapidly developing field.

The β-sheet motif present in various forms in α-peptides[5] has proven to be a tremendously fruitful design element to mimic Nature's channel-forming structures. The parallel or antiparallel multiple-hydrogen-bonding array between building blocks with a varying degree of curvature leads to the formation of stable assemblies ranging from β-barrels, through hollow β-helices, to stacked macrocycles (Figure 1).

Natural β-barrel proteins such as α-hemolysin[6] have inspired the construction of β-barrels from staves consisting of β-sheets. On the one hand, the design of rigid-rod β-barrels by Matile and co-workers is based on the finite assembly of rigid octa(*p*-phenylene)s that carry short α-peptide side chains interdigitated with side chains of adjacent staves to form antiparallel β-sheets.[7] On the other hand, Percec and co-workers created pores from amphiphilic dendritic α-dipeptides that self-assemble into a helical arrangement of short staves.[8,9] Whereas in the first approach the internal diameter is tuned by the incorporation of a varying number of staves and α-peptide side chains of differing lengths, the latter pore-forming construct produces various diameters by changing the configuration of the dipeptide fragment. In both approaches, the length is controlled indirectly by assembly of the tube within the constraint of a lipid bilayer.

An alternative design used in channel construction is illustrated by the gramicidin family.[2] A α-peptide strand with an alternating sequence of D- and L-α-amino acids is twisted to form a single-stranded β-helix in which the intramolecular hydrogen bonding resembles that in parallel β-sheets. Further interactions between different strands allow either stacked or intertwined β-helices. The number of amino acid residues per turn (4.8–8.2 units) is greater than in α-helices which leads to a wider inner cavity with diameters between 2.3 and 4.7 Å. Whereas diameter control is largely dependent on the cationic guest species, length control is intimately connected to the length of the amino acid sequence.

In an elegant extension of the β-helix design, Ghadiri et al. pioneered peptide tubes based on stacked macrocycles consisting of an even number of alternating D- and L-α-amino acids.[10] The high aspect ratio and the chemical stability of the tubular assembly originates from strong hydrogen-bonding

interactions between the individual rings to yield an extended, circular two-dimensional β-sheet. An increase in the number of repeat units per cycle from cyclooctamer to cyclododecamer leads to an increase in the inner diameter from 7 to 13 Å with a constant periodicity of 4.7 Å between stacked rings.[11] Control of the length of the tubes is again only possible by assembly within a lipid bilayer.[12]

From this brief overview it is apparent that a multitude of approaches to peptide tubes exists. But some unsolved problems and future challenges still face this field:

- The control of the length of a self-assembled tubular object without the external constraint of a bilayer is still unconquered territory.[13] One possible solution involves the addition of terminating agents to the supramolecular polymerization mixtures,[14] for example, Janus macrocycles that engage in hydrogen bonding on only one face of the ring.[15] Nevertheless, a broad distribution of lengths cannot be avoided. Perhaps the most promising approach to date towards finite self-assembly is that of Stupp et al. by means of crowded side chains, as exemplified by his nanomushrooms.[16]
- Controlled functionalization of the interior and exterior surfaces is absolutely crucial to render the tubular structures functional. Whereas inner functionalization affects both the efficiency and selectivity of transport processes, functional groups present at the periphery of the tubes mediate integration into bilayers or other hierarchically organized materials. In particular, peripheral modification with polymers represents an attractive route to tune materials properties and control pattern formation on the nanometer scale.[17] Peptide–polymer hybrids[18] can be prepared conveniently through controlled radical-polymerization techniques[19] that involve either post-functionalization by graft-from or attach-to routes or assembly from suitable macromonomers.[20]
- It is essential that the tubular building blocks be isolated and integrated into hierarchically organized structures to harness their beneficial properties by constructing hybrid materials.

Very recently, the group of Biesalski reported an interesting approach to address some of these issues.[21] They demonstrated the utility of a graft-from polymerization route initiated at the outer surface of self-assembled peptide nanotubes to tune their properties (Figure 2). Octameric D,L-alternating cyclo-α-peptides that bear bromoisobutyramide initiators on the lysine side chains were assembled into peptide nanotubes. After subsequent addition of *N*-isopropylacrylamide monomer and polymerization catalyst mixture, Biesalski and co-workers took advantage of the controlled nature of atom-transfer radical polymerization (ATRP) to grow a poly(*N*-isopropylacrylamide) (PNIPAM) shell of homogeneous thickness around the intact cylindrical peptide core. With the aid of atomic force microscopy (AFM) imaging before and after post-polymerization, it was shown that bundles of peptide nanotubes ranging from 100–500 nm in length were broken up to distinct rod-shaped structures with dimensions of 80 ± 20 nm length and 12 ± 3 nm height. The observed shorter length suggests the possibility of using synthetic control over molecular weight of the polymer arms to tune local steric crowding and therefore influence the length of the tubular hybrid assembly.

In a related, however very different, approach, Francis and co-workers demonstrated polymer functionalization of the tobacco mosaic virus (TMV), a well-defined tubular self-assembled entity. They utilized various novel bioconju-

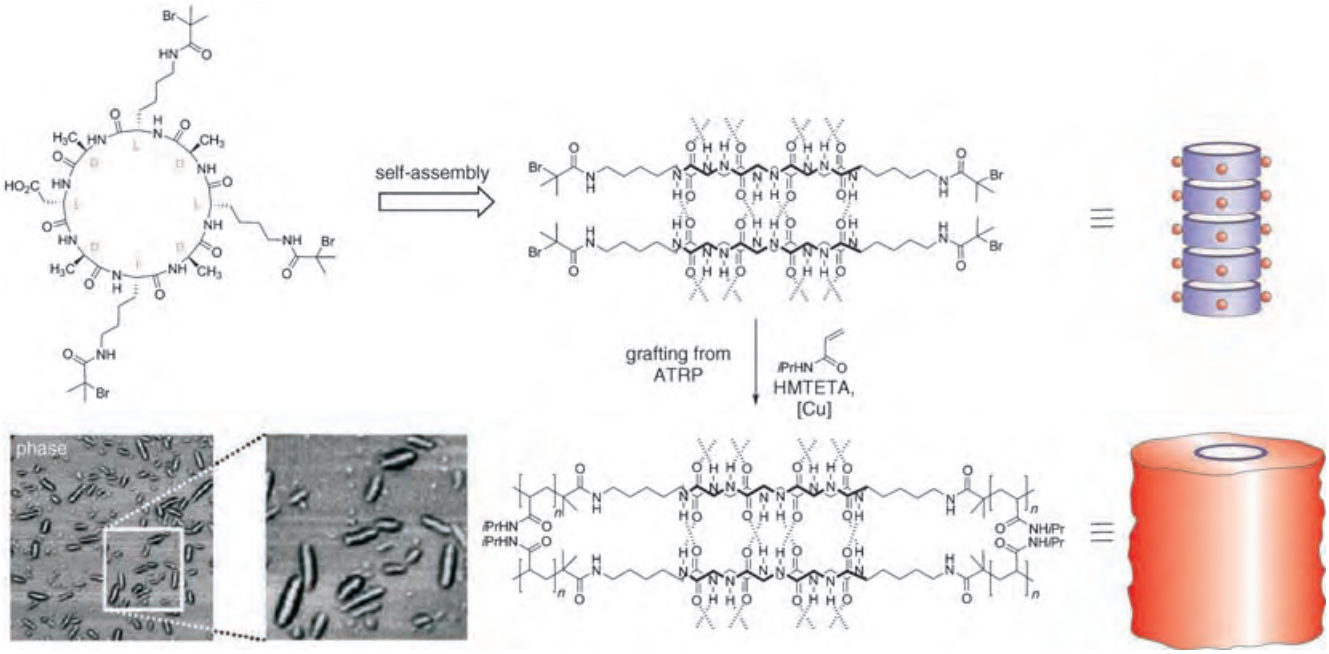

Figure 2. Grafting a polymer shell from preassembled peptide tubes:[21] D,L-Cyclo-α-peptides carrying initiator groups stack to form tubular structures from which PNIPAM is grown by ATRP; HMTETA = 1,1,4,7,10,10-hexamethyltriethylene. Figure 3. Attaching a polymer shell to preassembled TMV tubes:[23] Tyr 139 at the periphery of the TMV coat protein (protein data bank code: 1ei7) is functionalized by means of diazonium coupling chemistry to yield a ketone platform to which PEG-based hydroxylamines are attached. Bottom right shows a TEM image of the PEG-TMV hybrid after transfer to an organic solvent, that is, $CHCl_3$. Reproduced in part from reference [23].

gation approaches[22] to decorate the outer and inner surfaces of the TMV coat protein.[23] For instance, chemo- and regioselective modification of Tyr 139 located at the outer periphery of the TMV by means of electrophilic aromatic substitution was used to install ketone functionalities,[24] which reacted efficiently with various hydroxylamines, including poly(ethylene glycol) (PEG) derivatives (Figure 3). This attach-to route affords intact tubes that are readily soluble in a variety of organic solvents and therefore allow the use of conventional processing steps for materials applications of the PEG–TMV hybrids. Notably, this system enables the unique possibility of length control owing to the discrete nature of the interior RNA strand, which templates and directs self-assembly of the TMV-coat protein.

The work described herein truly represents the continuing trend of merging classical disciplines namely biology, organic synthesis, and polymer chemistry. Meshing the characteristics of these often-complementary fields helps to surpass limitations and greatly expands the freedom of designing custom-tailored de novo hybrid materials. The controlled modification of peptides and peptide-based objects by modern polymerization techniques will continue to thrive, and the ability to tune properties promises interesting new applications in the emerging bionanotechnology area.

Gold Catalysis

DOI: 10.1002/anie.200502735

The Catalysis Gold Rush: New Claims**

*A. Stephen K. Hashmi**

Keywords:
hydrogenation · alkenes · alkynes · gold · homogeneous catalysis

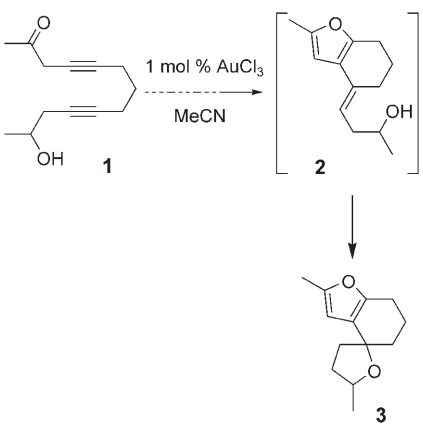
1. Introduction

Homogeneous catalysis by gold is not new: the roots reach back at least 70 years.[1] The catalysts are quite robust; an exclusion of water or oxygen in most cases is not necessary.[1,2] Nevertheless, only very few publications in this field appeared up to the end of the year 2003. In a review on homogenous gold-catalyzed reactions from that year,[1] I concluded with the sentence *"I am confident that these developments will accelerate in the near future, and that most people working in the field of homogeneous transition-metal catalysis will also give gold a chance on a regular basis"*. Obviously many investigators had the same thought: since 2004 a sharp and continuing increase of the publications on homogeneous catalysis by gold complexes can be observed. Here, I would like to "highlight" some of the exciting new "claims" in this emerging field (excluding aspects recently reviewed elsewhere).[3–5]

2. Nucleophilic Additions to Unactivated Olefins as Substrates: The Gate to Catalytic Asymmetric Synthesis

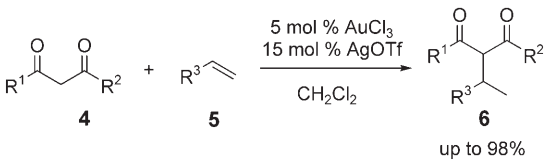
Hutchings was the first to recognize the superiority of gold catalysts for the electrophilic activation of alkynes.[6] This field has been reviewed,[3c] and further examples for that type of reaction have been reported recently.[7] In particular, the addition of water and alcohols to alkynes, which in the case of terminal alkynes cleanly delivers the Markovnikov product, has become a kind of benchmark for gold catalysts.[8] Intramolecular reactions investigated by Kozmin and Genet have proven to be useful tools for organic synthesis.[9]

In 2000 we described the formation of compound **3** from **1** and suggested the intramolecular addition of a hydroxy group to a furyl-substituted, styrene-like alkene **2** as the final step in its formation (Scheme 1).[10] This was not straightforward: Teles et al. had shown that alkynes were highly reactive,[8b] but they also claimed that alkenes do not react.[11] Our work,[10] work of Krause et al.,[12] and a beautiful application of Lee et al.[13] subsequently demonstrated that strained allenes also react.[14] But the twofold addition of alcohols to alkynes[8] indicated that even the intermediate enol ethers can be activated for the attack of a second alcohol nucleophile by the gold catalyst.

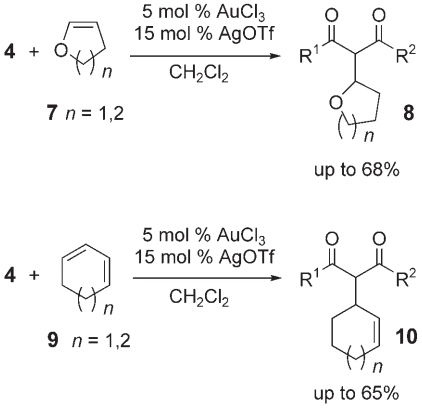


Scheme 1. Proposed pathway for the formation of **3**.

The first examples for such gold-catalyzed nucleophilic addition reactions were provided by Li et al.[15] In 2004, they successfully used 1,3-dicarbonyl compounds **4** as pronucleophiles and activated alkenes **5** (styrene derivatives; in one example also norbornene; Scheme 2). Li et al.[16] could also extend that principle to the intermolecular reaction of **4** with cyclic enol ethers **7** and cyclic 1,3-dienes **9** (Scheme 3). In these examples the authors propose that the gold catalyst might activate the C–H



Scheme 2. Addition of pronucleophiles to activated alkenes. R^1, R^2 = alkyl, aryl; R^3 = aryl.



Scheme 3. Addition of pronucleophiles to enol ethers and dienes. R^1, R^2 = alkyl, aryl.

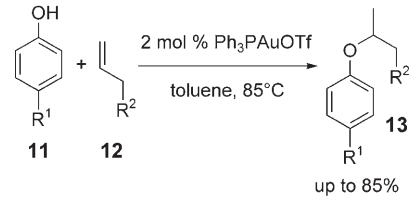
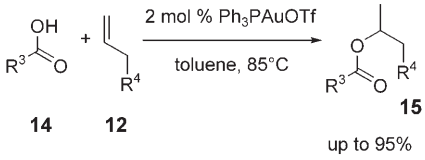
bond of the nucleophile instead of activating the alkene for a reaction with the enol tautomer of **4**, but so far there is no experimental data to support either model.

Just recently, in a remarkable paper He et al.[17] reported that at 85 °C in toluene even unactivated alkenes **12** reacted readily with weak nucleophiles like phenols **11** or carboxylic acids **14** (Scheme 4)! All these additions follow

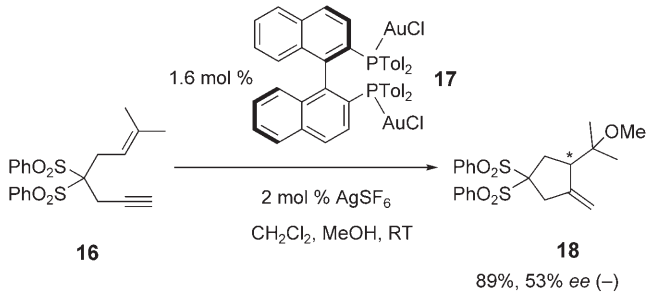




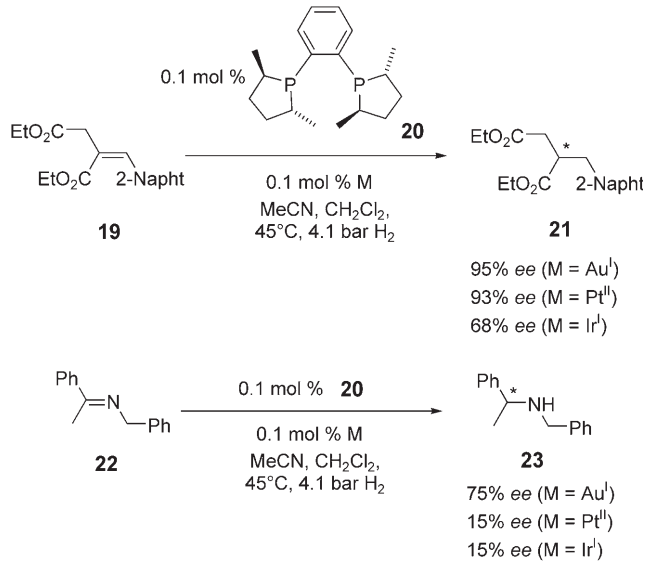
Scheme 4. Addition of weak nucleophiles to unactivated alkenes. R^1 = OMe, *t*Bu, CO_2Me, NO_2; R^2 = alkyl, aryl; R^3 = benzyl, alkyl; R^4 = alkyl, aryl.

Markovnikov's rule. This regioselectivity is, in contrast to the additions to alkynes, connected with the formation of new stereogenic centers even when terminal alkenes are the starting compounds. Now the possibility for the development of stereoselective catalysis was opened.

Ito and Hayashi[18] had provided the first example for asymmetric gold catalysts almost 20 years ago, and Echavarren et al. recently revived this aspect with the enyne cyclization catalyzed by **17** (Scheme 5).[7e] Although the *ee* values are still low, if we extrapolate from the Ito–Hayashi asymmetric aldol reaction better enantioselectivity can be expected.



Scheme 5. Catalytic asymmetric cyclization of an enyne.



Scheme 6. Catalytic asymmetric hydrogenation. Napht = naphthyl.

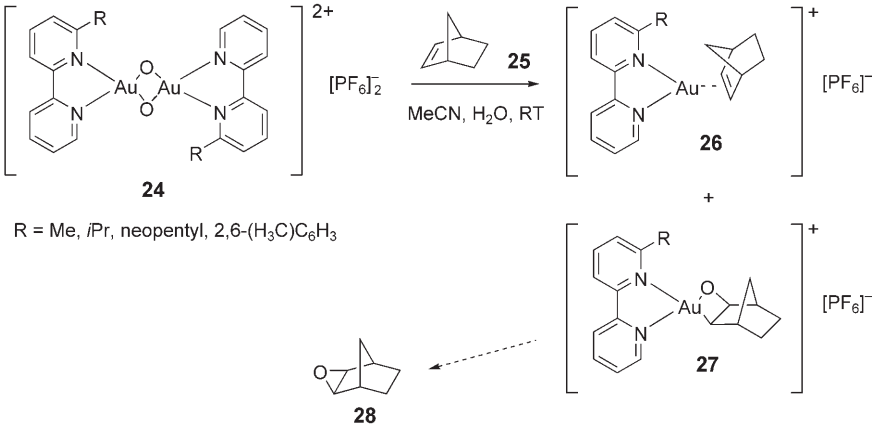
One first example documenting that trend was reported by Corma et al.:[19] The [$(AuCl)_2$\{(*R*,*R*)-Me-Duphos\}] complex (Me-Duphos = 1,2-bis(2,5-dimethylphospholanyl)benzene) can be used in catalytic enantioselective hydrogenations of esters **19** and imines **22** (Scheme 6). The activities were comparable to the activities of the analoguous Pt and Ir complexes, but with gold the *ee* values were superior. Rather than a dihydride formed by oxidative addition, the authors suggest a unique gold(I) monohydride complex as an intermediate.

3. The First Auraoxetane: Model Compound for an Organometallic Intermediate in Gold-Catalyzed Reactions

Despite significant effort, so far only two intermediates of gold-catalyzed reactions have ever been proven experimentally.[20] Unfortunately, these intermediates, a 5-alkylidene-4,5-dihydrooxazole and an arene oxide, were not organometallic but merely organic compounds. Now, in a spectacular paper Cinellu et al. managed to isolate and characterize the very first auraoxetanes[21] as stable organometallic analogues of intermediates in gold-catalyzed reactions. The reaction of the bridged μ-oxo dimer **24** with norbornene **25** led to the alkene complex **26**, also a representative of a rare species, and the unique auraoxetane **27** (Scheme 7). In addition, the epoxynorbornane **28** was identified as the final product of the reaction. A related reaction of a platinum(II) compound had been reported before, but there the oxygen always coordinated to two platinum centers and the formation of oxiranes was not observed.[22]

While Teles et al.[8b] initially suggested a *syn* oxyauration for the gold(I)-catalyzed additions of alcohols to alkynes, we have proven an *anti* oxyauration for the gold(III)-catalyzed oxazole synthesis.[20a] It will be a future challenge for both theoreticians and experimentalists to verify whether Cinellu's *syn*-addition mode is a general principle or the outcome of the preferred *exo* addition at the strained norbornene. The ligand used by Cinellu et al. might also serve as a lead structure for the detection of intermediates in other gold-catalyzed reactions. The diastereoselec-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

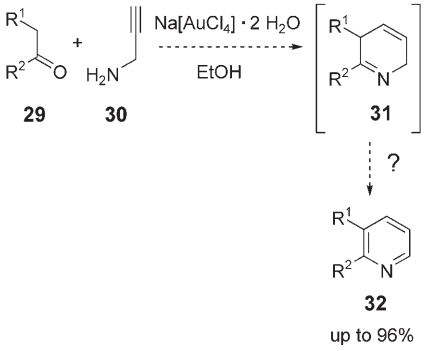


Scheme 7. Formation of auraoxetane **27**.

tivity is also of importance for asymmetric catalysis (see the end of the Section 2). The prognosis or understanding of the stereoselectivity observed is intrinsically linked to knowing whether a *syn* or an *anti* addition is occurring.

4. The Oxidation State of the Active Species: New Pieces of the Puzzle

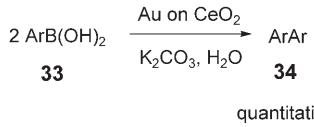
Often the same reaction can be catalyzed by gold(I) as well as gold(III).[1] Since it is conceivable that the active species is formed in situ from the precatalyst by a change of the oxidation state (for example, either by reduction of gold(III) or by disproportionation of gold(I) to gold(III) and gold(0)), the same catalyst might be operating in both cases. Periana et al. and Straub set out to resolve this question by theoretical calculations, but they could not rule out simultaneous catalysis by gold(I) and gold(III).[23,24] Nevertheless, all gold-catalyzed reactions discussed so far probably do not involve a change in the oxidation state of the gold catalyst (classical steps like oxidative addition or reductive elimination do not occur) in the catalytic cycle.



Scheme 8. Dehydrogenation as part of the gold-catalyzed synthesis of pyridine derivatives. R^1 = H, alkyl, aryl; R^2 = H, alkyl, aryl, heteroaryl.

Arcadi et al.[25] developed a synthesis of pyridines **32** from carbonyl compounds **29** and propargylamine **30** (Scheme 8). The initial isomerization product is the dihydropyridine **31**, which must be dehydrogenated somehow. Whether H_2, which potentially should reduce the catalyst, is released or a transfer hydrogenation to the alkyne occurs, was not investigated.

Corma et al. now have reported the remarkable observation that gold on supported nanocrystalline CeO_2 efficiently catalyzes the homocoupling of boronic acids (Scheme 9).[26] Since the reactivity correlates with the amount of gold(III) on the surface, it is assumed that



Scheme 9. Catalytic homocoupling of boronic acids.

the reaction is initiated by a twofold transmetalation from boron to gold(III) followed by reductive elimination of the biaryl compound. Now the catalytic cycle can be completed only when gold(I) is reoxidized. The reaction proceeds in the absence of oxygen, and H_2 could be detected by Raman spectroscopy. This suggests that possibly nanoparticles containing gold(I) are directly oxidized by protons. Corma et al. were also able to extend this principle to the reaction of homogeneous gold catalysts with N,O ligands and similar systems anchored in zeolites.[27] Unlike with palladium catalysts in the Suzuki coupling, cross-coupling products were not observed even in the presence of aryl iodides.

Ito, Sawamura et al.[28] discovered the chemoselective dehydrogenative silylation of alcohols (Scheme 10). The [AuCl(xantphos)] complex (**36**; xantphos = 9,9-dimethyl-4,5-bis(diphenylphosphanyl)xanthene) allows the formation of the silyl ethers from alcohols like **35** and triethylsilane in the presence of other functional groups like alkenes, alkynes, alkyl halides, tertiary alcohols, aldehydes, ketones, and carbamates. The mechanistic proposal, in analogy to Corma's asymmetric hydrogenation (see Section 2) also involves a gold monohydride.

The latest contribution addressing the oxidation state of the catalyst was delivered from Gevorgyan et al.[29] They used the haloallenyl ketones **38** in gold-catalyzed cycloisomerizations yielding furans (Scheme 11). With $AuCl_3$ they observed a preference for the product **40**, probably formed by carbonyl coordination and via a bromoirenium zwitterion intermediate, while $Au(PR_3)Cl$ exclusively delivered **42**, presumably by means of initial π coordination. This concept for the synthesis of halofurans had previously failed with Pd^{II} catalysts

and a bromoallenyl compound. Only with a chloroallenyl substrate was a low yield (2%) of the corresponding 2-chlorofuran obtained.[30]

Gevorgyan et al. presents the very first example for a gold-catalyzed reaction in which different oxidation states of the precatalyst lead to different products. This is a very important contribution to the discussion of the oxidation state of the active gold species.

5. Outlook

Gold catalysis has become a hot spot in organometallic chemistry. The many examples published for transformations that were previously possible only with other reagents or catalysts, or even multistep syntheses, demonstrate the benefits of the gold catalyst, for example, higher activity, higher selectivity, and milder conditions. It is no longer sufficient to simply reinvestigate known reactions and to show that gold has some activity there. Stereoselectivity will probably be a major synthetic focus in the future. The fact that in many reactions the gold catalysts are superior to other catalysts is still not understood. Here further mechanistic insight is a challenge for experiment and theory. And the digging for new, unprecedented reactions certainly continues.

This review highlights the use and great potential of liquid metals as exotic and powerful solvents (i.e. fluxes) for the synthesis of intermetallic phases. The results presented demonstrate that considerable advances in the discovery of novel and complex phases are achievable utilizing molten metals as solvents. A wide cross-section of examples of flux-grown intermetallic phases and related solids are discussed and a brief history of the origins of flux chemistry is given. The most commonly used metal fluxes are surveyed and where possible, the underlying principal reasons that make the flux reaction work are discussed.

1. Introduction

1.1. Intermetallic Phases in Science and Technology

Compounds containing exclusively two or more different kinds of metal (or metalloid) atoms are defined as intermetallic compounds. The difference between an intermetallic compound and a regular metal (e.g. a metallic element) is in the way the atoms bond. In metals, the bonding electrons distribute themselves throughout the material (i.e. the electrons are more delocalized), giving rise to predominantly nondirectional bonding in the solid. Intermetallic compounds, on the other hand, maintain a slight ionic and covalent character (i.e. the electrons are localized), and the atomic bonding becomes more directional. This difference in bonding character results in differences in material behavior. Chemists have often given secondary attention to intermetallic compounds as a class of materials, compared to the more ionic materials such as oxides, ceramics, chalcogenides, or halides. This lack of appeal may have been partly due to the difficulty in understanding some very basic characteristics of intermetallic compounds such as their compositions, bonding, and assignment of oxidation states for individual atoms. As a result, the bulk of synthetic activity and innovation in solid-state chemistry has focused primarily on the ionic type of materials, whereas typically the synthesis of intermetallic compounds has been carried out in only a few laboratories and requires very high temperature conditions which are achieved by the use of induction heating and arc melting.

Some important intermetallic compounds are aluminum-based and silicon-based materials. In commercial aluminum alloys (many of which also contain silicon), rare-earth or transition metals are included to improve the properties. A result of this approach is the formation of both known as well as yet unexplored multinary intermetallic compounds within the aluminum matrix.[1] The study of possible multinary compounds formed during the alloying process is vital to understand how to optimize the bulk material. Rare-earth-element-containing binary and ternary aluminides often have complex structures and interesting magnetic and electronic behavior.[2]

Silicides are both scientifically and industrially important,[3] and have been extensively studied during the past few decades. Because of their hardness, chemical stability, and high melting point, silicides are well known as high-temperature, oxygen-resistant structural materials which are used, for example, in making high-temperature furnaces[4] and for high-temperature coatings.[5] Transition-metal silicides are highly valued as electrical and magnetic materials, in addition to several new applications such as thermoelectric energy conversion,[6] and compatible electrode materials in electronics.[7] Some silicides are low-temperature superconductors.[8] Several reviews and papers regarding their preparation, properties, and crystal chemistry,[9] thermodynamics,[10] applications in silicon technology,[11] and materials aspects of silicides for advanced technologies[12] have been published.

Silicides are usually synthesized by direct reaction of the elements heated in vacuum or in an inert atmosphere. The

required reaction temperatures are usually over 1000 °C necessitating the use of an arc welder or inductive furnace. Although single crystals sometimes can be obtained by annealing or quenching the product, in most situations only powder samples are obtained using these methods. This situation often makes crystal-structure determination difficult and limits proper characterization.

Of course there are many other important intermetallic compounds including nickel superalloys and titanium- and molybdenum-based systems which are remarkably heat and corrosion resistant, finding applications in jet engines, as coatings, as well as in the biomedical and automotive industries.[13] Many titanium-based alloys are also used in orthopedic applications owing to their good biocompatibility, appropriate mechanical properties, and excellent corrosion resistance. Advanced copper alloys are of interest for fusion-reactor applications and to aerospace engine makers (as liners for thrust cell combustion chambers and nozzle ramps).[14] A large number of intermetallic systems based on a variety of elements including Ti, Fe, Al, Ni, Ga, and Mn exhibit interesting shape-memory effects with implications in a number of important applications.[15] The remarkable compound Ti_3SiC_2 is damage tolerant, not susceptible to thermal shock, has excellent oxidation resistance, and is as readily machinable as graphite.[16] Single-crystalline samples of $MnNi_2Ga$ have been shown to produce close to 10% magnetic-field-induced strain.[17] Platinum intermetallic compounds are also of interest for use as catalysts[18] and for high-temperature applications such as inert coatings for titanium alloys.[19]

Traditionally, the study of intermetallic phases has been mainly the subject of metallurgists who have synthesized many of the known compounds. As a result, intermetallic compounds are critical as structural materials in technological applications. Many new applications, however, are emerging or envisioned, and to go forward, advances in the understanding and in the discovery of new intermetallic compounds are needed. Solid-state chemistry has a significant role to play in this regard.

1.2. The Flux Method in Solid-State Chemistry

The synthetic toolbox of the solid-state chemist contains several powerful and productive means, each with its unique capabilities, advantages, and disadvantages. For intermetallic compounds these techniques generally involve very high temperatures as for example arc-melting and radio frequency (rf or high frequency (hf)) induction heating. These methods are necessary because the starting materials employed in such reactions are usually solids themselves and very high temperatures are necessary to cause sufficient diffusion for a reaction to take place. Often even high temperatures alone are not enough to overcome these barriers and the samples need to be ground to powders several times during the synthesis to expose fresh surfaces on which reactions can occur. These high temperatures give rise to two important synthetic limitations. The reactions generally proceed to the most thermodynamically stable products; the high energies involved often leave little room for kinetic control. These thermodynamically stable products are typically the simplest of binary or ternary compounds, which because of their high structural stability can become synthetic roadblocks, and often are difficult to circumvent. In addition, the rapid cooling of reactants from high temperatures along with the repeated grinding of the samples, as mentioned above, do not create a favorable environment for crystal growth. Single crystals can sometimes form through extended annealing, and even then the growth of crystals large enough for physicochemical analysis is not always seen. Microcrystalline products can limit the proper characterization of the new material both

Wolfgang Jeitschko, born 1936 in Prague, received his Ph.D. in 1964 with H. Nowotny with a thesis on ternary carbides at the University of Vienna. After postdoctoral years in the metallurgy departments of the universities of Pennsylvania and Illinois and as lecturer at the University of Illinois he worked as a crystallographer for DuPont in Wilmington. In 1975 he became Professor of Inorganic Chemistry at the Universität Gießen, in 1978 at the Universität Dortmund, and in 1981 at the Universität Münster. His research interests extend from the preparation of new solid-state compounds and their characterization mainly by X-ray and neutron diffraction to applications of materials science.

Rainer Pöttgen was born in 1966 in Meschede, Germany, and received his Ph.D. in 1993 at the University of Münster with Wolfgang Jeitschko, followed by postdoctoral studies at the ICMCB CNRS in Bordeaux (France) with Jean Etourneau (1993) and at the Max-Planck-Institut für Festkörperforschung in Stuttgart (Germany) with Arndt Simon (1994–1995). After habilitation at the University of Münster (1997) he became Professor for Inorganic Solid State Chemistry at LMU München (2000–2001). Since autumn 2001 he has been Chair of Inorganic Chemistry at the University of Münster. His research interests include the synthesis and structure–property relations of intermetallic compounds.

Mercouri G. Kanatzidis was born in Thessaloniki, Greece in 1957. After obtaining a B.Sc. from Aristotle University in Greece he received his Ph.D. in chemistry from the University of Iowa in 1984. He was a postdoctoral research associate at the University of Michigan and Northwestern University from 1985 to 1987 and is currently a University Distinguished Professor of Chemistry at Michigan State University where he has served since 1987. His research concerns metal chalcogenide chemistry, the development of solid-state synthesis by flux methods, hydrothermal, and solvothermal techniques. He is also active in the fields of new thermoelectric materials, the synthetic design of framework solids, intermetallic phases, and nanocomposite materials.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

structurally and physically, particularly when knowledge about anisotropic effects is desired, and may even prevent the proper identification of the products in extreme cases.

Methods that permit reactions to be carried out at lower temperature are likely to produce new phases. This thesis applies to all classes of compounds including intermetallic phases.[20–22] To increase the odds for new compound formation and avoid the thermodynamic traps, the reactant diffusion must be increased so that the activation energy barrier (associated with solid–solid reactions) is lowered. Under these conditions the reaction could proceed at lower temperatures to some other outcome. High diffusion rates (from a solid-state perspective) could be achieved by simply allowing soluble starting materials to react in a solvent.

To achieve enhanced diffusion of reactants in solid-state synthesis, molten solids can be used as solvents (i.e. fluxes). Such media (predominantly salts) have been employed for well over a 100 years for high-temperature single-crystal growth. Although many salts are high-melting species, eutectic combinations of binary salts and salts of polyatomic species often have melting points well below the temperatures of classical solid-state synthesis, making possible the exploration of new chemistry at intermediate temperatures. In many instances, these liquids act not only as solvents, but also as reactants, providing species which can be incorporated into the final product. In the latter case this is analogous to solvate formation or to cases where the solvent provides atoms to the compound being formed. Such a molten solvent is called a "reactive flux". Therefore, appropriate molten metals can act in such a fashion to become bona-fide solvents for synthesis. Lessons learnt from solution synthesis could be applied in this type of solid-state synthesis with, as we will show in this review, remarkable results.

2. Challenges in the Solid-State Chemistry of Intermetallic Compounds

Because the composition of most intermetallic compounds does not yield to the type of electron counting and oxidation-number analysis typically applied to more familiar solid-state compounds such as halides, oxides, and chalcogenides, it is very difficult to predict the type of composition that would be stable in a given system of metallic elements (except for special cases, such as Zintl, Laves, or Hume–Rothery phases). For example, whereas compositions of the type K_2MoO_4, Ag_2HgI_4, FeS_2, and Fe_2SnS_4 are well understood and can be predicted and therefore can be targeted for synthesis, the compositions $FeGa_3$, $YNiGe_2$, $RhSn_4$, Sm_2NiGa_{12}, or $SmNiSi_3$ appear totally strange to the average chemist. The situation is even more complicated when considering quaternary systems such as $Sm_2NiAl_7Si_5$ or $Sm_8Ru_{12}Al_{49}Si_{21}$. For intermetallics such stoichiometries are more the norm than the exception, whereas in more polar non-intermetallic compounds it is generally the other way around. Non-intermetallic compounds display more ionic character in their bonding, extensive charge transfer between different atoms, and as a result can be explained easily to a chemistry student, whereas this is difficult for intermetallic compounds. A different type of basic understanding and intuition is required, one that goes beyond the complexity of the electronic band-structure calculations usually done to deal with these kinds of compounds. How can such compositions be predicted, so they can be targeted for exploratory synthesis? Of course, the answer today is that they cannot be. Using liquid metals as fluxes, to carry out synthetic explorations, could serve as a great way to discovering (without having to predict) a large variety of intermetallic compounds.

Herein we present the use of liquid metals as reaction media to synthesize new classes of intermetallics and other non-oxidic solids, such as carbides, nitrides, and pnictides. The emphasis is placed on the utility of the fluxes to discover new materials rather than to grow large crystals of known materials. We highlight herein how the metal-flux technique is aimed at gaining control at lower temperatures and is a critical synthetic tool in the solid-state chemist's arsenal of methods. This review is not meant to be an exhaustive account of what has transpired since the first example of metal-flux synthesis was reported. Therefore a number of worthwhile reports may not be referenced. Instead our goal is to increase awareness of this synthetic approach by drawing attention to the possibilities it offers. This article is written from a solid-state chemist's point of view and we mainly focus on the recent literature with respect to the synthesis and crystal growth of new compounds.

3. Metallic Fluxes

The use of molten metals as media for the synthesis of new materials has been limited compared to the highly successful use of molten salts. In those cases where metallic fluxes have been used, new compounds have resulted that are interesting from the structural, physicochemical, and even the practical point of view. In the vast majority of cases, however, use of molten metals has been focused primarily on growing single crystals of known compounds, not for exploratory synthesis.[23,24] The purpose of this article is to give an overview of the known chemistry associated with exploratory synthesis using metallic fluxes and to highlight the potential of this approach.

Several key characteristics must be met for a metal to be a viable flux for reaction chemistry: 1) the metal should form a flux (i.e. a melt) at reasonably low temperatures so that normal heating equipment and containers can be used, 2) the metal should have a large difference between its melting point and boiling point temperatures, 3) it should be possible to separate the metal from the products, by chemical dissolution, filtration during its liquid state, or if necessary mechanical removal, 4) the metal flux should not form highly stable binary compounds with any of the reactants. This last point is critical.

4. Historical Perspective on the Preparation and Crystal Growth from Metallic Melts

Metallic fluxes were employed early on in the preparative chemistry of solids. Henri Moissan (1852–1907) tried to obtain

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

diamonds in many experiments by rapidly quenching carbon containing (in homogeneous and heterogeneous form) liquid iron and other metals from high temperatures using the electric furnace that he developed.[25] In this way he had hoped to create the required high pressure within the contracting metal jacket. After dissolving the metallic matrices in acids he found tiny, very hard crystals, some with octahedral shape which burned and produced carbon dioxide. Moissan died believing that he had made diamonds. His experiments were reproduced and resulted in carborundum (SiC, with the mineral name moissanite). It is interesting that industrial diamonds were first successfully synthesized in 1954 in the laboratories of the General Electric Company at high pressure, again in the presence of liquid iron. Without the metallic flux, much higher pressure is required. Thus, this process, generally regarded only as a high-pressure synthesis, may also be quoted as a crystal growth from a metallic flux. Now it is estimated, that about one hundred tons of synthetic diamonds are produced annually by this process.[26]

At around 1900 Paul Lebeau, a co-worker of Moissan, prepared various silicides of late transition metals from a copper flux, and Jolibois of that school has to be credited for being the first to employ a tin flux to grow nickel phosphides.[27] In subsequent years such solution growth from metallic fluxes has variously been called menstruum technique, Lebeau method, auxiliary bath method (Hilfsmetallbadtechnik), and molten metal solution growth. Many borides, carbides, silicides, and nitrides of the early transition metals have been obtained this way in well-crystallized form, usually with higher purity than by direct reaction of the elemental components. Some of the early literature about metallic fluxes is cited in the introductory paragraphs of various papers reporting on the recrystallization of transition-metal borides (e.g., TiB_2, ZrB_2, VB, NbB_2, W_2B_5) using iron, copper, aluminum, tin, or lead as fluxes,[28–30] the preparation of the high-melting carbides (e.g., TiC, WC, UC) with iron, cobalt, nickel, or aluminum as fluxes,[31] and the preparation of various silicides of early transition metals (e.g., $TiSi_2$, $CrSi_2$, Mo_5Si_3, $MoSi_2$, W_5Si_3, WSi_2) employing mainly copper or tin as fluxes.[32,33] Deitch reviewed the early literature on the growth of semiconductors, e.g., Si, SiC, AlP, GaAs, ZnS, ZnTe, $ZnSiP_2$, $CdSiP_2$,[34] and Lundström summarized the literature on the preparation and crystal growth of non-oxidic refractories using molten metallic solutions.[35] The handbooks on crystal growth by Elwell and Scheel[24] and Wilke and Bohm[36] list more than 100 references on the growth of single crystals of various, mostly binary compounds from metallic fluxes.

By using a metallic flux, it is not necessary to completely dissolve the elemental components of the desired products. The flux may act as a transporting medium, which dissolves a component in one place and grows the product at another location of the sample container. Nevertheless, it is important for the flux to have reasonable solubilities for the components to avoid exceedingly long growth times. Gumiński has published a compilation of experimental solubilities of metals in liquid low-melting metallic fluxes, such as mercury, gallium, indium, tin, lead, and bismuth. He also gives some estimates for combinations of metallic elements, where no experimental data are available.[37] The solubilities of various industrially important transition-metal disilicides MSi_2 with M = Ti, V, Nb, Ta, Cr, Mo, and W in metallic fluxes have been investigated experimentally.[38] The monograph edited by Hein and Buhrig[39] gives an extensive treatment of such data both for equilibrium and non-equilibrium conditions, and also from a theoretical point of view.

5. Peritectic Reactions and Reactive Fluxes

Some terms, commonly known by metallurgists and crystal growers, may be less appreciated by preparative chemists. A compound formed by a *peritectic* reaction may be such a case. Consider the phase diagram of the binary system cobalt–tin (Figure 1).[40,41] The compound designated as β-Co_3Sn_2 melts congruently (that is, the solid and liquid have the same composition) at 1180 °C. In contrast, CoSn melts incongruently at 966 °C, forming solid β-Co_3Sn_2 and a liquid ℓ of a composition, which is indicated by the large down-pointing arrow in that phase diagram. Conversely, if a melt of that composition (with a Co:Sn ratio of approximately 1:3) is cooled, the liquidus line will be reached at 966 °C. On further cooling, the compound CoSn will crystallize until the sample reaches 571 °C. At that temperature solid CoSn will react with the liquid (by what is called a peritectic reaction) to form $CoSn_2$. The problem is, that this phase forms an envelope around the reactant CoSn. Thus, this (peritectic) reaction can now only proceed by diffusion through the solid envelope of $CoSn_2$. This diffusion process takes time and may not be finished before the sample reaches the next peritectic equilibrium temperature of 345 °C. At that temperature (the high-temperature modification) β-$CoSn_3$ is formed. The melt changes its composition continuously, following the red, then the blue, and finally the green liquidus curves. The remaining melt will solidify at the eutectic temperature of 229 °C.

A scanning electron micrograph of a sample with a slightly higher tin content (Co:Sn ratio 1:4) is shown in the lower part of Figure 1. The very light areas of the micrograph have the lowest cobalt content; they correspond to the tin-rich eutectic. Naturally it will be very difficult to isolate single crystals of (one or the other modification of) $CoSn_3$ from such a sample.

A single-phase sample of α- or β-$CoSn_3$ (depending on the relatively low annealing temperature above or below 275 °C) can be obtained from a solidified melt of that composition (1:3) only by annealing for a very long time, for example, for several weeks. However, the situation changes dramatically if a large excess of tin is used. In this case, well-developed crystals of $CoSn_3$ can be grown by slow cooling down to the eutectic temperature. The crystals of $CoSn_3$ are then embedded in a tin-rich matrix, which can be dissolved in diluted hydrochloric acid.

Herein we have described the preparation of single-phase $CoSn_3$ by using an excess of tin as—what may be called—a *reactive flux*, thus avoiding the very slowly proceeding peritectic reaction. Frequently the phase diagram is not known, and guess work or trial and error are required to find the excess of the reactive flux needed to crystallize the desired product. This of course will be the normal situation in

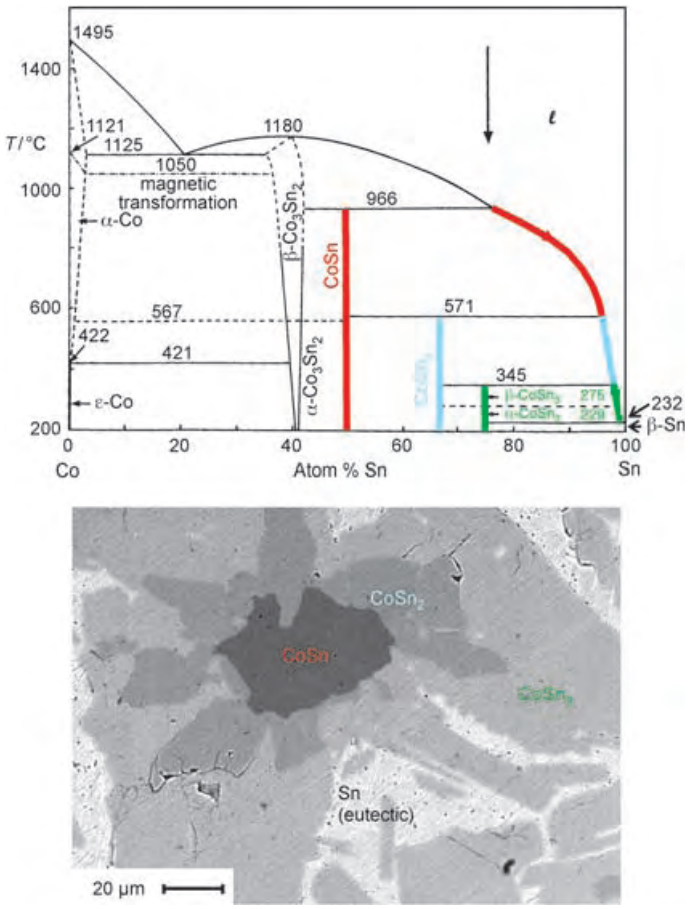

Figure 1. Peritectic reactions in the binary system Co–Sn. Top: the phase diagram of the Co–Sn system. By rapidly cooling a melt (liquidus, ℓ) of the approximate composition Co:Sn = 1:3 (large black arrow) crystals of composition CoSn are obtained first. Since these crystals have a higher Co content than the original melt, the liquid phase changes its composition on cooling along the red liquidus line. At 571 °C the crystals of CoSn start to react with the remaining melt, thereby forming a microcrystalline envelope of the compound $CoSn_2$. During this reaction, the liquid phase changes its composition along the blue line. After further cooling, at 345 °C, the melt, now with a Sn content of approximately 98 atom%, starts to react with $CoSn_2$ and forms another microcrystalline envelope this time of microcrystalline β-$CoSn_3$. Thereby the melt changes its composition along the green line. Finally, at 229 °C it solidifies, to form the eutectic, which consists of a matrix of a solid solution of Co in β-Sn with heterogeneous inclusions of α-$CoSn_3$. Bottom: A micrograph of a corresponding sample (with the slightly different overall composition Co:Sn = 1:4).[41] It is clear that well developed large crystals of α- or β-$CoSn_3$ cannot be grown by such a cascade of peritectic reactions. This sample has been cooled at the relatively slow rate of 100 °C h^{-1}. Nevertheless, it has not reached thermodynamic equilibrium. In its center it contains the remains of a primarily crystallized grain of CoSn, embedded in grains of $CoSn_2$. Before reaching equilibrium the sample had cooled to 345 °C, thus forming β-$CoSn_3$.

exploratory research, where the emphasis is on novel materials with potentially interesting properties. Such materials may contain several components and it may be impractical to work out the phase diagrams. However, it must be remembered, that the kind of the reaction product obtained will depend not only on the annealing conditions, but also on the amount of the reactive flux used.

When such transition metal stannide crystals are grown from a tin-rich flux, the solidified excess flux can be dissolved with hydrochloric acid, since the stannides are more stable than the flux. Figure 2 shows the experimental results for the preparation of $RhSn_4$ crystals. In the upper part of the Figure a partially dissolved matrix is shown, while one selected crystal is presented at the bottom.

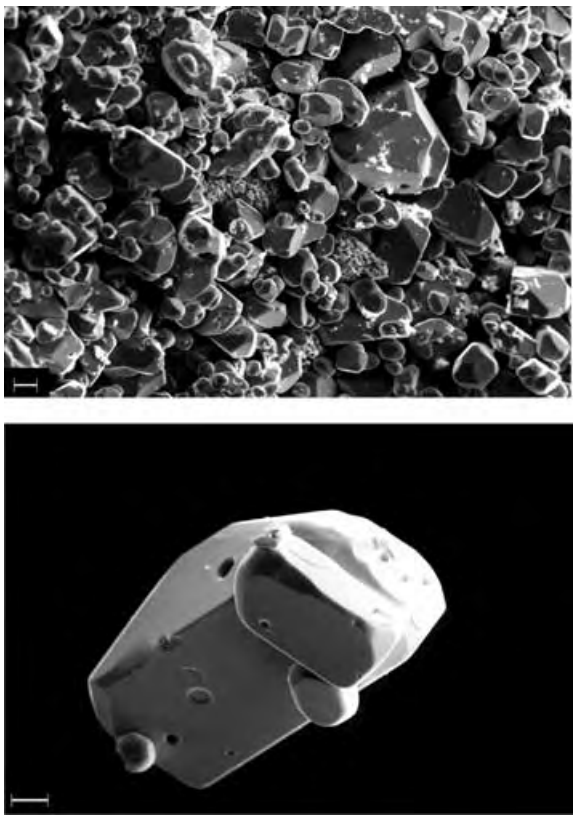

Figure 2. Single crystals of $RhSn_4$ grown in a tin flux. Top: the tin-rich matrix partially dissolved with diluted hydrochloric acid (scale bar 20 μm); bottom: a selected single crystal, with a few much smaller attached crystals (scale bar 10 μm)).

6. Experimental Techniques

To carry out exploratory reactions in a metallic flux, care must be taken to contain the liquid metal and prevent it from reacting with the container or evaporating. Therefore, the procedures and containers vary, depending on the liquid metal. Generally, liquid metals such as aluminum are highly reducing and react quickly with conventional container materials such as silica. Less reactive metals such as Sn, Ga, or In also react with silica if in contact for prolonged times and/or if the temperature is too high. A more attractive container material is alumina (Al_2O_3), which is inert to Al, Sn, or Ga. In this case alumina thimbles are used and are placed inside silica tubes, which are then sealed. Alternatively, for Sn or Ga fluxes graphite thimbles or crucibles can be used. Typically these are left open (i.e. without lid) because of the relatively low volatility of these metals at the temperatures used. Alumina and graphite, however, react with liquid alkali

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

metals, and therefore are unsuitable when these are used as fluxes. In some cases glassy carbon can be used as container material. Most metal fluxes do not react with this rather inert material. For reactions at higher temperatures tubes or crucibles of high-melting metals (Nb, Ta, Mo, W) may be used. Indium flux reactions have often been carried out in ZrO_2 crucibles. An extensive discussion of experimental techniques and procedures has been published by Fisk and Remeika.[42] For experimental details we refer to the original literature.

After the reaction is finished, isolation is either by recovering the solid ingot which contains the products embedded in the flux, or by immersing the entire thimble inside a flux-dissolving solution such as hydrochloric acid or aqueous sodium hydroxide. More exotic combinations can be used to dissolve the metal flux such as organic solvents containing various oxidants such as Br_2, I_2, peroxides. In the case of gallium and tin fluxes, the centrifugation technique has successfully been used for the separation of the crystals from the excess flux.[43–45] In the following sections we summarize recent results categorized by the respective flux medium.

7. The Tin Flux

The chemical and physical databases reveal a huge amount of literature dealing with the development of tin-based low-melting alloys for welding and soldering applications. We do not refer to this literature herein. In the case of tin fluxes we focus only on the preparation of new compounds.

7.1. Binary Phosphides and Polyphosphides

Elemental tin as a flux has already been used by Jolibois[27] to prepare the phosphides NiP_2 and NiP_3 in well-crystallized form. Crystal-structure investigations, carried out much later, showed that these compounds have P–P bonds. Such compounds are called polyphosphides today. Phosphides with high phosphorus content are difficult to synthesize by direct reaction of the elemental components. At relatively low temperatures (e.g. 500 °C), the reactions are too slow, and at higher temperatures polyphosphides tend to decompose into lower phosphides and phosphorus vapor. With the tin-flux technique this difficulty can be overcome as long as the desired polyphosphides are thermodynamically more stable than the corresponding stannides. Thus, phosphides and polyphosphides of the Mn, Fe, and Co group can be prepared this way, while Pd, Pt, and the coinage metals under similar conditions frequently form the corresponding transition-metal stannides (Figure 3) or ternary polyphosphides such as Cu_4SnP_{10}.[46] This limitation can be overcome to some extent by increasing the phosphorus and decreasing the tin content of the sample.

Usually, after such reactions, the tin-rich matrix of the binary or ternary transition-metal phosphides and polyphosphides can be dissolved in hydrochloric acid. The extent to which the acid attacks the phosphides and polyphosphides depends on the reactivity of the transition metal. Thus, for instance, after dissolving their tin-rich matrix, crystals of MoP_2 show rounded-off edges, whereas crystals of ReP_4 appear practically unattacked (Figure 4).

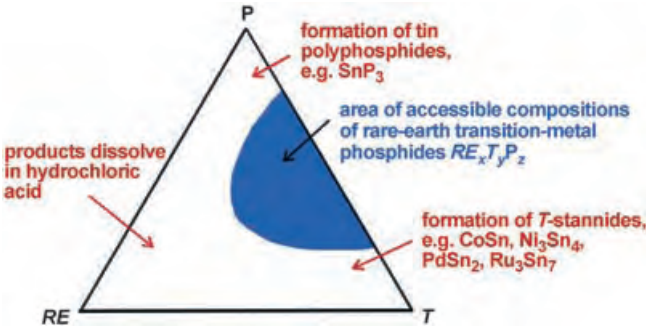

Figure 3. The use of a tin flux to prepare ternary phosphides of the type $RE_xT_yP_z$ (RE = rare-earth, T = transition-metal) Only phosphides within the blue area of the ternary phase diagram *RE*-*T*-P can be prepared well and isolated. Attempts to prepare samples with compositions which have high contents of phosphorus or with high contents of certain late transition metals may result in binary tin polyphosphides or transition-metal stannides, respectively. Ternary phosphides with a high content of rare-earth elements dissolve in hydrochloric acid and therefore are difficult to isolate from the tin-rich matrix.

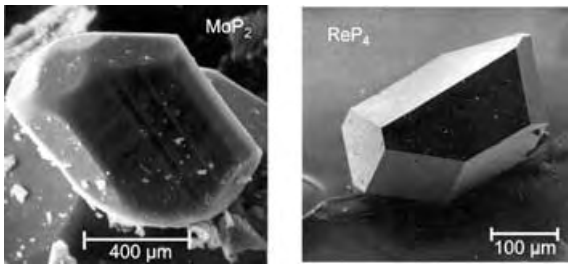

Figure 4. The appearance of the transition-metal polyphosphides MoP_2 and ReP_4 after their tin-rich matrix has been dissolved in diluted hydrochloric acid. Note that the edges of the MoP_2 crystal are rounded, while the crystal of ReP_4 has not been attacked by this acid.

Examples for binary phosphides and polyphosphides prepared in liquid tin are given in Table 1. It should be mentioned that the compounds SiP (sphalerite type),[47] *p*-SiP_2 (pyrite type),[47] CrP_4,[48] MoP_4,[48] and one modification of MnP_4[49]—subsequently called 8-MnP_4[50]—were first thought to be high-pressure compounds, because they could not be obtained by direct reaction of the elemental components at normal pressure. Their preparation by using a tin flux (for references see Table 1) showed that they must be considered as ambient-pressure compounds. In turn, the fact that these compounds could be prepared in the absence of tin, shows that they are not stabilized by small amounts of tin.

The preparation of binary rhenium phosphides and polyphosphides has been studied systematically, both using iodine as a mineralizer (somewhat similar to chemical vapor transport reactions, but over a shorter distance) or in a tin flux. As could have been expected, both preparation techni-

CuP_2	1:2:10	1 day, 1150 °C→5 °C h^{-1}→ 550 °C	[72, 75]

[a] **Caution**: Usually the less reactive modification of red phosphorus is used. Nevertheless, even this modification reacts violently with tin. Thus, care must be taken in heating the reactive mixtures of the elements. Frequently the samples are heated to the desired temperatures at very slow rates, for example, 5 °C h^{-1}. For detailed reaction conditions the original publications should be consulted.

ques yield essentially the same sequence of phases, however, the synthesis in the tin-flux proceeds faster and thermodynamic equilibria were reached at lower temperatures than in the reactions with iodine.[60] The compound Re_2P_5 was obtained only through the tin-flux synthesis. However, neither an energy dispersive X-ray fluorescence analysis, nor the structure determination gave any indication for it being stabilized by tin.[62] Furthermore, the structure of Re_2P_5 can be completely rationalized on the basis of a two-electron model, counting two electrons for each Re–Re, Re–P, and P–P interaction. In agreement with this extremely simple model, the compound shows semiconducting behavior. In contrast, the compound Re_6P_{13} with a very similar composition, prepared the same way by the tin-flux technique, lacks electrons to fill all the bonding states required according to the two-electron bond model. And in agreement with this result, its electrical conductivity is several orders of magnitude higher and has an inverse temperature dependence, thus indicating metallic behavior.[62] This result demonstrates not only the usefulness of the two-electron model for the rationalization of the physical properties of such transition-metal phosphides, but also that only insignificant amounts of tin were incorporated during the tin-flux syntheses of these compounds.

7.2. Ternary Phosphides and Polyphosphides of Rare-Earth and Transition Metals and Related Compositions

A large number of ternary rare-earth (*RE*) transition-metal (*T*) phosphides and polyphosphides were prepared by the tin-flux method. The polyphosphides with "filled" skutterudite type structure were the first to be investigated. They derive their name from the mineral $CoAs_3$ (Co_4As_{12}). Their crystal structure was determined for $LaFe_4P_{12}$. Some twenty phosphides are known to crystallize with this structure type, where iron may be substituted by its homologues ruthenium and osmium.[71,76] They were originally prepared from the elemental components in a tin flux with the atomic ratio *RE*:*T*:P:Sn = 1:4:20:50 in sealed silica tubes by slowly heating (to avoid violent reactions!) to 800 °C, annealing at that temperature for one week, followed by slow cooling (2 °C h^{-1}) to room temperature. After dissolving the tin-rich matrix in moderately diluted hydrochloric acid, crystals with diameters up to 2 mm can be obtained by this method.[77,78] As an example, we show a crystal of $NdFe_4P_{12}$ in Figure 5. In these compounds the *RE* components are usually the early-rare-earth elements from lanthanum to gadolinium. In addition, polyphosphides with the actinoids have also been synthesized from a tin flux: $ThFe_4P_{12}$,[79] $ThRu_4P_{12}$,[79] and UFe_4P_{12}.[80,81] The preparation of such polyphosphides without a tin flux has been successful mainly at high pressure (for references see ref. [82]). One exception is the sodium-containing filled skutterudite type polyphosphide $Na_{1+x}Fe_4P_{12}$ with excess sodium ($x \approx 1$), which has been prepared hydrothermally.[83] Another, very interesting exception is the series of metastable phosphides $LnFe_4P_{12}$, where the *Ln* components are late-rare-earth elements. These were prepared by heating of multilayer precursors at the relatively low temperature of 200 °C.[84] Many of these polyphosphides with $LaFe_4P_{12}$-type structure have interesting physical properties, including superconductivity and heavy fermion behavior. The purity of such samples prepared from a tin flux can be judged from the fact, that the cerium compounds are semiconducting—clearly, all four

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

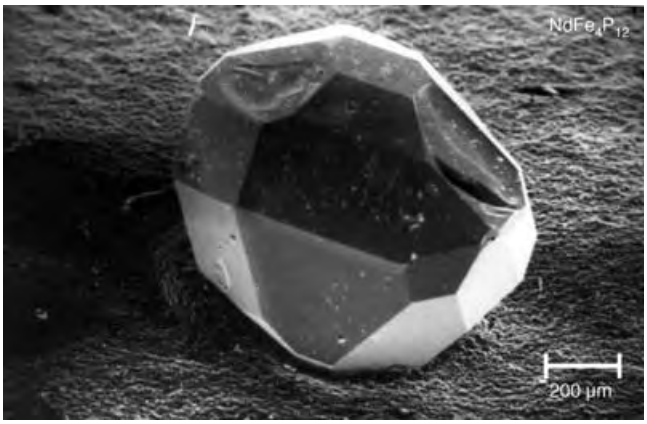

Figure 5. A crystal of $NdFe_4P_{12}$ with the cubic $LaFe_4P_{12}$ type structure grown from a tin flux.

valence electrons of the cerium atoms are involved in one way or the other in chemical bonding—whereas the skutterudite phosphides filled with the typically trivalent rare-earth elements are metallic conductors. The isostructural antimonides (RET_4Sb_{12}) have outstanding thermoelectric properties. Thus, the filled skutterudites have been studied by many research groups, details about their preparation can be found through the review articles.[82,85]

The ternary "filled" skutterudites RET_4P_{12} usually contain iron and its homologues ruthenium and osmium as the transition-metal components. When cobalt or its congeners rhodium and iridium are used as transition metals, the ternary compounds are nonstoichiometric with large defects at the *RE* positions, for example, $La_{0.2}Co_4P_{12}$ and $Ce_{0.25}Co_4P_{12}$.[86] With nickel as the transition metal the cubic compounds $Ln_6Ni_6P_{17}$ with $Ln = La$, Ce, Pr are obtained. These form by reactions of the elemental components in tin fluxes of greatly varying compositions. For example $La_6Ni_6P_{17}$ could be isolated from samples with the atomic ratios La:Ni:P:Sn = 1:1:8:20 and 3:1:6:10.[87] With analogous reaction conditions, using palladium as the transition-metal component, the low-temperature modification of the binary palladium stannide $PdSn_2$ is obtained (Figure 3), although the intended palladium compounds $La_6Pd_6P_{17}$ and $Ce_6Ni_6P_{17}$ could be prepared in microcrystalline form by direct reaction of the elemental components.[88]

Another large series of ternary phosphides frequently prepared by the tin-flux method have the composition AT_2P_2, where *A* is a lanthanoid or actinoid and *T* a late transition metal. Most of these phosphides crystallize with a body-centered tetragonal structure, variously called $BaAl_4$- and $ThCr_2Si_2$-type structures after the first binary or ternary representatives, respectively. From a crystallographic point of view, this structure type is interesting, because it is the one with the highest number of representatives, some 800. While the many silicides with this structure are usually prepared by direct reaction of the elemental components, the phosphides are best obtained by the tin-flux route, although most of these compounds have also been prepared in the absence of tin. Most phosphides of the three series AFe_2P_2, ACo_2P_2, and ANi_2P_2 (where A is practically all of the lanthanoids, including cerium, europium, and ytterbium which frequently show mixed-valent behavior in these compounds) have first been prepared from idealized starting compositions *A*:*T*:P:Sn varying between 1:2:2:3 and 1:2:2:25.[89,90a,b,91] Later, when the physical properties of these phosphides were investigated, it became important to prepare samples with higher purity and the starting compositions of the melts were optimized by trial and error. Thus, for instance the series of the nickel containing compounds ANi_2P_2 (A = Ca, La–Yb) were prepared with higher purity and yield from melts with the compositions A:Ni:P:Sn = 1.3:2:2.3:16.[92] Similar compositions have been used for the preparation of iron- and cobalt-containing phosphides with this structure.[93] Usually the mixtures of the elemental components are slowly heated (e.g. at a rate of 4 °C h^{-1}) to a temperature of between 850 and 950 °C, held at that temperature for one week, then quenched or slowly cooled to room temperature. After dissolving the tin-rich matrices, single crystals with edge lengths of up to 2 mm have been obtained from such fluxes (Figure 6).[94,95] Energy

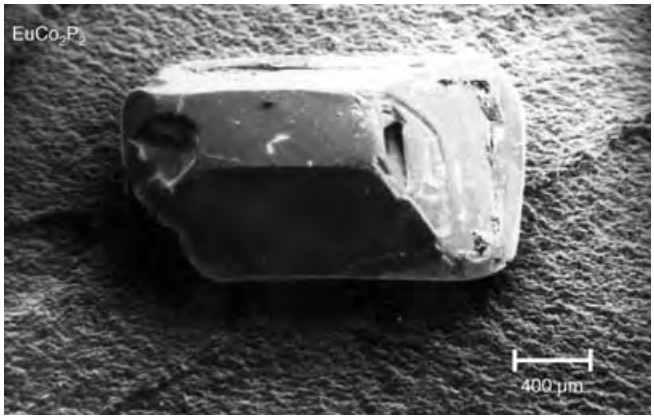

Figure 6. A 1.44 mm^3 single crystal of $EuCo_2P_2$ with the tetragonal $ThCr_2Si_2$ type structure grown from a tin flux.[95]

dispersive X-ray fluorescence analyses in scanning electron microscopes usually do not reveal any impurities such as tin or silicon (from the silica tubes) unless the reaction temperatures have been extremely high. However, heterogeneous inclusions of elemental tin have been observed in many cases, as concluded from the signals observed by difference scanning calorimetry at 232 °C, the melting point of tin.[96]

The phosphides with $ThCr_2Si_2$-type structure are known to crystallize with two different variants of this tetragonal structure with very different ratios of the unit cell dimensions *c*/*a* e.g., $EuCo_2P_2$ with $c/a = 3.01$ and $EuNi_2P_2$ with $c/a = 2.41$.[90] When the physical properties of these compounds became of interest, it was attempted to prepare samples of solid solutions between compounds with drastically different *c*/*a* ratios. Thus, the solid solutions $Ca_{1-x}Sr_xCo_2P_2$,[97] $LaCo_{2-x}Ni_xP_2$,[97] $LaFe_{2-x}Ni_xP_2$,[97] and $EuCo_{2-x}Ni_xP_2$[98] were investigated. More or less continuous changes in the *c*/*a* ratios were observed for $Ca_{1-x}Sr_xCo_2P_2$ between $x = 0.25$ and $x = 0.50$, for $LaCo_{2-x}Ni_xP_2$ between $x = 0.5$ and $x = 1.5$, and for $LaFe_{2-x}Ni_xP_2$ between $x = 1.0$ and $x = 2.0$. These samples were prepared by slowly heating powders in the ratio *A*-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

(Ca,Sr,La):*T*(Fe,Co,Ni):P:Sn = 1.1:2:2:20 at a rate of 40 °C h^{-1} to 880 °C and annealing at that temperature for 10 days. In contrast, a discontinuous change of the *c*/*a* ratio was observed for $x = 1.0$ in the pseudobinary system $EuCo_{2-x}Ni_xP_2$. The samples for this latter investigation were prepared by mixing powders of the end-members $EuCo_2P_2$ and $EuNi_2P_2$, and annealing these mixtures for two weeks at 910 °C in the presence of a relatively small amount of tin (29 mol %). This reaction was termed activated solid-state synthesis.[98]

With ruthenium as the transition-metal component the series ARu_2P_2 (A = Ca, Sr, La–Yb) with $ThCr_2Si_2$-type structure have been prepared from tin fluxes with atomic starting ratios varying between A:Ru:P:Sn = 1:2:2:5, 1:2:2:20, and 3:2:2:15. Of these products, $LaRu_2P_2$ becomes superconducting with a critical temperature of $T_c = 4.1$ K.[99] The compound $BaRu_2P_2$ has not been obtained this way, although it could be prepared by direct reaction of the elemental components.[100] Similarly, the palladium-containing phosphides of the series APd_2P_2 (A = Ca, Sr, Y, La–Er, Yb) with $ThCr_2Si_2$-type structure were obtained only by reaction of the elements.[88] The ternary actinoid phosphides $AnCo_2P_2$ (An = Th and U) crystallize with a primitive tetragonal $CaBe_2Ge_2$-type structure, which is closely related to the body-centered tetragonal structure of $ThCr_2Si_2$. These phosphides were also prepared from a tin flux using atomic ratios close to An:Co:P:Sn = 1:2:2:25.[90b,93b,93d] An entirely different orthorhombic structure, closely related to those of $BaZn_2As_2$ and $BaCu_2S_2$, was found for the phosphides $ThRu_2P_2$ and URu_2P_2. For the preparation of these phosphides with a tin flux, the binary phosphide RuP and a prereacted heterogeneous binary alloy of the overall composition "$U_{1.3}Ru_2$" were used with the starting ratios for both Th:RuP:Sn and $U_{1.3}Ru_2$:P:Sn of 1:2:10.[101a] Two modifications of $ThNi_2P_2$ with $BaCu_2S_2$-type and $CaBe_2Ge_2$-type structures, were prepared in a tin flux by annealing at 850 and 1000 °C, respectively, both with the same starting composition Th:Ni:P:Sn = 8:13:13:66.[101b] The manganese-containing compounds $EuMn_2Pn_2$ (Pn = P, As, Sb) have a simple hexagonal structure first determined for Ce_2O_2S and $CaAl_2Si_2$.[102a] For the physical characterization of the phosphide $EuMn_2P_2$ the crystal growth of this compound from a tin flux was optimized. Relatively large crystals with diameters up to 2 mm were obtained from a melt in the atomic ratio Eu:Mn:P:Sn = 14:4:11:265 ($\approx$ 90 atom % Sn). After slow heating, the sample was annealed at 1050 °C for 6 h, slow-cooled at 3 °C h^{-1} to 700 °C, and centrifuged at that temperature through silica wool into another vessel.[102b]

The uranium nickel phosphides UNi_3P_2,[103] $U_6Ni_{20}P_{13}$,[103] $U_2Ni_{12}P_7$,[103] and $U_3Ni_{3.34}P_6$[104] were prepared by reacting the elemental components in a tin flux with a tin content of 67 and 59 atom %, respectively. Two modifications of UCr_6P_4 were obtained by reactions of the binary uranium phosphide UP_2, phosphorus, and chromium in a tin flux of 70 atom %.[105]

A large family of closely related ternary rare-earth transition-metal phosphides has been found for compositions with a metal:phosphorus ratio of exactly or very close to 2:1. Most of the iron- and cobalt-containing compounds have been obtained in well-crystallized form with tin as a flux, while many of the corresponding nickel compounds were prepared in the absence of tin.[106] Nevertheless, the phosphides of the three series $RE_2Fe_{12}P_7$, $RE_2Co_{12}P_7$, and $RE_2Ni_{12}P_7$, were all prepared first using a tin flux with tin contents of between 70 and 80 atom % for the iron and cobalt containing compounds,[107] and between 25 and 35 atom % for the nickel compounds (note that the amount of tin flux tolerated for the nickel compounds is much lower, see Figure 3).[108] Needle-shaped crystals of $Tm_2Ni_{12}P_7$ with lengths of up to 2 cm were obtained by this preparation method.[109] The corresponding uranium compounds $U_2T_{12}P_7$ (T = Fe, Co, Ni) were also obtained this way.[110] Other compounds belonging to this structural family which were prepared by the tin flux technique include the two isotypic phosphides $LaNi_5P_3$ (La:Ni:P:Sn = 5:45:25:25)[91] and $EuNi_5P_3$ (Eu:Ni:P:Sn = 1:2:2:20),[111] the two isotypic series $RECo_5P_3$[112,113] and $REFe_5P_3$[107b] crystallizing with a different structure type, and the three isotypic phosphides $LaCo_8P_5$,[114,115] $PrCo_8P_5$,[115] and $EuCo_8P_5$.[115] In the case of the latter compounds the annealing was for 7 days at 880 °C, followed by controlled cooling (10 °C min^{-1}) to 600 °C and quenching. Crystals of the europium compound of up to 3 mm length and with diameters up to 1 mm were obtained this way. The barium nickel phosphide $BaNi_9P_5$ has also been prepared from a tin flux by slowly heating the components to 850 °C, and subsequent slow cooling at a rate of 2 °C h^{-1}. This resulted in equidimensional crystals with diameters of up to 3 mm.[116] The three series of phosphides $RECo_3P_2$,[113,117] $RE_5Co_{19}P_{12}$,[113,118] and $RE_6Co_{30}P_{19}$[119] were also prepared by the tin-flux technique, and they also belong to this large family of ternary structures with a metal/metalloid ratio of exactly or nearly 2:1. In this family the metalloid components are mainly silicon, phosphorus, and their homologues.[120]

The system scandium–cobalt–phosphorus contains the phosphides ScCoP, $ScCo_5P_3$, $Sc_2Co_{12}P_7$, and $Sc_5Co_{19}P_{12}$. They were all prepared using a tin flux of 80 atom %.[118] For the other ternary rare-earth–cobalt–phosphorus systems the phase equilibria, as far as they are accessible with a 75 atom % tin flux, have been investigated systematically for the sections at 850 °C. The samples were annealed for about two weeks, followed by quenching in air. Generally, between three and eight ternary phases were found in this way.[121] A remarkable result of this investigation is the fact that the sample composition required for the syntheses of certain isotypic phosphides, changes systematically with the rare-earth components. This situation is demonstrated in Figure 7 for three pairs of isotypic samarium and thulium phosphides with the three structure types first established for $Zr_2Fe_{12}P_7$,[122] YCo_5P_3,[112] and $HoCo_3P_2$.[117] It can be seen that higher phosphorus contents of the samples are needed for the synthesis of the thulium compounds than for the corresponding samarium compounds.

Ternary rare-earth and actinoid transition-metal phosphides prepared by the tin-flux technique with iron and nickel as the transition-metal components include the compounds $ScFe_4P_2$[123] and $ThFe_4P_2$,[124] which crystallize with two different structure types, $Th_5Fe_{19}P_{12}$[124] and isotypic $Yb_5Ni_{19}P_{12}$,[125] $ThFe_5P_3$,[126] $La_2Fe_{25}P_{12}$,[127] $Th_{11}Ni_{25}P_{20}$ and isotypic $U_{11}Ni_{25}P_{20}$,[128] $Yb_9Ni_{26}P_{12}$,[129] and $YbNi_5P_3$.[129] With chromium as the transition-metal component the compounds UCr_5P_3,[130] $A_2Cr_{30}P_{19}$ (A = U and Zr),[131,132] and $Zr_6Cr_{60}P_{39}$[133]

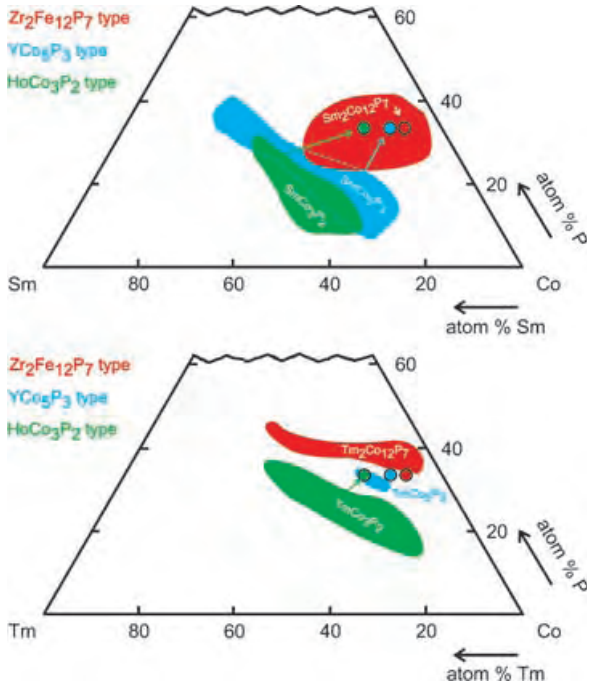

Figure 7. Sample compositions for the preparation of ternary Sm (top) and Tm (bottom) cobalt phosphides from a tin flux. All samples were prepared with 75 atom% tin as a flux. The diagrams indicate the ratio of the remaining 25% of the elements samarium, thulium, cobalt, and phosphorus. The phase diagrams contain several ternary phosphide phases. Only the sample compositions resulting in ternary phosphides with $Zr_2Fe_{12}P_7$-type,[107a] YCo_5P_3-type,[112] and $HoCo_3P_2$-type[117a] structures are shown. The compositions of the ternary phosphides are indicated by large colored dots. All samples were equilibrated for two weeks at 850°C and the tin-rich matrix was dissolved in diluted hydrochloric acid.[117b]

were prepared in well-crystallized form from a tin flux. For the syntheses of corresponding molybdenum compounds (e.g. $U_2Mo_{30}P_{19}$[131] and $U_6Mo_{60}P_{39}$[134]), however, arc-melting of prereacted pellets of the elemental components turned out to be more successful.

7.3. Ternary Transition-Metal Polyphosphides

Generally, the use of a tin flux for the preparation of phosphides containing two different kinds of transition metals has been explored less systematically than the investigations for the syntheses of ternary phosphides containing lanthanoids or actinoids as one metal component and a transition-metal element as the other. Ternary phosphides with a relatively high metal content of two different transition-metal elements can be prepared well by arc melting of the prereacted components. Only some polyphosphides, which are difficult to prepare otherwise (e.g. at high pressure), have been synthesized with a tin flux. The first examples seem to have been the isotypic diamagnetic semimetals $MoFe_2P_{12}$ and WFe_2P_{12}. For their preparation the elemental components were allowed to react in the atomic ratio Mo(W):Fe:P:Sn = 1:2:12:20. The annealing was at 970 K, with subsequent quenching in air. Annealing at lower or higher temperatures (870 and 1170 K) resulted in the binary polyphosphides MoP_2 and α-FeP_4 or MoP_2 and FeP_2, respectively.[135] The metallic conductor $TiMn_2P_{12}$ has a different structure. It could be prepared from the elemental components in the presence of iodine. For its preparation with a tin flux only a relatively small amount of tin was used: Ti:Mn:P:Sn = 1:2:30:20.[136] With similar atomic ratios the $TiMn_2P_{12}$-type compounds $NbMn_2P_{12}$ (5:2:10:17), $MoMn_2P_{12}$ (1:2:30:20), and WMn_2P_{12} (1:2:15:20) were prepared from a tin flux.[137] For the syntheses of the polyphosphides $MoNiP_8$ and $WNiP_8$ the elements were allowed to react in the ratio Mo(W):Ni:P:Sn = 1:1:40:50.[138]

The preparation of the compound Ti_2NiP_5 by reaction of the elemental components in a tin flux failed. However, this compound could be prepared by using powders of the binary alloy of the composition TiNi in a tin flux with the ratio TiNi:P:Sn = 1:20:25. After slow heating (it is important to remember the violent reactivity of phosphorus) the annealing was for one month at 650°C.[139] Apparently, when the metals Ti and Ni are used instead of the binary alloy TiNi, the binary phosphides of the transition metals are formed first. And at 650°C these react too slowly to produce the intended ternary phosphide. Similarly, powders of the binary alloys were used for the preparation of the ternary polyphosphides VNi_4P_{16}, $NbNi_4P_{16}$, and WNi_4P_{16}.[140] Three stacking variants of the binary manganese polyphosphide MnP_4 are known: 2-MnP_4,[56] 6-MnP_4,[50] and 8-MnP_4.[49] The missing stacking variant 4-MnP_4 could only be prepared in form of a solid solution with chromium: $Cr_{1-x}Mn_xP_4$ with x having values between 0.3 and 0.7. Again, for the preparation of these samples in a tin flux powders of binary Cr/Mn alloys were used.[141]

Many of the compounds listed in Table 1 are polyphosphides of the late transition metals. With copper as the transition-metal component, only CuP_2 could be prepared from a tin flux, although with Cu_2P_7 a polyphosphide with a still higher phosphorus content has been obtained in well crystallized form using iodine as a mineralizer.[142] Apparently, the presence of tin reduces the chemical activity of phosphorus to the extent that the higher polyphosphides cannot be prepared (Figure 3) and the ternary compound Cu_4SnP_{10} is formed instead.[46,142] Similarly, no silver phosphide could be obtained from a tin flux, although the compounds AgP_2[142] and Ag_3P_{11}[143] could be prepared in the presence of iodine. With the subsequent elements gold, zinc, cadmium, and mercury the presence of tin prevents the formation of binary phosphides and the ternary compounds $MSnP_{14}$ (M = Zn, Cd, Hg) and $Au_{1-x}Sn_{1+x}P_{14}$ are obtained.[144,145] Also, apparently, in trying to optimize the preparation conditions for the binary nickel polyphosphide NiP_3[27,71,73] from a tin flux, the ternary compounds Ni_2SnP[146] and $Ni_{1.17}Sn_{0.69}P_{0.31}$[147] were obtained using atomic ratios Ni:Sn:P of 2:6:1 and 4:40:1, respectively, at well defined temperatures.

7.4. Borides, Silicides, and Further Pnictides from Liquid Tin

The excellent wettability of tin enables the preparation of a large variety of compounds. Besides the numerous phos-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

phides reported in the previous sections, also some boron-rich solids such as YB_{25}[148] or the silicide boride $Er_8Si_{17}B_3$[149] have been synthesized in liquid tin. Binary silicides can be obtained in various metal fluxes. As discussed in Section 13, liquid copper has widely been used for the growth of such silicide crystals, but compounds such as V_3Si, V_5Si_3, VSi_2,[150] Mn_5Si_3, MnSi, or $Mn_{27}Si_{47}$[151] are also accessible from liquid tin.

In the case of ternaries, many compounds with two different main-group elements in ordered two- or three-dimensional networks have been synthesized. Single crystals of EuSnP[152] and Nb_5Sn_2Ga[153] can be obtained by the tin self-flux technique. The growth of larger crystals enables direction-dependent investigations of the physical properties. A larger family of compounds was observed for the silicon phosphides such as $ZnSiP_2$,[154] $Sn_{4.2}Si_9P_{16}$,[155] TSi_4P_4 (T = Fe, Ru, Os),[156] $RESi_2P_6$ (RE = La, Ce, Pr, Nd),[157] TSi_3P_3 (T = Rh, Ir),[158] $PtSi_3P_2$, and $PtSi_2P_2$.[159] Owing to the similar X-ray scattering power, the correct determination of the silicon and phosphorus sites is the main problem for this interesting class of compounds. Also some of the quaternary phosphide oxides of the series REFePO, RERuPO, and RECoPO,[160] and $Th_4Fe_{17}P_{10}O_{1-x}$[126] were first obtained from tin fluxes. Later most of these materials were been synthesized in NaCl/KCl salt fluxes. Some more recent developments are referred to in a paper on $Pr_3Cu_4P_4O_{2-x}$.[161]

Liquid tin is also a suitable flux for the higher homologues arsenic and antimony. For example, the ternary arsenide $Ba_{0.8}Hf_{12}As_{17.7}$ was synthesized in a tin flux at 950 °C.[162] With antimony, several ternary alkaline-earth, rare-earth metal, or uranium-containing compounds such as RE_3TiSb_5 (RE = La, Ce, Pr, Nd, Sm),[163] La_3ZrSb_5, La_3HfSb_5, $LaCrSb_3$,[164] $Sr_{21}Mn_4Sb_{18}$,[165] $Eu_{10}Mn_6Sb_{13}$,[166] or U_3TiSb_5 and U_3MnSb_5[167] have been obtained in well crystallized form. For instance, the latter two antimonides were obtained with the atomic starting ratios U:Ti:Sb:Sn = 1:3:2:6 and U:Mn:Sb:Sn = 1:3:2:9 in alumina crucibles. The temperature was allowed to oscillate between 600 and 700 °C for one week. After quenching, the tin matrix was dissolved in diluted hydrochloric acid, which attacked the needle-shaped hexagonal crystals of U_3TiSb_5 and U_3MnSb_5 at a much slower rate. The fact that these antimonides were also prepared without the tin flux—albeit in microcrystalline form—shows that they are not stabilized by small amounts of tin. Containing two main-group elements, the Zintl phases $Ba_2Sn_3Sb_6$,[168] $EuSn_3Sb_4$,[169] $Ba_3Sn_4As_6$,[170] and $SrSn_3Sb_4$[171] are accessible by a tin flux.

7.5. Binary and Ternary Stannides

As already discussed for some of the Zintl phases in Section 7.4, liquid tin is often used as a self-flux. As examples, we have already mentioned above the growth of the binary cobalt stannides CoSn, $CoSn_2$, and $CoSn_3$ by peritectic reactions.[41] This preparation technique has widely been used also for binary stannides of the early transition metals such as Ti_2Sn_3,[172,173] VSn_2,[174] or $MoSn_2$.[175] Stannides with even higher tin contents are formed with the noble metals. Recent examples are Os_4Sn_{17},[176] Os_3Sn_7,[177] $RhSn_3$,[177] $RhSn_4$,[177] Ir_3Sn_7,[178] and two modifications of $IrSn_4$.[177,179] Furthermore, a variety of mixed transition-metal stannides have been prepared, for example AuMnSn[180] or $Co_{1-x}Ni_xSn_2$ ($0.23 < x < 0.59$).[181]

The largest families of stannides that can be prepared from liquid tin are alkaline-earth or rare-earth transition-metal stannides. A good overview on the manifold phase relationships and the crystal chemistry of these intermetallics has been given by Skolozdra.[182] Three recent examples for crystal growth are the stannides $RE$$Mn_6Sn_6$ (RE = Tb, Ho, Er, Tm, Lu),[183] ScPtSn,[184] and $La_{4.87}Ni_{12}Sn_{24}$.[185]

8. The Lead Flux

Tin is a well known flux medium for the growth of single crystals of metal-rich phosphides and arsenides with a metal:phosphorus (arsenic) ratio close to 2:1. In some cases better crystal-growth results have been obtained using a lead flux rather than tin, especially for compounds with the platinum metals, which form very stable stannides, as already pointed out above. Recent examples for products from such reactions are $Ca_2Ir_{12}P_7$, $Ca_5T_{19}P_{12}$ (T = Rh, Ir), or $Eu_6Rh_{30}As_{19}$,[186] $AEIr_2P_2$ (AE = Ca, Sr, Ba),[187] $Sr_2Rh_7P_6$,[188] and $MgRh_6P_4$.[189] The elements can be treated with an excess of lead at 1100 °C in an alumina crucible that is sealed in a silica ampoule. A typical starting composition is approximately 60 equivalents of lead for one formula unit of the desired compound. A large advantage for crystal growth in the lead flux in these cases is the reduction of the reaction time. The conventional synthesis often requires repeated regrinding and annealing of the reaction components. The dissolution of the flux with hydrochloric acid is less suitable because lead chloride is only significantly soluble in hot water. In this case an elegant way to dissolve the flux is to use a mixture of concentrated acetic acid and H_2O_2 (30 %).

A lead flux was already used by Hittorf in 1865 for the recrystallization of elemental phosphorus. Some 50 years ago Krebs and co-workers reproduced these experiments.[190] They also used metallic fluxes, mostly lead, for the growth of polyphosphides with high phosphorus content, for example, CdP_4[191] and the compounds $MPbP_{14}$ (M = Zn, Cd, Hg).[192] Various other polyphosphides with $HgPbP_{14}$ type structure have been described later.[144,145] The polyphosphide Au_2PbP_2[193] was grown from a starting composition Au:Pb:P = 1:3:1. The sample was first heated to 400 °C within 20 min, held at that temperature for 16 h, heated to 800 °C at a rate of 5 °C h^{-1}, kept at that temperature for 100 h, and subsequently furnace-cooled.

Excellent crystals of the silicides $RE$$Mn_2Si_2$ (RE = Y, Tb–Lu) have been grown from molten lead under an argon atmosphere, Figure 8.[194,195] The rare-earth elements were mixed with manganese and lead in the ideal 1:2:2 atomic ratio and lead was added to these mixtures at a ratio of 3.8:1 in weight. This mixture was placed in a crucible of high-purity hexagonal boron nitride, annealed under argon at 1350 °C for 5 h, cooled to 800 °C at a rate of 50 °C h^{-1}, and finally quenched to room temperature. The excess lead had been dissolved in hydrogen peroxide and diluted acetic acid.

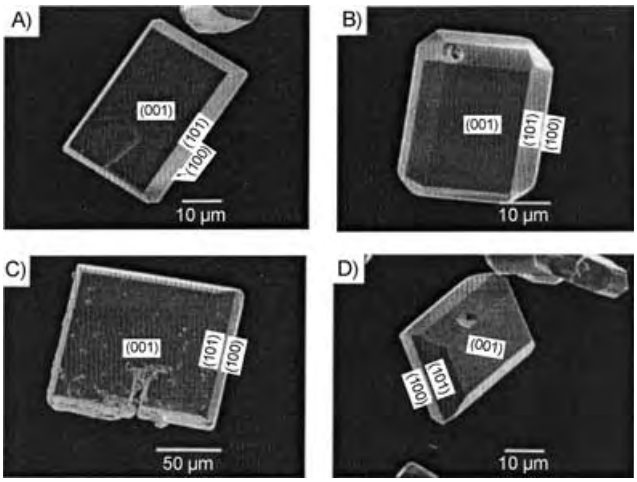

Figure 8. Scanning electron micrographs of $ErMn_2Si_2$ (A), $TmMn_2Si_2$ (B), $YbMn_2Si_2$ (C), and $LuMn_2Si_2$ (D) grown from a lead flux. From Okada et al.[195]

Lead fluxes have not had the type of extensive use in the syntheses of intermetallics as other fluxes described herein. In the examples cited, the reactions were run at rather high temperatures, many hundred degrees above lead's melting point, possibly because the solubility in lead of most elements is lower than that in tin. Nevertheless, it would be worthwhile to explore reactions in molten lead at lower temperatures as well, using longer annealing times.

9. Liquid Aluminum as a Flux

Aluminum melts at 660 °C and dissolves a large number of elements as can readily be seen from the extensive binary phase diagram information available in the literature.[40] Furthermore, it dissolves readily in non-oxidizing acids, for example, in hydrochloric acid. This property makes aluminum potentially a great flux system in which reactions can be carried out and indeed its utility as such has been demonstrated in the last few decades. A large variety of intermetallic aluminides have been prepared from liquid aluminum, many featuring fascinating new structures, and many being key components in advanced aluminum alloys.

9.1. Borides from an Aluminum Flux

Aluminum has been shown to be a useful flux in the synthesis of metal borides and ternary metal aluminides. Primarily Japanese, Swedish, and Russian groups have been active in boride synthesis using molten aluminum.[196] Some of the compounds reported include V_2B_3,[197a] Cr_3B_4, Cr_2B_3, and CrB_2,[197b] Ta_5B_6,[198a] Ta_3B_4, and TaB_2,[198b] LaB_6,[199a] LuB_4, $LuAlB_4$, and Lu_2AlB_6.[199b] Single crystals of TmB_4 and $TmAlB_{14}$ were obtained by the high-temperature aluminum-solution method using thulium powder and crystalline boron powder as starting materials. The optimum conditions required a temperature of 1500–1600 °C.[200] Crystals of the icosahedral B_{12} compounds $AlLiB_{14}$ and $AlMgB_{14}$[201] were grown from high-temperature aluminum solutions.

Also ternary transition-metal-containing borides can be prepared from liquid aluminum. MoAlB[202] and Fe_2AlB_2[203] were obtained from samples with starting compositions 1:6:1 and 35:35:30, respectively, were aluminum is used as a self-flux. These borides are stable in concentrated hydrochloric acid.

9.2. Binary and Ternary Aluminides

As is evident from the binary transition-metal–aluminum phase diagrams,[40] the aluminum self-flux technique is very useful for the preparation of binary aluminum-rich transition-metal aluminides. Some recent examples include Co_4Al_{13},[204] Re_4Al_{11}, $ReAl_6$,[205] $ReAl_{2.63}$,[206] and $IrAl_{2.75}$.[207]

Numerous ternary rare-earth– and actinoid–transition-metal aluminides have been prepared in recent years using an excess of aluminum as a reactive flux.[208a–o] Many of these have interesting magnetic properties.[208p–v] They crystallize with some ten different structure types sometimes in strange stoichiometries. For example, some 80 compounds have the compositions $A_6T_4Al_{43}$ (A = Y, La–Lu (with the exception of Eu), Th, and U; T = Ti, V, Nb, Ta, Cr, Mo, W, and Mn)[208a,b,r] and crystallize with a hexagonal structure which was determined for $Ho_6Mo_4Al_{43}$.[208a] The compounds of the series $RERe_2Al_{10}$ crystallize with four different structure types,[208i,k,n] one of which was determined some 20 years ago for $CaCr_2Al_{10}$.[209a] Some 20 isotypic aluminides have the general formula $RE_{7+x}T_{12}Al_{61+y}$ (T = Os and Re), where it could be shown for the rhenium compounds that their composition varies systematically between $Gd_{7.23}Re_{12}Al_{61.70}$ and $Lu_{7.61}Re_{12}Al_{61.02}$ depending on the size of the rare-earth atoms.[208d,n,p] Many representatives have been found for the compositions $A_2T_3Al_9$ (A = Lanthanoids and Actinoids, T = Co, Rh, Ir, and Pd),[208v] crystallizing with a structure first determined for $Y_2Co_3Ga_9$.[209b] Reactions in the systems RE–Au–excess Al (atomic ratio 1:1:10) produced low yields of $REAu_3Al_7$ with more prevalent products being $REAuAl_3$, and binary aluminides such as $REAl_3$. Increasing the amount of gold in the reaction (using a reactant ratio of 1:2:15) increased the yield of $REAu_3Al_7$.[210] Further preparation conditions of ternary aluminides grown from melts with an excess of aluminum can be found in the literature.[208]

9.3. Quaternary Compounds

The phase diagram of the binary system Al–Si shows that these elements form a eutectic system with a eutectic point at 577 °C and 12.2 mol % Si.[40] Aluminum melts dissolve some silicon, but they do not form any binary compounds. This situation is supported by the fact that silicon crystals are frequently found as by-products of reactions aimed at the synthesis and crystal growth of silicides. With rapid silicon diffusion in the melt, comes increased reactivity with the other metals which initiates phase formation. Most elements are to a certain extent soluble in aluminum and, in this sense,

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the flux reaction is not different from any conventional solvent.

There are few rare-earth aluminum silicides reported.[211] Most of them were synthesized as powders and their crystal structures have not been determined or refined. For Ho, Er, and Tm, only RE_6Al_3Si (RE = Ho, Tm)[212] and Er_4AlSi_3[213] have been reported.

In the late 1990s the first deliberate attempt was made to produce silicon intermetallics by reacting rare-earth elements with silicon in excess aluminum. Crystals of various metal–aluminum silicides grow easily in an aluminum melt below 900 °C, and a large number of such silicides has been identified. These reactions proceed rapidly; examples are the series $RE_2Al_3Si_2$ (RE = Ho, Er, Dy, Tm)[214] as well as the quaternary aluminum silicide $Sm_2Ni(Ni_xSi_{1-x})Al_4Si_6$. Crystals as long as 4 mm form readily in the aluminum flux. A crystal of $Ho_2Al_3Si_2$ grown in this fashion is shown in Figure 9. These

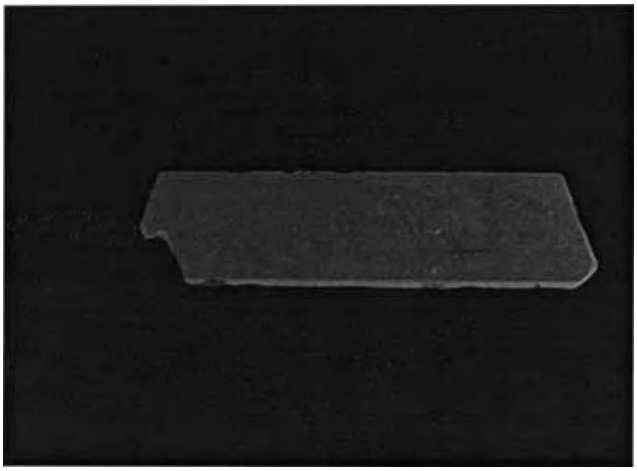

Figure 9. Scanning electron micrograph of a crystal of $Ho_2Al_3Si_2$ (length 0.5 mm).

compounds form with the late lanthanoids whereas the reactions with the mid and early lanthanoids, such as La, Ce, Nd, Sm, give REAlSi, and La, Sm, Tb, Yb give $REAl_2Si_2$. Neither of these two types of compounds has been found for Ho, Er, and Tm to date. Instead, the $RE_2Al_3Si_2$[214] and $REAl_{3-x}Si_x$[215,216] series seems to be favored. There are several old reports that claimed the production of binary silicides, such as $RESi_2$, $ThSi_2$, $MoSi_2$, and WSi_2 in molten aluminum. However, we find that most of these are in fact ternary metal aluminum silicides (e.g. REAlSi) rather than binary metal silicides.

The reaction of Sm, Ni, and Si in molten aluminum proceeds at approximately 750 °C to yield well-formed crystals of $Sm_2Ni(Ni_xSi_{1-x})Al_4Si_6$.[217] To obtain a single-phase product, it is necessary to use stoichiometric amounts of Sm, Ni, and Si with excess aluminum metal. To isolate the compound the excess aluminum metal was dissolved with NaOH (aq) because $Sm_2Ni(Ni_xSi_{1-x})Al_4Si_6$ ($x = 0.18$–0.27) decomposes in dilute hydrochloric acid and therefore its isolation in strong basic solution was important for its discovery.

The isostructural compounds $Dy_2Ni(Ni_xSi_{1-x})Al_4Si_6$, $Gd_2Ni(Ni_xSi_{1-x})Al_4Si_6$, and $Sm_{2-y}Y_yNi(Ni_xSi_{1-x})Al_4Si_6$ also form from an aluminum flux.[218] An intriguing observation in the structures of these compounds is the presence of certain crystallographic sites with mixed Ni/Si occupancy. Such mixed Ni/Si and Ni/Ge occupancies are often observed in *RE*/Ni/Si and *RE*/Ni/Ge phases. The really interesting part about these results is the complex stoichiometries of these compounds, which are unlikely to be discovered rationally by mixing these elements in direct-combination reactions. They are too difficult to guess. The flux chemistry leads to the most feasible result under the prevailing conditions of reactant ratio and concentration. In other words, it "finds" the accessible compositions regardless of complexity and this underscores the great potential of molten metals as reaction media for accessing novel multinary phases.

Many other *RE*/*T*/Al/Si phases were discovered in aluminum flux. An intriguing new compound is $Sm_5(Cu_{4.26}Si_{3.74})Al_8Si_2$,[218] which has a three-dimensional Cu/Al/Si framework with infinite zigzag silicon chains and crystallographic sites with extensive Cu/Si mixed occupancy, similar to the Si/Ni disorder described above. The zigzag silicon chains do not contain copper.

Additional examples include $RE_2NiAl_4Ge_2$,[219] $RENiAl_4Ge_2$, $RE_{1-x}T_2Al_{5-y}Si_y$, $RE_{2-x}T_2Al_4Tt_2(Al_{1-y}Tt_y)(Al_{1-z}Tt_z)_2$, ($RE$ = rare earth element; T = Ni, Co; Tt = Si, Ge)[220] $RE_4Fe_{2+x}Al_{7-x}Si_8$, and $REFe_4Al_9Si_6$. Along with the new structure types of these compounds, several isostructural analogues, such as $RENiAl_4(Si_{2-x}Ni_x)$ and $RENiAl_{6-x}Ge_{4-y}$, have also been synthesized. Explorations with 4d and 5d transition metals revealed intriguingly complex phases such as $Th_2[AuAl_2]_n(Au_xSi_{1-x})Si_2$,[221a] $Gd_{1.33}Pt_3Al_7Si$,[221b] and the series of the cubic compounds $RE_8Ru_{12}Al_{49}Si_9(Al_xSi_{12-x})$.[222] The latter feature unique $(Al/Si)_{12}$ cuboctahedral clusters. Figure 10 show several typical crystals of various compounds grown in liquid aluminum. Table 2 summarizes some of the ternary and quaternary compounds synthesized or discovered in aluminum flux.

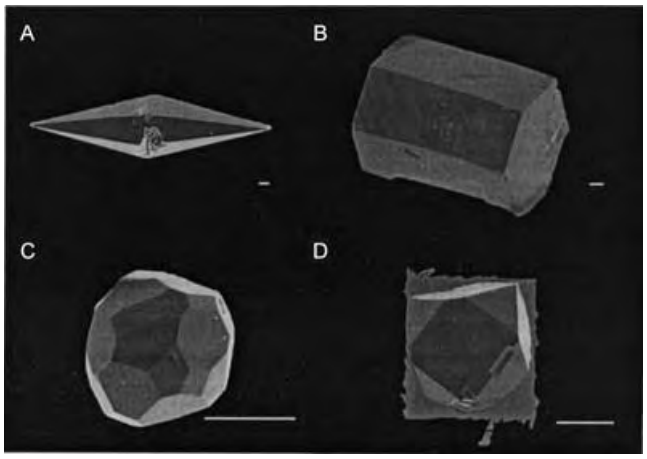

Figure 10. Typical crystals grown in liquid metals (scanning electron micrographs): A) $Sm_{2-x}Ni_2Al_4Si_2(Al_{1-y}Si_y)(Al_{1-z}Si_z)_2$, (from molten Al), B) $YNiAl_4Ge_2$, C) $CrSi_2$ (from molten In), and D) $RE_8Ru_{12}Al_{49}Si_9(Al_xSi_{12-x})$ (from molten Al). $RE_{1-x}T_2Al_{5-y}Si_y$ (RE=Y, Nd, Sm, Tb, Tm, Yb; T = Ni, Pd)	1:2:20:2	50→1000 in 15 h, 5 h at 1000, 1000→850 in 2 h, 72 h at 850, 850→50 in 36 h	[220]
$RE_{2-x}TAl_4Tt_2(Al_{1-y}Tt_y)(Al_{1-z}Tt_z)_2$ (RE=Sm, Dy, Er; T = Ni, Co; Tt = Si, Ge)	3:4:20:6	50→1000 in 15 h, 5 h at 1000, 1000→850 in 2 h, 72 h at 850, 850→50 in 36 h	[219]
$RE_4Fe_{2+x}Al_{7-x}Si_8$ (RE = Ce–Nd, Sm)	1:2:15:4	50→850 in 20 h, 96 h at 850, 850→500 in 72 h, 500→50 in 12 h	[220]
$RE_4Mn_{2+x}Al_{7-x}Si_8$ (RE = Ce–Nd, Gd)	1:2:15:4	50→850 in 20 h, 96 h at 850, 850→500 in 72 h, 500→50 in 12 h	[220]
$REFe_4Al_9Si_6$ (RE = Gd–Er)	1:4:20:6	50→850 in 20 h, 96 h at 850, 850→500 in 72 h, 500→50 in 12 h	[220]
$RE_8Ru_{12}Al_{49}Si_9(Al_xSi_{12-x})$ (RE = Pr, Nd, Sm, Gd, Tb, Er)	6.5:10:100:8	50→1000 in 15 h, 15 h at 1000, 1000→860 in 10 h, 96 h at 860, 860→500 in 72 h	[222]
$Gd_{1.33}Pt_3Al_7Si$	1:1:10:5	50→1000 in 12 h, 15 h at 1000,	[221b]
$Gd_{0.67}Pt_2Al_4Si$	0.33:1:10:5	1000→860 in 24 h, 48 h at 860, 860→RT in 72 h	
$Th_2AuAl_2Si_3$	1:1:10:5	50→1000 in 12 h, 15 h at 1000,	[221a]
$Th_2Au_3Al_4Si_2$		1000→860 in 20 h, 48 h at 860, 860→RT in 72 h	

$Gd_{1.33}Pt_3Al_8$ was synthesized by the combination of Gd and Pt in liquid aluminum.[221b] Addition of silicon resulted in the incorporation of a small amount of this element into the material to form the isostructural compound $Gd_{1.33}Pt_3Al_7Si$. Both compounds grow as facetted hexagonal rodlike crystals (Figure 11). The rods also appear to have corrugated surfaces; the corrugation lines are perpendicular to the long direction, indicative of polysynthetic twinning. The related compounds $Gd_{0.67}Pt_2Al_5$ and $Gd_{0.67}Pt_2Al_4Si$ also form as hexagonal rods, but they are not characterized by the aforementioned uneven surfaces. These complex intermetallics only account for 10–20% of the solid isolated after removal of the flux. The contains plate-like silicon crystals and crystals of $GdAl_2Si_2$. Evidently, in this case the flux does not completely meet criterion 4 mentioned in Section 3 and reacts to form undesirable phases.

Thorium metal reacts with gold and silicon in molten aluminum to give a mixture of the two quaternaries $Th_2AuAl_2Si_3$ (comprising about 40% of the solid product after soaking in NaOH) and $Th_2Au_3Al_4Si_2$ (40%), as well as small amounts of silicon crystals (10%) and $ThSi_2$ crystals (10%). The quaternary compounds are part of a homologous series of intermetallics, with the general formula $Th_2(Au_xSi_{1-x})[AuAl_2]_nSi_2$.[221a]

10. Reactions in Liquid Gallium

Gallium has been relatively little utilized as a synthetic flux medium. The success of molten aluminum melts, however, to uncover new materials naturally stimulates inquiry into the related gallium system. The known binary and ternary compounds of gallium are numerous.[223] Most work on these systems, especially with the 3d transition metals was carried out by Grin and co-workers. Some ternary rare-earth–transition-metal gallides with ruthenium and osmium as the transition-metal components and a high content of gallium, for example, the series $RERu_2Ga_8$ or $REOsGa_4$, have recently been prepared by Schlüter and Jeitschko.[224] Reports on quaternary intermetallic phases, such as silicides and germanides, are still few. It would be interesting to assess the behavior of liquid gallium in light of that of aluminum, by performing corresponding experiments using gallium as the solvent. There are again two types of reactions, those in which gallium is incorporated into the compounds (reactive flux) and those in which it is not.

Interestingly, analogous reactions to those with aluminum that give rise to $RE_2Ni(Si_{1-x},Ni_x)Al_4Si_6$ do not yield analogous results. In the case of the quaternary system Sm/Ni/Si/Ga, phase separation results in the silicide $SmNiSi_3$,[225] and the gallide Sm_2NiGa_{12}.[226] The latter has a fascinating tetragonal structure with a three-dimensional gallium network. It is noteworthy that many *RE*/Ni/Ga phases have been known for some time[227,228] and the Sm/Ni/Ga phase diagram contains a striking number of phases: SmNiGa, $SmNiGa_2$, Sm_2Ni_2Ga, $SmNi_3Ga_2$, $Sm_3Ni_6Ga_2$, $SmNiGa_3$, Sm_2NiGa_3, $SmNiGa_4$, $Sm_{26}Ni_{11}Ga_6$, Sm_4NiGa_7, and $Sm_{17}Ni_{58}Ga_{25}$.[223] None of these materials was synthesized in a gallium flux. It is therefore rather remarkable that despite the great number of ternary compounds in this system Sm_2NiGa_{12} is a new addition. Another gallide that was discovered in this fashion was $SmNi_3Ga_9$, a hexagonal compound which adopts the $ErNi_3Al_9$ structure type.[215]

The use of molten gallium as a nonreactive solvent was demonstrated to give single crystals for the ternary silicides $RE_2Ni_{3+x}Si_{5-x}$ (RE = Sm, Gd, and Tb).[229] This allowed the structure of these compounds to be solved and refined with great accuracy. The structure is related to the $U_2Co_3Si_5$ structure type; however, the new studies suggested that the earlier crystallographic site assignments in $U_2Co_3Si_5$ were incorrect.

Table 3 summarizes some of the ternary and quaternary compounds synthesized or discovered with a gallium flux. The compounds $RE_4FeGa_{12-x}Ge_x$[230] were discovered during investigations of reactions in liquid gallium involving *RE*, *T*, and Ge, where *RE* = Y, Ce, Sm, Gd, Tb; and *T* = Fe, Co, Ni, or Cu. These systems were investigated at various metal ratios and different heating regimes. A heating regime with a shorter isothermal step was shown to favor the formation of the cubic phases $RE_4FeGa_{12-x}Ge_x$. For example, when a six-day isothermal step (T = 850 °C) was used in the system Tb/Fe/Ga/Ge, the products were Tb_4FeGe_8[231] and $Tb_2Ga_2Ge_5$,[232,239] along with the cubic phase as a minor product. Whereas a shorter isothermal step of three days at 850 °C produced the cubic phase in high yield. For *RE* = Sm, the situation was similar, as the six day isothermal heating gave rise to Sm_3Ga_9Ge as the major component, and the cubic phase, $FeGa_3$, and Ge as minor components. Reducing the time by half brought about an increase in the yield of the cubic phase. From this it can be concluded that the cubic phases are essentially a kinetic product of the reaction. Furthermore, it is clear that the time can be an important reaction parameter allowing the chemical reactivity of a system to be explored and access to kinetic and thermodynamic products. Large single crystals of $Tb_4FeGa_{12-x}Ge_x$, measuring up to 2 mm each side, could be grown from molten gallium (Figure 12). The incorporation of gallium in these phases shows that in this case the solvent is reactive. This situation is in contrast to the Sm/Ni/Ga/Si system in which the gallium-free $SmNiSi_3$ phase could be obtained.

It is interesting that isostructural phases to $RE_4FeGa_{12-x}Ge_x$ were not observed when iron was changed to Co, Ni, or Cu. Instead, a variety of other quaternary compounds arising form liquid gallium were detected.[232,235,236] In addition, the type of rare-earth metal appears to be important in phase formation. Thus, in the system *RE*/Fe/Ga/Ge, when *RE* was Y, Ce, or Gd, the RE_3Ga_9Ge phases were obtained.

Recent studies of the reactivity and phase formation in the systems *RE/T*/Ga/Ge, where *T* = Ni and Co, in liquid gallium showed that different compounds are obtained depending on the *RE*:*T* ratio. When the ratio *RE*:*T* <1 the reactions resulted in the hexagonal compounds $RE_{0.67}T_2Ga_{5-x}Tt_x$, and $RE_{0.67}T_2Ga_{6-x}Tt_x$[235] (*Tt* = Si or Ge) that form readily within a rather broad range of synthetic conditions (time and temperature). However, ratios with *RE*:*T* ≥ 1, give results that depend strongly on the nature of *RE*. For these ratios the chemistry is significantly more sensitive to the reaction conditions. For these studies the following compounds were obtained $RETGa_3Ge$, $RE_2TGa_9Ge_2$ (*RE* = Y, Sm, Tb, Gd, Er, Tm; *T* = Ni, Co), $RE_3Ni_3Ga_8Ge_3$ (*RE* = Sm, Gd), and $RE_4Ni_3Ga_6Ge_4$.[232]

There is an interesting contrast in the behavior of nickel and cobalt. When *T* = Ni the reaction of different lanthanoid elements under otherwise identical conditions results in $YNiGa_3Ge$, $Ce_2NiGa_9Ge_2$, $Gd_3Ni_3Ga_8Ge_3$, and $TbNiGa_3Ge$.

$RE_4Ni_3Ga_6Ge_4$ (*RE* = Y,Tb)	*RE*:*T*:Ga:Ge 1:1:15:1	50→1000 in 15 h, 5 h at 1000, 6 days at 850, 850→250 in 75 h	[232]
$Tb_{1.8}Si_8C_2(B_{12})_3$	Tb:B:Ni:Si 1:6:1:1 + a 10-fold molar excess of Ga	50→1000 in 12 h, 96 h at 1000, 1000→500 in 60 h	[237]
β-SiB$_3$	B:Si:Cu:Ga 4:1:1:20	50→1000 in 12 h, 96 h at 1000	[238a]

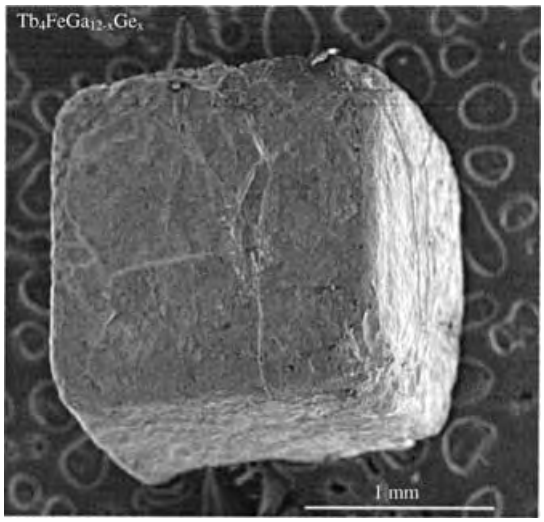

Figure 12. SEM image of a typical Ga-grown Tb$_4$FeGa$_{12-x}$Ge$_x$ crystal. The roughening of the surface is caused by an etching process during isolation.

The case is even more complicated for samarium, as up to three phases Sm$_2$NiGa$_9$Ge$_2$, SmNiGa$_3$Ge, and Sm$_3$Ni$_3$Ga$_8$Ge$_3$ could be observed. With Y and Tb, long reaction times (3–6 days) produced Y$_4$Ni$_3$Ga$_6$Ge$_4$ and Tb$_4$Ni$_3$Ga$_6$Ge$_4$, whereas shorter reaction times gave YNiGa$_3$Ge and TbNiGa$_3$Ge. Interestingly, when *T* = Co, the following phases form in quantitative yield: YCoGa$_3$Ge, Ce$_2$CoGa$_9$Ge$_2$, SmCoGa$_3$Ge, GdCoGa$_3$Ge, and ErCoGa$_5$. These phases probably have similar formation energies because they have common structural components.

The gallium flux medium works well for silicon/boron compounds probably because both silicon and boron are soluble in it and do not form binary compounds.[240] For example we have applied the gallium flux to *RE*/*T*/B/Si (borosilicides) in an attempt to produce lighter analogues of the *RE*/*T*/Al/Si compounds. We have shown that liquid gallium can provide an excellent route to complex quaternary silicon borides such as $Tb_{1.8}Si_8C_2(B_{12})_3$ that cannot be formed using high-temperature techniques such as arc melting.[237] Boron-containing solids have acquired renewed interest because of the discovery of superconducting quaternary borocarbides[241] and the binary MgB$_2$, a well-known compound with a very simple structure, but only recently recognized as a high-temperature non-oxidic superconductor.[242]

A spectacular illustration of the ability of liquid gallium to stabilize phases that are inaccessible by conventional synthetic routes is the discovery of the binary boride β-SiB$_3$.[238a] This was a surprising discovery because a phase with a similar formula, $Si_{1-x}B_{3+x}$ (α-SiB$_3$)[238b] and a rhombohedral structure has been known for decades.[243] In contrast, β-SiB$_3$ has a new structure type with very different structural features, physical and electronic properties. It is significant that the synthesis of β-SiB$_3$ requires metallic flux conditions, which permit the total bypass of the rhombohedral compound α-SiB$_3$.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

11. Indium Flux

Due to its low melting temperature of 157 °C, indium is an ideal metal for use as a reactive flux (self-flux condition). It has widely been used for the synthesis and crystal growth of indium-rich binary and ternary indides. In many cases, a slight excess of indium significantly increases the crystal growth. Good examples in the case of binary intermetallics are compounds such as $T\mathrm{In}_3$ (T = Co, Ru, Rh, Ir),[244,245] $\mathrm{Ti}_2\mathrm{In}_5$,[246] $\mathrm{Hf}_2\mathrm{In}_5$,[247] or IrIn_2.[248] In these cases, two strategies may be applied. Pure polycrystalline samples for physical-property measurements can be synthesized with the ideal starting composition, while high-quality single crystals for structure refinements can be grown from a flux with an indium excess. Indium has been exploited even less as a synthetic flux medium than aluminum and gallium. With indium there are again two types of reactions possible; those in which indium is incorporated in the products and those where it is acting strictly as a solvent. Its low melting point makes indium convenient for reaction chemistry at relatively low temperatures and facilitates its removal during isolation. Herein we will give some examples of phases crystallized in liquid indium.

11.1. Indium as a Reactive Flux

Besides the binary transition-metal–indium compounds, a large family of ternary rare-earth-metal–transition-metal indides has been synthesized in liquid indium. Several members of the compounds $\mathrm{Ce}T\mathrm{In}_5$ with HoCoGa_5-type structure and $\mathrm{Ce}_2T\mathrm{In}_8$ with $\mathrm{Ho}_2\mathrm{CoGa}_8$-type structure have been prepared in the form of relatively large single crystals for physical-property measurements.[249–252] Experimental details about the method are given in refs. [23, 24]. In a typical experiment, cerium, the transition metal, and indium are mixed in the atomic ratio 1:1:20 and placed in an alumina crucible which is sealed in a silica tube to prevent oxidation. The sample is then heated over several hours to 1100 °C, kept at that temperature for 2 h, and then slowly cooled to 700 °C at a rate of 10 °C h^{-1}. At that temperature the excess indium is decanted in a centrifuge resulting in well-shaped single crystals with volumes up to 1 cm^3. The melt-centrifugation method has also been used by Boström[43,44] for the crystal growth of manganese gallides and by Nylén et al.[45] for the crystal growth of palladium stannides.

A variety of other rare-earth-based indides has been obtained by using an excess of indium. For the growth of CeNiIn_2 crystals, an arc-melted CeNiIn_2 sample can be recrystallized using an excess of about 10 wt% indium in a ZrO_2 crucible.[253] The temperature is first raised to 1200 °C, kept at that temperature for 6 h, cooled at a rate of 5 °C h^{-1} to 600 °C, and quenched in air. Similar temperature profiles have been used for the synthesis of $\mathrm{Tb}_6\mathrm{Pt}_{12}\mathrm{In}_{23}$ and $\mathrm{Dy}_2\mathrm{Pt}_7\mathrm{In}_{16}$,[254] however in these cases, arc-melted precursor alloys TbPtIn_4 and $\mathrm{DyPt}_3\mathrm{In}_6$ were used for recrystallization from liquid indium. Selected single crystals of CeNiIn_2, $\mathrm{Tb}_6\mathrm{Pt}_{12}\mathrm{In}_{23}$, and $\mathrm{Dy}_2\mathrm{Pt}_7\mathrm{In}_{16}$ are shown in Figure 13.

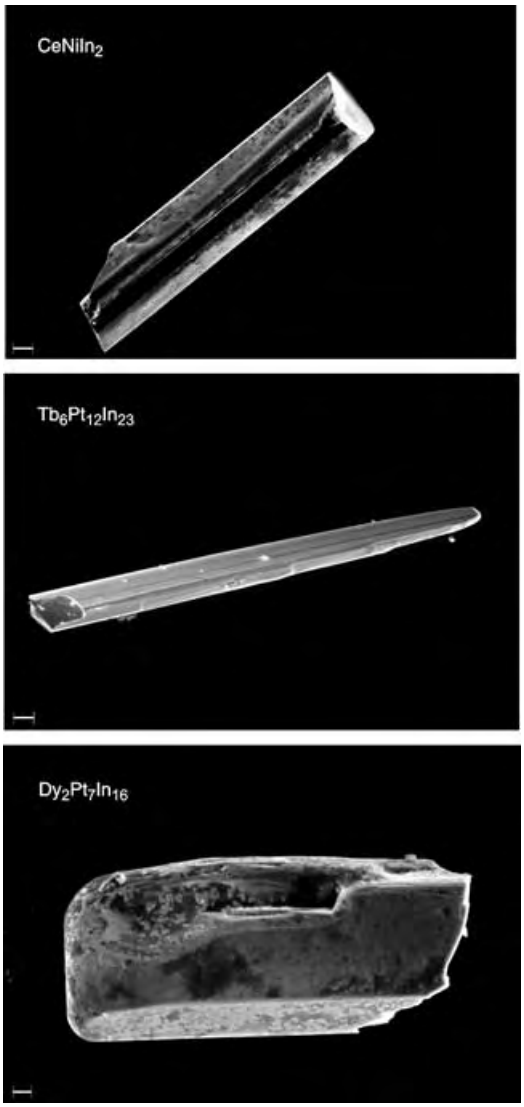

Figure 13. Scanning electron micrographs of CeNiIn_2 (scale bar 10 μm) $\mathrm{Tb}_6\mathrm{Pt}_{12}\mathrm{In}_{23}$ (scale bar 10 μm), and $\mathrm{Dy}_2\mathrm{Pt}_7\mathrm{In}_{16}$ (scale bar 3 μm) single crystals.

If only a small excess of indium is used for the self-flux technique, the melt-centrifugation technique cannot be applied. In this case it is better to dissolve the indium. This is a significant difference between indides and binary and ternary stannides, while most stannides resist 2 N hydrochloric acid, indides are often destroyed. The problem can be avoided by removing the melt with diluted acetic acid. The crystals shown in Figure 13 have been cleaned in this way. In most cases, the crystals have a thin indium coating which can easily be removed with diluted acetic acid.

The ytterbium based indides $\mathrm{Yb}T\mathrm{In}_5$ (T = Co, Rh, Ir) have been prepared from an indium flux with starting compositions Yb:T:In = 1:1:7.[255,256] Tantalum was used as crucible material and the samples were initially heated to 1050 °C, kept at that temperature for 6 h, and then cooled at a rate of 5 °C h^{-1} to 400 °C, with subsequent quenching to room temperature. A different procedure was used for YbPtIn_4.[255] An arc-melted

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

precursor alloy of approximate composition $YbPtIn_2$ was annealed with indium in the ideal ratio 1:2 in a molybdenum crucible. The initial step was rapid heating at 1100 °C, this temperature was maintained for 6 h, and then slow cooling at a rate of 5 °C h^{-1} to room temperature. The four ytterbium compounds were thus obtained as well-shaped crystals with edge lengths larger than 200 μm. Interestingly, the heavy-rare-earth-containing series of compounds RE_2Cu_2In (RE = Gd–Lu, except Yb) were also grown in an indium flux despite their relatively low indium content.[257]

11.2. Indium as a Nonreactive Flux

Similar to molten aluminum and gallium, indium is also attractive for its capacity to dissolve Si, Ge, and a host of lanthanoid and transition metals, which results in highly reactive forms of the elements. Further, In does not form binary compounds with Ge or Si.[258] For example, reactions of Cr, W, V, and several rare-earth elements with silicon in indium flux at 800–900 °C result in well formed single crystals of the corresponding disilicides $CrSi_2$, WSi_2, VSi_2, and $RESi_2$.[259] No indium incorporation is observed. Also single crystals of the ternary compound $CeCu_2Si_2$ were grown from indium flux. However, in this case elemental analysis showed that small amounts of indium had entered into the compound.[260]

When a transition metal such as nickel is added to the reactions with rare-earth elements and germanium in indium flux, new forms of the compounds β-$RENiGe_2$ (RE = Dy, Er, Yb, Lu) are obtained which crystallize with the $YIrGe_2$ structure type.[261] This result is intriguing because phases with the same composition (α-$RENiGe_2$) have been known for some time, but crystallize in the $CeNiSi_2$ structure type. In fact, many germanides $RETGe_2$ with RE = Y, Tb–Lu, and T = Pd, Pt, Ir with the $YIrGe_2$-type structure are known, but phases containing first-row transition metals were not known till the indium flux was used.

It is of note that the formation of β-$RENiGe_2$ occurs exclusively in liquid iridium. The yields from these reactions range from 60 to 70 % (based on the RE), with approximately 70 % purity. The main impurities were the α-phase and recrystallized Ge. When other methods, such as arc-melting or radio-frequency furnace heating, were used to synthesize $RENiGe_2$ compounds they only led to the α-form. Furthermore when the reaction times were increased from 48 to 96 h the α-phase was the dominant fraction at approximately 65 %. Likewise, if the isotherm temperature for the reaction was increased from 850 to 1000 °C a larger fraction of the reaction product, approximately 50–60 %, crystallized as the α-form. Two other experiments were also conducted where the elements Dy or Er, Ni, Ge, and In were combined in a 1:1:2:10 ratio, and then were arc-melted for 3 min, or heated with a radio frequency furnace for 1 h. Both of these methods, which employ much higher temperatures than the flux reaction, yielded practically pure α-form despite using excess indium. These results indicate that a combination of low temperature and excess indium are needed to arrive at the β-form and suggests that the α-phase is thermodynamically the more stable form, and the β-form is the kinetically stable phase.

12. Lithium and Sodium Fluxes

Among the alkali metals, lithium has the highest melting (180.5 °C) and boiling (1374 °C) point.[258] This difference in temperatures is a good prerequisite for use as a metal flux. Jung and Diessenbacher[262] reported on the growth of single crystals of the boride $Sr_2Ru_7B_8$ in a lithium flux from the starting composition Li:Sr:Ru:B = 50:2.3:7:8. A sealed tantalum tube was used as a container material and the annealing temperature was 1100 °C for 4 days.

The same technique was subsequently used for the crystal growth of various rare-earth-metal–transition-metal carbides.[263] The lithium flux is especially useful for the synthesis of ytterbium-based carbides. Owing to the low boiling temperature of ytterbium (1193 °C) a synthesis of such carbides by arc-melting always results in large weight losses. In contrast, liquid lithium served as an excellent medium for the synthesis of $YbAl_3C_3$.[264] The elements were combined in the atomic ratio Yb:Al:C:Li = 1:3:3:30, sealed in an iron ampoule (tube volume ca. 4 cm^3), annealed for one day at 800 °C, and finally cooled at a rate of 7 °C h^{-1} to room temperature. Lithium was dissolved in ethanol in an ultrasonic bath leaving silvery small hexagonal platelets. The single-phase reaction product was suitable for physical property investigations.

Iron or nickel ampoules can be used as container materials, since molten lithium reactively penetrates silica tubes. Typical tube sizes have an outer diameter of 10 mm and a wall thickness of 1 mm (100 mm length). The tubes are closed by 5-mm bolts that are sealed by arc-welding under an argon atmosphere.[265] For short reaction times (1–3 days) and moderate temperatures (< 500 °C), the metal ampoules can be annealed directly in a muffle furnace. For high-temperature annealing, the iron or nickel ampoules are sealed in silica tubes to prevent surface oxidation.

Using this experimental technique, the new carbides $Yb_2Cr_2C_3$,[266] $Yb_4Ni_2C_5$,[267] YbCoC,[268] and $Gd_{10.34}Mn_{12.66}C_{18}$[269] have been synthesized. At this point it is worth noting that an independent synthesis without lithium as flux medium is necessary to prove that lithium does not stabilize the respective structure. In all cases the carbides have independently been prepared by arc-melting, but these experiments did not result in single-phase samples.

The choice of the ampoule material is very important. Nickel, iron, and stainless steel are inexpensive, while niobium and tantalum are much more expensive. Especially iron and steel tubes contain small amounts of carbon which the liquid lithium is able to extract from the tube. Studies of recrystallizing praseodymium nickel arsenides in a lithium flux in steel tubes[270] resulted in well shaped single crystals of $PrNiC_2$.[271]

Besides lithium, the higher congener sodium has been widely used for the growth of crystals or fine powders for various industrially important nitrides such as BN, AlN, or GaN. A severe problem occurs for the production of

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

aluminum nitride powder. Owing to the large heat of formation of AlN, the AlN particles already sinter and form agglomerates during the reaction. These preparative problems can easily be overcome by using a sodium flux.[272] Aluminum metal powder can be reacted with the azide NaN_3 in a sealed stainless steel ampoule. Thermal decomposition of NaN_3 at 300 °C provides pure N_2 and Na. The reaction mixture is heated to 600 °C for 12 h and then to 700 °C and 24 h. The furnace is then turned off and the tube cooled to room temperature within the furnace. The sodium metal, including the fine AlN powder, is allowed to react with isopropanol and then with ethanol. The product can be cleaned with ethanol in an ultrasonic bath and may be collected by centrifugation. Finally the products can be dipped into distilled water for 10–20 h to ensure the removal of all free sodium.

The sodium flux technique with the azide route was also used for the growth of *h*-BN and GaN crystals.[273] In these cases, at the final reaction temperature of 800 °C a nitrogen pressure of 100 atm was generated by the decomposition of sodium azide. Especially for GaN, the influence of the N_2 pressure and various Na–Ga melts as the staring flux material have been investigated in detail.[274–276]

As well as the Group III nitrides, complex alkaline-earth-metal–transition-metal nitrides and nitride oxides with peculiar new crystal structures have also been discovered. Sodium flux was used to generate new nitride compounds, such as Ba_2GeGaN and $(Ba_xSr_{1-x})_3Ge_2N_2$,[277] $Sr_3Ge_2N_2$ and Sr_2GeN_2,[278] $Ba_3Ge_2N_2$,[279] and $Ba_5Si_2N_6$.[280] Additional examples are Ba_3ZnN_2O,[281] $Sr_{39}Co_{12}N_{31}$,[282] Sr_2NiN_2,[283] or $Ba_{14}Cu_2In_4N_7$.[284] Niobium ampoules were used as a crucible material for the synthesis of Ba_3ZnN_2O and $Sr_{39}Co_{12}N_{31}$. $Ba_{14}Cu_2In_4N_7$ was prepared in a BN crucible which was placed in a stainless steel container, while the synthesis of Sr_2NiN_2 was carried out in a nickel ampoule. For all nitrides, the products within the crucibles or within the ampoules were washed with liquid ammonia using a special glass apparatus.[285] The nitrogen pressure in the ampoules was generated through decomposition of sodium azide.

Liquid sodium is also a very suitable flux for the growth of subnitride and suboxide crystals of the alkaline-earth elements.[286–288] Examples are the subnitride series $Na_xBa_{14}CaN_6$ ($x = 8,14,17,21,22$) with the new cluster type $[Ba_{14}CaN_6]$, the binary nitride Ba_3N, or the mixed oxide $NaBa_2O$, or the mixed nitride $NaBa_3N$.[286,288] The excess sodium can either be distilled away or it may be separated from the reaction product using a special press.[289]

13. Miscellaneous Metallic Fluxes and Materials

Many other fluxes have been reported for the preparation of peculiar compounds or for crystal growth starting from polycrystalline materials. It is impossible to list all the work herein. In this last section we summarize some of the most interesting results.

13.1. Copper and Cobalt Flux

Copper has been used sporadically in growing crystals of boride compounds with very interesting results. In 1973 Johnson described in detail how to grow well formed octahedral crystals of MnSi by reaction of Mn and Si in a copper flux. A mixture of Mn, Si, and excess Cu is heated to 1200 °C over a period of 12 h and then cooled to 500 °C at 10 °C h^{-1}. The copper-rich Cu-Mn-Si matrix was dissolved in 8 N HNO_3 leaving octahedral crystals of MnSi.[290] More recently, the well-known silicide Mn_5Si_3 was reported to grow from liquid copper but interestingly no other known binaries such as $Mn_{27}Si_{47}$ formed under these conditions.[151]

Crystals of Cr_3Si and Cr_5Si_3 single crystals were prepared in copper flux using Cr and Si powders as starting materials in an argon atmosphere. The conditions for obtaining these crystals as single-phase materials and of a relatively large size were established.[291] Crystals of NbB, Nb_5B_6, Nb_3B_4, Nb_2B_3 (new phase), and NbB_2 were prepared similarly using Nb and B as starting materials in an argon atmosphere.[292] Crystals of W_2B, δ-WB, and WB_2 were prepared from copper solutions using tungsten metal and crystalline boron powders as starting materials under an argon atmosphere.[293]

Multinary boride compounds have been grown as well. The first such report involved the growth of the series $RERh_4B_4$ (RE = Y, Sm, Gd–Tm, and Lu).[294] Later, Japanese workers confirmed these results and reported the additional boride series $RERh_3B_2$ (RE = Gd, Dy, Er–Lu) and $RERh_3B$ (RE = Sm, Gd, Er, Tm) as well as the two boride carbides $RERh_2B_2C$ with RE = Er and Gd.[295a] The layered compound $PrRh_{4.8}B_2$ was obtained as hexagonal plates by a molten metal-flux growth method, using copper as a flux. The X-ray photoelectron spectroscopic study and electron probe microanalysis results showed the presence of a few monolayers of copper atoms between the crystals of $PrRh_{4.8}B_2$.[295b,c] Similarly, slow cooling molten copper solutions of the systems *RE*-Rh-B and *RE*-Rh-B-C gave single crystals of the above mentioned ternary borides $RERh_4B_4$, $RERh_3B_2$, and $RERh_3B$. Crystals of $ErRh_3B_2$ grew as hexagonal objects, crystals of $ErRh_4B_4$ were obtained as rectangular objects with a tetragonal structure, and single crystals of cubic $ErRh_3B$ were extracted as cubes. Single crystals of the new tetragonal compounds $RERh_2B_2C$ have been obtained as thin plates.[295] Clearly these results give a preview of what could be accomplished with copper.

The equiatomic transition-metal boride MoCoB[296] was prepared in a cobalt flux from a sample with the starting composition Mo:Co:B = 7:70:21. The excess cobalt was dissolved in concentrated hydrochloric acid, while the ternary boride is stable under these conditions.

13.2. Quasicrystals

Flux-growth techniques have been successfully applied by Canfield et al. for the preparation of several families of quasicrystals and related approximant phases. Large (up to 1 cm^3) single-grain samples have been obtained for icosahedral *RE*-Mg-Zn (RE = Y, Gd–Er) and Al-Pd-Mn, decagonal

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Al-Ni-Co, and other quasicrystals. Grown in a flux with a high content of magnesium and zinc by slowly cooling from 700 to 480 °C, the *RE*-Mg-Zn family of approximant phases (composition $\approx RE_9Mg_{34}Zn_{57}$) were the first rare-earth-containing quasicrystals that allowed the study of localized magnetic moments in a quasiperiodic environment (Figure 14).

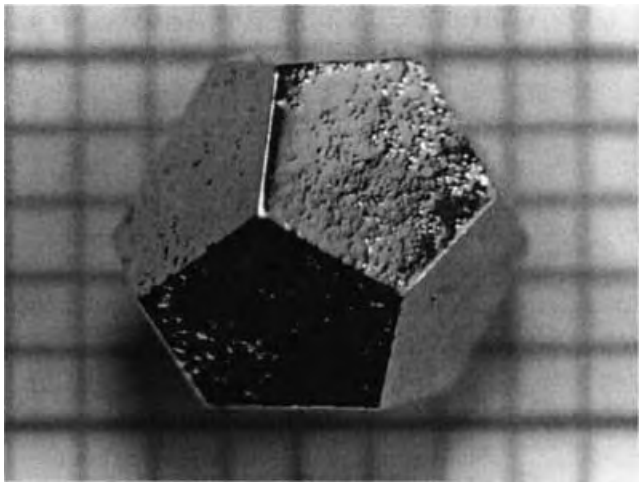

Figure 14. A well-formed Ho-Mg-Zn quasicrystal with dodecahedral morphology (mm grid) grown from a flux with a high content of magnesium and zinc.[297c]

Samples of the Al-Pd-Mn and the Al-Ga-Pd-Mn approximant phases were obtained by slowly cooling ternary (or quaternary) melts of a composition that intersects the primary solidification surface of the desired phase in the equilibrium ternary-alloy phase diagram. The metallic fluxes lead to almost strain-free quasicrystals and clearly allow the fascinating pentagonal growth habit to be revealed.[297]

13.3. Zinc Flux

Zinc is a metal with a comparatively low melting point (420 °C). Like for the preparation of binary stannides discussed in Sections 5 and 7, peritectic reactions are found also in the zinc-rich regions of the transition-metal–zinc systems.[40] Such reactions can occur when zinc coatings are used to protect iron- and steel-based materials. For this reason the Fe–Zn phase diagram has been investigated in detail.

The binary compounds Ti_3Zn_{22} and $TiZn_{16}$[298] have been prepared from samples of the starting compositions Ti:Zn 5:95 and 3:97, respectively. The 5:95 sample (silica tubes as crucible material) was first equilibrated for two days at 850 °C, then cooled at a rate of 5 °C h^{-1} to 500 °C and quenched in air from that temperature. The final annealing temperature for the 3:97 sample was 455 °C. Large crystals with edge lengths up to 4 mm were obtained after dissolution of the matrix in hydrochloric acid. With similar preparation conditions well-developed crystals of the compounds Zr_5Zn_{39} and $ZrZn_{22}$ were obtained.[299] As a by-product of these reactions $Zr_6Zn_{23}Si$[300] with a "filled" Th_6Mn_{23}-type structure was observed, where the silicon content arises from the quartz tube. Subsequently this compound was also prepared in alumina containers, where the silicon had to be added deliberately. By slow cooling of melts with very high zinc contents (98 and 99% Zn) the compounds $NbZn_3$, $NbZn_{16}$, and $MoZn_{20.44}$[301] were prepared in well-crystallized form. Also the rhodium-based compounds RhZn, Rh_2Zn_{11}, and $RhZn_{13}$ (Figure 15) are accessible in this way.[302]

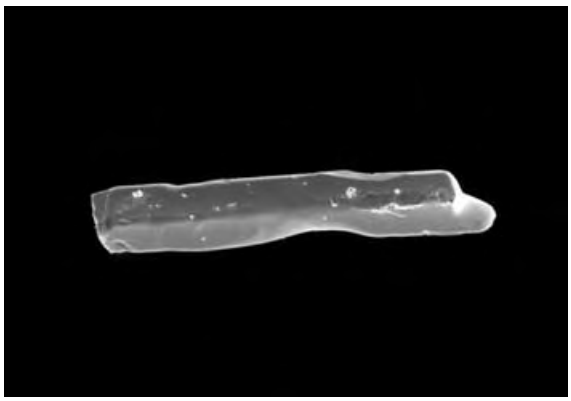

Figure 15. Scanning electron micrograph of a $RhZn_{13}$ single crystal (length ca. 0.2 mm).

Similar to the ternary aluminides reported in Section 9, ternary transition-metal–zinc compounds and rare-earth-metal–transition metal–zinc compounds can also be obtained from liquid zinc. Recent examples are the compounds RET_2Zn_{20} (T = Fe, Ru, Co, Rh, Ni),[303] TT'_2Zn_{20} (T = Zr, Hf, Nb; T' = Mn, Fe, Ru, Co, Rh, Ni),[304] or $RE_2T_3Zn_{14}$ (T = Fe, Co, Rh, Ni, Pd, Pt) with ordered Th_2Zn_{17} structure.[305] As an example a crystal of $HfRu_2Zn_{20}$ is shown in Figure 16. When carrying out reactions with zinc, care must be taken to control and handle the high vapor pressure of this metal at high temperatures.

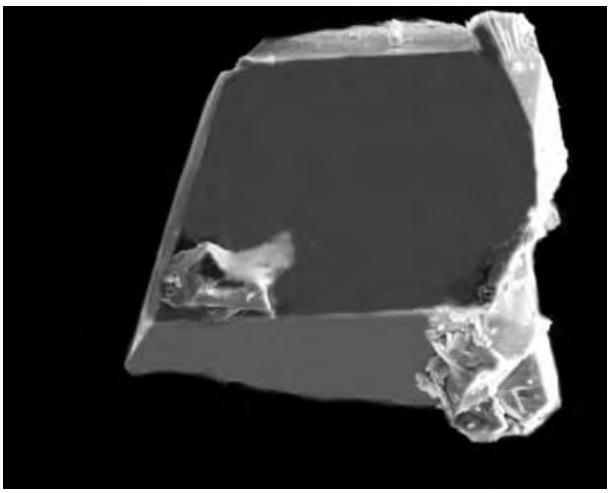

Figure 16. Scanning electron micrograph of a $HfRu_2Zn_{20}$ single crystal (length ca. 0.12 mm).

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

13.4. Mixed-Metal Fluxes

Almost all reactions reported in the previous sections used an excess of only one metal as flux. Even more preparation possibilities are available through multinary mixtures. An interesting approach by Hillebrecht and Gebhardt with different Cu–Al fluxes revealed a whole series of niobium boride carbides.[306] The molar ratios Cu:Al:B:C:Nb were 20:5:2:1:4 for Nb_3B_3C, 20:5:0.2:0.1:0.2 for $Nb_4B_3C_2$, 20:5:2:1:2 for $Nb_7B_6C_3$, and 20:5:0.1:0.1:0.2 for $Nb_7B_4C_4$. Alumina was used as crucible material with the following temperature program: room temperature to 1600 °C with 400 °C h^{-1}, 24 h holding, cooling to 1500 °C at a rate of 100 °C h^{-1}, to 1100 °C at a rate of 1 °C h^{-1}, and finally to room temperature at 150 °C h^{-1}. The metal excess was dissolved in half-concentrated nitric acid.

Reactions in combined Ga:Zn fluxes revealed a large series of compounds: $MoZn_6$, $NbZn_3Ga_3$, $TaZn_3Ga_3$, $MoZn_{4.5}Ga_{4.5}$, or $Mo_7Ga_9Zn_{43}$.[307] Such intermetallics show packings of polyhedra that resemble the structures of the metallic elements. Ti/Al/Sn fluxes have been used for the preparation of ternary titanium–aluminum–carbides.[308]

14. Concluding Remarks and Prospects and Opportunities for the Future

Fluxes are solvents in almost all respects and they have recently emerged as an important synthetic tool in solid-state chemistry for both crystal-growth studies and exploratory studies of new chemical systems. Because of the huge potential for new materials discovery in the realm of intermetallics, the molten metal-flux technique is proving to be an outstanding tool for preparation. The advantages of this method lie in the enhanced diffusion of the elements facilitated by the solvent and the lower reaction temperatures that can be tolerated. The latter allow better kinetic control that gives more flexibility for novel compositions and atomic arrangements to be adopted in the structure.

For the synthesis of intermetallic tetrelide (mainly Si and Ge containing) compounds, the option of molten metal fluxes presents a promising approach, particularly with the use of low melting metals of Group 13 (Al, Ga, and In). These metals have low melting points, large solubility limits for tetrelides at moderate temperatures, do not form binary compounds with tetrelides, and are easily isolable from the final products through either chemical or physical means.

Lower temperatures also facilitate the formation of kinetically derived materials that may not be accessible by traditional high-temperature synthetic methods, such as arc melting or radio-frequency heating. Even within the flux-growth scenario, variation of the reaction time and temperature can influence the product outcome within a system just as in any conventional solution-based process.

The results presented herein indicate that considerable advances in the discovery of novel and complex phases are achievable utilizing molten metal fluxes as solvents. The flux approach to exploratory synthesis is the solid-state equivalent of conventional synthetic approach in coordination chemistry. The underlying principal reasons that make the flux reaction work, are the lower temperatures and enhanced diffusion rates that become accessible. When the benefits of flux synthesis are combined with the constant need to explore the chemistry of most elements of the periodic table, we have a powerful means with which to grasp the potential for future inquiry in solid-state chemistry. Naturally, this type of research is largely synthetic in nature, but the results could affect both basic and applied chemistry as well as physics, since in the plethora of new compounds to be discovered, exciting materials are sure to exist that have a variety of interesting phenomena and applications.

The benefits of molten metal solvents are by no means limited to the liquid metals described herein. Many other metal fluxes, such as lead, indium, and bismuth, can be explored more systematically as elemental solvents with relatively low melting points. It is also easy to imagine the use of binary or ternary compositions with low melting temperatures as solvents for similar reactions, such as various eutectic compositions of Co, Ni, or Cu with boron.

The investigations at the WWU Münster have continuously been supported by the Degussa–Hüls AG and the Heraeus Quarzschmelze through generous gifts of noble metals and silica tubes. This work was financially supported by the Fonds der Chemischen Industrie and by the Deutsche Forschungsgemeinschaft. M.G.K. thanks the Alexander von Humboldt Foundation for allowing him an extended stay in Germany where this article was written. Research at Michigan State University was supported by the Department of Energy Office of Basic Energy Sciences.

Ed.* **2003**, *42*, 1929 – 1932; b) The phases SiB_3 and SiB_4 are listed separately in *Pearson's Handbook*[228] and are even listed as different structure types: isotypic with B_6P and $B_{13}C_2$, respectively. In fact SiB_3 and SiB_4 have the same structure, namely that of B_6P, and the variation in stoichiometry is the result of a compositional spread ranging from $SiB_{2.89}$ up to SiB_4. This stoichiometric flexibility arises from the substitution of varying amounts of Si into the polar sites of the B_{12} cages.
[239] $Tb_2Ga_2Ge_5$ crystallizes in the Ce_2GaGe_6 structure type.

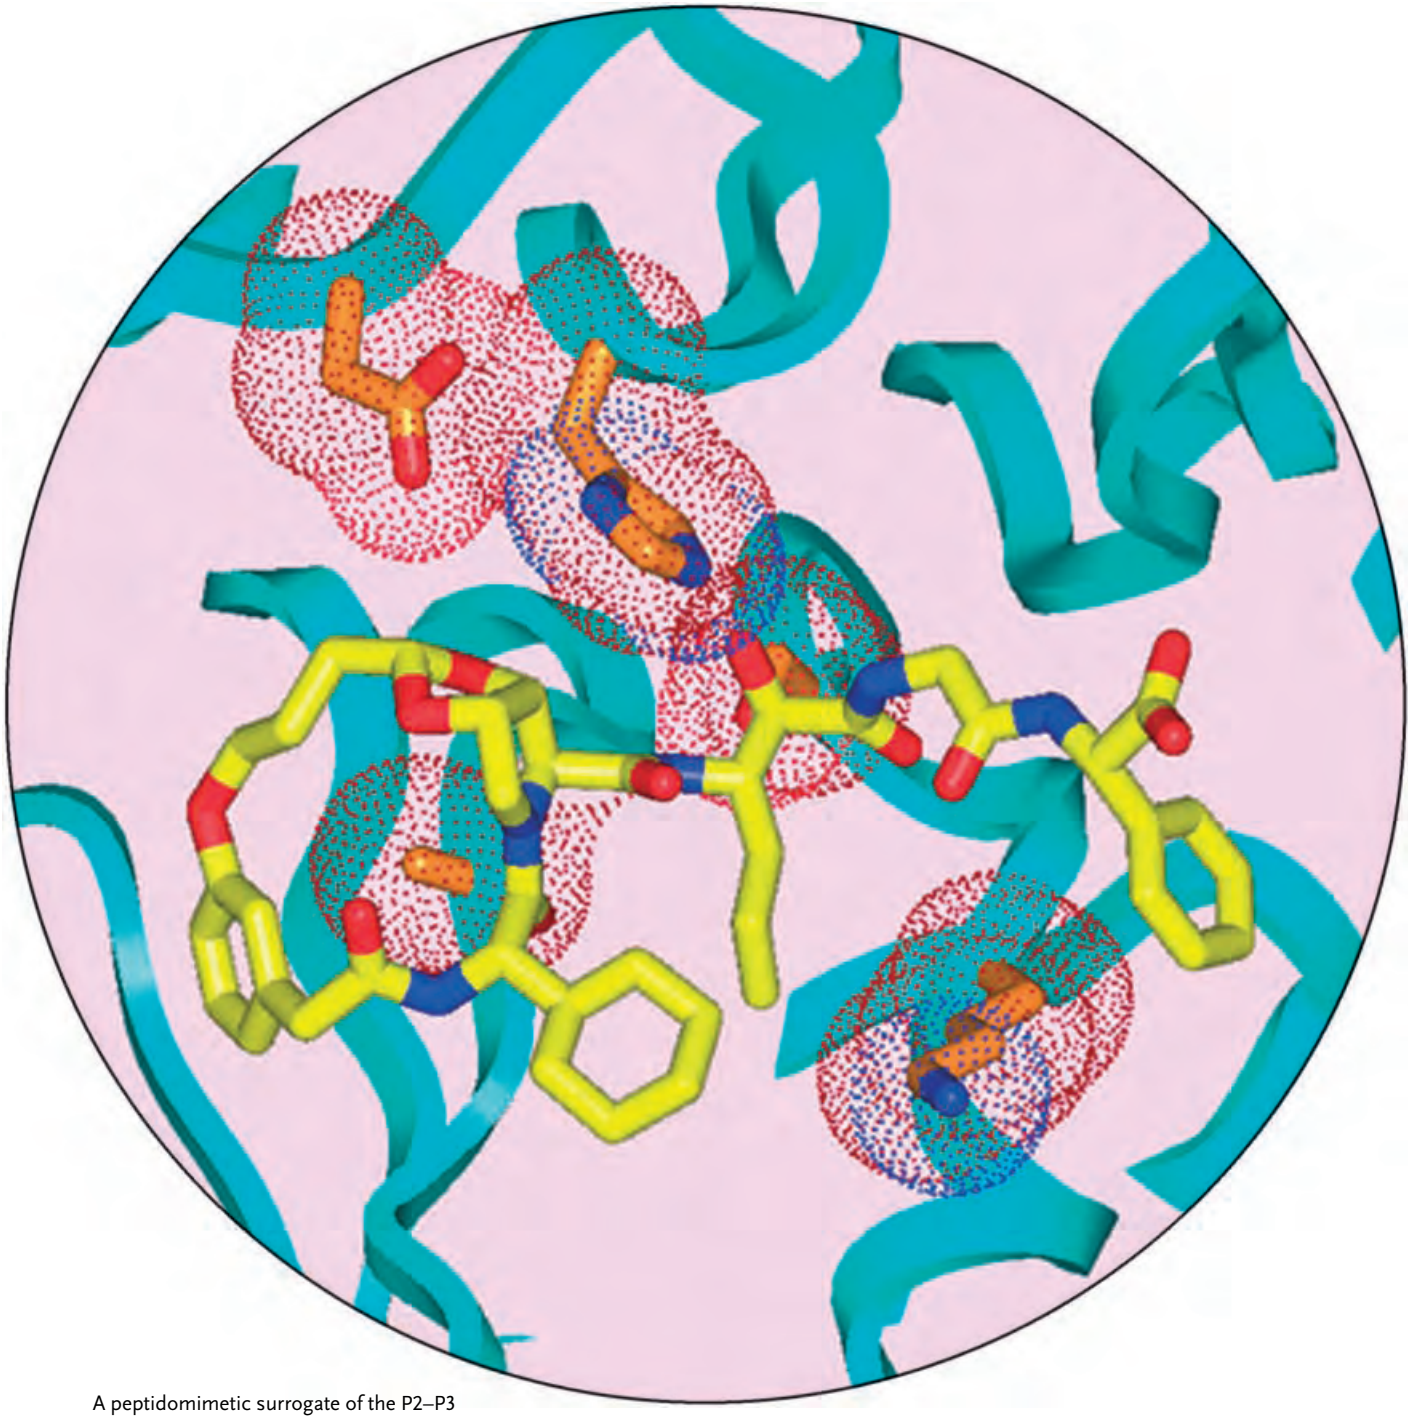
Communications

DOI: 10.1002/anie.200501553



A peptidomimetic surrogate of the P2–P3 dipeptide moiety acts as a potent hepatitis C virus (HCV) inhibitor. This proline-based macrocycle binds tightly with the Ala156 methyl group of HCV NS3 protease while the P2′ phenyl and P1 *n*-propyl groups form a C-shaped clamp around the Lys136 side chain. Proline-Based Macrocyclic Inhibitors of the Hepatitis C Virus: Stereoselective Synthesis and Biological Activity

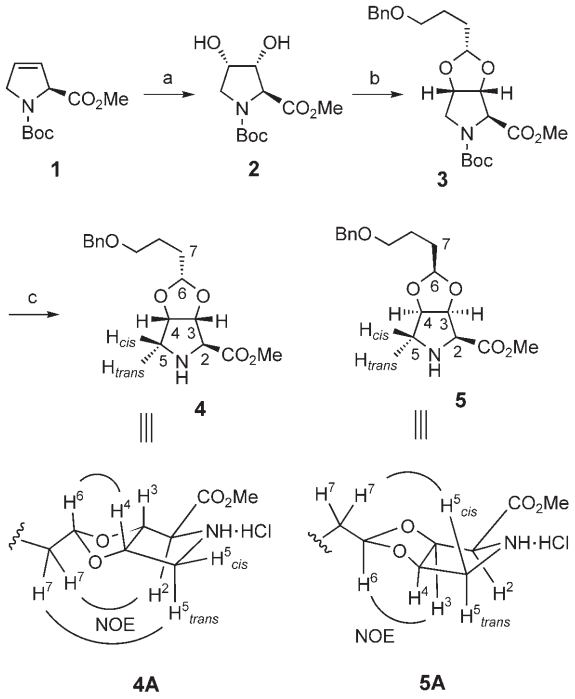
Kevin X. Chen, F. George Njoroge, Bancha Vibulbhan, Andrew Prongay, John Pichardo, Vincent Madison, Alexei Buevich, and Tze-Ming Chan*

The hepatitis C virus (HCV) is the leading cause of chronic liver disease and has infected more than 170 million people worldwide. It has emerged as a major public health threat.[1] Currently, the standard treatment is α-interferon that is attached to polyethylene glycol, in combination with the antiviral agent ribavirin.[2] This therapy is effective only in approximately 50% of patients and has considerable associated side effects. Given the prevalence of HCV infections, there is an urgent need to develop more-effective, less-toxic, and orally bioavailable small-molecule antiviral agents.

HCV is a single-stranded RNA genome that encodes a polyprotein of about 3000 amino acids. The polyprotein is processed into structural and nonstructural (NS) proteins by host peptidases and virally encoded proteases. The NS3 protease, located towards the N-terminal side of the NS3 protein, is a chymotrypsin-like serine protease.[3] As a result of its essential role in HCV replication, it has been an attractive target for intensive research for new anti-HCV therapy.[4] However, the fact that the NS3 protease has a shallow and solvent-exposed substrate-binding region makes it a formidable task to develop apropriate small-molecule inhibitors.[5]

During the course of our research in potency optimization and structure depeptization of peptide-based substrates of HCV NS3 protease,[6] we were interested in the incorporation of macrocyclic structures into our target molecules. The bicyclic-acetal proline-based macrocycle **9** (Scheme 2) was designed as a peptidomimetic surrogate for the P2–P3 dipeptide moiety on the substrate. We envisioned that the additional contact of the macrocycle with the Ala156 methyl group of the enzyme backbone would enhance binding of the inhibitors. We anticipated two major challenges in the synthesis: first, the stereoselective construction of 3,4-proline cyclic acetal core 3 (Scheme 1), and second, macrocyclization to the 17-membered ring **9**. The former could be achieved through an acid-catalyzed reaction between an aldehyde (or acetal) and 3,4-dihydroxyproline, and the latter through aryl alkyl ether formation under Mitsunobu reaction conditions.[7]

The synthesis started with osmium-catalyzed dihydroxylation of commercially available *N*-Boc-3,4-dehydroproline methyl ester (**1**; Scheme 1), to give an inseparable mixture of



1 **2** **3** **4** **5** **4A** **5A**

Scheme 1. a) OsO_4, NMO, *t*BuOH/H_2O/acetone/THF, RT, 77%; b) $BnO(CH_2)_3CHO$, *p*-TsOH, $MgSO_4$, CH_2Cl_2, RT, 91%; c) HCl (2 M, dioxane/EtOAc, RT, quant. NMO = *N*-methylmorpholine *N*-oxide, Boc = *tert*-butyloxycarbonyl, *p*-TsOH = *p*-toluenesulfonic acid.

3*S*,4*R*-diol **2** (major) and 3*R*,4*S*-diol (minor, structure not shown).[8] Both diols were then treated with 4-benzyloxybutyraldehyde in the presence of a catalytic amount of *p*-TsOH.[9] The product **3**, and its isomer were isolated as a mixture in excellent yield (91%) when 2 equivalents of the aldehyde were used. The two isomers could be separated in a ratio of 2:1, respectively, by column chromatography. 2D ^{1}H NMR spectroscopy experiments were conducted to determine the absolute configuration of the products and the stereochemical outcome of the acetal formation. To avoid interference from rotamers in **3**, it was necessary to perform the ^{1}H NMR spectroscopic analysis on amine **4** instead. The Boc protecting group was removed selectively in the presence of acid-sensitive acetal functionality when **3** was treated with hydrochloric acid (2 M). NOSEY experiments on compound **4** revealed the presence of NOE interactions between 6-H and 4-H, 7-H and 2-H, and 7-H and 5-H_{trans}. However, there was no observed coupling between protons 2-H and 3-H, which therefore indicates a *trans* relationship. This evidence led to the structural assignment of **4**, with **4A** as its preferred conformation. On the other hand, the amine derived from the minor isomer demonstrated NOE signals between 7-H and 5-H_{cis} as well as 6-H and 3-H, but not between 7-H and 2-H. The coupling constant between 2-H and 3-H ($J = 5.2$ Hz) suggests

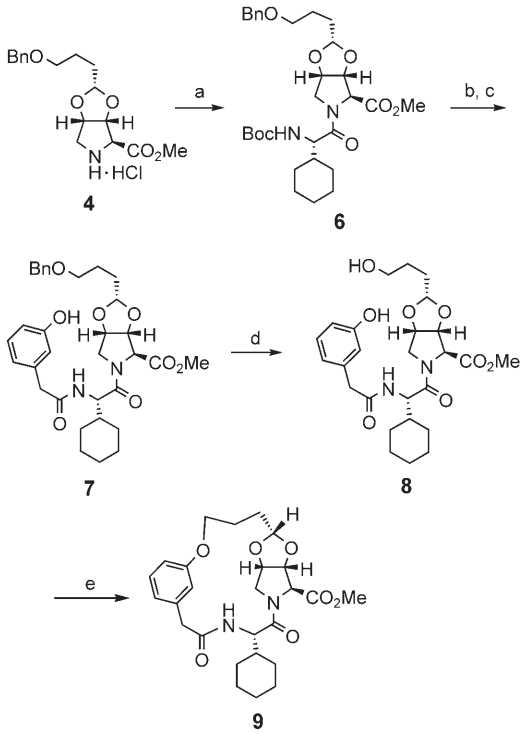
a *cis* relationship. As a result, the structure **5** and its preferred conformation **5A** was assigned. Significantly, the formation of the acetal with both 3*S*,4*R*- and 3*R*,4*S*-dihydroxyprolines led exclusively to the *endo* products.[10]

Once the stereochemistry was established, amine **4** was then coupled to *N*-Boc-cyclohexylglycine under standard conditions to give dipeptide **6** (Scheme 2). Selective removal

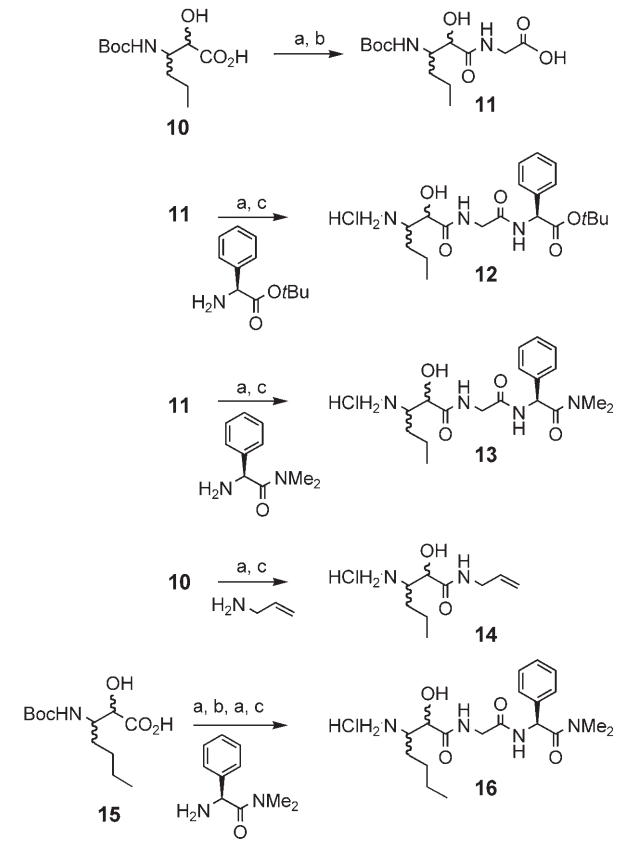


Scheme 2. a) *N*-Boc-Chg-OH, HATU, iPr$_2$NEt, CH_2Cl_2, 0 °C→RT, 76%; b) HCl (2 M), dioxane/EtOAc, RT, quant.; c) 3-OH-PhCO$_2$H, HATU, iPr$_2$NEt, CH_2Cl_2, 0 °C to RT, 98%; d) H_2, Pd C 10%, EtOH/EtOAc, RT, quant.; e) PPh_3, ADDP, CH_2Cl_2, RT, 72%. Chg-OH = cyclohexylglycine, HATU = *O*-(7-azabenzotriazol-1-yl)-*N*,*N*,*N*′*N*′-tetramethyluronium hexafluorophosphate, ADDP = 1,1′-(azodicarbonyl)dipiperidine.

of the Boc protecting group and subsequent coupling with 3-hydroxyphenylacetic acid provided compound **7**. Cleavage of the benzyl ether gave the phenol alcohol **8**, which is the substrate for the key Mitsunobu macrocyclization reaction.[11] Treatment of **8** with triphenylphosphane and 1,1′-(azodicarbonyl)dipiperidine furnished the desired macrocycle **9** in excellent yield (72%).

The "right-hand" segment (P1–P2′) of the molecule was prepared through a series of peptide couplings and deprotections, starting with α-hydroxy-β-amino acid norvaline (Nva) and norleucine (Nle) derivatives[12] (**10** and **15**, respectively; Scheme 3). The hydrochloride intermediates of the tripeptide amines **12**, **13**, **16**, and allyl amide amine **14** were obtained as mixtures of four diastereomers.

Finally, the macrocyclic "left-hand" segment and the α-hydroxyamide "right-hand" moiety were combined (Scheme 4). The methyl ester **9** was hydrolyzed to the carboxylic acid **17**, which was then coupled with amines **12**–**14** and **16**. The resulting hydroxyamides were oxidized to the



Scheme 3. a) respective amine, DhBtOH, $ClCH_2CH_2Cl$, NMM, DMF/CH_2Cl_2, −20 °C, 65–95%; b) H_2, Pd-C, EtOH, RT, 98%; c) 2 M HCl, dioxane/EtOAc, RT, quant. DhBtOH = 3,4-dihydro-3-hydroxy-4-oxo-1,2,3-benzotriazine, NMM = *N*-methylmorpholine, DMF = *N*,*N*-dimethylformamide.

corresponding α-ketoamides by using Dess–Martin periodinane.[13] The products were mixtures of two diastereomers at the P1–Nva/Nle α center. The *tert*-butyl ester isomers **18** and **21** and the dimethyl amides **20** and **23**, were separated. Treatment of **18** and **21** with TFA gave carboxylic acids **19** and **22**, respectively. The allyl amide **24** and the P1–Nle analogue **25** were an inseparable mixture of diastereomers.

All macrocyclic inhibitors **18**–**25** were tested in an HCV continuous assay[14] (Table 1). The inhibition constants (K_i^*) were determined by using NS4A-tethered single-strain NS3 serine protease.[15] The K_i^* values for compounds **18**, **19**, and **20** were 0.81, 0.36, and 0.21 μM, respectively. However, the opposite diastereomers **21**, **22**, and **23** were much more potent (K_i^* = 0.038, 0.038, and 0.044 μM, respectively). Based on the structure–activity relationship results from our acyclic peptide HCV protease inhibitors,[16] the more potent compounds **21**–**23** were assigned the *S* configuration at P1 and the less potent compounds **18**–**20** the *R* configuration. The P1–Nle analogue **25** was equally potent (0.076 μM) considering it was a mixture of two isomers, whereas the smaller tripeptide inhibitor **24** was only moderately active (3.1 μM).

The selectivity of these inhibitors against human neutrophil elastase (HNE), a structurally closely related serine protease, was also measured (Table 1). Compounds **18**–**23** were moderately selective against elastase (HNE/HCV =

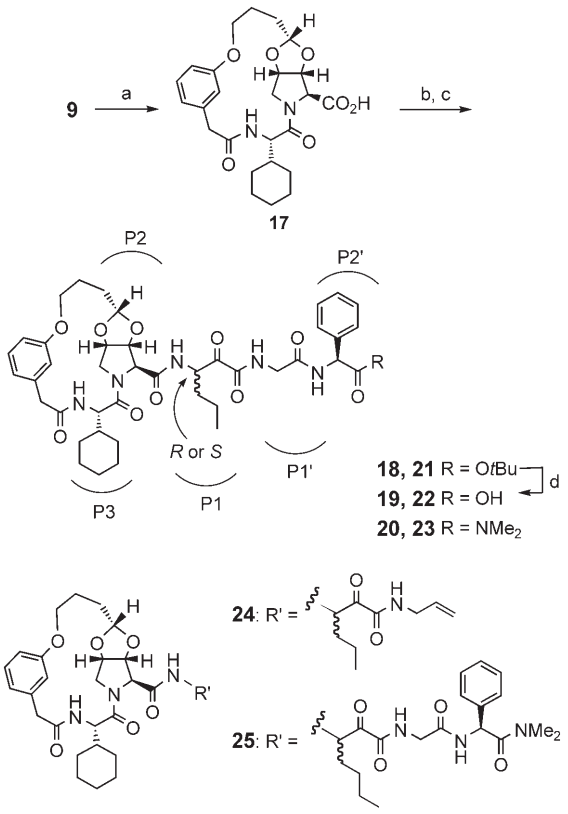

Scheme 4. a) LiOH, MeOH/THF/H_2O, RT, 93%; b) **12–14** or **16**, DhBtOH, EDC, NMM, DMF/CH_2Cl_2, −20°C, 50–85%; c) Dess–Martin periodinane, CH_2Cl_2, RT, 51–89%; d) TFA, CH_2Cl_2, RT, quant. TFA = trifluoroacetic acid

Table 1: Potency and selectivity of compounds **18–25** against HCV protease.

Compound	R	P1	K_i^*[μM]	HNE/HCV
18	O*t*Bu	(*R*)-Nva	0.81 ± 0.04	6
19	OH	(*R*)-Nva	0.36 ± 0.03	11
20	NMe_2	(*R*)-NVa	0.21 ± 0.04	32
21	O*t*Bu	(*S*)-Nva	0.038 ± 0.001	3
22	OH	(*S*)-Nva	0.038 ± 0.001	4
23	NMe_2	(*S*)-Nva	0.044 ± 0.009	5
24	–	(*R*,*S*)-Nva	3.1 ± 0.3	–
25	NMe_2	(*R*,*S*)-Nle	0.076 ± 0.006	383

3:32), whereas the P1–Nle derivative **25** was highly selective (383-fold). This indicates that the P1 residue plays an important role in selectivity. Pharmacokinetic (PK) studies in rats showed that compound **23** had a low oral AUC (area under the curve) value (0.1 μM h@3 mpk) and bioavailability (0.3%), whereas compound **24** gave a respectable AUC value (2.6 μM h). Presumably, the smaller size and fewer amide bonds of **24** contributed to the improved PK profile. The solubility of **18–23** in pH 7.4 buffer was in the range of 5–80 μM, with **19** and **20** at the higher end and **18**, **21, 22**, and **23** at the lower end.

The X-ray crystallography structure of compound **22** bound to the active site of HCV protease was obtained (Figure 1). It confirmed the absolute configurations at both

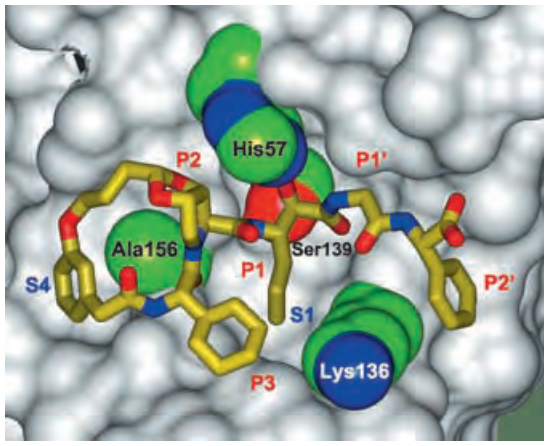

Figure 1. The X-ray crystal structure of compound **22** bound to HCV protease.

the acetal center and the P1 α center. As expected a reversible covalent-bond formation occurred between the carbonyl group of the ketone and the hydroxyl group of Ser139. Most importantly, the 17-membered macrocycle formed a perfect "donut" that surrounded the Ala156 methyl group. The P1 *n*-propyl side chain was buried in the S1 pocket and a "C"-shaped clamp was formed around the side chain of Lys136 along with the P2′ phenyl group. The P2 bicyclic praline derivitive, the P3 cyclohexyl ring and the phenyl group in the macrocycle all had hydrophobic interactions with the protein surface. Furthermore, there were several hydrogen bonds between the inhibitor peptide chain and that of the enzyme backbone. All these interactions contributed to the excellent potency of **22**.

In summary, a concise and highly stereoselective synthesis of the 17-membered macrocycle **9** was completed and the *endo* product was shown to form exclusively at the acetal center of the bicyclic proline core. The key macrocyclization provided excellent yields through a Mitsunobu protocol. The resultant macrocyclic inhibitors were active against HCV NS3 serine protease with the (*S*)-P1 isomers being the more potent. The X-ray crystal structure of compound **22** bound to the enzyme revealed that the macrocycle formed good contact with the enzyme by adopting a "donut"-shaped conformation above the methyl group of Ala156. Further evaluation of these compounds and the design of inhibitors with better potency and PK profiles are currently in progress.

The Origin of Stereoselectivity in Primary Amino Acid Catalyzed Intermolecular Aldol Reactions**

Arianna Bassan, Weibiao Zou, Efraim Reyes, Fahmi Himo, and Armando Córdova**

The asymmetric amino acid catalyzed aldol reaction is plausibly an ancient transformation,[1] which enzymes have catalyzed for billions of years. These enzyme-catalyzed stereoselective aldol reactions involve enamine intermediates (type I aldolases) or zinc enolates (type II aldolases) as the reactive nucleophile.[2] The catalytic residue of type I aldolases is the primary amino group of a lysine moiety, which forms enamine intermediates with the help of a proton relay system by neighboring amino acids.[2c]

The ability of amino acids to catalyze the asymmetric aldol reaction was discovered in the 1970s by Hajos and Parrish[3] and Wiechert and co-workers,[4] and amino acid mediated stereoselective Robinson annulations were utilized numerous times in natural-product synthesis.[5] In 2000, List and co-workers demonstrated that proline and its derivatives can be used as catalysts for intermolecular asymmetric aldol reactions between ketones and aldehydes with moderate-to-excellent enantioselectivities.[6–7] Both the proline-catalyzed intramolecular and intermolecular aldol reactions involve an enamine mechanism, in which one proline molecule takes part in the transition state, as established by Houk, List, and co-workers.[8]

We recently found that acyclic amino acids and their derivatives are able to catalyze asymmetric intermolecular aldol reactions with high stereoselectivity.[1b,9] For example, simple natural and unnatural primary amino acid derivatives catalyzed the reaction between cyclohexanone **1** and an

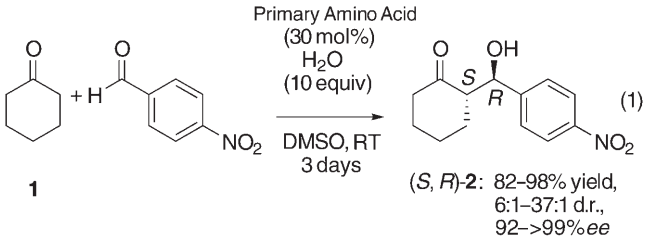
aldehyde in high yield and with up to >99% *ee* [Eq. (1); amino acid: (*S*)-alanine, (*S*)-aminobutyric acid, (*S*)-valine, (*S*)-asparatate, (*S*)-isoleucine, (*S*)-serine].[9]



Intrigued by the enzyme-like enantioselectivity of the acyclic amino acid catalyzed asymmetric aldol reaction, we became interested in unraveling the origins of its stereoselectivity. The origin of the stereoselectivity of acyclic amino acids is of great importance in understanding the origins of biological homochirality and the evolution of the catalytic mechanism of aldolase enzymes. In addition, the information gathered can aid the development of new organocatalysts.

Herein, we present how theoretical and experimental data can be combined to understand the stereochemistry of primary amino acid catalyzed intermolecular aldol reactions that involve enamine intermediates. We show that calculations provide key insight, not yet accessible by other means, into the mechanism and accurately predict the stereochemistry of the observed product.

We initially investigated the relationship between the enantiomeric excess of aldol product **2**, derived from the aldol reaction shown in Eq. (1), and the optical purity of the simplest chiral amino acid catalyst, (*S*)-alanine. Plotting the enantiomeric excess of alanine versus that of β-hydroxy ketone **2** showed a linear correlation (Figure 1).

Our results support the supposition that only one alanine molecule takes part in the transition state of the primary amino acid catalyzed asymmetric aldol reactions. This correlation together with previous theoretical findings by Houk and co-workers for proline-catalyzed aldol reactions[8] suggests that three possible mechanisms may describe the primary amino acid catalyzed asymmetric aldol reactions: the carboxylic acid catalyzed enamine mechanism, the amino catalyzed enamine mechanism, and the enaminium catalyzed mechanism (Scheme 1).

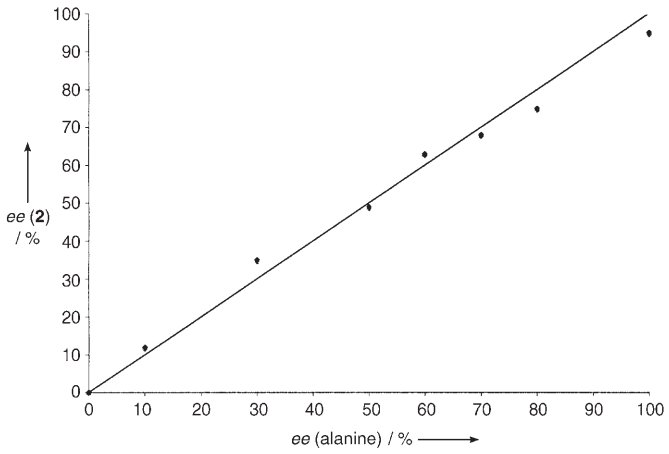


Figure 1. Relation between the enantiomeric excess of (*S*)-alanine and that of the aldol product **2** in the catalytic intermolecular asymmetric synthesis of **2**.

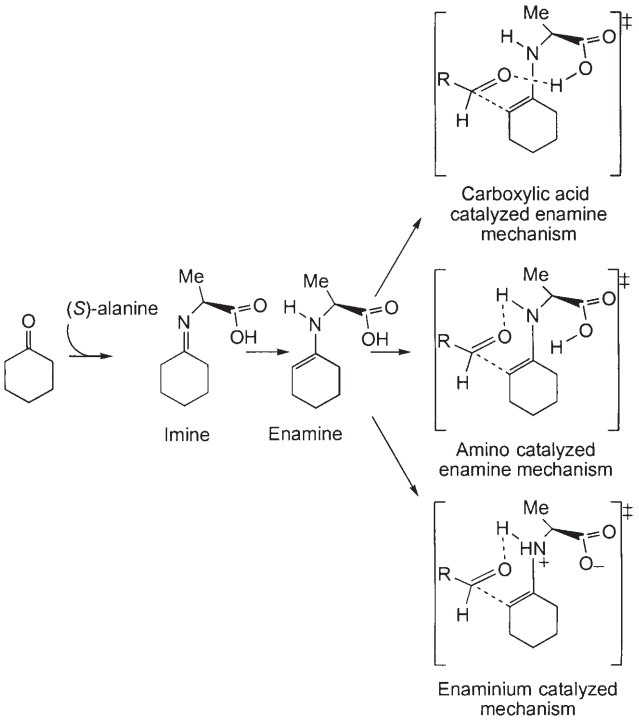

Scheme 1. The three possible mechanisms in the alanine-mediated aldol reaction which involve an enamine intermediate.

We then performed density functional theory (DFT) calculations on the alanine-catalyzed aldol reaction with **1** as the donor and benzaldehyde as the acceptor species. More specifically, we focused our attention on the nucleophilic attack of the enamine/enaminium moiety on the carbonyl group (see Scheme 1), as this step governs the configuration of the product, and located the possible transition-state structures associated with the C–C bond formation. Calculations indicate that the most accessible pathway corresponds to the enamine-catalyzed reaction, in which the C–C bond formation is coupled with proton transfer from the carboxylic group of the alanine moiety to the developing alkoxide (Scheme 1). Primary amino acids lead to an enamine intermediate that can rotate about the C_α–N bond in contrast to the corresponding proline-derived enamine intermediate, and thus more transition-state structures have to be envisioned. As shown in Scheme 2, different transition-state orientations that generate products with different configurations have been considered. For each of the eight orientations shown in Scheme 2, two possible proton-transfer arrangements have been studied together with two different conformations of the enamine ring, thus giving a total of 32 transition states. As an example, four transition-state structures that lead to the same *S*,*R* product are shown in Figure 2 (more transition-state structures are given in the Supporting Information).

Figure 3 shows the four transition-state structures that generate the four different stereoisomers with the lowest energy barriers. Among these four transition states, the one

that requires the lowest activation energy leads to the *S*,*R* enantiomer, which is indeed the product observed experimentally. The *R*,*S* enantiomer is formed through a transition-state structure that lies 3.2 kcal mol^{-1} higher in energy, which is in accordance with the experimental results (> 90 % *ee*).[9] The *S*,*S* enantiomer also requires a higher energy barrier (2.9 kcal mol^{-1}), thus explaining the high *anti* diastereoselectivity (d.r. > 10:1).

Scrutiny of the geometrical arrangements of the low-lying transition-state structures that lead to the different products (as shown in Figure 3) allows us to identify a few effects that contribute to the stereoselectivity of the reaction. First, it can be noticed that the electrostatic hydrogen-bonding interaction between the amino group and the developing alkoxide moiety plays an important role. The hydrogen bond (NH···O) is relatively short (about 2 Å) for the three lowest transition-state structures in Figure 3 (those that lead to the *S*,*R*-, *R*,*S*-, and *S*,*S*-enantiomeric products). This hydrogen-bonding interaction is absent in the transition-state structure that leads to the *R*,*R* product and in general in most of the transition-state structures with higher energies (see the Supporting Information). Another factor that regulates the stereoselectivity is the steric repulsion between the phenyl and cyclohexyl rings in the transition state. Accordingly, the eclipsed conformation of the phenyl and cyclohexyl rings in the transition state that leads to the *S*,*S* product results in higher energy relative to the *S*,*R* transition state, in which the two rings are in a staggered conformation instead. Finally, the methyl substituent of (*S*)-alanine interacts unfavorably with the cyclohexyl ring, thus leading to the higher energy of the *R*,*S* transition state relative to the *S*,*R* structure, in which the methyl group points away from the cyclohexyl moiety. The interplay between these effects ultimately determines the relative energies of the various transition states and, thus, drives the stereoselectivity of the primary amino acid catalyzed intermolecular aldol reaction.

The energy diagram associated with the formation of the observed product, the *S*,*R* enantiomer (see Figure 4), shows that the nucleophilic attack is slightly endothermic and, thus, reversible.

The other two mechanisms investigated herein, the enaminium- and the amino-catalyzed mechanisms, are presented in Scheme 1. In the calculations that involve zwitterionic-like structures, geometric optimizations in a dielectric

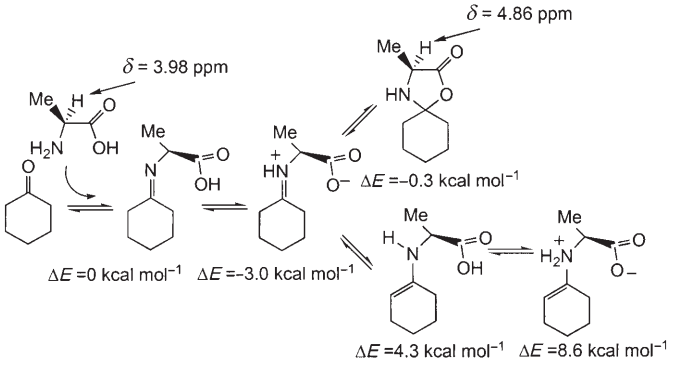
continuum medium were necessary to fully optimize the transition-state structures (more details of the calculations are described in the Experimental Section). The two alternative mechanisms require activation energies much higher than the corresponding energies of the carboxylic acid catalyzed enamine mechanism at the same level of theory (see details in the Supporting Information). The higher energy barriers, as found by computation (higher than 15 kcal mol^{-1}, as described in the Supporting Information), allow us to safely dismiss the enaminium- as well as the amino-catalyzed mechanisms in the alanine-catalyzed aldol reaction and, by extension, for the other primary amino acids as well.

The acyclic amino acid catalyzed aldol reaction is significantly accelerated by a small amount of water.[9] We therefore performed NMR spectroscopic analysis according to List et al.[7j] to reveal the possible presence of oxazolidinone intermediates formed between the ketone donor and alanine, which would thus reduce the enamine concentration and lead to a decrease in the reaction rate (Scheme 3). The



Scheme 3. Relative energies of different intermediates and of the oxazolidinone inhibitor in the alanine-mediated aldol reaction occurring by an enamine pathway.

formation of the oxazolidinone was indicated by a change in the chemical shift of the α proton of alanine from $\delta = 3.98$ to 4.86 ppm. In addition, calculations were made to shed light on the NMR spectral data. The computed relative energies of the imine, iminium, enamine, enaminium, and oxazolidinone moieties show that the formation of oxazolidinone from the imine functionality is a slightly exothermic and, thus, more favorable process (see Scheme 3). Moreover, the oxazolidinone lies lower in energy than the enamine, which is the reactive nucleophile in the aldol reaction. Hence, the competing oxazolidinone reaction may explain why the primary amino acid catalyzed aldol reactions are very slow in the absence of a few equivalents of water.[9]

In summary, our DFT calculations, supported by additional experimental data, provide a key basis for understanding primary amino acid intermolecular aldol reactions in which only one amino acid molecule is involved in the transition state. We showed for alanine that the carboxylic acid catalyzed enamine mechanism is more favorable than other mechanisms because it requires the lowest activation energy. Furthermore, the calculations demonstrate that such a mechanism accurately predicts the proper stereochemistry of the reaction.

Experimental Section

All ground-state and transition-state geometries were optimized by using hybrid density functional theory[10] and a standard double zeta plus polarization basis set (B3LYP/6-31G(d,p)) with the Gaussian03 software package.[11] Final energies for the fully optimized structures were obtained by using the larger basis set 6-311 + (2d,2p) and were corrected for zero-point effects derived from frequency analysis at the B3LYP/6-31G(d,p) level of theory. When zwitterionic-like structures were involved, geometry optimizations and frequency calculations were performed in the presence of a solvent by using the CPCM polarizable conductor calculation model ($\varepsilon = 36.5$);[12] the radii derived from the UFF force field were employed to build the cavity. This procedure was adopted in the evaluation of the energies of the imine, iminium, enamine, enaminium, and oxazolidinone moieties (Scheme 3), and in the investigation of the enaminium-catalyzed mechanism (see the Supporting Information); for comparison, it was also used for the amino-catalyzed enamine mechanism. To test the solvent effects in the carboxylic acid catalyzed enamine mechanism and to compare the energies of the three different mechanisms, three transition-state structures from the carboxylic acid catalyzed enamine mechanism (those with the lowest energy barrier) were reoptimized in the presence of the solvent. Their relative energies were not significantly affected by the different optimization procedure (see Figure 3 and the Supporting Information).

Polymorphism in Benzamide**

W. I. F. David, K. Shankland, C. R. Pulham, N. Blagden, R. J. Davey, and M. Song*

One of the major challenges of solid-state chemistry in the early 21st century is, without doubt, the understanding of the structural, thermodynamic, and kinetic factors associated with the crystallization of molecular compounds. Our limited ability to predict and control the appearance of desirable crystal phases of molecular materials has a major and lasting impact on both technological and commercial progress in the fields of pharmaceuticals, health care, specialty chemicals, and optoelectronics. Although there have been major advances in the field over recent years (in terms of strategies for structure prediction and nucleation control), apparently simple systems such as benzamide sometimes present seemingly intractable problems. In their seminal paper of 1832, Wöhler and Liebig[1] described how slow cooling of a "boiling hot" aqueous solution of benzamide resulted in solidification of the liquid in a white mass of silky needles (Figure 1a). They noted that the transformation of this mass gave a few well-formed rhombic crystals (Figure 1b,c) and identified this process as a phase transformation. This stable, rhombic form of benzamide has been widely studied over the years and its monoclinic crystal structure was first determined in 1959 by using single-crystal X-ray diffraction.[2–4] In contrast, the very existence of a metastable form appears to have been largely forgotten. In 1904, Mohr [5] performed some microscopic studies and Penfold and White[2] made a fleeting reference to it in 1959 but otherwise, probably as a result of its highly metastable nature,[6] it has not received any serious attention. The "plaitlike" fibrous intertwining of the birefringent, metastable crystals shown in Figure 1a, suggests a high degree of strain and structural disorder at the molecular level. Figure 1d reveals the possibility of a direct solid-state transformation between the two forms and gives an initial indication that the needle axis is related to the monoclinic *b* axis of the known stable structure.

With the availability of third-generation synchrotron sources, it is now possible to record diffraction data sufficiently quickly to determine the structures of transient species through powder-diffraction analysis, even in the presence of solvents and other crystalline phases. To this end, we performed a series of X-ray powder diffraction (XRPD) experiments on beamline ID31 at the European Synchrotron Radiation Facility in Grenoble, France. A hot aqueous solution of benzamide (0.347 M) was loaded into a glass capillary (1.5 mm), which was flame-sealed at both ends. The capillary was first warmed to ensure complete dissolution of the solid, cooled to 20 °C, and mounted on the goniometer of the diffractometer. The capillary was then rotated at 2 kHz to minimize the effects of the preferred orientation, and an incident wavelength of 0.8 Å was applied. Although the resulting XRPD pattern was dominated by the known monoclinic form, a small quantity of a new form was also observed. Through the use of a more-dilute aqueous solution of benzamide (0.173 M), cooled in situ on the diffractometer to 2 °C and then flash cooled through brief contact with a cotton bud soaked in liquid nitrogen, a substantial increase in the relative proportion of the new form was obtained; it was not possible to eliminate the known monoclinic form completely. This new form persisted for over 60 min, and the XRPD patterns collected during this period allowed the identification of just twelve diffraction peak positions that are attributable to the new form. These were indexed by using the program DICVOL91[7] to give an orthorhombic unit cell ($a = 17.4322$, $b = 14.1937$, $c = 4.9773$ Å) with excellent figures

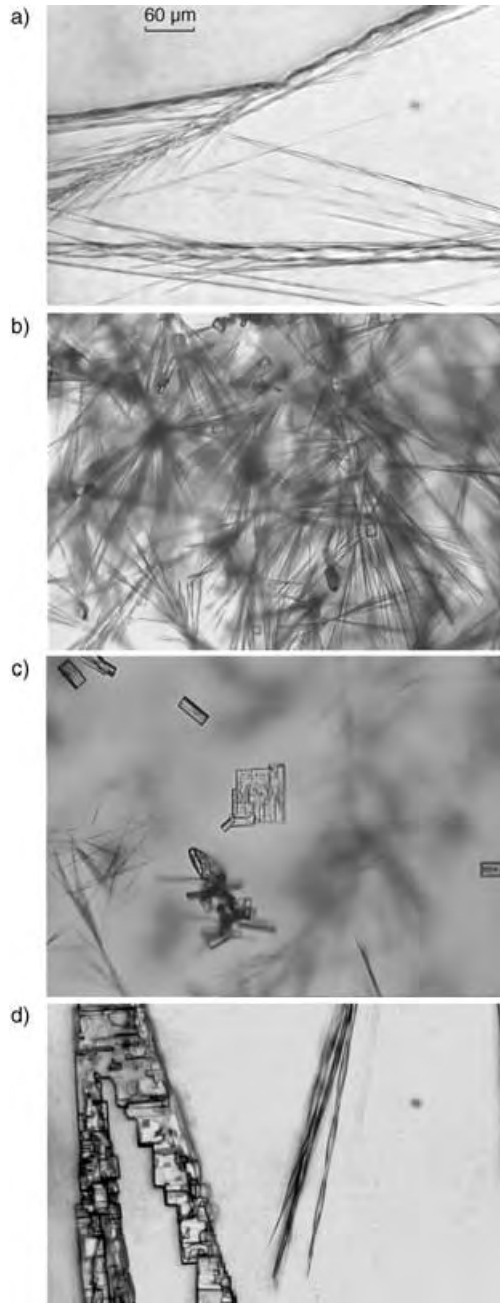

Figure 1. a) Needlelike plaits of the metastable form of benzamide in aqueous solution at room temperature. b) An aqueous suspension of needles taken 30 s after crystallization, and c) the same sample 60 s after crystallization shows the solution-mediated transformation of the needles to the stable form. d) An aggregate of stable monoclinic crystals (left) and a plait of needles (right). The individual crystals of the monoclinic aggregate are all aligned with their *b* axes along its length.[11] As this aggregate originated from the solid-state transformation of a metastable needle, it is reasonable to deduce that the directions of elongation in both forms share a common structural motif. In all photos the scale can be judged from the diameter of a needle, which (as seen from the 60-µm scale bar in a)) is about 30-µm in all cases.

of merit,[8] $M(12) = 63.6$ and $F(12) = 156.3$. The unit cell volume was 1231.52 Å^3, which is slightly less than double that of the monoclinic form (624.25 Å^3) and suggests, unusually, that the metastable form is denser than the stable form. A probabilistic analysis of the extracted reflection intensities, obtained by using the program DASH,[9] identified the most likely extinction symbol to be *Pba-* (the log-likelihood gain of *Pba-* over *P---* was 7.4), which corresponds to space group *Pba*2 or *Pbam*. The centrosymmetric space group *Pbam* was initially chosen as the most likely candidate for the crystal structure as it results in the presence of only one molecule in the asymmetric unit. Structure determination was performed by global-optimization methods by using DASH, and the molecular geometry of the benzamide molecule (excluding the torsion-angle value for the single rotation of the amide group relative to the benzene ring) was taken from the known crystal structure. However, no satisfactory solutions were found in this space group, either from the point of view of profile fitting or crystal packing. Indeed, the best Rietveld χ^2 value in *Pbam* was 254.0, which is very poor when compared with the Pawley χ^2 value of 4.0. Accordingly, structure determination was then performed in the noncentrosymmetric space group *Pba*2, which requires the use of two crystallographically independent benzamide molecules in the asymmetric unit. Ten independent global-optimization runs were conducted, and in eight of the ten attempts, the same excellent fit to the data was obtained with a Rietveld χ^2 value of 6.30, which is very close to the Pawley χ^2 value. Promisingly, the crystal structure that corresponds to these runs exhibited good packing and formation of favorable hydrogen bonds. To obtain reliable structural coordinates from the multiphase XRPD pattern, restrained refinement of the structure of the orthorhombic form was performed simultaneously with refinement of the structure of the known monoclinic form and the solvent background structure. The final Rietveld refinement of the crystal structure was performed with the program TOPAS[10] (refinement details are given in Table 1). The two independent benzamide molecules, which form a dimer in the structure, were modeled by using a constrained Z-matrix description for each molecule. Bond-length and planarity restraints were employed to maintain the dimer

Table 1: Rietveld refinement details for the XRPD data obtained at room temperature.

	Mixed-phase refinement

geometry. Separate isotropic temperature factors for each molecule were required to obtain an adequate structural refinement. The final fit between the observed and calculated diffraction patterns is shown in Figure 2, and the figures of

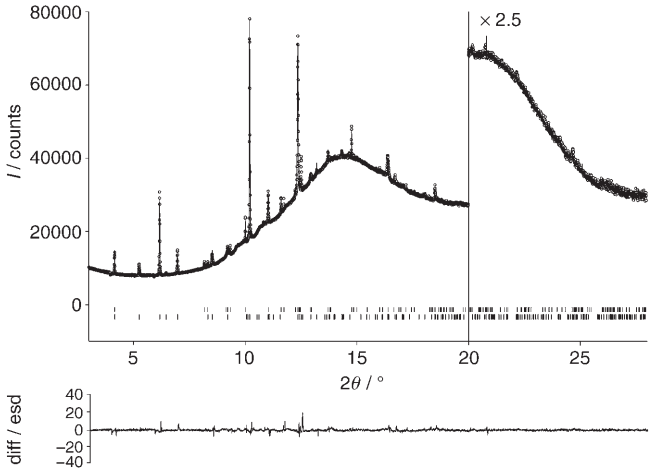

Figure 2. The powder X-ray diffraction pattern shows the excellent fit between the observed and calculated data based upon a two-phase refinement. The upper and lower tick marks indicate the positions of the Bragg reflections in the monoclinic and orthorhombic forms, respectively. The large background is a result of the water that surrounds the benzamide crystallites in the capillary. The *y* axis for the region beyond $2\theta = 20°$ is expanded by a factor of 2.5 for clarity. A difference over estimated standard deviation (esd) plot for the fit to the data is also shown.

merit ($R_{exp} = 8.4\,\%$ and $R_{wp} = 13.2\,\%$, background subtracted) confirm the excellent fit obtained. The sample was found to be comprised of approximately 20% monoclinic form and 80% orthorhombic form. A (001) projection of the resultant metastable orthorhombic crystal structure is shown in Figure 3a, with the corresponding (010) projection of the stable monoclinic form shown for comparison (Figure 3b). The intermolecular interactions perpendicular to the plane are essentially identical in both structures and confirm the evidence from optical microscopy for a common major-growth direction for both forms (Figure 1d); the needle axis of the metastable form is, therefore, along the short [001] direction, which was anticipated from basic crystal morphology arguments.[11] Anisotropic broadening of the Bragg peaks in the powder diffraction pattern also indicates that the needle axis of the metastable structure is along the *c* axis. This is indicated in Figure 4, where it can be seen that the (001) reflection is substantially broader than the other peaks at similar 2θ values. Interestingly, the 2θ dependence of the anisotropic broadening refinement indicates that the origin of the broadening is dominated not by size but rather by strain effects—the plaitlike habit is caused by strain effects that are predominantly associated with the needle direction in which the root-mean-square strain $\Delta d/d$, measured from the anomalous peak width, is approximately 0.004. Furthermore, the constrained refinement of the crystal structure revealed that the isotropic temperature factor for one of the molecules was anomalously large ($B = 12.4(3)$ Å^2, the other value being

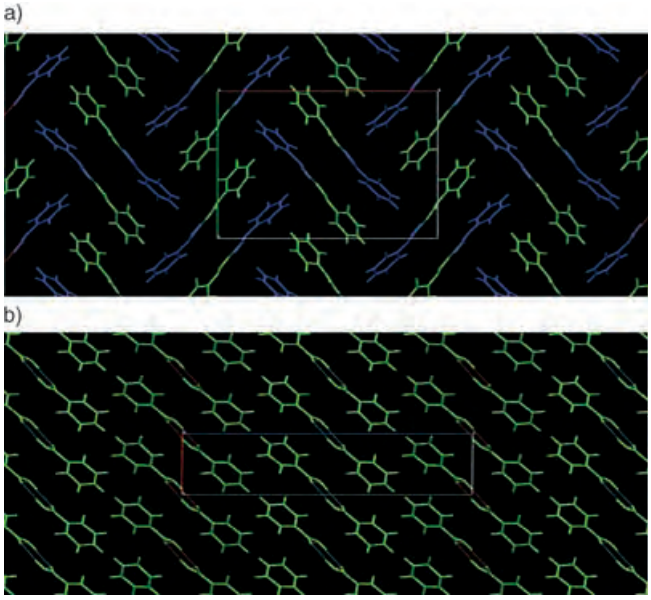

Figure 3. a) A projection of the orthorhombic needle structure looking along [001]. b) A projection of the stable monoclinic structure looking along [010]. In both cases, the views are along hydrogen-bonded ribbons that comprise molecular dimers. The transformation from one form to the other can conserve these ribbon directions and only involve the rearrangement of ribbons in the plane of the pictures. Symmetry-related molecules are shown in identical colors.

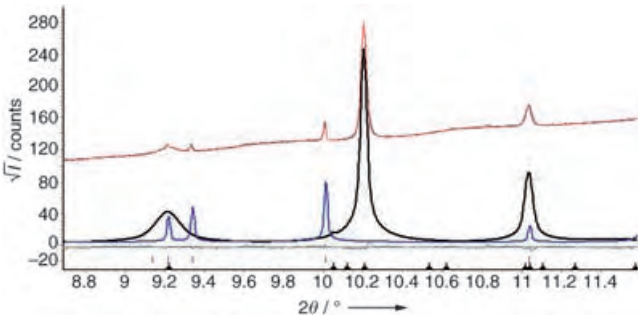

Figure 4. A section of the powder X-ray diffraction pattern that shows the excellent fit between the observed and calculated data based upon a two-phase refinement. The blue line and upper set of tick marks show the contribution of the monoclinic form to this portion of the diffraction pattern; the black line and the lower tick marks show the contribution of the orthorhombic form. The severe anisotropic line broadening in the orthorhombic form is clearly visible in the (001) reflection at just over $2\theta = 9.2°$.

4.3(3) Å^2), which is consistent with substantial structural disorder. Thus, the plaitlike morphology appears to be associated with the static disorder of only one of the molecules in the asymmetric unit. The XRPD data are of insufficient quality to allow a more-detailed characterization of the disorder beyond that of the initial observations.

The concomitant appearance of two distinct crystalline polymorphs of benzamide highlights the delicate balance that can exist between kinetics and thermodynamics in the appearance of polymorphic forms. The needlelike habit of the metastable form reflects rapid, uniaxial crystal growth with the molecular disorder possibly driving the formation of

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

fibrous, plaitlike aggregates. At the same time, the complex *ab* plane packing in the metastable form leads to a smaller specific volume than that of the stable monoclinic form, which is more energetically favorable. Furthermore, the entropic factors also favor structural disorder at higher temperatures. From these morphological and thermodynamic arguments, it is not surprising that the metastable structure grows rapidly at first. The subsequent rapid interconversion from metastable to stable polymorph, although clearly facilitated by the preservation of dimer ribbons along the fast-growth axes and their facile rearrangement within the *ab* orthorhombic plane, implies that overall the monoclinic form is significantly more stable than the orthorhombic modification.

Thus, 173 years after the discovery of the first polymorphic molecular crystal, benzamide, by Wöhler and Liebig,[1] the crystal structure of the metastable form has been determined from an in situ synchrotron XRPD experiment. A comparison of the metastable and stable structures provides an explanation not only for the mechanism of transformation but also for the initial rapid crystallization of the metastable structure. The research methods outlined herein are of general applicability to the area of polymorphism and phase transformations, and offer the prospect of the determination of relationships and transformations in numerous polymorphic systems, especially in cases in which metastable states are of a transitory nature.

