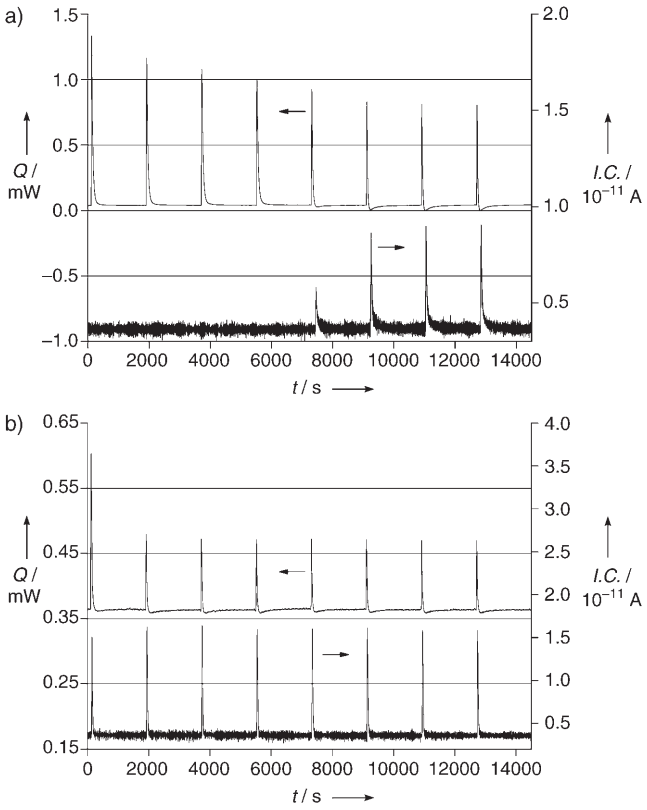

Figure 1. Results of calorimetric measurements of H_2 adsorption over Ru/C (a) and Ag/SiO_2 (b) catalysts in the presence of H_2 ($T_{ads} = 293$ K (a), 423 K (b)). The heat flow of the DSC (left ordinate) and the H_2 signal of the mass spectrometer (right ordinate) are shown. DSC = differential scanning calorimeter.

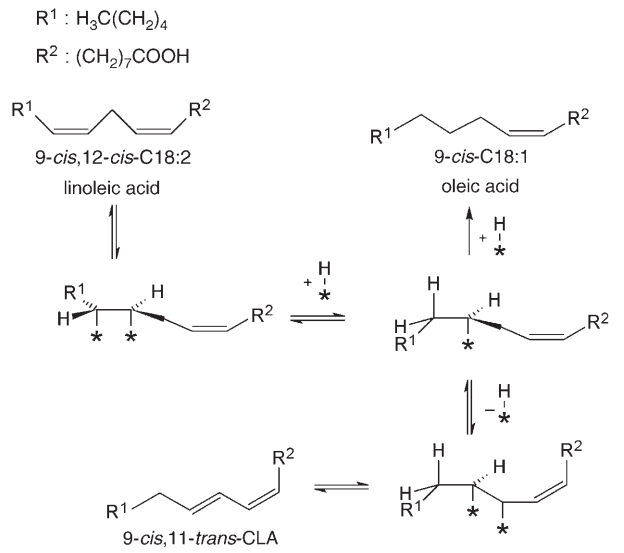

Scheme 2. Horiuti–Polanyi mechanism for the hydrogenation/isomerization of linoleic acid: weakly bonded hydrogen (on Ag) causes the desired CLA formation through an addition/elimination mechanism, whereas strongly bonded hydrogen (on Ru) causes the formation of oleic acid through consecutive H addition.

intermediate: addition of a further chemisorbed hydrogen atom under hydrogenation to give undesired oleic acid in the case of catalysts with high affinity to hydrogen chemisorption (Ru) versus elimination of a hydrogen atom with desired CLA formation in the case of weakly bonded hydrogen (Ag). Investigations are currently underway to examine the activation/adsorption of hydrogen on silver catalysts, which is rather unusual and is in contrast to the oxygen chemisorption known from oxidation catalysis, but comparable with gold catalysts.[24] Transient experiments with a Ag/SiO_2 catalyst preconditioned with H_2 in a TAP (temporal analysis of products) reactor and subsequent D_2 pulses revealed the formation of H–D and, thus, that H_2 dissociation must occur. This is not noticed over pure silver or SiO_2.[25]

The results presented herein show not only a direct route to CLAs but also a completely new method for the isomerization of (conjugated) double bonds. The prospects for the isomerization of linoleic acid to CLA in the presence of hydrogen and silver catalysts are obvious. After optimization of important catalyst properties (e.g. support material, silver particle size, and metal loading) the high CLA selectivity and yield as well as the simple reaction procedure in the presence of hydrogen permit the assignment to a continuous operation coupled with simple catalyst separation. Despite the high CLA selectivity, the product spectrum has to be further improved with respect to potential use in functional food. In particular, the fraction of 9-*trans*,11-*trans*-CLA must be decreased. Fundamentally, nothing should stand in the way of applying the presented principle of direct conversion of linoleic acid into CLAs over silver catalysts in the presence of H_2 as an alternative for the alkaline isomerization.

Experimental Section

General: The experiments were carried out in a 250-mL four-necked quartz-glass reactor, which was equipped with a reflux condenser, a drip funnel, a thermometer, a stirrer bar, and a gas-inlet tube. A magnetic stirrer with an oil bath was used as for heating and stirring. The Ag/SiO_2 catalyst was synthesized by incipient wetness impregnation from silver lactate (Fluka 85210) and SiO_2 (Alfa Aesar, "large pore") (Ag-content via ICP-OES: 7.7 wt %). The catalyst was dried at 353 K and reduced at 598 K under H_2 flow. A TEM examination (Philips CM 200 UT) resulted in an average Ag particle size of 14 nm. The Ru/C catalyst was a commercial product of Fluka (Ru content: 5 wt %). The calorimetric measurements of H_2 adsorption were carried out with a DSC 111 (Setaram) with mass spectrometer (Pfeiffer Vakuum) coupled to a pulse apparatus.

Example of an isomerization experiment: The catalyst ($m_{cat} = 800$ mg, grain fraction $d_{cat} = 200$–500 μm) was introduced into the reactor, and the mixture of linoleic acid (Aldrich, purity > 99 %) and *n*-decane was placed in the dropping funnel ($V = 70$ mL, $c_{LA} = 0.01$ mol L^{-1}). Nitrogen (100 mL min^{-1}) was flushed through the apparatus for 15 min to create an inert atmosphere and for degassing the linoleic acid/*n*-decane mixture. The catalyst was then activated under hydrogen flow (100 mL min^{-1}) for 1.5 h (including heating time) at 438 K. The linoleic acid/*n*-decane mixture was then added to the catalyst; this represents the starting time of the reaction ($t = 0$). The reaction mixture was kept at a reaction temperature of 438 K under permanent stirring (1100 rpm). Hydrogen (100 mL min^{-1}) was flushed through the mixture as reaction gas. Subsequent analysis was performed by means of temperature-programmed capillary gas chromatography (with FID) through an Agilent HP-5 column ($l = 25$ m, $d_i = 0.20$ mm, $t_f = 0.11$ mm), carried out according to the literature.[16b] Heptadecanoic acid was used as an internal GC standard. The samples were concentrated in a heating block and

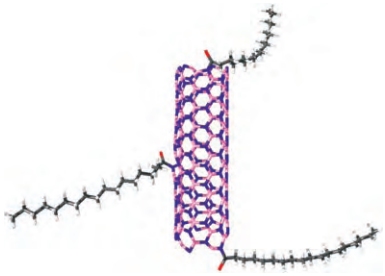
Covalent Functionalization: Towards Soluble Multiwalled Boron Nitride Nanotubes

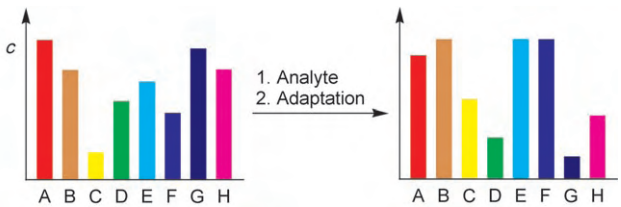


Playing with the band: Long alkyl chains are bound to boron nitride nanotubes (BNNTs) from the reaction of stearoyl chloride with amino groups on the BNNTs; the resulting functionalized BNNTs (see picture) are soluble in many organic solvents. Cathodoluminescence and UV/Vis absorption experiments indicate that the long alkyl chains may induce drastic changes in the band structure of BNNTs.

VIP **Sensors**

A. Buryak, K. Severin* ——— **7935 – 7938**

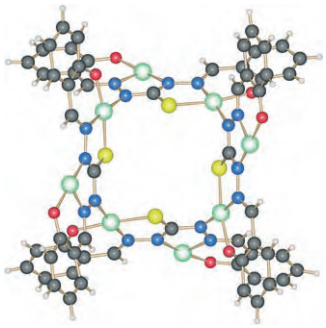
Dynamic Combinatorial Libraries of Dye Complexes as Sensors



A simple solution: Simply dissolving three commercially available dyes and two metal salts in a buffer is sufficient to create a sensor which allows the identification of dipeptides with high selectivity by using UV/Vis spectroscopy (see picture for the adaptive behaviour of a dynamic mixture of colored compounds A–H).

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Metallomacrocyclic arrays containing eight copper(II) centers (see picture; green Cu, blue N, red O, yellow S) were obtained by using a heptadentate thiocarbohydrazone ligand with a particular conformational and configurational flexibility, as well as an appropriate arrangement of metal-binding sites, coordination ability, and acid–base properties.



Cluster Compounds

Boron—A Meeting Point**

Holger Braunschweig and Daniela Rais*

Since 1971, boron chemists from all over the world meet every three years at the IMEBORON conference. The 12th meeting in this series was hosted by Y. Yamamoto in Sendai, Japan, during September 11–15, 2005. A scientific program comprising 22 invited lectures and 75 keynote lectures and short presentations was delivered to an audience of 300 participants from more than 20 countries, emphasizing the importance of the IMEBORON conferences in fostering international collaboration within the boron chemistry community. This year's meeting, which was overshadowed by the loss of Nobel laureate H. C. Brown, who died last year at the age of 92, offered contributions on all modern research areas of boron chemistry, focusing on applications of boron-containing compounds in catalysis, organic synthesis, and pharmaceutical chemistry, materials chemistry, and the evergreen area of cluster chemistry.

Highlights of the contributions on catalysis were the three invited lectures given by N. Miyaura (Hokkaido University), T. B. Marder (University of Durham), and M. R. Smith III (Michigan State University). After a brief historical overview on the evolution of transition-metal-catalyzed hydrocarbon borylation, culminating in the identification of $[(cod)Ir(OMe)]_2$ (cod = 1,5-cyclooctadiene) as the optimal catalyst precursor for aromatic borylation (Scheme 1), Miyaura described highly selective syntheses of aryl-, heteroaryl-, and alkenylboronate esters through iridium-catalyzed functionalization of C–Hbonds with pinacolborane and bis(pinacolato)diborane(4) .

The preferential borylation of sites that are distant from any substituent or ring junction was exploited by Marder and co-workers to achieve selective functionalization of polycyclic hydrocarbons, such as perylenes, in positions that are otherwise difficult to access through alternative electrophilic substitutions. Very recent developments on the borylation of pyridines and 2,2′-bipyridines were also presented, including rare examples of functionalization at the position *ortho* to the pyridinyl nitrogen atom or to a substituent on the pyridinyl ring.

The remarkable chemoselectivity of the iridium-catalyzed borylation process for aromatic C–H bonds, in the presence of other potentially reactive C–X sites (X = Cl, Br, I, etc.), was highlighted in the lecture by Smith.[1] This important feature allowed for further elaboration of the borylated products in one-pot catalytic cascade reactions, in which borylation was coupled with, most notably, Suzuki–Miyaura cross-coupling reactions to produce variously substituted biaryls.

Reports on the utilization of boron-containing compounds as reagents or intermediates in organic syntheses represented a prominent part of the conference program. The application of enantiomerically enriched B-allyl- or B-alkynyl-10-trimethylsilyl-9-bora[3.3.2]-bicyclodecanes to allylboration reactions of *N*-trimethylsilyl-substituted aromatic aldimines or 1,4-additions to their *N*-acyl-substituted analogues, leading to the asymmetric synthesis of secondary alkyl homoallylic amines or propargyl amides, respectively, was discussed by J. A. Soderquist (University of Puerto Rico).