Structural Evidence of Mechanical Shuttling in Condensed Monolayers of Bistable Rotaxane Molecules**

*Kasper Nørgaard, Bo W. Laursen, Sune Nygaard, Kristian Kjaer, Hsian-Rong Tseng, Amar H. Flood, J. Fraser Stoddart, and Thomas Bjørnholm**

Bistable, redox-controllable [2]rotaxanes constitute a class of artificial molecular machines[1,2] in which a mobile ring is confined to move between two different recognition sites (stations) along a dumbbell-shaped component. Linear motor molecules and nanoelectromechanical actuators[3] can be constructed from such redox-controllable [2]rotaxanes. These latter compounds have also been utilized[4,5] as electromechanical switches in molecular memory devices. In this context, the possibility of relative mechanical motion occurring within such bistable [2]rotaxanes in condensed phases has been questioned[6] and disputed.[7] Such motion has been demonstrated unequivocally in solution,[8] in polymer matrices,[9] and in self-assembled monolayers on gold electrodes[10] to result in the movement of the ring from one primary station to a secondary one and then back again in a stepwise manner. One glaring deficiency, however, has been the lack of structural characterization methods for these switching processes in nanoscale systems that can be applied directly to highly condensed phases on surfaces and at interfaces.

Herein, we describe the use of surface-sensitive synchrotron X-ray reflectometry[11] (XR) to provide the first direct structural investigation of the redox-controlled switching process in condensed monolayers of amphiphilic, bistable [2]rotaxanes at the air/water interface. We find that efficient shuttling of the ring component in such [2]rotaxanes takes place in the condensed liquidlike monolayers. The ring travels the 37 Å between the two stations of the dumbbell along a path that is largely confined to the plane of the monolayer. This movement causes insignificant changes in the overall monolayer thickness. Our study has focused on exactly the same molecules whose switching within molecular monolayers has recently been characterized,[12] albeit indirectly, by Langmuir π-A isotherms and the Langmuir–Blodgett (LB) technique in combination with X-ray photoelectron spectroscopy (XPS). By contrast, XR has previously been demonstrated to provide direct detailed information about monolayer organization in general[13] and of amphiphilic bistable rotaxanes at the air/water interface in particular.[14] The working principle of XR is illustrated schematically in Figure 1 a. The incident (α_i) and exit (α_f) grazing angles are varied simultaneously ($\alpha_f = \alpha_i$) while the intensity pattern that results from the interference of X-rays reflected from different depths of the sample is recorded. Data inversion[15] yields—on an absolute scale—the out-of-plane electron-density distribution across the water/monolayer/air interface. The density profiles are smeared by the intrinsic roughness (ca. 3 Å (rms)) of the water surface on account of capillary waves.[16] The bistable [2]rotaxanes **R1**$^{4+}$ and **R2**$^{4+}$ (Figure 1 b) consist of a tetracationic ring component (dark blue) encircling a linear dumbbell-shaped component, which contains two different stations for the ring: 1) a tetrathiafulvalene (TTF) unit (green) and 2) a 1,5-dioxynaphthalene (DNP) unit (red). The two recognition sites are separated by a rigid *p*-terphenylene spacer (black). Both molecules are terminated by a hydrophilic (light blue) and a hydrophobic (gray) stopper at opposite ends of the dumbbell component. This constitution renders the molecules amphiphilic and accordingly enables them to form monomolecular (Langmuir) layers when deposited at the air/water interface. The [2]rotaxanes **R1**$^{4+}$ and **R2**$^{4+}$ are constitutional isomers, differing only in the relative positions of the TTF and DNP units with respect to the two stoppers. The ring will therefore move in an opposite direction (up or down) when the TTF unit of **R1**$^{4+}$ and **R2**$^{4+}$ is oxidized, thus allowing critical internal comparisons to be made.

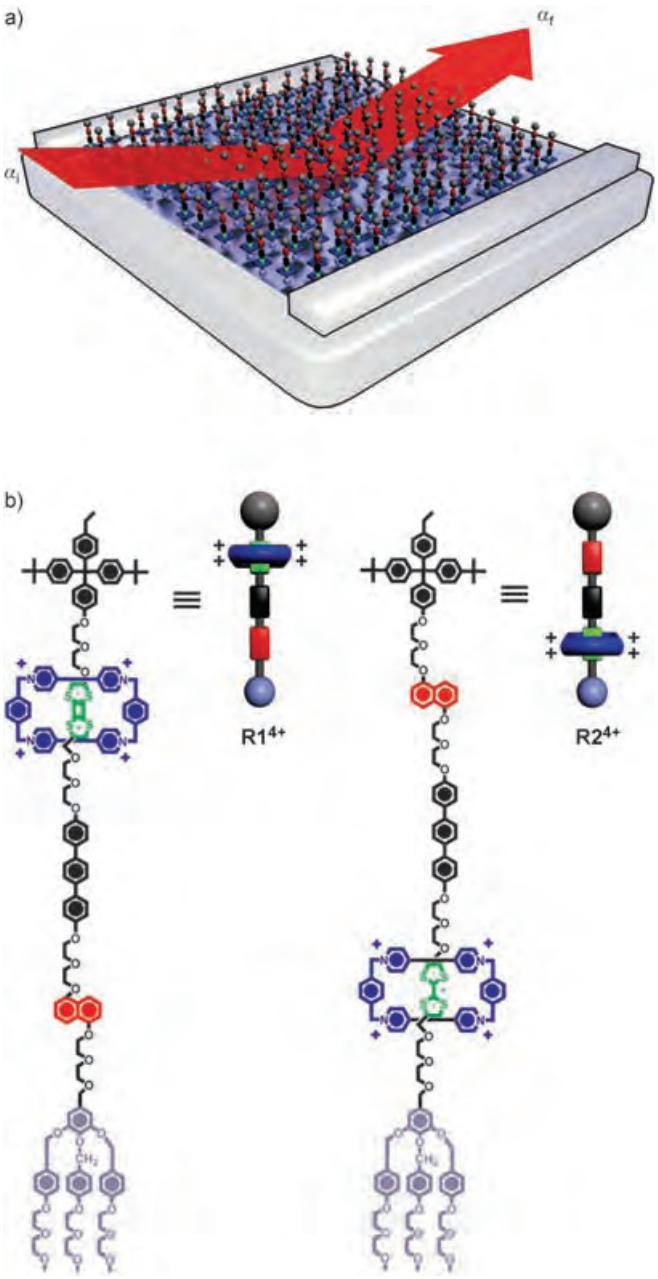

Figure 1. a) A schematic illustration of the working principle in specular X-ray reflectivity measurements of Langmuir monolayers. b) Graphical representations and structural formulas of the amphiphilic, bistable [2]rotaxanes **R1**$^{4+}$ and **R2**$^{4+}$.

Electrochemical switching of the relative position of the ring within these particular bistable [2]rotaxanes is well documented from solution-phase studies,[8,17] and for closely related bistable [2]rotaxanes across a range of different environments.[8c,9,10] In the initial states within each environment, the rotaxane exists in its ground-state co-conformation with the cyclophane encircling the TTF station preferentially by a factor of greater than 9, relative to the DNP station.[18] However, the monocationic TTF$^{\bullet+}$ or dicationic TTF^{2+} species that is produced upon oxidation repels[8–10,17] electrostatically the tetracationic cyclophane and induces the ring to move to the DNP station. In condensed media akin to the Langmuir films characterized here, this switching behavior and the two states associated with the two different locations of the ring have thus far only been observed by indirect methods of structural analysis, such as XPS[12] and electrochemistry.[10] XR investigations, on the other hand, give direct structural information about the electron distribution in thin films, and hence of the two isomeric structures associated with the location of the ring—up or down.

The experimental approach followed in this work, including oxidation of the rotaxane monolayers in situ, is illustrated schematically in Figure 2. Solutions of **R1**$^{4+}$ and **R2**$^{4+}$ in chloroform were spread onto the pure water surface of a

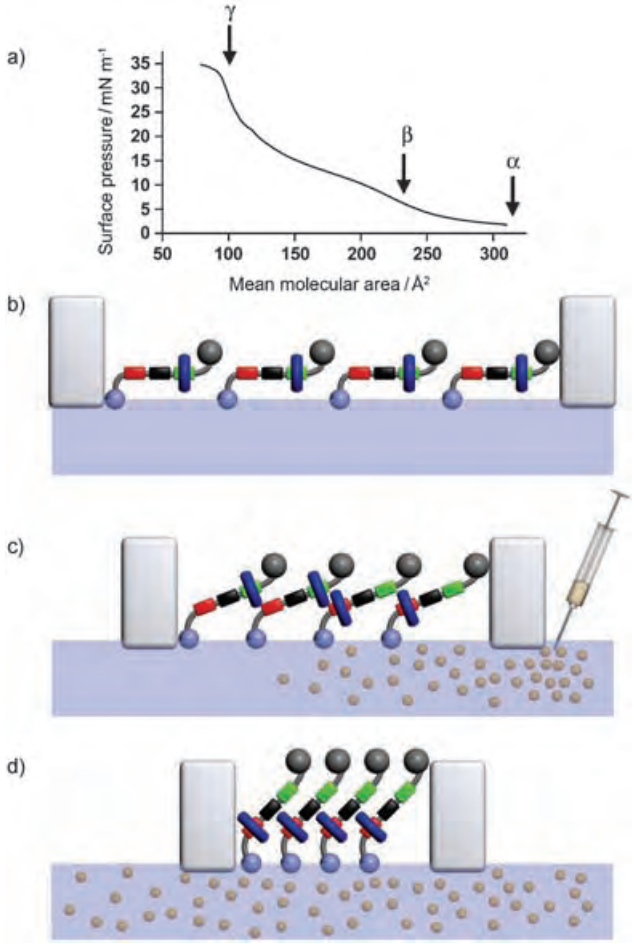

Figure 2. Illustration of the experimental procedure. a) Compression isotherm (surface pressure versus area) for $\mathbf{R2}^{4+}$. b) A schematic representation of a moderately expanded monolayer of $\mathbf{R1}^{4+}$ at the air/water interface. c) Injection of the oxidant $Fe(ClO_4)_3$ into the water subphase at various points along the isotherm (α, β, or γ). d) A densely compressed monolayer of the oxidized form of $\mathbf{R1}^{4+}$.

Langmuir trough, and the resulting monolayers were compressed at a constant rate while the surface pressure was monitored as a function of the mean molecular area (Figure 2a,b). Oxidation of the monolayers was performed[12] in situ by injecting an aqueous solution of the oxidant $Fe(ClO_4)_3$ into the water subphase beneath the Langmuir monolayer to obtain a nominal concentration of 5×10^{-4} M (Figure 2c). The oxidant was injected at decreasing mean molecular areas of 330, 230, or 100 Å^2, as indicated on the compression isotherm (Figure 2a). After injection, one hour was allowed for the oxidant to diffuse to the surface, and the monolayer was typically compressed to a mean molecular area of 100 Å^2 to maximize the electron density changes along the surface normal resulting from the reduced molecular tilting and folding (Figure 2c,d).[19] This area corresponds[12,19] to a very closely packed Langmuir monolayer (Figure 2d). All experiments were performed on a subphase containing 10^{-3}–10^{-4} M $NaClO_4$ to allow efficient ion exchange[12] of PF_6^- with ClO_4^- ions, regardless of the presence of the oxidant. This condition is the only deviation from the procedure described in the literature.[12]

The in-plane structure of the rotaxane monolayers was investigated by grazing-incidence X-ray diffraction.[11] As expected for such flexible molecules that bear a rich array of subunits capable of intra- and intermolecular interactions mediated by noncovalent forces, none of the Langmuir monolayers showed any crystallinity at any of the surface pressures investigated. XR measurements, which probe the out-of-plane structure, as described in Figure 1a, were performed on Langmuir monolayers of the unoxidized rotaxanes, as well as on the oxidized states of the monolayers at several positions (Figure 2a) along the compression isotherm. Figure 3a shows the resulting electron-density profiles for the highly compressed Langmuir monolayers of $\mathbf{R1}^{4+}$ with the ring up, measured at a mean molecular area of 100 Å^2. The green line represents the monolayer of unoxidized $\mathbf{R1}^{4+}$ and the red line corresponds to the monolayer of $\mathbf{R1}^{6+}$, oxidized in situ. The oxidation was performed on a moderately condensed monolayer with a mean molecular area of 230 Å^2 that was subsequently compressed to 100 Å^2. The areas above the horizontal dashed lines represent the total number of electrons in one molecule (including counterions). The horizontal dotted lines correspond to the approximate positions of the interfaces with bulk water and were chosen as the point on the curve where the electron density is 5% larger than that of bulk water. The discrepancy between the dashed and dotted lines in Figure 3 is caused by the inclusion of a small number of water molecules (ca. 10 per rotaxane molecule, see Supporting Information) from the subphase into the hydrophilic parts of the rotaxane monolayer. This water inclusion is less pronounced in highly compressed Langmuir monolayers than in less closely packed monolayers.[14]

Two distinct features emerge from the data analysis shown in Figure 3a: 1) The profiles of $\mathbf{R1}^{4+}$ and $\mathbf{R1}^{6+}$ contain two peaks with a vertical separation of approximately 12 Å. These peaks correspond to regions of high electron density within the Langmuir monolayer, and are therefore ascribed (see below) to the locations of the two stations along the rod segments of the dumbbell components in the two bistable [2]rotaxanes. This assignment is corroborated[20] by recent molecular dynamic simulations of similar systems.[14] 2) The relative densities of the two peaks associated with $\mathbf{R1}^{4+}$ and $\mathbf{R2}^{4+}$ change significantly upon oxidation of the monolayers. Hence, a shift of the electron distribution towards the water surface (namely, down) is observed in oxidized monolayers of $\mathbf{R1}^{6+}$ relative to the unoxidized case. This shift is in agreement with a vertical change in the position of the ring upon oxidation from the "upper" station (TTF) to the "lower" station (DNP), analogous to the movement known[8,17,18] to take place in solution. The shaded areas between the red and green curves represent the net number of electrons that change vertical position upon oxidation. Since the movement of the ring is compensated by reorganization of the local environment, the effective number of electrons changing places upon oxidation is relatively small. We notice, however, that the shift in electron density is symmetrical around the intersection point, which shows that the switching is a local

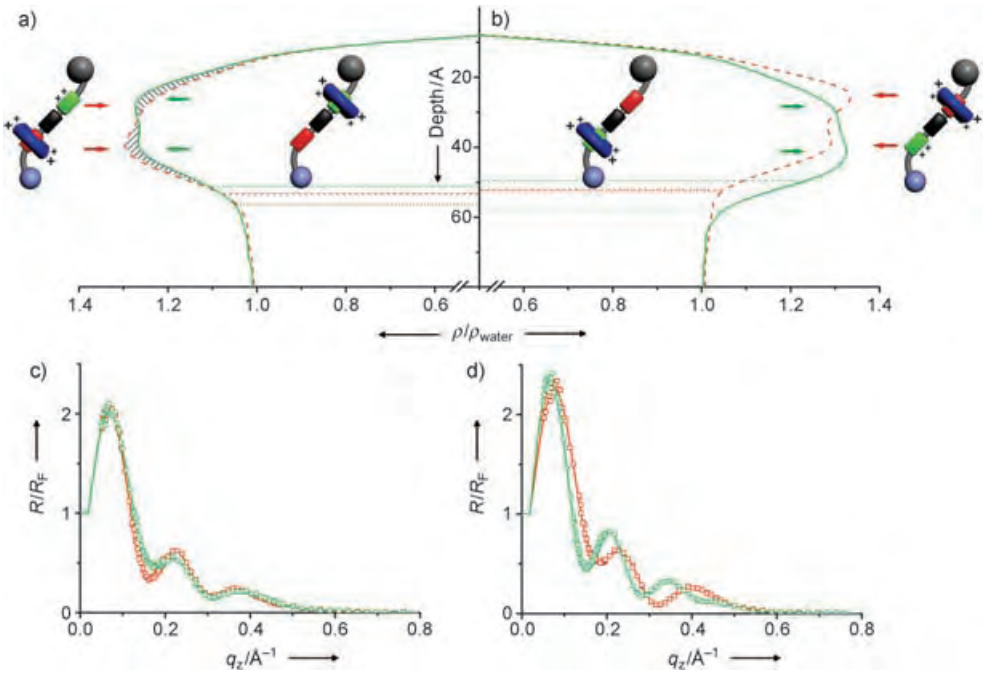

Figure 3. X-ray reflectivity measurements. a,b) Electron-density profiles for $\mathbf{R1}^{4+}$ and $\mathbf{R2}^{4+}$, respectively, inverted from the reflectivity data for the tetracationic starting compounds (green lines) and the hexacationic compounds $\mathbf{R1}^{6+}$ and $\mathbf{R2}^{6+}$ oxidized in situ (red lines). The areas above the horizontal dashed lines correspond to the numbers of electrons in one molecule, while the dotted lines represent the approximate position of the interface to bulk water. c,d) The measured reflectivities R (open circles or squares; normalized to the Fresnel reflectivity of bare water, R_F) and the best fits to the data (solid lines) corresponding to the $\rho(z)$ curves in (a) and (b) for $\mathbf{R1}^{4+}$ and $\mathbf{R2}^{4+}$, respectively. The green lines and circles correspond to the starting compounds and the red lines and squares correspond to the oxidized compounds. The data was obtained at beamline BW1 at the DESY synchrotron facility in Hamburg, Germany.

reorganization that does not change the overall hydration state of the rotaxane. If nearly all of the rings are located initially on the TTF station—as documented for solution-phase experiments[8,17,18]—then this symmetry also indicates that almost all of the rings move from the upper to the lower station upon oxidation because a fractional displacement (for example, 50%) would otherwise lead to a smearing of the two peaks, which is not observed. The 12-Å vertical shift is less than the expected distance between the two stations in a fully stretched and vertically aligned rotaxane. Molecular modeling studies[12] indicate that this distance is 37 Å. This value implies that at a mean molecular area of 100 $Å^2$ within the Langmuir monolayer, the rotaxane molecules are tilted and locally folded,[19] even in these very compressed Langmuir monolayers.[21] Similar attenuation of the distance traveled out of the plane was observed in the XPS data of Langmuir monolayers transferred onto SiO_2 substrates.[12] Consequently, the movement of the ring must have a significant component in the plane of the Langmuir film. Further evidence of folding and tilting comes from observations of the total monolayer thicknesses, which fall in the range 50–55 Å (Figure 3) and are notably smaller than the thickness (ca. 80 Å) expected for a monolayer of fully extended and nontilted rotaxanes. The electron-density profiles of $\mathbf{R1}^{4+}$, measured for both low and moderately compressed Langmuir monolayers, show that the molecules are folded and tilted to an even greater extent with respect to the normal of the water surface, as illustrated schematically in Figure 2b,c. This observation is consistent with our previous investigations[14] of similar amphiphilic, bistable [2]rotaxanes. The local folding of molecular segments along the rod can be considered to be a consequence of the large differences between the cross-sectional areas of different segments along the fully stretched rod. To fill space, the slimmer segments must fold and tilt, which, in turn, gives rise to a fluidlike, disordered local environment within the monolayer. This property allows the ring to be displaced in a fluidlike environment without any significant changes[20] in the overall thickness of the film, as is clearly illustrated by the density profiles in Figure 3a. This latter observation indicates that switching would also be possible in films sandwiched between two solid surfaces, as for example, in crossbar memory devices.[4,5]

In a control experiment, monolayers of the constitutionally isomeric $\mathbf{R2}^{4+}$ were examined by using identical experimental procedures. The monolayers of $\mathbf{R2}^{4+}$ show (Figure 3b) the opposite effect upon oxidation to that observed for $\mathbf{R1}^{4+}$, that is, the peak in the electron distribution shifts upwards. This result, therefore, supports the notion that the observed shift in electron density is caused by a net movement of the ring component relative to the dumbbell (in the case of $\mathbf{R2}^{4+/6+}$, from the lower TTF to the upper DNP station) and is not a consequence of the movement of water or counterions. It is evident from Figure 3b that the unoxidized monolayers of $\mathbf{R2}^{4+}$ contained more water molecules than was observed for $\mathbf{R1}^{4+}$. This condition may be related to the proximity of the tetracationic ring to the water surface.

Analogous XR measurements for $\mathbf{R1}^{4+}$ and $\mathbf{R2}^{4+}$ were performed at different mean molecular areas. Similar trends were observed at 230 $Å^2 mol^{-1}$ (Figure 4), albeit with less distinct changes in the electron density, presumably on account of a larger in-plane component of the movement—that is, the amphiphilic bistable rotaxanes have ample room to lie down at the interface. Attempts to perform the entire oxidation at a mean molecular area of 100 $Å^2 mol^{-1}$ did not result in any changes in the electron density profiles, an observation which indicates that the oxidant is unable to react with the TTF unit in these extremely dense monolayers, or that ring movement is inhibited.[21]

In summary, X-ray reflectivity data have provided direct structural evidence for the molecular motion of the ring

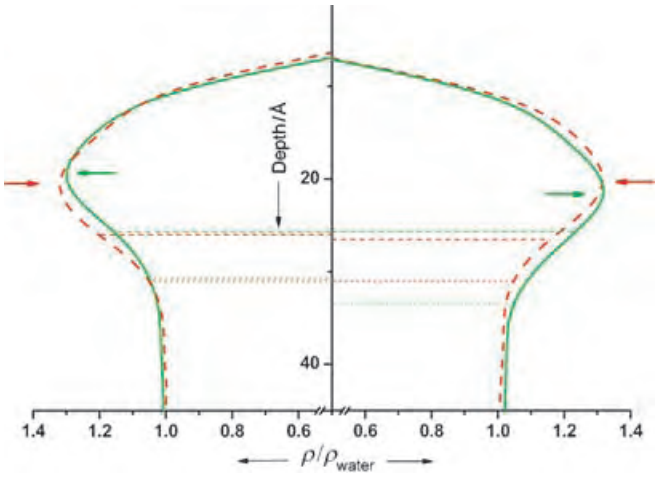

Figure 4. Electron-density profiles for $\mathbf{R1}^{4+}$ (left) and $\mathbf{R2}^{4+}$ (right), both measured at a mean molecular area of 230 Å^2. The profiles are inverted from the reflectivity data for the starting compounds (green lines) and the oxidized compounds (red lines). Oxidation was performed in situ at a mean molecular area of 230 Å^2. The areas above the horizontal dashed lines correspond to the numbers of electrons in one molecule, whereas the dotted lines represent the approximate position of the interface to bulk water. A comparison of these density profiles with the profiles measured at mean molecular area of 100 Å^2 (see Figure 3) shows that the ring motion contains a large in-plane component.

component of amphiphilic bistable [2]rotaxanes in condensed, oriented monolayers during redox-controlled switching.

[18] Quantitative measurements of the preference of the ring for the TTF station are based on solution studies of model, degenerate rotaxanes bearing either two TTF or two DNP stations, each with the *p*-terphenylene spacer used in $\mathbf{R1}^{4+}$ and $\mathbf{R2}^{4+}$. The barriers to shuttling measured for the two degenerate rotaxanes are 17–18 kcal mol^{-1} and 15 kcal mol^{-1}, respectively. The difference of 2–3 kcal mol^{-1} is related to the energy difference between the preferences of the cyclophane for the TTF station over the DNP station, which leads to ratios of 96:4–99.3:0.7; see: S. Kang, S. A. Vignon, H.-R. Tseng; J. F. Stoddart, *Chem. Eur. J.* **2004**, *10*, 2555–2564. In order to reflect these thermodynamic differences, we have introduced the term ground-state co-conformation for the translational isomer with the cyclophane residing at the TTF station and metastable state co-conformation when it is at the DNP station; see references 8c and 9 for more details.

[21] The XPS data recorded on LB films of $\mathbf{R1}^{4+}$ oxidized at a mean molecular area of approximately 150 Å^2 per molecule indicate, although indirectly, that oxidation and movement are still favored at these densities; see reference 12 for more details. Films at densities of approximately 150 Å^2 per molecule were also used to prepare molecular memory devices, see reference [4].

Banana-Shaped Oligo(aryleneethynylene)s: Synthesis and Light-Emitting Characteristics**

Yoshihiro Yamaguchi, Shigeya Kobayashi, Tateaki Wakamiya, Yoshio Matsubara, and Zen-ichi Yoshida**

Bent (so-called banana-shaped) molecules which consist, for example, of an aromatic unit and ester unit are currently attracting interest in the field of liquid crystals.[1] However, to the best of our knowledge, the light-emitting efficiency of banana-shaped molecules have not been reported so far, even though bent light emitters have been reported.[2] In view of the growing importance of highly efficient light-emitting materials in biological, chemical, and materials science, we report here the synthesis and light-emitting characteristics of banana-shaped oligo(arylene ethynylene)s **2**–**6** containing pyridine rings as it is not clear what influence pyridine ring(s) would have on the emission characteristics.

In regard to the banana-shaped molecules, we considered **1** (the simplest trimeric hydrocarbon system), **2** (with a pyridine ring substituting the central benzene ring of **1**), **3** (with a pyridine ring substituting both terminal benzene rings of **1**), **4** (a donor/acceptor (OMe group/pyridine C=N group) trimeric system), **5** (donor/acceptor pentameric system with a single banana structure), and **6** (a donor/acceptor pentameric system with a double banana structure).

The synthesis of **4**–**6** was achieved by using the Sonogashira C–C coupling reaction[3] as the key step (Scheme 1). Although **1**,[4] **2**,[5] and **3**[6] are known compounds, we prepared them in a similar manner to **4**, that is, in a different way from the reported methods.[4–6] The structures of **1**–**6** were confirmed by spectral data (^{1}H and ^{13}C NMR spectroscopy and HR-FAB MS, see the Supporting Information).

The emission and absorption characteristics of **1**–**6** and the rod-shaped donor/acceptor pentameric systems (**15** and **16**)[7] together with the radiative rate constants (k_r), radiationless rate constants (k_d), k_r/k_d (our measure for emissivity), and emission life times (τ) are shown in Table 1. Since the k_r and k_d values are related to the corresponding emission quantum yields and life times by $\Phi_f = k_r\tau$ and $k_r + k_d = \tau^{-1}$, it is possible to calculate the values of k_r and k_d whenever quantum yield and life time data are available.[8]

The important results contained in Table 1 are as follows: First, the Φ_f and k_r/k_d values for **1**–**3** demonstrate that the emission efficiency markedly increases when the central pyridine ring is present (Φ_f: 0.48, k_r/k_d: 0.92 for **2**), while it greatly decreases when terminal pyridine rings are present (Φ_f: 0.03, k_r/k_d: 0.03 for **3**). Second, the introduction of MeO groups into both benzene rings of **2** (construction of the donor/acceptor system) leads to a more efficient light emitter (Φ_f: 0.58, k_r/k_d: 1.38 for **4**) than **2**. The maximum emission of **4** (λ_{em}: 397 nm) appears at a longer wavelength (by 49 nm) than that of **2** (λ_{em}: 348 nm). Third, and the most remarkable finding, is that the donor/acceptor pentameric system shown in single banana structure **5** is a highly efficient violet-light emitter (Φ_f: 0.84, λ_{em}: 414 nm, k_r/k_d: 5.25), and the donor/acceptor pentameric system shown in double banana structure **6** is an excellent violet-light emitter (Φ_f: 0.91, λ_{em}: 417 nm, k_r/k_d: 10.11) despite the interruption of the π conjugation by one *meta* substitution in the former and by two *meta* substitutions in the latter. It is evident that the Φ_f values for **5** and **6** are greater than those of the rod-shaped donor/acceptor pentameric systems **15** (Φ_f: 0.75, k_r/k_d: 3.00) and **16** (Φ_f: 0.76, k_r/k_d: 3.17).

The superior emissive properties of **5** and **6** (in particular of **6**) relative to **15** and **16** is ascribed to the decrease in their k_d values compared to those of **15** and **16**, since the k_r values of **5** and **6** are similar to those of **15** and **16**. It is well known that *meta*-substituted systems are weaker light emitters than the corresponding *para* isomers, as exemplified by bis(phe-

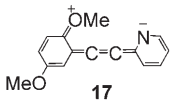
nylethynyl)benzenes (Φ_f: 0.50, λ_{em}: 345 nm for the *para* isomer; Φ_f: 0.14, λ_{em}: 330 nm for the *meta* isomer), and terphenyls (Φ_f: 0.54, λ_{em}: 342 nm for the *para* isomer; Φ_f: 0.039, λ_{em}: 331 nm for the *meta* isomer).[9] We previously reported the importance of π extension and donor/acceptor groups on the emission efficiency of the rod-shaped oligo(*p*-phenyleneethynylene)s.[10] The banana-shaped molecules **5** and **6**, which consist of alternately arranged pyridine (acceptor) and dimethoxybenzene (donor) rings, have a *meta*-substituted structure in addition to a *para*-substituted (rod-shaped) structure. Since oligo(*p*-phenyleneethynylene) has an almost acetylenic structure, even in the excited singlet state,[10,11] and the excited singlet state has a dipolar structure, the higher emission efficiency (Φ_f) of **5** and **6** relative to that of **15** and **16** might be explained by assuming that the emission efficiency depends on the movability of the dipolar structure (**17**) among the structurally equivalent donor/acceptor diads



17

(dimethoxyphenylethynylpyridine units) in the excited singlet state molecules (in other words, the number of structurally equivalent dipolar diad units to **17**). The pyridine ring in the banana-shaped molecules (**5** and **6**) is able to move the dipolar structure **17** by both the half π bonds (C_2–N and C_6–N), while the pyridine ring in the rod-shaped molecules (**15** and **16**) is not able to move the dipolar structure because of the interruption of the dipolar structure.

The fluorescence spectra of **5** and **6** are relatively sharp relative to that of **4** (Figure 1).

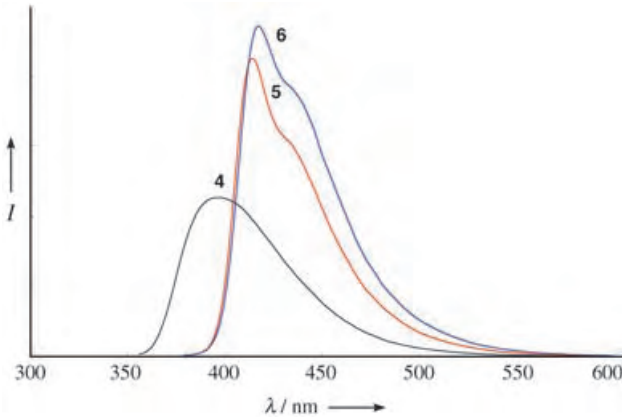


Figure 1. Fluorescence spectra of banana-shaped donor/acceptor oligo(aryleneethynylene)s **4** (black), **5** (red), and **6** (blue) in $CHCl_3$ at 295 K.

The effect of solvent on the emission efficiency of **5** and **6** is noteworthy (Table 2). Almost no solvent effect is observed for the absorption spectra of both **5** and **6**, while the fluorescence maxima of **5** and **6** are slightly shifted to longer wavelengths as the solvent polarity increases. Although the quantum yield of **5** is not similarly altered with a change in the solvent polarity, that of **6** remarkably decreases with an increase in the solvent polarity. The observed effect of the solvent on the Φ_f values of **5** and **6** can be interpreted by a change in the k_r and k_d values of **5** and **6** with a change in the solvent polarity: The k_r and k_d values for **5** are not so affected by solvent polarity. However, the k_r value of **6** decreases with an increase in solvent polarity even though the k_d value does not change, except for the cases of benzene and $CHCl_3$, where the k_d values decrease. The vastly different solvent dependency of the Φ_f values of **5** and **6** might be explained by the marked disparity between the distribution of the difference density (difference in the atomic charge in the excited state from that in the ground state) of **5** and **6**. The INDO/S difference density distribution (DDD) in the excited state of **5** and **6** is shown in Figure 2. It is evident that the marked change in the DDD in the excited state is not observed for **5**, while it is seen between the terminal regions and the central part of **6**, thus suggesting that the solvent polarity dependence of the Φ_f value should be negligible for **5**, but large for **6**.

The behavior of banana-shaped molecule **3** having pyridine rings at both termini towards metal ions should be of interest in regard to the emission characteristics of the resulting complex.[12]

We have prepared the 1:1 complex **18** (Tf = trifluoromethanesulfonyl) both by reaction of a solution of **3** in CH_2Cl_2 with $[Ti^{IV}Cl_3]^+$ freshly generated from a solution of $TiCl_4$ in

Table 2: Effect of solvent on the absorption and fluorescence characteristics of **5** and **6**.[a]

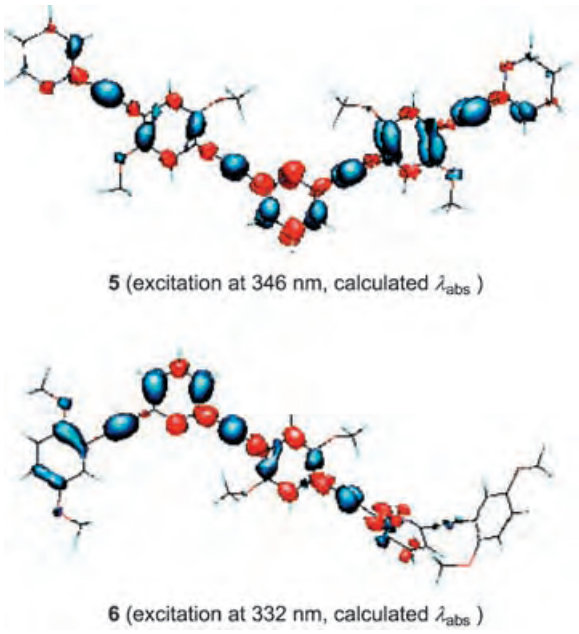

Figure 2. INDO/S difference density distribution of **5** and **6** in the excited singlet states (the red parts designate the atomic charges that are more negative in the excited state than in the ground state. The blue parts show the reverse situation. Colorless parts designate equal density in both the excited and ground states).

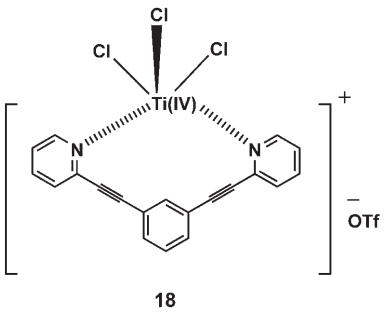

18

CH_2Cl_2 and a solution of AgOTf in benzene, and by mixing **3** (in CH_2Cl_2) first with AgOTf (in benzene) and then adding $TiCl_4$ (in CH_2Cl_2).[13] Complex **18** is stable in the solid state, and does not dissociate in solution. However, its ligand **3** can be replaced by stronger ligand(s) such as 2,2′-bipyridine.

Although X-ray diffraction analysis of **18** has not yet been accomplished, because of difficulty in growing suitable single crystals, the MM2 structure (Figure 3) of **18** is very similar to that of the 1:1 Sb^V complex (**21**) of tetrakisareneazaarenecyclyne (**20**) with respect to the ligand **3** (see the Supporting Information).[14,15] The ^{1}H NMR spectroscopic and FAB MS data (Supporting Information) support this structure.[16]

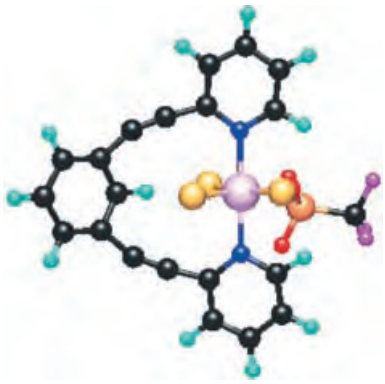

Figure 3. MM2 structure of **18**.

The absorption and fluorescence spectra of **18** are shown in Figure 4. The emission and absorption characteristics of **3** and **18**–**21** (**19:** trifluoromethanesulfonic acid salt of **3**) are summarized in Table 3.

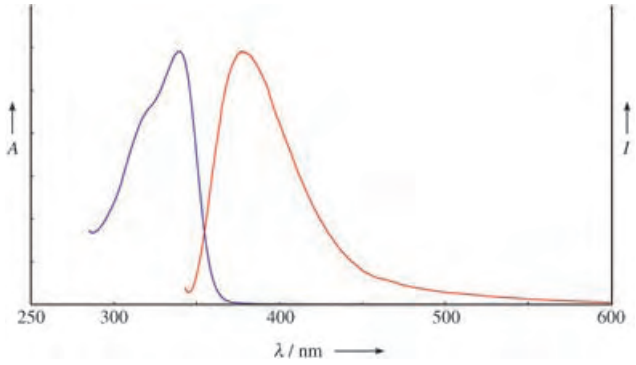

Figure 4. Absorption (blue) and fluorescence (red) spectra of **18** in CH_2Cl_2 at 295 K.

It is noted that the emission efficiency of **18** is about 60 times greater than that of **3**. An increase in the Φ_f value on formation of the metal bridge is also observed in **21**. In both cases, the k_d values decrease and the k_r values increase, thus resulting in an enhancement of the Φ_f value. Since a large increase in the Φ_f value is also seen for **19** (diprotonated **3**), the increase resulting from metal bridging is ascribed to the increase in the electron-accepting ability of the pyridine C=N groups by coordination to Ti^{IV} centers (formation of a positively charged sp^2 nitrogen atom).

In conclusion, we have created donor/acceptor banana-shaped molecules, and found that the donor/acceptor pentameric aryleneethyny-

lenes (**5** and **6**) with single and double banana structures are highly efficient light emitters despite the interruption of the π conjugation. The emission efficiency is interpreted in terms of k_r and k_d values. A new concept on movability of the dipolar dimethoxyphenylethynylpyridine structure (in other words, the number of dipolar diad units structurally equivalent to **17**) in the excited singlet state molecules is presented to explain the results. A quite contrasting effect of the solvent on the emission efficiency was observed for **5** and **6**, which might be explained by the marked disparity between the difference density distribution in the excited states of **5** and **6**. The emission efficiency of **3** (very weak fluorophore) was found to dramatically increase on formation of a Ti^{IV} complex. The main reason for this is ascribed to the increase in the electron-accepting ability of the pyridine C=N groups by the coordination to Ti^{IV} centers.

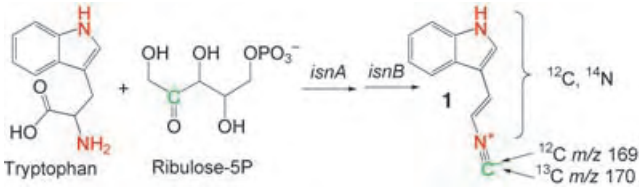
Systematic Investigation of the *Escherichia coli* Metabolome for the Biosynthetic Origin of an Isocyanide Carbon Atom**

Sean F. Brady and Jon Clardy*

In vivo studies on the biosynthesis of natural products are often hampered by the inability to predictably control the metabolome of the producing organism. In contrast, when biosynthetic pathways are expressed in well-understood model organisms, the ability to predictably control metabolism through the use of mutant strains allows pathways to be examined with a rigor that cannot be achieved in the wild-type-producing organism. Recently, we have described the isolation and characterization of the isocyanide-containing antibiotic **1** along with its biosynthetic genes (*isnA* and *isnB*) from an environmental DNA (eDNA) clone.[1] The ability to control *Escherichia coli* metabolism systematically through the mutagenesis of genes that code for primary metabolic enzymes has enabled us to elucidate the biosynthetic origin of the isocyanide functional group found in **1** (Scheme 1).



Scheme 1. Compound **1** is derived from tryptophan and C2 of ribulose-5P. Predicted *m/z* $[M+H]^+$ values for isotopically labeled **1** are shown.

Almost fifty years after the discovery of the first isocyanide-functionalized natural product, xanthocillin, no consensus view of isocyanide biosynthesis has emerged from the extensive feeding studies that use isocyanide-producing organisms.[2,3] The origin of the carbon atom of the isocyanide group found in **1** is presented herein.

In most biosynthetic studies, a hint as to the origin of a fragment can be seen in its structure, but the lone carbon atom of an isocyanide group contains no such clue. In a normal feeding study, labeled precursors are added to an unlabeled background to decipher the origin of the atoms in a molecule; however, because of the abundance of possible isocyanide precursors, we chose to use an "inverse-labeling" strategy to study the origin of the carbon atom of the isocyanide group. In this approach, ^{12}C precursors are added to a ^{13}C background, thus eliminating the need to synthesize a ^{13}C (or ^{14}C) sample of every precursor.

Feeding studies that used native-isocyanide-producing organisms have suggested that the isocyanide carbon atom might be derived from an amino acid.[2,3] To test this hypothesis, we carried out feeding studies using *isnA*/*B*, the biosynthetic pathway for **1**, expressed in *E. coli* amino acid auxotrophs.[4] Each auxotroph was grown in minimal media that contained ^{13}C-glucose, ^{12}C-tryptophan, and the appropriate ^{12}C-amino acids needed to compensate for the auxotrophies. Compound **1** isolated from these cultures always has an observed *m/z* value of 170, which is consistent with its containing ten carbon atoms from ^{12}C-tryptophan,[5] the isocyanide carbon atom from ^{13}C-glucose, and no carbon atoms from the other ^{12}C-amino acids added to the media. By using this strategy, the amino acids colored dark blue in the overview of the *E. coli* metabolome shown in Figure 1 were ruled out as precursors in the biosynthesis of the isocyanide functional group.

None of the amino acids tested labeled the isocyanide carbon atom, so we chose to examine the remainder of the *E. coli* metabolome systematically for the source of the isocyanide carbon atom. Figure 1 summarizes the differential labeling of **1** in a variety of *E. coli* strains deficient in key primary metabolic enzymes. Each strain was transformed with *isnA*/*B* and grown in an isotopically defined mixture of carbon sources such that unique regions of the metabolome were labeled in isotopically distinct manners. This approach allowed us to rapidly investigate the entire *E. coli* metabolome for the source of the isocyanide carbon atom. When the carbon flow between early and late glycolysis is blocked by a mutation in *gapA*, the *E. coli* metabolome is dissected into two distinct carbon pools (Figure 1). Compound **1** isolated from a *gapA* mutant transformed with *isnA*/*B* and grown in ^{13}C-glucose, ^{12}C-malate from the tricarboxylic acid cycle, and ^{12}C-tryptophan has an observed *m/z* value of 170. The isocyanide carbon atom is, therefore, derived from a descendant of ^{13}C-glucose before the conversion of glyceraldehyde-3P to 1,3-bis-phosphoglycerate by GAPDH. In addition to the dark-blue regions in Figure 1, the peach-colored area of the *E. coli* metabolome could now also be eliminated as a source of the isocyanide carbon atom.

The pentose phosphate pathway is central to the remaining portion of the *E. coli* metabolome from which the isocyanide carbon atom must be derived (Figure 1). We tested the major metabolic branches that arise from the pentose phosphate pathway as possible sources of the isocyanide carbon atom.[6] *E. coli* strains that contain mutations in genes that represent the metabolic entrance points into the following pentose pathway branch points were transformed with *isnA/B* (Figure 1):[6] glycerol-derived metabolites (*fba*), sugar phosphates (*manA* and *glmS*),

glmS	^{13}C-glucose	^{12}C-glucosamine	170/169	^{13}C/^{12}C
pgi/zwf	^{13}C-glucose	^{12}C-fructose	169	^{12}C
prs or *pyrB*	^{13}C-glucose	^{12}C-multiple	170	^{13}C
tpi	^{13}C-glycerol	^{12}C-glucuronic acid	170	^{13}C
zwf	^{13}C-2C-glucose	^{12}C-1,2,4,5,6C-glucose	170	^{13}C

Figure 1. The systematic differential labeling of **1** produced by *E. coli* strains deficient in specific primary metabolic enzymes (=) indicates that the isocyanide carbon atom is derived from the C2 atom (C) of an intermediate in the pentose phosphate pathway. Color is used to designate the region of metabolism that was ruled out with feeding experiments in different *E. coli* mutants. a.a. = amino acids, *gapA* = glyceraldehyde-3P dehydrogenase (GAPDH), *fba* = fructose-1,6-bisphosphate aldolase, *manA* = mannose-6-phosphate isomerase, *glmS* = L-glutamine:D-fructose-6-phosphate aminotransferase, *prs* = ribose-phosphate diphosphokinase, *pyrB* = aspartate transcarbamylase, *pgi* = phosphoglucose isomerase, *zwf* = glucose-6-phosphate-1-dehydrogenase, ATP = adenosine triphosphate, ADP = adenosine diphosphate.

nucleic acids (*prs* and *pyrB*), and glucose-derived metabolites (*pgi* and *zwf*).[7] Each strain was grown in ^{12}C-tryptophan, ^{13}C-glucose, and a ^{12}C-carbon source(s) that would supply an isotopically distinct carbon pool to the blocked region of metabolism (Figure 1).[7] In each feeding experiment, we observed that the isocyanide carbon atom was derived from the carbon source that is able to flux into the pentose phosphate pathway and not the blocked region of metabolism. In the case of *manA* and *glmS*, each of which block the exit of metabolites from the pentose phosphate pathway but not the entrance, we detected a mixture of labeled and unlabeled isocyanide groups (Figure 1). As with the other feeding studies, this suggests that the isocyanide carbon atom must be derived from the carbon source that is able to flux into the pentose phosphate pathway and not the blocked region of metabolism. The regions colored pink (glycerol metabolites, *fba*), purple (sugar phosphates, *manA* or *glmS*), orange (glucose metabolites, *pgi*/*zwf*), and light blue (nucleic acids, *prs* or *pyrB*) in Figure 1 could, therefore, now also be excluded as sources of the isocyanide carbon atom. Taken together, these feeding studies indicate that the isocyanide carbon atom is likely to be derived from one of the eight sugars directly involved in the pentose phosphate shunt (Figure 1, black), the major region of metabolism that was not eliminated by our feeding experiments.[8]

Additional feeding experiments were performed to determine which of the carbon atoms present in early glycolytic hexose intermediates feeds directly into the isocyanide carbon atom. In a triose-phosphate isomerase (*tpi*) mutant, the C1-C2-C3 and C4-C5-C6 units of early glycolytic intermediates can be differentially labeled using glycerol and glucuronic acid. Compound **1** that has been isolated from cultures of a *tpi* knockout, transformed with *isnA*/*B*, and grown in media that contain ^{13}C-glycerol and ^{12}C-glucuronic acid (Figure 1, brown) has an observed *m*/*z* value of 170. Therefore, the isocyanide carbon atom must arise from ^{13}C-glycerol,

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

which corresponds to the C1-C2-C3 portion of early glycolytic hexose intermediates (Figure 1, black). The carbon atoms derived from glucuronic acid (Figure 1, brown) could, therefore, also be eliminated as possible sources of the isocyanide carbon atom.

A *zwf*-deficient strain of *E. coli,* which helps to prevent the scrambling of labeled sugars in the pentose phosphate shunt by blocking the decarboxylation of 6P-gluconate, was used to determine which of the three remaining carbon atoms is incorporated into the isocyanide functionality. The *zwf*-knockout strain grown on C1-labeled ^{13}C-glucose did not produce ^{13}C-labeled **1**, whereas cultures grown on either universally labeled or C2-labeled ^{13}C-glucose almost exclusively produced ^{13}C-labeled **1** (Figure 2). In this system, the C2 atom in glucose specifically labels only six major sugars that were not excluded as a source of the isocyanide carbon atom by our other feeding studies. The six remaining metabolites (fructose-6P, fructose-1,6-bis-P, ribulose-5P, ribose-5P, xylulose-5P, and sedoheptulose-7P) are shown in Figure 1 and the C2 position of each is highlighted in green. Five of these six sugar phosphates are commercially available and were therefore tested in in vitro reconstitution experiments.[9] The in vitro reconstitution experiments using purified IsnA, IsnB, tryptophan, α-ketoglutarate, and both ribulose-5P and ribose-5P were found to produce a compound with the same retention time and mass as the naturally occurring **1**. Other commercially available C4–C7 sugars and sugar phosphates were tested in the same reconstitution system, and only arabinose-5P was found to result in isocyanide production.[10]

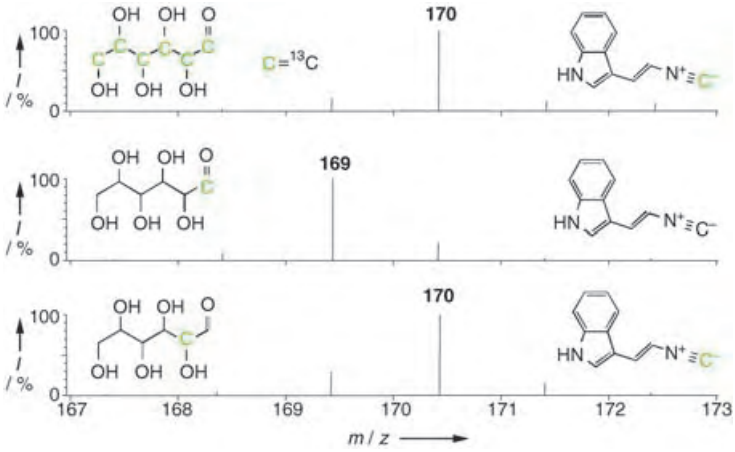

Figure 2. The *m*/*z* values observed for **1** obtained from cultures of *E. coli* transformed with *isnA*/*B* and grown in uniformly C1- and C2-labeled ^{13}C-glucose.

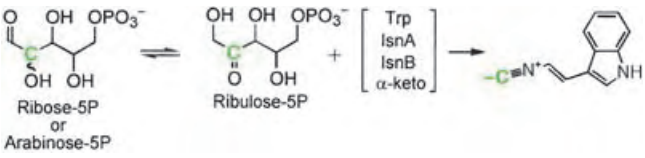
To investigate the source of the isocyanide carbon atom in vitro, C1- and C2-labeled ^{13}C-ribose were phosphorylated with recombinant *E. coli* ribokinase (rbsK), and each of the products was used for the in vitro biosynthesis of **1**.[11] As suggested by the in vivo feeding experiments, the C2 atom of the sugar phosphate is used in the enzymatic synthesis of **1**. C1-labeled ribose leads to the production of unlabeled **1** (*m*/*z* 169), whereas C2-labeled ribose leads to a ^{13}C-labeled isocyanide group (*m*/*z* 170). The tautomerization of ribose-5P and arabinose-5P to ribulose-5P either in solution or in an enzyme-assisted fashion could explain the use of all three sugars in the in vitro system (Scheme 2). 2-Deoxyriobose-5P, which cannot tautomerize to the equivalent keto sugar, does not serve as a substrate for the enzymatic synthesis of **1** by using this system.



Scheme 2. The tautomerization of aldo and keto sugars may explain the use of different regio- and stereochemical sugar isomers in the enzymatic synthesis of **1**.

The ability to control *E. coli* metabolism through the systematic use of strains that carry mutations in primary metabolic pathways allowed us to identify the origin of the isocyanide carbon atom in **1** as the C2 atom of ribulose-5P, or a tautomerically equivalent sugar. As shown previously, the isocyanide nitrogen atom can be traced to the amine functionality in tryptophan.[1] The isocyanide group present in many known microbial natural products can also theoretically be traced to the free amine moiety of an amino acid.[2] The proposed biosynthetic scheme for **1** may, therefore, be general for the biosynthesis of microbial-derived isocyanides. The differential labeling of natural products produced by microorganisms that carry mutations in primary metabolic genes that lead to predictable changes in the microbial metabolome can now be carried out in a systematic fashion in many model microorganisms and could be a generally useful strategy for the study of the biosynthetic origin of individual atoms found in microbial secondary metabolites.

Thermolysis of a Hybrid Organic–Inorganic Supramolecular Coordination Assembly: Templating the Formation of Nanostructured Fibrous Materials and Carbon-Based Microcapsules**

Wolfgang Schmitt, Jonathan P. Hill, Sharali Malik, Cynthia A. Volkert, Izumi Ichinose, Christopher E. Anson, and Annie K. Powell**

Materials of nanosize or bearing nanoscale features represent a significant class of substance that have the potential for advanced applications because of their superior chemical and physical properties.[1] The preparation and characterization of such substances is, therefore, of interest not only from a scientific viewpoint but because of their possible uses in such diverse fields as catalysis[2] and microelectronics.[3] Currently, much attention is focused on inorganic nanotubes, organic polymers, and nanostructured inorganic oxides whose properties endow them with considerable potential.[4]

The structures and properties of nanosized hybrid organic–inorganic materials are influenced by the functionalities present in both the inorganic and organic components,[5] whereas the use of coordination compounds as templates or precursors in decomposition processes is a

promising strategy for the synthesis of nanocomposites.[6] Supramolecular coordination compounds that contain nanosized features within their structures are ideal precursor candidates for these purposes. One aim of such investigations is to develop an understanding of how the structures of the precursor complexes influence the structure and stoichiometry of the decomposition products. Thermolysis of metal complexes is already widely used for the synthesis of superconducting, nanocrystalline mixed-metal oxides[7] and also for the incorporation of transition-metal ions into porous carriers, such as zeolites or silicates.[8] Hybrid materials themselves can have unique properties, and their synthesis on the atomic-to-mesoscopic scales can have significant impact on diverse fields of technology.[9]

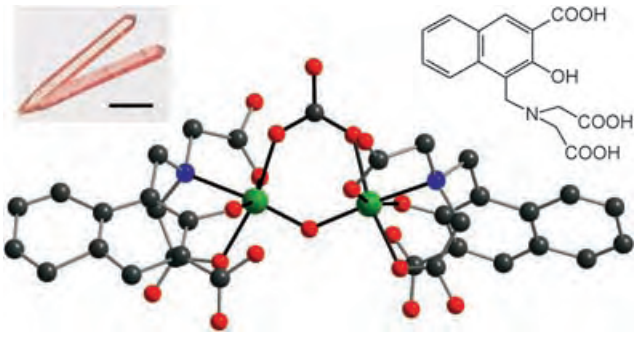

Figure 1. Structure of the dinuclear $[Fe_2(\mu\text{-}O)(\mu\text{-}CO_3)(chnida)_2]^{6-}$ unit contained in **1** (Fe: green, O: red, N: blue, C: gray). Inset: crystals of **1** (left; scale bar: 300 μm) and the organic chnida ligand (right).

Reaction systems that contain large organic hydrophobic ligands and hydrophilic ions favor the formation of cross-linked structures in which supramolecular aggregates are organized within vast areas of different polarities. We have previously described how increased steric hindrance around aromatic cycles (L) influences the topology and dimensionality of coordination chemistry networks based on $\{Fe_2(\mu\text{-}O)(\mu\text{-}CO_3)(L)_2\}$ units,[10,11] thus bringing a new dimension to the now classical isoreticular chemistry concept. Herein, we describe the pyrolysis of an example of one of these compounds. The coordination network used in these investigations, $Na_6[Fe_2(\mu\text{-}O)(\mu\text{-}CO_3)(chnida)_2]\cdot 13.5\,H_2O$ (**1**; chnida = *N*-[(3-carboxy-2-oxy-naphthyl)methylene]iminodiacetato), consists of a simple oxo/carbonato bridged diiron(III) unit coordinated by two chnida ligands. Figure 1 shows the basic diiron unit $[Fe_2(\mu\text{-}O)(\mu\text{-}CO_3)(chnida)_2]^{6-}$ within the structure of complex **1**, together with the chemical structure of the ligand and an optical micrograph of crystals of the complex. Within the dinuclear transition-metal complex, nitrogen and oxygen donors of the iminodiacetic acid moiety of the organic ligands occupy facial positions of the distorted octahedral coordination polyhedra, whereas the bridging O atom and the N-donors coordinate *trans* with respect to each other.

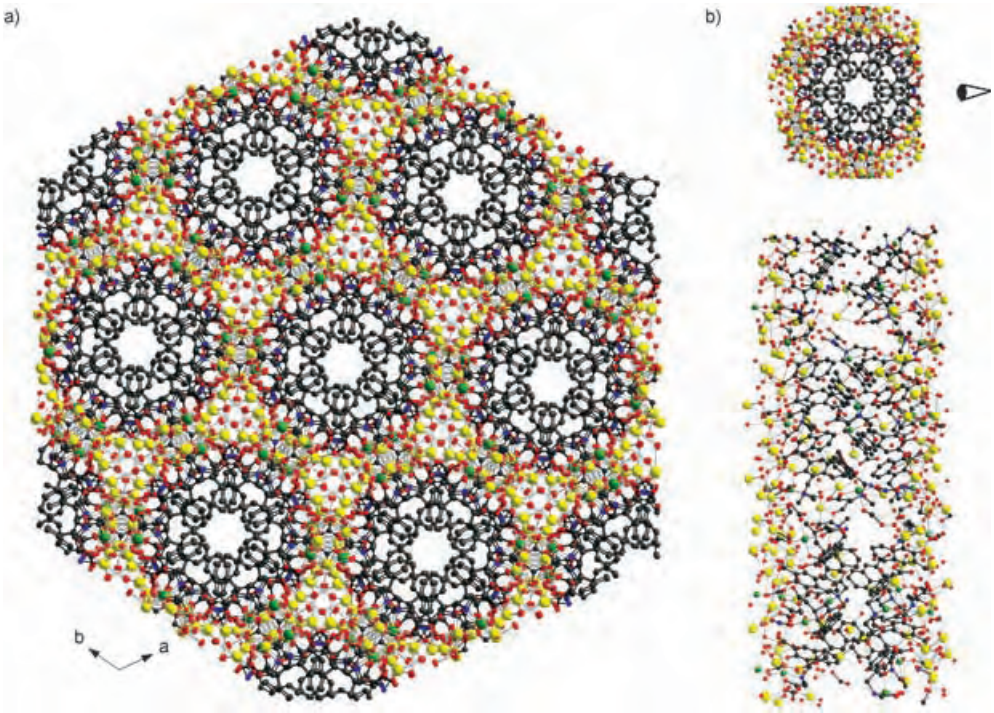

Figure 2. Supramolecular structure of **1**. a) Viewed along the *c* axis. b) Section through a channel viewed perpendicular to the *c* axis. (Fe: green, Na: yellow, O: red, N: blue, C: gray.)

Within the coordination ensemble (Figure 2), the $[Fe_2(\mu\text{-}O)(\mu\text{-}CO_3)(chnida)_2]^{6-}$ complexes are organized in such a way that the organic residues of the ligands are contained in tubular cavities that run along the long axis (crystallographic *c* axis) of the crystals. The intercavity spaces are occupied by hydrated sodium ions which are present to balance the negative charge of the diiron complex and which are linked to the complexes through oxygen donors. The hydrophobic cavities of this honeycomb-type structure have a maximum cross-sectional distance of approximately 1.2 nm. The preponderance for the hexagonal symmetry within the structure is consistent with the morphology of the compound, which crystallizes as needles with a hexagonal cross-section. Single-crystal X-ray analysis of **1** found its structure to be within the trigonal space group $R\bar{3}c$ and demonstrates that **1** is isostructural with its potassium analogue.[11,12] Further confirmation of the space-group assignment was gained from X-ray powder diffraction measurements and simulations (see the Supporting Information). The presence of clearly demarcated nanosized organic and inorganic regions organized into a honeycomb-type structure prompted us to speculate about the synthesis of materials with nanoscale features by using thermal decomposition.

Crystals of **1** are sensitive to solvent loss, and we investigated this behavior by cutting crystals, which had been stored for six weeks at room temperature, perpendicular to the *c* axis by using a focused gallium ion beam. Previously,

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

we have successfully used electron microscopic techniques to identify structural patterns within crystals[11] and, in this case, the scanning electron microscopy (SEM) observation of the resulting *a*–*b* surface revealed a transformation of some regions of the crystal into fibers with a diameter of approximately 50–100 nm (Figure 3a). These fibers are coagulated into bundles. The IR and UV/VIS spectra and X-ray powder diffraction patterns of the crystals prior to and following desolvation are similar, which demonstrates that the structure of the dinuclear Fe^{III} unit is intact and that the structures of single crystals and the observed hybrid organic–inorganic fibers are closely related.

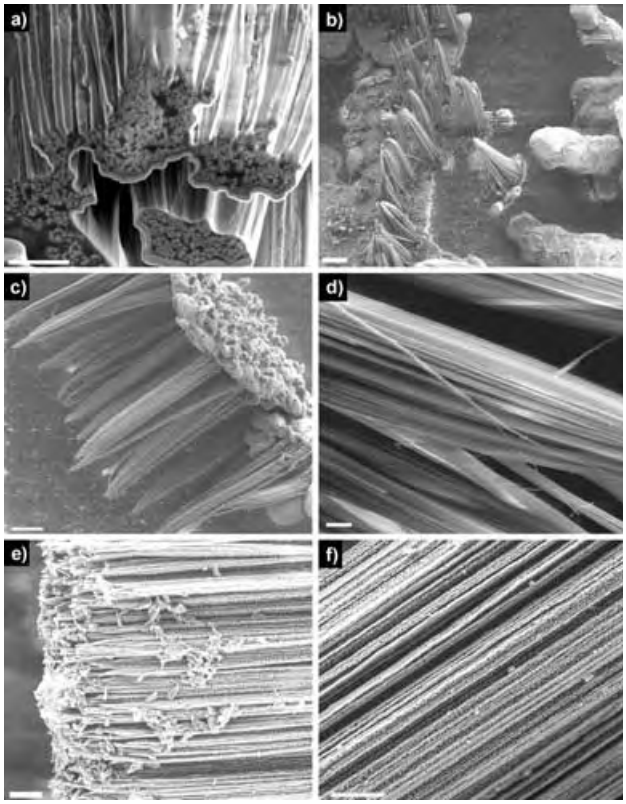

Figure 3. SEM images of **1**: a) A crystal cut perpendicular to the crystallographic *c* axis with a focused ion beam (scale bar: 2 μm). b) Crystals after thermolysis at 370 °C, thus showing fibers and burnt crystals in the same sample (scale bar: 20 μm). c) View of aggregated fibers (scale bar: 20 μm). d) Magnification showing some individual fibers (scale bar: 2 μm). e) and f) Further views of the fibrous structures (scale bars: 2 μm).

Thermolysis of crystals of **1** under nitrogen confirms fiber formation after desolvation (Figure 3b–f) and provides a means for variation of the fiber composition up to their decomposition at approximately 400 °C. Thermogravimetric analysis (TGA), in combination with TGA–MS, IR, and X-ray diffraction (XRD) analysis, provided information about the composition of the sample during thermolysis. On the basis of elemental analysis, the formula $Na_6[Fe_2(\mu\text{-}O)(\mu\text{-}CO_3)(chnida)_2]\cdot 9H_2O$ was assigned to crystalline samples of **1** used in this study. TGA events (Figure 4a) in the temperature range 25–140 °C result from solvent loss. The thermolytic destruction of the Fe^{III} complex occurs during the event between 250 and 350 °C and is accompanied by the formation of sodium carbonate, as demonstrated by FTIR and X-ray powder diffraction analysis (Figure 4b–d).[13] Samples thermolyzed at 350–370 °C were black in appearance because of deposition of amorphous carbon in the sample. This amorphous carbon was detected by TGA-MS (*m*/*z* 12 amu), and its formation is attributed to combustion of the ligand in an anoxygenic environment, such as that in the tubular channels of the crystals. This process is commonplace in the pyrolysis of organic molecules within zeolite templates in which efficient carbonization occurs at elevated temperatures.[14]

The combustion of the remnant carboniferous materials occurs between 380 and 480 °C. During this event, samples contain Na_2CO_3 and iron oxide species which further react between 480 and 600 °C with the loss of dioxide lost from the sample to form $NaFeO_2$.[15] X-ray powder diffraction patterns of samples of **1** heated to 600 °C identify the trigonal and orthorhombic phases of $NaFeO_2$ and γ-Na_2CO_3. Upon heating the sample to 1100 °C, sodium carbonate is no longer present and only the orthorhombic form of the binary sodium iron oxide can be observed (Figure 4c, d).[16]

We analyzed thermolyzed samples using scanning electron microscopy (SEM). Decomposition temperatures were selected by reference to thermogravimetric (TG) and differential thermogravimetric (*d*TG) data. Thus, the plateau between 350 and 390 °C in the *d*TG trace was selected as being of interest as it marks a borderline for the hybrid material transforming into purely inorganic product. At this point, the sample appears to be between two distinct weight losses. From the TGA–MS analysis, the first event entails loss of water, carbon dioxide, and small quantities of both benzene and naphthalene, whereas the second is dominated by loss of carbon monoxide, carbon dioxide, and water, together with benzene and other fragments from the incomplete combustion of the ligand. The SEM micrographs shown in Figures 3b–f and 5b show the result of the thermolysis of **1** at 370 °C and illustrate the formation of a highly aligned fibrous structure.

The energy dispersive X-ray analysis (EDAX) analysis confirms the presence of sodium carbonate in the fibrous material obtained at 370 °C, which is coated with a carbon-rich shell. The fibrous nature of the materials inside a thermolyzed crystal could also be observed through the carboniferous husks at several sites (see also Figure 5b). Closer observation of the fibers reveals that they have a cross-sectional thickness of 50 nm and tend to be segmented. This segmentation differs from the materials obtained at temperatures below 300 °C, in which the fibers are more homogeneous, or even microcrystalline, and contain the intact dinuclear complex.

To illustrate the structure of the product of the thermolysis of **1** at 370 °C, we have presented a scheme in Figure 5. Our observations and analysis rationalize the following thermally induced transformation process of single crystals. Components in a single crystal of **1** aggregate into fibers upon solvent loss. This process is enhanced by the morphology of the crystals and the supramolecular structure of the coordination compound, which contains nanosized channels of

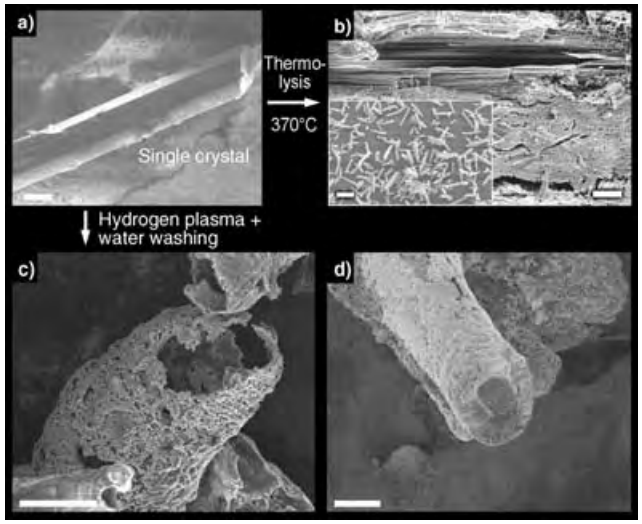

Figure 5. SEM images that illustrate microcapsular formations after crystal decomposition: a) Morphology of a single crystal (scale bar: 10 μm). b) Fibrous structure viewed through a break in the surface of a thermolyzed crystal (scale bar: 2 μm); inset: crystals thermolyzed in bulk (scale bar: 100 μm). c) Carbon microcapsule formed during plasma treatment of crystals of **1** after washing with water (scale bar: 10 μm). d) Cross-sectional view of broken carboniferous microcapsule (scale bar: 5 μm).

clearly separated polarity that run parallel to the longitudinal axis of the needlelike crystals. Heating of the resulting hybrid organic–inorganic fibers to 370 °C causes a chemical transformation in which they form sodium carbonate by decomposition of the dinuclear complex. The facile formation of sodium carbonate upon heating is dictated by the stoichiometry and the structure of the complex, which contains a large number of alkali-metal counterions that bind to carbonate and carboxylate oxygen atoms and are localized in the hydrophilic regions. Naphthoic acid derivatives are known to undergo facile decarboxylation upon heating, and the Na_2CO_3 formation is likely to be the result of this and other decomposition reactions. Further ligand decomposition at 370 °C and at higher temperatures enriches the carbon content at the outside of the burnt crystals so that sodium carbonate fibers are usually contained within capsules composed of amorphous carbon. Thus, it is relatively simple to remove the sodium carbonate by washing with water to leave the empty carbon capsule of micrometer dimensions, which is determined by the morphology of the crystalline precursor. Furthermore, it is possible to improve the formation of amorphous carbon by the application of a reductive process to the crystals of **1**, whereby the crystals are treated with a plasma of hydrogen gas at a temperature slightly higher than the decomposition temperature of 400 °C. In that case, much more robust carbon microcapsules are produced, as shown in Figure 5c,d.

High-surface-area sodium carbonates are used for the removal of SO_x, NO_x, HF, and HCl pollutants from industrial emissions.[17] The high activity of these sodium carbonates makes them the preferred substances for dry-sorbent injection processes; thus, they are used for flue-gas desulfurization and scrubbing, effectively decreasing the impact of acid rain on the environment.[17,18] Therefore, nanostructured particulates, or even better, sodium carbonate nanomaterials contained in microcapsular entities, are of substantial industrial interest. Such alkali or alkali-earth carbonates are currently used as NO_x storage/reduction catalysts for the cleansing of emissions from diesel engines.[19] Furthermore, alkali iron oxide phases also possess high activity for the reduction of

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

NO_x emissions[20] and are the main active components of the industrially applied Fe_2O_3 dehydrogenation catalyst for the production of styrene from ethylbenzene.[21] It is interesting that we obtain such alkali iron oxides (e.g., the different phases $NaFeO_2$, $KFeO_2$, and $K_xFe_{22}O_{34}$ ($x = 2$–4)) in our system, albeit at elevated temperatures.

In summary, we have demonstrated that a hybrid organic–inorganic coordination complex with an extended 3D structure that contains separated organic and inorganic regions can be used as a template in thermal decomposition reactions that produce nano- and microsized products. Comparable thermolysis studies of crystals of such a hybrid compound have not been reported, and our results validate a synthetic concept for the preparation of nanostructured materials by taking advantage of a pristine crystalline coordination compound that contains the starting components from the thermolysis reaction that are prearranged in a 3D form. Thus, the molecular structure, stoichiometry, and crystal morphology of the precursor determines the 3D structure and constitution of the decomposition products: we obtained aligned nanosized hybrid organic–inorganic fibers by desolvation. Thermolysis changes the fiber composition and results in mainly fibrous sodium carbonate and a concomitant deposition of amorphous carbon at the crystal surface. If sufficient carbon is deposited, stable microcapsules can be obtained after removal of the sodium carbonate by washing with water, thus leaving the carbon microcapsules intact. The components react at higher temperatures to give different phases of sodium iron oxides. We are currently investigating the inorganic products obtained from thermolysis of **1** by transmission electron microscopy (TEM). In addition, we are preparing derivatives of **1** in which sodium ions have been substituted with a variety of metal ions and are carrying out thermolysis of these novel supramolecular transition-metal assemblies under different atmospheres.

Experimental Section

The starting materials were purchased from Aldrich Chemical Co. and used without further purification. Thermogravimetric analyses were carried out using a Netzsch STA 409C operating in the TG mode under both nitrogen and oxygen. TGA–MS measurements were performed on a similar device equipped with a quadrupole mass detector by using electron impact ionization. In that case, the analysis was done under vacuum. Scanning electron micrographs were obtained using a LEO 1530 SEM with a spatial resolution of 1 nm at 20 kV and 3 nm at 1 kV and equipped with an energy-dispersive X-ray analysis system EDX INCA 400 from Oxford Instruments. Focused ion-beam sectioning and scanning-electron micrographs of the sections were obtained using a FEI 200 × P dual beam SEM/FIB. FTIR spectra were obtained with KBr pellets of the analytes with a Perkin-Elmer Spectrum One spectrophotometer. XRD analysis was performed on a STOE Stadi *P* diffractometer (equipped with Ge monochromator) using $Co_{K\alpha}$ radiation ($\lambda = 1.78897$ Å). Sample thermolysis of **1** was performed using a Netzsch STA 409C apparatus with sample heating and cooling rates of 2 or 5 °C min^{-1}. The sample was held isothermally at the selected thermolysis temperature for 1 min.

The chnida ligand was prepared by the Mannich reaction[22] of 3-hydroxy-2-naphthoic acid: ^{1}H NMR ($D_2O + Na_2CO_3$): $\delta = 3.62$ (s, 4H), 4.35 (s, 2H), 7.42 (m, 1H), 7.65 (m, 1H), 7.86 (d, 1H, J(H,H′) = 8.0 Hz), 7.99 (d, 1H, J(H,H′) = 8.6 Hz), 8.29 ppm (s, 1H).

1: Ligand chnida (0.088 g, 2.64×10^{-4} mol) was treated with iron(III) chloride hexahydrate (0.142 g, 5.28×10^{-4} mol) in methanol (30 mL), followed by addition of 2 M aqueous sodium hydroxide (2 mL). Ethanol (20 mL) was added after dissolution of all reagents, and the solution container was covered with parafilm, which was perforated several times to allow slow evaporation of the solvent. It is vital that the solution is open to the atmosphere to allow dissolution of carbon dioxide into the reaction mixture. Small well-formed needles with a hexagonal base of **1** formed after 10 days. Yield: 0.09 g (56% based on chnida). Elemental analysis (%) calcd for ($C_{33}H_{49}Fe_2N_2Na_6O_{31.5}$): C 32.3, H 4.0, N 2.3; found C 32.6, H 4.2 N 2.4.[23]

Ordered Mesoporous Polymers and Homologous Carbon Frameworks: Amphiphilic Surfactant Templating and Direct Transformation**

*Yan Meng, Dong Gu, Fuqiang Zhang, Yifeng Shi, Haifeng Yang, Zheng Li, Chengzhong Yu, Bo Tu, and Dongyuan Zhao**

Organic porous materials—a class of advanced materials—possess enormous potential for many high-tech applications, such as bioreactors,[1] dielectrics,[2] sensors,[3] microelectrophoresis,[4] thermal insulation,[5] and catalysts.[6] In general, they can be prepared by phase separation,[7] and a hard templating approach, such as those employing colloidal particles.[8] Phase separation can be derived from organic–organic phases, while the pore structures can be formed after etching, or by dissolving one block (A) from the assembled block copolymer (A–B).[9] However, most of the resulting porous polymer structures are disordered with wide pore size distributions because of the contraction and swelling from changes in volume, as well as the structured defects formed during template removal.[10] Large porosities have rarely been reported.[11] Furthermore, the resistance of the pore structure to heat and solvents is rather low because the materials are formed by weak van der Waals forces and physical twists between polymer chains, which means that the framework is not connected by covalent bonds. Recently, a procedure for cross-linking lyotropic liquid crystals (LLC) in water was introduced to prepare periodic porous organic mesostructures.[12] Unfortunately, polymerization only occurs between nearest neighboring head groups, and the mesostructured channels are fully occupied with solution.[13] Therefore, it is not surprising that porosity has yet to be reported.

Carbon materials, including nanotubes and fullerenes, have attracted considerable attention because of their remarkable properties.[14] The traditional carbonization process for active carbon and related materials can only generate

porosity with a tunable pore size, but not regular pore structures. Ryoo et al. developed a nanocasting method to prepare mesoporous carbon replicas through carbonization of sucrose-filled ordered mesoporous silica, with subsequent removal of the silica frameworks by HF or NaOH.[15] The replicas obtained from these time-consuming and costly procedures are ordered arrays of carbon nanorods or nanowires with reverse structures to the parent mesoporous silica. It remains a challenge to prepare ordered mesoporous carbon materials with open frameworks which may find applications in hydrogen-storage, catalysis, adsorption, separations, electrochemical double capacitors, or even ordered carbon nanotube arrays.

The organic-templating pathway has been applied extremely successfully to the preparation of ordered mesoporous inorganic oxides.[16–18] Amphiphilic surfactants and block copolymers can be used as templates to achieve highly ordered mesoporous materials, with large surface areas and uniform pore sizes (1.5–30 nm) that are suitable for countless potential applications.[16–18] Among these periodic solids, mesoporous silica materials are the easiest to prepare and the most widely investigated as a result of their highly stable, covalently bonded frameworks.[19] Many silica mesostructures, such as 2D hexagonal (*p6m*)[17] and 3D cubic (*Ia*$\bar{3}$*d*, *Im*$\bar{3}$*m*, *Pm*$\bar{3}$*n*)[20–22] structures, have been synthesized. However, perhaps because of thermal instability resulting from noncovalently bonded frameworks, the preparation of ordered mesoporous organic materials by the amphiphilic surfactant-templating approach has seldom been reported.[23,24] Although Hillmyer and co-workers have obtained ordered epoxy resin/amphiphilic block copolymer nanocomposites, the porosity of the nanocomposites was not reported as a result of difficulties in removal of the amphiphilic block copolymer template.[23] More recently, Tanaka et al.[24] used resorcinol/formaldehyde, and triethyl orthoacetate (EOA) as the carbon co-precursor under strongly acidic conditions (5 M HCl) in a direct carbonization method to prepare ordered mesoporous carbon frameworks with channel structures. The resulting materials have a hexagonal mesostructure, mainly as a result of EOA, which might reduce the polymerization and interaction of the precursors derived from resorcinol/formaldehyde.

Herein, we report a simple and reproducible synthesis of highly ordered and stable mesoporous polymers by an amphiphilic surfactant-templating approach that is derived from examination of the successful assembly of mesoporous silica. We chose resol (phenol/formaldehyde) as a cheap precursor which can form three-connected covalently bonded zeolite-like frameworks by thermopolymerization. We also demonstrate that these polymers, with rigid networks, can be directly transformed by a careful carbonization process into well-ordered and ultrastable ($>1400\,^{\circ}C$) open mesoporous carbon frameworks. The obtained mesoporous polymers have large uniform mesopores, surface areas, and pore volumes. Moreover, the mesostructures can be readily tuned from 2D hexagonal (*p6m*), to 3D caged cubic (*Im*$\bar{3}$*m*), and lamellar frameworks by simply adjusting the mass ratio of the polymer precursors and amphiphilic surfactants. The mesoporous carbon frameworks have homologous mesostructures with high surface areas, narrow pore size distributions, and large pore volumes.

Highly ordered mesoporous polymers can be synthesized by a solvent evaporation induced self-assembly method (EISA),[25] by using amphiphilic triblock copolymers (PEO-PPO-PEO) as templates, and a soluble low-molecular weight polymer of phenol and formaldehyde (resol; $M_w = 500$–5000) as precursors, followed by a thermopolymerization process (Figure 1). The choice of resol as a precursor is key to the successful organization of organic–organic mesostructures because resol has a large number of hydroxy groups (-OH) which can interact strongly with triblock copolymers through formation of H bonds.[26] Many kinds of amphiphilic surfactants, such as triblock copolymers containing a PEO segment, cationic surfactants,[27] and nonionic alkyl PEO oligomers[28] can be used as templates. Simple thermopolymerization of resol at low temperatures (100–140 °C) around the triblock copolymer can yield a rigid zeolite-like hydrocarbon network with three-connected benzene rings through formation of covalent bonds.[29] This feature makes the polymers stable and permits direct transformation to homologous carbon frameworks by carbonization to 900–1400 °C under nitrogen. The surfactant templates can be removed by solvent extraction assisted oxidation, or calcination at 300–500 °C under nitrogen. Low-cost, nontoxic, and commercially available copolymers are highly suitable templates because they contain a large amount of oxygen and can be easily decomposed. A carbonization process with a slow heating rate ($<2\,^{\circ}C\,min^{-1}$) under nitrogen is adopted to prepare ordered mesoporous carbon frameworks. The structures of the assembled frameworks can be controlled by varying the surfactant/resol ratio or choosing different surfactants. 2D hexagonal (*p6m*) and 3D cubic (*Im*$\bar{3}$*m*) structures can be obtained by using F127 (EO106PO70 EO106) as a template, whilst a lamellar mesostructure can be prepared using P123 ($EO_{20}PO_{70}$ EO_{20}) as a template (see the Supporting Information). The ordered mesoporous carbon frameworks have the same structures as the parent polymers as well as high surface areas and uniform pores. The walls of the carbon frameworks are amorphous, very thick (ca. 7 nm), and ultrastable ($>1400\,^{\circ}C$).

The X-ray diffraction (XRD) pattern (Figure 2a) for untreated mesoporous polymer (FDU-15) shows an intense diffraction peak and two weak peaks at a 2θ range of 0.5 to 2° that can be indexed as (10), (20), (21) reflections associated with 2D hexagonal *p6m* symmetry.[17] This observation indicates that untreated FDU-15 has a high degree of hexagonal mesoscopic organization. The intense (10) peak reflects a *d*-spacing of 12.8 nm, which corresponds to a large unit-cell parameter ($a_0 = 14.8$ nm). Small-angle X-ray scattering (SAXS; see the Supporting Information) reveals four well-resolved reflections, further confirming a highly ordered hexagonal mesostructure. After calcination of the sample under nitrogen at 350 °C, the XRD pattern (Figure 2b) shows four well-resolved peaks of a hexagonal mesostructure that is similar to that of mesoporous silica SBA-15, thus suggesting that the *p6m* morphology is preserved, although the XRD peaks appear at slightly larger 2θ values with a $d(10)$-spacing of 10.5 nm ($a_0 = 12.1$ nm). These results clearly indicate that the mesostructure is thermally stable in a nitrogen atmos-

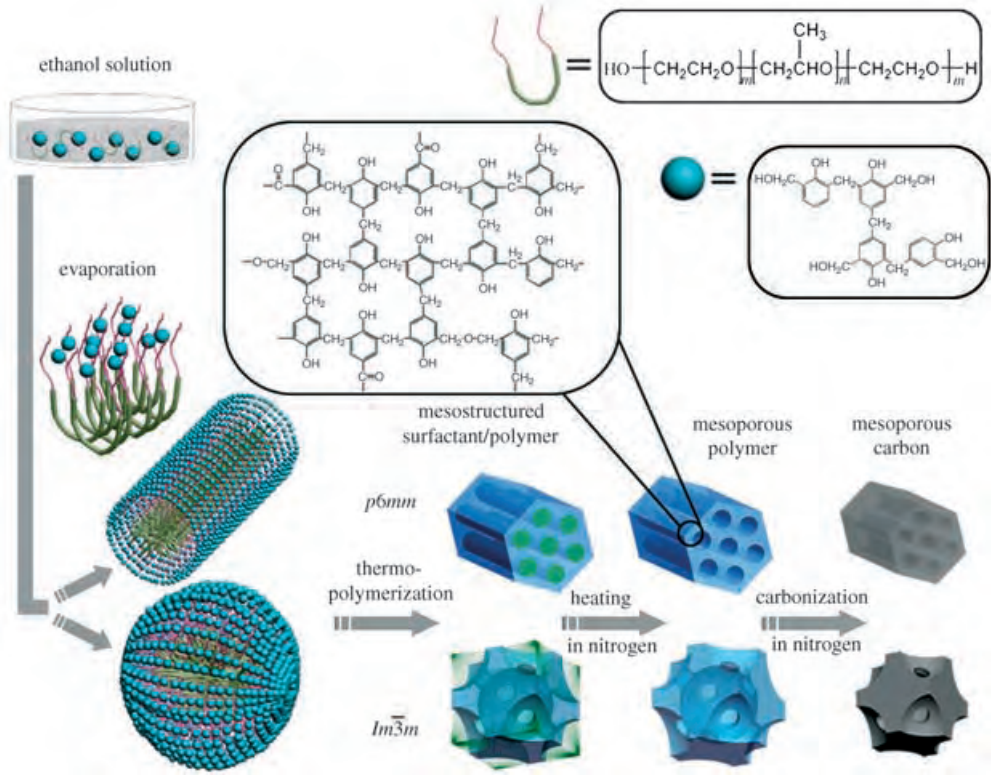

Figure 1. Schematic representation of the procedure used to prepare mesoporous polymers and carbon frameworks.

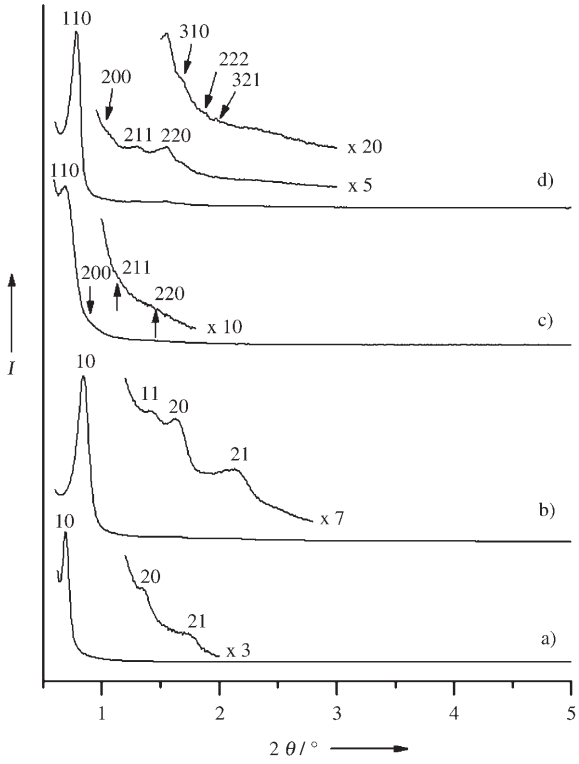

Figure 2. Powder XRD patterns of a) untreated FDU-15, b) FDU-15 calcined at 350 °C, c) untreated FDU-16, and d) FDU-16 calcined at 350 °C. The patterns were recorded on a Brucker D4 powder X-ray diffractometer using $Cu_{K\alpha}$ radiation.

phere, and the lattice of the framework shrinks by about 2.7 nm. The SAXS pattern shows three well-resolved peaks, thus providing evidence of thermal stability.

The photographic image of untreated FDU-15 (Figure 3 a) shows that it is a transparent and soft membrane, and indicates it is a homogeneous organic–organic composite. Transmission electron microscopy (TEM) images of FDU-15 calcined at 350 °C (C-FDU-15; Figure 3 b, c) show well-ordered hexagonal arrays of mesopores with 1D channels that are similar to SBA-15,[17] further confirming a 2D ordered hexagonal mesostructure. The cell parameter (a_0) estimated from the TEM images is approximately 11.5 nm, which is in agreement with the value calculated from XRD data.

The N_2 sorption isotherms (shown as circles in Figure 4 a) of FDU-15 calcined in a nitrogen atmosphere at 350 °C yield a type-IV curve with a sharp capillary condensation step at $P/P_0 = 0.6$–0.7 and an H_1-type hysteresis loop which is typical of large-pore mesoporous materials with cylindrical channels.[17] These results suggest that FDU-15 has uniform cylindrical mesoporous channels, similar to those of SBA-15.[17] The BET surface area and the total pore volume are calculated to be 652 $m^2 g^{-1}$ and 0.63 $cm^3 g^{-1}$, respectively. The pore diameter is about 6.8 nm with a narrow distribution. The wall thickness is estimated to be 5.3 nm, which indicates a thick organic network.

The ^{13}C solid-state NMR spectra (see the Supporting Information) reveal that calcination at 350 °C can decompose the triblock copolymers because they contain a large amount of oxygen, but the phenolic resin networks are preserved.

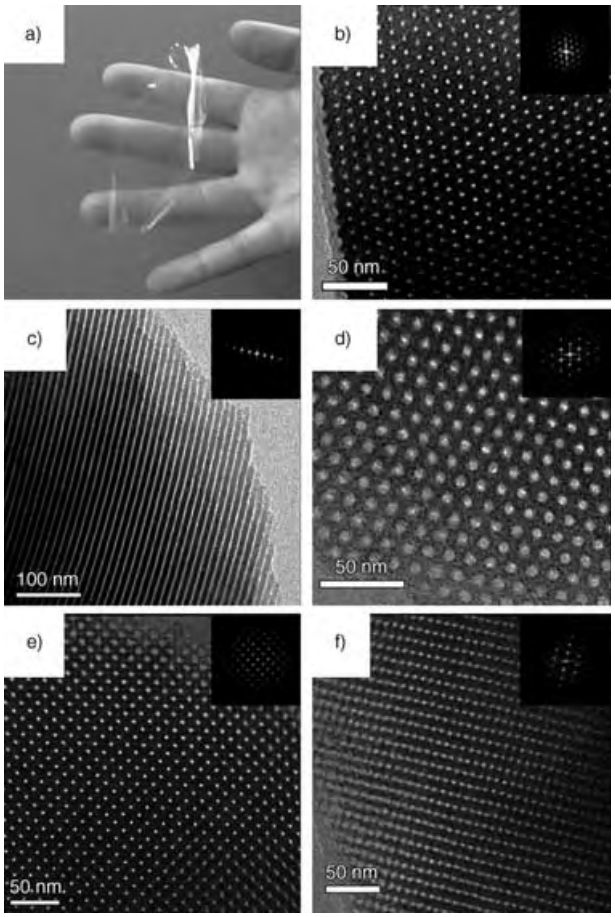

Figure 3. a) Photographic image of untreated FDU-15, b) TEM image of FDU-15 calcined at 350 °C viewed in the [001] direction, c) TEM image of FDU-15 calcined at 350 °C viewed in the [110] direction, d) TEM image of FDU-16 calcined at 350 °C viewed in the [111] direction, e) TEM image of FDU-16 calcined at 350 °C viewed in the [100] direction, and f) TEM image of FDU-16 calcined at 350 °C viewed in the [110] direction. TEM images were recorded on a JEOL 2011 microscope operated at 200 kV.

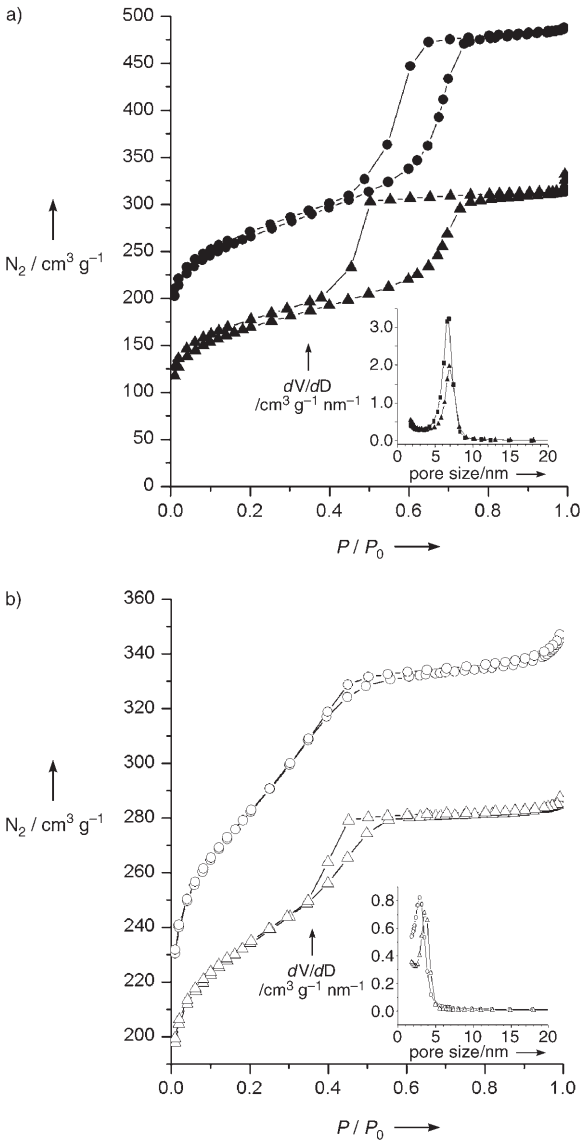

Figure 4. a) N_2 adsorption/desorption isotherms of FDU-15 (solid circles) calcined at 350 °C and FDU-16 (solid triangles) calcined at 350 °C, b) N_2 adsorption/desorption isotherms of C-FDU-15 (circles) calcined at 900 °C and C-FDU-16 (triangles) calcined at 900 °C. The pore-size distribution of FDU-15, FDU-16, C-FDU-15, and C-FDU-16 was determined by Barrett–Joyner–Halenda (BJH) analysis (inset). For clarity, the isotherms of C-FDU-15 in Figure 4a are offset along the *y* axis by 100 cm^3 g^{-1}. N_2 sorption isotherms were measured using a Micromeritics Tristar 300 analyzer at 77 K.

Elemental analysis reveals that calcined FDU-15 consists of C (77.97 %), H (5.20 %), O (16.8 %) with C/H/O molar ratio of 1:0.80:0.15, clearly suggesting a highly cross-linked phenol resin.

The 3D cubic mesoporous polymer structure (FDU-16) can be synthesized with a low F127/resol ratio. The XRD pattern for untreated FDU-16 (Figure 2c) shows one intense and three weak diffraction peaks. This result, combined with the SAXS pattern (see the Supporting Information), suggests a cubic mesostructure.[21] After calcination of the sample at 350 °C in a nitrogen atmosphere, the XRD pattern (Figure 2d) becomes more resolved, and seven diffraction peaks are observed. SAXS results (see the Supporting Information) show a well-resolved pattern. These reflection peaks can be indexed as (110), (200), (211), (220), (310), (222), and (321) of the body-centered cubic space group ($Im\bar{3}m$).[21] The lattice parameters are calculated to be 18.1 and 16.0 nm for untreated and calcined FDU-16, respectively. The lattice shrinkage is about 2.1 nm (11.6 %), which is slightly smaller than that for FDU-15 (18.2 %).

The large domain regularity of calcined FDU-16 is verified by TEM images (Figure 3d–f). These images viewed along the [111], [100], and [110] directions, together with electron diffraction data, further confirm an ordered cubic ($Im\bar{3}m$) mesostructure. The cell parameter estimated from the TEM images is approximately 15.9 nm, which is consistent with the value determined from the XRD data.

The N_2 sorption isotherms (shown as triangles in Figure 4a) of C-FDU-16 show typical type-IV curves with an H_2-type hysteresis loop which imply a 3D caged pore structure

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

with a small entrance size (< 4 nm).[30] C-FDU-16 has a BET surface area of 590 $m^2 g^{-1}$, a pore volume of 0.51 $cm^3 g^{-1}$, and a narrow pore distribution at about 6.8 nm. The pore size is identical to that of FDU-16, thus suggesting there is a dependence upon the template.

The ^{13}C solid-state NMR and FT-IR spectra of FDU-16 (see the Supporting Information) indicate that the copolymers can be decomposed and result in polymer networks after calcination at 350 °C. Elemental analysis shows a composition of calcined FDU-16 with a molar ratio of C/H/O = 1:0.70:0.20 (C 75.10, H 4.36, O 20.5 %).

Thermogravimetric curves (see the Supporting Information) show that significant weight losses of about 55 and 43 % occurred from 270 to 380 °C for FDU-15 and FDU-16, respectively. This weight loss can be mainly attributed to the decomposition of copolymer F127. Slow weight losses of 25.6 and 26.5 % between 380 and 900 °C as a result of carbonization is observed for FDU-15 and FDU-16, respectively. The carbonization yield, calculated on the basis of the phenol resin, is 43.0 and 65.9 % for FDU-15 and FDU-16, respectively. Elemental analysis data indicate that carbonization (> 900 °C) is almost completely achieved, with < 5 % oxygen and hydrogen remaining, thus suggesting that a pure carbon, homologous framework is obtained.

XRD patterns (Figure 5 a) show that the ordered mesostructures are preserved during the carbonization process, even up to 1400 °C. A 2D hexagonal mesoporous carbon framework (C-FDU-15) can be obtained from polymer FDU-15 after carbonization at 900 °C. XRD patterns show that C-FDU-15 has a highly ordered hexagonal (*p6m*) mesostructure which is the same as that of FDU-15, in contrast to the mesoporous carbon replicas (CMK-3) which are made up of carbon nanorods or arrays of nanowires and have the reverse structure of the mesoporous silica template.[31] The cell parameter (a_0) is calculated from XRD data to be 8.7 nm. Comparison of this value with that of its parent shows that shrinkage is as large as 28 %. TEM images (Figure 6 a, b) show that C-FDU-15 has well-ordered hexagonal arrays with 1D channels even after calcinations at 1400 °C, thus indicating a high thermal stability.

The N_2 sorption isotherms (shown as circles in Figure 4 b) of C-FDU-15 obtained at 900 °C also show typical curves for mesoporous materials, with a sharp capillary condensation step at low relative pressures ($P/P_0 = 0.2$–0.4). A small hysteresis loop is observed, which is similar to small-pore mesoporous silica MCM-41.[16] A narrow pore size distribution at about 2.9 nm is obtained, even though the pore size shrinkage is as large as approximately 57 %. The wall thickness is calculated to be 5.8 nm, which is similar to that of FDU-15. C-FDU-15 obtained at 900 °C has a large BET surface area of 968 $m^2 g^{-1}$, and a pore volume of 0.56 $cm^3 g^{-1}$.

Our results show that the successful formation of ordered mesoporous carbon frameworks is due to the rigid resin networks and a slow carbonization process. With increasing temperature, the a_0 and pore size decrease rapidly at first then decrease more slowly after 600 °C (see the Supporting Information), thus implying that heating at low temperature (< 600 °C) may be an important step for stabilizing the carbon frameworks.

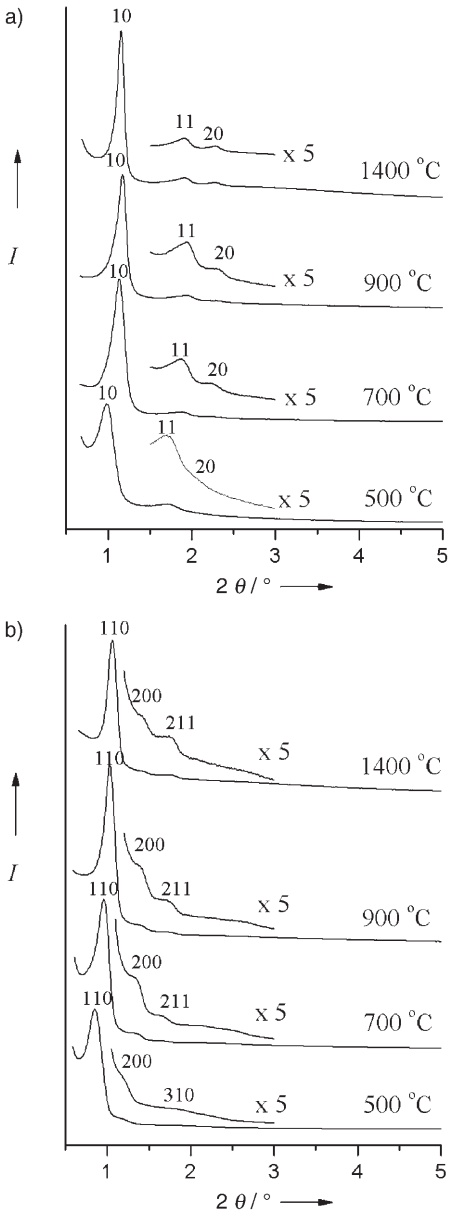

Figure 5. a) XRD patterns of C-FDU-15 calcined at temperatures ranging from 500 to 1400 °C, and b) XRD patterns of C-FDU-16 calcined at temperatures ranging from 500 to 1400 °C.

C-FDU-16 has a well-ordered cubic ($Im\bar{3}m$) mesostructure. Three well-resolved peaks can be observed in the XRD patterns (Figure 5 b). SAXS patterns (see the Supporting Information) confirm that the cubic mesostructure is retained during carbonization. The cell parameter (a_0) for the sample obtained at 900 °C is estimated to be 12.1 nm, and the shrinkage is about 24 %, which is slightly smaller than that for C-FDU-15. This observation implies that the 3D framework is more rigid than the 2D hexagonal structure. TEM images (Figure 6 c, d) show that C-FDU-16 has a large domain regularity with body-centered cubic symmetry ($Im\bar{3}m$) even after calcination at 1400 °C, which indicates ultrahigh thermal stability.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

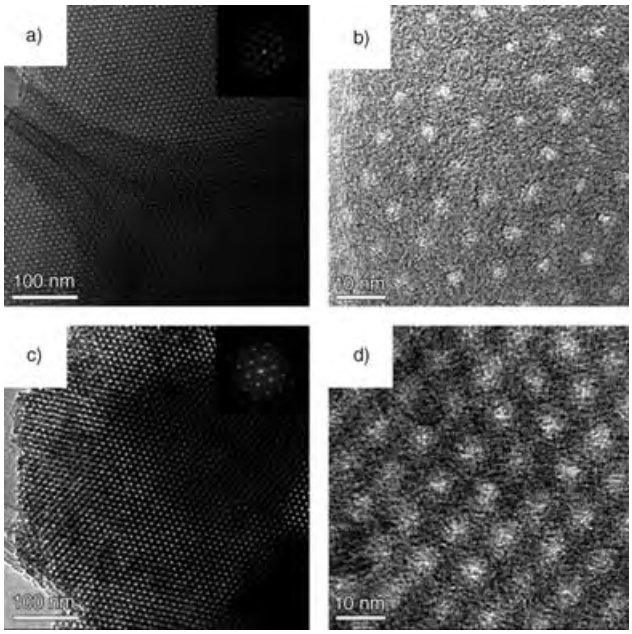

Figure 6. a) TEM image of C-FDU-15 calcined at 1400 °C, b) HRTEM image of FDU-15 calcined at 1400 °C, c) TEM image of C-FDU-16 calcined at 1400 °C, and d) HRTEM image of C-FDU-16 calcined at 1400 °C.

C-FDU-16 obtained at 900 °C also shows type-IV isotherms with a small H_2-hysteresis loop (shown as triangles in Figure 4b), thus implying small cage-like mesopores.[28] The pore size (ca. 3.7 nm), with a narrow distribution range, is smaller than that for its parent and the shrinkage (about ca. 45 %) is lower than that for C-FDU-15 which implies the cubic framework is more stable, and may be related to the 3D frameworks. C-FDU-16 obtained at 900 °C has a surface area of 778 $m^2 g^{-1}$ and a pore volume of 0.44 $cm^3 g^{-1}$.

The wide-angle XRD patterns (see the Supporting Information) for the carbon homologues are characteristic of amorphous carbon frameworks even after carbonization at 1400 °C.[32] The Raman spectra results (see the Supporting Information) also suggest an amorphous carbon framework.[32] High-resolution TEM (HRTEM) images (Figure 3d) of mesoporous carbon obtained at 1400 °C show that most of the carbon is amorphous, which suggests that graphitization is difficult.

In summary, highly ordered mesoporous polymers and carbon frameworks, with large uniform pores and surface areas, have been synthesized successfully. Two examples, FDU-15 and FDU-16, with hexagonal and cubic mesostructures, synthesized from triblock copolymers have been demonstrated. Ordered mesoporous carbon structures can be directly prepared from the polymers without defects. The resulting open carbon frameworks, connected by covalent bonds, have ultrahigh stability (> 1400 °C). The two new families of ordered mesoporous organic polymers and inorganic carbon solids, whose physical and chemical properties are quite easily distinguished from those of mesoporous silica, could have many potential applications in catalysis, separation, hydrogen storage, drug delivery, electrode materials, microdevices, and even in bioengineering.

Experimental Section

Resol precursor preparation: A soluble low-molecular-weight polymer ($M_w = 500$–5000) derived from phenol and formaldehyde (resol) was prepared by a basic polymerization method. Typical preparation procedure: Phenol (0.61 g, 6.50 mmol) was melted at 40–42 °C before 20 % NaOH (aq; 0.13 g, 0.65 mmol) was added slowly over 10 min with stirring. Formalin (37 wt %, 1.05 g) containing formaldehyde (13.0 mmol) was added dropwise, and the reaction mixture was stirred at 70 °C for 60 min. After cooling the mixture to room temperature, the pH of the reaction mixture was adjusted to neutral (7.0) using 0.6 M HCl solution. Water was then removed under vaccum below 50 °C. The final product ($M_w < 500$ measured by GPC) was redissolved in ethanol before use.

Synthesis of mesoporous polymer FDU-15 and FDU-16: Typical synthetic procedure of FDU-15: triblock copolymer poly(ethylene oxide)-*b*-poly(propylene oxide)-*b*-poly(ethylene oxide) (PEO-PPO-PEO, pluronic 127; 1.00 g) was dissolved in ethanol (20.0 g), then the ethanol solution of the above precursors containing phenol (0.61 g, 6.50 mmol) and (0.39 g, 13.0 mmol) formaldehyde was added by stirring for 10 min to form a homogeneous solution with the molar composition of F127/phenol/formaldehyde/ethanol of 0.012:1:2:67. The solution was transferred to a dish and the ethanol evaporated at room temperature over 5–8 h to produce a transparent membrane. The membrane was then heated in an oven at 100 °C for 24 h to thermopolymerize the phenolic resins. The products were calcined at 350 °C under nitrogen for 5 h with a temperature increase rate of 1 °C min^{-1} to obtain the porosity and decomposition of the amiphiphilic triblock copolymer template.

Cubic mesostructured resin polymers FDU-16 were synthesized by a procedure similar to that above, using triblock copolymer F127 (1.00 g), ethanol (15.0 g), resol precursor solution containing phenol (1.22 g, 13.0 mmol), and formaldehyde (0.78 g, 26.0 mmol). F127/phenol/formaldehyde/ethanol = 0.005–0.006:1:2:50.

Synthesis of lamellar mesostructured polymers from P123: Lamellar mesostructured polymer was prepared by using triblock copolymer pluronic P123 according to the above procedure. A homogeneous solution with the molar composition of P123/phenol/formaldehyde/ethanol = 0.022:1:1.2:50 was obtained and transferred into a dish to evaporate the ethanol. The resulting membrane was then heated in an oven at 100 °C for 24 h.

Synthesis of mesoporous carbon frameworks C-FDU-15 and C-FDU-16: Mesoporous carbon materials, C-FDU-15 and C-FDU-16, were prepared by direct transformation of the corresponding mesostructured polymers by carbonization under nitrogen. Carbonization was carried out in a tube oven under nitrogen at 700–1400 °C for 5 h. The temperature was increased at a rate of about 1 °C min^{-1} and held at 200, 350, and 500 °C for 2 h before reaching the final temperature. Elemental analysis results showed that the products contained > 90 wt % carbon, < 1.9 wt % H after carbonization at > 700 °C.

Measurements: XRD patterns were recorded on a Brucker D4 powder X-ray diffractometer by using $Cu_{K\alpha}$ radiation (40 kV, 40 mA). TEM images were obtained with a JEOL 2011 microscope operated at 200 kV. Samples for TEM measurements were suspended in ethanol and supported on a carbon-coated copper grid. N_2 adsorption isotherms were measured using a Micromeritics Tristar 3000 analyzer at 77 K. Before measurements were taken, all samples were degassed at 473 K for more than 12 h.

Multicomponent Organic Alloys Based on Organic Layered Crystals**

Kazuki Sada, Katsunari Inoue, Tomoyuki Tanaka, Attila Epergyes, Akira Tanaka, Norimitsu Tohnai, Akikazu Matsumoto, and Mikiji Miyata**

Inorganic mixed crystals or solid solutions such as metal alloys and intermetallic compounds are composed of two or more kinds of atoms or ions homogeneously mixed in the crystal.[1–3] They have been widely prepared and utilized as structural materials for daily life since ancient times. Formation of mixed crystals has been extensively investigated in the search for new functional materials with optical, electrical, and magnetic properties. Integration and fine-tuning of the functions have been often carried out by varying combinations of the components and the mixing ratios,[4] since the atoms and ions are easily mixed in the inorganic materials due to their spherical structures.

On the other hand, recrystallization from solution or crystallization from the melt is generally used for purification of crystalline organic compounds. Studies on organic mixed crystals have focused chiefly on well-defined molecular complexes in the crystalline state, such as inclusion crystals,[4] hydrogen-bonded cocrystals,[5] and charge-transfer complexes.[6] Less attention has been paid to formation of organic solid solutions or alloys that are composed of many kinds of organic molecules. Kitaigorodsky pointed out that similarity of molecular structures plays a crucial role in formation of organic solid solutions,[1] and some examples such as *n*-paraffins,[7] dicarboxylic acids,[8] naphthalene derivatives,[9]

and metal complexes[10] have already been reported. However, multicomponent organic solid solutions prepared from three or more organic molecules are quite rare,[11] because their sizes and shapes are incompatible for forming homogeneous solid solutions, and they recrystallize separately to form eutectic mixtures of the pure components. No other strategy to prepare multicomponent organic solid solutions has ever been reported. Herein, we report novel organic solid solutions based on a robust layered structure and a new strategy to construct multicomponent solid solutions composed of organic molecules with different sizes and shapes. Exploration of design and control of multicomponent organic solid solutions should allow functions of the organic molecules to be accumulated by the same strategy as employed with inorganic molecules.

Carboxylate salts of amines have been widely used for screening of functional organic crystalline materials. For example, they are used for optical resolution of racemic acids or bases,[12–14] crystalline-state reactions,[15] topochemical polymerizations,[16] host–guest crystals,[17] and so on. Salt formation has some advantages for crystal engineering: easy preparation, various combinations, and strong intermolecular interactions between the ion pairs, such as hydrogen bonds and electrostatic interactions. We previously reported that 1-naphthylmethylammonium (NMA) *n*-aliphatic carboxylates from acetate (**C2**) to triacontanate (**C30**) have the same layer structure independent of the length of the alkyl group (Figure 1a).[18] This phenomenon is ubiquitous for inorganic layered structures such as zeolites and smectite clays.[19] This prompted us to prepare organic solid solutions from mixtures of two or more NMA carboxylate salts, just like inorganic substitutional alloys.

Equimolar mixtures of two or more carboxylic acids were treated with NMA in methanol (Figure 1b), and removal of the solvent by an evaporator yielded white solids. They were characterized by XRD (Figure 2a). The sample prepared from a 1:1 mixture of propanoic acid (**C3**) and butanoic acid (**C4**) had an XRD pattern similar to those of the pure crystals (**C3s** and **C4s**), but it was not identical to their sum.

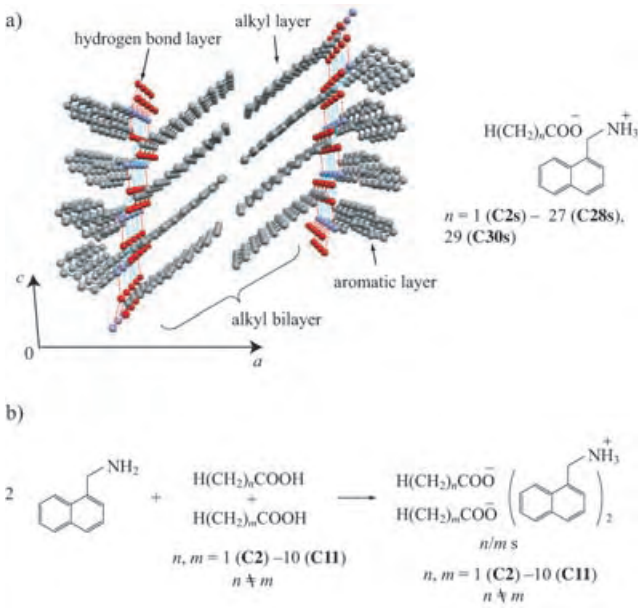

Figure 1. a) Bilayer structure in the crystalline state of **C9s**,[17] and b) the reaction scheme of the solid solutions.

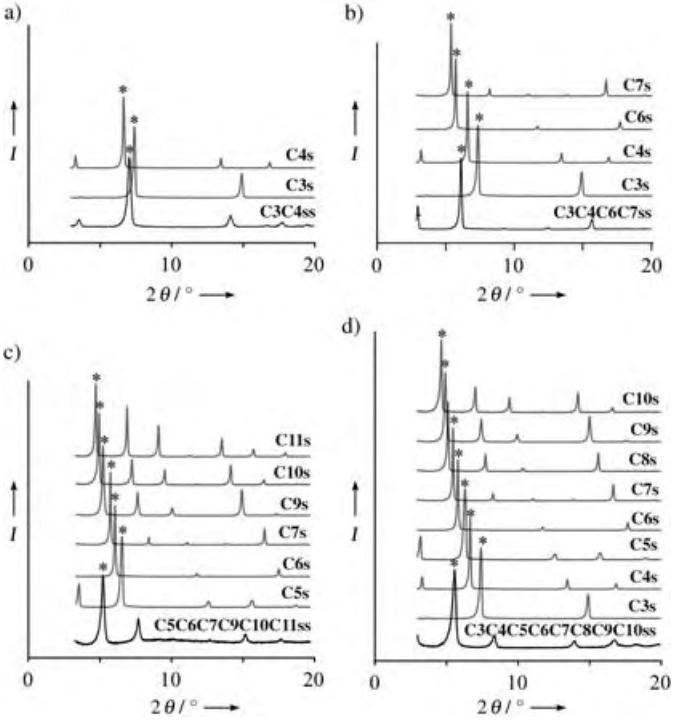

Figure 2. XRD patterns of solid solutions. a) Homogeneous solid solution from **C3** and **C4** (1:1) and the reference single-component salts **C3s** and **C4s**. b) Homogeneous solid solution from **C3**, **C4**, **C6**, and **C7** (1:1:1:1) and the reference single-component salts **C3s**, **C4s**, **C6s**, and **C7s**. c) Homogeneous solid solution from **C5**, **C6**, **C7**, **C9**, **C10**, and **C11** (1:1:1:1:1:1) and the reference single-component salts **C5s**, **C6s**, **C7s**, **C9s**, **C10s**, and **C11s**. d) Homogeneous solid solution from **C3**, **C4**, **C5**, **C6**, **C7**, **C8**, **C9**, and **C10** (1:1:1:1:1:1:1:1) and the reference single-component salts **C3s**, **C4s**, **C5s**, **C6s**, **C7s**, **C8s**, **C9s**, and **C10s**. Asterisks indicate 002 diffractions.

Differential scanning calorimetry (DSC) revealed that the melting point is 124.6 °C, which is lower than that of each pure salt (130.0 °C for **C3s** and 130.9 °C for **C4s**). From these results, we conclude that the white solid is a homogeneous solid solution of the two components (**C3C4ss**), rather than a eutectic mixture (**C3s** + **C4s**) of the individual crystals. The similarity in the XRD patterns suggested that the crystal structure of the solid solution **C3C4ss** resembles those of the pure salts. The FTIR spectrum of **C3C4ss** indicates the presence of the same hydrogen bonds as in the pure salts (carbonyl stretching bands of **C3C4ss**, **C3s**, and **C4s**: 1623, 1623, and 1623 cm^{-1}, respectively). The sharp 002 diffraction peak of the solid solution was observed at $d = 12.48$ Å, between those of **C3s** ($d = 11.87$ Å) and **C4s** ($d = 13.22$ Å). The interlayer distance of the solid solution was intermediate between those of the pure salts.[20]

Furthermore, we tried to prepare multicomponent solid solutions by mixing various carboxylate salts. We first investigated formation of a quaternary solid solution from

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

C3, **C4**, **C6**, and **C7** (1:1:1:1). The XRD pattern (Figure 2b) showed a single sharp profile, and the *d* spacing was 14.20 Å, which corresponds to **C5s** ($d = 13.97$ Å). This indicates that the quaternary mixtures gave the solid solution (**C3C4C6C7ss**) of these four components, and not their eutectic mixture (**C3s** + **C4s** + **C6s** + **C7s**). Six- and eight-component solid solutions also gave similar XRD results (Figure 2c and d). The *d* spacing from the single peak of the six-component solid solution **C5C6C7C9C10C11ss** was 17.66 Å, which corresponds to **C8s** ($d = 17.18$ Å). The *d* spacing from the peak of **C3C4C5C6C7C8C9C10ss** was 15.77 Å, which corresponds to the average value of **C6s** and **C7s** ($d = 15.17$ and 16.31 Å, respectively). These results provide insight into the structure and mechanism of formation of the solid solution. Mixing the four components can give the following ten possible *d* spacings (probabilities in parentheses): **C3s** (1/16), **C3C4ss** (1/8), **C4s** (1/16), **C3C6ss** (1/8), **C3C7ss** (1/4), **C4C6ss** (1/4), **C4C7ss** (1/8), **C6s** (1/16), **C6C7ss** (1/8), and **C7s** (1/16). However, the single peak around **C5s** ($d = 13.97$ Å) indicates that the bilayer is selectively composed of two sets of the alkyl chain pairs, namely, **C3**/**C7** and **C4**/**C6**. Otherwise, the peak should be much broader or split into several peaks due to the various layer distances. Indeed, as shown in Figure 3, a mixture

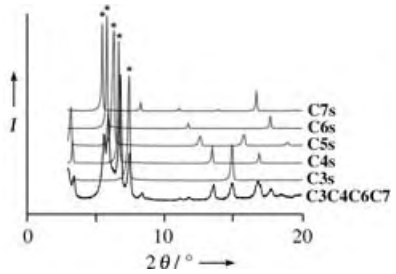

Figure 3. XRD patterns of a ground eutectic mixture of crystals of **C3s**, **C4s**, **C6s**, and **C7s** (black line), together with those of **C3s**, **C4s**, **C5s**, **C6s**, and **C7s** (grey lines). Asterisks indicate 002 diffractions.

prepared by grinding the pure salts shows corresponding peaks in each individual XRD pattern. Moreover, the six- and eight-component solid solutions have more possible *d* spacings, but they converged to averages among the mixtures. They should be composed of the following sets of alkyl-chain pairs: **C5**/**C11**, **C6**/**C10**, and **C7**/**C9** for **C5C6C7C9C10C11ss** and **C3**/**C10**, **C4**/**C9**, **C5**/**C8**, and **C6**/**C7** for **C3C4C5C6C7C8C9C10ss**. Each carboxylate anion recognized the sterically complementary partner. The sterically complementary pairs, for example, **C3**/**C7** and **C4**/**C6** for **C3C4C6C7ss**, have the same width in the alkyl bilayer structure, which provided the closest packing in the alkyl bilayer structure, and made them flat to form the two-dimensional hydrogen-bond network among the ion pairs and CH–π/π–π interactions between the naphthalene rings.[14] Furthermore, these results suggested random arrangement of the pairs. There are two hypothetical models to provide the averaged *d* spacing: a random model[20d] and a staged model[20d] (Figure 4). In staged model, a segregated layer is composed of one single carboxylate of the four carboxylates present, and the layer is paired with the specific partner.

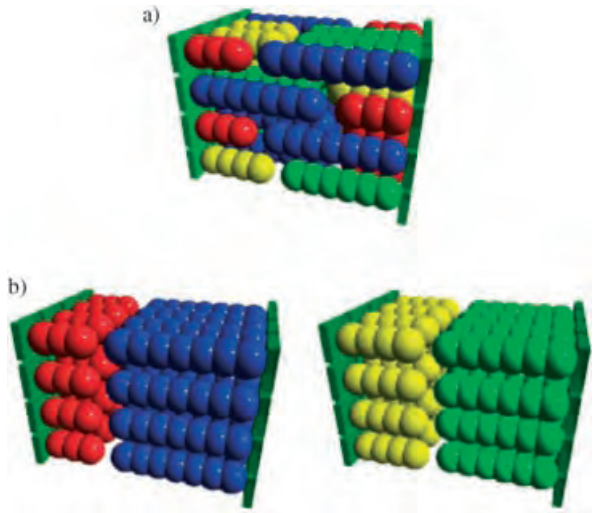

Figure 4. Schematic representations of the layer structures of the four-component homogeneous mixed salt a) with a random arrangement and b) with a staged arrangement.

There is no reason for selective stacking of these staged layers to afford layer structures with constant averaged *d* spacing. Therefore, the random layer is more likely. Thus, formation of the multicomponent solid solutions from more than two kinds of carboxylates was ascribed to specific pairing of the sterically complementary alkyl groups and their randomly disordered arrangement in the alkyl bilayer structure. During crystallization, the most probable pairs (e.g., **C3**/**C7** and **C4**/**C6** in **C3**, **C4**, **C6**, and **C7**) excluded the others by replacement of the counter alkyl group in the alkyl bilayer structure to keep the CH–π/π–π stacking and the two-dimensional hydrogen-bond networks parallel, and afforded the averaged layer distances.

The robust frameworks of NMA salts that accommodate isosteric pairs between their layers play a key role in formation of the solid solutions. These results indicate that robust structural motifs act as template for organic solid solutions and expand Kitaigorodsky's requirement for formation of binary organic solid solutions. Furthermore we could prepare the organic solid solutions from many components with different size and shape.[1] This strategy should be useful for designing wide ranges of the organic solid solutions. To our knowledge, the solid solution composed of eight organic molecules **C3C4C5C6C7C8C9C10ss** has the largest number of mixed components. Finally, introduction of functional groups into the isosteric pairs should provide integration of functions by a similar methodology to inorganic alloys.

Cloning and Heterologous Expression of Isocyanide Biosynthetic Genes from Environmental DNA**

Sean F. Brady and Jon Clardy*

Cultured soil bacteria have been an important source of biologically active, naturally occurring small molecules. Uncultured soil bacteria, which outnumber their cultured counterparts by at least two orders of magnitude, are likely to be an equally important source of such molecules. In an attempt to access the biosynthetic potential of uncultured soil bacteria, we have explored an approach that involves the cloning and heterologous expression of DNA extracted directly from environmental samples (environmental DNA, eDNA) into readily cultured bacteria. Earlier, we described the identification and characterization of small-molecule antibiotics from antibacterially active eDNA clones found using a high-throughput phenotypic screen.[1] This approach directly couples the biosynthesis of each natural product that is found to a relatively small piece of cloned eDNA and therefore permits the characterization of both new natural products and their biosynthetic gene clusters simultaneously. Herein, we report the isolation and characterization of the isocyanide-containing eDNA-derived antibiotic **1**, its biosynthetic genes (*isnA* and *isnB*), the origin of the isocyanide nitrogen atom, and the general outline of the biosynthesis of **1**.

CSLG18, the eDNA clone that produces **1**, was found in a cosmid library constructed from blunt-ended gel-purified high-molecular-weight eDNA extracted directly from soil collected in Boston (MA, USA). The cosmid library was screened for antibacterially active clones by using a top agar overlay which contained *Bacillus subtilis*.[1] Clones that produced a zone of growth inhibition in the overlayed *B. subtilis* lawn were recovered from the assay plates and tested for the production of extractable organic antibacterial activities.[1]

Bioassay-guided fractionation of the antibacterially active extract in ethyl acetate from cultures of CSLG18 led to the isolation of **1**, an isocyanide-functionalized C3-substituted indole. The indole and *trans* olefin were readily inferred from standard 1D and 2D NMR spectroscopic experiments.[2] The triplet resonance observed at $\Delta\delta = 107.4$ ppm in the ^{13}C NMR spectrum suggested the presence of the isocyanide functionality as ^{13}C–^{14}N coupling between the nitrogen atom and the adjacent carbon atom of the isocyanide group results in a triplet resonance for the carbon atoms, which is a hallmark of this functional group. The proposed structure of **1** was subsequently confirmed by single-crystal X-ray diffraction (Figure 1).[3] Although the *cis* isomer of **1** has been obtained from cultured bacteria, to the best of our knowledge **1** has never been reported as a natural product.[4]

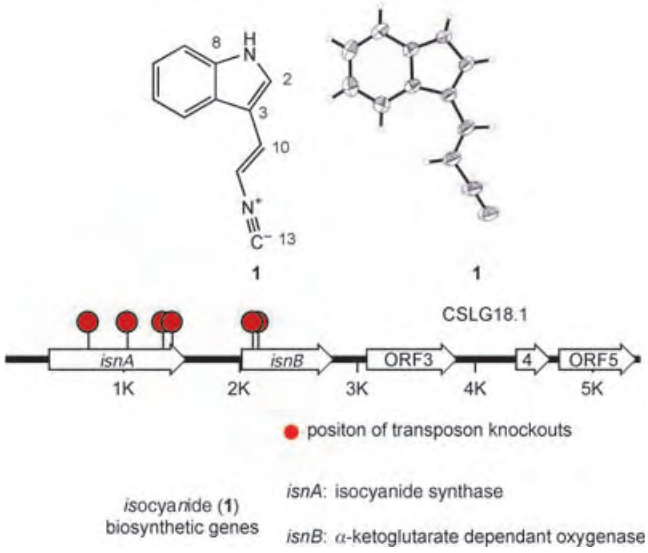

Figure 1. The natural-product antibiotic **1** was isolated from the culture broth of a 5.5-kB antibacterially active subclone of the eDNA cosmid, pCSLG18. The genes *isnA*/*B* are necessary and sufficient to confer the production of **1** to *E. coli*.

The genes responsible for the biosynthesis of **1** were sought in pCSLG18.1, a 5.5-kB antibacterially active EcoRI subclone (58.8% GC content) of the original eDNA cosmid, pCSLG18.[5] Two predicted open-reading frames (ORFs) contained in pCSLG18.1 (Figure 1) were identified by transposon mutagenesis as necessary for the production of **1** and have been given the names *isnA* and *isnB* (*is*ocya*n*ide, *iso*nitrile), respectively. The predicted translation product of *isnA* shows the highest-sequence identity to predicted proteins related to PvcA of pyoverdine chromophore biosynthesis (33%) and Dit1 of yeast-spore wall biosynthesis (21%). Neither PvcA nor Dit1 has been functionally characterized, although both are thought to be involved in the biosynthesis of C–N bonds.[6,7] The predicted translation product of *isnB* shows the highest-sequence identity to non-heme iron α-ketoglutarate dependent oxygenases, including the oxygenase from clavaminate biosynthesis and PvcB, a second enzyme thought to be involved in pyoverdine chromophore biosynthesis.[8] Three additional ORFs (>100 amino acids) were found in CSLG18.1; ORFs 4 and 5 are related to hypothetical proteins of unknown function and ORF 3 is related to prenyltransferases.

The successful expression of *isnA* and *isnB* (*isnA*/*B*), the biosynthetic genes for **1**, in *E. coli* allowed the biosynthesis of

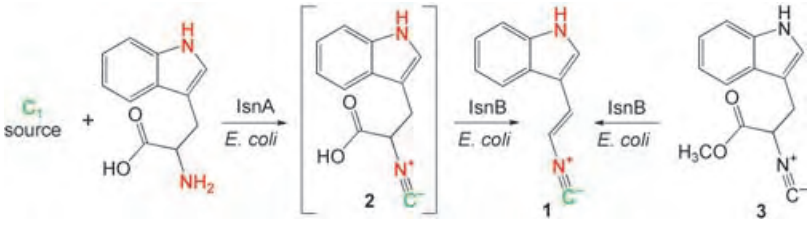
1 and, more specifically, the isocyanide functional group to be studied in detail. As with many isocyanide-containing natural products isolated from cultured bacteria and fungi, the structure of **1** suggests that the isocyanide nitrogen atom is likely to be derived from the amine of an amino acid. Feeding studies that used native-isocyanide-producing organisms have not, however, always supported this hypothesis.[9] The cloning and heterologous expression of isocyanide biosynthetic enzymes in *E. coli* allowed us to perform controlled feeding experiments which could not be carried out in less well-understood microbes and plants.



Scheme 1. Feeding experiments in *E. coli* indicate IsnA uses tryptophan in the biosynthesis of **1**. The proposed intermediate **2** is suggested by feeding experiments that use the methyl ester **3**.

The role of tryptophan in the biosynthesis of **1**, and its connection with the isocyanide nitrogen atom especially, was investigated by using *isnA*/*B* expressed in an *E. coli* host with a genetic background selected to eliminate the ambiguity seen in feeding experiments carried out in wild-type-isocyanide-producing organisms. To assess the role of tryptophan in the biosynthesis of **1**, doubly labeled ^{15}N-tryptophan was fed to a culture of a tryptophan auxotroph (*trpC*) and transaminase-deficient (*aspC*, *ilvE*, and *tyrB*) strain of *E. coli* (DL39W) transformed with *isnA*/*B*.[10] Incorporation of the ^{15}N label into **1** was determined by LCMS. The tryptophan auxotrophy ensures that the doubly labeled ^{15}N-tryptophan is the only tryptophan present in the culture, and the transaminase deficiencies ensure that the ^{15}N-labeled amine group of tryptophan is not lost during the feeding experiment. If both nitrogen atoms are incorporated into **1**, the observed *m*/*z* value $[M+H]^+$ for **1** would be 171; whereas if tryptophan is not used in the biosynthesis of **1**, no ^{15}N label will be incorporated into **1** which would result in an observed *m*/*z* value of 169. If only one of the two ^{15}N-labeled nitrogen atoms, either from the indole unit or the free amine group, is incorporated into **1** the observed *m*/*z* value for **1** would be 170.

In the presence of the doubly labeled ^{15}N-tryptophan, the general transaminase- and tryptophan-deficient strain of *E. coli* transformed with *isnA*/*B* produces **1** with *m*/*z* 171 being observed. Both the nitrogen atoms in **1**, including the isocyanide nitrogen atom, are therefore derived from tryptophan (Figure 2 and Scheme 1). Almost all of **1** obtained from a wild-type (transaminase-proficient) *E. coli*, contained a single ^{15}N label (*m*/*z* 170). Labeling studies performed in wild-type-isocyanide-producing organisms would be likely to give the same result and could explain the ambiguous feeding results obtained from these organisms previously. Many of the drawbacks traditionally associated with feeding studies can be significantly reduced or completely eliminated in model microbial systems by using mutants that create an appropriately controlled metabolic background.

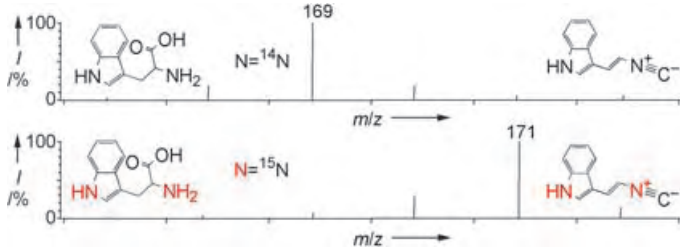


Figure 2. The *m*/*z* values observed for **1** obtained from cultures of *E. coli* transformed with *isnA*/*B* and grown in either ^{14}N-tryptophan or ^{15}N-tryptophan. A transaminase-deficient (*aspC*, *ilvE*, and *tyrB*) *E. coli* strain was used in these feeding experiments to prevent the loss of the labeled amine group.

IsnA and IsnB individually expressed as glutathione-*S*-transferase fusion proteins (IsnA-GST and IsnB-GST, respectively) were used to elucidate the overall scheme for the biosynthesis of **1** (Table 1). Cultures of *E. coli* that overexpressed either IsnA-GST or IsnB-GST individually did not accumulate **1**. However, **1** accumulated in the culture broth when these two strains were cocultured in the same flask. IsnA and IsnB are therefore necessary and sufficient to confer the production of **1** to *E. coli*, and one of the two enzymes must produce a diffusible intermediate that is converted into **1** by the other. *E. coli* that express IsnA-GST grown in media preconditioned with the growth of *E. coli* that express IsnB-GST does not lead to the accumulation of **1** in the culture broth; however, cultures of *E. coli* that express IsnB-GST grown in media preconditioned with the growth of *E. coli* that express IsnA-GST do accumulate **1** in the culture broth. The diffusible intermediate is therefore produced by IsnA and converted into **1** by IsnB (Scheme 1). All attempts to isolate this intermediate from cultures that either overexpress IsnA-GST or are transformed with *isnA*/*B* were unsuccessful.

Table 1: Results from feeding experiments used to decipher the overall biosynthetic approach to **1**.

N-formyl and *N*-methyl compounds have been proposed as possible isocyanide intermediates in what could be a two- or three-step isocyanide biosynthetic scheme.[11] However, *N*-formyl and *N*-methyl derivatives of tryptophan and tryptamine (0.1 mg mL^{-1}) did not serve as substrates for the

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

production of **1** when added to cultures that overexpress IsnB-GST. It seemed plausible that IsnA might form the isocyanide function in a single enzymatic step and that the role of IsnB would be the oxidative decarboxylation of the proposed isocyanide-functionalized intermediate **2**. In our hands, the synthetic intermediate **2** was not stable and, therefore, could not be used in feeding experiments to test this hypothesis. However, we were able to synthesize the methyl ester of **2** (**3**) and thought that the slow cleavage of the methyl ester by promiscuous bacterial esterases might circumvent the instability problem.[12] The addition of **3** (0.1 mg mL^{-1}) to cultures that express IsnB-GST led to the accumulation of **1** in the culture broth, and when the cultures of CSLG18.1 were spiked with **3**, they showed increased production of **1** relative to the control cultures of CSLG18.1. Compound **1** was not detected in the extracts in ethyl acetate from the vector control cultures spiked with **3** or from IsnA-GST cultures spiked with **3**. These feeding studies suggest that the isocyanide group seen in **1** is formed in a single enzymatic step on IsnA and that the proposed isocyanide-containing intermediate **2** is oxidatively decarboxylated by IsnB to give **1** (Scheme 1). The lack of stability of **2** is likely to be responsible for our inability to isolate the proposed intermediate.

The eDNA approach, used in this study to discover antibiotic **1**, directly couples natural products with their biosynthetic gene clusters, thus providing both a means for the isolation of previously inaccessible natural products from uncultured bacteria and a direct link to their biosynthetic enzymes. Characterization of the antibacterially active eDNA clone CLSG18 led to the identification of the isocyanide-containing natural-product antibiotic **1**, and in turn to the first isocyanide synthase, IsnA. The origin of the isocyanide carbon atom is an intriguing, but unanswered question, for all naturally occurring isocyanides. This question will be addressed in due course.

functionalized intermediates in the elaboration of complex organic molecules.[1] One class of chemical reagents that is continuously finding new applications in this area of synthetic organic chemistry is composed of hypervalent λ^3- and λ^5-iodanes.[2] Herein we report a new phenol dearomatization process that involves the use diaryl λ^3-iodanes (i.e., Ar_2IL, L = Cl, BF_4, OTs)[3] to promote regioselective *ortho* phenylation to give 6-phenylcyclohexa-2,4-dienones. Diaryl-λ^3-iodane reagents have previously been used with success to give α-arylated ketones, esters, silyl enol ethers, and various 1,3-dicarbonyl compounds,[3–5] but the only products that were obtained when phenolic substrates were used under basic conditions were derived from an O-arylation process.[6] The reaction conditions unveiled herein permit us to direct the entry of an aryl group to a substituted position on the starting phenol and offer an alternative to stoichiometric processes that involve the use of toxic aryl–lead or aryl–bismuth reagents[7,8] and an alternative to transition-metal-catalyzed processes that only furnish diaryl products.[9]

We selected 2,3,5-trimethylphenol (**1a**, see Table 1) as a first model substrate to search for appropriate C-phenylation conditions and treated it with chlorodiphenyl-λ^3-iodane (Ph_2ICl) in dimethylformamide (DMF) in the presence of potassium *tert*-butoxide (*t*BuOK, 1.1 equiv) for 20 h at room temperature. Only the diaryl ether **2a** was isolated with a yield of 53%, but no formation of the desired cyclohexa-2,4-dienone **3a** was observed (Table 1, entry 1).[10] The first glimpse of success was obtained by changing the reaction solvent to a protic solvent with a low dielectric constant (i.e., *t*BuOH),[11] whereupon **3a** was isolated with a yield of 8% (Table 1, entry 1). It is worth noting that no diaryl product, which could have resulted from introduction of the phenyl group at the unsubstituted C6 position of the starting phenol **1a**, was observed. A small and weakly electron-donating substituent such as a methyl group at an *ortho* position thus appears sufficient to direct delivery of the phenyl unit to that substituted position. In accordance with this first observation, only diaryl ether products were obtained in good yields when starting from phenol (**1b**) or from the *meta*-substituted phenol, 3,5-dimethylphenol (**1c**; Table 1, entries 2 and 3). Moreover, the symmetrically *ortho*-substituted 2,6-di- and 2,4,6-trimethylphenols, **1d** and **1e**, gave rise to the formation of the desired cyclohexa-2,4-dienones, **3d** and **3e**, in 37% and 42% yields, respectively (Table 1, entries 4 and 5). Interestingly, the *para*-methylated phenol **1e** also afforded 4-phenylcyclohexa-2,5-dienone (**4e**) in 7% yield. Biasing the system with sterically demanding alkyl groups at the two *ortho* positions should lead to a quasi-exclusive phenylation at the *para*-alkylated position. This was indeed the case with 4-methyl-2,6-di-*tert*-butylphenol (**1f**), the use of which only furnished 4-methyl-4-phenylcyclohexa-2,5-dienone (**4f**) in an excellent yield of 94% (Table 1, entry 6). Further evidence of the role played by the methyl group in mediating transfer of a phenyl group from Ph_2ICl was then obtained by performing the same reaction with 2,6-di-*tert*-butylphenol (**1g**; not shown), in which case no phenylation product was isolated.

Having thus established the prominent role that is played by alkyl substituents in the regiocontrol of this λ^3-iodane-mediated phenylation of phenols, we turned our attention to a series of 1-naphthols, each bearing an electronically different *ortho* substituent. Experiments carried out with Ph_2ICl on 2-methyl- (**1i**), 2-methoxy- (**1j**), and 2-nitrosonaphthol (**1k**) revealed a somewhat different reactivity from that of the phenols as no diaryl ether was observed. Nevertheless, the expected dearomatization products, **3i**, **3j**, or **3k**, were isolated as the sole products in increasing yields ranging from 36 to 74% (Table 2, entries 1–3). Naphthols, as well as phenols, that bear an electron-demanding *ortho* substituent such as 2-carboxymethoxynaphthol (**1l**), 2-nitronaphthol (**1m**; see Scheme 2), 2-hydroxynaphthaldehyde, and 4-nitrophenol (**1n**, **1h**; not shown) were all found to be refractory substrates at room temperature (see below). Only the ester **1l** gave rise to the formation of the diaryl ether **2l** and the desired dearomatized phenylation product **3l**, albeit in low yields (Table 2, entry 4).

In contrast to the unsubstituted 1-naphthol (**1o**; not shown) that led to a complex product mixture, the unsubstituted 2-naphthol (**1p**) was reactive towards Ph_2ICl and underwent both O- and C-phenylation to furnish three products: the diaryl ether **2p** (9%), 1-phenyl-2-naphthol (**3p**, 18%), and the diaryl ether **4p** (22%) through trans-

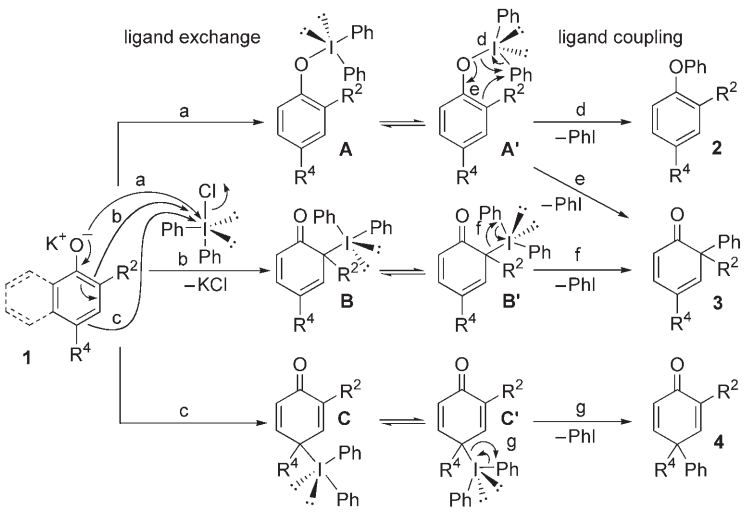
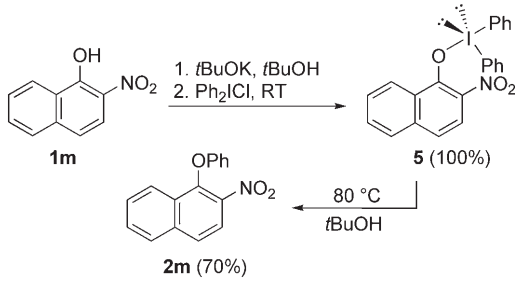
ferring a second phenyl unit to **3p** (Table 2, entry 5). The C-phenylation course is thus globally favored over the O-phenylation alternative for this unsubstituted 2-naphthol treated under basic conditions in a protic solvent.[11] It is interesting to note that 2-naphthol (**1p**) was also the only phenol among those we used to furnish a diaryl product through phenylation at its unsubstituted C1 center. This is probably due to the more pronounced ambident character of the delocalized 2-naphthoxide anion relative to that of unsubstituted phenoxide anions[11] and to the aromaticity retained when this anion engages itself in bond formation at C1, but not at C3.

We next wondered about the mechanism that is operative in these phenylation reactions of phenols and naphthols as they constitute a novel aspect of hypervalent iodine chemistry. The first experimental observations of mechanistic relevance were that iodobenzene was formed as a by-product and that no reaction took place in the absence of a base strong enough to deprotonate the starting phenol. The delocalized phenolate nucleophile can then attack the iodine(III) center of Ph_2ICl in a ligand-exchange step, thus displacing the chloride anion ligand to furnish (aryloxy)diphenyl-λ^3-iodanes of type **A** (Scheme 1, path a) and/or their C-iodanylated cyclohexadienone variants of types **B** and **C** (Scheme 1 paths b and c) depending upon the electronic and steric demands of the substituents on the starting phenol.

Alternatively, the phenolate anion could engage itself in an aromatic nucleophilic-substitution reaction (i.e., S_NAr) and directly attack Ph_2ICl at one of its two phenyl carbon atoms bonded to the iodine(III) center. This S_NAr mechanistic path is generally proposed to rationalize the reactivity of species such as Ph_2ICl towards nucleophiles.[12] It must be recalled that these species are not tetrahedral diaryliodonium salts, as commonly thought, but 10-I-3 T-shaped pseudotrigonal bipyramidal entities, as expected for hypervalent I^{III} species.[3] To find evidence for one or the other mechanistic alternative, we revisited some of the reactions we had performed with the aim of characterizing any stable reaction intermediates. This was accomplished by isolating an intermediate from the reaction performed at room temperature with the apparently refractory substrate, 2-nitronaphthol (**1m**, see above). This intermediate was characterized as the type-**A** (2-nitronaphthoxy)diphenyl-λ^3-iodane, **5** (see Supporting Information and Scheme 2). In contrast to reactions



Scheme 1. Mechanistic description of the phenol phenylation reactions through direct ligand coupling. **A**, **B**, and **C**: 10-I-3 trigonal-bipyramidal intermediates; **A**′, **B**′, and **C**′: tetragonal-pyramidal intermediates. R^2, R^4: various substituents.



Scheme 2. Evidence of ligand exchange: isolation of type-**A** intermediate **5** and its heat-induced conversion into the diaryl ether **2m**.

carried out with phenols bearing electron-releasing *ortho* substituents, this intermediate does not further evolve at room temperature but gives the starting naphthol **1m** upon chromatography on silica gel. However, compound **5** furnishes the O-phenylated product **2m** in 70% yield when heated to reflux in *t*BuOH for 8 h (Scheme 2).

These observations are in agreement with an initial ligand-exchange step, but not with a direct S_NAr-type mechanism. Furthermore, the isolation of the 10-I-3 species **5** is particularly revealing of the mechanistic path followed in this process as the presence of a strongly electron-withdrawing *ortho* substituent on the starting phenol is usually

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

associated with the stabilization of S_NAr Meisenheimer-type intermediates.[12,13]

Hence, the phenylation products observed with concomitant reductive elimination of iodobenzene can, in principle, result either from collapse of the λ^3-iodanyl intermediate into a phenyl and a phenoxy radical, which would then pair off, or from a concerted ligand coupling on the iodine(III) center itself.[4,13] To address this question, the efficient phenyl radical trapping agent, 1,1-diphenylethylene (DPE)[5g,8d,8e] was added to the reaction medium during the phenylation of **1e, 1j**, and **1k** (Table 1, entry 5 and Table 2, entries 2 and 3). The presence of DPE did not affect the outcome of the reaction, thus showing that no radical-based intermediate plays any determinant role in the process. These observations are in agreement with the proposal of an exclusive nonradical ligand-coupling mechanism. Thus, the 10-I-3 intermediates of types **A**, **B**, and **C** may evolve through coupling of their phenolate-derived ligand with one of the phenyl groups. Ligand coupling is symmetry-forbidden on these trigonal-bipyramidal structures, but bond-forming events can occur from tetragonal-pyramidal transient species of types **A′**, **B′**, and **C′** during ligand pseudorotation around the iodine(III) center (Scheme 1).[3,12,13]

Formation of diaryl ethers of type **2** would then result from intermediates of type **A′** through a nonsynchronous *ipso–ipso* coupling (path d) with a polar transition state as a consequence of the difference of polarity between the two ligands (i.e., LC_N-type coupling).[13] The formation of cyclohexa-2,4-dienone products of type **3** could either also arise from intermediates of type **A′** through an *ipso–allyl* $LC_{N'}$-type coupling (path e) or from **B′** through a quasi-synchronous *ipso–ipso* LC-type coupling (path f).[13] The fact that Ph_2ICl was also capable of transferring one of its phenyl ligands to the *para* position of 2,4,6-trimethylphenol (**1e**) and 4-methyl-2,6-di-*tert*-butylphenol (**1f**) to furnish cyclohexa-2,5-dienone products of type **4** (Table 1, entries 5 and 6) can only be rationalized in terms of a passage through intermediates of type **C′**, which then evolve through an *ipso–ipso* LC-type coupling (path g).

Semiempirical and Hartree–Fock calculations that we performed at the AM1 and 6-31G* levels to determine the electrostatic charge distribution and the relative magnitudes of the atomic coefficients of the highest occupied molecular orbital (HOMO) of the phenolate forms of **1a, d–g** illustrate the contribution of *ortho* and *para* methyl groups in controlling the regiochemical outcome of these phenylation reactions (see Supporting Information). In all cases, the negative charge is mostly localized on the oxygen atom, and the presence of a methyl group at one *ortho* position (**1a**) reinforces partial localization of the charge at the unsubstituted *ortho* and *para* positions (i.e., C6 and C4). Similarly, when comparing data for **1d** versus **1e** and **1f** versus **1g**, it can be read that the presence of a methyl group at the *para* position decreases the extent of partial localization of the charge at this locus. Hence, the O-phenylation path of the reaction may benefit from this charge distribution, but not its C-phenylation alternatives. However, the presence of a methyl group at C2 of **1a** or at C4 of **1e** and **1f** renders the relative magnitudes of the HOMO atomic coefficients at these centers larger in comparison to those at the unsubstituted *ortho* position in **1a** and at the unsubstituted *para* position in **1d** and **1g**, respectively. The dearomatizing C-phenylation path of the reaction would thus seem to be essentially under this orbital control. The results obtained with naphthols **1i–l** are in agreement with this substituent-controlled modulation of reactivity, since the more electron-releasing the substitutent at C2, the better is the yield of the dearomatizing *ortho*-phenylation reaction (Table 2, entries 1–3).

In conclusion, the work described herein presents a novel aspect of the versatility of hypervalent iodine(III) reagents in organic synthesis, which is illustrated by the use of the diaryl-λ^3-iodane Ph_2ICl to promote regioselective C-phenylation of *ortho*- and/or *para*-substituted phenols to give cyclohexadienone derivatives under basic conditions. The presence of a small electron-donating substituent at the *ortho* and/or *para* positions of the starting phenol determines the efficacy and regioselectivity of the process, which involves a nonradical coupling of the phenolate-derived and phenyl ligands directly around the iodine(III) center. Evidence of such a direct ligand-coupling mechanism is also given for the competitive O-phenylation process, which is commonly thought to follow an intermolecular aromatic nucleophilic-substitution reaction path.

Hydrogen-Bond-Mediated Self-Assembly of Aminopyrazolones: Macrocyclic Quartets—Single and Stacked One-Dimensional Motifs**

*Hegui Gong and Michael J. Krische**

A broad goal of modern research resides in the development of selective protocols for the organization of matter across length scales.[1] Toward this end, the self-assembly of molecular components has garnered considerable success as a procedure for the spontaneous generation of well-defined discrete and recurrent architectures.[2,3] Hydrogen-bond-mediated self-assembly has proven especially effective,[3] largely because of the design of tailored recognition elements in the form of hydrogen-bond donor–acceptor arrays, which allows the free energy and "orthogonality" of recognition events to be tuned.[3c] The utility of hydrogen-bond recognition elements is highlighted by their application to the design of oligomers (foldamers) that adopt specific secondary structures,[4,5] molecular strands that engage in specific modes of intermolecular aggregation,[6] polymers possessing non-covalent main chains[7] and side chains,[8] as well as the self-assembly of dendritic macromolecules.[9]

We recently developed duplex molecular strands based on the aminotriazine and diaminopyridazine hydrogen-bonding motifs as part of a program concerning hydrogen-bond-mediated self-assembly.[10] These systems engage in high-affinity twofold self-association, as established by isothermal titration calorimetry (ITC), ^{1}H NMR dilution studies, vapor pressure osmometry (VPO), and single-crystal X-ray diffraction analysis. With the goal of developing synthetic strands that self-assemble to form transmembrane channels,[11] we sought oligomers incorporating recognition elements that direct fourfold self-association. While quadruplexes based on guanosine and their structural relatives are commonplace,[12] other heterocyclic molecules that participate in hydrogen-bond-mediated fourfold self-association are exceptionally uncommon.[13] 3,5-Disubstituted pyrazoles are known to form dimers **A**, as well as cyclic trimers **B** and tetramers **C**, in solution and in the solid state (Scheme 1).[14] It was postulated that the hitherto unexplored aminopyrazolones **1** should preferentially engage in fourfold self-association through heteromeric aggregation (amide–amidine), as the quadruplex type arrangement is reinforced by four additional hydrogen bonds as in $\mathbf{1}_4$. However, homomeric association (amide–amide, amidine–amidine) of aminopyrazolone **1** may compete to provide 1-dimensional motif $\mathbf{1}_n$. Finally, because ditopic association is relatively weak, arrangements involving unrequited hydrogen-bond donor–acceptor sites are probable in the solid state.[15]

Aminopyrazolones **1a**–**1c** were synthesized according to a literature procedure.[16] Specifically, ethyl cyanoacetate was subjected to exhaustive alkylation followed by hydrazination to afford dibutylaminopyrazolone **1a**, didodecylaminopyrazolone **1b**, and dibenzylaminopyrazolone **1c**. Synthesis of the optically pure C_2-symmetric bis(aminopyrazolone) **1d** was achieved through the alkylation of a chirally modified cyanoacetate ester based on (1*S*,2*R*,4*R*)-10-dicyclohexylsulfamoylisoborneol (Scheme 2).[17]

Single crystals of compounds **1a**–**1d** were obtained and subjected to X-ray diffraction analysis to determine the mode of assembly in the solid state. Analysis of crystals of dibutylaminopyrazolone **1a** obtained from ethyl acetate reveal a 1-dimensional hydrogen-bonding motif involving homomeric association of the ditopic hydrogen-bond donor–acceptor sites (amide–amide, amidine–amidine; Figure 1). The N–H···N and N–H···O hydrogen bonds in the linear aggregate $(\mathbf{1a})_n$ have equal lengths of 3.07 Å. In contrast, X-

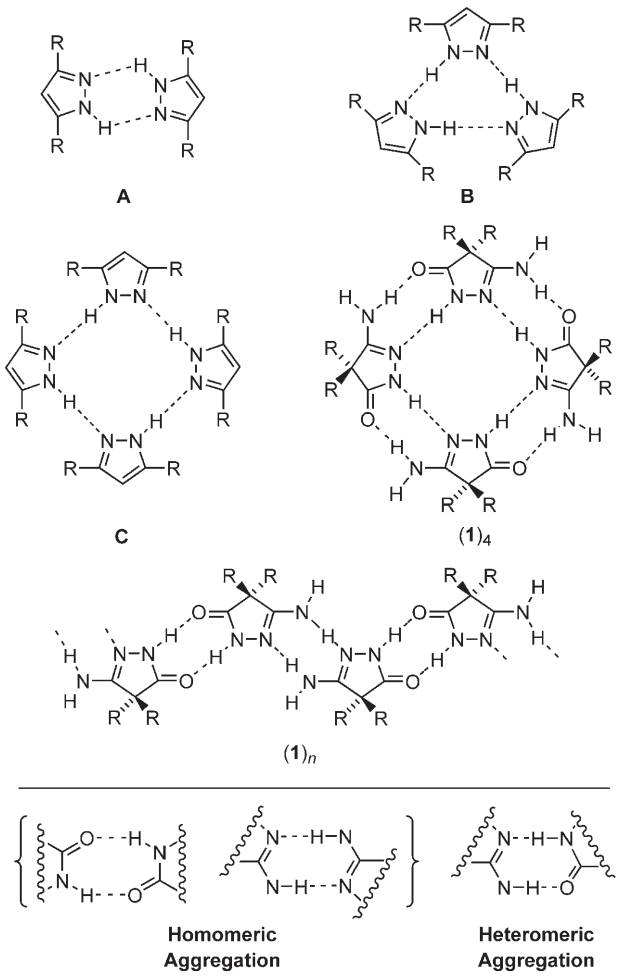
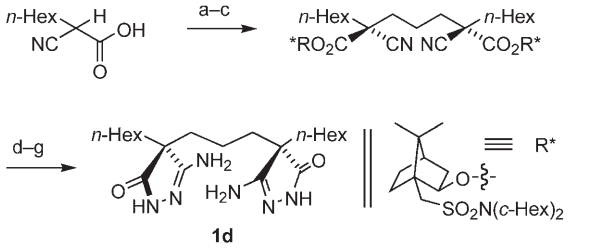


Scheme 1. Assembly modes established for 3,5-disubstituted pyrazoles and those proposed for aminopyrazolones **1**.



Scheme 2. Synthesis of bis(aminopyrazolone) **1d**. Reagents: a) PCl_5 (100 mol%), Et_2O (0.3 M), 25 °C. b) R*OH (50 mol%), AgCN (75 mol%), $PhCH_3$ (0.1 M), 60 °C, 70% over two steps. c) LDA (120 mol%), 1,3-diiodopropane (50 mol%), HMPA (150 mol%), THF (0.1 M), −78 °C to 25 °C, 38%. d) LiOH in MeOH (1.83 N, 1830 mol%), 25 °C, 83%. e) PCl_5 (212 mol%), Et_2O (0.1 M). f) MeOH (excess), 25 °C, 97% over two steps. g) NH_2NH_2-H_2O (1000 mol%), 105 °C, 70%. LDA = lithium diisopropylamide, HMPA = hexamethyl phosphoramide.

ray diffraction analysis of crystals of didodecylaminopyrazolone **1b** obtained from 1,2-dichloroethane reveals the desired cyclic quartet structure $(\mathbf{1b})_4$ derived through heteromeric association (amide–amidine, amide–amidine; Figure 2). The N–H···N and N–H···O hydrogen-bond lengths in the cyclic

aggregate are 3.02 Å and 2.93 Å, respectively. A pore size of approximately 2.6 Å is estimated when the van der Waals radii are taken into account; hence, the pore size is sufficiently large to accommodate lithium, sodium, and potassium ions. The solid-state structure of dibenzylaminopyrazolone **1c** reveals a non-coplanar arrangement of the aminopyrazolone rings.[18] The energetic driving force represented by the packing preferences of the phenyl moieties in **1c**, appears to supercede the free energy of hydrogen-bond formation, as only one of the four hydrogen-bond donor–acceptor sites forms a contact with another aminopyridazine molecule. Finally, X-ray diffraction analysis of a crystal of C_2-symmetric bis(aminopyrazolone) **1d** obtained from 1,3-dimethyl-2-imidazolidinone reveals a stacked 1-dimensional motif. In this stacked motif, N–H···N and N–H···O hydrogen-bond lengths of 3.01/3.02 Å and 2.89 Å are observed, respectively.

In summary, initial studies on the hydrogen-bond-mediated self-assembly of aminopyrazolones have established that two primary modes of aggregation are evident for *n*-alkyl-substituted aminopyrazolones **1a**, **1b**, and **1d** in the solid

state. Homomeric aggregation (amide–amide, amidine–amidine) of aminopyrazolones **1a** and **1d** gives rise 1-dimensional architectures $(\mathbf{1})_n$, while heteromeric aggregation (amide–amidine) generates the desired macrocyclic quartets $(\mathbf{1})_4$. The self-assembly of aminopyrazolones in solution is currently under investigation. These studies suggest that suitably tailored aminopyrazolone oligomers may spontaneously assemble to form channel-type aggregates.

Janus-Faced Aluminum: A Demonstration of Unique Lewis Acid and Lewis Base Behavior of the Aluminum Atom in $[LAlB(C_6F_5)_3]$**

Zhi Yang, Xiaoli Ma, Rainer B. Oswald, Herbert W. Roesky, Hongping Zhu, Carola Schulzke, Kerstin Starke, Marc Baldus, Hans-Georg Schmidt, and Mathias Noltemeyer*

Compounds of aluminum with a formal +3 oxidation state on aluminum, such as trihalides, trialkyls, and triaryls, show classical behavior of Lewis acids.[1] In recent years, another class of compounds containing aluminum with the +1 oxidation state has attracted great interest.[2] These compounds, which have a nonbonding lone pair of electrons at the aluminum center, are proposed to have singlet, carbene-like character and they exhibit the potential for Lewis base behavior. In 2000, Cowley and co-workers reported the first example of an aluminum(I)–boron donor–acceptor bond, in $[Cp^*Al{\rightarrow}B(C_6F_5)_3]$ ($Cp^* = C_6Me_5$),[3] and one year later a corresponding Al–Al bond in $[Cp^*Al{\rightarrow}Al(C_6F_5)_3]$.[4] In neither of these systems did an aluminum center show both Lewis acid and Lewis base behavior.

The reduction of $[I_2AlL]$ ($L = HC(CMeNAr)_2$; $Ar = 2,6\text{-}iPr_2C_6H_3$) with potassium resulted in the formation of monomeric [LAl] (**1**).[5] This was the first stable two-coordinate aluminum(I) compound to be prepared and structurally characterized in the solid state. The fascinating aspect of **1** is its dual Lewis acid and Lewis base character. Ab initio calculations[6] with analysis of the Laplacian of the electron density[7] within the plane show a geometrically active lone pair of electrons on the aluminum atom with a probable quasi-trigonal-planar orientation of orbitals. This observation clearly indicates that **1** is Lewis basic. Moreover, charge depletion close to the aluminum atom in the semiplane of the six-membered ring indicates that **1** is Lewis acidic. Herein, we report the reaction of [LAl] (**1**) with $B(C_6F_5)_3$ to yield $[LAlB(C_6F_5)_3]$ (**2**), the first aluminum compound displaying both Lewis base and Lewis acid character at the metal center.

The reaction of a 1:1 molar ratio of [LAl] (**1**) and $B(C_6F_5)_3$ in toluene between −78 °C and room temperature resulted in the formation of **2** (Scheme 1). Compound **2** was characterized by ^1H, ^{13}C, ^{11}B, ^{19}F, and ^{27}Al NMR spectroscopy, as well as EI mass spectrometry and elemental analysis. ^1H, ^{13}C, ^{11}B, and ^{19}F NMR spectroscopic analysis was carried out at room temperature in $[D_6]$benzene or $[D_8]$toluene. No resonance signals were observed in the ^{27}Al NMR spectra of **2** in C_6D_6 or C_7D_8; consequently, the measurement was carried out in the solid state. The ^{19}F NMR spectrum of **2** exhibits nine partly overlapping resonances, and therefore an unambiguous assignment is not possible. However, this pattern indicates a distorted $B(C_6F_5)_3$ group caused by an Al–F interaction. The EI mass spectrum shows the molecular ion of **2** (*m*/*z* 956). Single crystals of **2** suitable for X-ray crystallographic analysis were obtained by keeping the hexane solution at room temperature for two weeks.[8] The solid-state structure consists of individual molecules of the Lewis acid/base adduct (Figure 1). An Al–F interaction arises from close intramolecular contact between one of the *ortho* fluorine atoms and the Al atom with the formation of an $AlBC_2F$ five-membered ring (Figure 2). There is a distorted tetrahedral geometry around the aluminum atom, with an average Al–N bond length of 1.892(6) Å. This distance is considerably shorter than the Al–N bonds in **1** (av 1.957(6) Å). This observation is consistent with the partial transfer of the lone pair of electrons on the aluminum center upon formation of the donor–acceptor bond. The Al–B bond in **2** (2.183(3) Å) is slightly longer than that in $[Cp^*Al{-}B(C_6F_5)_3]$ (2.169(2) Å). Also, the geometry of the $B(C_6F_5)_3$ group changes from trigonal planar to distorted tetrahedral in **2**. The extent of the geometrical change has been taken as an indication of the strength of the donor–acceptor interaction.[9] The sum of the C-B-C angles around the boron atom in **2** (330.3(2)°) is the smallest of those (333.5(2)–342.2(2)°) reported for $B(C_6F_5)_3$ compounds.[3,10,11] Thus, **1** appears to be a stronger base than {Cp*Al}. However it must to be considered that the relatively close Al–F contact in **2** (2.156(2) Å) changes the electron density on the aluminum center. The noticeable Al–F interaction is indicated by the lengthening of the C–F bond (1.414(6) Å) relative to the remaining 14 C–F bonds (av 1.355 Å). In addition, the C(41)-B(1)-Al(1) angle is clearly smaller

Selected bond lengths [Å] and angles [°]: Al(1)–B(1) 2.183(5), Al(1)–F(42) 2.156(3), C(42)–F(42) 1.414(4), Al(1)–N(2) 1.885(4), Al(1)–N(1) 1.900(3), C(33)–F(33) 1.371(5); C(41)-B(1)-Al(1) 100.4(3), C(51)-B(1)-Al(1) 115.1(3), C(31)-B(1)-Al(1) 110.1(3), F(42)-Al(1)-B(1) 85.99(15); $\Sigma\sphericalangle$CBC 330.3(2)°.

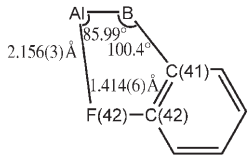

Figure 2. Depiction of Al-B-C(41)-C(42)-F(42) five-membered ring.

(100.4(3)°) than the C_{ipso}-B-Al angles (115.1(3)° and 110.1(3)°) of the two non-interacting perfluorophenyl rings. These data indicate that the lengthening of the C–F bond and the narrowing of the Al-B-C angle are due to the F→Al interaction and are consistent with a F→Al donor–acceptor behavior.

It is evident from the crystallographic data that there is a weak interaction between the aluminum and fluorine F(42) centers. To gain a better understanding of the bonding situation, **2** was examined by means of ab initio calculations. The first and crucial step in these calculations is to reproduce the crystallographic data with a reliable quantum-chemical method. Starting from this structure, the analysis of the molecular orbitals and bond order gives the most accurate picture of the electronic structure.

The calculated structural parameters (Al–F(42) 2.1626 Å, F(42)–C(42) 1.4384 Å, and F(42)-Al-B 85.236°) are in good agreement with the crystallographic data (Figure 1). The bond-order analysis reveals that the electron density of the fluorine atom is distributed between the carbon and aluminum centers with a (Al–F)/(F–C) ratio of 0.2930/0.7148, which indicates that there is a significant interaction between the fluorine and aluminum centers. The consequence of this interaction is the elongation of the C(42)–F(42) bond by 0.075 Å (calcd 1.4385 Å) relative to the other C–F bonds in the same ring (calcd range 1.3633–1.3636 Å). From natural bond order (NBO) analysis,[12] the bond between aluminum and fluorine can be described as the overlap of two hybrid orbitals of sp^n type with one located at Al (16.24% s and 83.76% p) and the other at F(42) (11.56% s and 88.44% p). The bonding orbital located on C(42) has $sp^{2.72}$ character, whereas the remaining carbon atoms in this ring have $sp^{2.22}$ character. This situation is also clearly visible in the corresponding orbital picture. Figure 3 shows the contour plots of two orbitals contributing to the formation of the Al–F bond.

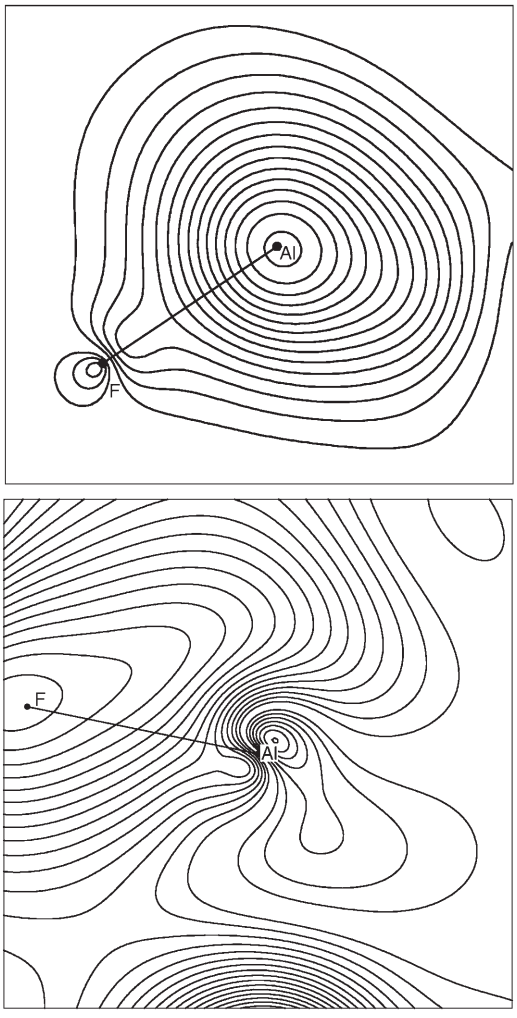

Figure 3. Schematic representation of the Al–F linkage resulting from the overlap of wave functions centered on aluminum and fluorine. The two relevant orbitals are shown here as contour plots. The clearly visible deformation in the second plot is due to the fact that there is a strong interaction with orbitals forming the Al–N bonds.

In conclusion, we have prepared $[LAlB(C_6F_5)_3]$, a unique compound of aluminum showing Lewis base and Lewis acid character at the aluminum center. There are no known precedents of this type of bonding in the literature.

Experimental Section

All manipulations were performed under a dry, oxygen-free atmosphere (N_2 or Ar) by using Schlenk and glove-box techniques.

2: Toluene (20 mL) was added to a mixture of **1** (0.223 g, 0.5 mmol) and $B(C_6F_5)_3$ (0.256 g, 0.5 mmol) at −78 °C. The mixture was stirred and slowly warmed to room temperature. After stirring the mixture for an additional 15 h, the solvent was removed under reduced pressure, and the solution was treated with hexane (30 mL). The solution was filtered and allowed to stand for two weeks at room temperature to afford colorless crystals of **2**. Yield: 0.09 g (19 %); m.p. 208–209 °C; EI-MS: *m/z* (%) 956 (10) [M^+], 403 (100) [L−Me]; ^{1}H NMR (300.13 MHz, C_6D_6): $\delta = 6.80$–6.75 (m, 6H, Ar-H), 4.91 (s, 1H, γ-H), 2.80 (sept, $^3J_{H,H} = 6.8$ Hz, 4H, C*H*Me$_2$), 1.61 (s, 6H, Me), 1.15 (d, $^3J_{H,H} = 6.8$ Hz, 12H, CH*Me*$_2$), 0.87 ppm (d, $^3J_{H,H} = 6.8$ Hz, 12H, CH*Me*$_2$); ^{13}C NMR (75.48 MHz, C_6D_6): $\delta = 173.33$ (CN), 142.75, 139.49, 129.27, 124.76 (Ar), 150.25, 147.13, 140.75, 138.63, 137.38, 134.95 (br, C_6F_5), 102.07 (γ-C), 24.53, 25.09(CH*Me*$_2$), 22.68 (CH*Me*$_2$), 20.74 ppm (Me). ^{11}B NMR (95.29 MHz, C_6D_6): $\delta = -26.52$ ppm; ^{19}F NMR (188.28 MHz, C_7D_8) $\delta = -124.28$ (br m), −128.26 (br m), −129.97 (d), −154.41 (t), −156.49 (br m), −157.27 (t), −158.86 (br m), −160.24 (t), −160.99 ppm (t); ^{27}Al NMR (400 MHz, 16 KHz, MAS, $AlCl_3$): $\delta = 0$–50 ppm; elemental analysis (%) calcd for $C_{47}H_{41}AlBF_{15}N_2$ ($M_r = 956.61$): C 59.01, H 4.32, N 2.93; found: C 58.66, H 4.67, N 2.70.

Details of ab initio calculations: The well-established B3LYP[13,14] method was employed for all the ab initio calculations because of the size of the system. Two different basis sets were used for the computations: a small one as the 3-21G basis set, and an extended one in which the aluminum atoms are described with functions taken from the 631-G basis set including double-diffuse functions.[15,16] The Gaussian G03[17] program suite was used to optimize the structure with the 3-21G basis first, and this structure was used as the starting geometry for a further optimization with the larger basis set to give an appropriate description of the aluminum atom and its binding situation. The resulting structure was used for visualization of the orbitals. The nature of the quantum-chemical method results in a wave function that produces molecular orbitals involving nearly every atom. Therefore, this method leads to a picture that, despite being mathematically correct, is difficult to interpret. A more descriptive picture is obtained by localizing the orbitals at those atoms according to the Boys Method.[18] Quantitative data about the bond between Al and F(42) was obtained by analyzing the bond order following a proposal of I. Mayer.[19]

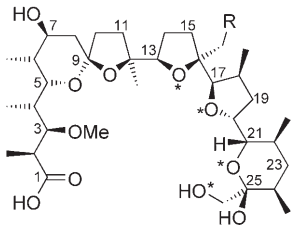
Accumulation of an *E*,*E*,*E*-Triene by the Monensin-Producing Polyketide Synthase when Oxidative Cyclization is Blocked**

*Apoorva Bhatt, Christian B. W. Stark, Barbara M. Harvey, Andrew R. Gallimore, Yuliya A. Demydchuk, Jonathan B. Spencer, James Staunton, and Peter F. Leadlay**

Monensin A (**1a**) from *Streptomyces cinnamonensis* is an antibiotic ionophore[1] widely used in veterinary medicine and in animal husbandry (Scheme 1). It is one of the most important and best-studied members of a large family of structurally related polyketide secondary metabolites, the ionophoric polyethers, which are attracting renewed interest for their activity against drug-resistant strains of malaria.[2] As with all natural polyethers, the molecule contains a multiplicity of asymmetric centers, but only one stereoisomer (out of a possible 2^{17}) is produced by *S. cinnamonensis*. The molecular basis for this exquisite stereocontrol is not known, and even the nature of the intermediates in polyether biosynthesis remains obscure. Early feeding studies established that monensin A (**1a**) is derived by a classic polyketide pathway from five acetate, one butyrate, and seven propionate units[3] and that oxygen atoms at C1, C3, C5, C7, C9, and C25 arise from the carboxylate oxygen atoms of the corresponding carboxylic acid precursor units, whereas the remaining oxygen atoms at C13, C17, C21, and C26 are derived from molecular oxygen.[4] On this basis, the "cascade" mechanism shown in Scheme 2a was proposed for the key oxidative steps.[4b] This mechanism involves the intermediacy of the linear *E*,*E*,*E*-triene **2** and of the triepoxide **3** as enzyme-free intermediates. However, it has proved difficult to obtain direct experimental support for this mechanism, and in particular, a synthetic sample of the full-length putative linear *E*,*E*,*E*-triene precursor **2** was found not to be incorporated into monensin A by *S. cinnamonensis*.[5] The configuration of the double bonds in a putative linear precursor of monensin, as well as the mode of oxidative cyclization, therefore, remained undefined, and alternative pathways for oxidative cyclization[6] that involved either a *Z*,*Z*,*Z* triene[6d,e] or a *E*,*Z*,*Z* triene[6f] have been subsequently proposed (Scheme 2b).



1a: R = CH_3
1b: R = H

Scheme 1. The polyether ionophores monensin A (**1a**) and monensin B (**1b**). Oxygen atoms arising from molecular oxygen are denoted by *.

The recent total sequencing of gene clusters for the biosynthesis of monensin[6f,7] and of nanchangmycin[8] revealed, in each case, large open reading frames (ORFs) encoding a modular polyketide synthase (PKS) with the anticipated number of extension modules consistent with the production of a linear "pre-polyether" polyketide chain of the requisite length. Complete deletion of the gene cluster from *S. cinnamonensis* resulted in loss of monensin production, thus confirming its role in monensin biosynthesis.[7] Each cluster contains numerous other genes, in particular four ORFs which, on the basis of database comparisons, appear to relate to the unusual oxidative cyclizations that are required to produce the polycyclic product.[6f,7] Thus, the monensin-producing cluster contains an epoxidase gene (*monCI*), a gene with apparent similarity to an epoxide-opening enzyme (*monCII*), and two mutually homologous genes (*monBI* and *monBII*) with apparent similarity to the Δ^5-3-ketosteroid isomerase of *Comamonas testosteroni* and which were considered initially to possibly function as *cis–trans* isomerases.[6f,7] Further proof that MonCI was an epoxidase was obtained when a *Streptomyces coelicolor* strain that overexpressed monCI converted the unsaturated terpene (±)-linalool into linalool oxide at levels 10–20-fold higher than a control strain.[7] Subsequently, it proved possible to interrupt polyketide-chain synthesis by genetically relocating a chain-terminating thioesterase (TE)/cyclase domain, obtained from the modular PKS that governs the biosynthesis of the macrolide erythromycin A in *Saccharopolyspora erythraea*,[9] to downstream of extension module four of the monensin PKS. In the pentaketide released by this recombi-

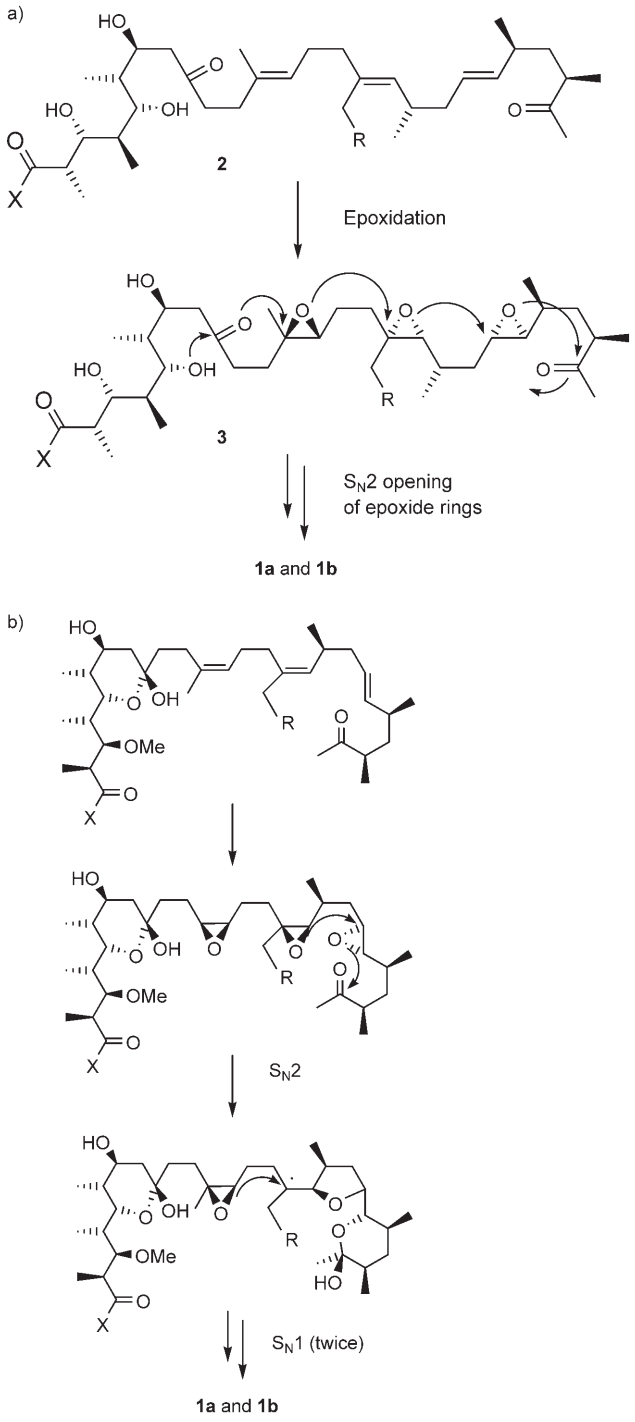

Scheme 2. Alternative mechanisms for oxidative cyclization to produce monensins A and B. a) A polyepoxide cyclization cascade that starts from an *E*,*E*,*E* triene[6b]; b) a polyepoxide cyclization cascade starting from an *E*,*Z*,*Z* triene[6f] **3**. X = OH, SCoA, or S-protein.

nant strain, the configuration of the disubstituted double bond was unequivocally shown to be *E*,[10] which weighed in favor of **2** as an intermediate[6b] or a variant of **2** in which the other bonds are *Z*,[6g] but ruled out the mechanistic proposal of Townsend and Basak.[6d] Based on these results, we reasoned that if *monCI* were indeed the sole initiator of oxidative cyclization in monensin biosynthesis then the deletion of this single gene in *S. cinnamonensis* ought to allow the accumulation of a linear molecule, such as **2** (or perhaps of a shunt product derived from such a compound) whose structural characterization might reveal the likely pathway for cyclization, thus allowing discrimination between the mechanistic proposals of Scheme 2.

Deletion of *monCI*, which encodes the putative flavin-dependent epoxidase from the monensin cluster, was accomplished by homologous recombination into wild-type *S. cinnamonensis* through two successive single crossover events, thus leading to replacement by a hygromycin resistance gene.[11a] Correct integration into the chromosome was proved for the mutant strain ABΔCI by Southern hybridization. Further confirmation of its identity was provided by complemention with the cloned gene borne on an expression plasmid (see the Supporting Information) which restored monensin production (data not shown). By further engineering of the *monCI*-deleted strain so that it also contained an in-frame deletion in *monBI*, the additional blocked mutant ABΔCIΔBI was obtained. Further mutants with insertional inactivation of both of the adjacent genes[6f,7] *monCI* and *monBII* (BHΔCIBII) and of all three genes *monCI, monBII*, and *monBI* (BHΔCIBIBII) were created in the same way as for the strain ABΔCI.

Neither monensin A (**1a**) nor monensin B (**1b**) was produced by any of these mutants, as judged by HPLC–mass-spectrometric analysis of the crude extracts.[11a] The analyte from the ABΔCI strain showed a major peak that corresponds to the predicted mass of **4a**, (Scheme 3) a triene lactone that differs only from **2** by the presence of a δ-lactone structure.[11a] A second smaller peak had the predicted mass of a similar triene lactone **4b** that lacks a methylene moiety, thus corresponding to the mass difference between **1a** and **1b**. To confirm the structure and the configuration of **4a** and **4b**, a culture of mutant ABΔCI (7 L) was grown under standard conditions,[6f,11a] and the crude extract of the supernatant was purified by column chromatography on silica gel, which yielded 1.4 mg of **4** and 1.2 mg of **5**. Detailed NMR spectroscopic analysis of these lactones[5,11] proved unequivocally that all the double bonds were *E* configured, that is, the structures of **4a** and **4b** as shown. The 1D NMR spectra collected were similar to that reported by Robinson and coworkers for the synthetic *N*-acylcysteamine thioester of a *E*,*E*,*E* triene.[5] The disubstituted double bond between H20 and H21 was assigned from the coupling constant of $J =$ 15.3 Hz for the double-bond protons, which is indicative of a *trans* double bond as confirmed by NOE interaction studies between H22 and H20 and between H21 and H19 (Scheme 4).[11a] The NOESY NMR spectrum[11a] shows an interaction between H17 of a trisubstituted double bond and H15, whereas no interactions are seen between H17 and H16′ or H16″, thus showing the double bond to be *E* configured. Similarly the NOE interaction observed for H13 with H11 but not with H12′, also confirms an *E* configuration. No evidence was obtained in these analyses for the presence of an oxidized derivative of either **4a** or **4b**, which suggests (although it does not prove) that the epoxidase encoded by *monCI* is necessary and sufficient for the epoxidation of all three double bonds in

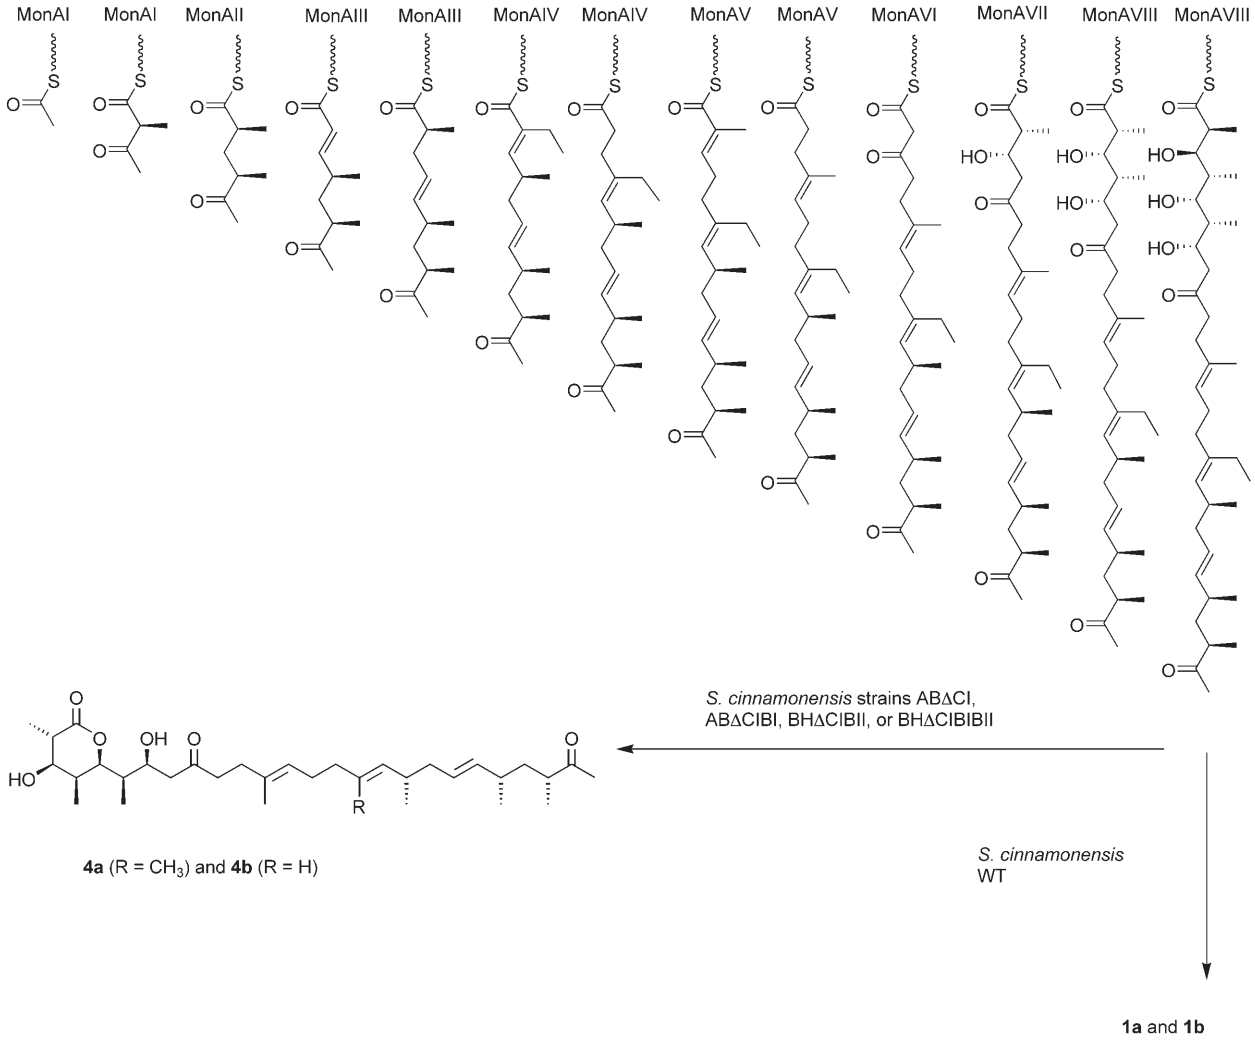
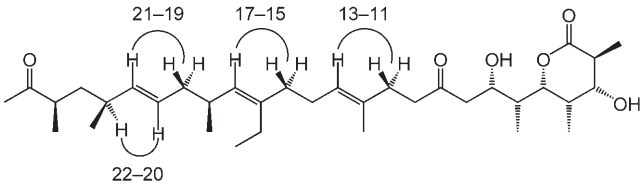


Scheme 3. The monensin PKS, which consists of a loading module and 12 extension modules distributed across eight multienzymes (MonAI–MonAVIII), produces *E*,*E*,*E*-trienes **4a** and **4b** when gene *monCI* is deleted, irrespective of whether additional genes *monBI* and *monBII* are also deleted. WT = wild type.



Scheme 4. The critical NOE interactions for the assignment of the double-bond geometry in lactone **4a** as the *E*,*E*,*E* isomer.

the linear intermediate to form **1**. This remarkable transformation is apparently catalyzed at all three target double bonds with complete stereoselectivity and stereospecificity. There is no effect of additional mutations in one or other or both of the *monB* genes.[11a] The MonB gene products were considered initially, given their significant sequence similarity to the δ-5(3)-ketosteroid isomerase of *C. testosteroni*,[6f,7] to be involved in the alteration of the geometry of two of the double bonds in the triene intermediate at the point during polyketide-chain growth at which they are activated by conjugation with the thioester that links the growing polyketide chain to the PKS multienzyme. As **4a** and **4b** are likely to be shunt metabolites rather than true intermediates in the biosynthetic pathway, such a role is not completely excluded, but the fact that no isomer of **4a** or **4b** with an altered geometry about the double bonds was found undermines such a hypothesis (see also below).

These results taken together confirm that *monCI* is essential for monensin biosynthesis, indicate directly that the all-*E* configuration of **4a** and **4b** is derived from intermediates in monensin biosynthesis, and that these *E* configured double bonds are the targets for the epoxidase MonCI that initiates oxidative cyclization.[6f,7] These results are more consistent with the original proposal of Cane et al.[6b] (Scheme 2a) than with the modification of this proposal in which trisubstituted double bonds are isomerized before epoxidation (Scheme 2b).[6f] Consequently, fresh questions are posed as to the true role of the MonB proteins and their

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

counterparts in nanchangmycin biosynthesis, which are found fused head to tail as the product of the single gene *nanI*.[8] Evidence that they play a role in epoxide ring opening will be presented separately.[13] The stage is set for dissection of the respective contributions of these and the other "post-PKS" enzymes to the stereocontrol of polyether biosynthesis. In addition, the successful isolation of novel polyketides **4a** and **4b** underscores the potential of the targeted engineering of polyketide biosynthetic pathways to produce novel stereochemically rich molecules that profoundly differ in structure from the parent molecule. In the present case, **4a** and **4b** are not expected to have ionophoric properties; intriguingly, their structures more closely resemble δ lactones isolated from a number of marine organisms, such as the potent antitumor compounds discodermolide[13] and callystatin.[14] It may be that the elusive PKSs for such marine polyketides are actually closely related to those for ionophoric polyethers.

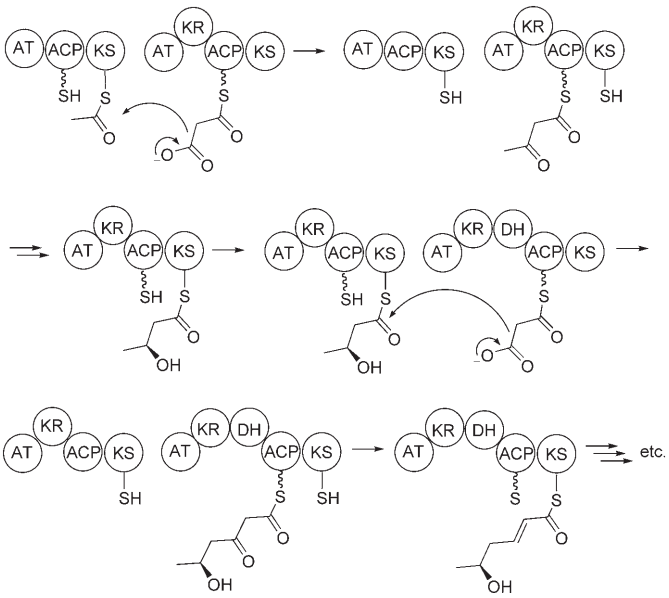
A Method for Trapping Intermediates of Polyketide Biosynthesis with a Nonhydrolyzable Malonyl-Coenzyme A Analogue**

*Dieter Spiteller, Claire L. Waterman, and Jonathan B. Spencer**

There are currently about 10000 natural products that have been classified as polyketides. Their structures range from simple molecules, such as 6-methylsalicylic acid,[1] to complex natural products, such as brevetoxin.[2] Polyketides are an invaluable source of bioactive compounds with many being clinically important, for example, the antibiotic erythromycin and the immunosupressant rapamycin.[3] Despite their diversity, all polyketides share a common biosynthetic pathway; a starter unit, which is normally acetyl coenzyme A (CoA), undergoes sequential condensation with an extender unit (usually malonyl or (*S*)-methylmalonyl-CoA) in a similar manner to fatty acid biosynthesis. However, unlike fatty acid biosynthesis, the carbonyl group is not always completely reduced after each condensation, which partly accounts for the huge variety of polyketide structures (Scheme 1).[3]

Experiments with labeled precursors, in combination with mechanistic considerations, have been extensively used to investigate the details of polyketide biosynthesis.[1,3] However, it has proven very difficult to isolate intermediates directly as they are covalently attached to the polyketide synthases (PKSs).[3] One approach that has been possible with the cloning and sequencing of genes for many PKSs[4] is to design mutants that halt the biosynthesis at a desired point. For instance, by genetically engineering the fusion of the thioesterase from the third subunit of the deoxyerythronolide synthase onto the first subunit, deoxyerythronolide biosynthesis was stopped after two rounds of (*S*)-methylmalonyl-CoA condensations and the intermediate removed in sufficient quantity to be fully characterized.[5] Whereas this strategy has potential with all type I modular PKSs, it is very limited when applied to type I iterative, type II, and type III PKSs, as the same catalytic activities are usually used repeatedly. For example, if a mutation is made in the ketosynthase, polyketide synthesis could not occur at all. To address this point, we sought to develop a chemical approach that used a non-hydrolyzable malonyl-CoA analogue which can potentially trap polyketide intermediates from these classes of PKSs.



Scheme 1. Schematic diagram of the mechanism of two rounds of polyketide biosynthesis by a polyketide synthase (AT: acyl transferase, KS: ketosynthase, ACP: acyl carrier protein, DH: dehydratase, KR: ketoreductase). In type III polyketide synthases, such as the stilbene synthase from *Pinus sylvestris*, malonyl-CoA is used directly for the elongation instead of the corresponding ACPs.

Analogues of coenzyme A[6–8] have been used previously to investigate a range of enzyme reaction mechanisms, such as the condensation of acetyl-CoA with oxaloacetate catalyzed by citrate synthase[7] and the enzymic carboxylation of acetyl-CoA by acetyl-CoA carboxylase.[9] However, malonyl-CoA analogues have never been used before to investigate the biosynthesis of polyketides. In our strategy, the malonyl-CoA analogue would react with the growing polyketide chain but would not be able to undergo transesterification back onto the PKS resulting in the accumulation of polyketide intermediates attached to the analogue (Scheme 2a).

The analogue of malonyl-CoA **3** used in this study contains an additional methylene unit between the thiol of the coenzyme A and the malonate moiety. This methylene unit could possibly be detrimental to the correct positioning of the analogue at the active site of a PKS, as the malonyl moiety is displaced by one carbon atom. However, we felt that this potential disadvantage was out-weighed by the straightforward preparation of **3** in two steps. Commercially available ethyl 4-chloro-3-oxobutanoate (**1**) was treated with coenzyme A in aqueous 0.11M Li_2CO_3.[7,8] After purification with

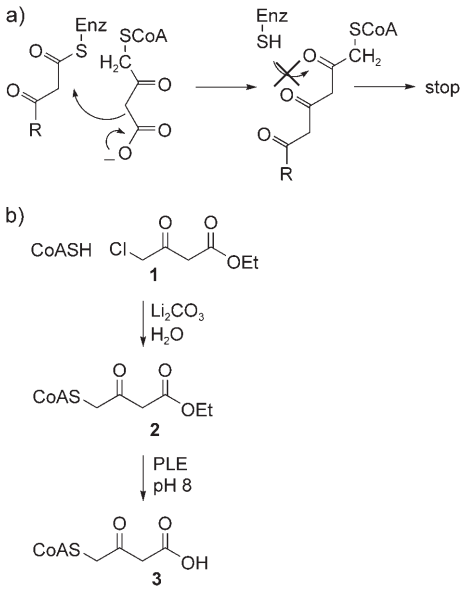


Scheme 2. a) Trapping intermediates of polyketide biosynthesis with a malonyl-CoA analogue **3**; b) synthesis of **3**. Enz = enzyme.

RP-18 HPLC, the ethyl ester **2** was hydrolyzed to **3** with pig liver esterase (PLE; Scheme 2b).[10] As anticipated, **3** was found to undergo decarboxylation more readily than malonyl-CoA (**4**) during purification, therefore it was used directly after precipitation of the PLE.

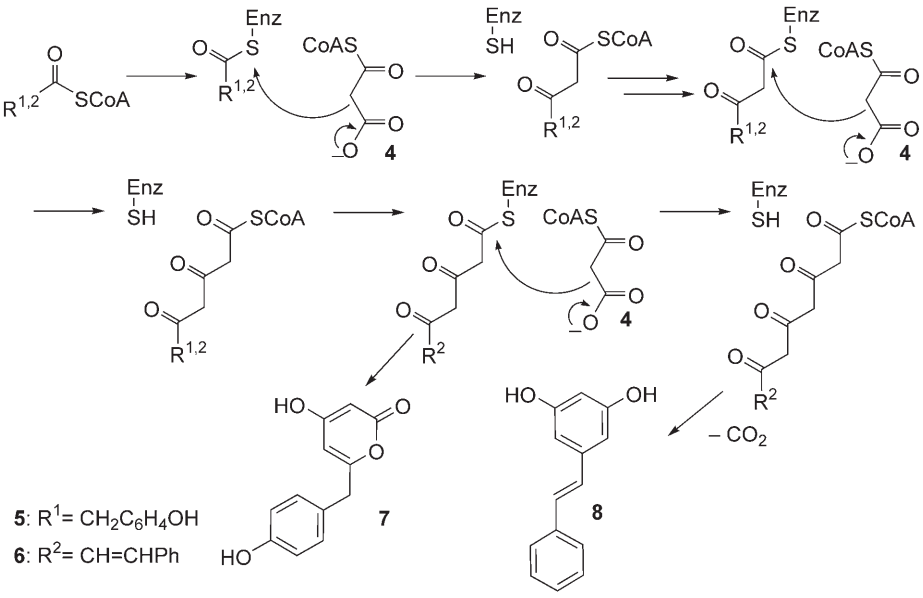
The potential of **3** to trap intermediates of polyketide biosynthesis was investigated with the type III PKS stilbene synthase (STS) from *Pinus sylvestris*[11,12] as a model system. This class of PKS is the simplest to investigate this approach with as it uses **4** directly, in contrast to type I and II PKSs that carry out condensations with malonyl acid carrier proteins (ACPs).[3] STS has a broad substrate specificity with regard to the starter unit, thus producing a number of stilbene and pyrone products.[13] If cinnamoyl-CoA (**6**) is used as the starter unit, the enzyme catalyzes its sequential condensation with three molecules of **4** to form the stilbene pinosylvin (**8**),[12] and with 4-hydroxyphenylacetyl-CoA (**5**), only two condensations with **4** occur to give the pyrone **7** (see Scheme 3).

For our initial experiments, **5** was used as a starter unit and the ratio of **3** to **4** was varied. Formation of the products was followed by LC-MS, and across a range of conditions (a ratio of 3:4 of **3**/**4** was found to give the highest yield) we observed ions at *m*/*z* 958 and 1000 that correspond to one and two condensation steps, in addition to the ion at *m*/*z* 219 for the normal pyrone product **7** (Figure 1).

Interestingly, we also observed the ions at *m*/*z* 958 and 1000 at very low levels in the control samples without the addition of the enzyme. Although not totally unexpected, to our knowledge, the non-enzymic formation of polyketides from malonyl-CoA has not been previously reported.

Several closely eluting peaks, all exhibiting *m*/*z* 1000, were observed in some LC-MS traces of **10** instead of a single one, thus suggesting the presence of isomers of **10** probably formed by enolization and/or cyclization.

The MS/MS spectrum of both intermediates that exhibit ($[M+H]^+$) peaks at *m*/*z* 958 and 1000 showed characteristic fragments for the presence of coenzyme A derivatives (see Figure 2 and the Supporting Information). In the case of the triketide intermediate **10**, the fragments at *m*/*z* 591 and 428 are characteristic for the cleavage of the phosphodiester bond of the coenzyme A unit of the molecule (Figure 2). Furthermore, a fragment at *m*/*z* 493 was also observed that corresponds to loss of the 3′-phospho adenosine diphosphate moiety from the alkyl chain. The observed fragmentation pattern for the intermediates of *m*/*z* 958 and 1000 is in agreement with a study of the MS/MS fragmentation of other coenzyme A derivatives by Burns et al.[14]



Scheme 3. Formation of the pyrone-type and stilbene-type products **7** and **8**, respectively, by stilbene synthase from *Pinus sylvestris* using either **5** or **6** as the starter unit and **4** for chain elongation.

To provide further evidence for the isolation of these intermediates, assays were carried out with [$^{13}C_3$]malonyl-CoA.[15] The incorporation of the labeled substrate should shift the mass of the $[M+H]^+$ ion to 1002 amu in the case of **10**, as one molecule of [$^{13}C_3$]malonyl-CoA is utilized in its formation. Figure 2 clearly shows that the MS/MS spectra complement and confirm the MS/MS spectra of the unlabeled assay. All signals at *m*/*z* 1002, 984, 593, 575, 495, and 477, which contain the polyketide chain in their fragments, are shifted by 2 amu, whereas the signals at *m*/*z* 428 and 410, which correspond to the 3′-phospho adenosine diphosphate moiety, remained unchanged.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

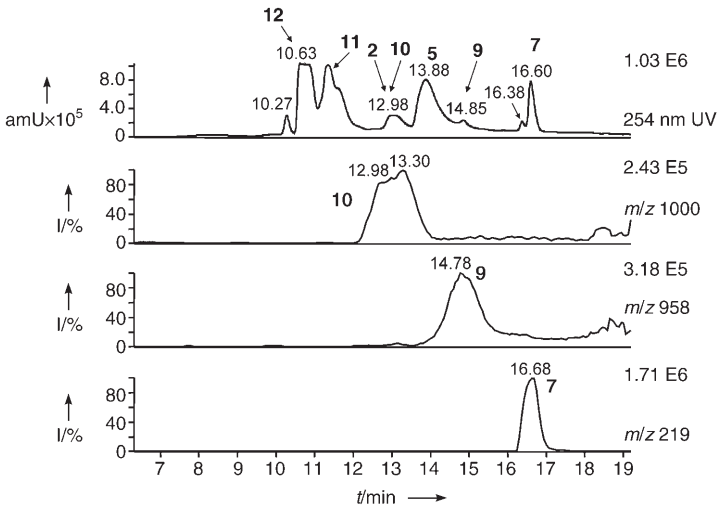


Figure 1. UV chromatogram and ion traces *m/z* 219, 958, and 1000 observed after the reaction of the stilbene synthase with **5** and **4** in presence of **3.** Peaks: Coenzyme A (**12**); decarboxylated malonyl-CoA analogue **11**; ethylmalonyl-CoA analogue **2**; STS intermediate formed from two condensations condensations **10**; 4-hydroxyphenylacetyl-CoA **5**; STS intermediate formed from one condensation **9**; 4-hydroxyphenylacetylpyrone (**7**).