The asymmetric synthesis of homoallylic amines through allylboration of *N*-metalloimines with α-pinene-based organoboron reagents was addressed in the contribution offered by P. V. Ramachandran (Purdue University), while allylic organoboranes and their application to the synthesis of a variety of

nitrogen-containing bicyclic and cage-type compounds were described by Y. N. Bubnov (Russian Academy of Sciences, Moscow). The synthesis of nitrogen-containing heterocycles and a variety of amine derivatives through one-step, three-component reactions between organoboron compounds, amines, and carbonyl substrates was described by N. A. Petasis (University of Southern California).

M. Suginome (Kyoto University) delineated the successful efforts of his research group towards the utilization of aminoboranes as "iminium ion generators" in amination reactions. Diaminoboranes that incorporate nucleophilic groups, such as a cyano substituent, and the aminoborane-based "universal iminium ion generator" *N*,*N*-diisopropyl-4*H*-benzo[d][1,3,2]-dioxaboririn-2-amine, which is designed to aid reactions in the presence of external nucleophiles and free amines as the amino source, were employed in Mannich-type transformations.

P_π–π^* conjugation between a π-conjugated system and the vacant p orbital of an sp^2-hybridized boron atom confers intriguing electronic and photophysical properties to boron-containing materials. Y. Chujo (Kyoto University) detailed the optical properties associated with conjugated polymers featuring pyrazabole units and triply bridged poly(pyrazabole)s in the main chain, while the stereoselective hydroboration of di- and triethynyl-substituted aromatic systems and the subsequent application of the resulting vinylboronate esters to Suzuki–Miyaura cross-coupling reactions with chromophore-containing coupling partners were employed by S. O. Kang (Korea University) in the synthesis of fluorescent dyes and light-emitting polymers. Further efforts towards the synthesis of fully conjugated electron-rich borole-containing systems, as well as the development of green/blue-luminescent materials based on phenoxyoxazolylboron compounds were also sketched.

A number of fascinating systems were highlighted by S. Yamaguchi (Nagoya University) in his lecture. Highly conjugated materials comprising the dibenzoborole unit and their photophysical properties were presented. The concept of π-conjugated molecular bundles that stem from a sixfold functionalization of the hexagonal borazine core with π-conjugated substituents was also introduced, and the great potential of this molecular motif for the generation of new π-electron materials was highlighted (Figure 1).[2] Interestingly, the propensity of the boron center to interact reversibly with Lewis bases, modifying its hybridization and interrupting the π conjugation with the organic framework, was utilized, for instance, in designing boron-based colorimetric sensors for fluoride anion. The design of similar chemosensors for the quantitative detection of glucose and other saccharides was illustrated by S. Shinkai (Kyushu University).

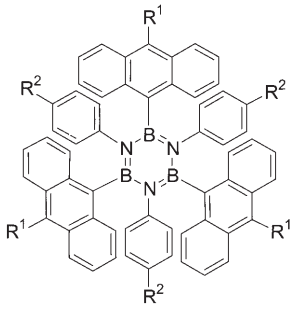

Figure 1. Borazine-based π-conjugated molecular bundle.

Fluorescent conjugated materials with a boron–nitrogen core were also presented by W. E. Piers (University of Calgary). Cyclization reactions of 2,6-dialkynylpyridine adducts of borabenzenes yield luminescent B–N analogues of pyrene. The photophysical properties of various pyridazine-2,2′-diborabiphenyl adducts and their reduction products were also reported.

Numerous contributions focused on fundamental aspects as well as novel and applicative developments of carborane chemistry, a multifaceted topic of long-standing interest for the boron chemistry community. Particularly impressive for their quality of results and future applications were the lectures held by M. F. Hawthorne (University of California, Los Angeles) and L. G. Sneddon (University of Pennsylvania). On the basis of the known chemistry of Ni^{III} and Ni^{IV} *commo*-bis-7,8-dicarbollyl metallacarboranes, Hawthorne described his group's efforts towards the design and synthesis of rotary molecular motors powered by a redox process.[3] Oxidation of Ni^{III} to Ni^{IV} determines a change from a transoid, that is, a disposition where the two carbon atoms on the cages are related through an inversion center, to a cisoid disposition of the two carborane cages. Such redox-driven interconversion of the two geometries constitutes the basis for the rotational motion, which can be induced chemically, electrochemically, or photochemically (Figure 2).

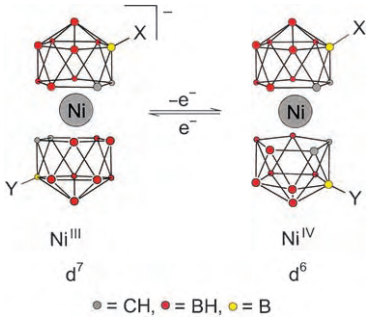

Figure 2. Nickelacarborane-based rotary molecular motors.

The lecture by Sneddon related to recent developments concerning the reactions of polyborane with unsaturated organic substrates in ionic liquids. Functionalized decaboranes are obtained in high yields upon metal-free hydroboration of polyborane olefins, while insertion rather than hydroboration occurs with a variety of alkynes, providing a new, versatile one-step route to functionalized *ortho*-carborane clusters. A survey of the reactivity of Group VI to IX metallaboranes with alkynes was provided by T. P. Fehlner (University of Notre Dame), while details on the chemistry of bis- and tris-mercaptoborates and lanthanacarboranes were provided by S. Shore (Ohio State University) and N. S. Hosmane (Northern Illinois University), respectively.

Reports on pharmacologically active boron-containing compounds were also presented. After an interesting overview on the mechanisms and consequences of biofilm formation, M. Srebnik (Hebrew University) presented his results on the synthesis and antimicrobial activity evaluation of differently substituted oxaborolidines. The quest for engineering porous supramolecular networks

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

based on hydrogen-bonding interactions between boronic acids was detailed in the lecture given by J. D. Wuest (Université de Montréal), while N. C. Norman (University of Bristol) commented on the first structural determination of diboronic acid, $B_2(OH)_4$, and provided details on a synthetic route to pure boron(II) oxide, together with spectroscopic and analytical data on this elusive compound.

In conclusion, a comprehensive overview of all modern aspects of boron chemistry was presented, demonstrating the importance of boron-containing compounds in topical areas of research, such as the functionalization of hydrocarbons and materials science. The boron community looks forward to IMEBORON XIII, the next event in the series, which will be hosted by F. Teixidor in Barcelona-Girona in 2008.

Molecular Motors

Cell motility, virus transport and developmental asymmetry are examples of biological processes related to the function or malfunction of the minute machinery of molecular motors. This handbook brings together current knowledge on the functionality, regulation, and interactions of cytoskeletal, DNA, and rotary motors. Leading experts present principles and applications ranging from atomic structure, biochemistry, and biophysics to cell biology, developmental biology and pathology - all set to become a "classic" in the years to come.

"...essential reading for graduate students in the field of cell motility and molecular motors... recommend it enthusiastically..."

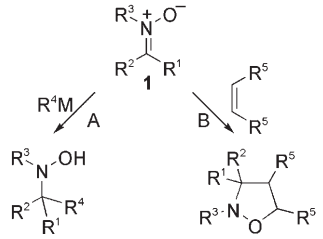
The Discovery of Novel Metal-Induced Reactions of Nitrones: Not Only Electrophiles and Reagents for [3+2] Cycloadditions

*Francesca Cardona and Andrea Goti**

Keywords:
cycloaddition · nitrones · organic synthesis · samarium · ytterbium

Dedicated to Professor Dr. Rolf Huisgen on the occasion of his 85th birthday

Nitrones **1** have been known for more than a century, and their main reactivities as electrophiles towards organometallic reagents (Scheme 1, reaction A)

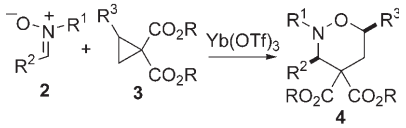


Scheme 1. Reactions of nitrones as electrophiles and 1,3-dipoles.

and as 1,3-dipolar reagents in cycloadditions (Scheme 1, reaction B) have long been recognized.[1] Nowadays, these reactions are employed profusely and nitrones have assumed a prominent role as extremely useful and reliable intermediates in synthetic applications, most notably through the exploitation of diastereo- and enantioselective procedures.[2]

In the last few years a multitude of novel reactions involving nitrones have been discovered which yield structurally diverse and highly functionalized useful products. Most of the new C–C bond-forming reactions have been effected by the use of metal derivatives, which alter the usual nitrone reactivity. The reactions which showed broader scope and potential, and have already witnessed useful synthetic application, are two metal-mediated cycloadditions, namely a formal [2+2] (the Kinugasa reaction, which affords β-lactam derivatives and has recently been reviewed)[3] and a formal [3+3] cycloaddition, as well as a coupling reaction based on umpolung reactivity of a nitrone as a nucleophile.[4] The two latter reactions are illustrated herein.

Young and Kerr discovered a completely new [3+3] cycloaddition of nitrones **2**, which reacted with 1,1-cyclopropane diesters **3** under $Yb(OTf)_3$ catalysis to give the quite uncommon tetrahydro-1,2-oxazine ring (Scheme 2).[5,6] This structural unit occurs in a few natural products, such as FR900482 and related compounds.[7]

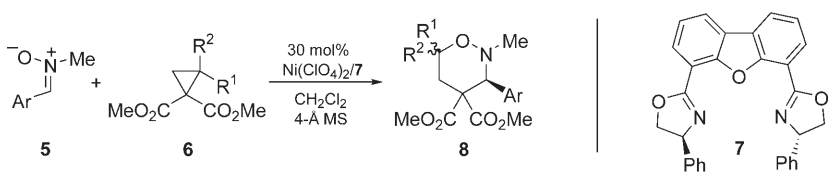


Scheme 2. [3+3] Cycloaddition of nitrones **2**. Tf = trifluoromethanesulfonyl.

This unique reaction, which has been described as a homo [3+2] dipolar cycloaddition, was completely regioselective and stereoselective, and afforded the *cis* adducts **4** exclusively. The same authors developed a three-component version of this reaction, in which the nitrones were formed in situ by reaction of hydroxylamines with aldehydes.[8] Screening of a number of other Lewis acids showed that anhydrous MgI_2 is also an effective promoter of the reaction, and acts in a complementary manner to $Yb(OTf)_3$.[9] In some cases the reaction with MgI_2 was not completely *cis*-diasteroselective, and some of the *trans* isomer were formed.

Very recently, Sibi et al. accomplished the first enantioselective version of this reaction. Asymmetric induction was achieved by addition of nitrones **5** to activated cyclopropanes **6** under catalysis by Lewis acids in the presence of chiral bis(oxazoline) ligands (Scheme 3).[10] The best results were achieved with $Ni(ClO_4)_2$ and ligand **7** (up to 99% yields and 89–99% *ee*). In contrast to $Yb(OTf)_3$, this chiral catalyst gave almost no *cis*/*trans* diastereoselectivity, but gave excellent enantioselectivity for both diastereoisomers of **8**.

Several different pathways have been proposed by the authors to explain



Scheme 3. Enantioselective [3+3] cycloaddition of nitrones. MS = molecular sieves.

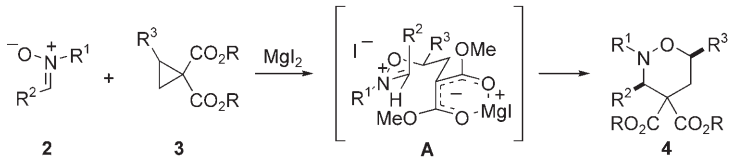
the findings of this interesting addition of nitrones to activated cyclopropanes,[9,10] which depends on the metal catalyst employed. The mechanism proposed by Ganton and Kerr[9] is outlined in Scheme 4, and accounts for the formation of the *cis* isomer through ring closure of the initially formed chairlike intermediate **A**. The *trans* isomer would be generated by a chair-flip or conformational change of the iminium ion in intermediate **A**. However, more detailed studies are needed to clarify the intimate mechanistic aspects of the reaction.



Scheme 4. Proposed mechanism for the addition of nitrones to activated cyclopropanes.

Although the scope of this novel [3+3] cycloaddition is clearly limited by the need for cyclopropanes substituted with two strongly electron-withdrawing groups in the geminal positions, its synthetic utility has already been demonstrated by an elegant approach to the tetracyclic core of nakadomarin A (Scheme 5). Nakadomarin A is an uncommon alkaloid related to manzamines recently isolated from a sea sponge[11] which possesses a range of useful bioactivities (anticancer, antifungal, antibacterial). The 3,2′-linked oxazine–furan motif in **12** was assembled by a key three-component cycloaddition catalyzed by $Yb(OTf)_3$.[12] A selective reduction of the ester group *cis* to the furyl substituent followed by Horner–Emmons olefination then furnished compound **13**, which underwent a Heck reaction to **14**. Hydrogenolysis of the N–O bond and subsequent mesylation gave the fused 5,5,5 tricyclic moiety **15** of the alkaloid, on which the fused six-membered ring was assembled by straightforward synthetic transformations to give compound **16** (Scheme 5).

Another lanthanide compound was the key for the recently discovered umpolung reactivity of nitrones, which react with electrophiles at the carbon atom in the presence of SmI_2. These coupling reactions also appear to be of broad scope and several applications have already been reported. The method was first described by Py and coworkers for aldehydes or ketones **17** as the acceptors and afforded β-hydroxyamino alcohol derivatives **18** (Scheme 6, reaction A).[13]

An initial chemoselective single-electron transfer (SET) from SmI_2 to the nitrone was ascertained, and a subsequent radical coupling was proposed to occur.[14] However, no conclusive proof of the mechanism of this and the related subsequent reactions has been obtained, and a process involving further reduction of the initially formed radical by a second equivalent of SmI_2 followed by nucleophilic attack of the generated carbanionic species cannot be ruled out. Irrespective of the mechanism, the method turned out to be of considerable scope, and several examples of acyclic and exocyclic nitrones reacting with a large series of aldehydes, ketones, and oxoaldehydes, either in an inter- or intramolecular fashion, were reported. Nitrones proved to be far superior to imines, oximes, and hydra-

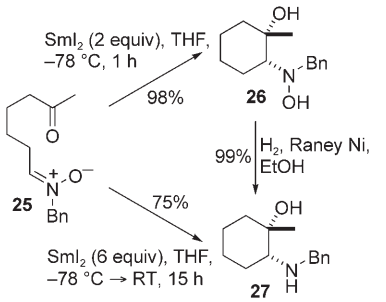
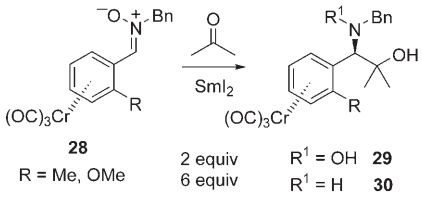
zones for this intermolecular coupling reaction.

Interestingly, reduction of the hydroxyamino functionality to the corresponding amino group was also accomplished when an excess of SmI_2 (6 equiv) was used, and afforded β-amino alcohols directly. This reaction is exemplified by the domino intramolecular coupling/deoxygenation of **25** to the amino alcohol **27** (Scheme 7).[13]



Scheme 7. Domino intramolecular coupling/deoxygenation of **25**. Bn = benzyl.

A highly stereoselective version employing planar chiral tricarbonylchromium complex **28** of *C*-arylnitrones has been developed, which afforded β-hydroxyamino and β-amino alcohols **29** and **30** (Scheme 8), respectively, in excellent yield. The reaction also often gave one diastereoisomer exclusively as a result of a highly preferred approach of the ketone or aldehyde to the face of the nitrone opposite to the bulky (tricarbonyl)chromium moiety.[15] Enantiomerically pure starting nitrones resulted in an enantioselective synthesis of benzylamines after decomplexation.



Scheme 8. Stereoselective version of the intramolecular SmI_2-mediated coupling reaction.

A variation of this reaction which employed conjugated unsaturated esters or amides as the acceptors (Scheme 6, reactions B) was reported independently soon afterwards by Py and co-workers as well as by Riber and Skrydstrup.[16] Again, a large number of acyclic as well as exo- and endocyclic nitrones, including chiral ones, has been shown to take part in the reaction. Not only are acrylates and acrylamides **19** suitable partners as acceptors, but even propiolates **20**, for which intermolecular SmI_2-induced additions had not been recorded previously, can be used. These acceptors afford γ-hydroxyamino esters and amides **21**, and γ-hydroxyamino-α,β-*E*-unsaturated esters **22**, respectively, through conjugate addition reactions. The adducts of acrylic derivatives have been transformed into γ-amino acids or into small peptides containing γ-amino acids.[16b] The reactions must be performed at low temperature (−78 °C) to achieve a fine balance of chemoselectivity when using reagents possessing similar reactivity: reduction and homocoupling of the acceptor compete at higher temperature. The effect of added water is very important, and results generally in rate acceleration and improvement in the reaction yield. Methacrylates and (*E*)-crotonates can also be used in this reaction to furnish products with high diastereoselectivity (up to > 90:10 d.r.) in favor of the *syn* and *anti* isomers, respectively.

Chiral auxiliaries have been used, either as substituents at the nitrone nitrogen atom or at the unsaturated ester or amide, to achieve enantioselectivity (Scheme 9).[16,17] The latter approach afforded up to 90:10 d.r. (for example, in the synthesis of γ-hydroxyaminoester **33**),[16b] while the former one gave moderate to very good enantioselectivity for *N*-benzyl-type substituents[16a] and excellent enantioselectivity for *N*-glycosylnitrones, such as **34**.[17] In this case, opposite absolute configuration at the new stereogenic center was achieved by changing the carbohydrate auxiliary from a D-mannose to a D-ribose derivative.

More recently, a very interesting variant of these reactions has been discovered, which employs enantiopure *N*-*tert*-butylsulfinylimines **23** as acceptors (Scheme 6, reaction C), and affords vicinal *N*-hydroxy-*N*′-sulfinyldiamines **24** which could be transformed into 1,2-diamines by reductive procedures and treatment with acid.[18] This reaction was the first example of an enantioselective cross-coupling between two different imine species. The addition reaction was highly stereoselective (> 7:1 d.r., but in many cases only one diastereoisomer was detected), and ultimately gave enantiomerically pure diamines that are relevant for use in natural products synthesis and as chiral ligands in asymmetric catalysis. The high level of stereoselectivity in the addition was rationalized on the basis of a preferred chelated transition state with the *Si* face of the nitrone approaching the less hindered *Si* face of the sulfinylimine to accommodate the two substituents R^1 and R^8 at the reacting carbon atoms in an antiperiplanar conformation (Figure 1).

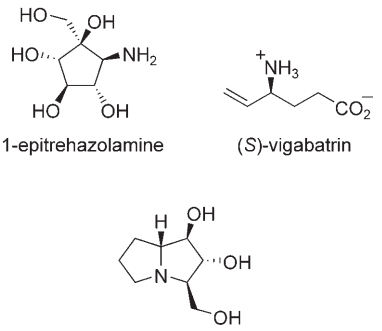
flexible new procedures involving nitrones is likely to warrant access to many structurally diverse nitrogen compounds in the near future. This proposal is corroborated by the elegant applications already reported. An intramolecular nitrone–ketone coupling was the key step for the synthesis of the aminocyclopentitol 1-epitrehazolamine (Scheme 10).[19] The coupling of acrylates with chiral nitrones were strategic in the synthesis of (*S*)-vigabatrin,[20] an irreversible inhibitor of GABA amino transferase, and of the pyrrolizidine alkaloid hyacinthacine A_2 (Scheme 10).[21,22]



Scheme 10. Natural products synthesized by the SmI_2-induced coupling of nitrones with electrophiles.

These novel reactions serve to exemplify the extent to which unexpected and undisclosed new reactivities may come to light when metals come into play, even when "old" compounds, whose chemistry is considered completely known, are concerned.

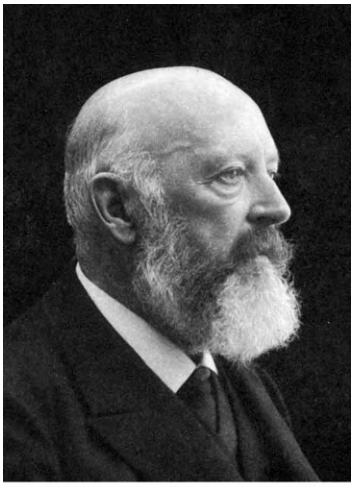
Adolf von Baeyer: Winner of the Nobel Prize for Chemistry 1905

*Armin de Meijere**

Keywords:
benzene · history of chemistry · indigo · nitroso compounds · von Baeyer, Adolf

On December 10, 1905, Johann Friedrich Wilhelm Adolf Ritter von Baeyer (*October 31, 1835 in Berlin, † August 20, 1917 in Starnberg) received the Nobel Prize for Chemistry of the Royal Swedish Academy of Sciences in Stockholm. It was the fifth Nobel Prize for chemistry at all, and it was awarded to von Baeyer "in recognition of his services in the advancement of organic chemistry and the chemical industry, through his work on organic dyes and hydroaromatic compounds". Adolf von Baeyer was a doctoral student in the group of Kekulé in Heidelberg until 1858. He succeeded Justus von Liebig as director of the Chemical Laboratory of the Bavarian Academy of Sciences in Munich in 1875. This latter period was preceded by 12 fruitful years as Professor at the "Gewerbeinstitut" (forerunner to the Technical University) in Berlin and 3 years at the University of Strasbourg, after his Habilitation in 1860 in Berlin. Even before his time in Munich he described the first synthesis of barbituric acid (1864), the polycondensation of phenol with formaldehyde (1872), the structural elucidation of compounds within the uric acid group (from 1860) and other *N*-heteroarenes (from 1868), the preparation of phthaleins (from 1869), nitroso compounds (from 1869), as well as hydroaromatic compounds (from 1866) and their transformations into benzene derivatives. An excellent review of Adolf von Baeyer's scientific achievements has been provided in an article by Rolf Huisgen that appeared in this journal twenty years ago.[1] On the occasion of the 100th anniversary of the Nobel Prize being awarded to Adolf von Baeyer, some thoughts on the current relevance of his research are mentioned here.[#]



Adolf von Baeyer
(1835–1917)

Quite personally, I became interested in the scientific work of von Baeyer at the very beginning of my work towards my first thesis (Master's degree). At that time I was engaged in the synthesis and conformational analysis of cyclopropane derivatives, especially of bicyclopropyl, by spectroscopic methods. Naturally, I had become acquainted with von Baeyer's theory of ring strain during my undergraduate education, but it was not until I prepared my sample lecture for my Habilitation 10 years later that I read the original paper concerning this often quoted theory.[2] I was surprised to find that this publication entitled "On Polyacetylene Compounds" in reality described the synthesis of a series of oligoacetylene derivatives such as diacetylene dicarboxylic acid, tetraacetylene dicarboxylic acid, diiodoacetylene, and diiododiacetylene. In the context of his conjectures concerning the observed explosive properties of the new acetylenes, von Baeyer expressed some thoughts about the "*Theory of Ring Closure and the Double Bond*" in an appendix ("Theoretical considerations") and he summarized these in one core sentence after six generally accepted sentences about the bonding ability of the carbon atom (Figure 1): "*The four valences of the carbon atom act in the directions that connect the center of a sphere with the corners of a tetrahedron and that form an angle of 109° 28′ with each other. The direction of the attraction can experience a deviation that will, however, cause an increase in strain correlating with the degree of this deviation.*"

These considerations of von Baeyer were initiated by the fact that his young English doctoral associate, William Henry Perkin, had just prepared the first cyclopropane derivatives in his laboratory in Munich,[3] even though

VII. Die vier Valenzen des Kohlenstoffatoms wirken in den Richtungen, welche den Mittelpunkt der Kugel mit den Tetraederecken verbinden, und welche mit einander einen Winkel von 109° 28′ machen.

Die Richtung der Anziehung kann eine Ablenkung erfahren, die jedoch eine mit der Grösse der Letzteren wachsende Spannung zur Folge hat.