These results show that the malonyl-CoA analogue **3** can be successfully used to trap the growing polyketide chain. It is also interesting that the tetraketide is not observed. This result indicates that the triketide formed from the starter unit and two malonyl-CoA molecules either rapidly cyclizes to the observed pyrone **7** or is not readily transferred back onto the STS after the final condensation.

To see if longer intermediates could be trapped, we used **6** as starter unit because the favored product in this case is the stilbene **8** formed from the tetraketide intermediate. Therefore, the addition of **3** to the assay could trap three different intermediates during the stilbene formation. However, no intermediates were detected above the background levels under a range of conditions. It is possible that the positioning of the analogue in the active site of the STS is better matched with **5** as a starter unit because it has one less carbon atom than **6** and **3** has one more carbon atom than **4**. This observation indicates that the positioning of the growing polyketide chain bound to the active-site cysteine unit is strongly influenced by the structure of the starter unit. A smaller starter unit may allow the necessary flexibility in the active site for the analogue to be able to be correctly positioned and react.

In summary, we have shown for the first time that intermediates of polyketide biosynthesis can be trapped for detailed analytical studies with a non-hydrolyzable malonyl-CoA analogue. This finding potentially opens the way to the determination of the timing of crucial events, such as cyclization of the polyketone chain. It is highly likely that the analogue can be transferred to ACPs with Sfp, a phosphopantetheinyl transferase from *Bacillus subtilis*, as this enzyme has been shown to have a wide substrate specificity.[16]

This approach should allow type I and II PKSs to be investigated. Experiments to apply this concept to other polyketide synthases and the synthesis of alternative analogues that may be better steric matches for malonyl-CoA are currently under investigation.

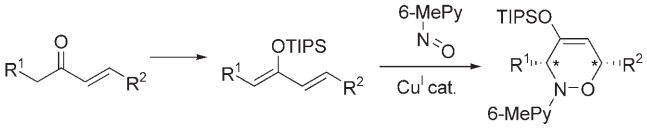
Catalytic Asymmetric Nitroso-Diels–Alder Reaction with Acyclic Dienes**

*Yuhei Yamamoto and Hisashi Yamamoto**

The nitroso-Diels–Alder reaction has long been a valuable synthetic operation for multistep syntheses given that the resulting adducts serve as 1-amino-4-hydroxy-2-ene derivatives after a single step. Subsequent to earlier studies by Kresze and co-workers[1] on the use of simple nitroso derivatives, many research groups have made significant contributions to the steady improvement of this methodology.[2] Recently, we enhanced this transformation to catalytic and enantioselective methods through the use of nitrosopyridine as a dienophile in the presence of a chiral copper catalyst.[3] Unfortunately, the new asymmetric reaction did not proceed as smoothly for acyclic dienes as it did for cyclic systems, which therefore limits its range of application. Herein, we report catalytic regio-, diastereo-, and enantioselective nitroso-Diels–Alder reactions of acyclic 2-silyloxy-1,3-dienes that have a broad substrate scope. The pathway for the present catalytic enantioselective transformation is outlined in Scheme 1.



Scheme 1. The present pathway for the catalytic enantioselective transformation of acyclic 2-silyloxy-1,3-dienes. TIPS = triisopropylsilyl, Py = pyridine.

The nitroso-Diels–Alder reaction of pentadiene and 6-methyl-2-nitrosopyridine in the presence of $[Cu(MeCN)_4(segphos)]PF_6$ gave a mixture of 1- and 4-amino derivatives in a 3:1 ratio with up to 10% *ee*. The reactivity of the diene was increased, and (2*Z*,4*E*)-3-trimethylsilyloxy-2,4-hexadiene[4] (**1a**) was examined in the presence of a catalytic amount of

$[Cu(MeCN)_4(segphos)]PF_6$. Although this experiment gave complete regioselectivity[5] (4-silyloxy/5-silyloxy ≥ 99:1), the enantioselectivity (16% *ee* for the 4-silyloxy derivative) remained low. Surprisingly, the low enantioselectivity was improved significantly by simply increasing the size of the silyl group (**1a**γ**1b**γ**1c**): Up to 98% *ee* in the presence of Cu^I–segphos[6] and >99% *ee* with $[Cu(MeCN)_4(difluorophos)]PF_6$[7] were attained in the reaction of the triisopropylsilyl derivative **1c** (Table 1).

The applicability of this reaction was demonstrated for the functionalized dienes **1c–m** (summarized in Table 2). All of the reactions proceeded in high yields and enantioselectivities, with complete regio- and diastereoselectivities. The dialkyl-substituted dienes generally gave high enantioselectivities (Table 2, entries 1–3 and 11). Interestingly, reactions with trienes proceeded in a completely regioselective manner and provided only a single regioisomer (Table 2, entries 4 and 5).[8] Phenyl-substituted alkenes (R^2 = Ph) gave a relatively lower enantioselectivity (Table 2, entries 6 and 10), whereas methoxyphenyl derivitive **1i** and heteroaromatic **1j** gave high enantioselectivities (Table 2, entries 7, 8). Lewis basic substituents such as protected alcohols (Table 2, entry 3) and ester functional groups (Table 2, entries 10 and 11) were also used in the reaction and gave highly functionalized products enantioselectively.

Table 2: Reaction with various dienes.[a]

[a] The reaction was conducted with catalyst (10 mol%), nitrosopyridine (1 equiv), and silyloxydiene (1.4 equiv) in a N_2 atmosphere at −85 °C and gradually warmed to −20 °C over 5 h. [b] The *ee* values were determined by HPLC (Supporting Information). TMS = trimethylsilyl.

The products **3c–m** can be cleanly converted into the respective protected amino alcohol. For example, after hydrolysis of the silyl enol ether **3c** by TBAF/AcOH, reduction of the ketone gave the corresponding alcohol **6** as a single diastereomer.[8] Further transformations then gave the protected amino alcohol with a defined configuration that is found in several important natural products (Scheme 2).[9]

The absolute and relative configurations of the nitroso-Diels–Alder adducts were assigned by X-ray crystallographic analysis. Compound **8** was prepared under the standard reaction conditions discussed above, then further transformed into the 3,5-dinitrobenzoic acid ester **9**, which was crystallized from Et_2O (Scheme 3, Figure 1).[8]

The absolute stereochemical course of the reaction was found to be in accordance with the mechanistic model we previously reported (Scheme 4).[3] This model strongly supports the importance of the pyridine moiety in the formation of a highly organized chelating intermediate during the reaction. Such an effect could not be expected for nitrosobenzene.[2i]

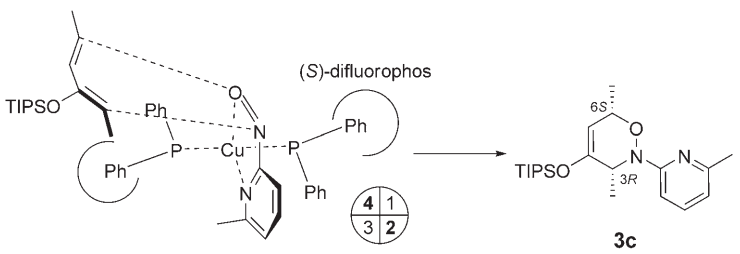
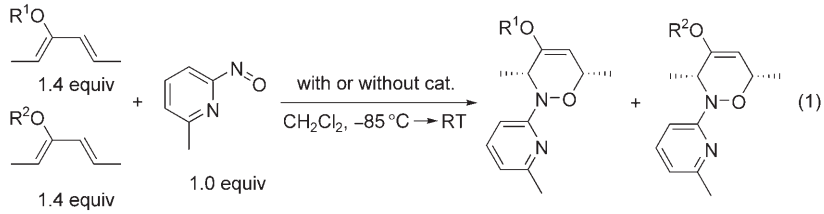
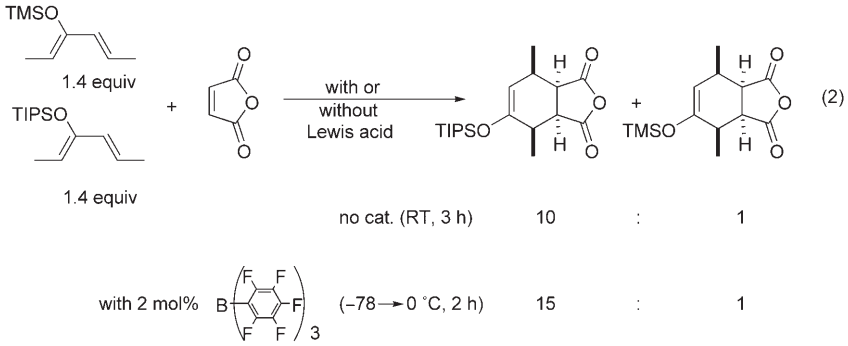


Scheme 4. Model for a plausible chelate intermediate.

The acyclic nitroso-Diels–Alder reaction proceeds exceedingly smoothly with TIPS derivatives, but rather slowly with TMS ethers, a fact that is of great mechanistic interest. 6-Methyl-2-nitrosopyridine (1 equiv) was treated with a 1:1 mixture of two silyloxydienes (1.4 equiv each) in competitive experiments with and without the use of a copper catalyst [Eq. (1)]. The OTIPS diene was clearly shown to be far more reactive than the OTMS or OTBS dienes.[10,11] A similar trend of differences in reactivity was observed for the Diels–Alder reaction of maleic anhydride with and without Lewis acid catalysis [Eq. (2)].

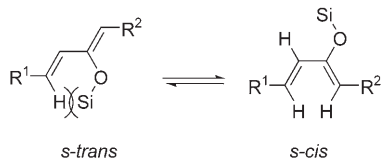


R^1 = TIPS, R^2 = TMS			
no catalysis	>99	:	<1
with $[Cu(MeCN)_4]PF_6$/difluorophos	>99 (99% *ee*)	:	<1
R^1 = TIPS, R^2 = TBS			
no catalysis	3	:	1
with $[Cu(MeCN)_4]PF_6$/difluorophos	11 (99% *ee*)	:	1



no cat. (RT, 3 h)	10	:	1
with 2 mol% (–78 → 0 °C, 2 h)	15	:	1

The above reactions provide strong evidence that the high reactivity arises from the bulk of the TIPS group, which forces the diene to adopt an *s-cis* configuration in favor of the concerted [4+2] cycloaddition reaction [Eq. (3)].[12] A large



NOE interaction (10.7%) was observed between H1 and H4 of the OTIPS diene, whereas no significant NOE interaction was observed for the OTMS diene.[13] The difference in

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

reactivity between Me_3Si and iPr_3Si can also be attributed to the exceedingly rapid copper-catalyzed nitroso-Diels–Alder reaction.

In summary, we have developed a highly practical and promising method for the regio-, diastereo-, and enantioselective introduction of oxygen and nitrogen groups into simple acyclic unsaturated ketones.

Nickel-Foam-Supported Reticular CoO–Li_2O Composite Anode Materials for Lithium Ion Batteries**

Yan Yu, Chun-Hua Chen, Jiang-Lan Shui, and Song Xie*

Since the early 1990s[1] people everywhere have been enjoying the great convenience brought about in daily life through the use of rechargeable lithium-ion batteries (LIBs): Modern portable consumer electronics such as laptops, cellular phones, camcorders, and MP3 players are mostly powered by LIBs. Compared with other battery systems, LIBs show the advantages of high energy density, long cycle and shelf life, and no memory effect. The search for better electrode materials has been the most dynamic motivation behind the research and development of lithium-ion batteries.[2–10] Graphite is the state-of-the-art anode material with a specific capacity of 320–340 $mA\,h\,g^{-1}$ (theoretically 372 $mA\,h\,g^{-1}$).[11,12] Transition metal oxides such as CoO and Cu_2O represent a new class of anode material with significantly higher capacities up to 800 $mA\,h\,g^{-1}$.[5,7,13–15] However, such a high capacity can only be achieved with the help of

carbon additives, and is accompanied by a large irreversible capacity loss of up to 30%. Graphite-based composite electrodes that are modified with metal oxides (for example, SnO, CuO, and NiO) have displayed increased first-cycle lithiation capacity, but with even greater capacity loss.[16–18]

Here we present a new carbon-free anode, that is, CoO–Li_2O composite films, prepared by the electrostatic spray deposition (ESD) technique.[19–21] The structure of the films is controlled as a novel reticular morphology supported on a conducting nickel-foam substrate. This new composite electrode has an initial capacity loss of only 16.4% and 13% at 0.2C and 1C cycling rates, respectively, and yet retains a very high capacity (up to 877 mA h g^{-1} at a 0.2C rate) and excellent rate capability.

The first novelty of our study is the use of a very porous nickel-foam substrate (Figure 1a) rather than a conventional dense metal foil (for example, copper) as the current

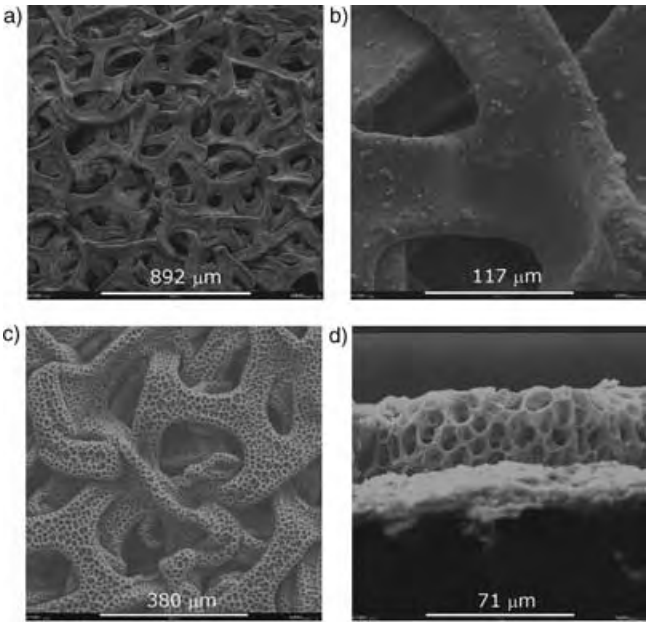

Figure 1. SEM images of the substrate and the CoO–Li_2O thin films. a) The porous nickel-foam substrate; b) surface morphology of a dense film from nitrate precursors; c) surface morphology of a reticular film from acetate precursors; d) cross-section of the reticular film from c). See the Experimental Section.

collector. This change results in maximization of the contact area between the electrode and the electrolyte. Similar to the well-established results obtained with a dense substrate,[19] depending on whether nitrates or acetates are used as the precursors, dense (Figure 1b) or reticular films (Figure 1c) are formed. The thickness of the reticular film is about 30 μm (Figure 1d). The formation of film textures that show a very high degree of conformity to the substrates represents an advantage of the ESD technique. It results from a preferential landing mechanism in ESD, that is, the charged droplets of a precursor solution may "land" preferentially on the conducting parts of a substrate and become discharged there.

Except for the diffraction peaks from the nickel substrate, no other peaks can be discerned from the X-ray diffraction patterns (not shown). However, the X-ray diffraction patterns of the as-deposited films prepared under the same conditions but on an aluminum-foil substrate (lighter than nickel) clearly show the diffraction peaks from CoO in addition to those from the aluminum substrate (Figure 2). Nevertheless, the weak and broad CoO peaks indicate that the CoO in the films

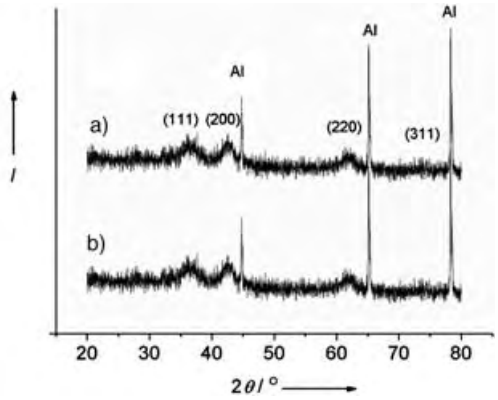

Figure 2. The X-ray diffraction patterns of the CoO–Li_2O thin films deposited on the aluminum substrate at 235 °C in air. a) Dense film; b) reticular film. The diffraction peaks from CoO are indexed in the patterns. I = intensity.

must be nanocrystalline or even amorphous. No peak is seen for any lithium compound, suggesting that the lithium product, which can be reasonably believed to be Li_2O formed at 235 °C, is amorphous. Therefore, the film is a CoO–Li_2O composite. The introduction of Li_2O, which alone is usually thought as an inactive component, in the composite is the second novelty of this work.

The voltage profiles of the electrochemical cells CoO–Li_2O/Li (Figure 3a,b) indicate that these composite electrodes have the typical characteristics of CoO electrodes, that is, a long voltage plateau at about 0.75 V followed by a sloping discharge curve down to the cut-off voltage of 0.01 V during the first discharge step.[5] After the first discharge, the 0.75 V discharge plateau does not appear anymore, suggesting a heterogeneous reaction mechanism of lithium insertion and extraction.[10,14,22] Remarkably, the first discharge step delivers a specific capacity of 900 mA h g^{-1} for the reticular CoO–Li_2O film (1:1 Co/Li molar ratio; Figure 3a) and 730 mA h g^{-1} for the dense CoO–Li_2O film (Co/Li 1:1; Figure 3b) at a current density of 0.1 mA cm^{-2}. Both values are significantly higher than the theoretical capacity (596 mA h g^{-1}) expected if only the film component CoO is active. On the other hand, the surface of the nickel substrate can be slightly oxidized at 235 °C in air. An independent measurement on an oxidized nickel substrate showed that the capacity owing to the substrate could account for about 10% of the total capacity of the reticular electrode film (see the Supporting Information). Even if the contribution from the substrate is discounted, the capacity of the electrode is still markedly higher than 596 mA h g^{-1}. Tarascon et al. have established that the extra capacity is likely due to the reversible formation and decomposition of a polymeric gel-like film on the surface of the CoO particles.[14,15] This film results from kinetically activated electrolyte degradation enabled by the active metal nanoparticles (Co). The presence of the film component Li_2O

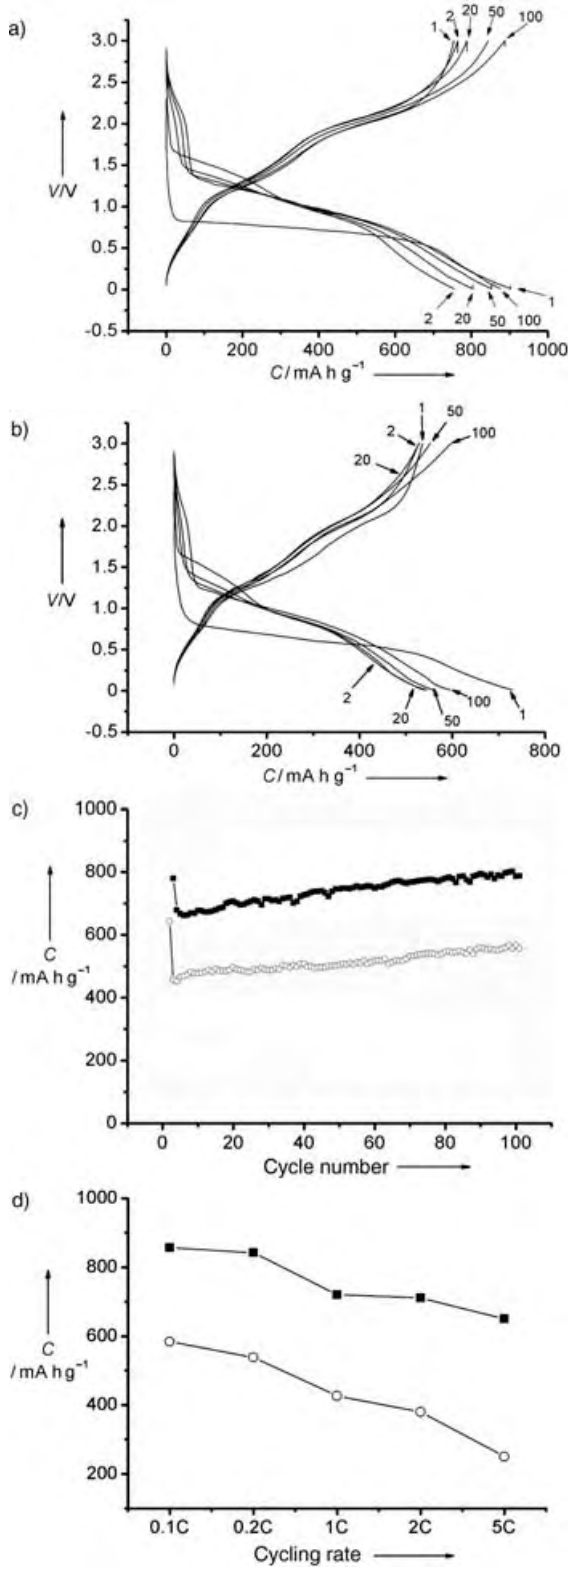

Figure 3. The electrochemical performance of the CoO–Li_2O thin-film electrodes cycled between 0.01 V and 3 V vs. Li^+/Li. a), b) Plots of the voltage–capacity curves of a reticular (a) and a dense (b) CoO–Li_2O film at a cycling rate of 0.2C (the numbers indicate the cycle number); c) the capacity–cycle-number curves of the CoO–Li_2O films at a cycling rate of 1C; d) the discharge capacity of the CoO–Li_2O films as a function of the cycling rate (0.1C–5C). ■ = reticular film, ○ = dense film; *C* = capacity, *V* = cell voltage.

may prohibit the growth of CoO particles and thus create a maximum CoO surface area. Hence, the capacity associated with the polymeric film is maximized.

The discharge capacity of the CoO–Li_2O composite films at a 0.2C cycling rate drops from 903 to 755 $mA\,h\,g^{-1}$ for the reticular morphology (Figure 3a) and from 729 to 538 $mA\,h\,g^{-1}$ for the dense morphology (Figure 3b) after the first cycle. However, the discharge capacity is gradually restored during the subsequent cycles; at the 100th cycle, it is 877 and 595 $mA\,h\,g^{-1}$ for the reticular and dense films, respectively. At a higher current density of about 1C rate, the capacity of the CoO–Li_2O composite films follows a similar trend as for a lower current density, although the values at different cycles decrease a little (Figure 3c). For the reticular CoO–Li_2O film, the specific capacity is 781 (1st cycle), 679 (2nd), 673 (10th), 695 (20th), 779 (80th), and 788 $mA\,h\,g^{-1}$ (100th). The phenomenon of an initial drop in capacity followed by a gradual increase (Figure 3c) is well documented in the literature, and is attributed to some irreversible Li_2O generated in the first discharge step.[14,23] Nonetheless, in the present study, the rise in capacity during cycling is also partly attributed to the increase in Co valence (see below). The reticular film also shows excellent rate capability; it reaches a specific capacity of 650 $mA\,h\,g^{-1}$ when cycled at a 5C rate (Figure 3d). For comparison, the 5C rate capacity is only 250 $mA\,h\,g^{-1}$ for the dense film. The difference in the rate capabilities for the two different morphologies originates from the difference in their impedance (see the Supporting Information); the reticular film leads to relatively small cell impedance. The high capacity achieved at a high cycling rate implies that this electrode can be used for high-power applications such as hybrid electric vehicles (HEV).

To investigate the effect of composite composition (that is, the Li/Co molar ratio) on the electrochemical performance, we prepared reticular films of five different Li/Co ratios ranging from 1:4 to 4:1. We found that there is an optimal composition around Li/Co = 1 for achieving a maximum specific capacity. The capacity of the cells measured at a 1C rate is shown in Figure 4. The capacity of the cells with the two extreme compositions is 545 $mA\,h\,g^{-1}$ for Li/Co = 1:4 and 267 $mA\,h\,g^{-1}$ for Li/Co = 4:1. According to the curve shape, it is expected that pure CoO must have a reasonably high capacity while pure Li_2O is electrochemically inactive. In fact, it is difficult to prepare a reticular-structured pure CoO film under similar deposition conditions. The electrochemical performance of the non-reticular CoO film is markedly worse than that of the Li_2O-containing composite films (see the Supporting Information).

As mentioned before, the Li_2O in the composite plays an important role in optimizing and even enhancing the electrochemical performance of the CoO component. Firstly, as Li_2O prohibits the particle growth of CoO, a maximized CoO surface area may be obtained so that the capacity related to the polymeric gel-like film can be enhanced. Secondly, Li_2O is an oxidant that converts CoO into Co_3O_4 or even Co_2O_3 during cycling according to the reactions (1) or (2), where the

$$Li_2O + 3\,CoO \rightarrow Co_3O_4 + 2\,Li \quad (1)$$

$$Li_2O + 2\,CoO \rightarrow Co_2O_3 + 2\,Li \quad (2)$$

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

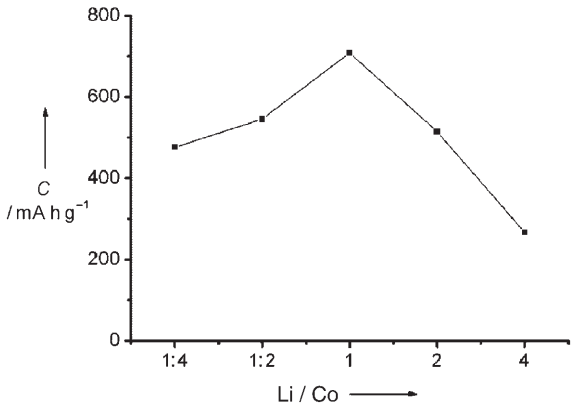

Figure 4. Plot of the discharge capacity of reticular CoO–Li_2O thin-film electrodes as a function of the Li/Co molar ratio in the precursor solutions. The cycling rate was 1C.

Li from Li_2O is transferred to the lithium metal electrode. The resulting increase in valency of the Co ions must partly account for the capacity that exceeds the theoretical value and the capacity rise of the composite films (Figure 3). The Li/Co molar ratios derived from these two reactions are 2:3 and 1:1, respectively, which are close to the optimal Li/Co ratio (Figure 4).

With a reticular CoO–Li_2O film (Li/Co 1:1) on a copper foil substrate, we confirmed the conversion of CoO into Co_3O_4 after five cycles (Figure 5). The third role of Li_2O is its

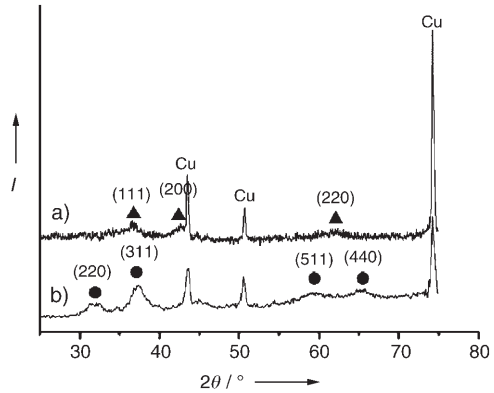

Figure 5. The X-ray diffraction patterns of CoO–Li_2O thin films (Li/Co 1:1) on a Cu foil substrate: as-deposited (a) and disassembled from a fully charged cell after five cycles (b). The diffraction peaks of CoO and Co_3O_4 are indexed in the patterns. ▲ = CoO, ● = Co_3O_4; *I* = intensity.

likely buffering effect by relieving the stress caused by the volume change during the reduction of CoO, so that the structural integrity of the electrode can be readily maintained. Notable is the absence of a carbon additive in the composite films studied in this work. The nickel-foam substrate provides an excellent electronic conduction pathway for the electrochemical processes.

In conclusion, carbon-free CoO–Li_2O composite films with a novel reticular morphology supported on a conducting nickel-foam substrate have been prepared by the ESD technique. The initial discharge capacity of a CoO–Li_2O film (Li/Co 1:1) reaches 903 mA h g^{-1} with a first-cycle capacity loss of only 16.4%. After 100 cycles, this film electrode retains a discharge capacity of 877 mA h g^{-1}. It also shows excellent rate capability with a 5C-rate capacity of up to 650 mA h g^{-1}. The Li_2O component in the composite is believed to play a threefold role: as a prohibitor for the CoO particle growth during synthesis, as an oxidizer for the conversion of Co^{2+} to Co^{3+}, and as a structural buffer. Such a composite anode opens the possibility of producing lithium-ion batteries with higher energy densities.

Experimental Section

With a precursor solution of lithium and cobalt acetates or nitrates in butyl carbitol ($CH_3(CH_2)_3OCH_2OCH_2CH_2OH$; 0.005 M), composite films of cobalt oxide and lithium oxide were deposited by the ESD technique for 2 h on a nickel-foam substrate heated at 235 °C (feeding rate 4 mL h^{-1}). A distance of 2–3 cm was kept between the needle and the substrate; the applied voltage was 11–13 kV. The composition and crystal structures of the as-deposited films were characterized by X-ray diffraction. The surface morphology was analyzed with a scanning electron microscope (Hitachi X-650).

The CoO-Li_2O films were used as the electrodes of electrochemical cells CoO–Li_2O/Li with 1 M $LiPF_6$ in ethylene carbonate and diethyl carbonate (EC/DEC 1:1 v/v) as the electrolyte. The cells were assembled in an argon-filled glove box (MBRAUN LABMASTER 130; moisture and oxygen levels less than 1 ppm) and cycled in the voltage range between 3.0 V and 0.01 V with a battery test system (NEWARE BTS-610).

To study the phase evolution of the CoO–Li_2O electrodes during cell cycling, a reticular CoO–Li_2O film (Li/Co 1:1) on a was deposited copper-foil substrate and assembled into a CoO–Li_2O/Li cell. The as-deposited film and the film disassembled from a fully charged cell after five cycles were characterized by X-ray diffraction.

Tetraazapentalene Chemistry: Unexpected Intramolecular Electron Rearrangement Induced by Highly Reactive ψ-Dinitroso Substituents**

My Hang V. Huynh, Michael A. Hiskey,* David E. Chavez, and Richard D. Gilardi*

Tetraazapentalenes (TAP),[1–4] tetraazaphosphapentalenes (TAPP),[5] tetraazathiapentalenes (TATP),[6–7] tetraazaselenapentalenes (TASP),[8–9] and their derivatives (Scheme 1) are of special interest owing to their unusual electronic structure and chemical behavior which is governed by the striking orientations of the heteroatoms. These heterocyclic systems promise a variety of applications including in organic synthesis, redox chemistry, and in industry, military, and space programs. Some examples of these applications include the derivatization of π-hypervalent heterocyclic TATP,[10–12] the synthesis of versatile heterocyclic compounds,[13–15] exotic metal carbene chemistry,[16–20] shaped charges for downhole penetrators,[21] and thermally stable high-energy materials.[22–26] Much attention has been focused on the preparation (precursors and methods) and properties of the heterocyclic tetraazapentalenes and their derivatives because their applications depend significantly on their thermal stability, performance, and synthetic practicality.

We are interested in the preparation of high-nitrogen-content energetic materials, heterocyclic high-density materials, and green primary explosives for a wide variety of applications through the utilization of tetrazines,[27] tetrazoles,[28] triazines,[29] furazans,[30] triazoles,[31] pyridines,[32] and azetidines.[33] Our interest in heterocyclic tetraazapentalenes was to probe the explosive performance (detonation velocity (V_D) and detonation pressure (P_{CJ})) of previously synthesized, thermally stable high-energy compounds and to

develop candidates with a better performance for realistic and yet practical applications.

Maquestiau et al. reported the preparation and partial physical characterization (MS: $[M^+] = 389$; IR: $\tilde{\nu} = 1530$ and 1320 cm^{-1}) of **1**, but neither crystal structure, thermal stability, sensitivity, nor explosive performance were provided.[34–35] Herein, we report an improved preparation of **1**, its full characterization, including energetic properties, and its novel reactivity through intramolecular electron rearrangement. The details of the three-step preparation are shown in Scheme 2.

The condensation reaction between benzotriazole and 2-chloro-3-nitropyridine was performed in acetonitrile in the presence of Na_2CO_3, to give regioisomer **1A**, which then underwent ring closure by treatment with $P(OEt)_3$ in refluxing xylene to yield **1B**. After its dissolution in H_2SO_4 (98%) at

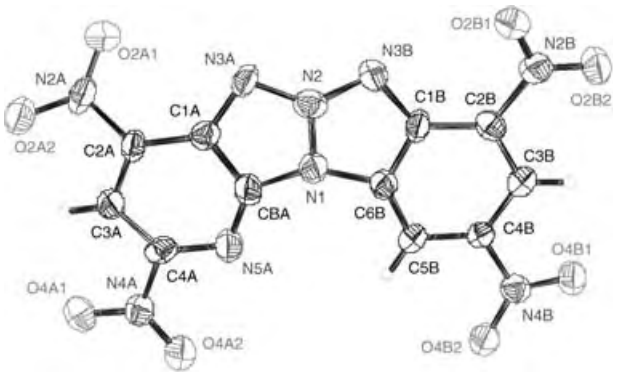

Figure 1. The ORTEP diagram (ellipsoids drawn at the 25% probability level) with labeling scheme for **1**. Selected bond lengths [Å] and angles [°]: N1-N2 1.370(14), N2-N3A 1.337(12), N2-N3B 1.330(13), N1-N2-N3A 114.2(11), N2-N1-C6A 108.3(11), N3A-C1A-C6A 111.5(12).

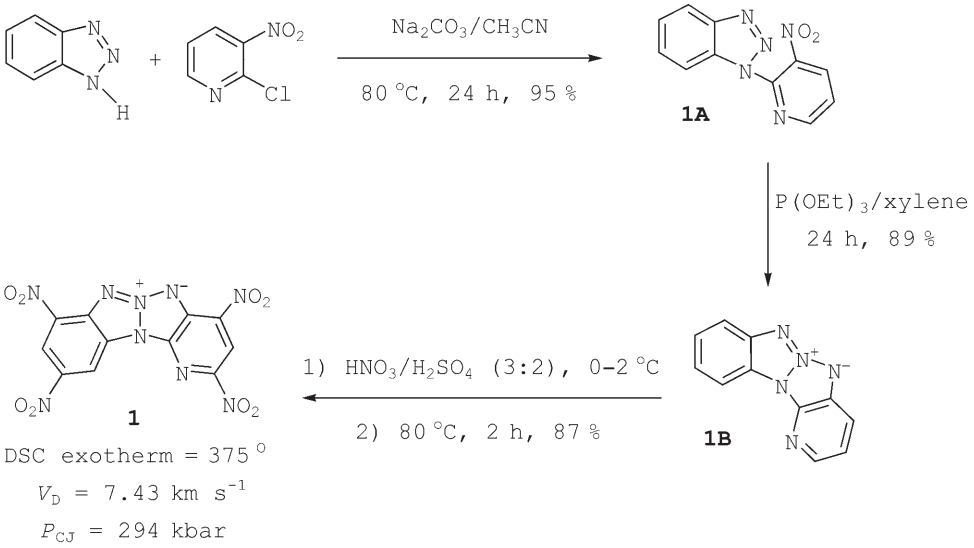


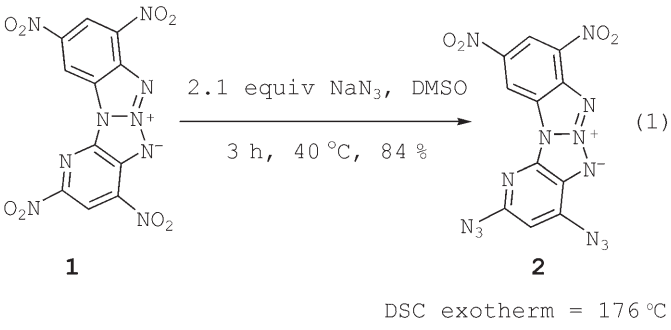
Scheme 2. Detailed preparation of **1**.

5 °C, HNO_3 (90%) was slowly added, while the temperature was maintained below 2 °C. The reaction mixture was stirred vigorously at 80 °C for 2 h, cooled to room temperature, and poured onto crushed ice. Once filtered and washed with cold water, the yellow product was triturated consecutively with a minimum amount of acetone, acetonitrile, and methanol to remove any remaining acids.[21]

Isolated **1** was characterized by X-ray crystallography,[36a] differential scanning calorimetry (DSC, exotherm of fast decomposition), heat of formation, and UV/Vis, IR, and ^1H and ^{13}C NMR spectroscopy.[37] The X-ray crystal structure of **1** (grown through the slow evaporation of a solution in nitromethane), is shown in Figure 1.

Overall, the reaction sequence shown in Scheme 2 gives **1** in 74% yield, which is two and half times greater than that reported by Maquestiau et al.[34–35] Furthermore, the duration of the nitration reaction is much shorter (2 vs 48 h), and both solvents (acetonitrile from the condensation reaction and xylenes from the ring-closure step) are subsequently distilled to allow recovery and reuse. Compound **1** has a thermal stability similar to that of the other well-known thermally stable analogues shown in Scheme 3, but exhibits the highest experimentally measured V_D and P_{CJ}. As a consequence, the combination of better reaction yield, cheaper production cost, and higher performance has made **1** attractive for use in realistic and practical applications.[21]

A stoichiometric reaction between **1** and NaN_3 in DMSO at 40 °C gave **2**. After the reaction was cooled to room temperature, water was added to precipitate the analytically pure brown product, which was filtered, washed thoroughly with water, and air-dried, [Eq. (1)].



(1)

Compound **2** was characterized by DSC, elemental analysis, and UV/Vis, IR, and ^1H and ^{13}C NMR spectroscopy.[38] **Caution!** Compound **2** is very sensitive to sparks, friction, and impact,[39] hence, plastic spatulas should be used. This reaction should be performed within a fume hood fitted with a thick blast shield. Grounding straps, thick gloves, and a face shield should be worn at all times.

The reaction shown in Equation (2) exhibits the same nucleophilic disubstitution of the benzopyridotetraazapenta-

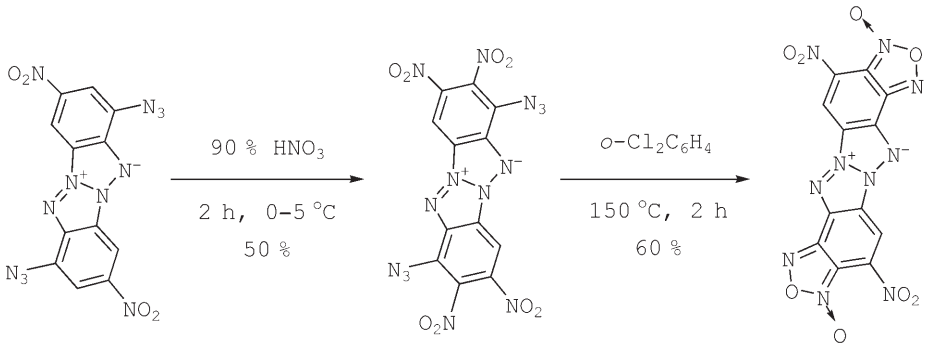
lene (BPTAP) backbone. However, it was necessary to use a large excess of nucleophile (sodium methoxide or piperidine) in the appropriate solvent and to heat the reaction mixtures at reflux or at 80 °C. The isolated product was purified through column chromatography.

The disubstitution pattern of **2**, **5**, and **6** in Equations (1)

Based on the preparation of **12** (nitrogen atoms form a Z-shaped structure) from **7**[22] [Eq. (3)] or the analogous compound from **8** (the nitrogen atoms in a T-shaped structure),[23] we predicted that the nitration of **2**, followed by azido–nitro ring closure, would give the corresponding furoxano–tetrazolo product **13** as shown in Equation (4).

The reaction shown in Equation (4) did not form **13**, but rather took a substantially different pathway as shown in



7 → **11** → **12** (3)

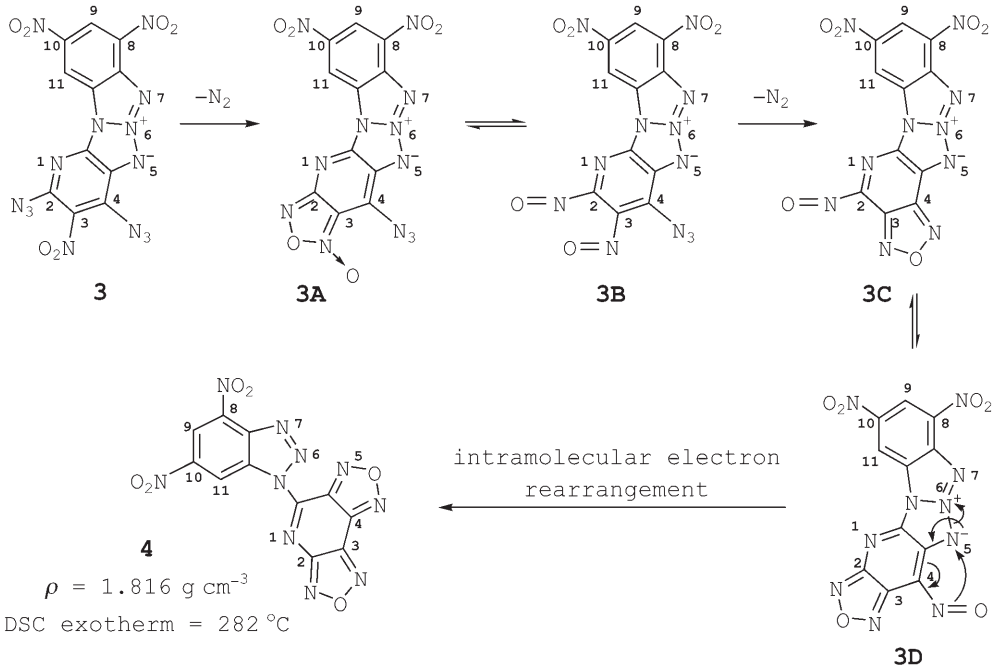
(4)

Scheme 5. The adjacent 2-azido and 3-nitro positioning provoked the elimination of molecular nitrogen followed by ring closure to form the corresponding furazan *N*-oxide compound **3A** or the resonance hybrid ψ-2,3-dinitroso compound **3B**. The presence of the ψ-3-nitroso group triggers the elimination of the second nitrogen molecule and subsequent ring closure to form **3C**, which is the valence isomer of **3D**. The ψ-4-nitroso substituent in **3D** stimulates an intramolecular electron rearrangement to open the T-shaped tetraazapentalene backbone to form **4**. This is the first example of the ring opening of the T-shaped tetraazapentalene isomer. This ring opening is unlike the ring scissions of the Z-shaped TACOT, which was attacked either by oxidation with peracetic acid,[41] reduction with lithium aluminum hydride (or copper(I) cyanide),[41] or nucleophilic substitution with sodium methoxide.[42] The unpredicted product **4** was confirmed through the X-ray crystal structure shown in Figure 2,[36b] and fully characterized by DSC, elemental analysis, and UV/Vis, IR, and ^{1}H and ^{13}C NMR spectroscopy.[43]

These results are important in demonstrating the improved preparation of **1**, which may lead to a variety of realistic and yet practical applications. Ring scission of the T-shaped tetraazapentalene isomer is novel as it occurs through an unpredicted intramolecular electron rearrangement activated by the highly reactive ψ-dinitroso substituents of **3c**.



Scheme 5. Proposed reaction mechanism for the formation of **4**.

Mass Spectrometric Profiling of Intact Biological Tissue by Using Desorption Electrospray Ionization**

Justin M. Wiseman, Satu M. Puolitaival, Zoltán Takáts, R. Graham Cooks, and Richard M. Caprioli**

Imaging mass spectrometry has emerged as a powerful technique based on time-of-flight secondary-ion mass spectrometry (TOF-SIMS)[1] and matrix-assisted laser desorption/ionization (MALDI).[2,3] However, until now, the mass-spectrometric analysis of biological tissues has been limited to techniques that require sample preparation after which the sample is confined to the high-vacuum region of the instrument, thus making this approach inaccessible to further physical or chemical manipulations. Herein, direct chemical profiling of biological tissues is achieved under ambient conditions at atmospheric pressure by desorption electrospray ionization mass spectrometry (DESI-MS),[4] which is a new and versatile method for the creation of ions from surfaces outside of the mass spectrometer. The profiling of lipids in biological tissues by using DESI-MS provides highly sensitive and chemically specific information almost instantaneously. This capability is illustrated by examples in which phospholipid profiles of mouse pancreas, rat brain, and metastatic human-liver adenocarcinoma tissues are obtained without any sample pretreatment.

Biological membranes serve as crucial mediators in cellular differentiation and proliferation; the former being important in tumor formation, the latter in tumor progression. Phospholipids play important roles in maintaining the structural integrity of the cell by forming of the characteristic bilayer of the membrane and by serving as key mediators in important cellular events, for example, cell signaling and protein sorting on so-called lipid rafts. As such, the chemical and physical properties of the cell membrane are determined by the phospholipid composition. Alterations in the phospholipid composition of tissues have been reported for certain diseases, including cancer and Alzheimer's disease.[5] Importantly, the abundance of certain phospholipids and their enzymatic by-products has been associated with malignant transformations in some tissues.[6] These findings emphasize the importance of the determination of the composition of phospholipids in biological tissues, information which may serve as prognostic variables in diseased and nondiseased tissues.

Mass spectrometry has been used extensively to investigate lipids (e.g., phospholipids),[7] although not under ambient conditions. MALDI-TOF has been used for the analysis of lipids in lens tissue[8] and has emerged as a particularly powerful technique for profiling the spatial distributions of peptides and proteins in biological tissues.[3,9] An alternative molecular imaging method, TOF-SIMS, has been applied to the investigation of the phosphocholine distribution in *Tetrahymena* mating junction by monitoring the phosphocholine head group at m/z 184.[10] In another report, TOF-SIMS imaging of lipids in mouse-brain sections was performed and various sulfatides, as well as phosphatidylinositol, phosphatidylcholine, and cholesterol, were identified and their spatial distributions determined.[11]

DESI belongs to the family of spray ionization methods, such as electrospray ionization (ESI),[12] as well as to the family of desorption ionization methods.[13] DESI allows direct and rapid analysis of surfaces without sample preparation or the need to introduce the sample into a vacuum system.[4] The methodology has been applied to the analysis of trace levels of many classes of compounds, including peptides, proteins, nucleotides, nitroaromatic compounds, and others.[14] Semiquantitative results have been obtained from

the crude profiling of plant tissue for alkaloid content,[15] whereas a computer-controlled moving stage has been used for the direct analysis of dyes and other compounds on chromatography plates.[16] In another example, DESI was combined with an ion-mobility time-of-flight mass spectrometer to probe the conformations of proteins desorbed from an insulating surface.[17]

Herein, DESI-MS is used to investigate the lipid distributions in mouse-pancreas, rat-brain, and metastatic human-liver adenocarcinoma tissue; additional data is presented for whole tissue analysis. These experiments represent the first application of DESI to biological-tissue imaging. The secondary-ion signals in DESI-MS are affected by solvent composition, that is, polarity, pH value, salt concentration, applied voltage, backing pressure in the source, and surface chemistry, as well as other factors.[4,14] These parameters can be adjusted to enhance signals from other compound classes. Direct investigation (without tissue preparation except for microtoming) of biological tissues by using DESI-MS showed very intense peaks because of the phospholipids present. Strong ion signals from phosphatidylcholine (PC) species are consistent with the fact that these species constitute the majority of biological membranes (Figure 1 a). The mass-to-charge (m/z) range 700–900 in Figure 1 a shows the phospholipids detected in untreated mouse-pancreas tissue. The phospholipids appear as potassium adducts as a result of endogenous potassium in the tissue (Figure 1 b). Chemical assignments were confirmed by tandem mass spectrometry (Figure 1 a, inset). Similar studies on rat-brain sections were performed and gave results typified by those shown in Figure 2. As expected,[11] the rat-brain sections produced phospholipid profiles composed mainly of saturated fatty acids, specifically palimitate and stearate.

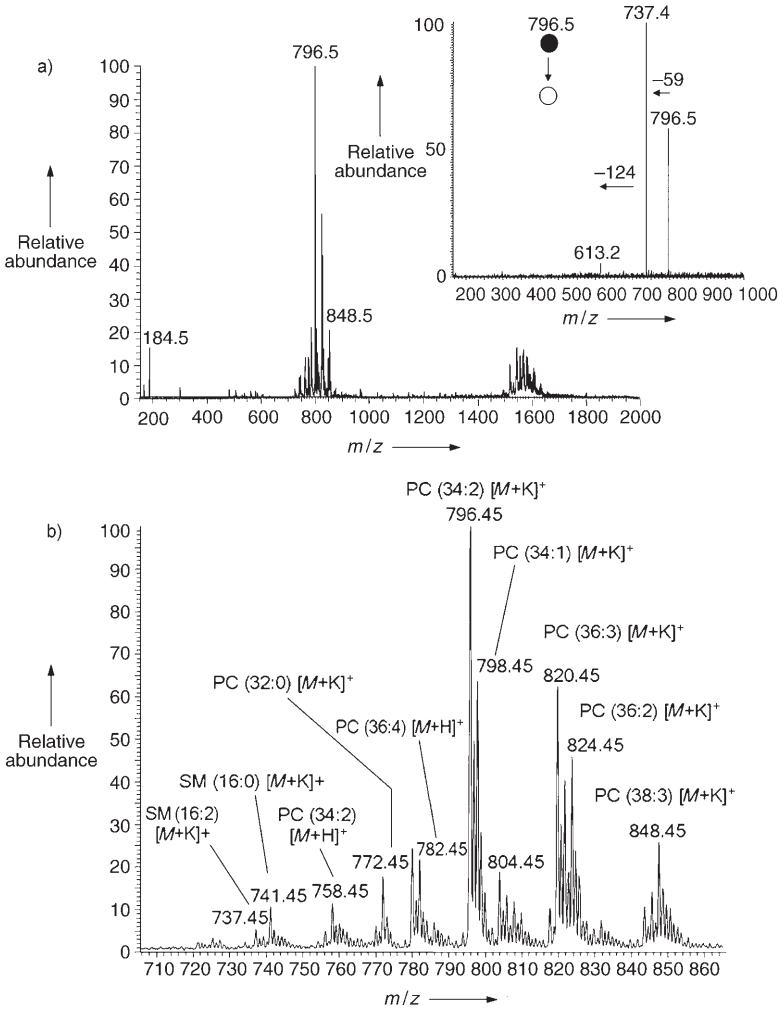

Figure 1. a) Positive-ion DESI mass spectrum recorded on mouse-pancreas tissue with methanol/water (1:1) with 1% acetic acid as the spray solvent at a flow rate of 3 μL min^{-1} and a nebulizing N_2 back pressure of 7 bar. The ions at m/z 184 represent the phosphatidylcholine (PC) head group, thus indicating the presence of free phosphocholine. The ions present at m/z 1550–1650 are phospholipid dimers. The inset shows the MS/MS spectrum of the base peak, and the characteristic neutral losses that were observed make its identification as PC (34:2; $[M+K]^+$) unequivocal. b) An expanded view between m/z 700 and 900 which shows individual phospholipid species and their potassium adducts. The ratio of number of carbon atoms/number of double bonds is given in brackets.

Because considerable information on the disease state of a tissue can be obtained by determination of the distribution of marker compounds, such as phospholipids, investigations of biological tissue utilizing DESI-MS were carried out on metastatic human-liver adenocarcinoma tissue. Lipid distributions in cancerous tissues are known to vary in composition from noncancerous tissue.[18] It has been shown in some cases that elevated levels of phosphatidylcholine species are linked to malignant transformations in cancer cells.[6] In addition, cell-signaling molecules, such as ceramides, derivatives of the sphingomyelin species, are involved in cell-signaling cascades that are directly related to tumor survival. In some cases, extracellular vesicles rich in sphingomyelin have been reported to induce angiogenesis in tumor-proliferating cells.[19] These prior findings emphasize the importance of the determination of the composition of phospholipids in biological tissues and indicate that such information may serve as a prognostic variable in diseased and nondiseased tissues.

Herein, spot sizes are less than 1 mm and the tissue is untreated and examined in the ambient environment. Approximately 50 scans (25 s) were taken on average per spot to obtain high-quality data; however, chemically specific information can be obtained in less than 5 s per spot, including the use of MS/MS.[15] Figure 3 shows a comparison of DESI mass spectra collected from two different regions of metastatic human-liver adenocarcinoma tissue. In the nontumor regions, the lipids are predominantly in the form of palmitic acid containing phospholipids (Figure 3 a). In the transition region from nontumor tissue to cancerous tissue, the lipid distribution is composed of mostly unsaturated fatty acids containing phospholipids (Figure 3 b), whereas the cancerous portions of the tissue showed elevated levels of sphingomyelin (Figure 3 c), which may be associated with a dysfunctional ceramide-mediated apoptosis pathway.[20] In the case of healthy cells, sphingomyelinase can be activated, which results in lower sphingomyelin concentrations.

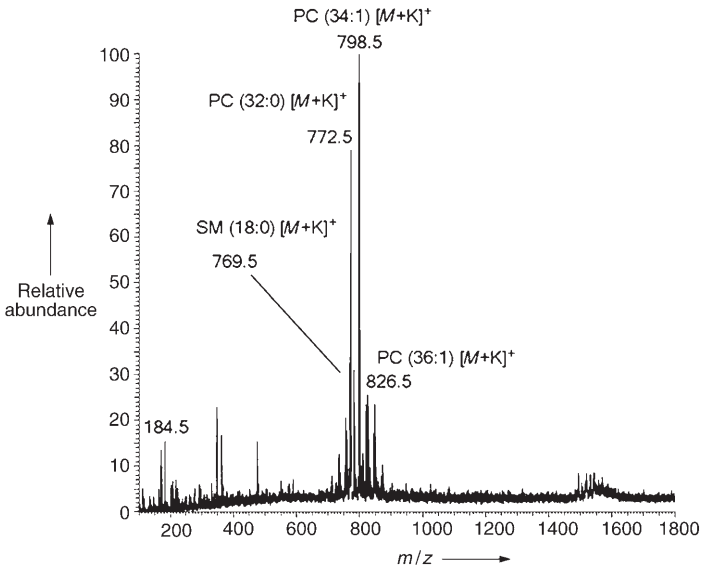

Figure 2. Positive-ion DESI mass spectrum recorded on rat-brain tissue with methanol/water (1:1) with 1% acetic acid as the spray solvent at a flow rate of 3 μL min^{-1} and a nebulizing N_2 gas back pressure of 7 bar. The base peak is identified as the potassium form of phosphatidylcholine (34:1). The ratio of number of carbon atoms/number of double bonds is given in brackets

Intact nonsectioned tissues can also be examined by DESI. Results from the analysis of adipose tissue in situ surrounding a chicken heart are presented in Figure 4. The mass spectrum indicates the presence of free fatty acids on the tissue surface, whereas other spectra collected from a freshly cut surface of chicken heart feature small peptide components, as well as constituents of hemoglobin (heme and Hb (α_a, α_d, and β chains)).

These results serve as the basis for in vivo/in situ applications to tissue under ambient conditions, a topic with implications for basic biochemistry, as well as pathology, food safety, and real-time diagnosis during surgery. In summary, DESI allows: 1) the direct and rapid analysis of intact biological tissues, including whole organs; 2) sensitive and specific molecular detection; 3) adequate secondary-ion yields for chemical confirmation by tandem mass spectrometry; 4) samples to be used that do not need to be confined under high vacuum or subjected to any other preparation procedure; 5) chemical imaging with spot sizes of less than 1 mm.

Experimental Section

All experiments were performed on a Thermo Finnigan LTQ mass spectrometer (San Jose, CA) equipped with a desorption electrospray ion source, (prototype Omni Spray Ion Source, Prosolia Inc., Indianapolis, IN) which is described elsewhere.[4,14] After dissection, the mouse-pancreas, rat-brain, and human-liver tissues were frozen in liquid nitrogen and stored at −80 °C. Prior to analysis, the tissue sections were prepared by cryosectioning with a Leica CM3050 S (Leica Microsystems, Inc., Bannockburn, IL) to a thickness of 16 μm, thaw mounted directly onto a microscope glass slide, and stored under vacuum until analyzed. No further treatment of the tissue samples was necessary. DESI-MS analysis of the tissues was carried out by directing the

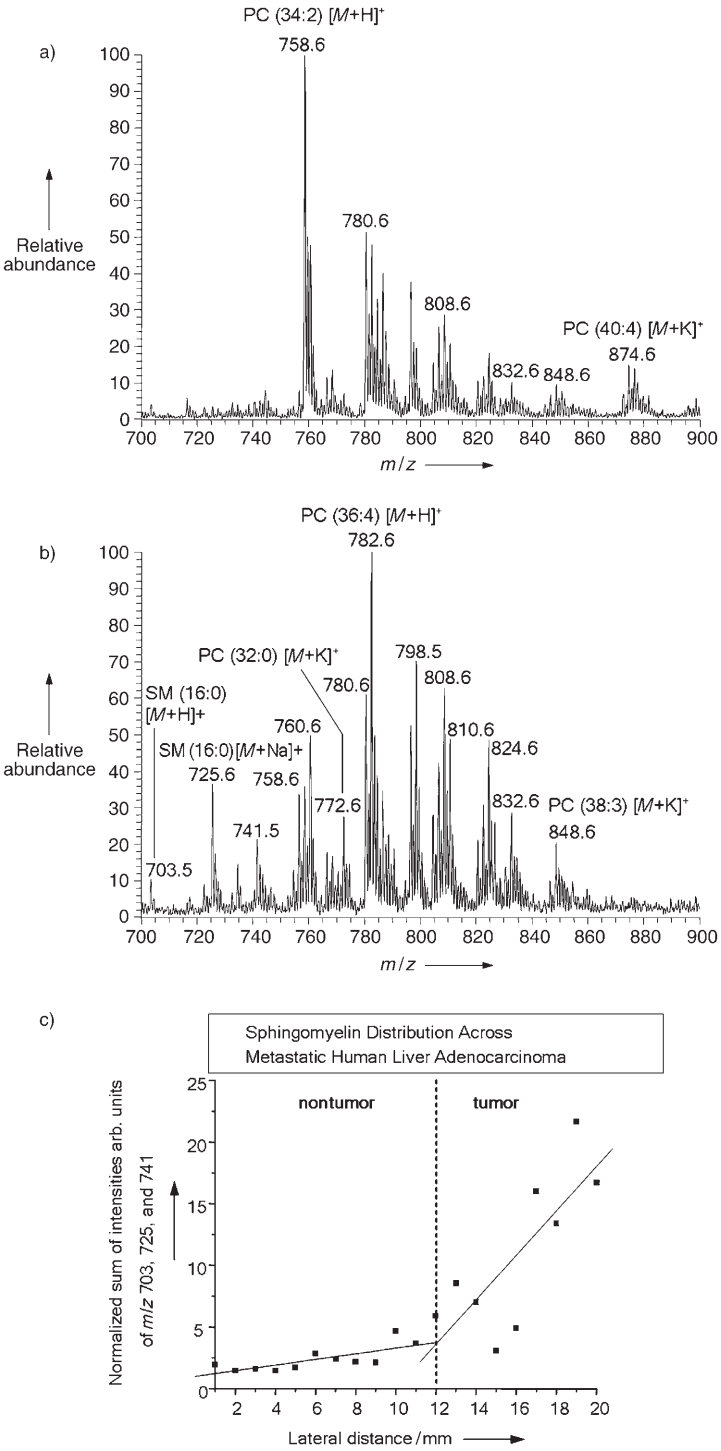

Figure 3. Positive-ion DESI mass spectra recorded on metastatic human-liver adenocarcinoma tissue. The experiment was conducted with methanol/water (1:1, v/v) with 0.1% NH_4OH added. Line scans were performed by moving the sample stage in 1 mm increments across the tissue at 50 scans step^{-1} (25 s step^{-1}). a) DESI mass spectrum representative of the nontumor region of the tissue. b) DESI mass spectrum representative of the cancerous region of the tissue. Enhanced signals from sphingomyelin species at *m/z* 703, 725, and 741 are detected in this region of the tissue. c) Ion-intensity distribution of the sum of the *m/z* values 703, 725, and 741 which correspond to the protonated, sodium, and potassium forms of sphingomyelin (16:0), respectively, versus position in the tissue. The intensities were normalized to the ion intensity at *m/z* 184, which corresponds to phosphocholine. The ratio of number of carbon atoms/number of double bonds is given in parentheses.

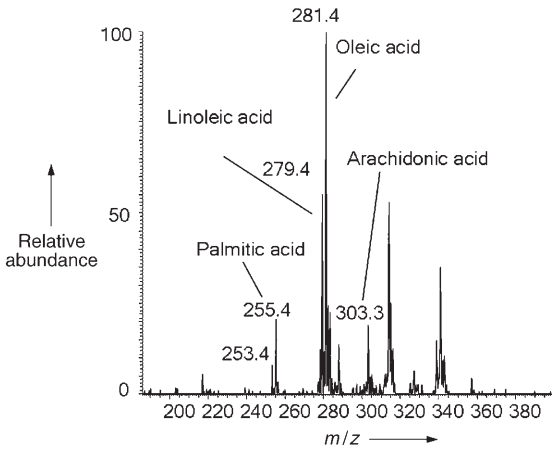

Figure 4. A negative-ion DESI mass spectrum recorded on adipose tissue that surrounds gallus heart with methanol/water (1:1) with 1% acetic acid as the spray solvent at a flow rate of 3 μL min^{-1} and a nebulizing N_2 gas back pressure of 7 bar.

electrospray (5 kV), composed of either methanol/water/acetic acid (50:49:1 v/v) or methanol/water/ammonium hydroxide (50:49.9:0.1 v/v), at an incident angle of approximately 50° toward the tissue. The volumetric flow rate and the back pressure in the source were 3 μL min^{-1} and 7 bar, respectively. Ions generated from the surface were collected using a standard heated capillary interface with an orifice diameter of 500 μm at approximately 10°.

Superoxidation of Bisretinoids**

Ilyas Washington, Steffen Jockusch, Yasuhiro Itagaki, Nicholas J. Turro, and Koji Nakanishi**

In addition to their role in vision, retinoids, for example, **1a–k** and their derivatives, have been found to affect fetal development, cell differentiation, metabolism, and organ and cell regulation.[1] They also provide lead structures for various anticancer, anti-inflammatory, and antibacterial drugs. In plants and food, they act as hormones, pigments, flavors, aromas, and as defense substances.[1]

The polyenes **1a–k** react readily with singlet oxygen.[2,3] Reactions with oxygen can be initiated by light, in the presence or absence of a photosensitizer, or by autoxidation.[3] The oxidized products often show biological activity and are responsible for various aromas and tastes of food.[2,3] Identification of the oxygenated products is complicated by the fact that the initial species are reactive dioxetanes, peroxides,

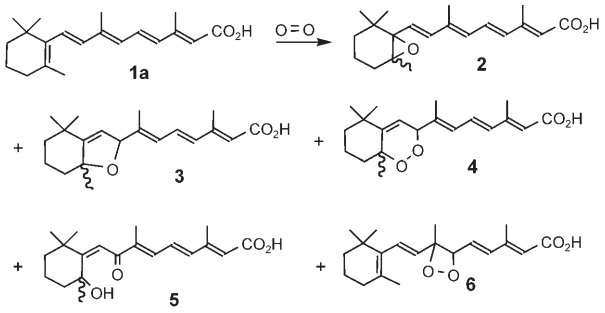
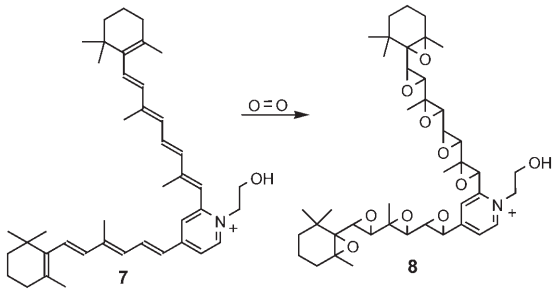
epoxides, and endoperoxides that can undergo secondary reactions and rearrangements upon chromatographic separation and identification.[2,3] Furthermore, various *cis*/*trans*, stereo-, and regioisomers are often obtained.

To date, nine different products have been reported for the reaction of retinoic acid (**1a**) with singlet oxygen (Scheme 1).[3f,g] These products include epoxide **2**, furan **3**



Scheme 1. The reaction of retinoic acid (**1a**) with singlet oxygen.

(through rearrangement of **2**), endoperoxide **4**, hydroxyketone **5**, dioxetane **6**, and four degradation products (products with molecular weights lower than that of the parent retinoic acid). Similar oxidation products have also been reported for the oxidation of retinal (**1b**),[3d,e] retinol (**1c**),[3a,c] and retinol palmitate (**1d**).[3a] In most cases, the oxidation is reported to stop upon the addition of two oxygen atoms, with either the major or sole initial product proposed to be 5,8-endoperoxide (similar to **4**).[3] In contrast, A2E (**7**), a bisretinoid isolated from human lipofuscin, reacts with singlet oxygen to form the polyepoxide species **8** (Scheme 2).[4a] This is in contrast to retinoids **1a**–**d**, which add two oxygen atoms. In the case of **7**,



Scheme 2. The reaction of A2E (**7**) with singlet oxygen to form the polyepoxide species **8**.

a maximum of nine oxygen atoms can add to the polyene chain. The epoxides of **7** have been shown to be biologically active and are speculated to be involved in age-related macular degeneration.[4b] Polyepoxide **8** was not isolated, and its structure was proposed based on mass-spectrometric measurements.[4a]

To explain the difference between the reactivity of **7** and that of retinoids **1a**–**d** towards singlet oxygen and to explore the reactivity of singlet oxygen towards polyenes, several bisretinoids **10**–**12** (Schemes 5–7) as well as several monoretinoids **1a**–**c** and **1e**–**k** (Scheme 1) were treated with singlet oxygen. Through MS analysis of the reactant mixtures, it was concluded that the polyene chains, when held in proximity to one another, react readily with oxygen to give superoxygenated species. On the other hand, the oxidation of spatially isolated polyenes stops upon the addition of two oxygen atoms.

The photoreactions were carried out for 1–3 h at 25 °C in CH_2Cl_2 in the presence of tetraphenylporphyrin (TPP) as a photosensitizer. The irradiation was effected by a 300-W halogen lamp that was equipped with a 400-nm cut-off filter. The exposure of solutions of the reagents in acetone (in a borosilicate glass vile with a UV cut-off of 340 nm) to sunlight for 3–6 h in the absence of added sensitizer gave similar results. All samples were analyzed directly by MS without any further manipulation. Figure 1 shows the fast-atom-bombard-

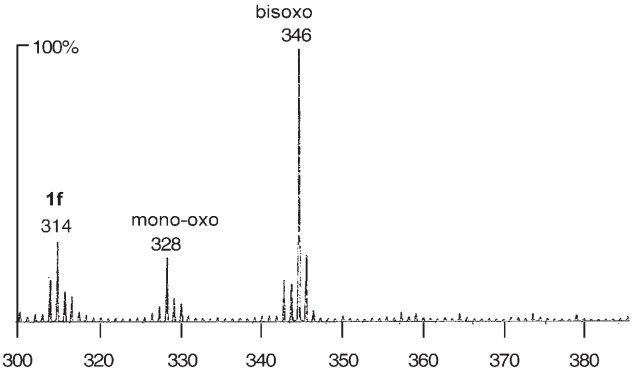


Figure 1. FAB MS of the products of **1f**, 3 h after irradiation (300 W) at 25 °C in CH_2Cl_2 in the presence of tetraphenylporphyrin as a photosensitizer. The maximum increase by m/z 32 (two oxygen atoms)

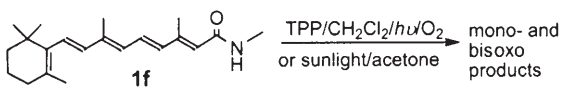
ment (FYB) mass spectrum of the products of the amide **1f** after 3 h of irradiation (Scheme 3). The peak at m/z 314 corresponds to **1f** $[M+1]$. The spectrum has a strong signal at m/z 346, which corresponds to the mass of **1f** plus two oxygen atoms $[M+1]$. The smaller peak at m/z 328 represents the mono-oxygen adduct of **1f** $[M-1]$. No peaks were found above m/z 346 which suggests that oxidation of **1f** stops cleanly after the addition of two oxygen atoms.

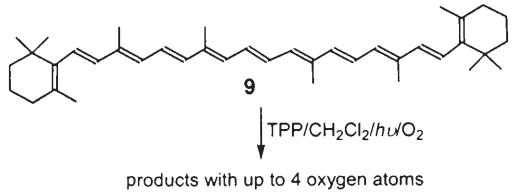


Scheme 3. The irradiation of amide **1f**. Oxidation was shown to cease after the addition of two oxygen atoms.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Similarly, retinoids **1a–c** and **1e–k** were prepared, irradiated, and the reactant mixture analyzed by MS. All the measured spectra were similar to that shown in Figure 1, with a maximum peak at +32 Da, which corresponds to the parent ion of the retinoid plus two oxygen atoms, and a smaller peak at +16 Da, which corresponds to the addition of one oxygen atom to the parent ion. The peaks located at 16 and 32 Da are consistent with literature reports for the formation of the 5,6-epoxide and the 5,8-endoperoxide, respectively, which are two well-characterized photo-oxidation products of retinoic acid (**1a**), retinal (**1b**), retinol (**1c**), and retinol palmitate (**1d**).[3]

Beta-carotene (**9**) was also examined (Scheme 4). The mass spectrum showed a maximum mass that corresponds to



Scheme 4. The irradiation of beta-carotene (**9**), which results in the addition of up to four oxygen atoms.

an increase of 64 Da, which is double that observed for the compounds **1a–c** and **1e–k**. Furthermore, peaks that correspond to the addition of one, two, and three oxygen atoms were also observed. The mass spectrum is consistent with the previously characterized products of singlet-oxygen-mediated oxidation products of beta-carotene, which are mixtures of bis and mono 5,6-epoxides and 5,8-endoperoxides.[3h]

Figure 2 shows the electrospray ionization mass spectrum obtained after 1 h of irradiation of a solution of bisretinoid *ortho*-**10** (Scheme 5). The peak at *m*/*z* 672 corresponds to the

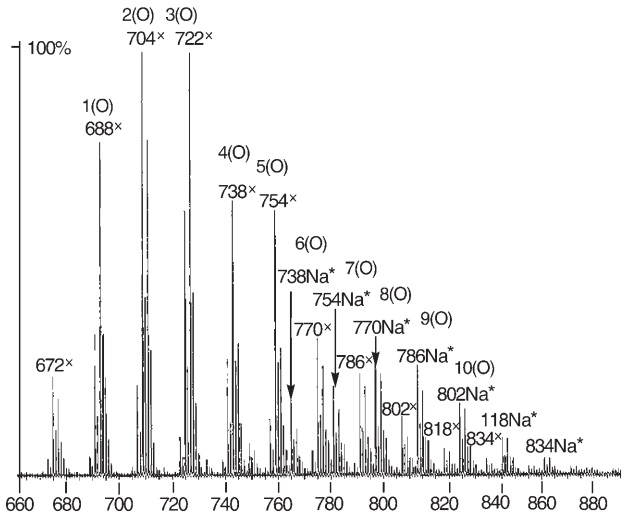


Figure 2. ESI MS of the reaction mixture of *ortho*-**10** after irradiation (300 W) for 1 h at 25 °C in CH_2Cl_2 in the presence of tetraphenylporphyrin as a photosensitizer. Labels show the consecutive increase by 16 Da and the corresponding sodium adducts, × represents the addition of an oxygen atom, * are sodium adducts (+23 Da).

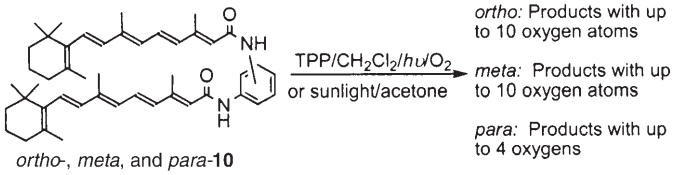
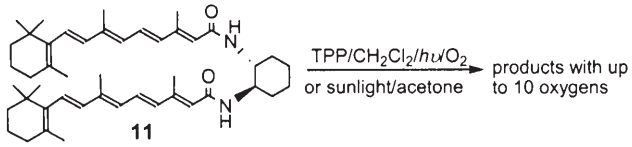


Scheme 5. The irradiation of a solution of bisretinoid *ortho*-, *meta*-, and *para*-**10**, which results in the addition of ten, ten, and four oxygen atoms, respectively.

parent mass of *ortho*-**10**. Subsequent peaks (labeled with an ×) were found at increments of 16 Da, which corresponds to the addition of one oxygen atom. The peaks labeled with an * are sodium adducts (+23 Da). The spectrum shows the maximum *m*/*z* at 834 or 856 (834+Na) which corresponds to the addition of ten oxygen atoms. The spectrum is similar to that observed after the irradiation of **7,** which was reported to yield the polyepoxide species **8**. Superoxidation was also observed by MS for the isomer *meta*-**10**. When the isomer *para*-**10** was irradiated, the mass spectrum showed a maximum peak that corresponds to the addition of only four oxygens, and was similar to that observed for beta-carotene (**9**).

For the *trans*-substituted cyclohexane derivative **11**, there is no conjugation between the two polyene chains. However, superoxidation is still observed by MS (Scheme 6). When the



Scheme 6. Irradiation of the *trans*-substituted cyclohexane derivative **11**, despite the absence of conjugation between the two polyene chains, resulted in superoxidation.

two polyene chains are held together by a flexible linker as in **12**, oxidation was found mostly to stop upon the addition of one to four oxygen atoms (Figure 3 and Scheme 7). After the complete conversion of **12** (*m*/*z* 652) as shown by MS, only small peaks located at *m*/*z* 733 and 749, which correspond to

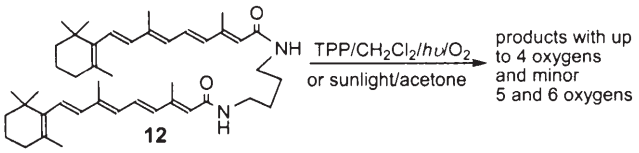

Scheme 7. The irradiation of **12**, in which the two polyene chains are held together by a flexible linker. No further oxidation occurred after the addition of one to four oxygen atoms.

the addition of five and six oxygen atoms, respectively, were found.

The λ_{max} of **11** in ethanol is blue shifted by 5 nm relative to the similar retinoids **12** and **1f**. Retinoid **11** has a fluorescence quantum yield in ethanol of 0.08 at 25 °C relative to 9,10-diphenylanthracene ($\Phi_F = 0.95$).[5] The fluorescence quantum yield of **12** and **1f** were measured to be 0.07 and 0.05, respectively. This is in accord with the reported fluorescence quantum yields for retinal, retinol, and retinal acetate, which are between 0.03 and 0.01 at 25 °C.[6] Retinoids do not stack in apolar or polar solutions.[7] A slight increase in fluorescence is expected for **11**, as the proximity of the polyene chains restricts their movement, thus a greater amount of excited energy is emitted rather then dissipated by isomerization or vibrational motion. The blue shift in the absorption spectrum and the greater fluorescence of **11** relative to **12** and **1f** suggest that the polyene chains in **11** are stacked. Similar observations have been reported for retinoids.[7]

The rate constants for the quenching of singlet oxygen by **11** and **1f** were determined through pseudo-first-order treatment of the singlet oxygen phosphorescence decays by using TPP as a sensitizer and a pulsed Nd–YAG laser (532 nm) to generate singlet oxygen.[8] Rate constants of $(2.0 \pm 0.1) \times 10^6\,M^{-1}s^{-1}$ and $(1.9 \pm 0.1) \times 10^6\,M^{-1}s^{-1}$ were determined for the quenching of singlet oxygen by **11** and **1f**, respectively. The determined values are in accord with the reported rate constants for the quenching of singlet oxygen by *trans*-retinal ($3.6 \times 10^6\,M^{-1}s^{-1}$) and retinol acetate ($7 \times 10^5\,M^{-1}s^{-1}$).[9] As the number of double bonds in bisretinoid **11** is doubled, an increased rate constant for quenching would have been expected. The observed value suggests that some of the double bonds are less accessible to singlet oxygen in the bisretinoid **11** when both retinal arms are in proximity.

The similarity between the rate constants of the quenching of singlet oxygen by **1f** and **11** and the fact that different products are obtained from the reactions of monoretinoids and bisretinoids with oxygen suggest that they are oxidized by two species: singlet oxygen and oxygen radicals or oxygen radical anions. The endoperoxide products, typically observed after light-mediated oxidation of retinoids, are the products of the [2+4] addition of singlet oxygen. The higher energy oxygen radicals or oxygen radical anions are expected to give a more complex mixture of products,[10] as seen for the oxidation of the bisretinoids. Upon irradiation, retinoids **1a–c** have been shown to produce both singlet oxygen and radical species.[11] It has also been reported that singlet oxygen plays a minor role in the oxidation of **7**.[12] Singlet oxygen chemistry often competes with or produces oxygen radicals or oxygen radical anions. In the case of the bisretinoids, the latter species may be formed to a greater extent and play a larger role in oxidation.

These data suggest that when two polyenes chains are able to communicate through space they react with oxygen upon exposure to light to give superoxidized species. Oxidation is limited, however, in the absence of such communication. The enhanced oxidative damage of bispolyenes versus monopolyenes may have implications with regard to the mechanisms of action of naturally occurring bispolyene compounds.[13]

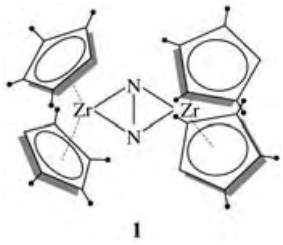
How Many Methyl Groups in $[\{(\eta^5\text{-}C_5Me_nH_{5-n})_2Zr\}_2(\mu_2,\eta^2,\eta^2\text{-}N_2)]$ Are Needed for Dinitrogen Hydrogenation? A Theoretical Study**

Petia Bobadova-Parvanova, Qinfang Wang, Keiji Morokuma, and Djamaladdin G. Musaev**

Nitrogen fixation under mild conditions is one of the most fascinating processes of modern chemical and biochemical sciences.[1] The major fraction of all nitrogen required in human nutrition derives from biological nitrogen fixation,[1c] which uses the nitrogenase enzyme and proceeds by a protonation-and-reduction mechanism of a coordinated N_2 molecule. In industry, almost all dinitrogen fixation comes from the Haber–Bosch process, which transforms dinitrogen to ammonia through hydrogenation. In contrast to biological fixation, the Haber–Bosch process requires extreme temperatures ranging from 400 to 650 °C and pressures ranging from 200 to 400 atm. Therefore, for more than a century scientists have searched for an alternative and economically more effective hydrogen-fixation process.

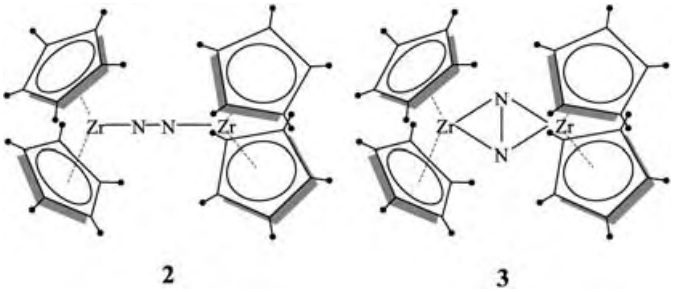
It was demonstrated previously that the side-on, η^2 coordination of N_2 in transition-metal systems is required for its hydrogenation.[2] This coordination ensures significant back-donation from d orbitals of the transition metal to the π^* orbital of the N–N bond. The stronger the back-donation, the more activated the N–N bond would be. The back-donation from the metal center, M, to N_2 is considerably smaller for end-on, η^1 coordination of N_2.

The side-on coordination of N_2 to the transition-metal center could occur in multinuclear transition-metal complexes and clusters. Although it was predicted theoretically a few years ago that N_2 in binuclear zirconium–N_2 complexes could be hydrogenated and add several dihydrogen molecules,[3] it was only last year that Chirik and co-workers showed experimentally that the side-on-coordinated dinitrogen molecule in $[\{(\eta^5\text{-}C_5Me_4H)_2Zr\}_2(\mu_2,\eta^2,\eta^2\text{-}N_2)]$ (**1**) is hydrogenated under mild conditions and even produces small amount of ammonia.[4] This reaction is still not catalytic, but its importance to the field is indisputable. It is intriguing that



1

the same complex with a slightly different ligand, $C_5Me_5^-$ instead of $C_5Me_4H^-$, coordinates an N_2 molecule with an end-on, η^1 mode (**2**, Figure 1); the addition of H_2 follows a different path and dinitrogen is not hydrogenated.[5] Thus, replacing only one methyl group on each cyclopentadienyl ligand with a hydrogen atom significantly alters the reactivity of the complex.[6] What causes this remarkable difference?



2 **3**

Figure 1. Structures of the coordination isomers $[\{(\eta^5\text{-}C_5Me_5)_2Zr\}_2(\mu_2,\eta^2,\eta^2\text{-}N_2)]$ (**2**) and $[\{(\eta^5\text{-}C_5Me_5)_2Zr\}_2(\mu_2,\eta^1,\eta^1\text{-}N_2)]$ (**3**).

To elucidate the factors controlling the N_2 coordination and to rationalize the role of the methyl substitution, we studied computationally side-on and end-on coordination of an N_2 molecule in mono- and binuclear complexes, $[(Cp')_2Zr(N_2)]$ and $[(Cp')_2Zr(N_2)Zr(Cp')_2]$, in which $Cp' = C_5H_{5-n}Me_n$, $n = 0$–5. All calculations were performed in the gas phase by using the Gaussian 03 program[7] at the B3LYP/CEP-31G level with additional d-type polarization functions on the N atom (CEP-31G(d)). Previously, this approach was shown to accurately describe the energetics and geometries of similar complexes.[3] All structures were optimized until no imaginary frequencies were found.

At first, we examined the role of the methyl groups on the coordination mode of N_2 by studying the side-on- and the end-on-coordinated mononuclear complexes $[(Cp')_2Zr(N_2)]$. The relative energies of the optimized structures (including zero-point-energy (ZPE) corrections) are shown with open squares in Figure 2. The optimized Cartesian coordinates of these and all other examined structures are given in the Supporting Information. For all values of n, the complexes with side-on coordination are more stable than those with end-on coordination. The energy difference slightly increases with the number of methyl groups, n. Thus, the presence of methyl substituents on the Cp′ ring favors side-on coordination. This effect is caused by electron donation from the methyl groups as can be seen from the data shown in Table 1. For side-on-coordinated complexes, an increase in the number of methyl

[a] Natural population analysis.

groups leads to an increase in negative charge on the two N atoms ($n = 0$: −0.28 e; $n = 5$: −0.38 e). In the case of end-on complexes, the trend is still valid, but the charges are much smaller in absolute terms and the negative charge on the remote N atom is negligible (see Table 1). The stronger back-donation makes the N–N bond in side-on complexes longer (1.20–1.21 Å) than in end-on complexes (1.16 Å). The electrostatic repulsion between the two negative charges also leads to a longer N–N bond in side-on-coordinated complexes. The above results suggest that the steric repulsion caused by the methyl substituents is small as they are far away from the coordinated dinitrogen ligand.

Our study of mononuclear complexes suggests that an increased number of methyl groups would favor the side-on coordination, but what happens with the binuclear complexes? We examined the full set of side-on- and end-on-coordinated binuclear complexes, $n = 0$–5. Their relative energies (ZPE corrected) are shown with closed circles in Figure 2. For $n \leq 4$ the side-on coordination is more stable than the respective end-on coordination. However, the energy difference between the two coordination modes decreases as *n* increases. Finally, for $n = 5$, the end-on-coordinated complex **2** is more stable than the side-on-coordinated complex **3** (see Figure 1); the energy difference is small, only 2.04 kcal mol^{-1}, but the trend is clear. With C_5Me_5 as the ligand, the side-on coordination is less stable than the end-on coordination. Therefore, the more stable end-on structure which cannot lead to N_2 hydrogenation is the dominant species. This is consistent with the experimental results.[5]

The results for mononuclear complexes show that the electronic effect favors side-on coordination when more methyl groups are on the Cp' ring. For binuclear complexes, the electronic effect has a similar influence (Table 1). Increasing the number of methyl groups increases the negative charge on the N atoms from −0.72 e to −0.84 e for side-on complexes, and from −0.53 e to −0.69 e for end-on complexes. However, our calculations show that for binuclear complexes the energy trend is opposite to that of the mononuclear complexes: the more methyl groups there are the less stable the side-on coordination is. What causes this opposite trend is not the electronic effect but the increasing steric repulsion with an increasing number of methyl groups. For $n = 0$ the steric repulsion is minimal and ΔE has the largest value (Figure 2). The more methyl groups we add, the stronger the steric repulsion becomes and ΔE decreases. The case of $n = 4$ represents a boundary line for which the steric repulsion is yet not strong enough and the side-on coordination is more stable than the end-on coordination. At $n = 5$, however, the steric repulsion is so strong that ΔE drops substantially (by more than 15 kcal mol^{-1}); the end-on complex is more stable and N_2 cannot be hydrogenated. This is the reason for the experimental observation that the pentamethyl complex does not activate N_2 towards hydrogenation. In principle, in all other cases N_2 can be activated. Our calculations suggest that any complex with 0–4 methyl groups may lead to N_2 hydrogenation under appropriate experimental conditions.

Our conclusion is in agreement with the experimental study of Pool et al. on the reaction of the complex $[\{(\eta^5\text{-}C_5Me_5)(\eta^5\text{-}C_5Me_4H)Zr(\eta^1\text{-}N_2)\}_2(\mu_2,\eta^1,\eta^1\text{-}N_2)]$ with dihydrogen,[8] which resulted in the liberation of dinitrogen rather than its hydrogenation. As concluded by the authors, one of the reasons for this reactivity is the steric protection provided by the ancillary ligand framework in their complex that prevents the the side-on coordination of the N_2 ligand, which is essential for dinitrogen hydrogenation.

Computational studies by Pool et al. on the electronic structure of **1** demonstrated that twisting of θ (the dihedral angle between the metallocene wedges) is essential—it prepares the side-on-coordinated N_2 molecule for hydrogenation.[8] They showed that twisting of **1** ($\theta \approx 60°$) changes the symmetry of the highest occupied molecular orbital (HOMO) and allows π bonding between Zr and N_2, thus reducing the strength of the N–N bond and activating it. The authors also examined a hypothetical untwisted ($\theta \approx 0°$) structure of $[\{(\eta^5\text{-}C_5H_5)_2Zr\}_2(\mu_2,\eta^2,\eta^2\text{-}N_2)]$ (**4**; Figure 3). In this case, the HOMO does not have the appropriate symmetry

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

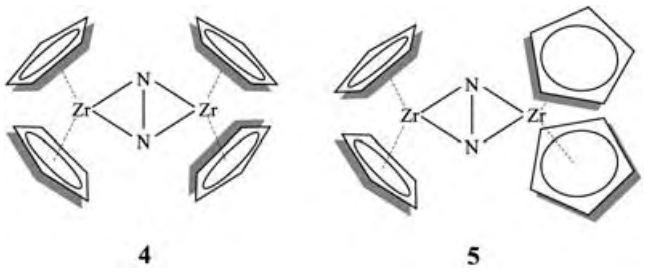

Figure 3. Untwisted (**4**) and twisted (**5**) structure of $[\{(\eta^5\text{-}C_5H_5)_2Zr\}_2(\mu_2,\eta^2,\eta^2\text{-}N_2)]$. The twisted structure ($\theta = 49°$) is more stable than the untwisted structure ($\theta = 2°$) by 6.19 kcal mol^{-1}.

to allow significant back-bonding with the N_2 ligand and the complex is not active toward hydrogenation.

We have further elaborated the role of the angle θ and found that all the optimal structures of $[\{(\eta^5\text{-}C_5Me_nH_{5-n})_2Zr\}_2(\mu_2,\eta^2,\eta^2\text{-}N_2)]$ for $n = 0$–4 (including $n = 0$) are twisted and have dihedral angle of 49°, 54°, 60°, 61°, and 63°, respectively. As a result, the HOMO orbitals of all complexes have the appropriate symmetry for significant π bonding between Zr and the N_2 ligand. Thus, we predict that all complexes with $n = 0$–4 can be used for N_2 hydrogenation.

We found that the untwisted structure **4** ($\theta = 2°$) is 6.19 kcal mol^{-1} higher in energy than the twisted conformer **5** ($\theta = 49°$, Figure 3). In addition, we scanned the potential-energy surface by fixing the twisting angle, θ, and by optimizing all other geometrical parameters. The results are shown in Figure 4. The open rhombuses correspond to

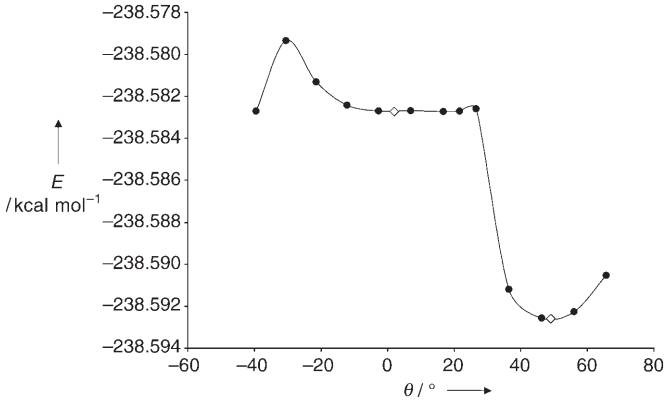

Figure 4. Total energy (E) of $[\{(\eta^5\text{-}C_5H_5)_2Zr\}_2(\mu_2,\eta^2,\eta^2\text{-}N_2)]$ as a function of the twisting angle, θ. The white rhombuses correspond to structures **4** ($\theta = 2°$) and **5** ($\theta = 49°$), respectively.

structures **4** and **5**. The potential-energy surface is very flat around $\theta = 2°$; the untwisted structure represents a flat and very shallow local minimum. There is almost no barrier (around 0.06 kcal mol^{-1}) between structures **4** and **5**. Even if structure **4** is formed it will transform into the active structure **5**.

To further prove that **5** could serve as a N_2 fixation catalyst, we examined the addition of H_2. The details of the study will be given elsewhere.[9] We found that there is no principal difference when $C_5Me_4H^-$ or $C_5H_5^-$ is used as the ligand. As previously shown,[4] the rate-determining step of such reactions is the H–H bond activation, which occurs with a barrier of 17.9 kcal mol^{-1} in the case of $C_5Me_4H^-$ and with a barrier of 18.8 kcal mol^{-1} in the case of $C_5H_5^-$. These similar barriers suggest that there is no principal difference between the two complexes, at least in the first phase of the reaction. Our theoretical study predicts that the presence of $C_5H_5^-$ gives an active twisted structure, which could be used for N_2 cleavage and hydrogenation. We encourage experimentalists to follow up our suggestion.

In summary, we examined the mono- and binuclear complexes $[(Cp')_2Zr(N_2)]$ and $[(Cp')_2Zr(N_2)Zr(Cp')_2]$ ($Cp' = C_5H_{5-n}Me_n$, $n = 0$–5). We found that the case $n = 4$ represents a boundary in the ability to activate N_2 for hydrogenation. When $n \leq 4$, the complex is active and leads to N_2 fixation. When $n = 5$ the active side-on complex is no longer stable and the inactive end-on complex is formed instead. Our results explain why the C_5Me_5 complex is inactive.

Cartesian coordinates of all optimized structures of mononuclear $[(Cp')_2Zr(N_2)]$ and binuclear $[(Cp')_2Zr(N_2)Zr(Cp')_2]$ complexes and the complete reference [7] are given in the Supporting Information.

Epoxidation Catalysts

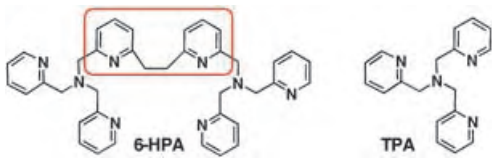
DOI: 10.1002/anie.200501825

A Diiron Center Stabilized by a Bis-TPA Ligand as a Model of Soluble Methane Monooxygenase: Predominant Alkene Epoxidation with H_2O_2**

Masahito Kodera, Motoharu Itoh, Koji Kano, Takuzo Funabiki, and Marius Reglier*

Models of soluble methane monooxygenase (sMMO)[1] are useful for studying peroxodiiron(III) and oxodiiron(IV) intermediates in O–O activation,[1] as well as for developing an efficient oxidation catalyst.[2] Our synthetic efforts to obtain models for dimetal biosites yielded a series of dinucleating polypyridine ligands.[3] The diiron complex of the hexapyridine ligand efficiently catalyzes the oxidation of alkanes and forms a thermally stable peroxo complex.[3d–f] Diiron complexes of tris(2-pyridylmethyl)amine (TPA) and related ligands are known as effective sMMO models.[4] However, such ligands do not stabilize the diiron core in solution,[5] and the resulting complexes display varied reactivity, depending on them being mono- or diiron complexes.[6,7] Iron complexes of TPA derivatives catalyze alkene oxidation with H_2O_2 to give the 1,2-*cis*-diol and epoxide, and Rieske dioxygenase-type monoiron active species have been proposed.[6] However, predominant epoxidation was observed with the iron complex of the ligand *N*,*N*′-dimethyl-*N*,*N*′-bis(2-pyridylmethyl)ethane-1,2-diamine (MEP), which is similar to TPA, and an sMMO-type diiron species was proposed.[7] Therefore, a TPA-containing dinucleating ligand capable of stabilizing a diiron core in solution would be useful for the development of an effective sMMO model.

We prepared 1,2-bis[2-{bis(2-pyridylmethyl)aminomethyl}-6-pyridyl]ethane (6-HPA) as a bis-TPA dinucleating ligand. Herein, we describe the synthesis, structure, and application of the diiron complex of 6-HPA as a highly useful sMMO model. The complex can catalyze epoxidation with H_2O_2 with high yields and large turnover numbers. Spectral studies showed that a peroxodiiron(III) complex is formed as an intermediate. ^{18}O-labeling studies demonstrated that the O atoms of μ-oxo and μ-peroxo groups in the peroxo intermediate were incorporated equivalently into the epoxide. Thus, the oxo- and peroxo-derived O atoms in the active species scramble one another.



6-HPA forms the diiron complexes $[Fe_2(6\text{-HPA})(O)(OH_2)_2](ClO_4)_4$ (**1**) and $[Fe_2(6\text{-HPA})(TfO)_4]$ (**2**; TfO = triflate). The structure of **1** was revealed by X-ray structure analysis (Figure 1).[8] The distances and angles of the diiron

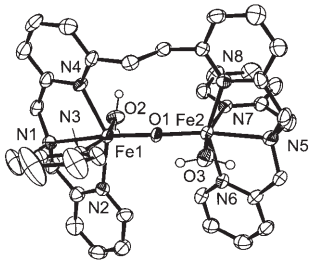


Figure 1. ORTEP view (40% probability) of the structure of the cation in **1**. Selected distances [Å] and angles [°]: Fe1···Fe2 3.607(3), Fe1-O1 1.795(2), Fe2-O1 1.812(2), Fe1-O2 2.084(7), Fe2-O3 2.059(2), Fe1-N1 2.244(1), Fe1-N2 2.151(5), Fe1-N3 2.114(1), Fe1-N4 2.187(7), Fe2-N5 2.235(5), Fe2-N6 2.152(7), Fe2-N7 2.120(9), Fe2-N8 2.196(6); Fe1-O1-Fe2 179.2.

core in **1** are almost equivalent to those in a corresponding diiron(III) complex of TPA, $[Fe_2(TPA)_2(O)(OH_2)_2](ClO_4)_3$ (**3**),[9] which indicates that 6-HPA stabilizes the diiron core without distortion. The ESI mass spectrum of **1** exhibited a major peak at *m*/*z* 1033 arising from $\{[Fe_2(6\text{-HPA})(O)(OH_2)_2](ClO_4)_3\}^+$, and the spectrum of **3** showed two major peaks at *m*/*z* 362 and 445 that resulted from the monoiron species and two minor peaks at *m*/*z* 923 and 1007 arising from the diiron species. These results clearly show that 6-HPA specifically stabilizes the diiron core of **1** in solution.

Efficient and predominant epoxidation of alkenes with H_2O_2 catalyzed by **1** was achieved, and the results are summarized in Table 1.[10] Cyclooctene was converted to the epoxide and 1,2-*cis*-diol in 75 and 2% yields, respectively. In an effort to determine the durability of **1** as a catalyst, an experiment with repeated additions of H_2O_2 was performed under similar conditions, in which the turnover number of **1** exceeded 100. For other alkenes, the epoxide was formed

Table 1: Oxygenation of alkenes with H_2O_2 catalyzed by **1** and **2**.

alkene [IP (eV)][b]	Yield[a] [%] (turnover number) epoxide/*cis*-1,2-diol **1**	**2**
cyclooctene [8.98]	75(7.5)/2(0.2)[c] 70(105)/2(3.0)[d]	42(4.2)/24(2.4)[c]
trans-β-methylstyrene [8.08]	91(9.1)/0[c]	
cis-β-methylstyrene [8.48]	79(7.9)/0[c]	
styrene [8.49]	63(6.3)/0[c]	
1-octene [9.52]	37(3.7)/0[c]	

[a] Yield based on the H_2O_2 used. [b] IP is the ionization potential of the alkene. [c] 10 equiv of H_2O_2 was added. [d] 150 equiv of H_2O_2 was added.

predominantly and the 1,2-*cis*-diol was not detected. The *trans*-epoxide was obtained from *trans*-β-methylstyrene in 91% yield. Given the large turnover number and high epoxide yield, it can be stated that **1** is an effective sMMO model. The epoxide yield increased with decreasing ionization potential (IP)[11] of the alkene (Table 1); *trans*-β-methylstyrene, which had the lowest IP value, gave the highest epoxide yield. Moreover, epoxidation was not stereospecific, as *cis*- and *trans*-epoxides were obtained from *cis*-β-methylstyrene with an RC value of 63%.[12] These data indicate that the first step in the epoxidation represents a one-electron oxidation of the alkene by an active species, and that the radical cation generated undergoes a *cis*-to-*trans* configuration change. As 6-HPA stabilizes the diiron core of **1** in solution, the active species generated from **1** must be a dinuclear complex relevant to sMMO.

Interestingly, when the diiron(II) complex **2**, which does not have bridging oxo or hydroxo groups, was used as a catalyst for the oxygenation of cyclooctene, the 1,2-*cis*-diol was a main product (see Table 1). When 1 equiv of H_2O_2 was added to **2**, the epoxide/*cis*-1,2-diol product ratio was 0.15:0.85. With an increase in the amount of H_2O_2 added, the yield of epoxide was increased and that of *cis*-1,2-diol was decreased according to the following epoxide/*cis*-1,2-diol ratios: 0.26:0.74, 0.53:0.47, and 0.64:0.36 for 2, 5, and 10 equiv of H_2O_2 added, respectively. These results clearly show that **2** mainly produces *cis*-1,2-diol, and **1** gradually generated by oxidation of **2** with H_2O_2 mainly produces epoxide. This finding indicates that the μ-oxo bridge in **1** plays an essential role for the sMMO-type reactivity.

Addition of 2 equiv of H_2O_2 to a solution of **1** in CH_3CN at −40 °C generated a green species **4** that exhibited absorption bands at 490 ($\varepsilon = 1130\ M^{-1}cm^{-1}$), 670 (1060), and 882 nm (sh, 370). These data are similar to those of the peroxodiiron complex $[Fe_2(O)(O_2)(6\text{-}Me_3\text{-}TPA)_2](ClO_4)_2$ (**5**; 6-Me$_3$-TPA = tris(6-methyl-2-pyridylmethyl)amine).[13] The cold-spray ionization (CSI) mass spectrum of **4** showed a parent peak at *m*/*z* 865 arising from a peroxodiiron complex, $\{[Fe_2(O)(O_2)(6\text{-}HPA)](ClO_4)\}^+$, as the strongest peak (Figure 2). The ion exhibited an isotope intensity pattern that matched the calculated one. Upon addition of $H_2{}^{18}O_2$ instead of $H_2{}^{16}O_2$, the mass of the ion increased by four units. These results indicate that **4** is best formulated as $[Fe_2(O)(O_2)(6\text{-}HPA)](ClO_4)_2$. Spontaneous decomposition of **4** in CH_3CN monitored at 680 nm obeyed first-order kinetics with $k = 1.6 \times 10^{-3}\ s^{-1}$ at 243 K (the half-life $\tau_{1/2} = 7.2$ min). This value was equivalent to that of **5** under the same conditions.[13] Compound **4** was as stable as **5** but without steric hindrance, as was the case with the Me groups of 6-Me$_3$-TPA in **5**. When *trans*-β-methylstyrene was added to the solution of **4** generated as described above at −40 °C, the decay of **4** was not accelerated at all. The mixture was analyzed after warming to room temperature; the epoxide yield was increased to almost quantitative.

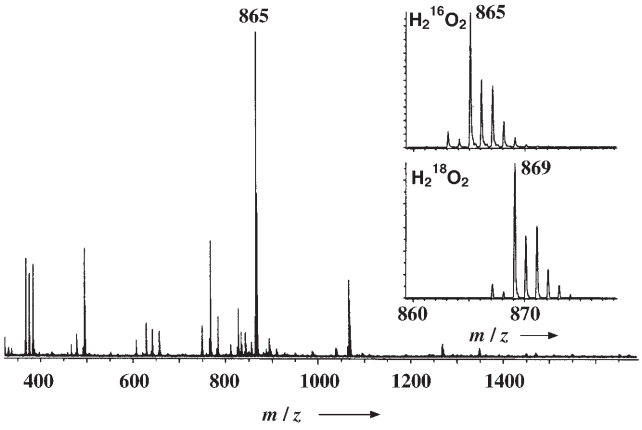

Figure 2. CSI mass spectrum of **4** obtained at −40 °C in CH_3CN. The isotope patterns assignable to $\{[Fe_2(O)(^{16}O_2)(6\text{-}HPA)](ClO_4)\}^+$ and $\{[Fe_2(O)(^{18}O_2)(6\text{-}HPA)](ClO_4)\}^+$ are shown in the insets.

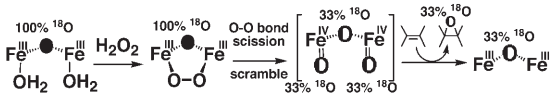
Isotope-labeling experiments with *trans*-β-methylstyrene as substrate were carried out by using $H_2{}^{18}O_2$ and μ-^{18}O-**1** under argon to gain insight into the O–O activation mechanism. Upon addition of 10 equiv of $H_2{}^{18}O_2$ to **1**, ^{18}O was incorporated into 94% of the epoxide, whereas addition of 1 or 3 equiv of $H_2{}^{16}O_2$ to μ-^{18}O-**1** resulted in incorporation of ^{18}O into 31 or 17% of the epoxide, respectively. Thus, μ-^{18}O is incorporated into the epoxide in addition to $H_2{}^{18}O_2$. This finding can be explained if it is assumed that a dioxo-μ-oxodiiron(IV) moiety is generated from **4** as an active species via homolytic scission of the O–O bond, and that three O atoms in the active species scramble one another. Accordingly, with $H_2{}^{16}O_2$ (1 equiv)/μ-^{18}O-**1**, 33% of each oxo group in the active species was labeled with ^{18}O, and thus the theoretical yield of the ^{18}O-epoxide was 33% (Scheme 1).



Scheme 1. Incorporation of the ^{18}O atom on labeling with μ-^{18}O-**1**.

Similarly, with $H_2{}^{16}O_2$ (3 equiv)/μ-^{18}O-**1** or $H_2{}^{18}O_2$ (10 equiv)/**1**, the yield of ^{18}O-epoxide is estimated to be 16 or 95%, respectively. The theoretical values of 33, 16, and 95% agree with the experimental results of 31, 17, and 94%, respectively.

Further experiments with an excess amount of $H_2{}^{18}O$ or under $^{18}O_2$ revealed the unique reactivity of the active species. With $H_2{}^{18}O/H_2{}^{16}O_2$/**1** (1000:10:1), only 1.5% of the epoxide was labeled with ^{18}O, which shows that O-atom exchange of the active species with H_2O was much slower than O-atom transfer to the alkene.[14] When the reaction was carried out with $H_2{}^{16}O_2$ (10 equiv)/**1** under $^{18}O_2$, 5% of the epoxide was labeled with ^{18}O. This result suggests that a one-electron oxidation of the alkene by the active species occurs to form a radical cation and a diiron(III),(IV) species, as ^{18}O labeling from $^{18}O_2$ must occur by autoxidation of the radical cation. The remaining 95% of nonlabeled epoxide could be accounted for by O-atom transfer from the resultant diiron(III),(IV) species to the radical cation. We are presently attempting to detect the diiron(III),(IV) and diiron(IV) species, which would be generated from **1** and H_2O_2 via the peroxo intermediate **4**.

Experimental Section

6-HPA: An aqueous solution of NaOH (2.3 M, 5 mL) was added dropwise with vigorous stirring to a solution of TPA (0.77 g, 3.87 mmol) and 1,2-bis(6-bromomethyl-2-pyridyl)ethane·2 HBr (1.03 g, 1.94 mmol) in water (5 mL) at room temperature. The reaction mixture was stirred for 24 h at room temperature and then extracted with $CHCl_3$. The extracts were dried over Na_2SO_4 and the product 6-HPA was isolated as a white solid (0.71 g, 60 %). Mp.: 133.5–135.0 °C. Elemental analysis (%) calcd for $C_{38}H_{38}N_8$: C 75.22, H 6.31, N 18.34; found: C 74.99, H 6.34, N 18.34. ^{1}H NMR (Me_4Si, in $CDCl_3$): $\delta = 8.52$ (dq, 4H, py′-6), 7.65 (m, 6H, py-4 and py′-4), 7.49 (s, 4H,py′-3), 7.36 (d, 2H, py-5), 7.13 (s, 4H, py′-5), 6.96 (d, 2H, py-3), 3.89 (s, 8H, $pyCH_2N(CH_2py)_2$), 3.86 (s, 4H, $pyCH_2N(CH_2py)_2$), 3.19 ppm (s, 4H, CH_2); ^{13}C NMR (Me_4Si, in $CDCl_3$): $\delta = 160.3$, 159.3, 158.5 (py-2, py-6, py′-2), 148.8 (py′-6), 136.4, 136.2, 122.6, 121.7, 120.9, 119.9 (py-4, py′-4, py′-3, py′-5, py-5, py-3), 60.0, 59.9 (methylene), 38.0 ppm (ethylene). FAB MS: m/z 607 $[M+H]^+$.

1: 6-HPA (60.5 mg, 0.1 mmol) was dissolved in water (1 mL), a solution of $Fe(ClO_4)_3·9H_2O$ (103 mg, 0.2 mmol) in water (1 mL) was added, and the mixture was stirred overnight. **1** precipitated as a brown powder (yield 86.5 %) and was recrystallized from C_6H_6/CH_3CN to give crystals suitable for X-ray structure analysis. Elemental analysis (%) calcd for $C_{38}H_{50}N_8Cl_4O_{23}Fe_2$: C 36.80, H 4.06, N 9.03, Fe 9.00; found: C 36.62, H 4.03, N 9.04, Fe 8.73. UV/Vis absorption (in CH_3CN): $\lambda_{max} = 515$ nm^{-1} ($\varepsilon_{max} = 110$ M^{-1}cm^{-1}). IR (KBr disk): $\tilde{\nu} = 3072$, 3032 (aromatic C–H), 2959, 2924 (aliphatic C–H), 1607, 1572 (pyridine ring), 1113, 1084 (ClO_4), 810 cm^{-1} (Fe–O–Fe). ESI MS: m/z 1033 $[M-2H_2O-ClO_4]^+$, 466 $[M-2H_2O-2ClO_4]^{2+}$.

μ-^{18}O-**1:** 6-HPA (20.3 mg, 33 μmol) and $Fe(ClO_4)_3·9H_2{}^{18}O$ (35.9 mg, 67 μmol) were dissolved in $H_2{}^{18}O$ (1 mL) and the mixture was stirred overnight. μ-^{18}O-**1** precipitated as a brown powder (yield 65 %) and was recrystallized from dry C_6H_6/CH_3CN. IR (KBr disk): $\tilde{\nu} = 3069$, 3034 (aromatic C–H), 2953, 2922 (aliphatic C–H), 1607, 1572 (pyridine ring), 1092 (ClO_4), 768 cm^{-1} (Fe–O–Fe). ESI MS: m/z 1035 $[M-2H_2{}^{18}O-ClO_4]^+$, 467 $[M-2H_2{}^{18}O-2ClO_4]^{2+}$, 278 $[M-2H_2{}^{18}O-3ClO_4]^{3+}$.

2: A solution of 6-HPA (30.75 mg, 0.051 mmol) in CH_2Cl_2 (1 mL) was added to a solution of $Fe^{II}(TfO)_2·2CH_3CN$ (40.1 mg, 0.11 mmol) in THF (2 mL) and the mixture was stirred overnight under Ar. Complex **2** precipitated as a pale yellow powder, and was isolated by filtration (46.8 mg, yield 70 %) and recrystallized from CH_2Cl_2/CH_3CN/Et_2O under Ar. Elemental analysis (%) calcd for $C_{42}H_{38}N_8F_{12}S_4O_{12}Fe_2$: C 38.37, H 2.91, N 8.52, Fe 8.50; found: C 38.29, H 2.89, N 8.31, Fe 8.19. UV/Vis absorption (in CH_3CN): λ_{max} (ε_{max} M^{-1}cm^{-1}) = 355 (1600), 540 nm^{-1} (20). IR (KBr disk): $\tilde{\nu} = 3119$, 3082 (aromatic C–H), 2984, 2926 (aliphatic C–H), 1607, 1576, 1466, 1447 (pyridine ring), 1283, 1254, 1167, 1030 cm^{-1} (CF_3SO_3). ESI MS (in CH_3CN): m/z 1165 $[M-CF_3SO_3]^+$, 508 $[M-2CF_3SO_3]^{2+}$, 289 $[M-3CF_3SO_3]^{3+}$.

Isotope-labeling experiments were carried out under similar conditions in the presence of an excess amount of $H_2{}^{18}O$ or under $^{18}O_2$. The epoxidation reaction was also performed with μ-^{18}O-**1**/H_2O_2 ratios of 1:1 and 1:3 under Ar. The resultant mixtures were analyzed by GC-MS, and the rate of ^{18}O labeling was determined from the isotope-intensity pattern.

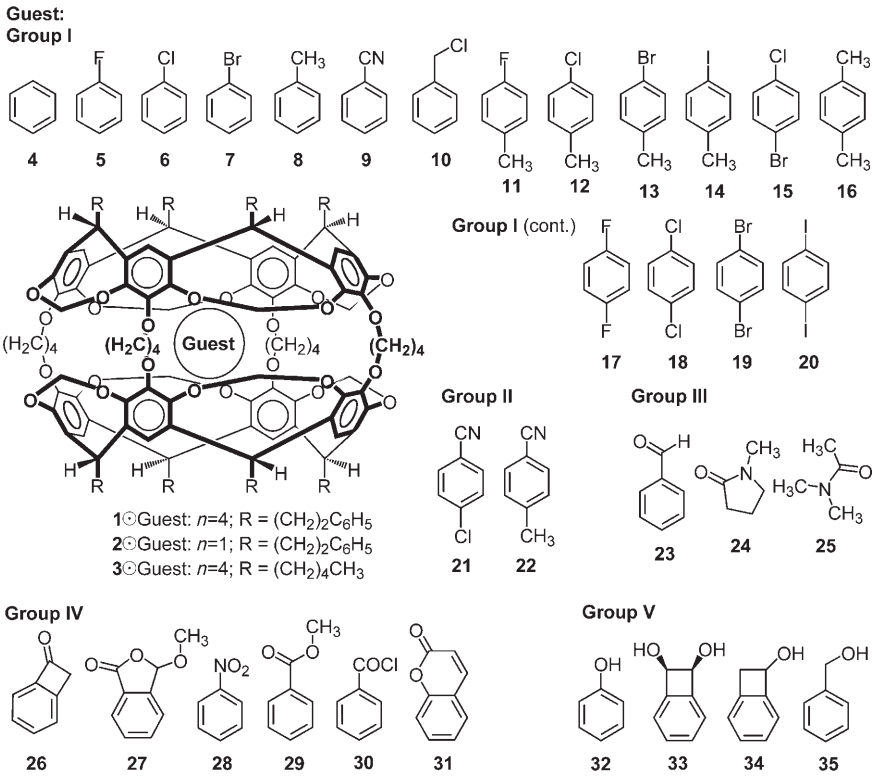
A "Through-Shell" Binding Isotope Effect**

*Yong Liu and Ralf Warmuth**

Isotope effects play an important role in chemical and biological sciences.[1] In particular, kinetic isotope effects allow the probing of reaction mechanisms,[2] transition-state geometries,[3] tunneling contributions to reaction rates, and steric requirements in the rapture of mechanical bonds.[4,5] In addition, substantial differences in noncovalent interactions that underlie olfaction,[6] enzyme–cofactor binding,[7] retention on normal and reversed phase HPLC columns,[8,9] and molecular encapsulation have been observed upon deuteration.[10,11] Isotopic substitution also affects the thermodynamic properties of molecules, thus leading to changes in the vapor pressure and melting point, as well as to the phase segregation of polymers.[12–14] However, the origin of binding isotope effects (BIE) and how specific molecular interactions influence the volume, energy, and entropy of a molecule and give rise to the observed changes in properties upon isotopic substitution is not fully understood.[15] It is well established that the molar volume of a molecule decreases upon deuteration as a consequence of the smaller zero point energy (ZPE) of the C–D bond relative to the C–H bond and the anharmonicity of the potential energy surface, which leads to different equilibrium interatomic distances. For example, the difference in the mean C–H and C–D bond lengths of methane is $\Delta l = 0.004$ Å, as determined by gas-phase electron-diffraction studies.[16]

Here we introduce a novel supramolecular approach for the determination of the changes in the bond lengths and volume upon deuteration which allows determination of the differences in the C–H/C–D bond lengths of a single molecule that is isolated inside a highly polarizable medium.[17] A comparison of the apparent differences in the C–H/C–D bond lengths in different media might provide new insights into the magnitude of the intermolecular and intramolecular contributions to the observed molar volume isotope effect.[18] In our approach, a hemicarcerand serves as a sensitive "molecular ruler" that allows the precise determination of small size differences between two incarcerated guests from the chromatographic properties of both hemicarceplexes. We also provide for the first time a quantitative analysis of the chromatographic behavior of hemicarceplexes and an understanding of how the molecular information that is stored in the encapsulated guest (size, shape, chirality, electrostatic potential, and local and global dipole moment) is translated through the hemicarcerand shell into a surface–hemicarceplex interaction.[19,20] A detailed understanding of such inside–outside information transfer[19–21] might shed light on similar processes in biological systems and should be important for applications of container molecules or self-assembled capsules as molecular switches, sensors, information storage devices, or new tools in separation technology.[21a,22]



Scheme 1. Hosts and guests investigated in the study.

In an investigation that addressed how the guest of hemicarceplexes **1** ⊙ guest (guest: **4**–**35**; Scheme 1)[23–25] communicates with an external chromatographic stationary phase we noted a large increase in the HPLC retention factor $k' = (t_R - t_0)/t_0$ (t_R = solute retention time; t_0 = retention time of unretained solute; mobile phase: CH_2Cl_2/0.5% Et_2O;

1 mL min^{-1}) with increasing guest size. The value of k' increased 35-fold between the fastest (**1** ⊙ benzene; $k' = 1.5$) and slowest eluting hemicarceplex (**1** ⊙ 7-methoxyphthalide; $k' = 51.86$). Furthermore, retention did not correlate with guest polarity; for example, the value of k' increased in the order **1** ⊙ **4** < **1** ⊙ **5** < **1** ⊙ **6** < **1** ⊙ **9** < **1** ⊙ **8** ≈ **1** ⊙ **7** ≪ **1** ⊙ **16**. The flexible $O(CH_2)_4O$ linkers of **1** allow adaptation of the inner phase of the host to the size and shape of the guest in order to maintain an optimal space occupancy.[26] Thus, it is tempting to assume that the retention times are related to the size and shape of the hemicarceplexes: An increased outer surface should increase the surface–surface interaction. To test this hypothesis we carried out molecular dynamics simulations (MDSs) for each hemicarceplex **1** ⊙ guest (guest: **4**–**35**) and chose the distance d between the center of the two squares formed by connecting the four ether oxygen atoms of a cavitand as a measure for the change in the hemicarcerand size (Figure 1). These MDS studies (Amber*, 300 K, 10 ns) provided time-averaged values for d and

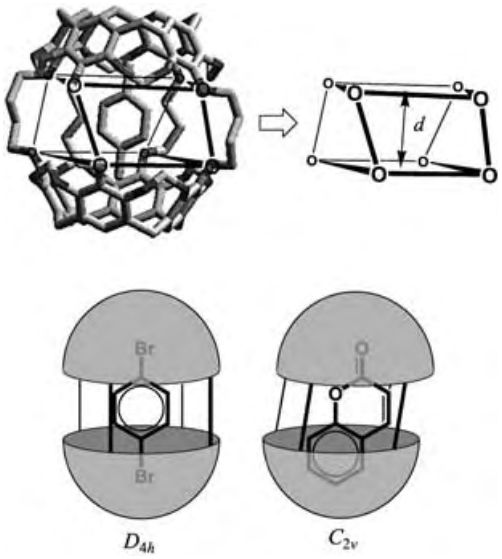

Figure 1. Definition of d for the energy-minimized structure of **1** ⊙ **16** (left) and shapes of hemicarceplexes: D_{4h}: guests **4**–**25**, **32**, **35**; C_{2v}: guests **26**–**31**, **33**, **34**.

information about the shape of the hemicarceplexes, which we categorized as D_{4h}- (guests **4**–**25**, **32**, **35**) or C_{2v}-symmetric (guests **26**–**31**, **33**, **34**) according to the relative orientation of the cavitands.[27] We were delighted to find that $\ln k'$, which is proportional to the change in free energy ΔG upon transferring a hemicarceplex from the mobile phase to the stationary phase, correlates almost linearly with the value of d for hemicarceplexes having nearly D_{4h} symmetry (group I hemicarceplexes in Scheme 1; Figure 2).

What is the physical basis behind this correlation? Further analysis of the MDS studies shows that elongation of a hemicarceplex leads to an increased outward rotation of the lone pairs of electrons on the oxygen atoms of the $O(CH_2)_4O$ linker. Since an outward pointing lone pair of electrons on an oxygen atom is able to engage in polar Si–OH···O_{host}

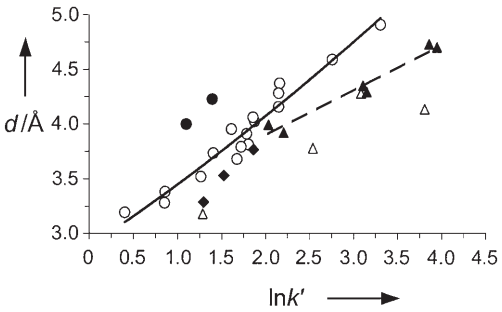

Figure 2. Semilogarithmic plot of hemicarceplex **1** ⊙ guest length (d) and retention factor ($\ln k'$): guests of group I (○); guests of group II (●); guests of group III (◆); guests of group IV (▲); guests of group V (△; see Scheme 1); and best fit for the correlation of group I guests. (CH_2Cl_2/0.5% Et_2O; 1 mL min^{-1}; Phenomenax, Luna Si (2), 15 cm × 4.6 mm, 5 μm; 22 °C).

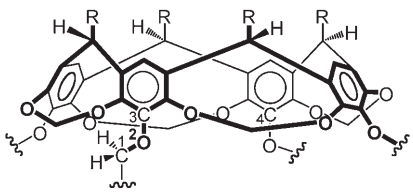
interactions with the silica surface of the stationary phase, this will increase the retention of the hemicarceplex. In fact, a good linear correlation between $\ln k'$ and the time-averaged sum of all the C_1-O_2-C_3-C_4 dihedral angles (θ) is observed (see Scheme 2 and Supporting Information).



Scheme 2. Definition of C_1-O_2-C_3-C_4 dihedral angle θ. Lone pairs of electrons on the oxygen atoms are fully protected (inwards) for $\theta = 180°$ and fully exposed (outwards) for $\theta = 0°$.

Thus, differences in the retention times of the hemicarceplexes with D_{4h} symmetry are primarily controlled by the length of the hemicarcerand through the time-averaged orientation of the lone pairs of electrons on the ether oxygen atoms. However, several hemicarceplexes deviated from this behavior and showed weaker (group II, Scheme 1) and stronger retention (group III, Scheme 1) than predicted based on their length. Even though the exact reason for their different behavior is not fully understood, it might be a consequence of the particularly large dipole moment of the guest, which influences the hemicarceplex–silica interaction. In fact, Cram and co-workers explained the differences in the thin layer chromatography retention factors of hemicarceplexes **2** ⊙ DMF, **2** ⊙ *N*,*N*-dimethylacetamide, and **2** ⊙ DMSO on the basis of such modulations of carceplex–silica dipole–dipole interactions induced by the dipole of the guest.[19] In the group II hemicarceplexes the CN groups are aligned along the polar axis of the host and are "pushed" into the cavitand such that the positively charged C atom is in the same horizontal plane as the cavitand's oxygen belt. We believe that the proximity of the positive pole of the CN group leads to a slight weakening of all Si–OH···O_{host} interactions involving these oxygen atoms. A related but opposite effect could explain the retention behavior of the group III hemicarce-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

plexes: their guests possess a carbonyl group, whose negative pole is in proximity to the oxygen atom rim of a cavitand leading to a slight strengthening of local Si–OH···O_{host} and dipole–dipole silica–hemicarceplex interactions by roughly an equal amount in all three hemicarceplexes.

Hemicarceplexes whose guest induces C_{2v} symmetry of the host (group IV, Scheme 1) are retained more strongly than hemicarceplexes of group I with a comparable *d* value, but still show a linear correlation between $\ln k'$ and *d*. Because of the limited number of hemicarceplexes in this series and the fact that each guest has a polar functional group, is not fully clear whether the increased hemicarceplex–silica surface interaction is a result of the shape of the hemicarceplex or the presence of the polar functional group.

Finally, hemicarceplexes whose guest has a hydroxy group all show stronger retention, as predicted (group V, Scheme 1). A logical explanation would be through-shell guest-OH···O-silica hydrogen bonds that increase the binding interaction of the hemicarceplex with the surface.

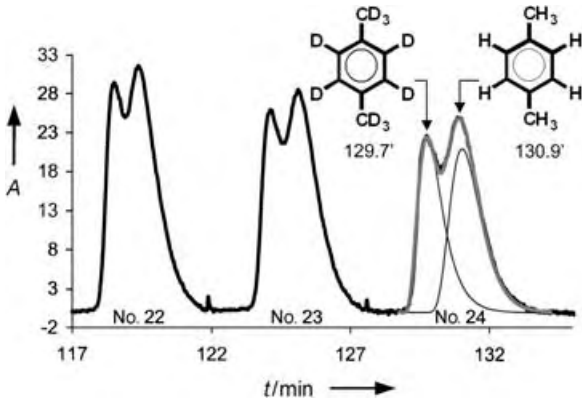


Figure 3. Normal-phase HPLC recycle chromatogram (thick blackline) of a 1:1 mixture of **3** ⊙ *p*-xylene and **3** ⊙ [D_{10}]-*p*-xylene and peak deconvolution of the 24th cycle (mobile phase: A/B, 65:35, A: 2.0 v% Et_2O in CH_2Cl_2, B: CH_2Cl_2; 1 mL min^{-1}; Phenomenax, Luna Si (2), 25 cm × 4.6 mm, 5 μm; 22 °C). Gray line: best fit of the double peak of the 24th cycle; thin black line): peak **3** ⊙ [D_{10}]-*p*-xylene and **3** ⊙ *p*-xylene.

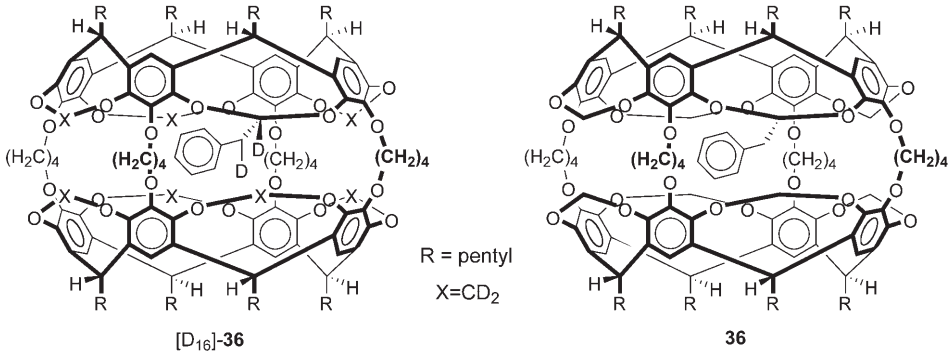

Even though the dipole moment or OH group of a tightly bound guest is able to "communicate" with the silica surface, the length of the hemicarceplex is the key factor that controls retention in all hemicarceplex groups (I–V). If this is indeed true, separation of isotopomeric hemicarceplexes that differ solely in the extent of guest deuteration might be possible. We tested this idea with the **1** ⊙ *p*-xylene/**1** ⊙ [D_{10}]-*p*-xylene pair. Initial attempts to separate both hemicarceplexes failed even with recycling chromatography because of strong tailing of the peaks. A screen of other hemicarceplexes with different appending groups showed reduced tailing for **3** ⊙ **16** and, indeed, the onset of separation of **3** ⊙ **16** and **3** ⊙ [D_{10}]-**16** was observed after 14 chromatographic cycles, with **3** ⊙ [D_{10}]-**16** eluting before **3** ⊙ **16** as predicted from the volume isotope effect of the guest (Figure 3).[28] From the difference in the retention times in the 24th cycle (Figure 3), we determined $\Delta\ln k' = \ln k'_H - \ln k'_D = 0.013(1)$ and a binding isotope effect of $k'_H/k'_D = 1.013(1)$. This binding isotope effect is conceptionally new since it depends primarily on the volume difference between the two isotopomers, which induces a small structural change in the surrounding hemicarcerand that leads to the observed change in the binding energy of $\Delta\Delta G = 7.6(6)$ cal mol^{-1}. The following observations rule out participation of the guest's C–H/D bonds in the hemicarceplex–silica interaction: 1) the isotopomeric hemicarceplexes **36** and [D_{16}]-**36**, in which the outward-pointing acetal C–H/D bonds interact with the stationary phase, show a reversed elution order;[8] 2) the absence of separation for the pair **3** ⊙ **16** and **3** ⊙ [D_4]-**16**, in which the aryl protons of the guest more exposed to the bulk phase are labeled, but partial separation for the pair **3** ⊙ **16** and **3** ⊙ [D_6]-**16**, in which the shielded methyl groups of the guest are labeled. The latter experiments also demonstrate that the partial separation of the pair **3** ⊙ **16** and **3** ⊙ [D_{10}]-**16** is a consequence of deuterating the methyl groups of the guest.

If the volume isotope effect of the guest were the sole cause of the difference in the retention time between **3** ⊙ **16** and **3** ⊙ [D_{10}]-**16**, what would be the difference in the C–H/C–D bond lengths? From the $\Delta\ln k'$ value and the slope of the $\ln k'$ versus *d* plot for hemicarceplexes **3** ⊙ guest (guest = **4**–**8**, **11**–**19**; see Supporting Information), we calculated the hemicarceplex contraction upon guest deuteration as $\Delta d = 0.0098 \pm 0.0009$ Å. MDS studies of *p*-xylene hemicarceplexes in which we systematically constrained the C–H bonds of the guest to a length between 1.0 and 1.1 Å showed that a shortening of the methyl C–H bonds by 0.01 Å decreased *d* by 0.0204 Å. Thus, the measured Δd value corresponds to a difference in the C–H/C–D bond lengths of $\Delta l = 0.0048 \pm 0.0005$ Å. Bartell and Roskos used $\Delta l = 0.005$ Å in model calculations that accurately predicted the measured volume isotope effect of benzene.[29] Likewise, Bates et al. found a good agreement between the experimentally observed and modeled differences in the unit cell dimensions of crystalline $C_{36}H_{74}$ and $C_{36}D_{74}$ by assuming $\Delta l = 0.005$ Å.[18a] The close match between these and our measured bond lengths suggest that the volume isotope effect of the guest is likely the main reason for the observed chromatographic isotope effect. However, other contributions to the observed difference in the deuteration-induced hemicarceplex length cannot be

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

excluded. For example, the higher polarizability of a C–H bond relative to a C–D bond would result in stronger CH–π interactions between the host and guest and a decrease in the difference in length between **3**⊙**16** and **3**⊙[D_{10}]-**16**.[18a,b] Furthermore, Rebek and co-workers showed that a CD_3 group is more strongly attracted to the inner surface of a cavitand than is a CH_3 group.[10] This result has been explained with a blue shift of the C–H/C–D stretching frequency upon formation of a CH/CD–π interaction that leads to an increased ZPE splitting.[15] Since hemicarceplexes are fluxional in solution,[30] a tighter host–guest complex is expected for **3**⊙[D_{10}]-**16** than **3**⊙**16**, which will increase the difference in length between **3**⊙**16** and **3**⊙[D_{10}]-**16** beyond what is expected based on the different dimensions of the C–H and C–D bond.[16]

In conclusion, we have unraveled some of the mechanisms that lead to the observed large differences in the chromatographic behavior of hemicarceplexes. Our investigations show that guest size plays a crucial role in modulating the hemicarceplex–surface interactions and that even such subtle changes resulting from deuteration lead to a measurable change in the retention time. We believe that simple correlations between retention behavior and structural parameters, such as the computed length and shape of the complex also exist for other hemicarcerands and capsules. If indeed such correlations can be found for chiral hemicarceplexes,[18b] novel and powerful methodologies for chiral separation and the determination of the absolute configuration of a chiral guest molecule might become available.

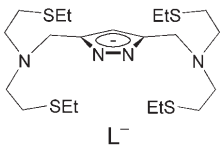
Hysteretic Magnetic Bistability Based on a Molecular Azide Switch**

*Guido Leibeling, Serhiy Demeshko, Sebastian Dechert, and Franc Meyer**

Dedicated to Professor Gottfried Huttner on the occasion of his 68th birthday

Materials that exhibit hysteretic bistability at temperatures not too far from ambient conditions are expected to have great potential for future memory or sensing applications.[1] The two relatively stable states should be clearly distinguished by their physical properties, such as their magnetic or optical characteristics. Thermal magnetic hysteresis with an abrupt and rapid property change around room temperature is particularly rare for molecule-based materials,[2] with spin-crossover compounds providing the most prominent examples.[3] More recently, magnetic hysteresis has also been observed for some molecular organic radicals[4] or transition metal coordination compounds,[5,6] where switching between two states occurs through a thermal phase transition with orientational changes in the 3D crystal lattice. Herein, we report thermal hysteresis of the magnetic susceptibility for single crystals of the molecular dinickel(II) complex $[LNi_2(N_3)_3]$ (**1**), in which a $\mu_{1,3}$-azido ligand functions as an on/off switch for the intramolecular antiferromagnetic coupling between the two metal ions.

Pyrazolate-based compartmental ligands such as L^-, which bears thioether side-arms, have previously proven suitable as dinucleating scaffolds for the synthesis of preorganized azidonickel(II) complexes that can serve as modules for the assembly of oligonuclear species or 1D extended chain compounds;[7] the bimetallic complex **1** was prepared as a potential building block in this context. Single crystals of **1** were grown from acetone/hexane, and an initial X-ray crystallographic analysis was carried out at 133 K (Figure 1).[8] As anticipated, both nickel ions in the C_2-symmetric array are nested within their respective ligand compartment (with two sulfur and one nitrogen donors from the ligand side-arm) and are spanned by the bridging pyrazolate. A $\mu_{1,3}$-azido bridge is found within the bimetallic pocket, and an additional terminal azide fills the remaining site at each of the six-coordinate metal ions.



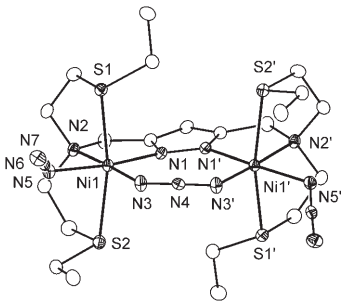


Figure 1. ORTEP plot (30% probability thermal ellipsoids) of the structure of **1** at 133 K. All hydrogen atoms have been omitted for the sake of clarity.

Since **1** did not exhibit any unusual structural features at this stage, the temperature dependence of its magnetic susceptibility was highly unexpected. The product $\chi_M T$ for a polycrystalline sample of **1** is depicted in Figure 2 for both decreasing and increasing temperature. The value of $1.82\ cm^3 K mol^{-1}$ at 300 K is somewhat lower then the spin-only value expected for two uncoupled high-spin nickel(II) ions ($2.14\ cm^3 K mol^{-1}$ for $g = 2.07$), and decreases only slightly upon lowering the temperature to 220 K. At 215 K, however, an abrupt drop of $\chi_M T$ occurs (centered at $T_\downarrow = 212$ K), followed by a much more rapid decline at lower temperatures; below 50 K $\chi_M T$ tends towards zero. The low-temperature data are indicative of strong antiferromagnetic coupling and an $S = 0$ ground state, while coupling is apparently only weak above 220 K. $\chi_M T$ shows an analogous behavior when measured as a function of increasing temperature, but exhibits thermal hysteresis with $\Delta T \approx 13$ K ($T_\uparrow$

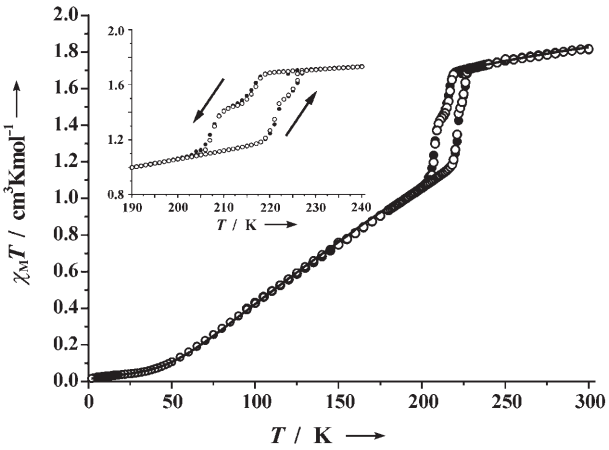

Figure 2. Plot of $\chi_M T(T)$ at two different magnetic fields (closed circles: 5000 G; open circles: 2000 G) for decreasing and increasing temperature. The solid lines represent the calculated curve fits at high and low temperature (see text). The inset shows an enlargement for the temperature region between 190 und 240 K.

centered at 223 K). No field dependence of the magnetic data was observed. Complex **1** thus undergoes a reversible and field-independent switching of the magnitude of the magnetic exchange interaction, with hysteresis occurring not too far from room temperature.

The experimental magnetic data were modeled separately in the range from 200 to 5 K and above 230 K using Equation (1), which is deduced from the Hamiltonian $\mathscr{H} = -2J\hat{S}_1\hat{S}_2$, with additional terms accounting for residual amounts of paramagnetic impurity (ρ), and for the temperature-independent paramagnetism (TIP).

$$\chi_M = \frac{N g^2 \mu_B^2}{k T}\frac{2e^{2(J/kT)} + 10e^{6(J/kT)}}{1 + 3e^{2(J/kT)} + 5e^{6(J/kT)}}(1-\rho) + \frac{2N g^2 \mu_B^2}{3kT}\rho + \mathrm{TIP} \qquad (1)$$

Good fits were obtained with the parameters $g = 2.24 \pm 0.01$, $J = -(81 \pm 1.5)\ \mathrm{cm}^{-1}$ ($\rho = (0.6 \pm 0.1)\%$; $\mathrm{TIP} = 1.2 \times 10^{-3}$) at low temperatures and $g = 2.07 \pm 0.01$, $J = -(24 \pm 1.0)\ \mathrm{cm}^{-1}$ ($\rho = (0.8 \pm 0.1)\%$; $\mathrm{TIP} = 1.0 \times 10^{-4}$) above 230 K,[9] thereby confirming the drastic differences in the strength of the antiferromagnetic coupling for the two temperature domains, with strong or weak antiferromagnetic coupling below or above the hysteretic transition, respectively.

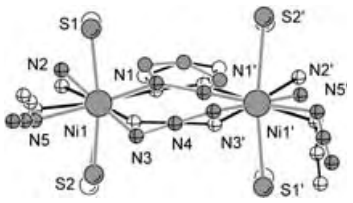

Figure 3. Overlay of the molecular structures at 253 K (grey) and 133 K (white) of **1**, showing the changes of the dihedral angles. Selected interatomic distances [Å] and angles [°] at 133 K [253 K]: Ni1-N1 2.071(3) [2.065(2)], Ni1-N2 2.139(3) [2.136(3)], Ni1-N3 2.056(3) [2.078(3)], Ni1-N5 2.079(3) [2.067(3)], Ni1-S1 2.4279(9) [2.436(1)], Ni1-S2 2.5319(9) [2.496(1)], Ni1···Ni1′ 4.5538(8) [4.5201(8)], N3-N4 1.174(3) [1.170(3)]; N1-Ni1-N5 170.6(1) [171.2(1)], N2-Ni1-N3 177.3(1) [178.4(1)], S1-Ni1-S2 167.96(3) [169.26(4)], N1-Ni1-N2 82.6(1) [82.3(1)], N2-Ni1-N5 88.7(1) [88.9(1)], N5-Ni1-N3 91.4(1) [92.7(1)], N3-Ni1-N1 97.5(1) [96.1(1)], N4-N3-Ni1 120.7(3) [116.7(3)], N3-N4-N3′ 176.4(5) [177.5(5)]. Symmetry transformation used to generate equivalent atoms (′): 1−*x*, *y*, 1.5−*z*.

Table 1: Unit-cell parameters and selected dihedral angles for **1** at different temperatures.

T [K]	*a* [Å]	*b* [Å]	*c* [Å]	*V* [Å^3]	Ni1-N1-N1′-Ni1′ [°]	Ni1-N3-N3′-Ni1′ [°]
133	15.9739(12)	8.6167(8)	22.8983(17)	3151.8(4)	23.1(6)	4.3(4)

223	16.3424(12)	8.6933(8)	22.9634(15)	3262.4(4)	−39.8(7)	−48.7(4)
253	16.3677(10)	8.7169(7)	22.9876(13)	3279.8(4)	−38.8(6)	−46.6(4)

In order to elucidate the molecular cause of this unexpected magnetic behavior and to characterize the magnetic phase transition, a single crystal of **1** was investigated crystallographically at different temperatures. The crystal was first mounted at room temperature and data sets were then collected at 253, 173, 223, and 195 K (in that order). In each case the temperature was allowed to equilibrate for one hour before data collection was started. It is apparent from the crystallographic data that the crystal stays intact upon temperature variation and repeated shuttling through the hysteresis range as the crystal system remains orthorhombic for all temperatures. Inspection of the molecular structures above and below the hysteresis temperature, however, reveals significant differences of the bimetallic scaffold. These differences can clearly be seen by overlaying the molecular structures of the central dinickel core obtained at 133 and 253 K (Figure 3).

Structural alterations are basically expressed through changes of the dihedral angle formed by the two metal centers and the outer nitrogen atoms of the bridging azide (N3 and N3′) as well as the dihedral angle formed by the metals and the pyrazolate nitrogen atoms (N1 and N1′) (Table 1). A major change is observed between 195 and 223 K, which is consistent with the abrupt drop of the magnetic susceptibility in this temperature range. Between 133 and 195 K or between 223 and 253 K, however, the dihedral angles show no significant variation, which is again in agreement with the magnetic data.

The unusual magnetic properties of **1** can be rationalized on the basis of the crystallographic findings. While some contribution to magnetic coupling from the pyrazolate is certainly present, it is likely that the azide provides the dominant intramolecular pathway.[10] Magnetostructural correlations for $\mu_{1,3}$-azido bridged dinickel(II) complexes have revealed that two geometric parameters, namely the Ni-N-N angles and the dihedral angle, ϕ, along the azide ligand, are of major importance.[11,12] For a Ni-NNN-Ni torsion angle of $\phi = 180°$, the antiferromagnetic coupling is predicted to have a maximum at Ni-N-N angles of around 108° and to decrease at larger angles. On the other hand, the maximum coupling for all Ni-N-N angles is expected for a torsion of 180° (or 0°). In the absence of any constraining ligand scaffold, Ni-N-N angles in dinuclear complexes or 1D extended systems with a single $\mu_{1,3}$-azido bridge tend to lie in the range 115–145°, with $\phi = 140$–180°, thus resulting in J values in the range −17 to $-100\ \mathrm{cm}^{-1}$.[11] A particularly strong antiferromagnetic coupling of around $-100\ \mathrm{cm}^{-1}$ has been observed for some 1D chain complexes with a *trans*-{Ni-($\mu_{1,3}$-N_3)-Ni} motif featuring acute Ni-N-N angles (120.9 or 115.6/116.8°, respectively) and a large ϕ (180 or 175.5°, respectively),[11,13] or in a dinickel(II) complex with extremely obtuse Ni-N-N angles of 109.9°.[14] Similar correlations appear also to be valid for μ_3- or μ_4-azide linkages.[7]

In the case of **1** the Ni1-N3-N4 angles are quite acute and are similar at 133 K [120.7(3)°] and 253 K [116.7(3)°], whereas the torsion Ni-NNN-Ni differs dramatically [4.3(4) versus −46.6(4)°]. Given the above-mentioned magnetostructural correlations, a large antiferromagnetic intramolecular coupling of the order of almost $-100\ \mathrm{cm}^{-1}$ can thus be anticipated for the low-temperature phase (where the torsion angle is close to 0°), while a significantly diminished coupling should result from the severe tilting of the azide bridge in the high-temperature species, in accordance with the experimental

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

findings ($-(81\pm1.5)$ versus $-(24\pm1.0)\,cm^{-1}$). Hence, the bridging azide within the bimetallic pocket of the dinickel(II) scaffold of **1** can be viewed as a molecular on/off switch for the antiferromagnetic coupling between the two metal ions.

Close inspection of the crystallographic changes accompanying the phase transition reveals that the sulfur-bound ethyl groups of the ligand side arms of L^- are disordered about two positions above the hysteresis range (at 223 and 253 K), with temperature-dependent occupancy factors for S2-Et, whereas this disorder disappears below the hysteresis range. Concomitantly, an abrupt shrinkage of the crystallographic *a* axis upon cooling below the hysteresis range is observed, whereas the changes of the *b* and *c* axes are only minor (Table 1). As can be seen from the unit-cell plot (Figure S1 in the Supporting Information), the disordered ethyl group bound to S2 affects the stacking along the *a* axis. The abrupt shrinkage of this axis can thus be linked to the disappearance of the disorder, which apparently allows a more efficient packing of the molecules at low temperatures. However, it is still unclear at this stage how the appearance or disappearance of the disorder is coupled to the changes of the dihedral Ni-NNN-Ni angle within the bimetallic molecules.

Interestingly, a two-step behavior of the phase transition is discernible from the magnetic data. The DSC curve not only reflects the approximately 20-K hysteresis, but also this two-step behavior of the phase transition (Figure 4). Determination of the cause of this unusual feature and a more detailed analysis of the phase transition is currently under investigation.

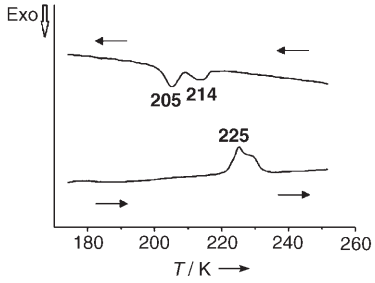

Figure 4. DSC curve for **1** showing the two-step thermal hysteresis between 205 and 230 K.

While phenomenologically reminiscent of spin-crossover behavior, the origin of the thermal magnetic bistability of **1** is fundamentally different: both metal ions retain their individual high-spin ($S=1$) state, but the bridging azide acts as a toggle switch that turns the antiferromagnetic coupling between the nickel(II) ions on or off. While phase transitions associated with small changes in magnetic properties have been observed for polymeric metal azide systems,[15] a hysteresis as distinct as that observed for **1** is unprecedented, and to the best of our knowledge this is the first case where both the high- and low-temperature phases have been characterized crystallographically to reveal the azide functioning as a well-defined molecular switch. Current work focuses on, inter alia, elucidating the cause of the two-step hysteretic behavior as well as investigating pressure effects on the magnetic bistability of **1**.

Experimental Section

Caution! Although no problems were encountered in this work, transition metal perchlorate and azide complexes are potentially explosive and should be handled with due care.

$[LNi_2(N_3)_3]$ (**1**): A solution of HL[16] (512 mg, 1.07 mmol) in methanol (65 mL) was treated with KO*t*Bu (1 equiv, 120 mg, 1.07 mmol). After stirring the mixture for 1 h at room temperature, $Ni(ClO_4)_2\cdot 6H_2O$ (2 equiv, 783 mg, 2.14 mmol) was added and the reaction mixture was stirred overnight. Any white precipitate was then removed by filtration and the resulting green solution was treated with 3.5 equiv of NaN_3 (244 mg, 3.75 mmol) and the mixture again stirred overnight. The light-green precipitate was separated by filtration and the resulting green solution was evaporated to dryness. The residue was taken up in acetone (15 mL) and layered with hexane (15 mL) to obtain green crystals of **1** (275 mg, 36%). IR (KBr): $\tilde{\nu}=$ 2965 (w), 2924 (w), 2870 (w), 2854(w), 2043 [(vs), $\nu(N_3^-)$], 1454 (w), 1418 (w), 778 (w) cm^{-1}. MS(FAB+): m/z (%) = 677 (100) $[LNi_2(N_3)_2]^+$, 635 (15) $[LNi_2(N_3)]^+$. $C_{21}H_{41}N_{13}Ni_2S_4$ (721.3): calcd.: C 34.97, H 5.73, N 25.24; found: C 35.03, H 5.75, N 24.60.

Chemo-, Regio-, and Stereoselective Cobalt-Mediated [2+2+2] Cycloaddition of Alkynyl Boronates to Alkenes: 1,3- and 1,4-Diboryl-1,3-cyclohexadienes**

*Vincent Gandon, David Leboeuf, Sabine Amslinger, K. Peter C. Vollhardt, Max Malacria, and Corinne Aubert**

Alkenylboranes are useful intermediates for the preparation of a wide range of important organic compounds.[1] Specifically, mono- and diborylated 1,3-dienes have found various applications in dienylations,[2] Diels–Alder reactions,[3] and in the synthesis of α,β- or γ,δ-unsaturated ketones.[4] Their cyclic counterparts, namely boryl-1,3-cyclohexadienes, are as yet unknown. Considering that the 1,3-cyclohexadiene nucleus is a key subunit of many natural and/or biologically active compounds,[5] including those of the didehydroretinol and -carotene families,[6] borylated 1,3-cyclohexadienes constitute valuable reagents with which to introduce this synthon directly. The latter task has been accomplished in the past by using 1,3-cyclohexadienyl–metal complexes,[7] triflates,[8] or phosphates,[9] although these reagents have to be generated in several steps from enolizable cyclohexenone derivatives; this methodology has not been applied to dimetalated 1,3-cyclohexadienes.[10] We report here the preparation of 1,3- and 1,4-diboryl-1,3-cyclohexadienes by means of the cobalt-mediated [2+2+2] cocyclization of alkynyl boronates with alkenes.[11] Alkynyl boronates have recently been used as substrates in various transition-metal-mediated reactions[12] that lead to valuable building blocks, because the newly formed C_{sp^2}–B bonds can be subjected to couplings[13] and a plethora of other functional group transformations.[14] Siebert et al. have shown

that catechol-substituted mono- and diborylalkynes undergo facile catalytic cyclotrimerization in the presence of cobalt(0) or cobalt(I) complexes to furnish oligoborylarenes.[12g] We have recently disclosed that alkynyl(pinacol)boronic esters add to α,ω-diynes under similar experimental conditions to assemble fused arylboronic esters.[12i]

The success of the present study was predicated on the employment of η^5-cyclopentadienylbis(ethene)cobalt (**1**),[15] which we have employed previously as an active source of CpCo in cooligomerizations of alkynes with alkenes.[11c–e] Preliminary experiments were carried out under an ethene atmosphere by treating **1** with two equivalents of alkynyl(pinacol)boronic esters **2**–**6** in THF (Table 1).[16] Under these

[a] Yields of product isolated after flash chromatography. [b] Unseparated mixture. [c] The yield is the sum of those for isolated **9C** (56%) and **9D** (37%). [d] The yield is that for complex **11D**, obtained pure by crystallization from the mixture in hexane. The presence of **11C** was surmised on the basis of the ^{1}H NMR spectroscopic data of the mixture.

conditions, alkyne cyclotrimerization[12g,i] was suppressed in favour of the formation of mixtures of the regioisomeric 1,2- and 1,3-diboryl(η^4-cyclobutadiene)cyclopentadienylcobalt complexes **A** and **B**, respectively, as well as the 1,4- and 1,3-diboryl(η^4-1,3-cyclohexadiene)cyclopentadienylcobalt complexes **C** and **D**, respectively. The 2,3-diboryl(η^4-1,3-cyclohexadiene) substitution pattern was notably absent.

These air-stable products were purified by flash chromatography on silica gel. As shown in Table 1 (entry 1), only the 1,3-diboryl(η^4-cyclobutadiene)cyclopentadienylcobalt complex **7A** was formed for R = *t*Bu. Its structure was confirmed unambiguously by an X-ray analysis (see Supporting Information). Changing the alkynyl substituent to the less bulky *i*Pr group (entry 2) resulted in the formation of a mixture of **8A** and **8B** in 54% yield, accompanied by 18% of the 1,4-diboryl(η^4-1,3-cyclohexadiene)cyclopentadienylcobalt complex **8C**. Following this trend, the reaction with the hexyl-substituted boronic ester **4** afforded products **9C** and **9D** in an excellent 93% yield in the ratio 1.5:1 without side products (entry 3). Similar yields (84% and 92%, respectively), but better regioselectivities for 1,3-diborylated products (9:1 and 20:1, respectively) were obtained with **5** or **6** as starting materials (entries 4 and 5). The less symmetrical structures of isomers **9D**–**11D** were readily assigned by NMR spectroscopy, and the structure of **11D** was confirmed by a single-crystal X-ray analysis (Figure 1).[17] Interestingly, boryl substitution

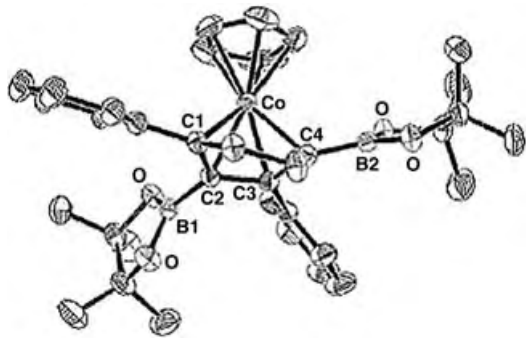

Figure 1. ORTEP view of complex **11D** in the solid state (30% probability thermal ellipsoids). Selected bond lengths [Å] and angles [°]: Co–C_{Cp} 2.05 (av), C2–B1 1.565(5), C4–B2 1.546(5), B–O 1.37 (av), C–C_{diene} 1.44 (av), Co–C1 2.062(3), Co–C2 1.996(3); C1-C2-C3-C(4) 3.9.

does not cause significant structural alteration of the CpCo(η^4-1,3-cyclohexadiene) core of the component fragments.[18] The higher symmetry of complexes **8C**–**10C** was again evident from their NMR spectra, and a distinction between the 2,3- and 1,4-diboryl substitution pattern was possible on the basis of the characteristic chemical shifts of the complexed diene carbons,[11c,e,18a] in conjunction with the effect of boron nuclear quadrupole broadening. Hence, the clearly resolved peaks at $\delta = 110.0$, 105.2, and 100.1 ppm are diagnostic of alkyl-substituted internal quaternary diene carbons in **8C**, **9C**, and **10C**, respectively, whereas the terminal carbons are either unobservable (**8C**, **10C**) or appear as a broad signal at $\delta = 46.7$ ppm (**9C**).

The results in Table 1 are consistent with the notions that steric effects dominate the chemistry of the putative intermediate CpCo(dialkyne) complexes and the resulting metallacycles, which are the relay points on route to the metalated cyclobutadiene and cyclohexadiene products.[11,19] When R is bulky, the route leading to the former is favored[19b] and the steric hindrance retards alkene incorporation to the latter; cyclohexadiene formation is dominant for less bulky R groups. Similarly, the regioselectivity appears to be controlled by the largest substituent, thus favoring the ostensibly least sterically demanding 2,4-substitution in the cobaltacyclopentadiene. When R is larger or smaller than $B(OR)_2$ such control is extensive (**7A**, **10D**, **11D**), whereas when R is comparable to $B(OR)_2$ it is not. Remarkably, an electronic influence of the boryl group is not evident.[20]

The cyclization is not restricted to ethene, and with **6** as the alkyne component and five equivalents of alkene the

results summarized in Table 2 and Table 3 were obtained. Specifically, the alkene and **1** were stirred initially in THF at room temperature for 4 h,[21] during which ethene evolution was visible. Subsequently, **6** was added at −40 °C, followed by stirring at room temperature for 4 h. With 2,5-dihydrofuran, cyclopentene, and cyclohexene, the reactions proceeded completely regioselectively in very good overall yields, with moderate to excellent stereoselectivity and no competing ethene insertion (Table 2). Stereochemical assignments were based on the characteristic chemical shifts of the tertiary cyclohexadiene hydrogen atoms, which are shielded when located *anti* to cobalt and deshielded when located *syn*.[11c,e,18a,22] The *endo* diastereomer was favored in all cases, in agreement with the stereochemical preference of cycloadditions of some α,ω-diynes to pyrimidines[23] and indoles.[24]

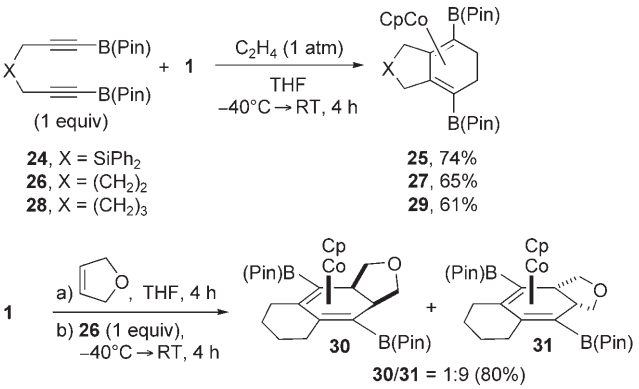
	$SnBu_3$	H	**23**, *exo* (11)

[a] The designations *exo* and *endo* refer to the configuration of the precursor cobaltacyclopentadiene(alkene) complexes and are in analogy to Diels–Alder cycloaddition terminology. Regio- and stereochemical assignments were made by chemical shift, NOE, DEPT, and 2D-NMR (COSY, HMBC) analyses. [b] Yields of product isolated after flash chromatography on SiO_2, except for **22** and **23**, for which basic alumina was used.

In the case of acyclic, particularly internal, alkenes, competition with ethene becomes an issue (Table 3). For example, *trans*-stilbene failed to undergo cycloaddition, the reaction mixture rendering only **11D** in 70% yield. On the other hand, *cis*-stilbene provided **18** as a single diastereomer, albeit in moderate yield (entry 1), diminished by the generation of **11D** (50% yield). Terminal alkenes proved more amenable and revealed interesting stereo- and regioselectivities. For instance, styrene (entry 2) yielded only the *endo*-2,4,6-triphenyl derivative **19** (50% yield). A similar, but attenuated, preference for placing the substituted ethene carbon adjacent to the boron-substituted terminus was found with vinyltrimethylsilane and vinyl(tributyl)tin (entries 3 and 4, respectively). However, in sharp contrast to styrene, the stereochemistry of addition was exclusively *exo*, an outcome that is most likely caused by steric factors.

The scope of the reaction was expanded to the cycloaddition of various α,ω-diboryldiynes to alkenes (Scheme 1). These substrates enforce the 1,4-orientation of the boryl substituents in the resulting diene and grant access to the first polycyclic 1,4-diborylcyclohexa-1,3-diene derivatives. The reactions proceed in good yield (61–80%) and, in the case of **26**, high stereoselectivity, which bodes well for synthetic application to more complex structures. The ^{13}C NMR spectroscopic data confirm the location of the boryl groups in complexes **8C**–**11C**. The structure of **27**, while showing some disorder of one of the boryl groups, was confirmed by an X-ray analysis (Figure 2).[25] Again, the effect of the boryl substituents on the remainder of the molecule appears minimal.



Scheme 1. CpCo-mediated cocyclizations of α,ω-diboryldiynes with alkenes leading to bicyclic and tricyclic 1,4-diborylcyclohexadiene complexes.

While the reported cyclizations furnish the desired organic products complexed to cobalt, this outcome is advantageous as it stabilizes the ligands and, at the same time, potentially activates them towards hydride abstraction and further substitution.[11,22,24,26] Nevertheless, the air- and heat-sensitive free dienes could be liberated by rapid oxidative demetalation with iron(III) chloride (1.5 equiv) in acetonitrile (Table 4, entries 1–11). As expected, the respective *endo*- and *exo*-cyclopentadienylcobalt diastereomers

gave the same diborylcyclohexa-1,3-diene after cobalt removal, thus providing additional proof for the structure of the starting complexes. Aromatization was also accomplished, albeit in only moderate yields so far, using ceric ammonium nitrate (CAN), either starting from the free ligand (entry 12) or directly from the complex (entry 13).

In this work we have described the extensively chemo-, regio-, and diastereoselective assembly of mono-, bi-, and tricyclic 1,3- and 1,4-diboryl-1,3-cyclohexadienes by means of the CpCo-mediated cycloaddition of alkynyl pinacolboronates to alkenes. This method provides a rapid entry into highly functionalized 1,3-cyclohexadiene synthons of potential use in complex molecule synthesis. A mechanistic rationale for the regio- and diastereoselective outcome of this cycloaddition reaction is currently being sought by means of density functional computations.

Gold Clusters

DOI: 10.1002/anie.200502795

Experimental and Theoretical Investigation of the Electronic and Geometrical Structures of the Au_{32} Cluster**

Min Ji, Xiao Gu, Xi Li, Xingao Gong, Jun Li,* and Lai-Sheng Wang**

Gold clusters and nanoparticles have received significant attention in cluster science because of their potential applications in nanotechnology.[1–4] The discovery of unexpected catalytic properties of nanosized gold particles supported on substrates[5] has rekindled extensive interest in the chemical and physical properties of gold clusters. The strong relativistic effects of gold[6] results in Au clusters exhibiting many unique properties that are different from the other coinage metals. For example, gold clusters assume two-dimensional (2D) structures even at relatively large sizes, whereas the corresponding Cu and Ag clusters are three-dimensional (3D).[7,8] The most recent surprise in Au cluster chemistry is the prediction of a highly stable Au_{32} cage cluster,[9,10] which was calculated to have the same icosahedral (I_h) symmetry as C_{60} and can be regarded as having one atom located on each of the 32 faces of C_{60}. Such a high symmetry structure with a hollow core is intriguing, but completely unexpected for a metal cluster. Explanations involving aromaticity and the tendency of Au to form 2D structures have been proposed to account for the stability of this unusual cluster.[9,10] Should such a Au_{32} cage be stable enough to be synthesized, it is anticipated to possess some fascinating physical and chemical properties. However, this structure has not been confirmed experimentally and it is not known how stable this structure would be in a charged state or upon ligand coordination. The stability towards ligand coordination will be particularly important if bulk quantities of Au_{32} are to be made.[11]

Although the direct experimental determination of cluster structures has been challenging, electron diffraction studies of trapped ions have recently shown considerable promise.[12] Photoelectron spectroscopy (PES) of size-selected anions in combination with quantum-mechanical calculations has been shown to be a powerful indirect approach to yield structural information for clusters.[13–15] By using this approach, we recently discovered that Au_{20} possesses a highly symmetric and compact structure,[16] which has since been confirmed in numerous studies to be the global minimum of Au_{20}.[17–19] Herein, we describe the combination of PES and density functional theory (DFT) calculations to elucidate the electronic and geometrical structures of Au_{32} and Au_{32}^-.

The experiment was performed by using a laser vaporization magnetic-bottle PES apparatus[20] similar to that used in our previous studies on Au_{20}^-.[16] The anionic Au_{32}^- clusters were produced by laser vaporization of a gold foil and their mass was analyzed by means of time-of-flight mass spectrometry. PES spectra of Au_{32}^- (Figure 1) were measured at two

photon energies (266 nm (4.661 eV) and 193 nm (6.424 eV)) at an electron kinetic energy resolution of $\Delta E_k/E_k \approx 2.5\,\%$ (ca. 25 meV for 1-eV electrons). The general spectral pattern in Figure 1 agrees with a previous PES study of the coinage metal clusters,[21] but considerable fine features were resolved in the current spectra in the lower-binding-energy range: a total of seven discrete bands were resolved (labeled as X, A–F). The higher-binding-energy range (> 5.5 eV) exhibited continuous spectral features derived from the Au 5d band. The discrete, lower-binding-energy features were ascribed primarily to the Au 6s states and should be very sensitive to the structure of the cluster. The well-resolved bands in this spectral range make it possible to compare the results with theoretical calculations. The X band revealed the electron affinity of Au_{32} to be 3.96 ± 0.02 eV. The PES spectral pattern indicates that Au_{32} has a closed-shell electronic structure with a relatively small energy gap of 0.30 eV, defined by the X–A separation (Figure 1). It should also be pointed out that the observed main spectral features (X, A–F) were not dependent on the source conditions, which suggests that higher-energy isomers were not present in the beam in significant amounts.

Our calculations are based on plane-wave and Slater-basis DFT with the generalized gradient approximation (GGA) as implemented in the VASP[22] and ADF[23] codes.[24] Our previous theoretical search showed that for neutral Au_{32}, the I_h cage is the most stable structure with the nearest-energy isomer (D_{6h}) 0.94 eV higher in energy.[10] We found that the I_h cluster with a slight Jahn–Teller distortion (D_{3d}) remains the lowest energy structure for Au_{32}^- (Figure 2a and Table 1), but the closest-energy noncage isomer (C_1-I; Figure 2b) is only 0.40 eV higher in energy on the basis of the ADF calculations. Four other low-lying isomers of Au_{32}^- are also shown in Figure 2. Table 1 gives the electron configuration, relative energy, adiabatic detachment energy (ADE), and vertical detachment energy (VDE) for the six isomers of Au_{32}^-, as well as the electron configurations and the energy gaps for the corresponding neutral Au_{32} isomers. The Jahn–Teller effect meant that several lower-symmetry species had to be considered for the cage structure of Au_{32}^-. The structural distortions are all very minor and the four lower-symmetry structures are close in energy (Table 1). With the exception of the planar (C_{2v}) structure, the other low-lying isomers (C_1-I, D_{6h}, C_2, and C_1-II) of Au_{32}^- are also close in energy. The two C_1 isomers have no symmetry elements and can be characterized as being amorphous. These two structures and the C_2 isomer are three dimensional, whereas the I_h and D_{6h} structures are cages, which can be considered to be quasi-2D because they are hollow. The three low-symmetry 3D structures are more compact and can be regarded essentially as distorted cages with two to four atoms inside.

The I_h Au_{32} cluster has been shown to possess a very large

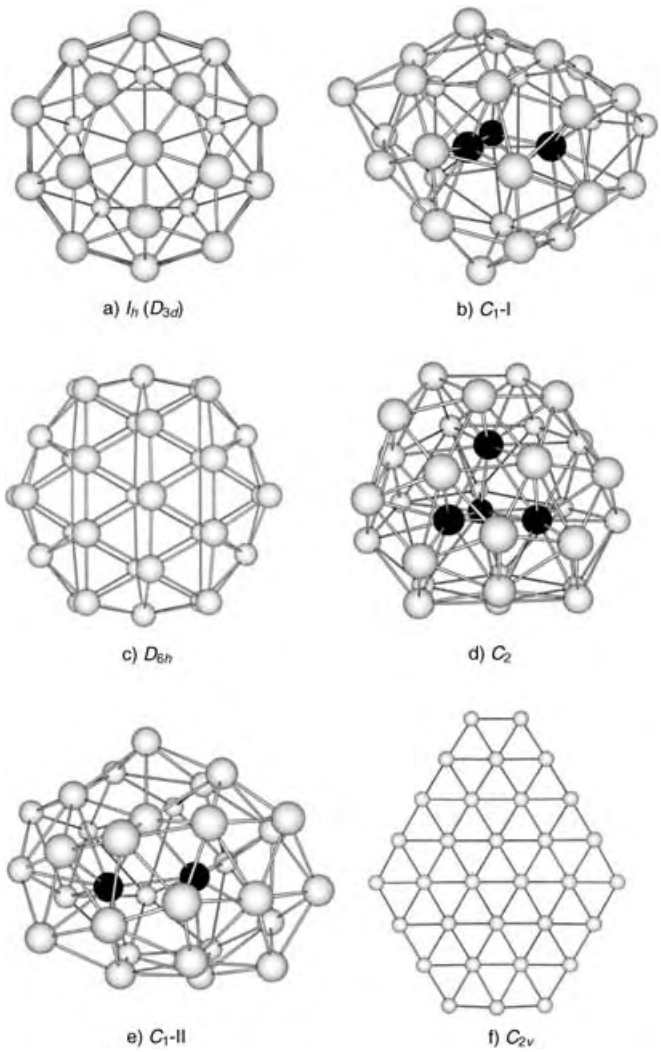

Figure 2. Selected structures of the Au_{32}^- cluster: a) the global minimum icosahedral cage structure, b) first isomer with C_1 symmetry (C_1-I), c) isomer with D_{6h} symmetry, d) isomer with C_2 symmetry, e) second isomer with C_1 symmetry (C_1-II), f) planar structure with C_{2v} symmetry.

Table 1: Optimized structures and electron configurations for Au_{32} and Au_{32}^-, HOMO–LUMO energy gaps (ΔE_{HL}) for Au_{32}, relative total energies [ΔE(tot)], and adiabatic (ADE) and vertical (VDE) detachment energies for Au_{32}^-, all calculated by the ADF PW91/TZ2P method.[a]

HOMO–LUMO gap because of its high symmetry. Energy gaps of 1.7 and 2.5 eV were evaluated from the BP86 and PBE0 functions, respectively,[9] whereas an energy gap of 1.5 eV was given by using the VASP code.[10] These values are considerably larger than the 0.30 eV measured in our PES spectra of Au_{32}^-, which suggests that the experimentally observed Au_{32}^- cannot be the I_h cluster. To help determine the structure of Au_{32}^-, we computed the ADE and VDE of all the six low-lying isomers for comparison with the experimental PES spectra. As shown in Table 1, the calculated ADEs for the C_1-I isomer (3.96 eV) and the C_2 isomer (3.94 eV) are both in agreement with the experimental value (3.96 ± 0.02 eV), whereas that of the I_h structure is considerably smaller. The calculated ADEs of the other isomers are also in poor agreement with the experimental value. The computed VDE spectra, convoluted with Gaussian-shaped bands (0.05 eV full width at half-maximum (fwhm)) to approximately simulate the PES spectra,[16] are shown in Figure 3

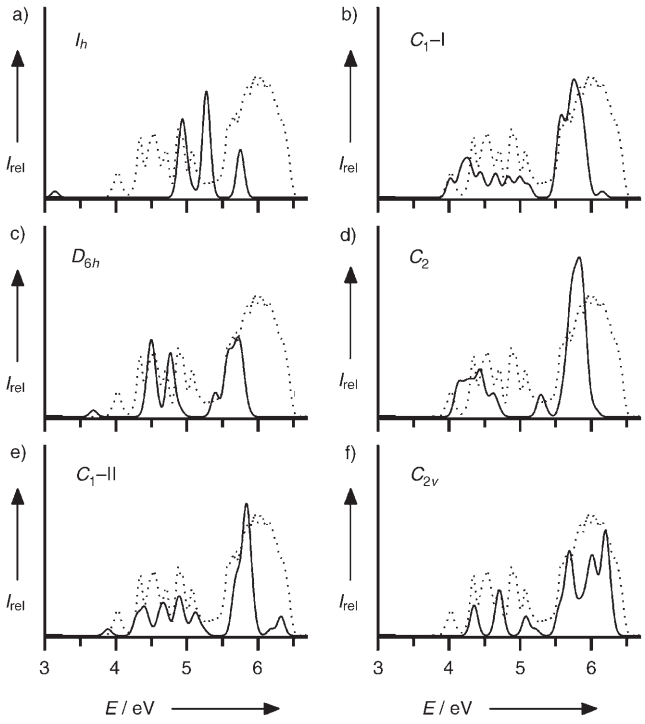

Figure 3. Simulated photoelectron spectra for the different isomers of Au_{32}^- overlaid with the experimental spectrum at 193 nm (dotted curves): a) the icosahedral cage structure, b) the C_1-I structure, c) the D_{6h} structure, d) the C_2 structure, e) the C_1-II structure, f) the planar C_{2v} structure. The simulated spectra were constructed by fitting each of the vertical detachment transitions with a Gaussian of 0.05 eV width.[16]

overlaid with the experimental PES spectrum at 193 nm. The simulated spectrum of the I_h isomer (Figure 3a) is very simple as a result of its large HOMO–LUMO gap caused by the high symmetry of this cage structure. The simulated spectra of the D_{6h} and the C_{2v} planar structures are also quite simple because of their relatively high symmetries. These spectra clearly disagree with the experimental PES data (Figure 3c and f).

The simulated spectra of the three low-symmetry structures display some similarities (Figure 3b, d, e): all have an intense band above 5.5 eV derived from the high density of states of the 5d electrons. However, the lower-binding-energy parts of the simulated spectra are highly structured and exhibit clear differences, which seem to be quite sensitive to the detailed structure of the clusters. The simulated spectrum of the C_2 structure (Figure 3d) is very congested near the threshold region between 4.0 and 4.8 eV, which is followed by a gap and another band at 5.3 eV. This simulated pattern is clearly inconsistent with the observed PES spectra shown in Figure 1. At first glance, the simulated spectrum of the C_1-II structure (Figure 3e) seemed to display some similarity to the experimental spectra. However, the calculated ADE for the first peak of this structure (3.74 eV) is considerably smaller than the experimental value (3.93 eV). The number of bands between 4.2 and 5.1 eV is also inconsistent with the experimentally observed bands. Furthermore, the total energy of the C_1-II structure is 0.81 eV higher than the ground state, which means that this structure is unlikely to be present under our experimental conditions (see below). On the other hand, the calculated ADE of the C_1-I structure (3.96 eV) is in excellent agreement with the experimental data (3.96 ± 0.02 eV), so that the first peak of the simulated spectrum of the C_1-I structure (Figure 3b) coincides with the first experimental peak. The calculated HOMO–LUMO gap (0.22 eV) for the C_1-I structure seems to be slightly smaller than the measured gap of 0.3 eV. The number of bands and their positions in the low-binding-energy part of Figure 3b (except the HOMO–LUMO gap) are in excellent agreement with the observed PES spectra for Au_{32}^-. Overall, the simulated spectrum of the C_1-I structure agrees best with the PES spectra.

Although the C_1-I isomer lies closest in energy above the I_h structure on the basis of our DFT calculations, it is still 0.4 eV higher. Why was this isomer observed experimentally, whereas the energetically more favorable Au_{32}^- cage was not? To understand this apparent paradox, we considered the relative stabilities of the various isomers as a function of temperature by taking into account the contribution of entropy, that is, by considering the free energy. We calculated the free energies of all of the six low-lying structures of Au_{32}^- by using the calculated total binding energies (E_0) from ADF at zero temperature and the harmonic vibrational entropy with Equation (1).[25]

$$F = E_0 - \frac{1}{2}\sum_i \hbar\omega_i + k_B T \sum_i \ln\left(\exp\frac{\hbar\omega_i}{k_B T} - 1\right) \quad (1)$$

In this equation, F is the free energy, E_0 is the total binding energy calculated with ADF, and the last two terms give the vibrational entropic contribution to the free energy at finite temperature by using the harmonic approximation and summing over all the vibrational degrees of freedom ($3n-6=90$ for Au_{32}^-). Figure 4 shows the computed curves for the free-energy of the six low-lying structures of Au_{32}^- relative to that of the D_{3d} cage structure as a function of temperature. We found that although the I_h cage is the most stable structure at zero temperature, the relative stability of

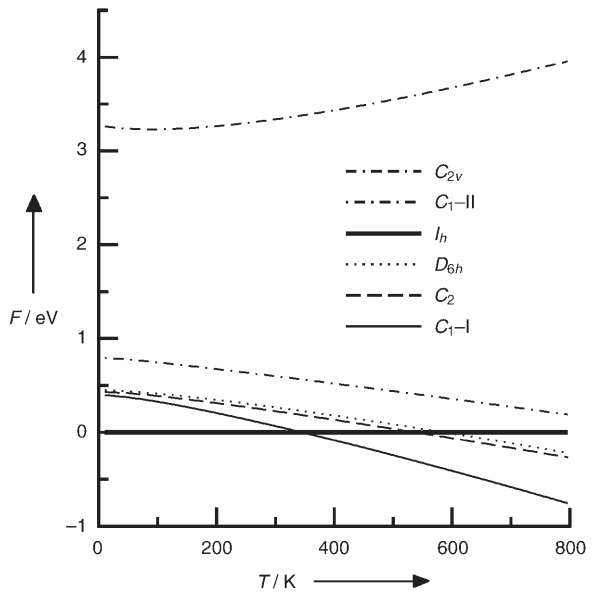

Figure 4. Free energies of the six low-lying isomers of the Au_{32}^- cluster as a function of temperature, calculated using a harmonic approximation and the ADF total binding energy at zero temperature. The free energies are plotted relative that of the D_{3d} cage structure to show more clearly that several low-symmetry isomers become more stable at high temperatures as a result of the entropic effect. Note that the C_1-I structure becomes the most stable isomer at temperatures $> \approx 300$ K.

the C_1-I isomer increases rapidly with temperature because of the contributions from vibrational entropy. Significantly, we observed that the C_1-I isomer becomes the most stable cluster above approximately 300 K. Although the actual cluster temperature in our experiment was not known, our previous experience shows that for medium-sized Al clusters, a vibrational temperature of room temperature or slightly lower can be achieved.[26] The large size of the Au_{32}^- cluster and the ineffectiveness of the supersonic cooling means our best estimate for its vibrational temperature even under our relatively cold source conditions is that it was probably around or slightly below room temperature. Considering the approximate nature of the free-energy calculations, we conclude that the formation of the amorphous C_1-I Au_{32}^- cluster in our experiment was indeed controlled by the vibrational entropy. It should be pointed out that the C_1-II isomer is higher in energy than the lowest-energy C_1-I isomer at room temperature by 0.5 eV, which makes it very unlikely that it is significantly formed under our experimental conditions. This view is reinforced by the observation that the C_2 and D_{6h} isomers, which are both more stable than the C_1-II isomer, do not seem to have any contribution to the observed spectra. Furthermore, aurophilic interactions,[6] which may not be completely accounted for in the DFT calculations, are expected to favor the 3D structures, which would bring the energy of the C_1-I structure even closer to the cage structure. All these observations lend credence to our assignment that the C_1-I structure is the dominant cluster observed in our experiment.

In a similar recent study on the B_{20}^- cluster, we found that although a 3D ring-type structure was predicted by DFT calculations to be the global minimum, only planar structures were observed experimentally because of the large entropy contributions of the planar structures at finite temperatures.[27] This recent study along with the current work suggest that vibrational entropies are important in controlling the stabilities of relatively large cluster structures when isomers are closely lying in energy. Thermal effects have to be considered when comparing experiments performed at finite temperatures with theoretical calculations.

[22] In the VASP calculations (G. Kresse, J. Furthmuller, *Phys. Rev. B* **1996**, *54*, 11169), the $5d^{10}6s^1$ valence electrons were treated explicitly and their interactions with the ionic cores are described by the PAW potentials (G. Kresse, D. Joubert, *Phys. Rev. B* **1999**, *59*, 175) with scalar relativistic effects included. The wave functions were expanded in plane waves with an energy cutoff of approximately 230 eV. We used a simple cubic cell of 30 Å edge length with periodic boundary conditions, and the Γ point approximation for the Brillouin zone sampling. To test the accuracy of the theoretical method, we calculated the bond

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

length of the Au dimer and the lattice constant of the crystalline solid. The values obtained are in agreement with experimental data to within 2%. To facilitate comparisons with the experimental results, we carried out an extensive search for the global minimum of Au_{32}^- by simulated annealing, starting with various structures previously found for neutral Au_{32},[10] as well as many other low-symmetry structures. The atomic structures were optimized by the conjugated-gradient method with a force convergence of 1.0×10^{-3} eV Å^{-1}.

[23] The Amsterdam density functional (ADF) calculations (ADF 2004, SCM, Theoretical Chemistry, Vrije Universiteit, Amsterdam, The Netherlands (http://www.scm.com)) were performed by using the GGA of Perdew–Wang 1991 (PW91; J. P. Perdew, Y. Wang, *Phys. Rev. B* **1992**, *45*, 13244) and triple-zeta Slater basis sets plus p- and f-polarization functions (TZ2P) for the valence orbitals of the Au atoms. The frozen-core approximation was applied to the $\{1s^2 4f^{14}\}$ core, and the $5s^2 5p^6 5d^{10} 6s^1$ electrons were explicitly treated variationally. The scalar and spin-orbit relativistic effects were taken into account through the zero-order-regular approach (ZORA; E. van Lenthe, E. J. Baerends, J. G. Snijders, *J. Chem. Phys.* **1993**, *99*, 4597). The simulations of the PES spectra were performed by using procedures described previously.[16]

[24] The VASP code is an efficient simulated-annealing method, which allows local minima to be readily identified. The ADF code, which has higher-quality basis sets and involves advanced relativistic treatment, is used to produce the final energy profiles for comparison with the experimental results. The good performance of ADF for Au clusters has been well tested in our previous studies in conjunction with PES data (see reference [16], for example).

Selective Glycosylations

DOI: 10.1002/anie.200502694

Development of an Arming Participating Group for Stereoselective Glycosylation and Chemoselective Oligosaccharide Synthesis**

*James T. Smoot, Papapida Pornsuriyasak, and Alexei V. Demchenko**

Dedicated to Professor Andras Liptak on the occasion of his 70th birthday

Carbohydrates are involved in many harmful processes such as bacterial and viral infections, development and growth of tumors, metastasis, tissue rejection, etc. Many of these processes are directly associated with deadly diseases of the 21st century including AIDS, cancer, meningitis, hepatitis, septicemia, etc.[1] Elucidation of the exact mechanisms of the carbohydrate involvement in disease pathogenesis would be significantly facilitated if we could rely on the comprehensive knowledge of the structure, conformation, and properties of the carbohydrate molecules. It is critical to make complex carbohydrates more accessible to general chemical, biochemical, and industrial audiences to keep pace with the exploding area of glycobiology.[2] One way to increase the access to carbohydrates is to develop reliable methods for stereoselective glycoside synthesis and convergent oligosaccharide assembly that would be applicable to both laboratory and industrial preparation.

Many, if not all, known convergent strategies for oligosaccharide synthesis are based on the selective activation of one leaving group (LG) over another, which allows a decrease in the number of synthetic steps.[3,4] One of the most efficient procedures, the Fraser–Reid "armed–disarmed" approach, is based on the chemoselectivity principle.[5,6] Accordingly, in the presence of a mild promoter, a benzylated (armed) glycosyl donor is chemoselectively activated in preference to an acylated (disarmed) derivative bearing the same type of leaving group (Scheme 1). At this stage, a 1,2-*cis*-linked disaccharide is obtained preferentially as a result of the necessity to use the ether-type substituent (arming nonparticipating group). The obtained disaccharide can then be used

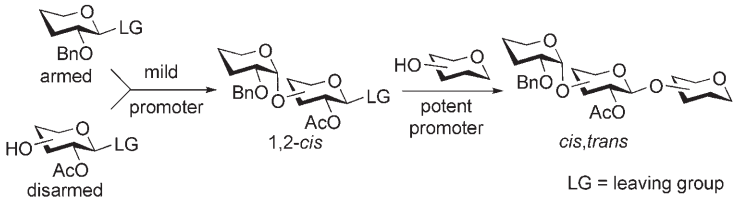
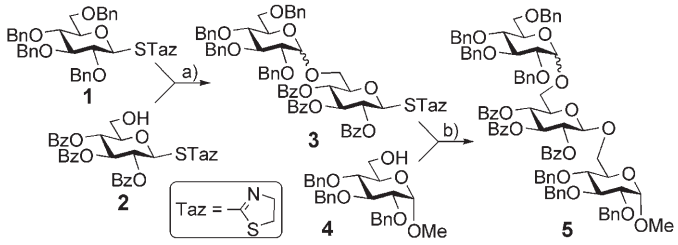


Scheme 1. The "armed–disarmed" strategy. Bn = benzyl

directly for 1,2-*trans* glycosylation (in the presence of a more potent promoter that can activate the disarmed leaving group) to afford a *cis*,*trans*-linked trisaccharide.

This concept was initially designed for *O*-pentenyl glycosides and was further explored for the chemoselective glycosidations of other glycosyl donors, including thioglycosides,[7] selenoglycosides,[8] fluorides,[9] phosphoroamidates,[10] substituted thioformimidates,[11] and S-benzoxazolyl glycosides.[12] Glycal reactivity was also found to be influenced by disarming acyl substituents.[13] Fraser-Reid et al.[14] and Ley and co-workers[15] found that torsional effects of cyclic acetal and dispiroketal protecting groups also promote anomeric deactivation. Moreover, Zhu and Boons demonstrated that thioglycosides that are protected as cyclic 2,3-carbonates are even less reactive than traditional disarmed acylated derivatives.[16] The chemoselective activation principles were summarized and expanded on by Ley and co-workers,[17] Wong and co-workers,[18–20] and other groups.[21,22] As a result, programmable multistep reactivity-based techniques, including highly efficient one-pot approaches, have become available.

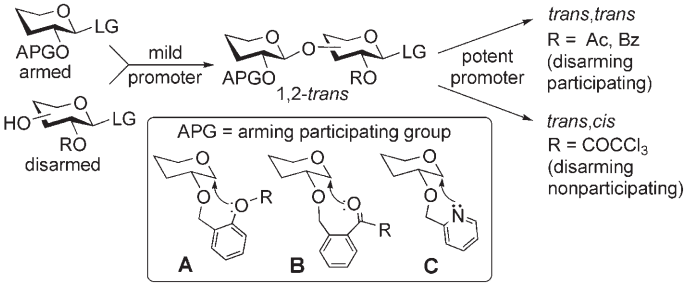
S-thiazolinyl (STaz) glycosides, recently developed in our laboratory, were found to be compatible with the armed–disarmed procedure. Thus, chemoselective activation of **1**[23] over **2**[24] in the presence of either AgOTf or $Cu(OTf)_2$ afforded the disaccharide **3** as an anomeric mixture in 79–88% yield (Scheme 2). The latter was then converted into the *cis*,*trans*-linked trisaccharide **5** by treatment with the acceptor **4**.



Scheme 2. Chemoselective activation of the STaz glycosides. a) 1. AgOTf, 1,2-DCE, 1 h, room temperature, 79%, $\alpha/\beta = 2:1$; or 2. $Cu(OTf)_2$, 1,2-DCE, 3.5 h, room temperature, 88%, $\alpha/\beta = 1.5:1$; b) AgOTf, 1,2-DCE, 2.5 h, room temperature, 83%. Bz = benzoyl, Tf = trifluoromethanesulfonyl, DCE = dichloroethane.

The armed–disarmed strategy thus offers an efficient tool for the synthesis of oligosaccharides with a *cis*,*trans* glycosylation pattern. Although the synthesis of *cis*,*cis*-linked derivatives is also possible,[5,6] this method is not applicable to the synthesis of *trans*,*cis*- or *trans*,*trans*-linked oligosaccharide fragments. The use of other techniques, such as orthogonal[25] or semiorthogonal synthesis[26] offer further advantages; however, these strategies require a set of at least two orthogonal leaving groups, which may not always be accessible. To address this challenge, we initiated studies of the "inverse armed–disarmed strategy", which would enable the stereoselective introduction of a 1,2-*trans* linkage prior to another 1,2-*trans* or 1,2-*cis* linkage.

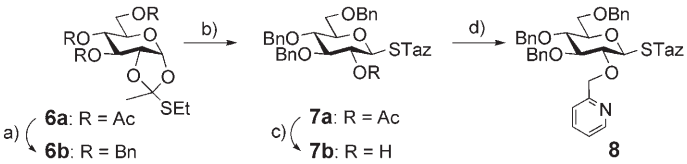
Such an inverse approach would require the use of a neighboring substituent that is capable of both activation and participation (arming participating group (APG)). For this purpose we investigated a number of substituents **A**–**C** as APGs (Scheme 3). Our studies were based on STaz glycosides



Scheme 3. Outline of an inverse armed–disarmed strategy.

owing to their superb glycosyl-donor properties.[23] The preliminary results obtained with a 2-*O*-(*o*,*o*-dimethoxybenzyl) glycosyl donor (type **A**) showed a fairly high diastereoselectivity (up to α/β 1:5), which was a significant improvement over the 2:1 α/β ratio found with perbenzylated STaz glycosyl donor **1** under the same reaction conditions. Nevertheless, it remained uncertain if the high β stereoselectivity is attributable to the anticipated participation of a seven-membered transition state (Scheme 3 or rather to the increased steric hindrance of the bottom face of the ring. The same uncertainty was anticipated for glycosyl donors of type **B**. To exclude the possibility of the increased steric hindrance, our further studies focused on the investigation of the 2-pyridylmethylpicolyl group, which is capable of a six-membered ring participation through the nitrogen atom (**C**, Scheme 3).

The glycosyl donor **8** bearing a picolyl substituent at C2 was synthesized from thioorthoester **6a**[27] (Scheme 4). Conveniently, the picolyl moiety was introduced with commercial picolyl bromide in the presence of NaH in DMF. In this



Scheme 4. Synthesis of the glycosyl donor **8**. a) 1) MeONa, MeOH, 2) BnBr, NaH, DMF, 85%; b) HSTaz/TMSOTf, CH_2Cl_2, 85%; c) MeONa, MeOH, 92%; d) PicBr, NaH, DMF, 90%. DMF = *N*,*N*-dimethylformamide, Pic = picolyl, TMS = trimethylsilyl.

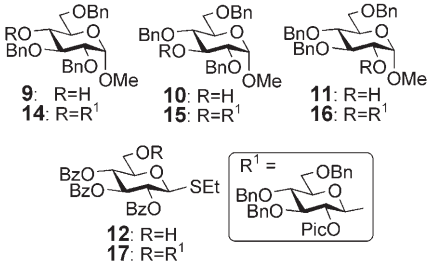
context, although an approach for the control of the anomeric stereoselectivity with a neighboring substituent that is capable of six-membered participation is relatively unexplored, a number of moieties for stereoselective glycosylation have recently been reported.[28,29]

Having synthesized the glycosyl donor **8**, we turned our attention to glycosidation studies. For this purpose, a range of differently protected glycosyl acceptors **2**, **4**, and **9**–**12** was selected. Based on our preliminary results



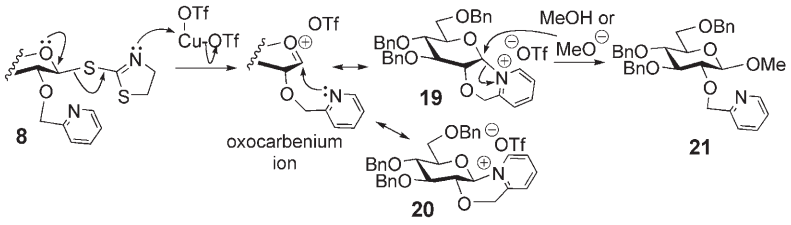
(Scheme 2), we employed $Cu(OTf)_2$ either alone, or in combination with catalytic TfOH as a promoter. All of the glycosylations summarized in Table 1 proceeded with complete 1,2-*trans* stereoselectivity.

Table 1: Synthesis of 1,2-*trans*-linked disaccharides **13**–**18**.

Entry	Acceptor	Promoter	Product	Yield [%]
1	**4**	$Cu(OTf)_2$	**13**	80
2	**9**	$Cu(OTf)_2$	**14**	84
3	**10**	$Cu(OTf)_2$/TfOH	**15**	82
4	**11**	$Cu(OTf)_2$/TfOH	**16**	80
5	**12**	$Cu(OTf)_2$	**17**	77
6	**2**	$Cu(OTf)_2$/TfOH	**18**	74

Notably, the glycosidation of **8** at room temperature required significantly more time than that of **1** (48 vs. 1–3 h, respectively). Therefore, to shorten the reaction time (12–16 h), all of the glycosylations shown in Table 1 were performed in 1,2-DCE at 50 °C. As the chemoselective activation of **8** in reference to the benzoylated acceptor **2** was also possible under these reaction conditions, the observed phenomenon could not be simply explained by the very low reactivity of **8**. In this context, perbenzoylated STaz glycosides typically require 1–20 h for glycosidation at room temperature.[23] The working hypothesis for subsequent studies was that upon departure of the promoter-assisted leaving group, the formed oxocarbenium ion is converted into a stable intermediate, such as **19**, which results from the anticipated 2-*O*-picolyl participation through a six-membered ring (Scheme 5).

To establish whether the process actually follows the anticipated pathway, the AgOTf-promoted glycosidation of **8** with methanol was monitored by ^{1}H NMR spectroscopy (synthesis of **21**, Scheme 5). It was determined that **8** is entirely consumed in approximately 1 h, regardless of whether the reaction is performed at room temperature or at 50 °C. At this stage, the ^{1}H NMR spectrum shows the



Scheme 5. Proposed reaction mechanism for the glycosidation of **8**.

presence of peaks that correspond to two compounds, presumably **19** (major) and **20** (minor) with a ratio that varied with the reaction conditions (5:1 (50 °C) to 20:1 (room temperature)). During this transition, the signal for the anomeric H atom of **8** (1-H, Figure 1 a) shifted downfield from $\delta \approx 5.30$ to ≈ 6.15 ppm for the anticipated intermediate **19** (1-β-H) and $\delta \approx 5.75$ ppm for the anticipated intermediate **20** (1-α-H, Figure 1 b), which could be an indication of the N-glycosidic linkage.

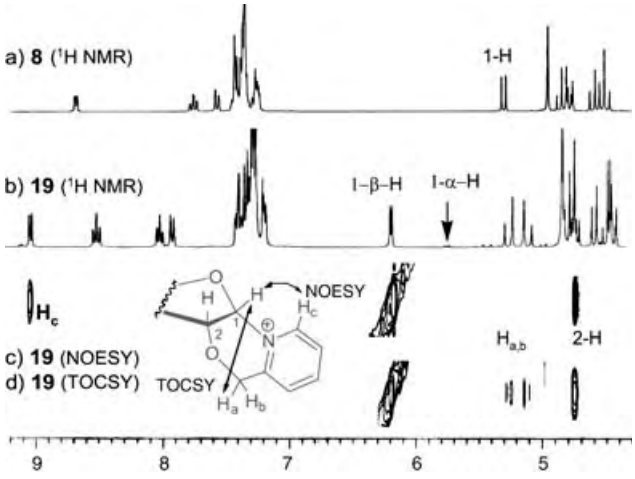


Figure 1. NMR analysis of the reaction of **8**, indicating the formation of the major intermediate **19**. a) 1H NMR spectum of **8**; b) 1H NMR spectrum of the major intermediate **19** and the minor intermediate **20**; c) NOESY spectrum of **19**; d) TOCSY spectrum of **19**.

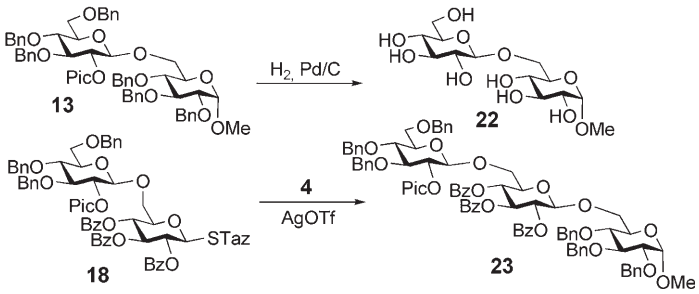
Glycosylation experiments performed through glycosyl donor preactivation with subsequent addition of the glycosyl acceptor, provided a very similar outcome. The bicyclic intermediate **19** was isolated from the reaction of **8** with $Cu(OTf)_2$ (2 h at room temperature) and purified by column chromatography (silica gel).[30,31] The intermediate **19** was found to be reactive with potent nucleophiles such as NaOMe, even in the absence of a promoter, to afford **21** (Scheme 5). However, in all cases the β intermediate **20** remained completely inert and could typically be isolated from the reaction mixture.[32]

The 2D NMR determinations were also found to be very informative for the structural elucidation of **19**. Thus, correlations in the NOESY experiment between 1-H ($\delta =$ 6.15 ppm) and the aromatic H atom located adjacent to the picolyl nitrogen atom (H_c, $\delta = 9.00$ ppm) indicated that these

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

H atoms were situated in close proximity (Figure 1c). The TOCSY data revealed that 1-H and the benzylic H atoms of the picolyl group (H_a and H_b, $\delta = 5.15$ ppm) were part of the same spin system (Figure 1d). Furthermore, long-range coupling between C1 ($\delta = 84.89$ ppm) and H_c was confirmed by the HMBC data, which indicated that C1 and H_c were three bonds apart.

Subsequently, to broaden the scope of the developed approach, we demonstrated that the 2-*O*-picolyl moiety could be removed under conventional catalytic hydrogenation conditions (Pd/C). Thus, hydrogenolysis of the *O*-picolyl moiety in **13** with concomitant removal of the benzyl protecting groups afforded **22** in 92% yield (Scheme 6). The



Scheme 6. Picolyl moiety removal and the synthesis of a *trans,trans*-linked trisaccharide **23**.

disaccharide **18**, obtained by the chemoselective activation of **8** in preference to **2** (Table 1), was glycosidated with **4** in the presence of AgOTf to afford *trans,trans*-linked trisaccharide **23** in 91% yield (Scheme 6). Further investigation of this approach and its application to convergent target synthesis is underway in our laboratory. We anticipated that the use of a disarming nonparticipating group for the second activation step would be required to achieve the 'inverse' *trans*, *cis*-linked oligosaccharide pattern. This type of a neighboring moiety includes, but perhaps is not limited to, halodenoacyls (trichloroacetyl, Scheme 3) or other functionalities recently reported by Crich et al.[33]

In conclusion, a new method for stereocontrolled glycosylation was developed. We demonstrated that complete 1,2-*trans* selectivity can be achieved with the use of a 2-*O*-picolyl moiety, a novel neighboring group that is capable of efficient participation through a six-membered intermediate. The 2-*O*-picolyl moiety has been shown to retain the glycosyl donor in the armed state as opposed to conventional acyl participating moieties. The application of a novel arming participating moiety to complementary chemoselective oligosaccharide synthesis also has been developed. This new armed–disarmed glycosylation strategy allows chemoselective introduction of a 1,2-*trans* glycosidic linkage prior to other linkages, in contrast to the Fraser-Reid approach. We expect that the developed technique, along with the classic armed–disarmed approach will allow convergent chemoselective synthesis of virtually any oligosaccharide sequence.

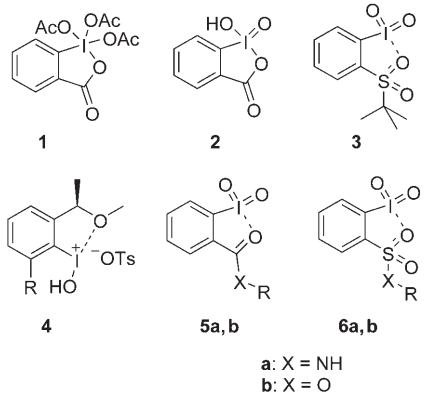
Synthesis, Structure, and Chemoselective Reactivity of *N*-(2-Iodylphenyl)acylamides: Hypervalent Iodine Reagents Bearing a Pseudo-Six-Membered Ring Scaffold**

Uladzimir Ladziata, Alexey Y. Koposov, Ka Y. Lo, Jeff Willging, Victor N. Nemykin, and Viktor V. Zhdankin**

During the past decade, hypervalent iodine compounds have gained significant attention as mild, selective, and environmentally benign reagents in synthetic organic chemistry.[1,2] The oxidation of sensitive and complex alcohols[2a,b] and amines,[2c] the cyclization of anilides,[2d] the introduction of α,β unsaturation into carbonyl compounds,[2e] and the aromatization of tetrahydronaphthalene-1,4-diones[2f] are among elegant synthetic transformations effected by organic iodine(v) compounds (λ^5-iodanes). However, the major reagents used for these unique protocols, Dess–Martin periodinane (DMP, **1**)[2a] and its precursor 1-hydroxy-1,2-benziodoxol-3-(1*H*)-one (IBX, **2**; see Scheme 1,[2b] suffer from a number of drawbacks, namely, DMP is highly sensitive towards moisture[3a] and unstable to prolonged storage, whereas IBX is explosive under impact or on heating to $>200\,^{\circ}C$,[3b] is nonrecyclable, and has limited solubility in most organic solvents except dimethyl sulfoxide (DMSO).