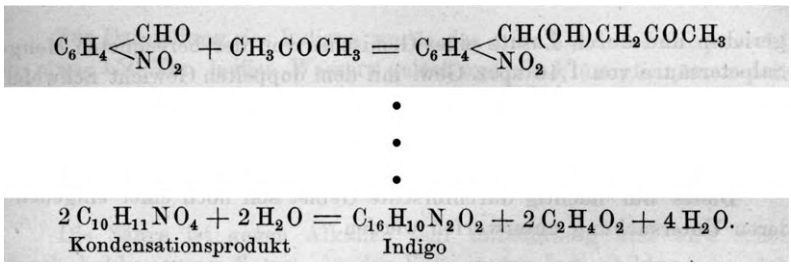
Figure 1. Reproduction of the passage from reference [2], in which von Baeyer expresses his thoughts on the origin of ring strain. (*I. Theory of Ring Closure and of the Double Bond. The ring closure is apparently the phenomenon that can provide the most detailed information about the arrangement of atoms. ... VII. " The four valences of the carbon atom act in the directions that connect the center of a sphere with the corners of a tetrahedron and that form an angle of 109° 28′ with each other. The direction of the attraction can experience a deviation that will, however, cause an increase in strain correlating with the degree of this deviation."*

Adolf von Baeyer himself and especially his meanwhile famous former student Viktor Meyer only a few years earlier had doubted whether three-membered carbon rings could exist at all.[4] During his studies, Perkin observed that cyclopropane derivatives undergo ring-opening reactions upon treatment with strong acids such as hydrogen bromide, and Adolf von Baeyer explained this behavior with an inherent ring strain that leads to an enhanced reactivity. It is also remarkable that Perkin published the first syntheses of small-ring molecules with his own name only, without that of his thesis mentor Adolf von Baeyer.

Subsequently, von Baeyer was criticized for his theory of ring strain, because he also conceived six- and higher-membered rings as being planar with bonding angles that deviated from the tetrahedral arrangement. The concept of ring strain, however, is as valid today just as it was 120 years ago for three- and four-membered rings, but in the meantime it is known that the total strain of a ring consists of three increments: one for angle strain (Baeyer strain), one for conformational strain (Pitzer strain) and a third for transannular strain (van der Waals strain).[5] The latter two concepts, however, became common knowledge only some 40 years later, and thus it is now well understood why seven-membered and larger rings—only the cyclohexane ring is unstrained—experience a certain degree of strain in spite of their not being planar. Incidentally, Adolf von Baeyer included ethylene in his concept of ring strain, and was thereby the first to consider ethylene as a two-membered ring. Through the work of Pauling (1931, 1958) it has become well known that ethylene, like the cyclopropane ring, can be described in terms of bent bonds, and that this theoretical description is an equivalent alternative to the more popular description with σ and π bonds first formulated by Erich Hückel in 1930.

Thus, Adolf von Baeyer became famous with an initially peripheral remark in one of his 305 publications,[1,6] and his concept of strain in small rings is mentioned in every first-year organic chemistry lecture as well as in every decent organic textbook. Baeyer's contributions to the chemistry of acetylenes and diacetylenes (a total of five publications), like the cited reference [2], continue to have an impact in modern times. Because of their manifold reactivities, acetylenes have always been popular and frequently applied building blocks for organic syntheses. Indeed, a whole branch of the chemical industry that existed into the 1960s was based on the chemistry of acetylenes and thus on the original contributions of Baeyer and later Reppe.[7] Acetylene chemistry has recently gained popularity once again, as acetylene derivatives are being used increasingly to construct some of the most unusual molecular architectures, most of them with several triple bonds. Such compounds may eventually achieve economic importance as so-called nanomaterials.[8]

Early on in my career, I also became acquainted with another two of the 14 major research areas of von Baeyer:[1,9] The chemistry of nitroso compounds and that of indigo. Both were research topics of my thesis mentor Wolfgang Lüttke in Göttingen. Lüttke et al. elucidated the basic chromophore of indigo by quantum-chemical calculations[10] and proved the theoretical predictions by experimental studies.[11,12] Naturally, the formation of indigo from *o*-nitrobenzaldehyde and acetone upon addition of dilute sodium hydroxide, barium hydroxide, or ammonia[13] discovered by von Baeyer, was adopted towards the synthesis of new, variously substituted indigo derivatives. Baeyer at his time had not innocently accepted this observation, but started "*a deeper investigation of the events that took place during this remarkable reaction*" (Figure 2).



$$C_6H_4\!<\!\begin{matrix}CHO\\NO_2\end{matrix} + CH_3COCH_3 = C_6H_4\!<\!\begin{matrix}CH(OH)CH_2COCH_3\\NO_2\end{matrix}$$

•
•
•

$$2\,C_{10}H_{11}NO_4 + 2\,H_2O = C_{16}H_{10}N_2O_2 + 2\,C_2H_4O_2 + 4\,H_2O.$$

Kondensationsprodukt — Indigo

Figure 2. Equations for the formation of indigo from *o*-nitrobenzaldehyde and acetone, as presented in the original publication.[13] Kondensationsprodukt = condensation product.

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

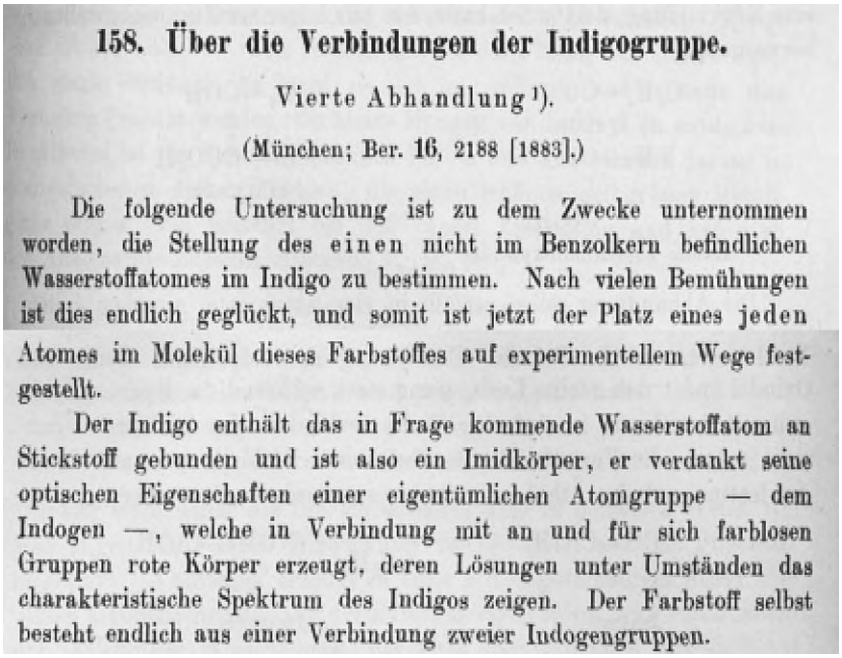
He observed that indigo is only formed upon treatment of the aldol product (in the original publication this is called "condensation product") with dilute aqueous sodium hydroxide (or aqueous barium hydroxide or ammonia)—and not from the condensation product of *o*-nitrobenzaldehyde and acetone, *o*-nitrocinnamyl methyl ketone—and that the yield of indigo is even considerably better, when the aldol is first isolated and then treated with sodium hydroxide. Water plays an important role in this cyclizing condensation, and acetic acid is cleaved off. The mechanism of this multistep transformation was only fully elucidated in 1932 by Tanasescu and Georgescu.[14]

Even though this synthesis of indigo was not applied in its industrial production (just like the very first sequence from phenylacetic acid via isatin[15] and two additional syntheses, which were also developed by von Baeyer), it has substantially contributed to the final elucidation of the structure, which von-Baeyer disclosed in 1883 with a certain degree of pride (Figure 3).[16] The structural elucidation and the first syntheses by von Baeyer soon thereafter also formed the basis of the industrial production of indigo from anthranilic acid, which was developed at the Badische Anilin- und Sodafabrik (BASF) by Heumann.[17] The economic importance of this synthetic access to the "king of natural dyestuffs" was immense, and the fame of von Baeyer grew accordingly. Because of the timeless popularity of denim clothing, BASF still produces indigo, in spite of the fact that much better nonfading and hard-wearing synthetic dyes have long been available. But jeans, even when brand new, are preferred by their owners to look worn.

For von Baeyer, the intense occupation with indigo had developed from his previous studies of compounds within the uric acid group (13 publications between 1860 and 1866) as well as nitrogen-containing heteroaromatic compounds (21 publications between 1868 and 1883). He was not the first to conduct research in these areas, as he later stated in a lecture "On the History of the Indigo Synthesis," which he gave at a ceremonial meeting of the German Chemical Society on October 20, 1900: "*My studies on isatin originated from those on uric acid. They were initiated by Adolf Schlieper, who in 1860 asked me to continue his research, which he had carried out 15 years earlier in the laboratory of Liebig.*"[16] But the *N*-nitrosoamines as well as the aromatic and aliphatic *C*-nitroso compounds and their chemistry were developed by von Baeyer himself, in part together with Heinrich Caro (Figure 4) from the very beginning.[19,20]

Whereas he published only two papers on *N*-nitroso compounds, he occupied himself with *C*-nitroso compounds (at that time called "real nitroso structures") more intensively (12 publications) and for a longer period of time (1869–1902). It was once again Viktor Meyer [21] who questioned this work, believing that "*there is an unsurmountable natural aversion to the formation of real nitroso compounds, in which the nitroso group is bound to carbon through its nitrogen*" and who also doubted that the "*nitrosobenzene*" discovered by von Baeyer "*was a real nitroso structure.*" Of course, one has to take into account that all this happened long before modern spectroscopic methods,[22] and that proof for the constitution of novel compounds could only be obtained by elemental analysis, molecular-mass determination, melting and boiling points, as well as chemical transformations of known compounds into the new ones or of the new ones into known compounds. Baeyer succeeded in proving his structural assignment in the case of *C*-nitroso compounds, among others, with the observation that the blue products formed by the addition of nitrosyl chloride to tetramethylethylene, to $\Delta^{4(8)}$-terpenol acetate, and to other unsaturated terpenes, re-formed the olefins by cleaving off nitrosyl chloride upon heating.

Although the *N*-nitroso compounds, especially *N*-nitrosodimethylamine, enjoyed a short period of preparative applications,[23] they rapidly became infamous after the discovery of their carcinogenicity and after traces were even detected in beer. This has long been circumvented by modification of



158. Über die Verbindungen der Indigogruppe.

Vierte Abhandlung [1]).

(München; Ber. 16, 2188 [1883].)

Die folgende Untersuchung ist zu dem Zwecke unternommen worden, die Stellung des einen nicht im Benzolkern befindlichen Wasserstoffatomes im Indigo zu bestimmen. Nach vielen Bemühungen ist dies endlich geglückt, und somit ist jetzt der Platz eines jeden Atomes im Molekül dieses Farbstoffes auf experimentellem Wege festgestellt.

Der Indigo enthält das in Frage kommende Wasserstoffatom an Stickstoff gebunden und ist also ein Imidkörper, er verdankt seine optischen Eigenschaften einer eigentümlichen Atomgruppe — dem Indogen —, welche in Verbindung mit an und für sich farblosen Gruppen rote Körper erzeugt, deren Lösungen unter Umständen das charakteristische Spektrum des Indigos zeigen. Der Farbstoff selbst besteht endlich aus einer Verbindung zweier Indogengruppen.

Figure 3. Introduction in the paper by von Baeyer on the final elucidation of the indigo structure. ***158. On the Compounds of the Indigo Group.*** **Fourth treatise**[1]. *(Munich; Ber.* ***16****, 2188 [1883].) The following investigation has been carried out in order to determine the position of the pne hydrogen atom in indigo which is not attached to the benzene nucleus. After many efforts, this has been successful, and thus the position of each atom in the molecule of this dye has now been determined experimentally. Indigo contains the hydrogen in question bound to nitrogen and thereby is an imide structure; it owes its optical properties to a peculiar atom grouping—the indogen—which, in connection with groups that are themselves colorless, generates red bodies, solutions of which possibly show the characteristic spectrum of indigo. The dyestuff itself consists of a composition of two indogen groups.*

52. Über die Bildung von Nitrosokörpern.

(Berlin; Ber. 2, 682 [1869].)