Scheme 1. Cyclic and pseudocyclic hypervalent iodine reagents.

Supporting information for this article is available on the WWW under http://www.angewandte.org or from the author.

The low solubility of **2**, which restricts its practical application, arises from strong intermolecular secondary I···O, hydrogen-bonding, and π-stacking interactions observed for IBX in the solid state.[4] Several research groups have tried to overcome this preparative limitation by performing oxidation at elevated temperatures,[5a] using an ionic liquid and water as a reaction medium,[5b] or functionalizing the IBX aromatic core.[5c] Also, a number of solid-supported reagents in which the IBX scaffold is linked to a polymer have been reported.[6] Another fruitful approach coined by Protasiewicz, Wirth, and co-workers[7a–e] involves the incorporation of an *ortho*-substituent into λ^5- and λ^3-iodanes (e.g., sulfone **3** and benzyl ether **4**), thus resulting in intramolecular secondary bonding interactions. This *ortho*-stabilization leads to a partial disruption of the polymeric network, and consequently enhances solubility. More recently, investigations from our group have resulted in a series of stable and soluble IBX analogs: IBX amides **5a**,[7f] IBX esters **5b**,[7g] as well as IBX sulfonamides **6a** and IBX sulfonate esters **6b**.[7h] A planar pseudo-benziodoxole moiety that arises from the intramolecular nonbonding iodine–oxygen interaction is a key structural feature present in this series of compounds, as shown by X-ray crystallographic analysis. The readily available hypervalent iodine reagents **5**–**6** possess reactivity similar to IBX and DMP and have proved to be useful oxidizing reagents towards alcohols[8a] and sulfides.[8b] The synthesis of polymer-supported IBX esters and amides has been reported as well.[8c]

We report herein the elaboration of the *ortho*-stabilization concept with regard to λ^5-iodanes. Our initial aim was to furnish an aryl iodyl species with a pseudo-six-membered ring unit such that the iodine(v) atom and *ortho*-sustituent donor atom were located in the 1,6-position. To obtain the required scaffold, we decided on an amide group as the *ortho* sustituent. Indeed, changing the aryl amide function in the substituted IBX amide to an aryl carbamoyl group yields *N*-(2-iodylphenyl)acylamides **7** with the required pseudo-benziodoxazine structure (Scheme 2). Assuming that an isosteric switch will not substantially change the molecular electronic parameters of the system when carried out, one can expect **7** to be close to the IBX amides in oxidative properties. Furthermore, the *ortho*-amide group offers a large variety of structural modifications, which may allow control over the reactivity profile of the title compounds.

A set of sixteen pseudo-benziodoxazines **14**–**17** was prepared to investigate the influence of the structure of the *ortho* sustituent on the oxidative activity of the target *N*-(2-iodylphenyl)acylamides and to explore the chemistry of these novel reagents (Scheme 2). Synthesis of **14**–**17** was performed by acylation of the commercially available 2-iodoaniline (**8**) with a range of acyl chlorides. Subsequent treatment of the obtained amides **9a**–**e** and **10** with NaH in dry THF, followed by alkylation with MeI and BnBr in the case of **9a**–**e**, led to pyrrolidinone **13** and substituted amides **11a**–**e** and **12a**–**e**. Oxidation of iodoarenes **11**–**13** with 3,3-dimethyldioxirane afforded **14**–**17** in good yields. All the products were isolated in the form of stable, white solids.[9]

Compounds **14**–**17** were identified by spectroscopic and ESI-mass-spectrometric analysis; single-crystal X-ray analysis

was also used in the case of **15e**. IR spectra of all compounds showed a strong absorption for I=O at 760–780 cm^{-1}. With a few exceptions (amides **14e**, **15c–e**, **16e**, and **17**), the expected carbonyl absorption appeared as two strong bands: the first band at 1640–1675 cm^{-1} (characteristic amide C=O stretch)[10] and the second at 1600–1620 cm^{-1} (C=N–Ar stretch).[10] Compounds **14e** and **15c–e** showed a single band at 1600–1620 cm^{-1}, whereas **16e** and **17** were characterized by a sole band at 1643 cm^{-1}. ^1H NMR analysis indicated practically no downfield shift for the proton *ortho* to the iodine atom relative to iodo derivatives **9–13**. In the ^{13}C NMR spectra of iodyl arenes **14a–e** and **17**, the signal for C–IO_2 was observed at approximately $\delta = 133$ ppm, whereas for amides **15–16** this signal emerged at $\delta = 142$ ppm. The ESI-HRMS spectra of **14–17** demonstrated strong peaks that correspond to dimers $[2M+Na]^+$, as well as weaker $[M+Na]^+$ peaks. These data will be rationalized later during the discussion of the reactivity profile of compounds **7**.

Single crystals of **15e** of X-ray-diffraction quality were obtained by slow evaporation from a methanol solution.[11] As anticipated, the structure of **15e** exhibits a strong I(1)···O(4) intramolecular interaction which affords the pseudo-benziodoxazine ring (Figure 1). The observed I(1)···O(4) distance of 2.647 Å is a typical for I^v pseudocyclic moieties.[7a–h] The resulting pseudo-benziodoxazine scaffold is not planar and a torsion angle of 41.33° was observed for the C(6)-C(11)-N(5)-C(13) fragment. This observation is rather intriguing because all known five-membered pseudocyclic iodine(v)-containing compounds have a planar geometry. Such a dramatic difference can be explained by the steric interaction between the hypervalent iodine center and the carbonyl oxygen atom. Indeed, the rotation of the C(6)-C(11)-N(5)-C(13) fragment to a zero-degree torsion angle results in a I(1)···O(4) distance of 1.86 Å, which is typical for the I=O bond, and therefore a planar geometry in the case of **15e** cannot be achieved. Another important feature of the crystal structure of **15e** is an unusual arrangement of the 3D polymeric network. As with the previously reported IBX analogues,[7a–h] molecules of **15e** form infinite polymeric chains in the bis-μ-oxo motif. This structure, however, differs from those observed earlier in two ways: First, the I(1)···O″(2) and I(1)···O′(3) distances are unusually different, with the latter close to the intramolecular I(1)···O(4) distance, whereas the former is close to the sum of the iodine and oxygen van der Waals radii (Figure 1). Second, the observed polymeric chain is spiral shaped along the principal *c* axis, whereas in previously reported IBX analogs such polymer motifs were close to a linear geometry. Overall, the formation of a six-membered pseudocycle in **15e** leads to several unique features in the solid-state structure.

The solubility of **14–17** varies appreciably depending on the nature of the substituents. Specifically, **14a–d** and pyrrolidinone **17** have very limited solubilities in polar organic solvents, such as dichloromethane, 1,2-dichloroethane (DCE), and acetonitrile. In contrast, **15a–e** and especially **16** exhibit

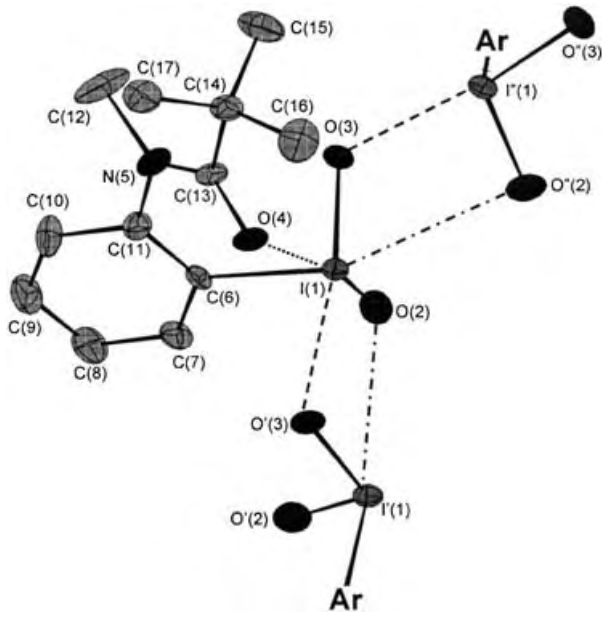

Figure 1. CAMERON drawing of a polymeric chain in the solid-state structure of **15e** at the 30% probability level (hydrogen atoms are omitted for clarity, Ar = 2-$C_6H_4NMeCOtBu$). excellent solubility in polar organic solvents, for example, the solubilities of **15d**, **15e**, and **16e** in CH_2Cl_2 are 0.97, 0.12, and 1.4 M, respectively. The plausible reason for the low solubility of **14** is the formation of intermolecular hydrogen bonds through amide hydrogen atoms which cause extra reinforcement of the polymeric network. In the case of **17**, the low solubility could be explained by the presence of a compact pyrrolidinone ring which offers minor steric demand and, thus, causes no disruption of the polymeric structure.

The oxidation activity of **14**–**17** was evaluated by studying the oxidation of benzyl alcohol and methyl *para*-tolyl sulfide. Preliminary reactivity investigations with **16d** (reagent/substrate = 1:2) showed that these oxidations proceed quantitatively at reflux within 1.5 hours and with MeCN or DCE as the optimal reaction solvents. Reaction at reflux is essential for fast conversions; for example, full conversion requires 36–48 hours at room temperature in DCE as the solvent. To compare reactivity, **14**–**17** were reacted under uniform conditions (the results are presented in Table 1).

The experimental results show that the oxidative activity of **14**–**17** depends on the nature of the *ortho*-substituent to a significant extent. On examination of the oxidative ability of **14**–**17**, a clear pattern emerges: First, unsubstituted amides **14**, with the exception of pivalamide **14e**, exhibit virtually no oxidative activity. This fact appears to arise from the negligible solubility of these compounds in MeCN. Compound **14e** renders moderate solubility and, hence, oxidizes benzyl alcohol. Interestingly, amide **14e** is not reactive towards methyl *para*-tolyl sulfide. Furthermore, series **15**, with **15d** displaying the optimal activity, also demonstrates similar selective oxidative behavior. In series **16**, the selectivity vanishes and both benzyl alcohol and methyl *para*-tolyl sulfide were oxidized effectively. In both sets of compounds, the acetamide derivatives (**15a** and **16a**) display considerable reactivity towards methyl *para*-tolyl sulfide. Finally, **17** does not oxidize alcohols, but reacts slowly with the sulfide functionality.

The character of such a structure–activity relationship can be explained by examination of the equilibrium between amide **7** and benziodoxazine **18** (Scheme 3). The cyclic form **18** apparently has decreased electrophilic reactivity because of its zwitterionic structure with the negative charge on the iodyl moiety and is, thus, not able to react with sulfides to form either intermediates **19** or **20**. On the other hand, the iodyl moiety in benziodoxazine **18** is possibly basic enough to abstract a proton from an alcohol to yield the protonated cyclic form **21**. Subsequent attack by an alkoxide leads to alkoxyiodane **23**, which undergoes decomposition to form

Table 1: Oxidative activity of **14**–**17** towards benzyl alcohol and methyl *para*-tolyl sulfide.

an aldehyde according to the conventional mechanism.[3a] In contrast, the open form **7** is more electrophilic and reacts unselectively with both the alcohol and sulfide groups. We can speculate that **14e** and **15c–e**, which are selective towards alcohol oxidation, have **18** as the major form in solution. The cyclic form **18** of **14e** and **15c–e** is possibly stabilized by the electron-donating effect of the R^1 group and especially the R^2 group through the decrease in the positive charge on the nitrogen atom (see **24**). In **15a**,**b**, the Me and *n*Pr substituents offer less stabilization, and minor amounts of the open form **7** is present in solution. Hence, partial oxidation of the sulfur atom is observed in **15a**,**b**. For series **16**, the cyclic form **18** is highly disfavored because of steric reasons (Scheme 3; see **25**), and no selectivity is observed. Compound **17** possesses lowered reactivity because of low solubility, and it is exclusively reactive towards the sulfide group. This behavior could be explained by the fact that the formation of benziodoxazine **26** is also highly disfavored because of the formation of a double bond at the bridgehead of a bicyclic system.

The proposed mechanism is supported by experimental and spectral data. In their IR spectra, **14e** and **15c–e** showed a single band at 1600–1620 cm^{-1}, which is a typical C=N–Ar stretch. Compounds **16e** and **17** were characterized by a single band at 1643 cm^{-1}, thus indicating an amide carbonyl function. All other compounds showed carbonyl absorptions in both of these regions. The ^{13}C NMR spectra of **15a** in [D_6]DMSO revealed pairs of close signals for C=O, C–NRCO, and C–IO_2 (Figure 2). We assume that this phenomenon results from the coexistence of forms **7** and **18** in solution. The same type of spectrum is observed for **15b** and **16a–d** in [D_6]DMSO and CD_3CN (but not in CD_3OD). Addition of MsOH (Ms = methanesulfonyl; approximately 1.0 equiv) led to upfield signals for C–NRCO and C–IO_2, whereas the upfield signal for C=O vanished, thus putatively yielding the mesylate species similar to the open form **7** (Figure 2). Indeed, no selectivity was observed when oxidations were carried out with **15d** in the presence of a catalytic amount of TsOH (Ts = *para*-toluenesulfonyl; Table 1, entry 17). Conceivably, the formation of electrophilic species **22**, which is close to **7** in reactivity, is responsible for such a major change in the oxidative behavior. The ^{13}C NMR spectra of **15e** and **16e** correspond to the cyclic and open forms of **15a**, respectively (Figure 2). The latter spectroscopic data match the reactivity profile of **15e** and **16e** perfectly but contradict the X-ray data obtained for **15e**. This data can be rationalized by the supposition that the zwitterionic cyclic form **18** exists only in solution, in which charge separation is stabilized by polar solvent molecules, and thus could not be observed in the solid state.

To validate the chemoselective reactivity of **15d**, the oxidation reactions of thioalcohols **26** and **28** were studied (Scheme 4). However, when 0.5 equivalents of oxidant in DCE at reflux were used, considerable amounts (approximately 30% by GCMS) of the respective sulfoxides were formed along with the main products **27** and **29**. Probably, the

initially formed alkoxyiodane **23** can oxidize the sulfur atom to yield the sulfoxide functionality. To avoid this complication, MeSEt (1.0 equiv) was added to the reaction mixture and the quantity of **15d** was increased to 1.0 equivalent. This alteration in the protocol afforded target aldehydes **27** and **29** (sole oxidation products of **26** and **28** as determined by GCMS) in good preparative yields (Scheme 4); furthermore, small amounts of MeSOEt were also isolated. It is notable that oxidation of the thioalcohol **28** using DMP gives only 20% yield of the aldehyde **29**.[12]

In conclusion, the design, preparation, structure, and oxidative properties of novel *N*-(2-iodylphenyl)acylamides **14**–**17** have been described herein, and a mechanistic proposal that accounts for the reactivity pattern of **14**–**17** has also been sufficiently espoused. X-ray studies of **15e** revealed a unique pseudo-benziodoxazine structure, the first reported example of a six-membered pseudocyclic scaffold for iodine(v), with intramolecular secondary I···O bonding interactions. Preliminary experiments indicate that the reagents **14**–**17** can oxidize alcohols and sulfides and that the reactivity largely depends on the substitution pattern of the amide group adjacent to the iodyl moiety. This discovery suggests that the pseudo-benziodoxazine scaffold is a promising lead structure for the design of new regio- and stereoselective hypervalent iodine oxidants. Investigations into mechanistic and reactivity aspects of **14**–**17**, as well as the design of a polymer-supported derivative of the described reagents is ongoing and will be reported in due course.

Supported Au Catalysts

DOI: 10.1002/anie.200502101

Catalysis by Gold: Isolated Surface Au^{3+} Ions are Active Sites for Selective Hydrogenation of 1,3-Butadiene over Au/ZrO_2 Catalysts**

*Xin Zhang, Hui Shi, and Bo-Qing Xu**

In recent years, there has been an increasing interest in catalysis by nanosized gold catalysts,[1–5] which are active in reactions such as CO oxidation,[1–10] propylene epoxidation,[1–3] hydrogenation of unsaturated compounds,[3,12–15] vinyl chloride synthesis,[5] and others.[2,3,5,11] Despite such a diverse spectrum of reactions, efforts have been mainly devoted to elucidating the catalytically active sites in the oxidation reactions.[1–10] Little attention has been paid to the nature of active gold, especially cationic gold species,[5,11] in the other reactions such as hydrogenation of unsaturated compounds.[12–17] This is surprising, since catalytic hydrogenation is one category of the best studied and industrially most important reactions on conventional transition metal catalysts,[18,19] and Au^{3+} ions in solution can activate carbon–carbon double and triple bonds and are finding applications as efficient homogeneous catalysts in many organic reactions.[20,21] Hydrogenation of 1,3-butadiene has long been a model reaction for the study of active sites on conventional metal catalysts.[18,19] A few preliminary investigations[12,13] on the hydrogenation of 1,3-butadiene with supported gold catalysts showed that small gold nanoparticles were active in the reaction, although theoretical calculations seem to suggest that the surface of metallic gold is chemically inert for hydrogen activation.[22,23]

By using Au/ZrO_2 catalysts with very low loadings of Au ($< 0.1\,\%$), we have now discovered that isolated surface-type Au^{3+} ions are actually the active sites for the selective hydrogenation of 1,3-butadiene. The activity and selectivity of these Au^{3+} ions are comparable to those of conventional precious transition metals such as Pd and Pt. This finding that low loadings of Au^{3+} ions are more active for the hydrogenation reaction than high loadings of Au nanoparticles could raise intensive interest in exploring the potential of surface-type Au^{3+} ions in heterogeneous catalytic reactions. The use of isolated and heterogenized Au^{3+} ions in catalysis and related materials may be the key to using the noble gold in areas usually reserved for conventional precious metal catalysts, for example, to significantly improve the economics and reduce the use of other precious metals.

Figure 1 shows the effect of gold loading on 1,3-butadiene conversion over Au/ZrO_2 catalysts calcined at 200 °C. No butane (i.e., the product of complete hydrogenation) but only butenes were detected as the hydrogenation products over all catalysts used. The conversion was less than 1 % in our blank test with bare ZrO_2 support as catalyst. The activity was enhanced greatly on loading with gold, and only a slight decrease in catalyst activity was observed up to 6 h of reaction time on stream (TOS). Surprisingly, higher conversion (ca. 50 %) is obtained over 0.05 % Au/ZrO_2 than over 0.23 % Au/ZrO_2 catalyst (ca. 40 %). The 1,3-butadiene conversions are converted to show the specific mass activity of gold in the catalysts in Table 1. The catalytic turnover frequencies (TOFs) based on surface gold atoms or nonmetallic Au "atoms" are also given in the table. These catalytic rates decreased sharply when the Au loading was increased from 0.05 to 0.23 % and higher. It is noteworthy that the TOFs are very similar (ca. 0.40 s^{-1}) for the catalysts containing 0.05 and 0.01 % Au, that is, the gold "atoms" in these two samples are equally active for the selective hydrogenation reaction.

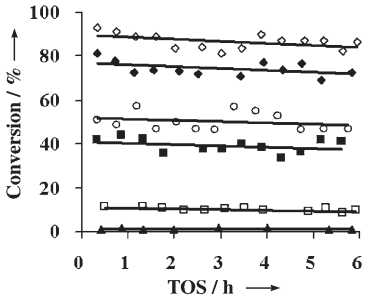

Figure 1. Conversion of 1,3-butadiene at 120 °C over Au/ZrO_2 catalysts (calcined at 200 °C) containing 0.76 (◆), 0.23 (■), 0.08 (◇), 0.05 (○), and 0.01 % Au (□). The (▲) data show the conversion over bare ZrO_2 support. TOS = reaction time on stream.

The same high TOFs of the Au/ZrO_2 catalysts containing no more than 0.05 % Au would mean that the active gold species are atomically dispersed and isolated from each other on the surface of the zirconia support. It was shown previously[11,25] that treatment of supported gold catalysts with an aqueous solution of NaCN can dissolve the gold particles and create isolated gold cations on the support surface. Using a similar procedure (Supporting Information), we treated the 0.76 % Au/ZrO_2 sample with an aqueous solution of 2 % KCN. According to measurements of the Au content by inductively coupled plasma atomic emission spectrometry (ICP-AES), such treatment removed about 90 % of the gold from the solid catalyst and gave a 0.08 % Au/ZrO_2 catalyst. The ICP-AES analysis detected no contamination by K^+ or Na^+ of the sample after treatment. The catalytic activity data of this 0.08 % Au/ZrO_2 catalyst in 1,3-butadiene conversion are included in Figure 1 for comparison

0.76[c]	11.7	0	0	0	0.02	0.03

[a] Sample obtained by treatment of the 0.76% Au/ZrO_2 catalyst with 2% KCN solution. [b] Sample calcined at 300 °C. [c] Sample calcined at 500 °C. [d] The average particle size of Au was determined according to the equation $d = \Sigma n_i d_i / n_i$ by randomly measuring for each sample ca. 200 particles by TEM; the TOF data were calculated on the basis of Au atoms exposed on the surface, which were obtained from the average particle sizes by assuming closed-shell Au particles of spherical shape. All of the nonmetallic Au "atoms" in the catalyst containing less than 0.1% Au were assumed to be the catalytic sites in calculating the TOF data. [e] nd: no metallic Au particle was found in the high-resolution TEM image.

with the other catalysts of different Au loadings. To our surprise, this 0.08% Au/ZrO_2 catalyst effected the highest 1,3-butadiene conversion (ca. 85%). Assuming that every gold "atom" in this 0.08% Au/ZrO_2 catalyst was active for the reaction, we obtained a TOF of 0.42 s^{-1}, which is basically the same as those of the 0.05% Au/ZrO_2 and 0.01% Au/ZrO_2 catalysts (Table 1). This is remarkable, since these rates reveal that the loaded gold "atoms" were 100% accessible for the reaction at these low loadings. According to references [11,25], the 0.08% Au/ZrO_2 sample obtained by treatment of 0.76% Au/ZrO_2 with aqueous 2% KCN solution should contain only surface-type gold cations. The unchanged TOFs of gold at such low loadings could hint that the catalytic active sites are gold cations rather than gold nanoparticles.

We then studied the effect of calcination temperature of the 0.76% Au/ZrO_2 catalyst on the selective hydrogenation reaction, since the calcination temperature appears to affect the ratio of Au^{3+}/Au^0 in oxide-supported gold catalysts.[25,26] We found that the conversion of 1,3-butadiene clearly increased with decreasing catalyst calcination temperature in the range of 200–500 °C (Figure 2). We used a combination of temperature-programmed reduction (TPR) and X-ray photoelectron spectroscopy (XPS) to quantitatively characterize the oxidation states of gold. The XPS data (Figure 3) showed that the sample calcined at 500 °C contained only metallic Au^0 showing $4f_{7/2}$ and $4f_{5/2}$ signals at 83.7 and 87.6 eV, respectively.[26] In addition to metallic Au^0, XPS spectra of samples calcined at 300 and 200 °C also contained the $4f_{7/2}$ (86.1 eV) and $4f_{5/2}$ (89.4 eV) signals from Au^{3+} ions. Thus the Au^{3+}/Au^0 ratio increases with decreasing catalyst calcination temperature.

Figure 4 shows the temperature-programmed reduction (TPR) profiles of the bare ZrO_2 support as well as 0.08% and 0.76% Au/ZrO_2 catalysts. Bare ZrO_2 showed no consumption of hydrogen up to 800 °C. The TPR profiles of the samples calcined at 200 and 300 °C feature two hydrogen consumption peaks, one at low (210–230 °C) and the other at high temperature (550–580 °C). However, only the high-temperature peak appeared for the sample calcined at 500 °C. With reference to the XPS characterization data, the low-temperature peak should be due to reduction of Au^{3+} ions, while the high-temperature peak can be assigned to partial (< 3%) reduction of surface Zr^{4+} ions of the zirconia support to Zr^{3+}.[14]

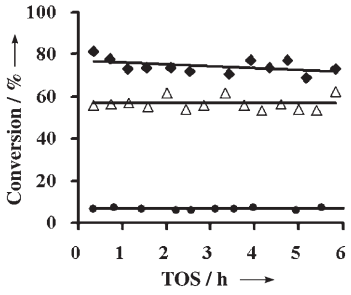

Figure 2. Effect of the catalyst (0.76% Au/ZrO_2) calcination temperature on 1,3-butadiene conversion: (◆) 200, (△) 300, and (●) 500 °C.

The samples with very low Au loadings (< 0.1 %) were also characterized by the TPR technique. The TPR profile of the 0.08 % Au/ZrO_2 sample is presented as the profile (d) in Figure 4. Calibration of the hydrogen-consumption peak showed that the number of hydrogen molecules (H_2) consumed under the low-temperature peak was just 1.5 times the molar number of gold in the 0.08 % Au/ZrO_2 sample. Since this sample should contain only gold cations after treatment with 2 % KCN solution,[11,25] such stoichiometry ($H_2/Au = 1.5$ or $H/Au = 3.0$) of the reduction proves that the gold cations in the 0.08 % Au/ZrO_2 sample are actually Au^{3+}. The TPR profiles of the samples containing 0.01 and 0.05 % Au were very similar to that of 0.08 % Au/ZrO_2 (not shown in Figure 2). Their reduction stoichiometries (Table 1) also prove that these two samples contain only Au^{3+} ions.

We then measured the Au^{3+}/Au^0 ratios in the 0.76 % Au/ZrO_2 catalysts by calibrating the reduction peaks of their Au^{3+} ions; the ratios were 0.33 and 0.20 for samples calcined at 200 and 300 °C, respectively. For 0.23 % Au/ZrO_2, the measured Au^{3+}/Au^0 ratio was 0.83.

The effects of catalyst calcination temperature and Au loading on the catalyst activity are also compared in Table 1. The 0.76 % Au/ZrO_2 catalyst calcined at 500 °C, which contains only metallic Au particles but no Au^{3+} ions, exhibited a TOF of 0.03 s^{-1}, which is comparable to those of 0.01–0.02 s^{-1} at 150 °C of the most active metallic Au nanoparticles supported on TiO_2 and Al_2O_3 in reference [13]. However, this activity of the metallic gold (0.03 s^{-1}) in the 0.76 % Au/ZrO_2 catalyst is one order of magnitude lower than that of catalysts containing only small amounts of Au^{3+} ions (0.4 s^{-1}). The specific mass activity of the supported metallic Au particles in the 0.76 % Au/ZrO_2 catalyst, as well as in the 1 % Au/TiO_2 and 1 % Au/Al_2O_3 catalysts in ref. [13], is even two orders of magnitude lower. These remarkable differences demonstrate that the surface-type Au^{3+} ions are far more active than the Au^0 atoms at the surface of metal nanoparticles. Earlier, Guzman and Gates[15,16] reported that mononuclear organo-Au^{3+} complexes supported on MgO were active in the catalytic hydrogenation of ethene, while metallic Au^0 particles were inactive. Cationic gold was also found to be responsible for the activity of Au/CeO_2 catalysts in the water-gas shift reaction involving oxygen-containing reactants ($CO + H_2O$).[11] It is noteworthy in the present study that the Au^{3+} ions "fixed" at the ZrO_2 surface are stable and active even under a completely reducing atmosphere (H_2).

The catalytic activity in terms of conversion of 1,3-butadiene (Figures 1 and 2) or mass of gold (Table 1) is apparently not in proportion with the number of Au^{3+} ions in the catalysts containing 0.23 and 0.76 % Au. The numbers of Au^{3+} ions in the 0.23 % Au/ZrO_2 (5.3 μmol g^{-1}) and 0.76 % Au/ZrO_2 (e.g., 9.6 μmol g^{-1} for the sample calcined at 200 °C) catalysts were much higher than that in the 0.08 % Au/ZrO_2 (4.1 μmol g^{-1}) catalyst, but their activities were significantly lower. This indicates that the highly active Au^{3+} ions are not those with interaction to the metallic gold particles but those independently "fixed" at specific locations of the zirconia surface. The surface density of Au^{3+} ions in the most active 0.08 % Au/ZrO_2 catalyst is 0.02 per square nanometer. This surface density of Au^{3+} ions is sufficiently low to ensure that the most active sites for the hydrogenation reaction are isolated surface-type Au^{3+} ions.

Structure sensitivity is an important issue in gold catalysis even in the case of selective hydrogenation.[14,17,27] Since the present work is intended to show the important catalytic implications of Au^{3+} cations at the zirconia surface, it is not clear whether the selective hydrogenation of 1,3-butadiene is structure sensitive or not with respect to the ZrO_2-supported Au particles. We note, however, that in work by Haruta et al.[13] the same reaction was almost insensitive to the size of the Au particles and nature of the support, while an earlier paper by Buchanan and Webb[28] suggested a strong influence of the support materials. Claus et al. found that the same reaction over metallic Au is also sensitive to the nature of the support oxide,[17] but the hydrogenation of acrolein is mainly affected by the percentage of edge/corner atoms relative to the total surface atoms.[14,27]

Due to their ability to activate carbon–carbon double and triple bonds (e.g., alkynes and allenes), Au^{3+} ions (i.e., gold salts) in solution are finding applications as efficient homogeneous catalysts in many organic reactions.[20,21] If the Au^{3+} ions can be properly heterogenized onto a solid surface while still maintaining their catalytic efficiency in the homogeneous systems, the "golden gate"[21] of catalysis by homogeneous gold would be even more useful for advanced heterogeneous catalysis. By reducing the loading of gold to very low levels (< 0.1 % Au), the present work is the first to demonstrate that high loadings of Au nanoparticles are actually not required for the hydrogenation reaction; the very low concentration of Au^{3+} ions (0.02 Au^{3+}/nm^2) heterogenized on zirconia surface from a cheap inorganic gold source ($HAuCl_4$) is enough to grant much higher catalytic activity. Moreover, the present heterogenized Au^{3+} ions were simply prepared from an inorganic gold salt in aqueous solution and were stable in ambient air, which can be very important in practical applications.

The TOF of the isolated Au^{3+} ions (0.4 s^{-1}) is comparable to that of conventional supported precious metals (e.g., ca. 0.2–1.0 s^{-1} for Pd).[18,19] Interestingly, the hydrogenation of 1,3-butadiene over the present Au/ZrO_2 catalysts has 100 % selectivity for butenes; no butane is detected even over the most active 0.08 % Au/ZrO_2 catalyst at high conversions of 1,3-butadiene (80–90 %; see Figure 1). The major component of the product butenes is 1-butene (ca. 60 %), and the *trans*/*cis* ratio of 2-butene is in the range of 0.3–1.0 over all of the Au/ZrO_2 catalysts (Figure 5). This *trans*/*cis* ratio is much lower than that obtained over supported Pd (*trans*/*cis* = 10–14) but close to that over supported Pt and other group VIII metals (*trans*/*cis* = 1.5–2.0).[18,19,29] The comparable activity (TOF) of the surface-type Au^{3+} ions to those of the group VIII precious metals and their unique selectivity in the hydrogenation reaction are of potential for many selective hydrogenations and related reactions. The isolated nature of the active Au^{3+} ions can also have important applications in improving the economics of gold catalysis.

Although this work was successful in demonstrating that the most active sites for the selective hydrogenation reaction are isolated Au^{3+} ions at the surface of zirconia, the mechanism of hydrogen activation by these surface-type

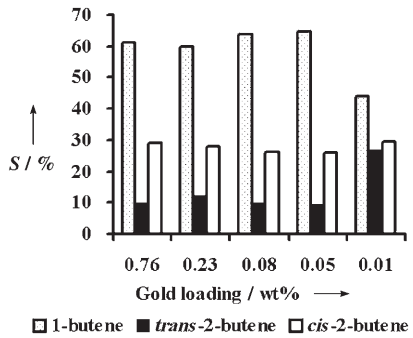

Figure 5. Product selectivity *S* of 1,3-butadiene hydrogenation over Au/ZrO_2 catalysts of different Au loadings.

Au^{3+} ions remains to be elucidated. Hydrogen chemisorption on supported gold was occasionally detected, but sometimes it has not been detectable at all.[3,27] The remarkable activity difference discovered between surface-type Au^{3+} ions and metallic Au^0 atoms could mean a different mechanism for hydrogen activation. Comprehensive in situ spectroscopic studies will be needed to understand the mechanistic aspect of the surface-type Au^{3+} cations in the hydrogen activation.

In conclusion, we have shown that isolated Au^{3+} ions on a zirconia support are obtained by loading very small amount ($< 0.1\,\%$) of gold with simple methods. These heterogenized Au^{3+} ions are highly active for the selective hydrogenation of 1,3-butadiene to butenes. Further exploration of the potential of the surface-type Au^{3+} ions in heterogeneous catalysis may be the key to using the noble metal gold in areas usually reserved for conventional precious metal catalysts such as Pt and Pd.

Experimental Section

A conventionally prepared $ZrO(OH)_2$ hydrogel was calcined at 400 °C to produce a ZrO_2 support with BET surface area of $120\ m^2\,g^{-1}$.[24] Samples of Au/ZrO_2 were prepared by loading the support with appropriate amounts of Au by the deposition–precipitation method with $HAuCl_4$ precursor,[8] the concentration of which was adjusted to yield catalysts containing 0.76, 0.23, 0.05, and 0.01 wt % Au (ICP-AES analysis). The 0.76 % Au/ZrO_2 sample was treated with an aqueous solution of KCN in a process similar to that reported by Fu et al.[11] to give 0.08 % Au/ZrO_2 catalyst. The Au/ZrO_2 catalysts were dried and calcined at 200 °C in flowing air. We also prepared 0.76 % Au/ZrO_2 catalysts at different calcination temperatures, that is, 200, 300, and 500 °C. TPR was used in combination with XPS measurements to quantitatively characterize the oxidation state of gold. TEM/HRTEM images were recorded on a JEM-2010F (200 kV) transmission electron microscope.

Hydrogenation of 1,3-butadiene was conducted at 120 °C in a fixed-bed stainless steel reactor (i.d. 4 mm) at atmospheric pressure. The reaction feed (2.15 vol % 1,3-butadiene in H_2) was introduced to the catalyst at a flow rate of $13.5\ mL\,min^{-1}$ (gas hourly space velocity (GHSV) = $8100\ mL\,h^{-1}\,(g\,cat.)^{-1}$. Before reaction all samples (ca. 80–120 mesh, 0.1 g diluted with 0.45 g quartz powder) were pretreated in situ in $30\ mL\,min^{-1}$ Ar at 200 °C for 2 h. The selected reaction conditions precluded any significant mass-transfer limitation in a series of pre-experiments at fixed space velocity (GHSV = $8100\ mL\,h^{-1}\,(g\,cat.)^{-1}$) so that the conversion of butadiene (ca. 75 %) over the 0.76 % Au/ZrO_2 catalyst (calcined at 200 °C) was not significantly affected by changing the flow rate of the reaction feed and the catalyst pellet size (40–120 mesh). The reactor effluent was analyzed in situ by gas chromatography. Experimental details and representative TEM images of the Au/ZrO_2 catalysts can be found in the Supporting Information.

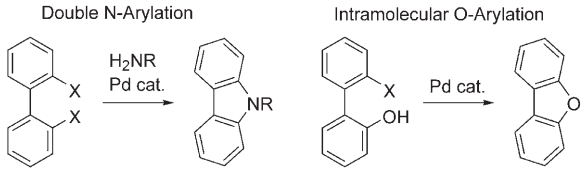
Stereospecific Synthesis of Hetero[7]helicenes by Pd-Catalyzed Double *N*-Arylation and Intramolecular *O*-Arylation**

*Koji Nakano, Yuko Hidehira, Keita Takahashi, Tamejiro Hiyama, and Kyoko Nozaki**

Helicenes consist of *ortho*-annulated aromatic and/or heteroaromatic rings endowed with a helical chirality.[1] Enantiopure helicenes can be isolated because of their stable and rigid helical conformation; furthermore, some of them form aggregates to give helical supramolecular architectures potentially applicable to nonlinear optics, electrooptic switches, and circularly polarized luminescent materials.[2] To expand the application of helicene molecules as functional materials, it is important to develop an efficient synthetic strategy for the production of helicenes with a variety of frameworks and substituents in enantiopure form. The classical methodology to synthesize helicenes is an oxidative photocyclization of stilbene-type precursors.[3] Several non-photochemical synthetic methods have been reported,[4] which have been applied to the syntheses of enantioenriched helicenes.[4a,f,5] Among these previous examples of helicene synthesis, however, only a few demonstrate the synthesis of azahelicenes with pyrrole rings or oxahelicenes with furan rings in spite of their potential to alter molecular properties,[5g,6,7] which prompted us to develop a new synthetic route that would produce aza- and oxahelicenes.

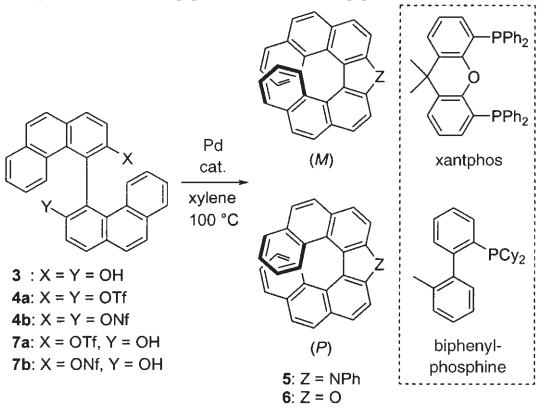
The key reactions in the heterohelicene syntheses are shown in Scheme 1. Carbazole derivatives can be prepared by the double N-arylation of primary amines with dihalobiphenyls or biphenylylene disulfonate **1**, as we reported recently.[8] The intramolecular O-arylation of 2′-hydroxybiphenyl-2-yl halides or sulfonates **2** is anticipated to give dibenzofuran, which we refer to as the palladium-catalyzed intermolecular diaryl ether synthesis.[9] These reactions of biphenyls were applied to biphenanthryls to form an efficient synthetic route to hetero[7]helicenes.



Scheme 1. Key reactions for the synthesis of heterohelicenes.

The target aza[7]helicene *rac*-**5** was obtained in 64% yield by the reaction of aniline with racemic 4,4′-biphenanthryl-3,3′-ylene ditriflate (*rac*-**4a**), which was prepared from racemic 4,4′-biphenanthryl-3,3′-diol (*rac*-**3**; Table 1, run 1). Oxa[7]helicene *rac*-**6** was produced as a by-product (10% yield) through the intramolecular O-arylation of 3′-hydroxy-4,4′-biphenanthryl-3-yl triflate (*rac*-**7a**), which was formed by

Table 1: Syntheses of aza[7]helicene and oxa[7]helicene.



Run	Substrate	Conditions[a]	t [h]	Product	Yield [%]
1	*rac*-**4a**	A	141	*rac*-**5**	64[b]
2	*rac*-**4b**	A	123	*rac*-**5**	88
3	(*S*)-**4b**	B	123	(*P*)-**5**	94 (>99% *ee*) $[\alpha]_D^{22} = +2310$ (c=0.10, $CHCl_3$)
4	*rac*-**7a**	C	18	*rac*-**6**	45[c]
5	*rac*-**7b**	C	96	*rac*-**6**	62
6	(*S*)-**7b**	C	96	(*P*)-**6**	60 (20% *ee*)
7	(*S*)-**7b**	D	13	(*P*)-**6**	49 (94% *ee*) $[\alpha]_D^{23} = +1430$ (c=0.10, $CHCl_3$)

[a] Reaction conditions: A: H_2NPh (1.2 equiv), $[Pd_2(dba)_3]\cdot CHCl_3$ (5 mol%), xantphos (10 mol%), K_3PO_4 (2.8 equiv); B: H_2NPh (1.2 equiv), $[Pd_2(dba)_3]\cdot CHCl_3$ (10 mol%), xantphos (20 mol%), K_3PO_4 (2.8 equiv); C: $[Pd_2(dba)_3]\cdot CHCl_3$ (5 mol%), biphenylphosphine (20 mol%), K_3PO_4 (2.0 equiv); D: $[Pd_2(dba)_3]\cdot CHCl_3$ (10 mol%), biphenylphosphine (40 mol%), K_3PO_4 (2.0 equiv). [b] A 10% yield of *rac*-**6** as a by-product was obtained. [c] Consumption of the substrate was confirmed by TLC; the major by-product was diol *rac*-**3**. Cy = cyclohexyl, dba = dibenzylideneacetone.

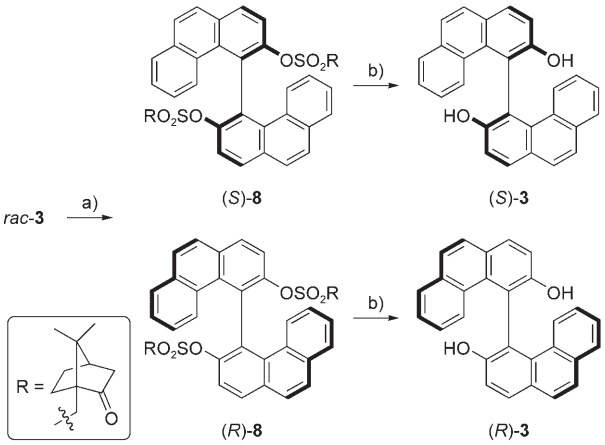
the partial hydrolysis of *rac*-**4a**. The hydrolysis of the sulfonate functionality was successfully avoided by using a nonaflate (Nf) group instead of a triflate (Tf).[10] Thus, the yield was elevated to 88% (run 2) under the optimized reaction conditions (*rac*-**4b** with aniline (1.2 equiv), $[Pd_2(dba)_3]$ (5 mol%), xantphos (10 mol%), K_3PO_4 (2.8 equiv), xylene, 100°C, 123 h).

The optical resolution of *rac*-**3**[11] was investigated for the preparation of optically active heterohelicenes (Scheme 2).



Scheme 2. Optical resolution of *rac*-**3**. a) RSO_2Cl (3.0 equiv), 4-(*N*,*N*-dimethylamino)pyridine (5.0 mol%), Et_3N, DMF, 0°C→RT, 15 h, separation by column chromatography on silica gel ((*S*)-**8**: 49% yield; (*R*)-**8**: 47% yield); b) THF, MeOH, aq. NaOH (5.0 M), reflux, 15 h ((*S*)-**3** and (*R*)-**3**: 95% yield; (*S*)-**3**: >99% *ee*; (*R*)-**3**: >99% *ee*). DMF = dimethylformamide.

The esterification of *rac*-**3** with the commercially available (1*S*)-10-camphorsulfonyl chloride gave diastereomers of disulfonate **8**, which were readily separated by column chromatography on silica gel. Hydrolysis of the obtained two single diastereomers gave (*S*)-**3** and (*R*)-**3** in enantiopure form.

A single enantiomer of **5** was readily prepared from (*S*)-**4b** by a stereospecific double N-arylation reaction; transformation of (*S*)-**4b** (>99% *ee*) gave (*P*)-**5** in 94% yield with >99% *ee* (Table 1, run 3). The absolute configuration of (*P*)-**5** was confirmed by its optical rotation ($[\alpha]_D^{22} = +2310$ ($c = 0.10$, $CHCl_3$)) and CD spectrum,[12] both of which are similar to those of the known dextrorotatory (*P*)-heterohelicenes.[5g,6a,13] Thus, the absolute configuration of (*S*)-**4b** is maintained under the reaction conditions (100°C, 123 h) in contrast to the O-arylation of (*S*)-**7b** (see below).

Oxa[7]helicene **6** was successfully synthesized through intramolecular O-arylation. The reaction of triflate *rac*-**7a** or nonaflate *rac*-**7b** using a palladium catalyst gave the desired *rac*-**6** in yields of 45 or 62%, respectively (runs 4 and 5). Unlike the double N-arylation of (*S*)-**4b** (run 3), however, the reaction of optically active (*S*)-**7b** (>99% *ee*) gave (*P*)-**6** (20% *ee*) with significant loss of enantiomeric excess (run 6; 100°C, 96 h). Racemization was suppressed effectively by shortening the reaction time (13 h) to afford (*P*)-**6** in 49% yield with high enantiopurity (94% *ee*; $[\alpha]_D^{23} = +1430$ ($c = 0.10$, $CHCl_3$); run 7). It should be noted that racemization of (*P*)-**6** takes place under the reaction conditions: treatment of optically active (*P*)-**6** (92% *ee*) in toluene at 100°C for 88 h resulted in partial racemization (42% *ee*). In contrast, none of (*S*)-**7b** (98% *ee*), (*R*)-**4b** (>99% *ee*), and (*M*)-**5** (97% *ee*) underwent racemization in toluene at 100°C. These results indicate that the stereospecific intramolecular O-arylation of (*S*)-**7b** gives (*P*)-**6** without any significant loss of enantiopurity, and the racemization takes place after the formation of (*P*)-**6**. The lower tolerance of **6** to racemization relative to **5** may be attributed to the differences in their structure. Indeed, the single-crystal X-ray analyses suggested that **6** has a less-distorted structure than **5** (Figure 1), thus indicating that the terminal two rings in **6** have weaker steric repulsions which should lead to a lower racemization barrier.[14,15]

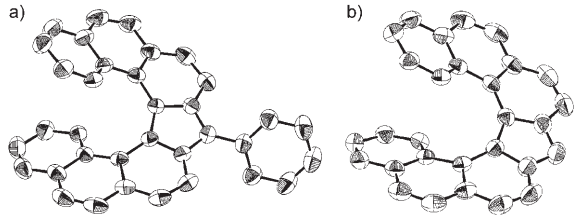


Figure 1. ORTEP drawings of a) **5** and b) **6**, with thermal ellipsoids shown at the 50% probability level. All hydrogen atoms and the $CHCl_3$ molecule are omitted for clarity.

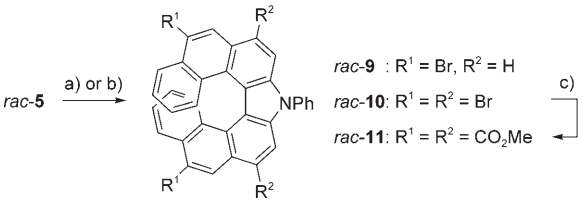
The introduction of substituents into aza[7]helicene was investigated toward the development of hetero[7]helicenes as functional materials. Regioselective bromination was successfully achieved by the treatment of *rac*-**5** with two and four equivalents of NBS to yield di- and tetrabromoaza[7]helicenes *rac*-**9** and *rac*-**10**, respectively (Scheme 3).[16] The



Scheme 3. Functionalization of *rac*-**5**. a) NBS (2.0 equiv), SiO_2 (2.0 g mmol^{-1} NBS), CH_2Cl_2, RT, 31 h (*rac*-**9**: 61% yield; b) NBS (4.0 equiv), SiO_2 (2.0 g mmol^{-1} NBS), CH_2Cl_2, RT, 43 h (*rac*-**10**: 84% yield); c) *t*BuLi (8.4 equiv), THF, −78°C, 4 h, then $ClCO_2Me$ (8.4 equiv), −78°C→RT, 13 h, (*rac*-**11**: 44% yield). NBS = *N*-bromosuccinimide.

substituted positions were determined by single-crystal X-ray analyses.[17] These brominated aza[7]helicenes should be useful intermediates for further functionalizations; for example, *rac*-**10** was converted into tetraester *rac*-**11** in 44% yield (Scheme 3).

In conclusion, we have reported an efficient strategy for the synthesis of aza- and oxa[7]helicenes **5** and **6** from the same precursor, 4,4′-biphenanthryl-3,3′-diol (**3**); highly enantioenriched **5** and **6** were successfully obtained in good yields. In addition, tetrabromoaza[7]helicene **10** was produced by

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the regioselective bromination of **5**. Aggregates of the aza[7]helicenes, which are potentially attractive new materials, could be synthesized by further functionalization of **10**, with the introduction, for example, of long alkyl chains.[2]

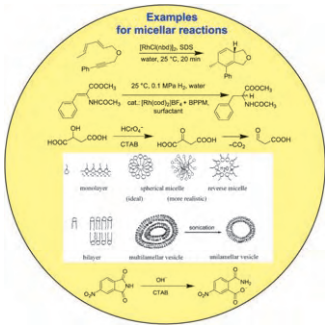
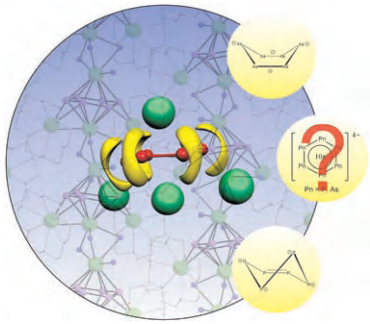
Cover Picture

Marcin Fialkowski, Kyle J. M. Bishop, Victor A. Chubukov, Christopher J. Campbell, and Bartosz A. Grzybowski*

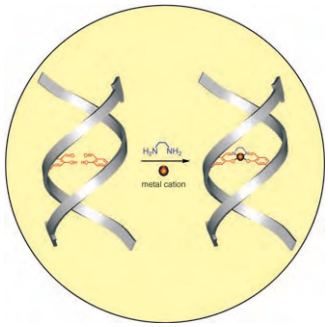
Organic synthetic reactions are treated as a connected network so that the mechanism by which organic chemistry evolved can be studied. In their Communication on page 7263 ff., B. A. Grzybowski and co-workers analyze organic syntheses reported between 1850 and 2004, thus revealing the architecture and evolution of the synthesis of molecules, and discuss the application of this technique to the chemical industry. The cover picture shows a typical "hub" in a network of organic chemistry.



Micelles
The increased selectivities and activities achieved in catalytic organic reactions carried out in water and by using micelle-forming amphiphilic agents is described in the Review by G. Oehme and co-workers on page 7174 ff.



Cluster Anions
Through use of the electron-localization function, N. Korber and co-workers attempt, in their Communication on page 7200 ff, to clarify the nature of the chemical bond in the P_6^{4-} and As_6^{4-} ions.



DNA Structures
Stabilization of a DNA duplex containing two salicylic acid aldehyde nucleosides results from its treatment with ethylenediamine and Cu^{2+} or Mn^{2+} ions, as described by T. Carell and co-workers in their Communication on page 7204 ff.

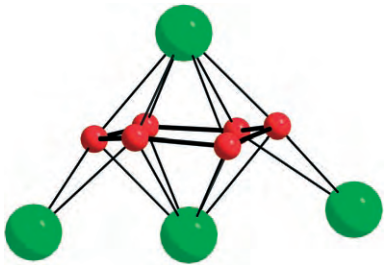
Reactions in Micellar Systems

Communications

Are the homoatomic ring anions P_6^{4-} and As_6^{4-} really planar and 10π aromatic outside of the binary alkali-metal compounds? With the crystal structure of $\{Rb[18]crown\text{-}6)\}_2Rb_2As_6 \cdot 6\,NH_3$ (see structure of the $\{Rb_4As_6\}$ core; Rb green, As red) and the electron localization function, an attempt is made to clarify the nature of the chemical bond in these pnictides.



Cluster Anions

Chemical Bond in the Cyclic Anions P_6^{4-} and As_6^{4-}: Synthesis, Crystal Structure, and Electron Localization Function of $\{Rb[18]crown\text{-}6)\}_2Rb_2As_6 \cdot 6\,NH_3$

Stabilizing influence: When a DNA duplex containing two salicylic aldehyde nucleosides facing each other is treated with ethylenediamine and one equivalent of a Cu^{2+} or Mn^{2+} salt, a metal–salen base pair is formed within the DNA. The resulting stabilization of the DNA structure is attributed to the cross-linking of the salicylic aldehyde units with ethylenediamine.

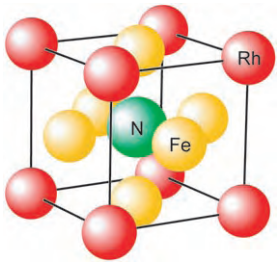
Predictions confirmed: The phase $RhFe_3N$ (see unit cell), which was recently predicted by total-energy density functional calculations and proposed to have exciting magnetic properties, was synthesized for the first time. The experimental lattice parameter is in good agreement with the theoretical prediction, and the phase appears to be a semihard itinerant ferromagnet. The atomic magnetic saturation moment, μ_a^s, is 8.3 μ_B per formula unit, and the Curie temperature, T_C, is 505(25) K.



Magnetic Storage Materials

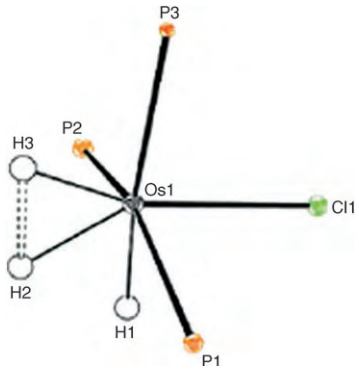
A Neutron Diffraction Study of $[OsClH_3(PPh_3)_3]$: A Complex Containing a Highly "Stretched" Dihydrogen Ligand

Elastic bonds: The structure of $[OsHCl(\eta^2\text{-}H_2)(PPh_3)_3]$ has been determined by neutron diffraction (see figure). The complex presents an unusual H···H contact of 1.48(2) Å and can be regarded either as a highly stretched dihydrogen complex or as a compressed dihydride complex.

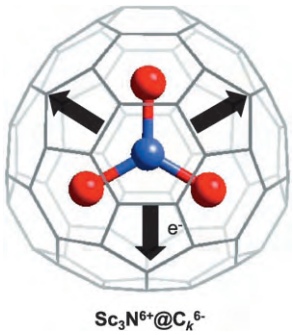


Fullerenes

J. M. Campanera, C. Bo, J. M. Poblet* — **7230 – 7233**

General Rule for the Stabilization of Fullerene Cages Encapsulating Trimetallic Nitride Templates

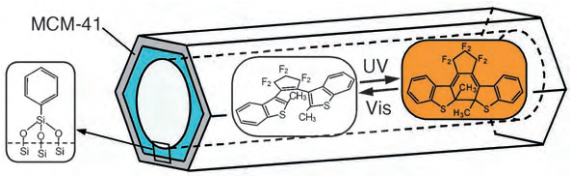
Ruling the cage: The bonding in trimetallic nitride template (TNT) endohedral metallofullerenes is widely described by the ionic model $Sc_3N^{6+}@C_k^{6-}$. The ability of the fullerene cage to accept six electrons determines its capacity to encapsulate the TNT unit (see picture). Only free fullerene isomers with a large (LUMO+3)–(LUMO+4) gap can capture and stabilize these four-atom units.



Photochemistry

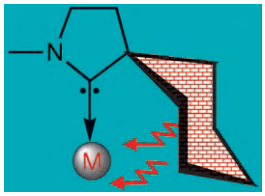
H. Okada, N. Nakajima, T. Tanaka, M. Iwamoto* — **7233 – 7236**

Improvement in Photocyclization Efficiency of Diaryl Ethenes by Adjusting the Pore Size of Mesoporous Silica



Photochromism in nanospace: Reversible photochromic reaction of a diaryl ethene (DE) takes place in the pores of MCM-41s modified with organic groups. The efficiency of the photocyclization reaction increases fourfold when the diameter of the pore is decreased to approximately the same size of the DE, which indicates that the conformation of the open-ring isomer is regulated in the confines of the pore (see picture).

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

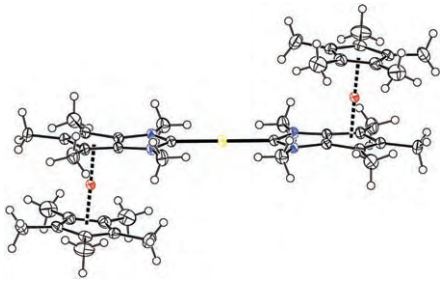


A protecting wall for low-coordinate metal centers, reinforced by agostic interactions, is provided by a rigid cyclic (alkyl)(amino)carbene ligand (CAAC), as shown by the preparation of [RhCl(CO)(CAAC)] and [Pd(All)(CAAC)]$^+BF_4^-$ complexes (All = allyl). The former is related to the active species of Wilkinson's catalyst, and the latter is the first isolated cationic, formally 14-electron Pd^{II} species.

Low-Coordinate Complexes

V. Lavallo, Y. Canac, A. DeHope, B. Donnadieu, G. Bertrand* **7236 – 7239**

A Rigid Cyclic (Alkyl)(amino)carbene Ligand Leads to Isolation of Low-Coordinate Transition-Metal Complexes



A zwitterionic ligand yields a trimetallic carbene complex (see structure), in which the metal centers are electronically coupled by a single ligand that employs both σ and π bonding. This imidazol-2-ylidene complex, derived from the imidazolium-cyclopentadienide zwitterion, reveals a carbene-ligand architecture that allows the incorporation of multiple metal and/or main-group element centers.

Carbene Ligands

A. J. Arduengo III,* D. Tapu, W. J. Marshall **7240 – 7244**

The Generation of a Metallocene-Fused Imidazol-2-ylidene and Its Mercury Complex

Current affairs: Incorporation of a 1,4-phenylene bridge into *meso* aryl-substituted decaphyrin and octaphyrin has a profound impact on the structural and electronic properties of the macrocycles. Bridged decaphyrin has two oxidation states, one of which shows a rather strong diatropic ring current. X-ray crystal structure analyses reveal bridged octaphyrin possesses a *p*-quinodimethane unit, while bridged decaphyrin has a phenylene unit (see picture).

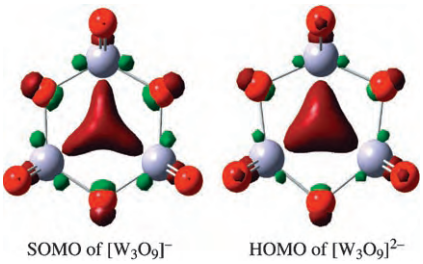
Cluster Compounds

X. Huang, H.-J. Zhai, B. Kiran, L.-S. Wang* ——— **7251 – 7254**

Observation of d-Orbital Aromaticity

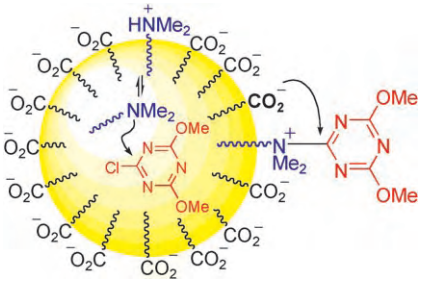


The metal oxide clusters $[W_3O_9]^-$ and $[Mo_3O_9]^-$ were studied by photoelectron spectroscopy and theoretical calculations, which show that $[W_3O_9]$ and $[Mo_3O_9]$ both have a D_{3h} structure with a low-lying unoccupied molecular orbital formed from the metal d orbitals. Occupation of this orbital by one or two electrons leads to aromatic anions (see picture) with strong three-center, one-electron and three-center, two-electron metal–metal bonds, respectively.

Micelles

M. Kunishima,* H. Imada, K. Kikuchi, K. Hioki, J. Nishida, S. Tani **7254 – 7257**

Unusual Rate Enhancement of Bimolecular Dehydrocondensation To Form Amides at the Interface of Micelles of Fatty Acid Salts

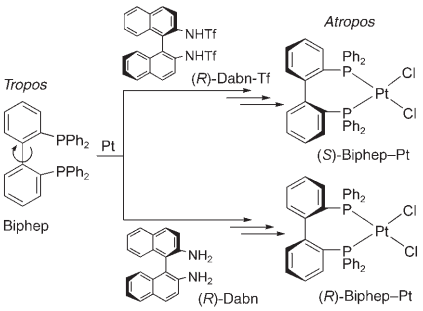


Speeding up: A micelle–water interface acts as a suitable reaction field for dehydrocondensation. The coupling reaction of fatty acid salts with a triazine-type amphiphilic dehydrocondensing agent in a micellar system (see picture) underwent up to 2000-fold acceleration. The rate enhancement can be attributed to the higher local concentration and preorientation of the reactants in the micelles.

Asymmetric Catalysts

K. Mikami,* H. Kakuno, K. Aikawa ——— **7257 – 7260**

Enantiodiscrimination and Enantiocontrol of Neutral and Cationic Pt^{II} Complexes Bearing the *Tropos* Biphep Ligand: Application to Asymmetric Lewis Acid Catalysis

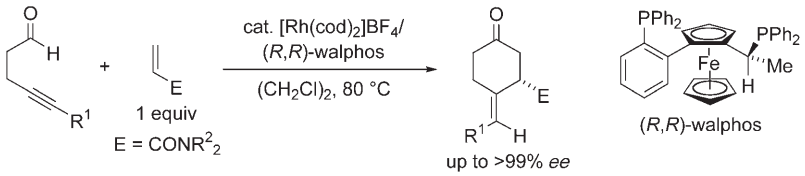


The stereochemically stable, enantiopure biphep–Pt complexes can be employed as an *atropos* asymmetric catalyst at 50 °C or below. Both enantiomeric forms of this complex can be obtained by using either the chiral diamine (*R*)-dabn or its diamide (*R*)-dabnTf followed by chirally controlled formation of the single biphep–Pt enantiomer at higher (> 60 °C) temperatures (see scheme; Tf = trifluoromethanesulfonate).

Carbocyclization

K. Tanaka,* Y. Hagiwara, K. Noguchi ——— **7260 – 7263**

Rhodium-Catalyzed Regio- and Enantioselective Intermolecular [4+2] Carbocyclization of 4-Alkynals with *N*,*N*-Dialkyl Acrylamides



Selective rings: A cationic Rh^I–(*R*,*R*)-walphos complex catalyzes a highly regio- and enantioselective intermolecular [4+2] carbocyclization of 4-alkynals with *N*,*N*-dialkyl acrylamides to afford enantioenriched cyclohexanones (see scheme; cod = cycloocta-1,5-diene). This new route is attractive in view of the one-step access to 4-alkynals from commercially available reagents.

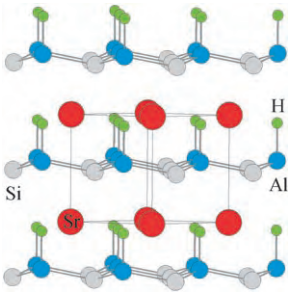
Organic syntheses reported in the literature between 1850 and 2000 are analyzed at the simplified level of a connected network (see the picture of the network for 1850). Fundamental statistical laws that govern organic syntheses are established. These laws allow the estimation of the synthetic and industrial usefulness of organic molecules.

Computational Chemistry

M. Fialkowski, K. J. M. Bishop, V. A. Chubukov, C. J. Campbell, B. A. Grzybowski* ——— **7263 – 7269**

Architecture and Evolution of Organic Chemistry

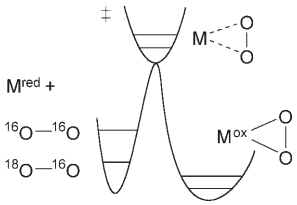


Stable and semiconducting: Polyanionic hydrides represent a new class of main-group-metal hydrides with unforeseen hydrogen-coordination environments. The hydrogen atom in SrAlSiH is attached exclusively to Al and forms part of a layered $[AlHSi]^{2-}$ polyanion (see figure). This material is the first narrow bandgap semiconductor hydride and combines the high thermal stability of saline hydrides with the air and moisture stability of interstitial transition-metal hydrides.

Semiconductor Materials

T. Björling, D. Noréus, K. Jansson, M. Andersson, E. Leonova M. Edén, U. Hålenius, U. Häussermann* ——— **7269 – 7273**

SrAlSiH: A Polyanionic Semiconductor Hydride

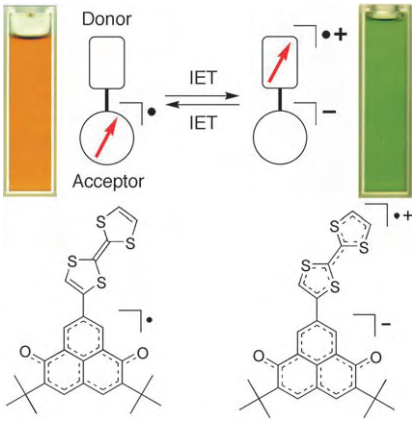


Kinetic isotope effects (KIEs) have been used to probe the mechanism of the binding of O_2 to classic inorganic compounds. The intermolecular ^{18}O KIEs decrease with increasing rate constants, and the correlation of the KIEs with the $\log k_{O_2}$ values establishes that the same oxidative addition mechanism is operative in all cases, but with marked differences in the transition-state structure (see figure).

Oxygen Activation

M. P. Lanci, D. W. Brinkley, K. L. Stone, V. V. Smirnov, J. P. Roth* ——— **7273 – 7276**

Structures of Transition States in Metal-Mediated O_2-Activation Reactions



Doctoring spin: Spin transfer and solvato-/thermochromism have been observed in a purely organic open-shell system comprising electron-donor and -acceptor moieties, in which a 6-oxo-phenalenoxyl neutral radical is directly linked with tetrathiafulvalene. Intramolecular electron transfer (IET, see scheme) causes this interconversion, which can be controlled by a moderate change in the solvent environment and temperature.

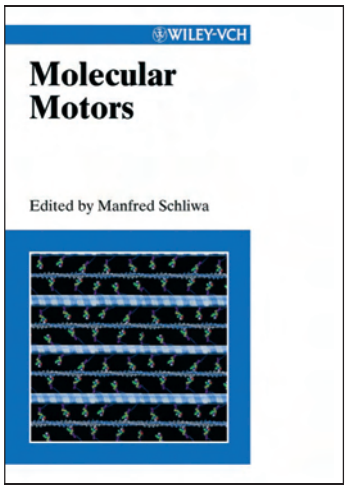
Concise Insight of 20 Years of Research



2002. XXII, 582 pages, 129 figures 48 in color, 20 tables. Hardcover. ISBN 3-527-30594-7
€ 179.- /£ 125.- /US$ 245.-

MANFRED SCHLIWA, University of Munich, Germany (Ed.)

Molecular Motors

Cell motility, virus transport and developmental asymmetry are examples of biological processes related to the function or malfunction of the minute machinery of molecular motors. This handbook brings together current knowledge on the functionality, regulation, and interactions of cytoskeletal, DNA, and rotary motors. Leading experts present principles and applications ranging from atomic structure, biochemistry, and biophysics to cell biology, developmental biology and pathology - all set to become a "classic" in the years to come.

"...essential reading for graduate students in the field of cell motility and molecular motors... recommend it enthusiastically..."

European Conference on Solid-State Chemistry in Sheffield**

Timo Sörgel* and Martin Schulz-Dobrick*

The European Conference on Solid-State Chemistry rotates biennially among the major European centers for solid-state chemistry. Following Zürich, Madrid, Oslo, and Stuttgart, the community got together for the 10th meeting at the University of Sheffield, which is celebrating its centenary this year. The team around Anthony West, Derek Sinclair, and Neil Hyatt organized the conference in nine oral sessions that focused on different aspects of solid-state chemistry and one poster session of almost 140 contributions. The conference counted about 200 participants, mostly from Great Britain, Germany, Russia, France, and Spain. The scientific program was opened by Sir John Meurig Thomas (University of Cambridge, UK) with a survey of his work on catalysis. He pointed out the increasing importance of developing catalysts with shape-, size-, regio-, or enantioselectivity. One of his concepts is the immobilization of homogeneous catalysts in nanoporous silica or aluminumphosphate. He demonstrated with several examples how these additional spatial restrictions increased the already existing selectivity of a catalyst or even accessed new reaction products.[1]

[**] 10th ECSSC in Sheffield (UK), August 29–September 1, 2005.

Recently, the pioneering work of Juza in the chemistry of lithium–transition-metal nitrides has received much renewed attention, as the ternary nitrides $Li_{3-x-y}M_xN$ (M = transition metal) have been proposed as possible anode materials in lithium batteries. This aspect was elucidated in the talk given by Duncan H. Gregory (University of Nottingham, UK). Additionally, his presentation dealt with Li_3N, a well known ion-conductor. This compound undergoes reversible reactions with hydrogen and could be used as a light material for hydrogen-storage applications. Gregory's group has been able to synthesize Li_3N nanorods by a transport reaction. Due to their large surface area, they undergo a much faster reaction with hydrogen compared to the bulk material.

Antoine Maignan (CRISMAT, Caen, France) reported that a small variation in the oxygen content of $Sr_{2/3}Y_{1/3}CoO_{8/3+\delta}$ leads to a drastic change of magnetic and electric properties. For $\delta = 0.00$, the compound is an antiferromagnetic isolator, while for $\delta = 0.04$, the average oxidation state of 3.08 for cobalt leads to a semiconducting ferromagnet. This observation can be explained by the additional O^{2-} ions, which give rise to a disorder of the CoO_4 tetrahedra.

Miniaturization in the computer industry still proceeds steadily. In the sector of hard-disc technology, a data storage area density of about 100 Gb/in^2 is accessible today. Storing a bit of information requires about 100–300 grains, each having a diameter of 10–12 nm. However, this technique is limited and the search for new data-storage materials remains an important field in current research. Andrei A. Eliseev (Lomonosovoscow State University, Russia) gave an introduction to this topic. He pointed out that magnetic particles are not only required to be larger than the superparamagnetic limit but also should exhibit a sufficiently high magnetic moment in order to store the information at higher temperatures. Furthermore, it is important that neighboring domains do not influence each other. One solution could be the patterning of surfaces with highly anisotropic particles. Eliseev's approach to the fabrication of such a material consists of the growth of nanoscale iron wires by using mesoporous silica or porous alumina as a template.

Reactions between metals and gaseous nonmetal halides at temperatures above 1000 °C, for example, of Fe with $SiCl_4$ to give FeSi,[2] were the topic of the presentation by Michael Binnewies (University of Hannover, Germany). Interestingly, the shape of the starting material is preserved during the reaction and, depending on the materials, porous or dense products are formed. A potential application of this elegant transformation between solids and gases would be the production of components out of otherwise barely processable hard materials.

Yuri Grin (MPI for Chemical Physics of Solids, Dresden, Germany) presented results of a joint project between solid-state chemists and physicists which concentrates on the search for new low-temperature thermoelectrics. The focus lies on clathrate-type compounds, in which rare-earth ions are enclosed by Ga/Ge cages.

Additional lectures in the field of cluster compounds were given by Jürgen Köhler and Martin Jansen (both MPI for Solid State Research, Stuttgart, Germany). Köhler reported on the class of low-valent platinum indium fluorides, which contain, as in the case of $Pt_2In_{14}Ga_3O_8F_{15}$, low-valent In^+ ions as well as $[PtIn_6]^{10+}$ cluster ions.[3] The new silver cluster compound $Ag_{13}OsO_6$ was introduced by M. Jansen. The crystal structure can be described by a CsCl-type arrangement of $[Ag_{13}]^{4+}$ icosahedra and OsO_6^{4-} octahedra. The icosahedra are linked along their twofold axis with alternating 90° rotations. Thus, a three-dimensional network of subvalent silver with the average oxidation state 13/4 is formed. The composition of cluster units can be recognized by using atomic force microscopy; indeed, surface steps of the height of an $[Ag_{13}]^{4+}$ cluster unit were observed with this method.

John E. Greedan's (McMaster University, Hamilton, Canada) extensive work on $Nd_{1-x}TiO_3$ has led to remarkable results. An almost continuous solid solution exists in the range of $0 \le x \le 1/3$. Interestingly, two metal–insulator phase transitions occur at $x = 0.1$ and $x = 0.2$, while $NdTiO_3$ and $Nd_{2/3}TiO_3$ are a Mott–Hubbard and a charge-transfer

WILEY InterScience DISCOVER SOMETHING GREAT

insulator, respectively. Introducing holes into the conduction band causes a loss of the long-range spin order. Upon reaching a critical carrier concentration, the antiferromagnetic interaction turns into a paramagnetic short-range order.

In the session on structure–property relations in the important family of perovskite oxides, Evgeny V. Antipov (Lomonosov Moscow State University, Russia) presented investigations on $PbVO_3$.[4] The structure consists of corner-sharing VO_5 pyramids, which are formed by an exceptionally large tetragonal distortion ($c/a = 1.23$). This observation can be explained by the V^{4+} ion readily adopting a quadratic-pyramidal coordination and the stereochemical activity of the Pb^{2+} lone pair, which shifts the Pb^{2+} ion from the center of the unit cell towards one of the two $[VO_2]$ sheets (Figure 1). The semiconducting properties of $PbVO_3$ can be attributed to this two-dimensional character of the structure.

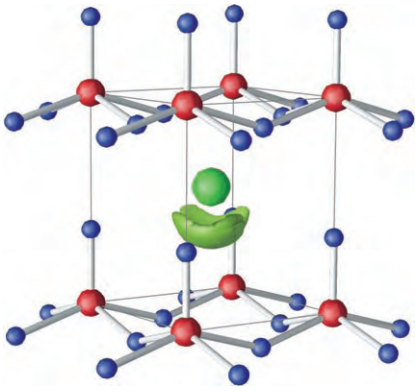

Figure 1. Visualization of the valence-ELF in the surroundings of Pb^{2+} in $PbVO_3$ ($\eta = 0.85$; Pb green, V red, O blue). The stereochemical orientation of the lone pair can clearly be seen (picture courtesy of E. V. Antipov, Moscow).

Philip Lightfoot (University of St Andrews, UK) has studied the hydrothermal synthesis of new metal fluorides and oxyfluorides with structure-directing organic ligands. The main goal is the fabrication of materials with second-harmonic generation properties in which the polarity of the building blocks is macroscopically preserved in the crystal.

The lecture by John B. Claridge (University of Liverpool, UK) pointed towards the more unusual class of transition-metal oxide hydrides. He had investigated several intermediate phases in the synthesis of $LaSrCoO_3H_{0.7}$, which exhibits antiferromagnetic order up to a temperature of 380 K. He showed that the magnetic and electronic properties strongly depend on the fraction of oxide and hydride ions.

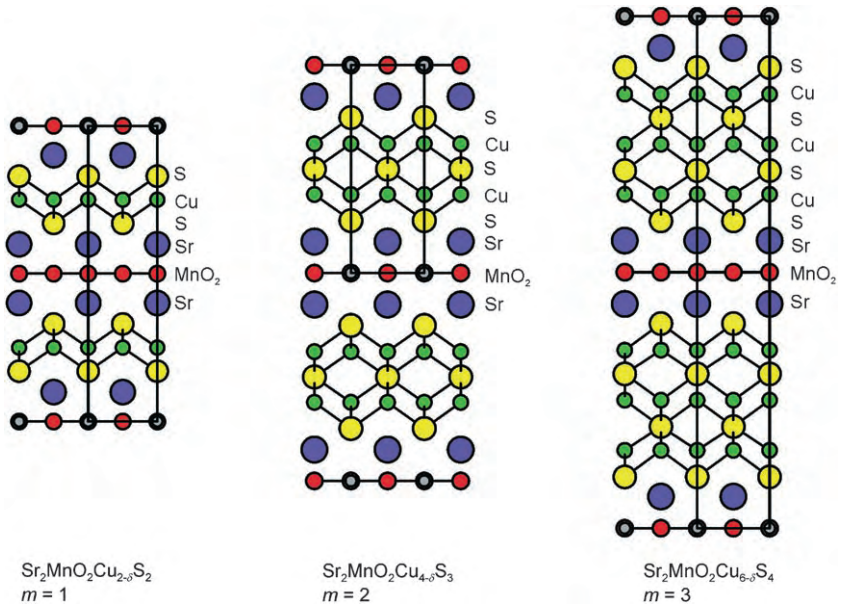

Figure 2. Homologous series $Sr_2MnO_2Cu_{2m-\delta}S_{m+1}$ with variable copper sulfide layer thicknesses ($m = 1, 2, 3$). The copper deficiency is reflected by $\delta = 0.5$ for all three compounds (picture courtesy of S. J. Clarke, Oxford).

Owing to the very different structural demands of O^{2-} and S^{2-} ions, oxysulfides often form layer-type structures, which consist of structure fragments formed by the respective oxide and sulfide. Simon J. Clarke (University of Oxford, UK) showed that the copper sulfide layer in the series of compounds $Sr_2MnO_2Cu_{2m-\delta}S_{m+1}$ ($m = 1, 2, 3$) can be varied in thickness (Figure 2). The copper position is not fully occupied, and the Cu–S distances in the CuS_4 tetrahedra are elongated as a response to the rigid Sr_2MnO_2 layers. Due to the copper deficiency, manganese is in a mixed-valent state with oxidation states of II and III which leads to interesting magnetic properties. The compounds are antiferromagnetic, while the spins on the Mn^{III} ions of consecutive layers order ferromagnetically in relatively low magnetic fields. The required field strength decreases with increasing values of m.

Welf Bronger (RWTH Aachen, Germany) outlined a comparison of atomic volume increments that were specified classically according to W. Biltz with those based on quantum chemistry according to R. F. W. Bader or the ELF (electron-localization function) method. The change in the volume of the highly polarizable hydride ion can be followed from ionic to metallic hydrides on the basis of all three concepts.[5]

Transparent, conducting main-group-metal oxides are found in many applications, such as flat-panel displays, energy-efficient window coatings, photovoltaics, and light-emitting diodes (LEDs). As not all required properties are combined in one single material, the search for new transparent conducting oxides and a fundamental understanding of their properties are of great current interest. According to Patrick M. Woodward (Ohio State University, Columbus, USA), the crucial point in such compounds is the presence of a low-lying dispersive conduction band, which is well separated from other conduction bands. Furthermore, it must be possible to dope the respective oxide to introduce charge carriers in the conduction band without essentially affecting the charge-carrier mobility. A structural feature of many of these oxides are edge-sharing octahedra in addition to a large covalent cation–anion interaction. Woodward reported that the desired

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

physical properties are mostly due to the highly symmetric environment of oxygen.[6]

The progressing miniaturization in the field of GHz telecommunication applications has increased the demands for dielectric ceramics. Besides a high relative permeability, a high Q value and an almost temperature-independent resonance frequency are the most important criteria. Robert Freer (University of Manchester, UK) reported on such dielectric ceramics. In different systems, he has investigated how the dielectric properties depend on the applied processing conditions and thus the grain sizes, twinning, and the presence of surface phases and point defects. Understanding these correlations plays an important role in the search for improved materials.

The social highlight was the conference dinner in the richly decorated Cutlers' Hall, built in 1832, during which host Anthony R. West thanked his organizing committee and announced that the 11th ECSSC will take place in the French city of Caen. During the conference it became clear, that solid-state chemistry is a constantly developing and fascinating field of research, where the interplay of chemistry, materials science, and physics—in experiment and theory—gains an increasingly important role.

The right choice of materials is essential for satisfying the consumers and customers needs.

"Materials Science and Technology" is forming the basis for modern research in the interdisciplinary field of materials science. It encompasses all different classes of materials - metals, alloys, ceramics, composites, semiconductors and polymers – and is essential for anyone involved in production and development of new products in modern industry.

This softcover edition offers the wealth of information of the renowned series "Materials Science and Technology" in one complete set of eleven volumes.

Gene Synthesis on Microchips**

*Joachim W. Engels**

Keywords:
chemical biology · hybridization · microchips · oligonucleotides · polymerase chain reaction

With gene synthesis we will in future be able to synthesize complete genomes. From there, we will be able to answer essential biological questions, for example, how chemical reactions proceed within a cell. The first step, genome sequencing, especially of the human genome, has created a huge amount of data. It is currently estimated that humans have about 25000 genes. Chemically speaking, genes are merely defined sequences of long DNA stretches. In the last 40 years, methods for the chemical synthesis of DNA have improved drastically.[1–3] These processes are based on the stepwise coupling of individual nucleotide building blocks to yield oligonucleotides. These in turn, arrange themselves into double-stranded DNA owing to their base complementarity. Hydrogen bonding followed by chemical or chemoenzymatic ligation of the phosphoric esters results in the stable duplexes. By exploiting this principle, Khorana and co-workers were able to synthesize the first gene in 1970, the yeast $tRNA^{Ala}$ gene.[3] Since then, synthetic methods have been refined, most noteworthy by the application of the polymerase chain reaction (PCR), and the goals have become more ambitious.[4–6] The subsequent years witnessed the syntheses of the following genes: α-interferon (1985),[7] the interleukin-2 receptor α (1987),[8] and a plasmid (1990).[9] The year 2002 saw the synthesis of a polio virus DNA[10] with around 7500 base pairs. Its biological activity was proven by its infectivity. The synthesis of the bacteriophage ΦX174 with 5386 base pairs was reported in 2003;[11a] this molecule was first sequenced by Fred Sanger with the newly developed dideoxy sequencing method.[11b] The longest recorded gene

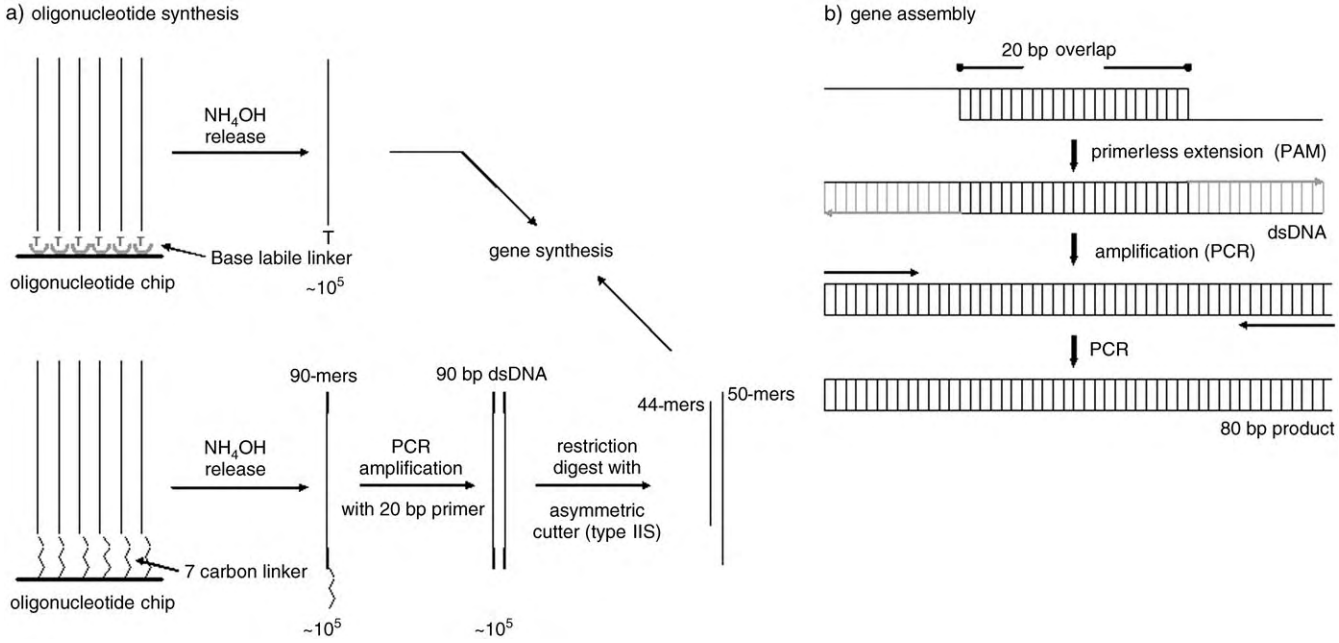

Figure 2. Oligonucleotide und gene assembly synthesis. a) On-chip oligonucleotide (50-mer) synthesis with and without PCR amplification and cleavage of the primer. b) Polymerase-assisted synthesis of genes, fill-in reaction (primerless extension), and PCR of two 50-mer oligonucleotides.

synthesized to date is the 32 000 base pair polyketide synthase gene cluster (2004).[12] This gene was also biologically active and yielded 6-deoxyerythronolide after transformation in *E. coli*.

Combinatorial or parallel syntheses yield a variety of chemical structures, whose functions can be analyzed through appropriate assays. Genes on the megabase scale (e.g. human DNA) can, in principle, be synthesized chemically or chemoenzymatically. Oligonucleotides in the range of 20 to 100 mers are now commercially available for about 0.10 euro per nucleotide and have error rates of around 1:100 to 1:400. These errors are mainly due to problems that occur during the chemical synthesis, such as incomplete reactions during coupling and deprotection and side reactions caused by the reagents used (e.g. Michael addition of acrylonitrile to thymine). High-throughput gene synthesis is limited by economic factors and error rates; cloning and sequencing raise the price about tenfold.

Consequently, parallel syntheses on microchips were introduced to reduce the costs. The yield of the oligonucleotides turned out to be problematically low (atto- and femtomolar range). These 10^5–10^9 molecules must then be amplified by PCR to 10^9–10^{12} molecules.[13] Gao, Church, and co-workers have recently showed[14] how approximately 4000 oligonucleotides can be synthesized simultaneously on light programmable microarrays (Figures 1a and b).[15–17] Photolabile protecting groups or photoliberated protons and the dimethoxytrityl (DMTr) protecting group allow on-chip synthesis according to the phosphoramidite method of Caruthers and Beaucage.[1] As mentioned above, errors appear during the chemical synthesis on chip and hence Gao, Church, and co-workers chose stringent hybridization as a cheap means of quality control, utilizing so-called quality assessment chips synthesized with the complementary oligonucleotides. Error-containing oligonucleotides, for example, oligonucleotides with the incorporation of wrong bases (point mutations) were purified by affinity chromatography on immobilized short complementary oligonucleotides. In this step it is important to synchronize the melting points (T_m values) isothermally by choosing oligonucleotides of different lengths.

An important point in gene design is the selection of the restriction enzymes to be used. Restriction enzymes of the type IIS were chosen which cut the DNA outside the recognition sequence and thus liberate internal sequences at will—in this case gene sequences (Figure 2). The authors used the enzymes BsaI with the recognition sequence 5′-GGTCTC(1/5) and a four-base 5′-overlap and BseRI with the recognition sequence 5′-GAGGAG(10/8) and a two-base 3′-overlap of undefined sequence. In addition to the gene sequences, selection oligonucleotides immobilized on streptavidin beads through a biotin linker (Figure 3) were used for separation. Only the unmodified, error-free oligonucleotides (in this case 50-mers) were selected! The exactly fitting oligonucleotides were filtered out in two steps with the help of 25-mer complementary oligonucleotides R and L (so-called capture probes). Following this purification by selection, the gene-assembly experiment is developed on microtiter plates (e.g. 96 or 384 wells) by the polymerase assembly multiplexing (PAM) reaction. In this case the dsDNA, which is held together by hydrogen-bonding interactions, is assembled into a gene by the action of polymerases, without a primer. The quality of the oligonucleotides used for gene synthesis was tested in three different formats: 1) unpurified (as synthesized), 2) purified by gel electrophoresis, and 3) purified through hybridization on affinity beads.[18] The latter method showed the lowest error rate (1:1394 bp), which is an improvement

(roughly by a factor of 10) over the assembly by chemical synthesis on a polymer support followed by enzymatic ligation.

As an example for the application of this method in synthetic biology, Gao, Church, and co-workers[14] synthesized codon-varied genes for 21 proteins of the small 30S ribosome subunit of *E. coli*.[19] It is known that the expression rate of these 21 proteins in vitro is low and it was hoped that the translation efficiency would be increased by choosing the appropriate codons. Secondary structures of the mRNA have been discussed as the cause of low synthetic efficiency. It was hoped that the formation of these secondary structures could be limited by decreasing the G/C content of the DNA. Thus, 50-mer oligonucleotides were chosen with PCR primer binding sites on both ends, yielding 70-mers. The experiment shows the result of a successful PAM assembly strategy, which was checked by means of a computer program to be unequivocal for finding the right oligonucleotide partner by hybridization. All 21 genes, their transcribed RNA, and the resulting proteins were successfully detected on gel. Finally, a complete operon of 14.6 kb for all 21 genes was assembled (Figure 4). The error rate for the oligonucleotides was estimated to be 1:7300 bp! This clearly proves that the error rate of synthetic oligonucleotides is the limiting step in chemoenzymatic gene synthesis and not the precision of the polymerases, which have an error rate of about 1:100000 bp.

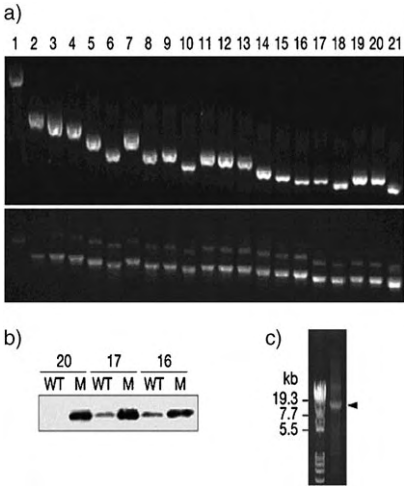

Figure 4. Gene constructs and their transcriptional (mRNA) and translational products (proteins) on polyacrylamide gels. a) Synthetic genes of 21 ribosomal proteins (upper gel) and their RNA transcribed in vitro (lower gel). b) Western blot of the selected translated genes of ribosomal proteins 16, 17, and 20 (WT = wild-type, M = synthetic variant). c) Final assembly of the 14.6-kb operon for all 21 ribosomal proteins. Reproduced from reference [14] with permission of Nature Publishing.

This experiment clearly demonstrates the potential of on-chip oligonucleotide synthesis. Given the present capacity of microchips, large-scale gene-synthesis experiments are possible. A rough calculation indicates the possibility of lowering the costs for gene synthesis from 10 bp per euro to 20 kbp per euro. This is possible by using, for example, microchips from NimbleGen (www.nimblegen.com) with an oligonucleotide density of 95000–382000, to give a final sum of 2–18 Mbp DNA.

In an effort to reduce the error rate for the synthetic gene even further, a correction of the assembled oligonucleotides or gene fragments by a protein from the DNA-repair machinery (e.g. mutS) is being pursued.[20] Thus, Jacobson and co-workers corrected a synthetic DNA with the fixed mismatch binding protein mutS from *Thermus aquaticus*. They eliminated mismatch products and obtained DNA with an error rate of around 1:10000. Another alternative to obtain completely error-free DNA is a cheap high-throughput-sequencing method in which thousands of sequences can be read simultaneously.[21]

In summary, the methods and procedures for the synthesis of genes were mostly known, but they have now been combined in a new way to allow more-efficient and economic access to error-free genes in the 10-kb range. The individual steps include (estimated times in brackets):[14]

a) Design and modeling of the appropriate oligonucleotide building blocks for the gene synthesis (2 h).
b) Oligonucleotide synthesis in microfluidic devices (8 h).
c) Amplification of the synthetic, on-chip oligonucleotides by PCR (14 h).
d) Cutting the amplified oligonucleotides by type IIS restriction enzymes to the appropriate size (50-mers).
e) Selection of the correct sequences through hybridization (30 h).
f) Assembly of the final gene by polymerase fill-in followed by PCR (4 h).
g) In vitro transcription/translation and detection of mRNAs and proteins (1 h).

As potential application one can envisage the synthesis of gene clusters for natural products such as polyketides or the resynthesis of bacterial cell genomes(e.g. mycoplasma). Thus gene synthesis will be a way to evolve new secondary metabolites such as polyketides or peptide antibiotics to obtain non-natural isomers of natural products. Gene synthesis is key to functional

genomics and will result in the assignment of all chemical reactions within a cell. The ultimate goal of biological synthesis will be to find new arrangements of genes from a gene pool and hence to search for new solutions for new products.

Toward the Systematic Decomposition of Benzene

*Paul G. Wenthold**

Keywords:
benzene · bond energy · dissociation · radicals · reactive intermediates

Open-shell organic molecules have been the subject of considerable interest ever since the first report of the triphenylmethyl radical over 100 years ago by Gomberg.[1] In the intervening century, the study of organic radicals has advanced from the controversial isolation of a stable, trivalent carbon molecule to the generation of polymeric polyradicals with 10000 unpaired electrons,[2] with many variations in between. The properties of radicals that have been considered include their thermochemical stability, molecular structure, spectroscopic characteristics, chemical reactivity, and electronic structure, such as spin density and magnetic properties.

The concept of bond dissociation underlies many of the features of organic radicals. In principle, hypovalent organic systems can be considered to arise from a bond-dissociation process. Radicals, for example, are formed by homolytic bond dissociation of closed-shell precursors. Breaking a second bond in the precursor (or breaking a bond in the radical) leads to the formation of didehydro systems, such as carbenes and diradicals. Triradicals result from breaking bonds in diradicals and dissociate to give tetraradicals, and thus the process continues.

However, a discussion of radicals in the context of bond dissociation does more than provide an idealized genesis for their formation, it also provides a basis for understanding many of their unusual characteristics. Because bond dissociation is an energetically costly process, radicals are generally high energy species and, consequently, will undergo transformations normally considered to be disfavored if the energy benefit is greater than the cost. The enhanced reactivity of hypovalent systems reflects the positive effect of stabilizing the open-shell wave function through bond formation in an addition reaction or by atom abstraction to form a more stable radical.

In molecules with more than one unpaired electron, electron–electron interactions can have a significant role in the stabilization of the system. Bond formation that results from direct orbital overlap is highly favorable and, thus, is an overriding consideration in all low-spin polyradicals, even to the extent that the system is better described as being a strained, closed-shell state as opposed to a polyradical. In cases in which bonding cannot occur, indirect interactions that are usually insignificant, such as electron exchange and spin polarization, can have significant impact.

Significant attention has been paid to the determination of thermochemical properties because of the important role that bond-dissociation energies (BDEs) play in providing a fundamental understanding of structure and reactivity. Not only do thermochemical properties help to evaluate the stability of the reactive species, but variations in BDEs provides a means to investigate the effects of their origins. In this way, it is possible to assess the influence of the geometric distortions and electronic interactions that occur in the reactants and products.

A commonly used systematic approach to the investigation of BDEs and how they are affected by structure involves measuring the energetics for the sequential decomposition of an organic molecule.[3,4] In 1990, Ellison and co-workers reported the energetics for the dissociation of ethylene into component atoms (Figure 1).[5] They were able to describe the energetics for the dissociation of ethylene by all possible pathways by measuring the thermochemical properties of the intermediates, including vinyl and acetylenic radicals and vinylidene. Similar schemes can be constructed for other simple systems, such as formaldehyde, and some larger systems, such as ketene, are also nearly completely known.[4]

The decomposition of a much larger molecule, such as benzene, becomes a much more complicated process, with many possible pathways available. However, studies of reactive molecules derived from benzene have led to insight into the initial steps that result from breaking C–H bonds. The phenyl radical, generated by breaking the first C–H bond, is well characterized spectroscopically[6] and thermochemically.[7] *Ortho*, *meta*, and *para* benzynes **1**-*o*,*m*,*p* (Scheme 1), which are generated by breaking a second bond in benzene, are also very well known. The thermochemical properties of the singlet and triplet states have been determined,[8,9] and IR spectroscopy has been carried out for the *ortho*[10] and *meta* isomers.[11] The structure of *o*-benzyne has even been investigated by using NMR spectroscopic analysis.[12] Thus, only the *para*-isomer **1**-*p* awaits detailed spectroscopic characterization, although limited spectroscopic data are available.[9]

Recent investigations[13–15] have focused on the properties of the dehydrobenzynes, which are triradicals formed by dissociation of a third bond in benzene. As indicated in Scheme 1, there are many different C–H bonds in the benzynes that can be broken, but there are only three dehydrobenzynes

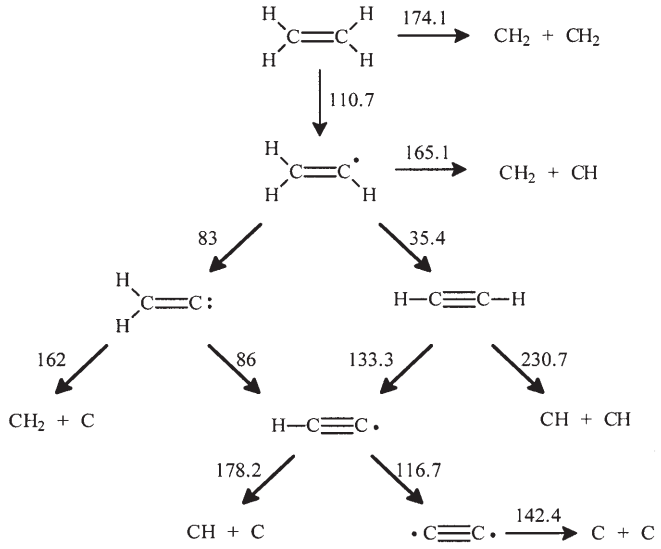

Figure 1. Bond-dissociation energies (kcal mol^{-1}) for the decomposition of ethylene.[5] Hydrogen-atom fragments have been omitted for simplicity.

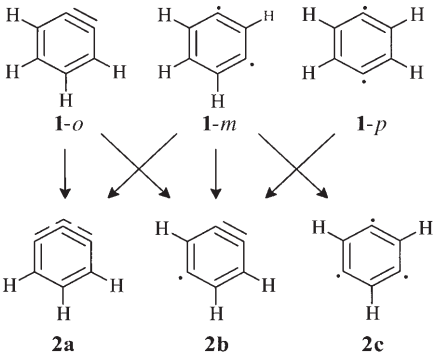
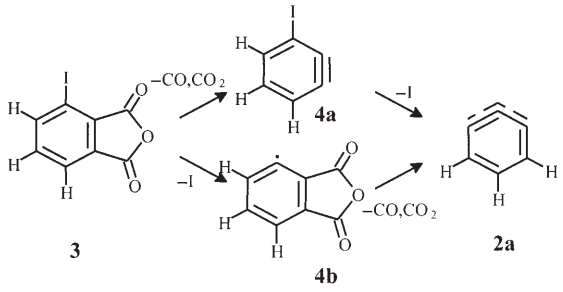


Scheme 1.

that can be formed. The first experimental study of a dehydrobenzyne was a determination of the heat of formation of the 1,3,5-tridehydrobenzene isomer **2c** by Lardin et al.[13] The measured heat of formation of **2c** reflects a BDE of 109.2 ± 5.6 kcal mol^{-1} at the 5-position of *m*-benzyne [Eq. (1)].

The similarity between the BDE in *m*-benzyne and that in benzene (112.9 ± 0.5 kcal mol^{-1})[7] indicates little interaction between the newly formed radical center and the *m*-benzyne moiety. This was explained by consideration of the electronic structure of the triradical formed. A molecular-orbital energy diagram for D_{3h}-symmetric **2c** is shown in Figure 2. In the high-symmetry structure, the system consists of one electron in a degenerate pair of e′ orbitals and, therefore, undergoes a Jahn–Teller distortion to a lower symmetry C_{2v} structure. Whereas two distortions are possible, electronic-structure calculations predict that the lower energy state is the $^2A_1$ state, in which the unpaired electron is in an orbital with an antibonding interaction with the bonding molecular orbital of the *m*-benzyne. Therefore, there is little interaction between the unpaired electron and the *m*-benzyne moiety.

Sander and co-workers[14] reported recently the formation of 1,2,3-tridehydrobenzene **2a** in a neon matrix. Their approach to the generation of the triradical involves photodissociation of 3-iodophthalic anhydride [**3**, Eq. (2)].



The results provide insight into the mechanism for the formation of **2a**. For example, other products formed upon the photodissociation of **3** in a neon matrix [Eq. (2)] include 3-iodobenzyne (**4a**) and the phthalic anhydride radical **4b**. However, **4a** prepared independently from 1,2,3-triiodobenzene in an argon matrix does not produce the 1,2,3-triradical, thus suggesting that 3-dehydro-*o*-benzyne is formed from **4b**, although matrix effects cannot be ruled out.

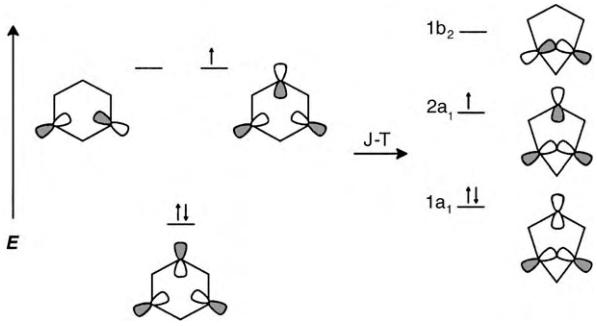


Figure 2. Orbital-energy diagram for **2c**. The orbitals on the left are for D_{3h} symmetry, and the orbitals on the right are for the C_{2v} state that results from Jahn–Teller distortion.

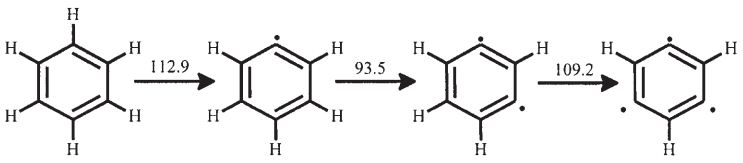

(1)

An important and surprising conclusion of the IR spectroscopic study[14] of **2a** is that the triradical has a $^2A_1$ ground state, as opposed to the $^2B_2$ state predicted in a recent computational study by Cristian et al.[15] The

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

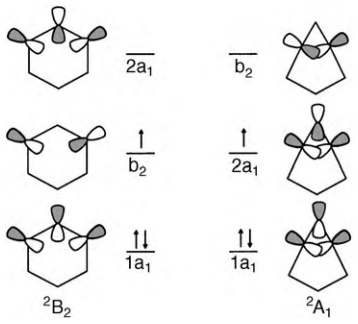

Figure 3. Electronic structures of the $^2B_2$ and $^2A_1$ states of 1,2,3-tridehydrobenzene.

difference between the states can be seen by consideration of the nonbonding molecular orbitals in Figure 3. The properties of the nonbonding molecular orbitals in **2a** are reminiscent of those in the allyl radical, with bonding ($1a_1$), nonbonding (b_2), and antibonding ($2a_1$) orbitals. Initial considerations suggest an electronic structure that consists of two electrons in the bonding orbital and single occupation of the nonbonding orbital (calculations indicate little multiconfigurational character),[14,15] similar to the allyl radical, thus creating the $^2B_2$ state. Consequently, one might expect this state to benefit from "allylic stabilization", which results from delocalization of the unpaired electron. However, whereas Cristian et al.[15] concluded that $^2B_2$ is the ground state of the system, they did not find it to be especially stable and calculated little energy difference for the three isomers of **2**.

The IR spectroscopic data reported by Sander and co-workers indicate the presence of the $^2A_1$ state.[14] In this state, the unpaired electron occupies the "antibonding" molecular orbital $2a_1$. However, the characterization of the $2a_1$ orbital as antibonding is misleading. Unlike in the allyl radical, there is a significant interaction between the terminal carbon atoms in the triradical **2a**. Thus, as shown by Sander et al.,[14] there is a significant energy dependence on the distance between the dehydrocarbons in both electronic states. The $^2B_2$ state, with the unpaired electron in a b_2 orbital that has an antibonding relationship between the dehydrocarbons, is favored at longer C–C lengths, whereas the $^2A_1$ state, with the unpaired electron in the orbital that is involved in the bonding interaction between the dehydrocarbons, prefers a short C–C length. Restricted open-shell coupled-cluster calculations reported by Sander and co-workers predict that the $^2A_1$ state has the absolute lowest energy, with a C–C bond length of 1.69 Å. Therefore, the bonding interaction in **2a** is even stronger than that in *m*-benzyne or **2c**, in which the distances between the carbon atoms are approximately 2 Å.[15,16]

Given the $^2A_1$ ground state of 1,2,3-tridehydrobenzene, the view of a triradical stabilized by a σ-allylic interaction must be refined. Instead of viewing the system as an allylic-like radical in which the electrons are delocalized through resonance, the stabilization results from delocalization of the radical through direct overlap of orbitals. At the very least, the system can be described as a *m*-benzyne compound that lacks a hydrogen atom. However, given the additional bonding interactions between the dehydrocarbons, the localized picture of bicyclic radical **5** is not unreasonable and may actually be a more accurate depiction of the interactions that are present.

5

Whereas modern theoretical methods can provide detailed descriptions of geometries and electronic structures, experimental results alone still reveal the important qualities of the bonding in a system. However, detailed experimental studies become much more challenging as the systems become more reactive. How much dissociation can occur and still produce a stable species? Remarkably, Graham and co-workers have reported the generation and isolation of the cyclic C_6 unit—benzene without hydrogen atoms.[17] Thus, it is apparently possible to strip benzene down to its simplest fragments. Undoubtedly, the exploration of the pathways that can be used to realize this species, and the intermediates accessed along the way, will continue.

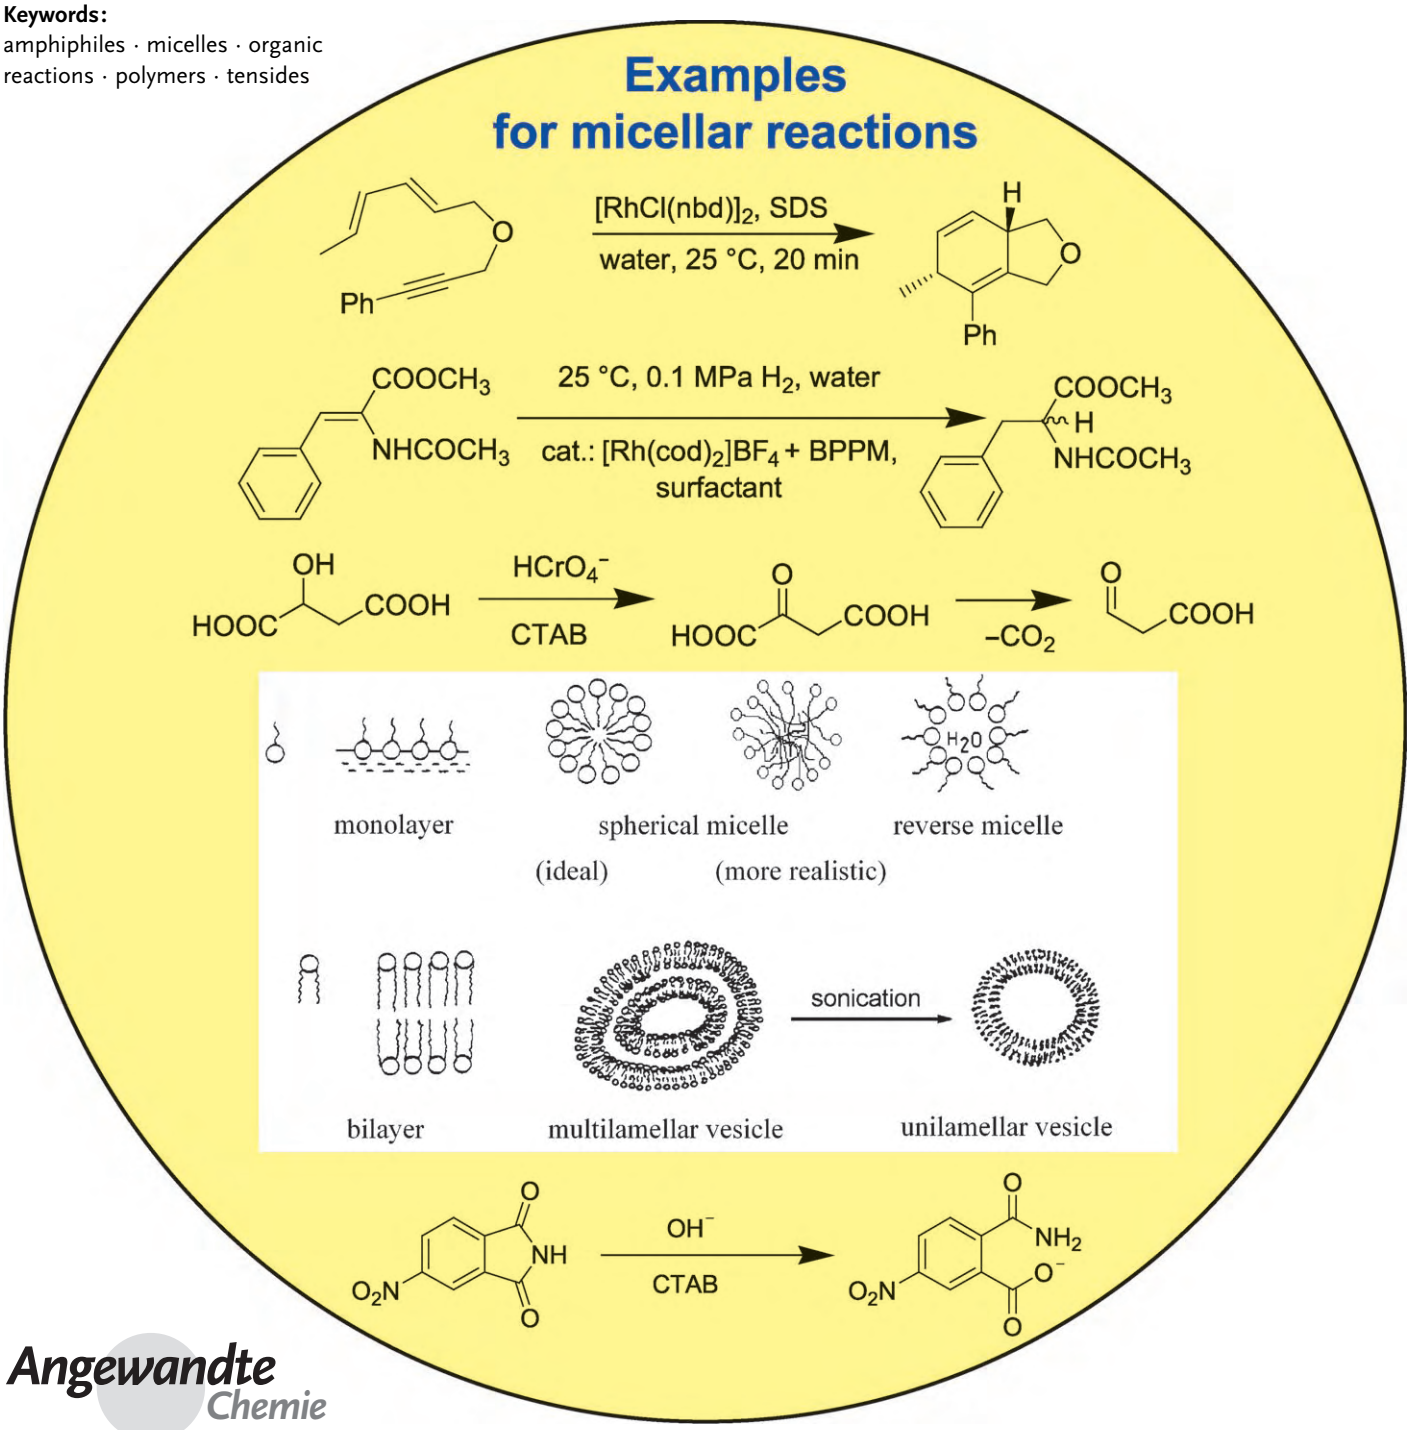
Micelles

Reactions in Micellar Systems

*Torsten Dwars, Eckhard Paetzold, and Günther Oehme**

Keywords:
amphiphiles · micelles · organic reactions · polymers · tensides



© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The notion of "green chemistry" has encouraged even synthetic organic chemists to include water as a solvent. Incredible selectivities and activities can be achieved through the addition of amphiphiles with a defined structure. The morphology of supramolecular assemblies or associates formed by surfactants vary according to the temperature and concentration. As a rule, reactions are typically conducted using simple spherical aggregates, that is, micelles in the nanometer range. The strong polarity gradient present between the hydrophilic surface and the hydrophobic core of the micelle means that both nonpolar and polar reagents can be solubilized. This solubilization results in reactants becoming more concentrated within the micelle than in the surrounding water phase and leads to an acceleration of the reaction and causes selective effects. The kinetic treatment of reactions in micellar systems can be accomplished by considering them as microheterogeneous two-phase systems.

1. Introduction and Overview

This Review deals with chemical reactions which take place in the presence of amphiphilic (synonym: amphipathic) compounds and are decisively affected by them under certain conditions.[1] Amphiphiles are molecules consisting of a hydrophilic head group and a hydrophobic (lipophilic) tail, and are thus able to interact with both polar and nonpolar compounds. When the hydrophobic tail reaches a certain chain length, the amphiphiles reduce the unusually high surface tension of water and are referred to as tensides (or surfactants).[2] Very practical effects are associated with this property, for example, the "detergent effect", the stabilization of emulsions and foams, and the application as an aid for dispersions. In this context we speak of detergents. These effects are caused by associates of surfactants whose form is dependent on the temperature, concentration, and molecular structure.[3] Since cohesion occurs through noncovalent forces, we speak of supramolecules or supramolecular structures.[4]

Micelles are especially simple spherical supramolecules, which are formed by amphiphiles in water or media similar to water. A micellar system appears to be homogeneous since these aggregates are of colloidal size; however, in reality the absorbed reactants are in a microheterogeneous two-phase system.[5] Micelles can cause an acceleration or inhibition of a given chemical reaction relative to the equivalent reaction in an aqueous medium. This phenomenon was recognized relatively early on and was investigated extensively, as reflected in early review articles and a monograph published in 1975.[6]

In general, the micellar effect is referred to as "micellar catalysis" when it refers to the acceleration of the rate of a reaction; this assignment is however only an approximation for a kinetic analysis.[7] It is interesting that micellar catalysis is described together with the catalysis of functionalized polymers or macromolecules in most of the older review articles. A connection with enzymatic catalysis was sought as hydrophilic and hydrophobic regions exist in both supramolecular and macromolecular structures.[8]

It is now virtually impossible to cover the entire area of catalysis in micellar systems in one review article. Work from the last 20 years in which transition metals play a catalytic role will be predominately reviewed in this article.[9] Important trends and developments will also be highlighted, and older work of fundamental importance will, however, also be included in the discussion.

2. Micelles and Related Aggregates

Some typical micelle-forming amphiphiles together with their critical micelle concentrations (CMCs) are shown in Table 1. The CMC is the lowest concentration at which spherical micelles form. The formation of micelles is characterized by an often sharp discontinuity in system properties, such as surface tension, conductivity, light scattering, self-diffusion, and the molality of dissolved compounds.[10] A prerequisite however is sufficient solubility of the amphiphile in water, the medium in which the micelles are formed. The temperature at which the concentration of the amphiphile reaches the CMC is defined as the Krafft point or Krafft

	1.2×10^{-3}
	7.7×10^{-5}
	4.7×10^{-10}

temperature, and is generally associated with a sudden increase in solubility.[11]

The amphiphiles shown in Table 1 all possess a long alkyl chain, which is an important precondition for the formation of micelles. The hydrophilic head group can be cationic (tetraalkylammonium, alkyl pyridinium), anionic (alkyl sulfate, alkyl sulfonate), zwitterionic (trialkylammoniopropanesulfonate), or non-ionic (polyoxyethylenealkyl ether, alkyl glycoside). The relationship between the hydrophilic head group and the hydrophobic chain is given by the hydrophilic–lipophilic balance (HLB), which is generally calculated by increments.[12] The hydrophobic chain must have a certain length ($>C_{10}$) to enable successful micelle formation. The CMC generally drops as the chain length increases.

Amphiphiles with short alkyl chains (for example, tetrabutylammonium halides, sodium butyl sulfate) do not form micelles, but they do influence the hydrogen-bonding structure of water and are termed hydrotropes. Hydrotropes can also form associates, but these have a much smaller size than micelles.[13] An aggregation of approximately 50 monomers is typical for micelles. Perfluorinated alkyl chains represent a special type of amphiphile, which are especially hydrophobic and form micelles even with short chain lengths ($>C_8$).[14] Spherical micelles only exist in relatively dilute dispersions. The formation of "rodlike" structures occurs relatively quickly with increasing concentration, and this is then followed by hexagonal phases.[15] Some principle morphologic structures are shown in Figure 1.

A characteristic of amphiphiles with *one* long alkyl chain is that they initially form a unimolecular layer on the surface

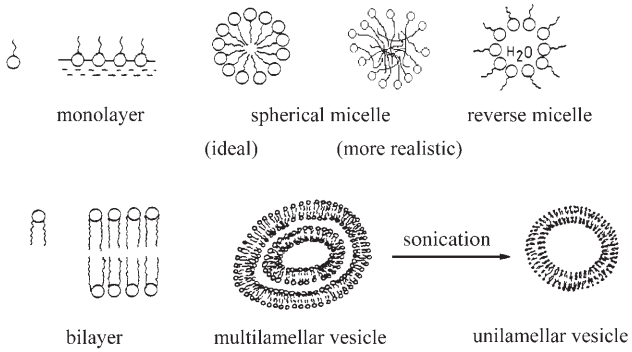

Figure 1. Schematic representation of micelles and vesicles.

of the water, that is, at the interface between water and air, through which the surface tension of the water is reduced. Micelles only form spherical aggregates upon reaching the CMC. As is to be expected, the hydrophilic head groups form the phase barrier to the water, while the hydrophobic alkyl chains orientate themselves inwards and form the core of the micelle. A frequently used representation in which the chains are arranged coaxially towards the centre of the micelle is not realistic, since this is not compatible with the geometry of the amphiphile as a whole. A more probable representation, reported by Menger,[16] is where an irregular arrangement of the chain occurs, which in principle also allows an orientation of the polarity gradient from the hydrophilic region towards the center (Figure 1).

The counterion must also be taken into account in the case of ionic surfactants. Depending on the charge density and hydrophilicity, the counterion is to be found in the immediate proximity of the micellar surface, in the so-called "Stern layer". As a rule 70–90 % of the ion pairs are located on the surface of the micelle.[17] Dissociated counterions can advance to the nearest Guy–Chapman layer. The interactions between the micelles and the counterions have been thoroughly investigated. The strongly electronegative and hydrated fluoride and hydroxide ions assume a special status as they

Torsten Dwars completed his degree in teaching mathematics and chemistry in secondary schools in 1995. He studied for his PhD between 1995 and 1999 in the research group of G. Oehme at the Institute of Organic Catalysis Research in Rostock. After spending four months in the "technical chemistry" research group of Prof. Kragl (University of Rostock), he has worked as a scientific researcher at the Institute of Organic Catalysis Research in the field of plasma polymerization of amphiphilic aggregates in aqueous media.

Eckhard Paetzold studied chemistry at the Ernst–Moritz–Arndt University of Greifswald, Germany, and obtained his PhD in 1983 under the supervision of Horst Pracejus in the former working group Complex catalysis of the Academy of Science of the GDR in Rostock. Since then he has worked as a scientific researcher at the Leibniz Institute of Organic Catalysis Research. His interests focus on C–C coupling in aqueous (micellar) phases and more recently the modification of renewable resources.

remain in the aqueous phase. The structure and character of micelles can be influenced by exchange equilibria resulting from the addition of salts to the aqueous phase that contain ions different to those of the surfactant.

The extraordinary variety of phase behavior of amphiphiles can be found in other review articles.[18] An original proposal is contained in a monograph by Fuhrhop and Köning, in which the term "synkinone" is suggested for associative amphiphiles and the term "synkinese" is suggested for the aggregation process.[19]

Aggregations of surfactants with two long alkyl chains per head group are also shown in Figure 1. These amphiphiles form bilayers in water which unite at a given concentration to form multilamellar or unilamellar vesicles. These are bubble-like structures in which a water-containing interior is enclosed by a double-layer membrane. Such double-layer membranes are models of naturally occurring membranes in which the building blocks are lipids, and can be relatively complex structures.[20] Vesicles formed from lipids are called "liposomes".[21] The literature about the formation, structure, and application of vesicles is very extensive.[22] Knowledge about the structural requirements for the formation of vesicles has been extended considerably, especially through the introduction of so-called "bolaamphiphiles" which are alkyl chains with a head group at each end.[23] Despite their great significance for the simulation of natural processes, we will only occasionally draw comparisons to reactions in vesicles within the scope of this article. Micelles and vesicles differ not only in their structure but also in their size; while the diameter of a micelle is 3–7 nm, multilamellar vesicles have a size in the range of about 1000 nm and unilamellar vesicles in the range of about 25 nm.[24]

The formation and morphology of amphiphile aggregates in water are dependent on the balance of two opposing forces: the hydrophobic interaction between the alkyl chains and the polar repulsion between the head groups.[25] The attraction of the alkyl chains is a mainly entropic effect. Water displays a high degree of order along the alkyl chains, because more hydrogen bonds exist to neighboring water molecules than are formed in the bulk water phase. The loss of entropy is cancelled ("hydrophobic effect") through the assembly of the alkyl chains.[26] Little is known about the dispersive forces between nonbinding alkyl groups.[27] An attempt at analysis can be found in studies by Blokzijl and Engberts,[28] Evans,[29] as well as Ruelle and Kesselring.[30] The free enthalpy of formation is almost constant over a large temperature range, which shows that enthalpy–entropy compensation occurs. Associates of amphiphiles and especially micelles can be formed in solvents which have a similar polarity and hydrogen-bonding structure to water.[31]

The stability of micelles and vesicles is strongly dependent on the mobility of the alkyl chains, as shown by experiments with spirotensides and spirophospholipids.[32] The hydrated head groups, which are aligned to the interface with water, repel each other as a result of their uniform polar structure and thereby determine the curvature of the spherical micelle (Figure 2).[33]

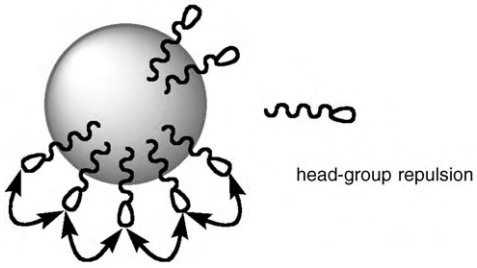

Figure 2. Principle of opposed forces during micelle formation: Repulsion between head groups and attraction between the hydrophobic chains.

The conical order of the structural units is achieved by entanglement of the alkyl chains. "Conical molecules" themselves do not exist.[19] The distance between the polar groups is larger and thus the curvature smaller in bilayers of vesicles formed from amphiphiles with two alkyl chains per head group, mainly as a consequence of compensation by polar groups on the opposite side of the bilayer.

Associates of amphiphiles are kinetically labile. Micelles are formed and decay within milliseconds, which is in general more rapid than thermally induced reactions.[34] It is thus problematic to understand the polymerization of micelles, which consist of unsaturated surfactants.[35] Vesicles containing amphiphilic bilayers are kinetically much more stable.

A wide range of new amphiphiles (surfactants) have been synthesized in recent decades to keep pace with increasing technical demands.[36] Typical aspects that have been considered include biological degradability and physiological compatibility,[37] cleavability,[38] the ability to form polymers,[39] and the photolytic formation of amphiphiles.[40] Variations were mostly incorporated into the head groups. The purity of the surfactants is often uncertain, which casts doubt on the validity of the characterization data, and extreme techniques aimed at purification have been suggested.[41]

Extensive synthetic modifications are available for vesicle-forming reagents which act as carriers for drugs and have to be recognized by certain biological targets.[42] Block copolymers of the type $(EO)_n$-$(PO)_m$-$(EO)_n$, which consist of polypropylene oxide as the hydrophobic component and polyethylene oxide as the hydrophilic component, are becoming increasingly important and are biological fairly harmless.[43] These non-ionic amphiphiles can be used for micellar

Günther Oehme studied chemistry in Köthen and Halle on the Saale and obtained his PhD with Alfred Schellenberger at the Martin-Luther University of Halle-Wittenberg in 1966. Since 1967 he has worked at the Institute of Organic Catalysis Research. He become a Professor of the Academy of Science of the GDR in 1986, and between 1987 and 1998 he was the head of the Institute in Rostock. His areas of research include asymmetric reactions in multiple-phase systems and under micellar conditions, enantiomeric analysis, photoaccelerated reactions, and C–C coupling. He received emeritus status in 2003.

reactions. In this Review, surfactants whose head group has been modified to allow them to function in a catalytic manner in a given reaction play an important role. We will discuss such "functionalized" amphiphiles individually (see Section 5).

Since both micelles and vesicles can be easily destroyed by organic solvents mixed into the water phase (lysis), the idea of stabilization through polymerization seems reasonable and would entail the transformation of a supramolecular aggregate into a macromolecule. It has been proven in numerous examples that the shape existing after polymerization is similar to that before polymerization.[44] This situation is especially true for the kinetically more stable vesicles;[45] however, encouraging results have also been obtained with micelles.[46] A further possibility is the utilization of amphiphilic polymers.[47] The systematic construction of "unimolecular" micelles (dendrimers) is synthetically time-consuming but has already yielded interesting results (see Sections 6 and 8).

3. Solubilization

Solubilization refers here to an increase in the solubility of hydrophobic compounds in water through the influence of amphiphilic molecules. We are particularly interested in solubilization in aqueous micelles, which is a prerequisite for reactions to be influenced by micelles.[48] Since a micelle possesses regions of different polarity, both polar and nonpolar reagents can be incorporated into the micelle.

This process can be described by using a pseudophase model in which water and the micelle are considered as two phases. The micelle is described in terms of the associate M of the free surfactant molecule S (Scheme 1). The additive (reactant R) can be added to this associate in a stepwise manner until the "maximum additive concentration" (MAC) of MR_m has been reached. Since the micelle as an associate is not really monodisperse, the MAC should be considered as the maximum of a Poisson distribution.[49] The MAC can rise above the CMC. The concentration of hydrophobic reactants per mole of micelle-forming surfactant increases with the chain length of the alkyl tail of the surfactant on one hand, while the MAC drops with increasing hydrophobicity of the reactant on the other hand. The CMC with non-ionic micelles of the polyoxyethylene type decreases with increasing temperature as a result of dehydration, since the surfactant becomes more hydrophobic and its solubilization capacity increases. Added salts can bring about a similar effect with ionic micelles. In this case a decrease in the CMC and an increase in micelle size occurs, since the repulsion between the head groups diminishes. A consequence of this is the expansion of the "palisade layer", the border region between the head groups and the hydrophobic chains.

$$n\,S \overset{K_n}{\rightleftharpoons} M$$

$$M + R \overset{K_1}{\rightleftharpoons} MR_1$$

$$MR_1 + R \overset{K_2}{\rightleftharpoons} MR_2$$

$$\cdots$$

$$MR_{m-1} + R \overset{K_m}{\rightleftharpoons} MR_m$$

Scheme 1. Stepwise inclusion of reactants into micelles.

The solubilizing capacity of a micelle for hydrophobic compounds can be increased by the addition of cosolvents, for example, long-chain alcohols. A microemulsion might be formed if the MAC of a component is exceeded and if a new phase comes into being. The importance of microemulsions will be covered briefly in Section 7. If the solvent effects for a given compound are known, then information about the location of the solubilized compound within the micelle can be obtained by using spectroscopic techniques. This possibility is especially true for colorants and fluorescent compounds.[50] It has been established that nonpolar compounds such as hydrocarbons are generally to be found in the hydrophobic core while semipolar and polar compounds such as alcohols, carboxylic acids, and amines are located in the palisade layer. Aromatic compounds are often found to be present in both the head-group region and the core, and can be described using equilibria.

Solubility data for gases are important for reactions with gaseous reactants. In this respect the high solubility of oxygen in fluorinated micelles is noteworthy.[51] Vesicles represent more-complex solubilizing systems than micelles since an additional water phase is present in the core, which is surrounded by a bilayer membrane and can absorb hydrophilic substances.[52] The permeability of the membrane is of great importance since vesicles (liposomes) are frequently employed as carriers of active hydrophilic substances in physiological systems. The permeability of the membrane is often increased with respect to encapsulated hydrophilic compounds by adding lipophilic compounds, through which the membranes become more fluid.[53] The encapsulation of substances in the inner water phase usually takes place during the formation of the vesicle, while solubilization of substances into the membrane from the outer water phase is possible at any time for hydrophobic or hydrophilic compounds in equilibrium. Thus, effects can be observed which are similar to those in micelles. A special role is played by vesicle membranes for separated reaction spaces, as, for example, is necessary in the simulation of photosynthesis.[54] It can also be assumed that the alkyl chains of amphiphiles in vesicle membranes are ordered in a regular fashion as in micelles, which should be advantageous for stereoselective reactions.

4. The Kinetics of Micellar Effects

Morawetz[6b] presented and discussed three typical possibilities for micellar catalysis in an earlier review:

1. A reagent is amphiphilic and forms a micelle which then changes during the reaction.
2. The interactions between reactants and the micellar surfactant influence the rate of the reaction.
3. The micelle possesses catalytically active groups and functions as a catalyst.

Almost all micellar effects can indeed be categorized into one of the above possibilities. The origin of the acceleration or inhibition of reactions in micelles will now be discussed. The feature that makes a micelle special with respect to its functioning as a micro- or nanoreactor is the proximity of extremely polar and nonpolar regions. The effect of micelles

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

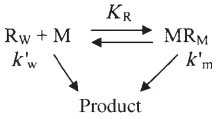
on reactions can, according to Brown et al.,[55] be ascribed to a combination of the following factors:

1. The dielectric constant in the micelle is lower than in water, which causes a solvent effect.
2. The transition state of the reaction can be stabilized by interaction with the polar head groups.
3. The reactants are concentrated relative to the surrounding water phase through interactions with the micelle surface or through insertion into the micelle itself, thus leading to an increased rate of bimolecular reactions. The acidity or basicity of ionic amphiphiles can be significantly higher on the surface of micelles than in the surrounding aqueous phase.

The concentration effect can be considered as dominant in many cases.

A kinetic treatment of micellar effects requires some approximations. From a purely formal approach, the Michaelis–Menten methods known from enzyme chemistry can be recognized, and many authors attempt to discern a type of enzyme mimetic. The effects observed in micelles are in general much smaller than for enzymes with respect to both the increase in reaction rate as well as the influence on reaction selectivity.

Kinetic considerations are most frequently based on the so-called pseudophase model,[56] in which the aqueous medium and the micelle are viewed as separated phases with which the substrate is in thermodynamic equilibrium [Eq. (1)]. R_W and R_M designate a reactant in the aqueous and



(1)

the micellar phase, respectively, M is the surfactant bound in the micelle, K_R is the equilibrium constant of the reactants between the aqueous and the micellar phases, and k'_w and k'_m are the first-order rate constants, which come from the aqueous and micellar phases and lead to product. According to the law of mass action, Equation (2) is valid for the

$$K_R = \frac{[M R_M]}{[R_M][M]} \quad (2)$$

equilibrium constant K_R. For the surfactant bound to the micelle: $[M] = [T_{total}] - CMC$. The observed rate constant can be described mathematically as Equation (3), a derivation of the Michaelis–Menten equation.

$$k_{obs.} = \frac{k'_w + k'_m K_R [M]}{1 + K_R [M]} \quad (3)$$

Kinetic measurements are usually conducted at low concentrations (ca. 10^{-4} M) to ensure the existence of only a single type of surfactant aggregate, so that the reactant does not alter the structure of the micelle. The pseudophase model only takes into account the occurrence of the reactants in two phases and gives no information about the reaction site within the micelle. Equation (3) can be used to describe so-called "spontaneous reactions" fairly convincingly. These spontaneous reactions are of first or pseudo-first order and follow condition (2), thus requiring the transport of only one reactant into the micellar phase. Examples include some decarboxylation reactions,[57] reactions in which water acts as both the reactant and catalyst,[58] and intramolecular ring-closing reactions.[59]

The distribution of the substrate between the aqueous and micellar pseudophase is strictly governed by charge and determines the micellar effects.[60] Thus, the conversion of anionic substrates into product is usually accelerated in cationic micelles, but is not influenced by anionic micelles. Hydrolysis reactions with water are frequently inhibited by micelles, as although the micelles can incorporate the substrate, the reaction takes place predominantly in the aqueous pseudophase. The acceleration of the rate of reactions by micelles is often interpreted as solvent effects.[61]

Competition of the nucleophile with the counterion of the surfactant must be taken into account in the case of a bimolecular reaction with a uncharged hydrophobic substrate and an anionic nucleophile in a cationic micelle. This is possible by the introduction of an ion-exchange equilibrium [Eq. (4); Nu^-: nucleophile, X^-: counterion]. The ionic con-

$$K_X^{Nu} = \frac{[Nu_W^-]\,[X_M^-]}{[Nu_M^-]\,[X_W^-]} \quad (4)$$

centration in the aqueous and the micellar pseudophase can be calculated using Equation (4). The underlying model is called the pseudophase ion-exchange (PIE) model.[62] An important requirement for the validity of this model is the continual coverage of the micelle surface by the counterion, which is expressed by the mole fraction β, where $\beta = 1-\alpha$ and the mole fraction α represents the free charge on the micelle surface. The value of β is dependent on both the charge and the affinity component of the counterion. A typical β value for Br^- in CTAB is for example 0.8. Comparable values are found for Cl^-, I^-, NO_3^-, and tosylate, while the extremely hydrophilic OH^- and F^- ions have β values near 0.5 and hardly compete with the ions mentioned above. A similar problem occurs with H_3O^+ and anionic micelles. A limit of the PIE model is reached here. Nucleophilic reactions conducted at low concentrations with OH^- can, however, be described satisfactorily with the model.

A formal problem encountered during the treatment of bimolecular reactions in micellar systems should be pointed out. The relationship between one of the first-order constants (k'_w or k'_m) and one of second order (k_w or k_m) can be expressed by Equation (5). The units of k_m are s^{-1}, and the units of k_w are

$$k'_w = k_w[Nu_W^-] \;\text{ or }\; k'_m = k_m \frac{[Nu_M^-]}{[M]} \quad (5)$$

$L\,mol^{-1}\,s^{-1}$ ($M^{-1}\,s^{-1}$). To achieve a comparable second-order constant for the pseudomicellar phase, the molar volume of the reaction site in the micelle V_M is introduced [Eq. (6)]. V_M

$$k_2^m = k_m V_M \quad (6)$$

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

has a value of between 0.14 and 0.37 $L\,mol^{-1}$.[63] The combination of Equations (3) and (5) gives an expression for bimolecular reactions [Eq. (7)]. The condition $[R] \ll [M]$ must be fulfilled. It is further assumed that a micellar reaction only takes place within one micelle and not between micelles. Only in this way is it possible to understand the typically observed dependence of k_{obs} and [M]: An increasing concentration of M in micellar accelerated reactions results in k_{obs} initially rises rapidly, going through a maximum, and then falling again, which can be interpreted as a dilution effect. In practical analyses, the values of k_{obs} are frequently based on the TON values for the productivity and TOF values for the activity of a catalyst. (see the Glossary at the end of this section).

$$k_{obs} = \frac{k_w[Nu_W^-] + k_m K_R[Nu_M^-]}{1 + K_R[M]} \quad (7)$$

The "mass action" model was developed as an alternative to the PIE model with hydrophilic ions acting as reactants.[64] The distribution of the reactive ions on the surface of the micelle is expressed by the Langmuir isotherm. As an example, Equation (8) can be generated for OH^- as a nucleophile. The counterion of the micelle can also be included in this equation. A substantial quantity of kinetic data for reactions ranging from micelle-soluble hydrophobic reactants, hydrophilic reactants bound to the surface of the micelle, to reactions run at a moderate concentration can be satisfactorily represented with the mass-action model, although a physical interpretation is hard to find.

$$K'_{Nu} = \frac{[Nu_M^-]}{[Nu_M^-]([M]-[Nu_M^-])} \quad (8)$$

A further possible description of ionic interactions is based on coulombic forces, that is, where the macro ion micelle and the counterion are considered as point charges.[65] Specific ionic interactions are initially neglected. Consideration of these specific interactions is, however, possible using a Volmer isotherm, where the spatial requirement of ions located on the micelle surface is included [Eq. (9)]. The factor f describes the mole fraction of the micelle surface that is covered by the counterion X^-, and the parameter δ contains the specific interactions between X^- and the cationic micelle surface.

$$f = \frac{\delta\exp(-f/(1-f))[X_W^-]}{1 + \delta\exp(-f/(1-f))[X_W^-]} \quad (9)$$

The coulombic interactions are described by a modified Poisson–Boltzmann expression,[66] and is thus designated a PBE model. It is assumed that micellar reactions take place within a reaction shell of diameter Δ located near the surface of the micelle. The kinetic expression obtained for the reaction of a hydrophobic reactant R with a nucleophile Nu^- is given by Equation (10). The specification of Δ is problematic, since added counterions compete with the nucleophile and thus inhibit the reaction. In contrast to the PIE model, reactions where both reactants carry charge can be described by the PBE model. However, a problem occurs if the micelle and the ionic reagent have the same charge: Although complete inhibition of the reaction might be expected, nucleophilic reactions in anionic micelles also yield a finite amount of product. An acceleration of the reaction rate is often observed when counterions are added, since free charges are no longer available on the micelle surface. This situation can be treated by using the PBE model.

$$k_{obs} = \frac{k_w[Nu_M^-] + k_2^m K_R[M][Nu_\Delta^-]}{1 + K_R[M]} \quad (10)$$

Both the PIE and PBE models describe the dependence of the rate constants on the surfactant concentration and both are only valid at high dilution. The PIE model fails to describe the situation where ions of drastically different hydrophilicity compete, while the PBE model is able to describe these situations since it is based on coulombic and specific interactions. In the PIE model the reactive volume V_M is independent of the form and size of the micelle, while in the PBE model this volume is dependent on the reaction shell diameter Δ and the micelle radius. The PBE model assumes the micelles are spherical and of uniform size.

Functional micelles containing a bound reagent (for example, the nucleophile) or a bound catalyst in the head group are of considerable interest. In this way, a high concentration of the reactant is always ensured on the surface of the micelle and a similarity to enzymatic reactions becomes apparent. This area includes metallomicelles.

It is frequently observed in bimolecular reactions that the rate constants in water and in the micelle are fairly similar, which would imply that the acceleration effect is predominantly based on concentration differences.[67] It can also be concluded that the reactions take place in the proximity of the head group, where the polarity is very similar to that of the water. It was indeed possible to achieve a small increase in the rate constants by stepwise modification of the head group from $-N^+Me_3$ to $-N^+(n\text{Bu})_3$ for a series of spontaneous reactions. Furthermore, measurement of the Hammett curve for the hydrolysis of substituted benzene sulfonates in cationic micelles led, on the basis of the ρ values, to the conclusion that the polarity in the head group can be totally different from the surrounding water.[68]

The pseudophase model can be applied to vesicles, microemulsions, and reverse micelles. Engberts and co-workers[69] found an enthalpy–entropy compensation for the decarboxylation of 6-nitrobenzeneisoxazole-3-carboxylate in micellar and vesicular media, with the highest reaction rate being observed in vesicles of low fluidity in the membrane layer (below the phase transition).

Glossary

CMC	critical micelle concentration
R_W	reactant in the aqueous phase
R_M	reactant in the micellar phase
T	tenside, surfactant
M	micelle-bound surfactant
k_{obs}	observed rate constant

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

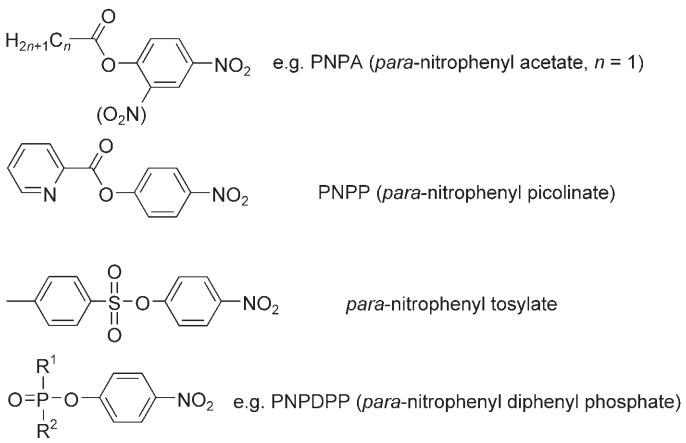
k'_w	pseudo-first-order rate constant in the aqueous phase
k'_m	pseudo-first-order rate constant in the micellar phase
K_R	equilibrium constant for reactant R between the aqueous and micellar phases
Nu^-_W	anionic nucleophile in the aqueous phase
Nu^-_M	anionic nucleophile in the micellar phase (Stern layer)
X^-_W	counterion in the aqueous phase
X^-_M	counterion in the micellar phase (Stern layer)
K^{Nu}_X	equilibrium constant for the nucleophile and counterion between the aqueous and micellar phases
k_w, k_m	second-order rate constant in the aqueous and micellar phases, respectively
k^m_2	corrected second-order rate constant for the micellar phase ($k^m_2 = k_m V_M$)
V_M	molar volume of the reaction site in the micelle
K'_{Nu}	Langmuir isotherm for a nucleophile Nu^-
f	Volmer isotherm (mole fraction of the coverage of the micelle surface by anion X^-)
δ	Volmer parameter for specific interactions between X^- and the cationic micelle surface
Δ	diameter of a reaction shell in which the micellar reaction takes place
TON	turnover number: mole conversion per mole of catalyst (measure of catalyst productivity)
TOF	turnover frequency: mole conversion per mole of catalyst per time unit (measure of catalyst activity)

5. Reactions in Micelles

In the following sections some more-recent examples of organic reactions conducted under micellar conditions are presented. Catalytic reactions have been treated preferentially. Reactions from inorganic chemistry which take place in micelles,[70] photochemical reactions in organized systems,[71] systematically constructed "artificial enzymes",[72] and the very extensive area of surfactant-influenced polymerization are not considered.[73]

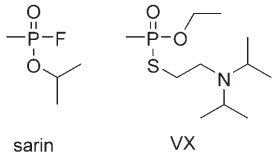
5.1. Solvolyses and Metalloenzyme Models

A comprehensive summary and discussion of solvolytic reactions can be found in Ref. [63]. The solvolyses of esters and related nucleophilic reactions in micelles have been investigated extensively. Nitroaryl esters of alkane carboxylic acids and phosphoric acid, phosphonic acid, or sulfonic acid are frequently used to enable easier access to kinetic data. Selected structures of this compound class are shown in Scheme 2.



Scheme 2. Nitrophenyl esters as substrates for solvolytic reactions in a micellar medium.

Biomimetic systems, including micelles, are frequently developed to gain a more in-depth understanding of biological systems. Enzymatic and enzyme-analogous systems have a practical significance for the hydrolytic detoxification of organic compounds.[74–78] Examples of toxic organophosphorus compounds (chemical weapons) which can be detoxified by micellar systems (hydrolyzed) are shown in Scheme 3.



Scheme 3. Toxic organophosphonates.

Certain basic phenomena are observed time after time, although the reaction in the ionic bilayer of the aggregate, the Stern layer, competes with the reaction of the free substrate in the aqueous phase during solvolytic reactions in a micellar medium. Reactivity maxima are frequently found for substrates of a certain chain length in reactions in micellar aggregates, which leads to the conclusion that there must be an optimal reaction site for the reactions where the rate is increased the most. The proximity of the reaction partners (hydroxide ions and the carbonyl group of the ester in the case of alkaline ester hydrolysis) in the Stern layer determines the higher rate of reaction relative to that in aqueous media and thus allows the introduction of the term "micellar catalysis".[56a,63,68,79–82]

Buffers can be of great importance for solvolytic reactions in micellar systems since micelles or their constituents, surfactants, can influence the pH value at the reaction site. Buffers can also influence the CMC, number of molecules in an aggregation, or the shape of the micelle. Studies have proven that buffered aqueous micellar systems are highly complex. An exchange of the counterion for the buffer ions can occur, especially for ionic amphiphiles. The so-called "salt effect", that is, the influence of the reaction rate through the addition of an inert salt to micellar dispersions, is frequently

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

observed for solvolyses (hydrolyses). The salt effect is larger the lower the charge density in the palisade layer is and the more hydrophobic the ions are.[83,84]

Metal ions frequently play the role of activators in the active site of enzymes (for example, by lowering the pK_a value) for nucleophiles such as water or OH^- groups at physiological pH values. Micellar surroundings influence the complexation of the nucleophile through electrostatic effects and thus also effect the function of the nucleophile in reactions.[85] Biologically interesting metal ions display differing catalytic behavior in different micellar media. Functionalized micelles containing a bound nucleophile accelerate reactions at acyl or phosphoryl groups.[74,86–96]

In general, cationic micelles accelerate the reaction of neutral substrates with anionic reactants, for example, hydroxide ions,[46,97–101] oximate ions,[84,86,102–104] fluoride ions,[83] or thiolate ions.[105] Miller et al.[100] found that the main causes for the 16.5-fold increase in the reaction rate of the basic hydrolysis of homologous nitrophenyl esters of carboxylic acids in latices functionalized with quaternary ammonium groups was a 90000-fold increase in substrate concentration and a 10-fold increase in the hydroxide ion concentration. Boutevin et al.[46] observed a comparable effect (a 3.3-fold acceleration) with increasing degrees of polymerization in polymerized micelles formed from cationic micelle precursors.

Alkoxide ions of the type $C_{12}H_{25}O(CH_2CH_2O)_n-CH2CH2O^-$, originating from the action of hydroxide ions on non-ionic micelle precursors containing terminal hydroxy groups, accelerate the hydrolysis of phosphoryl nitrophenyl esters in non-ionic micelles and are phosphorylated. The phosphorylation is repressed in the presence of 1-chloro-2,4-dinitrobenzene, and dinitrophenyl ethers are formed (Scheme 4). Bunton and co-workers[101] asserted that the reason for this affect was the different reactivity of hydroxide and alkoxide ions to phosphoric esters at the reaction site in the palisade layer. Moreover, phosphoric nitrophenyl esters are deeply embedded in the hydrophobic region of the micelle. Chlorodinitrobenzene is, however, more hydrophilic and resides closer to the head groups in the micellar aggregate.

Work has recently been published which used micellar-accelerated ester hydrolysis to examine the influence of β-cyclodextrins on micellar systems. β-Cyclodextrin forms a complex with CTAB, but the micellar hydrolysis of esters is only influenced at high cyclodextrin concentrations.[106] Dorrego et al.[107] found during investigations into the stoichiometry of various β-cyclodextrin–surfactant complexes that micelle formation in water also does not begin after complete complexation of the cyclodextrin, but rather that normal micelle formation competes with complexation.

Some research groups investigated the effect of various metal ions on ester hydrolysis. Yu et al.[89] found, for example, that micelles formed from cationic amphiphiles inhibit metal-ion-catalyzed hydrolysis in water, while this reaction is catalyzed by anionic aggregates (for example, from SDS). The order of reactivity of $Cu^{2+} > Ni^{2+} > Zn^{2+} > Co^{2+} > La^{3+}$ in the hydrolytic reaction (Table 2) is mainly affected by the polarizability of the solvated metal ion in the micellar medium.

Table 2: Pseudo-first-order rate constants in the hydrolysis of PNPP (Scheme 2) at pH 7 and 25 °C.[89]

Amphiphile	Metal ion					
	without	Cu^{2+}	Zn^{2+}	Ni^{2+}	Co^{2+}	La^{3+}
without	0.02	16.20	0.92	1.10	0.81	0.47
CTAB	0.02	14.50	0.86	0.95	0.80	0.21
SDS	0.02	20.00	0.98	1.67	1.84	0.88
Brij 35	0.03	16.70	0.92	1.13	0.82	0.47

Huang et al.[92] observed differences in reactivity in the Cu^{2+}-catalyzed hydrolysis of PNPP and PNPA substrates (see Scheme 2) in metallomicelles, which can be explained by there being different structures. The hydrolysis of PNPA is an intermolecular reaction and the saponification of PNPP an intramolecular reaction, which can presumably be explained by the coordinative ability of the substrate to the metal ion (Cu^{2+}).

A more effective catalysis appears to be possible using metal complexes with hemilabile amphiphilic ligands (Scheme 5),[91] which promote hydrolysis by nucleophilic attack on the carboxyl group of the ester (system in Ref. [91a] (Zn^{2+}, ligand, CTAB) results in a 7000-fold acceleration). For this reason metal-ion complexes with multiple OH groups are common in hydrolytic metalloen-

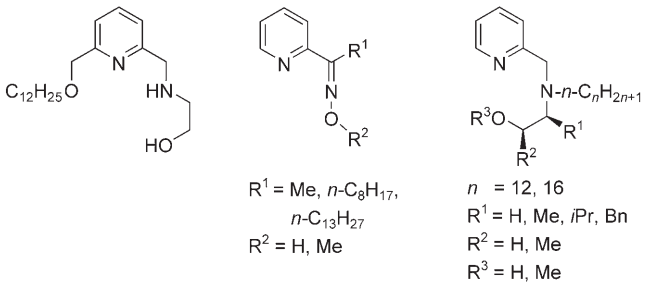
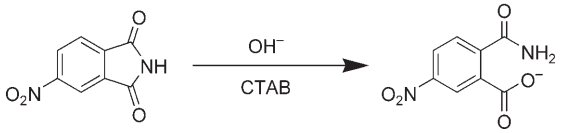


Scheme 5. Examples of hemilabile amphiphilic ligands for the formation of metallomicelles.

zyme model reactions. These groups function like metal-ion-activated nucleophiles. The positively charged Stern layer of CTAB micelles increases the electrophilicity of the metal ions with respect to the micellar-bound substrate. Furthermore, a different complexation of the metal ions in CTAB (Cu/L = 2:1) and in Brij 35 (Cu/L = 1:2) was observed (Brij 35 = polyoxyethylene(23)monolauryl ether).[93,94]

An enantioselective hydrolysis of amino acid esters has been described by You et al.[108] The highest enantioselectivity towards racemic *N*-dodecanoyl-leucine-4-nitrophenyl ester ($k_S/k_R = 3$) could be achieved with metallomicellar systems containing lipophilic L-histidinol and zinc ions.

Descriptions of solvolytic reactions in micellar systems in the literature are not just restricted to the hydrolysis of nitrophenyl esters. Khan et al. investigated the effect of salts and the addition of organic solvents on the conversion of both phthalic acid[109] (Scheme 6) and salicylic acid derivatives[110] in micelles.

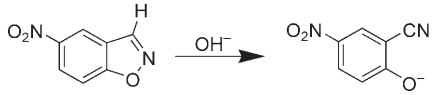


Scheme 6. Alkaline hydrolysis of phthalic acid derivatives.

An increase in the CMC and the stepwise lysis caused by the addition of organic solvents such as acetonitrile results in a reduction in the reaction rate by a factor of approximately 10. An additive (NaBr) containing the same counterion as the cationic micelle precursor (CTAB) also leads to a reduction in the rate of reaction, which can be attributed to the exchange of hydroxide ions for halide ions which cause a reduction in the concentration of the reaction partner in the Stern layer.

The maximum reaction rate was found to depend on the surfactant concentration in the reaction of dinitrochlorobenzene with hydroxide ions.[111] With increasing concentration of tetradecyltrimethylammonium bromide (TTAB), the rate of reaction also increased as a result of the solubilization of the hydrophobic substrate.

Vesicle-forming agents and their aggregates are, just like micelles, frequently utilized as models for natural membranes. The Kemp elimination depicted in Scheme 7 proceeds up to 65 times more rapidly in a vesicular bilayer of dioctadecyldimethylammonium chloride and sodium didecyl phosphate

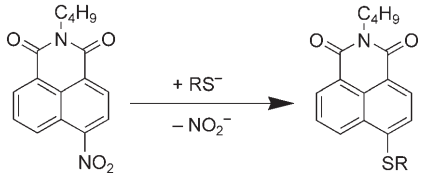


Scheme 7. Kemp elimination of 5-nitro-1,2-benzisoxazole.

than in water.[112] The maximal reaction rate observed at a particular composition is caused by the locally raised hydroxide ion concentration in the pseudophase.

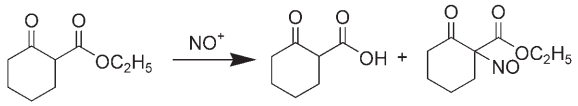
The hydrolysis of benzoyl chloride and benzene sulfonyl chloride in aqueous micelles has been investigated by Bunton.[113] The micellar reactions are inhibited in anionic micelles more than in cationic micelles relative to reactions in the aqueous phase.

The acceleration in the nucleophilic substitution of nitro groups by thiols (Scheme 8) by a factor of 400000 brought about by the addition of CTAB is caused by an increased concentration of the starting material in the micelles as well as by local effects on the acid–base relationship of the nucleophilic thiolation equilibrium.[114]



Scheme 8. Thiolytic substitution of a nitro group. R = Ph.

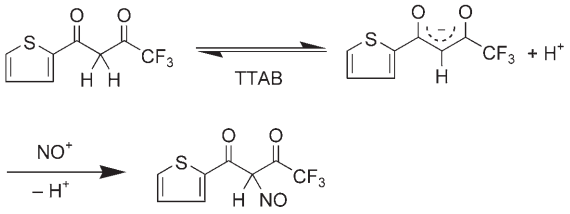
Iglesias[115] studied the behavior of diketones and β-keto acids in micelles in the presence of acids and bases. It was found that hydrolysis and nitrosylation compete depending on the type of surfactant used (Scheme 9). Cyclohexanone-2-



Scheme 9. Hydrolysis and nitrosylation in aqueous micelles.

carboxylic acid esters react in acidic micellar media formed from cationic (tetradecyltrimethylammonium halide, TTAX) and anionic (SDS) surfactants. While micelles of cationic surfactants inhibit the nitrosylation, this reaction is preferred to ester hydrolysis in SDS dispersions.[115,116]

The acidity of the diketo compound shown in Scheme 10 is drastically increased by stabilization of the enol form



Scheme 10. Nitrosylation in a micellar medium.

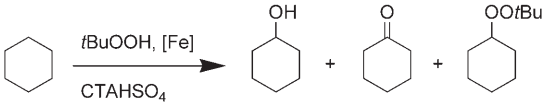
through the micellar environment, and reaction with electrophiles such as nitrosyl ions can take place up to 30 times more rapidly in the positively charged boundary layer than in water.[117]

5.2. Oxidations

Oxidations play a rather secondary role as micellar reactions. The (enzymatic) degradation of toxic organic substances in ground and drinking water is, however, of great interest,[118–120] and since organic substances normally have a low solubility in water, micellar dispersions are frequently utilized for such reactions.

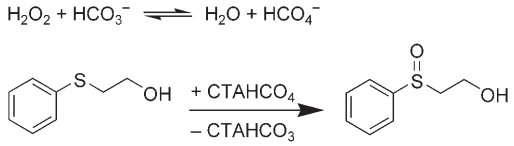
In the oxidation of cyclohexane with *tert*-butylhydroperoxide in the presence of iron-containing biomimetic methane monooxygenase enzyme complexes (for example, [Fe] = $[Fe_2O(\eta^1\text{-}H_2O)(\eta^1\text{-}OAc)L_2]^{3+}$ (L = tris[(2-pyridyl)methyl]-amine),[121] the TON of the oxidation products (Scheme 11)



Scheme 11. Oxidation of cyclohexane in a micellar medium.

increases by a factor of 10 with increasing surfactant quantities and is directly comparable to the TON obtained in non-aqueous systems (acetonitrile as the solvent). A graph of the TON against surfactant concentration shows there is a point of inflexion after reaching the CMC of the surfactant employed.

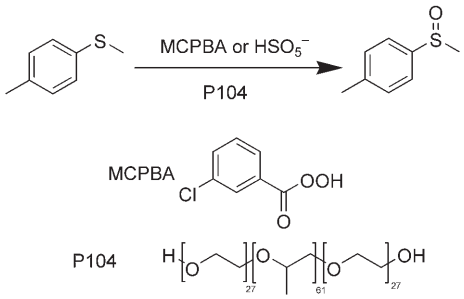
The reaction rate of the sulfoxidation of thiols using amphiphilic hydrogen peroxycarbonate ions ($CTAHCO_4$), produced themselves through the oxidation of cetyltrimethylammonium hydrogen carbonate ions with hydrogen peroxide (Scheme 12), was increased by up to 180-fold.[122] Peroxides



Scheme 12. Sulfoxidation with amphiphilic hydrogen peroxycarbonate ions.

produced and activated by bicarbonate in this way have been suggested for use as "green oxidants" in organic synthesis, for the decomposition of chemical weapons, and for bleaching processes.[123–125]

A different reaction behavior was observed for the sulfoxidation with water-soluble peroxomonosulfate and with the less-water-soluble *meta*-chloroperbenzoic acid (MCPBA) in water and in micellar media, respectively.[126] The increased reactivity for the oxidation of hydrophobic sulfides using hydrophobic *meta*-chloroperbenzoic acid has been accounted for by the increased concentration of the reactants in the inner region of the micelles formed from the triblock copolymer (P104) (Scheme 13). In contrast to this, the oxidation with peroxomonosulfate takes place more easily in water than in micellar systems because in micellar systems the reactants have less contact with each other because of their different solubility.

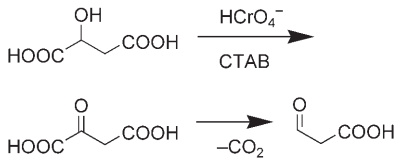


Scheme 13. Sulfoxidation with different peroxide sources.

Enzymes can also be utilized in the chemical synthesis of sulfoxides. Kadnikova and Kostic[127] found a three- to fivefold increase in the yield with enantioselectivities up to 40% for the oxidation of sulfides using hydrogen peroxide in micellar media by immobilization (encapsulation, physisorption or chemisorption, or covalent attachment to SiO_2) of microperoxidase 11.

Different catalytic activities for various micelle-forming agents could be measured in the epoxidation of styrol in micellar media using manganese porphyrinato complexes, a biomimetic system for cytochrome P450, in the presence of sodium hypochlorite as the oxidant.[128] The fact that a conversion of 90% was achieved using cetylpyridinium chloride, but only 25% with CTAB, can be explained through π interactions between the pyridinium structure and the aromatic system of the substrate in the palisade layer of the micelle. An increased aggregation number and an enhanced solubilization support this argument.

The rate of oxidation of malic acid to oxaloacetic acid or carbon dioxide and β-oxopropanoic acid with chromium or manganese catalysts (Scheme 14) could be doubled by



Scheme 14. Oxidation of malic acid in a micellar medium.

changing the reaction system from an aqueous to a micellar system.[129,130] Exchange of the counterion (bromide) in cationic micelle-forming agents such as CTAB for an oxidizing species such as $HCrO_4^-$ would have as a consequence a further increase in the reaction rate as a result of an increased local concentration of the anionic reactant in the Stern layer of the micelle. No such acceleration was found for anionic micelles.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Enzymatic electron-transfer reactions are of outstanding importance in biochemistry. Comparable redox reactions conducted in micellar systems can serve as model systems for biological processes. Das et al.[131,132] found that anionic micelles accelerated and that cationic micelles formed by cetylpyridinium chloride inhibited the Cr^{VI}-catalyzed oxidation of alcohols to aldehydes, which implies the existence of a positively charged transition state.

The abstraction of an electron from phenyl hydrazine by $[Fe(CN)_6]^{3-}$ is impeded by anionic micelle-forming agents (for example, SDS).[133] The extent of the inhibition depends on the concentration of the substrate in the proximity of the micellar surface. Thus, addition of urea causes a displacement of the substrate from the Stern layer, and leads to a further retardation of the oxidation reaction.

The redox reaction of alkyl ferrocenes with glucose oxidase was investigated in different micellar environments by Ryabov et al.[134] The rate of the electron transfer is dependent on the alkyl chain of the ferrocenes and the charge of the micelle. In comparison to micelles formed from nonionic triton X-100 (octylphenoxypolyethoxyethanol), a 14-fold acceleration in the rate was observed in cationic micelles (CTAB) with *n*-butylferrocene, and a 3000-fold inhibition was observed in anionic micelles (SDS) with pentylferrocene.

Zeng and co-workers[135,136] recently described the oxidation of hydroquinone with hydrogen peroxide in a micellar system catalyzed by a transition metal (Cu, Fe, Co, and Mn). The cause of the micellar acceleration was attributed to a concentration effect as well as the electrostatic influence of the micelle-forming agent on the substrate and on the transition state.

The kinetics of the oxidation of hydroxylamine by vanadium(v) compounds has been described by Swain and Panigrahi.[137] Micelles from SDS cause a moderate acceleration in the rate of the reaction.

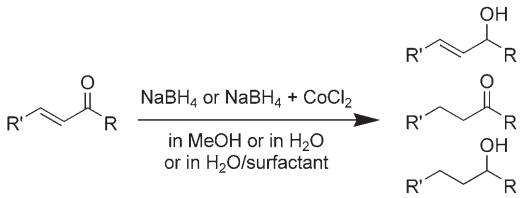
Polypeptides are frequently used as models for naturally occurring proteins or enzymes. The catalytic oxidation of *N*-alkyl-1,4-dihydronicotinamides was investigated in micellar media in the presence of a peptide consisting of 53 amino acids by Tomizaki et al.[138] The use of micelle-forming molecules extends the possibility of increasing the substrate concentration at the catalytic active site. The longer the alkyl chain of the surfactant, the greater the affinity for the hydrophobic substrate, through which the rate of the oxidation reaction can be increased by up to six times.

5.3. Reductions

The most commonly reported examples of reductions conducted in micellar systems include reactions of carbonyl compounds with sodium borohydride and hydrogenations of olefin double bonds with elemental hydrogen. Most of the substrates are prochiral, and thus the possibility of enantioselective reactions exists. Chirality can be induced either through optically active surfactants or through optically active hydrogenation catalysts. The classical results in optically active micelles range between two extremes. In 1978 Goldberg et al.[139] reported an induction of 1.66% *ee* for the reduction of phenyl-*n*-propylketone in micelles formed from α-phenylethyldodecyldimethylammonium bromide. In contrast, in 1988 Hui and Yang reported a spectacular enantiomeric excess of 98% for an analogous reduction of acetophenone in aqueous micelles formed from dodecyl-β-D-glucopyranoside.[140] It is conceivable that the reducing agent sodium borohydride reacts with the surfactant in an initial reaction step to form a chiral reagent, since the induction obtained with a homochiral micelle is usually small.

The low stereochemical induction might arise from the dynamic instability of the micelles. It was shown in more recent work that a considerably higher enantiomeric excess (> 50% *ee*) could be achieved for the reduction of prochiral ketones in micelle-analogous optically active dendrimers, used as models of stabilized micelles, than in corresponding supramolecular aqueous micelles or vesicles (less than 10% *ee*).[141] Cerichelli et al.[142] reduced substituted acetophenones in cationic micelles (formed from CTAB and cetyltrimethylammonizm chloride (CTAC)). Kinetic analysis of the results showed that the rate constant for the reaction in the aqueous pseudophase is considerably larger than in the micellar phase.

The regioselectivity of the reduction of α,β-unsaturated ketones with sodium borohydride was investigated by Aramini et al.[143] (Scheme 15). The authors also utilized the



Scheme 15. Reduction of α,β-unsaturated ketones with sodium borohydride in a micellar medium.

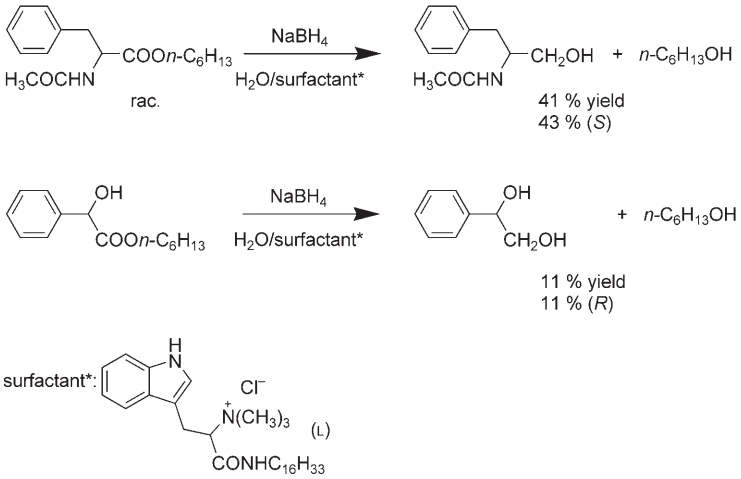
alternative $NaBH_4 + CoCl_2$ reduction system and used MeOH, water, or water in combination with a micelle-forming surfactant. Each of the three possible products could be formed selectively depending on the choice of the system. Finally, however, only SDS and CTAB were chosen as optimal from the large number of surfactants examined. The combination of $NaBH_4 + CoCl_2$ proved to be especially favorable.

High regioselectivities were observed when α,β-unsaturated ketones were reduced in the presence of glycosidic amphiphiles. The unsaturated alcohols are formed almost exclusively with sodium borohydride. If cyclic ketones are used as starting materials, the reduction occurs amazingly stereoselectively with respect to the formation of *cis*/*trans* isomers. The enantioselectivity of the reaction was not examined.[144]

Esters have also been reduced successfully with $NaBH_4$ under cationic micellar conditions.[145] The yields were dependent on the structure of the residues R and R′ in RCOOR′ as well as on the structure of the surfactant. Especially favorable results were obtained with cetyldimethylhydroxyethylammonium bromide as the surfactant. Kinetic resolution

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

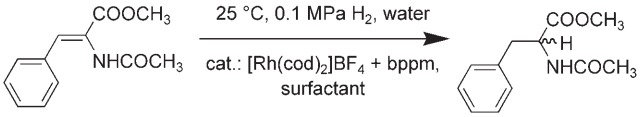
was observed for racemic chiral esters when an optically active surfactant derived from L-tryptophan was employed (Scheme 16).



Scheme 16. Kinetic resolution using chiral surfactants.

Aqueous micelles can take on an interesting role in the homogeneous asymmetric hydrogenation of amino acid precursors. While only a stabilizing effect of the amphiphile on the catalyst system was found in earlier experiments,[146] the hydrogenation of (*Z*)-α-acetamidocinnamic acid methyl ester with an optically active rhodium–phosphane complex and in the presence of amphiphiles led to a significant increase in the activity and enantioselectivity relative to the corresponding hydrogenation conducted in pure water.[147] The effect could be observed with completely different types of surfactants, as shown in Table 3. The isolation of the product was accomplished by extraction into chloroform, while the surfactant and catalyst remained in the aqueous phase. The surfactant was present in substoichiometric quantities (20 mol%) relative to the substrate. A significant effect on the activity and enantioselectivity above the CMC implies the manifestation of a micellar effect.

Table 3: Hydrogenation of amino acid precursors in the presence of tensides.



Surfactant	$t_{1/2}$ [min]	*ee* [%]
without surfactant in methanol	2	90

BPPM = (2*S*,4*S*)-*N*-*tert*-butyloxycarbonyl-4-diphenylphosphanyl-2-diphenylphosphanylmethylpyrrolidine.

Recycling of the catalytic system and the clean separation of the surfactant and catalyst from the product are made possible by the use of polymerized micelles,[148] amphiphilic polymers,[149] or alternatively immobilized amphiphiles.[150] Such macromolecular amphiphiles could be used in a membrane reactor.[151] Besides a series of dehydroamino acid derivatives,[152] the asymmetric hydrogenation of dehydrophosphonic acid esters[153] and dehydrophosphinic acid esters[154] could also be performed successfully. Unexpectedly high increases in the enantioselectivity were obtained in the latter cases.[155]

In the previous examples the enantioselectivity was induced by the catalyst. Only low inductions of up to 11% have been observed when nonchiral catalysts and optically active surfactants, such as derivatives of cholesterol,[156] carbohydrates,[157] and α-amino acids,[158] have been employed. The use of (D)- and (L)-prolinates as well as (D,D)-, (L,L)-, (D,L)-, and (L,D)-prolylprolinates as hydrophilic head groups have given particularly important clues about the reaction site within the micelle.[158] The transfer of chirality implies that the hydrogenation takes place in the palisade layer, that is, at the interface of the head group with the hydrophobic core.[2a] Other important hints at a intramicellar mechanism were gained from "pulsed field gradient spin echo" NMR (PGSE-NMR) measurements.[159]

The micelle-forming surfactant could be functionalized with an optically active rhodium complex at the head group. The micelles formed from this surfactant showed a rather disappointing effect at first, as the coverage of the surface with catalyst was so complete that mutual inhibition occurred. An optimal effect was only achieved in "mixed micelles", with SDS acting as an inert surfactant[160] (see also Section 6).

A CH/CD exchange occurs predominantly in the α position of the ester in the product during the hydrogenation if deuterium oxide is chosen as the medium instead of water.[161] While this exchange can be significantly increased by using a cationic micelle-forming agent, SDS acts in an inhibitory way, probably because SDS micelles are less permeable to D_2O.[162] A consequence of this is that hydrogenations in SDS micelles are less pH-dependent than hydrogenations in cationic, zwitterionic, and non-ionic micelles.[163] Mechanistically, the activation step for the hydrogenation needs to be classified differently to that of the CH/CD exchange.[164]

The kinetics of the micellar hydrogenation of (*Z*)-α-acetamidocinnamic acid methyl ester catalyzed by a rhodium complex has been investigated by Weitbrecht et al.[165] They used SDS as an anionic surfactant and marlipal O13/80 (eightfold ethoxylated C_{13} alcohol) as a non-ionic surfactant and found unambiguously that the dissociation constants of the catalyst substrate complexes under micellar conditions are considerably smaller than if methanol is used as the solvent. The insertion of hydrogen is thus clearly the rate-limiting step.

If these kinetic measurements are used to attempt to explain the previously obtained results of hydrogenations conducted in micellar media, the increase in the activity compared to the corresponding hydrogenation in water can

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

be interpreted as a concentration effect: the substrate and catalyst meet in a small, confined space and form a stable initial complex. There is no reliable data about the solubility of hydrogen in micelles, but it is surely more soluble in micelles than in water. It is more difficult to interpret the sometimes spectacular micellar effects on enantioselectivity. Probably a solvent of favorable molecular order is present in the micelle.

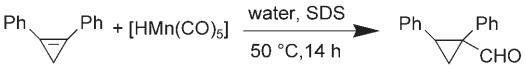
Yonehara et al.[166] showed that a series of unsaturated substrates can be successfully hydrogenated with rhodium phosphinite complexes under micellar conditions, however the enantioselectivity was found to be strongly dependent on the structure of the substrate.

The effect of surfactants and also mixed surfactant systems on the hydride transfer of methylene blue in the leukoform to 2,5-dihydoxy-1,4-benzoquinone was studied by Zeng and co-workers.[167] Ionic micelles generally acted in an inhibitory way, while non-ionic surfactants had practically no effect, thus indicating electrostatic interactions with the charge-transfer complex.

5.4. C–C Coupling Reactions

Hydroformylation is, from an industrial viewpoint, the most important homogeneous catalyzed reaction. Over nine million tons of product are formed by hydroformylation reactions each year, from which a large portion is produced in aqueous systems.[168] Although propene can be successfully hydroformylated in an aqueous medium, this process can not be extended to higher olefins as their solubility in water is too low. Surfactants can be applied here as phase mediators and this application is discussed below.

As one of the first and stoichiometric hydroformylations in an aqueous micellar system, cyclopropene was converted in the presence of SDS and an excess of $[HMn(CO)_5]$ into approximately 90% of the corresponding aldehyde (Scheme 17).[169]



Scheme 17. Stoichiometric hydroformylation with manganese pentacarbonyl hydride.

Riisager and Hanson[170] reported the hydroformylation of 1-octene in aqueous systems where the catalyst was prepared in situ from $[Rh(CO)_2acac]$ (acac = acetylacetonate) and tris(*meta*-sulfonatophenyl)phosphane sodium salt (TPPTS) in the presence of CTAB. Intense interactions between the CTAB of the micelle and TPPTS were shown to exist by NMR experiments. Optimal concentrations were determined for the amphiphile and the ligand.

Gimenez-Pedros et al.[171] hydroformylated 1-octene and 1-decene in two-phase aqueous systems with water-soluble rhodium complexes, which contained tetrasulfonated 1,3-bis(diphenylphosphanyl)propane or 1,4-bis(diphenylphosphanyl)butane, in the presence of various surfactants. The best results were achieved with cetyltrimethylammonium hydrogen sulfate.

Li et al.[172] hydroformylated 1-dodecene with the water-soluble $[RhCl(CO)(tppts)_2]$ complex as the catalyst in the presence of various micelle-forming agents. The best results with respect to yield and regioselectivity (*n*/*iso* ratio of the aldehyde) were observed in mixed micelles from cetylpyridinium chloride with SDS, dodecyl benzenesulfonate, triton X-100, or Brij 35.

An investigation of the hydroformylation of 1-dodecene in an aqueous two-phase system in the presence of CTAB using $[RhCl(CO)(tppts)_2]$ as the catalyst precursor was conducted by Mao and co-workers.[173] They obtained impressive *n*/*iso* aldehyde selectivities (up to ca. 20:1) with moderate substrate/Rh catalyst ratios, which also showed a dependence on the speed of stirring. The authors postulated that the catalysis takes place in the phase border layer between the surface of the micelles and the water phase (Stern layer).

Li and co-workers[174] investigated the hydroformylation of 1-olefins (C_6–C_{12}) with Rh–TPPTS complexes in aqueous organic two-phase systems with CTAB as the phase mediator. Regioselectivities of 96% were achieved with respect to *n*-tridecanal at 120 °C and 20 bar CO/H_2 in the hydroformylation of 1-dodecene using [RhCl(CO)(tppts)(bisbis)] (bisbis = sodium salt of the sulfonated 2,2′-bis(diphenylphosphanylmethyl)-1,1′-biphenyl) as the catalyst in aqueous two-phase systems. The existence of larger mixed micelles is assumed and SDS was found to inhibit the reaction.

Jin and co-workers[175] investigated the hydroformylation of 1-olefins using various rhodium complexes in aqueous two-phase systems in the presence of thermoregulatable amphiphilic ligands, for example, $P[p\text{-}C_6H_4O(CH_2CH_2O)_nH]_3$. These ligands serve as catalyst-transfer reagents in organo-aqueous systems: At low temperatures (for example, room temperature) they are found in the aqueous phase, but at 120 °C they are in the organic phase. The recovery of the catalyst system is possible by cooling to room temperature. This principle was convincingly demonstrated for 1-decene, where the catalyst system was recycled 20 times without a large loss of activity or selectivity. At moderate decene/Rh ratios TONs > 19000 and TOFs of approximately 200 h^{-1} can be achieved. Initial attempts at the hydroformylation of the renewable resource oleyl alcohol resulted in internal aldehydes.[175c]

Oehme et al.[176a] found that the hydroformylation of 1-dodecene gave good conversions with rhodium complexes of the water-soluble ligands $Ph_2P(CH_2)_2S(CH_2)_2SO_3Na$ or $Ph_2P(CH_2)_2S(CH_2)_3SO_3Na$ in aqueous two-phase systems at 120 °C and 60 bar CO/H_2 with the addition of amphiphilic additives. The dodecene/Rh ratio amounted to 10000:1. For the recycling of the catalyst a TONs of approximately 50000 were found without the addition of phase-active materials and a TON of about 65000 when polyoxyalkylene triblock copolymers were used. The advantage of the triblock copolymer in comparison to low-molecular-weight surfactants is that the organic phase can be easily separated from the aqueous phase. The application of surfactants immobilized on inorganic carriers in the hydroformylation reaction was

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

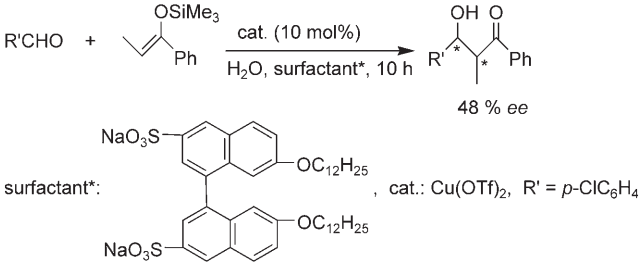
examined, but did not yield the activities which were hoped for.[176b]

Zarka et al.[177] prepared amphiphilic water-soluble diblock copolymers based on 2-oxazoline with *N*-heterocyclic rhodium–carbene complexes. The catalysts obtained were applied to the hydroformylation of 1-octene in aqueous two-phase systems and were able to be recycled three times, but an accompanying drastic drop in the *n*/*iso* ratio was observed. Hydroformylation in microemulsions[178] is also a possibility.

Other C–C bond-forming reactions under aqueous micellar conditions shall be discussed because of their general significance in the synthesis of organic compounds. Bassetti et al.[179] conducted Michael additions with butenone and 2,4-pentanedione in aqueous solutions in the presence of cationic surfactants. Interestingly, the two partners react in the micelles without the addition of a base.

Kobayashi et al.[180] developed water-stabile Lewis acids (for example, lanthanide triflates) as effective catalysts for aldol and related reactions in aqueous media. The conversions of numerous reactions were able to be increased by the addition of surfactants such as SDS and triton X-100 ("LASC = Lewis acid/surfactant combined catalyst"). Asymmetric aldol reactions were realized by means of various LASCs (for an example see Section 6).

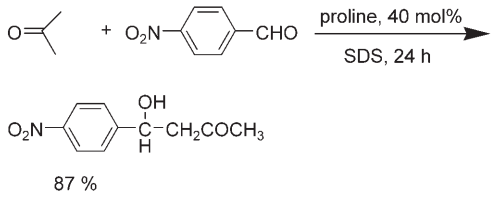
An asymmetric Mukaiyama–aldol reaction in water using chiral disulfonated binapthyl dialkyl ethers (Scheme 18) with $Ga(OTf)_3$, $Sc(OTf)_3$, and $Cu(OTf)_2$ as Lewis acids which generated moderate *ee* values (< 50%) was described by Li et al.[181] The chiral amphiphile was used in an equimolar amount relative to the substrate.



Scheme 18. Asymmetric Mukaiyama aldol synthesis by means of a chiral amphiphilic disulfonate.

The L-proline-catalyzed aldol reaction between nitrobenzaldehyde and various ketones was also investigated in aqueous anionic micelles.[182] Various micelle-forming agents were used in reactions lasting up to 120 h and SDS was found to be the most favorable detergent, which gave 87% conversion after 5 h with acetone and 40 mol% proline (Scheme 19). *Syn*/*anti* product ratios of between 93:7 and 1:1 were found when butanone, cyclopentanone, or cyclohexanone were used as the ketone. No enantiomeric excess data was given.

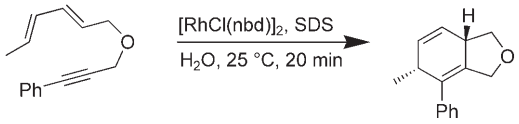
Otto et al.[183a] observed a millionfold increase in the rate of reaction for the Diels–Alder reactions of substituted 2-propenones with cyclopentadiene in water using a combination of Lewis acids and micellar systems. The micellar effect of SDS, CTAB, and dodecyl heptaoxyethylene ether in the



Scheme 19. Micellar aldol synthesis catalyzed by L-proline.

presence of copper and zinc bis(dodecyl sulfate) was investigated. It was shown by the same research group that these reactions take place up to 580 times more rapidly in vesicles than in micelles.[183b,c]

A phosphane-free intramolecular stereoselective [4+2] diene–yne cycloaddition in water in the presence of SDS and $[RhCl(nbd)_2]$ (nbd = norbornadiene) was reported by Motoda et al.[184] The yields were between 71 and 97% in the best cases (Scheme 20).



Scheme 20. Rhodium-catalyzed [4+2] diene–yne cycloaddition in SDS micelles.

Uozumi et al.[185] developed amphiphilic polysterol/polyethylene glycol resins with anchor groups for binding allylpalladium complexes. These polymer-bound amphiphilic complexes were tested in various catalytic reactions under mild conditions (room temperature) over long reaction periods (for example, Heck, Suzuki, Sonogashira, and hydroxycarbonylation reactions). Optical inductions of up to 99% *ee* were achieved in the asymmetric allyl alkylation with chiral imidazoindolphosphane anchor groups as ligands.

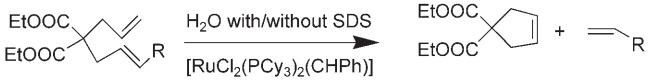
Three amphiphilic water-soluble diblock copolymers based on 2-oxazoline with N-heterocyclic-bound palladium carbene groups were synthesized by Nuyken and co-workers.[186] The polymer-bound complexes formed aggregates with hydrodynamic radii of 10–30 nm in water. The complexes were applied to the Heck reaction and showed TOFs of up to 570 h^{-1}. Analogously immobilized Grubbs-II metathesis catalysts were utilized for ring-forming polymerization in an aqueous medium. The catalysts could be recycled up to five times, but was accompanied by a large loss in conversion.

Oehme and co-workers[149a,176b,187] have investigated C–C coupling reactions in the presence of surfactants. The Heck, Sonogashira, and especially the Suzuki reactions between aryl halides and boronic acids were investigated with water-soluble Pd–phosphane complexes, where $[PdCl_2\{Ph_2P(CH_2)_4SO_3K\}_2]$ was employed as the catalyst precursor. Substituted iodo-, bromo-, and chloroarenes were tested as aryl halides with differently substituted boronic acids. Monomer surfactants such as CTAB and SDS are able to significantly increase the activity and selectivity of the reaction, but act as a hindrance to both the phase separation

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

and product isolation. A simplification of the product separation was achieved by immobilization of the amphiphile on silica gel.[176b]

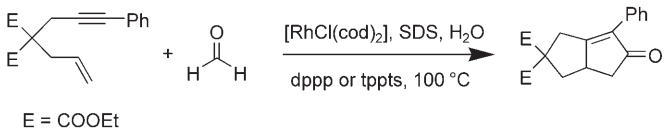
Davis and Sinou[188] have reported the ring-closing metathesis (RCM) of dienes using $[RuCl_2(PPh_3)_2(=CHPh)]$ as the catalyst in water, both with and without surfactants (Scheme 21). The substrates and catalyst were virtually



Scheme 21. Ring-closing metathesis of dienes. Cy = cyclohexyl.

insoluble in water and surfactants enabled the formation of a dispersion, with SDS being especially effective. A conversion of 51 % was obtained after one hour in the absence of an amphiphile, while the conversion was 100 % after the same time in the presence of SDS acting as an amphiphile. Surprisingly, no differences were found when R was phenyl.

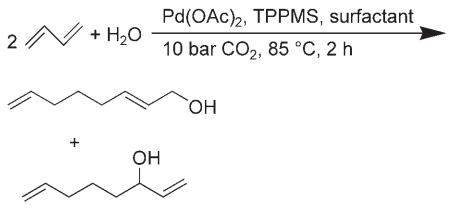
Fuji et al.[189] described a Pauson–Khand reaction in a micellar system, in which the ring closure of an enyne occurs with concomitant incorporation of CO. In addition to the surfactant SDS, both tppts and diphenylphosphanylpropane (dppp) ligands are necessary in the rhodium complex to attain almost quantitative conversion (Scheme 22).



Scheme 22. Paulson–Khand reaction in a micellar system. cod = cycloocta-1,5-diene.

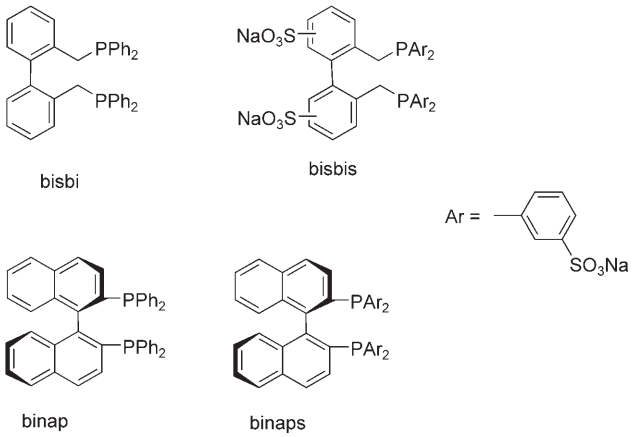
The asymmetric Pd-catalyzed alkylation of 1,3-diphenyl-2-propenyl acetate with C and N nucleophiles takes place in water in the presence of a surfactant, a base, and 2,2′-bis(diphenylphosphanyl)-1,1′-binaphthyl (binap) as the chiral ligand. Enantiomeric excesses of greater than 90 % were obtained when K_2CO_3 was used as the base[190] and cetyltrimethyl ammonium hydrogen sulfate as the surfactant.

The selective telomerization of 1,3-butadiene to 2,7-octadien-1-ol was investigated in micellar systems in the presence of hydrophobic and hydrophilic phosphanes as ligands for the palladium complexes (Scheme 23).[191] Activities and selectivities of the individual systems are strongly



Scheme 23. Selective telomerizations in micelles.

dependent on the steric properties of the phosphane and the nature of the respective phosphane/surfactant combination. In each case the presence of CO_2 is necessary. The various phosphanes (tpp, tppms, tppts, ttpts) used in this reaction and some of the ligands cited in this Review are depicted in Scheme 24.



Scheme 24. Compilation of phosphanes used in complex catalysis. tpp = triphenylphosphane; dppe = diphenylphosphanylethane; dppp = diphenylphosphanylpropane; tppms = triphenylphosphane-*meta*-monosulfonate sodium salt; tppds = triphenylphosphane-di-*meta*-sulfonate sodium salt; tppts = triphenylphosphane-tri-*meta*-sulfonate sodium salt; ttpts = tri-2-tolylphosphane-tri-5-sulfonate sodium salt; dpps = diphenylphosphanylpropansulfonate sodium salt, $Ph_2P(CH_2)_3SO_3Na$; dpbs = diphenylphosphanylbutansulfonate sodium salt, $Ph_2P(CH_2)_4SO_3Na$.

5.5. Other Reactions

In a series of investigations Broxton et al.[192] examined the conversion of aryl halides into phenols in cationic micellar systems.[70] Conclusions about the CMC of the surfactant under the reaction conditions could be drawn from kinetic data. Interestingly, a variety of counterions only had a small effect. Hydroxy-functionalized surfactants of the general type $C_{16}H_{33}N^+(R_2)CH_2CH_2OH\ Br^-$ with R = Me, Et, *n*Bu[192b] proved to be particularly advantageous. Presumably the aryl halide forms an intermediary ether with the micelle, which is then cleaved by OH^- ions [Eq. (11)].

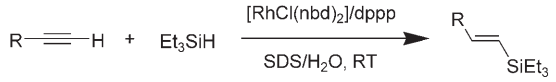
$$\begin{aligned} &C_{16}H_{33}N^+(R_2)CH_2CH_2OH\ Br^- + ArX \rightarrow \\ &C_{16}H_{33}N^+(R_2)CH_2CH_2OAr\ Br^- + OH^- \rightarrow ArOH \end{aligned} \quad (11)$$

A surprising observation was reported by Kobayashi and co-workers:[193] Typical reactions, which proceed by loss of water, for example, the formation of esters, ethers, thioethers, or dithioacetals, can be conducted with the help of 10 mol % dodecylbenzenesulfonic acid in excellent yield in water. The conversion clearly takes place in catalytic micelles formed from the sulfonic acid, from which the water formed during the reaction is lost and thus removed from the equilibrium. It can be recognized from this example that the possibility exists for "green chemistry" through the application of micellar reactions.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The transfer of the nitroso group from *N*-methyl-*N*-nitroso-*para*-toluenesulfonamide to a series of secondary amines in various amphiphile associates (micelles, vesicles, microemulsions) was studied by Garcia-Rio et al.[194] A kinetic analysis according to the pseudophase model shows a strong dependence on the hydrophobicity of the amines and the hydrophobicity of the reaction medium. The highest activation was measured in a vesicular medium and the smallest in a micellar medium.

A stereoselective hydrosilylation of alkynes in aqueous SDS micelles was reported by Sato et al.[195] (Scheme 25). The reactions require only mild conditions (room temperature). Normally the *E* isomer is formed, but the selectivity is reversed upon addition of one equivalent of NaI and predominantly the *Z* isomer is formed.



Scheme 25. Micellar hydrosilylation of alkynes.

6. Enantioselective Reactions

As has been seen during the discussion of the various reactions, enantioselective catalytic reactions can be conducted very successfully in micellar media. The stereochemical induction originates in this case from the catalyst and can be promoted by embedding it into the micelle. An interesting question is whether chirality can also be transferred from optically active surfactants in supramolecular arrays to prochiral substrates. In fact small to moderate effects have been observed for all reaction types: nucleophilic conversions, oxidations, reductions, and C–C bond-forming reactions. A summary of earlier work can be found in the reviews by Bunton and Savelli and from Kunitake and Shinkai.[67,196] Mechanistic considerations have been reported, for example, by Moss et al.[197] as well as by Ueoka et al.[198] Moss et al.[197] made the observation that alcohols formed from the nitrosation of optically active secondary amines in a micellar medium showed up to 22% retention, while inversion was predominately found for the same reaction in water—clearly water attacks the intermediate carbenium ion from various sides. The effect of the micellar medium is promoted by hydrophobic counterions such as BF_4^- or ClO_4^-, as these can occupy the back side of the carbenium ion. The problem was reinvestigated later by Brosch und Kirmse,[199] who used primary octylamine deuterated in the 1-position. Salt formation with $HClO_4$ led to a micelle-forming ammonium salt, which reacted with 90% retention in the substrate above the CMC, while 95% inversion of the configuration occurred in water.

An interesting model reaction was jointly pursued by the research groups of Ueoka[200] and Moss. As shown in Scheme 26, the *para*-nitrophenyl esters of *N*-lauroylphenylalanine were hydrolyzed under the catalytic influence of a tripeptide in aggregated amphiphiles. The hydrolysis constants for the L- and D-phenylalanine derivatives were determined separately and their ratio (k^L_{obs}/k^D_{obs}) was plotted against the mole fractions of the micelle-forming agent (CTAB or SDS or triton X-100) and the vesicle-forming agent (ditetradecyldimethylammonium bromide). Massive increases in the enantioselectivity were observed for the addition of small amounts of micelle-forming agents (for SDS 15–20 mol%). The authors ascribed this result to morphological changes in the aggregates. Thus, stepwise addition causes a transformation of the vesicular structures into a "rodlike" form. A maximum enantioselectivity was found in a pure vesicular state at a temperature above the transition point of the gel phase into the liquid-crystalline phase.

Extensive work on the hydrolysis of activated chiral amino acid esters has been conducted with so-called metallomicelles as catalysts. The head group of the surfactants contains a chiral ligand, which is coordinated with hydrolytically active metal ions such as Cu^{2+} or Zn^{2+}. The function of a metalloenzyme is thus formally approached—the enantioselectivities are, however, not yet satisfactory.[91b,201] Excellent summaries exist with respect to mechanistic considerations for the formation of intermediary diastereomeric complexes with the substrate.[61,202] In a more recent study by You et al. lipophilic L-histidinol was suggested as a ligand and complexed with a series of heavy metal ions (for example, Ni^{2+}, Co^{2+}, Mn^{2+}, Cu^{2+}, and Zn^{2+}).[108] The best activities and enantioselectivities in the hydrolysis of a *N*-lauroyl leucine-*p*-nitrophenyl ester were obtained using the zinc complex.

An amphiphilic ligand with the structure shown in Figure 3 was also developed for the hydrogenation of a prochiral dehydro-amino acid derivative.[160b] Enantioselec-

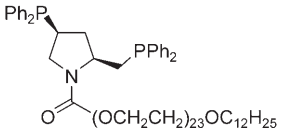

Figure 3. Chiral amphiphilic ligands for asymmetric hydrogenations.

tivities of only between 85–91 % were obtained after complexation with rhodium(I) and treatment with α-acetamidocinnamic acid methyl ester in an aqueous micellar medium. Only after addition of the SDS surfactant did the enantiomeric excess of the product increase to over 94 %.

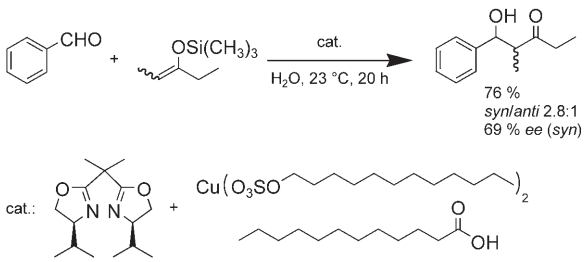
Examples of high enantioselectivities with catalytic systems in micelles from nonfunctional surfactants were shown in Section 5.3. The micelles should be regarded here as the medium. The increase in the enantioselectivity can be dependent on the structure of the chiral rhodium complex. Thus, Selke and co-workers[159] found that seven-membered-ring chelates are considerably more effective than five- and six-membered-ring chelates. The increase in the selectivity in the transition from water to a micellar medium can be better represented by enantiomer ratio than by the enantiomeric excess *ee*.

Fundamental statements concerning the chiral induction of surfactants on enantioselective reactions were made by Rico-Lattes and co-workers.[141b] They synthesized micelle-forming and vesicle-forming surfactants with carbohydrates as optically active head groups and transferred analogous building blocks to the amino groups of third-generation dendrimers (PAMAM = poly(amidoamine)). The resulting dendrimer was morphologically similar to a micelle, but did not display their kinetic instability. While inductions of < 10 % *ee* were observed in the reaction of acetophenone with $NaBH_4$ in micelles and vesicles, 50 % *ee* was achieved in the presence of the dendrimer (unimolecular micelle), and values higher than 82 % *ee* were seen when THF was used as the solvent. It thus appears that micellar (vesicular) dynamics limit chiral induction.

Chiral inductions were also observed in C–C coupling reactions in micelles. Sinou and co-workers[190a,203] investigated the effect of various surfactants on the asymmetric alkylation of 1,3-diphenyl-2-propenyl acetate with malonic acid dimethyl ester in the presence of potassium carbonate as the base and with a palladium complex catalyst. The best results with respect to activity and selectivity (> 90 % *ee*) were attained with binap as the ligand and cetyltrimethylammonium hydrogen sulfate as the surfactant.

In an older publication, Zhang et al.[204] described the asymmetric Michael addition of nitromethane or thiophenol to chalcone (1,3-diphenylprop-2-en-1-one) in aqueous micelles of *N*-dodecyl-*N*,*N*-dimethylephedrinium bromide or *N*-hexadecyl-*N*,*N*-dimethylephedrinium bromide. The maximum enantioselectivity so obtained was 17 % *ee*.

New catalysts for the asymmetric aldol synthesis (Scheme 27) were developed by Kobayashi et al.[180b,c] by combining asymmetric-substituted Lewis acids with amphiphilic counterions. This is also a type of metallomicelle, and a principle that other authors have also adopted.[181] A short



Scheme 27. Stereoselective aldol synthesis with LASC (see Section 5.4).

overview of asymmetric reactions in aqueous micelles has been written by Lindström.[205]

There are only suppositions about the mechanism of enantioselective reactions in micelles. Ueoka et al. summarized some observations, especially regarding the enantioselective cleavage of activated amino acid esters,[200] and showed that a spatial separation of the intermediate diastereomer structure should be possible, and is favored by the hydrophobicity of the medium. Since hydrogen bonds often play a role in the selection, water should, as far as possible, be excluded as a competing reagent.[206] Investigations into the structure of the chiral surfaces of micelles can be found in work by Shinitzky and Haimovitz.[207]

7. Selected Reactions in Reverse Micelles

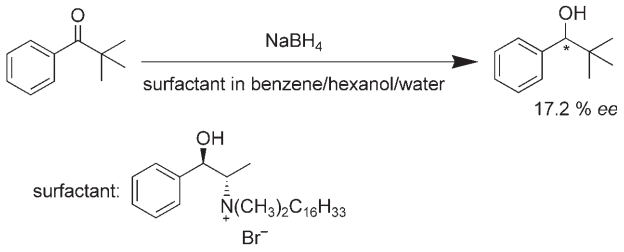
Water is practically immiscible with nonpolar solvents under normal conditions. The addition of surfactants enables the formation of transparent dispersions, which are termed microemulsions.[208] Morphologically, they are a microheterogeneous phase distribution on a nanometer scale. Depending on the ratio of the components, a spherical ordering is observed, in which microdroplets of the nonpolar solvent are stabilized in water by the surfactant, or at the other extreme, water droplets are stabilized by surfactant molecules in nonpolar solvents. Following the formalism that is depicted in Figure 1, one speaks of a reverse micelle in the latter case, and this shall be addressed in this section.[209] Quite complicated phase relations occur between the two extremes of a spherical oil/water (o/w) and water/oil (w/o) structure which can often be modified by the addition of cosolvents. Microemulsions are very versatile solvent systems, which also play an outstanding role as reaction media. Since this is a very extensive research area, both from a physical and technical viewpoint, the reader is referred here to other review articles.[210]

Reverse micelles are complementary systems to aqueous micelles and can be divided into three phases in regard to reaction media: The aqueous core, the hydrophilic–hydrophobic interphase, and the surrounding hydrophobic medium. Water in the core displays deviating electrophilic and nucleophilic properties relative to free "bulk water" because of hydrogen bonds between the head groups of the surfactant and the counterion. Thus, the effect on reactions is often dependent on the water/surfactant (w) ratio. The surfactants

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

known from the field of aqueous micelles are also in principle suited to form reverse micelles, with the sodium salt of the bis(2-ethylhexyl)ester of sulfosuccinic acid (AOT) proving to be especially suitable, probably for geometric reasons.[211] As in the case of aqueous micelles, reactions in reverse micelles are only possible at high dilution. This is not generally valid for microemulsions, which sometimes have remarkable solubilizing capacities. Examples of potential applications for reverse micelles are the decontamination of chemical weapons, as suggested by Menger and co-workers,[212] and C–C coupling with palladium catalysts, similar to those developed by Beletskaya.[213]

Typical reactions in reverse micelles include the reduction of ketones with $NaBH_4$. Zhang and Sun[214] described the reduction of a series of phenyl allyl ketones in benzene/hexanol/water systems in the presence of a chiral alkylephedrinium bromide. The highest enantioselectivity of 17.2 % *ee* was observed in the reaction shown in Scheme 28. The enantioselectivity could be increased further by the addition of D-glucose or D-fructose to the aqueous phase.

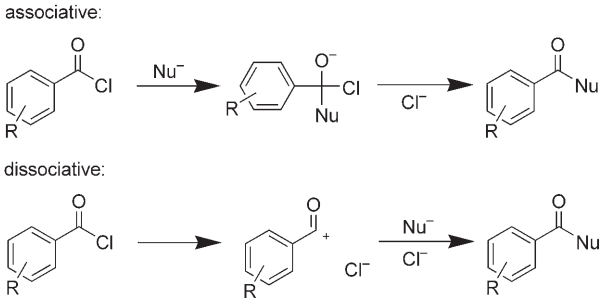


Scheme 28. Stereoselective ketone reduction in chiral reverse micelles.

The kinetics of reduction of various substituted acetophenones were investigated by Cerichelli and co-workers[215] in water/AOT/isooctane, water/AOT/toluene, water/BHDC/isooctane, and water/BHDC/toluene (BHDC = benzylhexadecyldimethylammonium chloride). While the anionic surfactant inhibits the reaction relative to free water, the cationic surfactant causes an acceleration of the reaction in the micelle. This latter result can be attributed to the interaction with the anionic reagent BH_4^-. Isooctane is a better medium than toluene. The reaction rate of the nucleophilic aromatic substitution of 2,4-dinitrofluorobenzene with piperidine, which has been conducted in water/AOT/benzene and water/BHDC/benzene in reverse micelles, was accelerated (relative to the reaction in pure benzene) only in the presence of a cationic surfactant.[216]

Ghosh and Tiwary[217] found a clear dependence of the rate constants on the ratio [water]/[AOT] (w) in the hydrolysis of salicylhydroxamic acid in water/AOT/isooctane. A maximum occurred at $w = 12.3$, which according to the authors shows that water not bound to the head groups is involved in the rate-determining step.

The solvolysis of various benzoyl halides in water/AOT/isooctane was investigated by Garcia-Rio et al.[218] With increasing values of w, a limiting value of $\log k$ was quickly reached, which was however still below that in pure water. The hydrolysis probably occurs in reverse micelles predominately through an associative mechanism (Scheme 29), which is favored by the increased nucleophilicity of the water bound to the surfactant. A high negative activation entropy supports this hypothesis.



Scheme 29. Solvolysis of benzoyl halides in reverse micelles.

A clear acceleration of the imidazole-catalyzed hydrolysis of acetylsalicylic acid was found by Shervani and Ikushima[219] in a water/AOT/sc-ethane (sc = supercritical) system. The largest acceleration of the reaction rate occurred at low water contents ($w = 1$). Supercritical systems are especially suited for the isolation of products. In this way the oxidation of toluene to benzoic acid was successfully achieved in water using oxygen from the air as the oxidant and cobalt bromide as the catalyst in supercritical CO_2 and with various fluorinated surfactants; oxygen is very soluble in this reaction mixture.[220]

A kinetic analysis of the properties of water in the core of water/AOT/isooctane reverse micelles was attempted by Ruasse et al.[221] by means of the electrophilic bromination of alkenes. Water can display an increased H-donor ability of up to 65 times in the core of the micelles, relative to normal water, as a consequence of interactions with the surfactant. This makes the removal of the bromide ion easier, as shown by the transition state in Figure 4.

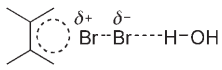


Figure 4. Probable transition state during the bromination of alkenes in reverse micelles.

Water catalysis in reverse micelles is much more intensive than in water itself. Some of the best results in reverse micelles were obtained by Elsevier and co-workers[222] for regioselective C–H activation by means of a sodium tetrachloroplatinate catalyst in a D_2O/AOT/methylcyclohexane or D_2O/AOT/*n*-heptane system. CH/CD exchange was found only in the methyl group of the nonpolar solvent under mild conditions (80 °C).

An example of enantioselective sulfoxidation in reverse micelles was described by Tohma et al.[223] Quantitative yields and enantioselectivities up to 72 % *ee* were possible using iodoxybenzene as the oxidizing agent and a tartaric acid derivative as the source of chirality in a water/CTAB/toluene system without the presence of metal.

Reverse micelles have an important significance in the preparation of monodisperse organic latices as well as in the preparation of other nanomaterials. Dadyburjor et al.[224] described the synthesis of an iron sulfide catalyst for coal

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

hydrogenation, and Hong et al.[225] reported TiO_2/SiO_2 nanoparticles having an increased photoactivity with respect to the decomposition of *para*-nitrophenol.

It is possible to disperse a series of enzymes in a predominantly organic medium by using reverse micelles, thus enabling substrates not soluble in water to be used.[226] New types of reactions are favored by the special structure of the water within the micelle,[227] which can lead to acidity and basicity gradients located close together.

Two introductory review articles by Sanchez-Ferrer and Garcia-Carmona[228] and by Holmberg[229] should be cited from the extensive literature. In the first review, reverse micelles are compared with reverse vesicles, which were uniquely described for the first time in 1991.[230] The application of reverse micelles in biocatalysis is limited by their capacity. The enzymatic esterification using a lipase in a "microaqueous" two-phase and a reverse micellar media were compared in a "strategic study" by Borzeix et al.[231] and shows that the solubilization ability of the micelle appears to be too small.

While aqueous micelles form and dissociate very rapidly, the dynamics of reverse micelles are total different: Collisions, fusions, and subsequent separations can occur.[228] A reverse micelle stabilized by polymerization was reported relatively recently, although the formation and dissociation takes place more slowly than with aqueous micelles.[232] A certain permeability for small molecules evidently remains, so that application to catalytic reactions appears to be possible.

8. Some Special Applications of Surfactants

The term micellar autocatalysis can be traced back to the observation that nonlinear behavior occurs in the two-phase basic hydrolysis of ethyl octanoate: The reaction proceeds very slowly at first and then suddenly approaches completion at a high rate.[233] Since the alkali-metal octanoate is a micelle-forming agent and the increase in the reaction rate only takes place above the CMC, it is postulated that the two-phase saponification is displaced by an intramicellar reaction. An argument against this postulate is that the OH^- ions required as reactants can hardly penetrate the anionic surface of the micelle. Micheau and co-workers[234] developed a mechanism in which the octanoate micelles assume a phase-transfer function and transport ester molecules into the aqueous phase. The mechanistic work is discussed in a review.[235] A comparable effect was noticed in the hydrolysis of benzoic acid esters. It is known that alkali-metal benzoates form layer associations with benzoic acid esters and that they are able to assume a transport function.[236] A further self-replicating micellar system, the autocatalytic formation of dodecyl dimethylamine-*N*-oxide, was reported by Kust and Rathman.[237]

Battal and Rathman also investigated two-phase systems, for example, the alkylation of phenolate with *n*-bromobutane. The conversion into product in this reaction was considerably increased by the addition of a cationic surfactant (CTAB), with the reaction taking on the character of a micellar reaction. The addition of a typical phase-transfer reagent (tetrabutylammonium bromide) resulted in the rate of the reaction increasing still further and the reaction progression becoming nonlinear.[238] The authors interpret the acceleration as being based on facilitated transport of the reactants into the micelle and speak of a micellar phase-transfer catalysis (MPTC). No explanation has yet been found for the nonlinear course of the reaction.

Micelle-forming surfactants have proven to be considerably better as phase-transfer reagents than the more usual short-chain amphiphiles in some two-phase systems. This observation has been interpreted in terms of the transfer function of the surfactant *and* a micelle reaction.[182a,239] The effect is a lot smaller with polymerized micelles, since transport from the organic phase into the micelle is inhibited.

In addition to micelles, vesicles, and microemulsions, other associates of amphiphiles can exert an influence on reactions. As the simplest model, monolayers or bilayers of amphiphiles should be mentioned here. These are formed on the surface of water and are strictly ordered by their alignment (head group aligned to the water, hydrophobic chain aligned to the air). The order and pressure can be influenced through compression of the film. Such Langmuir films have been transferred to glass surfaces and have been employed as Langmuir–Blodgett films for reactions.[240]

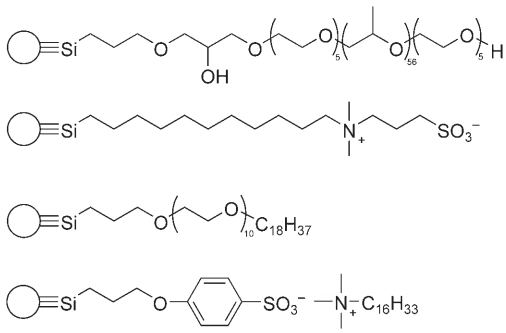
Only a few selected studies will be cited here, which are however representative of a larger number of investigations. Miyasaka et al.[241] found that amphiphilic amino acid esters spontaneously condense to give a polypeptide monolayer in a Langmuir film. Mingotaud and co-workers[242] reported that the epoxidation of (*E*)-cinnamic alcohol in a Langmuir film of an amphiphilic manganese–salen complex was strongly dependent on the pressure applied to the film. Milstein and co-workers[243] prepared a Langmuir–Blodgett film from an amphiphilic rhodium–2,2′-dipyridyl complex, and found considerably higher conversions in the hydrogenation of ketones and aldehydes were achieved than is possible in homogeneous media.

Amphiphile layers can be immobilized onto organic or inorganic polymers under certain conditions to give fixed micelle membranes. In the simplest case, surfactants can be adsorbed on Al_2O_3 or SiO_2 surfaces to give "admicelles", which have been successfully applied as reaction media.[244] Moreover, there is a series of proposals of how to bind thin, unimolecular surfactant layers on carriers.[55,150a,b,176b,245] Some of these proposals are outlined in Scheme 30.

These immobilized surfactants can successfully take on the function of micelles in hydrogenation reactions with hydrogen, in oxidations with oxygen, and even in Suzuki reactions, and then can be simply recycled by filtration. In the case of hydrogenation, for example, the optically active rhodium catalyst remained solubilized in the surfactant layer. After 10 cycles the enantioselectivities were still high, but the activity clearly diminished.[150a,b]

The stabilization of micelles formed from unsaturated surfactants by polymerization has already been mentioned several times. In addition to conventional polymerization methods, a polymerization by exposure to low-temperature plasma was suggested.[246] An important addition are "unimolecular micelles", which are systematically constructed

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 30. Examples of immobilized amphiphiles.

dendrimers with hydrophilic interfaces.[247] Micelle-analogous dendrimer micelles and polymerized micelles might be superior because of their dynamic stability and internal regularity. A prerequisite for stereoselectivity has already been mentioned in Section 6. The work from the research group of van Koten[248] should be mentioned here because of its high potential in catalysis.

Dendrimer chemistry is extremely versatile and also plays an important role in the preparation of nanomaterials, but in comparison to micellar chemistry is elaborate and synthetically time consuming.[249] A comparable role is played by amphiphilic star-shaped polymers, which are used in the field of nanomaterials.[250] The application of amphiphilic polymers in micellar chemistry is becoming ever more significant, in that macromolecules are used as carriers for reactions in membrane reactors and colloids for the preparation of nanomaterials. The use in catalysis has been pointed out at various places in this Review. A more recent study by Zarka et al.[251] in which a new type of block copolymer was used in the asymmetric hydrogenation of an amino acid precursors is cited here as a representative example. The preparation of an oxidation catalyst through the combination of a functionalized amphiphilic polymer with an inorganic carrier also appears to be of interest.[252] A recent review article covers the synthesis and micellar properties of block polymers.[253]

The development of the field of nanoparticles has resulted in amphiphilic and dendrimetric systems becoming of outstanding significance, both in terms of their synthesis and application. In the simplest case, monomeric surfactants are used as aggregates.[254] Of increasing significance are micelles formed from polymers, whose hydrophilic core is removable and whose spherical shape is stabilized by polymerization ("shell cross-linked micelles").[255]

As examples of catalysis with metal nanoparticles stabilized by amphiphiles, polymeric micelles, or dendrimers are arene hydrogenation,[256] alkene hydrogenation,[257] as well as dehalogenation[258] and C–C coupling.[259]

Finally it should be pointed out that surfactants, surfactant polymers, and dendrimers as templates are of great significance for modern mesoporous materials.[260] A review about the template synthesis of porous organic polymers has been written by Hentze and Antonietti.[261]

9. Summary and Conclusions

The present Review should demonstrate that surfactant associates considerably extend organic chemistry in water and lead to notable effects on the rate of reaction and the selectivity of reactions. In general, this is only true for high dilution and low concentrations, but there are examples where surfactants can be used in substoichiometric quantities with respect to the substrate, for example, in enantioselective hydrogenation or in aldol condensations. Despite the original results, "micellar catalysis" is only occasionally employed above a laboratory scale. It does, however, have a firm place in kinetic analytical processes.[262] Likewise, there are uses in medical diagnostics and in cosmetics,[263] and surfactants play a large technical role in emulsion polymerization.[264] The combination of surfactants with classical phase-transfer reagents might extend the field of phase-transfer reactions and micellar reactions.

The limited applicability to organic chemistry has its origin in the problematic work-up of the reactions, since separation of the aqueous and organic phases is difficult. New perspectives are emerging from the development of polymers and polymer-bound amphiphiles. Attempts at immobilizing surfactants have stimulated three-phase catalysis, as described by Regen.[265] Above all, amphiphilic block copolymers—which have been prepared in many variations—should be highlighted.[266] Functionalization of such macromolecules opens the way to their use as catalysts in membrane reactors. Competing with this, however, is the use of dendrimers possessing an amphiphilic structure (unimolecular micelles).

The significance of aggregated surfactants in photochemistry and for the solubilization of enzymes in organic media should also be pointed out. It can also be expected that the use of surfactants will in some way be inevitable in such technically important reactions as the hydroformylation of higher olefins in aqueous systems.

We would like to thank Professor Matthias Beller for both stimulating and supporting our work. We also thank our coworkers cited in this Review.

The bonding in the As_6^{4-} ion is studied in the unusually low-coordination environment provided by the compound $\{Rb[18]crown\text{-}6)\}_2Rb_2As_6 \cdot 6\,NH_3$. Theoretical analysis of the related P_6^{4-} ion indicates an unusual P=P bond which contains major contributions from the lone pairs. Outside a highly coordinating environment, these Pn_6^{4-} (Pn = P, As) species do not seem to be planar, 10π aromatic, or lone-pair aromatic. For details, see the Communication by N. Korber and co-workers on the following pages.

Chemical Bond in the Cyclic Anions P_6^{4-} and As_6^{4-}: Synthesis, Crystal Structure, and Electron Localization Function of $\{Rb[18]crown\text{-}6)\}_2$-$Rb_2As_6{\cdot}6NH_3$**

*Florian Kraus, Tobias Hanauer, and Nikolaus Korber**

Dedicated to Professor Henri Brunner on the occasion of his 70th birthday

The cyclohexaphosphide anion P_6^{4-} is only encountered in the very air and moisture sensitive binary compounds M_4P_6 (M = K, Rb, Cs)[1–3] in the solid state or as a ligand in organometallic complexes. In both cases the P_6^{4-} ion has a molecular shape close to D_{6h} symmetry.[4–8] Solvation of the binary compounds M_4P_6 in ethylenediammine or liquid ammonia, does not yield stable solutions of P_6^{4-} ions (according to NMR spectroscopy) because these react to form a variety of compounds such as the lone pair aromatic cyclotetraphosphide anion P_4^{2-}[9] and the cyclopentaphosphide anion P_5^-,[10] the heptaphosphanorticyclane anion P_7^{3-} and also the undecaphosphatrishomocubane anion P_{11}^{3-}.[11] Thus, the isolation of the P_6^{4-} ion in solvate crystals, in crystals containing it as an isolated anion without metal contacts, or as an ion complex has not been possible, and to date, attempts to detect it in liquid ammonia solution have also failed. A previous report on the existence of P_6^{4-} in an ethylenediammine solution has been shown to be in error, in this case a singlet in the ^{31}P NMR spectra was falsely assigned to P_6^{4-} instead to P_4^{2-}.[2,9]

Arsenic, the heavier congener of phosphorus, forms the compounds M_4As_6 (M = Rb, Cs),[12] which are isotypic to the hexaphosphides. Upon solvation in liquid ammonia, these hexaarsenides form heptaarsenide As_7^{3-},[13] tetradecaarsenide $[(As_7)_2]^{4-}$,[14] and the lone pair aromatic cyclotetraarsenide As_4^{2-} as crystalline products.[15,16] However, in contrast to the hexaphosphide anion, the hexaarsenide anion seems to be moderately stable in liquid ammonia solutions, and we have now been able to dissolve Rb_4As_6 congruently in it. We isolated the As_6^{4-} ion as an ion complex in which only four rubidium cations coordinate to it instead of fourteen as in the solid-state compound Rb_4As_6.

Herein we report the structure of the ammoniate $\{Rb([18]crown\text{-}6)\}_2Rb_2As_6{\cdot}6NH_3$ (**1**) which was obtained as a single crystal. As the compound crystallizes in the polar space group $P2_1$, all the six arsenic atoms of the cyclohexaarsenide anion As_6^{4-} are crystallographically not equivalent. The As_6^{4-} ring has a chair conformation with As–As bond lengths in the range 2.399(4) to 2.415(3) Å and bond angles close to 120° (Figure 1a). The arsenic atoms As1 and As4 are located, respectively, 0.421(3) Å above and 0.266(3) Å below an averaged plane defined by the arsenic atoms As2, As3, As5, and As6 (torsion angle As2-As3-As5-As6 2.4(2)°). The anion is coordinated by the rubidium cations Rb1 and Rb2 which are, respectively, 2.624(3) Å above and 2.693(3) Å below the aforementioned plane with Rb–As bond lengths in the range 3.434(3) to 3.718(3) Å. Additionally, the rubidium cation Rb3 coordinates to As3 and As4 with bond lengths of 3.638(3), 3.659(3) Å and Rb4 coordinates to As1 and As6 (bond lengths 3.581(3), 3.687(3) Å). In addition to this η^2-like coordination to the As_6^{4-} ion, the rubidium cations Rb3 and Rb4 are each sequestered by a molecule of [18]crown-6, which leads to a coordination number of eight. This unit may be considered as a $[\{Rb([18]crown\text{-}6)\}_2As_6]^{2-}$ entity. Additional to the η^6-like coordination of the rubidium ions Rb1 and Rb2 by the As_6^{4-} ring, these rubidium ions each coordinate to four molecules of ammonia. Three of these ammonia molecules form bridges between the two rubidium cations above and below neighboring As_6^{4-} rings, resulting in a dicationic $[NH_3(Rb(\mu\text{-}NH_3)_3Rb)NH_3]^{2+}$ unit (Figure 1b). Through the η^6-like coordination of the $[\{Rb([18]crown\text{-}6)\}_2As_6]^{2-}$ units to these symmetry equivalent dicationic $[Rb_2(NH_3)_5]^{2+}$ fragments, one-dimensional infinite strands of $^1_\infty[Rb_2(NH_3)_5(As_6)\text{-}\{Rb[18]crown\text{-}6\}_2]$ are formed, which run parallel to the crystallographic *b*-axis (Figure 1b).

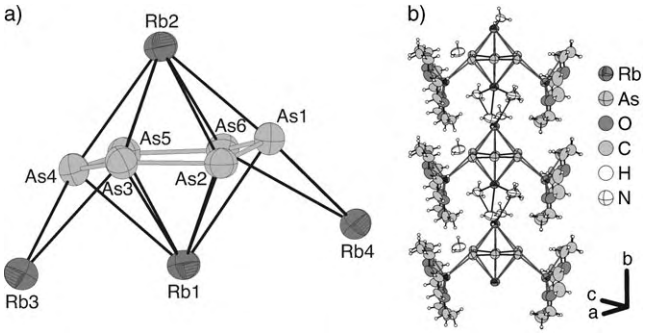

Figure 1. Structure of **1** in the solid state: a) coordination of the As_6^{4-} ion by the rubidium cations. b) A section of the $^1_\infty[Rb_2(NH_3)_5(As_6)\text{-}\{Rb([18]crown\text{-}6\}_2]$ strand. Thermal ellipsoids are drawn at the 70% probability level. Selected bond lengths [Å] and angles [°]: As1–As2 2.399(4), As1–As6 2.415(3), As2–As3 2.420(4), As3–As4 2.414(4), As4–As5 2.407(4), As5–As6 2.395(4); As2-As1-As6 118.4(1), As1-As2-As3 118.4(1), As4-As3-As2 119.2(1), As5-As4-As3 119.4(1), As6-As5-As4 119.1(1), As5-As6-As1 119.8(1).

With ab initio calculations and a topological analysis of the electron localization function (ELF),[17–23] we examined the bonds and lone pairs of the arsenic atoms of the As_6^{4-} species. Several energy minima of the free As_6^{4-} ion show that the boat conformation (C_{2v}) is a frequently encountered ground state—the point groups D_{3d}, D_{6h}, and C_2 correspond to

transition states and to date we have not encountered other ground states. For the base of the boat conformer, the calculated As–As bond lengths (Figure 2a) are only 2.258 Å, which is quite short for As–As bonds. The bonds of the four arsenic atoms of the base to the two arsenic atoms forming the bow (As_{bow}) are 2.413 Å long. This finding suggests the localization of two double bonds and is also confirmed by the ELF calculations. Figure 2b shows the short basal As–As bonds each consist of two localization domains, their population, however, does not add up to four electrons (Table 1). The variance in these basins is quite high which indicates the delocalization of electrons. Looking at the lone pairs, that is, the monosynaptic valence basins of these arsenic atoms, three electrons with a very high variance are found in each which again shows the delocalization in the system. A calculation of the covariance for one of these monosynaptic valence basins clarifies the delocalization: The arsenic core basin C(As) contributes 18.2%, the disynaptic valence basin V(As–As_{bow}) 6.9%, and the disynaptic valence basin V(As–As) 5.6% to the population, but the neighboring V(As) contributes 4.3% whereas the two V(As_{bow}) only contribute 2.4% in total to the population. Consequently, these As=As bonds cannot be described properly within the Lewis model, since a large contribution to the double bond is made by the lone pairs. It might be possible to isolate this conformational isomer if noncoordinating, or weakly coordinating, counterions were present.

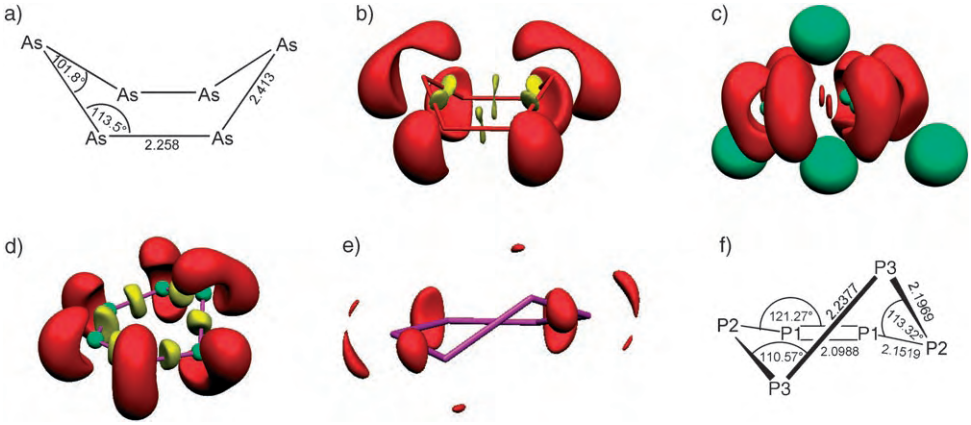

Figure 2. Calculated structures and electron localization functions of As_6^{4-} and P_6^{4-}: a) calculated structure of the free As_6^{4-} ion. b) ELF of the boat conformer of As_6^{4-} with $\eta(r) = 0.81$. c) ELF of $\{Rb_4As_6\}$ in the geometry found in the crystal structure of **1** $\eta(r) = 0.70$. d),e) ELF of P_6^{4-} in C_2 symmetry with $\eta(r) = 0.82$ (d) and $\eta(r) = 0.948$ (e; at this high value for the ELF, the localization of the negative formal charges becomes evident since the atoms P2 and P3 have two monosynaptic valence basins each). f) Calculated structure of the free P_6^{4-} ion. Green: core basins, red: monosynaptic valence basins, yellow: the disynaptic valence basins.

The topological analysis of the $\{Rb_4As_6\}$ unit found in the crystal structure (Figure 2c, Table 1) shows all the arsenic–arsenic bonds to have a similar population of about 1.45 electrons with a rather low variance of 1.00. Twelve monosynaptic valence basins are found, that is, for each arsenic atom there are two lone pairs with a population of 2.31 and a variance of 1.32, and the covariance matrix shows no distinctive contributions of neighboring lone pairs to the delocalization. Thus, the arsenic–arsenic bonds in the $\{Rb_4As_6\}$ ion complex are better described as depopulated single bonds. In contrast to As_4^{2-},[15] no lone pair aromaticity seems to be present in As_6^{4-}, which also means that this anion should not be 10π aromatic.

The isolation of an As_6^{4-} ion that is less coordinated than that in the binary solid also suggests that it might be possible to obtain the P_6^{4-} ion in a similar solvate crystal. Since we do not have further experimental evidence for the possible existence of the P_6^{4-} ion outside of the compound types mentioned above, we used ab initio calculations to look for ground states for the free P_6^{4-} ion. Several different starting geometries, such as D_{6h}, D_{3d}, D_{3h}, and C_{2v}, yielded only transition states, with geometries close to the D_{6h} case. The D_{2h} symmetric P_6^{4-} ion in the crystal structures of α-K_4P_6, Rb_4P_6, and Cs_4P_6 (space group *Fmmm*) is not a ground state of the free anion. However, a structure in point group C_2 yields a ground state (Figure 2d–f). This result is surprising since the P_6^{4-} ring was once thought to be a 10π aromatic ground state system in Hückel and Hartree Fock (HF) calculations.[2,24,25]

These results are not verified by ab initio calculations at the HF[15,26] or B3LYP[15] level of theory which include the evaluation of the Hesse matrix. The topological analysis of the ELF[17–23] of the P_6^{4-} ion indicates a localized P=P double bond (Figure 2d,e). As can be seen from Figure 2d–f and Table 1, the four formal negative charges are localized on the phosphorus atoms P2 and P3, because these atoms have two monosynaptic valence basins (two lone pairs), each with a population close to two electrons. The phosphorus atoms P1 each

Table 1: Compilation of the basin populations and variances of As_6^{4-}, $\{Rb_4As_6\}$ in **1**, and P_6^{4-}.

As_6^{4-} (boat conformation) basin	population [e] (variance)	$\{Rb_4As_6\}$ crystal geometry basin	population [e] (variance)	P_6^{4-} (C_2 symmetry) basin	population [e] (variance)

have only one monosynaptic valence basin with a high population of 3.04 electrons and a very high variance of 1.31 which shows a high degree of electron delocalization. The P–P bonds shorten along the series P3–P3 (2.2377 Å) to P2–P3 to P1–P1 (2.0988 Å). The population of the long bond is 1.81 electrons with a variance of 1.04, whereas the population of the short bond is very high with 2.46 electrons and a high variance of 1.27, which again indicates the delocalization of the electrons. The covariance matrix shows a value of −0.13 (4.3 %) for the exchange between the monosynaptic basins on the two P1 atoms, but only −0.06 (2 %) for the delocalization between the monosynaptic valence basins of P1 and P2. The covariance is even lower for the exchange between P2 and P3 or from P3 and P3. Additionally, the covariance is high, with a value of −0.34 (11.2 %), between V(P1) and V(P1,P1). There is also some delocalization between V(P1) and V(P1,P2) which explains the higher population of the latter. So, the bond between the phosphorus atoms P1 is not a double bond in the sense of the C=C double bond, since a large contribution to the bonding is made by the lone pairs on the P1 phosphorus atoms. Furthermore, the system seems neither to be 10π aromatic nor lone pair aromatic.

It is gratifying to see that the ELF model of the P_6^{4-} ion corresponds closely to the simplest Lewis formula for this anion; even the C_2 symmetry may be predicted using VSEPR considerations. On the other hand, our results show that the Pn=Pn (Pn = P, As) double bonds differ markedly from the traditional hybridization model, since major contributions to the double bonds are made by the lone pairs. Another model describing such bonds in terms of the hybridization defect concept is extensively discussed by Kutzelnigg.[27] As was evidenced by the isolation of **1** and confirmed by ab initio calculations, the Pn_6^{4-} species seem not to be planar outside a highly coordinating environment and do not seem to be 10π or lone pair aromatic either.

Experimental Section

All procedures were carried out under an atmosphere of purified argon and by excluding moisture and air. Liquid ammonia was dried and stored over sodium metal. [18]Crown-6 was purified by sublimation. Rb_4As_6 was synthesized from the elements,[12] $AsPh_3$ (97 %) was obtained commercially from Aldrich. The crystal structure was recorded at 123 K on a Stoe & Cie GmbH Imaging Plate Diffraction System I with graphite-monochromatized $Mo_{K\alpha}$ radiation (λ = 0.71073 Å), the crystal was mounted on a nylon loop in perfluorinated polyether oil.

1 was synthesized from Rb_4As_6 (134 mg, 0.17 mmol), $AsPh_3$ (77 mg, 0.51 mmol), [18]crown-6 (89 mg, 0.34 mmol), through the addition of liquid ammonia (approximately 20 mL) at −78 °C. Without the $AsPh_3$, the As_7^{3-} ion was formed as the major product. After storage for one month at −40 °C, green needle-shaped crystals of **1** had formed.

Single crystal X-ray diffraction analysis of **1**: $C_{24}H_{66}As_6N_6O_{12}Rb_4$, M_r = 1422.23 g mol^{-1}, crystal size 0.3 × 0.02 × 0.02 mm^3, monoclinic, space group $P2_1$, a = 11.492(1), b = 9.2227(7), c = 23.888(2) Å, β = 99.03(1)°, V = 2500.4(4) Å^3, Z = 2, ρ_{calcd} = 1.889 Mg m^{-3}, $F(000)$ = 1387, $\mu(Mo_{K\alpha})$ = 7.882 mm^{-1}, θ = 2.11–21.49°, measured/independent/observed ($I > 2\sigma(I)$) reflections 9169/5720/3908, R_{int} = 0.1107, *hkl* range −11 to 11, −9 to 9, −24 to 23, $R(F)$ (all data) = 0.0781, $wR(F^2)$ (all data) = 0.1388, S (all data) = 0.886, data/parameter/restraints 5720/501/1, Flack parameter x = −0.07(2), $(\Delta/\sigma)_{max}$ = 0.001, max./min. residual electron density: 0.834/−0.713 e Å^{-3}. The structure was solved in space group $P2_1$ using direct methods (SHELXS-97).[28] After all non-hydrogen atoms were located and refined anistropically (SHELXL-97)[29] an absorption correction using DELrefABS of the PLATON suite was applied.[30] Hydrogen atoms were located and refined isotropically using a riding model or with Fourier cycling methods. CCDC-276490 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Theoretical Procedures: All energy minimizations were carried out with the Gaussian03[31] package at the HF level of theory and 6-311++G(3df)[32–35] was applied as a basis set for phosphorus, 6-311G[36] for arsenic. For rubidium the 3-21G[37–39] basis was used. To assure the usage of ground-state geometries in all calculations, the Hesse matrix was checked for the absence of imaginary entries. The electron localization functions and basin populations were calculated with the ToPMoD package from the Gaussian HF wavefunctions, a resolution of at least 0.1 Å was used throughout the calculations.[40,41] For visualization, Molekel4.0[42] and Molden[43] were used.

A Highly DNA-Duplex-Stabilizing Metal–Salen Base Pair**

*Guido H. Clever, Kurt Polborn, and Thomas Carell**

The incorporation of one or multiple metal ions into nucleic acids in a defined fashion is currently of great interest for the development of alternative base pairs and the generation of DNA and RNA with novel catalytic and electronic properties.[1] The general idea regarding catalysis is that the metal ion provides a unique catalytic property, while the nucleic acids surrounding it serve as a chiral ligand amenable to evolutionary optimization.[2,3] Recently, the groups led by Leumann,[4] Meggers,[5] Schultz,[6] Shionoya,[7] Switzer,[8] and Tor[9] presented metal-coordinating nucleic acids, so-called ligandosides, which are able to hold a metal ion inside the double helix.

Regarding electronic application, Shionoya et al. achieved the incorporation of five consecutive metal–base pairs, thereby creating a double helix in which five copper ions are presumably stacked on top of each other.[1] On the way to the goal of creating metal-based catalytic nucleic acids, it would be desirable to create new metal–base pairs in DNA or RNA from chemical entities known to be "privileged ligands" for the construction of powerful catalysts.[10] We therefore decided to develop a DNA metal–base pair based on the *N*,*N*′-bis(salicylidene)ethylenediamine (salen) ligand,[11] which is today one of the most versatile ligands used for the generation of metal catalysts. Metal–salen complexes are able to accelerate a wide range of reactions such as cyclopropanations, epoxidations,[12] and oxidations[13] and are applicable for kinetic resolutions.[14]

The development of our metal–base pair is based on earlier studies of Sheppard and Gothelf et al., who assembled intrastrand salen complexes from phosphate-bound salicylic aldehydes.[15] To create a salen-based metal–base pair that fits optimally into the double-helix structure, we decided to connect the salicylic aldehyde at the C4 atom to the C1′ position of 2′-deoxyribose. Based on molecular modeling we

envisioned that two such ligands facing each other in a duplex structure may assemble in the presence of a suitable metal ion and ethylenediamine to give a metal–salen complex (Figure 1). This complex was envisioned to stack inside the duplex structure, presenting the metal in the minor groove. In contrast to the metal–base pairs investigated so far, the salen–base pair requires both the metal and ethylenediamine for assembly. The inclusion of ethylenediamine gives the resulting complex cross-linking character, although in water imine formation is generally highly reversible.[16]

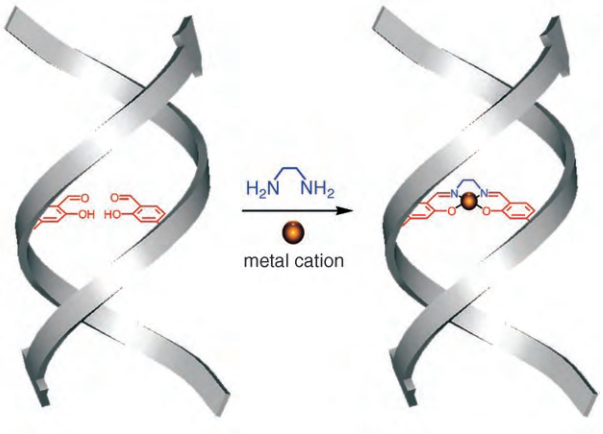

Figure 1. Depiction of the salicylic aldehyde base pair (LL) and assembly of the metal–salen complex inside the duplex.

The protecting groups on the ligand were chosen to comply with ligandoside synthesis and DNA chemistry. The triisopropylsilyl (TIPS) protecting group for the phenol is cleavable under the conditions used to remove the synthesized DNA from the solid support. The aldehyde functionality was protected as an acetal, cleavable with 2% dichloroacetic acid in wet dichloromethane. This reagent is also used for the cleavage of the 5′-DMT protecting groups during DNA synthesis.

The preparation of the protected salicylic aldehyde nucleobase was achieved as depicted in Scheme 1 by ortho-formylation of 3-bromophenol (**1**) with paraformaldehyde in the presence of $MgCl_2$ and triethylamine.[17] The formylation was followed by first an acetalization according to a special procedure for salicylic aldehydes[18] and second by TIPS protection to yield the protected ligand **2**. The C-glycosidation[19] was achieved after lithium–bromine exchange with *tert*-butyllithium, transmetalation, and reaction of the resulting aryl copper species with α-2′-deoxyribosylchloride **3**, which was prepared in two steps from 2′-deoxyribose.[20] After separation of the α and β anomers of nucleoside **4** by column chromatography (the configuration at C1′ of both anomers was assigned by evaluation of the NOESY contacts between the hydrogen atoms C1′-H, C2′-H, and C3′-H), we depro-

tected the sugar hydroxy groups under Zémplen conditions[21] and protected the 5′-OH group with DMT-Cl followed by the synthesis of phosphoramidite **5**. In order to establish the configuration at C1′ unambiguously, **4** was treated with tetrabutylammonium fluoride and dichloroacetic acid to yield the fully unprotected C-nucleoside **6** for crystallization. The crystal structure of the salicylic aldehyde **6** finally confirmed the desired β configuration (Scheme 1).

DNA synthesis was performed using a standard phosphoramidite protocol on an Expedite DNA synthesizer with prolonged coupling times for the incorporation of the salicylic aldehyde phosphoramidite. After additional treatment of the assembled DNA with wet dichloroacetic acid in CH_2Cl_2 and final cleavage from the solid support with saturated ammonia in water/ethanol, the oligonucleotides **7**, **8-a**, and **8-b** containing the salicylic aldehyde nucleobase were purified by reversed-phase high-performance liquid chromatography (RP-HPLC) and analyzed by MALDI-TOF mass spectrometry. The presence of the aldehyde was additionally proven by reaction of the obtained DNA with an amine; the resulting yellow color was indicative for the formation of salicylic aldimines. In addition, reaction of the DNA with *O*-benzylhydroxylamine and reductive amination using different primary amines and sodium cyanoborohydride gave quantitatively the corresponding *O*-benzyloximes and amines, respectively, as shown by mass spectrometric analysis.

All the prepared DNA duplexes and DNA hairpins together with their measured melting temperatures are listed in Table 1. In one sequence, replacement of an AT base pair (entry 1) with the salicylic aldehyde base pair (LL, entry 7) was found to decrease the melting temperature by 9.0 K. Addition of an excess of ethylenediamine (en) to a solution containing the DNA duplex caused an increase of the melting temperature by 4.8 K (Table 1, entries 4 and 5) accompanied by changes in the fluorescence and emission spectra indicative for the formation of salicylic aldimines. More important, however, is our observation that the careful titration of a solution of divalent metal ions to the ethylenediamine-containing DNA solution resulted in systematically increasing duplex stabilization (Figure 2a,b) accompanied by changes of the CD spectra (Figure 3a,b). One equivalent of Cu^{2+} induced a shift of the melting temperature to 82.4 °C (Table 1, entry 3), a shift of more than 30 K with respect to a normal AT base pair (+42.5 K with respect to the duplex containing the LL "base pair", Table 1, entry 2 and Figure 2a). Additional Cu^{2+} had no further effect. To the best of our knowledge, this is the most dramatic increase in duplex stabilization ever observed with a metal–base pair. Addition of one equivalent of Mn^{2+} (which is known to be oxidized to Mn^{3+} upon complexation by salen ligands)[22] increased the T_M by 28.1 K to 68.8 °C (Table 1, entries 4 and 6; Figure 2b).

[a] For sequences see Scheme 1. In **8-A-a** and **8-T-b** the salicylic aldehyde is replaced by A and T, respectively. All samples contained 3 μM DNA (duplex or hairpin) and 150 mM NaCl. Melting profiles were measured from 0 °C to 85 °C (for Cu^{2+}: 95 °C) with a rate of 0.5 K min^{-1}. Further details are given in the Supporting Information. [b] All experiments using Cu^{2+} and corresponding controls were carried out in 10 mM Ches (*N*-cyclohexyl-2-aminoethanesulfonic acid) buffer at pH 9.0. [c] All experiments using Mn^{2+} and corresponding controls were carried out in 10 mM Hepes (*N*-(2-hydroxyethyl)piperazine-*N*′-(2-ethanesulfonic acid)) buffer at pH 9.0. [d] Measured in 10 mM Tris(2-amino-2-(hydroxymethyl)propane-1,3-diol) buffer at pH 7.4. [e] Reproducible differences in de- and renaturing profiles due to thermal instability of the complex (see the Supporting Information). [f] No T_M determined (see the Supporting Information).

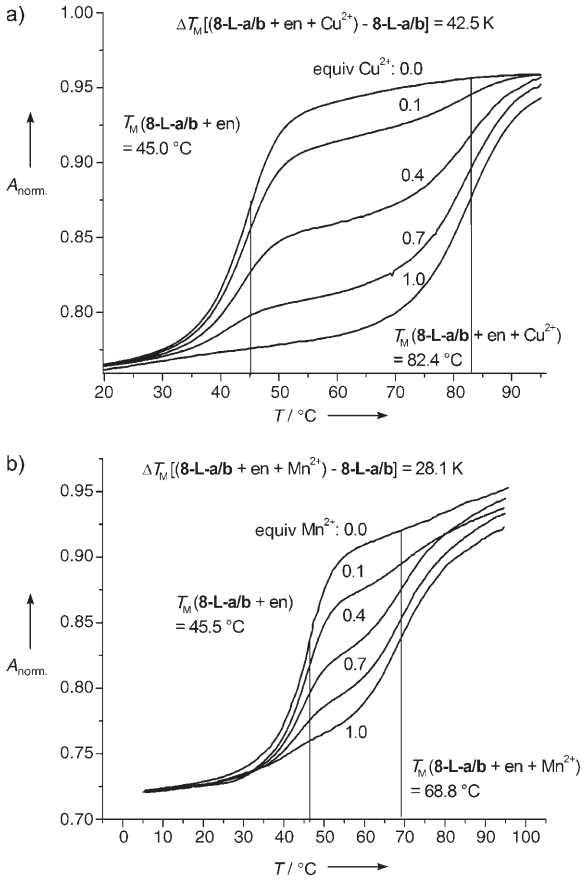

Figure 2. Melting profiles of 3 μM **8-L-a/b** with 100 μM ethylenediamine (en) in the presence of various amounts of a) Cu^{2+} (0–1 equiv) and b) Mn^{2+} (0–1 equiv). The samples contained 150 mM NaCl and 10 mM buffer (Ches pH 9 for Cu^{2+}, Hepes pH 9 for Mn^{2+}).

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

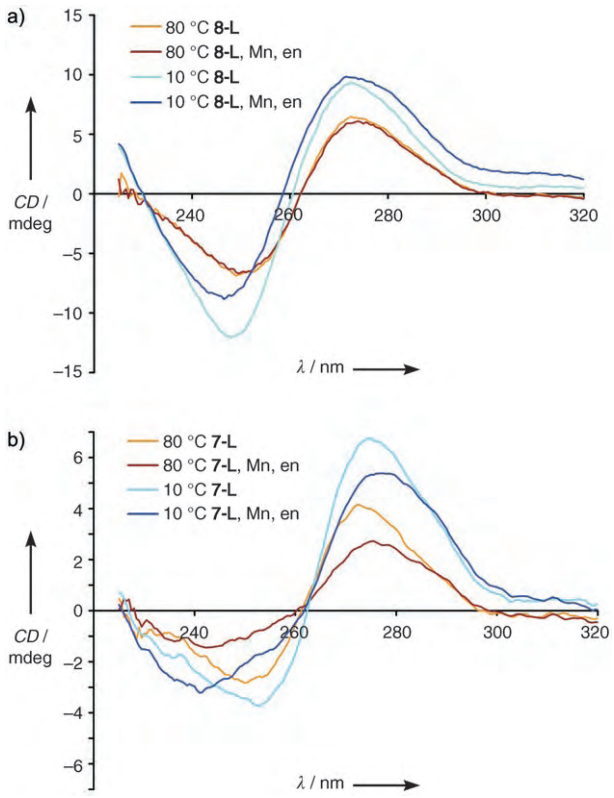

Figure 3. Comparison of CD spectra at 10 °C and 80 °C of a) **8-L-a/b** and b) **7-L** in the absence and presence of ethylenediamine and Mn^{2+}.

Again, additional Mn^{2+} did not further increase the melting temperature. Addition of Zn^{2+} gave an increase of T_M by 7.7 K (Table 1, entries 7 and 8). Interestingly, addition of Ni^{2+} caused reproducibly a decrease of the melting temperature by 4.6 K (Table 1, entries 7 and 9; see the Supporting Information). For Zn and Ni, however, high concentrations of the metal salts were required. When ethylenediamine was replaced by propylenediamine, only Cu^{2+} was able to shift the melting point (addition of butylenediamine had no effect). Addition of Cu^{2+} and not ethylenediamine resulted in an increase of T_M by 15.0 K relative to the melting temperature of the duplex with the pure LL "base pair" (Table 1, entries 2 and 11). In contrast, Mn^{2+} did not cause a shift in melting temperature when ethylenediamine was absent. No changes in the melting temperatures were observed in the absence of either one or both salicylic aldehyde nucleobases, showing that formation of the salen complex inside the duplex is indeed responsible for these dramatic shifts. Formation of the salen complex could be completely reversed by addition of an excess of EDTA to the DNA solution. In order to estimate the effect of the cross-linking, we added to the LL-containing duplex **8-L-a/b** first Cu^{2+} and then methylamine. In this case, a much smaller stabilization of only 12 K was observed (Table 1, entry 10).

Formation of the salen complex inside the duplex was further confirmed by CD spectroscopy of the DNA duplex **8-L-a/b** and the DNA hairpin **7-L** measured with and without metal and ethylenediamine (Figure 3). The CD spectra measured between 80 °C and 10 °C show clearly formation of B-type DNA structures in all cases (see the Supporting Information).[23] Addition of ethylenediamine and either Mn^{2+} or Cu^{2+} resulted in changes of the CD spectra below the individual melting temperatures, indicating formation of the salen complex (only the spectra with Mn^{2+} are shown). Above the melting temperatures the obtained CD spectra of the duplex are undistinguishable from those of DNA strands without the metal. However, the CD spectrum of the hairpin **7-L** at 80 °C in the presence of Mn^{2+} is clearly different from that without the metal. This indicates that the salen complex may stay intact to some extent in the hairpin even at rather high temperatures. (Analogous results were obtained for samples with Cu^{2+}).

In conclusion, we have described the synthesis of a salen-based metal–base pair inside a DNA duplex, in which the metal is located inside the duplex structure. We believe that the extreme increase of the melting temperature by more than 40 KC is induced by the reversible cross-linking of the ligand with ethylenediamine and additionally maybe by axial coordination of the metal with heteroatoms present in the base pairs below and above the metal–base pair.

Artificial Peptide Receptors

DOI: 10.1002/anie.200501812

Charge Interactions Do the Job: A Combined Statistical and Combinatorial Approach to Finding Artificial Receptors for Binding Tetrapeptides in Water**

Carsten Schmuck, Martin Heil, Josef Scheiber, and Knut Baumann*

Intermolecular interactions involving oligopeptides or protein fragments are important supramolecular events responsible for a variety of biochemical and medicinal processes. Therefore, artificial peptide receptors are not only interesting as model systems for studying the principles of the underlying supramolecular recognition event but also as starting points for the development of sensors or drug candidates.[1] For this purpose strong complexation of the given target peptide by the artificial host under physiological conditions (in water) is necessary. This is, however, quite challenging.[2,3] On the one hand, hydrophobic interactions, which are especially important in water, are rather nonspecific, making the design of selective host molecules difficult.[4] On the other hand, electrostatic interactions such as ion pairs and H bonds, which as a result of their specificity and in the case of H bonds also directionality[5] are quite useful for imposing selectivity in the formation of supramolecular complexes,[6] are significantly weakened because of competitive solvation by the polar water molecules.[7] To the best of our knowledge no artificial oligopeptide receptor has been reported up to now that is capable of binding its substrate in water solely based on H bonds in combination with ion pairing. All known receptors for larger oligopeptides require additional hydrophobic,[8] aromatic,[1b,9] and/or the much stronger metal–ligand interactions[10] for efficient substrate binding.

We could recently show, for example, that one-armed tripeptide-based cationic guanidiniocarbonyl pyrrole receptors strongly bind the anionic tetrapeptide *N*-Ac-L-Val-L-Val-L-Ile-L-Ala-OH,[2b] a model for the C terminus of the amyloid β-peptide Aβ (1–42) and even interfere with fibril formation of the native Aβ (1–42) in vitro.[11] Complex formation in this case is, however, critically dependent on hydrophobic interactions with the alkyl side chains. Similar observations were also made by Kilburn et al., who screened a library of guanidinium-based flexible tweezer receptors for tripeptide binding.[2d] In aqueous solvent, efficient binding of the dye-labeled anionic tripeptide Glu(O*t*Bu)-Ser(O*t*Bu)-Val was observed ($K = 8 \times 10^4\,\text{M}^{-1}$). But the deprotected substrate was not bound at all. This indicates again that complex formation is mainly driven by hydrophobic interactions (probably with the bulky *t*Bu protecting groups). Ellman et al. described a synthetic vancomycin analogue, a rigidified tripeptide composed of nonnatural hydrophobic amino acids attached to vancomycin's carboxylate binding site; this receptor relies heavily on hydrophobic interactions for substrate binding.[2e]

Here, in a quantitative experimental screening of a medium-sized but focused combinatorial receptor library **1** in combination with a statistical QSAR analysis (QSAR = quantitative structure–activity relationship), we show that the binding of a nonhydrophobic tetrapeptide **2** in water by an artificial receptor **1** is possible without additional hydrophobic or metal–ligand interactions. To our knowledge this is the first example of tetrapeptide binding in water based on a combination of H bonds and ion pairing, and our study underlines the power of this combined experimental and theoretical approach for the identification of supramolecular receptors.

The general design of the receptor library **1** is shown in Figure 1. An efficient carboxylate binding site for the C terminus of the tetrapeptide[12,13] is attached to a linear tripeptide unit, allowing for the formation of a hydrogen-bonded β sheet with tetrapeptide substrate **2**. Interactions between the amino acid side chains both in the substrate and the receptor further stabilize the complex and provide the necessary substrate selectivity. Based on this receptor design (abbreviated CBS-AA^1-AA^2-AA^3) facile and fast solid-phase peptide synthesis can be used. By using a combinatorial variation of the amino acids in the tripeptide unit, structural diversity can be introduced.[14]

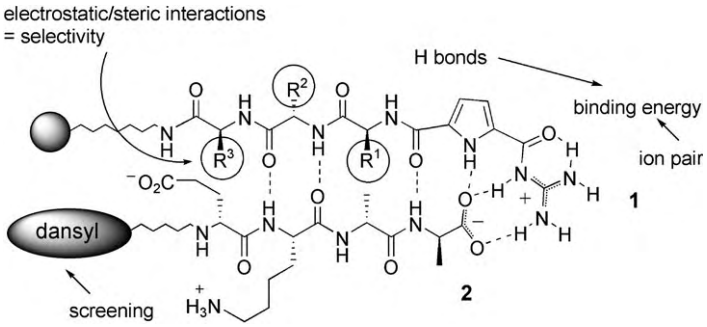

Figure 1. Schematic representation of complex formation between the receptor library **1** and the dansylated tetrapeptide substrate **2**. Dansyl = (dimethylamino)naphthalene-1-sulfonyl.

Table 1: Selected association constants K_{ass} for the complexation of the dansylated tetrapeptide **2** (EKAA) by receptors of type **1** (CBS-AA^1-AA^2-AA^3-resin).[a]

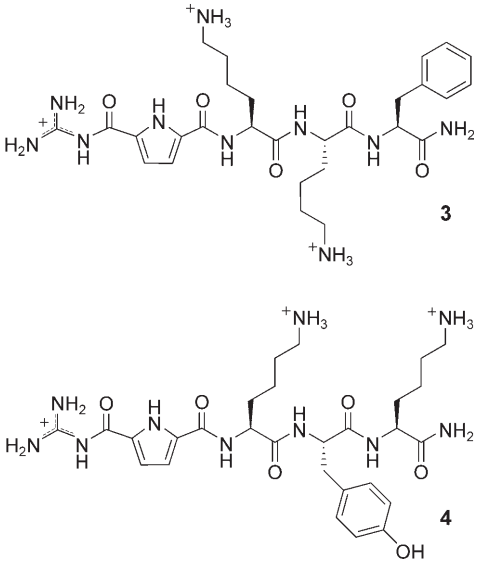
Entry	Receptor	K_{ass} [M^{-1}]
1	CBS-KKF	17100
2	CBS-KKL	15400
3	CBS-KKE	15300
4	CBS-KLF	8800
5	CBS-FKK	6200
6	CBS-KYK	5900
7	CBS-FEK	1600
8	CBS-VFF	660
9	CBS-VYV	360
10	CBS-KEE	100

[a] Obtained from quantitative screening of the library in buffered water (experimental errors of K are estimated to be ±20%).

We synthesized a combinatorial receptor library **1** on Amino-TentaGel as the solid support according to a standard Fmoc protocol using the split-mix approach[15] in combination with the IRORI radio-frequency tagging technology.[16] In each of the three coupling steps the same eight amino acids were used: Lys(Boc), Tyr(*t*Bu), Ser(*t*Bu), Glu(OBzl), Phe, Val, Leu, and Trp. The resulting library had 512 members. These specific amino acids used were chosen among the twenty proteinogenic amino acids to provide a representative range of varying polar, charged, and hydrophobic residues within the final receptor library. The side chains in the final library were deprotected on-bead using HBr (25%) in acetic acid to provide the receptors as charged species. As a first target for this library the polar tetrapeptide D-Glu-L-Lys-D-Ala-D-Ala-OH (EKAA) was chosen. This substrate is not only challenging because of its highly flexible and polar character but also biologically relevant as it plays a critical role in bacterial cell wall maturation.[17] To assess the binding properties of the 512 combinatorial receptors in aqueous solvents, a fluorescent and water-soluble derivative **2** of this tetrapeptide EKAA was synthesized on Wang resin as a solid support again using a standard Fmoc protocol. Full experimental details on the synthesis of the labeled substrate are provided in the Supporting Information.

In a first experiment a qualitative on-bead binding assay in water (incubation of the library with a 5 μM solution of the labeled tetrapeptide **2** in 20 μM bis-tris buffer, pH 6.0; bis-tris = 2,2-bis(hydroxyethyl)iminotris(hydroxymethyl)methane) indicated that receptors of the general structure **1** are indeed capable of binding the tetrapeptide substrate **2** under these conditions. We then determined the binding affinities of all of the 512 receptors in the library using an on-bead quantitative fluorescence assay in 200 μM bis-tris buffer at pH 6.0 in combination with a high-throughput microtiter-plate reader.[2b,18] According to this assay, the binding affinities for tetrapeptide **2** within the library vary from $K_{ass} = 17100\,M^{-1}$ (best receptor) to $K_{ass} < 20\,M^{-1}$ (worst receptor; Table 1). This amounts to a difference in activity of more than two orders of magnitude!

To validate the binding data obtained from the solid-phase screening, we performed complexation studies in solution for the selected receptors **3** and **4**, which were resynthesized on Rink-amide resin using standard Fmoc protocol. (Experimental details on the syntheses can be found in the Supporting Information.) Receptor **3** (CBS-KKF) was the most efficient in the on-bead screening (entry 1, Table 1), whereas **4** (CBS-KYK) showed a medium affinity (entry 6). UV-titration experiments[19] (Figure 2) confirmed that these two receptors form stable complexes with the unlabeled tetrapeptide *N*-Ac-EKAA-OH also in solution. Furthermore, the calculated binding constants obtained from the nonlinear regression analysis of the binding isotherms ($K_{ass} = 15400\,M^{-1}$ for **3** and $6200\,M^{-1}$ for **4**) are in good agreement with the values obtained from the quantitative on-bead screening assay ($K_{ass} = 17100\,M^{-1}$ and $5900\,M^{-1}$, respectively).



Hence, the on-bead screening results indeed represent the situation in free solution. An inspection of the relative binding affinities within the library (Table 1) reveals that complex formation is strongly correlated with the positive charge of the receptors. Those receptors containing two lysine residues next to the guanidinium cation form the strongest complexes with binding affinities $K_{ass} > 10^4\,M^{-1}$ (e.g. entries 1–3 in Table 1), whereas overall neutral or anionic receptors do not bind the substrate efficiently. For example, the binding

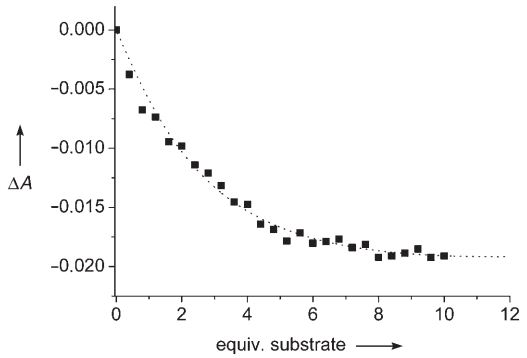

Figure 2. Binding isotherm for the complexation of tetrapeptide *N*-Ac-EKAA-OH by receptor **3** as obtained from a UV titration experiment corrected for absorption changes due to dilution. The dotted line represents the curve fitting for 1:1 complexation.

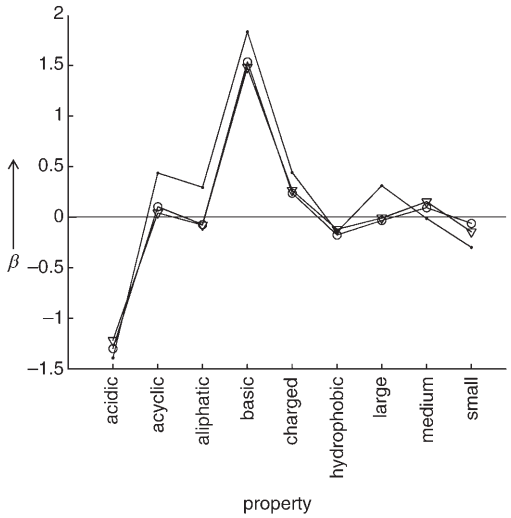

Figure 3. Comparison of the regression coefficients (β) for the binary descriptors. The charge of the amino acid (AA) strongly affects complex stability. For basic AAs (positive charge under physiological conditions) K_{ass} is greater (positive sign for β); for acidic AAs K_{ass} is less. All other descriptors such as hydrophobicity have hardly any influence. In general, the AA in the first position is more important than the other two (increased magnitude of β). –•–• first AA, ○ second AA, ▽ third AA.

affinity drops from $K_{ass} = 15300\,M^{-1}$ for CBS-KKE (entry 3) to $K_{ass} \approx 100\,M^{-1}$ for CBS-KEE (entry 10). This correspond to a change in affinity by two orders of magnitude for a single amino acid substitution, an exchange that transforms an overall dicationic receptor into a neutral one. Hydrophobic interactions are not important for substrate binding. Receptors with just hydrophobic side chains (e.g. entry 8 or 9) have only modest affinities ($K \leq 1000\,M^{-1}$).

These qualitative trends for the binding affinities of our flexible receptors **1** for the tetrapeptide EKAA (**2**) were then quantified using a statistical QSAR analysis. To get a rough impression of the most important structural features determining efficient binding, a simple binary structure descriptor was used first. The following nine different properties of the amino acids constituting the receptor were encoded in binary fashion: acidic (= negatively charged under physiological conditions), acyclic, aliphatic, basic (= positively charged), charged (= either acidic or basic), hydrophobic, large, medium, and small.[20] Figure 3 shows the regression coefficients for these nine binary variables and each of the three amino acids within the receptor as obtained from the statistical analysis. It can be seen that the property basicity (= positively charged side chain), in particular of the first amino acid next to the carboxylate binding site, has a strong positive effect on $\lg K_{ass}$, while the property acidity (= negatively charged side chain) has a negative effect, and other properties, for example, hydrophobicity have hardly any effect at all. This clearly shows that complex formation between receptor **1** and the tetrapeptide **2** is strongly dependent on charge interactions.

Next, a quantitative mathematical QSAR model was used to predict the binding affinity of receptors that were not part of our initial library used for the screening. To improve the quality of the mathematical model for this purpose we first extended the initial rough set of nine descriptors, which for example, do not allow to distinguish between basic amino acids such as lysine or histidine, to a set of 49 selected physicochemical, energetic, and conformational properties.[21] This model allows an individual description of all 20 proteinogenic amino acids. This descriptor set is a subset of the amino acid index[22] that resulted from a cluster analysis conducted by Tomii and Kanehisa.[21,22] A plot of the experimental $\lg K_{ass}$ values versus the cross-validated predictions of $\lg K_{ass}$ is shown in Figure 4.[23]

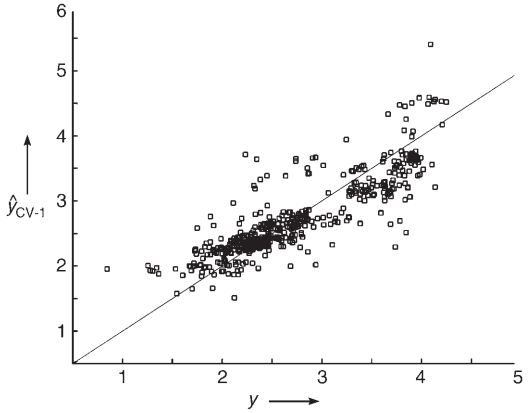

Figure 4. Experimental (*y*) vs. predicted values of $\lg K_{ass}$ ($\hat{y}_{CV\text{-}1}$).

A quantitative inspection of this elaborated mathematical model using a variable-selection routine[24,25] again confirmed that tetrapeptide binding is based solely on charge interactions.[26] The descriptors encoding hydrophobicity, aromatic character, and van der Waals interactions hardly affect the quality of the model.

Finally, the full model (i.e. all $3 \times 49 = 147$ variables) was used to predict the binding affinities of a virtual combinatorial library containing all possible tripeptide sequences in the receptor that can be obtained from the common 20 proteinogenic amino acids (library size $n = 8000$ members). This virtual library is 15 times larger than the initial experimental

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

receptor library **1** used for the screening (512 members). But even out of the 7488 virtual receptors not yet synthesized, no receptors with significantly improved binding properties for tetrapeptide **2** are expected based on the QSAR analysis. The most efficient receptor in this much larger virtual library, CBS-KKR, is predicted to be only less than three times better than the best hit (CBS-KKF) in our initial library ($K = 50\,000\,\text{M}^{-1}$ vs. $17\,100\,\text{M}^{-1}$, respectively). Hence, the additional investment of time and money for the synthesis and screening of this 15-times larger virtual library based on the full set of all 20 proteinogenic amino acids instead of just the focused library based on the preselected subset of eight amino acids used here would not have paid off.[27]

In summary, quantitative combinatorial library screening in combination with the statistical QSAR analysis reveals three important points: 1) Fully flexible one-armed artificical receptors **1** efficiently bind polar tetrapeptides such as EKAA in water. 2) For this substrate, ion-pair formation in combination with H bonds is the main driving force for complex formation. Hence, additional hydrophobic or aromatic interactions are not necessarily required to achieve strong peptide binding under physiological conditions. 3) Small but carefully designed libraries ("focused libraries") are sufficient to explore the features of even much larger ensembles. Hence, the size of a combinatorial library alone is not decisive as long as the library contains the correct range of diversity for the given problem.[28] Currently, we are exploring the potential of such peptide receptors as identified here for the design of selective peptide sensors.

[20] Even for these simple binary descriptors the quality of the cross-validated model was quite satisfactory given the limited accuracy of the experimental screening data. 72 % of the variation in the data could be explained ($R^2_{\text{CV-1}} = 0.72$, $RMSEP_{\text{CV-1}} = 0.87$, $n = 476$). The figures of merit for test set prediction (average over 100 splits) were virtually identical to those of the cross-validation ($R^2_{\text{Test,Avg}} = 0.72$, $RMSEP_{\text{Test,Avg}} = 0.87$, $\theta = 3$) underlining the stability of the model.

[21] a) M. M. Gromiha, M. Oobatake, A. Sarai, *Biophys. Chem.* **1999**, *82*, 51 – 67; b) M. M. Gromiha, *J. Chem. Inf. Comput. Sci.* **2003**, *43*, 1481 – 1485.

[22] K. Tomii, M. Kanehisa, *Protein Eng.* **1996**, *9*, 27 – 36.

[23] Since these 49 indices were measured on different scales (e.g. molecular weight vs. isoelectric point), the variables were autoscaled prior to analysis (i.e. subtraction of the mean and division by the standard deviation of the variable). The resulting model using these 49 diverse descriptors for each amino acid ($m = 147$) yielded a model quality similar to the simple binary model ($R^2_{\text{CV-1}} = 0.71$, $RMSEP_{\text{CV-1}} = 0.88$, $\theta = 3$, $n = 476$; $R^2_{\text{Test,Avg}} = 0.73$, $RMSEP_{\text{Test,Avg}} = 0.85$) but now allows to dinstinguish between all 20 proteinogenic amino acids.

[24] a) K. Baumann, H. Albert, M. von Korff, *J. Chemom.* **2002**, *16*, 339 – 350; b) K. Baumann, M. von Korff, H. Albert, *J. Chemom.* **2002**,*16*, 351 – 360.

[25] M. Stone, *J. Roy. Statist. Soc. Ser. B* **1974**, *36*, 111 – 147.

[26] The isoelectric point of the amino acid side chain alone is sufficient to predict the binding affinity of the receptors. Using only this one variable for each of the three amino acids alone results in only a slightly decreased model quality as compared to the full set of 49 descriptors ($R^2_{\text{CV-1}} = 0.69$, $RMSEP_{\text{CV-1}} = 0.91$, $\theta = 1$, $n = 476$; $R^2_{\text{Test,Avg}} = 0.69$, $RMSEP_{\text{Test,Avg}} = 0.91$).

[27] For a critical comment on library size in the context of drug-development see: R. Breinbauer, I. R. Vetter, H. Waldmann, H. *Angew. Chem.* **2002**, *114*, 3002 – 3015; *Angew. Chem. Int. Ed.* **2002**, *41*, 2878 – 2890.

[28] A lot of effort is nowadays directed to find this correct diversity in designing combinatorial libraries. See for example : a) G. Chen, S. Zheng, X. Luo, J. Shen, W. Zhu, H. Liu, C. Gui, J. Zhang, M. Zheng, C. M. Puah, K. Chen, H. Jang, *J. Comb. Chem.* **2005**, *7*, 398 – 406; b) B. K. Shoichet, *Nature* **2004**, *432*, 862 – 865; c) S. L. Schreiber, *Chem. Eng. Magnetic Storage Materials

DOI: 10.1002/anie.200502579

Synthesis, Crystal Structure, and Magnetic Properties of the Semihard Itinerant Ferromagnet $RhFe_3N$**

*Andreas Houben, Paul Müller, Jörg von Appen, Heiko Lueken, Rainer Niewa, and Richard Dronskowski**

Since the invention of magnetic data recording by Poulsen more than a century ago and the development of the first magnetic hard disc by the IBM company,[1] there has always been a persistent demand for magnetic storage devices. At present, the capacity of hard discs doubles every year and, fortunately enough, this expansion outpaces the performance enhancement of computer chips predicted by Moore's law.[2] If data storage should continue to keep ahead of data production, intense research for new materials needed in high-performance magnetic recording devices will remain a challenge for solid-state chemistry.[3] But this is merely the logical continuation of the impressive history of solid-state magnetochemistry, as demonstrated by well-known example of the maghemite phase.[4]

Within the realm of nitrogen-containing materials, the binary nitride γ′-Fe_4N has been studied intensively both by experimental[5–7] and also theoretical[8,9] methods. In addition to its remarkable chemical inertness, the phase exhibits fascinating magnetic properties that make γ′-Fe_4N a possible material for high-performance magnetic recording heads. In particular, the very large specific saturation magnetization of $\sigma^s = 208\ A\,m^2\,kg^{-1}$ (which is close to that of α-Fe, $\sigma^s = 218\ A\,m^2\,kg^{-1}$) and also the low coercive field of $H_C = 460\ A\,m^{-1}$ have attracted major attention.[6] γ′-Fe_4N adopts a perovskite-like crystal structure (Figure 1) with the space group $Pm\bar{3}m$ and the lattice parameter $a = 3.7900(6)$ Å.[7]

It was realized some time ago that the magnetic properties of γ′-Fe_4N may be influenced by replacing the iron atoms on Wyckoff positions 1*a* and/or 3*c*. The newly introduced atoms mainly control the crystal growth, yielding magnetic particles with a pronounced anisotropic shape and a high coercive field which makes them suitable for high-density storage materi-

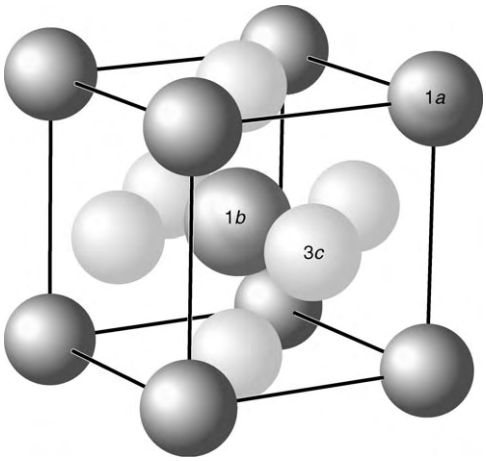

Figure 1. The crystal structure of γ′-Fe_4N in space group $Pm\bar{3}m$ ($a = 3.7900(6)$ Å).[7] The large nitrogen atom (gray) occupies the very center (Wyckoff position 1*b*), and the iron atoms (dark and light gray) are found at the corners (1*a*) and face centers (3*c*). In $RhFe_3N$, the 1*a* position is completely substituted by Rh.

als.[10–12] We know—without claiming completeness—of a couple of reports dealing with berthollide ternary nitrides of the general form $M_xFe_{4-x}N$ with M = Ru,[10] Os,[10] Co,[11] Ir,[10] Cu,[13] Ag,[14] and Zn[15] ($x \ll 1$) as well as Sn ($0 \le x \le 1.2$),[16–18] Mn,[12] and Ni[5,19–21] ($0 \le x \le 4$). In contrast, replacing Fe with Pd,[22] Pt,[5] Au,[14] or In[15] leads to daltonide ternary nitrides MFe_3N of the simple perovskite type.

There have been early attempts to relate preference for substitution at the Wyckoff positions 1*a* and 3*c*[23] to the relative affinities of Fe and M atoms to the nitrogen atom and, even more importantly, the relative sizes of the metal-atom radii. Only if the radius of the substituting M atom is smaller than that of the Fe atom ($r_{Fe} = 1.24$ Å), are both Wyckoff positions statistically occupied. This is found for Mn with $r_{Mn} = 1.17$ Å. Otherwise, the larger atoms clearly prefer position 1*a* because the coordination sphere of the 1*a*-centered cuboctahedron in γ′-Fe_4N is much larger than that of the 3*c* position. This is easily rationalized by the fact that the ^{1a}Fe–^{3c}Fe distance (2.68 Å) is longer than the ^{3c}Fe–^{1b}N distance (1.90 Å) or, alternatively, by the fact that the 1*a* position does not have nearest nitrogen neighbors but is subject to an fcc-like environment of Fe atoms.

These classical ideas have been corroborated recently and quantified by quantum-mechanical total-energy calculations from first principles, and the Aachen group has also predicted, by means of parameter-free enthalpy calculations, the existence of an enthalpically stable and also ferromagnetic ternary nitride phase, namely $RhFe_3N$. Based on density-functional theory and the GGA exchange-correlation functional,[24] the plausible chemical reaction [Eq. (1)] will be

$$FeRh + Fe + FeN \rightarrow RhFe_3N \qquad (1)$$

exothermic with an energy (enthalpy at 0 K) gain of about $\Delta E = -7$ kJ mol^{-1} and a larger −23 kJ mol^{-1} when the starting materials are Rh, Fe, and FeN. Also, the GGA lattice parameter of $RhFe_3N$ in space group $Pm\bar{3}m$ is predicted to be $a = 3.87$ Å, but one has to keep in mind that the GGA is known to overestimate this value by ca. 1%. In addition, the calculations clearly predict that only the 1*a* position of $RhFe_3N$ will be occupied by the rhodium atom, fully and exclusively. In other words, $RhFe_3N$, yet to be made, must be a daltonide phase. Its magnetic saturation moment μ_A^s is predicted to be 9.2 μ_B per formula unit, with local moments of 0.96 and 2.76 μ_B for Rh and Fe, respectively.[24]

We have now succeeded in preparing $RhFe_3N$ for the first time, and there are at least two synthetic routes. In the first approach elemental Rh and Fe or ε-Fe_3N are mixed in a planetary ball mill under Ar atmosphere for 40 h until the products are nearly X-ray amorphous. Subsequent nitridation in flowing ammonia at temperatures above 600 °C leads to two-phase samples containing $RhFe_3N$ and FeRh. Although the percentage of FeRh decreases upon increasing Fe/Rh molar ratio, the relative intensities of the ternary nitride and its unit cell parameter remain practically unaltered, thereby indicating the absence of a significant homogeneity range in the sense of $(Rh_{1-x}Fe_x)Fe_3N$.

Alternatively, one may follow the coupled-reduction route[25,26] developed by Klemm and co-workers, in which the reduction of a metal oxide is accompanied by the simultaneous formation of an intermetallic alloy. Ternary nitrides such as $RhFe_3N$ are accessible by this method starting with an NH_3/H_2 ammonolysis (1:1 ratio) of iron(III) oxide, Fe_2O_3, and elemental rhodium; in fact, the best results are achieved upon using these starting materials. Nonetheless, other iron oxides may also be utilized in combination with rhodium, and even a solid mixture of iron/rhodium oxides eventually leads to $RhFe_3N$ but with slightly lower yields. We also note that the coupled-reduction principle also explains, in retrospect, the early existence of $NiFe_3N$, $PdFe_3N$, and $PtFe_3N$ by the original thermodynamic considerations made four decades ago.[25,26]

Probably because of the minute enthalpy of formation (see above) of $RhFe_3N$, its synthesis is always accompanied by the formation of competing phases. At high temperatures the second phase FeRh ($Pm\bar{3}m$; $a = 2.9825(3)$ Å) is observed, whereas at lower reaction temperatures different iron nitrides come into play, mainly ε-Fe_3N ($P6_322$; $a = 4.699(2)$ Å, $c = 4.382(4)$ Å). The above-mentioned ammonolysis of oxide/element precursors results in the highest $RhFe_3N$ yield (85 wt.% or 75 mol%) at 1100 °C, whereas at around 1000 °C, the yield decreases to approximately 70 wt.%. Neverthess, we believe that it should be possible to obtain pure $RhFe_3N$ samples by non-equilibrium synthetic techniques.

The phase and structure determination is based on high-resolution X-ray powder diffraction. An aluminum foil was inserted into the X-ray beam line to reduce the effect of Fe fluorescence radiation that results from the $Cu_{K\alpha 1}$ radiation. A typical diffraction pattern including the Rietveld refinement[27] is shown in Figure 2.[28]

Although γ′-Fe_4N and $RhFe_3N$ have very similar lattice parameters, the intensities of the 100 and 110 Bragg reflections help to easily discriminate between the two phases. Both reflections are quite weak for the binary nitride but of medium intensity for the ternary nitride. Also, the 100

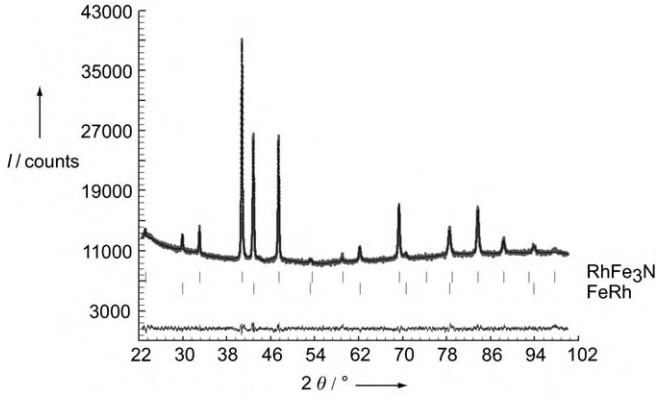

Figure 2. Diffraction pattern and Rietveld refinement of $RhFe_3N$ (first phase: $Pm\bar{3}m$; $a = 3.8292(2)$ Å) and FeRh (second phase: $Pm\bar{3}m$; $a = 2.9825(3)$ Å). The vertical bars designate the positions of the Bragg reflections.

intensity is almost twice as large as the 110 intensity for the case of γ′-Fe_4N. But, on the other hand, the 100 intensity is only about one-third as strong as the 110 intensity for $RhFe_3N$. As predicted from the theoretical calculations, the refinement clearly indicates that among the two possible Wyckoff positions (1*a* and 3*c*) only the 1*a* site is taken by the Rh atom, and no substitution of Fe by Rh is found for position 3*c*. In addition, position 1*a* is fully occupied by rhodium. Thus, $RhFe_3N$ is indeed a daltonide compound.

In accord with the larger radius of rhodium ($r_{Rh} = 1.34$ Å) compared to that of iron ($r_{Fe} = 1.24$ Å), the lattice parameter of $RhFe_3N$ ($a = 3.8292(2)$ Å) is also slightly larger (by about 1%) than that of γ′-Fe_4N. The theoretical prediction by the GGA method ($a = 3.87$ Å) overestimates the lattice parameter by 1%, which is characteristic of the GGA method.[24,29]

The magnetic properties of $RhFe_3N$ samples, which are unavoidably admixed with ca. 15 wt.% FeRh, were determined by SQUID magnetometry (MPMS-5S, Quantum Design) in the temperature range 300–650 K at an applied field of $B_0 = 0.01$ T. At a temperature of 5 K, a hysteresis loop was recorded in the field range ± 5 T. To allow for the magnetic contribution of FeRh, a corresponding pure sample of FeRh was also prepared and magnetically characterized under the same conditions, and its signal was subtracted from the original susceptibility data. Diamagnetic corrections and contributions from conduction electrons cancel to a large extent and have therefore been neglected.

The results of the magnetization measurements before and after subtraction of the magnetic FeRh contribution are presented in Figure 3 in a plot of the atomic magnetic moment μ_a per formula unit as a function of the temperature. On heating $RhFe_3N$ above 400 K one finds behavior typical of a ferromagnetic compound, and T_C is estimated to be 505(25) K. (T_C is given by the intersection of the linear fit of the steepest part of the magnetization curve with the T axis.[30]) The accuracy is somewhat limited not only because of the uncertainty of the amount of FeRh in the sample but also because of the annealing effects of the latter phase.[31] The hysteresis loop at 5 K is given in Figure 4. Its evaluation results in a coercive field H_C approximately one order of

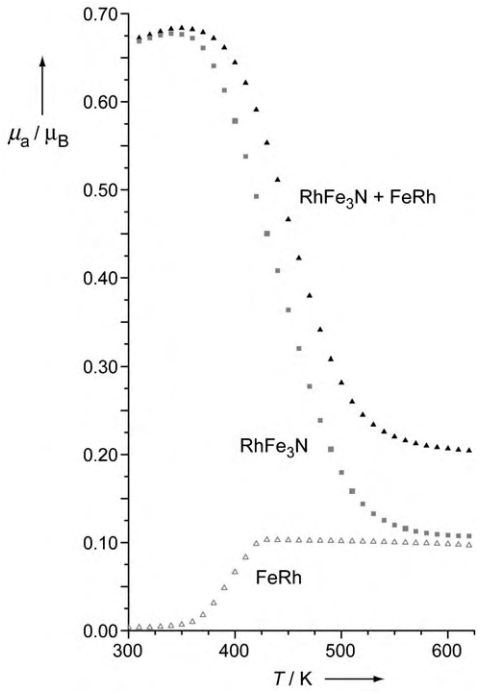

Figure 3. Variation of the magnetic moment μ_a per formula unit $RhFe_3N$ at a field of $B_0 = 0.01$ T as a function of the temperature, with actual measured data (▲), the FeRh contribution (△), and the $RhFe_3N$ contribution (■).

magnitude larger than that of γ′-Fe_4N. This finding in combination with a remanence of $\mu_0 M_R = 0.52(1)$ T allows us to categorize $RhFe_3N$ as a semihard ferromagnetic material.[32] At $B_0 = 5$ T the specific saturation magnetization reaches $\sigma^s = 163(2)$ A m^2 kg^{-1}, corresponding to $\mu_a^s = 8.3(1)$ μ_B per formula unit. Why H_C of $RhFe_3N$ is enhanced relative to that of γ′-Fe_4N is unknown as yet, and the 11% discrepancy between the experimental value for μ_a^s (8.3 μ_B) and the theoretical (9.2 μ_B) is probably a result of a theoretically overestimated (GGA) local moment of the Rh atom. Neutron diffraction measurements are needed to fully answer that question, and corresponding experimental studies are underway.

The density-functional (GGA) prediction of the bulk modulus K_0 (which serves as a simple measure of the phase's mechanical hardness) of the binary γ′-Fe_4N results in the theoretical value of 172 GPa, which compares satisfactorily with the recently determined experimental value[33] of 155(3) GPa; the small theoretical overestimation must be considered quite acceptable for the GGA functional. Interestingly, the bulk modulus of $RhFe_3N$ is predicted even to be larger, namely 187 GPa. Consequently, the ternary phase is not only a magnetically semihard ferromagnet, but it is also mechanically harder than γ′-Fe_4N itself; this is a truly promising combination of physical properties for recording heads.

In summary, the new ternary iron rhodium nitride $RhFe_3N$ was synthesized and structurally characterized. $RhFe_3N$ is a daltonide phase in which exclusively Rh occupies the 1*a* position, just as predicted by density-functional theory. The

magnetic properties indicate that the new phase is a semihard itinerant ferromagnet with a saturation moment of 8.3 μ_B per formula unit and a Curie ordering temperature of $T_C \approx 505$ K.

Cross-Coupling

DOI: 10.1002/anie.200501860

Efficient Aryl–(Hetero)Aryl Coupling by Activation of C–Cl and C–F Bonds Using Nickel Complexes of Air-Stable Phosphine Oxides**

Lutz Ackermann, Robert Born, Julia H. Spatz, and Daniel Meyer*

Transition-metal-catalyzed cross-coupling reactions of organomagnesium compounds[1–4] are useful tools for the synthesis of unsymmetrically substituted biaryls, which are valuable building blocks for the synthesis of natural products, liquid crystals, polymers, and ligands.[5] Predominantly aryl iodides and bromides, and more recently aryl chlorides,[6] are employed as electrophiles. In contrast, the catalytic activation of unreactive C–F bonds remains extremely challenging because of the inherent strength of the C–F bond.[7,8] The activation of C–F bonds in general is of utmost importance because this transformation contributes to the fundamental understanding of the reactivity of very stable bonds, and because the selective synthesis of partially fluorinated compounds is still a challenge.

Herrmann showed elegantly that efficient nickel-catalyzed[9] cross-couplings between electronically nonactivated aryl fluorides and aryl Grignard reagents[10] can be accomplished at ambient temperature,[11] if appropriate stabilizing ligands are employed.[12,13] Recently, we employed modular air-stable dioxo- and diaminophosphine oxides in palladium-catalyzed Suzuki cross-coupling reactions between aryl chlorides and boronic acids.[14] Herein, we report the use of air-stable phosphine oxide preligands[15] for the activation of C–Cl and C–F bonds[16] in cross-coupling reactions.

The catalytic activity of different preligands was first evaluated in the Kumada cross-coupling reaction of electronically deactivated 4-chloroanisole (**1a**) with phenyl magnesium chloride (**2a**) at ambient temperature (Table 1 and the Supporting Information).[17] Diaminophosphine oxide **7** gave rise to more efficient catalysis than the corresponding diaminophosphine chloride **6**[14] (Table 1, entries 1 and 2). However, significant amounts of the undesired homocoupling product **5a** were also generated. Similar results were obtained with dioxophosphine oxides **8** and **9** (Table 1, entries 3 and 4). A more selective reaction was achieved with sterically hindered phosphine oxide **10** and particularly **11**, which bear aromatic substituents on nitrogen (Table 1, entries 5 and 6). Again, the corresponding phosphine chloride **12** gave rise to less efficient and less selective catalysis (Table 1, entry 7).

Recently, Dankwardt showed that a sterically encumbered phosphite facilitates efficient nickel-catalyzed Kumada cross-coupling reactions at elevated temperature.[11] However, neither the corresponding phosphite **13** (Table 1,

entry 8) nor arylphosphonate **14**[18] (Table 1, entry 9) exhibited reactivity comparable to that observed with phosphine oxide **11**. In contrast, alkyl-substituted secondary phosphine oxides yielded quantitative conversion of electrophile **1a** (Table 1, entries 11 and 12). In particular, the sterically hindered 1-adamantyl-substituted derivative **17**[19] gave rise to selective catalysis (Table 1, entry 12).[20] The high catalytic activity achieved with secondary phosphine oxides is most likely a result of the generation and subsequent deprotonation of phosphinous acid nickel complexes featuring anionic electron-rich P-bound ligands.[21]

The catalyst derived from phosphine oxide **11** facilitated efficient conversion of a representative set of electron-rich aryl chlorides at ambient temperature (Table 2). Also the functionalization of pyridyl chlorides (Table 2, entries 8–10) proceeded in high yields.

With optimized catalytic systems in hand, we tested the air-stable phosphine oxides **11**, **16**, and **17** as preligands in the cross-coupling of aryl fluoride **18a** (Table 3, entries 1–3). Interestingly, diaminophosphine oxide **11** exhibited superior catalytic activity in the activation of C–F bonds (Table 3, entry 1). Highly efficient catalysis was achieved with this preligand even at ambient temperature with different Grignard reagents (Table 3, entries 1, 4, and 5). These results suggest an improved reactivity compared to that in known protocols for nickel-catalyzed cross-coupling of aryl fluorides at ambient temperature.[12] Heteroarenes (Table 3, entries 7–10) gave rise to the corresponding products in high yields.[13a] Also the synthesis of terphenyl derivatives (Table 3, entries 11 and 12) and an amino-substituted biaryl (Table 3, entry 13), as well as the conversion of sterically more hindered naphtha-

[a] Reaction conditions: **18** (1.00 mmol), **2** (1.50 mmol), [Ni(acac)$_2$] (3 mol%), **11** (3 mol%), THF (2 mL), 20°C; yield of isolated product; Mes = 2,4,6-Me$_3$C$_6$H$_2$. [b] **16** (3 mol%) instead of **11**. [c] **17** (3 mol%) instead of **11**. [d] [Ni(acac)$_2$] (5 mol%), **11** (5 mol%). [e] [Ni(acac)$_2$] (8 mol%), **11** (8 mol%).

lene fluoride **18h** (entries 14 and 15), was feasible with phosphine oxide **11**. However, electron-poor polyfluorinated **18i** was not converted.

Finally, a combination of a palladium-catalyzed amination[14] and a nickel-catalyzed Kumada cross-coupling of the resulting electron-rich aryl fluoride **18j** was used for the regioselective functionalization of fluorobenzene **1h** (Scheme 1).

In summary, we reported the first use of air-stable secondary phosphine oxides for the activation of C–F bonds in aryl fluorides. In particular, a complex derived from the sterically congested preligand **11** showed activity superior to that of known protocols for the nickel-catalyzed cross-coupling reactions of aryl Grignard reagents at ambient temperature.

Experimental Section

Representative procedure for nickel-catalyzed cross-coupling reactions of aryl fluorides (Table 3, entry 15): A solution of [Ni(acac)$_2$] (7 mg, 0.03 mmol, 3 mol%) and **11** (13 mg, 0.03 mmol, 3 mol%) in dry THF (0.5 mL) was stirred for 10 min at ambient temperature under N_2. 1-Fluoronaphthalene (**18h**) (148 mg, 1.01 mmol) was added, and the solution was stirred for 5 min. Thereafter, **2b** (0.5 M in THF, 3.0 mL, 1.50 mmol) was added. The resulting dark solution was stirred at ambient temperature for 15 h. Et_2O (75 mL) and H_2O (75 mL) were added to the reaction mixture. The separated aqueous phase was extracted with Et_2O (2 × 75 mL). The combined organic layers were dried over $MgSO_4$ and concentrated in vacuo. The remaining residue was purified by column chromatography on silica gel (*n*-pentane/Et_2O, 300:1→200:1→150:1→100:1) to yield **3o** as a pale yellow solid (223 mg, 94%).

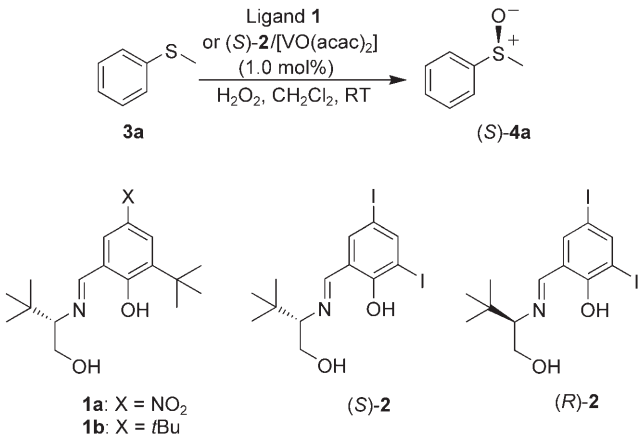
Vanadium-Catalyzed Sulfur Oxidation/Kinetic Resolution in the Synthesis of Enantiomerically Pure Alkyl Aryl Sulfoxides**

*Carmelo Drago, Lorenzo Caggiano, and Richard F. W. Jackson**

Chiral sulfoxides are an important class of compounds that find increasing use as chiral auxiliaries in asymmetric synthesis.[1,2] Current interest also reflects the existence of products with biological properties containing a sulfinyl group with a defined configuration.[3]

Several methods for the asymmetric oxidation of prochiral sulfides have been reported, including the use of chiral oxidants, such as chiral oxaziridines,[4] chiral hydroperoxides,[5] and enzymes.[6,7] The majority of investigations have concentrated on the use of chiral metal complexes[1,3,8–11] following the initial reports by Kagan and co-workers[12,13] and Modena and co-workers[14] on the use of variously modified Sharpless reagents for this reaction.

One of the most widely studied metal-based systems has been that discovered by Bolm and Bienewald,[15,16] who employed a combination of Schiff bases **1** derived from chiral amino alcohols and $[VO(acac)_2]$ (1.0 mol%; acac = acetylacetanoate), with aqueous hydrogen peroxide as the oxidant, in a two-phase system using dichloromethane as the solvent at 20°C (Scheme 1). The advantages of the system developed by Bolm et al. include high activity, the very simple reaction conditions, and the use of hydrogen peroxide as the oxidant. The only drawback associated with the initial ligands tested was that the levels of enantiomeric excess were good, rather than excellent. Other research groups sought to optimize the system, by variation of the aromatic aldehyde,[17–19] the amino alcohol,[20] and the manner of addition of hydrogen peroxide,[21] and in many cases it is striking that the best outcome was usually obtained when the reaction was conducted in dichloromethane at 0°C. A very nice application of the system developed by Bolm et al. was the asymmetric oxidation of di-*tert*-butyl disulfide, reported by Ellman and co-workers,[22] who have since reported the results of spectroscopic studies



Scheme 1. Vanadium-catalyzed asymmetric oxidation of alkyl aryl sulfides.

with a view to understanding the nature of the active catalytic species better.[23] The nature of the active species is still not completely established, but while spectroscopic studies indicate the presence of a vanadium(v)oxomonoperoxo species,[24] recent calculations suggest that the active species may be a vanadium(v)oxohydroperoxide.[25] Recently, the use of analogous salan ligands has been reported to give high levels of enantioselectivity (95% *ee*) in the oxidation of methyl phenyl sulfide, but lower levels of enantioselectivity were observed with other substrates.[26]

Anson and co-workers screened a variety of chiral Schiff base ligands, and found that the 3,5-diiodo ligand (*S*)-**2**, in combination with $[VO(acac)_2]$ gave excellent results in the catalytic asymmetric sulfoxidation of alkyl aryl sulfides with hydrogen peroxide, again in dichloromethane at 0°C.[27] For example, methyl phenyl sulfide was oxidized to (*S*)-methyl phenyl sulfoxide (81%, 90% *ee*). Recently, Bolm and co-workers reported that a combination of this ligand with iron is also very effective for the asymmetric oxidation of prochiral sulfides,[28,29] especially in the presence of substituted benzoic acids and with the corresponding lithium salts as additives.[30,31]

In all asymmetric oxidations of prochiral sulfides to sulfoxides, the possibility of subsequent kinetic resolution of the product sulfoxide by oxidation to the corresponding sulfone exists. Uemura and co-workers had demonstrated the viability of this process as long ago as 1993; they observed stereoselectivity factors of 7.4–8.5 for kinetic resolutions[32] using a catalyst prepared from $Ti(OiPr)_4$, 2,2′-dihydroxy-1,1′-binaphthyl (binol), and H_2O.[33] A more recent example makes use of a catalyst derived from WO_3 and cinchona alkaloids for the kinetic resolution of alkyl aryl sulfoxides using hydrogen peroxide.[34] The process developed by Uemura and co-workers[33,35] has been exploited by Scettri and co-workers (using furyl hydroperoxides as the oxidant)[36] and more recently by Chan and co-workers (using *tert*-butylhydroperoxide as the oxidant).[37] Specifically, Chan and co-workers described a process in which an initial oxidation at 0°C (at which temperature the enantioselectivity is optimum) and then at 25°C (where the kinetic resolution is most efficient) allowed the isolation of sulfoxides in reasonable

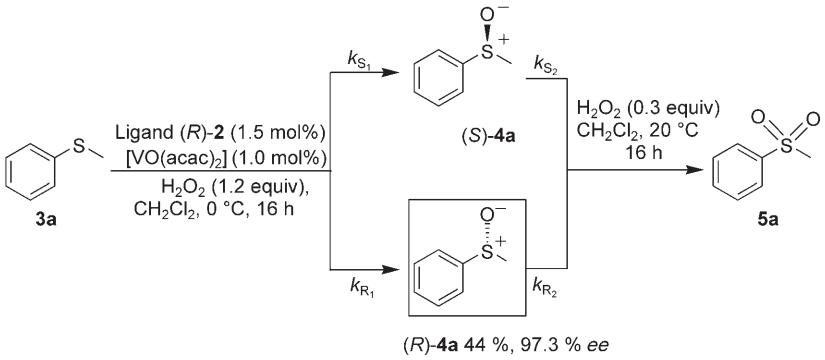
yields and excellent *ee* values (65% and 99.9% *ee* in the case of methyl *para*-tolyl sulfoxide, the best so far published).[37] However, it appears that no significant kinetic resolution in the oxidation of sulfoxides has so far been reported in studies in which chiral vanadium(IV)–Schiff base complexes were used. Nevertheless, such an effect has been reported in the case of vanadium–salan systems (selectivity factor $S = 7.3$ for the resolution of methyl phenyl sulfoxide) when larger amounts of catalyst (5 mol%) were used.[26]

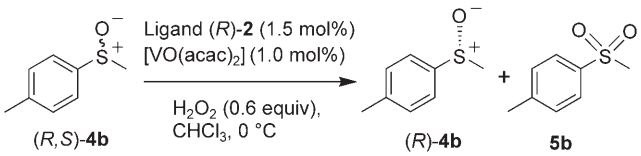
In an initial experiment it was confirmed that there was no significant kinetic resolution in the oxidation of racemic methyl phenyl sulfoxide using 3,5-diiodo ligand (*R*)-**2** (prepared from (*R*)-*tert*-leucinol, which has recently become commercially available) in combination with $[VO(acac)_2]$ and hydrogen peroxide in dichloromethane at 0°C ($S = 1.1$). However, a significant effect was observed ($S = 5.8$) when the kinetic resolution was carried out at 20°C. A tandem catalytic approach to the asymmetric oxidation of methyl phenyl sulfoxide using a combination of (*R*)-**2** with $[VO(acac)_2]$ in dichloromethane was developed: an initial oxidation step at 0°C followed by the addition of further oxidant to the same reaction vessel and warming to 20°C allowed the isolation of (*R*)-methyl phenyl sulfoxide (44%, 97.3% *ee*; Scheme 2). While this was an interesting result, the modest yield meant that it was not ideal from a preparative perspective.

Given the striking effect of temperature on the efficiency of the kinetic resolution, it seemed appropriate to explore the influence of the solvent. After substantial solvent screening in the oxidation of racemic methyl phenyl sulfoxide (**4a**) using (*R*)-**2** and $[VO(acac)_2]$ as the catalyst, and hydrogen peroxide as oxidant (0.5 equiv), it was found that the use of chloroform as the solvent[38] resulted in an improved kinetic resolution effect at 20°C ($S = 7.7$). No other solvent that was screened gave comparable results. The kinetic resolution in chloroform was more efficient at 0°C ($S = 11.6$). The highest value so far reported ($S = 28$) was obtained when the kinetic resolution of



Scheme 2. Oxidation/kinetic resolution process for the preparation of (*R*)-methyl phenyl sulfoxide (**4a**).

racemic methyl *para*-tolyl sulfoxide (**4b**) at 0°C was investigated (Scettri and co-workers reported $S = 23$ by using a stoichiometric process).[36] This kinetic resolution could be adapted for preparative use (with 0.6 equiv of hydrogen peroxide), which allowed the isolation of (*R*)-methyl *para*-tolyl sulfoxide (**4b**, 41% of a maximum of 50%, 98.0% *ee*), as well as sulfone **5b** (Scheme 3).



Scheme 3. Kinetic resolution of methyl *para*-tolyl sulfoxide.

The observation that the optimum temperature for the kinetic resolution of racemic sulfoxides with the catalyst derived from (*R*)-**2** and $[VO(acac)_2]$ in chloroform was 0°C (the optimum temperature for most previous asymmetric oxidations of prochiral sulfides using chiral vanadium(IV)–Schiff base complexes) suggested that these conditions might also be extremely effective for the enantioselective preparation of alkyl aryl sulfoxides. This indeed proved to be the case, and Table 1 shows results from the oxidation of a range of alkyl aryl sulfides to give the (*R*)-alkyl aryl sulfoxides (Scheme 4). In each case, the corresponding sulfone **5** was also observed, thus indicating that, as expected, some kinetic resolution had taken place. The only unsatisfactory result was the oxidation of methyl *para*-nitrophenyl sulfide (**3d**), which gave the product **4d** in only 86.9% *ee*.

Table 1: Asymmetric oxidation of alkyl aryl sulfides **3** in chloroform using ligand (*R*)-**2** with $[VO(acac)_2]$ and H_2O_2 (1.2 equiv).

Ar	R	Product	Yield [%][a]	*ee* [%][b]

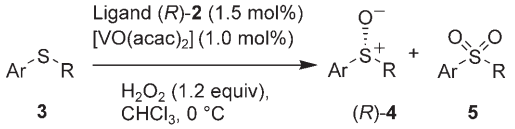
[a] Yield of isolated product. Reactions were conducted on a 1.5 mmol scale. [b] Determined by HPLC of the purified products on a chiral stationary phase using a DAICEL Chiralpak AS column.

These encouraging results on a small scale prompted an investigation into scaling the reaction up. Oxidation of methyl phenyl sulfide (**3a**) with 60.0 mmol of substrate under the same reaction conditions (albeit with an increase in the reaction time from 16 h to 48 h) allowed the isolation of (*R*)-



Scheme 4. Optimized asymmetric oxidation of alkyl aryl sulfides.

methyl phenyl sulfoxide (**4a**; 87%, 93% *ee*). The oxidation was also performed on the same scale using methyl *para*-tolyl sulfide (**3b**), to give (*R*)-methyl *para*-tolyl sulfoxide (**4b**; 82%, >99.5% *ee* after one recrystallization from Et_2O/hexane), and methyl *para*-bromophenyl sulfide (**3g**), to give (*R*)-methyl *para*-bromophenyl sulfoxide (**4g**; 77%, >99.5% *ee* after one recrystallization from Et_2O/hexane). In these latter two cases, the efficiency of the process was even higher than that observed on a small scale.

The combination of very high *ee* values with high yield, the consequence of an efficient initial asymmetric oxidation followed by an efficient kinetic resolution process, makes this system very practical for the catalytic asymmetric oxidation of simple alkyl aryl sulfides. Both enantiomers of ligand **2** are easily prepared on a multigram scale from commercially available precursors, and the ligands may be stored at room temperature on the open bench without any special precautions.

Experimental Section

Typical large-scale asymmetric oxidation procedure for the preparation of (*R*)-**4b**: A solution of [VO(acac)$_2$] (159.0 mg, 0.60 mmol) in chloroform (15 mL) was added to a solution of (*R*)-**2** (425.8 mg, 0.90 mmol) in chloroform (15 mL) and the reaction mixture was stirred for 2 h. A solution of **3b** (8.29 g, 60.0 mmol) in chloroform (30 mL) was added and the reaction mixture stirred for 30 min at room temperature before cooling it to 0 °C. After 30 min, 30% H_2O_2 (7.36 mL, 72.0 mmol) was added to the reaction mixture, which was stirred vigorously at 0 °C for 48 h. Samples (1–2 μL) were then removed at different times and diluted with 20% isopropanol/heptane for analysis by HPLC. The reaction was quenched with 10% $Na_2S_2O_3$ solution (200 mL) and the mixture extracted with chloroform (3 × 100 mL). The extracts were combined, washed with brine (3 × 100 mL), and dried ($MgSO_4$). Finally, the solvent was removed under reduced pressure. The crude product was purified by flash chromatography (EtOAc/petroleum ether 50:50). The purified product was dissolved in the minimum amount of hot diethyl ether, and hexane was added until the solution became turbid. The solution was then gently warmed to give a clear solution, which was allowed to cool to room temperature and then kept at −15 °C overnight to give the product sulfoxide as needles. The crystalline solid was then filtered and washed with cooled (−15 °C) hexane to (*R*)-**4b** (7.60 g, 82%), *ee* > 99.5% (determined by HPLC on a Daicel Chiralpak AS column, with 15% isopropanol in heptane, and a flow rate of 1.0 mL min^{-1}), $[\alpha]_D^{20} = 151$ ($c = 1.0$, acetone); [(Lit.[39] (*R*)-**4b**; *ee* 95%); $[\alpha]_D^{20} = 142$ ($c = 1.5$, acetone)].

Synthesis and Characterization of 2,4-Pentadiynenitrile—A Key Compound in Space Science**

*Yann Trolez and Jean-Claude Guillemin**

Many molecules have been detected in the interstellar medium, around the stars, in comets, and in the atmospheres of the planets or satellites of the solar system.[1,2] Several of these molecules were probably also present on primitive Earth. Among the satellites, Titan, the largest moon of Saturn, is considered as a frozen model of early Earth. Many compounds were observed in the atmosphere of Titan, and assessments by astrobiologists have revealed that it could have similar atmospheric components and pressure conditions as Earth had four billion years ago. It is generally believed that the first chemical steps that led to life might have taken place in the atmosphere of Titan, and that the products were kept by freezing.[3]

The family of compounds that associates one or several C–C triple bonds and only one carbonitrile substituent (H−(C≡C)$_n$−C≡N) plays an important role in astrobiology.[4] As an example, the largest molecule detected in the interstellar medium is $HC_{11}N$ ($n=5$). The first member of this family, cyanoacetylene (HC≡C−C≡N (**1**)), has been observed in the atmosphere of Titan,[3] in the interstellar medium,[1] in comets,[2] and in numerous laboratory simulations of planetary atmospheres.[5] It was often proposed as a key compound because it reacts readily with many nucleophiles,[6,7] and that could be the starting point of a rich organic chemistry in these media and particularly on primitive Earth.[8] Cyanobutadiyne (2,4-pentadiynenitrile, HC≡C−C≡C−C≡N (**2**)) is the second member of this family. It has been detected in the interstellar medium,[1] in comets,[2] and appears in numerous laboratory simulations of Titan's atmosphere.[5]

To confirm (or to disprove) models that foresee the presence of cyanobutadiyne on Titan, it is essential to have this molecule at hand. An infrared spectrum of the pure product would allow an estimation of the partial pressure of this molecule on Titan, provided it is detected there. The reaction of this compound with many reagents is of great interest in itself and by comparison with cyanoacetylene and cyanopropyne.[6,7] Moreover, the synthesis of pure cyanopolyynes with the formula H−(C≡C)$_n$−C≡N is the key to a better knowledge of this family of compounds.

However, although the preparation of cyanoacetylene was reported long ago,[9] cyanobutadiyne has never been prepared in a pure form. The most important approaches are the desilylation of the corresponding trimethylsilylcyanobutadiyne[10] and a direct-current discharge in a mixture of cyanoacetylene and acetylene.[11] The recent detection of HC_5N in the pyrolysis of pyridine at 1200 °C in the presence of PCl_3[12] shows, once again, how challenging the preparation of this species is. In these approaches, the analysis was performed in the gas phase by microwave or infrared spectroscopy, but cyanobutadiyne has never been characterized in the condensed phase (by NMR spectroscopy, for example).

We now report the first isolation of cyanobutadiyne, its characterization by ^{1}H and ^{13}C NMR spectroscopy and by HRMS. We also described photochemical studies to propose syntheses of this compound in the interstellar medium or on planetary atmospheres, and some chemical reactions (the addition of Me_2NH, NH_3, and *t*BuSH) to study its reactivity with nucleophiles.

In 1993, Knochel and co-workers reported the synthesis of cyanooctyne by the reaction of commercially available *para*-toluenesulfonyl cyanide (**3**) with an octynylzinc derivative.[13] Some other organometallic compounds have also been used in such cyanation reactions.[14] Most of these compounds were prepared in low-boiling-point solvents (mainly ethers) and were not easily isolated in pure form. Hence, even if the reaction of alkynyl metal compounds with **3** could give the expected product, the extraction of a kinetically unstable product from the reaction mixture and its purification would be a very difficult problem. Other heterocompounds, such as silicon derivatives, can only be obtained by heating the reaction mixture for long periods of time, and these methods cannot be used to prepare kinetically unstable compounds in a facile manner.[15] However, tin derivatives with various functional groups are easily prepared, can be isolated in pure form, and are often reasonably reactive. For instance, 1,3-butadiynyltributylstannane (**4**), a potential precursor for cyanobutadiyne, has already been synthesized.[16] Thus, we sought an approach starting from **4** that would allow the continuous extraction of cyanobutadiyne from the reaction mixture as it is formed.[17]

The reaction of **4** with excess cyanide **3** led to the cyanobutadiyne **2**, which was selectively trapped at −80 °C to remove low-boiling-point impurities [Eq. (1)]. The high-boiling-point impurities were removed in the first trap cooled at −30 °C. The compound was obtained in pure form but in only 15 % yield. About 300 mg of cyanobutadiyne (**2**) has been prepared in one experiment through this approach. The

dilution of the reagents in a solvent (DMSO, dichlorobenzene, tetraethyleneglycol dimethyl ether, BMI-PF6 (an ionic liquid)) gave the product in similar or lower yields. The ^{1}H NMR signal was observed at $\delta = 2.41$ ppm, slightly upfield of the chemical shift for cyanoacetylene ($\delta = 2.51$ ppm). In the ^{13}C NMR spectra, the five signals for H-C5≡C4-C3≡C2-C1≡N were easily assigned by the decrease in the coupling constants between 5-H and the five carbon atoms. The molecular ion was detected by HRMS. Pure cyanobutadiyne can be kept indefinitely in dry ice, but decomposes slowly at −40 °C in pure form or at room temperature in $CDCl_3$.

This reaction between an unsaturated stannane and **3** can be extended to the preparation of cyanopropyne (85 % yield) or cyanoacetylene (37 % yield). Crotylstannane and allenylstannane reacted with a partial allylic transposition (crotyl/1-methallyl cyanide = 3:2, 43 % yield; allenyl/propargyl cyanide = 2:3, 72 % yield respectively).

The formation of cyanobutadiyne in the interstellar medium or in planetary atmospheres could occur photochemically.[18] Our synthesis of **2** allows traces of this molecule to be detected easily by ^{1}H NMR spectroscopy in various mixtures of compounds. Its presence can be confirmed by the addition of small amounts of an authentic sample to the NMR sample solutions and the observation of only one signal at $\delta_H = 2.41$ ppm. Thus we tried to determine which mixtures of gases would allow the photochemical formation of cyanobutadiyne. We irradiated gas mixtures with a mercury lamp ($\lambda =$ 185 and 254 nm or $\lambda = 254$ nm) with mercury UV lamps. We studied the photolysis of cyanoacetylene by itself, of cyanoacetylene with acetylene or butadiyne (**5**), and of dicyanoacetylene (**6**) with acetylene or butadiyne. All these compounds have been observed in the interstellar medium and the atmosphere of Titan. Several compounds were formed during the irradiations,[19] but we only discuss cyanobutadiyne.

We did not detect cyanobutadiyne in the photolysis of cyanoacetylene (50 mbar) by itself at 254 nm or at 185 and 254 nm. However, traces were detected in the photolysis of cyanoacetylene (50 mbar) with acetylene (50 mbar) at 185 and 254 nm. The best results were obtained when cyanoacetylene (3 equiv) absorbed most of the light (80 %).[19] Cyanobutadiyne was not observed in the same experiment with the 254-nm lamp. These results allow us to propose a reaction pathway that accounts for the fact that the breaking of the H–C bond of cyanoacetylene [Eq. (2)] and acetylene [Eq. (3)]

$$HC{\equiv}C{-}C{\equiv}N\ (\mathbf{1}) \xrightarrow{h\nu} H^{\cdot} + {}^{\cdot}C{\equiv}C{-}CN \tag{2}$$

$$H{-}C{\equiv}C{-}H \xrightarrow{h\nu} {}^{\cdot}C{\equiv}C{-}H + H^{\cdot} \tag{3}$$

does not occur at 254 nm irradiation.[20,21] A radical recombination of ethynyl and cyanoethynyl radicals could lead to the formation of **2** on a third body [Eq. (4)]. However, the

$${}^{\cdot}C{\equiv}C{-}H + {}^{\cdot}C{\equiv}C{-}CN \xrightarrow{M} \mathbf{2} \tag{4}$$

amounts of both radicals are probably too low to allow them to come close enough to each other to react. Consequently, the addition of the cyanoethynyl radical to acetylene [Eq. (5)]

$${}^{\cdot}C{\equiv}C{-}CN + H{-}C{\equiv}C{-}H \rightarrow \mathbf{2} + H^{\cdot} \tag{5}$$

or of the ethynyl radical to **1** [Eq. (6)] with concomitant

$${}^{\cdot}C{\equiv}C{-}H + \mathbf{1} \rightarrow \mathbf{2} + H^{\cdot} \tag{6}$$

elimination of a hydrogen radical is a more likely reaction pathway. On the basis of previous studies[18,22] and by comparison with the addition of cyanide to acetylene,[23] the reaction pathway corresponding to Equations (2) and (5) seems to be the most favourable.

A mixture of **1** (50 mbar) and **5** (50 mbar) was irradiated at 254 or at 185 and 254 nm. In both cases, cyanobutadiyne (**2**) was not detected. A mixture of dicyanoacetylene (**6**) (50 mbar) and acetylene (50 mbar) was also irradiated. Traces of **2** were detected in the sample irradiated at 254 or at 185 and 254 nm. In this case, the absorption coefficients of each reactant gas are quite similar at 185 nm but only **6** absorbs light at 254 nm.[19] Compound **2** could possibly be formed by the breaking of an NC–C bond of **6** [Eq. (7)] and

$$NC{-}C{\equiv}C{-}CN\ (\mathbf{6}) \xrightarrow{h\nu} N{\equiv}C^{\cdot} + {}^{\cdot}C{\equiv}C{-}CN \tag{7}$$

then by addition of cyanoethynyl radical to acetylene [Eq. (5)]. On the other hand the formation of cyanoacetylene (**1**) in these reactions can be attributed to the addition of the cyanide radical to acetylene.[23]

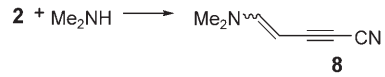
Under irradiation at 254 or at 185 and 254 nm, the photolysis of mixtures of **5** (50 mbar) and **6** (50 mbar) led to small amounts of **2**. The addition of the cyanide radical to **5** [Eq. (8)] gives a simple explanation of these results.[24]

$$N{\equiv}C^{\cdot} + H{-}C{\equiv}C{-}C{\equiv}C{-}H\ (\mathbf{5}) \rightarrow \mathbf{2} + H^{\cdot} \tag{8}$$

It also seems possible that cyanohexatriyne (HC≡C–C≡C–C≡C–C≡N (**7**)) is formed by the addition of the cyanoethynyl radical to butadiyne. Similarly, **7** might be formed in the photolysis of mixtures of **1** and **5** reported above. In both cases, without an authentic sample of **7**, we were not able to confirm its presence on the sole basis of the signal observed at $\delta_H = 2.38$ ppm. For the moment we have demonstrated that cyanobutadiyne (**2**) is easily formed in the photolysis of several mixtures of gases. More sophisticated experiments will be necessary to quantify its formation.

Cyanoacetylene reacts readily with nucleophiles such as ammonia, primary or secondary amines, and thiols to give the corresponding adduct.[6,7,25,26] In the same way, we investigated the reactivity of cyanobutadiyne, particularly with nucleophiles, and determined the products formed. Cyanobutadiyne can potentially undergo 1,4- or 1,6-addition. In this preliminary study, we carried out the addition to cyanobutadiyne in a solvent of Me_2NH, NH_3, and *t*BuSH.

N,*N*-Dimethylamine reacts with cyanobutadiyne (**2**) to give the corresponding 1,6-adduct. The 5-(dimethylamino)-4-penten-2-ynenitrile (**8**) was analyzed by HRMS and by ^{1}H and ^{13}C NMR spectroscopy [Eq. (9)]. Compound **8** decomposes upon standing at room temperature. Similarly, ammonia



(9)

8

reacts with cyanobutadiyne to give 5-amino-4-penten-2-ynenitrile (**9**), which is kinetically unstable at room temperature, even when diluted in $CDCl_3$ ($\tau_{1/2} = 1$ h) [Eq. (10)]. A

(10)

9

stable adduct, 5-[(1,1-dimethylethyl)thio]-4-penten-2-ynenitrile (**10**) was obtained by the addition of *t*BuSH to **2** in the presence of a catalytic amount of triethylamine [Eq. (11)]. In all cases, only the product corresponding to the 1,6-addition reaction was observed.

(11)

10

In conclusion, cyanobutadiyne (**2**) was synthesized in pure form by the reaction of the 1,3-butadiynyltributylstannane with *p*-toluenesulfonyl cyanide. This approach paves the way to the synthesis of other cyanopolyynes and the corresponding isotopomers. According to our study, cyanobutadiyne can possibly be formed on Titan or in the interstellar medium by photolysis of mixtures of acetylene and cyanoacetylene or dicyanoacetylene or mixtures of dicyanoacetylene and butadiyne. Compound **2** only undergoes 1,6-addition with nucleophiles. The measurement of the gas-phase IR spectrum of a pure sample of **2**, the study of its photochemistry, and the extension of this approach to other cyanopolyynes are currently underway in our laboratory.

Experimental Section

2: Two traps equipped with stopcocks were attached to a vacuum line. 1,3-Butadiynyltri-*n*-butylstannane (**4**; 0.54 g, 1.6 mmol) and *p*-toluenesulfonyl cyanide (**3**; 0.90 g, 5.0 mmol) were introduced into a flask equipped with a stirrer bar and the flask was attached to the vacuum line. The flask was immersed in a bath and slowly warmed to 70 °C over 1 h. The cyanobutadiyne (**2**) formed was continuously removed by distillation in vacuo from the reaction mixture. The first trap, cooled at −30 °C, selectively removed the less-volatile products, and **2** (18 mg, 0.24 mmol, 15 %) was selectively condensed in the second trap cooled at −80 °C. IR (gas phase): $\tilde{\nu} = 642$, 1272, 2190 ($\nu_{C\equiv C}$), 2253 ($\nu_{C\equiv N}$), 3328 cm^{-1} ($\nu_{C\text{-}H}$); ^1H NMR ($CDCl_3$, 400 MHz, 298 K): $\delta =$ 2.41 ppm; ^{13}C NMR ($CDCl_3$, 100 MHz, 298 K): $\delta = 48.9$ ($^4J_{C,H} <$ 1 Hz; C2), 66.0 ($^2J_{C,H} = 52.2$ Hz; C4), 66.9 ($^3J_{C,H} = 6.4$ Hz; C3), 71.7 ($^1J_{C,H} = 265.0$ Hz; C5), 104.8 ppm (C1); HRMS: calcd for HC_5N: 75.01090; found: 75.0109; MS: *m/z* (%): 76 (3.6), 75 (100), 74 (11.2), 50 (3.4), 49 (6.8).

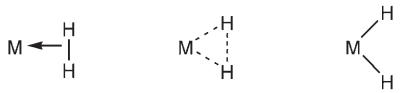
Dihydrogen or Dihydride?

DOI: 10.1002/anie.200502297

A Neutron Diffraction Study of $[OsClH_3(PPh_3)_3]$: A Complex Containing a Highly "Stretched" Dihydrogen Ligand**

Muhammed Yousufuddin, Ting Bin Wen, Sax A. Mason, Garry J. McIntyre, Guochen Jia, and Robert Bau**

Oxidative addition of dihydrogen to a transition metal is one of the most important steps in many catalytic processes.[1] Some years ago, Kubas and co-workers[2] used neutron diffraction to show for the first time that H_2 could bind to a metal in a sideways fashion as η^2-H_2, now called the nonclassical dihydrogen ligand (**I**). Further insertion of the metal into the dihydrogen ligand, upon continuation of the oxidative addition process, weakens the H–H bond causing it to lengthen (**II**) and finally cleave to form two terminal hydride ligands (**III**). The weakening of the H–H bond (**II**) is considered to be an intermediate step along the pathway, and it is this step that has garnered a considerable amount of interest.[3–5]



I **II** **III**

Structural studies[5] in this area have thus far provided significant information regarding the metal–dihydrogen interaction along the reaction pathway. The side-on, or nonclassical dihydrogen complexes **I**, have an H–H bond length of the order of 0.8–1.0 Å (not much longer than the H–H distance of 0.74 Å in H_2 itself[6]) while classical dihydride complexes **III** (with essentially no H···H interactions) generally have H···H distances greater than 1.7 Å. The intermediate, or stretched dihydrogen complexes **II** (also called "compressed dihydride" complexes[3a,f,g]) have H–H distances in the range 1.1–1.5 Å.[4] Although a moderate number of stretched dihydrogen complexes have been reported, the H–H distances in these complexes have mainly been obtained from NMR spectroscopic data (T_1 and $J_{H,D}$ measurements) or from X-ray data, which are not very sensitive to H positions.[3]

The most reliable technique to determine H–H distances in hydride complexes is neutron diffraction. However, only a few examples of molecules exhibiting the intermediate stage **II** have been structurally characterized by this technique.[4,5] Intramolecular "reaction trajectories" have been mapped out before in a classical series of studies of organic molecules by Bürgi and Dunitz using X-ray crystallography.[7a] In addition, Crabtree et al.[7b] have used a series of X-ray and some neutron structures to map the lengthening of a C–H bond during metal insertion, although the variation in those C–H distances (±0.1 Å) is much less pronounced than the large distributions of H···H distances we will discuss later in Table 1. Several authors have pointed out[3a,h,i] that the energy barrier for moving the H···H distance from 1.00 to 1.60 Å is only about 4 kcal mol^{-1}, which suggests that the ligand environment around the metal atom should have a significant effect.[3c] Clearly, a more complete set of stretched dihydrogen ligands is needed to obtain a clearer understanding of this intriguing interaction. In this regard, we report herein a new example of the stretched dihydrogen phenomenon in the complex $[OsClH_3(PPh_3)_3]$ (**1**).

The title complex was prepared by the reaction of $[OsCl_2(PPh_3)_3]$[8a] with H_2 in the presence of NEt_3, as described by Caulton and co-workers.[8b] The compound **1** was first made about 30 years ago, but was wrongly formulated as $[OsClH(PPh_3)_3]$.[8c] However, a careful analysis of the ^{1}H NMR spectroscopic data by Caulton et al. showed that the complex **1** was actually $[OsClH_3(PPh_3)_3]$ with a nonclassical dihydrogen ligand, as suggested by the short relaxation time ($T_1 = 26$ ms) of the hydride at −40 °C and 300 MHz. However, a minimum T_1 value could not be determined due to the low solubility of the Os complex at low temperatures, nor was it possible to conclude from the NMR study if the suspected dihydrogen ligand was *trans* to a chloride or a phosphane ligand.[8b] It was also difficult to determine the $J_{H,D}$ coupling constant for the isotopolog $[OsClHD_2(PPh_3)_3]$ due to the broadness of the hydride signal. Thus, it was impossible to estimate the H–D distance in the complex. In the present study, the structure has been unequivocally determined by a single-crystal neutron diffraction analysis.

The sample was initially characterized by X-ray diffraction[9] in order to determine the atomic coordinates used for neutron diffraction data analysis. The neutron data analysis was carried out both at room temperature and at 5 K on a crystal measuring $1.2 \times 0.8 \times 0.3$ mm^3 using the VIVALDI diffractometer at the Institut Laue–Langevin in Grenoble.[10] Full-matrix least-squares refinement of atomic positions yielded the following agreement factors for the low-temperature data set: $R(F) = 0.0831$ for 3560 independent reflections ($I > 2\sigma(I)$).[11]

Figure 1 shows the molecular sructure of **1** and its core at 5 K. Our results reveal the presence of a dihydrogen ligand

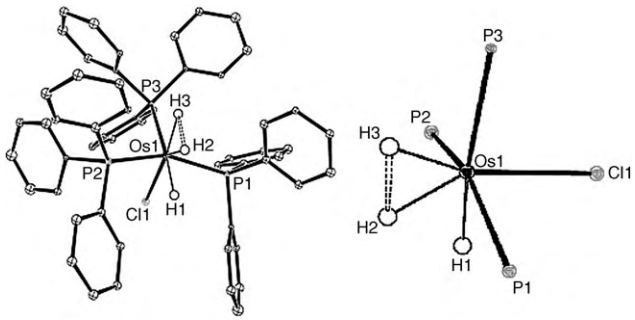

Figure 1. Molecular structure of $[OsClH_3(PPh_3)_3]$ (**1**, left) and its core (right). The H2–H3 distance is 1.48(2) Å and the H1···H2 distance is 1.67(2) Å, as determined from this neutron study. Other notable bond distances include: Os–H2 = 1.59(2) and Os–H3 1.61(1) Å.

(H2···H3), although not of the nonclassical type originally envisioned,[8b] but of the "stretched" variety (**II**), with an H···H bond distance of 1.48(2) Å. In addition, one terminal hydride ligand (H1) was located, plus one chloride and three phosphane ligands. The Os–H1 distance to the terminal hydride ligand (1.62(2) Å) is similar to other Os–H distances reported in literature,[12] and this terminal hydride ligand H1 is positioned 1.67(2) Å from the H2 atom of the dihydrogen ligand, a distance which is in the range of slightly nonbonding interactions.[5] It should be noted that, within experimental error, we found a barely significant increase in geometry between the neutron structures refined at 5 K and at 295 K,[13a] which is somewhat consistent with a theoretical study which suggests that the H···H distance in a stretched dihydrogen ligand could be temperature dependent.[13b]

The molecule is substantially distorted from an ideal octahedral geometry. The terminal hydride is located *trans* to a phosphane ligand (H1-Os1-P3 172.5(6)°) while the dihydrogen ligand sits essentially *trans* to the chloride ligand (X-Os1-Cl1 171.4(3)°, where X represents the center of the dihydrogen ligand). The dihydrogen, hydride, and chloride ligands lie in the same plane (Figure 1), which is similar to the atomic arrangement in $[IrCl_2H(H\cdots H)(PiPr_3)_2]$.[4e] Two other stretched dihydrogen moieties previously studied by neutron diffraction, in which the dihydrogen ligands were also located *trans* to negatively charged ligands, were also found in six-coordinate osmium complexes.[4b,c]

Speculation can be made as to the role of the chloride ligand in influencing the geometry of complex **1**. Some years ago we reported the results of a neutron diffraction analysis of $[OsH_4(PMe_2Ph)_3]$, which contains four terminal hydrides with an average Os–H bond distance of 1.659(3) Å.[12a] The only apparent difference between that complex and the present complex **1** (besides the difference in phosphane ligands) is the substitution of a chloride ligand for a hydride ligand. Perhaps the presence of the *trans* chloride ligand, which is more electronegative than hydride, promotes closer H···H interactions,[3h] and this could be the driving force for formation of the stretched dihydrogen ligand.

The main point of our communication is shown in Table 1, which summarizes experimental data, from which a crude approximation of a "reaction profile" can be derived, for the specific process of oxidative addition of a metal atom into an H–H bond. In this table, we have included all neutron diffraction data on H–H complexes that were available to us, with the exception of the last category at the bottom of the table ("classical" hydride complexes, in which there are no H···H bonding interactions), for which neutron results are too numerous to be listed in full.

Table 1: A selection of H···H distances [Å] and H-M-H angles [°] determined by neutron diffraction.[a]

	Compound	1 H–H	2 H-M-H	3 Av. M–H	4 "Adjusted" av. M–H[b]	5 M–X[c]	6 "Adjusted" M–X[b,c]

Columns 1, 2, and 3 list the experimental H–H distances, H-M-H angles, and M–H distances, respectively, sorted in the order of increasing H–H distance. One can discern a very crude general trend of longer H–H distances coupled with shorter M–H distances. However, one has to account for differences in atomic radii of the metal atoms, and so in column 4 we list "adjusted" M–H distances in which the differences in atomic radii are used as "correction factors", with the atomic radius of iron selected arbitrarily as a "standard". One can see that column 4 is somewhat "smoother" than column 3. Finally, recognizing that one should rather consider metal–ligand distances instead of metal–hydrogen distances, we have provided two extra columns in which M–X distances are tabulated (X is the midpoint of the H–H bond). Once again, we give "unadjusted" and "adjusted" values (columns 5 and 6, respectively), in which column 6 contains the values "corrected" for differences in atomic radii. The differences between M–H distances (column 3) and metal–ligand distances (column 5) are not large for true nonclassical H_2 complexes (top portion of Table 1), but the differences become more apparent where "slightly stretched" and "significantly stretched" dihydrogen complexes are concerned (middle portion of Table 1).

Perhaps the most meaningful comparison is between column 1 (or column 2) and column 6. Although there is obviously some scatter in the data, one can discern a definite trend in which an increasing H–H distance appears to be correlated with a decreasing metal–ligand distance. In other words, this is experimental evidence for the reaction pathway **I**→**II**→**III**. A somewhat similar conclusion for metal insertion into a C–H bond has appeared earlier,[7b] but in that case only a small spread of C–H distances was observed, much more subtle than the large spread in H–H distances listed in Table 1. One can conclude from this comparison that the process of oxidative addition into an H–H bond is intrinsically different to oxidative addition into a C–H bond.

[11] Crystals suitable for neutron-diffraction studies were grown by layering a minimum amount of hexane over a dichloromethane solution of the compound under an atmosphere of hydrogen. A triangular prismatic single crystal with a volume of less than 0.5 mm^3 was wrapped in aluminum foil in a helium-filled glove bag and glued to a vanadium pin. The crystal was then mounted in a He cryostat on the Very-Intense Vertical-Axis Laue Diffractometer ("VIVALDI") at the Institut Laue–Langevin in Grenoble, France. Initially, data collection proceeded at room temperature until a sufficient number of unique reflections was obtained for structure refinement. This was a precautionary step taken just in case the crystal cracked during the subsequent cooling procedure. The crystal was then cooled to 5 K and data collection repeated. Crystal data for **1** (unit cell dimensions from the X-ray analysis[9]): $C_{54}H_{48}ClOsP_3$, $M_r = 834$, approximate crystal dimensions $1.2 \times 0.8 \times 0.3$ mm^3; orthorhombic, space group $Pca2_1$, $a = 19.258(1)$, $b = 12.949(1)$, $c = 17.836(1)$ Å, $V = 4448(1)$ $Å^3$, $F(000) = 862$, $Z = 4$, $\rho_{calcd} = 1.245$ $g\,cm^{-3}$, $\mu = 0.310$ mm^{-1}. $\theta = 4$–$72°$, completeness = 72%, resolution d-(min) = 0.92 Å, white beam neutron source ($\lambda = 0.9$–2.7 Å), $T = 5$ K, 25311 measured data (VIVALDI instrument with cylindrical area detector made from Gd_2O_3-doped BAFBR:Eu^{2+} image plates), of which 4552 ($R_{int} = 0.2856$) were unique. Intensities were indexed and processed using LAUEGEN, reflections were integrated and the background removed using INTEGRATE+, reflections were normalized to a constant incident wavelength using LAUENORM, and neutron data were phased using the atomic coordinates determined from the X-ray structure. General Rule for the Stabilization of Fullerene Cages Encapsulating Trimetallic Nitride Templates**

*Josep M. Campanera, Carles Bo, and Josep M. Poblet**

Fullerenes containing a trimetallic nitride template (TNT) within the cage are a particularly interesting class of endohedral metallofullerenes. Not only are the cage properties modified by the presence of the incarcerated group but, almost uniquely among endohedral metallofullerenes, they are quite stable. Furthermore, they can be produced in multimilligram quantities, and these amounts should increase in the future. The electronic effect of the TNT is such that some fullerenes of sizes and symmetry that are otherwise relatively unstable become available for investigation.[1] The general formula of these TNT endohedral metallofullerenes is $A_{3-n}B_nN@C_k$ ($n=0$–3; A,B = group III, IV, and rare-earth metals; $k=68$, 78, and 80) with the archetypal examples of: $Sc_3N@C_{80}$,[2,3] $Sc_3N@C_{68}$,[4] and $Sc_3N@C_{78}$.[5] The structures of $Sc_3N@C_{78}$, $Sc_3N@C_{80}$, and $Sc_3N@C_{68}$ are displayed in Figure 1.

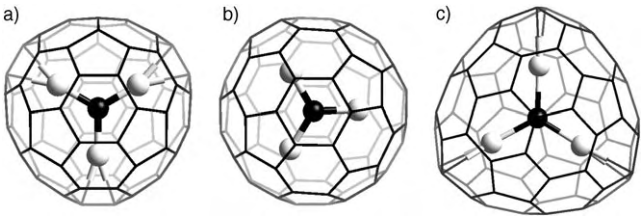

Figure 1. Optimized structures of the archetypal TNT endohedral metallofullerenes: a) D_{3h}-$Sc_3N@C_{78}$, b) C_s-$Sc_3N@C_{80}$ (I_h-C_{80}:**7**), and c) D_3-$Sc_3N@C_{68}$.

Special attention has been paid to lutetium-based TNT endohedral metallofullerenes, $Lu_{3-n}A_nN@C_{80}$ ($n=0$–2; A = Gd, Ga, and Ho), because they may prove useful as multifunctional contrast agents for X-ray, magnetic resonance imaging, and radiopharmaceuticals.[6] The aim of this research is to use methods based on density functional theory (DFT) to answer the questions: How can the stability of the TNT endohedral metallofullerenes be predicted? Which fullerene cages between C_{60} and C_{84} will be capable of encapsulating TNTs? Aihara and co-workers proposed the bond resonance energy (BRE)[7] to be an indicator of the particular stabilization of free fullerene cages when they encapsulate metal units.[8] However, this method was not a predictive tool because it could not answer whether or not new cages will be capable of encapsulating TNTs.

Up to now, only four carbon cages have been capable of encapsulating TNT units: D_3-C_{68}:**6140**, D_{3h}-C_{78}:**5**, D_{5h}-C_{80}:**6** and I_h-C_{80}:**7**. All these cages, except C_{68}, satisfy the isolated-pentagon rule (IPR). But it is interesting to see that in all cases the empty IPR fullerene isomers isolated so far are different from the carbon cages found in isolable TNT endohedral metallofullerenes. The incorporation of a TNT into the fullerene results in an electron transfer from the metal atoms to the carbon cage, in other words, the formation of a stable ion pair. It should be noted that these fullerene cages are produced only when they are negatively charged by the encapsulated species. Theoretical calculations indicated that the thermodynamic stability of a fullerene molecule depends heavily on the negative charge that resides on it.[9] The bond between the nitride and the cage is markedly defined by the ionic model $Sc_3N^{6+}@C_k^{6-}$ ($k=68$, 78, and 80).[10] From the geometric point of view, although the free Sc_3N molecule is pyramidal, this fragment has a planar structure inside the fullerene cage. When the Sc_3N unit is

encapsulated, there is a significant local distortion in the fullerene cage. This distortion results in the outward movement of the carbon atoms closest to the scandium ions, which gives rise to an increase in the tendency of the carbon structure to form a pyramid and an increase in the radius of the fullerene cage.

The first ^{13}C NMR spectroscopic analysis of $Sc_3N@C_{80}$ revealed that the Sc_3N moiety rotates freely in the highly symmetric I_h-C_{80}:**7** isomer.[2] Thus, several different orientations of the TNT were found for the slightly different TNT endohedral metallofullerenes of I_h-C_{80}:**7**—$Lu_3N@C_{80}$,[11] $ErSc_2N@C_{80}$,[12] $Sc_3N@C_{80}$,[2] and $Sc_3N@C_{80}$-$C_8H_6(OCH_3)_2$.[13] DFT calculations corroborated that the differences among the most stable isomers are rather small, <0.10 eV.[10,14] Later, a minor new isomer of $Sc_3N@C_{80}$, which corresponds to the Sc_3N fragment encapsulated by the D_{5h}-C_{80}:**6** isomer, was also isolated and characterized.[3] We focus our study only on the TNT endohedral metallofullerenes of I_h-C_{80}:**7** isomer. Neither of these C_{80} isomers have been isolated as empty fullerenes and are not even the most stable isomers among the seven distinct isomers that satisfy the IPR:[15] D_{5d}-C_{80}:**1**, D_2-C_{80}:**2**, C_{2v}-C_{80}:**3**, D_3-C_{80}:**4**, $C_{2v'}$-C_{80}:**5**, D_{5h}-C_{80}:**6**, and I_h-C_{80}:**7**.[16] Two empty-cage isomers, D_2-C_{80}:**2** and D_{5d}-C_{80}:**1**, have been isolated,[17] and theoretical calculations have shown that the I_h-C_{80}:**7** structure is the less-stable isomer overall.[18] However, electronic-structure calculations showed that the stability of the I_h-C_{80}:**7** isomer increases markedly when six electrons are added to the cage.[19] In the case of $Sc_3N@C_{78}$, the $D_{3h'}$-C_{78}:**5** isomer has not been calculated as the most stable nor has ever been isolated as an empty cage. There are five IPR isomers for the empty C_{78} cage with the following relative stability order: $C_{2v'}$-C_{78}:**3** > C_{2v}-C_{78}:**2** > D_3-C_{78}:**1** > $D_{3h'}$-C_{78}:**5** > D_{3h}-C_{78}:**4**.[20] Unlike in $Sc_3N@C_{80}$, in $Sc_3N@C_{78}$ the metal atoms reside over three pyracylene 6:6 C–C bonds. The fourth fullerene cage, which is capable of incarcerating four atoms, is the non-IPR D_3-C_{68}:**6140**. Other non-IPR structures have also been investigated for $Ca@C_{72}$,[21,22] $La_2@C_{72}$,[23] $Ca@C_{74}$,[21] $Sc_2@C_{74}$,[21,24] and $Sc_2@C_{66}$.[25] It is interesting to note that the only known violations of the IPR rule occur in endohedral metallofullerenes. For the C_{68} stoichiometry, the carbon surface of which consists solely of pentagons and hexagons, there are 6332 possible isomers. Nevertheless, the detailed structural characterization of $Sc_3N@C_{68}$ showed that the carbon cage is the 6140 isomer.[4] Although the cage radius of D_3-C_{68}:**6140** is not only considerably smaller but also distorted, the TNT guest can be encapsulated in a plane in which scandium atoms are directly connected to 5:5 ring junctions.[26]

Formally, a total of six electrons go from the highest occupied nitride orbitals to the lowest unoccupied cage orbitals. This formal electron transfer is accompanied by a large binding energy for the encapsulation process. These were calculated to be -173, -224, and -268 kcal mol^{-1} for $Sc_3N@C_k$ when $k=68$, 78, and 80, respectively.[10] The $D_{3h'}$-C_{78}:**5** isomer has a closed-shell ground state with three low unoccupied orbitals of symmetries a_2' (-5.15 eV) and e′ (-4.88 eV) that are π-antibonding orbitals basically centered in the set of pyracylene 6:6 C–C bond type. These unoccupied orbitals can receive six electrons from the three highest occupied orbitals of the TNT, which are very high in energy: a_1' (-4.44 eV) and e′(-3.51 eV), see Figure 2. For the I_h-C_{80}:**7** isomer, previous theoretical calculations have shown that it has the open-shell configuration $(t_{1g}+h_u)^{16}(g_g)^2(a_g+h_g)^0$.

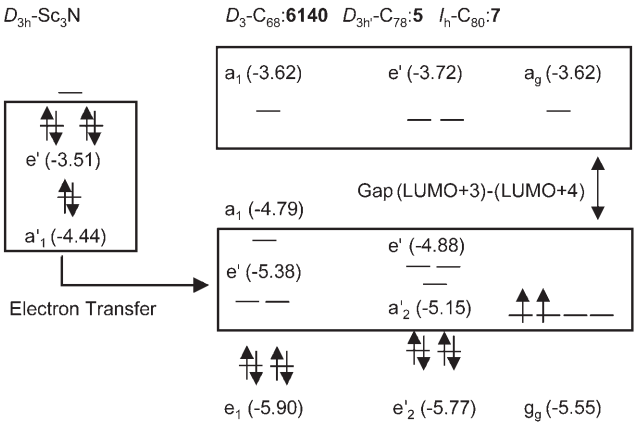

Figure 2. Representation of the ionic bond between the trimetallic nitride template (TNT) and the fullerene cages D_3-C_{68}:**6140**, $D_{3h'}$-C_{78}:**5**, and I_h-C_{80}:**7**. There is a formal transfer of six electrons from the three highest occupied orbitals of the TNT unit to the three lowest unoccupied orbitals of the fullerene cages. Consequently, the $M_3N@C_k$ ($k=68$, 78, and 80) complexes are described as $Sc_3N^{6+}@C_k^{6-}$ with a relatively large HOMO–LUMO gap nearly equal to the (LUMO+3)–(LUMO+4) found in the free cages: The (LUMO+3)–(LUMO+4) rule.

Moreover, I_h-C_{80}:**7** may deform to lower symmetries by Jahn–Teller distortion.[27] It represents an electronic configuration with only two electrons in four low-lying degenerate orbitals, -5.55 eV, which can easily accept six electrons. As a consequence of this electron-charge transfer, the resulting endohedral has a closed-shell configuration. D_3-C_{68}:**6140** has a closed-shell ground state with a HOMO–LUMO gap of 0.52 eV and with three low unoccupied orbitals of symmetries e′ (-5.38 eV) and a_1 (-4.79 eV), which can easily accept six electrons as the other two fullerenes do. Indeed, after the electron-charge transfer, the cage is stabilized as the final endohedral complex has a HOMO–LUMO gap of 1.27 eV. A similar gap was found for the TNT endohedral complexes of $D_{3h'}$-C_{78}:**5** and I_h-C_{80}:**7** with 1.24 and 1.18 eV, respectively. These electronic considerations are the key to rationalizing why only some cages can encapsulate TNTs.

On the one hand, the three cages studied here—D_3-C_{68}:**6140**, $D_{3h'}$-C_{78}:**5**, and I_h-C_{80}:**7**—have three very low-lying LUMOs accompanied with a large energy separation between the LUMO+3 and LUMO+4 (see Figure 2). On the other hand, the TNT has three HOMOs that are relatively high in energy. Consequently, the cage orbitals can easily accommodate six electrons that stem from the three destabilized orbitals. Moreover, the electronic structure of the empty fullerenes suggests that it acquires, presumably, a considerable HOMO–LUMO gap after a transfer of six electrons, thus giving stability to the final complex. The final HOMO–LUMO gap of the TNT endohedral metallofullerenes can be estimated from the gap between LUMO+3 and LUMO+4

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

of the free cages. The calculated and estimated values are 1.27/1.17 eV for $Sc_3N@C_{68}$, 1.24/1.16 eV for $Sc_3N@C_{78}$, and 1.18/1.93 eV for $Sc_3N@C_{80}$. The main conclusion that can be drawn from this observation is that we can predict HOMO–LUMO gaps by simply checking the molecular-orbital energies of the free fullerene cage. In principle, only the free isomers with a large (LUMO + 3)–(LUMO + 4) gap will be predisposed to encapsulate TNTs. To check whether this statement can be generalized, we calculated (LUMO + 3)–(LUMO + 4) gaps for all the IPR isomers from C_{60} to C_{84}. There are 51 IPR isomers: 1 of C_{60}, C_{70}, C_{72}, and C_{74}; 2 of C_{76}; 5 of C_{78}; 7 of C_{80}; 9 of C_{82}; 24 for C_{84}.[16] The result is quite surprising and conclusive: the (LUMO + 3)–(LUMO + 4) gap for all IPR cages is smaller than 1 eV, except for C_{60}, D_{3h}-C_{78}:**5**, D_{5h}-C_{80}:**6**, and I_h-C_{80}:**7** isomers, see Figure 3. C_{60} can be

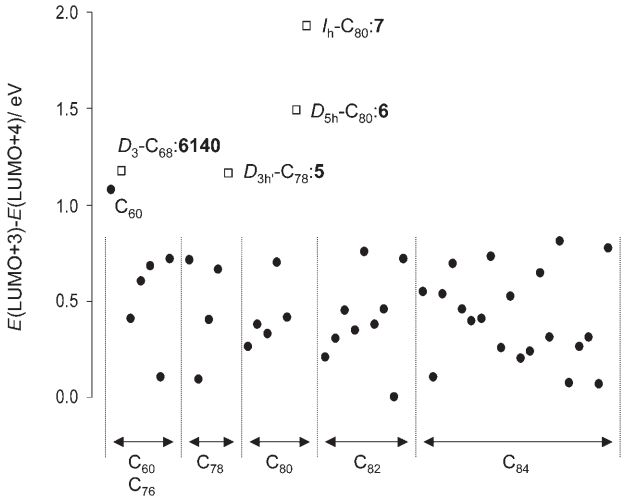

Figure 3. The (LUMO + 3)–(LUMO + 4) gap for all IPR isomers from C_{60} to C_{84} and also the non-IPR D_3-C_{68}:**6140**. Only isomers with the gap larger than 1 eV have been capable of encapsulating TNT units.

rejected because its cavity measured through the cage radius, 3.551 Å, is not big enough to encapsulate a four-atom unit. In the rest of fullerene cages the cavity is not a limitation for the encapsulation. Apart from the well-known TNT endohedral metallofullerenes we have encapsulated Sc_3N into D_{3h}-C_{78}:**4** and C_s-C_{84}:**3** isomers as a test case to corroborate our predictions. D_{3h}-C_{78}:**4** isomer is the least-stable isomer among all IPR C_{78} isomers and is 0.99 eV less stable than the $D_{3h'}$-C_{78}:**5** isomer. The cage seems to be suitable for the TNT encapsulation as the scandium atoms can be also oriented to the reactive 6:6 C–C bonds as occurs in $D_{3h'}$-C_{78}:**5**. However, the electronic configuration of the free cage does not seem to be favorable for the encapsulation due to a small (LUMO + 3)–(LUMO + 4) gap of 0.66 eV, which, according to the rule, prevents the maximum stabilization required for the formation. The final TNT endohedral complex of D_{3h}-C_{78}:**4** is 4.89 eV less stable than the TNT encapsulation inside $D_{3h'}$-C_{78}:**5**. Up to now, none of the C_{84} isomers has encapsulated TNTs although from the geometric point of view these cages have a big enough cavity. However, no C_{84} isomer has a (LUMO + 3)–(LUMO + 4) gap larger than 1 eV. For instance, C_s-C_{84}:**3** isomer has a (LUMO + 3)–(LUMO + 4) of 0.53 eV, which is a good prediction of the final HOMO–LUMO gap for the $Sc_3N@C_{84}$ complex, 0.48 eV.

In summary, we propose an easy way of determining which fullerene cages will be capable of encapsulating TNTs based on the electronic structure of the free fullerene cages. All TNT endohedral metallofullerenes are formed by the encapsulation of a metallic nitride template inside one of the following cages: D_3-C_{68}:**6140**; $D_{3h'}$-C_{78}:**5**; D_{5h}-C_{80}:**6**; I_h-C_{80}:**7**. None of these cages has ever been isolated or detected experimentally. $Sc_3N@C_k$ ($k = 68$, 78, 80) complexes may be formally described by the ionic model $Sc_3N^{6+}@C_k^{6-}$. A total of six electrons formally transfer from the three highest occupied TNT orbitals to three low-lying unoccupied cage orbitals. The resulting endohedral complex has a relatively large HOMO–LUMO gap, which gives it stability. We have shown that the final HOMO–LUMO gap of these TNT endohedral metallofullerenes can be estimated from the (LUMO + 3)–(LUMO + 4) gap found in the free cages, which corresponds to the hypothetical anion when six additional electrons are added to the free cage, C_k^{6-}. The search for large (LUMO + 3)–(LUMO + 4) gaps (> 1 eV) in the 51 IPR fullerene isomers from C_{60} to C_{84} revealed that only C_{60}, D_{3h}-C_{78}:**5**, D_{5h}-C_{80}:**6**, and I_h-C_{80}:**7** provide a suitable electronic structure for encapsulating the TNTs. From the geometrical point of view, C_{60} is the only fullerene cage limited by having a cavity too small to encapsulate a four-atom unit. Furthermore, on principle we can predict that no other IPR fullerene cages between C_{60} and C_{84} will be capable of encapsulating a TNT. At least, they will not be as stable as the TNT complexes already known now. The non-IPR D_3-C_{68}:**6140** cage also obeys the (LUMO + 3)–(LUMO + 4) rule. Therefore, the search for new fullerene cages that encapsulate TNTs must be focused on non-IPR fullerenes only.

Experimental Section

Methods: The calculations were carried out by using DFT methodology with the ADF2000 program.[28] The local-density approximation (LDA) characterized by the electron-gas exchange together with the Vosko–Wilk–Nusair (VWN) parameterization[29] for correlation were used. Gradients were corrected by means of the Becke[30] and Perdew[31] non-local corrections to the exchange and correlation energy, respectively. First-order Pauli scalar relativistic corrections were added in variation to the total energy for all systems. Triple-ζ polarization Slater basis sets were employed to describe the valence electrons of C, Sc, and N atoms.[32] The geometries of all fullerene cages have been extracted from the Fullerene Structure Library constructed by Mitsuho Yoshida.[33] Single-point calculations were used for all empty cages except for the free cages D_3-C_{68}:**6140**, $D_{3h'}$-C_{78}:**5**, I_h-C_{80}:**7**, and the TNT endohedral complexes, which were fully optimized.

Improvement in Photocyclization Efficiency of Diaryl Ethenes by Adjusting the Pore Size of Mesoporous Silica**

*Haruki Okada, Nozomi Nakajima, Toshihiro Tanaka, and Masakazu Iwamoto**

Photochromic compounds have attracted much attention because of their potential application in photonic devices such as optical memories and optical switches. Diaryl ethenes (DE) are known to show excellent thermal stability and resistance to fatigue,[1] and they are one of the most promising family of compounds for such applications. The two isomers, open-ring and closed-ring, undergo reversible cyclization/

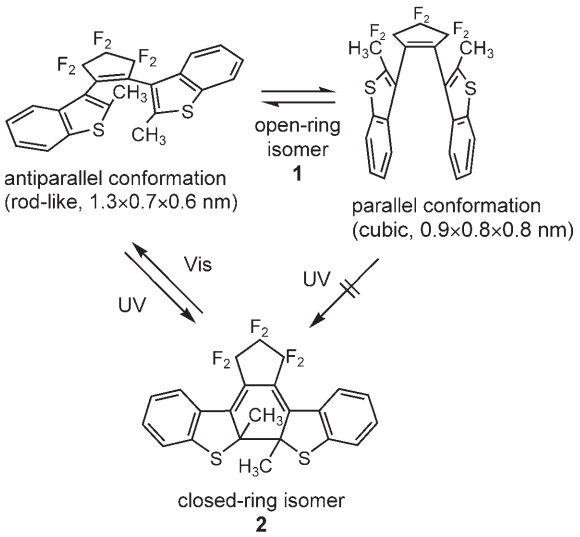
cycloreversion upon irradiation with UV and visible light (Scheme 1). There are two conformations, parallel and antiparallel, in the open-ring isomer. Since only the antiparallel conformation participates in the photocyclization, the quantum yield of photocyclization is usually lower than 0.5.[1] Effort has been made to increase the fraction of the antiparallel conformation by, for example, encapsulation of DE into the cylindrical framework of a cyclodextrin host,[2a] introduction of bulky substituents to the reactive carbon atoms of DE,[2b] incorporation of DE into the main chain of a polymer,[2c] and photochromic ractions in the crystalline phase.[2d–e]



Scheme 1. Photochromic reactions of **1**. Values for molecule size are given in nm, as in the text.

Mesoporous silica materials such as MCM-41 (M41) and FSM-16 have regular pore structures and uniform pore diameters. [3,4] The pore diameter can be adjusted by changing the carbon number—the number of carbon atoms in the backbone of the alkyl chain—of the surfactant micelles in the hydrothermal synthesis,[3,5,6] by adding swelling agents to the synthesis gels,[3] or by modifying the surface of the silica with organic silylating reagents.[3,7,8] Although the photochromism of azobenzene and spiropyran on mesoporous materials has already been studied,[9] no attention has been paid to the correlation between the pore diameter and the quantum yield of photoisomerization. This subject is dealt with here: the photocyclization rate constants were greatly dependent on the pore diameters of M41. In addition, reversible photochromism was observed in substrates with limited functional groups. Our findings establish a new technique to control photochromism by tuning the pore size.

M41 materials with different pore diameters were prepared by using surfactants with carbon numbers of 10, 12, 14, 16, and 22.[6] The M41 sample obtained with a dodecyltrimethylammonium salt, for example, is abbreviated as M41–12. Various organic groups (phenyl, methyl, 3-aminopropyl, 3-sulfanylpropyl, and 4-hydroxyphenyl) were planted on M41 and the resulting products are designated R-M41s (R = organic group). The DE 1,2-Bis[2-methyl-benzo[b]thiophen-3-yl]-3,3,4,4,5,5- hexafluoro-1-cyclopentene (**1**, Scheme 1) was used as a model photochromic compound. The diffuse-reflectance UV/Vis absorption spectrum of Ph-M41 was almost the same as that of $PhSi(OEt)_3$ itself (see Supporting Information). The observation of characteristic vibrational structures of the phenyl group reveals that there is no exciton coupling between the phenyl groups and no interaction between the phenyl groups and the silica surface; therefore, each phenyl ring is isolated on the M41 wall. The pore diameters measured by N_2 or Ar adsorption/desorption measurements are summarized in Table 1. The decrements in the pore diameters on modification were 0.9–1.3 nm on Ph-M41 and 0.4–0.5 on Me-M41; these values are very close to twice the lengths of Si–Ph (0.55 nm) and Si–Me units (0.22 nm), respectively, which indicates that each organic group is bonded upright on the surface.

Reversible and irreversible photoisomerization of **1** were observed, which were dependent on the surface states of the pore wall. The UV/Vis spectra for a typical example of the former are shown in Figure 1. The absorption bands at 358 and 525 nm, which are assignable to the closed-ring isomer **2**, increased with UV irradiation and decreased with visible-light irradiation. The diffuse-reflectance spectra are plotted in Figure 2 as a function of the alternating irradiation with UV and visible light: A reversible change in the UV/Vis bands was obtained on Ph-M41 (Figure 2a). The Me-, 3-aminopropyl-, or 3-sulfanylpropyl-modified M41 also provided this reversible, fatigue-resistant reaction (see Supporting Information). In contrast, the change that occurred on irradiating **1** loaded on unmodified M41 was irreversible (Figure 2b). After several UV/Vis irradiations, a new UV band at 388 nm emerged which could not be assigned (see Supporting

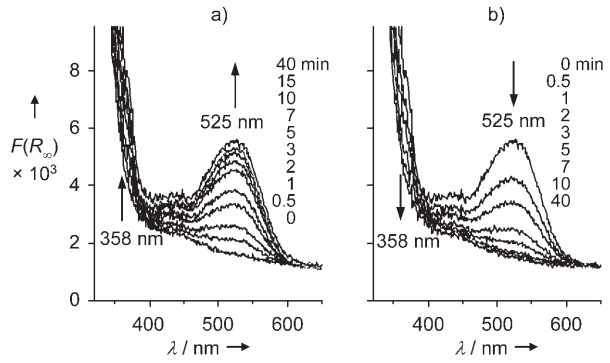

Figure 1. Changes in the diffuse-reflectance UV/Vis absorption spectra of Ph-M41-12 loaded with **1** during a) UV and b) visible-light irradiation. The amount of loaded **1** was 0.56 μmol g^{-1}. *F* is Kubelka–Munk function, R_∞ is the absolute reflectance.

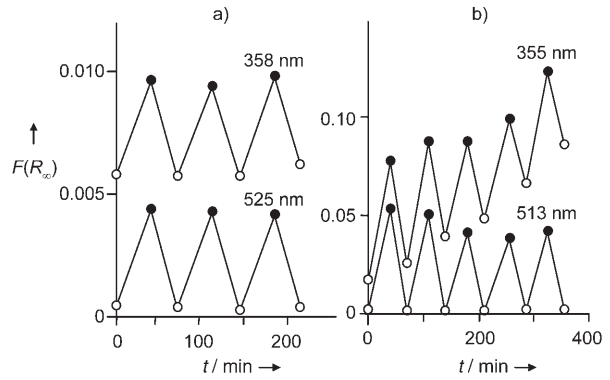

Figure 2. Changes in the intensities of diffuse-reflectance UV/Vis spectra of **1** loaded on a) Ph-M41-12 and b) M41-12 during alternate UV (●) and visible-light (○) irradiation. The amounts of **1** loaded on Ph-M41-12 and M41-12 were 0.56 and 1.57 μmol g^{-1}, respectively.

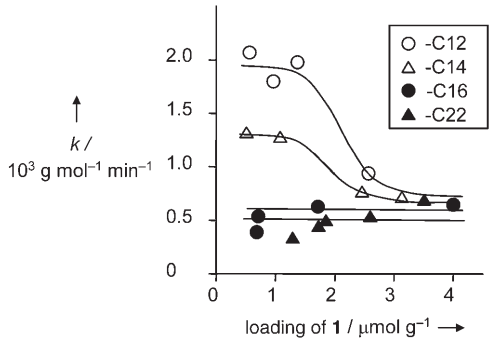

Figure 3. The *k* values for the photochromic reaction of **1** in Ph-M41 at different pore diameters and the loadings of **1**.

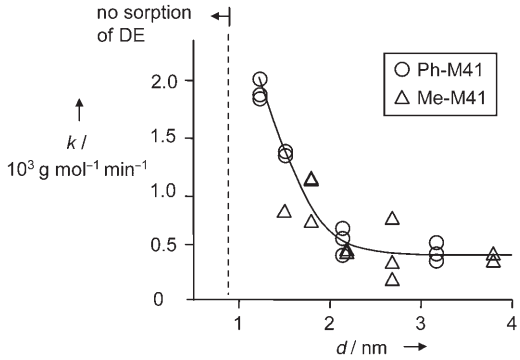

Figure 4. Dependence of *k* on the pore diameter of Ph-M41 and Me-M41.

Information). A similar phenomenon was also observed on 4-hydroxyphenyl-M41. The degradation mechanism is likely to be associated with the hydroxy groups on the surface of the M41.

The dependence of the coloration rate constant (*k*) of **1** on the pore diameter was studied on Ph-M41 and Me-M41 as the quantum yield was very difficult to determined in the present solid sample system. The *k* values were calculated from the changes in UV/Vis spectra (Figure 1) on the assumption of a pseudo-first-order reversible reaction and used to compare the efficiencies of photocyclization.[10] The dependence of the value of *k* on the amount of **1** loaded onto M41 was measured (Figure 3). Note that the *k* values were calculated per mole of supported **1**. The values were remarkably dependent on the amount of **1** in the cases of Ph-M41-12 and Ph-M41-14. Too high loadings of **1** gave incorrect *k* values due to insufficient irradiation of UV light so that *k* values should be determined only for loadings of **1** below 1.5 μmol g^{-1}.

As shown in Figure 4, the *k* value depended greatly on the pore diameter of the M41 samples. Two interesting findings are revealed: 1) The *k* value was 0.4–0.5 10^3 g mol^{-1} min^{-1} for pore diameters of 2.5–3.8 nm and it increased to about 2.0 10^3 g mol^{-1} min^{-1} when the pore diameter decreased to around 2.5 to 1.2 nm. When the pore size was below 0.9 nm, no molecules of **1** could be incorporated into the pore, which is reasonable in light of the molecular size of **1** (see Scheme 1). 2) There was no difference in the *k* values on Ph-M41 and Me-M41. Clearly, the *k* value is controlled only by the pore diameter and is independent of the organic groups on the surface of M41.

In conclusion, reversible photochromic reaction of **1** occurred without any deactivation in the pores of M41 modified with organic groups. The efficiency of the reaction increased with shrinking pore diameter in the range 1.2–3.8 nm, which results from how well the rod-like antiparallel form fits into the pore structure. The materials described here would be useful for high-density optical memory.

Experimental Section

The parent M41s were prepared by using colloidal silica or water glass according to a previously described method.[5,6] The modification of M41 was carried out as follows: M41 (1 g) was suspended in a solution (6 mmol) of R-Si$(OEt)_3$ in *n*-heptane (20 mL) and stirred for 24 h at 353 K. The resulting samples were filtered, washed with *n*-heptane and acetone, then dried at 323 K in air. The M41 samples were simply stirred with the *n*-heptane solution (1 mM) of **1**[11] for 6 h at room temperature. After the samples were isolated by filtration and washed with *n*-heptane, they were dried at 323 K in air.[12] The amount of loaded **1** was determined by measuring the difference between the concentrations of **1** in solution before and after the loading procedure.

UV and visible light came from a superhigh-pressure Hg lamp (USHIO, 500 W) with one or two filter papers and an optical filter UV-D33S or L-39 (Asahi technoglass). Diffuse-reflectance UV/Vis spectra were measured by using a Perkin Elmer Lambda 19 spectrometer with barium sulfate as a reference. The obtained spectra were converted into absorption spectra through the Kubelka–Munk function.

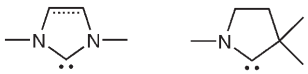
Low-Coordinate Complexes

DOI: 10.1002/anie.200502566

A Rigid Cyclic (Alkyl)(amino)carbene Ligand Leads to Isolation of Low-Coordinate Transition-Metal Complexes**

*Vincent Lavallo, Yves Canac, Alan DeHope, Bruno Donnadieu, and Guy Bertrand**

In the last decade the use of diamino N-heterocyclic carbenes (NHCs) **A** as ancillary ligands for transition-metal catalysts and as organic catalysts on their own has proven very fruitful.[1] The efficiency of NHCs is attributed to their strong σ-donor properties and sterically demanding structure.[1,2] Not only have NHCs yielded improved transition metal catalysts, but they have also lead to the isolation of unusual low-coordinate metal complexes,[2] which often play a key role in catalytic processes. Recently, we reported the synthesis of stable cyclic (alkyl)(amino)carbenes (CAACs) **B**[3] and demonstrated that CAACs can be even stronger σ donors than NHCs, and lead to highly efficient palladium catalysts for the α-arylation of ketones and aldehydes. Here we report that the peculiar steric and electronic properties of rigid CAAC ligands allow the preparation of low-coordinate metal complexes, hitherto not isolable with any other ligands.



A B

To further evaluate the electronic properties of rigid CAAC **B1**, we attempted to prepare the [RhCl(CO)$_2$(**B1**)] complex, since the CO stretching frequencies of this type of rhodium complexes are recognized as an excellent measure of the σ-donor ability of the ligand L, and a large amount of data is available for comparison.[4] Reaction of carbene **B1** with half an equivalent of [{RhCl(cod)$_2$}$_2$] (cod = 1,5-cyclooctadiene) afforded complex **1**, which after purification by column chromatography on silica gel was obtained as orange crystals in 79% yield (Scheme 1). The structure of **1** was unambiguously determined by single-crystal X-ray diffraction.[5] Following the classical procedure, a solution of **1** in chloroform was treated with an excess of CO. Surprisingly, the ^{13}C NMR spectrum of the product (95% yield) showed only

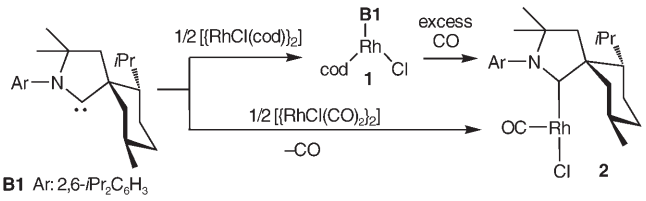

Scheme 1. Synthesis of [RhCl(CO)(**B1**)] complex **2**.

one CO signal, with a large coupling constant ($J_{Rh,C} = 134$ Hz), and not two signals with smaller J values ($J_{Rh,C} = 33$–82 Hz), as observed for $[RhCl(CO)_2(L)]$ complexes.[4] It is known that when bulky ligands L are present $[RhCl(CO)_2L]$ complexes can readily lose one CO ligand to give a chloro-bridged dimer.[6] However, single-crystal X-ray diffraction[5] revealed that even in the solid state complex **2** is formally a 14-electron [RhCl(CO)L] monomer (Figure 1).

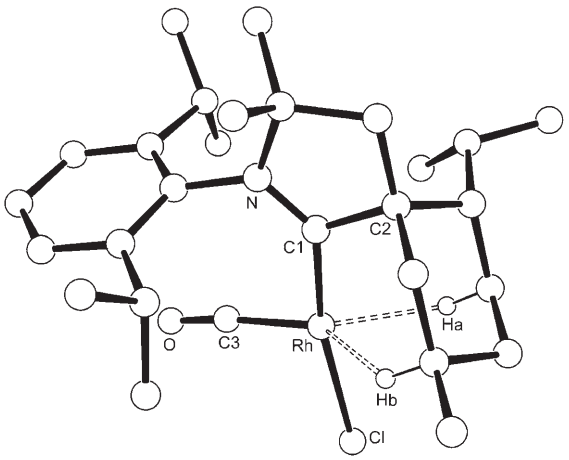

Figure 1. Molecular structure of **2** in the solid state. Selected bond lengths [Å] and angles [°]: N–C1 1.3174(14), C1–C2 1.5368(15), C1–Rh 1.9399(10) Rh–Cl 2.3740 (3), Rh–C3 1.7955(11), C3–O 1.1433(14), Rh–Ha 2.183(17), Rh–Hb 2.231(17); N-C1-C2 108.70(9), C1-Rh-C3 97.99(5), C3-Rh-Cl 94.55(4), C1-Rh-Cl 167.35(3), Rh-C3-O 173.46(10).

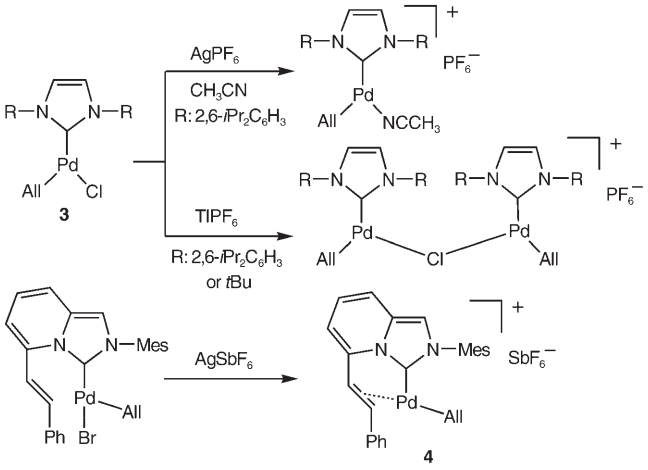
Interestingly, **2** can also be synthesized in 80% yield by reaction of one equivalent of carbene **B1** with half an equivalent of $[\{RhCl(CO)_2\}_2]$. The extreme hindrance provided by the menthyl ring of CAAC **B1**, which is locked in the most sterically demanding conformation with respect to the metal center, explains in part why dimerization does not occur. Moreover, the short Rh–Ha (2.183 Å) and Rh–Hb (2.231 Å) distances suggest the existence of agostic interactions, which bring additional stabilization to the metal center. In solution, an agostic interaction is also apparent in the ^{1}H NMR spectrum, which shows a broad multiplet (1H) at 0.08 ppm. Complex **2** is indefinitely stable at room temperature in air. Related $[RhClL_2]$ complexes, exemplified by the active species of Wilkinson's catalyst $[RhCl(PPh_3)_2]$, are known only as transient species.[7] They have only been generated in situ by ligand dissociation[8] or by hapticity changes;[9] otherwise they readily form chloro-bridged dimers, even when two very bulky ligands L are present.[6] Although other neutral T-shaped formally 14-electron Rh^I complexes have been isolated, they are still very rare, and none of them have a bridging-capable halide ligand like complex **2**.[10,11]

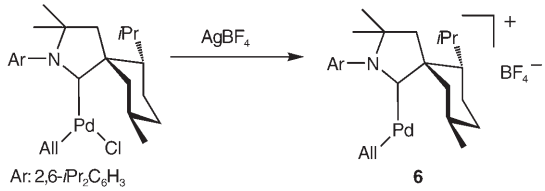
The isolation of this low-coordinate Rh^I complex **2** made us confident that other low-ligated transition-metal complexes could be stabilized by rigid CAAC **B1**. After close scrutiny of the literature, it came to our attention that other ligands, particularly NHCs, have consistently failed to allow the isolation of cationic 14-electron $[Pd(All)(L)]^+$ complexes (Scheme 2, All = allyl).[12] In 2003, Nolan et al.[12a] were able



Scheme 2. Previous attempts to prepare cationic 14-electron $[Pd(All)(L)]^+$ complexes.

to abstract chloride from complex **3**, but the cationic complex generated was either unstable and decomposed upon workup or isolated and structurally characterized as an acetonitrile adduct. In 2005, Porschke et al.[12b] reported that chloride abstraction with thallium salts from NHC complexes **3** led to ionic binuclear compounds, which result from combination of the transiently formed desired cationic species with the starting neutral complex. Most recently, Glorius et al.[12c] generated cationic complex **4**, which, despite intramolecular stabilization by double-bond complexation, appeared to be rather unstable and was only characterized by ^{1}H NMR spectroscopy.

In marked contrast, chloride abstraction from [PdCl(All)(**B1**)] (**5**)[3] with a stoichiometric amount of $AgBF_4$ produced the elusive cationic palladium complex **6** as yellow crystals (88% yield, Scheme 3). The structure of **6** was unambiguously established by single-crystal X-ray diffraction (Figure 2).[5] As expected, **6** has a T-shaped geometry with no interaction between the metal atom and tetrafluoro-



Scheme 3. Synthesis of $[Pd(All)(B1)]^+$ complex **6**.

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

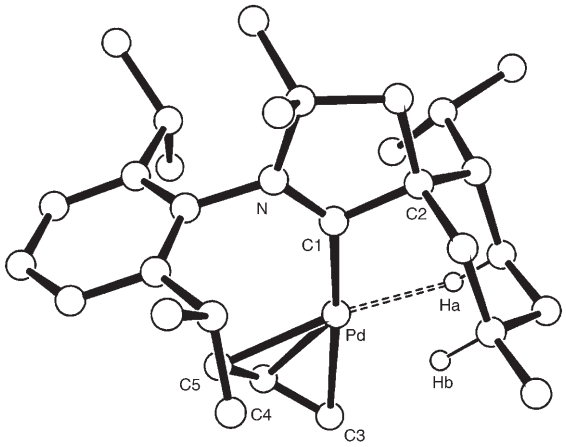


Figure 2. Structure of the cation of **6** in the solid state. Selected bond lengths [Å] and angles [°]: N–C1 1.293(3), C1–C2 1.519(3), C1–Pd 2.038(3), Pd–Ha 2.048, Pd–Hb 2.509, Pd–C3 2.272(13), Pd–C4 2.148(4), Pd–C5 2.126(9); N-C1-C2 109.4(2), N-C1-Pd 133.96(18), C2-C1-Pd 116.64(15).

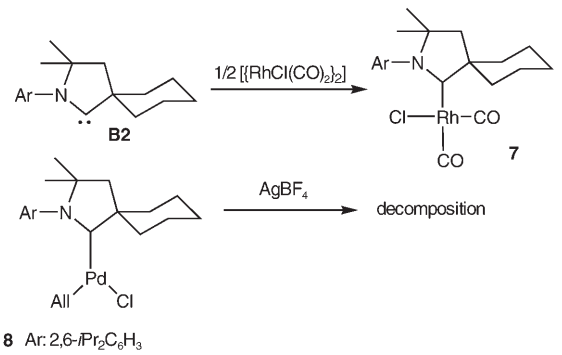
borate anion (shortest Pd–F distance 3.88 Å). Similar to the above-mentioned Rh^I complex **2**, at least one of the axial H atoms of the menthyl ring provides a stabilizing agostic interaction (Pd–Ha 2.048, Pd–Hb 2.509 Å). This interaction is also apparent from the ^{1}H NMR spectrum, which shows a broad multiplet (1H) at −0.17 ppm. This is the first example of a stable, formally 14-electron, Pd^{II} cation.[13]

To further demonstrate the increased stabilization of metal centers provided by the rigid menthyl moiety of carbene **B1**, we attempted to prepare complexes analogous to **2** and **6**, using the CAAC **B2**, featuring the unlocked and therefore flexible cyclohexyl ring.[3,14] Treatment of [{RhCl(CO)$_2$}$_2$] with two equivalents of carbene **B2** afforded exclusively the classical dicarbonyl complex **7**, while treatment of **8**[3] with $AgBF_4$ led to rapid formation of palladium black (Scheme 4). Clearly, in contrast to **B1**, the cyclohexane ring of CAAC **B2** can flip to the less sterically demanding conformation, in which no H atoms are available for strong agostic interactions with the metal center.

The isolation of complexes **2** and **6** clearly demonstrates the advantages of rigid CAACs over classical ligands. By manipulating the quaternary carbon atom adjacent to the carbene center it is possible to design ligands with an electronically active wall of protection for the metal center. We are currently exploring the possibility that CAAC ligands will stabilize even lower coordinate metal complexes.



Scheme 4. Synthesis of [RhCl(CO)$_2$(**B2**)] complex **7**, and attempted chloride abstraction from [PdCl(All)(**B2**)] complex **8**.

Experimental Section

All manipulations were performed under an inert atmosphere of argon by using standard Schlenk techniques. Dry, oxygen-free solvents were employed. ^{1}H and ^{13}C NMR spectra were recorded on Varian Inova 300, 500 and Bruker Avance 300 spectrometers.

1: A solution of carbene **B1**[3] (0.45 g, 1.18 mmol) in THF (10 mL) was added at −78 °C to a stirred solution of [{RhCl(cod)$_2$}$_2$] (0.26 g, 0.53 mmol) in THF (5 mL). The solution was warmed to room temperature and stirred for 3 h. After evaporation of the solvent under vacuum, washing with hexane (15 mL), and purification by column chromatography on silica gel with diethyl ether as eluant, complex **1** was obtained as an orange powder (0.52 g, 79 %). Recrystallization from diethyl ether/pentane at −20 °C afforded **1** as orange crystals (m.p. 184–186 °C). $[\alpha]_D^{23} = +189°$ ($CHCl_3$). ^{1}H NMR ($CDCl_3$, 25 °C, 300 MHz): δ = 7.41–7.54 (m, 2H, H_{ar}), 7.17–7.20 (m, 1H, H_{ar}), 5.44 (m, 1H, CH_{cod}), 4.65 (m, 1H, CH_{cod}), 4.21 (m, 1H, CH_{cod}), 3.06–3.23 (m, 5H), 2.68 (m, 2H), 2.51 (d, 1H, J = 12.9 Hz), 1.99–2.13 (m, 4H), 1.77 (d, 3H, CHCH_3, J = 6.0 Hz), 1.45–1.71 (m, 10H), 1.29 (d, 3H, CHCH_3, J = 6.6 Hz), 1.24 (d, 3H, CHCH_3, J = 6.6), 1.20 (s, 6H), 1.11 (d, 3H, CHCH_3, J = 6.3 Hz), 1.04 (d, 3H, CHCH_3, J = 6.3 Hz), 0.97 (d, 3H, CHCH_3, J = 6.6 Hz), 0.92 ppm (d, 3H, CHCH_3, J = 6.3 Hz). ^{13}C NMR ($CDCl_3$, 25 °C, 75 MHz): δ = 278.26 (d, J = 44.5 Hz), 148.76, 146.13, 138.42, 128.94, 127.28, 124.30, 100.03 (d, J = 6.0 Hz), 99.72 (d, J = 5.3 Hz), 76.62, 72.44 (d, J = 16.2 Hz), 70.69, 60.43 (d, J = 14.5 Hz), 54.96, 51.34, 49.81, 36.42, 35.53, 33.69, 32.93, 31.63, 29.63, 29.34, 29.13, 29.03, 28.48, 27.97, 27.70, 26.71, 25.78, 25.59, 24.90, 22.35, 22.27 ppm.

2: Carbon monoxide was bubbled (60 min) through a solution of complex **1** (0.58 g, 0.92 mmol) in chloroform (15 mL). After evaporation of the solvent under vacuum and washing with hexane (10 mL), complex **2** was obtained as an orange powder (0.48 g, 95 %). Alternatively, a solution of carbene **B1** (0.40 g, 1.04 mmol) in THF (5 mL) was added at −78 °C to a stirred solution of [{RhCl(CO)$_2$}$_2$] (0.18 g, 0.47 mmol) in THF (5 mL). The solution was warmed to room temperature and stirred for 2 h. After evaporation of the solvent under vacuum and washing with hexane (20 mL), a solid residue was obtained (0.41 g, 80 %). Recrystallization from chloroform by slow evaporation at room temperature afforded **2** as orange crystals (m.p. 251 °C decomp). $[\alpha]_D^{23} = -0.1°$ ($CHCl_3$). ^{1}H NMR ($CDCl_3$, 25 °C, 300 MHz): δ = 7.45 (m, 1H, H_{ar}), 7.28 (m, 2H, H_{ar}), 2.83 (sept, 2H, CHCH$_3$, J = 6.6 Hz), 2.60 (m, 1H), 2.47 (d, 1H, J = 13.5 Hz), 2.27 (m, 1H), 1.89–2.12 (m, 5H), 1.61 (d, 3H, CHCH_3, J = 6.6 Hz), 1.24–1.44 (m, 20H), 1.13 (d, 3H, CHCH_3, J = 5.7), 1.06 (d, 3H, CHCH_3, J = 6.9), 0.08 ppm (m, 1H, H_{agos}). ^{13}C NMR ($CDCl_3$, 25 °C, 75 MHz): δ = 248.47 (d, J = 48.8 Hz), 181.21 (d, J = 134.3 Hz), 146.20, 145.72, 136.90, 130.28, 125.82, 125.70, 77.67, 71.85, 51.85, 50.39, 46.26, 40.60, 35.13, 34.78, 30.58, 30.38, 29.13, 27.11, 26.43, 26.26, 24.29, 24.16, 22.63, 20.19 ppm. IR (CH_2Cl_2): $\tilde{\nu}$(CO) = 1989 cm^{-1}.

6: A 1:1 mixture of carbene complex **5**[3] (0.50 g, 0.9 mmol) and silver tetrafluoroborate was cooled to −40 °C and 5 mL of fluorobenzene was added. The suspension was warmed to room temperature and stirred for 30 min. After filtration, evaporation of the solvent under vacuum, and washing with hexane (10 mL), a solid residue was obtained (0.48 g, 88 %). Recrystallization from toluene/fluorobenzene at −20 °C afforded **6** as yellow crystals (m.p. 157–159 °C decomp). $[\alpha]_D^{23} = -6°$ (C_6H_5F). ^{1}H NMR (C_6D_5F, 25 °C, 300 MHz): δ = 6.78–7.15 (m, 3H, H_{ar}), 5.00 (m, 1H, H_{allyl}), 3.34–3.48 (m, 2H, H_{allyl}), 2.90 (m, 2H), 2.59 (m, 2H), 2.36–2.41 (m, 1H), 1.91–2.17 (m, 3H), 1.65–1.82 (m, 3H), 1.13–1.22 (m, 12H), 1.06 (d, 3H, CHCH_3, J = 6.3 Hz), 1.05 (d, 3H, CHCH_3, J = 6.9 Hz), 0.99 (d, 3H, CHCH_3, J = 6.9 Hz), 0.98 (s, 3H, CH_3), 0.88 (d, 3H, CHCH_3, J =

The Generation of a Metallocene-Fused Imidazol-2-ylidene and Its Mercury Complex**

Anthony J. Arduengo III, Daniela Tapu, and William J. Marshall*

Imidazolium salts and imidazol-2-thiones have been widely used as precursors for the synthesis of stable imidazol-2-ylidene.[1] We recently reported successful methodologies for the synthesis of the first directly annulated imidazolium cyclopentadienide zwitterion (**1**) and its ferrocenyl bis-(thione) derivative (**2**).[2] These structures provide an entry

into a new class of metallocene-fused imidazole-2-ylidenes. This new architecture for carbenes allows the incorporation of two or more metal centers into a molecule through a combination of σ and π bonding that is tightly coupled through the annulated ligand.

The ruthenocene **3**, a yellow solid that melts at 240–242 °C, was produced in 91 % yield from **1** and $[Cp^*Ru(CH_3CN)_3][CF_3SO_3]$ (Cp^* = pentamethyl cyclopentadienyl;[3] Scheme 1). A single crystal of **3** suitable

for X-ray crystallographic measurements was grown by recrystallization from THF (selected bond lengths and angles are given in Table 1). The 3D structure of **3** is depicted by the KANVAS[4] drawing in Figure 1. Ruthenocene **3** crystallizes in the triclinic space group $P\bar{1}$, and the two π-ligands (**1** and Cp*) are bound to the ruthenium center in a η^5-fashion. The planes of the two cyclopentadienyl ligands are essentially parallel ($\phi = 1.13°$) and adopt an eclipsed conformation. The average Ru–C(ring) length of 219.78(4) pm in **1** is slightly longer than the average Ru–Cp*(ring) length of 218.08(4) pm. This small difference is consistent with the more extensive π delocalization of the zwitterion. The N1-C2-N3 angle of 112.7(3)° is 2.33° greater than that found in **1** and also larger than those found in typical imidazolium ions.[5]

Metalation of **1** with chromium can be accomplished by treatment of **1** with tris(acetonitrile)tricarbonylchromium(0). The half-sandwich chromium complex **4** was obtained in almost quantitative yield (Scheme 1) as an orange solid which melts at 286–288 °C. Complex **4** is not soluble in nonpolar or halogenated solvents, but it is sparingly soluble in acetonitrile and readily soluble in dimethyl sulfoxide (DMSO).

The molecular structure of **4** was determined by X-ray crystallographic studies. Quality crystals were grown by slow diffusion of petroleum ether into a saturated solution of **4** in acetonitrile. The X-ray crystal structure of **4** is illustrated by the KANVAS[4] drawing in Figure 2, and selected bond lengths and angles in **4** are presented in Table 1. Compound **4** crystallizes in the monoclinic space group $P2_1/n$. The chromium atom is η^5-coordinated to the cyclopentadienyl ring with an average Cr–C(ring) length of 221.84 pm. The average Cr–CO and C–O lengths are 181.5 and 117.3 pm, respectively.

Generation of the free, stable carbenes in solution by deprotonation of **3** or **4** has proved problematic. These carbenes may be too electron-rich (nucleophilic) to allow easy isolation, or alternatively the in situ generated carbene is capable of reaction with the other electrophilic centers in the complex (e.g., ruthenium, chromium, or carbonyl centers). Carbene generation in the presence of electrophiles (metals or main-group elements) has, however, allowed the isolation of various carbene adducts.

A benchmark reaction[6] of the imidazol-2-ylidene with sulfur produced imidazole-2-thione **5** in almost quantitative yield (Scheme 2). The ruthenocene-substituted thione was isolated as an air-stable colorless solid that melts at 282–284 °C. An analogous reaction allowed a clean conversion of imidazolium salt **4** to thione **6**, which was characterized by NMR spectroscopy of the reaction mixture (Scheme 2).

Cooling a saturated solution of **5** in THF/petroleum ether allowed crystals suitable for X-ray structure determination to be grown. Thione **5** crystallizes in the monoclinic space group $P2_1/n$, and the asymmetric unit contains two unique molecules. The crystal structure is depicted as a KANVAS[4] drawing in Figure 3, and selected bond lengths and angles are presented in Table 1. The Cp* rings exhibit large axial positional variance. (A second position for the Cp* ring could not be refined rotationally along the metal–Cp* centroid, but prolate thermal ellipsoids (with the longest axis tangential to the Cp–ring) provided the best model. No hydrogen atoms

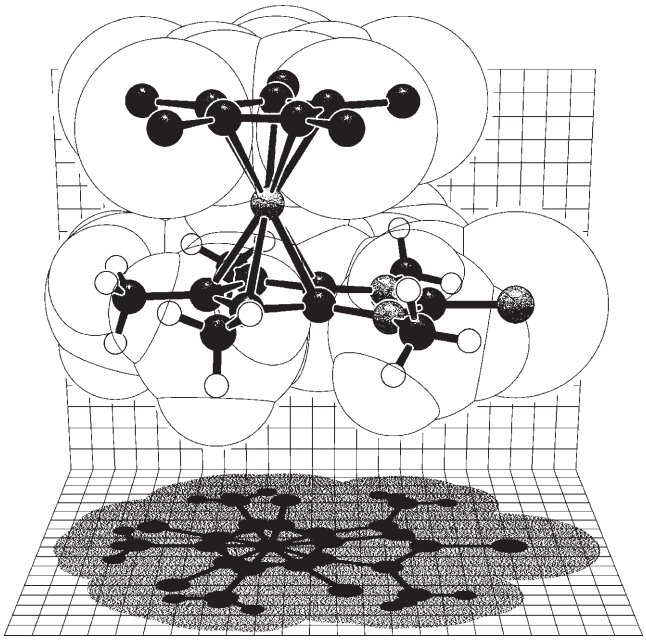

Figure 3. KANVAS[4] drawing of **5**.

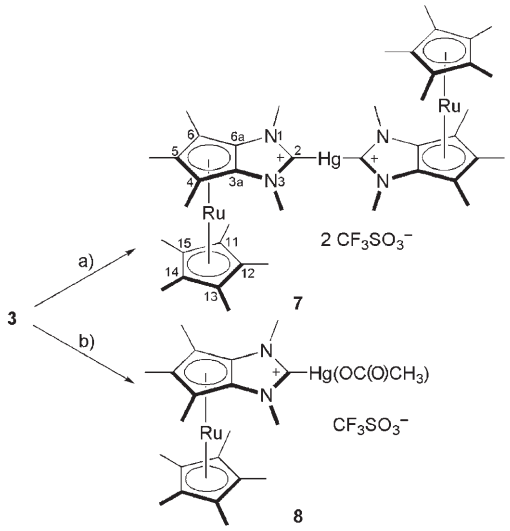
The first example of metalation of the carbene center in **3** was accomplished by mercuration. The imidazolium salt **3** reacted slowly with mercury acetate in different stoichiometries. When 0.5 equivalents of mercury acetate were employed in the reaction, after 20 days of stirring at 60 °C, 38 % conversion into the disubstituted mercury complex **7** was observed. No further conversion was observed after longer reaction times. A 1:1 stoichiometry led to a mixture of the mono- and disubstituted mercury complexes **8** and **7**. When a large excess of mercury acetate was used, the monosubstituted mercury complex **8** could be isolated as the only product of the reaction after 2 days at 60 °C (Scheme 3).



Scheme 3. Reactions of **3**. Reagents: a) 0.5 equivalents of $Hg(OAc)_2$, b) excess of $Hg(OAc)_2$.

Mercury bis(carbene) complex **7** is a yellow crystalline solid that is poorly soluble in most organic solvents except acetonitrile and DMSO. Crystals of **7** of suitable quality for X-ray crystallographic studies were obtained by recrystallization from acetonitrile. Figure 4 shows a KANVAS[4] drawing, and selected bond lengths and angles are given in Table 1.

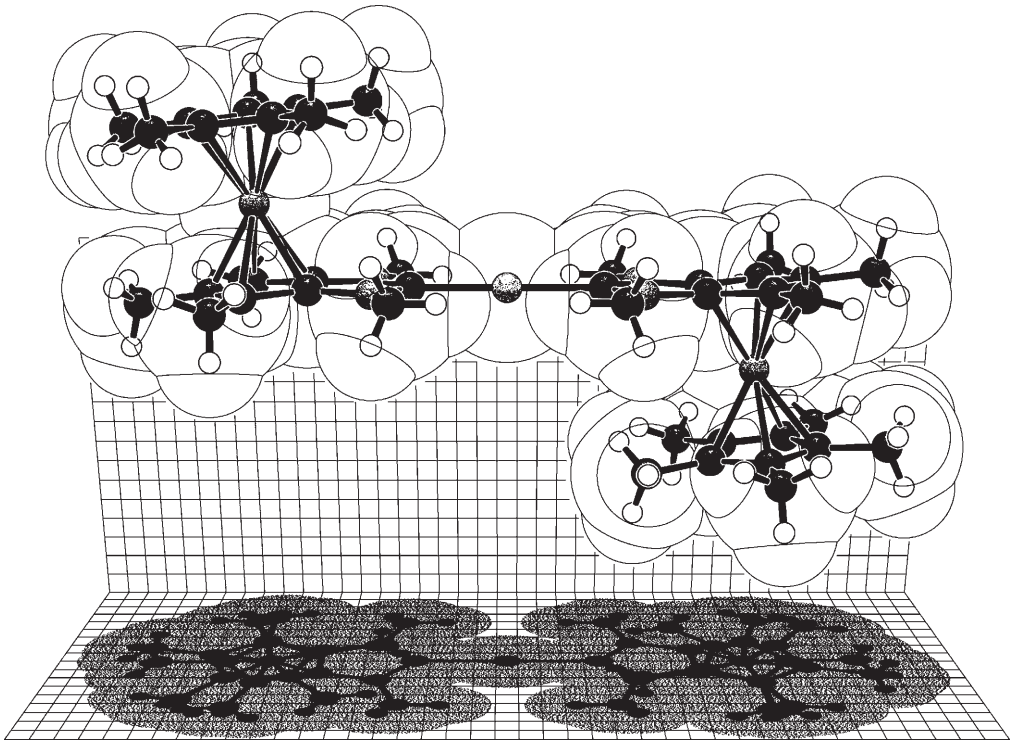


Figure 4. KANVAS[4] drawing of the X-ray structure of **7** (the triflate counterions are omitted for clarity).

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Complex **7** crystallizes in the triclinic space group $P\bar{1}$, with an asymmetric unit that contains half of a molecule, a triflate counterion, and an acetonitrile molecule. The ruthenocene fragments are oriented in an antiperiplanar conformation with a C2-Hg-C22 bond angle of 180°. The internal ring angle at the carbene center of 109.4(2)° is larger than that in typical imidazol-2-ylidene/mercury complexes.[7] The larger angle might be the result of strain that arises from fusion of the two five-membered rings.

A comparative analysis of the bond lengths and angles for the zwitterion fragments in all of the studied compounds reveals certain trends among this new class of organometallic compound. The lengths of the C2–N1(3) bonds are greater for thiones **2** and **5** and mercury complex **7** than those found in imidazolium salts **1**, **3**, and **4**. The N-C-N angle is smaller in **2**, **5**, and **7** relative to the corresponding angle in **1**, **3**, and **4**. These changes suggest diminished π delocalization in **2**, **5**, and **7** relative to the imidazolium salts and may reflect a tendency of π-bond fixation when the substituent at C2 is capable of p–π or d–π backdonation.

In summary, a new carbene (imidazol-2-ylidene) architecture has been realized that allows the incorporation of multiple metal and/or main-group element centers in a combination of σ- and π-bonding motifs. Zwitterion **1** combines these two major bonding concepts in organometallic chemistry in a single ligand, in which there is tight electronic coupling between the ligated centers. This investigation has reported the first bi- and trimetallic complexes of this ligand. Future reports will detail electronic interactions in these systems and their influence on structure, chemistry, and catalysis.

Experimental Section

The reactions were carried out in an atmosphere of dry nitrogen using Schlenk techniques or a dry box. Solvents were dried by using standard procedures.[8] The NMR spectra were recorded on a Bruker AMX 360 spectrometer. Melting points were obtained on a MEL-TEMP II apparatus (Laboratory Devices, USA) and were not corrected. Elemental analysis was performed by Atlantic Microlab, Inc., GA. The ruthenium-transfer reagent was prepared according to a reported procedure.[3] All other chemicals were purchased from commercial sources and used as received.

3: A solution of **1**[2b] (0.090 g, 0.51 mmol) in THF (5 mL) was added dropwise to a solution of pentamethylcyclopentadienylruthenium(tris(acetonitrile)) triflate (0.259 g, 0.51 mmol) in THF (25 mL). The reaction mixture was stirred overnight. After evaporation of volatiles, the resulting yellow solid was dissolved in dichloromethane (1 mL) and reprecipitated with diethyl ether (20 mL). After filtration and drying, a yellow product was obtained (0.259 g, 91% yield). M.p. 240–242 °C; ^{1}H NMR (360 MHz, $CDCl_3$): $\delta = 9.26$ (s, 1H), 3.79 (s, 6H), 2.02(s, 6H), 1.67(s, 15H), 1.63 ppm (s, 3H); ^{13}C NMR (90 MHz, $CDCl_3$) $\delta = 147.89$, 101.18, 88.16, 85.31, 67.44, 34.24, 10.43, 10.35, 9.52 ppm; elemental analysis (%) calcd for $C_{22}H_{31}N_2RuF_3SO_3$: C 47.05, H 5.56, N 4.99; found: C 46.96, H 5.53, N 5.09.

4: A solution of **1** (0.100 g, 0.56 mmol) in THF (5 mL) was added dropwise to a solution of tris(acetonitrile)tricarbonylchromium(0) (0.147 g, 0.56 mmol) in THF (10 mL), on which a yellow precipitate formed immediately. After stirring of the reaction mixture overnight, the volatiles were evaporated to obtain a yellow product (0.176 g, 99.4% yield). Crystals of suitable quality for X-ray crystallographic studies were obtained by slow diffusion of diethyl ether into a saturated solution of **4** in acetonitrile. M.p. 286–288 °C; ^{1}H NMR (360 MHz, [D$_6$]DMSO): $\delta = 8.57$ (s, 1H), 3.82 (s, 6H), 2.19(s, 6H), 1.77 ppm (s, 3H); ^{13}C NMR (90 MHz, [D$_6$]DMSO): $\delta = 222.25$, 144.77, 108.37, 99.42, 74.20, 33.92, 11.45, 10.23 ppm; elemental analysis (%) calcd for $C_{14}H_{16}N_2CrO_3$: C 53.85, H 5.16, N 8.97; found: C 53.76, H 5.13, N 8.88.

5: A 50-mL round-bottomed flask was charged with **3** (95.7 mg, 0.17 mmol), sulfur (18 mg, 0.56 mmol), and THF (10 mL), and a solution of potassium *tert*-butoxide (20 mg, 0.17 mmol) in THF (6 mL) was added dropwise. The reaction mixture was stirred for 40 min and then the volatiles were evaporated. The resulting residue was extracted with toluene (40 mL), and after filtration and evaporation of toluene, the product as obtained as a white solid (73 mg, 97% yield). Crystals of suitable quality for X-ray crystallographic studies were obtained by cooling a solution of **5** in THF/petroleum ether. M.p. 282–284 °C (decomp); ^{1}H NMR (360 MHz, $CDCl_3$): $\delta = 3.56$ (s, 6H), 1.96 (s, 6H), 1.70(s, 15H), 1.57 ppm (s, 3H); ^{13}C NMR (90 MHz, $CDCl_3$): $\delta = 175.23$, 100.57, 84.85, 82.55, 64.99, 32.49, 11.11, 10.39, 9.91 ppm; elemental analysis (%) calcd for $C_{21}H_{30}N_2RuS$: C 56.86, H 6.82, N 6.31; found: C 56.88, H 6.85, N 6.34.

6: A solution of potassium *tert*-butoxide (15 mg, 0.128 mmol) in THF (1 mL) was added to a mixture of **4** (40 mg, 0.128 mmol), sulfur (10 mg, 0.25 mmol), and THF (12 mL). The reaction mixture was stirred for 3 h and then concentrated under vacuum. ^{1}H NMR (360 MHz, [D$_6$]DMSO): $\delta = 3.35$ (s, 6H), 2.18 (s, 6H), 1.85 ppm (s, 3H); ^{13}C NMR (90 MHz, [D$_6$]DMSO): $\delta = 200.59$, 173.43, 112.21, 94.10, 76.53, 32.18, 25.03, 11.09 ppm.

7: A sealed bomb was charged with **3** (150 mg, 0.267 mmol), $Hg(OAc)_2$ (43 mg, 0.135 mmol) and DMSO (2 mL). The reaction mixture was stirred at 60 °C for 20 days. The volatiles were evaporated, and the crude reaction mixture was dissolved in acetonitrile (2 mL) and filtered through celite. This solution was allowed to stand overnight at −22 °C to induce crystallization. The crystalline product was collected by filtration and dried under vacuum to afford the product (68 mg, 39%; the mother liquor contained starting material). M.p. 325–326 °C decomp; ^{1}H NMR (360 MHz, CD_3CN): $\delta = 3.83$ (s, 6H), 2.06 (s, 6H), 1.69(s, 15H), 1.65 ppm (s, 3H; ^{13}C NMR (90 MHz, CD_3CN) $\delta = 186.97$, 104.55, 89.21, 85.59, 68.20, 37.44, 10.62, 10.42, 9.64 ppm; ^{19}F NMR: $\delta = -78.73$ ppm; elemental analysis (%) calcd for $C_{44}H_{60}N_4Ru_2HgF_6S_2O_6$: C 39.98, H 4.57, N 4.23; found: C 39.79, H 4.65, N 4.24.

8: A sealed bomb was charged with **3** (159 mg, 0.283 mmol), $Hg(OAc)_2$ (210 mg, 0.658 mmol), and DMSO (5 mL). The reaction mixture was stirred at 60 °C for 48 h. The volatiles were evaporated and the resulting brown oil contained only the desired complex **8** and excess mercury acetate. The crude reaction mixture was dissolved in $CHCl_3$ and filtered through celite. Further purification of the product was difficult because the monosubstituted complex converts into the disubstituted complex over time. ^{1}H NMR (360 MHz, CD_3Cl): $\delta =$ 3.88 (s, 6H), 2.06 (s, 3H), 2.01 (s, 6H) 1.64 (s, 15H), 1.62 ppm (s, 3H); ^{13}C NMR (90 MHz, CD_3CN): $\delta = 177.60$, 174.06, 104.11, 89.08, 85.57, 68.38, 36.92, 22.08, 10.58, 10.32, 9.58 ppm; ^{19}F NMR: $\delta = -78.73$ ppm; elemental analysis (%) calcd for $C_{24}H_{33}N_2RuHgF_3SO_5$: C 35.14, H 4.06, N 3.42; found: C 33.74, H 3.77, N 3.36.

Internally 1,4-Phenylene-Bridged *meso* Aryl-Substituted Expanded Porphyrins: The Decaphyrin and Octaphyrin Cases**

*Venkataramanarao G. Anand, Shohei Saito, Soji Shimizu, and Atsuhiro Osuka**

The chemistry of expanded porphyrins is the current focus of intensive research because of their unique properties.[1,2] Among their many expected properties, extensive aromaticity is realized in expanded porphyrins such as sapphyrins,[3] rubyrins,[1d,4] and hexaphyrins.[5] However, such aromaticity becomes increasingly difficult to obtain with larger expanded porphyrins, particularly for systems larger than octapyrroles, mainly because of intrinsic conformational distortion from planarity.[2c,d,6] Rare examples are the 34π-electron core-modified octaphyrin[1d,7] and 30π-electron cyclo[8]pyrrole,[8] both of which exhibit planar conformations and strong aromaticity, thus underscoring the influence of the conformation of the expanded porphyrins upon their electronic structures.

Several years ago we found that a series of *meso* aryl-substituted expanded porphyrins could be prepared by a simple one-pot reaction by using modified Rothemund–Lindsey conditions.[5c,9] These *meso* aryl expanded porphyrins can be regarded as real homologues of porphyrins in terms of regular alternate arrangements of pyrrole rings and methine carbon atoms. These molecules become more twisted with increasing number of pyrrolic subunits. It then occurred to us that suppression of this intrinsic twisting attribute may be a promising means to tune their conformational and electronic properties to generate large aromatic ring systems. We now report the influence of an internal 1,4-phenylene bridge that bisects large *meso* aryl-substituted expanded porphyrins—particularly the cases of decaphyrin and octaphyrin—on their structural and electronic properties.

A solution of one equivalent of 1,4-phenylene-bridged bis(dipyrromethane) **1a**[10] and two equivalents of tripyrrane diol **2** in dichloromethane was stirred in the presence of *p*-toluenesulfonic acid for 1 h, followed by oxidation with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) (2.6 equivalents relative to **1a**) for an additional 1 h. Separation of the products by column chromatography on silica gel gave internally 1,4-phenylene-bridged [46]decaphyrin **4a** as a major product with a green metallic luster in 7% yield. Neither the 1,4-phenylene-bridged pentaphyrin dimer nor its derived products[11] were detected in the reaction mixture. Treatment of **4a** with 10 equivalents of DDQ resulted in its quantitative conversion into [44]decaphyrin **5a**, with a color change from dark red to dark green. [44]Decaphyrin **5a** was in turn quantitatively reduced to **4a** with $NaBH_4$, thus indicating a reversible redox interconversion. Electrospray ionization mass spectrometry revealed a parent ion peak for **4a** at *m*/*z* 2179.2163 (calcd for $C_{104}H_{31}F_{40}N_{10}$ $[M+H]^+$, *m*/*z* 2179.2100) and that for **5a** at *m*/*z* 2177.2032 (calcd for $C_{104}H_{29}F_{40}N_{10}$ $[M+H]^+$, *m*/*z* 2177.1943).

The structures of both **4a** and **5a** have been confirmed by X-ray diffraction analyses. Decaphyrin **4a** exhibits a C_2-symmetric nonplanar, but not a "figure-eight", structure (Figure 1),[12a] in which the two twisted pentapyrrolic subunits are interconnected by the central 1,4-phenylene bridge. Each pentapyrrolic arm consists of a dipyrromethene unit (pyrrole rings A and B or F and G) and a tripyrrodimethene unit (pyrrole rings C, D, and E or H, I, and J), both of which are roughly planar but almost opposite each other. The central 1,4-phenylene unit (ring K) is tilted relative to the neighboring pyrrole rings A and J as well as E and F, with dihedral angles of 60.1° and 59.8°, respectively, hence allowing its deconjugation from the rest of the conjugated network.

Ar = pentafluorophenyl

Interestingly, the two C(pyrrole-α)–C(*meso*) bond lengths at the bridging positions are quite similar, thus suggesting effective conjugation over the overall macrocycle and in line with the 46π electronic circuit. The ^{1}H NMR spectrum of **4a** was quite broad at room temperature, indicative of fast conformational dynamics in solution relative to the NMR time scale. However, the spectrum became well resolved at 233 K with distinct differences in chemical shifts evident between the outer and inner protons of the macrocycle: the outer two NH protons at $\delta = 9.01$ ppm versus the inner four NH protons at $\delta = 5.84$ ppm; the outer β protons as two sets of mutually coupled doublets at $\delta = 7.36$ and 6.84 ppm and $\delta = 7.31$ and 7.19 ppm versus the inner β protons as a singlet at $\delta = 1.2$ ppm. The protons of the 1,4-phenylene bridge, assigned by comparison of the spectrum with that of the corresponding deuterated decaphyrin **4b**, appear as a sharp singlet at $\delta = 3.78$ ppm. These data support a diatropic ring current in **4**.