Die Bildung von Nitrosokörpern bei der Einwirkung von salpetriger Säure auf stickstoffhaltige Verbindungen scheint wesentlich von dem Vorkommen der Imidogruppe NH abzuhängen. Wirkt nämlich salpetrige Säure auf Amidosubstanzen, so bilden sich die Grießschen Diazokörper, indem nach Kekulés Erklärung der Sauerstoff des NO sich mit dem H_2 des NH_2 zu Wasser verbindet:

$$RNH_2 + NO.OH = RN.N.OH + H_2O.$$

Reagiert dagegen die salpetrige Säure auf Imidokörper, so scheint die ursprüngliche Reaktion immer darin zu bestehen, daß das OH der salpetrigen Säure mit dem H des NH Wasser bildet und ein Nitrosoderivat erzeugt (Heintz, Lieb. Ann. 138, 300):

$$RNH + NO.OH = RN.NO + H_2O.$$

Figure 4. Excerpt from the paper "On the Formation of Nitroso Bodies".[20] *The formation of nitroso bodies upon the action of nitrous acid on nitrogen-containing compounds appears essentially to depend on the occurrence of the imido group NH. Upon the action of nitrous acid on amido compounds, Griess's diazo structures are formed, in which according to Kekulé's explanation, the oxygen of the NO has combined itself with the H_2 of the NH_2 to yield water:* (see equation)- *However, when nitrous acid acts upon imido structures, the initial reaction appears to be that in which the OH of the nitrous acid forms water with the H of the NH, and thus generates a nitroso derivative (Heinz, Lieb. Ann.* ***138****, 300):* (See equation)

the malting process. *N*-nitroso compounds have since also been virtually banned as synthetic building blocks from the chemical laboratory. The *C*-nitroso compounds,[24] on the other hand, are experiencing a renaissance as versatile reagents for the preparation of nitrogen-containing open-chain and cyclic compounds.[25]

One might call it a typical research topic of time past, and to a certain degree it certainly was: The constitution of benzene and of hydroaromatic compounds. Adolf von Baeyer himself chose the area of organoarsenic compounds for his doctoral thesis, and he carried it out in association with Kekulé, when the latter still was a lecturer in Heidelberg. After he obtained his doctoral degree in Berlin in 1858, Baeyer followed Kekulé as an assistant to the University of Gent and returned to Berlin in 1860 for his habilitation. Occasionally, he called himself an autodidact, yet he was provably one of the most passionate disciples of Kekulé, as he himself stated in a letter to Kekulé in 1864: "*Your outline on aromatic compounds caught my attention only recently. It reminded me vividly how much I am your follower, since a few months ago I presented the theory of the aromatic group in the same form, with almost the same words.*" Kekulé had presented his structural theory[26] in 1858, and had published his thoughts about the constitution of benzene[27] in 1865. Subsequently, von Baeyer occupied himself intensively with these ideas, which were significantly ahead of the times.

The papers of Baeyer on this topic represent the largest block of his publications (40 out of 305). Initially, his questions were born out of skepticism with regard to the constitutional formula of Kekulé, but according to the results of his own investigations concerning the reduction of phthalic acid and terephthalic acid with sodium amalgam—a predecessor of the Birch reduction discovered much later—upon the addition of bromine to the dihydro derivatives and upon further transformation of the bromine adducts, he concluded with incredible logic that other structural proposals, such as that of Ladenburg and of Dewar, did not really represent the properties of benzene. At most, he flirted for a while with a modified version of the structural proposal of Adolf Claus (1867) with one valence each from the six carbon atoms connected with each other in a cycle, pointing into the center of the ring. As the main speaker at the famous Benzene Festival of the German Chemical Society in honor of August von Kekulé 25 years after his publication of the cyclic benzene formula, Baeyer made the point:[28] "*In your theory of benzene, you have for the first time expressed the thought that the atoms of carbon cannot only form simple and branched chains, but also rings.*"

Building on this basic idea of Kekulé, Baeyer made significant early contributions to the understanding of the chemistry of aromatic compounds, and thereby provided the foundations for this blooming field in chemical industry—the exact thoughts expressed on the certificate of his Nobel Prize. Thus, it is no wonder that Adolf von Baeyer is recognized for his extremely important contribution to organic chemistry which extends even into modern times. And above all, it must be stressed that he performed most of his experiments with his own hands.

Genotyping—From Genomic DNA to Genotype in a Single Tube

*Michael Strerath and Andreas Marx**

Keywords:
DNA recognition · DNA · genomics · polymerase chain reaction · single-nucleotide polymorphisms

Nucleotide variations in the human genome, such as single-nucleotide polymorphisms, have been researched more intensively since it became apparent that these deviations are linked to various diseases and also several side effects of drugs. The investigation of genomic DNA in the laboratory requires routine methods that are time-, labour-, and cost-effective. These criteria are fulfilled by so-called closed-tube methods, which are applied directly to isolated genomic DNA without any preamplification.

1. Introduction

Within the entire human genome, which comprises approximately three billion base pairs, individuals differ in approximately 0.1 % of their nucleotide sequence.[1,2] The most common of these three million sequence variations are single-nucleotide polymorphisms (SNPs).[3–5] SNPs are defined as sites in the genome at which the less-common variant has a frequency of at least 1 % in the population. There is a direct link between some of these dissimilarities and certain diseases, a topic dealt with in pharmacogenomics. Additionally, different effects of drugs on different patients can also be linked to SNPs.[3,5,6] Thus, considerable efforts are focused on finding new SNPs and elucidating their connection to certain phenotypes. To date, nearly 1.8 million SNPs have been discovered and characterized through a variety of methods. First, methods are needed to identify unknown nucleotide variations so that their medicinal relevance can be investigated. Once the exact sequence is known, other methods are required for high-throughput screening of populations in the search for known SNPs or to analyze individuals for SNP patterns. Thus, time-, labor-, and cost-effective analytical methods are clearly essential to allow routine studies of such nucleotide variations in the laboratory.[7–15] The efficacy of these methods is decisive for further advances in pharmacogenetics, which may, in the future, allow a therapy that is tailored to the genetic constitution of the individual. Treatments with drugs that are ineffective or cause severe side effects due to the genetic basis of the individual may be avoided.

Many methods are known for SNP diagnosis, but none has prevailed so far.[8–15] An important criterion for progress in this field is that the number of working steps must be kept to a minimum. However, most known methods require preamplification of the genomic target sequence through the polymerase chain reaction (PCR) prior to the actual analytical detection step. Hence, these methods usually involve at least two steps.[7–14] Methods that allow genotyping in one step directly from genomic DNA without preamplification would be ideal. In this Minireview, we focus on procedures of the latter type and discuss methods that link the amplification step with analysis in a closed-tube reaction. Furthermore, we focus on applications that exploit the properties of many enzymes to preferentially process canonically paired (according to the Watson–Crick rule) DNA constructs. For a general overview of methods applied in DNA diagnostics, we refer to several excellent reviews published recently.[7–15]

2. Sequence-Specific Invasive Cleavage of Oligonucleotide Probes: The Invader Assay

The invader assay can be divided into two reactions.[16,17] First, two oligonucleotides termed "signal probe" and "invasive probe" simultaneously anneal to a genomic DNA target sequence. The sequences of both probes are designed to form a characteristic structure when they bind to the target sequence (see Scheme 1 a).

The signal probe consists of two regions: one is complementary to the target and the other consists of a 5′-arm (Flap) and is not complementary to the target and invasive probes. The formed structure is recognized by certain 5′-3′-nucleases,

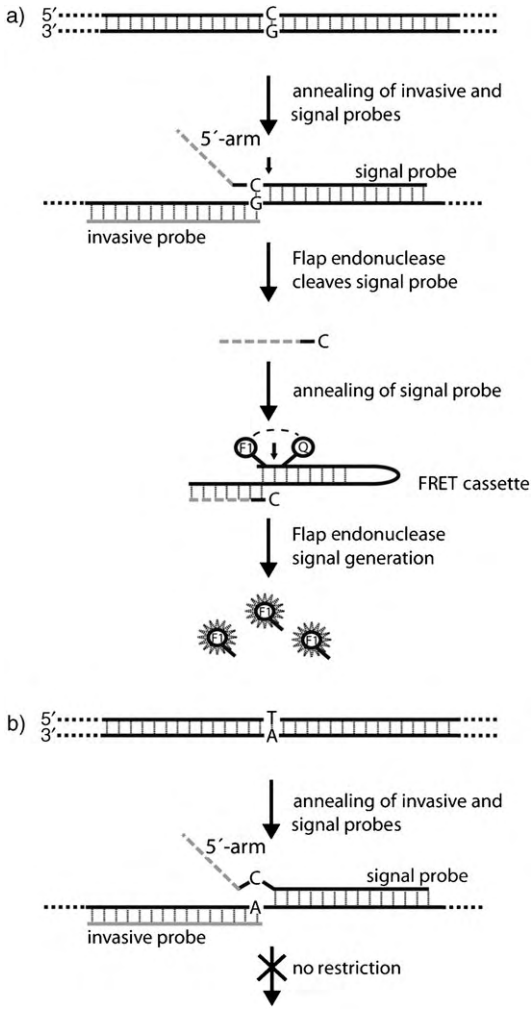

Scheme 1. Genotyping by means of the invader assay. Through annealing of two oligonucleotide probes (signal and invasive probe) a triplex structure is formed at the position of interest. a) In the case of a perfectly matched triplex, the Flap endonuclease is able to cleave the signal probe at the indicated position and the 5′-arm of the signal probe is released. The released 5′-arm anneals sequence specifically to a FRET cassette and catalyzes its restriction by the Flap endonuclease. This restriction cause a spatial separation between the fluorophore (F1) and the quencher molecule (Q), and a fluorescent signal is generated. b) If a noncanonical triplex is formed owing to the presence of a single-nucleotide variation, efficient restriction of the formed triplex structure is prevented, and the FRET cassette remains intact, thus causing quenching of fluorescence.

for example, Flap endonuclease I of *Archaeoglobus fulgidus* or DNA polymerase of *Thermus aquaticus* (which exhibits 5′-3′-exonuclease activity). The signal probe is cleaved at the indicated position to release an oligonucleotide,[18] which is composed of the 5′-arm and one nucleotide derived from its target-specific region. Remarkably, the cleavage rate is significantly enhanced by the presence of the invasive probe.[18,19] Furthermore, it is crucial to the cleavage process that the signal probe and target sequence are fully complementary at the SNP site. The discrimination between single-nucleotide variations in the invader assay derives from the ability of the enzyme to cleave canonical target–signal-probe complexes selectively. Single-nucleotide variations within the target site (e.g. because of a single-nucleotide polymorphism) result in a mismatched complex that is cleaved significantly less efficiently (Scheme 1b). If reactions are performed at elevated temperatures with an excess of the signal probe, the generated fluorescence signal will be amplified owing to the dissociation of the cleaved signal probe from the target and repeated annealing of a new and uncleaved signal probe.[19]

The signal can be amplified further by using a subsequent reaction step. In this second reaction, the cleaved strand anneals to a fluorescence resonance energy transfer (FRET) cassette and invades a short hairpin, which has a fluorophore and quencher pair at its 5′-end. Cleavage of the hairpin construct at the indicated position is again executed by the 5′-3′-exonuclease function of the enzymes mentioned above. The cleavage liberates the dye and generates a fluorescence signal owing to the separation of the fluorophore and the quencher. Therefore, the cleaved signal probe catalyzes the cleavage of a FRET cassette and releases a fluorophore in the second step of the invader assay.[20] In practice, both reactions are carried out in the same reaction tube, and an overall signal amplification of up to 10^7-fold within 4 h has been reported.[20] Direct SNP analysis can be performed from samples containing 10–100 ng of human genomic DNA.[17]

Michael Strerath studied chemistry at the University of Düsseldorf (Germany) where he completed his thesis work for his undergraduate degree under the guidance of Stefan Kubik in 2001. In the same year he moved to the University of Bonn, where he started his PhD with Andreas Marx. In 2004 he followed Andreas Marx to Konstanz University, where he completed his PhD studies on chemical und genetic approaches for genome analysis. Since August 2005 he has been working with Direvo Biotech AG in Cologne.

Andreas Marx studied Chemistry in Freiburg, Sussex, and Bochum, where he completed his Diplom with Peter Welzel in 1994. He obtained his PhD in 1997 with Bernd Giese at Basel University. After postdoctoral studies with Hisashi Yamamoto at Nagoya University as a EU/JSPS fellow, he started his independent research on the chemical biology of nucleic acids associated with Michael Famulok at Bonn University and obtained his habilitation in organic chemistry and biochemistry in 2003. Since January 2004 he has held the Chair of Organic Chemistry–Cellular Chemistry at Konstanz University.