On the other hand, [44]decaphyrin **5a** shows a D_2-symmetric framework that is distinctly different from that of **4a** (Figure 2).[12b] Pairs of neighboring pyrrole rings (A and B, D and E, F and G, and I and J) constitute planar dipyrromethene units, and the pyrrole rings C and H are completely inverted, with the pyrrolic nitrogen atoms pointing outward. Each pentapyrrolic arm adopts a twisted but relatively planar structure, which constitutes a so-called benzihexaphyrin macrocycle. The arms are connected by the central 1,4-phenylene spacer in an almost perpendicular arrangement. Decaphyrin **5a** exhibits a well-resolved ^{1}H NMR spectrum at room temperature, with the inner four NH protons as a singlet at $\delta = 13.6$ ppm; the outer β protons as doublets at $\delta =$ 6.82 and 6.30 ppm and a multiplet at $\delta = 6.36$ ppm; the inverted pyrrole β protons as a singlet at $\delta =$ 7.78 ppm, and the bridging 1,4-phenylene protons as a singlet at $\delta =$ 8.98 ppm. The protons of the 1,4-phenylene bridge were assigned by comparison with the ^{1}H NMR spectrum of **5b**. There is no distinct difference between the chemical shifts of the inner and outer protons in **5a**, which is indicative of its non-aromatic character, and in line with its 44π electronic circuit and solid-state structure. The absorption spectrum of **4a** shows a Soret-like band at 505 nm and strong Q-like split bands at 800 and 856 nm, while that of **5a** exhibits broad bands at 454 and 619 nm (Figure 3). Interestingly, protonation of **4a** with trifluoroacetic acid (TFA) led to an intense and sharp Soret-like band at 846 nm and a Q-like band at 1221 nm.

We then examined the reaction of **1a** with dipyrromethane diol **3**. A solution of **1a** and **3** in dichloromethane and THF (3:1) was treated with methanesulfonic acid for 1 h and the resulting solution was oxidized with *p*-chloranil for 2 h. Together with the expected 1,4-phenylene-linked porphyrin dimer[14] (1–2% yield) which appeared as a red band by TLC analysis of the reaction mixture, two violet bands were observed and the products were isolated in yields of 0.6 and 0.5%. Despite the low yields, the formation of these products is quite reproducible when *p*-chloranil is used as the oxidant and the reaction time of the secondary oxidation step is maintained at 2 h. High-resolution electrospray ionization mass spectrometry revealed the parent ion peak at *m*/*z*

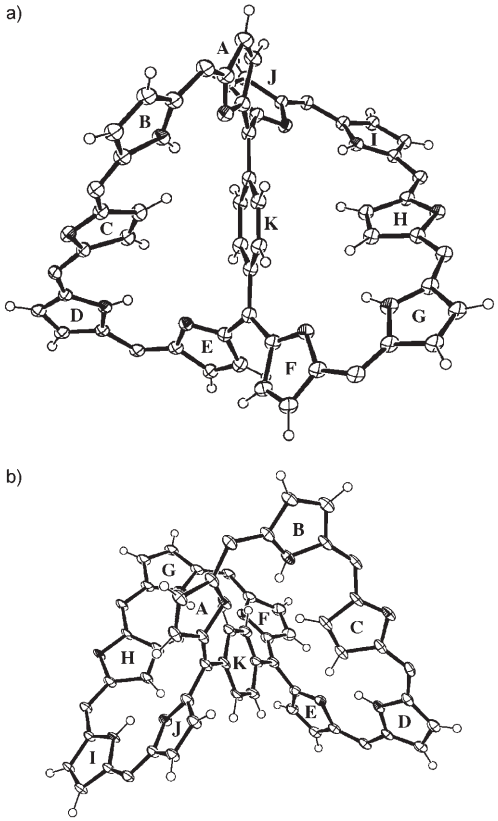

Figure 2. X-ray crystal structure of **5a**: a) top view and b) side view. Solvent molecules and *meso*-pentafluorophenyl groups are omitted for clarity.

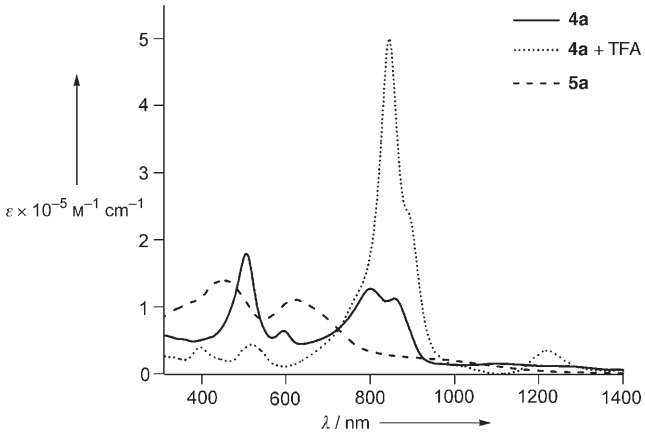

Figure 3. Absorption spectra of **4a**, **4a** + TFA, and **5a** in dichloromethane.

1693.1920 for **6a** (calcd for $C_{82}H_{27}F_{30}N_8$ $[M+H]^+$, m/z 1693.1874) and 1693.1915 for **7a** (calcd for $C_{82}H_{27}F_{30}N_8$ $[M+H]^+$, m/z 1693.1874). The absorption spectra of **6a** and **7a** are also quite similar to each other, with bands at 394, 593, and 895 nm, and 392, 593, and 898 nm, respectively. The structure of **6a** has been unambiguously revealed by X-ray diffraction analysis to be a *p*-quinodimethane-bridged calixoctaphyrin with two sp^3 meso carbon atoms at the diagonal positions and overall C_{2h} symmetry (Figure 4).[13] The bicyclic macrocycle adopts a saddle conformation consisting of four planar dipyrromethene units rather than a non-figure-eight structure. The quinodimethane structure is evident from a distinctly shorter C(22)–C(23) bond (1.367(4) Å) relative to that of C(21)–C(22) (1.430(4) Å). The angle C(23)*-C(21)-C(22) is 115.6(2)°, which is distinctly smaller than that of C(21)-C(22)-C(23) (122.7(3)°) and C(22)-C(23)-C(21)*

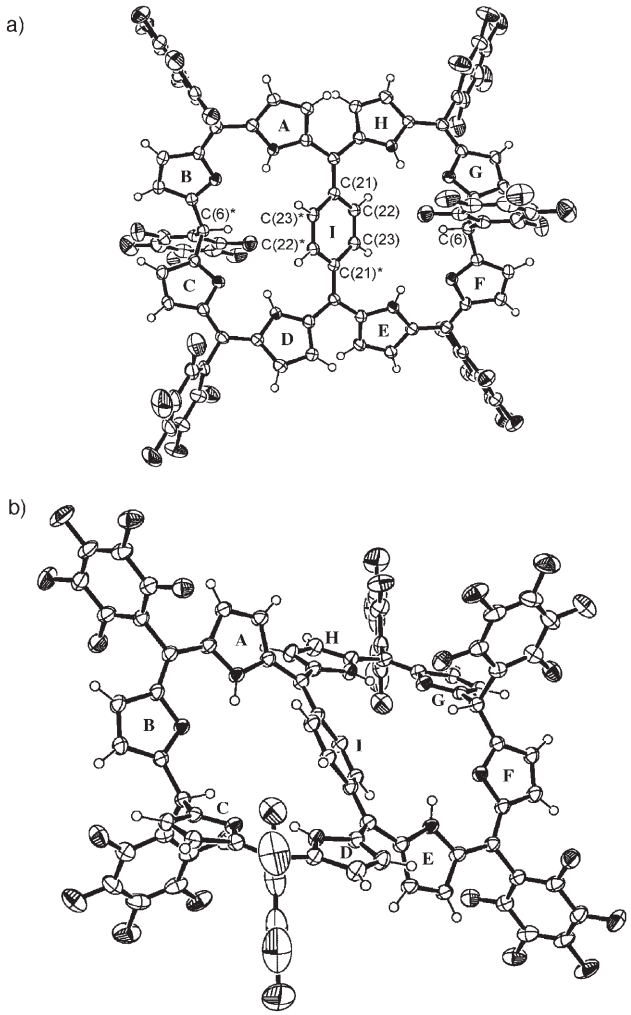

Figure 4. X-ray crystal structure of **6a**: a) top view and b) side view. Solvent molecules are omitted for clarity.

(121.7(3)°). The exo-methylene moieties in the quinodimethane unit are tilted by 18.1° relative to the six-membered ring. The dipyrromethene units are all maintained planar by hydrogen bonding, and thus all the pyrrolic nitrogen atoms point inward. The dipyrromethene units A, B and C, D are arranged with a dihedral angle of 60.9°, which are tilted relative to the central quinodimethane unit by 46.0 and 49.4°, respectively. The two pentafluorophenyl substituents at C(6) take anti and exo positions. The symmetric structure of **6a** is supported by its simple ^{1}H NMR spectrum, in which the central quinodimethane protons appear as a singlet at $\delta =$ 5.09 ppm and the meso protons appear as a singlet at $\delta =$ 2.71 ppm. The structure of **7a** has been revealed by a preliminary X-ray diffraction analysis to be almost the same as that of **6a** except for the positions of the pentafluorophenyl groups at C(6), which are both anti but not identical, each exo and endo (Supporting Information). The nonsymmetric structure of **7a** is in good agreement with the NMR data, with the central quinodimethane protons appearing as two singlets at $\delta = 5.21$ and 4.85 ppm and the *meso* protons appearing as two singlets at $\delta = 6.42$ and 2.45 ppm.

The reaction of **1** with dipyrromethane diol **8** afforded calixoctaphyrin **9** as a single major product as a violet solid in 3% yield. In the ^{1}H NMR spectrum of **9** the internal *p*-quinodimethane protons appear as a singlet at $\delta = 4.65$ ppm and the *gem*-dimethyl protons as two singlets at $\delta = 1.39$ and -1.03 ppm. The high chemical shifts of one of the dimethyl groups can be ascribed to its positioning just above the central bridge. Therefore, a *p*-quinodimethane structure may be considered to be a general concequence when a 1,4-phenylene bridge is incorporated in *meso* aryl-substituted calixoctaphyrins. In sharp contrast to **6a** and **7a** the calixoctaphyrin **9** is quite stable under oxidizing conditions.

This study shows that the incorporation of a 1,4-phenylene bridge into *meso* aryl-substituted expanded porphyrins has a profound impact on the structural and electronic properties of the macrocycles. Such modifications lead to suppression of the intrinsic property to take a twisting conformation and result in planar conformations. The structural modification result in diatropic ring current in the decaphyrin case, and forces a macrocycle to become calixoctaphyrin with an internal *p*-quinodimethane bridge in the octaphyrin case. Lastly, it is interesting to note that [46]decaphyrin is, to the best of our knowledge, the largest macrocycle that exhibits a diatropic ring current.

Synthesis of Chiral α-Fluoroketones through Catalytic Enantioselective Decarboxylation**

Masaharu Nakamura, Alakananda Hajra, Kohei Endo, and Eiichi Nakamura**

A number of biologically active compounds bear secondary stereogenic centers next to a carbonyl group as a key structural feature, which are often susceptible to racemization during manipulation, storage, synthesis, or under physiological conditions under which they are expected to exhibit useful functions. Optically active α-fluoroketones could serve as nonracemizable surrogates of these compounds and have received much attention in medicinal chemistry.[1,2] Interest in their synthesis therefore resulted in several recent reports on the enantioselective synthesis of α-fluorinated carbonyl compounds from the corresponding α-protio precursors,[3] but the scope of the known fluorination methods is still limited.[4] We report herein a new alternative synthetic strategy in which racemic α-fluoroketones are converted into optically active ketones through enantioselective C–C bond reorganization.

A racemic α-fluoro-β-ketoester **1** was converted into the corresponding optically active α-fluoroketone **2** by palladium-catalyzed extrusion of carbon dioxide (Table 1). On the basis of the original Tsuji reaction mechanism, we surmised that the reaction possibly proceeds first through the formation of a palladium enolate, through which the new chirality is introduced under the influence of a chiral ligand.[5] This palladium enolate, which is tetrasubstituted and bears a fluorine substituent *cis* to the carbonyl oxygen atom,[5b] is probably related to that generated by palladium-catalyzed decarboxylation of the corresponding enol allyl carbonate reported recently by the groups of Stoltz and Trost.[6]

Investigation of the reaction conditions by using [Pd_2-$(dba)_3$] as a catalyst precursor and a variety of chiral ligands

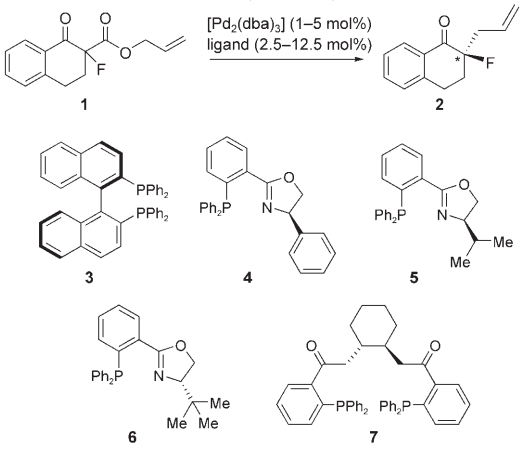
(1.25 equiv relative to Pd) gave us some insight into the nature of the catalytic process. A comparison of entry 1 of Table 1 with the remaining entries shows that the reaction is vastly accelerated by the phosphine ligands **3**–**7**. After screening of a variety of ligands[7] including binap (**3**),[8] which gave low selectivity (Table 1, entry 2), we found that chiral phosphinooxazolines **4**–**6**[9] were suitable for the reaction. The enantioselectivity is very sensitive to the substituent on the oxazoline ring: phenyl-substituted ligand **4** led to only 11% *ee*, whereas the selectivities improved greatly with the isopropyl- **5** (83% *ee*) and the *tert*-butyl-substituted **6** analogues (96% *ee*) (Table 1, entries 3–5). The catalyst loading can be decreased to 1 mol% at the expense of reaction rate, but without erosion of yield and selectivity (Table 1, entries 5–7). The choice of solvent is very important, as seen in the significant decrease in the selectivity when the reaction was carried out in dichloromethane (25% *ee*; Table 1, entry 9) instead of in THF or diethyl ether (96% *ee*; Table 1, entry 8). A decrease in the reaction temperature from 25 to 0°C did not change the performance of the reaction (Table 1, entry 10). The chiral bisphosphine ligand **7**, which gave good results in the related decarboxylative allylation reaction of allyl enol carbonates,[6b] was ineffective in the present reaction (Table 1, entry 11).

Table 1: Enantioselective decarboxylative allylation of tetralone **1**.[a]



Entry	Ligand	*t* [h]	Solvent	[$Pd_2(dba)_3$][b] [mol%]	Yield [%][c]	*ee* [%][d]
1	none	24	THF	5	0	–
2	**3**	5	THF	5	83	11
3	**4**	3	THF	5	91	11
4	**5**	3	THF	5	94	83
5	**6**	3	THF	5	95	96
6	**6**	4	THF	2.5	95	96
7	**6**	10	THF	1	93	94[e]
8	**6**	4	Et_2O	5	93	96
9	**6**	5	CH_2Cl_2	5	89	25
10	**6**	4	THF	2.5	94	96[f]
11	**7**	10	THF	5	9	n.d.[g]

[a] All reactions were performed on a 0.5-mmol scale at a 0.05 M substrate concentration at ambient temperature (22–25°C), unless otherwise noted. [b] dba = dibenzylideneacetone. [c] Yields of isolated product. [d] The enantiomeric excess was determined by chiral HPLC analysis on a Daicel Chiralcel OJ-H column. The antipode of **2** is the major product in entries 2, 3, and 4. [e] The reaction was conducted on a 1-mmol scale. [f] The reaction was performed at 0°C. [g] The *ee* value was not determined, and the yield is based on the ratio of areas of the uncalibrated GC peaks for **1** and **2**.

The scope of the reaction was examined and representative results are shown in Table 2. The α-fluorinated ketoester starting materials were readily obtained from the corresponding α-protio compounds in quantitative yields through standard methods.[11] Results obtained with α-alkyl- and α-alkenyl-β-ketoesters instead of α-fluoro compounds are also included (Table 2, entries 10–12).

The decarboxylation reaction of a methallyl tetralone compound (Table 2, entry 3) gave almost the same level of selectivity as the allyl analogue. The selectivity improved to 99% *ee* when the catalyst loading was doubled (Table 2, entries 2 and 3), which suggests that there are ligand-independent racemic pathways operating along with the desired enantioselective catalytic process. Methoxy substitution on the aromatic ring of tetralone that may exert certain conjugation electronic effects on the reaction did not affect the selectivity (Table 2, entry 4). Modification of the saturated ring of the tetralone structure affects the enantioselectivity (Table 2, entries 5 and 6), which suggests that the steric environment has larger impact on the selectivity. The aromatic moiety of the tetralone is not required for high enantioselectivity, as can be seen in the example of the cyclopentane analogue (Table 2, entry 7). However, the selectivity was slightly lower. This example shows that the decarboxylative mechanism dictates the regioselective formation of the more-substituted α-fluoro ketone. The reaction can also be applied to acyclic ketones but the selectivity is moderate (Table 2, entries 8 and 9). This seems reasonable because an *E*/*Z* mixture of the palladium enolate may form in situ and lead to lower selectivity. This issue is related to the reaction mechanism and needs further studies.

The reaction could be a viable method for the creation of nonracemic all-carbon quaternary centers (Table 2, entries 10 and 11).[12] This reaction seems to be related to that reported recently by the Trost and Stoltz groups,[6] but is different in practice as the method creates a quaternary carbon center from synthetically more-readily accessible β-ketoesters rather than from allyl enol carbonates. A few characteristics are noteworthy: The new chirality is also generated at a palladium enolate. The putative tetrasubstituted enolate intermediate bears three alkyl groups and one oxygen atom rather than a fluorine substituent, but the enantioselectivity was still found to be high (Table 2, entry 10). However, the selectivity decreases when the ketone is part of a five-membered ring (Table 2, entry 11) and when the substrate bears an α-alkenyl group (Table 2, entry 12).[13] The intermediate in this case is a conjugated dienolate of palladium instead of a simple palladium enolate. The undesirable effect of the conjugation is apparent, in contrast to the slightly positive effect of the highly electron withdrawing fluorine atom (Table 2, entries 3 and 10). Interestingly, the reaction still results in C–C bond formation at the α-carbon atom

Table 2: Enantioselective synthesis of chiral α,α-disubstituted ketones from racemic substrates.[a]

Entry	Substrate	Product	Yield [%][b]	*ee* [%][c]
1	**1**	**2**	95	96
2[d]			96	99
3	R = methallyl		95	97
4	 R = allyl		92	96
5	 R = allyl		94	91
6	 R = allyl		94	93
7			82[e]	85
8			89	51
9			91	55
10	 R = methallyl		94	95
11			87[e]	84
12			89	39

[a] All reactions were performed on a 1.0-mmol scale with a 0.05 M substrate concentration in THF for 4–10 h at 22–25 °C in the presence of $[Pd_2(dba)_3]$ (2.5 mol%) and ligand **6** (6.25 mol%), unless otherwise noted. [b] Yields of isolated product. [c] The enantiomeric excess was determined by chiral HPLC analysis, except in entries 7 and 11 for which it was determined by GC analysis (see Supporting Information). The absolute configuration of the major enantiomers was inferred from the sign of their circular dichroism spectra identical to those observed for the compounds in entries 10 and 11,[10] whose stereochemistry was determined by comparison of their optical rotation with that of the known compounds.[6] [d] The reaction was carried out with $[Pd_2(dba)_3]$ (5 mol%) and **6** (12.5 mol%). [e] The yield suffered from evaporative loss owing to the low boiling point of the product.

rather than at the distal carbon atom (which would produce a more-stable α,β-unsaturated ketone product).

In summary, we have developed a new class of enantioselective C–C bond-forming reactions that is useful for regio- and enantioselective synthesis of α-allyl-α-fluoro ketones as well as ketones that bear an α-quaternary center. The reaction is mechanistically different to the recently reported enantioselective synthesis of α-fluoro carbonyl compounds and appears to involve intriguing mechanistic details that are as yet to be explored by theory and experiments.

Experimental Section

A 50-mL two-necked round-bottomed flask equipped with a magnetic stirrer bar was flame dried in vacuo, cooled to room temperature, and charged with $[Pd_2(dba)_3]$ (22.9 mg, 0.025 mmol, 0.025 equiv) and ligand **6** (24.2 mg, 0.0625 mmol, 0.0625 equiv) under argon. The system was evacuated slowly and flushed with argon three times. THF (20 mL) was added. The mixture was stirred for 30 min, and ketoester **1** (248 mg, 1.0 mmol, 1.0 equiv) was added dropwise through a syringe to the reaction mixture. The resulting solution was stirred for 4 h at 25 °C (full conversion checked by TLC and GC), and the solvent was then evaporated in vacuo. Purification by column chromatography on silica gel (eluent: Et_2O/hexane 5:95) gave the fluoroketone **2** (193.9 mg, 95% yield) as a colorless oil.

Observation of d-Orbital Aromaticity**

*Xin Huang, Hua-Jin Zhai, Boggavarapu Kiran, and Lai-Sheng Wang**

Aromaticity is one of the most important concepts in chemistry and refers to planar cyclic hydrocarbon molecules that exhibit delocalized π-bonds and unusual stability, such as benzene. This concept has been extended to metal-substituted organic molecules,[1,2] as well as main group organometallic complexes.[3–6] The recent discovery of aromaticity in all-metal clusters, for instance $[Al_4]^{2-}$ in $[MAl_4]^-$ (M = Cu, Li, Na),[7] has led to a flurry of research activities[8–16] and predictions of new aromatic metal clusters,[17–23] among which is a class of interesting cyclic species containing Cu.[20,23]

While main group clusters can give rise to σ- and π-aromaticity, transition-metal-containing clusters can exhibit d-orbital aromaticity or, more interestingly, δ-aromaticity due to δ bonding interactions. However, d-orbital aromaticity requires significant d–d bonding interactions. Unlike valent s or p orbitals, d orbitals are spatially more contracted, and their tendency to participate in chemical bonding depends strongly on the position of the transition metals in the periodic table and their coordination environments. The predicted aromaticity in the cyclic Cu-containing species,[20,23] for example, has not been verified experimentally. More promisingly, d-orbital aromaticity is expected to be found in early or 4d/5d transition metal systems, where strong d–d interactions are known. Here, we report experimental and theoretical evidence of d-orbital aromaticity in two early 4d and 5d transition metal oxide clusters, namely $[M_3O_9]^-$ and $[M_3O_9]^{2-}$ (M = W, Mo).

Early transition metal oxide clusters have recently gained experimental and theoretical attention due to their importance in catalysis.[24–26] We investigated the structure and bonding of early transition metal oxide clusters using a combined photoelectron spectroscopy (PES) and theoretical approach with the aim of discovering specific structures or clusters that may mimic a catalytic site.[27,28] Our experiment was carried out with a magnetic-bottle PES apparatus with a laser vaporization cluster source. A pure metal target (W or Mo) was used in the laser vaporization with a helium carrier gas containing 0.5% O_2. $[M_xO_y]^-$-type clusters with various stoichiometry were produced from reactions between the laser-induced plasma and O_2 in the carrier gas and were separated in a time-of-flight mass spectrometer. The $[M_3O_9]^-$ clusters (M = W, Mo) of interest were selected and decelerated before being intercepted by a 157-nm laser beam from an F_2 excimer laser. Photoemitted electrons were collected by a magnetic bottle with nearly 100% efficiency and analyzed in a 3.5-m-long electron flight tube. The photoelectron spectra were calibrated against the known spectrum of Rh^- and the apparatus had an electron energy resolution of $\Delta E_k/E_k \approx 2.5\%$, i.e., approximately 25 meV for 1-eV electrons.

Figure 1 displays the 157-nm spectra of $[W_3O_9]^-$ and $[Mo_3O_9]^-$, which are similar, each with a weak and broad threshold band (X) followed by a large energy gap and more features at very high electron-binding energies. The X band in both spectra yields a similar threshold detachment energy of about 3.5 eV for $[W_3O_9]^-$ and $[Mo_3O_9]^-$, and vertical detachment energies (VDEs) of 4.2 and 4.0 eV, respectively. The neutral $[M_3O_9]$ clusters are stoichiometric species in which W and Mo assume their highest oxidation state, M^{6+}. Thus, the threshold band (X) should correspond to detachment of the extra electron in the anions that occupies an d-type orbital that is empty in the neutral species, whereas the higher detachment features should all derive from detachment from O 2p-type orbitals. Interestingly, the observed energy gaps in the photoelectron spectra (Figure 1) of about 3.3 eV (3.2 eV) for $[W_3O_9]^-$ ($[Mo_3O_9]^-$), are already very close to that for the corresponding bulk MO_3 oxides. The threshold band (X) in both spectra is extremely broad, in particular in the spectrum of $[W_3O_9]^-$, thus suggesting that there is a large difference in geometry between the anion and neutral ground state of the $[M_3O_9]$ clusters.

To understand the structures and bonding in the $[M_3O_9]$ and $[M_3O_9]^-$ clusters, we carried out density functional theory (DFT) calculations.[29] Figure 2 displays the ground-state structures for $[M_3O_9]$ and $[M_3O_9]^-$. The structures of neutral $[W_3O_9]$ and $[Mo_3O_9]$ are nearly identical, with D_{3h} symmetry, and each metal atom is bonded to two bridging O atoms and two terminal O atoms. The $[W_3O_9]^-$ and $[Mo_3O_9]^-$ anions also display D_{3h} symmetry, but the M–M distance is significantly reduced by 0.29 Å in $[W_3O_9]^-$ and 0.25 Å in $[Mo_3O_9]^-$ relative to the neutral structures, and this is accompanied by a large increase in the OMO angle and a large decrease in the MOM angle that makes the M_3O_3 ring almost a perfect hexagon in $[M_3O_9]^-$ (Figures 2b and 2e). These geometrical changes are consistent with the broad ground-state PES band for the two clusters (Figure 1). Our calculated VDEs of 4.39 and 4.11 eV agree well with the measured values of 4.2 and 4.0 eV for $[W_3O_9]^-$ and $[Mo_3O_9]^-$, respectively, and our calculated adiabatic detachment energies (ADEs) for the two anions are 3.0 eV, which is smaller than the experimental threshold value of 3.5 eV. The large differences between the calculated ADEs and VDEs are consistent with the large difference in geometry between the anion and neutral ground-states. The smaller value of the calculated ADE relative to the experimental threshold value suggests that the 0–0 transition from the ground state of the anion to that of the neutral clusters may have negligible Franck–Condon factors due to the large difference in geometry, and the measured threshold detach-

ment energy can only serve as an upper limit for the true adiabatic value.

The surprisingly large geometry change induced by addition of a single electron to $[M_3O_9]$ suggests that the molecular orbital that the extra electron occupies in the anion must involve strong metal–metal bonding. Figures 3a and 3b

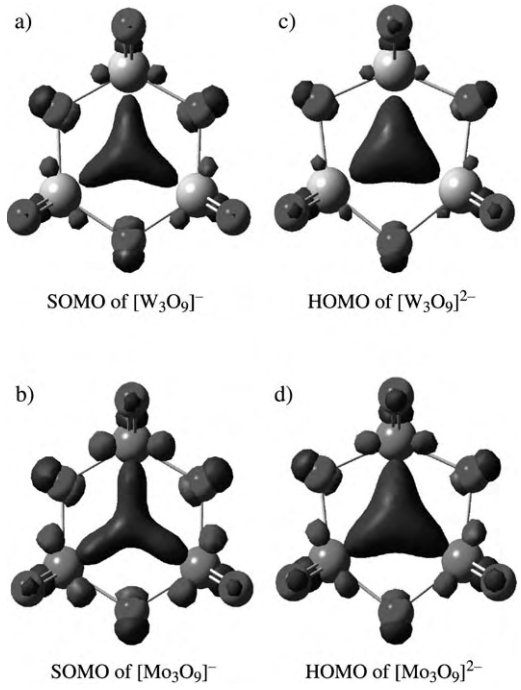

Figure 3. The singly occupied molecular orbital (SOMO) for $[W_3O_9]^-$ (a) and $[Mo_3O_9]^-$ (b) and the highest occupied molecular orbital (HOMO) of $[W_3O_9]^{2-}$ (c) and $[Mo_3O_9]^{2-}$ (d).

show the singly occupied molecular orbitals (SOMOs) for $[M_3O_9]^-$, which indeed describe nearly pure three-center M–M σ-bonding interactions with very little contribution from the O atoms. Judging by the huge M–M distance change induced by the single electron, these SOMOs must depict two strong three-center, one-electron (3c–1e) metal–metal bonds. The SOMO of $[M_3O_9]^-$ is a nondegenerate a_1' orbital. Addition of a second electron to this a_1' orbital gives rise to closed-shell $[M_3O_9]^{2-}$ dianions, which also display D_{3h} symmetry (Figure 2c, f) and a three-center, two-electron (3c–2e) bond (Figures 3c and 3d). Our calculations show that the dianions are also unusually stable despite the strong intramolecular coulomb repulsion. In fact, $[W_3O_9]^{2-}$ is predicted to be a stable gas-phase dianion with a calculated electron binding energy of 0.03 eV relative to $[W_3O_9]^-$. The $[Mo_3O_9]^{2-}$ dianion is predicted to be slightly unstable, with a small negative electron binding energy of −0.14 eV. More significantly, we found that the addition of a second electron to $[M_3O_9]^-$ also induces a considerable shortening of the M–M bond length of 0.19 Å (0.20 Å) for $[W_3O_9]^{2-}$ ($[Mo_3O_9]^{2-}$) relative to $[M_3O_9]^-$.

To gain further insight into the 3c–1e and 3c–2e bonds in $[M_3O_9]^-$ and $[M_3O_9]^{2-}$, we estimated their resonance energies (see Supporting Information).[30] Two isodesmic equations were used for $[W_3O_9]^{2-}$ to eliminate the potential influence of the different electrostatic interactions in the doubly charged anions. When the intramolecular coulomb interactions of the dianions involved are balanced by the K^+ cation a very large resonance energy of 1.05 eV is obtained, which is, in fact, comparable to the value estimated for benzene.[30] This large resonance energy suggests that the $[M_3O_9]^{2-}$ species may be viewed as highly aromatic. We further calculated their nucleus independent chemical shifts (NICS), which have been suggested as a magnetic criterion for aromaticity.[31] We obtained NICS values of −21.5 and −20.5 at the ring center for $[W_3O_9]^{2-}$ and $[Mo_3O_9]^{2-}$, respectively (see Supporting Information), that are much higher than those predicted for the cyclic Cu-containing clusters[20,23] and are comparable to the multiply aromatic $[Al_4]^{2-}$. The large resonance energies, the equal M–M bond lengths, and the large negative NICS values all suggest that $[W_3O_9]^{2-}$ and $[Mo_3O_9]^{2-}$ are highly aromatic species. More interestingly, we also obtained a sizable resonance energy for $[W_3O_9]^-$ (0.33 eV, see Supporting Information) even though it only contains a single delocalized electron, which suggests it may also be considered as aromatic; this was corroborated by the NICS values.

Trinuclear clusters of W and Mo have been studied extensively.[32,33] However, all these cluster complexes involve M^{4+} metal centers, typified by the $[M_3O_4]^{4+}$ core, whose metal–metal bonding can be described by three classical 2c–2e metal–metal bonds; they are therefore not expected to exhibit aromaticity. Quasi-aromaticity has been invoked to explain the strong M–O interactions in the $[M_3O_4]^{4+}$-type complexes,[34,35] but that is very different from the d-orbital aromaticity in the $[M_3O_9]^-$ and $[M_3O_9]^{2-}$ clusters discussed here. Aromaticity has also been considered in trinuclear Pt_3 and Os_3 metal complexes solely on the basis of molecular orbital topologies,[36,37] but it has not been verified using other criteria for aromaticity.

The $[M_3O_9]^-$ and $[M_3O_9]^{2-}$ clusters described here are unique in that they involve a single, fully delocalized metal–metal bond and may be considered as a new class of d-orbital aromatic molecules. The oxidation state of M can be considered to be fractional— +17/3 in $[M_3O_9]^-$ and +16/3 in $[M_3O_9]^{2-}$. Polyoxometalate clusters involving W and Mo are also well known.[38] The high stability of the $[M_3O_9]^-$ and $[M_3O_9]^{2-}$ clusters suggest that they may also be synthesized in the condensed phase. With the extra delocalized d-electrons, these clusters may exhibit novel chemical, electrochemical, and catalytic properties.

[29] The theoretical calculations were performed at the DFT level using the B3LYP hybrid functional (A. D. Becke, *J. Chem. Phys.* **1993**, *98*, 1372). A number of possible structures were evaluated, and the search for the global minima and vibrational frequency calculations were performed using analytical gradients with the Stuttgart 14-valence-electron pseudo-potentials and the valence basis sets (D. Andrae, U. Haeussermann, M. Dolg, H. Stoll, H. Preuss, *Theor. Chim. Acta* **1990**, *77*, 123) augmented with two f-type and one g-type polarization functions for W ($\zeta(f)=0.256$, 0.825; $\zeta(g)=0.627$) for Mo and ($\zeta(f)=0.338$, 1.223; $\zeta(g)=$ 0.744), as recommended by Martin and Sundermann (J. M. L. Martin, A. Sundermann, *J. Chem. Phys.* **2001**, *114*, 3408), and the aug-cc-pVTZ basis set for oxygen (R. A. Kendall, T. H. Dunning, Jr., R. J. Harrison, *J. Chem. Phys.* **1992**, *96*, 6796). Scalar relativistic effects, i.e., the mass-velocity and Darwin effects, were taken into account by using the quasi-relativistic pseudopotentials. Vertical electron detachment energies (VDEs) were calculated using the generalized Koopman's theorem (D. J. Tozer, N. C. Handy, *J. Chem. Phys.* **1998**, *109*, 10180). The extra-fine integration grid was used to obtain accurate DFT results. The geometry optimizations and vibrational frequency analysis were accomplished with the NWChem 4.6 program (*NWChem, A Computational Chemistry Package for Parallel Computers, Version 4.6*: E. Aprà et al., see Supporting Information) and the Molecular Science Computing Facility located at the Environmental Molecular Sciences Laboratory. GaussView 3.0 was used to generate the three-dimensional contours of the calculated Kohn–Sham orbitals. Nucleus-independent chemical shifts (in ppm) were computed at the centers of the optimized structures using the GIAO-B3LYP (SDD for W and Mo, 6-31+G* for O) method with the Gaussian03 program (Gaussian03 (Revision B.04): M. J. Frisch et al., see Supporting Information).

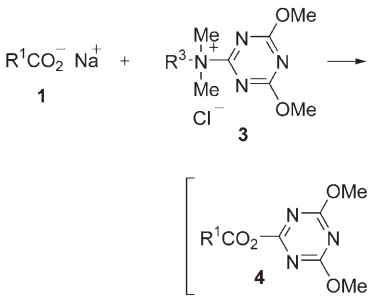
tively accelerated. In contrast, mankind has not yet succeeded in the practical application of either membrane–water or micelle–water interfaces as a reaction field. To enhance the rate of reactions in the micellar phase, the reactions must proceed in water, and all the compounds (reactants and intermediates) involved in the rate-determining step must be incorporated in the micelles to increase their local concentration. Furthermore, the molecules must be oriented appropriately for the reaction to take place. The fact that very few organic reactions (e.g. hydrolysis) meet these requirements makes it difficult to utilize micelles as a reaction field.

We believe that dehydrocondensation is most ideally suited for such rate enhancement in micelles, because all reactants that bear long hydrophobic alkyl chains, whether carboxylic acids, amines, or alcohols, are capable of forming micelles by themselves or can be incorporated in micelles formed by surfactants. Furthermore, the reacting moieties involved in the condensation (carboxy, ammonium, and hydroxy groups) are polar, and thus are located in close proximity to one another at the micellar interface. However, it has been very difficult to verify such a rate enhancement because of two major problems: 1) dehydrocondensations generally require dry conditions because many reagents and activated intermediates derived from carboxylic acids are susceptible to hydrolysis, and 2) hydrolysis reactions, the reverse reaction of dehydrocondensation, are originally promoted at the interface of micelles.[1]

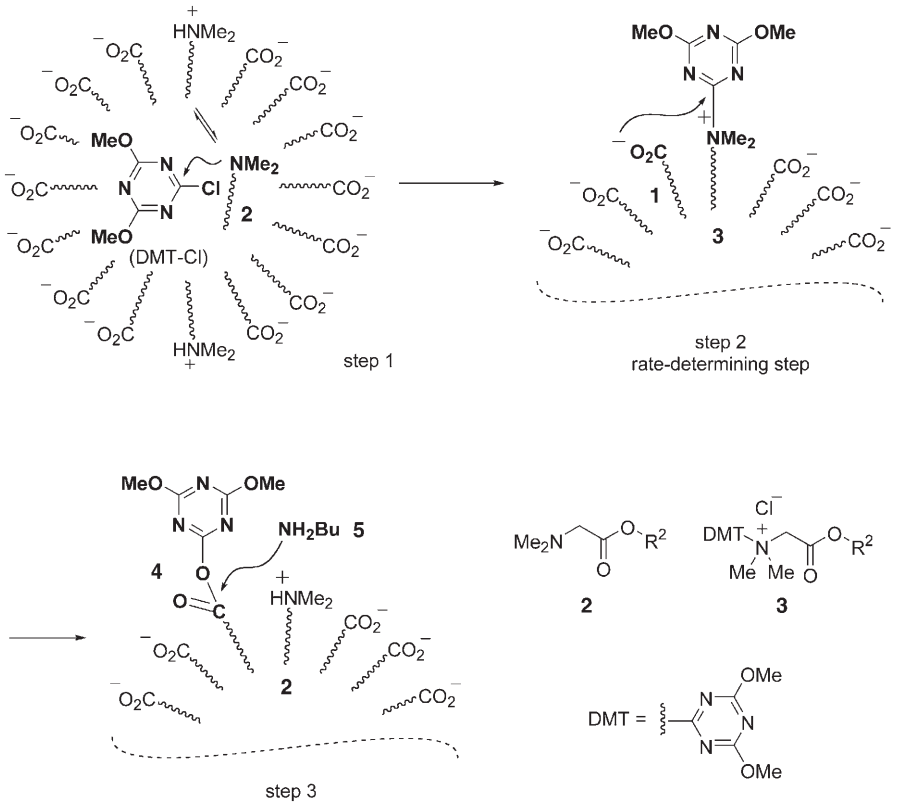
In contrast to the numerous studies of unimolecular hydrolysis reactions with micelles,[1–3] successful studies on bimolecular dehydrocondensation in micelles, which involves the activation of carboxylic acids in micelles formed in an aqueous medium, are very limited. Both lactonization with a carbodiimide[4] and lactamization in the presence of an amphiphilic Mukaiyama reagent[5] at a reverse micelle proceeded in low yields under dry conditions. Peptide synthesis at a reverse micellar interface in the presence of water proceeded in moderate yields.[6,7] As no significant rate acceleration was observed with these reactions, the micellar effect mentioned above would seem to be inadequate. More recently, Kobayashi and co-workers realized a 60-fold rate enhancement in acid-catalyzed esterification, which proceeded in the hydrophobic interior of emulsion droplets formed in water.[8,9]

In the course of our studies on 1,3,5-triazine-based dehydrocondensing agents that are available in an aqueous solvent,[10–12] we found that the reaction of the carboxylate **1** with the dehydrocondensing agent **3** to form acyloxytriazine **4** was the rate-determining step, because the reaction rate depended on the concentration of **1** [Eq. (1)]. Since both the reactants **1** and **3** have ionic structures, they should be aligned at the interface of micelles when a hydrophobic alkyl group is introduced into their structure. In the studies discussed herein, we employed amphiphilic dehydrocondensing agents based on 1,3,5-triazine to demonstrate that a large rate enhancement of bimolecular dehydrocondensation occurs in micelles as a result of both the proximity and the preorientational effects.



(1)

To simplify the reaction system, we employed the sodium salt **1** of a fatty acid which can serve both as a substrate and a surfactant. The reaction is illustrated in Scheme 1. Both hydrophobic 2-chloro-4,6-dimethoxy-1,3,5-triazine (DMT-Cl) and an amphiphilic tertiary amine **2** are incorporated in the micelles consisting of **1**. Nonionized amine **2** is buried in the micelle and then couples with DMT-Cl (step 1). This step can occur either in the outer core or in the palisade layer of the micelle[3] and can be accelerated by increasing the local concentration of the reactants. Amine **2** acts as a catalyst for the activation of DMT-Cl toward **1** through the formation of **3** (step 2). The resulting quaternary ammonium group of the amphiphilic agent **3** will be located at the interface of the



Scheme 1. Micellar effects on the catalytic dehydrocondensation.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

micelle, thus forming an ion pair with **1**. Therefore, as **1** is closely concentrated around **3**, it can readily attack the triazinyl group of **3** with concomitant liberation of **2**, which can be recycled to step 1. Step 2 is accelerated by the preorientational effect as well as the local concentration effect of the reactants at the micellar interface. The resulting activated triazinyl ester **4** undergoes aminolysis with butylamine (**5**), which is expected to be partitioned mainly in the aqueous phase, to form the amide **6** (step 3). As this step is known to be much faster than hydrolysis in water,[10] it is not rate-limiting and thus it appeared to be unimportant to ensure that it occurs in the micelle rather than at the aqueous phase.

We employed four sodium carboxylates **1A–D** with alkyl chains of different lengths. On the basis of the critical micelle concentration and Kraft points of these compounds, **1A** and **1B** should form a simple molecular dispersion phase in which these electrolytes are homogeneously dissolved in a dissociated form, whereas **1C** and **1D** should form a micellar phase at a concentration of 15 mM (25 °C).[13,14] If the bimolecular reaction rate constants between carboxylates **1** and **3** are assumed to be independent of their chain length, the observed change in reaction rate can be attributed to the micellar effect.

First, we examined the reaction of carboxylates **1A–D** with condensing agents **3a–d**[15] to estimate the acceleration of the rate-determining step (step 2) in the micelle. The reaction should be close to first-order with respect to **3**. The reaction was conducted using **1** (15 mM), **5** (as hydrochloride, 20 mM), and **3** (1.5 mM) in phosphate buffer (pH 8, 20 mM) containing MeOH (3 %)[16] at 25 °C (Table 1). The pseudo-first-order rate

A: $R^1 = C_3H_9$ **a**: $R^2 = C_2H_5$
B: $R^1 = C_7H_{15}$ **b**: $R^2 = C_8H_{17}$
C: $R^1 = C_{11}H_{23}$ **c**: $R^2 = C_{12}H_{25}$
D: $R^1 = C_8H_{17}CH{=}CHC_7H_{14}$ **d**: $R^2 = C_{16}H_{33}$

3	1A	1B	1C	1D
3a	1.0[a]	1.1	56	63
3b	0.7	3.0	1200	830
3c	21	280	860	840
3d	30	340	1400	690

[a] Pseudo-first-order rate constant: $k = 1.0 \times 10^{-3}$ min^{-1}.

constants for the reaction with respect to **3** were calculated based on the amount of the amide **6** produced. The relative rates were normalized to the reaction rate of **3a** with **1A** (rate defined as 1). In the reactions of **3a**, which has a short alkyl chain (ethyl group), no rate acceleration was observed in the reaction with octanoate **1B**, which has an alkyl chain that is four carbon atoms longer than that of butyrate **1A**, whereas the reaction with laurate **1C**, whose alkyl chain is elongated by an additional four carbon atoms, was accelerated by a factor of 56. In a series of reactions with **1C**, the reaction rate increased up to 1400 times by elongation of the ester alkyl chain of **3**. Interestingly, the reaction rates appeared to plateau with the **1C** series; reactions were not accelerated further when a longer acyl chain was used (see series **1D**).

As **1C** and **1D** form micelles under these reaction conditions, the large rate enhancements observed with these two carboxylates are attributable to the micellar effect (Scheme 1, step 2). Dehydrocondensing agents **3b–d** have alkyl chains with eight carbon atoms or more, which puts them on the borderline in their ability to be incorporated in micelles. Moderate accelerations in the reactions of **1B** with **3c** or **3d** do not arise from micelle formation but rather from a disordered aggregation owing to the hydrophobic effect. This explanation is based on the fact that **3c**, which is poorly soluble in water, does not form micelles under the reaction conditions. In fact, a white turbidity appeared upon addition of **3c** or **3d** to initiate the reaction with **1B**, whereas no turbidity was observed with **1C** and **1D**, presumably as a result of mixed micelle formation.

The substrate concentration dependence of the reaction rate in the micellar system when using **3b** was also examined. The reaction rate was found to be independent of the concentration of **1C** (15, 30, and 60 mM) whereas the reaction rate showed a linear relationship to the concentration of butylamine **5** (5, 10, 15, and 20 mM). The results indicate that step 3 becomes the rate-determining step in the micellar system instead of step 2.[17] The rate of aminolysis of the triazinyl ester with **5** dissolved in the aqueous phase is independent of the length of the acyl chain. Thus, in the micellar system, there was no significant difference between **1C** and **1D**, despite the difference in chain length (six carbon atoms).

Competitive reactions between **1A** and **1B** with either **3a** or **3b** afforded amides **6A** and **6B** (42:58 or 25:75, respectively) after the reaction mixture was stirred for 4 h at room temperature (Table 2). In contrast, the competitive reaction

Table 2: Substrate selectivity in the competitive reaction between two carboxylates in the stoichiometric system.

Carboxylates	3	*t* [h]	Yield [%]	Ratio
1A vs. **1B**	**3a**	4	16	**6A**/**6B** 42:58
1A vs. **1B**	**3b**	4	24	**6A**/**6B** 25:75
1A vs. **1C**	**3b**	1	88	**6A**/**6C** 0.4:99.6

between **1A** and **1C** with **3b** proceeded within 1 h in both good yield (88 %) and high selectivity (0.4:99.6). These selectivities are in good agreement with the relative reaction rates shown in Table 1.

Finally, the catalytic reaction of *N*,*N*-dimethylglycine alkyl esters **2** and DMT-Cl, which generate condensing agent **3** in situ, was also found to be accelerated by a factor of 140 in micelles (Table 3). The moderate acceleration in the catalytic system relative to the stoichiometric system may be attributed to the generation of **3** (step 1) which may become the rate-determining step after acceleration of step 2. This catalytic system can be considered as an acyl transferase model for preparing lipid molecules.

The amide-forming reaction in the cyclodextrin-based artificial enzyme was accelerated by a factor of 13 because of

a proximity effect resulting from the formation of an inclusion complex.[12] By comparison, the large rate enhancement of the present system should be ascribed to the micellar effect (preorientational effect and local concentration effect) illustrated in Scheme 1. Micelles of quaternary ammonium surfactants are known to promote the hydrolysis of both activated esters and condensing agents because the hydroxide ion with a negative charge opposite to that of the surfactant is concentrated at the interface.[1–7] As the present system employs carboxylate anions as surfactants, the hydroxide ion (with the same charge) does not concentrate at the micellar interface, and the hydrolysis of **3** and **4** does not become a serious side reaction. Thus, we have succeeded in demonstrating that amphiphilic dehydrocondensing agents based on 1,3,5-triazine offer the micellar interface as a superior reaction field for dehydrocondensation.

Experimental Section

General procedure: **3** (3 μmol) in aqueous methanol (40%; 0.15 mL) was added to a stirred aqueous solution (1.85 mL) of **1** (30 μmol) and **5**·HCl (40 μmol) in sodium phosphate buffer (pH 8) at 25°C. The initial concentration of reactants in the resulting solution were as follows: **1**: 15 mM; **5**: 20 mM; **3**: 1.5 mM; NaPi: 20 mM; and MeOH: 3%. The mixture was stirred at 25°C, and HCl (5M; 0.3 mL) was added at a specific time. The resulting mixture was applied to Extrelut NT (Merck, 2 g) and eluted with AcOEt. The product **6** was quantified by GC (silicone SE-30 for **6A**, silicone OV-17 for **6B**–**D**). The pseudo-first-order rate constants were determined from the slopes of liner plots of $\ln([\mathbf{3}]_t/[\mathbf{3}]_0)$ versus time (min).

Enantiodiscrimination and Enantiocontrol of Neutral and Cationic Pt^{II} Complexes Bearing the *Tropos* Biphep Ligand: Application to Asymmetric Lewis Acid Catalysis**

Koichi Mikami, Hitomi Kakuno, and Kohsuke Aikawa*

The development of asymmetric catalysts for organic reactions is one of the most challenging subjects in modern science and technology.[1] These catalysts are generally metal complexes that bear chiral and atropisomeric ligands, which require the enantioresolution and synthetic transformation of a chiral pool (atropisomeric is from the Greek *atropos*, *a* meaning not and *tropos* meaning turn).[2] However, we have already demonstrated that chirally flexible (*tropos*) 2,2′-bis(diphenylphosphanyl)biphenyl (biphep)[3] can act as a chiral ligand for Ru,[4] Rh,[5] and Pd[6] complexes through axial chirality control by chiral diamines. Therefore, the biphep complexes of Ru, Rh, and Pd can provide high levels of enantioselectivity in asymmetric hydrogenation, ene-type cyclization, and hetero-Diels–Alder reactions, respectively. Similarly, in the neutral biphep–Pt complex the chirality

control of the biphep moiety by chiral 1,1'-binaphthalene-2,2'-diol (binol) was reported not high enough (95:5) and hence recrystallization was essential to obtain the single biphep–Pt diastereomer and enantiomer.[7a,b]

Herein, we report the complete chirality control of both neutral and cationic biphep–Pt complexes without the need for recrystallization and the application of this complex to asymmetric Lewis acid catalysis (Scheme 1). Interestingly, both enantiopure (*S*)- and (*R*)-biphep–Pt complexes can be obtained quantitatively through enantiodiscrimination by using (*R*)-2,2′-bis(trifluoromethanesulfonylamino)-1,1′-binaphthyl (dabnTf) and (*R*)-2,2′-diamino-1,1′-binapthyl (dabn) with the same absolute configuration.

The highly effective enantiodiscriminating agent dabnTf was first used for enantiomer-selective complexation[8] of the neutral racemic biphep-$PtCO_3$ complex **1** (Figure 1)[7a] with complete enantiomer discrimination. Complexation of racemic complex **1** and (*R*)-dabnTf at a specified temperature was monitored by NMR spectroscopy until product (*S*)/(*R*)-**2** was precipitated. A combination of racemic complex **1** with 1.0 equivalent of (*R*)-dabnTf in [D_8]toluene gave the single diastereomer (*S*,*R*)-**2** along with the remaining (*R*)-**1** and (*R*)-dabnTf (0.5 equiv), which form a hydrogen bond between the proton of the diamide and oxygen atom of the carbonate complex (*R*)-**1**. In fact, treatment of [{(*S*)-binap}$PtCO_3$] with (*R*)-dabnTf (1.0 equiv) gave the (*S*,*R*) diastereomer complex, but the combination of [{(*R*)-binap}$PtCO_3$] with (*R*)-dabnTf (1.0 equiv) did not.[8] There was no isomerization of the remaining (*R*)-**1** enantiomer, which did not form a complex with (*R*)-dabnTf even at 50 °C after 120 h (Figure 1). Therefore, these results imply that complex **1** is *atropos* below 50 °C. At higher temperatures, isomerization of complex (*R*)-**1** followed by complexation with remaining (*R*)-dabnTf was observed. These results indicate that complex **1** is *tropos* at higher (> 60 °C) temperatures.

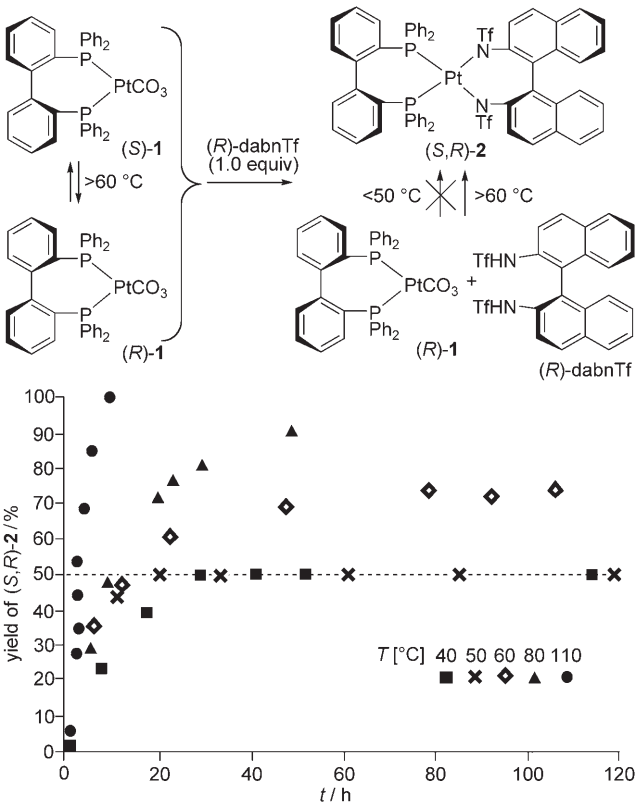

Figure 1. Temperature dependence of the isomerization of complex **1**.

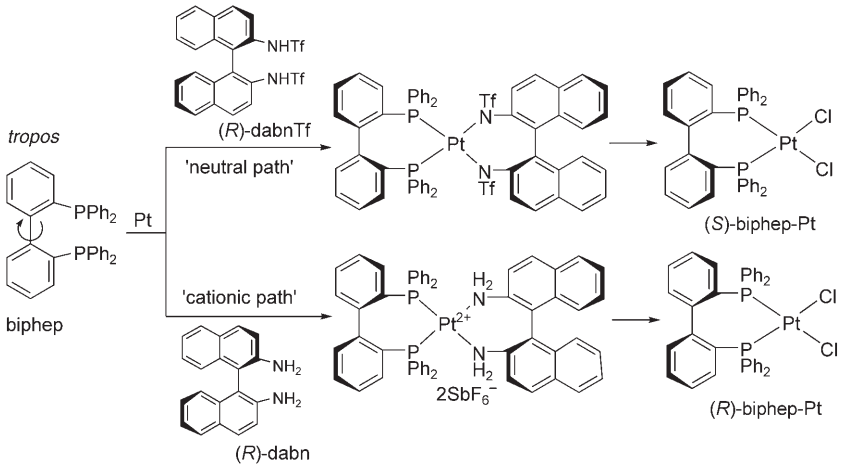

Scheme 1. Complete chirality control of both neutral and cationic biphep–Pt complexes.

After proving the *atropos* nature of biphep–Pt species even at 50 °C, we tried to isolate the enantiopure biphep–$PtCl_2$ complex **3** without epimerization. Upon addition of concentrated HCl in dichloromethane at room temperature, complex (*S*,*R*)-**2** provided the enantiopure (*S*)-**3** (> 99 % *ee*) quantitatively (Scheme 2).[7b] Pure dabnTf could also be recovered quantitatively. The enantiomeric excess (% *ee*) of (*S*)-**3** was determined by ^{1}H and ^{31}P NMR spectroscopies after complexation with enantiopure (*S*,*S*)-diphenylethylenediamine (dpen) and upon addition of 2.0 equivalents of $AgSbF_6$. In sharp contrast to the Pt complex, the Pd complex was protonated with concentrated HCl in dichloromethane even at 0 °C and the biphep moiety was epimerized (24 % *ee*) as biphep–Pd is stereochemically less stable through decomplexation of the sterically demanding dabnTf. These results show that the Pt center coordinates to the biphep diphosphine ligand more strongly than the Pd center.

We also clarified the *atropos* nature of cationic biphep–Pt complexes at room temperature. Chiral diamine

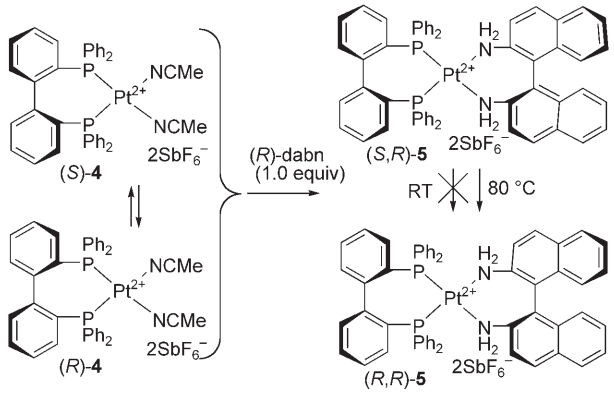
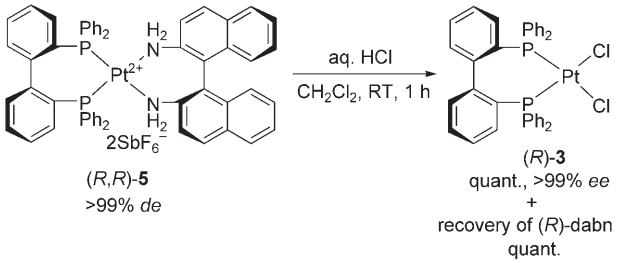
dabn was used for nonselective complexation and axial chirality control of the racemic cationic complex **4** (Scheme 3).[6b] With 1.0 equivalent of (*R*)-dabn, complexation of both enantiomers took place to afford a 1:1 ratio of a



Scheme 3. Complete chirality control of cationic biphep–Pt complex **4**.

diastereomer mixture of (*R*,*R*)-**5** and (*S*,*R*)-**5** complexes. The complex **5** bearing (*R*)-dabn did not isomerize at room temperature over 3 days but did isomerize at 80 °C after 30 h to afford exclusively the favorable (*R*,*R*)-**5** (> 99 % *de*). In the Pd complex, the favorable (*R*,*R*) complex is obtained exclusively after an even shorter period.[6b]

The complex (*R*,*R*)-**5** provided enantiopure (*R*)-**3** (> 99 % *ee*) quantitatively upon addition of aqueous HCl at room temperature (Scheme 4); dabn could also be recovered



Scheme 4. Quantitative isolation of the enantiopure (*R*)-**3**.

quantitatively. The enantiomer excess of (*R*)-**3** was determined by addition of enantiopure dpen under the same conditions as those shown in Scheme 2. The opposite axial chirality to that controlled by its amide (*R*)-dabnTf can be controlled by (*R*)-dabn with the same absolute configuration.

The structure of racemic complex **3** was determined by X-ray crystal structure analysis of a single crystal obtained from dichloromethane/hexane solution.[9] Indeed, the orientations of axial and equatorial phenyl groups in biphep portion were quite similar to those of biphep–Pd complexes.[6,10] In the enantiodiscrimination of the neutral (*R*,*R*)-**2** complex, there is strong steric repulsion between equatorial phenyl group of biphep and the trifluoromethanesulfonyl substituent (Tf) of chiral amide dabnTf (Figure 2a). In contrast, there is no steric repulsion in complex (*S*,*R*)-**2**. As a result, (*R*)-dabnTf could complex only with the single enantiomer (*S*)-**1** after isomer-

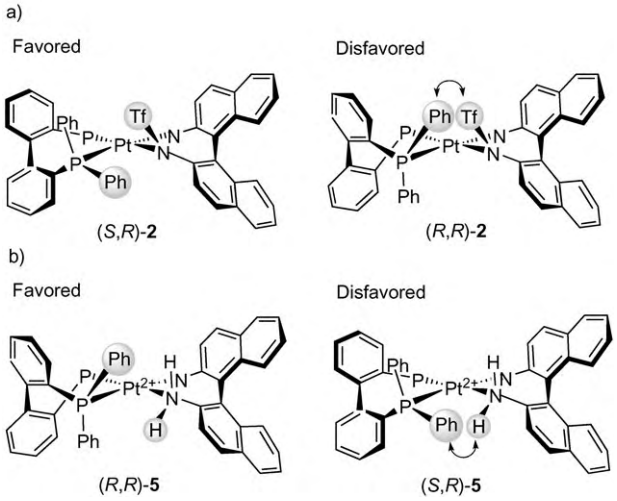


Figure 2. Enantiomer discrimination of (*R*)-dabnTf and (*R*)-dabn.

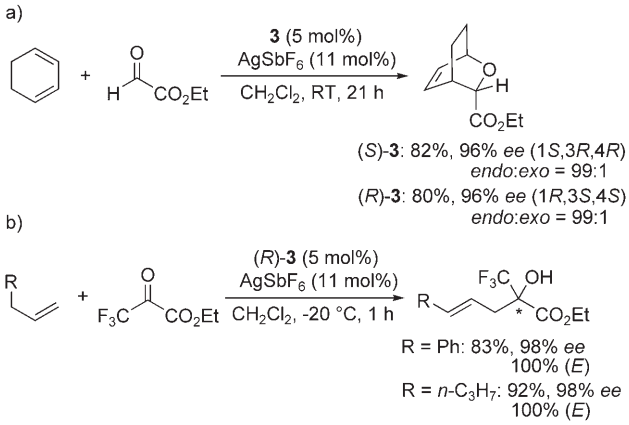
ization of the opposite enantiomer (*R*)-**1**. In the cationic (*S*,*R*)-**5** complex, there is strong repulsion between equatorial phenyl group of biphep and hydrogen atom of chiral diamine dabn. In contrast, there is no steric repulsion in the complex (*R*,*R*)-**5** (Figure 2b).

The enantiopure complex **3** thus obtained can be employed as an *atropos* asymmetric catalyst (Scheme 5).[5–7]



Scheme 5. Enantiopure **3** as an *atropos* asymmetric Lewis acid catalyst.

Indeed, the hetero-Diels–Alder reaction of 1,3-cyclohexadiene with glyoxylate[11] was catalyzed by enantiopure (*S*)-**3** (5 mol %) and $AgSbF_6$ (11 mol %) as a highly efficient Lewis acid catalyst. The hetero-Diels–Alder product was obtained with high enantioselectivity (96 % *ee*, *endo*:*exo* = 99:1) even at room temperature (Scheme 5a). Use of enantiopure (*R*)-**3** gave the hetero-Diels–Alder product with opposite absolute configuration in equally high selectivity. The complex (*S*)-**3** was obtained with (*R*)-dabnTf, and (*R*)-**3** was obtained with (*R*)-dabn. It was confirmed by addition of enantiopure dpen that racemization of the biphep moiety did not occur during the course of reaction. Additionally, enantiopure dicationic complex **3** gave high chemical yields and high levels of enantio- and *E*-selectivity in carbonyl-ene reactions with

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

trifluoropyruvate and with less reactive monosubstituted olefins (Scheme 5b).[12]

In summary, we have proven that the racemic Pt complexes even with *tropos* biphep ligands can be resolved as the *atropos* complex even at 50 °C but converted at higher temperatures into either enantiopure complex just by exchanging (*R*)-dabn and (*R*)-dabnTf with identical absolute configuration. In carbon–carbon bond-forming reactions, the enantiopure biphep–Pt complexes thus obtained can be used as the *atropos* catalysts to give high enantioselectivity.

Rhodium-Catalyzed Regio- and Enantioselective Intermolecular [4+2] Carbocyclization of 4-Alkynals with *N*,*N*-Dialkyl Acrylamides**

Ken Tanaka, Yuji Hagiwara, and Keiichi Noguchi*

Transition-metal-catalyzed cycloaddition is a powerful synthetic method for the construction of cyclic frameworks.[1] In particular, [4+2] cycloadditions of dienes or enynes with alkynes or alkenes have been widely examined for the construction of six-membered-ring systems.[2–4] However, [4+2] cycloadditions via cyclic acyl metal intermediates to give six-membered carbonyl compounds are rare.[5] Furthermore, although some transition-metal-catalyzed enantioselective intramolecular [4+2] cycloadditions have been reported,[3] enantioselective intermolecular [4+2] cycloaddition has not been established.

A recent report described the rhodium-catalyzed [4+2] carbocyclization of 4-alkynals with alkynes to afford cyclo-

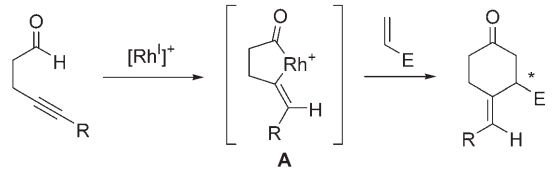
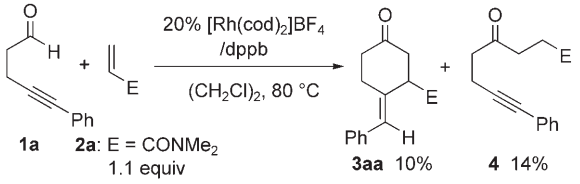
hexenones via five-membered acyl rhodium intermediates **A**, formed through the intramolecular hydroacylation of alkynes.[6] Murakami et al. also reported that similar five-membered acyl rhodium intermediates, formed by insertion of rhodium between the carbonyl carbon atom and the α-carbon atom of cyclobutanones, undergoes intramolecular reaction with alkenes to afford bicyclic cyclohexanones.[7] Herein we reveal that a cationic rhodium(I) complex of (*R*,*R*)-walphos (*R*,*R*-**7**)[8] catalyzes a highly regio- and enantioselective intermolecular [4+2] carbocyclization of 4-alkynals with *N*,*N*-dialkyl acrylamides to give enantioenriched cyclohexanones(Scheme 1).



Scheme 1. Regio- and enantioselective intermolecular [4+2] carbocyclization of 4-alkynals with alkenes.

We first examined the [4+2] carbocyclization of 5-phenyl-4-pentynal (**1a**) with alkenes. After screening various alkenes and rhodium(I) complexes, we found that the reaction of **1a** with *N*,*N*-dimethylacrylamide (**2a**) in the presence of catalytic [Rh(cod)$_2$]BF$_4$/dppb furnished cyclohexanone **3aa** in low yield along with alkynyl ketone **4** (Scheme 2). On the other hand, the use of dppe as a ligand did not furnished cyclohexanone **3aa** at all.



Scheme 2. [4+2] Carbocyclization of 5-phenyl-4-pentynal (**1a**) with *N*,*N*-dimethylacrylamide (**2a**).

The enantioselective [4+2] carbocyclization of **1a** with **2a** was examined with various chiral bidentate phosphine ligands (Table 1), which have large P-M-P natural bite angles to facilitate the reductive elimination step. The study revealed that the use of ligand (*R*,*R*)-**7** dramatically increased the yield and *ee* value of **3aa** (Table 1, entry 5). Although lower yield and *ee* were observed, the reaction can be carried out with a low catalyst loading of 5% (Table 1, entry 7). The reaction did not proceed at all in the presence of (*R*,*R*)-**6**, which bears a coordinating dimethylamino group (Table 1, entry 4).

A series of 5-substituted-4-pentynals **1a**–**f** was subjected to the above optimized reaction conditions (Table 2). The reactions of aryl- (Table 2, entries 1–4), alkenyl- (Table 2, entry 6), and alkyl- (Table 2, entry 7) substituted 4-pentynals with **2a** afforded the corresponding cyclohexanones in good yield with high enantioselectivity. The absolute configuration

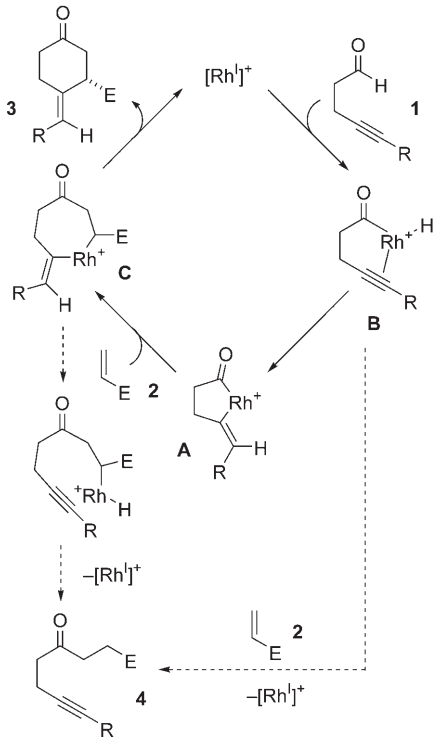
[a] No signals for other regioisomers were observed in the ^{1}H NMR spectra. The *ee* values were determined by chiral HPLC analysis. [b] Yields of isolated products.

benzaldehydes afforded the corresponding cyclohexanones in good yield with high enantioselectivity. Not only *N*,*N*-dimethylacrylamide (**2a**), but also *N*-acryloylpyrrolidine (**2b**) can be employed (Table 2, entry 5 and Table 3, entry 2).[10] In general, the reactions of 2-alkynylbenzaldehydes **1g–k** are more facile than those of 5-substituted-4-pentynals **1a–f**, which allows a lower catalyst loading. Because the [4+2] carbocyclization of 2-alkynyl benzaldehydes with alkynes did not proceed at all, this successful [4+2] carbocyclization of 2-alkynyl benzaldehydes with *N*,*N*-dialkylacrylamides is noteworthy. Importantly, these [4+2] carbocyclizations of 4-alkynals **1a–k** with **2a**,**b** are highly regioselective and no regioisomers were detected in the crude reaction mixtures.[11]

Scheme 3 shows a plausible mechanism for this carbocyclization. We infer that the rhodium catalyst oxidatively inserts into the aldehyde C–H bond to afford a rhodium acyl hydride **B**. The *cis* addition of the rhodium hydride species to the metal-bound alkyne then provides the five-membered acyl rhodium intermediate **A**.[12] Complexation of the alkene is followed by insertion to form metallacycle **C**. Reductive elimination furnishes the cyclohexanone **3** and regenerates the Rh catalyst. On the other hand, β-hydride elimination from metallacycle **C** can furnish the alkynyl ketone **4**. Alternatively, carbometalation of intermediate **B** with the alkene prior to hydrometalation can also furnish **4**.

In conclusion, we have developed a rhodium-catalyzed regio- and enantioselective intermolecular [4+2] carbocyclization of 4-alkynals with *N*,*N*-dialkylacrylamides. This method serves as an attractive new route to enantioenriched cyclohexanones in view of the one-step access to 4-alkynals from readily available terminal alkynes (1,4-addition to acrolein or Sonogashira coupling with 2-bromobenzaldehyde).



Scheme 3. Plausible mechanism for the rhodium-catalyzed [4+2] carbocyclization of 4-alkynals with *N*,*N*-dialkylacrylamides.

Experimental Section

Representative procedure (Table 3, entry 1): Under an Ar atmosphere, a solution of (*R*,*R*)-**7** (9.9 mg, 0.015 mmol) in CH_2Cl_2 (1.0 mL) was added to a solution of $[Rh(cod)_2]BF_4$ (6.6 mg, 0.015 mmol) in CH_2Cl_2 (1.0 mL) at room temperature, and the mixture was stirred for 5 min. H_2 was introduced to the resulting solution in a Schlenk tube. The mixture was stirred at room temperature for 0.5 h, and the resulting solution was concentrated to dryness. Benzaldehyde **1g** (61.9 mg, 0.300 mmol) and **2a** (29.7 mg, 0.300 mmol) were added to the residue by using $(CH_2Cl)_2$ (1.5 mL). The mixture was stirred at 80 °C for 20 h. The resulting solution was concentrated and purified by preparative TLC (hexane/EtOAc 1:4) to furnish (+)-**3ga** (73.3 mg, 0.240 mmol, 80 % yield, 97 % *ee*) as an orange solid. M.p. 56–58 °C; $[\alpha]_D^{25}$ +201.0° (acetone, *c* 1.534; 97 % *ee*); IR (neat): $\tilde{\nu}$ = 2930, 1680, 1630, 1600, 1445, 1400, 1282, 1240, 1142, 772, 758, 730, 700 cm^{-1}; ^{1}H NMR ($CDCl_3$, 300 MHz) δ = 8.12–8.02 (m, 1H), 7.37–7.28 (m, 1H), 7.27–7.07 (m, 7H), 6.67 (s, 1H), 4.04 (dd, *J* = 6.9 and 4.5 Hz, 1H), 3.25 (dd, *J* = 17.4 and 6.9 Hz, 1H), 3.20 (s, 3H), 2.94 (s, 3H), 2.87 ppm (dd, *J* = 17.4 and 4.5 Hz, 1H); ^{13}C NMR ($CDCl_3$, 75 MHz) δ = 196.2, 170.2, 137.5, 136.1, 134.1, 133.2, 132.2, 129.1, 128.9, 128.7, 128.5, 128.3, 127.5, 126.7, 48.7, 43.1, 37.6, 36.0 ppm; HRMS (EI): calcd for $C_{17}H_{13}O$ [*M*–$CONMe_2$]$^+$: 233.0967; found; 233.0984; HPLC: t_R = 18.3 min (major isomer) and 22.7 min (minor isomer) (CHIRALPAK AD, hexane/*i*PrOH 90:10, 1.0 mL min^{-1})

Architecture and Evolution of Organic Chemistry**

*Marcin Fialkowski, Kyle J. M. Bishop, Victor A. Chubukov, Christopher J. Campbell, and Bartosz A. Grzybowski**

For almost two centuries, chemists all over the world have applied their expertise and creativity[1–5] to the synthesis of new molecules. Since each individual chemist—or a collaborating group of chemists—tries to select unique synthetic targets[6–9] and come up with a maximally original and/or efficient method of making them, it might appear that the activities of such independent "agents" should be largely uncorrelated, and that no generalizations about the evolution of chemistry *en large* could be made. As we show here, however, there exist several statistical laws that describe how molecules are made and interconverted. We analyze organic synthesis at the level of an abstract network representation whereby molecules correspond to nodes characterized by molecular masses, and reactions to directed edges connecting these nodes (Figure 1a). We show, among others, that the connections between the nodes form a time-evolving scale free network[10–14] of structure similar to that of the world wide web (WWW),[12,15,16] and that masses of molecules in this network are governed by a single stochastic process.[17,18] Aside from fundamental interest, the trends we identify allow making predictions of potential economical impact for the chemical industry, for example, how many molecules will be synthesized in the future, molecules of which molecular

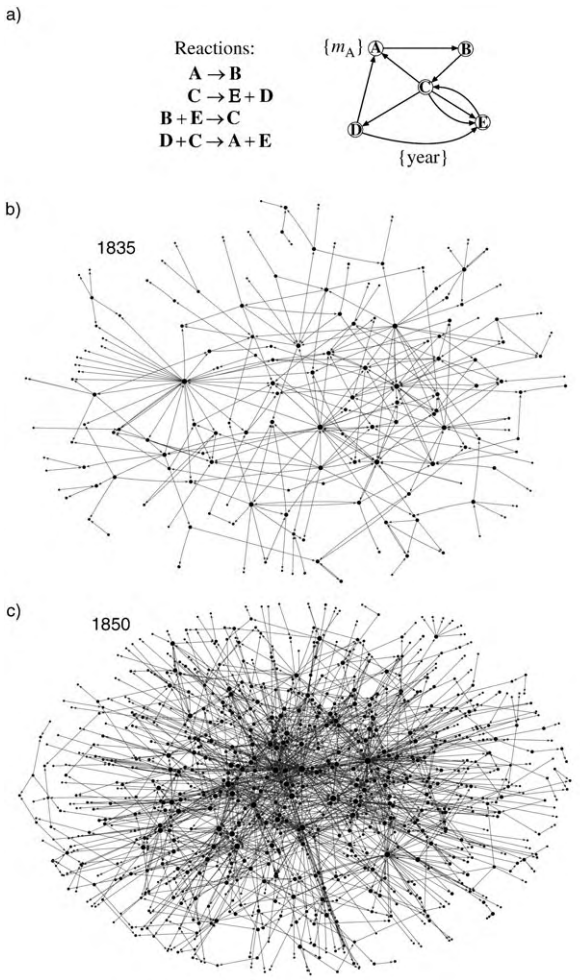

Figure 1. a) Illustration of the conversion of a collection of chemical reactions into a directed-graph (network) representation. Chemical compounds **A**–**E** correspond to the nodes of the network characterized by molecular masses, *m*. Directed edges are assigned for a given reaction by connecting all reactants to all products. The connectivity of each node is described by the number of incoming arrows, k_{in} (e.g., $k_{in}(C) = 2$), and the number of outgoing arrows, k_{out} (e.g., $k_{out}(C) = 4$). The edges are characterized by the earliest publication date of the corresponding reaction. Note that multiple edges—of the same or different directions—can connect two nodes if these nodes are involved in more than one chemical reaction (e.g., **C** and **E** above). b) Visual representation of the giant connected component (GCC)—that is, the largest subset of nodes that are connected to each other—of the organic-chemistry network in 1835. This network contains only 176 compounds; the size of a node corresponds to its total connectivity. Note the scale-free architecture in which most nodes connect to others through highly connected "hub" molecules. c) The GCC in 1850 contains 867 compounds. While the scale-free architecture remains unchanged, the complexity of the network has increased substantially within the elapsed 15 years. One can only imagine the network of organic chemistry in 2004, which contains approximately six million compounds! (The graphs were created using Pajek, a freely available software package for the visualization of large networks.)

masses are more likely to be made or used as substrates, how the network connectivities can be used to assess a molecule's industrial importance, and how the equation describing evolution of masses could help in designing fragment libraries for combinatorial chemistry.

Analysis was performed on data stored in the Beilstein database (BD),[19] which is the largest repository of organic reactions, containing (up to April 2004) 9550398 chemical substances and 9293250 reactions in which these substances participate. In choosing BD, we adopted its well-established criterion for the classification of chemical substances as "organic" and its comprehensive coverage of the chemical literature dating back to 1779 (see the Supporting Information and reference [19] for details of BD). Although we stress that BD is not without omissions, it provides the single, most-complete description of organic chemistry and its evolution. Therefore, it seems reasonable to assume that statistical laws derived from data described therein are indeed representative of organic chemistry in general, and we present them as such.

In the translation of organic synthesis into a network of chemical connectivity, each node represented a chemical compound characterized by its molecular mass (99.7% of the compounds had mass data). Substances that participated in no reactions or acted only as catalysts or solvents were excluded from the network, thereby decreasing the number of "active" nodes to 5957807. Reactions between these chemicals were used to assign directed edges, each characterized by the year in which the reaction was published (99.7% of the reactions had date information). Duplicate reactions—that is, reactions with identical reactants and products—were considered only once and characterized by the date of the earliest reaction. Reactions that lacked either reactants or products (that is, "half reactions") were not included in the network. Stoichiometry and reaction yields were not considered, as they were reported for only a few percent of database entries. After parsing, the total number of reactions was decreased to 6539158. In the conversion of the set of chemical reactions into a directed network, all reactants were connected to all products by directed edges, as illustrated in Figure 1a (see Supporting Information).

The starting point of our analysis was 1850, and since then both the numbers of molecules and the numbers of chemical reactions have increased exponentially. The corresponding growth rates were constant within time periods up to the beginning of the twentieth century ($r_m = 0.083\ \text{year}^{-1}$ for molecules and $r_r = 0.087\ \text{year}^{-1}$ for reactions) and afterwards ($r_m = 0.044\ \text{year}^{-1}$ and $r_r = 0.038\ \text{year}^{-1}$; Figure 2a). At the same time, the average connectivity between molecules (Figure 2b)—defined as the number of edges divided by the number of nodes—initially increased, reached a maximum by about 1885, and then steadily decreased to the value of approximately 2 in 2004. It appears that the early days of chemistry were dominated by "wiring" existing molecules (presumably, to perfect/optimize known synthetic methodologies); when these methodologies matured, exploration of unknown structural space became a dominant activity.

To establish the topological characteristics of the expanding network of chemical reactions, we analyzed distributions of the numbers of connections outgoing from a given node, k_{out} (i.e., the number of times a given molecule was used as a reaction substrate), and the number of connections incoming to a given node, k_{in} (i.e., the number of times a molecule was obtained as a reaction product). As shown in Figure 2c, the distributions of both $p(k_{out})$ and $p(k_{in})$ decay algebraically

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

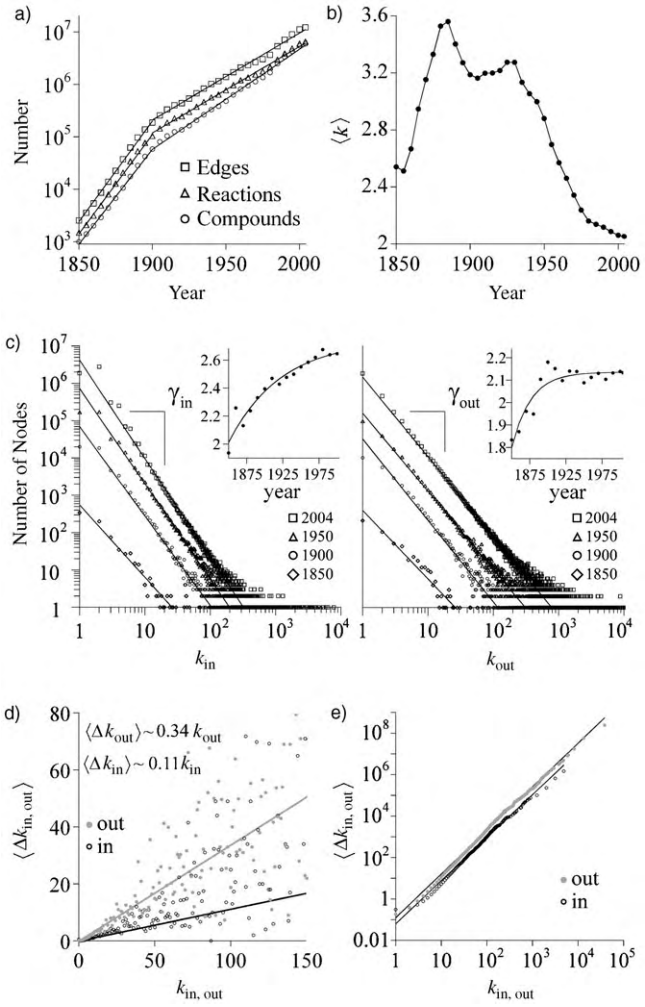

Figure 2. a) The number of chemical compounds, reactions, and graph edges as a function of time. Although all three grow exponentially with time, the rate of growth changes near the turn of the twentieth century. b) Average connectivity (degree)—defined as the number of edges divided by the number of nodes—as a function of time. In the nineteenth century, chemistry focused on "rewiring" existing compounds, whereas in the twentieth century, it has been dominated by the synthesis of new compounds. c) In- and out-degree distributions of molecules that comprise the chemistry network obey a power law $p(k) = k^{-\gamma}$ characteristic of scale-free networks. From 1850 to 2004, the power-law exponents γ_{in} and γ_{out} (inserts) have been steadily growing and approach constant values of approximately 2.7 and 2.1, respectively. d) Evolution of the chemistry network is governed by a "two-way" (i.e., both "in" and "out") mechanism of preferential attachment. The plots show the average increase in connectivities of one million random nodes from 1990 to 2000. The "strength" of preferential attachment (measured by the slope of the linear fit, $d\langle\Delta k\rangle/dk$) is approximately three times greater for out than for in connectivities. This helps to explain why the power-law exponent γ_{out} is smaller than γ_{in} and indicates that highly connected substrates are more likely to be found than highly connected products. e) The corresponding cumulative distribution for preferential attachment defined as $\kappa(k) = \sum_{k_i=0}^{k} \langle\Delta k_i\rangle$. The distribution follows a power law $\kappa(k) = k^{\sigma}$, where $\sigma \approx 2.1$ for both the in and out distributions, which implies that the preferential attachment distribution plotted in (e) is indeed linear ($\langle\Delta k\rangle \propto k^{\sigma-1} \approx k$).

with the number of connections, $p(k) \sim k^{-\gamma}$, and the γ exponents for both in and out distributions increase with time (measured in years) approximately as $\gamma_{in}(t) = 2.67[1-\exp(-(t-1780)/52.4)]$ and $\gamma_{out}(t) = 2.14[1-\exp(-(t-1780)/36.2)]$. Interestingly, the values these exponents asymptotically approach ($\gamma_{in} = 2.67$ and $\gamma_{out} = 2.14$) are similar to those that characterize the directed network of the WWW (2.71 and 2.1, respectively), thus suggesting that the network of chemistry and the WWW have similar topologies (although the latter is more highly connected; $\langle k\rangle = 7.5$ for the WWW in 2000 vs $\langle k\rangle = 2.1$ for chemistry in the same year).[16]

The observed power-law dependencies indicate that organic reactions—like the WWW,[12,15,16] the internet,[20] metabolic networks,[21] and even societies[22,23]—form a scale-free network,[10] whose architecture is distinguished by the presence of highly connected "hubs." These hub molecules of organic chemistry are directly analogous to those found in the scale-free network of the airline system in which they facilitate transportation from one poorly connected airport to another. Likewise, the synthesis of one molecule in organic chemistry from another by a series of chemical transformations will likely utilize one of these versatile hub compounds as an intermediate (as we shall see later, this also has an added economic advantage, since hub compounds are significantly less expensive than poorly connected ones).

The presence of a scale-free topology also provides evidence as to the mechanism by which the network evolves over time. Specifically, the connectivities of organic molecules evolve according to a two-way mechanism of preferential attachment (i.e., both in and out connections), which stipulates that well-connected substances are more likely to participate in new reactions than poorly connected compounds. We verified this mechanism directly, by analyzing how the connectivities of one million randomly chosen nodes changed over time. We found that the average increase in both in or out connectivities over a given time period was proportional to their values at the beginning of this period ($\langle\Delta k_{in,out}\rangle \propto k_{in,out}$; see Figure 2d,e). This result means that 1) the more times a molecule has been used as a synthetic substrate (i.e., large k_{out} value), the higher the chances that it will be used again in the future; 2) conversely, the higher its k_{in} value, the more likely that chemists will try to make it by a new reaction. Interestingly, this mechanism also implies that the evolution of a molecule's usefulness—measured by its participation in new reactions—increases exponentially over time. Therefore, highly connected compounds create exponential "explosions," thus leading to the formation of preferred substrates and target molecules (the "hubs") in organic chemistry.

The fact that the exponent characterizing outgoing connections, γ_{out}, is smaller than that characterizing incoming ones, γ_{in}, indicates (see Figure 2c) that the most connected hubs of the chemistry network have on average more outgoing than incoming connections—the most-connected molecules are usually used as synthetic substrates. At the same time, as chemistry develops, the degree of correlation between in and out connectivities of the molecules increases from $R(k_{out},k_{in}) = 0.327$ in 1850 to 0.571 in 2004 (see Support-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ing Information). The rationale for this trend is that the more useful a compound is as a synthetic substrate, the more ways are designed to prepare it (presumably, in an effort to maximize yields and minimize reaction costs); conversely, the more synthetic recipes exist for making a compound, the more available it becomes and can be used for further syntheses.

Information about the molecular masses (henceforth, simply "masses" or m) of the network's nodes (i.e., molecules) provides an additional source of information about its evolution. While mass is the simplest of the possible molecular descriptors, it was chosen because it was readily available from the database and because it correlated with several other scalar descriptors (e.g., molecular volume[24,25] or structural complexity factor[26,27] of organic molecules).

Figure 3a,b shows the frequency distribution of masses that were used as substrates ($g_{out}(m,t)$; left) and products ($g_{in}(m,t)$; right) in reactions reported between 1850 and 2004. The most commonly used substrates are those near $m = 150\,g\,mol^{-1}$ and the most common products near $m = 250\,g\,mol^{-1}$. Importantly, the shapes of both distributions and the locations of their maxima do not change with time but only shift upwards according to $g_{in,out}(m,t) = \theta_{in,out}(t)\,g^{*}_{in,out}(m)$, where $g^{*}_{in,out}(m)$ are "master" distributions (here, in 1850) and $\theta_{in,out}(t) = N_0^{in,out}\exp((t-t_0)/\tau_{in,out})$ are the propagating/scaling functions ($t_0 = 1850$, $N_0^{in} = 5910.1$, $N_0^{out} = 4869.0$, $\tau_{in} = 19.34$, $\tau_{out} = 19.07$)). These results show that the masses of the most popular substrates and products have not significantly changed for 150 years; moreover, these masses *will remain* the most popular in the future, as they correspond to the most rapidly connecting nodes of the network.

Abundances of molecules depend on their masses. Figure 3c shows the $M(m,t{=}2004)$ mass distribution of all nodes in the network. Aside from an obvious overall trend (few very small and very large molecules), the curve exhibits pronounced "high-frequency" oscillations. The Fourier spectrum of the distribution (Figure 3c, insert) shows a dominant, sharp peak at 2 and a broader peak centered at 14–15. The former indicates that there are significantly more molecules (indeed, by $\approx 48\,\%$) of even than of odd masses; the latter corresponds to the masses of the most common chemical "building blocks" (e.g., CH_2, CH_3, OH, NH_2, etc.) from which molecules are made.

More detailed, time-dependent analysis of $M(m,t)$ distributions (Figure 3d) reveals that chemists create molecules according to a single stochastic process. When plotted on a log–log scale (Figure 3e), the $M(m,t)$ curves for $t = 1850$–2004: 1) are log-normal for the majority ($> 90\,\%$) of masses around the peak; 2) decay algebraically, $M(m,t) \sim m^{-\beta}$ with the exponent $\beta \approx 4$, for $m > 800$; and 3) exhibit a characteristic "shoulder" for $m < 50$. Since 1850, the average mass increased from 200 to 350 (2004)

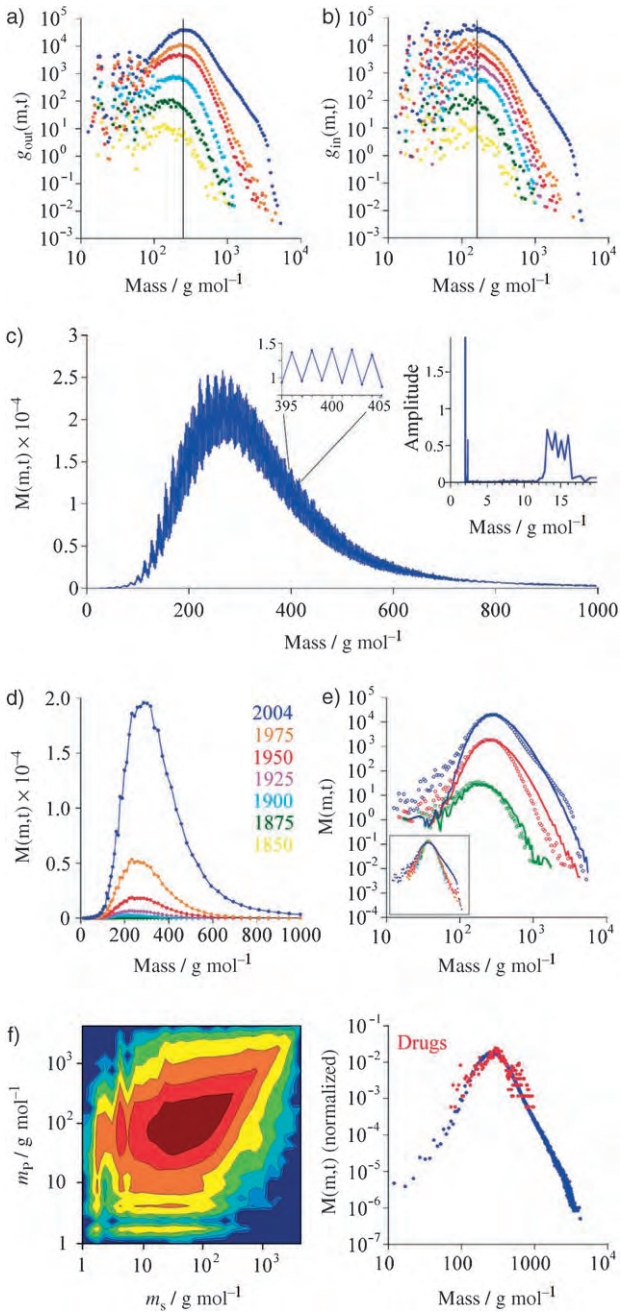

Figure 3. Frequency distributions of masses that were used as a) substrates ($g_{out}(m,t)$) and b) products ($g_{in}(m,t)$) in reactions reported in 25-year intervals between 1850 and 2004. Specifically, the substrate- and product-mass distributions were found by calculating the statistics of all masses weighted by k_{out} and k_{in}, respectively. c) Distribution of masses, $M(m,t)$, of all molecules in the chemistry network as of 2004. The zoom-in illustrates periodic variation in the abundances of molecules with even and odd masses. The insert is a Fourier spectrum of the $M(m,t)$ distribution. d) Evolution of mass distributions with time. All $M(m,t)$ curves are plotted against masses binned into $m = 2$ intervals; this binning removes high-frequency oscillations and simplifies calculations but does not, as we verified, affect the generality of the results. e) The lines in this log–log plot correspond to the theoretical mass distributions for 1875 (green), 1950 (red), and 2004 (blue) propagated from the initial distribution in 1850 according to the master equation; these simulated curves agree with the Beilstein data (points). The characteristic shape of the distributions indicates that molecules are created by a stochastic Kesten process. Insert: Mass distributions overlap when rescaled[20] with respect to the location of the peak and the total number of molecules. f) Correlation between masses of substrates m_S and products m_P based on all reactions stored in the database. g) Log–log plot of normalized mass distributions of all compounds stored in Beilstein (blue) and 1382 most important drugs (red). The two distributions are nearly identical with the goodness-of-fit $R^2 = 0.779$ (for which the Beilstein data is taken as the reference distribution).

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

according to $\langle m(t)\rangle = m_{fin}[1-\exp((t-1780)/\tau)]$, where $m_{fin} = 356.55\ g\,mol^{-1}$ and $\tau = 94.7$, and, as mentioned previously, the total number of masses (i.e., of molecules) increased exponentially with time. Importantly, when the $M(m,t)$ distributions for different times were rescaled,[28] they collapsed onto a single master curve (Figure 3e, insert).

The shapes and scaling properties of the mass distributions indicate that they evolve according to a Kesten-type mechanism,[17,18,29] in which new masses are created according to the multiplicative-additive master equation $m_{t+1} = \lambda_t m_t + \alpha_t$, where index t has a meaning of time. Briefly, at each update (i.e., time step), every molecule from a currently existing distribution $M(m,t)$ is used with equal, constant probability p_0 to generate a new molecule whose mass is prescribed by the master equation. The value of p_0 is determined by the "experimental" growth rate of the total number of molecules—$p_0 = \ln(N(2004)/N(1850))/n$, where n is the number of distribution updates simulated between 1850 and 2004—and sets the relationship between t and the real time. The number of updates, T, that correspond to one year is $T = 154/n$. After the update, both the "old" and the newly created masses are retained in a distribution $M(m,t+1)$, thus accounting for the increase in the number of molecules with time.[30] When stochastic (i.e., random) variables λ and α were sampled from uniform distributions (whose bounds—$\lambda_{min} = 0.9$, $\lambda_{max} = 1.091$ and $\alpha_{min} = 0$, $\alpha_{max} = 5.0$—were determined by fitting the mass distribution in year 2004), the master equation propagated experimental mass distributions faithfully; at every instant of time, these distributions were given by $M(m,t) = M(m,0)/(1+p_0)^t + p_0 \sum_{i=0}^{t-1} (1+p_0)^{i-t}\,\delta(m,i)$, where $M(m,0)$ is the initial mass distribution and $\delta(m,i)$ denotes the distribution of masses derived from $M(m,i-1)$ in the ith update.

Although the identified stochastic process reflects the fundamental statistical dependence between the masses of the substrates m_s and the products m_p in the network $m_p = a m_s + b$ (Figure 3f),[31] its practical significance goes well beyond this simple correlation. Because molecular masses evolve according to the master equation from the very inception of modern chemistry—irrespective of any prevalent "trends of the day" and constant progress in synthetic methodologies—this equation can be extrapolated into the future. In other words, it can be used to *predict* what masses (and with what probabilities) will be obtained in any reaction or set of reactions to be carried out.

Two important generalizations follow: First, the master equation indicates that very large and very small molecules are hard to make.[32] When large substrates are used, the multiplicative term dominates to give a product of a smaller mass; conversely, for small substrates, the additive term increases the mass. Beyond this common-sense result, the master equation provides quantitative information in the form of probabilities, which give an estimate of *how difficult* it is to make a molecule of a given mass. We stress that these observations should be understood only in a statistical sense and by no means exclude the possibility of the preparation of any particular small/large molecules. Second, the knowledge of the stochastic process that governs the generation of masses can be used to predict the outcomes of parallel (combinatorial) syntheses. Making a reasonable assumption that such syntheses are based on standard chemical transformations (i.e., likely described in BD), it is expected that the masses of the initial collections of fragments should evolve according to the master equation. This property could be used in designing fragment libraries[33,34] that would evolve into a desirable, final distribution of masses after a specified (and, hopefully, minimal) number of synthetic steps. An example of such an analysis for three potential libraries is illustrated in Figure 4a and further discussed in the Supporting Information.

One of the most prominent areas in which such desirable mass distributions are sought is in drug design—where it is widely believed that masses of druggable substances differ statistically from those of random ones.[35–37] Our analysis, however, reveals (Figure 3g) that this belief is unfounded and that most important drugs[38] have a mass distribution virtually identical to that of all chemicals stored in Beilstein. Whether this is a result of drugs being discovered by random sampling from the pool of existing substances or of synthetic limitations imposed by the master equation (see below) eventually leading to a log-normal distribution is an interesting, albeit speculative, question.

Unlike molecular mass, the network connectivity of a chemical is a valuable descriptor of its pharmacological or economic importance. As we have already suggested, it is reasonable to expect that for the most useful compounds, the number of ways in which they can be used should correlate with the number of ways in which they can be prepared. Indeed, for the 1382 most important drugs[38] and the top 300 most important industrial chemicals,[39] the correlations between k_{in} and k_{out} values are not only higher ($R \approx 0.6$) than for randomly chosen compounds, but are also historically persistent, as illustrated in Figure 4a, which shows time "trajectories" of these important substances in the $\ln(k_{in})$ versus $\ln(k_{out})$ plane. Their trajectories are long, highly focused, and linear—in sharp contradistinction to short and curvilinear paths traced by randomly chosen compounds. In other words, by looking at a historical evolution of the connectivity of a substance, one can make inferences about its industrial significance. In practice, this significance is often measured in monetary terms, and the prices of chemicals should be dictated by their uniqueness (here, measured by k_{in}, the known ways of preparing a chemical) and by the existing demand (measured by k_{out}, the number of reactions/chemists that use them). As expected, the prices per mole of the top 300 chemicals correlate well (Figure 4b) with these economic indicators and obey a power law of the form $\text{Cost} \propto k_{in,out}^{-\nu}$; the price of a chemical rapidly decreases with both k_{in} and k_{out}.

Of course, this and other trends we identified are only the first attempt to explore the richness of information contained in the history of chemistry. Although additional theoretical analyses can be envisioned with the Beilstein repository (e.g., network's centrality, diameter, shortest paths, aspects of molecular chirality and other structural descriptors, etc.), the unraveling of more economy-oriented trends will likely require the use of databases that report reaction stoichiometries, yields, and costs. Also, it would be interesting to see what

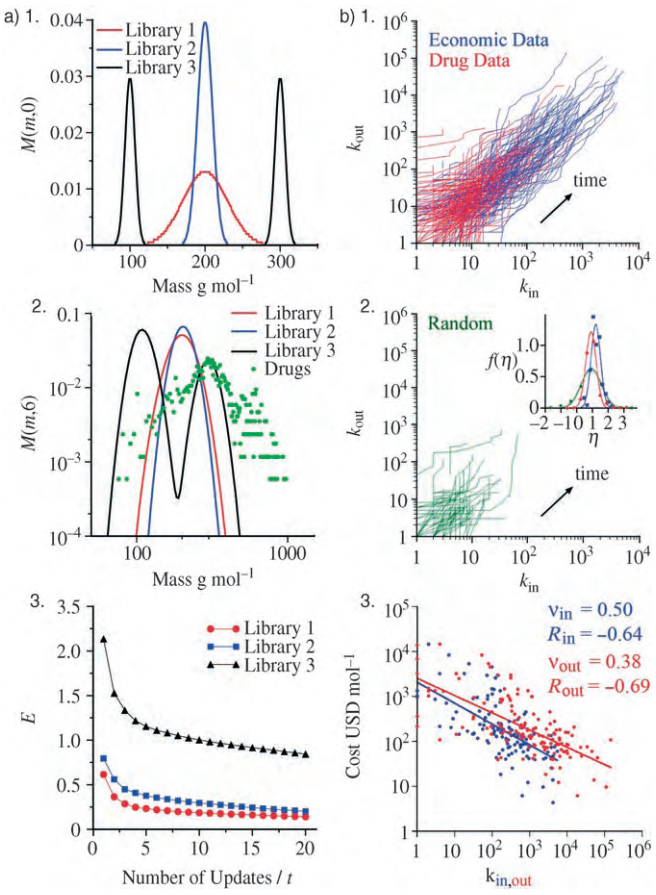

Figure 4. a) 1. Evolution of three initial "fragment libraries" in the realistic range of $m = 100$–300 simulated by the master equation. Libraries 1 and 2 represent normal distributions of masses centered at $m = 200\ g\,mol^{-1}$, and characterized by dispersions $\sigma_M = 30$ and $\sigma_M = 10\ g\,mol^{-1}$, respectively. The third library is a sum of two normal distributions of masses centered at $m = 100$ and $300\ g\,mol^{-1}$ and characterized by the same dispersion $\sigma_M = 7\ g\,mol^{-1}$. 2. Distributions obtained from the three initial "fragment libraries" after 6 updates. The target distribution of masses of 1382 most important drugs is also shown. 3. The average error coefficient, E, which measures similarity between the distributions ($E = 0$ if they are identical) obtained from Libraries 1, 2, and 3 and the target distribution of drugs plotted as a function of synthetic generations (i.e., the number of updates). The broadly distributed Library 1 converges most rapidly. b) Time trajectories of important (1382 drugs and the top 300 economically relevant chemicals and 2. 2000 randomly chosen molecules (right) plotted in the $\ln k_{in}$–$\ln k_{out}$ plane. The trajectories of the important chemicals are long and linear (i.e., $k_{out} \propto (k_{in})^{\eta}$ where $\eta \approx 1$), whereas those of "random" ones are short and of varying curvatures (with η between approximately -1.5 and 3). The insert shows probability distributions of the trajectory exponents η; the curves are best Gaussian fits to the data. Standard deviation of η is higher (0.64) for randomly chosen compounds than for economically relevant chemicals (0.30) and drugs (0.33). 3. Cost (per kmol) as a function of in and out connectivities of the top 300 economically relevant compounds. The power-law dependence indicates that more highly connected compounds are significantly less expensive. USD = US dollar.

trends could be established for particular branches of chemistry (e.g., the rapidly growing carbohydrate and lipid research, fluorine chemistry, etc.) and whether these trends would differ from the "mainstream" trends discussed herein.

On a fundamental level, our results provide yet another demonstration of how seemingly independent/uncorrelated activities of individual agents[40–44] fall into a larger scheme and obey—or, as proponents of emergence[11] would argue, "give rise to"—unifying statistical rules.[45]

[28] The rescaling procedure consisted of: 1) multiplying the distribution $M(m,t)$ by the ratio $N(t{=}2004)/N(t{=}1850)$, where $N(t)$ stands for the total number of molecules at time t, and 2) translation by $\Delta M = M_{max}(2004) - M_{max}(t)$, where M_{max} corresponds to the distribution maximum.
[29] In its original version, the Kesten process describes the transformation of an arbitrary distribution of variable x according to a multiplicative-additive equation $x_j = \lambda_j x_j + \alpha_j$, where j stands for the iteration number and λ_j and α_j are independent, positive stochastic variables. In the limit of large j, this procedure generates a log-normal distribution $w_K(x)$ with a characteristic "algebraic" tail $w_K(x) \sim x^{-(1+\mu)}$ in which the exponent is determined by the condition $\langle \lambda^\mu \rangle = 1$.
[30] This is unlike the pure Kesten process, in which the old distribution is discarded after each iteration.
[31] The values of the effective multiplicative ($a = 0.67$) and additive ($b = 179.94$) coefficients are commensurate with those derived from the stochastic master equation, $a = \langle \prod_{i=1}^{i=T} \lambda_i \rangle = 0.91$ and $b = \langle \sum_{j=1}^{j=T} \alpha_j \prod_{i=j+i}^{T} \lambda_i \rangle = 47.7$.
[32] These observations can also be understood in terms of combinatorial considerations and reflect the fact that 1) on one hand, there are relatively few combinations of atoms that give rise to structures of low molecular mass. It can be readily estimated that the possible numbers of molecules of mass m increase roughly exponentially with m. 2) On the other hand, when two large molecules are "stitched" together, there are many possible combinations (orientations) of doing so and achieving a selective, high-yield synthesis is problematic.

SrAlSiH: A Polyanionic Semiconductor Hydride**

*Thomas Björling, Dag Noréus, Kjell Jansson, Magnus Andersson, Ekaterina Leonova, Mattias Edén, Ulf Hålenius, and Ulrich Häussermann**

In 2000 Gingl et al. reported the synthesis and structural characterization of the novel compound $SrAl_2H_2$.[1] Contrary to the alanates $A_mAe_nAl_oH_{m+2n+3o}$ (A, Ae = alkali and alkaline-earth metal, respectively), this aluminum hydride is not fully hydrogenated and was described as a "Zintl phase hydride". It features a two-dimensional $[Al_2H_2]^{2-}$ polyanion in which the Al atoms are arranged as a puckered graphitic layer with three nearest neighbors. The vacant coordination site is taken by hydrogen and the compound appears to be charge-balanced (Figure 1a). A structural entity with both Al–Al and Al–H bonds had not been observed before and is indeed remarkable.

Herein we report the synthesis of SrAlSiH, which is a further example of a polyanionic hydride that is structurally closely related to $SrAl_2H_2$. However, it displays striking differences in its properties. In contrast to metallic, thermally labile $SrAl_2H_2$, isoelectronic SrAlSiH is an air- and moisture-stable semiconductor with a thermal decomposition temperature that is among the highest known for hydride compounds. Additionally, SrAlSiH displays a peculiar electronic structure that suggests interesting transport properties. The combination of properties of SrAlSiH is unexpected for a

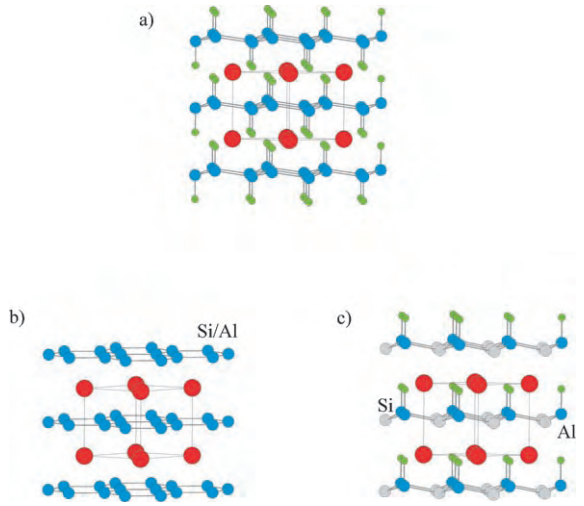

Figure 1. Crystal structures of $SrAl_2H_2$ (a), SrAlSi (b), and SrAlSiH (c) viewed along [110]. Red, blue, gray, and green circles denote Sr, Al (Al/Si), Si, and H atoms, respectively.

hydride and prompts an important issue: Polyanionic ("Zintl phase") hydrides provide novel coordination environments for H atoms and possess a huge compositional potential that is virtually unexplored. If physical properties inherent to hydrides and Zintl phases can be combined in these materials unexpected prospects are opened, thereby extending hydride materials' research beyond the traditional quest for hydrogen storage materials.[2]

SrAlSiH is obtained by hydrogenation of the alloy SrAlSi. This alloy is part of the solid solution $SrAl_{2-x}Si_x$ ($0.6 < x < 1.2$), which crystallizes in the hexagonal AlB_2 structure.[3] It is assumed that the Al and Si atoms in SrAlSi are more or less randomly distributed on the AlB_2 majority site, defining graphitic nets (Figure 1b). At a hydrogen pressure of 50 bar complete hydrogenation is typically obtained at temperatures between 600 and 700 °C and reaction times of 48 h. The refined lattice parameters of the final product are $a = 4.2139(3)$ and $c = 4.9550(6)$ Å. The c lattice parameter of the hydrogenated product is 5% larger than that of the starting material SrAlSi ($a = 4.2367(7)$, $c = 4.7442(9)$ Å), whereas the a lattice parameters are very similar. SrAlSiH possesses a gray and is air and moisture stable. This is remarkable in view of the sensitivity of other main group metal hydrides containing aluminium (e.g., alanates, $SrAl_2H_2$), which rapidly decompose when exposed to air and moisture. Another interesting observation is that when SrAlSi is employed in a compacted form for hydrogenation reactions (e.g. as a pellet or ingot), the shape of the starting material sample is completely preserved in the reaction product. In particular, single crystals of SrAlSi are transformed into identically shaped crystals of the hydrogenated product. Again, this is a remarkable feature because solid-state hydrogenations typically yield finely powdered products.

The structure of SrAlSiH (Figure 1c) was determined unambiguously by the refinement of neutron powder diffraction data of a deuterated sample (SrAlSiD) and by solid-state NMR investigations. It displays slightly puckered hexagon nets in which Si and Al atoms are arranged strictly alternately. H is exclusively attached to Al, and the Al–D distance in the deuteride is 1.77 Å. These puckered nets are stacked on top of each other, with the same orientation, and sandwich Sr atoms. Thus, compared with the starting material SrAlSi, the hydride experiences only small structural changes, which explains why single crystals of SrAlSi undergo hydrogenation into SrSiAlH without deterioration. In particular, the planar hexagon nets in SrAlSi become puckered in the hydride, and at the same time the interatomic distances within the nets increase from 2.46 to 2.50 Å. This leaves the a lattice parameter of both compounds about the same, whereas the c parameter is increased in the hydride.

Figure 2 shows magic-angle spinning (MAS) ^{27}Al (a), ^{29}Si (b), and ^{2}H NMR spectra (c) of a powder of SrSiAlD. Each spectrum is characteristic of a single site, as expected for a perfectly ordered structure consisting of hexagon nets of alternating Al and Si atoms, with ^{2}H exclusively attached to Al. As this sample displays comparatively long T_1 relaxation times for each of the nuclei involved, the absence of addi-

tional spectral components was verified by saturation-recovery experiments. The ^{27}Al NMR spectrum displays a characteristic second-order powder line-shape of a well crystalline compound.[4] In conjunction with 3QMAS data[5] and numerical simulations (not shown), we estimated the isotropic chemical shift and quadrupolar parameters as follows: $\delta_{iso} = 185.5 \pm 1.5$ ppm, $C_Q = e^2 q Q/h = 7.5 \pm 0.2$ MHz, and $\eta < 0.1$.[6] As expected from the proposed structure, the local symmetry around Al is associated with an axially symmetric electric field gradient tensor. The ^{2}H spectrum corresponds to a main resonance at $\delta = 0$ ppm flanked by a set of spinning sidebands generated from the quadrupolar interaction and associated with a small quadrupolar coupling constant, $C_Q = 26 \pm 3$ kHz.

The structure of SrAlSiH is very similar to that of $SrAl_2H_2$ (see Figure 1): half of the Al–H entities in the 2D polyanionic layer of $SrAl_2H_2$ are replaced by isoelectronic Si. This replacement occurs in a completely ordered way, that is, each Si atom is surrounded by three Al–H entities and vice versa. The center of inversion present in $SrAl_2H_2$ is lost in SrSiAlH and the space-group symmetry is reduced to $P3m1$. The interatomic distances and angles of $SrAl_2H_2$ and SrAlSiH are given as Supporting Information. The most conspicuous difference between the two structures is that the Sr atom in SrAlSiH is only coordinated by three H atoms. The Sr–H distance in SrAlSiH is considerably smaller than in $SrAl_2H_2$ (2.48 vs 2.65 Å) and the Al–H distance significantly larger (1.77 vs. 1.71 Å). Both compounds possess electron-precise polyanions—$[Al_2H_2]^{2-}$ and $[AlHSi]^{2-}$—with structures in accordance with the Zintl concept.

Despite their great structural similarity the thermal behavior of $SrAl_2H_2$ and SrAlSiH is strikingly different. Figure 3 displays heat-effect curves for both compounds at atmospheric pressure. Hydrogen desorption starts at 300 °C for $SrAl_2H_2$, whereas SrAlSiH only starts to decompose at temperatures above 600 °C. Higher decomposition temperatures are only known for some saline alkali and alkaline-earth metal hydrides.[7] Furthermore, hydrogen release of $SrAl_2H_2$ produces a mixture of the intermetallic compounds $SrAl_2$ and $SrAl_4$, whereas in the case of SrAlSiH the starting material SrAlSi is quantitatively regained. This means that although the Al–H distance in SrAlSiH is longer than in $SrAl_2H_2$, hydrogen is more tightly bound in SrAlSiH. This is easily explained by the higher positively charged environment that H experiences in SrAlSiH. Firstly, Al—to which H is attached—is positively polarized by the surrounding Si atoms in the polyanion, and secondly the Sr–H distance in SrAlSiH is considerably smaller. As a matter of fact, the Sr–H distance in SrAlSiH corresponds very well to the smallest Sr–H distances in saline SrH_2 (2.43–2.48 Å).[8]

Figure 4 compares the electronic density of states (DOS) of $SrAl_2H_2$ and SrAlSiH in their computationally relaxed equilibrium structures. The Fermi level for $SrAl_2H_2$ is situated at a pseudo gap. The metallic behavior of this compound is due to Al p bands crossing the Fermi level. In contrast, a real bandgap of about 0.65 eV is opened at the Fermi level for SrAlSiH and the compound is a semiconductor. The contribution of Sr atoms to the occupied states is rather low for both compounds, but rises sharply above the Fermi level (see Supporting Information). This is a typical feature of polar intermetallic and Zintl phases. The contribution of H is mainly into the intermediate energy regions of the DOS (between −6.5 and −2 eV), which are the parts where Al s and p bands mix strongly. The DOS of SrAlSiH is characterized by a pronounced singularity below the Fermi level. As can be seen in the band structure (Figure 4c), this singularity originates from a flat band corresponding to the Si p_z (lone pair) orbitals. These orbitals are virtually isolated in SrAlSiH and the arising band displays a very small dispersion. As a consequence, this compound attains a peculiar electronic structure in which a narrow bandgap is combined with a flat band exactly below the Fermi level.

According to the calculated band structure the bandgap is of indirect nature; the valence band maximum is located at Γ and the conduction band minimum at M. Optical absorption spectra obtained from diffuse reflectance measurements

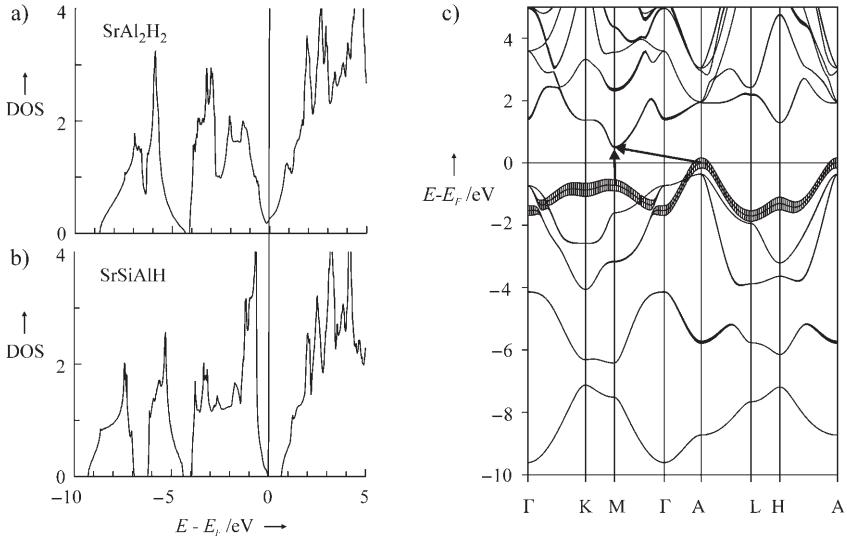

Figure 4. Electronic density of states, DOS (states $eV^{-1}Z^{-1}$), for $SrAl_2H_2$ (a) and SrAlSiH (b). The Fermi level is indicated by a vertical line. c) Band structure of SrAlSiH. The Si p_z orbital contribution is shown as broad-band representation. The lowest energy transition A→M, which is indirect, and the direct transition with lowest energy are indicated as arrows.

confirmed the presence of the bandgap. The experimental value of 0.63 eV is, coincidentally, in close agreement with the calculated one. The room-temperature resistivity of SrAlSiH is about 110 Ω cm, which can be compared to the intrinsic room-temperature resistivity of Ge (46 Ω cm) with a bandgap of 0.73 eV. The thermopower of SrAlSiH is around $-90\ \mu V\,K^{-1}$ at room temperature, and the negative sign of the Seebeck coefficient implies that electrons are the charge carriers in this material (see Supporting Information for further details).

In conclusion, we have reported on the novel semiconductor hydride SrAlSiH. Several aspects make this compound remarkable: 1) SrAlSiH is, after $SrAl_2H_2$, the second example of a "Zintl phase hydride" where H is part of a polyanion. The two-dimensional polyanion of SrAlSiH is composed of isolectronic, three-bonded $[Al{-}H]^-$ and Si^- entities and is charge balanced by Sr^{2+}. 2) SrAlSiH is a semiconductor with an indirect bandgap of about 0.65 eV. Metal hydrides with narrow bandgap (0.2–1.2 eV) semiconductor properties are unprecedented; fully hydrogenated main group metal systems are typically insulators. The wide homogeneity range of underlying AlB_2-type $SrAl_{2-x}Si_x$ ($0.6 < x < 1.2$) may allow triggering of a transition to a metallic $SrAl_{2-x}Si_xH_{2-x}$ for low values of x. In this case, the Fermi level would cut the singularity in the DOS which may give rise to superconductivity. On the other hand, for $x > 1$ a widening of the bandgap is expected. 3) The NMR investigation of SrAlSiD has provided the first ^{27}Al and ^{29}Si data for a structure involving direct Al–Si contacts and where spectral resolution is not limited by fast T_2-relaxation, which is observed in metallic compounds because of the conducting electrons.[9] The ^{29}Si chemical shift ($\delta_{Si} = -216$ ppm) implies large diamagnetic contributions due to the localized negative charge of a lone electron pair at Si. This shift is somewhat more shielded than observed for the ^{29}Si site in antifluorite-type Mg_2Si ($\delta_{Si} = -177$ ppm), where formally Si^{4-} is cubically surrounded by eight strongly polarizing Mg^{2+} ions.[10] The large paramagnetic contribution to the isotropic ^{27}Al chemical shift ($\delta_{Al} = 185.5$ ppm) arises from a high degree of charge asymmetry at the Al nucleus due to bonding to two different ligands, Si and D (also reflected in the relatively high quadrupolar coupling constant).[11] 4) Al and Si are strictly ordered in SrAlSiH. This is in contrast to the starting material SrAlSi, where Al and Si are distributed more or less randomly. It is known that conventional (disordered) SrAlSi is a superconductor with a T_c of 5.1 K.[3] However, the nature of the superconducting properties remains unclear.[12] Hydrogen desorption of SrAlSiH provides an elegant way to obtain ordered SrAlSi. The study of the ordered material could provide some deeper understanding of the superconducting properties of SrAlSi.

Experimental Section

Synthesis: All steps of the synthesis and sample preparation for diffraction experiments were carried out under dry argon. The starting materials $SrAl_2$ and SrSiAl were prepared by arc-melting stoichiometric mixtures of the pure elements. For hydrogenation, the starting materials were loaded in corundum crucibles, which were placed in stainless steel autoclaves. Reactions were carried out at 50–60 bar hydrogen pressure and temperatures of 200 °C and 700 °C for $SrAl_2$ and SrAlSi, respectively. SrAlSiD was prepared analogously. Starting materials and hydrides were characterized by Guinier powder patterns ($CuK\alpha_1$; Si standard) and EDX (energy-disperse X-ray) analysis in a JEOL 820 scanning electron microscope. SrAlSiH can be exposed to air and moisture without decomposition.

Structural characterization: Lattice constants of SrAlSi, SrAlSiH, and SrAlSiD were obtained from least-squares refinement of measured and indexed lines of the corresponding Guinier powder diffractograms.[13] Atomic positions of SrAlSiD were determined from a Rietveld refinement of neutron powder diffraction data[14] collected at the Studsvik Neutron Research Laboratory, Sweden (room temperature, $\lambda = 1.47$ Å, data resolution $\Delta d/d = 2 \times 10^{-3}$). SrAlSiD: space group $P3m1$ (no. 156); cell parameters (X-rays): $a = 4.2113(3)$, $c = 4.9518(5)$ Å, $V = 76.05$ Å^3, $Z = 1$; $R_B = 1.87\%$, $R_P = 9.49\%$, $R_{wp} = 9.44\%$, $\chi^2 = 1.44$ for 85 reflections (positional parameters are provided as Supporting Information).

NMR spectroscopy: MAS NMR experiments were carried out at room temperature on a Varian/Chemagnetics Infinity-400 spectrometer operating at 9.4 T, giving the Larmor frequencies −61.43, −104.28, and 79.50 MHz and for ^2H (spin 1), ^{27}Al (spin 5/2), and ^{29}Si (spin 1/2), respectively. Powders of SrSiAlD (99% enriched with respect to ^2H) were filled in zirconia rotors of outer diameters 3.2, 4, and 6 mm, and spun at 8.0 (for ^2H acquisitions), 13.0 (^{27}Al), and 8.0 kHz (^{29}Si), respectively. 48 ^2H signal transients were recorded with 90° pulses (76 kHz nutation frequency) and 120 s relaxation delays. The ^{29}Si spectrum was recorded using 30° pulses and 188 accumulated transients with 600 s relaxation delays. ^{27}Al acquisitions resulted from 840 transients, 60 s relaxation delays, and 11° pulses (86 kHz nutation frequency, measured with respect to Al^{3+}(aq)). No additional line-broadening was applied in the spectral processing. Chemical shifts are reported in deshielding (δ) units of ppm, referenced externally to D_2O (^2H), Al^{3+}(aq) (^{27}Al), and TMS (^{29}Si).

Thermal investigations: The thermal behavior of powdered samples of $SrAl_2H_2$ and SrAlSiH was investigated by differential thermal analysis (DTA-TG, Setaram Labsys 1600) and differential scanning calorimetry (Perkin Elmer DSC 7), respectively. $SrAl_2H_2$ was placed in a steel container, which was sealed with gold foil to prevent exposure to air and moisture, and the temperature was raised from 40 to 400 °C. SrAlSiH was placed in an open corundum crucible and the temperature was raised from 40 to 800 °C. Both experiments were performed under a flow of dry argon and with a temperature-increase rate of $5\ K\,min^{-1}$.

Diffuse reflectance measurements: Optical diffuse reflectance measurements were made on finely ground samples of SrAlSiH and SrAlSiD at room temperature. The spectrum was recorded in the region 3200–10500 cm^{-1} with a Bruker Equinox 55 FT-IR spectrometer equipped with a diffuse reflectance accessory (Harrick). The measurement of diffuse reflectivity can be used to determine bandgaps. For this, absorption data (α/S) were extracted from the reflectance data by using the Kubelka–Munk function.[15]

Resistivity and thermopower measurements: Resistivity measurements were performed using a four-point in-line contact arrangement on a $2 \times 3.3 \times 6$ mm^3 bar of SrAlSiH. This bar was obtained by polishing an ingot of SrAlSi and subsequent hydrogenation. The thermoelectric voltage, U, was measured for different temperature gradients ΔT between two sides of the bar. A straight line was fitted to $U(\Delta T)$, which has the slope $dU/d(\Delta T) = S_w - S_s$, where S_s is the thermopower of the sample and S_w is the thermopower of the connecting wires.

Electronic structure calculations: Total energy calculations for $SrAl_2H_2$ and SrAlSiH were performed in the framework of the frozen core all-electron Projected Augmented Wave (PAW) method,[16] as implemented in the program VASP.[17] The energy cut-off was set to 500 eV. Exchange and correlation effects were treated by the generalized gradient approximation (GGA), usually referred to as

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

PW91.[18] The integration over the Brillouin zone was done on special *k*-points determined according to the Monkhorst–Pack scheme.[19] Total energies were converged to at least 1 meV per atom. Structural parameters were relaxed until forces had converged to less than 0.01 eV Å^{-1}.

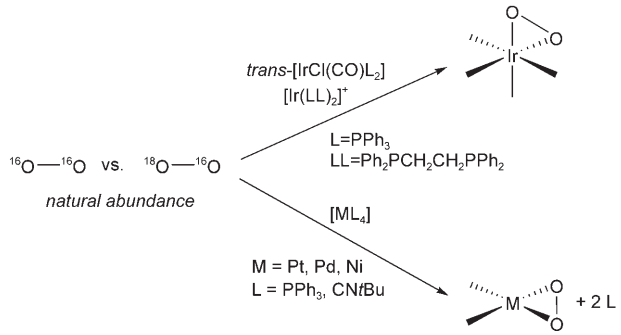
Structures of Transition States in Metal-Mediated O_2-Activation Reactions**

*Michael P. Lanci, David W. Brinkley, Kristie L. Stone, Valeriy V. Smirnov, and Justine P. Roth**

Enrichment of heavy oxygen (^{18}O) from its level at natural abundance is widely used to probe O_2-dependent processes in the atmospheric and biological sciences.[1–4] Here we describe the first application of this technique to O_2-binding reactions of classic inorganic compounds. Competitive ^{18}O kinetic isotope effects (KIEs)[5–7] reflecting the ratio of second-order rate constants for the formation of η^2-peroxide compounds from $^{16,16}O_2$ and $^{18,16}O_2$ ($k_{16,16}/k_{18,16}$) have been determined (Scheme 1). Related measurements on enzymatic



Scheme 1. Competitive ^{18}O isotope effect on the formation of η^2-peroxo complexes.

reactions[4,8–11] have been interpreted on the basis of equilibrium isotope effects (EIEs) and simple models that neglect variations in the transition-state structure. The present studies suggest that the proposed enzyme mechanisms may need to be reevaluated in light of the sensitivity of ^{18}O KIEs to changes in the height of the free-energy barrier for reactions involving the formation of a metal–O_2 bond.

Oxygenation of solutions prepared from *trans*-[IrCl(CO)-$(PPh_3)_2$], $[Ir(dppe)_2]Cl$, $[Pt(PPh_3)_4]$, $[Pd(PPh_3)_4]$, $[Ni(PPh_3)_4]$, and $[Ni(CNtBu)_4]$ (PPh_3 = triphenylphosphine, dppe = 1,2-bis(diphenylphosphino)ethane, $CNtBu$ = *tert-n*-butylisocya-

nide) affords the corresponding η^2-peroxides [IrCl(CO)O_2-(PPh_3)$_2$], [IrO_2(dppe)$_2$]Cl, [PtO_2(PPh_3)$_2$], [PdO_2(PPh_3)$_2$], [NiO_2(PPh_3)$_2$], and [NiO_2(CN*t*Bu)$_2$].[12–16] On the basis of early studies on *trans*-[IrCl(CO)(PPh_3)$_2$] and [Pt(PPh_3)$_4$],[13,14] concerted oxidative-addition mechanisms have been proposed in which two electrons transfer to O_2 at the same time that two metal–oxygen bonds form.[17,18]

This work describes O_2-binding mechanisms for a series of compounds in "anhydrous" *N*,*N*-dimethylformamide (DMF) and dimethylsulfoxide (DMSO).[19] In most cases, high yields of stable products were obtained, as revealed by $^{31}P\{^1H\}$ and ^1H NMR as well as UV/Vis spectroscopy.[20] Kinetics studies were performed by monitoring the disappearance of the reduced compound (0.05–0.35 mM) upon reaction with a greater than tenfold excess of O_2, either by conventional or stopped-flow UV/Vis spectrophotometry. The irreversible formation of η^2-peroxide products on the time scale of the experiments is reported in terms of the rate constant for O_2 binding (k_{O_2}) in DMF at 25 ± 2 °C unless noted.

Depending on the stability of the reduced compounds in Scheme 1, the reaction mechanisms range from simple to complex, thus making it a challenge to probe the relative energy barriers to O_2 activation. Bimolecular kinetics observed for *trans*-[IrCl(CO)(PPh_3)$_2$][21] and [Ir(dppe)$_2$]Cl indicate $k_{O_2} = 0.17 \pm 0.02\ M^{-1}s^{-1}$ and $2.8 \pm 0.4\ M^{-1}s^{-1}$, respectively. The slowest reacting complex, *trans*-[IrCl(CO)-(PPh_3)$_2$], has the lowest O_2 affinity ($\Delta G_{298K} = -5.6 \pm 0.2$ kcal mol^{-1} in DMF). No sign of reversible O_2 loss could be detected for any of the other peroxide compounds examined.[22] [Pt(PPh_3)$_4$], [Pd(PPh_3)$_4$], [Ni(PPh_3)$_4$], and [Ni-(CN*t*Bu)$_4$] dissociate in solution to two- and three-coordinate species[14,16,23] which are oxidized 10^2–10^5 times faster than *trans*-[IrCl(CO)(PPh_3)$_2$]. In the simplest case involving a d^{10} metal, disappearance of [Pt(PPh_3)$_4$] is first order in O_2 and the derived rate constant ($k_{O_2} = 32 \pm 8\ M^{-1}s^{-1}$) is independent of the PPh_3 concentration. This behavior is consistent with [Pt(PPh_3)$_3$] being the primary reactive species.[14]

The oxidation of [Pd(PPh_3)$_4$] is more than 10^3 times faster than that of [Pt(PPh_3)$_4$] and exhibits more complex kinetics. The reactions are first order with respect to O_2, yet the rate constant ($k_{O_2} = 41\,100 \pm 300\ M^{-1}s^{-1}$) decreases in response to added PPh_3 until a limiting k_{O_2} value of $2480 \pm 130\ M^{-1}s^{-1}$ is reached at a PPh_3 concentration of 0.025–0.08 M. This behavior is consistent with a two-term rate law and competitive binding of O_2 to [Pd(PPh_3)$_2$] and [Pd(PPh_3)$_3$] (Scheme 2). The first term in the rate law simplifies to k_{O_2} for [Pd(PPh_3)$_2$] when the reduced species are present in rapid equilibrium and $k_{-1}[L] \gg k_2[O_2]$, whereas the second term gives k_{O_2} for [Pd(PPh_3)$_3$] at high PPh_3 concentration.

Reactions of [Ni(PPh_3)$_4$] and [Ni(CN*t*Bu)$_4$] can also be understood in terms of Scheme 2. In the absence of added

$$[ML_3] \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} [ML_2] + L + O_2 \xrightarrow{k_2} [MO_2L_2]$$

$$[ML_3] + O_2 \xrightarrow{k_3} [MO_2L_2] + L$$

$$-\frac{d[ML_3]}{dt} = \frac{k_1 k_2 [O_2][ML_3]}{k_{-1}[L] + k_2[O_2]} + k_3[O_2][ML_3]$$

Scheme 2. Kinetic scheme for O_2 binding.

PPh_3, the disappearance of [Ni(PPh_3)$_4$] depends only slightly on the concentration of O_2. This behavior is consistent with dissociation of [Ni(PPh_3)$_3$] in a kinetically irreversible manner caused by fast trapping of [Ni(PPh_3)$_2$] by O_2. The addition of PPh_3 (0.15–0.34 M) causes ligand association to compete with O_2 binding and allows the determination of k_{O_2} ($230 \pm 10\ M^{-1}s^{-1}$) for [Ni(PPh_3)$_3$]. Spectroscopic evidence suggests that [Ni(PPh_3)$_2$(DMSO)] is the reactive species in DMSO (see Supporting Information), where the reaction is first order in O_2 without added PPh_3, and $k_{O_2} = 3300 \pm 80\ M^{-1}s^{-1}$. The kinetics of the oxygenation reaction of [Ni(CN*t*Bu)$_4$] give a linear first-order plot with a nonzero *y*-intercept, which suggests that the rates of ligand dissociation and O_2 binding are comparable, that is, $k_1 \approx k_3[O_2]$. Addition of CN*t*Bu causes the intercept to approach zero but the slope, which corresponds to $k_{O_2} = 3300 \pm 150\ M^{-1}s^{-1}$, remains unchanged; this is consistent with [Ni(CN*t*Bu)$_3$] being the reactive species.

The ^{18}O KIEs for the O_2-binding reactions were determined by a method in which stable-isotope mass spectrometry is used.[1,4] Experiments were performed under conditions of intermolecular competition by introducing a substoichiometric amount of metal compound into a sealed reaction vessel containing natural-abundance O_2. Subsequent to the reaction, isolation and analysis of the O_2 remaining in solution revealed ^{18}O enrichment as a result of a faster consumption of $^{16,16}O_2$ than $^{18,16}O_2$. Data were collected at varying concentrations of metal complex to determine $k_{16,16}/k_{18,16}$ (Figure 1). The ^{18}O

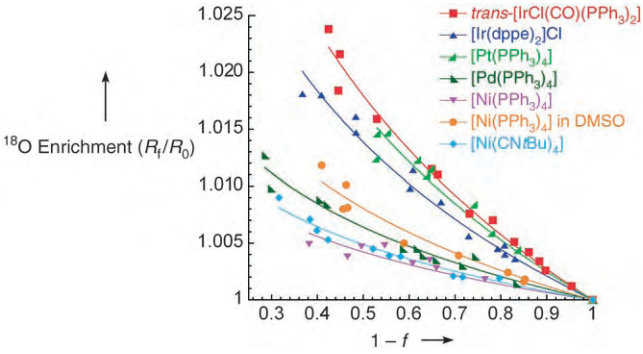

Figure 1. ^{18}O enrichment plot. Data are fitted to the equation: $R_f/R_0 = (1-f)^{((1/(k_{16,16}/k_{18,16}))-1)}$; R_0 and R_f are the $^{18}O/^{16}O$ ratios prior to reaction and at a fractional conversion (f), respectively.

KIEs are independent of both the fractional O_2 consumption and the ratio of O_2 consumed per mole of reduced compound. This ratio was 1:1 in most cases but as high as 1.6 ± 0.4:1 for [Pt(PPh_3)$_4$] and 2.3 ± 0.8:1 for [Ni(PPh_3)$_4$] because of the catalytic oxidation of PPh_3.[15,24] The $k_{16,16}/k_{18,16}$ ratio is a competitive effect and serves as a probe of all the steps from the encounter of the metal complex with O_2 to the first kinetically irreversible step. Thus, the KIEs in this work reflect O_2 binding concomitant with reduction to peroxide (O_2^{2-}) and are independent of ligand dissociation and subsequent ligand oxidation.

The formation of η^2-peroxide compounds is characterized by $k_{16,16}/k_{18,16}$ values from 1.0069 to 1.0268 (Table 1). The ^{18}O

KIEs are larger for the O_2-binding reactions with third-row metals than for the faster reactions with first- and second-row metals. This range of values is larger than that determined for iron-, copper-, and flavin-containing enzymes, which react with O_2 according to diverse mechanisms.[4] The formation of η^2-peroxide compounds is characterized by ^{18}O KIEs that are less than the EIEs ($K_{16,16}/K_{18,16}$) calculated from Bigeleisen's formalism[25] using normal mode stretching frequencies.[26–29] Although the products are structurally quite different, they exhibit similar shifts of oxygen-isotope-dependent stretching frequencies resulting in a narrow range of $(K_{16,16}/K_{18,16})_{calcd}$ values (1.026 to 1.031; see Table 1 and Supporting Information). The average value is three times greater than that reported for the reduction of O_2 to H_2O_2 (1.0089) and previously used as a benchmark to identify metal–peroxide intermediates in enzymes and O_2-carrier proteins.[4,8–10,26]

Heavy-atom KIEs are conventionally interpreted with transition state theory and the equation, $k_{16,16}/k_{18,16} = (\nu^{\ddagger}_{16,16}/\nu^{\ddagger}_{18,16})(K^{TS}_{16,16}/K^{TS}_{18,16})$, which includes contributions from the reaction-coordinate frequency ($\nu^{\ddagger}$) and the equilibrium constant for the formation of the transition state (K^{TS}).[6] The transition states for η^2-O_2 binding are visualized in terms of structures that are intermediate between the reactant and product states, in which the O–O bond is partially weakened and two new metal–O bonds are partially formed. The results reported here support an assumption that is commonly made when interpreting mechanisms based on ^{18}O KIEs: that $\nu^{\ddagger}_{16,16}/\nu^{\ddagger}_{18,16}$ is approximately 1 and that $K_{16,16}/K_{18,16}$ is the upper limit to $K^{TS}_{16,16}/K^{TS}_{18,16}$ and therefore to $k_{16,16}/k_{18,16}$.[4–7]

For inner-sphere electron transfer (ET), in which new bonds are formed during the redox reaction, the productlike character of the transition state can be defined in terms of the ratio of the ^{18}O KIE to the EIE. The parameter $[(k_{16,16}/k_{18,16})-1]/[(K_{16,16}/K_{18,16})_{calcd}-1]$ is expected to correlate with the barrier height ($\Delta G^{\ddagger} \propto \log k_{O_2}$) when the reaction coordinate includes the reorganization of bonds involving oxygen nuclei.[5] This is precisely the behavior observed in Figure 2, which supports the proposal that the reactions examined occur by oxidative addition of O_2. Alternative mechanisms, such as those involving η^1-superoxide intermediates, are unlikely in view of a) the absence of optically detectable intermediates in the kinetics experiments and b) ^{18}O KIEs that are significantly larger than the EIEs of 1.005 reported for η^1-binding of O_2 to metalloproteins.[4,26] Although the $k_{16,16}/k_{18,16}$ ratio for *trans*-[IrCl(CO)(PPh_3)$_2$] is very close to

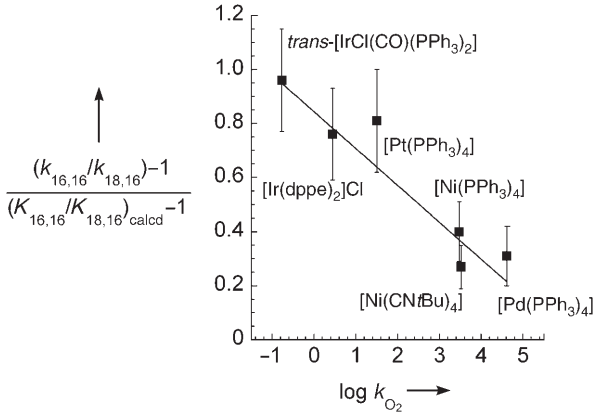

Figure 2. Isotope effects reflecting variation in transition-state structures for O_2 binding.

that reported for outer-sphere ET,[30] this mechanism can be ruled out because the value of $\Delta G°$ (44.7 kcal mol^{-1}) estimated from one-electron redox potentials[31,32] greatly exceeds the observed $\Delta G^{\ddagger}$ value (18.7 kcal mol^{-1}).

These studies show that ^{18}O KIEs are sensitive probes of transition-state structure in reactions where O_2 binds to a transition-metal center. Consistent with a productlike transition state, a value of $[(k_{16,16}/k_{18,16})-1]/[(K_{16,16}/K_{18,16})_{calcd}-1]$ close to 1 is obtained for *trans*-[IrCl(CO)(PPh_3)$_2$], the compound which exhibits the slowest and least thermodynamically favorable reaction with O_2. This parameter decreases for the other reactions as the transition state becomes more reactant-like. These reactions are ostensibly more exothermic as k_{O_2} increases systematically over five orders of magnitude. The trend can be explained in the context of the Marcus theory of electron transfer, in which the ^{18}O KIE arises from oxygen nuclear reorganization (λ).[30] As $\Delta G°$ becomes increasingly favorable, the contribution of this term to $\Delta G^{\ddagger}$ decreases as shown in Figure 3.

In summary, competitive ^{18}O KIEs have been used for the first time to probe the binding of O_2 to inorganic compounds. All KIEs are less than the theoretical EIEs calculated from the stretching frequencies of O_2 and the structurally defined η^2-peroxo products. The ^{18}O KIEs decrease as O_2-binding rate constants increase by over five orders of magnitude. This trend indicates that all the reactions occur by the same

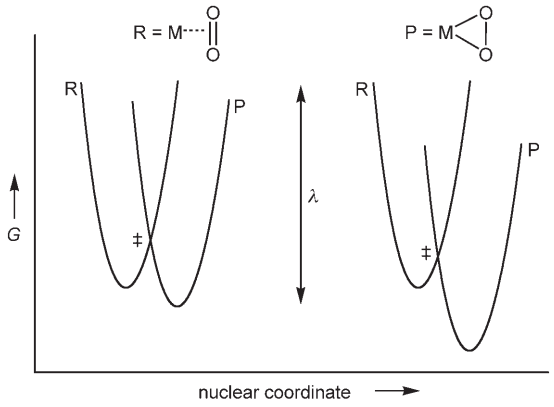

Figure 3. Model for the contribution of λ to the reaction barrier (designated ‡).

mechanism, albeit with measurable differences in the transition-state structure. The correlation of the product-like character of the transition state with the barrier height can be explained in terms of Marcus theory, where an increasingly favorable $\Delta G°$ value decreases the contribution of isotope-dependent nuclear reorganization to $\Delta G^{\ddagger}$. This property appears to differentiate reactions involving inner-sphere ET to O_2 from reactions proceeding by outer-sphere ET, in which ^{18}O KIEs appear to be relatively insensitive to the value of $\Delta G°$.[30] The highly variable ^{18}O KIEs determined in this work for a single class of metal-mediated oxidation reactions underscores the need for benchmarks and relevant models to interpret such measurements upon O_2-activation reactions of metalloenzymes.

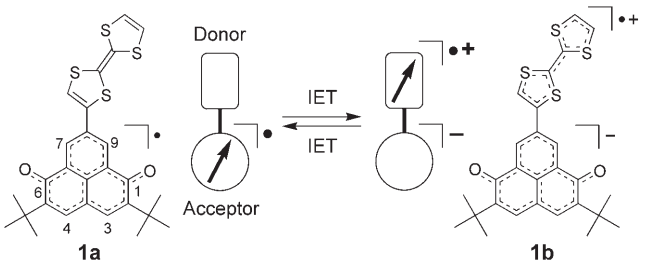
Spin Transfer and Solvato-/Thermochromism Induced by Intramolecular Electron Transfer in a Purely Organic Open-Shell System**

Shinsuke Nishida, Yasushi Morita, Kozo Fukui, Kazunobu Sato, Daisuke Shiomi, Takeji Takui,* and Kazuhiro Nakasuji**

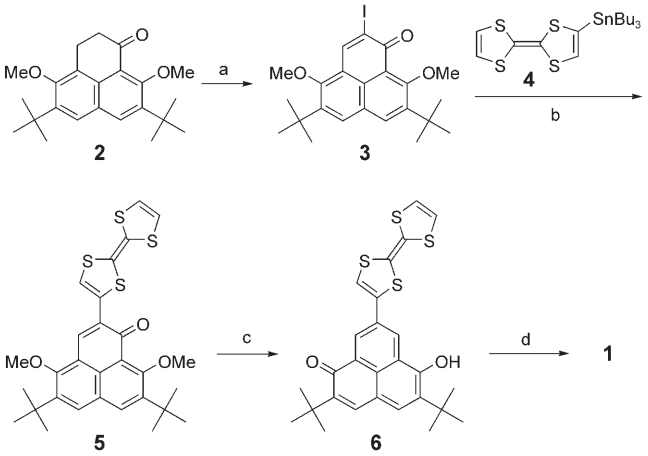
In search of organic functional materials, investigators have focused much attention on the switching of physical properties by using appropriate perturbation or stimuli. The integration of multiple controllable properties into a single-component system has been the subject of growing interest. Among such examples are the photoswitching of magnetic interaction by using a photochromic reaction[1] and thermal bistability in electric, magnetic, and optical properties of a crystalline neutral radical.[2] To realize spin-mediated new responsive materials, we are interested in reversible intramolecular electron transfer (IET), which can cause a complete transformation of magnetic and electronic properties in a purely organic system.[3] In an attempt to embody this concept, we have examined a stable neutral radical comprising electron-donor and -acceptor moieties, both of which can have spin before and after IET.

Taking advantage of the high electron-accepting ability of 2,5-di-*tert*-butyl-6-oxophenalenoxyl (6OP) stable neutral radical,[4] we have designed a diad system, **1**, in which 6OP radical is directly linked with a tetrathiafulvalene (TTF) molecule as an electron donor (Scheme 1).[5] In addition to the expected molecular spin, the diad **1** also meets the design criteria for organomagnetic materials,[6–8] single-component organic conductors,[2,9] and other potential applications.[10,11] Prior to the detailed characterization of its solid-state properties, we report herein the IET-induced transfer of spin that accompanies solvato-/thermochromism of **1** as a new molecular-scale function in solution, which is controlled by moderate change in the solvent environment and temperature.



Scheme 1.

The neutral radical **1** was synthesized from 2,7-dimethoxyphenalanone derivative **2**[4a] in five steps (Scheme 2). Iodophenalenone **3** was prepared by treating **2** with iodine and cerium(IV) ammonium nitrate (CAN). TTF was introduced into phenalenone skeleton by the Stille reaction of **3** with the tributyltin derivative **4**. Reduction and demethylation of the coupling product **5** afforded the 6-hydroxyphenalenone derivative **6**.[12] Oxidation of **6** with PbO_2 in toluene gave neutral radical **1** as a black powder,[13] which is reasonably stable in air at room temperature for weeks. The radical is very stable in degassed solutions.



Scheme 2. Synthesis of neutral radical **1**: a) I_2 (2.5 equiv), CAN (2.5 equiv), $AcOH/H_2O$, 50 °C, 91 %; b) **3**, $[Pd(PPh_3)_4]$ (2 mol %), CuI (10 mol %), THF, 80 °C, 76 %; c) $NaBH_4$ (40 equiv), EtOH/THF (3:1); then LiI (20 equiv), *N*,*N*-dimethylacetamide, 170 °C, 34 %; d) PbO_2 (5 equiv), toluene, RT, 87 %.

The cyclic voltammogram of **1** in PhCN solution showed three fully reversible redox waves (Figure 1a). The observed redox potentials are close to those of the two constituent molecules (Table 1), which suggests that **1** is reduced and oxidized in a stepwise manner, with each step occurring independently at each moiety. The potential difference ΔE ($= E_{1/2}^{ox1} - E_{1/2}^{red}$) can, in principle, be related to the likelihood of IET of **1**; a smaller ΔE could lead to easier IET. The use of a $PhCN/CF_3CH_2OH$ solvent mixture significantly changed the first reduction potential ($E_{1/2}^{red}$) of **1**, depending on the mixing ratio (Figure 1b and c), without affecting the oxidation

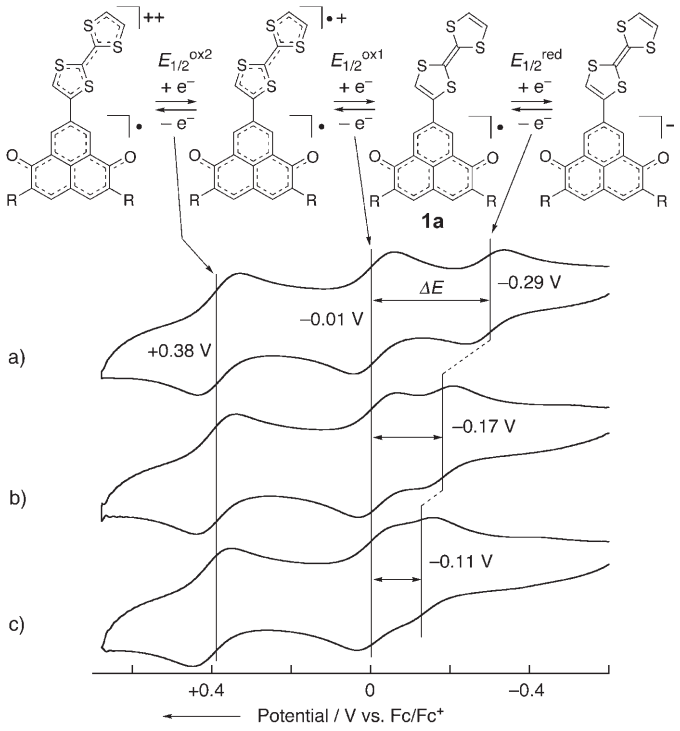

Figure 1. Cyclic voltammograms of solutions of **1** in PhCN/CF_3CH_2OH (1.0 mM) with the solvent ratio of a) 1:0, b) 9:1, and c) 4:1 measured at 293 K. Final potentials were calibrated with the ferrocene/ferrocenium (Fc/Fc^+) couple. R = *t*Bu.

Table 1: Redox potentials[a] of **1**, TTF, and 6OP.

	$E^{ox2}_{1/2}$	$E^{ox1}_{1/2}$	$E^{red}_{1/2}$
1	+0.38	−0.01	−0.29
TTF	+0.36[b]	−0.09	–
6OP	–	–	−0.36

[a] Potentials [V] vs. Fc/Fc^+ in PhCN at 293 K. Details are given in the Supporting Information. [b] Oxidation peak potential.

potentials for the TTF moiety ($E^{ox1}_{1/2}$, $E^{ox2}_{1/2}$). These results are interpreted as a marked effect of protonation or hydrogen-bonding interactions of a protic solvent to carbonyl groups, which stabilizes the anionic R-O^- structure.[14,15] This electrochemical study suggests that the IET of **1** can be controlled by the solvent environment.

The UV/Vis spectrum of a solution of **1** in CH_2Cl_2 (Figure 2a) showed a sharp absorption band at 414 nm, typical of the 6OP radical,[4a] which indicates the presence of the neutral radical **1a**. In addition, a weak broad absorption centered at 1315 nm was observed, which can safely be assigned to an IET band, not an intermolecular band, as proven by dilution studies (between 1.2×10^{-5} and 1.2×10^{-3} M). In contrast, a solution of **1** in CF_3CH_2OH did not show the sharp peak at 414 nm or the broad IET band while a new absorption at 605 nm appeared (Figure 2b). These changes are explained by assuming the zwitterionic structure **1b** with a TTF radical cation and 6OP anion moiety; all the spectral features can be reproduced by superimposition of the component spectra (see Supporting Information). Interestingly, the diad **1** shows solvatochromism depending on the IET states, as is evident from the different absorption wavelengths of **1a** and **1b** (Figure 2).

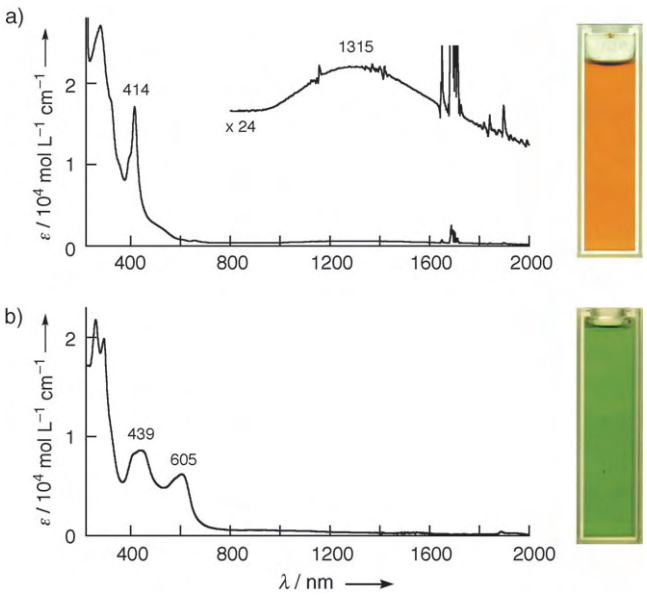

Figure 2. UV/Vis spectra and color of **1** in a) CH_2Cl_2 (1.2×10^{-4} M) and b) CF_3CH_2OH (7.6×10^{-5} M) solutions at 293 K.

To confirm the electronic structures of the two IET states, we have recorded the ESR spectra of **1** in aprotic and protic media. In a degassed toluene solution (1.0×10^{-4} M), radical **1** showed well-resolved hyperfine structures at 290 K with a *g* value of 2.0047 (Figure 3a). Electron-nuclear multiple resonance spectroscopy (^{1}H ENDOR/TRIPLE) unequivocally determined the hyperfine coupling constants (hfccs) of protons and their relative signs (Table 2). The obtained hfccs and *g* value are typical of 6OP radicals,[4a] which is clear evidence of the neutral radical structure **1a**. Although a small amount of spin density is delocalized into the TTF moiety, the spin structure virtually holds the 6OP-type distribution (Figure 4a).

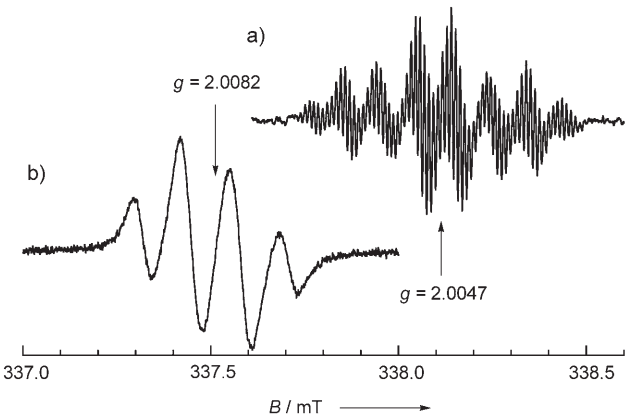

Figure 3. Liquid-phase ESR spectra of **1** in a) toluene (1.0×10^{-4} M) and b) CF_3CH_2OH (3.0×10^{-5} M) at 290 K. The microwave frequency used was 9.487717 GHz.

Table 2: Proton hyperfine coupling constants [mT] and *g* values of **1a**, 6OP neutral radical, **1b**, and TTF radical cation.

	3, 4	7, 9	2,5-*t*Bu	TTF	*g* value
1a[a]	+0.199	+0.082	+0.011	−0.096	2.0047
6OP[a,b]	+0.206	+0.078	+0.012	–	2.0046
1b[c]	–	–	–	−0.126	2.0082
$TTF^{\bullet+}$[d]	–	–	–	−0.126	2.0084

[a] In toluene. [b] See ref. [4a]. [c] In CF_3CH_2OH. [d] In CH_2Cl_2. See reference [18].

In contrast, an ESR spectrum of **1** in a degassed CF_3CH_2OH solution (3.0×10^{-5} M) at 290 K gave a more downfield absorption ($g = 2.0082$) with three nearly equivalent ^1H couplings (Figure 3b). The observed hfccs and *g* value (Table 2) identified this species as the zwitterionic radical **1b** in which the TTF radical cation moiety is the spin-bearing center (Figure 4b). The localization of the spin densities at the TTF moiety may be associated with a possible twisted structure of **1b** induced by charge separation due to IET.[16]

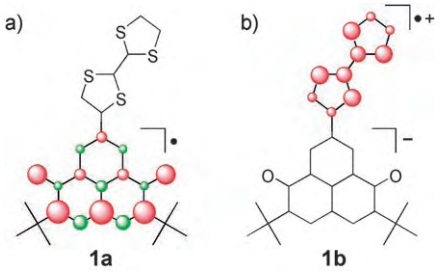

Figure 4. Postulated spin structures of a) **1a** and b) **1b**, assuming dominant contributions from 6OP neutral radical and TTF radical cation, respectively. Spin densities are calculated for the constituent molecules at the UBLYP/6-31G(d) level. Red and green denote positive and negative signs, respectively. Only the σ skeletons of **1a** and **1b** are depicted.

It is of interest to explore the possibility of the interconversion between the two states of **1** in a more controllable manner. By changing the solvent mixing ratio, we found an intermediate experimental condition that gave a mixture of **1a** and **1b**, which may be sensitive to additional perturbation or stimuli. A solution in CH_2Cl_2/CF_3CH_2OH (199:1) gave such an intermediate state at 263 K, the ESR spectrum of which is the superimposition of the spectra of **1a** and **1b** (Figure 5c). Furthermore, we observed a smooth transition from the **1b**-only pattern at 243 K to the **1a**-only pattern at 293 K in the ESR spectra (Figure 5). This process that accompanies themochromism is reversible, which suggests a temperature-dependent equilibrium between **1a** and **1b**. The mechanism of this interconversion needs to be studied further by considering quantitative analysis and solvent effects.[17]

In summary, we have described a purely organic open-shell donor–acceptor diad system, **1**, which exhibits an IET-induced spin transfer by solvatochromism, depending on the nature of solvent. Both the neutral radical, **1a**, and zwitterionic radical, **1b**, have been unequivocally characterized by

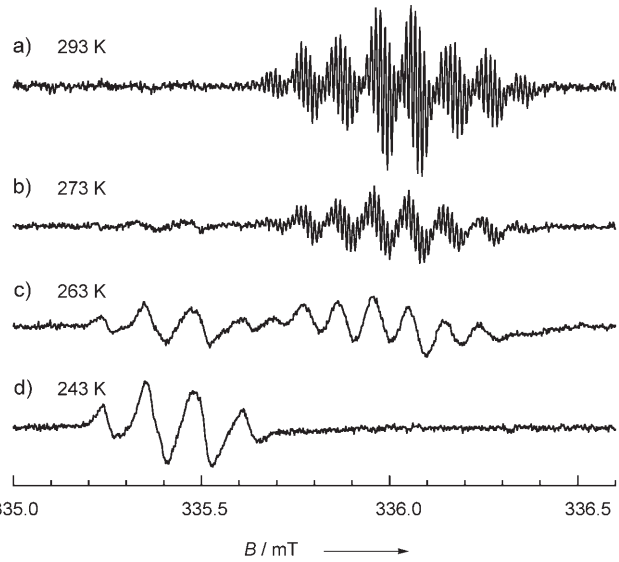

Figure 5. Temperature dependence of the liquid-phase ESR spectra of **1** in a CH_2Cl_2/CF_3CH_2OH (199:1) solution (7.7×10^{-5} M) at a) 293 K, b) 273 K, c) 263 K, and d) 243 K. The microwave frequency used was 9.4283 GHz.

UV/Vis and ESR spectroscopies in aprotic and protic media, respectively. The thermochromic interconversion between the two IET states of **1** has also been realized in a mixed solvent system. A possible switching of these combined properties by applying external stimuli such as an electrostatic field is of particular interest for molecular functionality, as well as for the characterization of its solid-state properties.

Binding of Naphthyridine Carbamate Dimer to the $(CGG)_n$ Repeat Results in the Disruption of the G–C Base Pairing

*Tao Peng and Kazuhiko Nakatani**

The expansion of the $(CGG)_n$ trinucleotide repeat in the FMR1 gene causes the neurological disorder fragile X syndrome.[1–3] The molecular basis for the $(CGG)_n$ expansion involves the formation of a metastable hairpin structure[4–6] consisting of continued 5′-CGG-3′/5′-CGG-3′ triads, in which a G–G mismatch is flanked by two G–C base pairs. We recently reported the remarkable binding of naphthyridine azaquinolone (**NA**) to the 5′-CAG-3′/5′-CAG-3′ triad in the hairpin form of the $(CAG)_n$ repeat, where the A–A mismatch was flanked by G–C base pairs. The ligand-bound structure was intriguing because 1) two **NA** molecules were bound to a single CAG/CAG triad which 2) induced the cytosine—which was hydrogen-bonded to the guanine—to flip out from the base stack (Figure 1).[7] The **NA**-immobilized sensor was useful for the rapid diagnosis of the $(CAG)_n$ repeat length. We have reported a series of ligands binding to a G–G mismatch,[8–10] and therefore the remarkable structure of **NA** bound to the CAG/CAG triad prompted us to investigate the mode of ligand binding to the CGG/CGG triad and, hence, the possibility of the cytosine flipping out in the ligand-bound complex. Herein, we report that naphthyridine carbamate dimer (**NC**)[11] binds to a single CGG/CGG triad with exclusively 2:1 **NC**/triad stoichiometry. The binding of **NC** to the CGG/CGG triad induced the disruption of the guanine–cytosine base pairing in the triad, and made the cytosine susceptible to the subsequent chemical cleavage reaction initiated by addition of hydroxylamine.

Among the ligands that we synthesized for binding to the G–G mismatch, **NC** showed a marked preference in binding to the CGG/CGG triad. The binding of **NC** to the CGG/CGG triad in the 13-mer duplex increased the melting temperature (T_m) by 23.1 °C, whereas the increase in T_m (ΔT_m) was only 6.7 °C for the GGC/GGC triad (Table 1). A survey of the effect of the flanking sequence suggested that the strong and selective **NC** binding to the CGG/CGG triad is most likely a consequence of the interaction of **NC** not only with the G–G mismatch, but also with the cytosine on the 5′ side and/or the guanine on the 3′ side.

[a] The UV melting curve was measured for a duplex (4.5 μM) in a sodium cacodylate buffer (10 mM, pH 7.0) containing NaCl (100 mM). The temperature was increased at a rate of 1 K min^{-1}. All measurements were made three times, and standard deviations are shown in parentheses. [b] T_m values of oligomers. [c] T_m values of oligomers in the presence of **NC** (100 μM). [d] ΔT_m was calculated as the difference between $T_m(+)$ and $T_m(-)$.

To determine the stoichiometry of the **NC**-CGG/CGG complex, cold-spray ionization time-of-flight mass spectrometry (CSI-TOF MS)[12] of the 11-mer self-complementary duplex containing the CGG/CGG triad was carried out (Figure 2). In the absence of **NC**, three ions derived from the oligomer were observed. One ion corresponded to the 3− ion of a single-stranded form ($[ss]^{3-}$; m/z: found 1118.13, calcd 1117.19). Duplexes were detected as a 5− ion ($[G–G]^{5-}$; m/z: found 1342.32, calcd 1340.83) and a 4− ion ($[G–G]^{4-}$; m/z: found 1678.07, calcd 1676.29). Upon addition of **NC** to the duplex with a 1:1 molar ratio, the intensity of the ions corresponding to $[ss]^{3-}$, $[G–G]^{5-}$, and $[G–G]^{4-}$ became weak, with the concomitant appearance of a new ion corresponding to the 5− ion of a 2:1 complex of **NC** and the duplex ($[G–G+2\mathbf{NC}]^{5-}$; m/z: found 1544.13, calcd 1542.13). A 1:1 complex was not detected. In the presence of two equivalents of **NC**, ions derived from the free duplex disappeared and only $[G–G+2\mathbf{NC}]^{5-}$ was detected. At an increased concentration of **NC**, the ion corresponding to $[G–G+2\mathbf{NC}]^{5-}$ was still predominant. These results clearly show that the binding of **NC** to the duplex containing the CGG/CGG triad proceeded exclusively with a 2:1 stoichiometry. The binding of **NC** to the CGG/CGG triad was further characterized by UV absorption titration experiments (see the Supporting Information). The crossover point of the Job's plot obtained from the titration was at 66%, which confirmed that the binding stoichiometry of **NC** to the CGG/CGG triad was 2:1, as determined by CSI-TOF MS (see the Supporting Information).

The high sequence preference and the 2:1 stoichiometry for **NC** binding are the same characteristic features that we observed for the binding of **NA** to the CAG/CAG triad.[7] Encouraged by these facts, we investigated whether the

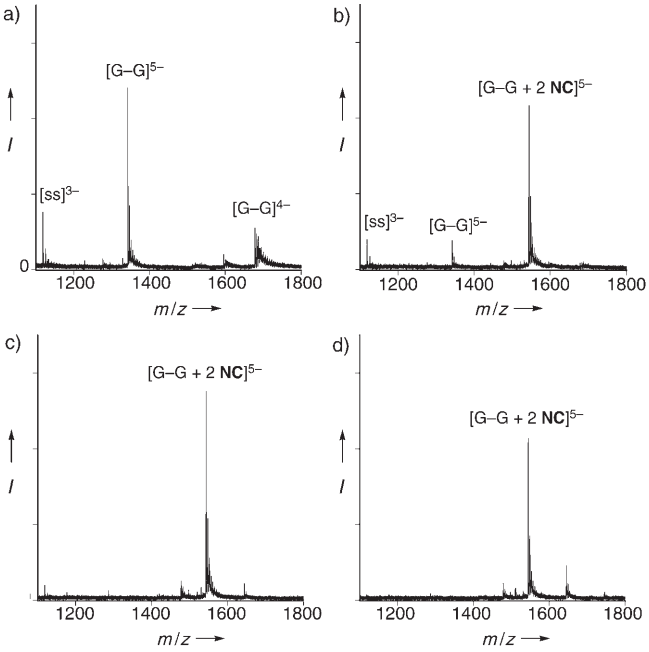

Figure 2. CSI-TOF MS of 11-mer self-complementary duplex 5′-d(TCAA CGG TTGA)-3′/5′-d(TCAA CGG TTGA)-3′ containing the CGG/CGG triad. cytosine in the CGG/CGG triad was free from the G–C base pairing upon **NC** binding. We examined the reaction of **NC**-bound CGG/CGG triad with hydroxylamine. Cytosines in the single-stranded regions and in the mismatched base pairs efficiently reacted with two molecules of hydroxylamine at the C4 and C6 positions, whereas those in the G–C base pair in a duplex were not susceptible to the addition of hydroxylamine. The cytosine modified with hydroxylamine underwent degradation on heating with piperidine, eventually leading to strand cleavage.[13]

The reaction of 11-mer self-complementary 5′-d(TCAA CGG TTGA)-3′ (**1**) with hydroxylamine was monitored by reversed-phase HPLC (Figure 3). The duplex of **1** (13 μM) was not reactive toward hydroxylamine (2.8 M, pH 6.0) at 0 °C for 12 h, whereas a new product **2** was produced in the presence of **NC** (40 μM). A prolonged reaction time (≈24 h) resulted in 70% consumption of **1** without the formation of any major by-products (see the Supporting Information), which suggests that both strands of **1** duplex reacted with hydroxylamine and produced **2**. MALDI-TOF MS showed that product **2** was the adduct of **1** with two molecules of hydroxylamine (*m*/*z*: found 3406.06, calcd 3403.62; see Scheme 1 and the Supporting Information).[13] After isolation by HPLC, product **2** was treated with piperidine at 90 °C for 30 min to give products **3** and **4**. The

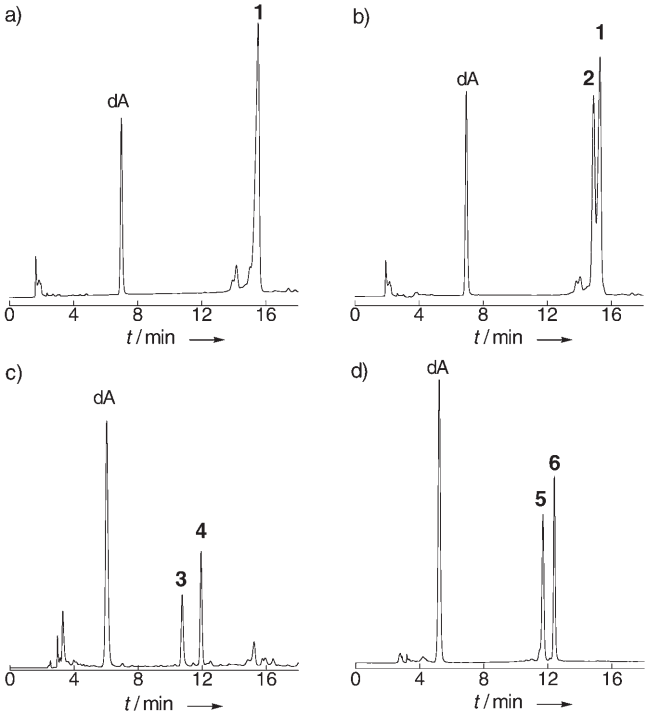

Figure 3. HPLC profiles for the hydroxylamine-induced cleavage at the cytosine moiety in the CGG/CGG triad. The 11-mer self-complementary oligomer 5′-d(TCAA CGG TTGA)-3′ (**1**) (13 μM as a duplex) in NaCl (100 mM) was treated with hydroxylamine (2.8 M, pH 6.0) in the a) absence and b) presence of **NC** (40 μM) at 0 °C for 12 h. c) Product **2** was isolated and treated with piperidine at 90 °C for 30 min. d) Products **3** and **4** were treated with alkaline phosphatase at 37 °C for 2 h. Deoxyadenosine (dA) was added as an internal standard.

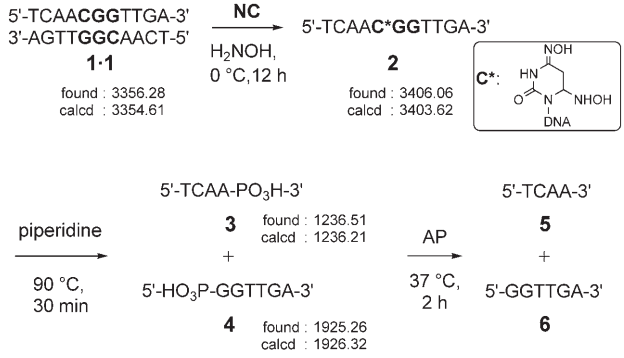

Scheme 1. Hydroxylamine-induced cleavage at cytosine in the **NC**-bound CGG/CGG triad. AP = alkaline phosphatase.

MALDI-TOF mass spectra showed that **3** was the oligomer 5′-d(TCAA)-PO_3H-3′ (*m*/*z*: found 1236.51, calcd 1236.21), whereas **4** was the oligomer 5′-HO_3P-d(GGTTGA)-3′ (*m*/*z*: found 1925.26, calcd 1926.32). The phosphorylated termini of **3** and **4** were removed by treatment with alkaline phosphatase to give 5′-d(TCAA)-3′ (**5**) and 5′-d(GGTTGA)-3′ (**6**), respectively. The oligomers **5** and **6** showed the same retention times as authentic oligomers, as observed by co-injection in reversed-phase HPLC. These HPLC analyses clarified that the cytosine in the CGG/CGG triad in **1** duplex became susceptible to the hydroxylamine upon binding with **NC**. The **1** duplex contained two kinds of cytosine, one in the CGG/CGG triad and the other in 5′-TCA-3′/5′-TGA-3′. The cytosine in the latter sequence was insensitive to hydroxylamine, regardless of the presence of **NC**. These results showed that the binding of **NC** to the CGG/CGG triad made the cytosine free from the base pairing to the guanine moiety in the opposite strand.

CSI-TOF MS measurements suggested that the 2:1 **NC**-CGG/CGG complex, which was confirmed for an oligomer duplex, was also produced in the $(CGG)_n$ repeat. CSI-TOF MS of $d(CGG)_{10}$ with **NC** showed the ions corresponding to $[d(CGG)_{10}+6\mathbf{NC}]^{6-}$ and $[d(CGG)_{10}+6\mathbf{NC}]^{7-}$, which suggests the formation of the 2:1 **NC**-CGG/CGG triad complex in the $d(CGG)_{10}$ repeat (see the Supporting Information). In addition, a large conformational change of $d(CGG)_{10}$ was observed in CD measurements upon binding with **NC** (see the Supporting Information), which supports the formation of a hairpin structure, as observed in the binding of **NA** to $d(CAG)_{10}$.[7]

In summary, the data presented herein have shown that 1) **NC** is the first molecule to bind to the CGG/CGG triad, and 2) the cytosine in the triad is free from hydrogen bonding to the guanine moiety upon **NC** binding. It is suggested that the 2:1 **NC**-CGG/CGG complex is produced in the hairpin structure of the $d(CGG)_n$ repeat, which is proposed to form in the replication leading to the repeat expansion. From the structural viewpoint, the **NC**-bound CGG repeats are particularly interesting. Base flipping as a result of the disruption of base pairing is one of the mechanisms for the repair enzyme to recognize the damaged bases and mismatched base pairs.[14–17] Therefore, **NC** could be a useful molecule for studying not only the repeat expansion mechanism, but also

the nucleobase–ligand interactions on the biologically important repeat sequence.

Molecularly Assembled Nanostructures of a Redox-Active Organogelator**

Tomoyuki Akutagawa, Keiko Kakiuchi, Tatsuo Hasegawa, Sin-ichiro Noro, Takayoshi Nakamura,* Hiroyuki Hasegawa, Sinro Mashiko, and Jan Becher*

Amphiphilic molecules in solution can form a variety of molecularly assembled structures, composed, for example, of gels, micelles, vesicles, tubes, or lamellas, in a variety of dimensions, shapes, and sizes.[1–3] Several types of low-molecular-weight molecules can form organogels that generate macroscopic phase-separated molecularly assembled structures in organic solvents.[4–7] Each molecule is assembled through specific intermolecular interactions and becomes part of a fibrous structure, which is entangled to form a three-dimensional (3D) pore structure.[4–7] In general, the most important type of intermolecular interaction in an organogel is hydrogen bonding. Therefore, the molecular structure of organogelators has been limited to about 30 kinds of molecules, such as fatty acids and their monovalent salts, steroids, anthryls, amino acids, and organometallic derivatives having hydrogen-bonding sites, such as hydroxy, carboxylic, amino, and carbonyl groups.[4–7] With the exception of 2,3-bis-*n*-decyloxyanthracene,[8] organogelators have been designed

on the basis of their ability to participate in hydrogen-bonding interactions.

Organogelators have a tendency to form fibrous structures, which can be used to construct electrically active low-dimensional nanostructures even though most organogelators do not possess an electrically active π-electron system.[4–7] Electrically and optically active molecules, such as phthalocyanine, porphyrin, and thiophene, have been used to construct organogels through hydrogen-bonding interactions.[6,9–11] Sulfur-containing π-electron systems are useful building blocks for constructing highly electrically conducting molecularly assembled structures. For example, a variety of molecular metals and superconductors have been developed by incorporating the radical ions of tetrathiafulvalene (TTF) derivatives.[12] Organogelators incorporating S-containing π-electron systems have been reported, namely amphiphilic thiophene and TTF derivatives with hydrogen-bonding sites, which exhibit a capacity to gelate despite the absence of π–π interactions. To the best of our knowledge, the electronic properties of these organogelators have not yet been characterized. New organogelators with S-containing π-electron systems capable of self-assembling into fibrous structures through strong intermolecular S–S and π–π interactions have the potential to form electron-conducting pathways through the formation of a π-band structure. Thus, the π-stacking interaction is intrinsically a prerequisite for the formation of electrically active organogels.

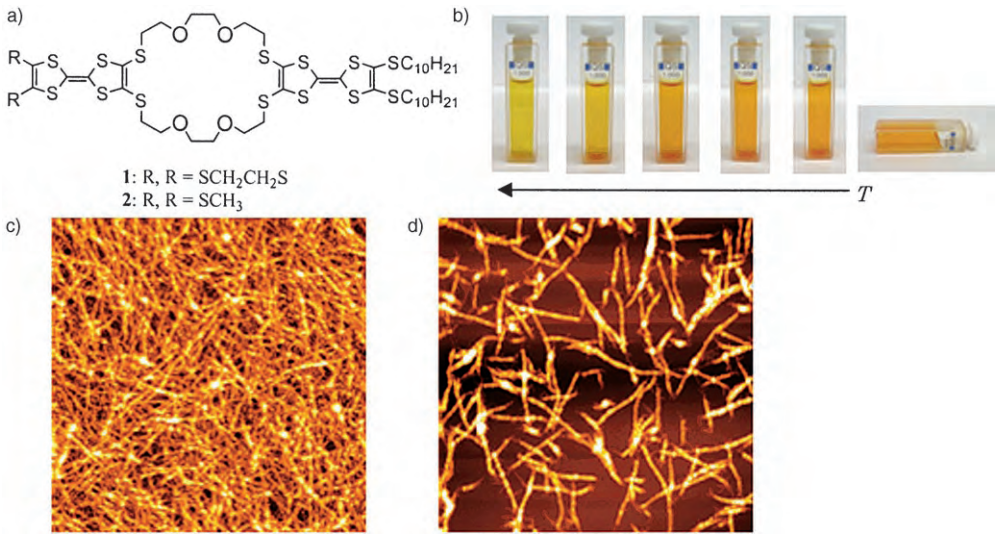

Figure 1. a) Molecular structure of amphiphilic bis-TTF annulated macrocyclic derivatives. b) Temperature-dependent organogelation of **1**. A 1 mM solution of **1** in $CHCl_3/CH_3CN$ (6/4) at 333 K was slowly cooled to 298 K. Organogelation was accompanied by a color change from yellow ($T = 333$ K) to orange ($T = 298$ K). c) Surface structure of the cast film of dried organogels on mica. d) Surface structure of a spin-coated film of dried organogels on mica. The rotational speed of the spinner was fixed at 4000 rpm. AFM images were recorded in a $10 \times 10\ \mu m^2$ scanning area.

We have constructed nanowires based on charge-transfer (CT) complexes of amphiphilic bis(tetrathiafulvalene) (bis-TTF) annulated macrocycles by molecular assembly as examples of electrically conducting nanostructures.[13,14] Formation of molecularly assembled nanowires with a typical dimension of $2.5 \times 50 \times \approx 1000\ nm^3$ has been achieved with a charge-transfer complex of a methylthio-substituted bis-TTF annulated macrocycle derivative.[2] Herein, we report a new amphiphilic bis-TTF annulated macrocycle derivative **1**, which can form redox-active organogels as well as electrically active nanostructures, such as nanowires and size-controllable nanodots (Figure 1 a).

Molecule **1** was synthesized to increase the magnitude of the intermolecular interactions: a terminal ethylenedithio group ($-SCH_2CH_2S-$) effectively enhances the intermolecular interactions through lateral S–S contacts in the molecularly assembled structures compared to those in **2**, which contains methylthio groups ($-SCH_3$).[13, 14] Molecule **1** was soluble in CH_2Cl_2, $CHCl_3$, toluene, 1,2-dichloroethane, but less-soluble in CH_3CN, acetone, CH_3OH, C_2H_5OH, and *n*-hexane. Slow cooling of a solution of **1** (1 mM) in $CHCl_3/CH_3CN$ (6/4) from 333 K resulted in the generation of organogels at 293 K (Figure 1 b). The yellow solution of **1** changed to an orange organogel upon cooling. The formation of organogels depended on the volume fraction of CH_3CN in the $CHCl_3/CH_3CN$ mixed solvent system. No organogels formed at room temperature at volume fractions of CH_3CN less than 40%. Other mixed-solvent systems such as $CHCl_3/CH_3OH$ (4/6), C_6H_6/CH_3CN (4/6), and $ClCH_2CH_2Cl/CH_3CN$ (4/6) also yielded organogels. However, the mixed-solvent systems of $CHCl_3/CH_3COCH_3$, $CHCl_3/C_2H_5OH$, and $CHCl_3/C_2H_5CN$ prevented formation of organogels.

Multiple hydrogen-bonding sites are the functional units that lead to one-dimensional fibrous structures in most organogelators. Although **1** possesses no hydrogen-bonding sites, the strong intermolecular π–π interactions enabled formation of an organogel. Organogelation of **1** results from replacing the terminal functional group by the ethylenedithio group since the bis(methylthio)-substituted bis-TTF annulated macrocycle **2** is incapable of forming organogels. It is known that a terminal ethylenedithio group sufficiently increases the dimensionality of intermolecular interactions through lateral interatomic S–S contacts along the peripheral direction in the π stacks.[12] Together with the π–π interaction, these intermolecular S–S interactions provide a two-dimensional electronic structure for a stable metallic and superconducting state in certain ion-radical salts of bis(ethylenedithio)-TTF.[12] Intermolecular S–S contacts of the terminal ethylenedithio group in **1** play an important role in increasing the intermolecular interaction to form fibrous structures in the organogel. The intermolecular interactions between

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

electrically active TTF units, which lead to a π-band structure in the solid state, are important for obtaining electrically conducting nanoscale materials.

Figure 1c,d shows organogel structures fabricated as a dried gel by cast and spin-coating techniques (1 mM $CHCl_3$/CH_3CN (6/4)), respectively, on mica. In the case of the cast film, the fibers were entangled to form a 3D structure. The film surface morphology was characteristic of an organogel:[16] introduction of organic solvents into the 3D pore yielded an organogel. By contrast, isolated fibrous structures were observed in the case of the spin-coated film. The average width and height of the fibers were 50 and 8 nm, respectively, as revealed by AFM measurements.

The fibrous shape of the organogels is conducive to constructing novel low-dimensional nanostructures. We employed the Langmuir–Blodgett (LB) technique to obtain nanostructures from organogelator **1**. Transfer of the film from the Langmuir layer on an aqueous 0.01M KCl subphase onto mica resulted in the formation of fibrous structures with an average dimension of $7 \times 70 \times$ ca. 10000 nm^3. A 2.2-nm-thick two-dimensional monolayer underlays the fibers and covers 90% of the surface area (Figure 2a). The fibers were distributed randomly on the monolayer. Although a uniform Langmuir layer was observed in the film transferred from pure water, no fiberlike domains were formed, thus suggesting that the addition of ions into the subphase contributed to the formation of the fibrous structures of donor **1** in the LB film. The addition of electrolytes, such as NaCl, NaBr, and KCl, to water decreases the surface tension of amphiphilic molecules at the air–water interface[15] as a result of the stronger adsorption of the molecules on the electrolyte-containing interface than on pure water. The decrease in the surface tension of donor **1** on the 0.01M KCl aqueous subphase accelerates the formation of micellelike molecularly assembled structures.

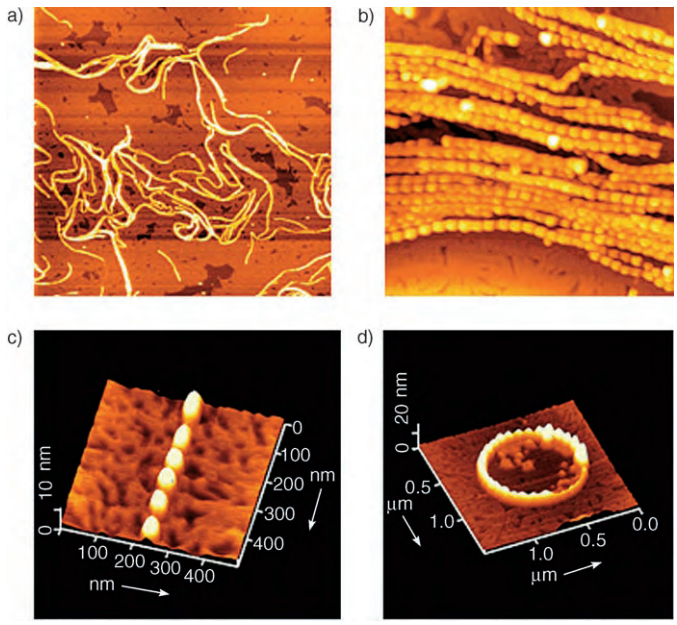

Figure 2. Surface structure of Langmuir–Blodgett films of **1** on mica. The films were fabricated by using a standard Langmuir trough at 291 K with a subphase containing 0.01 M KCl. The spreading solvent was a 0.5 mM solution of **1** in $CHCl_3$/CH_3CN (6/4) and the barrier speed was 50 $mm^2 min^{-1}$. Films were deposited by the vertical-dipping method at a constant surface pressure of 5 $mN m^{-1}$. a, b) The AFM images were recorded over an area of 10×10 and 2×2 μm^2. c, d) Expanded AFM images of a nanodot array. The nanodot-array structure has a connection of six nanodots (500×500 nm^2 image) and nanodot-ring structure is composed of about 40 nanodots (1.5×1.5 μm^2).

Each fiber was composed of a one-dimensional nanodot array (Figure 2b). The average diameter and height of the nanodots were 70 and 7 nm, respectively. The nanodots in the films often formed a regular array and ring structures (Figure 2c,d). The diameter of a nanodot ring consisting of about 40 nanodots was roughly 500 nm. The circumference of the nanodot ring (ca. 3 μm) was almost consistent with the sum of the average diameter of 40 nanodots (40×70 nm^2).

Although **1** forms nanofibers of nanodot arrays, these nanostructures are not expected to have a high electrical conductivity because of the closed-shell electronic structure. Molecule **1** shows a two-step redox behavior, with the first and second oxidation potentials at $E^1_{1/2} = 0.60$ and $E^2_{1/2} = 0.94$ V in CH_2Cl_2 (versus the saturated calomel electrode (SCE)), respectively, each of which corresponds to a two-electron ($2e^-$) oxidation reaction. The high electron-donating capacity of **1** enabled us to apply chemical oxidation by dissolving two equivalents of iodine (I_2) in a 0.5 mM solution of **1** in $CHCl_3$/CH_3CN (8/2).

The obtained CT complex of donor **1** with an open-shell electronic structure was subjected to spin coating using a drop (ca. 1 μL) of a 0.5 mM solution of **1**/$(I_2)_2$ in $CHCl_3$/CH_3CN on freshly cleaved mica. The rotational speed of the spinner was varied between 500 and 6000 rpm. Isolated nanodots were observed in spin-coated films (Figure 3a–d). No organogel was formed in the case of the 0.5 mM solution of **1**/$(I_2)_2$, thus indicating that the ability of **1** to form a fibrous structure was poor in the oxidized state. The diameter and height of the nanodots clearly depended on the rotational speed of the spinner (Figure 3e), with the nanodot diameter decreasing with increasing rotational speed. For example, the average diameter and height of the nanodots at a rotational speed of 6000 rpm were 200 and 20 nm, respectively, while those at 500 rpm were 800 and 400 nm, respectively. The diameters of the nanodots increased exponentially as the rotational speed decreases. The diameters of the nanodots can be varied from 200 to 1000 nm by adjusting the rotational speed of the spinner between 6000 and 500 rpm. The size of the nanodots can also be controlled by changing the experimental conditions, for example, the concentration of the CT complex and wetting angle of the substrate. Much smaller nanodots with a diameter of approximately 150 nm and a height of 13 nm were obtained in a diluted solution of the CT complex (0.1 mM) at a rotational speed of 4000 rpm. Small nanodots with a typical diameter of 20 nm and a height of 1.2 nm were often observed on the same spin-coated film.

The conductance of single nanodots fabricated on highly ordered pyrolytic graphite (HOPG) substrates was measured by conducting AFM (C-AFM).[16] The Pt-coated AFM tip directly contacted a single nanodot, thus forming an HOPG/nanodot/Pt sandwich. The red circles in Figure 4a at points I

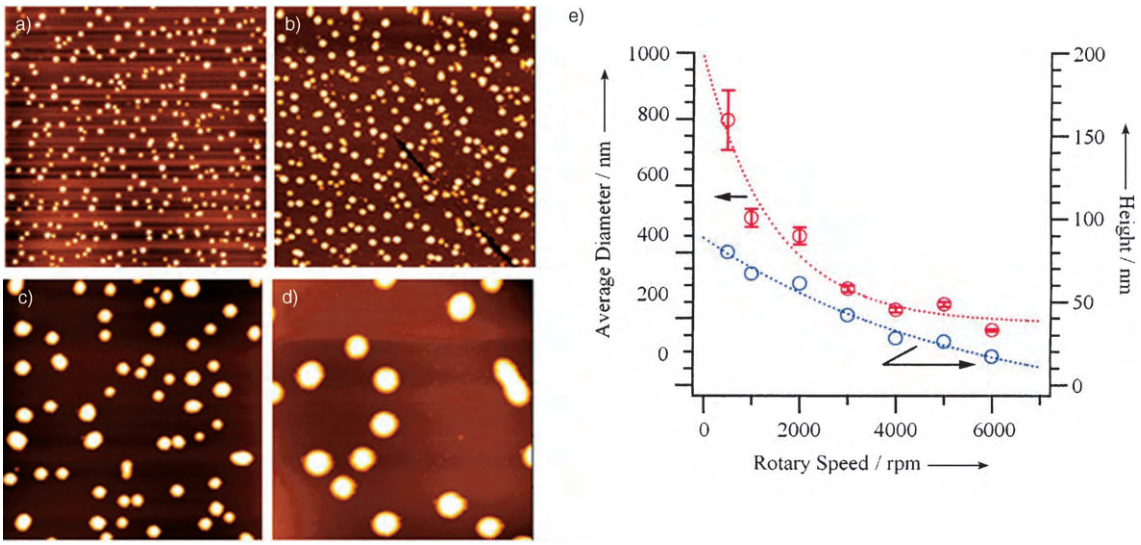

Figure 3. a–d) AFM images of size-controllable nanodots of the **1**/$(I_2)_2$ complex with an open-shell electronic structure on mica. The rotation speed of the substrate on the spinner was 6000, 4000, 2000, and 500 rpm for (a)–(d), respectively. The scale of all AFM images is $10\times10\ \mu m^2$. e) Rotational-speed dependence of the average diameter and height of the nanodots on mica. The average diameter and height of the nanodots were obtained by statistical analysis of the AFM images ($10\times10\ \mu m^2$).

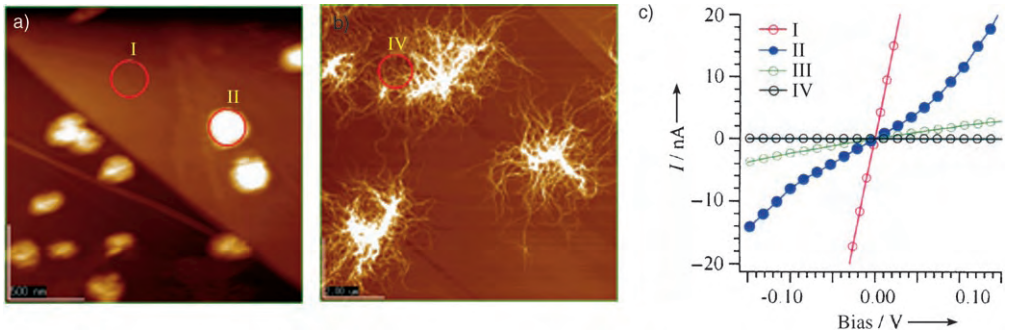

Figure 4. a) AFM image of nanodots of **1**/$(I_2)_2$ on HOPG for conducting-AFM (C-AFM) measurements ($2\times2\ \mu m^2$). After measurement of the topological image, the Pt-coated AFM tip contacted the bare HOPG surface (point I) and a single nanodot (point II) to measure their *I–V* characteristics. The nanodot structures were retained after the conductivity measurement, as confirmed by AFM measurement. b) AFM image of fibrous structures of **1** on HOPG ($10\times10\ \mu m^2$) prepared by spin casting of a 1 mM solution ($CHCl_3/CH_3CN$ 6:4). A Pt-coated AFM tip contacted a bundle of fibers with a height of about 2 nm (point IV). c) *I–V* characteristics at points I (HOPG), II (single nanodot in air), III (single nanodot in vacuum at 5×10^{-3} Pa), and IV (bundle of fibers). DC bias was applied from −0.2 to 0.2 V.

(bare HOPG) and II (single nanodot with a diameter of 200 nm and a height of 23 nm) correspond to the contact area of the C-AFM tip during *I–V* measurements. The conductance of bare HOPG and a single nanodot were obtained from the slope of the *I–V* curve to be 730 and 20 nS, respectively, at 5×10^{-3} Pa. The conductance of the nanodot increased to 86 nS under ambient conditions because of the effects of oxygen and/or water. The fibrous structure of **1** was formed on HOPG by spin coating using a 1 mM solution of **1** in $CHCl_3/CH_3CN$ (6/4). The surface morphology shows a neuronlike network structure (Figure 4b), with the bundles of fibers randomly distributed on the HOPG. The conductance of a fiber bundle with a height of about 2 nm (point IV in Figure 4b) was about 0.03 nS, which is four to five orders of magnitude smaller than that of a single nanodot with an open-shell electronic structure. The high conductance of single nanodots of the CT complex reflect the high concentration of the conduction carriers.

In conclusion, a new organogelator consisting of an amphiphilic bis-TTF annulated macrocyclic derivative was synthesized. The terminal ethylenedithio group increased the intermolecular interactions through lateral S–S contacts, in addition to the π–π interaction, which was responsible for organogelation. A three-dimensional entangled structure of fibers was confirmed in the dried organogel. The organogelator produced nanodot-array structures in Langmuir–Blodgett films. The chemically oxidized organogelator formed size-controllable isolated nanodot structures, which were simply fabricated by the spin-coating technique. The size of the nanodots depended on the rotational speed of the substrate, and was thus controllable. The conductance of a single nanodot with an open-shell electronic structure was four to five orders of magnitude higher than that of fibers of **1** with a closed-shell electronic structure. Nanostructures of molecular conductors can potentially be used in molecular electronic devices as electrically active units.

Experimental Section

1: Donor **1** was synthesized by a stepwise protection/deprotection protocol of the cyanoethylene groups. 2-Iodoethoxyethane was introduced into ethylenedithiolo-bis(2-cyanoethylthio)TTF by deprotection of a cyanoethylene group, then treated under high-dilution conditions in DMF. The [24]crown-8 macrocycle was formed by addition of two equivalents of CsOH to the bis(TTF) compound, which yielded the amphiphilic bis(TTF) annulated macrocycle **1**. The **1**/$(I_2)_2$ complex was prepared in situ by mixing donor **1** and two equivalents of I_2 in $CHCl_3/CH_3CN$ (8/2, v/v). The concentration of the CT complex solution was fixed at 0.5 mM with respect to **1**/$(I_2)_2$.

The spin-coated films were produced on a mica surface ($10 \times 10\ mm^2$) by adjusting the rotational speed from 500 to 6000 rpm. About 1 μL of the CT complex solution was dropped onto the rotating mica surface, which was rotated for a further 60 s. The floating monolayers were left for 30 min after spreading of the CT complex (NIMA633 D2/D1). The LB monolayers were transferred onto freshly cleaved mica surfaces at a fixed surface pressure of $10\ mN\,m^{-1}$ by a single up-stroke.

Dynamic mode AFM images were recorded on a Seiko SPA 400 with an SPI 3800 probe station and JEOL JSPM-5200. Commercially available Si cantilevers with a force constant of $13\ N\,m^{-1}$ were used. *I–V* characteristics of the nanodots were measured by direct contact of the Pt-coated AFM tip with single nanodots on the HOPG surface.

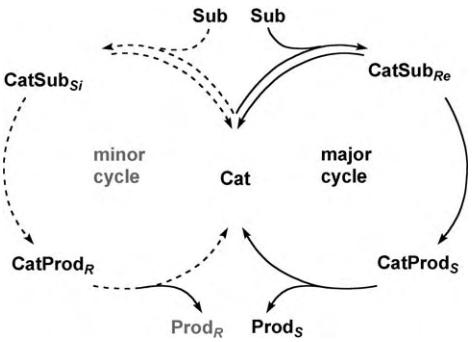
Origin of the Minor Enantiomeric Product in a Noyori Asymmetric Hydrogenation: Evidence for Pathways Different to the Major Mechanism**

*Yoshitaka Ishibashi, Yuhki Bessho, Masahiro Yoshimura, Masaki Tsukamoto, and Masato Kitamura**

In a typical asymmetric catalytic process, a prochiral substrate (Sub) is converted into a major ($Prod_S$) and a minor ($Prod_R$) enantiomeric product via diastereomeric catalyst–substrate (CatSub) and catalyst–product (CatProd) complexes (Scheme 1). The two cycles are diastereomorphic to each



Scheme 1. Competition between diastereomorphic catalytic cycles.

other, but they take place through a single mechanism. As such, the Arrhenius equation can be applied confidently to correlate the $Prod_S/Prod_R$ ratio to the relative stabilities of the diastereomeric transition states at the first irreversible step from CatSub to CatProd.[1] The energy profile thus obtained can be utilized to estimate the structural difference between the two transition states. In most cases, however, this premise of a single mechanism has not been confirmed.[2] We have long suspected that in some cases $Prod_S$ and $Prod_R$ may be

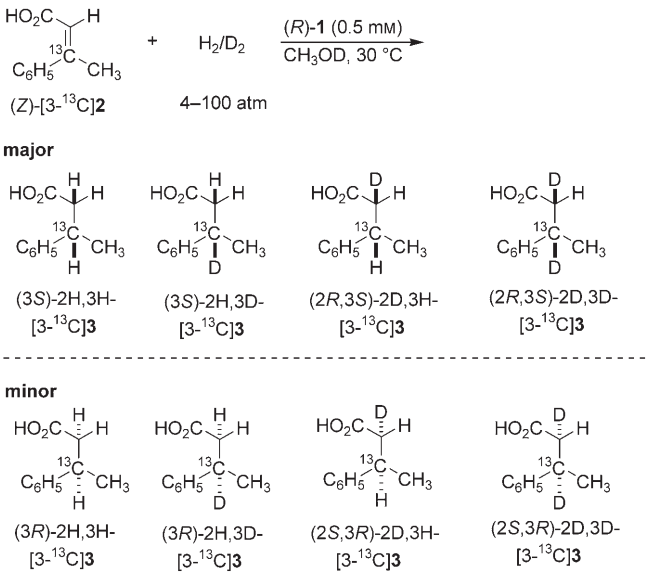
generated through entirely different catalytic cycles in which several chain carriers produced in a given reaction system convert the same substrate but with different reactivities and enantioselectivities. In such a catalytic process, various reaction parameters dynamically link the species, and therefore the observed enantioselectivity becomes the average contribution of the mechanistically different cycles.[3] Herein, we report for the first time a clear example of asymmetric catalysis that yields $Prod_S$ and $Prod_R$ from the same substrate but through different mechanisms.