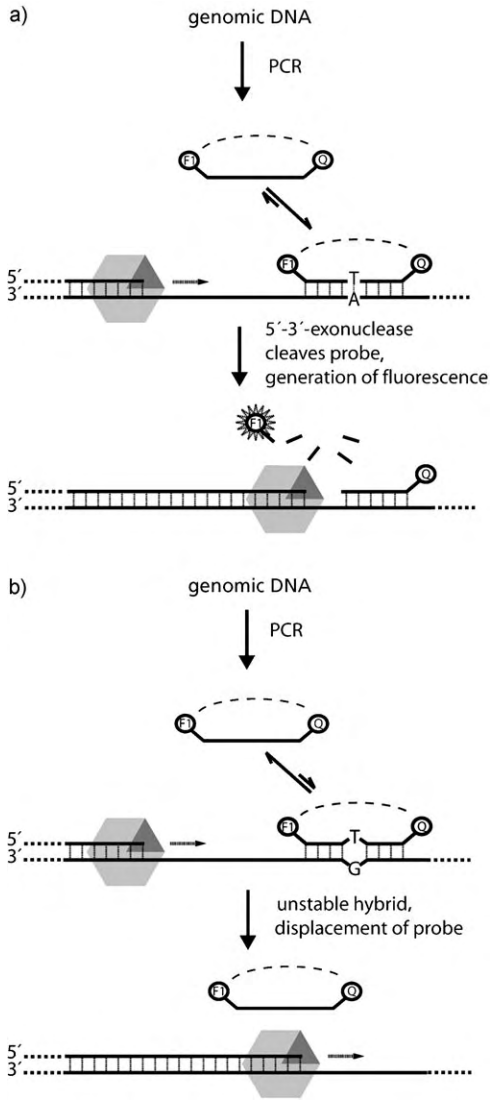
3. Genotyping through the 5′-3′-Exonuclease Activity of DNA Polymerases: The TaqMan Assay

The 5′-3′-nuclease proficiency of DNA polymerase of *Thermus aquaticus* is exploited in the TaqMan assay.[21] The characteristic steps of this approach are the DNA synthesis by DNA polymerase, partial strand displacement, and cleavage of a FRET DNA probe by the enzyme to generate a fluorescence signal through separation of the fluorophore and quencher (Scheme 2).[21–24]



Scheme 2. The TaqMan assay. a) The target sequence is amplified through a PCR by using *Taq* DNA-polymerase that exhibits 5′-3′-nuclease activity. The probe sequence is complementary to one allelic variant. b) In the case of the other allele, a mispaired complex is formed. The perfectly matched hybrid (a) is thermodynamically stable, whereas the mispaired hybrid (b) is thermodynamically unstable at the applied temperature. As strand extension proceeds, the 5′-3′-nuclease activity of *Taq* DNA-polymerase cleaves canonically bound probes and releases the fluorophore, thus resulting in the generation of a signal. In the case of noncanonical probe–target sequences, the displacement of a portion of the probe by the DNA polymerase lowers the thermodynamic stability even further, and the probe is released. Thus, cleavage of the probe is prevented and hence no signal is generated.

Several factors contribute to the capability of this approach to discriminate between single-nucleotide variations. First, probes with complementary sequences form duplexes with the target site that are inherently more stable than those that contain mismatches.[22] Accordingly, judicious tuning of the annealing and extension temperatures in the PCR favors formation of a perfectly matched duplex over a mismatched duplex. Duplex formation is mandatory for the 5′-3′-nuclease action of the DNA polymerase. Recognition and cleavage by an enzyme occur at the bifurcated end of a duplex. Therefore one to three nucleotides at the 5′-end of the probe must be displaced prior to cleavage of the probe. This further destabilizes a mismatched probe and promotes its dissociation, thereby preventing cleavage and signal formation. A crucial parameter for the success of this approach is the design of the probe. The probe must be long enough to build stable duplexes at the extension temperature ($\approx 70\,^{\circ}C$), but must be short enough to discriminate sufficiently between single-nucleotide variations within the target site. It has been shown that probes that are conjugated with a minor-groove binder have higher binding affinity to a complementary sequence and can still be processed by enzymes (Figure 1).[22,25,26] This allows application of shortened fluorogenic probes, which have better sequence selectivity.

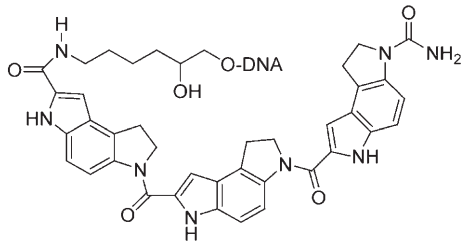


Figure 1. Structure of the DNA minor groove binder conjugated to DNA.

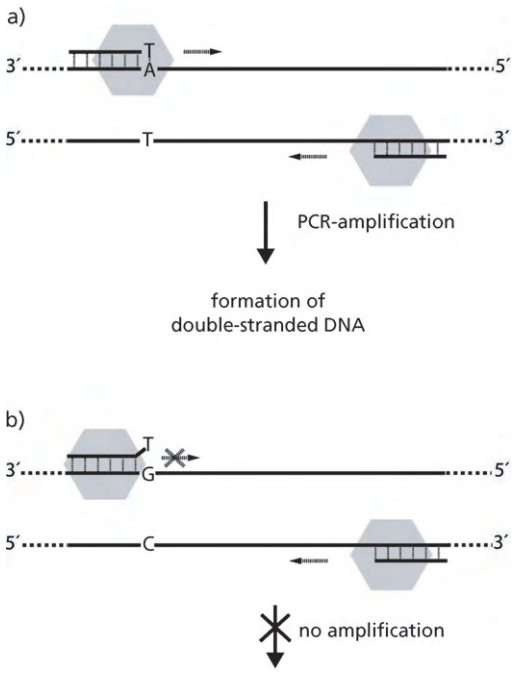
The entire process is carried out in a closed tube and does not require further post-PCR handling and processing steps. Additionally, the analysis can be conducted and monitored in real-time. The assay is sensitive and only minute amounts of genomic DNA (2–20 ng) are required.[22]

4. Genotyping through DNA Polymerase Selectivity: Allele-Specific Amplification

A conceptually simple approach to detect allele variations is realized in allele-specific amplification (ASA). ASA is used to determine nucleotide variations through either the presence or absence of a DNA product obtained by PCR amplification. The principle of ASA is based on the formation of matched or mismatched primer-template complexes through allele-specific primer probes. PCR amplification by a DNA polymerase proceeds from matched 3′-primer termini, whereas a mismatched primer terminus inhibits amplification (Scheme 3).[27–34]

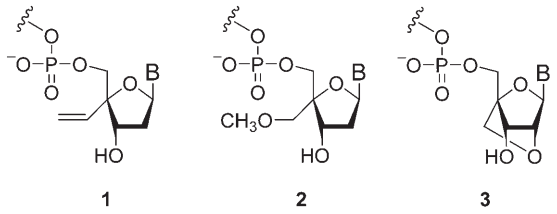
© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 3. Allele-specific amplification. The PCR primer pair is designed to amplify a part of the genomic DNA of interest. A 3′-end of a primer strand is positioned opposite to the SNP position, resulting in a matched (a) or a mismatched (b) complex, depending on the nature of the target nucleotide. In the case of the matched hybrid, the DNA polymerase elongates the primer which results in the exponential amplification of the PCR product. The elongation of the mismatched primer is hampered, and thus the formation of the PCR product is prevented.

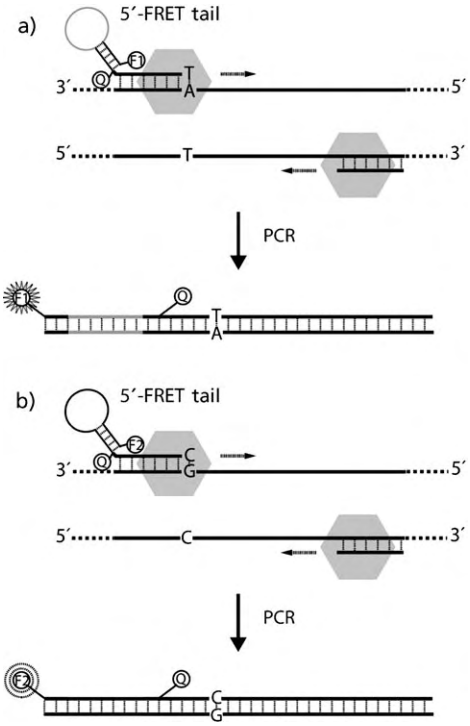
Ideally, the extension of a mismatched primer end by the DNA polymerase should be discriminated. In the case of a mismatch, exponential product formation by PCR is prevented, in contrast to the situation when both primers are complementary to the target site. Product formation can be detected by gel chromatography or monitored in real-time by using a double-stranded-DNA-specific dye (e.g. SybrGreen I), which shows fluorescence after binding to the PCR product in a sequence-independent manner.[35] The main advantage of this approach is that no relatively expensive fluorescence probes are required. However, only the formation of double-stranded DNA is detected without any sequence specificity and therefore false signals are generated from unspecific amplification, for example, the formation of primer dimers. To prevent the detection of false amplificates, sequence-specific FRET probes (e.g. molecular beacons) can be employed.[36] Such probes bind sequence specifically to the amplificate and thus link signal generation to amplification of the desired sequence. In many cases, however, the method still requires tedious costly and time-consuming optimization. Accordingly, any factors that increase the selectivity and reliability of the allele-specific PCR approach should have a significant impact on the reliability and robustness of direct SNP analysis by ASA.

Recently, it was reported that the selectivity of allele-specific PCR can be significantly increased through the employment of chemically modified primer probes.[37–41] Significantly higher amplification selectivity is observed by application of primer probes that bear small 4′-C-modifications such as vinyl (**1**) or methoxymethylene (**2**) groups at the 3′-end. A commercially available 3′-5′-exonuclease-deficient variant of a DNA polymerase from *Thermococcus litoralis* (Vent(exo−) DNA polymerase) was used for amplification (Scheme 4).[37–39]



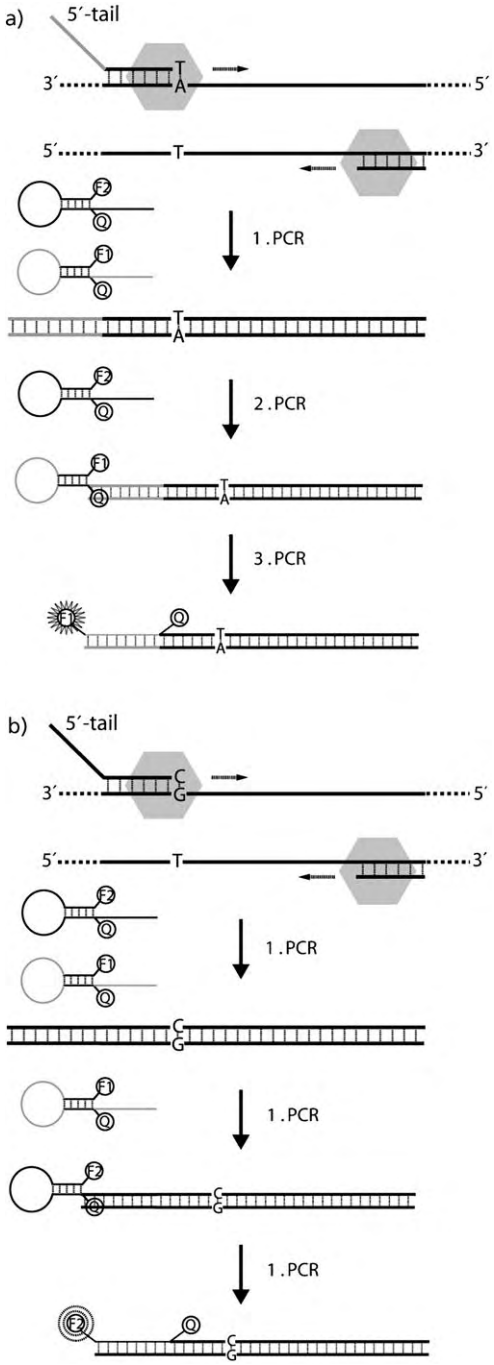
Scheme 4. Structures of modified primer strands employed in allele-specific PCR. B = nucleobase.

As already mentioned, the identification of single-nucleotide variations within genes is feasible in real time. This makes real-time PCR a rapid and convenient tool for the identification and analysis of allele variations. Interestingly,



Scheme 5. Multiplex allele-specific amplification. Each allele-specific primer is coupled to a specific oligonucleotide that is not complementary to the target tail sequence and forms a hairpin structure. Each stemloop bears a fluorophore–quencher FRET pair. During PCR the primer strands are elongated in an allele-specific manner, and the loop sequence is linearized. This leads to a separation of the fluorophore and quencher, and a fluorescent signal is generated. The wavelength of the construct is therefore coupled to the allelic variant, as shown for genotype A (signal F1 in (a)) and genotype G (signal F2 in (b)) as examples.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 6. Multiplex allele-specific amplification. Each allele-specific primer bears a specific tail sequence that is not complementary to the target sequence. During PCR, the allele-specific primer is elongated, and the tail complementary sequence is added to the PCR product. An allele-specific primer bearing a priming and a stem loop structure hybridizes to this sequence and is therefore coupled to the PCR product. During the proceeding PCR, the stem loop is linearized and results in a fluorescence signal. The wavelength of the construct is therefore coupled to the allelic variant as shown for genotype A (signal F1 in (a)) and genotype G (signal F2 in (b)).

modified building blocks that are bridged with a 2′-*O*-4′-*C*-methylene bridge (**3**) at the 3′-end of primer probes exhibit similar features (Scheme 4).[42]

So-called multiplex reactions in which two allele variants are differentiated in a single reaction tube are realized by adding a specific 5′-tail sequences to each allele-specific primer. The signal generation is thereby directly linked to the allele-specific primer in the PCR amplification. Two hairpin FRET structures bearing different fluorophores (which emit at different wavelengths) are added as an overhang sequence to the discriminating primer (Scheme 5).[36] During PCR, the overhang becomes double stranded and the hairpin is opened, thus resulting in an allele-specific fluorescence signal.

In another approach, a specific tail-complementary sequence is added which can be detected by the use of overhang primers as described above.[43] This method has the advantage that the primers that bear the overhang FRET cassette are independent of the target sequence and can therefore be used in a universal manner (Scheme 6). The same pair of FRET primers can be used for each sequence, and only the simple, allele-specific primers are varied. Allele discrimination was achieved with 40 ng of genomic DNA.

The ability of the enzyme to discriminate between mismatched primer ends was increased by mutating the DNA polymerase. A *Taq* DNA polymerase variant was identified that exhibits significantly higher single-nucleotide discrimination than the wild-type enzyme in allele-specific PCR.[44] This goal was accomplished through a combinatorial approach by randomization of a gene cassette of a DNA polymerase and subsequent screening for variants with higher mismatch-discriminating properties.

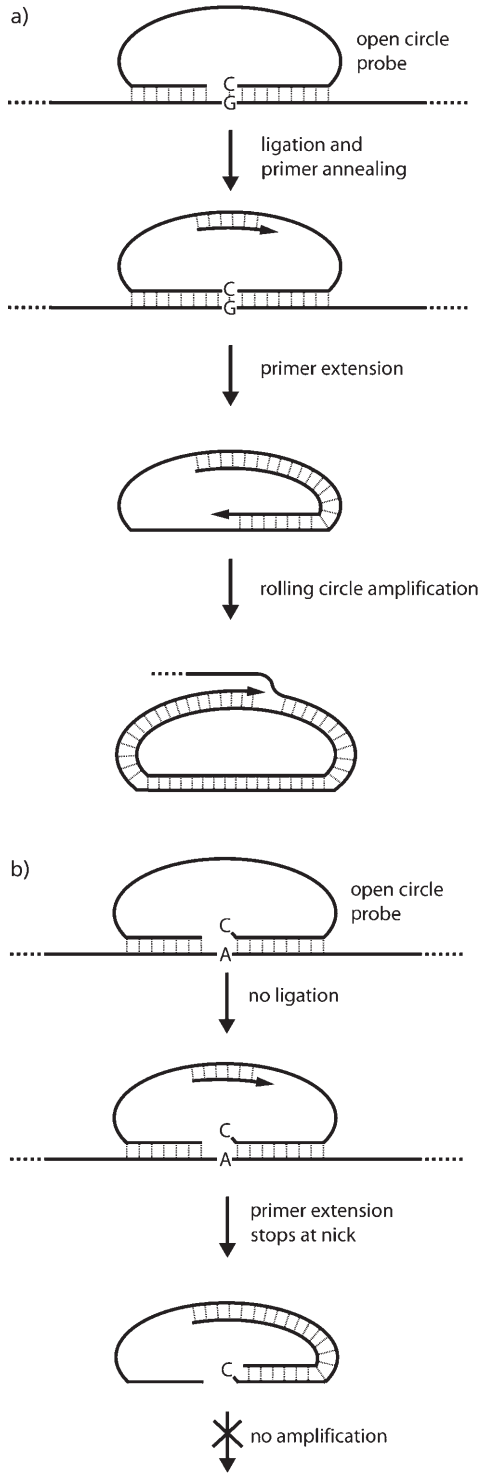
DNA diagnostic methods that do not employ labeled probes are highly promising candidates for further developments in terms of selectivity and robustness, as costly fluorescent probes could be replaced by standard primer strands that are required for PCR amplification anyway.

5. Isothermal Genotyping by Circularized Oligonucleotide Probes: Padlock Probes and Rolling Circle Amplification (RCA)

Padlock probes are circularized single-stranded oligonucleotides made up of 70–110 nucleobases. They are designed in an open circle form with two target-complementary regions at each end (see Scheme 7).[45]

In the presence of a complementary target sequence, the two ends of the open-circle oligonucleotides are covalently connected by a DNA ligase to form circularized padlock probes. It is possible to degrade open probes that are not ligated as a result of a noncanonical target sequence by treatment with exonucleases, whereas closed circles are resistant and remain intact. In many applications, the formation of circularized probes is followed by isothermal amplification by using a primer derived from a central region of the padlock probe. This results in hundreds of tandemly linked copies of the padlock probe. For this copy process, termed rolling circle amplification (RCA),[46] a DNA polymerase with strand-displacing properties is required. Typically, DNA polymerase Φ29 is used, but there are also applications in which thermostable DNA polymerases are employed.[47,48]

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



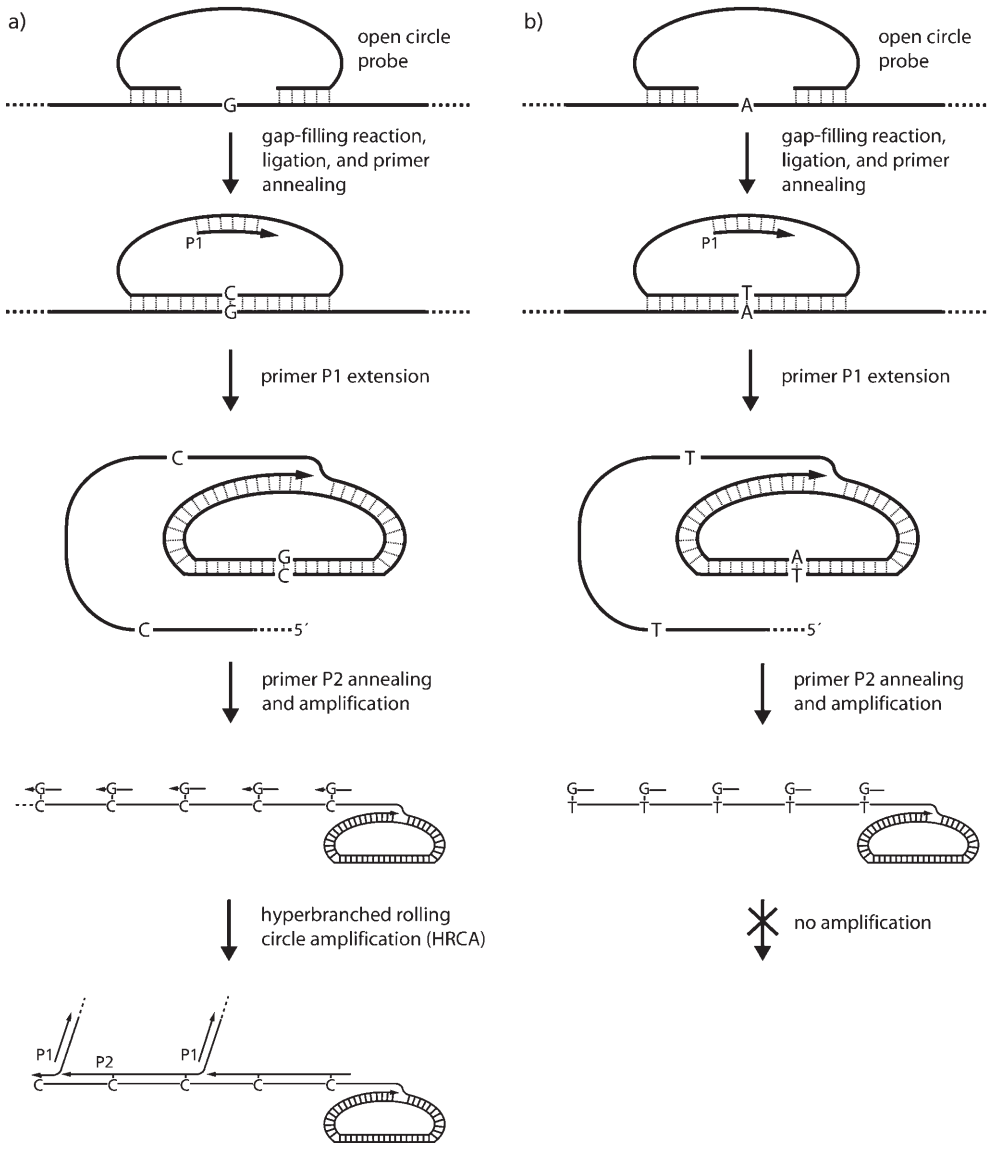
Scheme 7. Rolling circle amplification (RCA). a) In the first step, the open-circle probe (OCP) anneals to the target sequence with both of its target-complementary regions. Both ends lie adjacent to each other and form a nick. In the case of one allelic variant the 3′-end forms a perfectly matched hybrid (a). In the other case, a mismatch is formed (b). The perfectly matched ends are ligated by a DNA ligase and a circular molecule is generated. In the case of the mismatched complex, ligation cannot take place. The reaction mixture also contains an oligonucleotide that is complementary to a part of the OCP and that can serve as a primer. A DNA polymerase elongates this primer and stops at the nick site of the OCP in the case of a nonligated molecule (b). In contrast, if the probe is circularized by the DNA ligase, the elongation can proceed (a). After one round of amplification, the already hybridized oligonucleotide sequence is removed by the DNA polymerase strand. This results in thousands of tandem repeats of the complementary sequence of the closed circle.

The most common applications of padlock probes in allele diagnostics make use of the mismatch-discriminating properties of various enzymes, often in combination with hybridization assays. In the DNA-ligase-dependent method, the open-circle probe is designed to form either a perfectly matched or a single-mismatched 3′-complementary region according to the target sequence.[46] The mismatch-discriminating properties of the DNA ligase applied allow circularization of the probe in the former case. In contrast, no ligation occurs in the second case owing to the mismatched primer–target complex.[49] Additionally, the 5′-complementary part of the open-circle probes (OCP) is designed to hybridize tightly with the target sequence. On the other hand, the 3′-region is in an association–dissociation equilibrium with the target because of a calculated dissociation temperature that is 10 °C lower than the reaction temperature of 60 °C.[50] Accordingly the specificity of the ligation reaction is enhanced owing to the favorable hybridization of the perfectly matched OCP. After ligation, linear isothermal RCA can be used to determine whether the probe was circularized or not.

An additional application of padlock probe ligation followed by RCA makes use of the mismatch-discriminating properties of DNA polymerases.[47] The OCP is designed to form a gap of typically seven nucleotides between the target complementary parts (Scheme 8). This gap includes the sequence context surrounding the SNP site to be studied. In a first step, a DNA polymerase is used to fill the gap by copying the sequence context into the padlock probe. After the gap-filling reaction, a DNA ligase is used to circularize the probe. Subsequently, the circular padlock is amplified by RCA. The linear single-stranded product bears hundreds of tandemly linked repeated copies of the padlock probe, including the incorporated sequence context. These sequences are hybridized to an allele-specific primer (P2) and form either a perfectly matched (Scheme 8a) or mismatched (Scheme 8b) 3′-end.