This new case was identified in the hydrogenation of (*Z*)-3-phenyl-2-butenoic acid ((*Z*)-**2**) in the presence of [Ru-$(CH_3CO_2)_2$\{(*R*)-binap\}] ((*R*)-**1**).[4] Under standard conditions ((*R*)-**1** (0.5 mM), (*Z*)-**2** (100 mM), Sub/Cat = 200:1, methanol, 30 °C, 1–4 atm), (*S*)-3-phenylbutanoic acid ((*S*)-**3**) was obtained with 94 % ee when a pressure of 1–4 atm was applied. The value decreased to 92 % *ee* at 50 atm and to 88 % *ee* at 100 atm,[5] whereas the reaction rate was enhanced when the pressure of the hydrogen was increased.[6] The substrate (*Z*)-**2** is stable and undergoes neither *Z*/*E* geometrical nor α,β/β,γ (C2–C3/C3–C4) positional isomerization during the course of the hydrogenation.[5,7] To improve the accuracy of the isotope-labeling experiments, the ^{13}C-labeled substrate (*Z*)-[3-^{13}C]**2** was used, and the (*R*)-**1**-catalyzed hydrogenations were carried out in CH_3OD by changing the hydrogen pressure and the ratio of H_2 and D_2. All the reactions were stopped at low conversions to minimize complications caused by gas–solvent and gas–gas isotope exchange.[2,5] The enantiomeric products, (*S*)-**3** (major) and (*R*)-**3** (minor), were separated by chiral HPLC (CHIRALCEL OD (20 mm × 25 cm); eluent: hexane/2-PrOH/AcOH 1000:1:3),[5] and the ratio of the eight isotopomers (3*S*)-2H,3H-[3-^{13}C]**3**, (3*S*)-2H,3D-[3-^{13}C]**3**, (2*R*,3*S*)-2D,3H-[3-^{13}C]**3**,[9] (2*R*,3*S*)-2D,3D-[3-^{13}C]**3**,[9] (3*R*)-2H,3H-[3-^{13}C]**3**, (3*R*)-2H,3D-[3-^{13}C]**3**, (2*S*,3*R*)-2D,3H-[3-^{13}C]**3**,[9] and (2*S*,3*R*)-2D,3D-[3-^{13}C]**3**[9] was determined by $^{13}C\{^1H,^2H\}$ NMR spectroscopic analysis of the *S* and *R* products (Scheme 2).[5,10]

Figure 1 represents the change in the distribution pattern of the major and minor enantiomeric products in going from the H_2 to H_2/D_2 conditions. When the reaction was carried out in CH_3OD under a pressure of 4 atm of H_2, a mixture of (*S*)-**3** and (*R*)-**3** was obtained in a ratio of 97:3. The major *S* product consisted of 2H,3H, 2H,3D, 2D,3H, and 2D,3D isotopomers (10:89:0:1). Under an atmosphere of H_2/D_2 (1:1) in CH_3OD, the ratio shifted to 3:46:3:48. This change in distribution can be understood simply in terms of the Ru monohydride mechanism proposed in the Ru–binap-catalyzed hydrogenation of tiglic acid[11,12] or α-(acylamino)acrylic esters.[2,13] In short, a RuH species, generated from (*R*)-**1** and H_2, delivers hydride to the *Si* face at C2 of (*Z*)-**2** to form the (3*R*)-C3–Ru intermediate. Cleavage of the C–Ru bond utilizes both H_2 gas (the RuH/C3–Ru/H_2 route) and CH_3OD (the RuH/C3–Ru/H^+ route), and leads to a mixture of (3*S*)-2H,3H and (3*S*)-2H,3D (10:89).[14,15] Under a 1:1 mixture of H_2/D_2 gas, the RuH/C3–Ru/H_2 route should produce the four isotopomers in a 1:1:1:1 ratio (blue line) and the RuH/C3–Ru/H^+ route should produce 2H,3D and 2D,3D in a 1:1 ratio (green line); therefore, a relative proportion of ≈3 each for the (3*S*)-2H,3H, (3*S*)-2H,3D, (3*S*)-2D,3H, and (3*S*)-2D,3D isotopomers will be derived from the 10 part, and ≈44 for the (3*S*)-2H,3D and (3*S*)-2D,3D isotopomers from the 89 part. Simple calculation estimates the ratio to be 3:47:3:47, which is consistent with the observed ratio.



Scheme 2. Structures of the eight possible isotopomers from the reduction of (*Z*)-[3-^{13}C]**2** in CH_3OD under H_2/D_2 mixtures at different pressures.

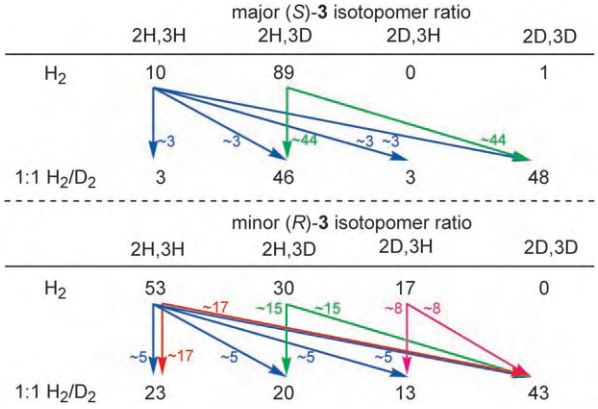


Figure 1. Change of the isotopomer ratios in the (*R*)-binap–Ru-catalyzed hydrogenation of (*Z*)-[3-^{13}C]**2** in CH_3OD under 4 atm of H_2 or H_2/D_2 (1:1). Top: (*S*)-[3-^{13}C]**3** obtained as the major product (97 %). Bottom: (*R*)-[3-^{13}C]**3** obtained as the minor product (3 %). The colored arrows indicate the reaction pathways and the estimated distribution of the isotopomers when the conditions are switched from H_2 to H_2/D_2 (1:1). → RuH/C3–Ru/H_2 and/or RuH/C2–Ru/H_2 (RuH/H_2); → RuH/C3–Ru/H^+; → RuH_2; → RuH/C2–Ru/H^+.

In contrast, the minor *R* enantiomer contained largely the (3*R*)-2H,3H (53 %) together with the (3*R*)-2H,3D (30 %) and (3*R*)-2D,3H (17 %) isotopomers. More gaseous hydrogen appears to be consumed in the formation of the minor product than in that of the major *S* enantiomer, and formation of the 2D,3H isotopomer is characteristic of the minor product. The reaction carried out in CH_3OD under a mixture of H_2/D_2 (1:1) generated a 23:20:13:43 mixture of the four 3*R* isotopomers. The ambiguous isotope-labeling patterns, which

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

are totally different from those of the major enantiomer, can be explained by assuming that the RuH_2 route[5] (red line) and the RuH/C2–Ru/H^+ route (purple line) are involved as well as the above two reaction pathways (blue and green lines) (Figure 1, minor). The two hydrides on RuH_2 are delivered from the same *Re*,*Si* face of (*Z*)-**2** to C2 and C3 in a pairwise manner.[16] In the RuH/C2–Ru route, a conjugate-type addition of the hydride of a RuH species onto the *Si* face of C3 generates a (2*R*,3*S*)-C2–Ru intermediate,[17] which then undergoes hydrogenolysis (RuH/C2–Ru/H_2) or protonolysis (RuH/C2–Ru/H^+). Thus, the 2H,3H, the 2H,3D, and the 2D,3H isotopomers in the H_2/CH_3OD reaction are produced through the pathways RuH_2 and RuH/H_2,[18] the RuH/C3–Ru/H^+ route, and the RuH/C2–Ru/H^+ route, respectively. In light of the 2H,3H:2H,3D:2D,3H:2D,3D distribution coefficients (1:1:1:1 for RuH/C3–Ru/H_2 and RuH/C2–Ru/H_2 (blue line), 0:1:0:1 for RuH/C3–Ru/H^+ (green line), 1:0:0:1 for RuH_2 (red line), and 0:0:1:1 for RuH/C2–Ru/H^+ (purple line)), the isotopomer ratio obtained by the replacement of H_2 with a 1:1 mixture of H_2/D_2 gas is calculated to be 22:20:13:45. Figure 2a shows the good agreement between the values estimated from the H_2/CH_3OD results (colored bars) and the experimental values (gray bars). The colors correspond to those of the reaction pathways shown in Figure 1.

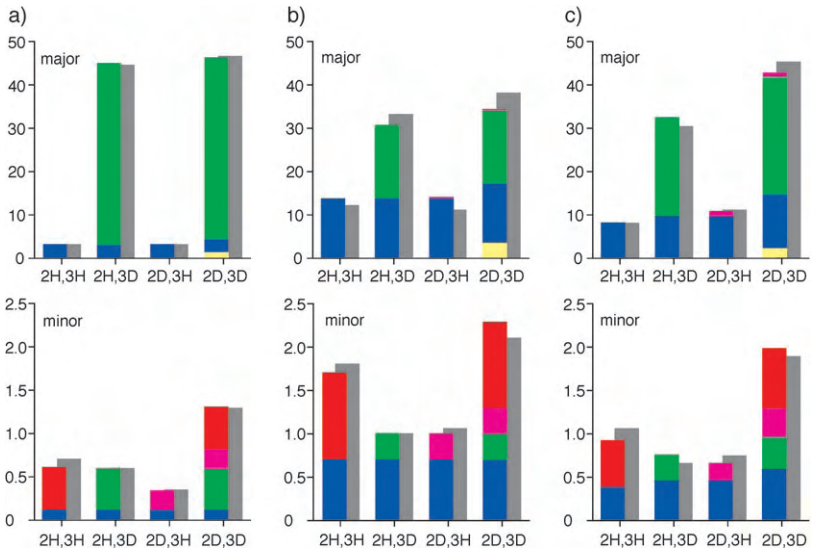

Figure 2. Observed (gray) and estimated (colored) isotopomer ratios of the major *S* and minor *R* products in the (*R*)-binap–Ru-catalyzed hydrogenation of (*Z*)-[3-^{13}C]**2** in CH_3OD under: a) 4 atm of H_2/D_2 (1:1), b) 100 atm of H_2/D_2 (1:1), and c) 50 atm of H_2/D_2 (44:56). Colored values are estimated from the experimental results of 4, 50, and 100 atm H_2/CH_3OD conditions. ■ RuH/C3–Ru/H^+; ■ RuH/C3–Ru/H_2 and/or RuH/C2–Ru/H_2; ■ RuH_2; ■ RuH/C2–Ru/H^+; ■ unknown mechanisms; *x* axis: isotopomers of **3**; *y* axis: yield [%].

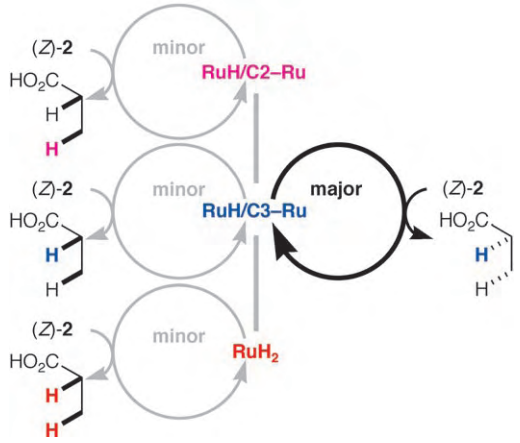
This tendency is also seen with changes in the pressure of the hydrogen gas and the H_2/D_2 ratio (Figure 2b,c).[19] An increase in hydrogen pressure from 4 to 100 atm in CH_3OD approximately tripled the formation of the minor enantiomer (Figure 2a, minor vs. Figure 2b, minor), and enhanced the contribution of gaseous hydrogen to both the major and minor product pathways. The amount of major product formed by the RuH/H_2 pathway (blue bars) increased approximately five times and was coupled with a significant decrease in the involvement of the RuH/C3–Ru/H^+ route (green bars), whereas the contribution of the RuH_2 pathway (red bars) to the formation of the minor product doubled. In the case of the reaction carried out in CH_3OD under H_2/D_2 gas (44:56) at 50 atm, the *S* and *R* products (96:4) consisted of the eight isotopomers in a 9:31:11:45:1.0:0.6:0.7:1.7 ratio, as indicated by the gray bars in Figure 2c. A reasonable agreement with the estimation from the results obtained from the reaction in CH_3OD under 50 atm of H_2 was observed after a 0.44/0.56 correction to the above distribution coefficients.

Each asymmetric catalytic cycle proceeding through the RuH/C3–Ru/H_2, RuH/C3–Ru/H^+, RuH/C2–Ru/H_2, RuH/C2–Ru/H^+, or RuH_2 routes, or other possible reaction pathways, has its own energy diagram, according to which the overall rate as well as the stereochemistry is determined.[20] Neither the details of the kinetics nor the structures of the intermediates are known at present, but a series of isotope-labeling experiments indicated that this Ru–binap-catalyzed asymmetric hydrogenation of an α,β-unsaturated carboxylic acid involves several catalytic species and that a significant amount of the minor *R* enantiomer is formed through the RuH/C2–Ru/H^+ and RuH_2 pathways, which are hardly involved in the formation of the major product (Scheme 3). Asymmetric catalytic reactions convert a prochiral substrate



Scheme 3. Possible catalytic cycles producing the major *S* and minor *R* enantiomers from the same (*Z*)-**2** substrate through different chain carriers. C3 substituents of (*Z*)-**2** and products have been omitted for clarity.

into an enantiomer-enriched chiral product. The observed enantioselectivity has generally been interpreted to result from competing diastereomorphic catalytic cycles caused by a single chiral catalyst. However, this supposition has not been substantiated. Together with earlier examples,[2,11,12] our study calls into question such a generalized treatment.

Proofreading and Error Removal in a Nanomaterial Assembly**

*Juewen Liu, Daryl P. Wernette, and Yi Lu**

Recent progress in the self-assembly of nanomaterials promises to revolutionalize a number of science and engineering fields such as molecular electronics, photonics, and computation.[1–7] A key hurdle to realizing such a potential is the presence of imperfect structures or errors in the assembly process. To overcome this problem, major efforts have been focused on optimizing the assembly process to minimize errors or to design devices that can tolerate errors.[8–11] We argue that it could be equally valuable to investigate proofreading and error removal during and after assembly, as demonstrated beautifully in a number of processes in biology, such as in mRNA-templated protein synthesis (Figure 1 a).[12] Herein, we provide the first experimental demonstration of proofreading and error removal in nanomaterial assembly by using DNAzymes to specifically locate and remove errors in DNA-templated gold nanoparticle assemblies (Figure 1 b). The concept demonstrated here can be applied to the assembly of other nanomaterials using other bio- or biomimetic molecules.

We chose to demonstrate the proofreading and error-removal process in a DNA-templated nanoparticle assembly because remarkable progress has been made in the field, which has resulted in both nanostructures with high resolution, controllability, and versatility[1–3,13–15] and nanomaterials with potential for practical applications such as colorimetric sensing.[16–19] For a design strategy, we searched biological processes for guiding principles. As shown in Figure 1 a, errors could occur in protein synthesis on an mRNA template where an incorrect amino acid might be incorporated. To prevent such a process, proofreading units (such as GTPase elongation factor-Tu) are employed to identify such an error and remove the wrong amino acid.[12] Similarly, errors could occur in a DNA-templated gold nanoparticle assembly, where each nanoparticle is coded by DNA molecules with a unique sequence, just as each amino acid is coded by a transfer RNA (tRNA) molecule. Among the three kinds of nanoparticles in the system, two (A and B) are defined as "correct" particles to be assembled on the template, while the remaining one (B′) is

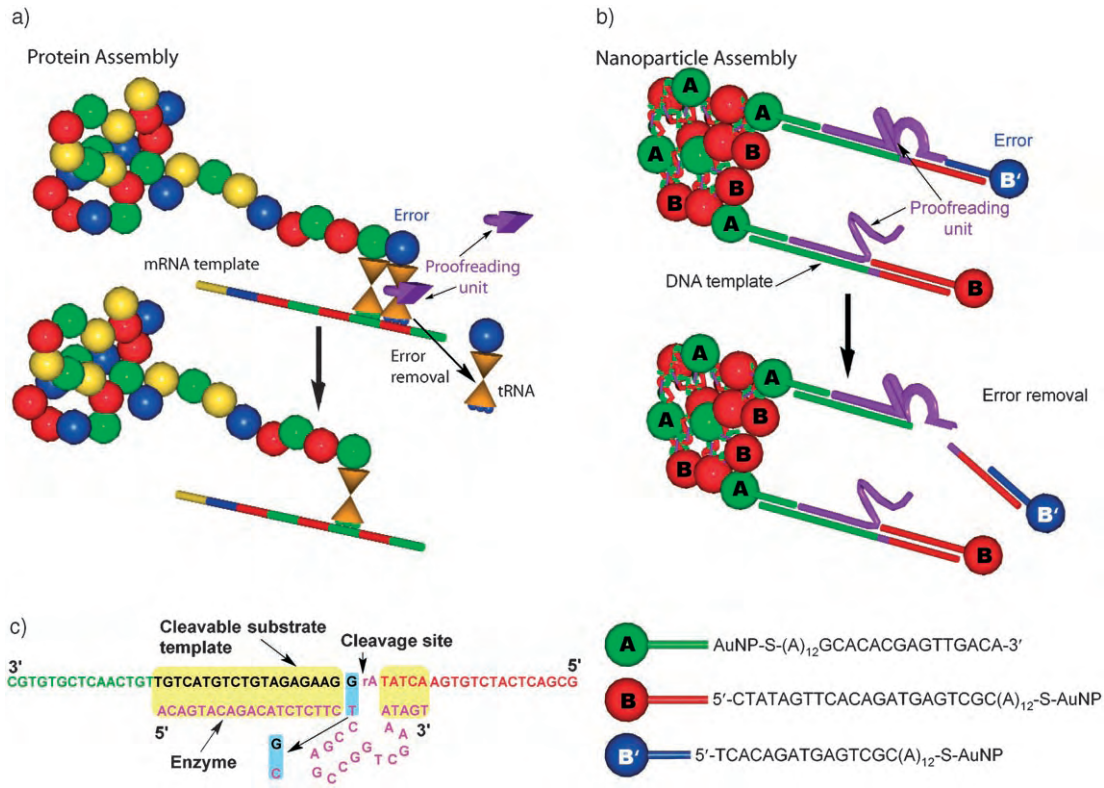

Figure 1. Proofreading and error removal in biology (a) and in materials science (b). a) The last tRNA moiety and its amino acid do not match the mRNA template (coded by colors) and are removed by the proofreading unit. b) The error-removal process is triggered by adding Pb^{2+} ions. c) Secondary structure of the DNAzyme used for proofreading and error removal in DNA-functionalized gold nanoparticle assemblies. The DNA sequences attached to gold nanoparticles (AuNP) are also shown. $(A)_{12}$ denotes a polyadenine spacer containing 12 A bases.

defined as an "error" particle (Figure 1b). Nanoparticle A can bind to the 3′ arm of the DNA template, while nanoparticle B binds to the 5′ arm of the template, both through sequence-specific hybridization. The error particle B′ can also bind to the 5′ arm of the template. However, the DNA attached to B′ is seven bases shorter than that attached to nanoparticle B. As a result, the affinity of B′ to the template is less than that of B, similar to the decreased affinity between an error tRNA and the mRNA template.

Instead of using protein enzymes for proofreading and error removal in protein synthesis, we chose to use a DNAzyme (DNA with catalytic activity), because it has the advantage of performing both structural roles to assemble nanoparticles and functional roles for proofreading and error removal.[20–22] The DNAzyme contains a substrate strand and an enzyme strand that form two duplex regions (Figure 1c, highlighted in yellow). In the presence of Pb^{2+} ions, the substrate is cleaved into two pieces at the rA position by the enzyme. The two duplex regions are designed to be asymmetrical, with one side containing 19 base pairs while the other side contains only five base pairs. Therefore, the cleaved fragment with the shorter binding arm can be easily released. To allow the DNAzyme substrate to be a template for nanoparticle assembly, the two overhangs on the substrate strand are complementary to the DNA attached to the nanoparticles. If a correct particle B is incorporated, binding of the longer arm of the enzyme to the DNA template is permitted while binding of the shorter arm to the DNA template is inhibited so that the active structure of the DNAzyme cannot form. As a result, the template is not cleaved and particle B is incorporated. When a B′ error particle is incorporated, the enzyme can bind both its arms to the substrate template and form an active structure to cleave the substrate and remove the B′ particle. This process is summarized in Figure 1b.

To demonstrate the specific removal of B′ particles from the assembly, a series of nanoparticle assemblies were prepared in such a way that the number of A particles equaled the sum of B and B′ particles. First, two extreme scenarios, 100% B (no B′) and 100% B′ (no B), were tested. The UV/Vis spectra of the two samples before and after error removal by Pb^{2+} addition are presented in Figure 2a and b, respectively. The sample with 100% B particles had only a slight increase of extinction at the 522-nm peak after error removal, which suggests that the assembly did not undergo significant changes (Figure 2a). However, for the sample with 100% B′ particles, the extinction at 522 nm increased whereas the extinction in the 700-nm region decreased significantly, thus resulting in a higher 522 to 700 nm extinction ratio. This finding suggests that nanoparticles in the A/B′ system were in the disassembled state (Figure 2b).[18,19] To test the effectiveness of proofreading and error removal in between the two extreme conditions, samples with various percentages of B′ particles were prepared and the 522 to 700 nm extinction

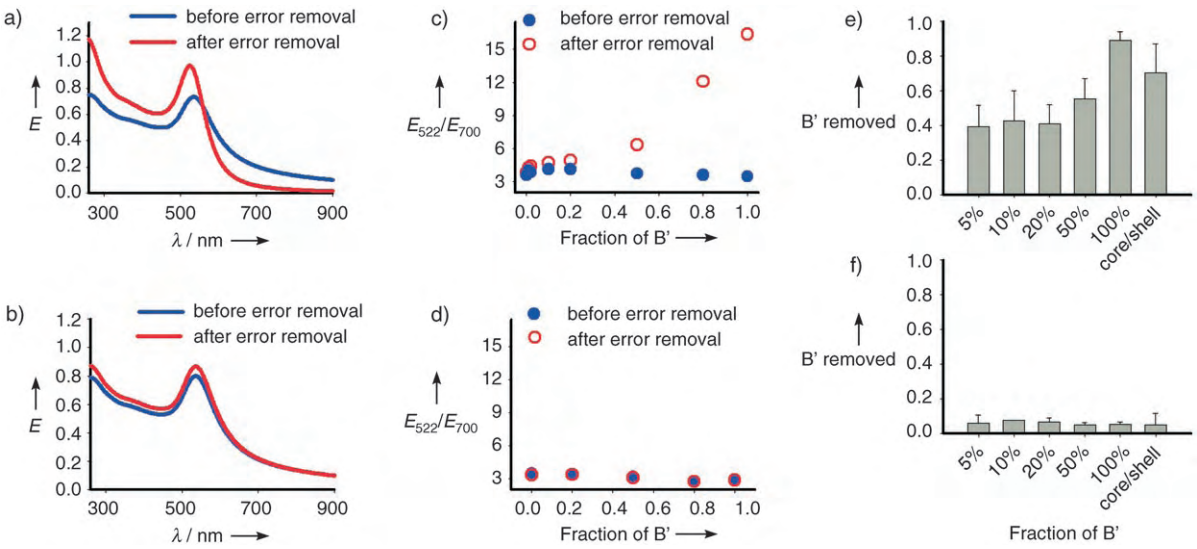

Figure 2. UV/Vis spectra of the nanoparticle assemblies made of particles A/B′ (a) or A/B (b) before and after proofreading and error removal. Extinction (*E*) ratios of the samples with various fractions of B′ particles before and after error removal with the native active enzyme (c) or mutated inactive enzyme (d). Fluorescence-based quantification of B′ particles removed from nanoparticle assemblies with the native active enzyme (e) or mutated inactive enzyme (f).

ratios before and after error removal were plotted against the fraction of B′ particles (Figure 2c). The extinction ratio increased with an increase of B′ particles, which suggests successful removal of the B′ particles from the assembly. To confirm that the change in the extinction ratio was a result of the error-removal mechanism, a control experiment was performed by replacing the enzyme strand with an inactive mutant. The mutated enzyme differs by only one base from the native enzyme (the T base highlighted in blue in Figure 1c was mutated to a C base.[23]) No change in the extinction ratio was observed by error removal with the mutated enzyme (Figure 2d). This control experiment strongly suggests that the DNAzyme is the key element in the proofreading and error-removal process.

To further investigate the extent of error removal, fluorescein-labeled DNA was used to functionalize the B′ particles in addition to the original fluorescein-free DNA. After addition of Pb^{2+} ions, the samples were centrifuged at 2000 rpm for 2 min. At such a speed, the nanoparticle assemblies were forced to the bottom, while dispersed particles remained in the supernatant. The isolated precipitate was redispersed and recentrifuged twice to completely separate the assembled nanoparticles from the dispersed nanoparticles. The fluorescein-labeled DNA was then displaced into solution by adding a high concentration of β-mercaptopropionic acid.[24] The percentage of B′ particles released from the assembled nanoparticles was calculated by comparing the fluorescence intensity from the assembled nanoparticles to that of the supernatant. As shown in Figure 2e, the percentage of B′ particles removed increased with the B′ particle percentage present in the assembled nanoparticles, from ca. 40% removal at a low percentage of B′ particles to almost complete removal at the 100% level. The incomplete removal of B′ particles at a low percentage in the assemblies is attributable to the fact that B′ particles embedded inside the assembled nanoparticles may not be released, even if the DNA template is cleaved. To support this hypothesis, assemblies of A and B particles were first prepared as a core, and then B′ particles were added as a shell to ensure that they were exposed on the surface of the assembly. Indeed, at a similarly low percentage of B′ particles, the percentage removal increased from ca. 40 to 70% for the core–shell structures. In addition, nonspecific release of nanoparticles in the process may contribute to the calculated percentage of error removal. This possibility was investigated by using the inactive enzyme mutant where the T base highlighted in Figure 1b was mutated to a C base (Figure 2f). Less than 10% of the B′ nanoparticles were released in the process of washing and handling. Therefore, nonspecific dissociations cannot account for the observed error removal.

The specific error-removal process was also confirmed by transmission electron microscopy (TEM). Instead of using 13-nm particles in all cases, 5-nm particles were used as the B′ error particles to differentiate them from the 13-nm correct particles (A and B). Typical TEM images of nanoparticle assemblies before and after error removal are presented in Figures 3a and b, respectively. The images indicate clearly that the number of 5-nm error particles in Figure 3a decreased significantly after error removal.

In summary, we have designed an experimental system for studying proofreading and error removal in a nanomaterial assembly. We showed that error particles can be specifically removed from the system. In addition, the error-correction process is controlled by a chemical stimulus (in this, case Pb^{2+} ions). By replacing the lead-specific DNAzyme with DNAzymes sensitive to other analytes, chemically controlled error removal can also be realized.[20,22,25,26] Finally, the concept presented here can be extended to other biomolecules, for example, to protein enzymes or biomimetic compounds such as chemical nucleases, for controlling the assembly not only of

nanoparticles with defined size, shape, or composition, but also of other nanomaterials such as nanotubes or nanowires.

Experimental Section

Gold nanoparticles of 13- and 5-nm diameter were prepared by the citrate reduction[27] and $NaBH_4$ reduction[28] methods, respectively. Thiol-labeled DNA molecules were attached to gold nanoparticles by methods described in the literature.[27] The nanoparticles were purified twice by centrifugation, removal of the supernatant, and replacement with new buffer (100 mM NaCl, 25 mM Tris acetate, pH 8.2). To prepare fluorescein-labeled B′ particles, 5′-FAM-$(A)_{12}$-SH-3′ (20%) was also added in addition to the original DNA (80%).

Nanoparticles A, B, and/or B′ were mixed at designated ratios with a final extinction at 522 nm of ≈ 2. The system also contained substrate (100 nM), the enzyme strand (or the mutated enzyme, 200 nM), NaCl (300 mM), and Tris acetate buffer (25 mM, pH 8.2). The assembled nanoparticles were prepared by heating the sample at 65 °C for 1 min in a water bath (containing 60 mL water), and subsequently cooling to room temperature for 1 h. The sample was then centrifuged at 2000 rpm for 1 min. The supernatant was removed and the assembled nanoparticles were redispersed in NaCl (100 mM) and Tris acetate (25 mM, pH 8.2). To prepare samples for the TEM experiment, the 5-nm B′ particles were added later to form a core–shell (A/B–B′) structure, so that the B′ particles were mostly on the surface of the assembled nanoparticles, thus facilitating their release and observation.

Typically, two aliquots were taken from the prepared nanoparticle assemblies. Pb^{2+} ions (final concentration 20 μM) were added to one of the aliquots to initiate the error-correction process (reaction time 30 min), and the other aliquot was used for comparison.

Mesoscopic Metallosupramolecular Texturing by Hierarchic Assembly**

*Sylvain Clair, Stéphane Pons, Harald Brune, Klaus Kern, and Johannes V. Barth**

Currently, there is a strong interest in improving the fabrication and mesoscopic integration of functional nanosystems at surfaces. In particular, new pathways need to be developed to provide methodologies for the synthesis and embedding of nanostructures across multiple length scales.[1–4] Herein, we introduce the combination of nanopatterning and controlled metal–organic assembly to process prestructured metallic templates and generate arrangements at a higher hierarchical level. We present results of scanning tunneling microscopy (STM) on the metal-directed assembly and mesoscopic organization of supramolecular architectures by using a textured metal substrate, that is, an Au(111) surface decorated with Fe or Co nanodot arrays. By tuning the local reaction conditions with co-deposited dicarboxylate linker molecules, distinct low-dimensional metallosupramolecular systems have been synthesized, which include regularly spaced iron terephthalate ribbons that form a grating whose extension is only limited by the substrate terrace morphology. These findings indicate that hierarchic assembly protocols blending physical nanopatterning[5–9] and supramolecular engineering[10–13] on surfaces are generally useful for fabricating nanomaterials with control of features at the mesoscopic level.

Metal-directed self-assembly of functional molecules provides a versatile strategy towards highly organized supramolecular systems.[14–17] Recent findings reveal that similar processes can be conducted at surfaces, where notably a series of metal–carboxylate architectures were generated, including mononuclear arrays, ladder structures, and nanoporous 2D metal–organic coordination networks.[13,18–21] However, until now these systems have been constructed on homogeneous substrates on which typically organic layers were exposed to a flux of metal atoms. To control the spatial distribution of surface coordination architectures, it is promising to explore prestructured surfaces, which—due to their intrinsic anisotropy, local concentration of reactants and site reactivity—allow us to direct and confine the assembly. This control is not possible with homogeneous substrates. Herein we present a temperature-controlled STM investigation of the steering of metallosupramolecular reticulation by using nanopatterned templates. This approach is a model for a two-stage assembly that combines self-organized metal-on-metal growth followed by chemical processing. This methodology may allow the fabrication of low-dimensional functional nanosystems, steer the formation of (metallo-) supramolecular assemblies, enable the study and control of metal–molecule interfacing, or structure template layers in the 100 nm regime for handling nanoscale objects.

Specifically, we employed regular lattices of transition metal dots by depositing small amounts of cobalt or iron on Au(111) at room temperature. Due to preferred nucleation of metal islands at the elbow sites of a reconstructed surface,[22] Fe or Co nanoarrays are readily obtained.[23,24] Islands of monoatomic height evolve as a consequence of Fe deposition, whereas bilayer dots are encountered with Co deposition. In agreement with earlier findings, the STM data confirm that the Au(111) reconstruction is maintained as demonstrated in the exemplary results in Figure 1. The superstructure is equivalent for the two elements. The lattice unit cell is nearly rectangular and ca. 15 nm × 7 nm in size. However, on smaller terraces and in the vicinity of defects substantial variations can occur. Typically 0.1 ML of Co or Fe atoms produces islands of about 140 atoms (one ML of metal atoms refers to a hypothetical perfect commensurate monatomic layer on the gold surface). As we will show, these islands act as nanoreservoirs for the metal-directed assembly of co-deposited terephthalic acid molecules (TPA, 1,4-benzenedicarboxylic acid).

While the TPA molecules are entirely preserved on the bare Au(111) substrate, where they form hydrogen-bonded sheets,[25] they readily react with an available Co or Fe atom at room temperature or at slightly elevated temperatures to form metal–organic nanostructures. The respective complexation is a reaction between the carboxyl groups of the molecules and one or more transition metal adatoms (M), which eventually can be extracted from the islands. This implies deprotonation of the carboxyl group, that is, an M–carboxylate evolves and leads to the formation of reticulated planar metal–organic arrangements. The resulting hydrogen atoms are expected to recombine to form molecular hydrogen, which is known to thermally desorb from noble-metal substrates under the conditions employed.[26] The complexation reaction is therefore irreversible and can be represented formally by the following net equation [Eq.(1)]:

$$2\,\mathrm{RCOOH} + \mathrm{M} \rightarrow (\mathrm{RCOO})_2 \cdots \mathrm{M} + \mathrm{H_2}(\uparrow) \qquad (1)$$

Since the diffusivity of the complexes is limited and the metal–organic bond has appreciable strength, the connection between building blocks can be kept localized in the vicinity of the originally deposited metal dots. In contrast, the high

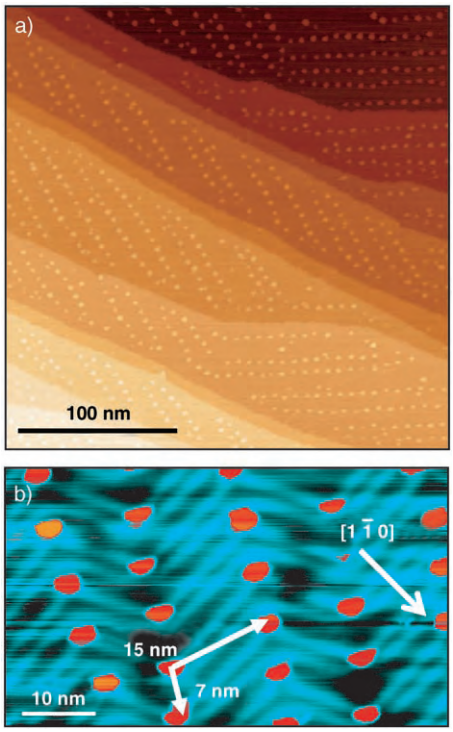

Figure 1. STM images of the Au(111) template with its chevron reconstruction dislocation pattern decorated with transition-metal arrays, which reflect preferential nucleation at elbow sites. a) Bilayer cobalt islands form regular lattices on several terraces (0.14 ML Co deposited at room temperature; image size 280×280 nm^2, $V=-25$ mV, $I=0.8$ nA, recorded at room temperature). b) Monolayer high Fe dots (red spots) on a single terrace with the characteristic double lines of the reconstruction simultaneously resolved. The unit cell of the regular lattice is ca. 15 nm×7 nm in size. (0.1 ML Fe deposited at room temperature; image size 60×35 nm^2, $V=20$ mV, $I=1$ nA, recorded at 5 K).

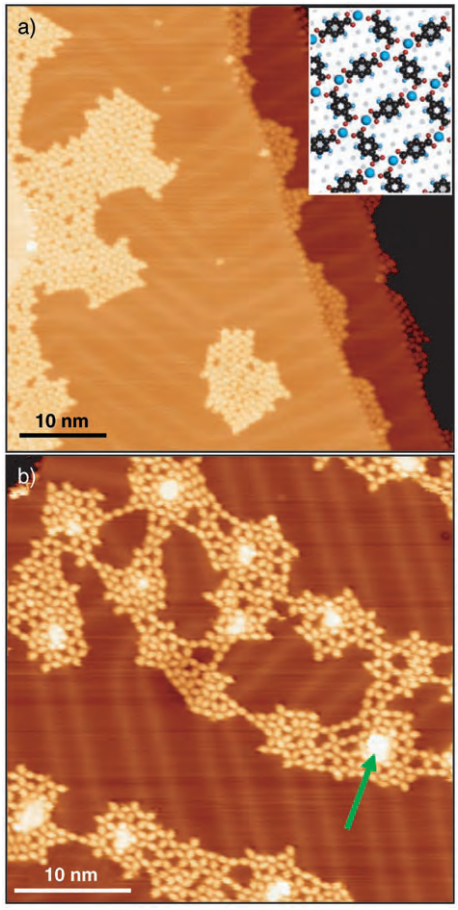

Figure 2. Controlling the Fe–TPA complexation reaction. a) Complete dissolution of Fe islands for a Fe–TPA stoichiometry of ca. 1:1 following deposition of TPA on the Fe nanoarrays at 355 K. Fe–carboxylate islands preferentially decorate step edges (image size 51×51 nm^2, $V=-2.5$ V, $I=0.5$ nA, recorded at 5 K). The inset shows a tentative model for an ideal Fe–TPA nanogrid where at each diiron center the endgroups of four molecular linkers come together. b) Localized reaction with TPA deposition at 325 K and 10 min post-deposition annealing at 330 K. The Fe islands are only partially consumed in the complexation reaction. The resulting nanogrid structure reflects selective growth of metal–organic islands at residual Fe dots (Fe island indicated by arrow; 0.1 ML Fe, 0.25 ML TPA; image size 38×38 nm^2, $V=1.5$ V, $I=0.2$ nA, recorded at 5 K).

mobility of TPA on bare Au(111) provides the necessary easy transport of the incoming molecule flux to the rims of the reactive metal islands.

Careful tuning of the conditions for molecular deposition has been used to steer the formation of various metal–carboxylate arrangements. In particular we have obtained architectures comprising regularly spaced nanoporous islands, extended metallosupramolecular ribbons, or one-dimensional systems. In general we observed that use of cobalt gives rise to better-ordered structures at the molecular scale than iron, while the latter allows easier steering at the mesoscopic level. The set of parameters that we optimized to obtain well-ordered architectures are the dosage (experiments were performed in the sub-monolayer range), the relative stoichiometry of M:TPA, the thermal energy of the adspecies tuned by the temperature of the substrate during deposition, and postdeposition annealing. With adequate temperature control, it is possible to obtain surface nanostructures comprising a) exclusively M–TPA compounds (M:TPA < 1) or b) coexisting residual metal nanodots and reticulated M–TPA compounds (M:TPA > 1).

Figure 2a shows an STM image of an Fe nanoarray on Au(111) after exposure to TPA with a stoichiometry of about one Fe atom per TPA molecule; the sample was maintained at $T=355$ K during the molecular deposition. This procedure resulted in the complete dissolution of the Fe dots and the formation of irregular islands that coexist with the unperturbed chevron pattern of the Au(111) substrate. While the presence of the latter clearly indicates that surface alloying between Fe and the substrate does not occur in the terraces, the irregular islands are clearly distinct from the extended close-packed quasi-hexagonal domains of hydrogen-bonded molecules that is characteristic of the adsorption of pure TPA.[25] The islands have open networks, which are reminiscent of the ordering found in nanoporous iron–carboxylate layers with TPA and related ditopic linear linkers on a square Cu(100) substrate.[13,18,28] Thus we conclude that these islands consist of iron–diterephthalate arrangements stabilized by metal–organic reticulation. The size of the characteristic open

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

nanogrids is about $1 \times 1.2\ nm^2$; their relation to the metal–organic networks on Cu(100) suggests that, similarly, the network nodes consist of diiron centers surrounded by four molecules.[13,18,28] This analogy is illustrated in the tentative model for an ideal Fe–TPA nanogrid with 1:1 stoichiometry depicted in the inset in Figure 2a. However, in contrast to the square Cu(100) substrate, the metal centers are not directly resolved by STM and the quasi-hexagonal lattice of Au(111) offers no match with an overlayer structure composed of rectangular motifs. As a consequence the Fe–TPA islands do not exceed 10 to 15 nm in size and present frequent distortions and misorientations. Indeed, we found that it is impossible to create extended regular nanogrid domains despite the smoothness of the substrate, which indicates that while the strength of the metal–ligand interactions is appreciable, it is not sufficient to dictate the entire overlayer structure. In contrast with Co/Au(111) nanotemplates, the Fe–TPA system is more sensitive to stoichiometry and temperature and is harder to control. While Co–TPA complexes organize in locally regular porous islands for the deposition parameters described above, Fe–TPA complex islands are rather disordered and give rise to a mixture of regular metal–organic grids and complicated irregular phases. Finally, the decoration of Au step edges is associated with local intermixing or coupling of Au and Fe, which is in agreement with findings for a pure Fe/Au(111) system,[29] and implies that Fe atoms can transport under these reaction conditions either directly by evaporation from the Fe dots or indirectly by release in the form of TPA–Fe complexes. In general, for Fe–TPA assemblies with 1:1 stoichiometry (see for example Figure 2a), step decoration occurs preferentially at the bottom edges.

By lowering the annealing or deposition temperature and reducing the TPA concentration, we succeeded in confining the complexation reaction. This confinement is demonstrated in the STM image of Figure 2b, which shows the result of a TPA dosage too small to form networks with all of the Fe atoms available on the surface. Consequently, there is merely a partial dissolution of Fe islands and the cores of the metal islands remain at the Au(111) elbow sites. These residual Fe dots act as anchoring sites for reticulated metal–organic assemblies. All Fe islands are decorated by nanoporous irregular islands and chainlike features where the endgroups of the rodlike molecules are connected. The formation of these open structures again is in direct contrast with the compact packing in hydrogen-bonded pure TPA layers.[25] Consequently these arrangements must be stabilized by the incorporation of metal centers and reflect the limited surface mass transport of the reactants under the conditions employed. Thus the Fe–TPA nanogrid structure is poorly developed but the metal–organic islands coalesce and local bridges have evolved between them.

The connection between the localized complex islands is favored along the symmetry axis of the chevron pattern along the elbows. Two aspects can explain this growth anisotropy. First, along this direction is the shortest distance between two metallic dots and, indeed, we observed that the closer two metal–organic islands are, the more likely they are to coalesce. Second, the substrate reconstruction pattern with its substantial lattice distortions at the elbows may induce directional molecular transport and orientations. By carefully controlling the molecular surface concentration, extended metallosupramolecular ribbons with regular residual Fe anchoring sites can be fabricated. This point is illustrated in the STM image of Figure 3, which shows the mesoscopic ordering of Fe–TPA ribbons induced by the chevron structure. The widths of the stripes in this architecture are usually around 5 to 10 nm, while their lengths can reach hundreds of nanometers, that is, they span entire terraces until they terminate at the Au step edges. Therefore, the aspect ratios of the ribbons frequently exceeds 40 and by using vicinal transition-metal decorated Au(111) substrates with parallel step edges,[7] macroscopically elongated metal–organic ribbons are expected to form.

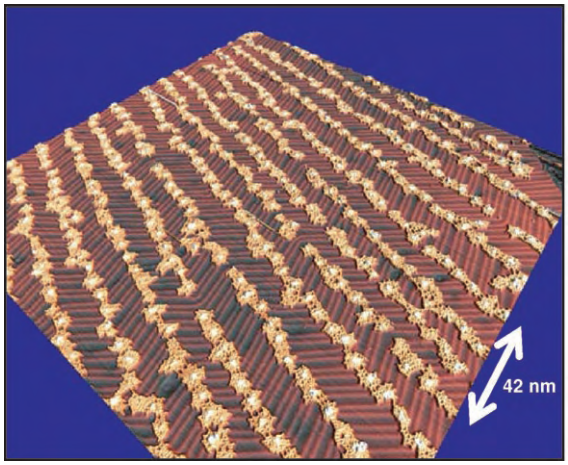

Figure 3. Mesoscopic ordering of metallosupramolecular ribbons. Fe–terephthalate linkages evolve between next-neighbor Fe islands following TPA exposure. The residual Fe dots at the elbow sites of the reconstruction anchor the pattern, that is, the spatial distribution of the Fe dots steers the organization. The length of the metal–organic ribbons is around several hundred nm, with typical widths of 5–10 nm. The respective aspect ratio of the stripes is commonly greater than 20 to 40 (image size $220 \times 220\ nm^2$, $V = -1.5$ V, $I = 0.8$ nA, recorded at 5 K; 0.1 ML Fe exposed to 0.25 ML TPA at 325 K, i.e., fourfold Fe excess with respect to ideal 1:1 nanogrid stoichiometry).

By further fine tuning the deposition parameters, we assembled monomolecular chains in the Co–TPA system on Au(111) as shown in Figure 4. Such metal–organic wires form at reduced molecular coverages but with limited success, and these 1D structures coexist with nanogrid patches (not shown). The wires establish a connection between two adjacent dots and therefore do not exceed 10 nm in length. The exact internal structure and stoichiometry of these chains composed of M–terephthalate segments could not be determined. However, the distance between the molecular building blocks in the chain increases by about 10% with respect to that in the hydrogen-bonded assemblies, which corroborates that it arises from a complexation of TPA and Co atoms, where distances of 0.2 nm between metal center and carboxylate oxygen atoms are expected. Moreover, the 1D Co–TPA chains anchored by the Co dots are stable at room temperature, which reflects the appreciable strength of metal–ligand

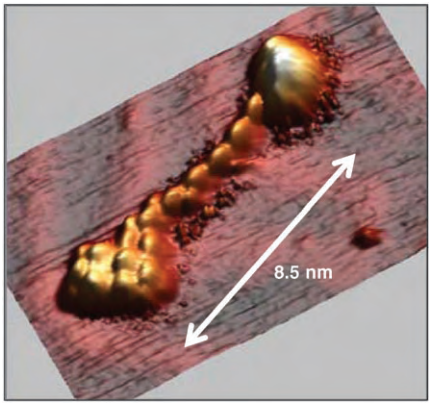

Figure 4. Monomolecular Co–TPA "wire" linking two cobalt nanodots. The rims of the Co islands are also decorated with molecules. This 1D structure coexists on the surface with regions covered by nanogrids (doses: 0.2 ML Co, 0.2 ML TPA; sample kept at 360 K during TPA deposition; image size 15×8 nm^2, $V=-700$ mV, $I=0.6$ nA, recorded at room temperature).

interactions that exceed hydrogen-bonding interactions of 1D TPA polymers. Accordingly, monomolecular hydrogen-bonded chains can neither be obtained by molecular self-assembly at room temperature[25] nor are they encountered under cryogenic conditions.

In conclusion we have demonstrated that substrates patterned with transition-metal nanoarrays can be processed by tuning and spatially confining their reaction with functional molecular species. Methodologies that use such hierarchic assembly protocols are conceivable for a great variety of systems and can be applied at substrates with different symmetries, physical, and chemical properties. Thus, they are a promising route for the metallo-supramolecular engineering of patterned templates by using linker molecules with specific functionalities. We expect that these findings will contribute to an improved control of matter at the nanoscale, the mesoscopic organization of template structures, and the design of supramolecular functional systems.

Experimental Section

Experiments were performed in a ultrahigh vacuum system (base pressure $<3\times10^{-10}$ mbar) comprising a home-built STM working at variable temperature (400–5 K) as previously described.[27] Data were recorded in constant-current mode; indicated voltages refer to the sample bias. The Au(111) substrate was prepared by repeated cycles of room-temperature Ar bombardment (≈5 μA cm^{-2} at 800 eV) then annealing at 900 K. Terraces larger than 100 nm were commonly observed. Iron and cobalt were evaporated at low deposition rates ($<{}^1/_3$ ML per minute). TPA molecules (FLUKA, purity $>99\,\%$) were evaporated with an organic molecular beam deposition (OMBD) source, by heating a crucible to 150 °C—the pertaining evaporation rate was ≈1 ML (i.e., a complete monomolecular layer) per minute.[27] A metal-to-TPA stoichiometry of 1:1 corresponds to a coverage ratio of ≈9:1.

A Thermal and Solvocontrollable Cylindrical Nanoshutter Based on a Single Screw-Sense Helical Polyguanidine**

Hong-Zhi Tang, Bruce M. Novak, Jiangtao He, and Prasad L. Polavarapu**

Controlling and switching the chiroptical properties, for example, electronic circular dichroism (ECD) and optical rotation, of helical polymers continues to attract great interest because of potential applications in sensor data storage, optical devices, and liquid crystalline displays.[1] Thermo-driven and/or solvent-driven switching helical polymers in particular have been studied extensively; examples include poly(L-aspartate β-esters),[2] polyisocyanates,[3] polysilanes,[1d,4] and polyacetylenes.[5] These helical polymers possess chiral moieties, which are introduced from chiral monomers, into the polymer backbones or side chains. These switching phenomena are generally interpreted to date as helical inversions that occur in the polymer backbones and which are driven by thermal or solvent-polarity changes.

We recently reported a novel thermal and solvocontrollable switching polyguanidine (poly-**1**, Figure 1), which was synthesized by helix-sense-selective polymerization of an achiral monomer.[6] Three possible mechanisms were proposed to explain this interesting switching phenomenon: helix inversions φ,[2–5] imine inversions ω,[7] and/or rotations around the N–$C_{anthracene}$ bonds θ[8] (Scheme 1). The switching phenomenon was further studied by using vibrational circular dichroism (VCD)[9] and computational modeling techniques to determine the specific mechanism. We herein report that the switching phenomenon arises from large-amplitude ordered synchronous wagging of the anthracene units without helical and imine inversions. This system is a new model for a nano molecular motor:[10] a cylindrical nanoshutter that transforms the low-input energy of thermal and/or solvent-polarity changes to mechanical output (work) through the synchronous wag of the aligned anthracene units. We also assigned the helicity of poly-**1** as *P* by means of density functional theory (DFT) calculations[11] and showed that it remains fixed during the reversible shuttering phenomenon.

Regioregular, stereoregular poly-**1** ($M_w = 16000$, $M_w/M_n = 2.7$) was obtained by helix-sense-selective polymerization of an achiral carbodiimide of **1** using chiral catalyst R–Ti.[6a] The chirality of this macromolecule is because of 1) its single-handed screw sense and 2) the stereoregular registry of both the anthracene units and the projection angle of the imine groups.

Full racemization requires transition through a symmetric intermediate which involves inversion of the helix sense φ and at least one or both of the molecular motions: free rotations around N–$C_{anthracene}$ θ and imine inversion ω. The complete racemization of poly-**1** in toluene requires high temperatures of nearly 80 °C for reaction times longer than 100 hours.

However, the ECD and UV/Vis spectra of poly-**1** are reversibly switched when a solution of poly-**1** in toluene is heated and cooled cyclically between 25 and 60 °C (Figure 2 A). Poly-**1** shows a positive Cotton effect of $\Delta\varepsilon = +2.0\,\text{M}^{-1}\,\text{cm}^{-1}$ at 382.0 nm and 25 °C, but a negative one of $\Delta\varepsilon = -2.6\,\text{M}^{-1}\,\text{cm}^{-1}$ at 382.0 nm and 60 °C. Poly-**1** shows an intense absorption of $\varepsilon = 5400\,\text{M}^{-1}\,\text{cm}^{-1}$ at $\lambda_{max} = 384.4$ nm and 25 °C, but a less intense absorption of $\varepsilon = 4700\,\text{M}^{-1}\,\text{cm}^{-1}$ at $\lambda_{max} = 382.4$ nm and 60 °C, thus corresponding to the ECD switching. It is of note that the wavelengths of the absorption maxima undergo a slight blue/red shift along with the heating–cooling cycles. Very large changes in the optical-rotation values are also observed between 31 and 40 °C (e.g., +297–−77°). The optical-rotation data indicate that the switching temperature is 38.5 °C. This switching phenomenon also can be observed when the polarity of the solvent is changed (Figure 2 B). For example, the ECD spectra of poly-**1** exhibit a negative Cotton effect in the polar solvents THF (dipole moment $\mu = 1.75$ D, dielectric constant $\varepsilon' = 7.5$) and $CHCl_3$ ($\mu = 1.15$ D, $\varepsilon' = 4.8$) at 25 °C, thus resembling that observed in toluene ($\mu = 0.31$ D, $\varepsilon' = 2.4$) at the higher temperature of 60 °C. The switching point occurs at 10 vol % of toluene in a mixed solvent system of THF/toluene.

Of the three possible mechanisms to explain this interesting switching phenomenon, that is, helix inversion, imine inversion, and/or rotation around the N–$C_{anthracene}$ bonds, partial rotation (reorientation) around the N–$C_{anthracene}$ bonds is the lowest-energy process. Notably, the free rotation around N–$C_{anthracene}$ is prohibited because the distance between two anthracene units is less than the length of one anthracene unit. Reversible switching occurs quickly (within seconds) in both the thermo-driven process at the lower temperature of 38.5 °C in toluene and in the solvent-driven process relative to the time-consuming (100 hours) and energy-demanding (80 °C) full-racemization process. This increase implies that the imine configuration inversion and the helix inversion in poly-**1** are not involved in the reversible switching process.

The barrier of imine inversion in small molecules is in the range 20–26 kcal mol^{-1} (coalescence temperatures are in the range 50–180 °C).[7] The required temperature is much higher than the switching temperature of 38.5 °C, which is hence further indication that the imine inversion is unlikely in the observed switching process.

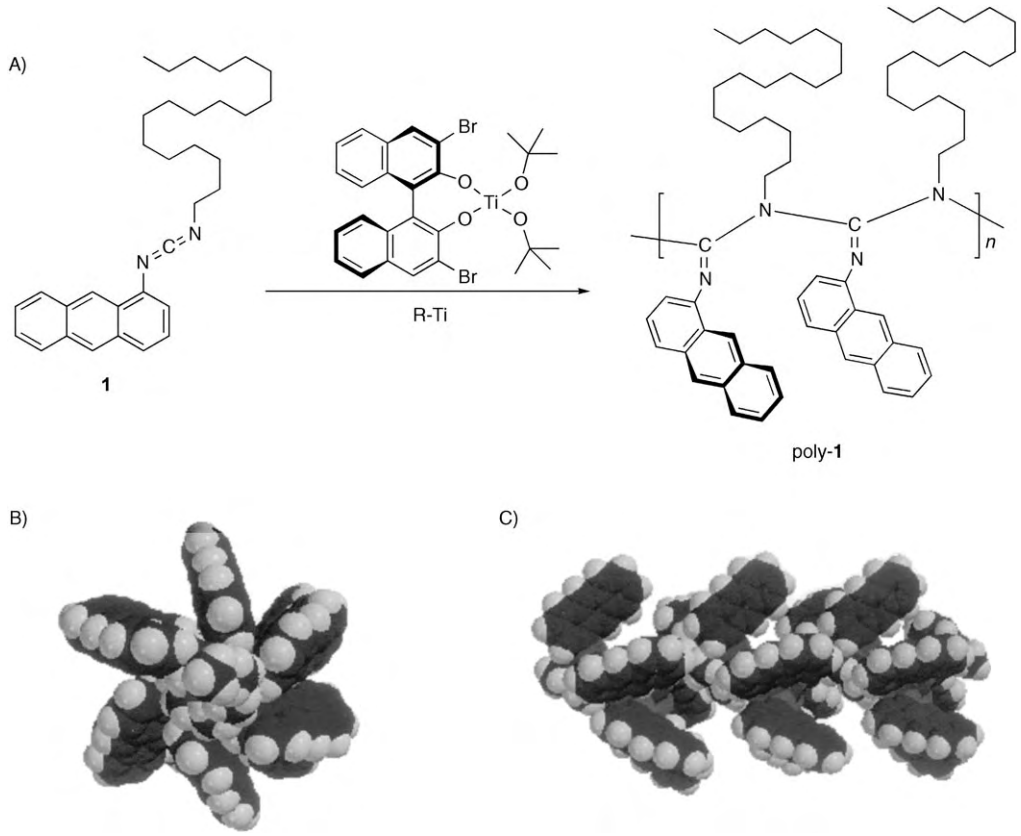

Figure 1. A) Synthesis of regioregular, stereoregular poly-**1**. B) Top view and C) side view of the 6_1-helical structure of poly-**1** (18-mer). Methyl groups replace *n*-octadecyl groups in poly-**1** to clarify the orientation of the anthracene units.

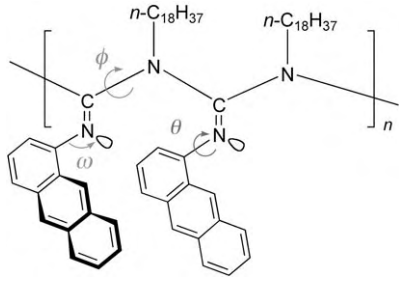

Scheme 1. Three possible molecular motions in the helical poly-**1**.

Standard variable-temperature (VT) ^{1}H and ^{13}C NMR spectroscopic experiments to elucidate the origin of the switching process were attempted (see the Supporting Information). However, these studies proved inconclusive because of signal broadening. VCD studies were then carried out in the polar solvent $CHCl_3$ and the less-polar solvent toluene at various temperatures to clarify the nature of the switching phenomenon in poly-**1** (as observed from the ECD and optical-rotation studies). To our surprise, the VCD spectra of poly-**1** remained unchanged except for a slight variation in intensity, unlike the ECD spectra. Typical VCD spectra of poly-**1** in $CHCl_3$ and toluene at 25 °C are shown in Figure 3 B, C in which a large bisignate couplet at 1641 cm^{-1} is exhibited that matches the vibrational absorbance of imine groups in the polyguanidine backbone (Figure 3 A). The concentrations used for the measurement of VCD are significantly greater than those for ECD. The ECD was measured at the concentrations used for the VCD studies to determine whether concentration may have had an influence. We found, however, that ECD spectra at higher concentrations have the similar ECD values as those at lower concentrations. These VCD data strongly support that the chirality of the helical polyguanidine backbone does not change during the reversible switching of the observed ECD and optical-rotation properties. The extremely slight change in the VCD intensity also implies that there is no change in the helical pitch during this switching process.

These two contradictory observations, namely, switching of the ECD and optical-rotation properties with temperature and solvent polarity and the lack of such switching of VCD, can only be reconciled if the anthracene units are considered to wag synchronously around the $N-C_{anthracene}$ bonds (thereby acting like a shutter). In that event, the orientation of the anthracene units relative to the position of the lone-pair electrons on the nitrogen atoms changes, which in turn changes the lone-pair/π-electron interactions, and hence the ECD and optical-rotation properties, but the chirality sensed by the vibrations of C=N bonds is not effected.

The blue/red shifts in the UV/Vis absorption and ECD bands above and below the switching temperature (Figure 2), also suggest that the orientation of the anthracene units cooperatively switch relative to the helix director (namely, wagging around $N-C_{anthracene}$ θ). Further computational mod-

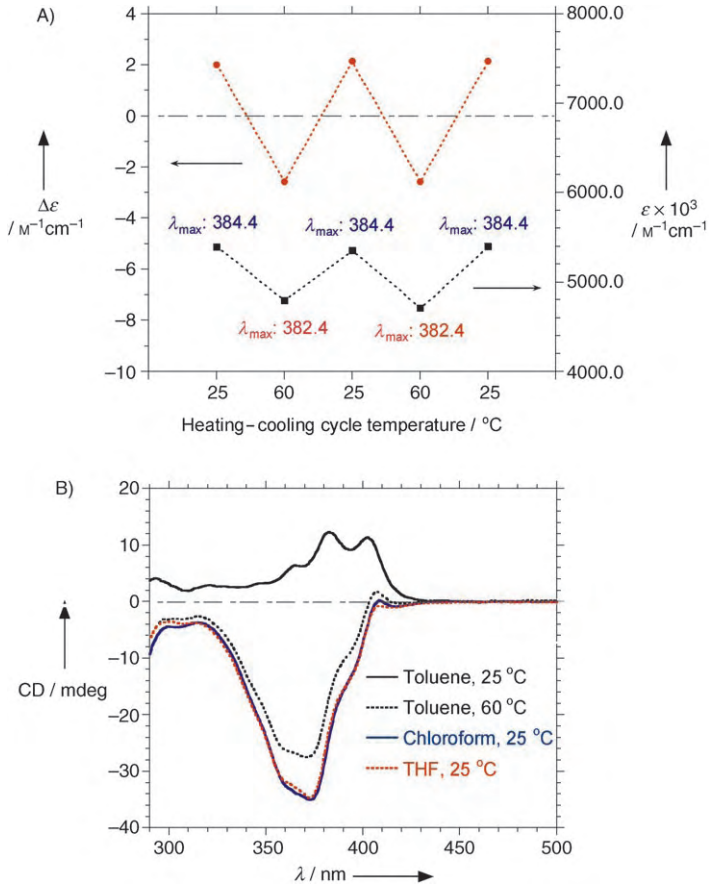

Figure 2. A) Heating–cooling thermal cycles of poly-**1** in toluene ($c = 2.1 \times 10^{-4}$ M, path length = 10 mm); wavelength for $\Delta\varepsilon$ is 382.0 nm. B) ECD spectra of poly-**1** in toluene at 25 and 60 °C, in $CHCl_3$ at 25 °C, and in THF at 25 °C; the intensities of the corresponding UV/Vis absorption maxima are normalized to 1.0. Very slight changes were observed in the ECD spectra of poly-**1** in THF and $CHCl_3$ when the solutions were heated to 50 °C. The ECD spectra of poly-**1** are independent of concentration in the range 2.1×10^{-4}–5.3×10^{-2} M. Dihedral angles [°] of **2**: C1-N2-C3-N4 −150, C1′-N2′-C3′-N4′ −153, N2-C3-N4-C5 −166, N2′-C3′-N4′-C5′ −168, C3-N4-C5-C6 63, C3′-N4′-C5′-C6′ 66, N2-C3-N2′-C3′ −103.

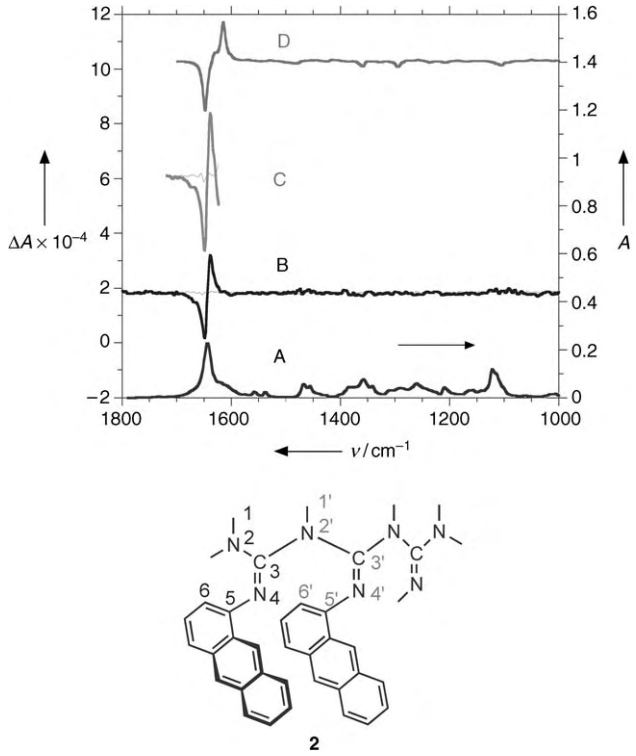

Figure 3. A) The experimental vibrational absorbance and B) VCD spectra of poly-**1** in $CDCl_3$ at 25 °C ($c = 10.0$ mg mL^{-1}, path length = 300 μm). c) VCD spectrum of poly-**1** in toluene at 25 °C ($c = 20.1$ mg mL^{-1}, path length = 200 μm) is also shown. The solvent absorption and VCD values were subtracted from the corresponding experimental spectra. The flat thin lines represent the noise level in the VCD spectra. D) The optimized *P* model **2** and its VCD spectrum calculated by density functional theory using B3LYP functional and 6-31G(d) basis sets. The calculated frequencies were scaled with 0.9613.

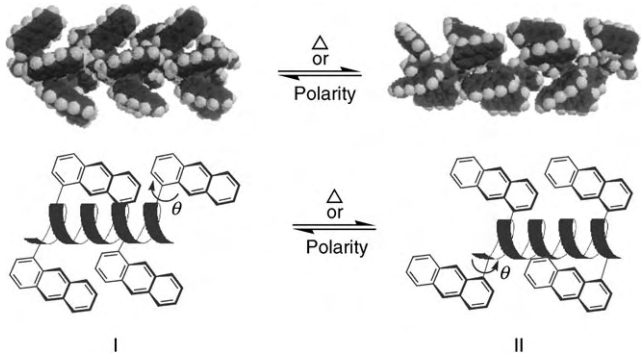

Figure 4. Theoretical models of the two states which result from the shutter-like motions of the anthracene unit. The geometries of these two states were determined by optimization of the repeat unit at the semiempirical level (AM1)[12] and then optimization of the 18-mer at the molecular-mechanics level (MMFF94).[13]

eling on this system was carried out to confirm these suggestions. Our working model (Figure 4) consists of a lower-energy state (**I**, $\mu_I = 6.9$ D), which has the dipole moments of the flipping ends of the anthracene aligned opposing the helix director, and a higher-energy state (**II**, $\mu_{II} = 7.7$ D), which has the dipole moments of the anthracenes aligned with the helix director; the polar solvents stabilize the more polar second state. In this reversible cooperative switching process, the chirality, the imine configuration, and the helical pitches remain unchanged.

It is a challenge to assign the chirality of poly-**1**. We built and initially optimized model compound **2** (Figure 3) with molecular mechanics MMFF94,[13] and optimized its *P* structure by DFT at the B3LYP/6-31G(d) level[14] with the Gaussian98 program. The VCD spectrum, calculated at this optimized geometry, is in excellent agreement with the experimentally observed VCD spectra of poly-**1** (Figure 3D), thus indicating that poly-**1** is a *P* structure.

We have clarified the mechanism of the unusually large reversible thermo- and solvent-driven shuttering phenomenon of poly-**1**. We have also successfully assigned the helicity of poly-**1** as *P* and showed that it remains fixed during the reversible shuttering phenomenon. This anthracene-containing polyguanidine nanoshutter underwent large-amplitude

Helical Folding in a Helical Channel: Chiroptical Transcription of Helical Information through Chiral Wrapping**

Takanobu Sanji, Nobu Kato, Masako Kato, and Masato Tanaka**

The helical structure is one of the most significant motifs in macromolecules. In nature, helical structures are often found in biomacromolecules and appear to play a critical role in biological phenomena such as molecular recognition and information storage. This is exemplified by the double helix of DNA and the α helix of proteins,[1] and some synthetic polymers also adopt a helical conformation.[2] Recently, the design and synthesis of macromolecules with a helical structure has attracted a great deal of interest as a result of their relationship to life sciences as well as their potential applications in materials science.[3] Herein, we show that linear oligosilanes acting as axle guest molecules within the internal helical channel of a polymer can be induced to form a preferential helical conformation. The helical sense of the guest molecules is then controlled by wrapping with either the left-handed or the right-handed helical conformation of the host polymer. The system presented herein offers a new approach in the field of helical expression in molecular and macromolecular systems.[4]

To explore the possibility of "helix-in-helix" supramolecular architecture, we have chosen host–guest combinations of linear polysaccharides and oligosilanes (Figure 1). One of the polysaccharides used is amylose, which is composed of α-1,4-linkages between D-glucopyranose residues. Amylose adopts a left-handed helical conformation and forms inclusion complexes as a result of hydrophobic interactions with guest molecules confined within the helical cavity.[5] The helical dimensions of amylose can be adjusted according to the size of the guest. The other polysaccharide examined was schizophyllan (SPG), which is composed of β-1,3-linkages between glucose units (β-1,3-glucan) and adopts a right-

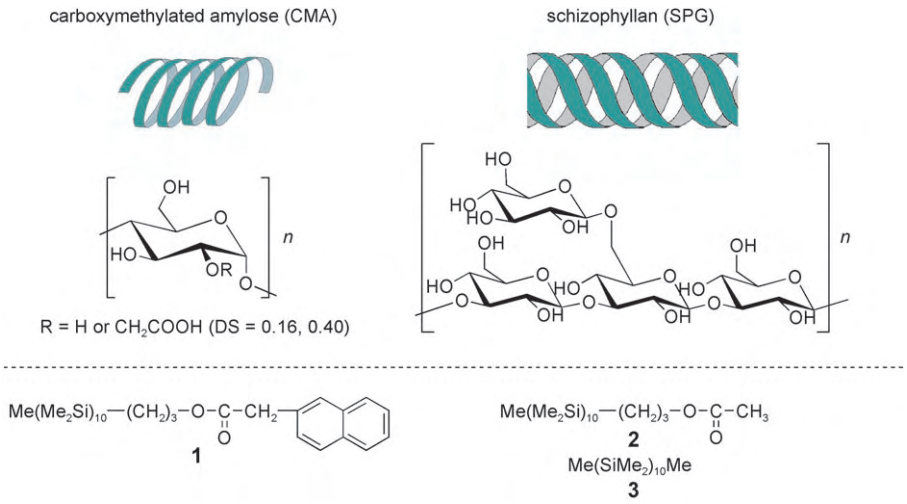

Figure 1. Combinations of host–guest complexation for linear polysaccharides and oligosilanes.

handed triple helix in nature.[6] On the other hand, oligosilanes **1**–**3**, used as the axle guests, are unique molecules that exhibit absorption in the UV region as a result of σ conjugation along the main chain. The absorption behavior of σ-conjugated systems is extremely sensitive to the conformation.[7] This sensitivity is exemplified by the behavior of helical poly- or oligosilanes in response to the chiral stimulus of their optically active substituents.[8] This allowed us to study photophysical properties that are dependent on the conformation of the main chain. Several reports have addressed control of the conformation of oligosilanes,[9] for example, by inclusion of a macrocyclic molecule (with α-1,4-glucopyranose units) into cyclodextrins.[10] Recently, we found the induction of a preferential helical-sense conformation in oligosilanes that are located within the internal cavity of cyclodextrins.[11]

Molecular mechanics was used to study models of the complexes at hand.[12] The minimum-energy structure of the simple model complex formed by the interaction between permethyldodecasilane and an amylose fragment that contains 16 repeating α-1,4-D-glucopyranose units is illustrated in Figure 2. The amylose fragment is shown to adopt a left-handed helical conformation by wrapping around the oligosilane axle. In the helical cavity created by the amylose wrapping, the oligosilane main chain assumes a helical conformation with a Si–Si torsion angle of about 165°.

In our experiments, we used partially carboxymethylated amylose (CMA), with DS = 0.16 or 0.40 (DS = the degree of carboxymethyl substitution) to increase the solubility of the resulting inclusion complex in water. In a typical preparation of the inclusion complex, a mixture of decasilane **1** (30 mg, 3.7×10^{-2} mmol) and CMA (DS = 0.16, 150 mg, 8.5×10^{-1} mmol glucose unit) in water (20 mL) was dispersed ultrasonically for 5 min and then stirred at room temperature for 8 days. The precipitate was collected by centrifugation and dried under vacuum to give the **1**–CMA complex (32 mg, 18%), which was slightly soluble in water (up to concentrations of $\approx 10^{-4}$ M).[13] In agreement with the model structure, the **1**–CMA inclusion complex exhibited CP MAS (cross-polarization magic-angle spinning) ^{13}C NMR and the MASGHD (magic-angle spinning gate ^{1}H decoupled) ^{29}Si NMR signals that arose from CMA and the incorporated oligosilane chain.[14] A powder X-ray diffraction study demonstrated that the reflection pattern was very similar to that reported for a complex of γ-cyclodextrin (a macrocyclic molecule consisting of eight α-1,4-glucopyranose units), which exhibits a channel-type structure.[11,15] These studies suggest that the amylose is probably adopts a 8_1-helical structure (eight α-D-glucopyranose resides per turn) with a cross-section diameter of 8.5–9 Å to fit to the sequential size of the dimethylsilylene units of **1** (≈6 Å).

As was envisioned, and reinforced by the molecular mechanics calculations, decasilane **1** is indeed located in a helical channel and confined by CMA wrapping. The absorption and CD spectra provided information on the conformation of the oligosilane main chain within the channel (Figure 3). Thus, the absorption spectrum of a **1**–CMA complex (DS = 0.40) in water, at room temperature, exhibits an absorption maximum at 280 nm owing to the conjugated Si backbone σ–σ* transition ($\varepsilon = 1.1\times10^{4}\,\text{M}^{-1}\,\text{cm}^{-1}$).[16,17] In the CD spectrum, the complex displays an intense positive CD signal in the absorption region of the oligosilane ($\Delta\varepsilon = 2.56\ \text{mol}^{-1}\,\text{dm}^{3}\,\text{cm}^{-1}$ at 275 nm). Decasilane **1** does not give rise to any CD signals because of an equal mixture of enantiomeric twisted or helical conformers. However, in the helical channel of CMA, the decasilane **1** is induced to adopt a preferential helical conformation as a result of diastereoselective complexation with the chiral host. In this case, the main chain assumes a predominantly transoid conformation with a Si–Si torsion angle of 160–175° (15/7 helix).[18,19] The dissymmetry ratio, g_{abs} ($=\Delta\varepsilon/\varepsilon$), is usually used to characterize helical structures, such as right- and left-handed helix populations. The dissymmetry ratio for the **1**–CMA complex, $g_{abs} = 2.3\times10^{-4}$, is of the same order of magnitude ($1\text{–}2\times10^{-4}$) as that observed for a range of polysilanes with optically pure substituents that adopt a preferential screw sense.[20]

SPG also acts as a helical host polymer.[21] Decasilane **1**, in the presence of SPG, exhibits an absorption maximum at 284 nm ($\varepsilon = 1.1\times10^{4}\,\text{M}^{-1}\,\text{cm}^{-1}$) that is attributable to the σ–σ* transitions of the oligosilane main chain (Figure 3). In the CD spectrum, an induced CD signal is observed in the same region ($\Delta\varepsilon = -2.88\ \text{mol}^{-1}\,\text{dm}^{3}\,\text{cm}^{-1}$ at 282 nm). This signal is indicative of **1** being induced to assume a preferential helical conformation by complexation with SPG. The CD signal of the **1**–SPG complex is slightly red shifted relative to that of the **1**–CMA (DS = 0.40) complex. This shift is presumably associated with the pitch of the helical conformation of **1**. Such a pitch is induced when **1** is confined by the helices of the polysaccharide host molecules, as the pitch and the diameter of the host helices are different.[22,23] Interestingly, complexation of **1** with SPG, which conforms to a right-handed helix in water, induces a negative CD signal, whereas complexation

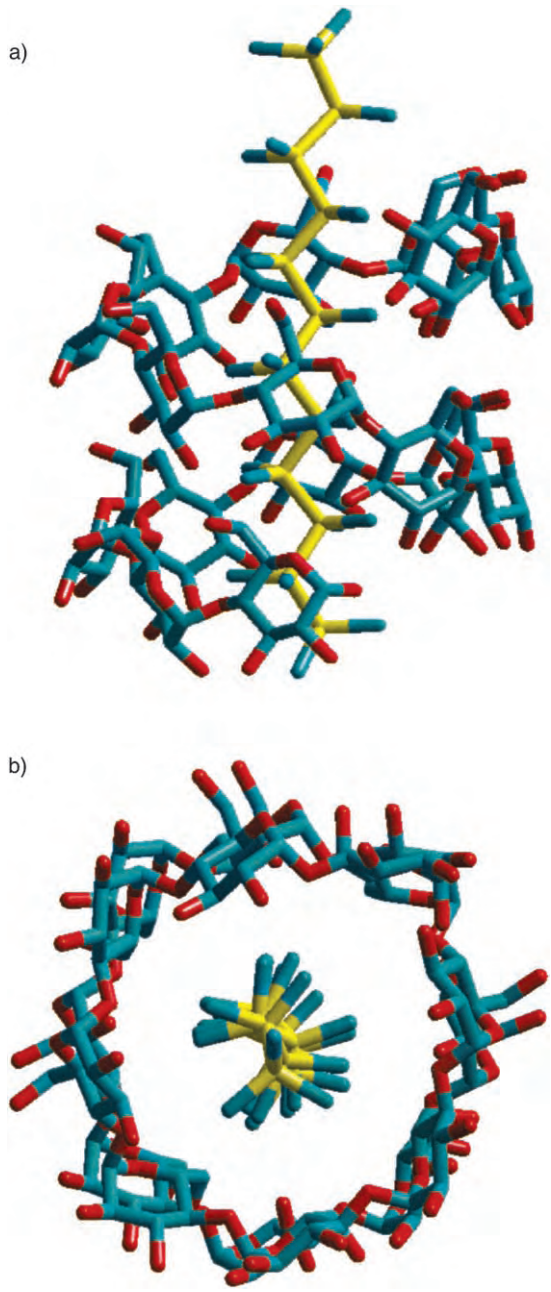

Figure 2. Energy-minimized models based on the AMBER force field for an inclusion complex of $Me(SiMe_2)_{12}Me$ with an amylose fragment containing 16 repeating α-1,4-D-glucopyranose residues: a) side view and b) top view. Carbon, oxygen, and silicon atoms are shown in blue, red, and yellow, respectively. The hydrogen atoms have been omitted for clarity.

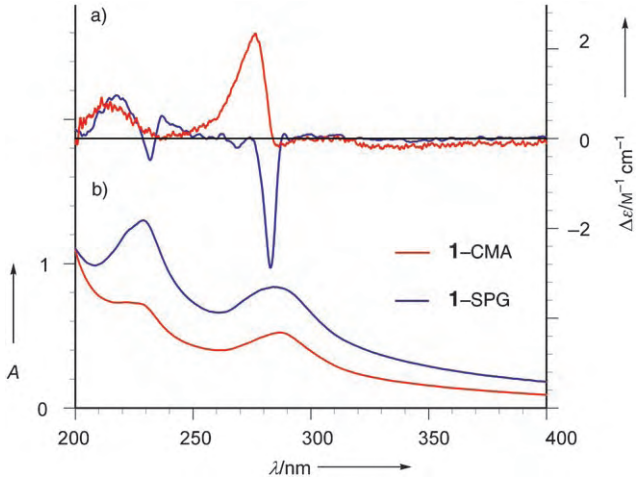

Figure 3. a) CD and b) absorption spectra of **1**–CMA (red line) and **1**–SPG (blue line) in water.

with CMA adopts a left-handed helical conformation in water and induces a positive CD signal (see above). Thus, the helical sense of the guest molecule is dependent on, and can be controlled by, the helical sense of the host polymer.

The time course of the absorption and CD spectra of a mixture of **1** and CMA revealed the progress of the folding process. The inclusion complex, generated in situ by mixing **1** and CMA in water for 40 h, showed an absorption maximum at 279 nm and a positive Cotton effect. However, the absorption undergoes a bathochromic shift to 293 nm over a period of a month without a change in the sign of the Cotton effect.[24,25] This can be attributed to changes in the helical pitch of the oligosilane to accommodate the dimensions of the helical channel. However, as **1** is confined by amylose wrapping, progress is slow as a result of the steric constraint. The fluorescence spectrum of the **1**–CMA complex discloses the more detailed structure of **1** in the channel. Thus, the **1**–CMA (DS = 0.40) complex, when excited at 298 nm, exhibits a local emission at 330 nm from both the naphthyl group and the oligosilane chain and an emission for the dimer at 400 nm from the naphthyl groups.[26] Accordingly, oligosilane **1**, within the complex, is envisioned to have aligned in a head-to-head fashion with the stacking of the naphthyl groups within the helical amylose.

Finally, a similar wrapping with CMA (DS = 0.16) has also been found to proceed with **2** and **3** as the guest molecules (Figure 1). The resultant complexes exhibit a positive Cotton effect; however, the intensities of the signals are weak. We presume that further to the hydrophobic interactions between the guest molecules and the helical cavity as the major driving force for complex formation, hydrogen bonding and/or π–π interactions within the channel also play an important role in the formation or stabilization of the complex.

In summary, we have demonstrated helical induction of oligosilane by using peripheral wrapping with amylose and schizophyllan. This system is the basis for a new and simple concept of helical expression in molecular and macromolecular systems.

[17] Although the absorption overlapped with that of the naphthyl group chromophore, the molar extinction coefficient of the permethyldecasilane was much higher than that of naphthylacetic acid ($\varepsilon = 500\,\text{M}^{-1}\,\text{cm}^{-1}$ at 273 nm). The absorption of **1**, which occurs at around 290 nm, was ascribed to the oligosilane.

[18] J. Michl, R. West, *Acc. Chem. Res.* **2000**, *33*, 821 – 823.

[19] The band widths of the absorption and the CD at 280 nm look somewhat different, probably due to incomplete inclusion of the oligosilane into the cavity or incomplete induction of the helical sense in the cavity. The other conformation of the oligosilane in the complex may also induce a Cotton signal.

[20] M. Fujiki, *Macromol. Rapid Commun.* **2001**, *22*, 539 – 563; S. Toyoda, M. Fujiki, *Macromolecules* **2001**, *34*, 640 – 644.

[21] Very recently, Shinkai and co-workers reported on a supramolecular chiral complex with SPG and polythiophene, see; C. Li, M. Numata, A.-H. Bae, K. Sakurai, S. Shinkai, *J. Am. Chem. Soc.* **2005**, *127*, 4548 – 4549.

[22] The helical CMA composed of α-1,4-D-glucopyranose residues assumes a 6/1–8/1 helical pitch (0.8 nm) with a 0.5–0.8 nm inner diameter, whereas the helical SPG composed of β-1,3-glucose residues assumes a 6/1 helical pitch (1.8 nm) with 1.75 nm inner diameter.

[23] Very recently, we found the supramolecular complex forms between a triple helix of SPG and two molecules of oligosilane **1**; for the detailed structure of the **1**–SPG complex, see: T. Sanji, N. Kato, M. Tanaka, *Chem. Lett.* **2005**, *34*, 1144 – 1145.

[24] The degree of carboxymethyl substitution on the amylose (DS) affects the helix formation of the amylose, the complexation ability between guest molecules and amylose, as well as the solubility in water. We found that complex formation between CMA and the oligosilanes depends on the DS. In the case of CMA (DS = 0.16), the complex, which was monitored with UV and CD measurements, was formed in a few hours after ultrasonic dispersion. In the case of CMA (DS = 0.40), complex formation was quite slow. Once the complex was formed, however, it was stable for more than a few months without alteration in the UV absorption intensity or the sign of the CD signal. We also examined the pH dependence of the complex formation under buffered conditions. In the neutral (pH 7.0) and the basic (pH 9.2) buffer solution, the situation of complex formation was almost the same. In the acid buffer solution (pH 5.0), however, complex formation was hardly observed. Furthermore, the thermostability of the complex was examined. At 80 °C no Cotton effect was observed, thus indicating that the complex was not stable at high temperature. We thank a referee for valuable suggestions.

[25] The material partially precipitates during complexation.

RNA Folding

DOI: 10.1002/anie.200502928

Modulation of RNA Tertiary Folding by Incorporation of Caged Nucleotides**

*Claudia Höbartner and Scott K. Silverman**

Photochemical caging groups[1] are often used to study biomolecular interactions, such as those between cofactors and enzymes or between neurotransmitters and their receptors.[2] In a caging experiment, a functionally important part of a molecule is modified by the strategic introduction of a non-natural moiety that disrupts key contacts or interferes with a critical reaction step. When the non-natural moiety is removed by photolysis, the native biomolecular interactions are restored. Photochemical caging has been used to study protein folding,[3] RNA catalysis,[4] secondary structure changes in RNA,[5] and other RNA-related phenomena,[6] but not higher-order tertiary folding of RNA.[7] When a caging group is appended at any specific nucleotide position, the effect on RNA tertiary folding is difficult to predict. This is unlike the situation of RNA catalysis (for which caging of an active-site hydroxy-group nucleophile is certain to disrupt reactivity) or of RNA secondary structure changes (for which reliable Watson–Crick interactions provide a strong predictive tool). Herein we report how an RNA molecule with a well-defined tertiary structure responds to the introduction of individual caging groups. Our results, which demonstrate varying local and global structural effects, have several implications for ongoing efforts to understand RNA folding.

We appended the photochemically removable (*S*)-1-(2-nitrophenyl)ethyl (NPE) group onto the nucleobase of each of the four standard RNA nucleotides (Figure 1).[8] The four corresponding phosphoramidites (NPE-U, NPE-C, NPE-A, and NPE-G) were prepared for conventional solid-phase RNA synthesis by using the 2′-*O*-triisopropylsilyloxymethyl (TOM) methodology.[9] The preparative route for the caged guanosine phosphoramidite was based on a recent report,[5] and the routes for the other three phosphoramidites are detailed in the Supporting Information. For each of the four phosphoramidites, solid-phase synthesis was used to prepare

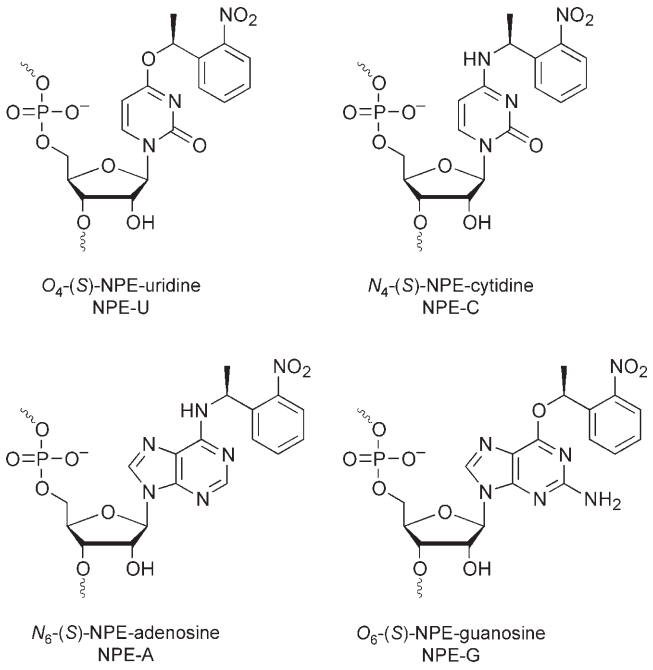

Figure 1. Structures of the (*S*)-NPE-caged RNA nucleotides.

15-mer and 24-mer RNA oligonucleotides, each of which incorporate a single caged RNA nucleotide at a specific internal position. In all cases, denaturing polyacrylamide gel electrophoresis (PAGE), anion-exchange HPLC analysis, and ESI mass spectrometry revealed that decaging proceeds to completion in less than 10 min by using a 300-W Xe-arc-lamp source (300–400 nm; Figure 2) or in approximately 30–60 min by using a handheld UV illuminator (365 nm; data not shown).[10]

We then placed individual caged nucleotides within a large RNA molecule, P4–P6. The 160-nucleotide P4–P6 domain of the *Tetrahymena* group I intron RNA adopts a characteristic tertiary structure in the presence of millimolar concentrations of Mg^{2+}.[11,12] As revealed by X-ray crystallography, the folded domain adopts a three-dimensional structure that resembles a candy cane (Figure 3).[13,14] The two largely helical domains of the RNA are held together, in part, by a key tertiary interaction between the GAAA tetraloop and its 11-nucleotide receptor.[15] Nucleotide and functional-group alterations within this tetraloop–receptor interaction have deleterious effects on the P4–P6 thermodynamic stability.[11,12,15–17]

We sought to probe the effects on P4-P6 folding of caging specific nucleotides with the NPE group. For this purpose, we synthesized modified P4–P6 variants by using a ligation strategy that joins a caged 15-mer or 24-mer oligonucleotide with an unmodified 145-mer or 136-mer T7 RNA polymerase transcript (see Supporting Information). We prepared 14 caged P4–P6 derivatives in this fashion. The caging sites were distributed throughout the RNA and were chosen on the basis of the X-ray crystal structure (Figure 3a). Caging sites were placed in positions where the NPE group was anticipated to have a combination of three effects: 1) alteration of the hydrogen-bonding interactions within either secondary- or

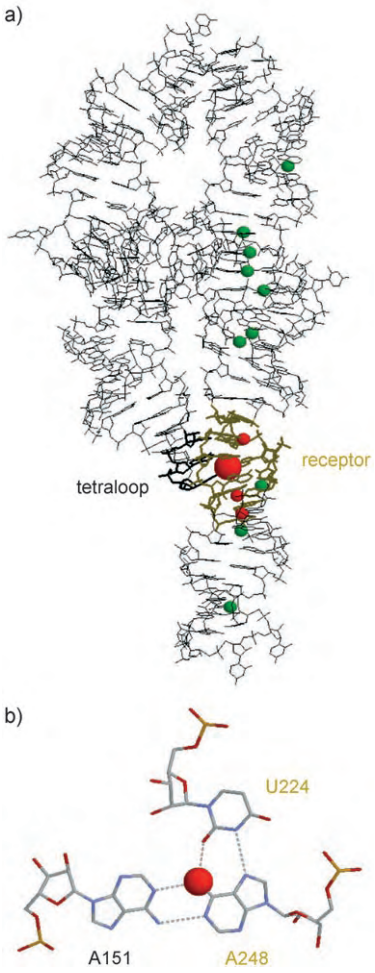

Figure 3. The 160-nucleotide P4–P6 RNA and sites of caging. a) X-ray crystal structure[13] with caging sites marked. Spheres are centered on the nucleobase atoms that bear the NPE caging groups and are colored red or green as in the data plots. The sphere marking the N6 atom of A248 is larger than the other spheres. Adenosine nucleotides A151, A152, and A153 of the GAAA tetraloop are thickened for emphasis. See Supporting Information for a picture of secondary structure. b) The base triple involving A248.

tertiary-structure elements; 2) disruption of base-stacking interactions; and 3) introduction of steric clashes (see Supporting Information for detailed images). In the NPE-A248 P4–P6 derivative, for example, the NPE caging group is placed on an adenine N6 group that is located in a densely packed region of RNA structure and at the interface between the GAAA tetraloop and the tetraloop receptor (Figure 3a). Because A248 is the central nucleotide of a base triple (Figure 3b) and because there appears to be no room to accommodate the bulky NPE group, NPE caging of A248 is expected to disrupt several hydrogen bonds and introduce a steric clash directly within the key tetraloop–receptor tertiary interaction. The determination of the consequences of such disruptions on RNA tertiary folding was a main experimental goal of this study.

The effects of individual caged nucleotides on P4–P6 folding were analyzed by nondenaturing (native) PAGE, which reports on global folding (Figure 4a).[17] The P4–P6 domain has a Mg^{2+}-dependent mobility on native PAGE; that is, when the RNA folds at higher Mg^{2+} concentrations, it adopts a more compact structure and thus migrates faster through the gel. Thermodynamic disruptions to the P4–P6 structure result in an increased Mg^{2+} requirement for folding, as quantified by the Mg^{2+} midpoint ($[Mg^{2+}]_{1/2}$ value) of a mobility versus $[Mg^{2+}]$ titration curve.[15,17,18] Our data allowed all 14 of the caged P4–P6 derivatives to be classified readily into just two types (Figure 4b): 1) those in which the caging group has a substantially destabilizing thermodynamic impact on tertiary folding (red), and 2) those in which the thermodynamic impact is small (green). Regardless of the effect of the caging group, its photolytic removal before analysis by native PAGE restored the RNA folding to that of the unmodified wild-type P4–P6 (Figure 4).

When the differential effects of caging the various nucleotides are considered in the context of their locations

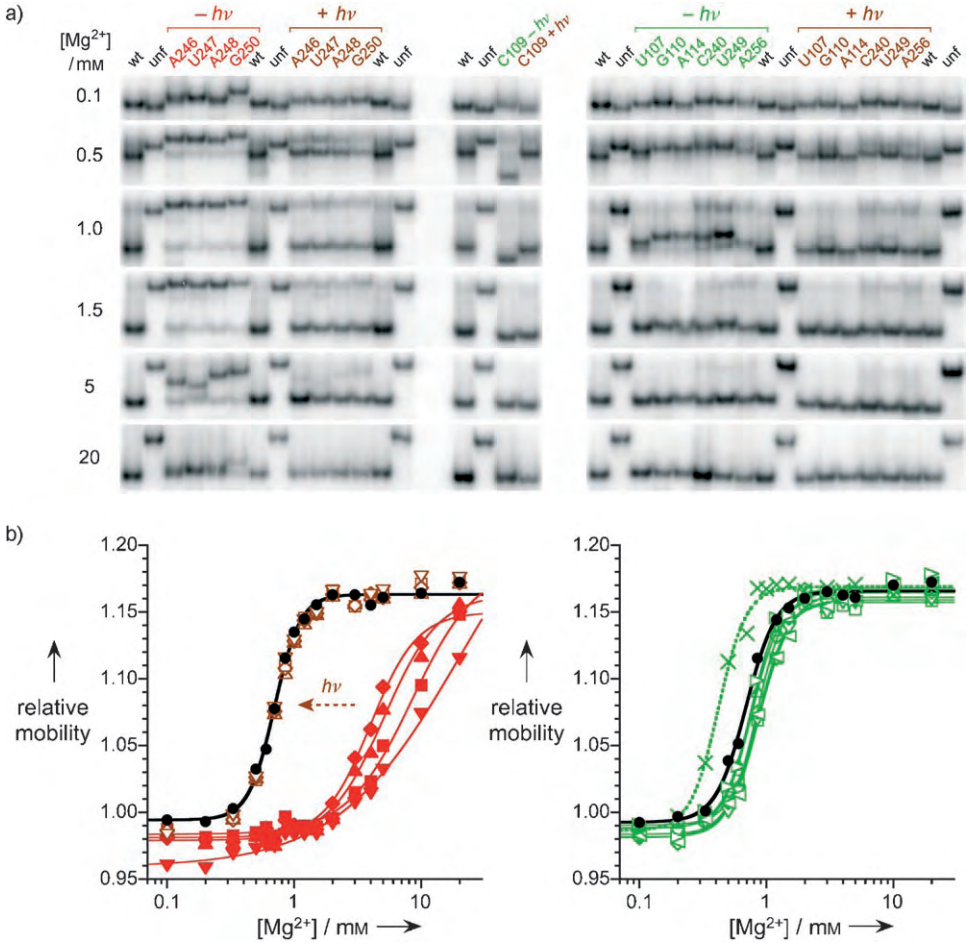

Figure 4. Native PAGE analysis of caged P4–P6 RNAs. a) Representative gel images. wt = unmodified wild-type P4–P6; unf = unfolded control that cannot fold even at high $[Mg^{2+}]$.[11,17,23] b) Mg^{2+} dependence of native gel mobility, computed for each caged derivative relative to the unfolded control. The wild-type P4–P6 is in black (●). Data in red represent positions where an unambiguous thermodynamic disruption is observed (▲ A246; ◆ U247; ■ A248; ▼ G250). Data in green represent positions where little effect is observed (× C109; the remaining symbols represent other positions from panel (a)). Photolysis of samples before native PAGE restored folding to that equivalent to the wild-type P4–P6 (brown). See the Supporting Information for experimental details.

within P4–P6, a clear pattern emerges. Caging of a nucleotide far from the tetraloop–receptor interaction has little effect on global folding. In sharp contrast, caging of a nucleotide that is located within (or very close to) the tetraloop–receptor interaction, such as A248, introduces a distinct thermodynamic destabilization. Nevertheless, native PAGE indicates that each of the latter derivatives eventually adopts the native global tertiary structure when the Mg^{2+} concentration is increased sufficiently (≥ 20 mM). For the NPE-caged A248 derivative, this finding is surprising because the tetraloop–receptor interaction must distort considerably to accommodate the NPE group, although the precise nature of the distortion cannot be discerned from these data. The only exception to the clear pattern is that the NPE-caged U249 derivative is not destabilized even though it is located within the receptor. Significantly, U249 is a bulged nucleotide in which the nucleobase does not form any tertiary hydrogen bonds, and inspection of the X-ray crystal structure suggests that the NPE caging group should be accommodated without causing a steric clash.

To provide an assessment of RNA folding that is independent of the native gel experiments, chemical probing with dimethyl sulfate was also performed. This reagent methylates either N1 of adenine or N3 of cytosine but only if the nucleobase is locally accessible to the reagent.[11,12,19] Tertiary folding of the RNA molecule buries some of the nucleobase functional groups within its interior;[20] this renders these functional groups inaccessible to dimethyl sulfate and thus protects them from methylation. Because the functional groups methylated by dimethyl sulfate are located on the Watson–Crick faces of the nucleobases, methylation inhibits primer extension by reverse transcriptase and leads to an abort band when the RTase reaction assay is examined by denaturing PAGE. The adenosine nucleotides of the GAAA tetraloop in unfolded P4–P6 (for example, P4–P6 in the absence of Mg^{2+}) are methylated readily by dimethyl sulfate. These nucleotides, however, are substantially protected from methylation when P4–P6 is folded properly owing to their sequestration in the tetraloop–receptor interaction.[11,12]

For several of the caged P4–P6 RNAs, dimethyl sulfate probing was performed at varying Mg^{2+} concentrations, and the accessibility of the GAAA tetraloop was monitored (Figure 5a). These experiments provide information on local structure that cannot be determined with native PAGE. Depending on the caging site, the dimethyl sulfate probing results revealed a difference in the accessibilities of the GAAA tetraloop at high Mg^{2+} concentrations (Figure 5b). The tested caging sites that are remote from the tetraloop–receptor interaction (U107, C109) had essentially no effect on Mg^{2+}-dependent accessibility of the tetraloop. In contrast, caging of nucleotides within or near the receptor (A246, U247, A248, and G250) significantly suppressed protection of the tetraloop from dimethyl sulfate modification upon an increase in the Mg^{2+} concentration. As with the native gel assays, U249 located within the receptor provides a predict-

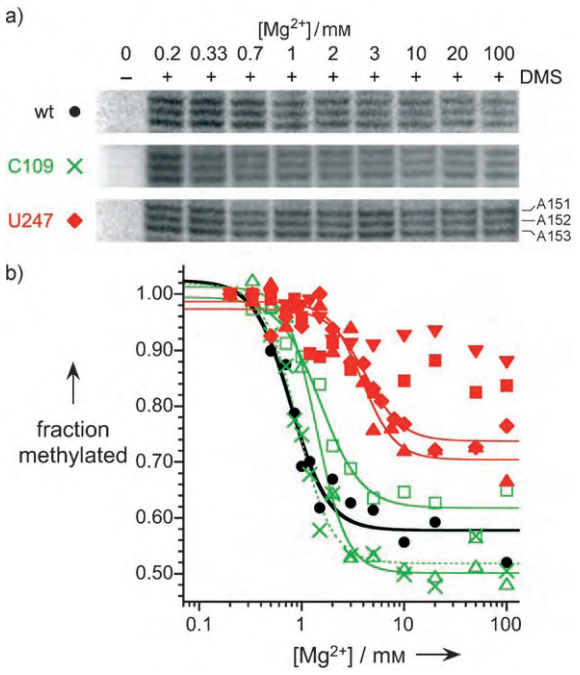

Figure 5. Chemical probing experiments with dimethyl sulfate of caged P4–P6 RNAs. a) Representative gel images for reverse transcriptase (RTase) assays of caged P4–P6 treated with dimethyl sulfate. The presence of an RTase abort band indicates methylation of the corresponding nucleobase with dimethyl sulfate, which must have been accessible to the reagent. The GAAA tetraloop includes nucleotides A151–A153. b) Mg^{2+} dependence of fraction methylated for the tetraloop adenosine nucleotides when various nucleotides are caged (● wild-type RNA; △ U107, × C109; □ U249; ▲ A246; ◆ U247; ■ A248; ▼ G250). A high fraction methylated implies high accessibility of the tetraloop to dimethyl sulfate. Photolysis of the samples before dimethyl sulfate probing restored protection from methylation (see Supporting Information).

able exception in this regard. These data show that the tetraloop–receptor interaction can be substantially perturbed on the local structural level, even when the global structure is essentially native. This conspicuous difference between local and global structural effects due to caging of specific nucleotides increases our understanding of how 'key interactions' contribute to RNA tertiary structure. Our results may also relate to the concept of compact, misfolded RNA states.[21] Some of the caged P4–P6 derivatives such as NPE-caged A248 adopt globally compact structures (as revealed by native PAGE) that nevertheless lack at least one native tertiary interaction (as indicated by dimethyl sulfate probing).

In summary, we have shown herein that nucleotides with caged nucleobases are readily incorporated into large RNA molecules that have complex tertiary structures, and the effects of the caged nucleotides are assessable with appropriate biochemical assays. From our results, we drew two conclusions that relate to the control of RNA folding by using caged nucleotides. First, incorporation of a bulky caging group can thermodynamically disrupt global RNA tertiary structure, but in all tested cases the disruption is relatively modest because it can be overcome by a sufficient increase in the Mg^{2+} concentration. This indicates that even 'key' tertiary contacts, such as the tetraloop–receptor interaction, are not strictly required for RNA tertiary folding. It also suggests that a chemically more sophisticated strategy (e.g., one that involves the attachment of a covalent tether at more than one position) is required to induce qualitative changes in global RNA structure that cannot be recovered simply by an increase in the Mg^{2+} concentration.[22] Second, comparisons of the native PAGE and dimethyl sulfate probing data indicate a clear differentiation between local and global structural effects upon the introduction of a chemical perturbation. This relates to the ability of individual caging groups to induce misfolded RNA states. A future direction for these studies will be to combine individual caging groups or photocleavable covalent tethers with time-resolved decaging to monitor RNA tertiary-folding processes in real time.

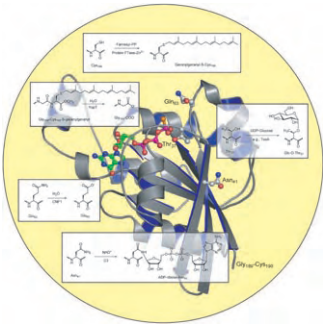
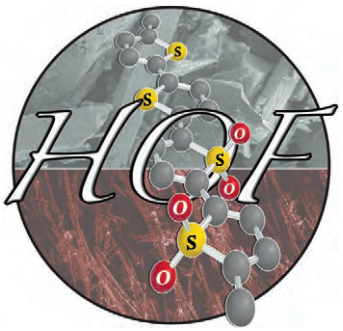
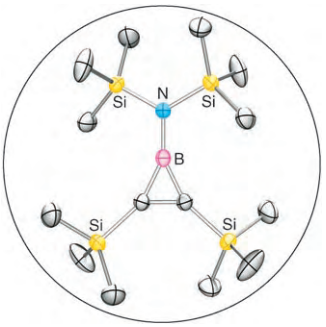
Nonplanar aromatic cores are used for the design of molecule-based electronic materials. In their Communication on page 7390 ff., C. Nuckolls and co-workers discuss the preparation of materials that can be applied to field-effect transistors as an active layer owing to their high carrier mobilities, low turn-on voltages, and high on/off current ratios. The cover picture shows the molecular structure of a new class of hexabenzocoronenes in which the core is severely distorted out of planarity.



Proteome Chemistry
The proteome encompasses far more proteins than predicted from the coding capabilities of DNA. The reasons for this diversity are directed posttranslational modifications, of which the main types and mechanisms are discussed by C. T. Walsh et al. in their Review on page 7342 ff.



Hypofluorous Acid
E. Amir and S. Rozen describe in their Communication on page 7374 ff. the use of $HOF{\cdot}CH_3CN$ in the synthesis of *S*,*S*-dioxide oligothiophene derivatives, which show significantly different properties compared to nonoxidized oligothiophenes.



Aromaticity
In their Communication on page 7461 ff., H. Braunschweig et al. report on borylene transfer to alkynes at room temperature to give boracyclopropenes (borirenes) and discuss the experimental evidence for the theoretically predicted aromaticity of this class of compounds.

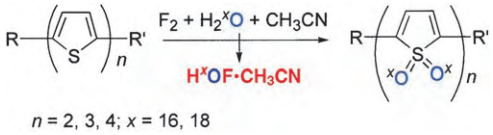
Protein Posttranslational Modifications: The Chemistry of Proteome Diversifications

Communications



Nonaromatic stable polyenes are obtained by dioxygenation of oligothiophenes using $HOF{\cdot}CH_3CN$ prepared in situ by passing F_2 through aqueous acetonitrile (see scheme). These fully *S*,*S*-dioxygenated derivatives have a considerably smaller HOMO–LUMO gap than the parent compounds; furthermore, in the solid state they tend to form favorable π–π stacking interactions, unlike most non-oxidized oligothiophenes which adopt the "herringbone" motif.

Oligomers

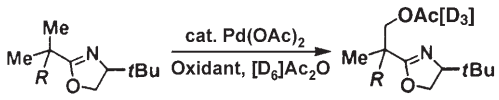
Aluminum–Magnesium Complexes with Linearly Bridging Carbon Dioxide

The linear μ(O,O′) bonding mode of CO_2 has been found for the first time in the magnesium–aluminum compounds $[\{R_2Al(\mu\text{-}NSiMe_3)(\mu\text{-}OSiMe_3)Mg(thf)_2(\mu\text{-}O_2C)\}_3]$ (**1** (R = Me) and **2** (R = Et); THF ligands omitted), which were obtained by bubbling CO_2 through a mixture of AlR_3 and $Mg[N(SiMe_3)_2]_2$ in THF.



Asymmetric Catalysis

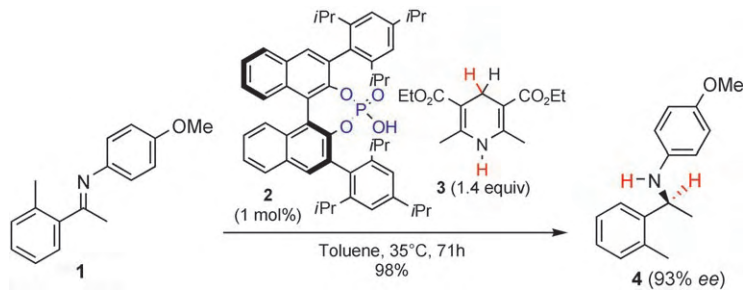
Pd-Catalyzed Stereoselective Oxidation of Methyl Groups by Inexpensive Oxidants under Mild Conditions: A Dual Role for Carboxylic Anhydrides in Catalytic C–H Bond Oxidation

Unactivated CH_3 groups in 2-oxazolines are oxidized by inexpensive oxidants, such as *tert*-butyl peroxyacetate and lauroyl peroxide, in the presence of a catalytic amount of $Pd(OAc)_2$. Carboxylic anhydrides are essential for both the oxidation of the Pd–C bonds and regeneration of $Pd(OAc)_2$. The use of $[D_6]Ac_2O$ as the solvent shows that the acetyl group incorporated into the product is from acetic anhydride rather than the oxidant (see scheme).



Asymmetric Catalysis

P. Seeberger Receives ESCS Award

Peter H. Seeberger (ETH Zürich) received the European Society of Combinatorial Sciences (ESCS) Award for his outstanding contribution to combinatorial carbohydrate chemistry. He presented his award lecture on "Automated Synthesis of Oligosaccharides: From Carbohydrate Arrays to Vaccines" at the Eurocombi-3 Conference.

P. Seeberger

Seeberger studied chemistry at the Universität Erlangen-Nürnberg and received his doctorate under the guidance of M. Caruthers (University of Colorado) in 1995. After a postdoctoral stay in the group of S. Danishefsky at the Sloan–Kettering Institute in New York, he began his independent research at the Massachussets Institute of Technology, where he became professor in 2002. A year later, he accepted a chair as professor of organic chemistry (successor to Dieter Seebach) at the ETH Zürich. Seeberger's research interest lies at the interface between chemistry and biology, with particular regard to glycoproteins and glycolipids. He recently reported in *Angewandte Chemie* on an anthrax tetrasaccharide antigen as a candidate vaccine against anthrax.[1] Seeberger is a member of the editorial board for *QSAR & Combinatorial Science*.

R. Metternich Takes On Responsibility for Schering Research

From January 1, 2006, Rainer Metternich will join the board of Schering AG and be responsible for the research division. In 2000, he joined Schering AG in Berlin as director of medicinal chemistry, and since 2001 he has led the European Research Center there. Between 1986 and 1997 he moved up the ranks in pharmaceutical research at Sandoz AG in Basel from laboratory to division leader. From 1997 to 2000 he worked as a senior chemistry expert and member of the global research management committee at Novartis.

R. Metternich

Metternich studied chemical engineering in Jülich (Germany), then chemistry at the Universität Marburg, where he completed his PhD in 1985 with R. W. Hoffmann on topics including the configurational stability of chiral organometallic reagents.[2] During a postdoctoral stay with D. A. Evans at Harvard University in Cambridge, MA (USA), he worked on stereoselective synthesis and the total synthesis of natural products. In 2001, he was named Honorary Professor of Organic Chemistry at the Technische Universität Berlin (Germany). Since 2004, Metternich has been a board member of the German Chemical Society (GDCh) as well as an editorial board member for *Angewandte Chemie*.

G. Wess Directs GSF Center

Günther Wess (formerly at Sanofi-Aventis, Frankfurt/M) succeeds E.-G. Afting as Scientific and Technical Director at the GSF – National Research Center for Environment and Health in Neuherberg (near Munich) from November 1, 2005. The Company for Radiation Research (Gesellschaft für Strahlenforschung, GSF) is a member of the Helmholtz Association of German Research Centers and is funded by the Federal Republic of Germany as well as the State of Bavaria.

Wess studied at the Universität Frankfurt (Germany) and earned his habilitation in pharmaceutical chemistry from the Universität Mainz in 1999. Since 2000, he has been Honorary Professor at the Johann-Wolfgang-Goethe-Universität, Frankfurt. Wess began his career in 1982 at Hoeschst AG. After a research stay with E. J. Corey (Harvard University), he went on to become leader of the medicinal development division at Hoechst Marion Roussel (Germany) in 1998 and its successor company Aventis, which merged into Sanofi–Aventis in 2004. Wess is a member of the editorial board for *ChemBioChem* and was co-editor of three special issues of this journal: "Systems Biology & Chemistry" (10/2004), "RNA Targeting" (10/2003), and "G-Protein-Coupled Receptors" (10/2002). He also highlighted the prospects and challenges in medicinal chemistry in an essay that appeared in *Angewandte Chemie* in 2001.[3]

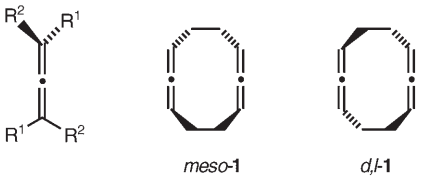
Allenophane and Allenoacetylenic Macrocycles: A New Class of Chiral Cyclophanes

*Takeshi Kawase**

Keywords:
allenes · chirality · cyclophanes · hydrocarbons · macrocycles

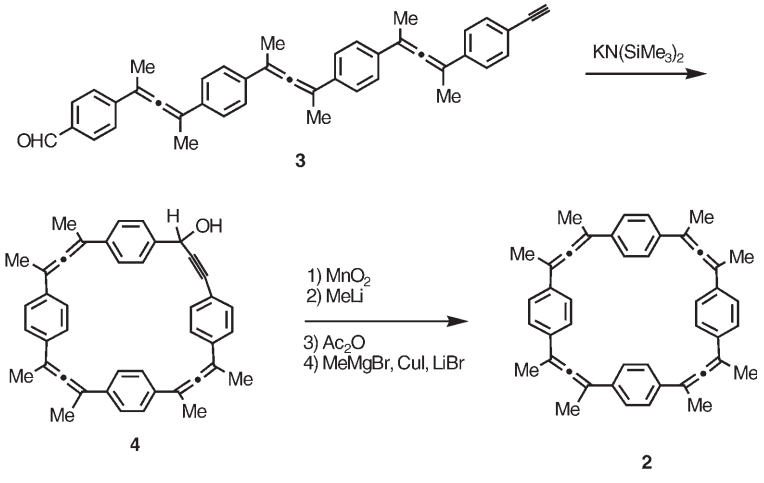
The determination of the relationship between molecular structure and physical properties is a major goal in organic chemistry. Cyclophane chemistry has continuously advanced and expanded over the years and has attracted the curiosity of organic chemists in pursuit of this goal. Researchers of this field have designed and created new cyclophanes with a variety of structures.[1,2] Recently, macrocyclic cyclophanes bearing acetylene bridges have received much attention. These cyclophanes with conformationally rigid and shape-persistent structures can also be regarded as dehydroannulenes.[3] The fruitful combination of cyclophane and annulene chemistry has furnished many new compounds; these substances exhibit unique molecular functions, such as aggregation behavior, host–guest complexation, and novel electronic properties.[1b,4]

In contrast, cyclophanes bearing allene (1,2-propadiene) bridges, termed allenophanes, have not been studied extensively, probably due to the difficulty of their synthesis and the high reactivity of allene moieties.[5] In 1875 van't Hoff predicted that the four substituents in allene must be arranged in two perpendicular planes.[6a] The proposal implied that suitably substituted allenes are axially chiral. The prediction was confirmed 60 years later.[6b] Thus, the incorporation of an allene skeleton in a compound leads to a three-dimensional structure and imparts chirality to the molecule. In 1961 the cyclic bisallene cyclodeca-1,2,6,7-tetraene (**1**) was synthesized from 1,5-cyclooctadiene by bisdibromocarbene addition and ring opening with methyllithium.[7] X-ray crystallographic analysis proved it to be a *meso* diastereomer. The corresponding *d*,*l*-**1** was not formed, probably due to its inherent strain. Strained cyclic allenes, including **1**, have been investigated theoretically and experimentally from the viewpoints of molecular strain and Möbius aromaticity.[5,8] However, the molecular structures have not been studied in detail because of their lability.



meso-**1** *d*,*l*-**1**

On the other hand, a number of natural products that bear an allene moiety have been isolated. Synthetic organic chemists have established synthetic procedures for the preparation of chiral allenes[9] that may pave the way for the synthesis of allenophanes. The first synthesis of a "true" allenophane, **2**, was presented by Thorand, Vögtle, and Krause in 1999.[10] The cyclophane consists of four 1,4-phenylene and four 1,3-dimethylallene moieties and exists as a mixture of four diastereomers with different topologies. The intramolecular cyclization, a key step of the synthesis, was effected by addition of the acyclic precursors **3** to a dilute solution of $KN(SiMe_3)_2$ in THF to form macrocyclic propargyl alcohol **4**. Further manipulation of **4** culminated in the construction of the fourth allene bridge through the action of a methyl cuprate species (Scheme 1). However, the synthesis was not stereoselective. In fact, the precursor **3** was synthesized and em-



Scheme 1. The synthesis of **2** by Thorand, Vögtle, and Krause.[10]

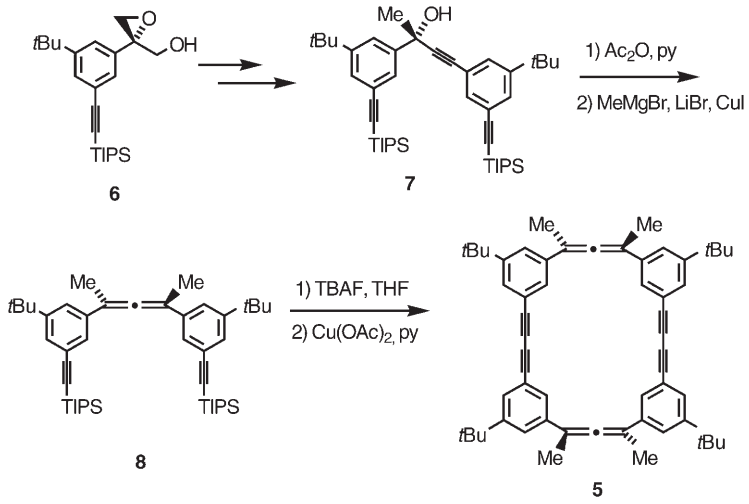


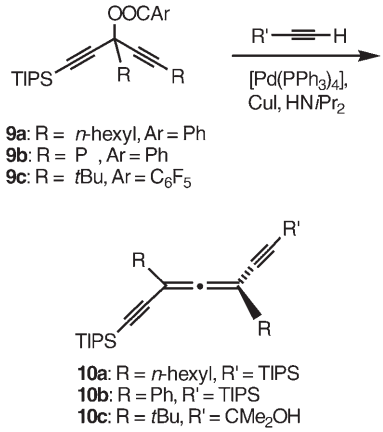
Scheme 2. The synthesis of **5** by Clay and Fallis.[11] TIPS = triisopropylsilyl.

ployed as a mixture of four diastereomers and afforded **2** as a mixture of diastereomers as expected. These isomers could not be separated by HPLC, and therefore the physical and chiroptical properties were not discussed.

Recently, some research groups have reported the synthesis of racemic and enantiomerically pure acetylenic allenophanes. Clay and Fallis reported the first synthesis of enantiomerically pure acetylenic allenophane **5**.[11] The synthesis started from the chiral epoxide **6** (88% *ee*), which was prepared by a Sharpless asymmetric epoxidation. The tertiary propargyl alcohol **7** (derived from **6**) led to chiral *S* allene **8** after a sequence of steps, including the addition of a methyl cuprate species (Scheme 2). Oxidative coupling of **8** afforded the *S*,*S* allenophane **5** in moderate yield. The molecular structure was not determined experimentally, theoretical calculations however revealed a helical structure for the molecule. The CD spectrum exhibits large bands at 263 and 270 nm owing to intramolecular interactions between the phenylene units of **5**.

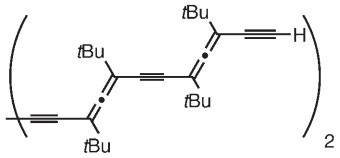
Diederich and co-workers have carried out extensive studies on π-conjugated systems consisting of acetylene and cumulene bonds for the construction of three-dimensional all-carbon networks and all-carbon backbone polymers and oligomers with novel physical and physicochemical properties.[12] In the course of their studies, they aimed to synthesize chiral acetylenic allenophanes that do not bear aromatic rings, which have become challenging and fascinating targets in this field.[13]

(±)-1,3-Diethynylallenes **10** are promising intermediates and were prepared by palladium-catalyzed cross-coupling of bispropargylic esters **9** and alkynes (Scheme 3). However, the labile

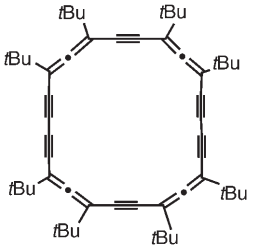


Scheme 3. The synthesis of (±)-1,3-diethynylallenes **10** by Diederich and co-workers.[15]

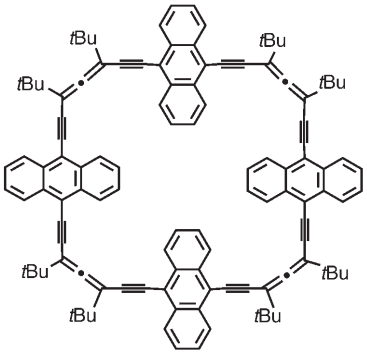
phenyl and *n*-hexyl derivatives **10a** and **10b** dimerize, even at low temperatures.[14] The relatively stable *tert*-butyl-substituted **10c** was obtained in high yield when pentafluorobenzoate was used as the leaving group. The bulky substituents of **10c** play an important role in the high stability of the molecule. The racemic allene **10c** was converted into an isomeric mixture of acyclic precursors **11**. Eglinton–Galbraith coupling of **11** under high-dilution conditions afforded cyclic tetraallene **12** in 80% yield.[15] Compound **12** was obtained as a mixture of five diastereomers



11



12



13

involving two enantiomers. The ratio of these diastereomers (1:1:4:1:1) corresponds roughly to the statistically controlled ring closure. These isomers were successfully separated with a combination of two different HPLC techniques. The major component of **12** was determined to be the C_1 isomer by NMR spectroscopy on the basis of the low symmetry. The formation of racemic C_1-symmetric **12** is expected to be favored over the formation of the other isomers. Moreover, an allenophane **13** that bears anthracene units was prepared from **10c**. All four isomers were also separated, the structures were characterized spectroscopically, and the structure of the D_4 isomer was confirmed by X-ray crystal-structure analysis. The isomers of **12** are colorless solids and those of **13** are brown. All compounds are stable under air at room temperature when

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

protected from light. Whereas **12** remains unchanged after irradiation from a xenon lamp, **13** undergoes photoisomerization to form a photostationary state ($C_2/C_{2h}/D_4/D_{2d} = 10:5:1:5$). The anthracene units in **13** may act as intramolecular sensitizers. To explore the chiroptical properties, the synthesis of an enantiomerically pure compound is the next step of this study.

Recently, chiral cyclophanes, particularly those with helical chirality, have received much attention,[16] because these compounds should provide insight into the relationship between structure and chiroptical properties. Moreover, these compounds should exhibit interesting properties as chiral ligands/hosts for metal ions and small guest molecules. The synthesis described herein is an important advance in cyclophane chemistry.

Hexaarylbenzenes—Prospects for Toroidal Delocalization of Charge and Energy

*Christoph Lambert**

Keywords:
amines · aromaticity · charge transfer · energy transfer · pi systems

Interactions between organic π systems govern to a large extent the electronic and functional properties of many microscopic and macroscopic photonic, electronic, and optoelectronic devices.[1] Prominent examples from nature are the light-harvesting complexes LH-I and LH-II in purple bacteria, where several dozen bacteriochlorophyll *a* molecules form a highly symmetrical ring that collects sunlight energy, which is ultimately transferred to a photosynthetic reaction center.[2] Delocalization of the excited state over many chromophore units (exciton delocalization) plays an important role in these systems. Examples of man-made systems are, for example, organic field effect transistors (OFETs), where a high charge (hole or electron) mobility is required which, up to date, can be achieved only in highly organized arrangements of π systems in thin-film transistors.[3] In this context, a detailed understanding of the interactions of π systems is required, and small model systems will help to elucidate the basic mechanisms that act on electron- and energy-transfer processes between π-system subunits.

For both processes one can distinguish between *delocalized* systems (charge or exciton delocalization) and *localized* systems (charge or exciton localization). While in the former case, either charge or energy is stabilized by resonance between two diabatic (formally noninteracting) states [Eq. (1a) and (1b)], in the latter case either charge

$$M^+/M \overset{\text{charge resonance}}{\leftrightarrow} M/M^+ \quad (1a)$$

$$M^*/M \overset{\text{exciton delocalization}}{\leftrightarrow} M/M^* \quad (1b)$$

or energy is transferred between different sites [Eq. (2a) and (2b)]. Whether

$$M^*/M \overset{\text{charge transfer}}{\rightleftharpoons} M/M^* \quad (2a)$$

$$M^*/M \overset{\text{energy transfer}}{\rightleftharpoons} M/M^* \quad (2b)$$

charge or energy is either localized or delocalized depends on the electronic coupling between the diabatic states relative to the reorganization energy for the considered process. Generally, if the coupling is much larger than the reorganization energy, delocalization occurs.

Hexaarylbenzene derivatives may serve as model compounds to investigate these processes between a number of π systems, because the six arene units can assume a ringlike arrangement in which the local C_2 axes of the aryl faces form 60° angles with each other. In addition, the arene planes are tilted (ca. 60°) rather than perpendicular to the central benzene ring (see Figure 1). The individual motion of the six arene moieties in this paddlewheel-like arrangement is to some extent correlated at low temperature due to steric interlinkage.

In a recent communication in *Angewandte Chemie* Kochi et al.[4] used the hexaarylbenzene motif to investigate the hole-transfer properties of radical cation **1**$^{\bullet+}$, in which all six benzene substituents are further substituted by dialkylamino redox centers in *para* position. Unlike hexakis(4-dianisylaminophenyl)benzene,[5] compound **1** shows partially resolved redox waves in the cyclic voltammogram which allowed the preparation and isolation of the salt of radical cation **1**$^{\bullet+}$ by either controlled coulometry or stoichometric chemical oxidation. This lucky circumstance is due to the relatively strong electronic

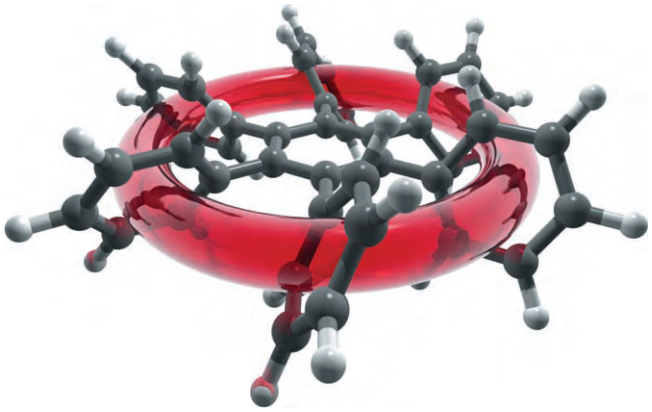

Figure 1. Toroidal delocalization of charge in hexaphenylbenzene radical cation (schematic representation).

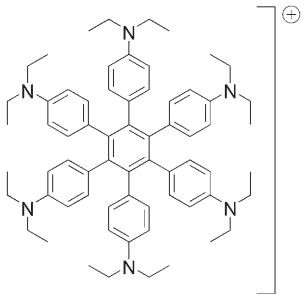
interaction between the dialkylaniline groups which separates the redox potential for **1**/**1**$^{\bullet+}$ from those of higher charged species.

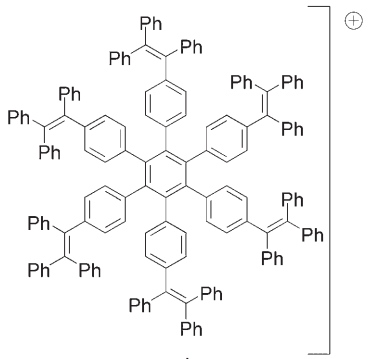


1$^{\bullet+}$

Kochi et al. were able to record the whole Vis/NIR spectral region down to $\tilde{\nu} \approx 2000\ cm^{-1}$ by combining the data from two separate Vis/NIR and FTIR measurements. The absorption spectrum of **1**$^{\bullet+}$ shows a structured signal between $\lambda \approx 900$ and ca. 5000 nm which was assigned to several optically induced hole-transition processes from an oxidized dialkylaniline group to five higher lying excited states. These observed absorption bands can be interpreted as intervalence charge-transfer processes (IV-CT). Adopting a methodology outlined by us a few years ago,[6] Kochi et al. described the adiabatic ground state and the five excited states by mixing of six diabatic states. The solution of an adequate secular determinant yielded the eigenvalues and eigenfunctions of the ground state and the five excited states. Kochi et al. used these eigenvalues together with estimated coupling energies and reorganization energies to deconvolute the experimental absorption bands into five Gaussian subbands by a repetitive fitting procedure. This fitting procedure also leads to optimized electronic couplings and reorganization energies without the effective electron-transfer distance being known. The latter is usually required for calculating the electronic coupling and is difficult to estimate.[7] The energies and intensities of these experimental transitions are in remarkable agreement with theoretical values based on the above-mentioned eigenvalues and evaluated by Mulliken–Hush theory.

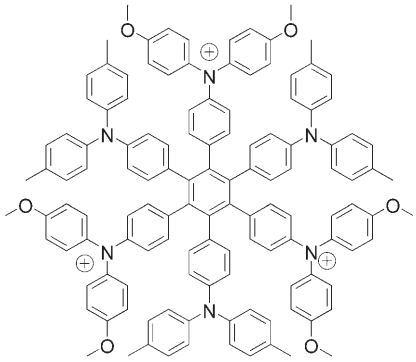
Owing to the relatively strong electronic coupling and the weak reorganization energy, the thermal hole-transfer barrier between different redox sites is very small, if at all present. These results indicate that the hole is (almost) delocalized over all the six redox centers in a toroidal fashion (see Figure 1) because of the geometrical arrangement of the redox sites whose π-orbital planes point face to face. This leads to a partial overlap of the π orbitals of the *ipso* carbon atoms (the atoms attached to the central benzene ring) of adjacent aniline groups.

Somewhat earlier Rathore et al.[8] investigated an analogous hexakis[(triphenylethenyl)phenyl]benzene radical cation **2**$^{\bullet+}$, for which the authors observed a broad and unresolved IV-CT band in the NIR. However, although spectra deconvolution yields a IV-CT band at 1450 cm^{-1} a further analysis that would allow the quantification of the associated hole-transfer processes was not described. The authors also suggest a toroidal hopping mechanism operating between the six equivalent redox sites. The fact that the IV-CT band is broad and featureless indicates a much weaker electronic interaction in **2**$^{\bullet+}$ than in **1**$^{\bullet+}$.



2$^{\bullet+}$

Our own studies on the trication of 1,3,5-tris[(4-dianisylamino)phenyl]-2,4,6-tris[(4-ditolylamino)phenyl]benzene (**3**$^{3+}$) stand in contrast to the results of Kochi et al. and of Rathore et al.[6] In this molecule it was possible to generate the trication owing to the significant difference in redox potential between the tolyl- and the anisyl-substituted amino groups. This trication **3**$^{3+}$ also shows a broad IV-CT band in the NIR. Deconvolution of this band indicated that the trication has a *localized* structure and that there is a significant barrier for the superexchange hole transfer from site to site.



3^{3+}

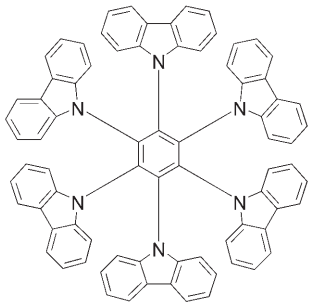
What is the reason for this difference between **1**$^{\bullet+}$ and **3**$^{3+}$? For toroidal delocalization it is necessary that the charge-bearing units are as close as possible. The closest contact between adjacent aniline groups in **1**$^{\bullet+}$ is 2.9 Å (C_{ipso}–C_{ipso}) and the greatest separation is 7.1 Å (N–N). If we assume that the charge in **1**$^{\bullet+}$ is delocalized within the aniline group with the center of charge distribution being somewhere between the nitrogen and the center of the aniline ring, there might be sufficient overlap of the C_{ipso} π orbitals to provide toroidal delocalization. In contrast, in **3**$^{3+}$ the individual charges are delocalized within the three (dianisylamino)phenyl moieties with the respective center of charge being likely even beyond the location of the nitrogen atom. Therefore, the partial charge at the C_{ipso} atoms in **3**$^{3+}$ is much less than that in **1**$^{\bullet+}$ which results in a much weaker interaction between the aryl groups and a localized electronic structure. From this interpretation I conclude that in order to gain perfect toroidal delocalization in hexaarylbenzenes one possible strategy would be to move the center of charge towards the C_{ipso} atoms by, for example, electron-withdrawing substituents rather than electron-donating substituents. This hypothesis is supported by the observation of Rathore et al.[9] that in hexakis[(4-methyl-2,5-dimethoxy)biphenyl]benzene radical cations there is no significant interaction between the aryl branches because the center of charge is even much farther away from the C_{ipso} atoms than in **3**$^{3+}$.

All of these studies were preceded by the work of Sagl and Martin.[10] In

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

1988 they analyzed the electronic structure of hexaiodobenzene dication by NMR spectroscopy and extended Hückel calculations and presented evidence for its σ aromaticity resulting from the overlap of iodine p orbitals and carbon orbitals in the molecular plane. Although I do not want to start a discussion of σ aromaticity at this point, it is worth noting that the delocalization in $\mathbf{1}^+$ results from the face-to-face overlap of π orbitals in a toroidal, that is, three-dimensional fashion rather than solely in a σ framework. Clearly, further theoretical work is necessary to establish the electronic interactions in hexaarylbenzenes and in hexaiodobenzene dication.

To some extent, energy-transfer processes are akin to electron-transfer processes. Some years ago Warman et al.[11] reported on the energy migration between carbazole chromophores in hexakis(carbazolyl)benzene **4**. The carbazole units show significant interaction in their absorption and fluorescence spectra compared to the monomeric analogue *N*-phenylcarbazole. Using time-resolved microwave conductivity methods, the authors showed that **4** exhibits a rapid rotary diffusion of the excimeric state which is initially localized at two neighboring carbazole moieties with a relaxation time of 3 ps. This means that within the 5-ns lifetime of the excited state, the excitation undergoes more than 1000 round-trips. Also from the viewpoint of hole-transfer processes, **4** would be an interesting candidate to examine.



4

Warman et al. described **4** as a "storage-ring". Not only this term is attractive, but this concept is also appealing because it points to new possible molecular properties of both toroidal energy- and charge-delocalized systems. Time will tell if such systems can be used to "store" (= stabilize) charges or energy more efficiently than other species of similar size.

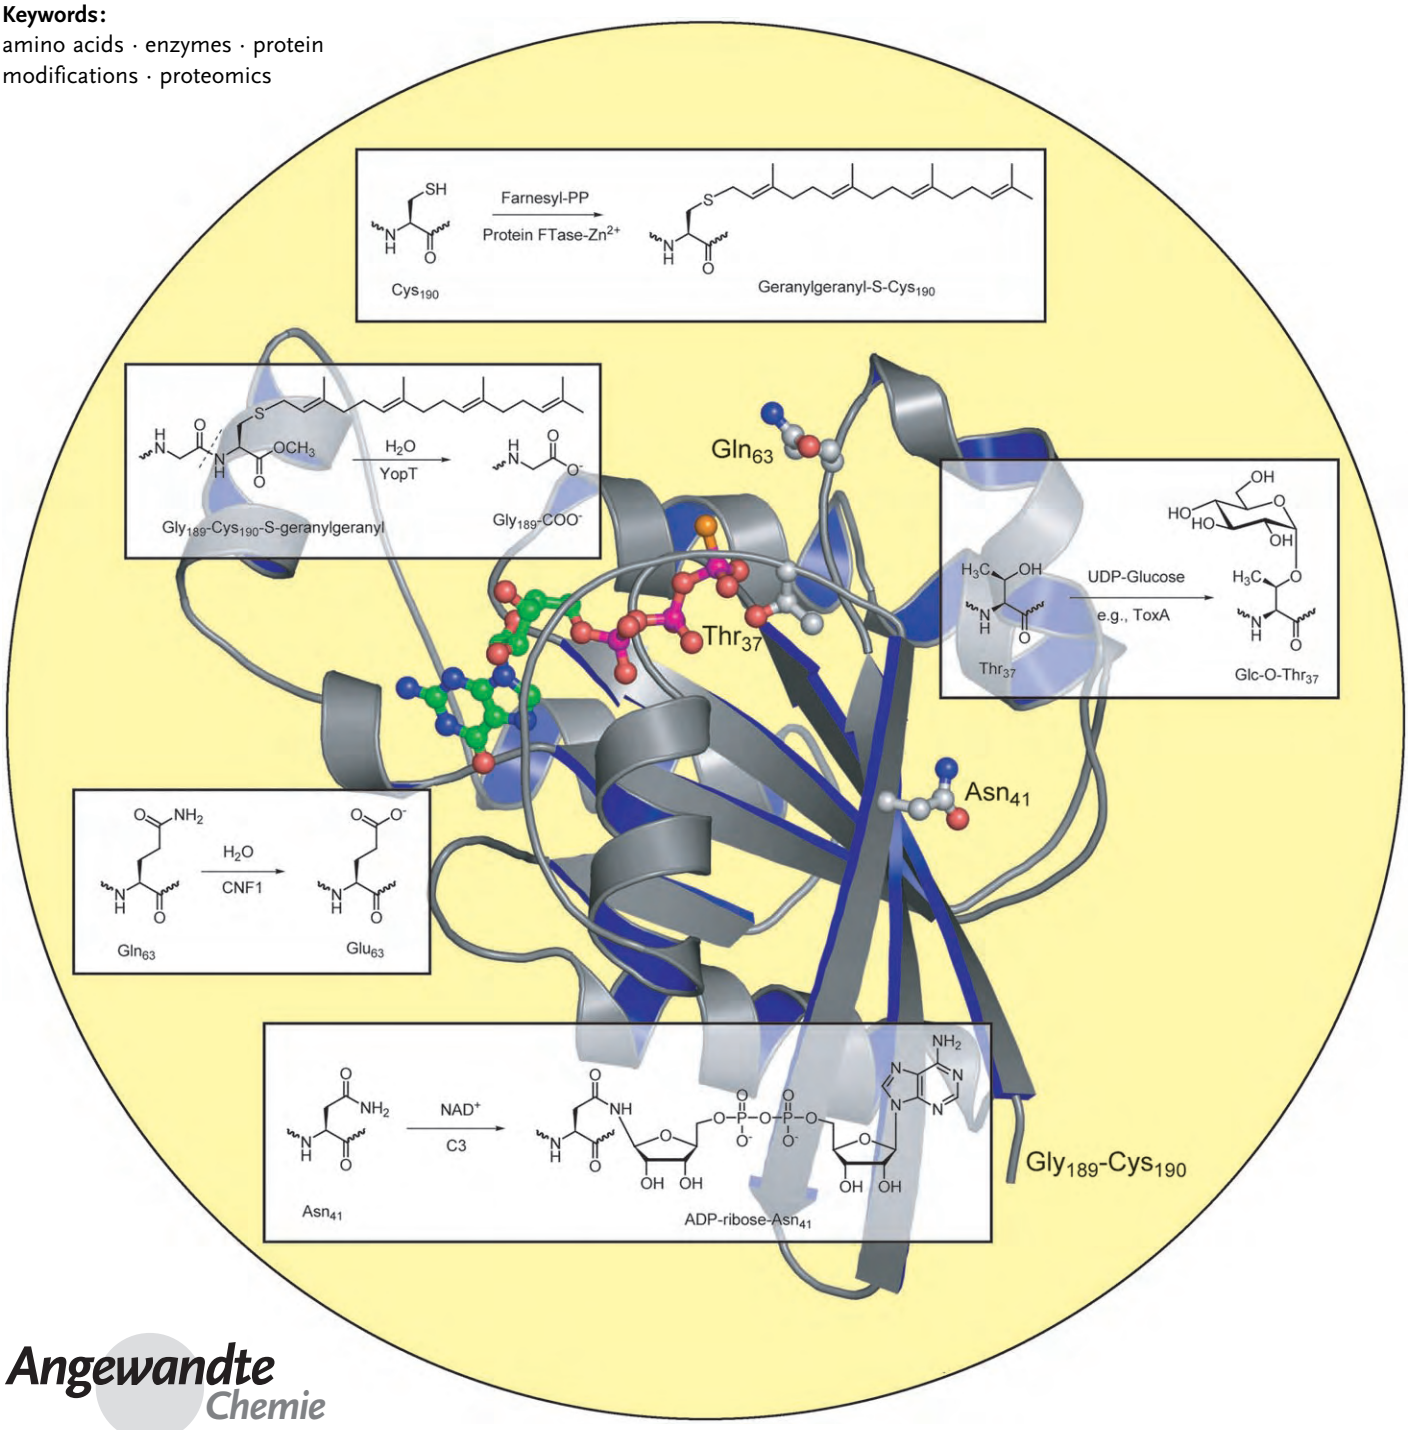
Protein Posttranslational Modifications: The Chemistry of Proteome Diversifications

Christopher T. Walsh, Sylvie Garneau-Tsodikova, and Gregory J. Gatto, Jr.*

Keywords:
amino acids · enzymes · protein modifications · proteomics



© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The diversity of distinct covalent forms of proteins (the proteome) greatly exceeds the number of proteins predicted by DNA coding capacities owing to directed posttranslational modifications. Enzymes dedicated to such protein modifications include 500 human protein kinases, 150 protein phosphatases, and 500 proteases. The major types of protein covalent modifications, such as phosphorylation, acetylation, glycosylation, methylation, and ubiquitylation, can be classified according to the type of amino acid side chain modified, the category of the modifying enzyme, and the extent of reversibility. Chemical events such as protein splicing, green fluorescent protein maturation, and proteasome autoactivations also represent posttranslational modifications. An understanding of the scope and pattern of the many posttranslational modifications in eukaryotic cells provides insight into the function and dynamics of proteome compositions.

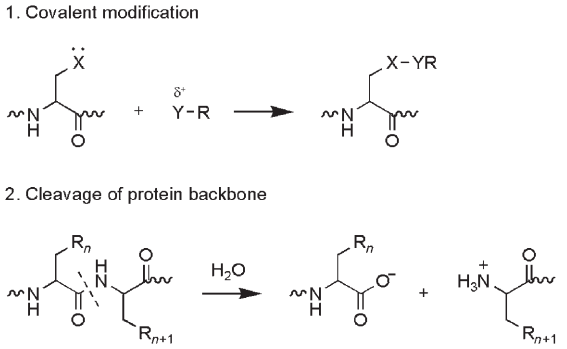
1. Introduction

There are two major mechanisms for expanding the coding capacity of the 6000 (yeast) to 30,000 (human) genes in eukaryotic genomes to generate diversity in the corresponding proteomes, the inventory of all proteins in a cell or organism. Proteomes may be two to three orders of magnitude more complex (>1000000 molecular species of proteins) than the encoding genomes would predict. The first route of diversification of proteins is at the transcriptional level, by mRNA splicing, including tissue-specific alternate splicing.[1,2] This is a central topic in RNA metabolism in eukaryotic biology.

The second route to proteome expansion is the focus of this Review: covalent posttranslational modification (PTM) of proteins at one or more sites.[3] As the name implies, these are covalent modifications that occur after DNA has been transcribed into RNA and translated into proteins. The nascent or folded proteins, which are stable under physiological conditions, are then subjected to a battery of specific enzyme-catalyzed modifications on the side chains or backbones. Proteome diversification by covalent modification occurs in prokaryotes but is much more extensively encountered in nucleated cells, both in terms of types of modifications and frequency of occurrence. About 5% of the genomes of higher eukaryotes can be dedicated to enzymes that carry out posttranslational modifications of the proteomes.

Two broad categories of protein PTM occur (Scheme 1). The first subsumes all enzyme-catalyzed covalent additions of some chemical group, usually an electrophilic fragment of a cosubstrate, to a side chain residue in a protein. The side chain modified is usually electron rich, acting as a nucleophile in the transfer. The second category of PTM is covalent cleavage of peptide backbones in proteins either by action of proteases or, less commonly, by autocatalytic cleavage. Limited proteolysis to control location, activity, and lifetime of each protein in intracellular and extracellular milieus is a central strategy for the regulation of the composition and function of proteomes.

Protein covalent modifications can be sorted along several axes. One is by the identity of the protein side chain modified; 15 of the 20 common proteinogenic amino acid side chains



Scheme 1. Two categories of posttranslational modifications of proteins: 1) covalent modification of a nucleophilic amino acid side chain by an electrophilic fragment of a cosubstrate; 2) cleavage of a protein backbone at a specific peptide bond.

undergo such diversification (Table 1). Another classification is that by the fragment of cosubstrate or coenzyme that is enzymatically coupled to the protein and the concomitant chemical nature of the protein modification. This catalogue includes *S*-adenosylmethionine (SAM)-dependent methylation, ATP-dependent phosphorylation, acetyl CoA dependent acetylation, NAD-dependent ADP ribosylation, CoASH-dependent phosphopantetheinylation, and phosphoadenosinephosphosulfate (PAPS)-dependent sulfurylation. A third axis of categorization of PTM is by the new function enabled by the covalent addition. These include gain in catalytic function of enzymes that have acquired tethered biotinyl, lipoyl, and phosphopantetheinyl groups, changes of subcellular address for proteins undergoing various lipid modifications (prenylation, palmitoylation, glycosyl phosphatidylinositol (GPI) anchor attachment), and targeting of the modified protein for proteolytic destruction by ubiquitylation to mark transport to lysosomes or proteasomes.

Christpher T. Walsh, born in 1944, majored in biology at Harvard and completed his PhD in biochemistry in the lab of Fritz Lipmann at the Rockefeller Institute of Medical Research. He was on the MIT faculty (1972–1987), and since 1987 has been at Harvard Medical School. He served as Chair of the Dept. of Chemistry at MIT (1982–1987) and of the Dept. of Biological Chemistry and Molecular Pharmacology at Harvard Medical School (1987–1995). His research interests lie in enzyme and inhibitor mechanisms and in the biosynthesis of non-ribosomal peptide antibiotics.

Sylvie Garneau, born in Québec, Canada, received her BSc (1995) and MSc (1997) in chemistry from the Université Laval, where she worked under the supervision of Robert Chênevert and Perséphone Canonne. She completed her PhD in chemistry in January 2003 at the University of Alberta with John C. Vederas on the studies of new antimicrobial agents acting on bacterial cell walls. She is currently a postdoctoral fellow with Christopher T. Walsh at Harvard Medical School, studying halogenation and pyrrole formation various of natural products.

Gregory J. Gatto, Jr., born in 1972, majored in chemistry at Princeton University, where he worked under the direction of Martin Semmelhack. In 2003, he received his MD and PhD degrees from the Johns Hopkins University School of Medicine. There, he worked in the lab of Jeremy Berg on the structural biology of peroxisomal targeting signal recognition. He is currently an NIH postdoctoral fellow in the lab of Christopher T. Walsh at Harvard Medical School, studying the biosynthesis of the macrolide immunosuppressants.

Table 1: Posttranslational protein modifications at the side chains.[a]

Residue	Reaction	Example
Asp	phosphorylation	protein tyrosine phosphatases; response regulators in two-component systems
	isomerization to isoAsp	
Glu	methylation	chemotaxis receptor proteins
	carboxylation	Gla residues in blood coagulation
	polyglycination	tubulin
	polyglutamylation	tubulin
Ser	phosphorylation	protein serine kinases and phosphatases
	O-glycosylation	notch O-glycosylation
	phosphopantetheinylation	fatty acid synthase
	autocleavages	pyruvamidyl enzyme formation
Thr	phosphorylation	protein threonine kinases/phosphatases
	O-glycosylation	
Tyr	phosphorylation	tyrosine kinases/phosphatases
	sulfation	CCR5 receptor maturation
	ortho-nitration	inflammatory responses
	TOPA quinone	amine oxidase maturation
His	phosphorylation	sensor protein kinases in two-component regulatory systems
	aminocarboxypropylation	diphthamide formation
	N-methylation	methyl CoM reductase
Lys	N-methylation	histone methylation
	N-acylation by acetyl, biotinyl, lipoyl, ubiquityl groups	histone acetylation; swinging-arm prosthetic groups; ubiquitin; SUMO (small ubiquitin-like modifier) tagging of proteins
	C-hydroxylation	collagen maturation
Cys	S-hydroxylation (S-OH)	sulfenate intermediates
	disulfide bond formation	protein in oxidizing environments
	phosphorylation	PTPases
	S-acylation	Ras
	S-prenylation	Ras
	protein splicing	intein excisions
Met	oxidation to sulfoxide	Met sulfoxide reductase
Arg	N-methylation	histones
	N-ADP-ribosylation	$G_{s\alpha}$
Asn	N-glycosylation	N-glycoproteins
	N-ADP-ribosylation	eEF-2
	protein splicing	intein excision step
Gln	transglutamination	protein cross-linking
Trp	C-mannosylation	plasma-membrane proteins
Pro	C-hydroxylation	collagen; HIF-1α
Gly	C-hydroxylation	C-terminal amide formation

[a] No modifications of Leu, Ile, Val, Ala, Phe side chains are known. A more extensive list can be found in reference [3].

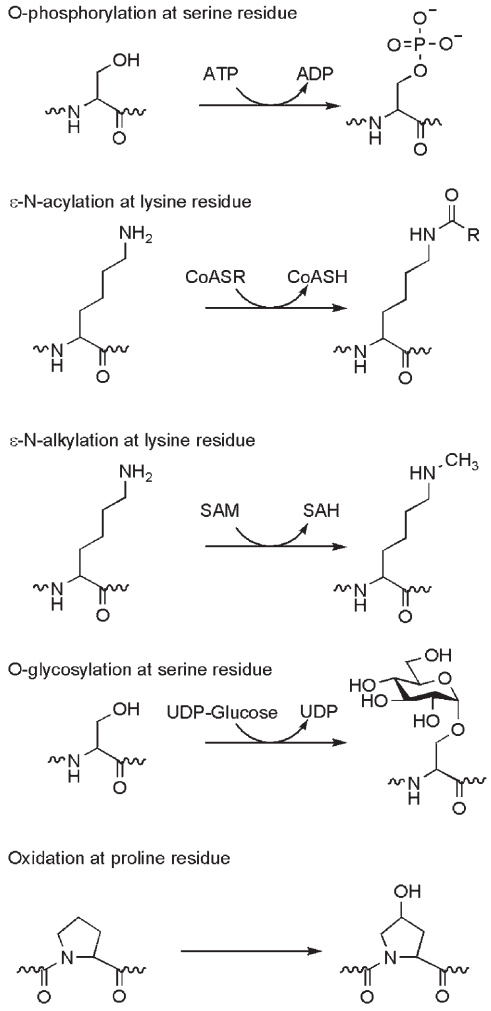
2. Covalent Addition: The Main Acts

The five most common types of covalent additions to proteins are phosphorylation, acylation, alkylation, glycosylation, and oxidation, which are catalyzed by dedicated PTM enzymes (Scheme 2). The protein products obtained in this manner make up subsets of the proteome of an organism: the phosphoproteome, the acyl proteome, the alkyl proteome, the glycoproteome, and the oxidized proteome. In turn, each of these subproteomes can contain substantial diversity.



Scheme 2. Five major types of covalent additions to protein side chains: phosphorylation, acylation, alkylation, glycosylation, oxidation.

2.1. Protein Phosphorylation

The mammalian phosphoproteomes have phosphoSer (pS), phosphoThr (pT) and phosphoTyr (pY) residues with a split of about 90:10 (pS, pT/pY; Figure 1).[4] Bacterial and fungal phosphoproteomes will also have phosphoHis and phosphoAsp residues derived from proteins in two-component signal-transduction cascades.[5] The pathogenic bacterium *Pseudomonas aeruginosa* exhibits more than 60 such pathways.[6]

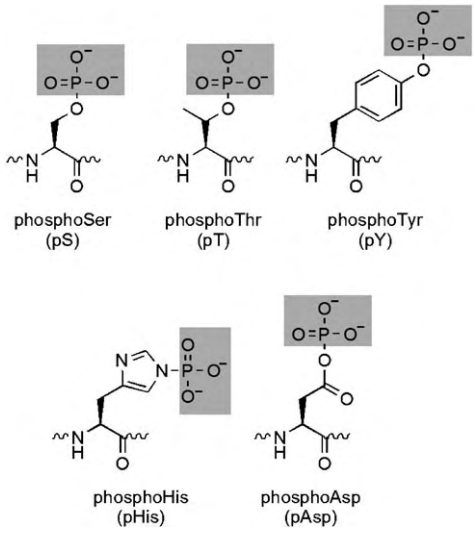


Figure 1. Phosphorylated forms of amino acid side chains in proteins: phosphoSer (pS); phosphoThr (pT); phosphoTyr (pY); phosphoHis (pHis); phosphoAsp (pAsp).

The enzymes dedicated to protein phosphorylation are among the largest class of PTM enzymes. This superfamily of protein kinases have been termed the kinome, with over 500 members in the human kinome.[7] If these acted on average on only 20 different protein substrates, or different residues within a smaller subset of proteins, 10000 distinct molecular forms of phosphorylated proteins would be produced. This is most probably a substantial underestimate of the true size of phosphoproteomes of higher eukaryotes, in which phosphorylation sites can be predicted but, as yet, cannot be completely measured. For example, the enzymatic activity of Abl protein kinase is modulated by phosphorylation at up to 11 distinct residues (Tyr, Thr, Ser; Figure 2).

Introduction of the charged, dianionic tetrahedral phosphate group induces altered conformations in local protein microenvironments[8] and is often paired with cationic arginine side chains (Figure 3). These local reorganizations of protein domains often create the architectural impetus for signal initiation, for example, in the four parallel MAP kinase pathways in eukaryotes and in the activation of many membrane receptor tyrosine kinases during autophosphorylation. The enzymatic conversion of a neutral OH side chain to dianionic phosphate has proven to be such a useful conformation switch in protein-domain restructuring that it has evolved into a major recurring theme in eukaryotic proteome diversity.

2.2. Protein Acylation

The most common acyl chains found in proteins that have undergone posttranslational modifications are C_2 (acetyl, e.g. histone tail acetylations),[9] C_{14} (myristoylation at glycine N termini),[10] and C_{16} (palmitoylated-*S*-Cys residues).[11] The 8-kDa chain of the small protein ubiquitin[12] (and congeners)

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

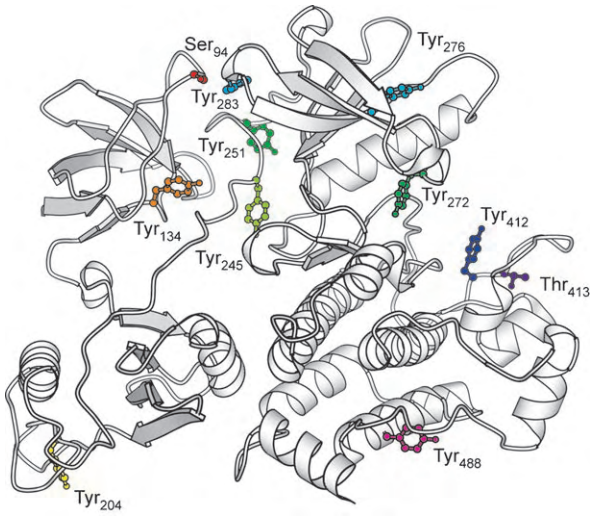

Figure 2. Eleven phosphorylation sites in the tyrosine kinase Abl, including Ser, Thr, and Tyr residues, color coded from red near the N terminus to purple near the C terminus. This figure and all other three-dimensional structural representations in this Review were generated with MolScript.[122]

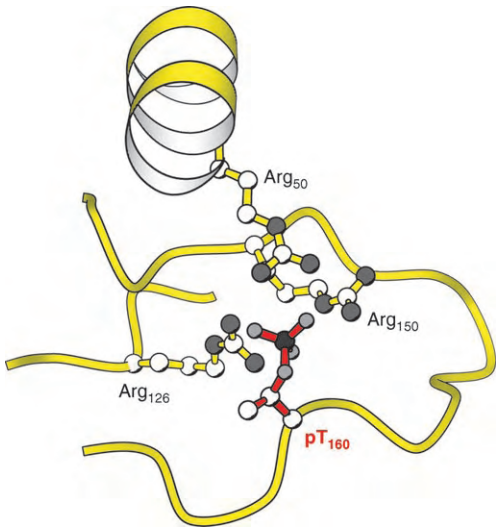

Figure 3. Conversion of a neutral OH side chain to a dianionic PO_3^{2-} side chain recruits cationic Arg side chains to make bifurcated charge-pairing interactions that can restructure the microenvironment of a protein region, induce a conformational change, and thereby initiate or propagate signaling information to partner proteins or small molecules. Shown is the interaction in Cdk2 of $pThr_{160}$ with the guanidinium side chains of Arg_{50}, Arg_{126}, and Arg_{150}.

is enzymatically transferred as an acyl moiety by ubiquityl ligases and chemically falls into this group of PTMs. The biological consequences of the acylation of a given protein with C_2, C_{14}, C_{16}, or 8-kDa chains are vastly different.

2.2.1. *ε-N-Acetylation of Lysine*

Acetylations of multiple lysine residues in histone N-terminal tails or at the C-terminus of the p53 transcription factor[13] are viewed as an integral part of the epigenetic code that controls selective gene transcription. The acetyl-group donor is the primary metabolite acetyl CoA, and dedicated histone acetyltransferase (HAT) isoenzymes select distinct combinations of the ε-NH_2 groups of Lys side chains in the N-terminal tails of histones: two Lys residues on histone H2A, four on H2B, four on H3, and four on H4 (Figure 4). Given

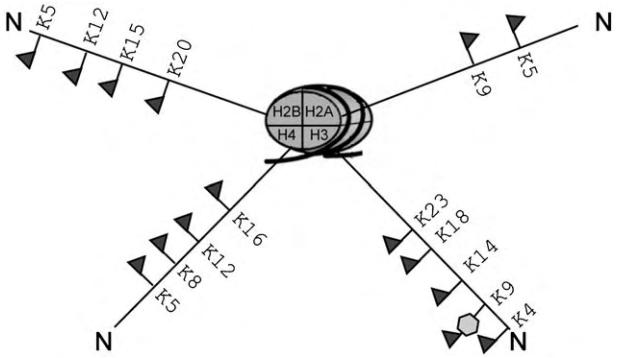

Figure 4. There are 15 Lys residues in the N-terminal tails of H2A, H2B, H3, and H4 that are sites for possible enzymatic acetylation. The dark gray flags represent sites of acetylation on the indicated lysine (K) residues.

two copies of each histone per octamer core in nucleosomes, there are $14 \times 2 = 28$ potential Lys side chains available for acetylation. Yeast histones with up to 13 acetylations have been reported,[14] which reflects almost 50% posttranslational modification. The combinatorial possibilities for differentially acetylated histone tails in nucleosomes become astronomically large.

The acetyl groups on Lys side chains convert potentially cationic side chains into groups, thus altering the charge distribution. The *N*-acetyl Lys group is also specifically recognized by discrete protein domains, termed bromodomains (Figure 5), which are embedded in transcription factors and associated proteins. Thus, the acetylation state of histone tails can regulate the recruitment of transcription factor machinery that controls the initiation of transcription of the genes in the region of chromatin covered by those nucleosomes.[14] In Section 5, we describe how five Lys residues at the C terminus of the transcription factor p53 can either be acetylated or ubiquitylated. Acetylation blocks the Lys side chains from ubiquitylation and prolongs the half-life of the p53 protein molecule.

2.2.2. *N-Myristoylation and S-Palmitoylation*

Myristoylation of eukaryotic proteins at an N-terminal glycine residue is catalyzed by the PTM enzyme protein N-myristoyltransferase, which utilizes the C_{14} myristoyl CoA as the donor substrate.[15] As protein synthesis is initiated with N-terminal methionine residues, cotranslational hydrolysis of the Met_1–Gly_2 bond by methionine aminopeptidase is a prerequisite to myristoylation (Scheme 3). The newly generated free amino group of the now N-terminal Gly is the nucleophile in the acylation reaction. The introduced hydrophobic C_{14} fatty acyl group can be a membrane-directing

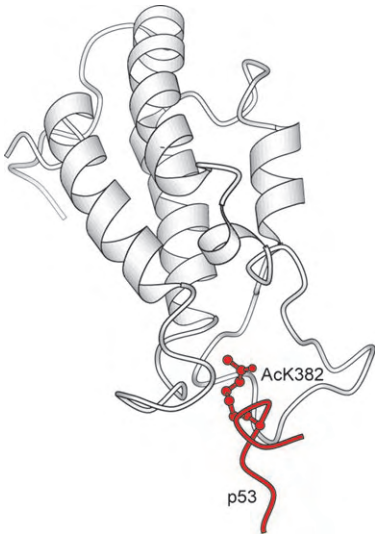

Figure 5. The acetylation status of the histone N-terminal tail can recruit partner proteins to control transcriptional activity on a nucleosome. The interaction of an acetyl-ε-NH-Lys side chain on a peptide fragment of histone H3 with a bromodomain of coactivator protein is redrawn from reference [32].

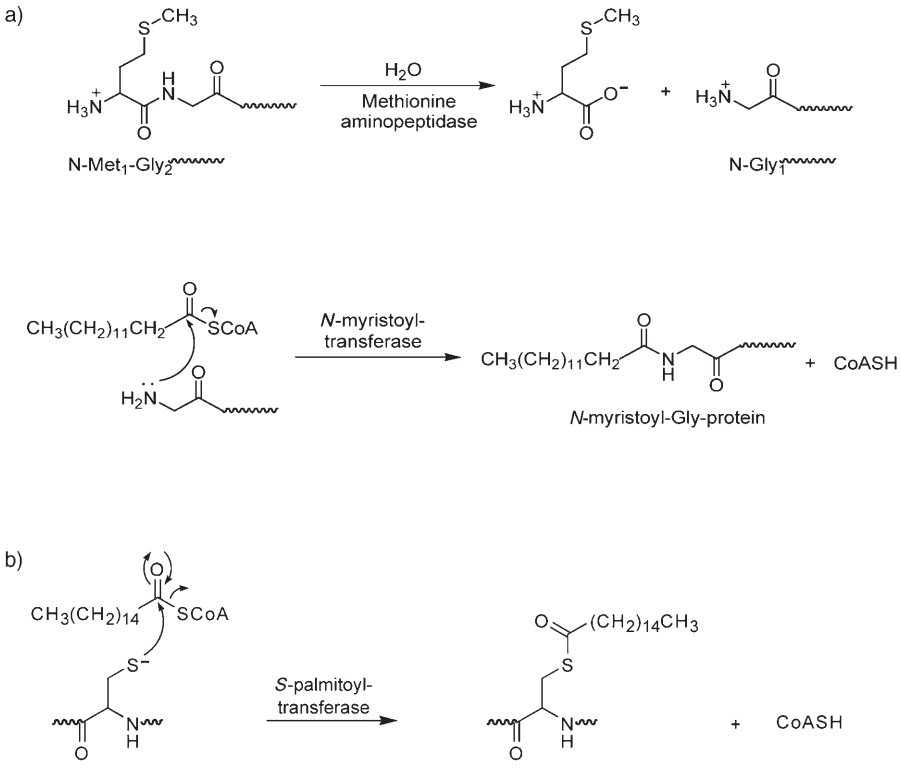

Scheme 3. a) Prior cleavage of the Met_1–Gly_2 peptide bond by methionine aminopeptidase liberates the NH_2 of the Gly residue for N-myristoylation by N-myristoyltransferase with myristoyl CoA as donor. b) The thiolate side chain of a Cys residue as nucleophile towards palmitoyl CoA, catalyzed by palmitoyl-*S*-protein transferases.

group to move proteins to membrane interfaces.[10] Additionally the myristoyl tail can switch from being buried in a cleft within the protein in one state to being available for membrane insertion in another conformational state.[16]

Examples of N-myristoylated proteins include HIV Gag protein and protein kinase A.[17]

Palmitoylation of proteins requires the C_{16} fatty acyl CoA as donor for the PTM acyltransferases, but the acyl group is typically transferred to the sulfhydryl side chains of Cys residues rather than to N-termini of proteins (Scheme 3).[11] Among the most-well-studied examples are S-palmitoylation of cysteines in the C-terminal regions of proteins such as the Ras GTPase. The lipidation of these nucleophilic thiolate side chains is consequential for partitioning Ras from the cytoplasm to membrane interfaces to meet up with its signaling partner proteins.[10] As explained in Section 5, the S-palmitoylation of Ras isoforms is part of a cascade of reversible posttranslational modifications involved in maturation and membrane anchoring of modified forms of Ras.[18] Protein substrates for S-palmitoylation can be transmembrane receptors such as the CD8α chain and the CCR chemokine receptor or cytoplasmic proteins such as the protein tyrosine kinase Lck.[11]

2.2.3. *Mono- and Polyubiquitylation of Proteins*

An extension of the logic of posttranslational transfer of low-molecular-weight (C_2, C_{14}, C_{16}) acyl chains to proteins is the acylation on lysine ε-amino groups by the carboxy terminus of the 8-kDa protein ubiquitin. In analogy to acyl CoA donors of the electrophilic acetyl, myristoyl, and palmitoyl acyl groups, the C-terminal carboxy group of the 76-residue ubiquitin must be preactivated for acyl transfer. The activation principle is the same as that of the acyl thioester system, but eukaryotic cells make use of ubiquityl-S-protein as donors instead of ubiquityl CoA.[19,20] The enzymatic activation machinery involves an enzyme 1 to make ubiquityl-AMP and a set of about a dozen thiol-containing enzymes 2 (Scheme 4) that provide the active-site nucleophile to capture the ubiquityl group as a set of ubiquityl-S-enzyme 2 family members. In general a third set of proteins, known collectively as enzyme 3 variants, are then required to catalyze the efficient transfer of the activated ubiquityl protein tag to Lys side chains of client proteins. Some of the enzyme 3 subclasses are multicomponent catalysts, with up to four subunits, which provide selectivity for a given protein target.[21] There are several hundred isoforms of such E3 ubiquityl ligases in higher eukaryotes, which allow subtle discrimination among many target proteins selected for ubiquitylation.[22]

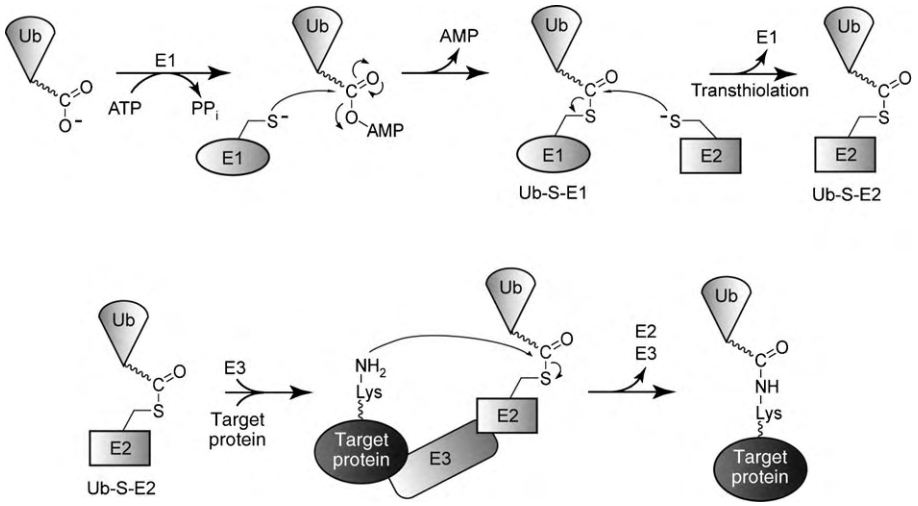

Scheme 4. Activation of the C-terminus of ubiquitin (at residue Gly_{76}) by enzyme 1 to make Ub-AMP, followed by transfer to a Cys thiolate in the active site of enzymes 2 to yield Ub-S-E2. Enzymes 3 can act as chaperones and recruiters of specific proteins for ubiquitylation at Lys side chains.

Unlike the small-molecule acyl groups described in Section 2.2.2., the ubiquityl acyl moiety provides an information-rich architectural scaffold (Figure 6) that can be read by particular partner proteins that control the downstream biological response. Two types of protein ubiquitylation can be distinguished according to the number of ubiquitins added: monoubiquitylation and polyubiquitylation. Polyubiquitylation specifically refers to the enzymatic construction of chains of ubiquitin molecules. As shown in Figure 6a, ubiquitin has Lys side chains on different surfaces and tandem attachment could go from any Lys unit on one ubiquitin monomer to the C-terminal Gly_{76} on the preceding monomer. It appears that polyubiquitin chains are built up most often through Lys_{48} side chains, although chains tethered through Lys_{63} are also well-known.[23] The X-ray structure of a Ub_4 chain is shown in Figure 6b. It is not clear how E3 ligases act processively to build up Ub_n chains (up to Ub_{20}) tethered to proteins in cells.

Monoubiquitylation and polyubiquitylation consign proteins to relocation in cells, most often with the net consequence of proteolytic degradation, albeit by quite different mechanisms. Protein monoubiquitylation at a Lys-ε-NH_2 group by an E3 ubiquitin ligase can initiate relocation of transmembrane receptor proteins from the plasma membrane to the trans Golgi network sorting compartments.[24–26] The covalent Ub tag is information-rich and recruits various partner proteins that contain one or more of several variants of Ub-binding domains. The partner proteins can act as chaperones for internalization of the ubiquitylated receptor, import into early endosomes, and transit to lysosomes in which lysosomal proteases can cause hydrolytic degradation (Scheme 5).[23] These pathways are part of the homeostatic regulation of receptor density and lifetimes at plasma membranes.

In contrast to the sorting fate of monoubiquitylated proteins, polyubiquitylation sends modified proteins to the chambered proteases that constitute the proteasome. Tandem attachment of four or more ubiquitin molecules to such a lysine side chain constitutes an architectural signal that recruits protein chaperones with ubiquitin-binding domains. The chaperone complexes then escort the marked protein to the proteasomes,[27] where the chaperones dissociate, and the polyubiquitin chain is removed hydrolytically, perhaps during ATP-driven unfolding of the targeted protein (Scheme 6). The unfolded protein is then threaded

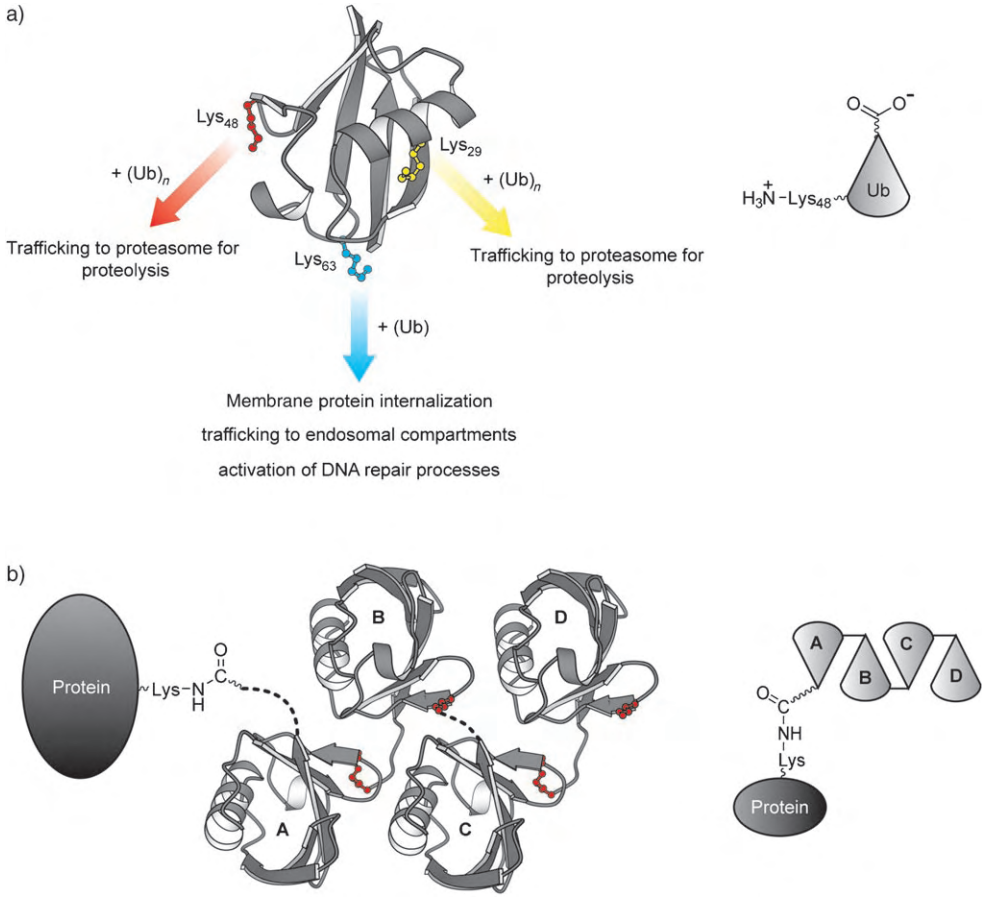

Figure 6. a) 3D trace of the 76-residue ubiquitin: $Lys_{29,48,63}$ side chains on different faces of ubiquitin offer different surfaces for tandem conjugation of growing polyubiquityl chains; b) structure of a tetraubiquityl unit, the minimum chain length to direct polyubiquitylated proteins to the proteasome.

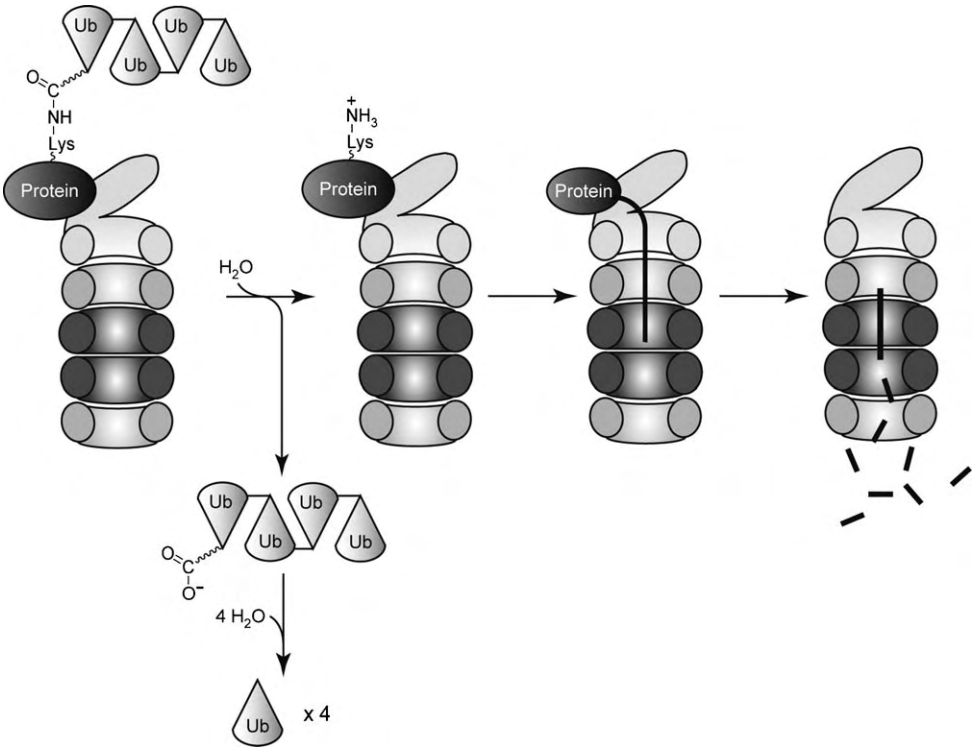
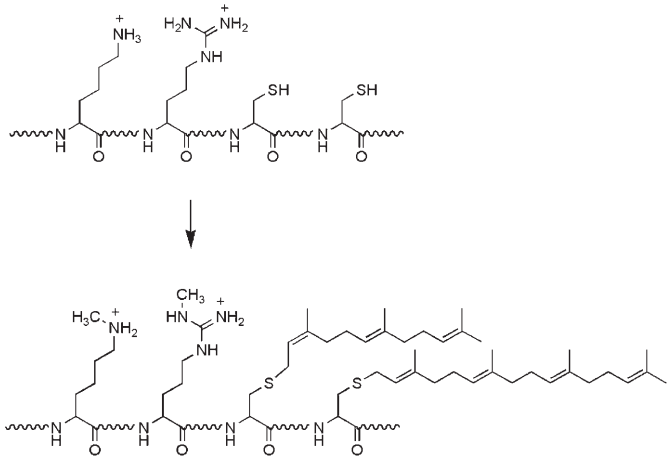
into the chamber of the proteasome where the active sites of the protease subunits degrade it to small peptides. The characteristic temporal control of proteins destroyed during the cell cycle, such as the cyclin subunits of cyclin-dependent protein kinases,[28,29] is effected by the E1–E2–E3 ubiquitin ligase machinery. The activity of various multisubunit E3 ligases can be controlled by posttranslational states of the catalysts or of the target proteins, such as phosphorylation of particular Ser and Thr residues.



Scheme 6. Recognition of Ub_n-tagged protein for chaperoning to proteasomes where the Ub_n tag is retrieved by hydrolysis of the isopeptide link to the target protein; the target protein is unfolded and threaded into the chamber of the proteasome.

2.3. Protein Alkylation

Alkyl substituents are attached regiospecifically to proteins by posttranslational modification enzymes. The three common alkyl groups transferred are the methyl (C_1), for example, in histone methylations of Lys and Arg side chains,[30] or the C_{15} and C_{20} isoprenyl (farnesyl and geranylgeranyl) groups (Scheme 7).[31] The small C_1 and the large



Scheme 7. Alkyl groups transferred to protein side chains: the methyl group from *S*-adenosylmethionine (SAM) is transferred most often to Lys and Arg side chains (although O-, S-, and C-methylations of protein side chains are known); the two isoprenyl units transferred by protein prenyltransferases to Cys side chains are the C_{15} (farnesyl) and the C_{20} (geranylgeranyl) groups from the corresponding prenyl diphosphate substrates.

hydrophobic C_{15} and C_{20} groups each serve to introduce hydrophobicity but they do so to very different degrees.

2.3.1. N-Methylations

Whereas C-, O-, and S-methylations of protein side chains are known,[3] the reactions of most contemporary interest are the N-methylations of Lys and Arg side chains, particularly on the same histone tails that are acetylated. Indeed, covalent posttranslational N-methylation of histone tails complements acetylation as the second main part of writing and reading the histone code (Figure 7). For example, 7 of the first 36 residues, $Arg_{2,17,26}$ and $Lys_{4,9,27,36}$ of histone H3 are known to be methylated

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

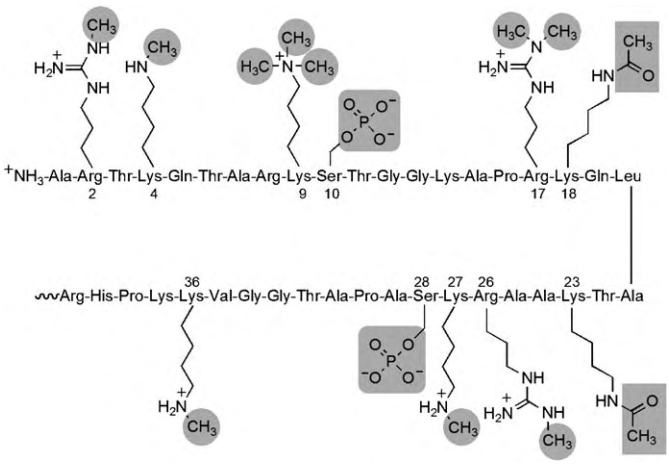


Figure 7. N-methylations can occur at $Arg_{2,17,26}$ and $Lys_{4,9,27,36}$ of histone H3. Lys_{18} and Lys_{27} can be acetylated and Ser_{10} and Ser_{28} phosphorylated.

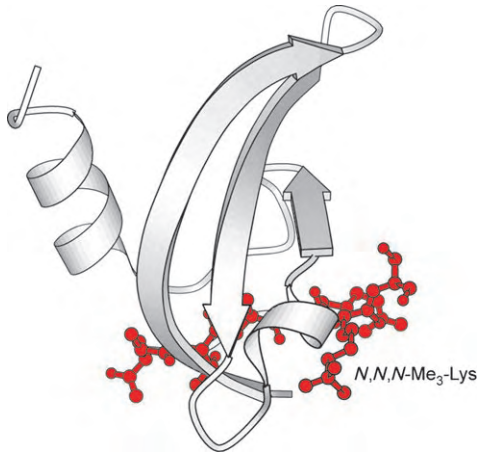

Figure 8. *N*,*N*,*N*-Trimethyl-Lys_9 of histone H3 as a ligand to recruit protein HP1 through its chromo domain.

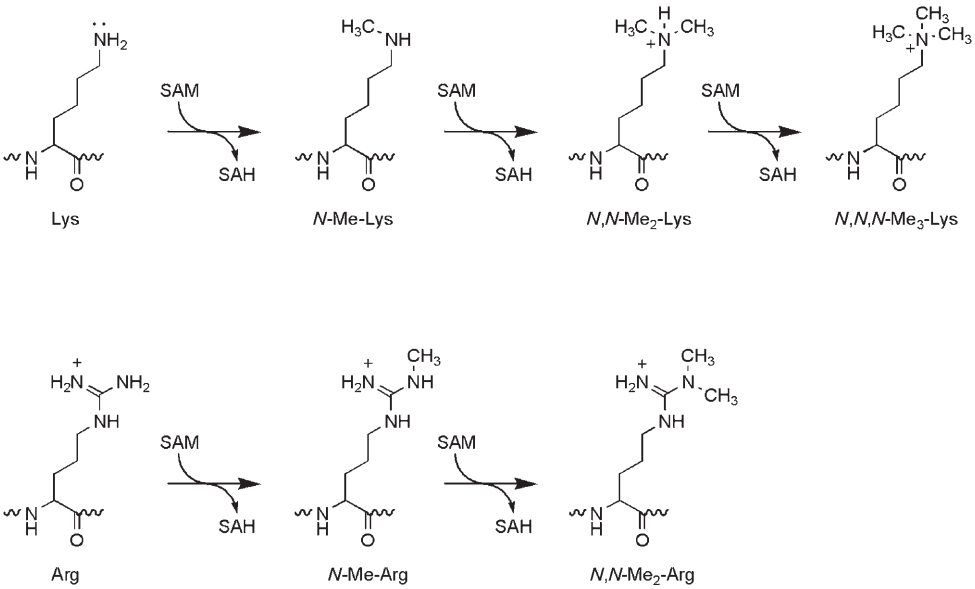
by a family of histone methyltransferases,[32] several of which are residue-specific. An additional layer of information content and combinatoric complexity is enabled by the fact that Lys-ε-NH_2 groups can be progressivly mono-, di-, or trimethylated, again with distinct distributions shown by different methyltransferases. Analogously both monomethyl- and dimethylArg residues are observed (Scheme 8). The size and hydrophobicity differences between monomethyl- and trimethyl substituents on Lys side chains enable selective recruitment of proteins involved in transcriptional control. For example, trimethyl-Lys_9 in H3 recruits partner protein HP1 by binding to its chromodomain (Figure 8) as part of transcription factor and coactivator protein complex assemblies.[14,32]



Scheme 8. Progressive mono-, di-, and trimethylation of Lys side chains and mono- and dimethylation of Arg side chains in histone N-terminal tail regions. SAH = *S*-adenosylhomocysteine.

N-Acetylations and N-methylations of side chains in histone tails can have opposite effects on gene transcriptional silencing and activation. Histone H3 is just one of the four histones, each present as a dimer, in the nucleosome core. The balance of the four acetylations and seven methylations on the tail of histone H3 give, on this subunit alone, $11 \times 2 = 22$ sites for titration of transcriptional coactivator and corepressor complexes.

2.3.2. *Protein S-Prenylation*

The C_{15} farnesyl and C_{20} geranylgeranyl lipid groups are built up from C_5 isoprenyl diphosphate primary metabolites by iterative alkyl extension by action of C–C bond-forming enzymes.[33] The farnesyl and geranylgeranyl-PP molecules can be used for further isoprene elongation (e.g. C_{15} dimerization to squalene in the cholesterol biosynthetic pathway) or they can be utilized as electrophilic alkyl donors in posttranslational protein prenylation (Scheme 9).[34] There are protein farnesyltransferases and protein geranylgeranyltransferases, which are αβ heterodimers that share a common α subunit. The Ras GTPase superfamily have members that can be prenylated on Cys thiolate side chains, some with the C_{15} and some with the C_{20} prenyl chain. Typically, Ras family proteins that have a CaaX motif at the C terminus are farnesylated, when X is a small amino acid such as Ala or Ser. When X is Leu as in both Rac and RhoA GTPases, then the cysteine residue (C) is geranylgeranylated (Scheme 10a). The Rab subfamily of GTPases, over 60 in number, have two cysteine residues at or near the C terminus, for example, in a CCXX arrangement. Both cysteine groups undergo posttranslational gera-

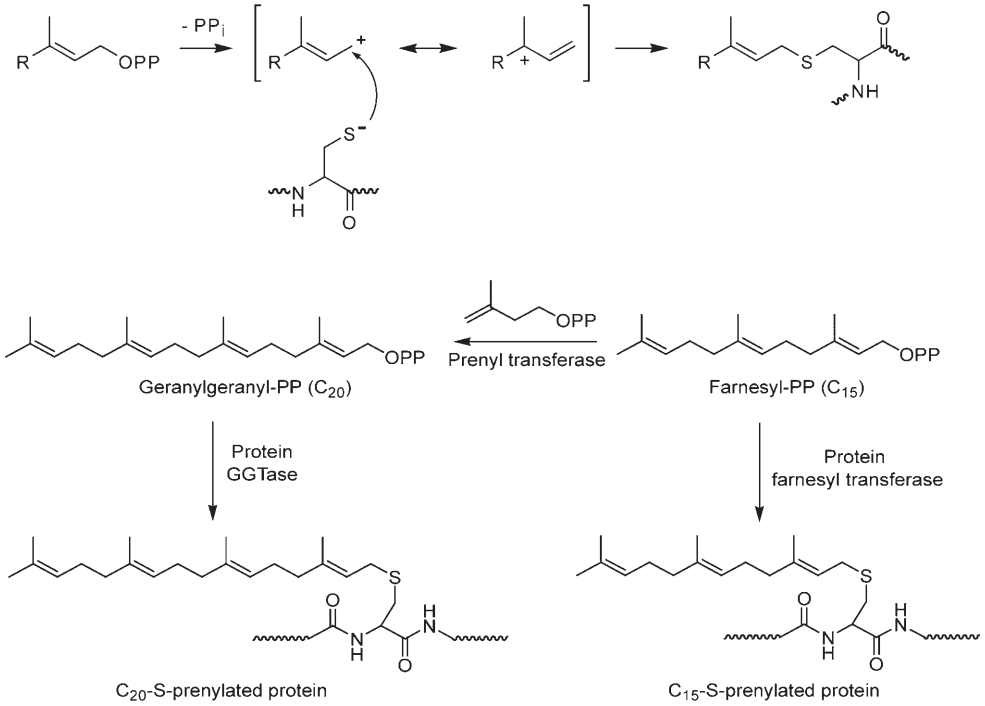


Scheme 9. Mechanism for Cys S-isoprenylation by protein prenyltransferases.

nylgeranylation (Scheme 10b), thus introducing two C_{20} lipid anchors.[35] Rab proteins cycle between membrane vesicles in the secretory system; escort proteins are used to control location and cycling.[36,37]

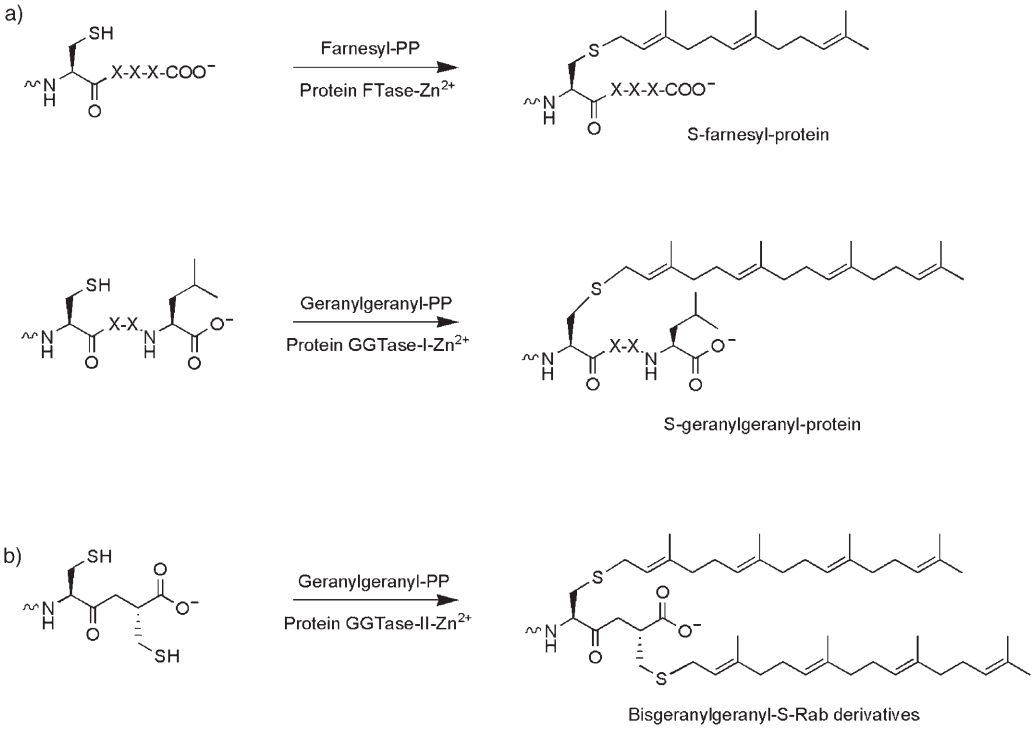
Some proteins undergo both N- and S-acylation and some combination of S-prenylation. All of these lipid anchors drive the modified proteins to partition more to membranes, thus controlling subcellular localizations.

2.4. Protein Glycosylation

Covalent glycosylation of proteins is relatively rare in prokaryotes and quite common in eukaryotes. C-glycosylation, O-glycosylation, and N-glycosylation of proteins are known, but C-glycosylation, specifically mannosylation of C2 of the indole ring of tryptophan residues,[38] is quite rare.

2.4.1. N-Glycosylation

N-glycoproteins are both more common and typically more complex in structure and architecture than O-glycoproteins in eukaryotes.[39] The branching glycan unit in N-glycoproteins is preassembled on a lipid diphosphate scaffold by a series of membrane-associated glycosyltransferases in the endoplasmic reticulum.[40] The assembled N-glycan unit that serves as a substrate for the multisubunit oligosaccharyltransferase is a tetradecasaccharyl-PP-dolichol substrate



Scheme 10. Prenylation reactions at the C termini of the Ras protein superfamily: a) farnesylation of the C terminus of Ras at CaaX (X = Ala, Ser). Geranylgeranylation of Rac at CaaX (X = Leu); b) double geranylgeranylation of the CC carboxy terminus of Rab proteins.

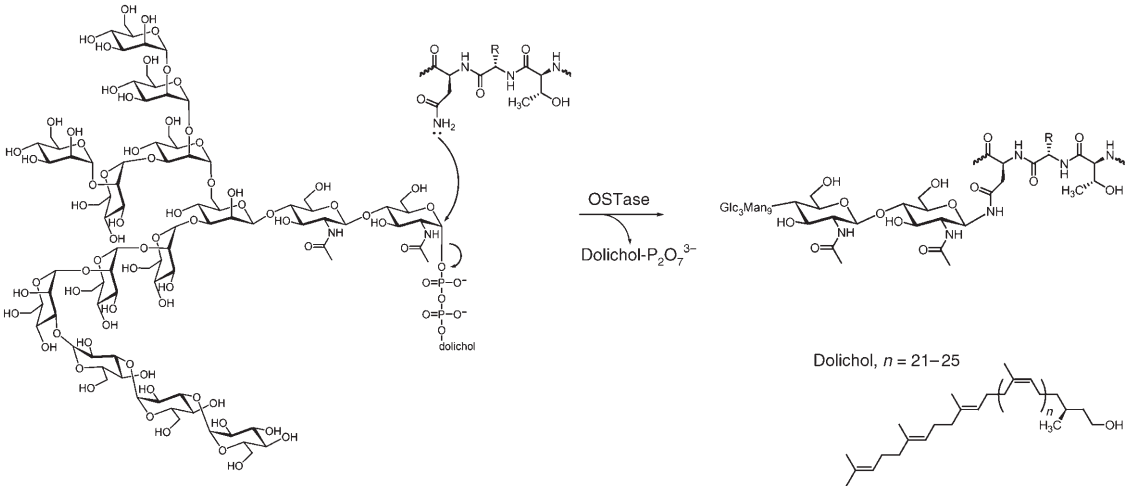
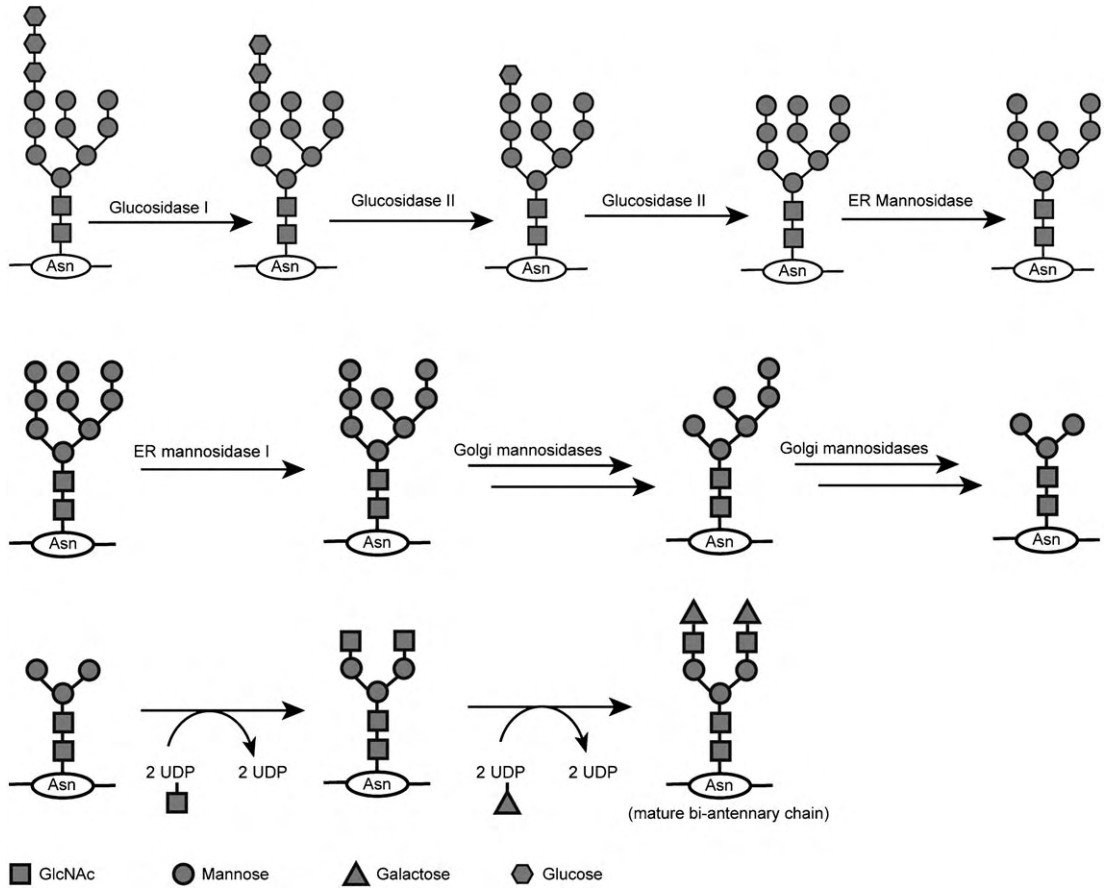


Scheme 11. The branched tetradecasaccharyl-PP substrate is the donor substrate in the Asn N-glycosylation reaction catalyzed by the oligosaccharyltransferase that initiates N-glycoprotein modifications.

(Scheme 11).[41] The side-chain atoms that are modified in N-glycoprotein biogenesis are the carboxamide nitrogen atoms of asparagine groups, almost always in the sequence Ser/Thr-X-Asn. The low nucleophilicity of the Asn $CONH_2$ is thought to be enhanced by hydrogen bonding to the Ser/Thr-OH side chain but the initial glycan transfer step is still poorly understood.

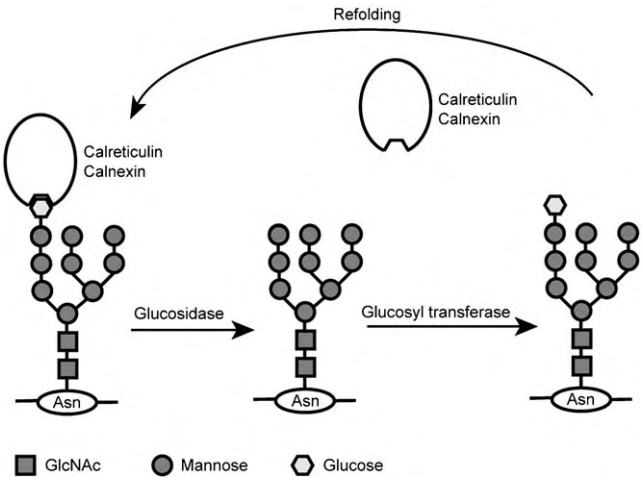
The initial tetradecasaccharyl chain $Glc_3Man_9(GlcNAc)_2$ then undergoes a remarkable enzymatic hydrolytic trimming and refashioning of the identity and linkages of the N-glycan chains (Scheme 12). The first hydrolytic tailoring enzymes are



Scheme 12. Progressive trimming of the initial N-linked $Glc_3Man_9(GlcNAc)_2$ glycan chain to $Man_9(GlcNAc)_2$ in the ER and then to the core pentasaccharide $Man_3(GlcNAc)_2$ in the Golgi complex before being built back up to mature N-glycan chains found on N-glycoproteins that have transited the secretory system.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

two glucosidases in the ER lumen which generate the dodecasaccharyl $GlcMan_9(GlcNAc)_2$ N-linked proteins. These are ligands for calnexin and calreticulin, protein chaperones that recognize the dodecasaccharyl chain and help refold the nascent glycoproteins as they are extruded through the ER membrane into the lumen. As the remaining Glc is hydrolyzed by the ER glucosidase, the chaperones lose affinity for the undecasaccharyl-N-protein products. A UDP-glucose glycoprotein glucosyltransferase[42] puts the Glc residue back on the undecasaccharide unit to give the calreticulin and calnexin chaperones another round of assisted refolding. Thus, this is a refolding/protein-quality-control way station during glycoprotein secretion. If the glycoprotein cannot be refolded after several cycles of deglucosylation/reglucosylation, it is targeted for export back to the cytoplasm. There it undergoes polyubiquitylation, and proteasome-mediated degradation of the unfolded protein by a glycoprotein-targeting E3 ligase as part of the ER-accelerated degradation (ERAD) quality-control pathway (Scheme 13).[42]



Scheme 13. Cycling of the oligosaccharyl chain between $GlcMan_9(GlcNAc)_2$-Asn and $Man_9(GlcNAc)_2$-Asn in the ER from opposing action of glucosidase and UDP-glucose glycoprotein glucosyltransferase. The Glc-containing oligosaccharyl chain is recognized by the chaperone proteins calreticulin and calnexin to help refold the nascent N-glycoproteins that have been glycosylated and extruded cotranslationally into the ER lumen. The glucosylation cycle is part of the protein quality-control system for proteins secreted into the endoplasmic reticulum.

For $Man_9(GlcNAc)_2$–N-glycoproteins that have refolded and passed into the Golgi compartment, six of the mannose residues are then trimmed hydrolytically by mannosidases to yield the $Man_3(GlcNAc)_2$ pentasaccharyl core found in all mature N-glycoproteins. At this point the branched oligosaccharide core is rebuilt back up to biantennary and triantennary oligosaccharides characteristic of mature N-glycoproteins present on the cell surface.[43] The multiplicity of glycosyltransferases in the Golgi can create enormous diversity in the mature N-glycan chains.

Multiple Asn side chains can be glycosylated in a given protein, and the identity of the glycan chains at each Asn residue can vary depending on stochastic encounters with at least 10 trimming and rebuilding enzymes during passage through the ER and Golgi compartments.[41,43] It has been estimated that about a third of all proteins that enter secretory pathways in eukaryotic cells may be N-glycosylated, and so tens of thousands of glycoprotein variants may coexist in eukaryotic cells. For example, 52 glyco forms of the prion protein have been reported.[44,45]

2.4.2. *O-Glycosylation*

O-glycosyl chains in eukaryotic proteins are generally shorter and less complex than those in N-glycoproteins. Many proteins contain the monosaccharide GlcNAc[46] that is put on by a specific O-GlcNAc transferase and removed by a corresponding hydrolase. Other proteins such as the signaling protein Notch contain tri- and tetrasaccharides in the EGF repeat domains (Figure 9).[47,48] O-glycosylation is a crucial

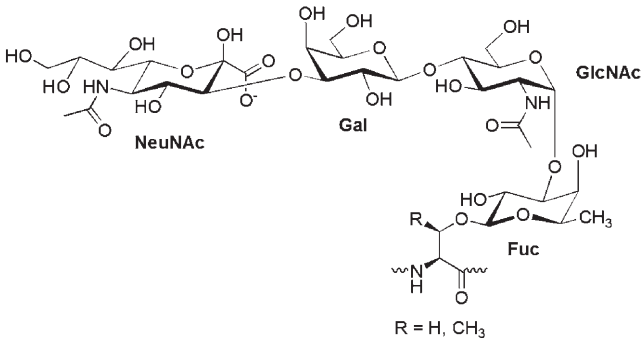


Figure 9. The O-linked tetrasaccharide sialyl-α-2,3-Gal-x-1,4-GlcNAc-β-1,3-fucosyl-Ser attached to the protein Notch during its transit through the secretory pathway on the way to the cell surface.

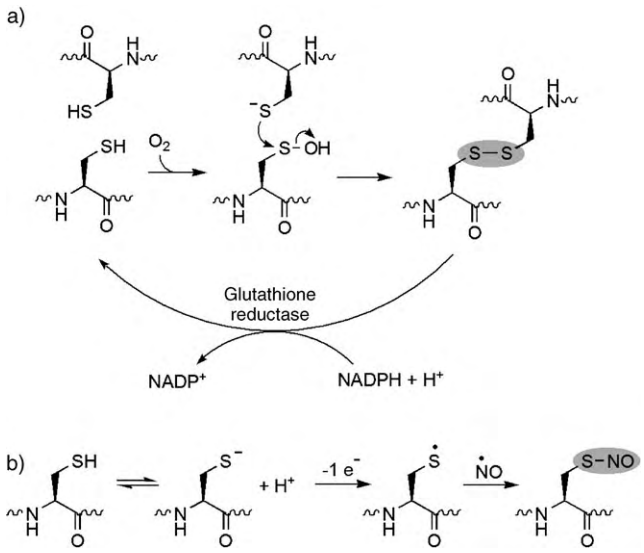
part of the maturation of Notch during its transit through the secretory pathway to the cell surface. The short O-linked sugar chains are important in a variety of functional contexts, from modulating transcription factor activity,[49] to acting as essential recognition elements in signaling by Notch at cell surfaces.[50,51]

2.5. *S–S Bond Formation*

Two main types of linkages serve to cross-link proteins, or portions of proteins, covalently. By far the more common are disulfide links from oxidation of cysteinyl residue thiolate side chains.[52,53] The cytoplasmic and nuclear compartments in eukaryotic cells are reducing microenvironments, as reflected in the 100:1 ratio of the redox-active tripeptide glutathione in reduced (GSH) to oxidized (GSSG) state.[54] The high reducing ratio is maintained by the high levels of NAD(P)H and enzymes, such as glutathione reductase and thioredoxin reductase[3] that use the reduction potential of NAD(P)H to re-reduce disulfides in proteins that have become oxidized (Scheme 14a). As proteins pass through the secretory pathway in eukaryotic cells, the levels of total glutathione and reduced nicotinamide coenzyme fall, compartments become

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



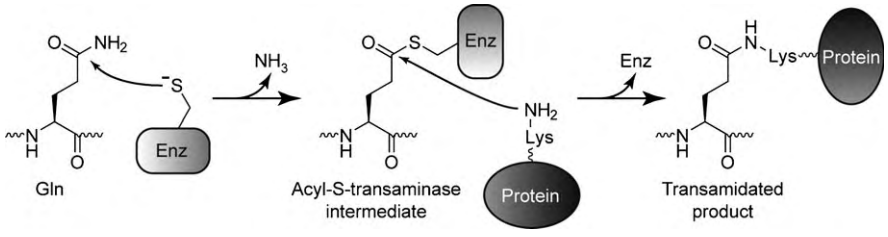
Scheme 14. Oxidation of thiolate side chains of cysteine residues: a) oxidation of dithiols to disulfides (for example via sulfenic acid intermediates) and reversible reduction back to dithiols by glutathione reductase action; b) oxidation of Cys-S^- side chain to S-nitrosyl-Cys by nitric oxide (·NO).

more oxidizing, and disulfide links predominate. The disulfide bonds may stabilize protein architectures as proteins reach cell outer surfaces or are excreted into extracellular spaces. The formation of disulfide bonds in zymogen forms of pancreatic protease as they are packaged into the oxidizing microenvironment of zymogen granules is a prototypical case.

The mechanism for oxidation of protein dithiols to disulfides typically involves oxidation of the electron-rich thiolate side chains of Cys residues. One-electron oxidation would yield thiyl radicals that could dimerize to the disulfides. Alternatively, thiolate side chains can be oxygenated by a variety of oxygen-derived oxidants (peroxide, hydroxyl radical) to generate sulfenic acid (-SOH) side chains. Capture of the sulfenate by a neighboring Cys-S^- generates disulfides. Regeneration of the dithiol forms is mediated by thiol–disulfide interchange using reduced glutathione or the low-molecular-weight dithiol protein thioredoxin (TSH). The oxidized GSSG or TSST are recycled at the expense of NADPH oxidation by thioredoxin reductase and glutathione reductases.

The electron-rich thiolates and the thiyl radicals can be captured by other oxidants and radicals, including ·NO. Such S-nitrosylation of thiolate side chains of cysteine residues is documented in many proteins by radical species derived from nitric oxide (Scheme 14b). These Cys-SNO moieties have been proposed to be widespread in oxidative signaling events.[55]

The second PTM cross-link strategy is nonoxidative and involves transglutaminase catalysis in which glutamine side chains in protein substrates are deaminated via acyl-S-transaminase intermediates, which are captured by Lys-ε-NH_2 groups to effect net transamidations (Scheme 15).[56,57]



Scheme 15. Nonoxidative cross-links introduced by transglutaminases; the amide bond in Gln side chains is replaced by the ε-NH of Lys to create Glu-ε-Lys isopeptide cross-links.

3. Covalent Addition: The Supporting Cast

While the five chemical types of posttranslational modifications discussed in Section 2 are abundant and well-characterized in cells, there are many additional classes of purposeful enzymatic modification of proteins that expand the metabolic and signaling capacities of organisms.

3.1. Protein Hydroxylation

One additional category of protein posttranslational oxidation is enzyme-mediated hydroxylation. Hydroxylations occur at nonnucleophilic sites in aminoacyl side chains to generate 3-OH-Pro, 4-OH-Pro, and 5-OH-Lys (Figure 10) in collagen at Pro-Gly and Lys-Gly sites. These hydroxylations are key modifications for proper maturation of collagen fibers.[58] Some of the 5-OH-Lys residues are then subsequently tandemly glycosylated on the newly introduced OH group to create an O-disaccharide linkage. 4-Hydroxyproline modifications, about tenfold more abundant than the hydroxylations at C3 of Pro residues, are involved in the triple helical strands of collagen, with the 4-OH pointing away from the helix.

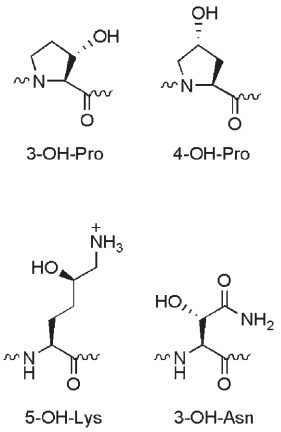


Figure 10. Hydroxylated amino acid residues generated by posttranslational Fe^{II}-dependent monooxygenases: 3-OH-Pro, 4-OH-Pro, 5-OH-Lys, 3-OH-Asn.

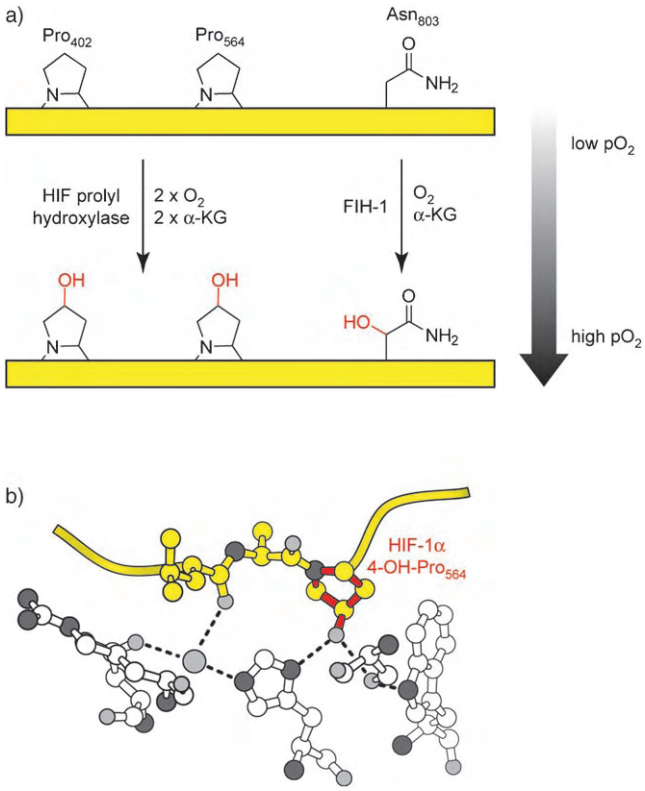
A third side chain in which a CH_2 group is converted into CH-OH is

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

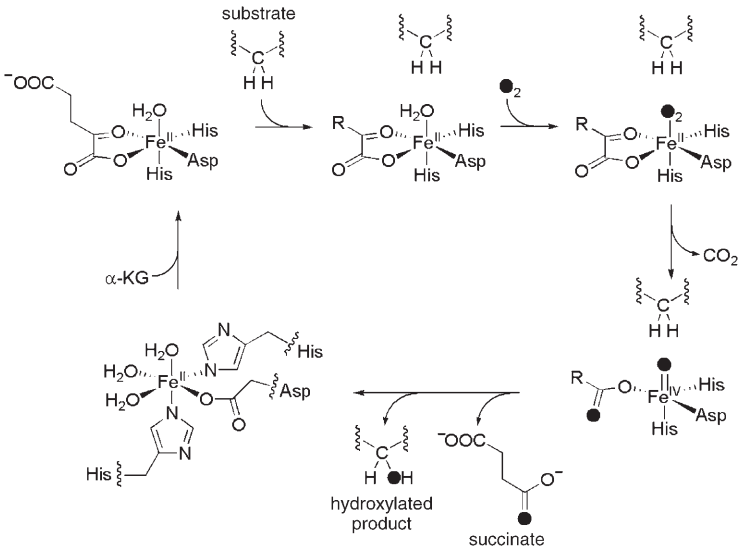
Asn (to 3-OH-Asn, Figure 10) in a small number of proteins, including the transcription factor HIF (hypoxia inducible factor).[59] HIF transcription is initiated at low partial pressures of O_2 and induces the transcription of hundreds of genes, including the gene that encodes erythropoietin to make more red cells that can carry more O_2 to hypoxic tissues.

The HIF-1α subunit in the HIFαβ heterodimer is post-translationally hydroxylated by hydroxylases, one specifically acting at two Pro residues to create 4-OH-Pro[60] and the other acting at a particular Asn residue to generate 3-OH-Asn.[61] These are determinative changes in the oxygen-sensing cascade in mammalian tissues (Scheme 16).[62] The lifetime of the HIF-1α subunit in cells is controlled by proteolysis in the ubiquitylation pathway, which involves chaperoned escort to the proteasome, unfolding, and threading into the proteasome chamber for proteolysis to limit peptides. The polyubiquitylation of HIF-1α is carried out by a particular E3 ligase, the von Hippel-Lindau (VHL) protein.[63,64] The hydroxylation status of Pro_{402} and Pro_{564} in HIF-1α controls the affinity for the VHL E3 ligase.[60] At low pO_2 in cells the Pro hydroxylase is not saturated with its substrate O_2 and has low activity. At high pO_2 the hydroxylase is active and converts the two Pro residues into 4-OH-Pro residues. The hydroxy side chain in $HO\text{-}Pro_{564}$ provides about a 1000-fold tighter binding of modified HIF-1α over unmodified HIF-1α for the VHL ubiquityl ligase.[60] This is the mechanism for selective polyubiquitylation of the hydroxylated forms of HIF-1α, which leads to its proteasome-mediated destruction at high pO_2 levels but its persistence at low pO_2. Persistence means a longer lifetime for the heterodimeric HIF-1αβ and the longer gene-transcriptional-activation response characteristic of hypoxia.

The protein hydroxylases that catalyze the side-chain hydroxylations noted in this section belong to the family of non-heme Fe^{II} monooxygenases that have two His and one Asp side chains to provide three of the six coordination sites to the Fe^{II} (Scheme 17).[65] Two additional coordination sites are filled by cosubstrate α-ketoglutarate and the sixth by O_2. When both O_2 and α-KG are bound, the organic diacid is oxidatively decarboxylated to succinate. O_2 is cleaved in such a way that one atom ends up in succinate and the other is coordinated to the iron as a high-valent $Fe^{IV}=O$. This high-valent oxoiron complex is a sufficiently powerful oxidant to cleave the unactivated C–H bonds at C3 and C4 of Pro residues, C5 of Lys residues, and C3 of Asn residues to generate transient ·CH radicals and Fe^{III}-OH. OH· transfer from the Fe^{III}-OH to the carbon-centered radical yields the hydroxylated protein side chains. The polarity of these side-chain hydroxylations is quite distinct from the bulk of the other posttranslational modifications considered in this Review. The amino acid side chains undergoing modification are not electron rich or nucleophilic. Instead, the iron-based modifying enzyme generates a powerful oxidant and leads to homolytic cleavage of unactivated C–H bonds with regio- and stereospecificity.



Scheme 16. a) Hydroxylation of Pro and Asn residues in the HIF-1α subunit; b) interaction of the $HO\text{-}Pro_{564}$ residue of HIF with the E3 ligase that will catalyze polyubiquitylation of HIF.



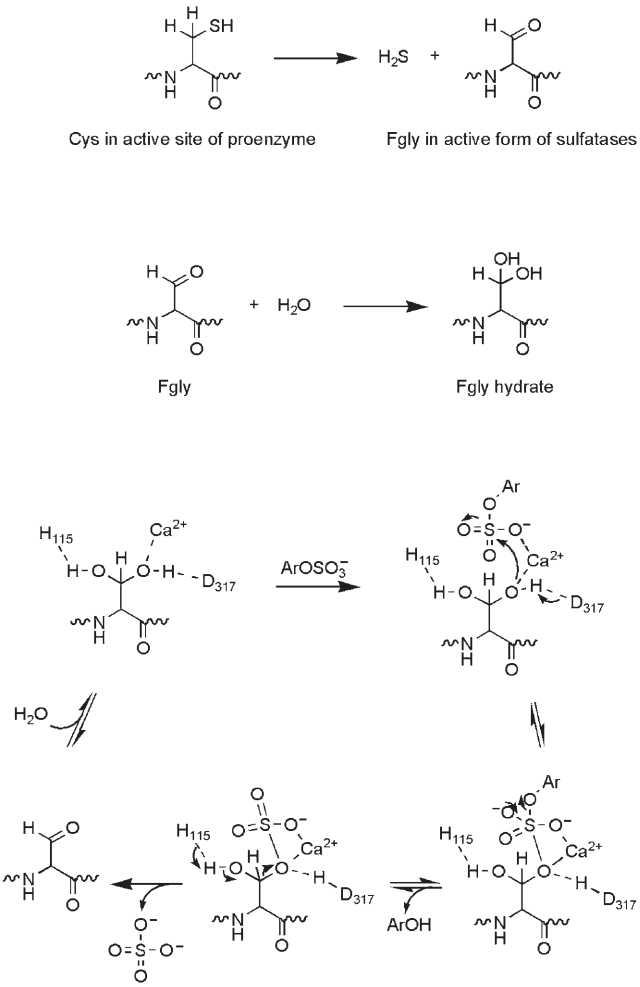
Scheme 17. Mechanism of protein hydroxylation by the nonheme Fe^{II} monooxygenases. The active site iron(II) is coordinated by three residues from within the protein (two His, one Asp). Subsequent coordination by α-ketoglutarate and O_2 results in the cleavage of dioxygen and formation of a high-valent $Fe^{IV}=O$ species. This iron complex cleaves the unactivated C–H bond of the substrate, yielding hydroxylated product and succinate.

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

3.2. Protein Sulfur Transfer

Phosphoryl groups are not the only inorganic moieties transferred to protein side chains. The SO_3^- group is also transferred from phosphoadenosine phosphosulfate (PAPS) to tyrosine side chains in proteins.[66] PAPS is the biological reagent for transfer of activated sulfuryl (SO_3^-) groups to nucleophiles in both small molecules (e.g. oligosaccharides such as heparin[67]) as well as proteins and proteoglycans. Enzymatic sulfation of four tyrosine residues occur in the Golgi complex at the N-terminus of the CCR5 receptor (Scheme 18) during its transit to the plasma membrane[68] where the N-terminus is displayed at the extracellular surface. This cluster of anionic Tyr-OSO_3^- modifications is important for recognition by the CCR5 chemokine ligand.

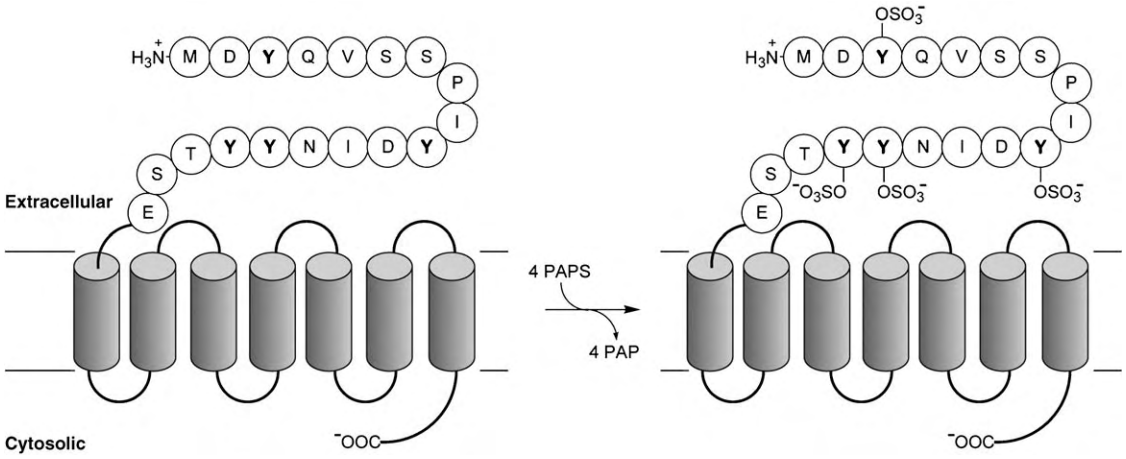
Once sulfated molecules are internalized, the sulfate ester bond is hydrolyzed enzymatically by sulfatases in the secretory compartment, predominantly in lysosomes.[69–71] The set of sulfatases known to degrade aryl sulfate ester substrates are themselves in inactive proenzyme forms until they undergo posttranslational activation. This involves oxidative conversion of an active-site cysteine residue into an aldehyde in the form of formylglycine (Fgly).[70] This conversion of a thiolate nucleophile into an electrophilic carbonyl is followed by a hydration equilibrium to distribute the Fgly between the aldehyde and the *gem* diol, the aldehyde hydrate (Scheme 19). It is the hydrated form of the aldehyde group in the formylglycine side chain that initiates covalent attack on sulfated protein substrates bound in the sulfatase active sites[72] with resultant O–SO_3^- bond cleavage.



Scheme 19. Oxidative conversion of an active site Cys-S^- to the aldehyde of formylGly (Fgly) converts inactive precursors of sulfatases to active catalysts. Hydration of the Fgly side chain generates a *gem* diol, which is the active nucleophile that attacks the Ar-OSO_3^- substrate on sulfur to initiate the O-SO_3^- bond cleavage.

3.3. Protein Modification by Bacterial Toxins

Bacteria that invade eukaryotic cells secrete a complement of proteins into the host cell to neutralize its defense mechanisms. Among these virulence factors are three types of enzymes that act as posttranslational modification catalysts for ADP ribosylation, glucosylation, and deamidation of host target proteins.[3]



Scheme 18. Transfer of four SO_3^- groups from PAPS to the phenolate oxygen atoms of four side chains of Tyr residues at the N-terminal region of the CCR5 receptor during its passage through the secretory compartments to the cell surface.

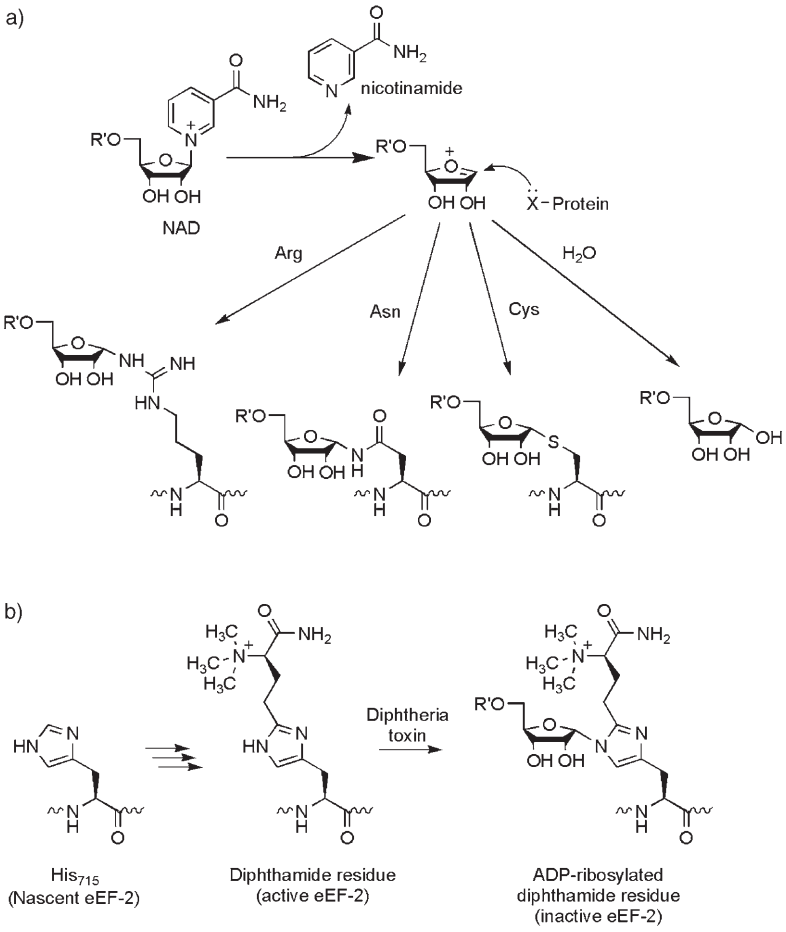
3.3.1. ADP Ribosylation

Several famous bacterial exotoxins, including the cholera toxin, the diphtheria toxin, the pertussis toxin, and the botulinum C3 toxin,[73] are ADP ribosyltransferases. The donor substrate of the ADP ribosyl moiety is the readily available coenzyme NAD. The positively charged nicotinamide group departs in a transition state involving the ribaoxacarbenium ion of the transferring ADP ribosyl group (Scheme 20a). This ion can be captured by robust nucleophiles in protein cosubstrates in the active site of the toxin, such as thiolate side chains of Cys, for example when pertussis toxin modifies the α subunit of the inhibitory GTPase G_i that regulates cyclic AMP production. The transferring ribaoxacarbenium ion can also be captured by weak nucleophiles such as the guanidino group of Arg in the α subunits of the G_s GTPase by the cholera toxin. Another example of the capture of the potent electrophilic form of the ADP ribosyl moiety is the modification of the weakly nucleophilic Asn_{41} in the Rho subfamily of small GTPases by the C3 toxin from *Clostridium botulinum*, ultimately leading to a net depolymerization of the actin mesh work in the host cell.

A fourth example of bacterial toxin ADP ribosyltransferase activity on a specific host protein with deleterious consequence is the action of the diphtheria toxin on His_{715} in the protein synthesis factor eukaryotic elongation factor 2 (eEF-2). That histidine in mature eEF-2 has already undergone a preparatory set of posttranslational modifications involving the aminocarboxypropyl transfer from cosubstrate *S*-adenosylmethionine (SAM), N,N,N-trimethylation by three additional SAM molecules, and glutamine-mediated amidation to convert His_{715} into a diphthamide residue. This is the molecular form of eEF-2 that undergoes ADP ribosylation by the diphtheria toxin (Scheme 20b) and rendered inactive in its essential elongation functions, bringing host protein synthesis to a halt in the infected cell.[73]



Scheme 20. ADP ribosylation of protein substrates by bacterial toxins: a) Cleavage of NAD releases nicotinamide and generates a stabilized ribaoxacarbenium ion in the active site. This can be captured by a range of cosubstrate nucleophiles, from the robust Cys-S^- in pertussis toxin catalysis to the weak Asn and Arg side chains in botulinum and cholera toxins. Water is a natural nucleophile and leads to NAD glycohydrolase side reactions; b) diphtheria toxin catalyzes ADP ribosylation of a modified histidine residue in the eukaryotic host cell protein synthesis elongation factor eEF-2. The residue, His_{715} in the nascent eEF-2 undergoes five posttranslational steps of transfer of the methionyl moiety from SAM, N,N,N-trimethylation, and amidation to yield the diphthamide residue at position 715. This is the residue targeted for ADP ribosylation on N_3 of the imidazole ring by the diphtheria toxin.

3.3.2. Other Modification Activities of Bacterial Toxins

The Ras and Rho GTPase families are also targets of additional bacterial toxin enzymes that inactivate the GTPases by chemical modifications distinct from ADP ribosylation. One is the lethal toxin protein from *Clostridium sordelli* which also is a protein glycosyltransferase. In this case it is not transfer of the ADP ribosyl moiety from NAD but instead the transfer of a glucosyl group from UDP-glucose that is catalyzed by the protein toxin. The target nucleophile is the β-OH of Thr_{35} in Ras. This O-glucosylation blocks the catalytic activity of Ras.[74,75]

A distinct type of posttranslational modification strategy is deamidation of Gln_{61} in Rho by the cytotoxic necrotizing protein from pathogenic strains of *E. coli*.[76] This Gln carboxamide side chain is in the GTPase active site and its hydrolysis to the γ-COO^- of Glu_{61} disrupts the active-site machinery. Altogether, the small GTPase families, because they act as thermodynamic switches at so many cellular intersections of signaling and metabolism, are subjected to a diverse set of programmed chemical modifications. The covalent modifications alter localization and control function both in normal maturation and in pathogen interceptions.

3.4. Installation of Swinging-Arm Cofactors

Several enzymes central to primary metabolism are nonfunctional until posttranslation-

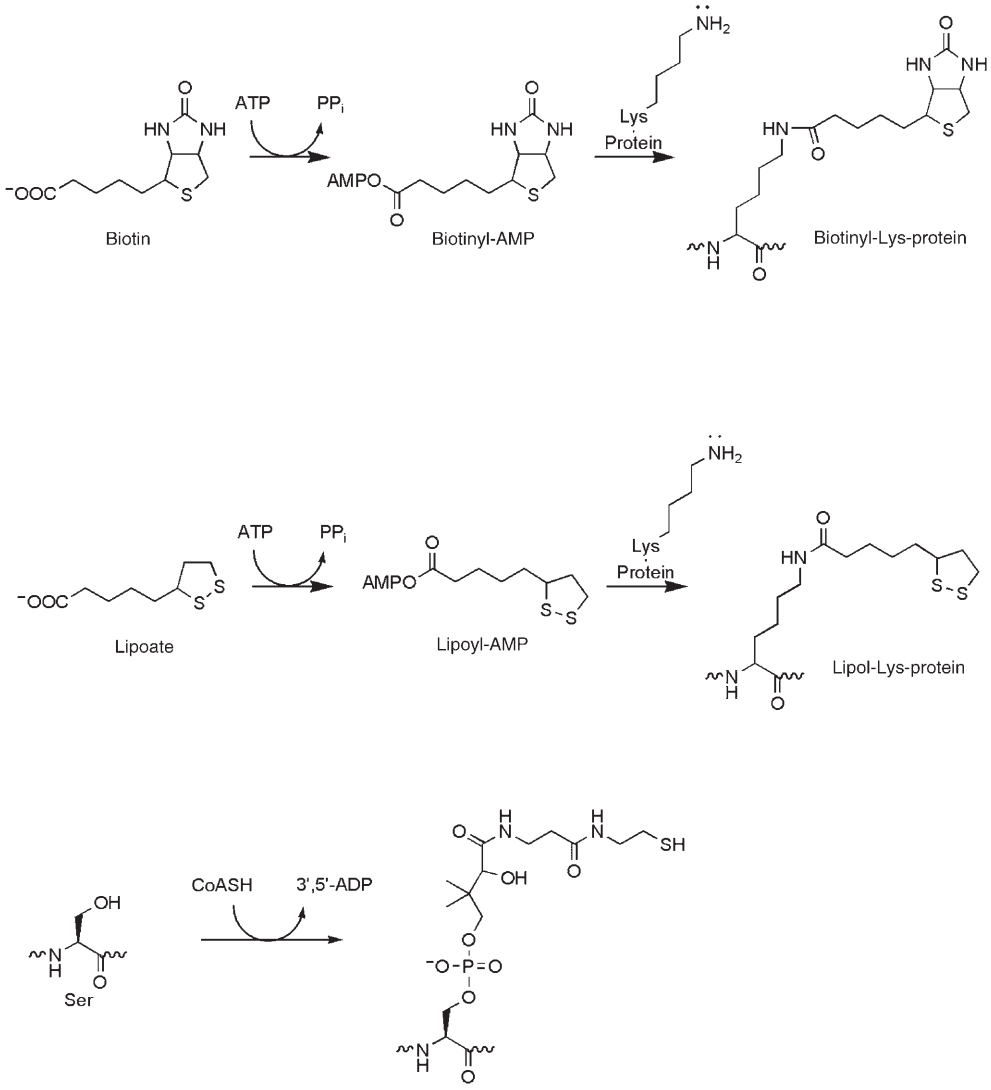
© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ally primed with prosthetic groups that provide key functional groups to enable acyl- and carboxyl-transfer chemistry. The acyl-transfer coenzymes are lipoic acid and phosphopantetheine. The carboxyl-transfer prosthetic group is biotin (Scheme 21). All three cofactors are covalently attached to side chains of target apo proteins by dedicated activating/loading enzymes. Biotin and lipoate can be activated as the acyl AMP species and captured by the ε-NH_2 of lysine side chains presented in folded 100-residue domains of the target proteins to create the biotinylamide and lipoamide linkages. The full reach of the Lys biotin and Lys lipoate chains is about 20 Å, leading to the historical connotation as swinging-arm prosthetic groups that can visit different domains in multienzyme complexes.[77] In analogous logic the phosphopantetheinyl moiety of CoASH as donor substrate can be captured by the β-OH side chain of a specific Ser side chain in a 80–100-residue acyl-carrier protein domain, again to create a tethered prosthetic group on a 20-Å pivot. In this case the chemical bond is not an amide linkage but a phosphodiester.

The tethered biotinyl cofactor is used for the transfer of C_1 groups in the form of CO_2. In carboxylases that fix HCO_3^- into acetyl CoA and propionyl CoA, to yield malonyl and methylmalonyl CoA products, there are multiple subsites or distinct subunits with different chemical functions. In the biotin carboxylase subunit, ATP is used as cosubstrate with HCO_3^- to generate a transient carboxyphosphate mixed anhydride that is captured by the biotinyl-Lys on the N_1 ureido nitrogen atom to produce N_1-carboxybiotinyl-Lys-enzyme (Scheme 22). This form of fixed CO_2 is shuttled to the active site where the C_2 carbanion on the acetyl moiety of acetyl CoA is generated and used to attack the N-carboxybiotinyl tether. This action leads to C–C bond formation as acetyl CoA is carboxylated to malonyl CoA, one of the key building blocks for fatty acid biosynthesis in cells.

The other two tethered coenzymes, lipoamide and pantetheinyl-phosphate, are used to ferry substrate-derived acyl groups between active sites of multidomain enzymatic assembly lines.[77,78] The lipoamide prosthetic group is found in all α-keto acid dehydrogenase complexes that carry out oxidative decarboxylation, for example, of pyruvate at the end of glycolysis and of α-ketoglutarate in the citric acid cycle. For example, in pyruvate dehydrogenation the disulfide form of the lipoamide cofactor is the electron sink for ring-opening capture by the C_2 carbanion of hydroxyethylthiamine-PP (Scheme 23). The transferring two-carbon fragment has been oxidized from the acetaldehyde to the acetate oxidation state and captured as an activated acetyl-*S*-lipoamide thioester as the disulfide link of oxidized lipoamide is reduced. This is the prototypic redox/energy-capture role for the lipoamide prosthetic group. In the second half-reaction, the acetyl-*S*-lipoamide arm moves to a separate active site and docks next to a CoASH molecule, thus allowing acetyl transfer to the thiolate of $CoAS^-$, an isoenergetic transfer that now releases the oxidized acetyl moiety as the diffusible cellular energy currency acetyl CoA.

A third example of cofactor tethering, the pantetheinyl moiety on acyl-carrier protein domains (ACPs), also offers a terminal nucleophilic thiolate for capture of acyl groups. Its central role in primary metabolism is in fatty acid biosynthesis in which acyl chains are built up by two carbon atoms at a time by cycles of Claisen condensation followed by redox tailoring to convert



Scheme 21. Coenzymes that are tethered in the active sites of enzymes to act as swinging-arm prosthetic groups, carrying CO_2 or acyl groups between active sites: biotin and the resultant biotinylamide-Lys; lipoate and the resultant lipoamide-Lys; CoASH and the resultant pantetheinyl-OPO_3-Ser linkages.

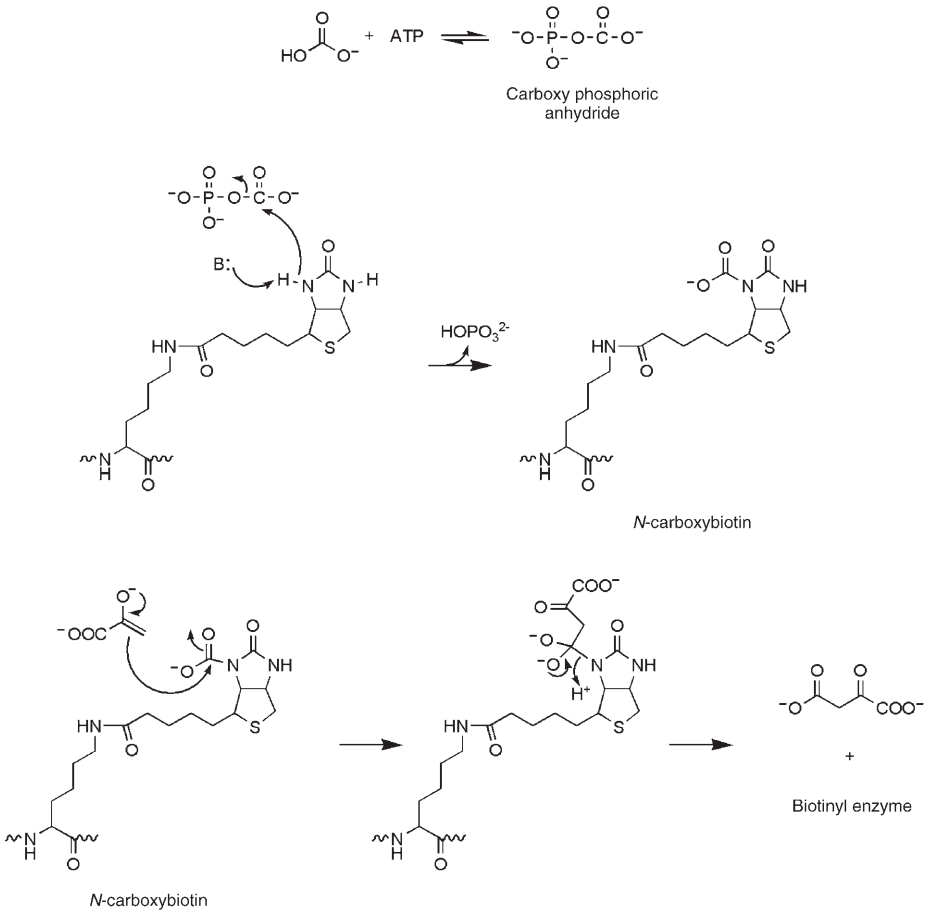
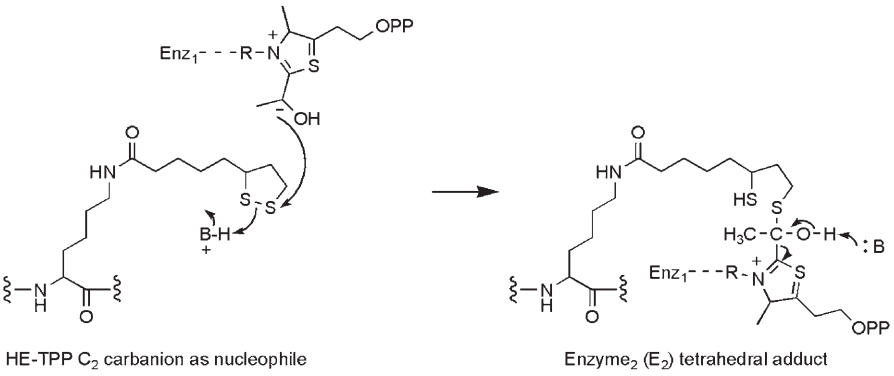
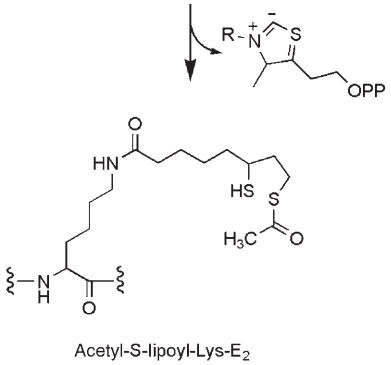


Scheme 22. N-carboxylation of biotinylamide by ATP and HCO_3^- in the biotin carboxylase active site followed by ferrying of the tethered CO_2 to the acetyl CoA carboxylation active site for C–C bond formation as malonyl CoA is produced.





Scheme 23. The oxidized disulfide form of lipoamide is the electron sink for capture by the C_2 carbanion of hydroxyethylthiamine pyrophosphate (HE-TPP), resulting in release of the TPP thiazole carbanion and generation of acetyl-S-lipoamide. The transferring two-carbon-atom fragment has undergone oxidation, the lipoamide disulfide has undergone reduction, and energy has been captured in the acetyl thioester linkage, which is maintained in subsequent transfer of the acetyl moiety to $CoAS^-$.

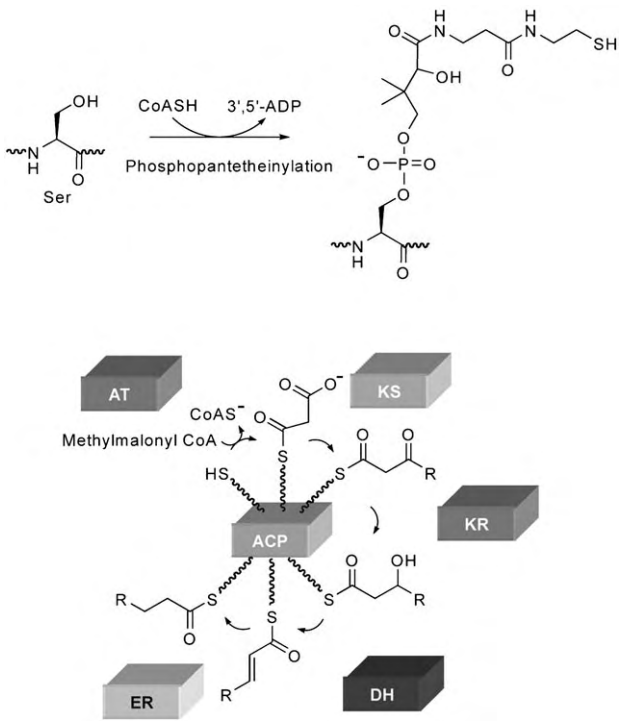
elongated beta keto acyl-*S*-ACP intermediate into the beta methylene acyl-*S*-ACPs for the next round of C_2-unit elongation (Scheme 24).[78] The acyl groups are proposed to visit ketosynthase, ketoreductase, dehydratase, and enoyl reductase active sites sequentially while tethered to the flexible phosphopantetheinyl arm.

It would appear that Nature has invented the coenzyme covalent tethering strategy in these three cases to fix small-molecule acyl fragments or CO_2 and ferry them to distinct sites on multienzyme complexes and assembly lines. There are other examples in which cofactors are tethered to lysine side chains of proteins, through hydrolyzable imine links between the Lys-NH_2 and an aldehyde carbon atom in the cofactor. This is true for the aldehyde form of vitamin B6, pyridoxal phosphate, in all pyridoxal phosphate dependent enzymes, and in the visual pigment proteins, the rhodopsins, in which vitamin A aldehyde (retinal) is the aldehydic chromophore.

3.5. Posttranslational Carboxylation of Glutamyl Residues for Bidentate Calcium Binding

A family of proteins involved in blood coagulation in mammals undergoes posttranslational modifications at sets of closely spaced glutamate residues during passage through secretory compartments on their way to the extracellular space. These modifications involve fixation of CO_2 to the γ-methylene carbon atoms of Glu residues, thus creating malonyl-type side chains, known as γ-carboxy Glu (Gla). The Gla side chains provide the possibility for bidentate chelation of divalent cations, of which interaction with Ca^{2+} ions is most significant. The proteins that undergo tandem γ-Glu carboxylation include the proenzyme forms of proteases such as prothrombin, proFac-

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 24. The terminal thiolate of the phosphopantetheinyl prosthetic group is the nucleophile that captures the starting acyl fragment in fatty acid biosynthesis and serves as the platform on which the acyl chain is elongated by two carbon atoms in each subsequent cycle. The pantetheinyl arm carries the growing acyl chain between the active sites of ketosynthase, ketoreductase, dehydratase, and enoyl reductase in each cycle, converting the β-ketone into the four-electron-reduced β-methylene oxidation state.

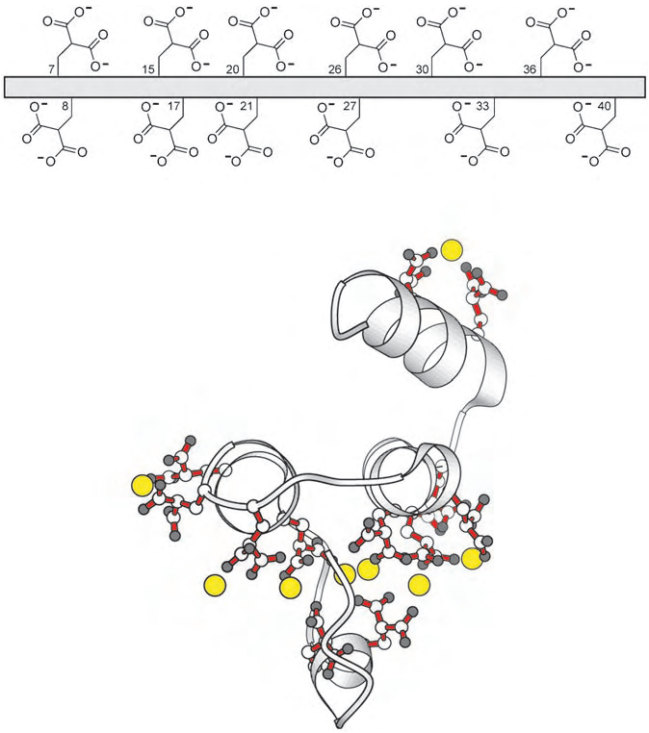


Figure 11. Twelve closely spaced Glu residues in the carboxylation domain of the pro form of the coagulation protease factor IX are modified to γ-carboxy-Glu (Gla) residues and provide a high local concentration of bidentate malonyl side chains for Ca^{2+} coordination. The 3D fold of dodecaGla region complexed to eight calcium ions (yellow spheres) emphasizes the divalent metal-ion-dependent structuring of this region of the protein.

tor IX, and proFactor X.[79] The carboxylation of 10–12 glutamate side chains to γ-carboxy-Glu residues in a 40-residue stretch of the proenzyme forms of proteases creates a local high density of bidentate chelators for Ca^{2+} ions (Figure 11). The conformations of the Gla domains are altered in the presence of Ca^{2+} and drive the association of the proteases on platelet surfaces, leading to the formation of protein complexes and the activation of neighboring proteases to initiate and propagate blood coagulation cascades.[79]

Unlike the carboxylation reactions discussed in Section 3.4, which use tethered biotin as the CO_2 carrier between the active sites of the enzymes, the Gla-forming carboxylations of glutamyl residue side chains do not use biotinyl amide dependent enzymes. Instead, the naphthoquinone vitamin K, in its only well-defined role in mammalian metabolism, is the requisite cofactor for CO_2 fixation in the Gla modifications. In fact it is the dihydro-naphthoquinol form of vitamin K, that is the active form for the vitamin K dependent protein carboxylase. O_2 is also a required cosubstrate and the mechanism of the carboxylase (Scheme 25) is proposed to involve formation of the K-OOH peroxy adduct. Cyclization of this quinone hydroperoxide to the alkoxide anion of the 2,3-epoxide of vitamin K generates the strong base required to abstract a proton from the glutamyl-γ CH_2 side chains. The carbanion generated is required to attack CO_2 and form the new C–C bond of the malonyl side chains of Gla residues in the product.

4. Cataloguing the Posttranslational Modification

Consideration of major and minor categories of posttranslational modifications above leads to at least hundreds of thousands, perhaps millions, of possible molecular variants of proteins in eukaryotic cells. The analytical problem is immense, and the challenge to integrate across the subproteomes and decipher connections for a systems biology perspective even greater. Much of the contemporary effort in PTM research involves the development of methodologies to evaluate such inventories. Mass-spectrometric approaches are dominant owing to issues such as femtomolar sensitivity of detection and simultaneous identification of many peptide fragments bearing a particular type of chemical modification.[80] Notable recent studies include the detection of hundreds of pS and pT peptides from the phosphoproteome of yeast[81] and the isolation of His-tagged ubiquitylated proteins of yeast. The latter method allows the identification of more than 100 ubiquitylated proteins that contain polyubiquityl chains connected through different Lys residues in the ubiquitin monomers.[82]

At any moment in time, sampling of the proteome in a given organism or cell provides only a snapshot of a highly dynamic process, confounding the analytical problem and ultimately arguing for time-resolved inventories. Heterogeneity can arise in several ways. Because posttranslational modification enzymes do not work off templates, the mod-

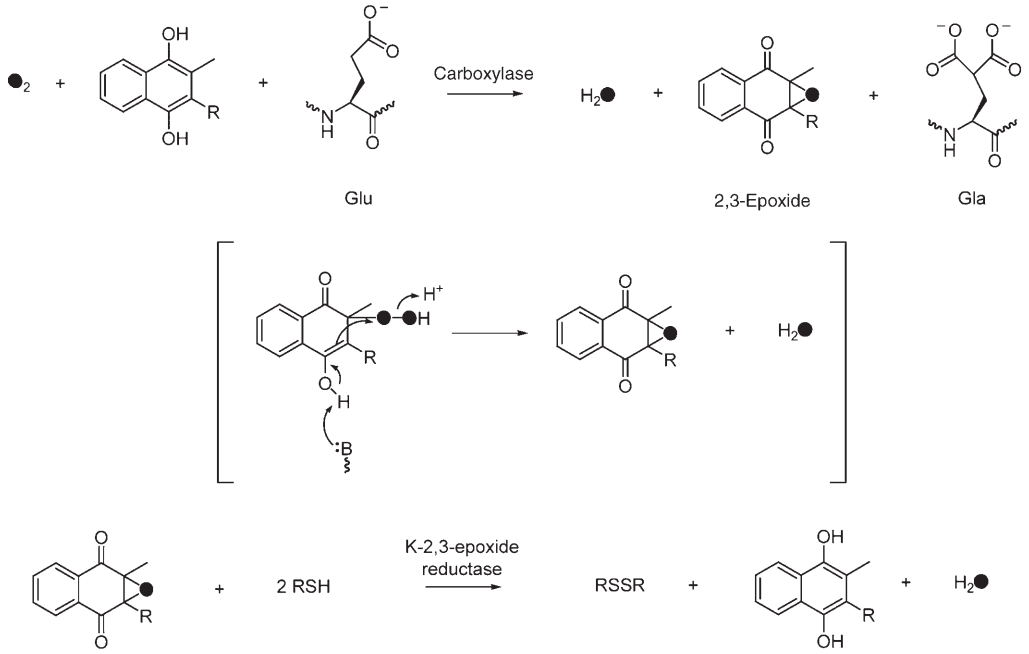

Scheme 25. Proposed mechanism for the function of the dihydro form of vitamin K (KH_2) as cosubstrate in the Glu to Gla posttranslational protein carboxylations. KH_2 reacts with cosubstrate O_2 to produce a hydroperoxy vitamin K intermediate, which can proceed to the 2,3-epoxy-vitamin K alkoxide. The alkoxide is argued to be a strong enough base to abstract one of the Glu γ-CH_2 hydrogen atoms as a proton, transiently generating the γ-carbanion required to attack CO_2 to produce the new C–C bond in the Gla product residue.

ifications are stochastic and likely to be incomplete across a target protein population. The fractional efficiency of modification of a site, for example, N-glycosylation of a particular Asn residue in an Asn-X-Ser sequence favorable for modification, may depend on the amount of time the protein region bearing that Asn is unfolded during passage across the ER membrane. The accessibility of the carboxamido nitrogen atom may be fleeting. The concentration of oligosaccharyl-N-transferase in the microenvironment may be limiting such that the dwell time of protein substrate and enzyme catalyst is too short to ensure complete modification at 100% of that site in the protein population. In the multistep maturation of N-glycan $Man_3(GlcNAc)_2$ core in glycoproteins there are up to a dozen such substrate–catalyst encounters. A 90% yield at each step would produce the kind of complex and heterogeneous glycoprotein mixtures that are often detected. As noted earlier, the prion protein has been shown to exist in some 52 glycoforms.[45]

5. Multiple and Tandem Posttranslational Modification of Proteins

Posttranslational modifications often occur at multiple sites or in tandem cascades that are crucial for function. Thus, the Abl tyrosine kinase is found phosphorylated at 11 different sites, (nine tyrosines, one serine, one threonine) spread over the different catalytic and regulatory domains of the protein[83] (see Figure 2). In principle, $11! = 40\,420\,800$ distinct phosphorylated isoforms are possible just for this one protein alone. Fractional occupancy is likely at the distinct sites, making for a large nested array of different phospho forms of this one protein.

Multiple lysine acetylations and methylations, one serine phosphorylation, and one N-terminal ubiquitylation are typical for the tails of the histone octamers in nucleosomes so that modifications at 28 sites are possible as described in Sections 2.2 and 2.3. (Surely not all of the 28! possibilities will have been explored in Nature.) Kelleher and co-workers[84] recently devised bioinformatic methods coupled with high-resolution mass spectrometry to predict, search for, and identify particular histone variants. For example, they detected one particular hexamodifed form of the N-terminus of histone H3 with an [M+238] mass signature (Figure 12) to address such a functional covalent diversity of protein isoforms. (This is the equivalent of finding one needle in a haystack. The systems approach to PTMs would be to assess how many such needles altogether are in the "haystack" of proteins.) The multiple modifications of histone tails are

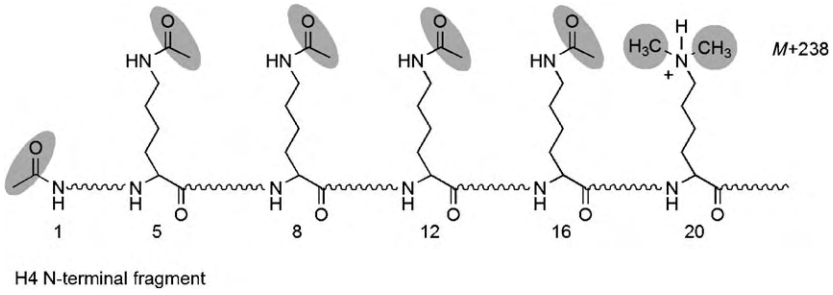

Figure 12. Tandem enzymatic posttranslational tailoring of the N-terminal tail of histone H4 generates a heptamodified protein in which the N-terminal residue is acetylated, $lysines_{5,8,12,16}$ are acetylated, and $lysine_{20}$ is N,N-dimethylated.

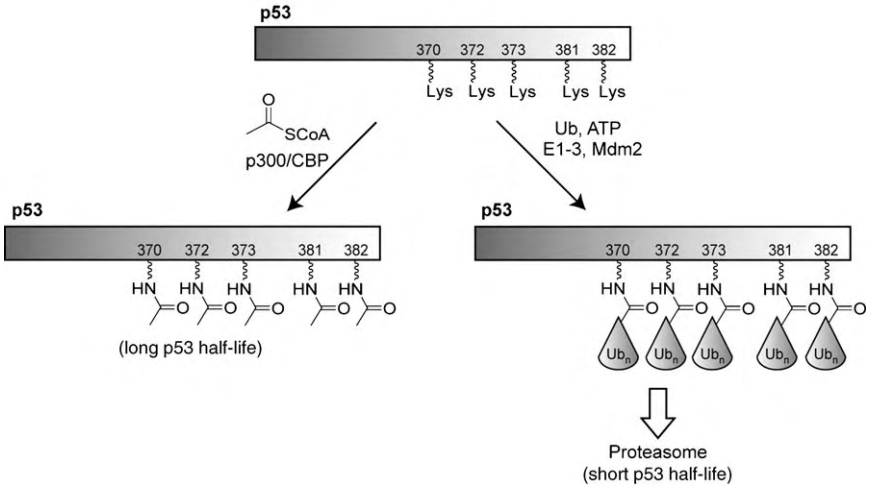
presumed to be written and read by enzymatic machinery in specific temporal patterns for selective recruitment of transcriptional repressors and activator complexes.

Tandem posttranslational modifications are known in many other proteins and comprise the multilayered informational content driving the molecular logic of posttranslational modifications. The consecutive four-step modification of the C-termini of Ras proteins—1) S-prenylation, 2) S-palmitoylation of neighboring cysteine residues, 3) specific endoproteolytic cleavage to reveal one of the cysteines as the new C-terminus, and 4) methylation of that new C-terminal carboxylate—comprise the integrated maturation process that moves modified Ras to membranes to dock with its upstream protein kinase partners (Scheme 26).[35] We have noted above in Section 3.3 that the related RhoA family of GTPases can undergo ADP-ribosylation, O-glucosylation, and deamidation of the active-site Gln. Adding in this sequence of prenylation, proteolysis, and C-terminal carboxymethylation for Rho brings the total to seven specific steps of posttranslational modification. The mature RhoA can also be cleaved by the YopT protease from *Yersinia pestis* as that pathogen executes part of its virulence program.[85]

The threshold nature of tandem posttranslational modifications to provoke a biological signal is illustrated clearly in the successive addition of a minimum of four ubiquitin 8-kDa tags to a target protein to set off the cascade of events leading to proteolysis. A polyubiquitin moiety of length at least four ubiquitin units appears to be the threshold for recognition by protein chaperones to send the tagged proteins to proteasomes.[27]

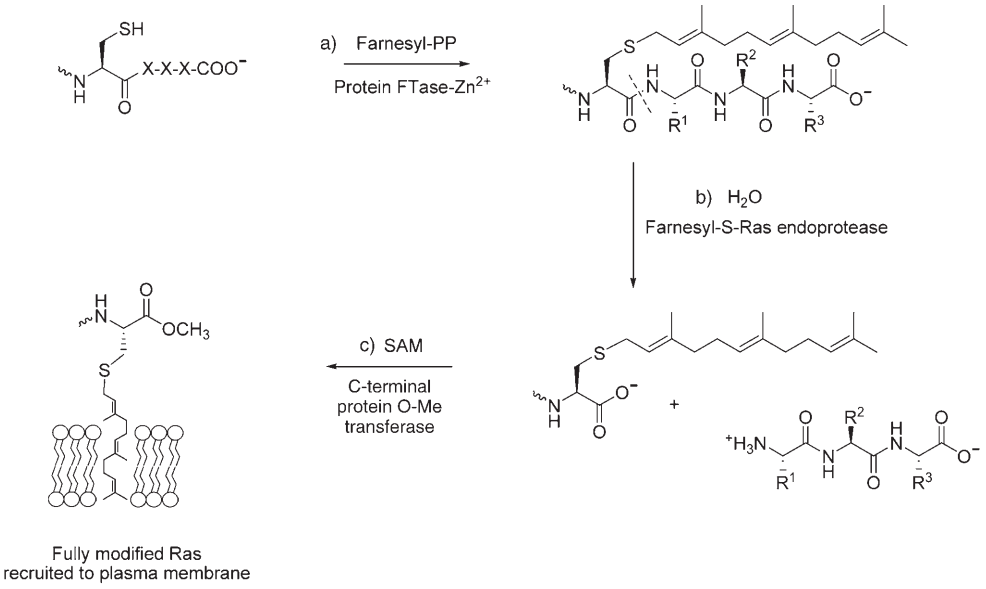
Finally, there is good evidence for competition between posttranslational modifications, with opposing functional consequences for the target proteins. Two such examples involving competition between ubiquitylation and acetylation are 1) SMAD7 protein in TGFβ signal transduction pathway[86] and 2) five lysine side chains near the C-terminus of the transcription factor p53. The Lys ε-NH_2 residues can be acetylated or ubiquitylated (Scheme 27) and then extended to polyubiquitin chains, leading to proteolytic removal of p53 or SMADs. The acetylations block ubiquitylations and consequently lengthen the lifetime of the proteins in cells.[13]



Scheme 27. Competition between acetylation and ubiquitylation at the ε-NH of $Lys_{370,372,373,381,382}$ near the C terminus of the transcription factor p53.

6. Reversible versus Irreversible Posttranslational Modification

Depending on the biological purpose of a particular covalent modification of a protein, reversibility may or may not be an important parameter to control. The prototype of reversible modification is protein phosphorylation, consistent with its evolution to the dominant role in protein-based signaling in eukaryotes. Of the five major categories of PTMs noted in Section 2 (phosphorylation, acylation, glycosylation, thiol-disulfide chemistry, and alkylation), all but alkylation have dedicated enzymes, often large enzyme families, that catalyze the removal of the covalent modifications. The enzymes that reverse phosphorylation, acylation, and glycosylation are, by and large, specific hydrolases, whereas disulfide bonds are cleaved by reductases. We note below that an oxidative enzymatic route has now been discovered for alkylation that involves removal of N-methyl substituents from the histone tails.



Scheme 26. Multistep modification of the Ras GTPase involves a) S-prenylation, b) endoproteolysis, and c) C-terminal O-methylation.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Protein kinases usually occur as low-activity "off" forms in basal states in the absence of a specific stimulus. When a signal is propagated and the kinases activated, often involving covalent autophosphorylation of Thr residues to pT or TXY sequons to doubly phosphorylated pTXpY loci in MAP kinases, the activated protein kinases modify their partner target proteins with much higher catalytic efficiency.[8] The cyclic AMP activated protein kinase A, for example, phosphorylates over 100 proteins[87] on Ser and Thr residues to propagate signals.

To control the duration and intensity of phosphoprotein signaling, the signals need to be turned off. Termination is accomplished by hydrolytic removal of the PO_3^{2-} group by phosphoprotein phosphatases (Scheme 28a). There are about 150 protein phosphatases encoded in the human genome, including pS-, pT-selective phosphatases, pY phosphatases, and dual-specificity (pS and pY) phosphatases.[88] Of these, 107 are pY protein phosphatases.[89] The much smaller number of pS/pT phosphatases is balanced by the presence of many regulatory subunits that control subcellular location and substrate recognition for the pS/pT hydrolytic enzymes.

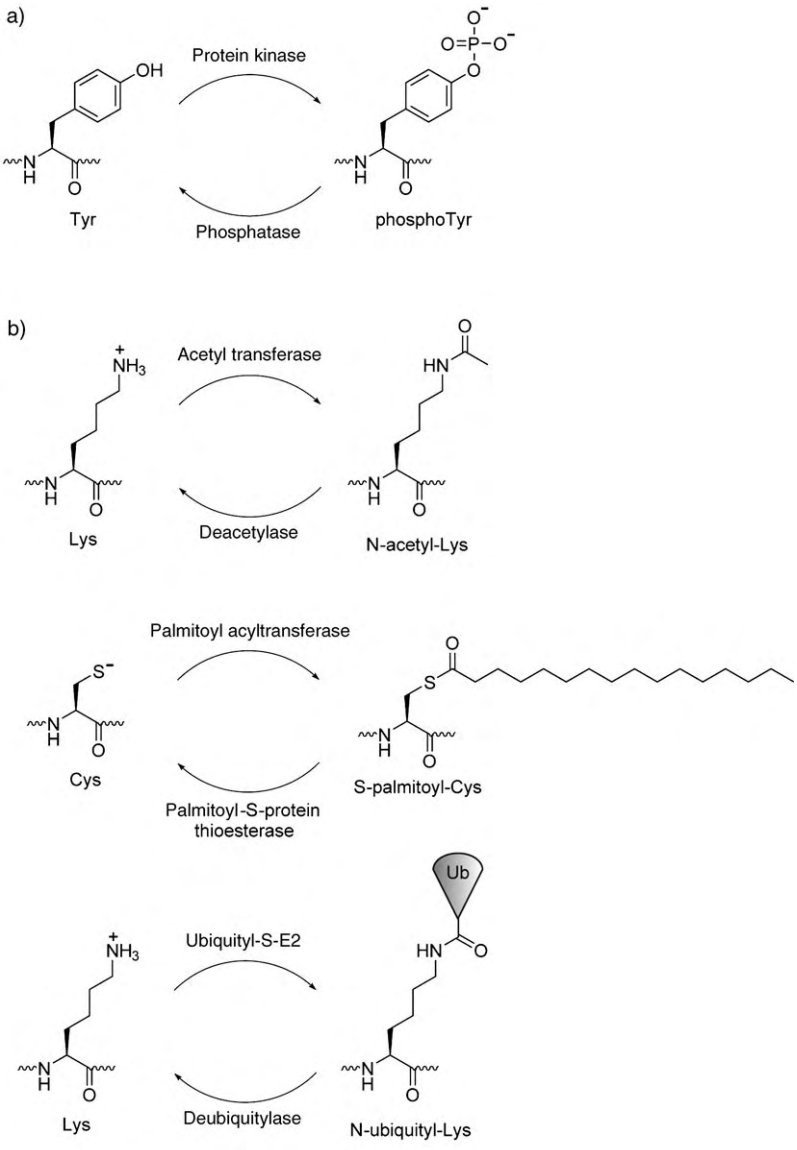
One practical consequence of PTM enzyme-mediated reversibility is that the phosphoproteome content in any cell at any given time represents the balance of activity of the 500 protein kinases/150 protein phosphatases towards their diverse protein substrates, allowing an almost infinite number of set points to a cell and true complexity for phosphoproteomicists.[90,91]

Protein acetylation, protein ubiquitylation, and protein-S-palmitoylation are three other classes of covalent modifications that are readily reversed (Scheme 28b), and so qualify for regulation and signaling roles. Histone acetyltransferases (HATs) are opposed functionally by a family of histone deacetylases (HDACs).[92,93] Some HDACs are catalytic domains embedded in multimodular proteins dynamically recruited to acetylated and methylated lysine tails of histones. A separate family of NAD-cleaving histone deacetylases, the sirtuins, are involved in gene silencing functions and couple energy metabolism with transcriptional regulation.[94,95]

Histone Lys-N-methylation, unlike Lys-acetylation, is not susceptible to enzymatic or non-enzymatic hydrolytic reversal because there is no obvious path for hydrolytic cleavage of the N-alkyl bonds. Thus, in terms of writing and rewriting the histone code, it has been assumed that acetylation can be readily erased, but not methylation. However, the recent discovery of FAD-dependent methyl-Lys deaminases provides an oxidative route for counteracting the action of histone methyltransferases.[96] Oxidative enzymatic conversion of an N-methyl-Lys into the $CH_2{=}NH$-Lys product linkage (Scheme 29) now creates a product imine labile to hydrolysis to yield the unmodified H_2N-Lys residue and 1 equivalent of formaldehyde.

The dozens/hundreds of protein ubiquitin ligases create ubiquityl-ε-NH-Lys-protein isopeptide bonds in tagged proteins. These linkages are resistant to normal proteases but the isopeptide bonds are cleaved by a family of several dozen deubiquitylases (DUBs),[97,98] presumably selective for subsets of ubiquitylated proteins at different parts of the cell at different times and rescuing those from proteasome destruction.

Palmitoylated cysteine residues involve covalent thioester linkages. They can hydrolyze non-enzymatically, but this can be slow in membranes and there are specific palmitoyl



Scheme 28. Reversibility of covalent modifications in proteins; a) Phosphoprotein phosphatases oppose the effects of protein kinases; b) protein acetylations, S-palmitoylations, and ubiquitylations are reversed by deacetylases, palmitoyl-S-protein thioesterases, and deubiquitylases.

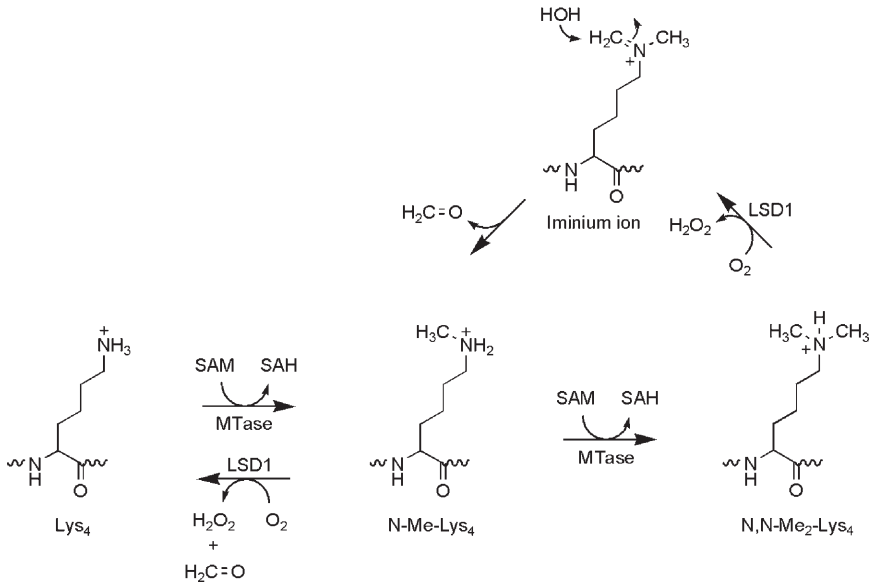


Scheme 29. Reversal of lysine ε-N-methylation occurs by oxidation (not hydrolysis) by action of a flavoprotein to generate the hydrolytically labile imine product.

protein thioesterases[11] to control lifetime and consequent localization of the protein at membrane interfaces.

In contrast to the above reversible categories of post-translational modifications are sets that are functionally irreversible. Cys-S-prenylations are thioether linkages, and in contrast to the Cys-S-palmitoyl thioester linkages are not hydrolytically reversible. (Again, oxidative routes are known but probably occur during prenylated protein degradation in lysosomes.) Thus the enzymatic strategy for attaching the two common lipid anchors for proteins, palmitoylation or prenylation, provides reversible or irreversible modification of proteins targeted to membranes. The C-carboxylation of Glu residues to Gla residues is irreversible as is side-chain hydroxylation, for example, of Pro and Asn residues on HIF-1α in oxygen sensing.

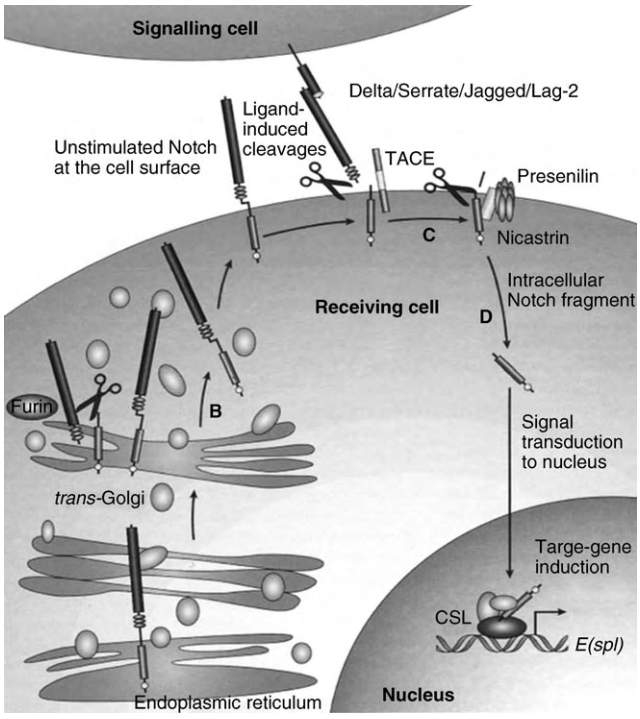
The quintessentially irreversible posttranslational modification is the second major category of covalent change to proteins: the proteolytic cleavage of peptide bonds.

7. Controlled Proteolysis

The life cycle of every protein in intracellular and extracellular compartments in an organism is controlled by homeostatic functioning of proteases, which cleave the covalent peptide backbones to release the constituent amino acids back into the monomer pool. Large subsets of proteins within eukaryotic cells may undergo consecutive limited proteolytic clipping as part of the normal temporal and spatial maturation process. These controlled proteolytic cuts at specific peptide sequences within a given set of protein substrates are effected by proteases that do not degrade but rather are involved in protein-substrate maturation and tailoring processes.

Essentially every protein that enters the endoplasmic reticulum in eukaryotic cells undergoes cleavage of the N-terminal 25–30 amino acids, the signal sequence that specified transit into the ER, by signal peptidases.[99] This first step in protein maturation can be followed by action of proprotein convertases later in the Golgi and *trans* Golgi network[100,101] of the secretory compartment. A prototypical example is the cleavage of proinsulin to insulin, whose two chains are connected by disulfide bonds. The hormone cholecystokinin undergoes six–eight cleavages and trimming proteolytic maturations to convert the 115 residue initial translational product into the eight-residue sulfated mature hormone.[102]

The maturation of the O-glycoprotein Notch by limited proteolysis occurs in four spatially and temporally distinct steps (Scheme 30): 1) signal peptide cleavage in the ER; 2) cleavage by proprotein convertases into two subunits that remain associated in the *trans* Golgi network on the way to the cell surface; 3) removal of the extracellular domain at the plasma membrane by action of sheddase-type proteolytic activity, triggered upon engagement of protein ligands; 4) regulated intramembrane proteolysis (RIP) of the truncated Notch as the fourth maturation event.[99,103,104] The cytoplasmic stub of Notch, now with only a few remaining



Scheme 30. Maturation of the Notch protein by four sequential proteolytic cleavages at specific sites and specific places in a eukaryotic cell: a) Cleavage of the N-terminal signal peptide upon secretion into the endoplasmic reticulum (not shown in figure); b) hydrolytic clip by proprotein convertases during passage through the *trans* Golgi network; c) hydrolytic clip by a protein sheddase at the cell surface; d) regulated intermembrane proteolysis releases the cytoplasmic stub of Notch to go to the nucleus and act as transcription factor. Reproduced with permission from reference [121].

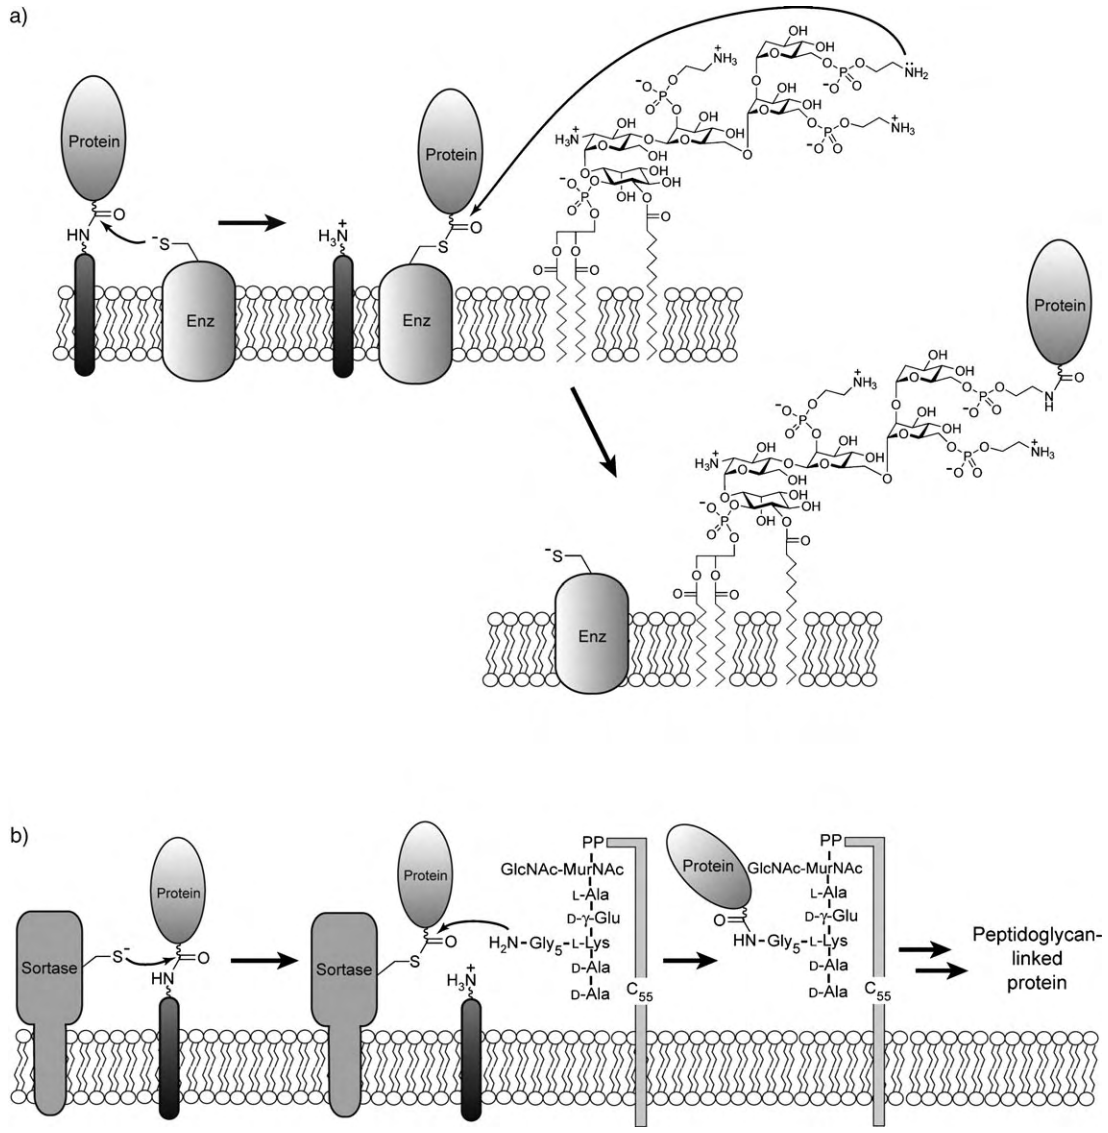
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

amino acids in the vesicle membranes, can then partition back to the cytoplasm, enter the nucleus, associate with partner proteins, and act as a selective transcriptional activator. The sequence of four limited proteolytic steps, separated in time and space, control the location and activity of Notch. It can be directed through the ER and the Golgi complex to the cell surface, function as a cell surface receptor, and then be liberated back into the cytoplasm as a transcriptionally activating fragment that can target the nucleus. Doubtless there are many other examples of multistep action of proteases to direct the location and function of client proteins and control their lifetimes in cells.

A variant of controlled proteolysis occurs when a short C-terminal peptide is excised from protein substrates by protease-like catalysts that generate transient covalent proteinyl-S-Cys-enzyme intermediates (Scheme 31). In the coupling of GPI lipid anchors to eukaryotic proteins, the transferring protein acyl group is specifically captured by an ethanolamine group in the cosubstrate GPI anchor,[105] a net switching of the C-terminal peptide of the initial translation product by the GPI anchor. In the action of bacterial sortases,[106] the incoming amine nucleophile that captures the staphylococcal proteins to be displayed as antigens at the bacterial cell surface is a Gly or Ala-NH_2 terminus from cross-bridges in the peptidoglycan layer of the cell walls. Both of these C-terminal modifications are net transamidations, in which the incoming nucleophile is an amine to give an aminolytic product rather than water in hydrolysis.

8. Autocleavage and Peptide-Bond Rearrangement

There is a set of autocatalytic processes that leads folded proteins to catalyze rearrangements of the backbone connectivity at one or more specific peptide bonds in the folded proteins. Most often these rearrangements lead to cleavage of

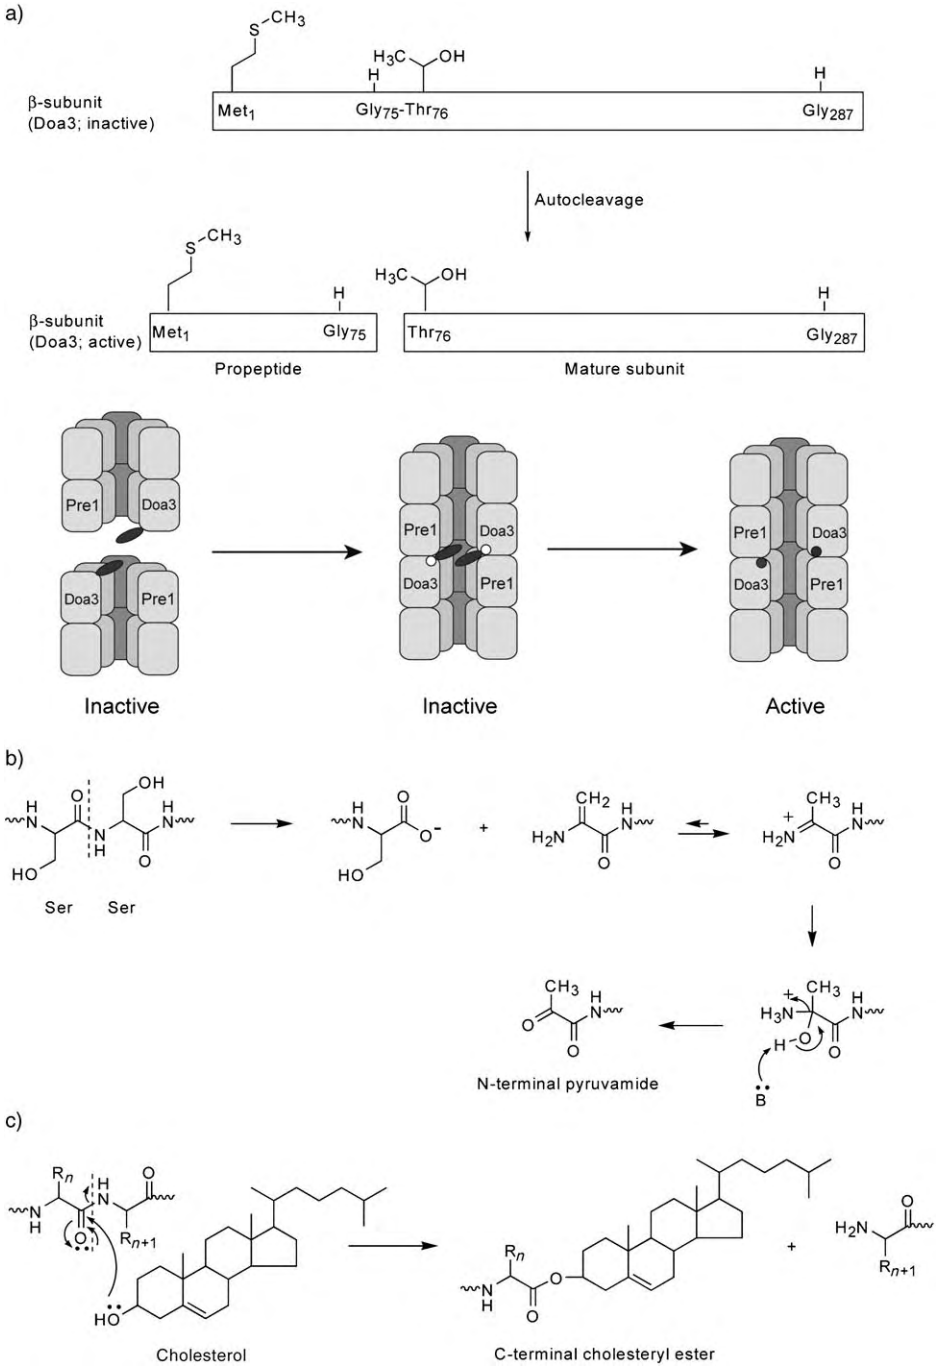


Scheme 31. Protease-like catalysts use active-site Cys nucleophiles to transfer protein-substrate-derived acyl fragments to nonprotein amine acceptors via acyl-S-Cys enzyme intermediates: a) GPI anchor attachment through enzymatic transamidation; b) cross-linking and display of proteins to the peptidoglycan cross-bridges in *Staphylococcus aureus* cell wall assembly by transamidation by the enzyme sortase.

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

those specific peptide bonds. The fate of the acyl fragment of the autocleaving peptide can vary depending on the capturing nucleophile. Water as cosubstrate results in hydrolysis. An alcohol as cosubstrate generates an ester product, as in the capture of the N-terminal fragment of Hedgehog protein by cholesterol. Capture by an amine, when the amine is downstream in the same protein, is the essence of protein splicing, although the amine capture is indirect as we shall note. A common type of intermediate is observed for all three such capture processes.

A second major variant of autocatalytic peptide backbone rearrangements occurs in two contexts (Section 9). One is the autoconversion of a tripeptide moiety into the highly conjugated aromatic fluorophore of the green fluorescent proteins and its relatives. The second is a related rearrangement of a tripeptide in the active site of the pro forms of phenylalanine and histidine deaminases to create the imidazolone cofactors that serve as essential electron sinks in deaminase catalysis.

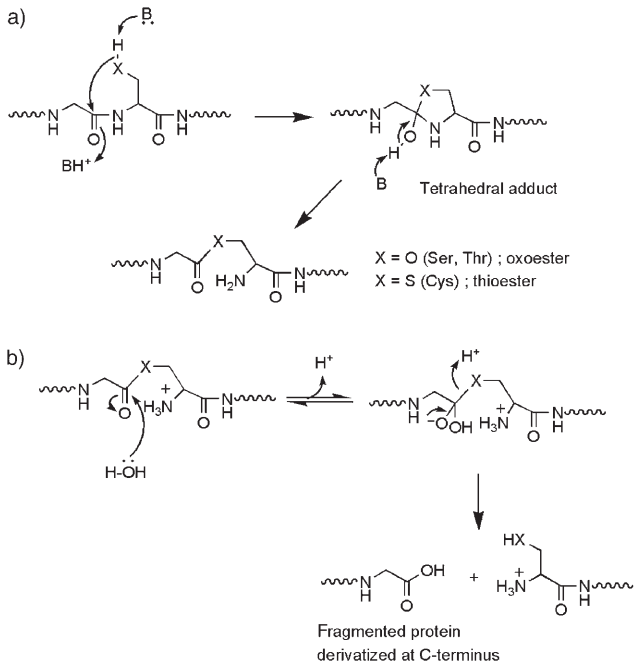


Scheme 32. Autoproteolysis at specific peptide linkages to create the active forms of enzymes in the fragmented protein products; a) autocleavage of the precursor forms of the β subunits of proteasomes to liberate the catalytic Thr nucleophile; b) autocleavage of the precursor form of aspartate decarboxylase generates the N-terminal pyruvamide electron sink; c) autocleavage of the Hedgehog precursor and capture by the 3-OH of cholesterol generates the active N-terminal fragment as a membrane-tethered cholesterol ester.

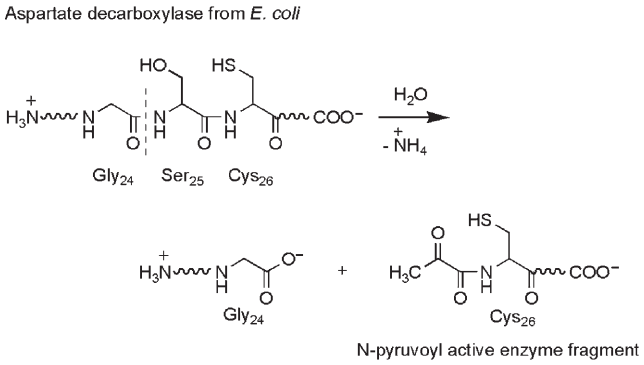
8.1. Autocleavage of Specific Peptide Bonds in Proteins During Precursor Activation

A relatively small subset of folded proteins have the capacity to convert themselves from a single-chain inactive precursor form into an active two-chain form by hydrolysis of a specific peptide bond in the precursor (Scheme 32). Three examples of variants of autoproteolytic activation are: 1) cleavage of the precursor single chain forms of the β-subunits of proteasomes; 2) cleavage and uncovering of an N-terminal pyruvamide group in aspartate α-decarboxylase; 3) cleavage and activation of Hedgehog family proteins resulting in alcoholysis of the peptide bond by cholesterol. All three enzymes use the side chain of a Ser, Thr, or Cys residue to attack the immediately adjacent upstream peptide carbonyl to generate a five-membered tetrahedral adduct (Scheme 33). If that adduct is protonated on nitrogen and reopens with cleavage of the C–N bond, then the peptide bond has been cleaved. The two parts of the protein chain are still held together, by an O-ester (Ser, Thr) or an S-thioester (Cys) linkage. This is the common thread of all three examples. The O-ester or S-thioester linkage is now labile to capture by even relatively weak nucleophiles such as water,

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 33. Peptide-bond autocleavage mechanism proceeds via a) a tetrahedral cyclic adduct arising from attack of a nucleophilic side chain on the immediate upstream peptide bond; resolution of the adduct proceeds through C–N bond cleavage, breaking the original peptide bond and generating an oxo/thioester connectivity; b) the ester can be captured by a range of nucleophiles, including water.



Scheme 34. Peptide autocleavage at an X-Ser linkage can be followed by elimination of the Ser-β-OH and tautomerization to an N-terminal pyruvamide group. This is an electron sink that can engage in imine formation with amino acid substrates to facilitate kinetically accessible substrate carbanions, in this case for net decarboxylation of Asp.

the alcohol group of cholesterol, or downstream Ser and Cys side chains.

The proteasome is organized in an $\alpha_7\beta_7\beta_7\alpha_7$ four-layered cylinder.[107] In yeast, three of the seven β subunits in each heptad ring are active, arising by autocleavage of the precursor β chains at Gly_{75}–Thr_{76}, releasing the Thr as the new N-terminus of the cleaved β subunit.[108–110] Cleavage occurs when the side chain of Thr_{76} attacks the adjacent peptide carbonyl to intiate cleavage. The liberated amino group of this new Thr_1 is the nucleophile in catalysis as protein substrates are cleaved, explaining why the precursor is inactive.[111] The proteasomal β subunit is one of several proenzymes that autocleave and liberate the N-terminal nucleophile as the catalytic residue.[109]

A related class of precursor forms of enzymes uses the side chain CH_2OH of a specific serine residue to initiate cleavage in the folded precursor on the adjacent upstream peptide carbonyl. As noted above, the tetrahedral adduct decomposes to an O-ester, cleaving the original C–N linkage of the peptide bond. Elimination of the RO group from this ester yields an N-terminal dehydroalanyl residue at the downstream chain of the two-chain product (Scheme 34).[109] The N-terminal dehydroalanyl moiety hydrates and ketonizes to accumulate as a pyruvamide group at the N terminus of the active enzyme. This directed autoproteolytic process has uncovered a ketone moiety, an N-terminal electrophile rather than the N-terminal nucleophile above, which acts as an active-site electron sink for the substrate aspartate. Decarboxylation of the aspartyl imino enzyme followed by hydrolysis of the bound product imine yields β-alanine, a required intermediate in CoASH biosynthesis.[112]

The third variant of precursor protein autoproteolysis is represented by the maturation of the protein Hedgehog that signals at plasma membranes of eukaryotic cells after two-dimensional diffusion in the plane of the membrane. The protein is tethered to the membrane by a C-terminal covalent lipid anchor, in this case by esterification of a cholesterol moiety with the C-terminal carboxylate.[113] This arises from the autocleavage intermediate common to the above two cases in which rearrangement of a peptide bond in the precursor to an oxoester occurs by an identical mechanism. Now, rather than capture of the acyl fragment of the precursor protein by water for net hydrolysis, there is a specific binding site for cholesterol. Its 3′-OH is the kinetically competent nucleophile, yielding the peptidyl cholesterol ester as the cholesterolysis product that is biologically active (see Scheme 32).

These three variations of folded protein-precursor autocleavage in Scheme 32 yield either a) two normal peptide fragments, b) a downstream fragment with an N-terminal pyruvamide, or c) an upstream fragment with a C-terminal cholesterol ester. This shows the versatility of this autocatalyzed peptide bond route by selective control of the fate of the common rearranged ester intermediate. In all three cases the peptide bond fragmentations are irreversible.

8.2. Autocleavage and Religation: Protein Splicing

In the final variant of autocleavage of protein precursors the ester intermediate (or thioester intermediate when a Cys thiolate attacks the adjacent upstream peptide bond) is captured by an intramolecular nucleophile rather than an external one such as HOH or ROH. The internal nucleophile is a side chain Ser, Thr, or Cys in a folded downstream domain of the precursor protein. This is the essence of protein splicing, autocleavage, and peptide-bond religation, practiced by over a hundred bacterial and yeast proteins,[109,114] including DNA polymerases and ATPases. The first peptide bond is

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

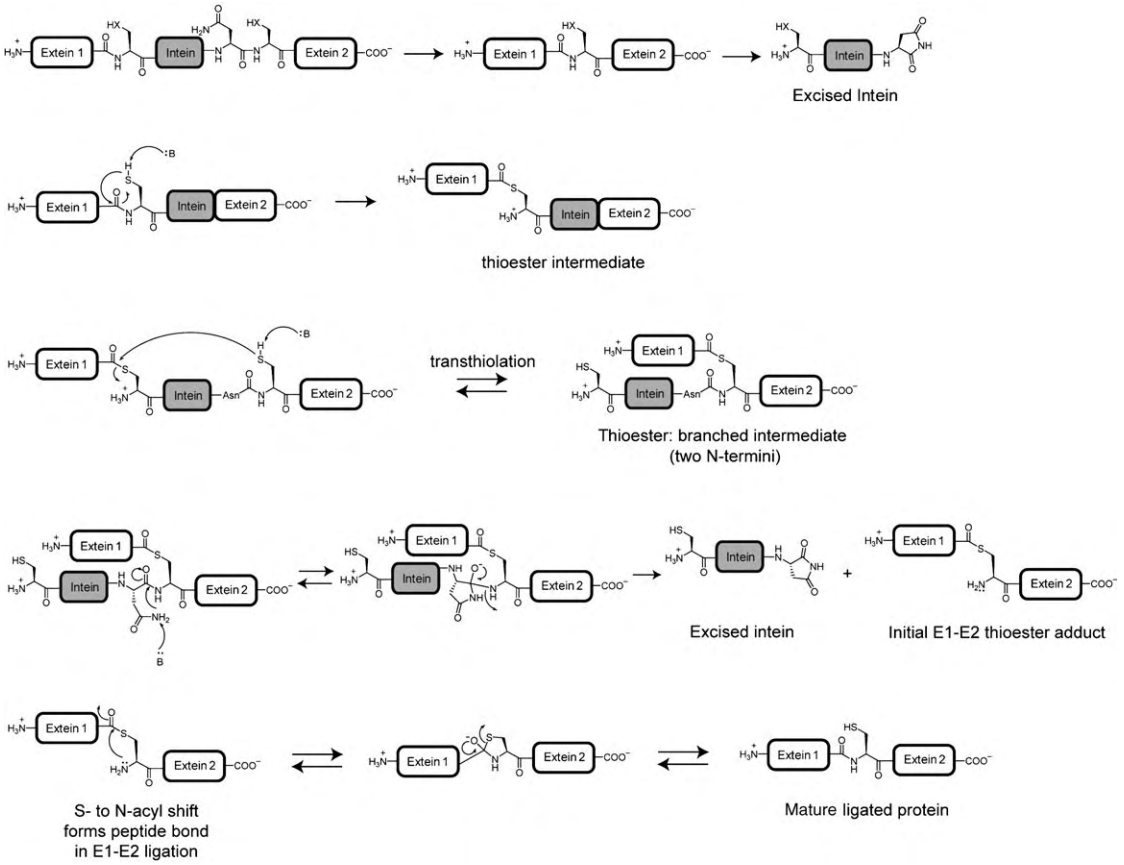
cleaved at the junction of upstream extein and intein. The internal nucleophile capturing the extein 1-intein-O-ester intermediate is at the boundary of the same intein and extein 2 (Scheme 35). The new intermediate has a lariat structure. Excision of the intein is completed with participation of an Asn side chain at the downstream boundary of the intein. This yields a second ester (thioester) intermediate as the lariat is resolved. Re-formation of the peptide bond joining extein 1–extein 2 is driven by thermodynamically favored acyl-O or acyl-S to N shifts and completes an in-frame ligation.

This is ancient protein biochemistry in an evolutionary sense (found in archaeal proteins) and may be the harbinger of the other autocleavage reactions noted in the above section. The net reversibility of such peptide-bond cleavage is the remarkable outcome and is controlled by structural features in the folded intermediates to keep water from being a competent, interfering nucleophile to the intramolecular acyl transfers within the self-splicing proteins. To the extent that this is ancient protein chemistry, it emphasizes that acyl oxoester and acyl thioester intermediates were primordial species in protein reactions; they are still intermediates in many posttranslational reactions in contemporary protein maturations. Furthermore, protein splicing has many practical applications in modifications of recombinant proteins with synthetic peptides by protein ligation.[109,115]

9. Peptide Bond Rearrangement without Autocleavage

9.1. Fluorophore Formation in Green Fluorescent Protein

An additional spectacular class of autocatalyzed PTM rearrangement of the peptide backbone in folded proteins is the maturation of chromoproteins of the green fluorescent protein (GFP) and red fluorescent protein families (Scheme 36a).[116] The precursor protein folds into a β cyclinder structure and the native conformation is required for the subsequent chromophore generation. A tripepetide loop of $Ser_{65}Tyr_{66}Gly_{67}$ in the folded colorless GFP precursor is sterically compressed, populating a conformer that allows attack of the Gly_{67} amide N-H on the adjacent peptide carbonyl to generate a five-membered tetrahedral adduct reminiscent of the initial steps in the rearrangements described in Section 8. This adduct is dehydrated, and the resultant stable cyclic species is slowly autoxidized to create a double bond in conjugation with the phenol ring of Tyr_{66}. This oxidative last step generates the chromophore with absorption maximum at 506 nm and the green fluorescence useful to the producing coelenterate for energy-harvesting functions. A variant with QYG in the starting tripeptide is found in related coelenterates and yields the DsRed fluorophore after rearrangement and oxidative maturation (Scheme 36b).[117] Fluo-



Scheme 35. Autocleavage, intein excision, and peptide religation during protein splicing: thioester formation during peptide bond autocleavage, followed by transthiolation to the cysteine at the intein–extein$_2$ boundary creates a lariat intermediate, that resolves by participation of the Asn at the C terminus of the intein. The resultant thioester reforms the extein$_1$–extein$_2$ peptide bond by acyl S to N shift.

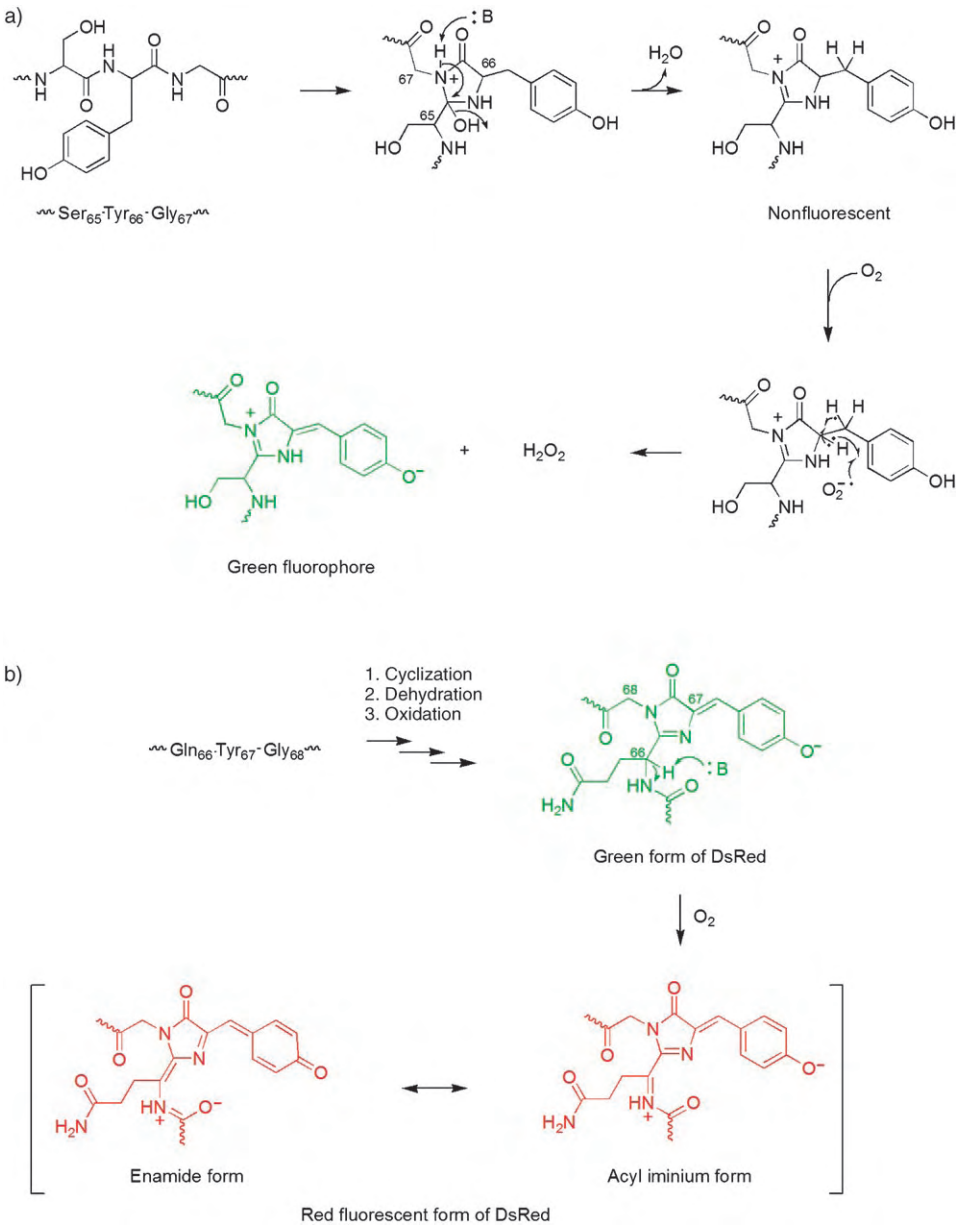

Scheme 36. a) Autoconversion of $Ser_{65}Tyr_{66}Gly_{67}$ in the precursor of green fluorescent protein (GFP) to the green fluorescent form: formation of a cyclic tetrahedral adduct followed by dehydration generates the heterocycle that is not yet fluorescent. Extension of the conjugated system is a slow, oxygen-dependent oxidation that brings the Tyr chromophore into conjugation and completes fluorophore formation. b) A related protein with a $Gln_{66}Tyr_{67}Gly_{68}$ tripeptide instead of the SerTyrGly sequence is the fluorophore in the DsRed protein from coral. It proceeds through a green intermediate on the way to the final red form.

rophores with altered colors, including cyan and gold, have been generated by protein engineering and evolution approaches, allowing many fluorescence-energy-transfer studies between pairs of variant GFPs.

9.2. The Methyleneimidazolone Chromophore

Related rearrangements of a tripeptide sequon in a loop of the folded proenzyme forms of phenylalanine and histidine deaminases produce a related cyclic imidazolone group that then functions as the active-site electrophile for substrate amine deamination (Scheme 37a).[118,119] In the *Pseudomonas* histidine deaminase, $Ala_{142}Ser_{143}Gly_{144}$ in a loop region autoconverts to a compact heterocycle in which the Gly_{144} amide nitrogen is proposed to attack the carbonyl of Ala_{142}. The cyclic tetrahedral adduct can lose water and form the C=N of the imidazolone. Loss of the -OH from the Ser_{143} side chain forms the new double bond in conjugation to produce the 4-methylene-5-imidazolone (MIO) prosthetic group. This set of transformations fashions an electrophilic heterocyclic cofactor from the tripeptide loop to generate the active enzyme. The MIO heterocycle in the mature, active enzyme could be attacked by the substrate amino group. An elimination reaction initiated by β-H removal would then generate urocanate and the amino moiety still attached to the cofactor (Scheme 37b). Release of NH_3 regenerates the starting MIO cofactor for the next catalytic cycle.[120]

10. Conclusions

This summary of posttranslational modifications of proteins has not attempted exhaustive coverage of the more than 200 known covalent modifications (see reference [3] for more complete coverage). Rather, emphasis has been on how the addition of chemical groups from common cofactors and coenzymes to side chains of 15 of the 20 amino acids found in proteins expands the proteome structurally and functionally. The dramatic enhancement of the capabilities of the limited scaffold of genetically encoded protein backbones creates new functional capacities. The modified proteins now have expanded opportunities for catalysis, initiation and termination of signal cascades, integration of information at many metabolic intersections, and alteration of cellular addresses. The posttranslational diversification of the proteome illuminates the underlying molecular logic for epigenetic acquisition of new protein functions.

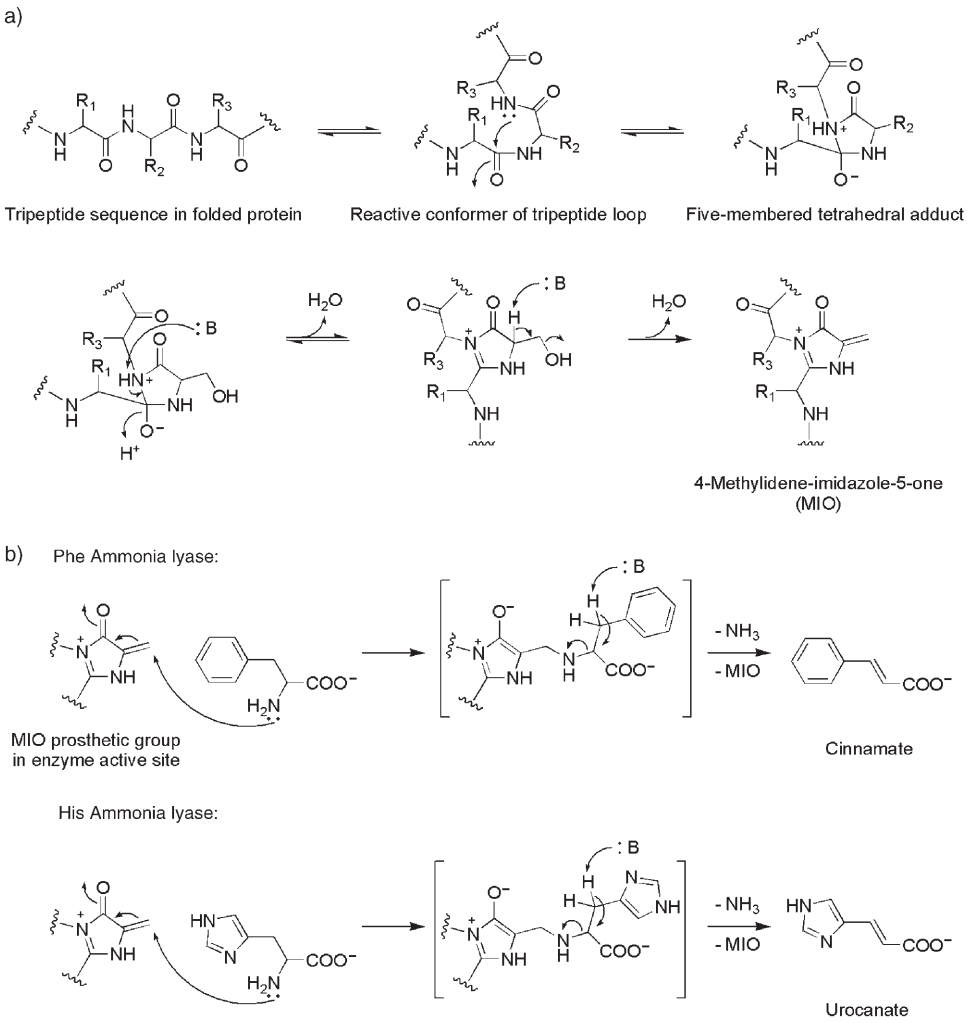

Scheme 37. a) A rearrangement of a tripeptide loop, analogous to that in GFP maturation, occurs in autoactivation of histidine and phenylalanine ammonia lyases. $Ala_{142}Ser_{143}Gly_{144}$ is converted into a compact heterocycle termed MIO (4-methylene-5-imdiazolone). b) The MIO is an electrophilic cofactor that can be attacked by the amino groups of Phe or His to set up net α,β-elimination of NH_2 and H to produce ammonia and the olefinic, deaminated acids urocanate and cinnamate.

The controlled cleavage of specific peptide bonds in particular protein substrates, especially those transiting eukaryotic secretory pathways, shows explicitly that proteases need not be blunt instruments in cellular control inventories. The life cycles of proteins secreted to the cell surface, engaged by ligands, and then retrieved to the nucleus by consecutive rounds of limited proteolysis show ingenious and sophisticated use of the molecular logic of proteolytic trimming of precursors.

Proteins can clearly help themselves for posttranslational creation of new functional groups. Folded protein precursor forms exhibit remarkable properties for autocatalytic conversion of peptide loops into cyclic derivatives for catalysis or light-energy harvesting. Controlled autocatalytic cleavages, presumably vestigial capacities of proteins during evolution, set up N-terminal nucleophiles, N-terminal electrophiles (pyruvamides), and C-terminal cholesterol esters by routing common intermediates down different decomposition pathways. The apotheosis of these autocleavages are the error-free religations in protein splicing reactions in which inteins are excised and exteins self-splice in frame to convert inactive precursors into mature proteins. Splicing may have been an important route to shuffling domains within proteins as a part of multidomain protein evolution pathways.

A given protein can be posttranslationally modified at many residues with the same group, for example, eleven phosphorylations of Abl, five acetylations at the C terminus of p53. Or a protein can be subjected to tandem modifications by several kinds of covalently introduced groups, as exemplified by the two lipidations of Ras followed by regiospecific proteolysis and C-terminal O-methylation, or the multiple modifications of Rho by bacterial protein toxins that disrupt eukaryotic cell cytoskeletal apparatus. The coordinated orchestration of acetylations, methylations, phosphorylations and ubiquitylations of histone tails on nucleosomes give insight into the finely tuned molecular logic of protein posttranslational modifications for gene-expression control.

With the advent of many variations of high-resolution mass spectrometry it is possible to detect and localize covalent changes in proteins beyond the genetically encoded sequence. Cataloguing the protein variants in various subproteomes (such as the phosphoproteome, the ubiquitylated proteome, the molecular variants of histone modifications in nucleosomes of differing transcriptional activity) will continue to be important parameters to allow a full description of the protein composition of proteomes. This information will be a necessary preamble to understanding how the diverse molecular forms of proteins carry out their integrated functions.

We thank M. Fischbach for assistance with the production of the frontispiece.

Complete S-oxygenation of oligothiophenes using HOF·CH_3CN yielded *S*,*S*-dioxide oligothiophene derivatives. In the background, scanning-electron microscopy images of the starting oligothiophenes (top) and the better-organized clusters of the products (bottom) are shown. Details of these studies can be found in the Communication by E. Amir and S. Rozen on the following pages.

Synthesis of [all]-*S*,*S*-Dioxide Oligothiophenes Using HOF·CH_3CN**

*Elizabeta Amir and Shlomo Rozen**

The last decade witnessed an exponential growth in the number of reports devoted to the development of electronic devices based on organic materials. The main synthetic effort is centered on oligothiophenes (OTs) and their many derivatives, such as thienylenvinylenes,[1] alkyl fluoride oligothiophenes,[2] ethylenedioxidethiophenes,[3] or thiazolothiazol thiophenes,[4] to mention just a few. A short search in the *Chemical Abstracts* resulted in thousands of reports concerning this subject from the last five years alone.

The channeling of such huge research efforts started in the late 1980s when Garnier and co-workers had shown for the first time that short conjugated thiophene oligomers could serve as efficient active layers in field-effect transistors (FETs).[5] Since then, the will to develop such organic semiconductors for light-emitting diodes (LEDs), molecular wires, and many other optoelectronic devices[6] has become an irresistible driving force for many chemists to continue the exploration of the possibilities offered by various types of oligothiophenes.

The major goals of the numerous OT modifications are to lower the highest-occupied molecular orbital (HOMO)–lowest-unoccupied molecular orbital (LUMO) gap and obtain highly ordered semiconducting films, as both features are responsible for the efficiency of n-type semiconductors. One of most obvious and promising modifications had already been suggested in 1989: A theoretical prediction had been made that the corresponding *S*,*S*-dioxides of OT would be better materials than OTs themselves, as the HOMO–LUMO gap should be significantly smaller.[7] Chemists tried to test this hypothesis, but the use of orthodox oxygen-transfer agents was the main reason for a complete synthetic failure of making [all]-*S*,*S*-dioxide OTs longer than bithiophene. Each time such an attempt was undertaken, only a low yield of partially oxygenated thiophene rings was achieved, even after prolonged reaction times.[8] Another approach toward the synthesis of partially oxygenated *S*,*S*-dioxide OTs was taken by Barbarella et al. who coupled 2-(dimethyl-*tert*-butylsilyl)-5-bromothiophene-*S*,*S*-dioxide with the corresponding oxygen-free derivatives, thus obtaining alternately oxygenated OTs.[9]

Some years ago, we developed a new type of oxygen-transfer agent, HOF·CH_3CN, which was unique in the sense of that it possessed a truly electrophilic oxygen center.[10] After some time, this complex was dubbed the best oxygen-transfer agent offered in organic chemistry and was instrumental in the first synthesis of 1,10-*N*,*N*-phenanthroline dioxides,[11] the first oxidation of geminal diamines[12] and azides,[13] the epoxidation of electron-depleted olefins,[14] and many other firsts or difficult transformations.[15] Among these reactions was also the mild oxidation of various thiophenes to their corresponding *S*,*S*-dioxides[16]—not an easy task considering the harsh conditions usually required to overcome the aromatic stabilization—thus possibly leading to Diels–Alder reactions and/or SO_2 eliminations. The successful preparation of these monothiophene *S*,*S*-dioxides with HOF·CH_3CN prompted us to explore the possibilities of making the long sought after oligothiophene *S*,*S*-dioxides (OTDOs). This reagent, prepared from diluted elemental fluorine and aqueous acetonitrile, was indeed able to transfer as many oxygen atoms as needed to construct the oligothiophene [all]-*S*,*S*-dioxides investigated. We report herein the synthesis and certain characteristics of some of these OTDO compounds. It is worth mentioning that previous attempts to fully oxidize 5,5′-dihexyl-2,2-bithiophene (**1e**) with *m*-chloroperoxybenzoic acid (MCPBA) were unsuccessful and only 5,5′-bis(dimethyl-*tert*-butylsilyl)-[2,2′]bithiophene (**1f**) could be oxidized to the tetraoxide **2f** in 47% yield after 12 h.[8,9] So far, this reaction was the only example of a preparation of a fully oxygenated *S*,*S*-dioxide OT; however, HOF·CH_3CN has changed this situation.

5,5′-Dimethyl-[2,2′]bithiophene (**1a**)[17] was cooled to −10 °C and treated with a slight excess of the acetonitrile complex of hypofluorous acid.[18] The corresponding, previously unknown, bis(*S*,*S*-dioxide) **2a** was obtained in about 10 s and in 85% yield. No partly oxidized regioisomers or other by-products, usually associated with long reaction times and high temperatures, were observed. Replacing the methyl groups with the bulky *tert*-butyl groups, as in **1b**,[17] did not change the outcome, and the as-yet unknown bis(*S*,*S*-dioxide) **2b** was obtained in a short reaction time at 0 °C in 83% yield. Replacing one or even both of the electron-donating alkyl groups at the 5,5′ positions with the electron-withdrawing bromine atom(s), as in 5-bromo-5′-hexyl-[2,2′]bithiophene (**1c**)[19] or 5,5′-dibromo-[2,2′]bithiophene (**1d**),[20] did not have a negative effect on the reaction and **2c** and **2d** were obtained after 5 min in 87 and 66% yield, respectively (Scheme 1).

Longer OTs were also treated successfully. It took only one minute for HOF·CH_3CN to transfer six oxygen atoms to all three sulfur atoms of the 5,5″-di-*tert*-butyl-[2,2′,5′,2″]terthiophene (**3b**),[21] thus affording the tris(*S*,*S*-dioxide) **4b** in 82% yield. This reaction is the first example of a fully oxygenated terthiophene compound. For comparison, treatment of terthiophene with MCPBA for 48 h resulted in the transfer of oxygen atoms to only the terminal rings.[8] Again, leaving two electron-withdrawing groups for future synthetic manipulation, as in 5,5″-dibromo-[2,2′,5′,2″]terthiophene

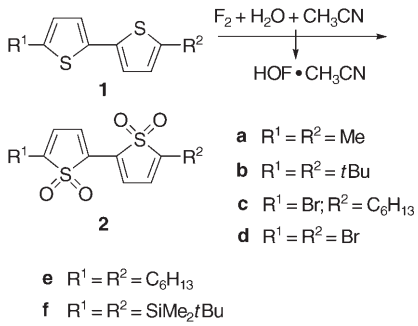
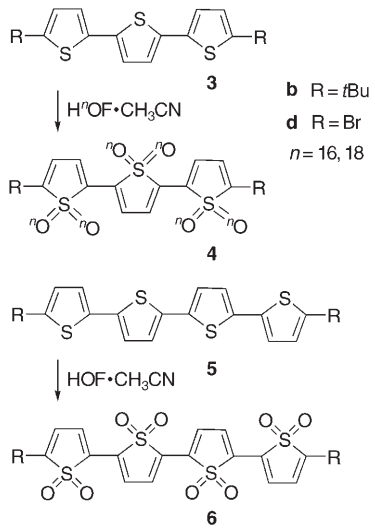


Scheme 1. Oxygenation of dithiophenes.

(**3d**),[20] did not prevent the oxygen-transfer process that forms tris(*S*,*S*-dioxide) **4d** in 60% yield. One of the advantages of HOF·CH_3CN is the origin of its electrophilic oxygen atom from water, which is the most convenient source for all oxygen isotopes; therefore, an opportunity to prepare **4b** with all six oxygen atoms being the expected ^{18}O isotope (EI MS: *m*/*z* 468.1 [M^+]) was presented.

The derivative with four thienyl rings, 5,5‴-di-*tert*-butyl-[2,2′,5′,2″,5″,2‴]quaterthiophene (**5b**),[21] was also subjected to oxygenation with the HOF·CH_3CN complex. In this case, a twofold excess (16 molar equivalent) of the oxidant and reaction times of up to 40 minutes at room temperature were required, but the main product was the tetra-*S*,*S*-dioxide **6b** in 52% yield (Scheme 2). It seems that the somewhat smaller



Scheme 2. Oxygenation of oligothiophenes.

yield in this case is caused by solubility problems, and we are working now on the preparation of some more soluble derivatives.

These results enabled us to test some of the theoretical predictions about the OTDOs prepared so far. Table 1 lists the UV/Vis data for both starting materials and the *S*,*S*-dioxo oligomers. There are two well-defined differences between the spectra of the two groups. Whereas in the starting materials, as well as in the partially oxygenated *S*,*S*-dioxides,

[a] HOMO–LUMO energy gap was derived from the UV/Vis spectroscopic data and DFT calculations. [b] These spectra consist of an underlined maximum and corresponding vibronic splitting. [c] HOMO–LUMO gap from the low-energy band of the UV/Vis spectrum. [d] These calculations obtained from DFT computations are in very good agreement with the UV measurements (for comparison purpose, see reference [9]). [e,f] Lowering the HOMO–LUMO gap following the oxygen-transfer reaction ([e] from spectral data, [f] from DFT calculations).

the reported spectrum presents a single absorption maximum, the corresponding [all]-*S*,*S*-dioxides display three major peaks because of the rigidification of the OTDO backbone.[9] A constant interval in the order of 18–32 nm between the high-energy band ($\lambda_{1,max}$), main absorption ($\lambda_{2,max}$), and low-energy transition ($\lambda_{3,max}$) was observed in all products. This energy spacing can be attributed to the stretching mode of the conjugated double bonds of the oxidized OT core. As reported previously,[22] the bathochromic shift between an OT and the same compound with one oxygenated thiophene ring is about 60 nm, whereas a second *S*,*S*-dioxide unit adds an additional shift of about 20 nm. This trend of additivity is fully expressed in the completely *S*,*S*-oxygenated derivatives. As a result, dearomatized oligothiophenes show a maximal bathochromic shift that indicates a considerable narrowing of the HOMO–LUMO gap (ΔEg), as reflected by the low-energy transition ($\lambda_{3,max}$) absorptions of the products[22] (Table 1).

To obtain a good estimation of the frontier molecular orbitals, we performed ab initio DFT/B3PW91 computations using 6-311G** and 6-31G* bases sets for the bromo and *t*Bu derivatives, respectively. The results indicated that the energies of both the HOMO and LUMO were indeed considerably lower for the oxygenated compounds, with the LUMO values dropping almost twice as much as those of the HOMO. Consequently, this lowering leads to derivatives with a significantly higher electron affinities. Table 1 reveals quite a good agreement between the computed energy-gap values and those obtained from the UV/Vis measurements concerning the narrowing of the HOMO–LUMO gap between the starting materials and the products.

Cyclic-voltammetric measurements for the pairs **1b** and **2b** and **3b** and **4b** (starting materials and products, respec-

tively) were carried out on Pt electrodes (1.44 cm^2) in CH_3CN/Et_4NBF_4 (0.1M) and with 1×10^{-3}M substrate at 20 $mV\,s^{-1}$. The voltage was measured versus a Ag/AgCl electrode. The obtained oxidation ($E_{Ip,a}$) and reduction ($E_{Ip,c}$) peak potentials are presented in Table 2 and Figure 1.

Table 2: Oxidation ($E_{Ip,a}$) and reduction ($E_{Ip,c}$) peak potentials.

Compound	$E_{Ip,a}$ [V]	$E_{Ip,c}$ [V]
1b	1.21	−1.22
2b	2.24	−0.93
3b	1.06	−1.40
4b	2.14	−0.44

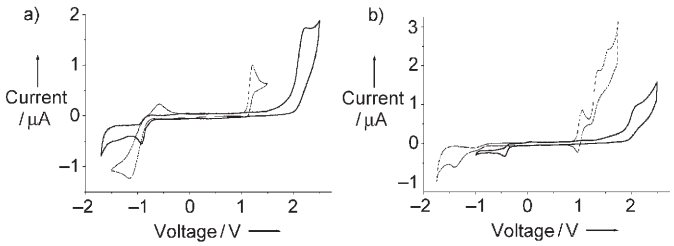

Figure 1. Cyclic voltammograms: a) dashed line: **1b**, solid line: **2b**; b) dashed line: **3b**, solid line: **4b**.

These results indicate that the reduction potential of **2b** is shifted toward the more positive value relative to its fully aromatic precursor **1b**, and the shift for the tris(*S*,*S*-dioxide) (transformation of **3b** into **4b**) is even more conspicuous. It should be emphasized, however, that although the trend is clear, it is difficult to address quantitatively the actual oxidation–reduction potentials from the above peak potentials as no reversible redox couple is observed and the addition of one electron to the oligomer alters its dimensions. What is more, caution should be exercised in the comparison of the electrochemical results of OTs that possess different chemical and regiochemical substitution because rules for such permutations have not yet been formalized.[2] The above observations, however, clearly indicate that full *S*,*S*-oxygenation of OTs leads to materials that are better electron acceptors, a trend that is strongly enhanced when the length of the oligomer is increased. As the reduction potentials are related to the LUMO energies, the conclusion is that the longer the fully *S*,*S*-oxygenated OTs are, the lower their LUMO values. This feature is of course desirable when the issue is the acceptance of electrons from an outside source. The very high oxidation peak potentials, relative to other partially oxygenated OTs,[23] points to yet another advantage, namely, a greater stability of the fully oxygenated OTs toward air and damaging oxidation processes. In addition, indirect indication of the stability of these compounds can be deduced from their melting points. All OTDOs tested were thermally stable up to 250–300 °C and beyond; they tend to blacken at these temperatures, but in some cases do not melt even at 350 °C (see the Supporting Information).

X-ray structural analysis was performed on **4d**,[24] which showed that it crystallizes in a monoclinic system with a *C*2/*c* space group and has four molecules in the unit cell. The thienyl rings of each molecule exhibit an all-*anti,* nearly planar conformation, and the torsion angles between the mean planes of the rings are 3–9° (Figure 2a), which are in a

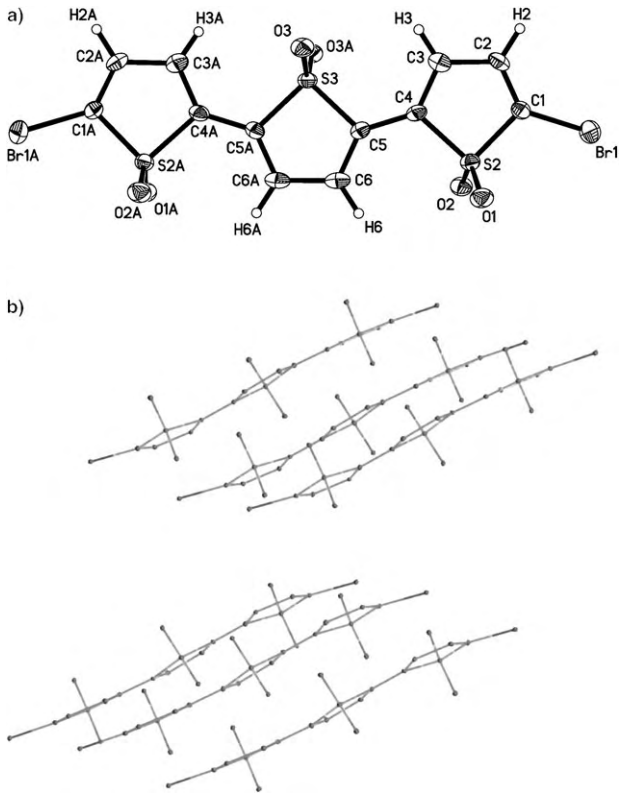

Figure 2. a) X-ray structure of **4d** and b) molecular structure and crystal packing of the unit cell of **4d**.

good agreement with the values reported for the unsubstituted α-3T.[25] The most promising feature of **4d**, however, is found in the molecular packing. It has been shown previously that, with a few exceptions,[3,26] most OTs studied so far have a typical "herringbone" (HB) arrangement with angles of 40–70° between the mean planes of the adjacent molecules. This packing is probably the best way for those molecules to decrease the intermolecular repulsion between the π orbitals, but it may also be responsible for their decreased transport properties in the direction of the long molecular axis.[27] In contrast, **4d** overcomes such repulsion and adopts an important π–π stacking arrangement of the molecular chains with an angle of 0° between the mean planes of the adjacent molecules (Figure 2b).

This favorable solid-state organization of the molecular chains may have an influence on the molecular nanoscale packing of the oligothiophene *S*,*S*-dioxides relative to the starting materials. Although not much can be said in this stage on the images obtained by scanning electron microscopy (SEM) for the OT **3b** and the product OTDO **4b**, there are some obvious differences in size and spatial distribution of the corresponding clusters. Under identical conditions, **3b** is rougher and has obvious discontinuities at grain boundaries. The *S*,*S*-dioxide **4b** displays many more clusters per a given

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

area that are about ten times smaller in width, thus hinting at a greater cohesion between its crystals (Figure 3).

In conclusion, contrary to a long-held belief, working with dilute fluorine is not problematic. HOF·CH_3CN generated

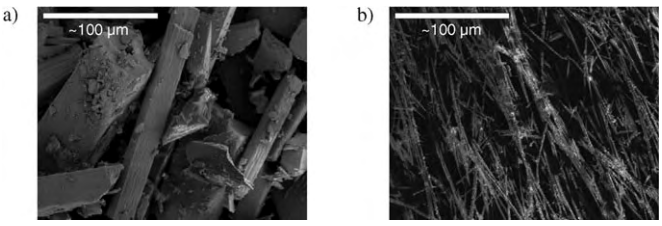

Figure 3. SEM images of a) OT **3b** and b) OTDO **4b**. Enlargement: 500× (≈100 μm).

in situ easily from F_2 and H_2O seems indeed to be the best oxygen-transfer agent offered in chemistry. Its strongly electrophilic oxygen atom opens up the only route so far that leads to the synthesis of the long sought after oligothiophene [all]-*S*,*S*-dioxides, whose initial characteristics are promising for use as field-effect transistors and other optoelectronic devices.

Experimental Section

A detailed procedure of how to work with F_2 and prepare HOF·CH_3CN can be found in reference [18]. We present a typical experiment for making the hexaoxide of the terthiophene **4b**. For full characterization of all the oxygenated compounds, see the Supporting Information.

4b: Terthiophene **3b**[21] was dissolved in CH_2Cl_2 at 0 °C. A solution of HOF·CH_3CN, kept at a similar or lower temperature, was added in one portion to the reaction mixture and the reaction was stopped after 1 min by addition of $NaHCO_3$. The organic material was extracted with CH_2Cl_2, washed with water, and dried over $MgSO_4$. The product was purified by vacuum flash chromatography on silica gel 60-H (Merck) and recrystallized from $CHCl_3$. Yield: 82%. M.p. 290–292 °C (turning black; from $CHCl_3$); ^{1}H NMR (200 MHz, $CDCl_3$): 7.28 (2H, s), 7.13 (2H, d, $J = 5$ Hz), 6.61 (2H, d, $J = 5$ Hz), 1.42 ppm (18H, s); ^{13}C NMR(50.2 MHz, $CDCl_3$): 155.3, 130.6, 129.3, 124.2, 123.9, 121.9, 35.0, 29.0 ppm; EI MS *m*/*z* (%): 456.1 ([M^+]); elemental analysis (%) calcd for $C_{20}H_{24}O_6S_3$: C 52.61, H 5.30, S 21.07; found: C 52.82, H 5.45, S 20.92.

[23] In several works on OT, this gap was determined from the very onset of absorption as no other alternative was to be found. This procedure can lead to rather large uncertainties and artificially high values. As the OTDO present distinguished low energy λ_{max}, we felt more comfortable and used that value for calculating the HOMO–LUMO gaps.

Ordered Multistep Synthesis in a Single Solution Directed by DNA Templates**

*Thomas M. Snyder and David R. Liu**

The use of DNA templates to direct chemical reactions enables the principles of biological evolution to be applied to the discovery of synthetic molecules and new chemical reactions.[1] In addition, the use of DNA hybridization to modulate the effective molarity of DNA-linked reactants allows synthetic molecules to be manipulated in ways that cannot be accessed using traditional synthetic methods.[2] For example, many oligomeric natural products, including proteins, nonribosomal peptides, and polyketides, are biosynthesized in a strictly ordered manner even though all of their constituent building blocks are simultaneously present in the cellular milieu.[3] Nature achieves single-solution ordered multistep synthesis by increasing the effective molarity of specific sets of reactants at precise moments during biosynthesis. Compared to the strategy most frequently used by chemists to execute ordered multistep synthesis—dividing the construction of a molecule into a sequence of isolated reaction steps—nature's single-solution approach is not only remarkably elegant and efficient but also sufficiently selective to obviate the need for protecting groups.

In the absence of enzymes, ordered multistep synthesis in a single solution has proven to be a challenge. The ordered oligomerization of nucleotides on nucleic acid templates[1a,4] has been achieved, but these methods have not allowed the synthesis of non-nucleic acid structures. Tamura and Schimmel[5] have used RNA-templated synthesis to direct peptide-bond formation in an order determined by intrinsic differences in substrate reactivity. Relying on substrate reactivity differences, however, imposes significant constraints on the order of building blocks within the possible products. Even with precisely tuned reactivities, multistep syntheses generally still require sequential additions of reactants to form ordered products. Herein, we report the ordered multistep syntheses of both a triolefin and a tripeptide using DNA-linked substrates of comparable intrinsic reactivity that are simultaneously present in one solution. In both cases, temperature-sensitive variations in DNA secondary structure orchestrate a series of effective molarity changes among four reactants to primarily generate one ordered product out of many possibilities. These results represent two strategies for ordered synthesis in a single solution without the structural constraints imposed by enzymes and can significantly enhance the efficiency and selectivity of multistep DNA-templated synthesis.[6]

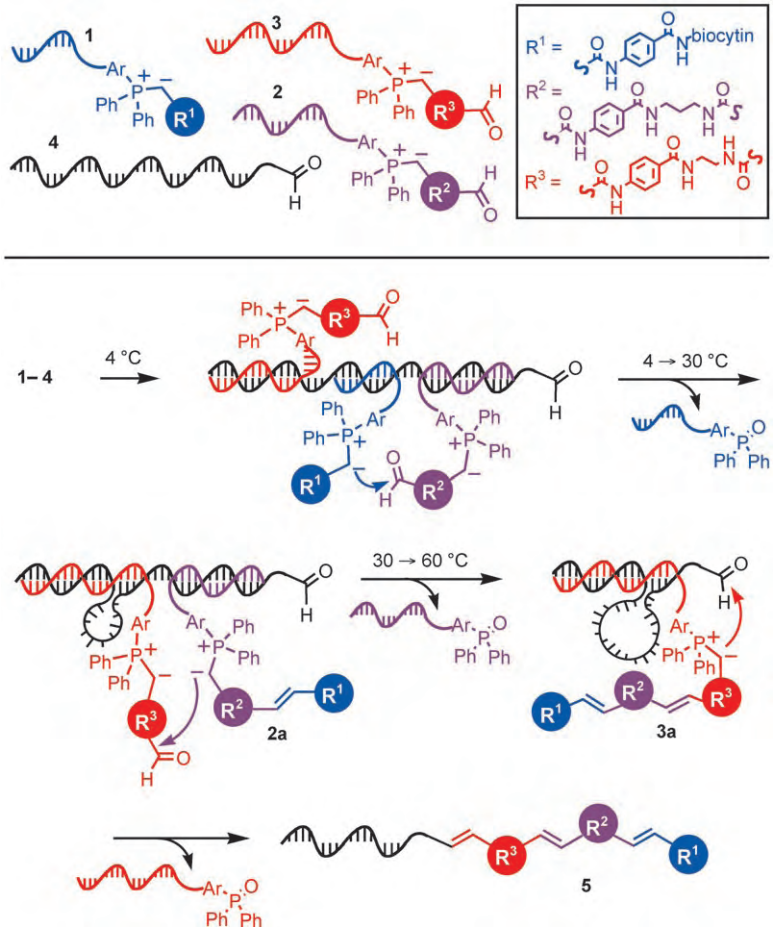

Figure 1. Strategy for the single-solution synthesis of an ordered triolefin. Building blocks are transferred sequentially among phosphorane reagents **1**–**3** before addition to an aldehyde-linked template **4**. The rigidity of double-stranded DNA enforces Wittig olefination regioselectivity. As the reaction temperature is elevated, the DNA secondary structure undergoes sequence-programmed changes that enables the desired Wittig olefination to take place selectively.

The first strategy (Figure 1) passes synthetic intermediates from site to site on a template in a manner controlled by changes in the DNA secondary structure. Three Wittig olefination substrates (**1**–**3**, with **1** containing a biotin group),[7] each linked to DNA oligonucleotides of varying melting temperature (T_m), were prepared and hybridized to an aldehyde-terminated DNA template **4** at 4 °C. If these substrates were combined at the high concentrations (mM–M) typical of organic synthesis, a complex mixture of many

products would result from their random reaction. At a concentration of 100 nM each, however, only substrates juxtaposed in a productive way by DNA hybridization react at a significant rate.[8] Upon phosphonium deprotonation, seven intermolecular Wittig olefinations were in principle possible among these four reactants. At the lowest temperature (4 °C), however, six of the seven possible Wittig reactions are precluded because their reactants are separated by double-stranded DNA. As we previously demonstrated, the rigidity of double-stranded DNA can enforce the separation of substrates that flank duplex DNA, thus preventing their reaction.[8] At 4 °C, the only phosphorane–aldehyde pair not separated by the duplex DNA was **1** and **2**, which reacted to generate DNA-linked monoolefin **2a**.

As the temperature was elevated to 30 °C, the species with the lowest T_m value (the phosphine oxide of **1**) dissociated from the template, thus allowing reactants **2a** and **3** to react to form diolefin **3a**. When the temperature was increased to 60 °C, the phosphine oxide of **2** dissociated, which enabled the final reaction to take place between **4** and **3a** to generate ordered triolefin **5** (Figure 1).

Following the capture of R^1-linked products with immobilized streptavidin, we obtained triolefin **5** in 24% overall yield (Figure 2a, lanes C and D). As expected, captured products lacking the R^1 group were not detected. Truncated products represented less than 10% of the isolated material, as analyzed by denaturing polyacrylamide gel electrophoresis (PAGE) analysis. To confirm the order of the building blocks in the products, control reactions were performed with reactants lacking aldehyde groups. Removing the aldehyde group from **2** prevented the reaction of **1** with **2** and resulted in a diolefin template-R^3-$R^{2\prime}$ product (Figure 2a, lane B). Removing the aldehyde group from both **3** and **2** prevented all reactions except for the reaction of **3** with template **4** to generate the monoolefin template–$R^{3\prime}$ (Figure 2a, lane A). MALDI-TOF mass-spectroscopic analysis was consistent with the expected product structures (Figure 2b).

We repeated the ordered triolefin synthesis and control reactions using reagents in which the R^2 and R^3 groups were interchanged on **2** and **3**. The resulting products contained the expected R^2-R^3-R^1 building-block order (Figure 2c). Consistent with our reactivity model, control reactions using sequence-mismatched reagents **1c**, **2c**, or **3c** resulted in either no transfer of the biotinylated R^1 group to **4** (using **1c** or **3c**) or in the direct reaction of **1** and **4** (using **2c**; see the Supporting Information). Collectively, these results demonstrate that the order of Wittig olefination in this system is tightly controlled by sequence-programmed changes in the DNA secondary structure and is not determined by intrinsic reactivity differences among the substrates.

Our second target was the synthesis of an ordered tripeptide from a single solution containing three *N*-hydroxysuccinimidyl (NHS) ester activated amino acids. Because the DNA-linked NHS by-product of amine acylation is capable of transesterification with NHS esters (see the Supporting Information), the transfer of building blocks between

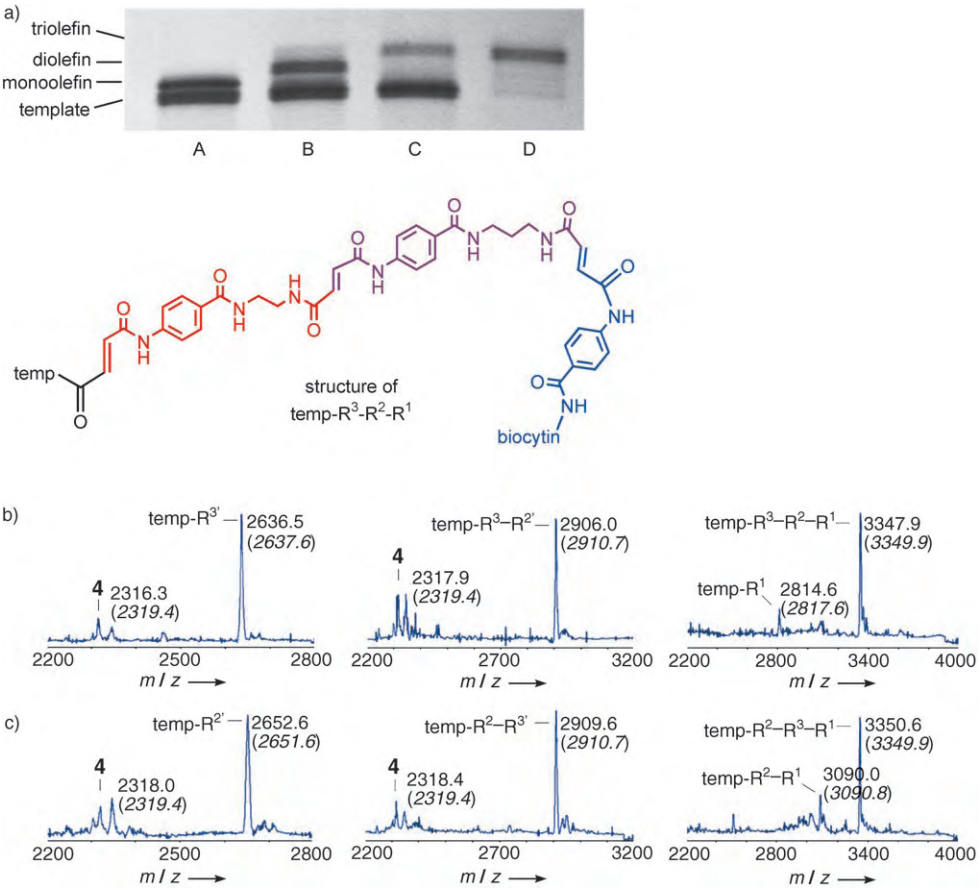

Figure 2. a) Denaturing PAGE analysis of the ordered triolefin synthesis. Conditions: 100 nM of **1**–**4** were hybridized in aqueous 50 mM NaOAc (pH 5.0), 1 M NaCl; treated with 0.1 M *N*-tris(hydroxymethyl)methyl-3-aminopropanesulfonic acid (TAPS; pH 8.0), and 1 M NaCl; and incubated for 1 h at 4 °C, 1 h at 30 °C, and 2 h at 60 °C. The crude reaction mixture is shown in lane C with the streptavidin-captured product in lane D. Control reactions lacking an aldehyde group on both **2** and **3** (lane A) or on **2** only (lane B) were performed under identical conditions to produce either a monoolefin or diolefin, respectively. b) MALDI-TOF mass-spectroscopic data of products from reactions shown in (a). The three spectra correspond, from left to right, to lanes A, B, and D from (a), respectively. c) MALDI-TOF mass-spectroscopic data for the reactions using swapped building blocks (R^3 attached to **2**, and R^2 attached to **3**). Expected masses for (b) and (c) are listed in parentheses; the expected error is ±6 Da. The prime designation ($R^{2\prime}$ and $R^{3\prime}$) in (b) and (c) refers to the forms of these building blocks lacking aldehyde groups (see the text). temp = template **4**.

reagents as in Figure 1 is not possible without significant loss of the desired product through capture by DNA-linked NHS groups. Instead, a different strategy is required that allows three consecutive transfers from three NHS ester reagents to a growing template-linked molecule. We hypothesized that oligonucleotide masks designed to selectively block the hybridization of DNA-linked reagents at certain temperatures could be used to achieve this goal (Figure 3a). Indeed,

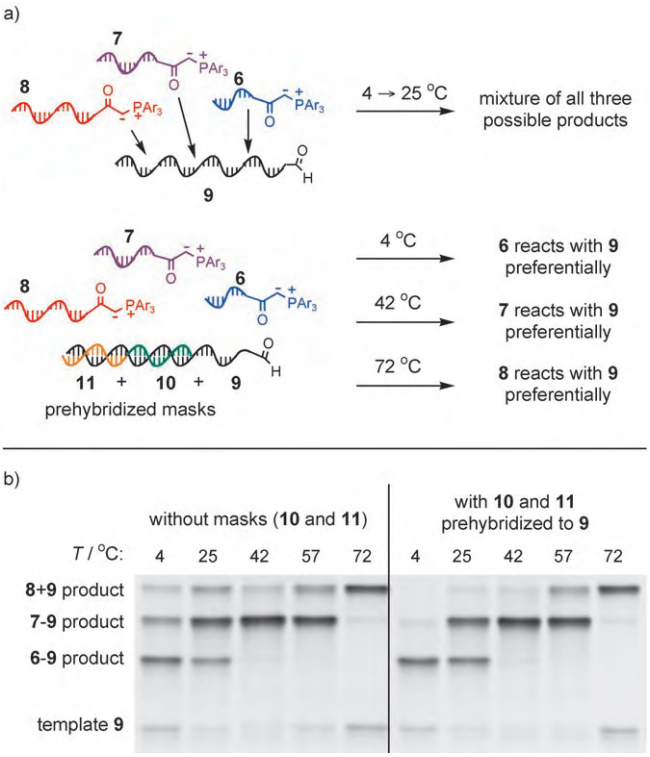

Figure 3. a) Strategy for using oligonucleotide masks **10** and **11** to order the reaction of three reagents **6**–**8** with a template (**9**). When all masks are hybridized (4 °C), only **6** can react. At an intermediate temperature (42 °C), mask **10** is melted from the template allowing **7** to react exclusively. At a high temperature (72 °C), only **8** can react. b) Denaturing PAGE analysis of the reactions in (a). Conditions: 150 nM of **9** (with or without masks **10** and **11** at 225 nM) was incubated at the indicated temperature. Reagents **6**–**8** were added simultaneously to 200 nM each and the reaction was incubated 1 h before analysis.

although a mixture of all possible products was formed when DNA-linked phosphoranes **6**–**8** were added simultaneously to aldehyde-linked template **9**, when masks **10** and **11** were prehybridized to the template before the addition of **6**–**8**, reactivity became strongly dependent on the reaction temperature approaching or exceeding the T_m value of each mask (25–30 °C for **10** and 60–65 °C for **11**; Figure 3b).

Using this approach, we performed a single-solution ordered tripeptide synthesis (Figure 4a). An amine-terminated template **12** was prehybridized with masks **10** and **11** at 4 °C. When NHS ester linked reagents **13**–**15** were combined with the masked template **10** + **11** + **12** at 4 °C for 20 min, only **13** could hybridize to the template and react to generate a monopeptide. As the solution was heated to 37 °C for 20 min, both the expended first reagent and the first mask **10** dissociated from the template, thus exposing the binding site for the second reagent **14**, which then hybridized and reacted to generate a template-linked dipeptide. At the highest temperature (62 °C for 2 h), all masks and expended reagents were melted except for **15**, which reacted to form the ordered tripeptide **16**. Unlike the first strategy in which incomplete reactivity reduces overall yield but does not generate truncated biotinylated by-products, this strategy requires each step to proceed in high yield to generate the tripeptide (and not truncated mono- or dipeptides) as the major product.

Aliquots of the reaction mixture taken after incubations at 4 and 37 °C were quenched with 1M tris(hydroxymethyl)aminomethane (Tris). Analysis by MALDI-TOF-MS (Figure 4b) revealed that **13** reacts exclusively with the template at 4 °C, followed by the reaction of **14** at 37 °C. Biotinylated templates that arise from the reaction of **15** were isolated using streptavidin-linked beads in 45% yield, as determined by denaturing PAGE, and analyzed by MALDI-TOF-MS (Figure 4b). The strongest signal in the purified product mixture is the desired tripeptide **16** with the most significant side product being the dipeptide R^1–R^3 which results from the lack of reaction with **14**. Sequence-mismatched reagents **13b** or **14b** were unable to react in place of **13** or **14** (see the Supporting Information).

When the oligonucleotides linked to the R^1 and R^2 groups were swapped, the order of building-block addition was also switched (R^2 added first at 4 °C, then R^1 added at 37 °C; see the Supporting Information). The biotinylated products of this reaction sequence, including the ordered tripeptide **12**-R^2-R^1-R^3, were isolated in 38% yield after streptavidin purification. For this reaction, the desired tripeptide and truncated side products were resolvable by denaturing PAGE (unlike in the case of **16**), revealing that 55% of the isolated material (21% total overall yield) is the ordered tripeptide (see the Supporting Information). Taken together, these findings indicate that the use of temperature-controlled template masking enables substrates that would normally form a vast mixture of oligomeric products to react in a predominantly ordered manner.

These results represent single-solution ordered multistep syntheses using comparably reactive substrates in the absence of enzymes with only a temperature gradient needed to coordinate the timing of three successive reactions. Both strategies offer faster, higher-yielding routes to multistep DNA-linked products constructed from autocleaving reagents[6] than past examples (indeed, a previous DNA-templated tripeptide synthesis using three discrete steps proceeded in 3% overall yield).[6] In addition to enabling a mode of chemical reactivity that is not possible in a conventional synthesis format, these concepts may also facilitate the design of additional systems that mimic the efficiency and selectivity of organic synthesis in the cell without the structural constraints imposed by enzymes.

Small-Molecule Diversification from Iterated Branching Reaction Pathways Enabled by DNA-Templated Synthesis**

*Christopher T. Calderone and David R. Liu**

As synthetic small molecules continue to interface with an increasingly large swath of biology,[1,2] researchers have sought new approaches to rapidly create collections of highly diverse small molecules.[3] Early small-molecule libraries generally contained a single core scaffold decorated by different chemical groups.[4] Later efforts introduced modest structural variation in the central scaffold.[5] More recently, researchers have introduced libraries based on "folding pathways", in which library intermediates undergo diverse rearrangements, and "differentiation pathways", in which intermediates are treated with different reagents to yield different scaffolds.[3] Incorporating such branching reaction pathways into library syntheses is a promising strategy for the creation of small-molecule diversity beyond what can be accessed by using nonbranched synthetic routes.[6]

The vast majority of current library synthesis efforts are based on solid-phase, split-pool methodologies.[7,8] Although these methods offer technical advantages, they also limit the diversity of structures that can be created. With relatively few exceptions,[5,9–11] it is generally not possible to direct a specific subset within a mixture of beads (for example, those beads containing molecules with a primary amine group) to one of several possible subsequent reaction conditions (for example, exposure to an acylating agent). As a result, every intermediate in a split-pool library synthesis must be reactive toward any reactant it may encounter in a subsequent step. Moreover, it is usually not possible to purify unreacted support-bound starting material away from desired products after each library synthesis step, so only highly efficient reactions can be used. As a result, the diversification of scaffolds during library synthesis has thus far been limited to a single (predominantly terminal) step.[12–15]

We recently demonstrated the ability of DNA-templated organic synthesis (DTS) to direct multiple, otherwise incompatible reactions in a single vessel.[16] We speculated that this feature and other properties of DTS,[17] such as the ability to purify library intermediates away from starting materials independent of product structure in a single manipulation,[18,19] would enable DTS-driven library synthesis to exploit branching reaction pathways at multiple steps, thus creating a network of reaction sequences that generates highly diverse families of molecules within a single library.[16] To implement the concept of iterated branching reaction pathways in a DNA-templated format, we set out to transform a single solution containing five DNA templates into five diverse types of product structures, each arising from a unique sequence of reactions. We designed a synthetic route (Scheme 1) that combines base-labile sulfone[18] and thioester[20] linkers, previously developed for multistep DTS, together with amine acylation,[21] aldehyde thiazolidination, Wittig olefination,[21] carboxylate amidation, and palladium-catalyzed cross-coupling chemistries.[21,22]

In previous DNA-templated libraries,[19] split-pool oligonucleotide synthesis was used to generate starting-template pools in which every combination of reagent annealing sequence ("codons") was represented. In the case of libraries constructed from branching reaction pathways, however, only a fraction of such a collection of templates would encode productive reaction sequences. For example, only 36% of the possible templates of the format (reaction 1 codon)–(reaction 2 codon)–(reaction 3 codon) encode three-step products in the branching library synthesis shown in Scheme 1. To address this problem, we developed a cassette ligation strategy to generate starting-template pools. In this strategy, single-stranded DNA overhangs at the ends of each cassette were designed such that ligation is only possible between adjacent cassettes that encode productive reaction sequences (see the Supporting Information).

To validate each three-step pathway, we optimized the five syntheses individually such that all step-1 reactions, all step-2 reactions, and all step-3 reactions are carried out under reaction conditions (a), (b), or (c), respectively (Figure 1). Each pathway was then individually executed starting with amine-terminated oligonucleotide **1**. After each step, the reaction mixture was captured on immobilized streptavidin and washed to remove any starting material template. The desired template-linked product eluted from the beads upon base-induced linker cleavage.[18]

All five pathways begin with amine acylation (step 1). In step 2—the first branching step—the step-1 products participate in one of three reactions (acylation, thiazolidine formation, or Wittig olefination) dictated by the identity of the previous reaction partner of each molecule. For example, the step-1 products containing phosphorane groups exclusively participate in step-2 Wittig olefination reactions. Step 3 represents a second branch point, in which each reaction type is dictated by the structure established in step 2.

Pathway I consists of amine acylation followed by thiazolidine formation and amidation. Disulfide-protected L-cysteine was sequence-specifically delivered to the template **1** upon addition of 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide (EDC) and *N*-hydroxysulfosuccinimide (*s*-NHS) in 26% yield of isolated product. After disulfide reduction,

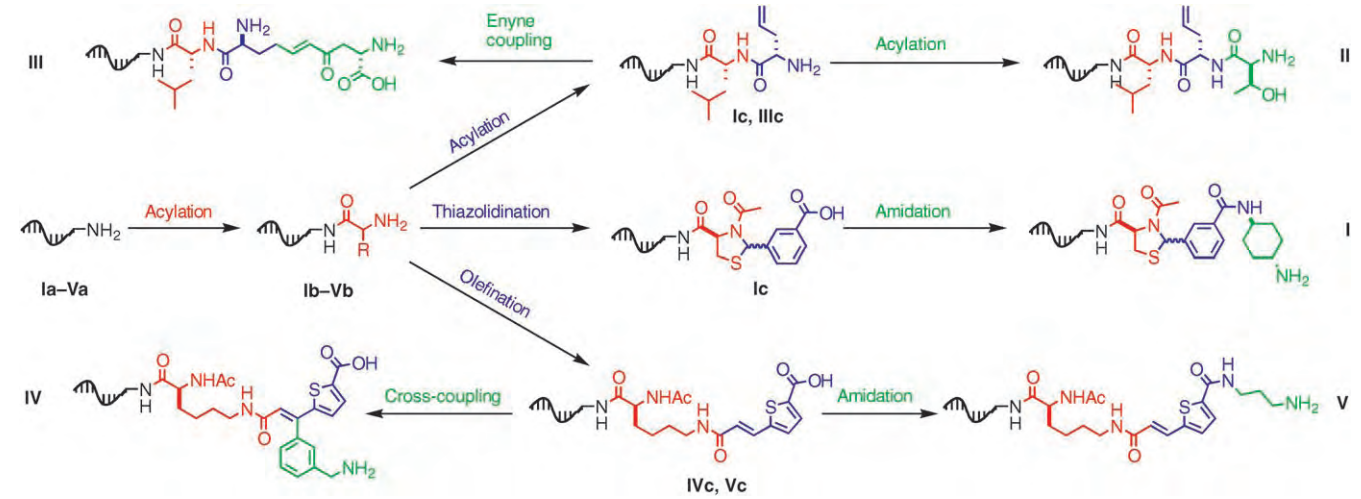

Scheme 1. Synthetic strategy for iterated branching reaction pathways.

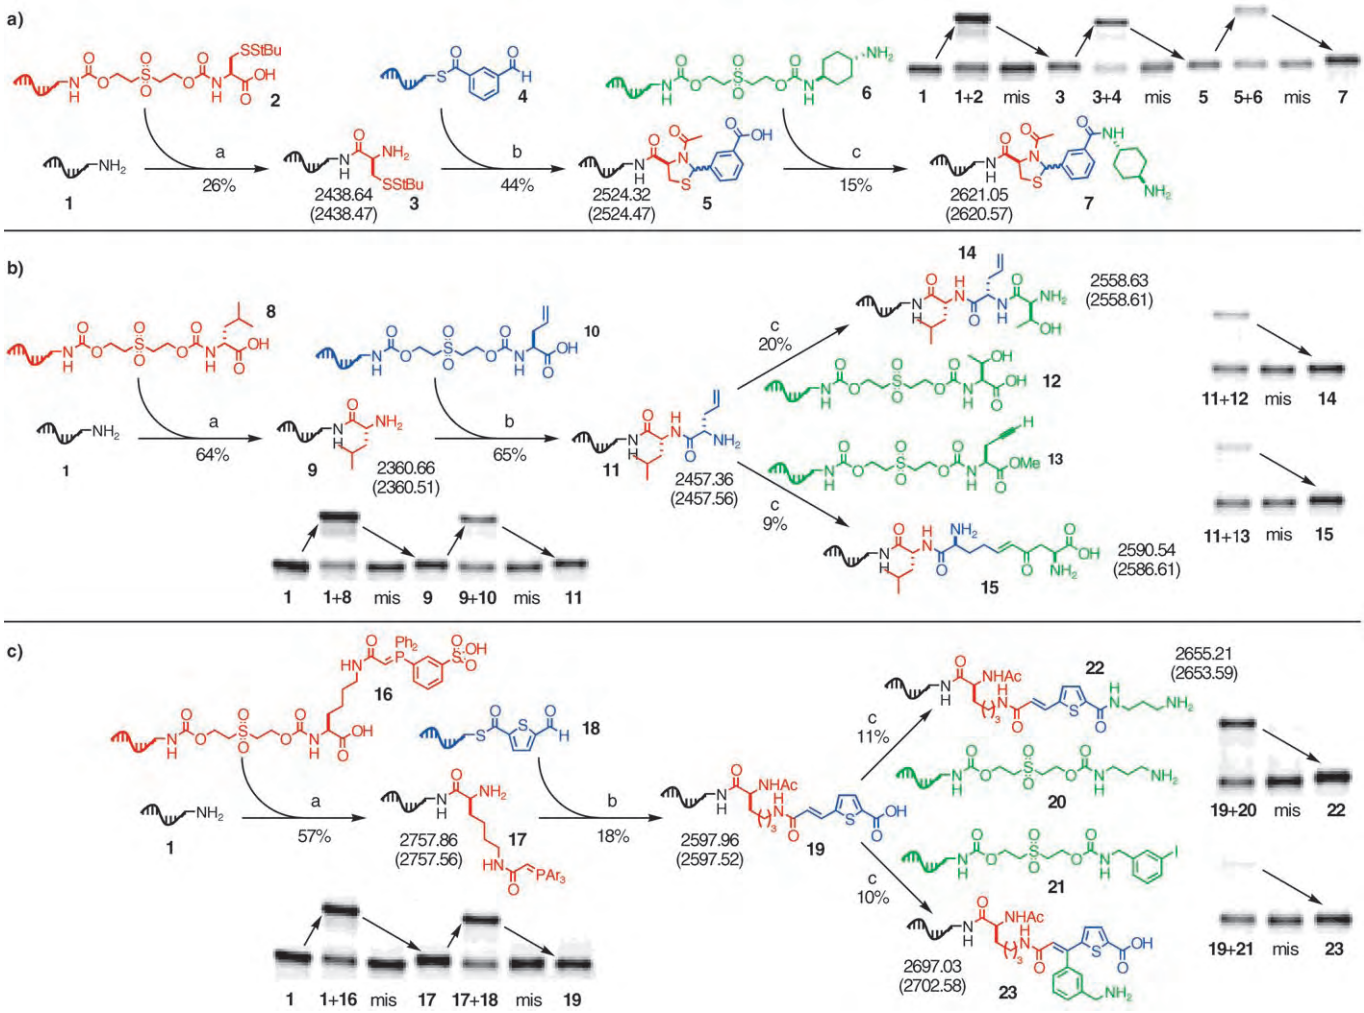

Figure 1. Individual validation of the five reaction pathways. Template amine **1** was separately treated with the specified oligonucleotide-linked reagents to yield **7**, **14**, **15**, **22**, and **23**. In each denaturing polyacrylamide gel electrophoresis (PAGE) image, lower bands represent template **1** or functionalized derivatives thereof, and upper bands represent covalently linked template–reagent pairs. Each cleaved intermediate was digested with *Eco*RI and subjected to mass-spectrometric analysis as shown, with calculated masses given in parentheses. To verify sequence specificity of each DNA-templated reaction, a sample of each template intermediate was treated with a reagent oligonucleotide containing a scrambled DNA sequence ("mis"). Reaction conditions: a) 20 mM EDC, 15 mM *s*-NHS, pH 6.0, 12 h, 23 °C, then pH 10.0 buffer, 2 h, 37 °C; b) 25 mM 1,4-dithiothreitol (DTT), pH 8.5, 1 h, 37 °C, then pH 7.0 buffer, 90 min, then 20 mM EDC, 15 mM *s*-NHS, 12 h, 23 °C, then 1:200 volume Ac_2O, 1 h, then pH 12.0 buffer, 10 mM 2-mercaptoethanol, 1 h, 37 °C; c) 1 M NaBr, 50 μM $Na_2[PdCl_4]$, pH 6.0, 4 h, 37 °C, then 25 mM DTT, 10 min, 85 °C, then 20 mM EDC, 15 mM *s*-NHS, pH 6.0, 12 h, 23 °C, then pH 12.0 buffer, 30 min, 23 °C.

treatment with a complementary DNA-linked thiol bearing 3-formylbenzoic acid for 90 min before the addition of EDC/*s*-NHS and acetylation yielded thiazolidine **5** in 44% yield. Treatment with Pd^{II} at 37°C for 4 h and addition of EDC/*s*-NHS yielded product **7** in 15% yield (2% overall yield of isolated product over three steps, Figure 1a).

Pathways II and III use identical reaction conditions as pathway I but effect two consecutive amine acylations in steps 1 and 2. The third step of pathway II consists of a final amine acylation to yield a tripeptide, whereas the third step of pathway III uses a palladium-catalyzed alkene–alkyne coupling to generate an enone.[22] To validate these pathways, D-leucine and L-allylglycine were sequentially added to template **1** (steps 1 and 2) in 64 and 65% yields of the isolated products, respectively, to form **11**. In step 3, the allylglycine was either acylated with L-threonine to yield tripeptide **14** in 20% yield (pathway III, 8.3% yield of the isolated product over three steps) or was cross-coupled[22] with the alkyne group in L-propargylglycine to yield enone **15** in 8% yield (pathway IV, 3.6% yield of the isolated product over three steps; Figure 1b).

Finally, pathways IV and V begin with amine acylation followed by Wittig olefination. The third step of pathway IV is carboxylate amidation, whereas the third step in pathway V is a palladium-catalyzed Heck reaction. Thus, a lysine derivative bearing a side-chain phosphorane **16** was coupled to **1** (step 1) in 57% yield of the isolated product followed by incubation with the DNA thioester of formylthiophene carboxylic acid (step 2) to yield **19** in 18% yield of isolated product. In the third step, treatment with amine **20** yielded disubstituted olefin **22** in 11% yield of isolated product (1.7% yield over three steps), whereas the Heck coupling with aryl iodide **21** yielded trisubstituted olefin **23** in 10% yield of isolated product (0.8% yield over three steps; Figure 1c). All five pathways were monitored by gel electrophoresis and MALDI-TOF mass-spectrometric analysis. Each pathway yielded intermediates and final products whose electrophoretic behavior and mass-spectrometric characterization were consistent with the desired structures. The reaction sequences resulted in product yields similar to those reported for previous three-step DNA-templated synthetic sequences, despite requiring compromises among the different optimal reaction conditions in steps 2 and 3.[18–20]

Having developed each of the pathways individually, we next performed the simultaneous synthesis of **I**–**V** in a single solution per step (Figure 2). The ligated and gel-purified pool of templates was treated with 1.5 equivalents of each functionalized-reagent DNA per step and was incubated under the same conditions used to verify each pathway individually. After each step, we observed only the presence of desired products by nuclease digestion followed by MALDI-TOF-MS. To evaluate the sequence specificity of each reaction, each step was repeated using reagents linked to noncomplementary (mismatched) oligonucleotides. No significant product formation (< 5%) was observed (Figure 2). Because not all five templates yield step-1 and -2 products that are distinguishable by mass, we also treated an aliquot of material at each step with a reactive oligonucleotide uniquely complementary to each template (**I′**–**V′**), thus converting a portion of each pool into a higher-molecular-weight species

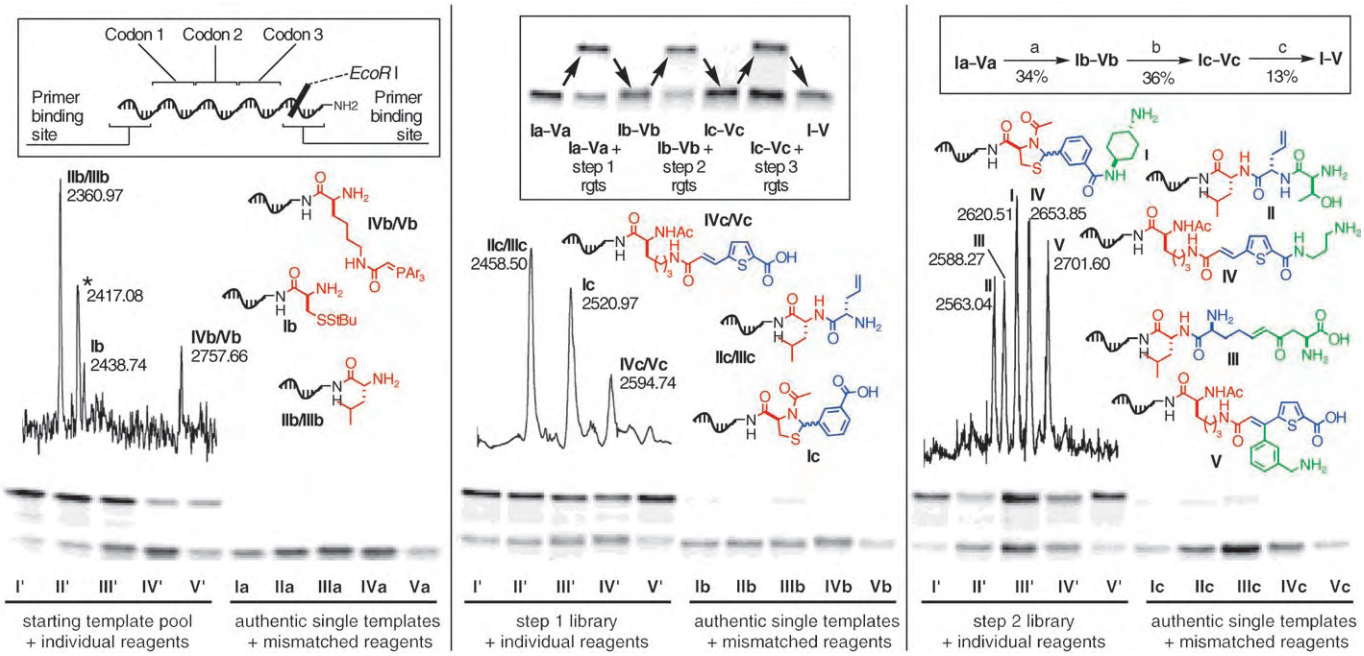

Figure 2. Characterization of the single solution per step (pooled) synthesis of **I**–**V**. PAGE analysis of the three pooled steps is shown in the upper gel image. In the mass spectrum of step 1, the peak denoted with an asterisk arises from the decomposition of **IVb** and **Vb** during mass-spectrometric analysis (see the Supporting Information). In each of the lower gels, the five lanes furthest on the left show the reaction of the starting-template pool, step-1 product pool, or step-2 product pool with each of the reagents **I′**–**V′**, which are reactive with and uniquely complementary to templates **Ia**–**Va**, respectively. The five lanes furthest on the right of each lower gel image show the reaction of individual starting materials for each step under conditions identical to those of the actual library synthesis (see Figure 1), but with sequence-mismatched reagents.

and confirming that all five templates were present at every step of the pooled synthesis (see the Supporting Information).

From 8 nmol of template, we obtained 125 pmol of **I**–**V** which corresponds to an average overall yield of 1.6% of isolated product. This quantity of material, even if hypothetically divided among thousands of library members, is sufficient for >1000 in vitro selections and PCR-based amplifications needed to identify library members with desired properties.[19,23] Our initial use of iterated branching reaction pathways demonstrates the promise of such an approach in the synthesis of diverse small-molecule libraries that would be challenging to create by using current library synthesis methods. The structures created in this work also include several of the most complex synthetic small-molecule products translated from DNA to date.

Anion-Induced Synthesis and Combinatorial Selection of Polypyrrolic Macrocycles**

*Evgeny A. Katayev, G. Dan Pantos, Marina D. Reshetova, Victor N. Khrustalev, Vincent M. Lynch, Yuri A. Ustynyuk, and Jonathan L. Sessler**

One of the current challenges in the area of supramolecular chemistry involves the preparation of anion receptors with high selectivity for specifically targeted anionic guests.[1] Such systems could have an important role to play in a variety of applications, including sensing, analysis, waste remediation, and drug development. One approach for designing highly efficient anion receptors is to use anion-templated strategies to produce macrocyclic systems whose geometry is complementary to that of the targeted guests.[2] Although this concept has yet to be extensively exploited in the case of pyrrole-based systems, recently we prepared cyclo[*n*]pyrroles through self-coupling of bipyrroles under oxidative conditions in the presence of suitable anionic templates. In earlier work, we found that bipyrrole-amide-derived catenanes[3] and the Schiff base expanded porphyrin **1** ("USAphyrin")[4] could be synthesized using anion-templated processes. Finally, in the case of the 2,6-diamidopyridine-containing system **2**, we noted that improved yields were seen when the initial macrocycle-forming reaction was carried out in the presence

1 2

of sulfuric acid or trifluoroacetic acid.[5] Given these results, we sought to explore the effects of such putative anion-template effects in the case of other 2,6-diamidopyridine pyrrolic macrocycles. Herein, we report the anion-induced synthesis of a new class of 2,6-diamidopyridine-bipyrrole macrocyclic receptors that undergo combinatorial selection as the result of their interaction with anionic guests. This stimulus-driven reaction outcome bears analogy, and provides an interesting complement, to recent macrocycle-forming strategies based on dynamic combinatorial processes.[6]

The incorporation of 2,6-diamidopyridine subunits into appropriately designed macrocycles has been shown by us[5,7] and others[8] to result in systems that display selectivity for tetrahedral over trigonal-planar anions. A different structural motif, namely, bipyrrole, has also been used extensively by our groups to produce anion receptors, including several that display selectivity towards sulfate and other tetrahedral anions.[9,10] Thus, we were keen to explore whether macrocycles containing these two key subunits could be readily prepared and, if so, whether the reactions leading to their formation could be mediated by anion templation. To this end, the diformylbipyrrole **4**[11] was treated with diamine **3** in methanol under acidic conditions (Scheme 1). This led to the formation of Schiff base containing macrocycles along with linear oligomeric species. The choice of the acid used to promote these reactions (HCl, HBr, CH_3CO_2H, CF_3CO_2H, H_3PO_4, H_2SO_4, HNO_3) plays a critical role in defining the product distribution. In most cases, the products precipitated as the corresponding acid salts. These precipitates and the reaction mixtures themselves were analyzed by ESI and MALDI-TOF mass spectrometry. For instance, the use of hydrochloric and hydrobromic acids led to the formation of oligomers with high molecular weights ($m/z > 3000$) as the major products, with only small amounts of the [1+1] macrocycle being produced under these conditions. This latter product displayed low stability and appeared to undergo decomposition during the workup and purification stages. The use of acetic, trifluoroacetic, and phosphoric acids led to the formation of the [2+2] macrocycle **5**, which was contaminated with appreciable quantities of uncharacterized oligomers. When nitric acid was employed, only oligomeric species with high molecular weights were formed. In contrast, the use of sulfuric acid produced the [2+2] macrocycle **5**, nearly free of other side products. The resulting salt, $\mathbf{5}\cdot 2\,H_2SO_4$, was then suspended in CH_2Cl_2 and treated with triethylamine to give the free macrocycle **5** in 75% isolated yield based on **4**.

A single-crystal X-ray diffraction analysis of **5** (Figure 1) provided proof for the proposed structure and revealed that

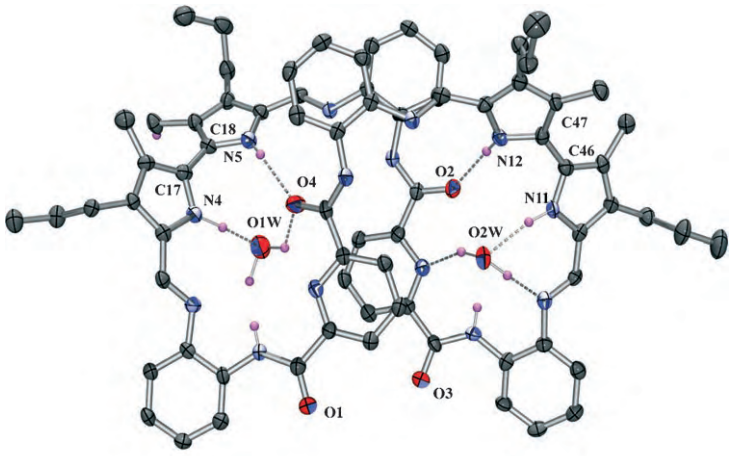

Figure 1. ORTEP-rendered view of **5** showing the two bound solvent water molecules. Three dichloromethane molecules and most hydrogen atoms have been omitted for clarity. Thermal ellipsoids are scaled to the 50% probability level. C gray, N blue, O red, H pink; dashed lines indicate hydrogen-bonding interactions. Key bond parameters: N5-H···O4 (N···O 3.109(4), H···O 2.29(4) Å, N-H···O 169(3)°); N12-H···O2 (N···O 3.013(4), H···O 2.18(4) Å, N-H···O 177(3)°).

the macrocycle adopts a figure-of-eight conformation in the solid state.[12] This three-dimensional structure is stabilized by a pair of intramolecular hydrogen bonds between the pyrrole NH protons and the amide oxygen atoms O2 and O4 that point towards the interior of the cavity. The bipyrrole fragments are twisted in both bipyrrole units, displaying dihedral angles N4-C17-C18-N5 and N11-C46-C47-N12 of 50.5(6)° and 34.4(6)°, respectively. The 2,6-diamidopyridine fragments are in a *trans*

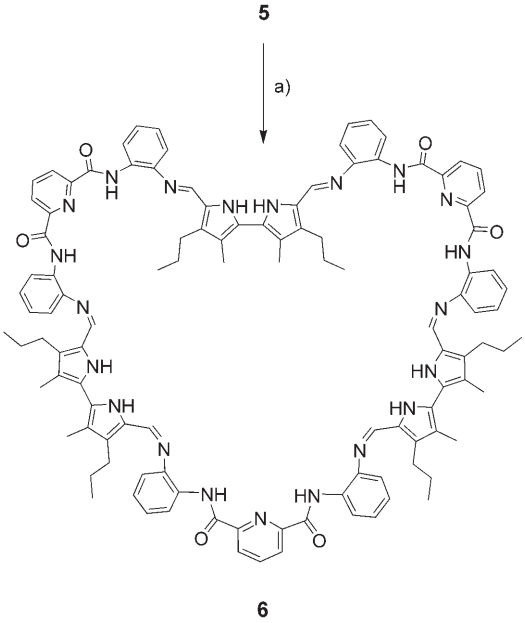
orientation, and the amide oxygen atoms O1 and O3 that point towards the exterior of the cavity are hydrogen bonded to one dichloromethane molecule and one water (O1W) molecule, respectively. These latter intermolecular interactions presumably account for the dimerization of **5** observed in the solid state (see Supporting Information). One water molecule (O1W) is partially constrained within the macrocycle, while a second water molecule (O2W) is entirely trapped within the macrocycle. The hydrogen-bonding interactions that stabilize these species are described in the Supporting Information.

The ^{1}H NMR spectrum of **5** in $CDCl_3$ at room temperature reveals a nonequivalence for all the methyl and methylene signals, as well as a complex patterns in the aromatic region that is most readily interpreted in terms of the retention of the figure-of-eight conformation of **5** in this nonpolar solvent. At 60 °C the spectrum simplifies dramatically. Such a simplification is also observed in polar solvents (e.g. pyridine, THF) at room temperature. Presumably, this reflects the fact that in both cases the intramolecular hydrogen bonds that stabilize the figure-of-eight conformation in $CDCl_3$ at room temperature are weakened or destroyed.

The presence of bound water molecules in the solid-state structure of **5** (see Figure 1), along with the presence of what appears to be two well-defined binding pockets, led to the consideration that **5**, like its congener **2**, might act as an effective receptor for anions. Anion-binding studies were thus performed using UV/Vis spectroscopic titrations. To maintain consistency with previously reported results,[5,7] these studies were carried out in CH_3CN at 23 °C using various tetrabutylammonium (TBA) salts. Where appropriate, binding stoichiometries were determined using Job plots. On this basis it was found that macrocycle **5** interacts strongly with the tetrahedral anions HSO_4^- (1:1; $K_a = 63\,500 \pm 3000\,\text{M}^{-1}$) and $H_2PO_4^-$ (2:1; $K_{a1} = 191\,000 \pm 15\,400\,\text{M}^{-1}$; $K_{a2} = 60\,200 \pm 6000\,\text{M}^{-1}$; $K_a = 107\,000 \pm 9600\,\text{M}^{-1}$ where $K_a = (K_{a1} \times K_{a2})^{0.5}$), weakly with acetate (1:1, $K_a = 26\,000 \pm 2400\,\text{M}^{-1}$), and essentially not at all with the other anions tested, namely chloride, bromide, and nitrate (K_a values were below the detection limits in all cases). Such findings are not surprising in light of the fact that the initial "synthetic selection" in favor of macrocycle **5** was performed using a tetrahedral anion (HSO_4^-) as the template.

Interestingly, of the two tetrahedral anions subject to study, namely HSO_4^- and $H_2PO_4^-$, dihydrogen phosphate is bound more strongly and by a stepwise 2:1, as opposed to 1:1, guest/host binding process (see the K_a values given above). This result is in accord with our previous finding[5] that the related flexible macrocyclic receptor **1** also binds dihydrogen phosphate more strongly than sulfate ions and likewise displays a 2:1 guest/host binding stoichiometry.

While macrocycle **5** proved quite stable under most laboratory conditions, when dissolved in acetonitrile and allowed to stand for 5 days in the presence of dihydrogen phosphate and hydrogen sulfate (tetrabutylammonium salts) it was found to undergo rearrangement to give the corresponding [3+3] analogue **6** in quantitative and 47% yield, respectively (Scheme 2).[13] The use of chlorinated solvents during this transformation did not produce **6** but rather



Scheme 2. a) $TBAHSO_4$, acetonitrile, 5 days, room temperature without stirring, followed by Et_3N; or $TBAH_2PO_4$, acetonitrile, 5 days, room temperature without stirring.

yielded traces of the [1+1] macrocycle (as inferred from mass spectrometric studies) along with a wide variety of soluble compounds, which as yet have not been characterized. This behavior was observed whether the reactions were performed at room temperature or at reflux. However, the ring-expanded product was formed only in traces when the reaction mixture was subject to stirring for 2 days in the presence of $TBAHSO_4$; in this case, a precipitate of $\mathbf{5}\cdot 4\,H_2SO_4$ was observed to form, along with soluble oligomeric compounds. The isolated yield for $\mathbf{5}\cdot 4\,H_2SO_4$ following this latter procedure was 30%. The salt $\mathbf{5}\cdot 4\,H_2SO_4$ (characterized by elemental analysis) differs from $\mathbf{5}\cdot 2\,H_2SO_4$ in its chemical properties and displays, for instance, different solubility in organic solvents. Pure free base **5** may be obtained in quantitative yield by treating solutions of $\mathbf{5}\cdot 4\,H_2SO_4$ in methylene chloride with triethylamine. Also note that there is no evidence that the ring-expanded product **6**, in either its neutral or acid salt form, is generated during the initial anion-induced synthesis of **5**.

From these observations we postulate that the kinetics and thermodynamics of product formation are a subtle function of the reaction conditions. In particular, we suggest that when the reaction mixture is subject to stirring, the salt $\mathbf{5}\cdot 4\,H_2SO_4$ is formed quickly (kinetic product) and under conditions that favor its precipitation, a follow-up process that also serves to affect the thermodynamics of the reaction. By contrast, in the absence of stirring, the precipitation of $\mathbf{5}\cdot 4\,H_2SO_4$ is slow and allows the isolation of **6** as the thermodynamic product. Further tests that are designed to confirm or refute such mechanistic rationalizations are currently underway.

While macrocycle **6** proved to be relatively stable in acetonitrile, both as the free base and as its H_2SO_4 salt, it was found to undergo decomposition, often rapidly, in other

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

solvent systems. Decomposition was also induced upon the addition of anions other than sulfate or phosphate, a finding that served to underscore the special, anion-specific conditions that lead to its formation.

Proof for the structure of **6**, came from a single-crystal analysis of its hydrogensulfate salt, **6**·H_2SO_4 (Figure 2[14]).

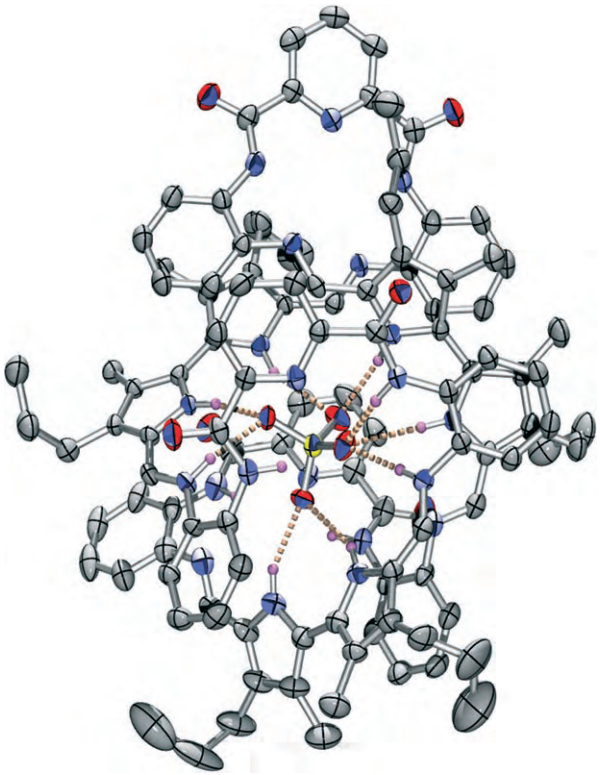


Figure 2. View of the macrocyclic complex **6**·H_2SO_4. Displacement ellipsoids are scaled to the 50% probability level. Solvent molecules (2×CH_3CN and 1×pentane), as well as hydrogen atoms, have been removed for clarity. C gray, N blue, O red, H pink; dashed lines indicate hydrogen-bonding interactions.

Although complicated, the resulting structure clearly reveals a doubly twisted, diprotonated macrocyclic dication that encapsulates a sulfate dianion. This dianion is coordinated through an intricate network of hydrogen bonds (see Supporting Information). The hydrogen-bond donors in this network consist of the NH protons from the three bipyrrole subunits, three NH protons from two 2,6-diamidopyridine subunits, and two NH protons from two protonated imine fragments. Several of these key interactions are highlighted in Figure 3. All the 2,6-diamidopyridine subunits are in their respective *cis* orientations.

The present findings provide evidence for an anion-templated reaction between diamine **3** and bipyrrole dialdehyde **4**, as well as the anion-triggered combinatorial selection of a given macrocyclic product under a particular set of experimental conditions. The present reorganization reaction differs from dynamic combinatorial libraries in that selection from a true equilibrium mixture does not occur. Instead, the choice of the anion template serves to drive the reaction towards the formation of the most stable species under the

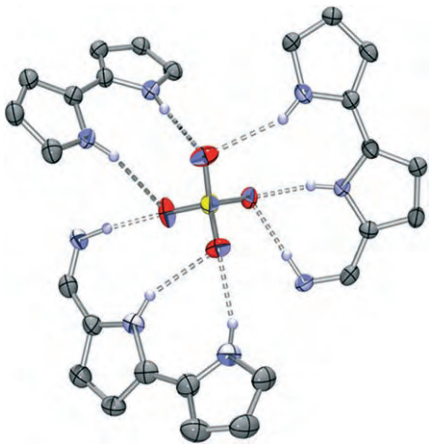

Figure 3. ORTEP–Povray-rendered view of bipyrrole and tethered protonated imine fragments forming hydrogen bonds with the sulfate ion. All other parts of the molecule have been omitted for clarity. specific reaction conditions involved. In other words, the modifications used to obtain **6** from **5** (i.e. addition of the appropriate anion) serve to change the fundamental thermodynamic conditions of the system as a whole. As a consequence, a stable molecule (e.g. **5**) undergoes partial or complete decomposition only to be reassembled into a more stable homologue (**6**). Under the most favorable of conditions, an impressive degree of selectivity is observed which leads us to suggest that this strategy could provide a new concept for the design and synthesis of novel receptor systems. Work designed to explore this intriguing possibility is currently in progress.

Molecular Wires from Contorted Aromatic Compounds**

*Shengxiong Xiao, Matthew Myers, Qian Miao, Sébastien Sanaur, Keliang Pang, Michael L. Steigerwald, and Colin Nuckolls**

Dedicated to Professor Thomas J. Katz

The use of planar molecules is one unifying design feature in essentially all the molecules that have been tested to date in organic field-effect transistors.[1–7] The concept explored herein is whether a nonplanar aromatic core could yield efficacious electronic materials. One significant aspect of using a nonplanar core is that the aromatic rings would be forced to adopt new and unusual intermolecular contacts that are typically unavailable to flat molecules. Moreover, these informationally rich subunits could form the basis for self-assembled and self-healing electronic materials if the core could be bent into a shape that was self-complementary.

Herein, we detail the first studies of the self-assembly and electrical properties of a new type of hexabenzocoronene (HBC) **1**, whose aromatic core is distorted away from planarity by steric congestion in its proximal carbon atoms. We became interested in this class of compound because it combines structural elements of linear acenes, which are well-

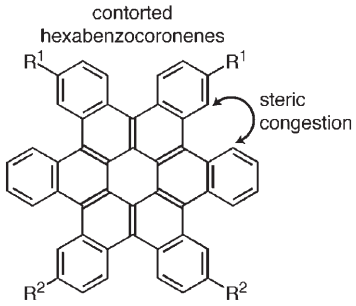
known electronic materials,[2,5,8–11] with a disk-shaped and potentially columnar liquid-crystalline core.[12–20] Methods for the synthesis and derivatization of **1** are essentially unknown.[21] Our important finding is that some derivatives of this new class of compound self-organize into liquid-crystalline phases composed of molecular stacks that orient themselves parallel to the surface. Field-effect transistors based on these materials show high charge-carrier mobilities, high on/off ratios, and low turn-on voltages.



1a: $R^1 = R^2 = H$
1b: $R^1 = H$, $R^2 = OC_{12}H_{25}$
1c: $R^1 = R^2 = OC_{12}H_{25}$

Compounds **1a–c**[22] are yellow-orange solids that are readily soluble in a number of common organic solvents; for example, more than 200 mg of **1c** can be dissolved in 1 mL of $CHCl_3$. Furthermore, these solutions have an intense optical emission in the visible region. The thermal and oxidative stabilities of these compounds are also remarkable, as no loss of color is observed when oxygen is bubbled through solutions of **1a–c** over a period of a few hours under ambient light. Under identical conditions, solutions of pentacene lose their color within a few minutes through photooxidation.[23] Differential scanning calorimetry (DSC) showed no decomposition of **1a–c** up to temperatures well above 320 °C. Uniform films (approximately 100-nm thick) could be formed by spin-casting **1c** from 1,2-dichloroethane or $CHCl_3$. In contrast, films formed from **1a** and **1b** were granular in appearance and of a low quality. The ability to form good films of **1c** is a harbinger of the electrical properties described below.

Field-effect transistors were fabricated on spin-cast films of **1a–c** (Figure 1a shows the structure of the resulting devices). Transistors fabricated from **1c** have good electrical characteristics, whereas those prepared from **1a** and **1b** showed no useful properties. We deposited Au source and drain electrodes by thermal evaporation onto the spin-cast films through a metal-shadow mask. The channel length was 75 μm and the electrode width was 2 mm, and the transconductance and transistor output are shown in Figure 1b,c. The mobility (0.02 $cm^2 V^{-1} s^{-1}$) shown is calculated from the linear portion of the data in Figure 1b[24] and uses a capacitance of 11.3 $nF cm^{-2}$ for the gate dielectric layer (300 nm of SiO_2 and a monolayer of octadecyltrichlorosilane).[11] The gate dielectric capacitance comes from measurements made over a range of frequencies[11] and is as expected for a 300-nm-thick layer of silicon oxide with few defects.[25] Other critical parameters, such as the threshold voltage for the device to turn on (as low as −3 V for some

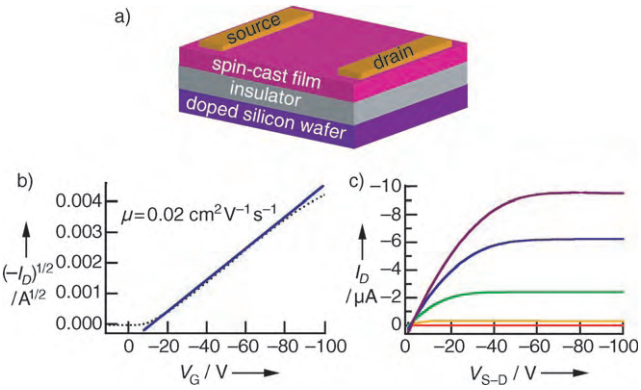


Figure 1. a) Schematic diagram of a field-effect transistor that was fabricated by evaporating source and drain electrodes onto a spin-cast film of **1c**. b) Transconductance: the blue line is a fit of the linear portion of the data points (the source–drain voltage V_{S-D} was held at −60 V). c) Transistor output for thin-film transistors from **1c**.

devices prepared from **1c**) and the on/off current ratios in the device (10^6:1), are also very good. These values are the best field-effect transistor properties achieved for a columnar discotic material[16,17,26,27] (see below) and are good for spin-cast films in general.[8,28–34] These results are even more impressive because it is likely that these properties could be improved by adjustment of critical parameters such as grain size, deposition conditions, and direction of column growth.

Encouraging electrical properties are only developed in the more substituted derivatives of **1**, thus indicating self-organization. One of the hallmarks of many self-assembled systems is the presence of liquid-crystalline phases. Each of these compounds were investigated by DSC, polarized light microscopy, and X-ray diffraction to determine whether mesophases are present (the DSC trace for **1c** is shown in Figure 2a). An extra transition that indicates the presence of an intermediate phase can be seen from both the heating and cooling cycles for **1c**. The microscopy and X-ray diffraction studies of **1c** (see below) indicate that it is a liquid-crystalline phase between 91 and 285 °C, whereas above these temperatures it melts to form an isotropic liquid. The enthalpy values, particularly going from the liquid-crystalline phase to the isotropic liquid phase, are larger than those typically observed for discotic liquid crystals.[12] This difference implies that **1c** associates strongly in this intermediate phase, possibly because it is not a flat disk.[35] DSC studies do not show any evidence for a liquid-crystalline phase for **1a** and **1b**; they simply melt, **1a** at 516 °C[21] and **1b** at 220 °C. The appearance of a mesophase correlates with **1c** having good electrical properties and indicates the potential of self-organized materials for electronic applications.

The structure of this phase was probed by powder X-ray diffraction studies and was found to be a hexagonally ordered columnar liquid-crystalline phase for **1c**. In the X-ray diffraction studies, **1c** was heated (in a Lindemann capillary tube) to an isotropic liquid (295 °C) and cooled into its mesophase. The data shown in Figure 2b were collected upon cooling to 120 °C. The diffractogram is dominated by an intense reflection characteristic of $d \approx 26$ Å. The only other discernible features of the diffractogram are two very weak,

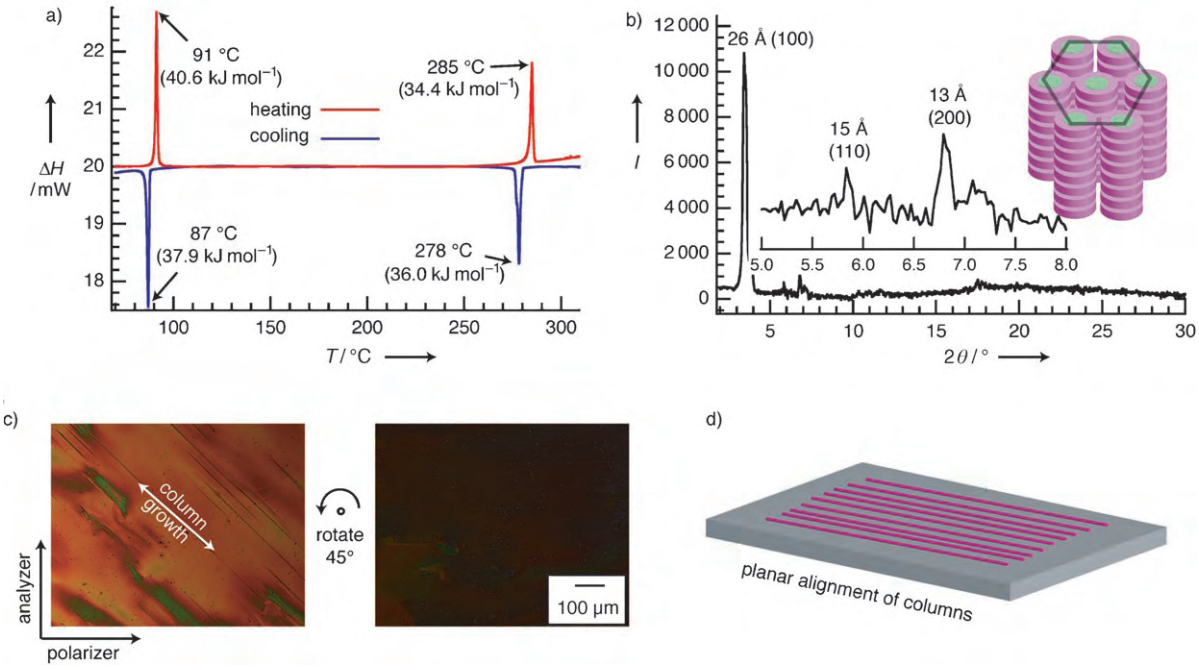

Figure 2. a) DSC trace of **1c** (scan rate = 5 °C min^{-1}) showing a mesophase. b) X-ray diffraction studies of **1c** cooled into its mesophase from 295 to 120 °C and a hexagonal lattice of columns. c) Polarized light micrograph of **1c** cooled into its mesophase which shows a planar alignment of columns that are extinguished when aligned with the polarizer or analyzer axes. The cooling rate was 5 °C min^{-1}, and the exposure time was the same for each picture. d) Schematic diagram of columns aligned parallel to the surface.

higher-order reflections ($d = 15$ and 13 Å) that allow the lattice to be indexed to a hexagonal arrangement of columns. The lack of intensity in these higher-order reflections indicates that the columns are not well correlated with each other, which is likely to be a result of the subunits not having a perfect disk shape, as is implied by the molecular model in Figure 3. The fourfold substitution would signal that at some level there is a competition between rectangular and hexagonal lattice formation.

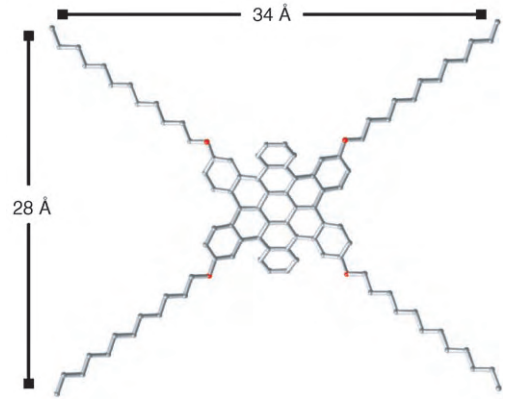

Figure 3. Molecular model of **1c** with its side chains fully extended.

Polarized light microscopy revealed that these materials tend to orient their columns parallel to the surface. The micrograph of a sample cooled to just below 278 °C and captured as the mesophase formed is shown in Figure 2c. The birefringence of the domains is extinguished when the column axes are aligned with the polarizer or analyzer (Figure 2c) and is maximally bright when the stage is rotated by 45°. The micrograph is characteristic of a planar arrangement[36] of columns in a discotic mesophase (shown schematically in Figure 2d). This arrangement of columns is important because the current flow in thin-film transistors is parallel to the surface and, in this case, runs along the column axis.

Strong aggregation of **1c** occurs in solution, thus further indicating its tendency to self-associate. NMR, UV/Vis, and fluorescence spectroscopic techniques were used to monitor this aggregation in solution. All the resonances from the protons of the aromatic ring shifted upfield as the solutions of **1c** were concentrated. For example, the ring protons of **1c** shift upfield by approximately $\Delta\delta = 0.13$ ppm in $CDCl_3$ as the concentration is increased from 6.3 to 126 mg mL^{-1}. This shift is a result of shielding from the ring current of neighboring aromatic compounds within a cofacial stack.[37–39] This face-to-face association of molecules can be further probed by UV/Vis absorption and fluorescence emission spectroscopy. In both cases, the maxima are red-shifted as the solutions become more concentrated. This behavior is not unique as there are many discotic materials that also aggregate in solution to form isolated molecular columns which show similar shifts in their UV/Vis and fluorescence spectra.[40–43] The formation of the columns from the interlocking of gearlike molecular subunits is the model that develops from these spectroscopic data.

When films of these materials are spin-cast onto transparent substrates, birefringent domains form that have the same extinction as that described for the bulk films in

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Figure 2c, thus indicating that the films also have their columns aligned parallel to the substrate. Aggregation in solution that causes the formation of columns, which can then be deposited by spin-casting, is likely to be responsible for the good electrical properties of **1c**.

Crystals of the parent HBC **1a** were grown to investigate the underlying molecular structure of the HBCs.[44] The crystals were grown from 1,2,4-trichlorobenzene and shown to include two disordered solvent molecules oriented over the coronene core. The molecular structure of this HBC moiety is shown in Figure 4a–d. The three intersecting pentacene

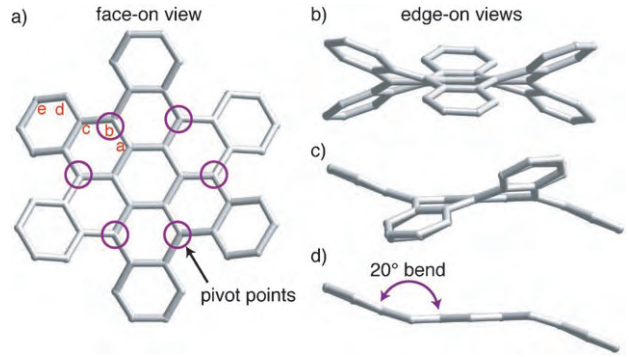

Figure 4. Crystal structure of **1a** grown from 1,2,4-trichlorobenzene. Hydrogen atoms have been removed for clarity. a) Face-on view with marked pivot points (magenta circles). The C_a–C_b bond is relatively short and the C_b–C_c bond is relatively long. Side views are given in (b) and (c). d) Side view of one of the acene segments extracted from the crystal structure. The other atoms of the HBC are hidden from view.

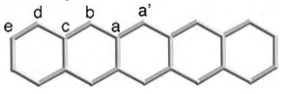
subunits contort into a zigzag conformation. This bending of the acene core is visualized most clearly in Figure 4d, in which portions of the structure have been suppressed to show only one pentacene subunit of the HBC. Essentially all of the bending is concentrated in pairs of carbon atoms that act as pivot points (these are highlighted with magenta circles in Figure 4a). A comparison of some of the bond lengths in this HBC with those from the pentacene crystal structure[45] is given in Table 1. One of the most interesting features is that the C_a–C_b bond is short in the HBC relative to the pentacene,

Table 1: Comparison of C–C bond lengths between **1a** and pentacene.

	C–C bond length [Å]	
	1a[a]	Pentacene[b]
C_a–$C_{a'}$	–	1.44
C_a–C_a	1.43	1.46
C_a–C_b	1.40	1.42
C_b–C_c	1.45	1.38
C_c–C_c	1.42	1.45
C_c–C_d	1.42	1.43
C_d–C_e	1.38	1.35
C_e–C_e	1.42	1.43

[a] The atom labeling scheme is shown in Figure 4a. [b] The atom labeling scheme of the pentacene skeleton is shown below.



whereas the C_b–C_c bond is relatively long. A strong contribution from the radialene resonance would explain these unusual bond lengths.

In summary, this study puts forth a new design strategy for molecule-based electronic materials in which a nonplanar rigid core is used. We prepared a new class of hexabenzocoronene that is readily substituted to form columnar liquid-crystalline phases, and these columnar materials have good electrical properties in thin-film transistors. Structures with nonplanar aromatic units, such as **1**, may be able to achieve much higher mobilities than those available to flat hydrocarbons because the π surfaces of contorted molecules can approach each other and arrange themselves in very different ways. Moreover, these molecules make interesting starting materials for the synthesis of other topologically interesting hydrocarbons by oxidative closure of the proximal carbon atoms to form five-membered rings.

Controlling Molecular Assembly in Two Dimensions: The Concentration Dependence of Thermally Induced 2D Aggregation of Molecules on a Metal Surface**

Meike Stöhr, Markus Wahl, Christian H. Galka, Till Riehm, Thomas A. Jung, and Lutz H. Gade**

The "bottom-up" construction of functional structures relies on the sophisticated interplay between individual structural units.[1–3] In most cases, the assembly of these building blocks is based on noncovalent interactions that shape extended supramolecular entities in variable dimensions.[4–6] Herein, well-ordered molecular patterns on surfaces are created from highly mobile precursor molecules which are transformed subsequent to their deposition and form autocomplementary species in the process. The end groups of the mobile precursors are activated by a thermally induced surface-assisted reaction to enable intermolecular hydrogen-bonding interactions which then lead to the formation of highly ordered structures. We demonstrate control over the 2D pattern of the assembly and over the dimensionality of the aggregate by variation of the surface concentration of the precursor prior to its transformation. Furthermore, we show that the combination of resonance-assisted hydrogen-bonding[7] and the interaction of the rectangular-shaped molecules with the metal surface leads to highly robust supramolecular networks which may serve as templates for the incorporation or trapping of guest molecules.