Afterwards, the mismatch-discriminating properties of a DNA polymerase such as Vent(exo−) are used in an allele-specific amplification to distinguish the allelic variants. The products of this second amplification represent tandem repeats of the original padlock probe. These sequences bear multiple binding sites for the first RCA primer (P1). The extension of primers bound to these sites generates a continuous pattern of double-stranded DNA with branches and is therefore called hyperbranching RCA (HRCA). In contrast to allele-specific PCR, mispriming events will only incorporate the incorrect base in the primer itself so that nonspecific priming is a nonpropagating event in HRCA. By this method up to 10^9 copies of each circle can be generated in 90 min.[47]

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 8. Hyperbranching rolling circle amplification (HRCA). The two ends of the open-circle probe hybridize to the target strand in such a way that a short gap is formed. In a first gap-filling reaction, a DNA polymerase closes the gap by copying a part of the target sequence into the probe. Subsequently, a ligase circularizes the probe and RCA can proceed, starting from the primer P1. The single-stranded product includes repetitions of the short incorporated sequence containing the SNP site. A second oligonucleotide with a 3′-end is complementary to one allelic variant at the SNP site and serves as a primer (P2) in a second reaction. It can only be elongated when it is perfectly matched (a), whereas no extension proceeds in the mismatched case (b). The product of this extension consists of the original circle probe sequence. Thus the first primer P1 can bind to these new synthesized products, and the target sequence is amplified. The result is the amplification of a highly branched DNA product.

In 2001, Qi et al. introduced a procedure to perform DNA probe ligation and RCA under identical buffer conditions which enabled closed-tube or closed microplate formats.[48]

6. Outlook

Currently, all known methods exhibit advantages and disadvantages, and none of the described procedures has prevailed so far. Thus, improvements are needed to facilitate general application in daily practice.

To ensure allelic discrimination in a more robust and selective manner, methods that use enzymes in the discriminating step might be further optimized by mutagenic engineering the respective enzymes. The high costs associated with the assays are still a matter of concern and prevent general application. These costs could be reduced by the development of methods that do not make use of probes with covalently linked dyes, as their synthesis is time- and cost-intensive.

The development of cheaper and faster closed-tube detection methods should put the aim of adopting SNP detection for general use in clinical practice within reach.

Interest in catalysis by metal nanoparticles (NPs) is increasing dramatically, as reflected by the large number of publications in the last five years. This field, "semi-heterogeneous catalysis", is at the frontier between homogeneous and heterogeneous catalysis, and progress has been made in the efficiency and selectivity of reactions and recovery and recyclability of the catalytic materials. Usually NP catalysts are prepared from a metal salt, a reducing agent, and a stabilizer and are supported on an oxide, charcoal, or a zeolite. Besides the polymers and oxides that used to be employed as standard, innovative stabilizers, media, and supports have appeared, such as dendrimers, specific ligands, ionic liquids, surfactants, membranes, carbon nanotubes, and a variety of oxides. Ligand-free procedures have provided remarkable results with extremely low metal loading. The Review presents the recent developments and the use of NP catalysis in organic synthesis, for example, in hydrogenation and C–C coupling reactions, and the heterogeneous oxidation of CO on gold NPs.

1. Introduction

In a recent "Focus" Article in *Chemical Communications*, Somorjai emphasized that catalysis is the central field of nanoscience and nanotechnology,[1a] and finds parallels between enzyme catalysis and heterogeneous catalysis, even though this idea in reality remains a dream. As admitted by Somorjai, selectivity is still a major problem in heterogeneous catalysis that involves the top-down approach, even though up-to-date techniques, such as size-reduction lithography, permit access to nanocatalysts.[1] On the other side of the catalysis world, mononuclear transition-metal complexes have recently achieved an amazing level of performance in terms of selectivity;[2] just think of the amazing progress in C–C coupling[2a–c] and metathesis[2d] reactions. The ultimate goals of recoverable catalysts, their criteria of evaluation, and their role in "Green Chemistry" have been emphasized in recent articles.[3]

Many important homogeneous catalysts are used in industry in biphasic systems or by fixation on supports, the bridge between these two approaches is now being built through the use of nanoparticles (NPs; sometimes called giant clusters, nanoclusters, or colloids) whose activity is very high under mild conditions because of their very large surface area.[4–11] This frontier domain is sometimes called "semi-heterogeneous". Contrary to classic heterogeneous catalysts,[1] these NPs are synthesized by the bottom-up approach from molecular precursors including a metal salt, a molecular stabilizer, and a reducing agent (a typical preparation is given in Equation (1); M = Metal from Group 8–10, X = Cl or Br, R = C_{4-12} alkyl, Red = M′H with M′ = H, Li, $LiBEt_3$, $NaBEt_3$, $KBEt_3$).[4–7,11] Physical means of preparation,[6–8,10,11] such as the electrochemical route developed by Reetz,[7] are also numerous.[4,5,7,11]

$$MX_n(NR_4)_m + (n-m)\,Red \xrightarrow{THF} M_{NP} + (n-m)(Red^+X^-) + m\,(NR_4{}^+X^-) \quad (1)$$

Another modern synthesis, inspired by the 150-year old method of Faraday[8a,b] and popularized by Schiffrin's group in 1993,[8a,c] involves reduction by $NaBH_4$ of a metal precursor such as $HAuCl_4$[8a,c] or Na_2PdCl_4[8d] in a biphasic organic-solvent–water system in the presence of the phase-transfer reagent $[N(C_8H_{17})_4]Br$ and subsequent addition of a stabilizer such as a thiol for AuNPs and (4-dimethylamino)pyridine in the case of PdNPs. NPs can be soluble and thus act homogeneously (soluble AuNPs were discovered over 2500 years ago and were used for aesthetic and curative purposes).[8a] The stabilization of NPs during their synthesis can be by electrostatic, steric, electrosteric (a combination of steric and electrostatic, see Figure 1) means or through the use of ligands.[4,5,8,11] M^0NP synthesis can also be carried out by the vaporization of the atomic metal or of M^0 complexes.[11] In view of the catalyst recycling, NP catalysts often are immobilized or grafted on inorganic or organic polymer supports.[4,5,8,11] There are many reviews on the numerous synthetic routes for NPs,[4–11] and herein in we will not cover

this aspect in detail. We will rather focus on catalysis with emphasis on the most recent work, after a brief survey of the background. For this Review, we will classify and discuss the categories of NP catalysts by the type of support.

2. Pioneering Studies

The use of NPs in catalysis appeared in the 19th century with photography (AgNPs) and the decomposition of hydrogen peroxide (PtNPs).[5d] Pioneering catalytic applications of NPs were reported in 1940 by Nord on nitrobenzene reduction,[9a] in 1970 by Parravano on hydrogen-atom transfer between benzene and cyclohexane and oxygen-atom transfer between CO and CO_2 using AuNPs.[9b] The real breakthrough came with Haruta's seminal studies on oxide-supported AuNP-catalyzed CO oxidation by O_2 at low temperatures.[9c–e] In the 1970s, Bond and Sermon[9f] and Hirai et al.[9g] disclosed AuNP-catalyzed olefin hydrogenation. In 1986 Lewis demonstrated the colloidal mechanism for the catalysis of olefin hydrosilylation by silanes using organometallic complexes of Co, Ni, Pd, or Pt including the Speier catalyst (alcoholic H_2PtCl_6).[9h] These catalysts were formerly believed to follow the classic monometallic organometallic mechanism (oxidative addition of the Si–H bond of the silane onto the transition-metal center and subsequent alkene insertion and reductive elimination). That decade saw the beginning of extended NP catalytic studies especially in the fields of redox catalysis, photocatalysis (photocatalytic water splitting and photo-hydrogenation of alkenes, alkynes, and CO_2),[10a–g] hydrogenation of unsaturated substrates, and oxidation.[10h,i] In the mid-1990s, pioneering studies of PdNP catalysis were reported by Reetz for Heck C–C coupling, such as the reaction between butyl acrylate and iodobenzene or aryl bromides and styrene.[7]

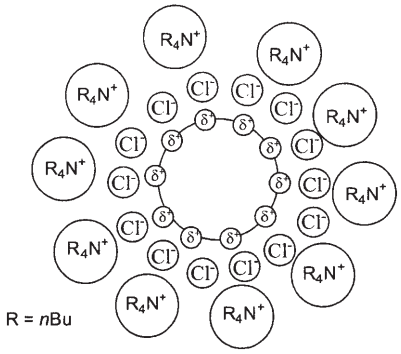

Figure 1. "Electrosteric" (that is electrostatic and steric) stabilization of metal nanoparticles obtained by reduction of a metal chloride salt in the presence of a tetra-*N*-alkylammonium cations. The halide anions provide electrostatic stabilization, and the tetrabutylammonium cations steric stabilization) (Bönnemann-type synthesis based on Equation (1)). The presence of chloride or other anions (and not the ammonium cations) at the nanoparticle surface was demonstrated. Anions stabilized IrNPs in the following order: polyoxometallate > citrate > polyacrylate ≈ chloride. Thus, the stabilization of metal NPs by anions can also have an important steric component.[25f,g]

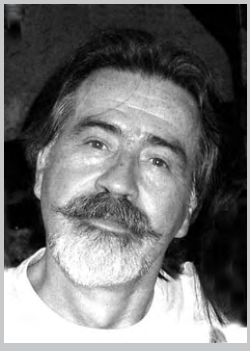
Didier Astruc, born in Versailles, 1946, obtained his PhD in Rennes with Prof. R. Dabard (ferrocenes-cages) and was a NATO post-doctoral fellow at MIT with Prof. R. R. Schrock. He has been a Senior Member of l'Institut Universitaire de France since 1995, a Member of the French CNRS committee since 2000, and the President of the Coordination Chemistry Division of Société Chimique de France since January 2002. He was awarded numerous prizes including the 1989 Humboldt Prize and the 2000 Le Bel Prize. His research interests are now mainly focused on metallodendrimers and nanoparticles.

Feng Lu obtained his PhD under the supervision of Prof. C. Elschenbroich in Marburg in 2002, then joined Professor Didier Astruc at University BordeauxI with where he worked for a year on nanoparticle catalysis. He is presently a post-doc with Professor Chistopher B. Gorman in North Carolina State University at Raleigh working on metallodendrimers. His research interests cover biocatalysts, biosynthesis, dendrimers, electron transfer, molecular electronics, organometallic chemistry, and solar energy conversion.



Jaime Ruiz Aranzaes studied at the Catholic University Santiago (Chile) where he passed his Master degree in chemistry with Professor E. Roman, then moved to Bordeaux to prepare a PhD on the kinetics of substitution reactions of 19-electron complexes with Professor Didier Astruc and then his Habilitation on polyaromatic-iron chemistry. He is presently guiding a research group in the same laboratory, his interests being in the area of the synthesis, chemistry, electrochemistry, and physical properties of redox-active nano-organometallics.

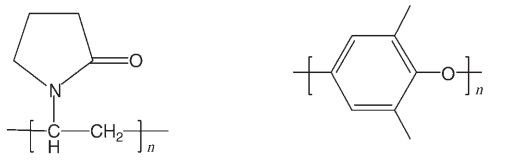
The first years of the 21st century have seen an exponential growth in the number of publications in the NP field. The main goals are 1) improving catalyst activities and selectivities and 2) understanding the catalytic mechanisms.[11] The modes of preparation of catalytically active NPs have been diversified and currently include impregnation,[12a] co-precipitation,[12a,b] deposition/precipitation,[12c] sol–gel,[12a,d] gas-phase organometallic deposition,[12f] sonochemical,[12g] micro-emulsion,[12h] laser ablation,[12i] electrochemical,[12j] and cross-linking.[12k]

3. Stabilizors for Metal Nanoparticles

3.1. Polymers

Polymers provide stabilization for metal NPs through the steric bulk of their framework, but also by binding weakly to the NP surface through heteroatom that play the role of ligands. Poly(*N*-vinyl-2-pyrrolidone) (PVP) is the most used polymer for NP stabilization and catalysis, because it fulfill both steric and ligand requirements (Scheme 1).[5f] PVP-

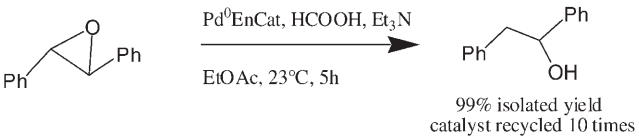
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 1. Two major polymer families used as metal NP supports for catalysis.

stabilized Pt-, Pd-, and RhNPs, that are synthesized by the reduction of the corresponding metal halide in refluxing ethanol and immobilized in an ionic liquid, 1-*n*-butyl-3-methylimidazolium hexafluorophosphate ([BMI][PF_6]), are very efficient olefin and benzene hydrogenation catalysts at 40 °C that can be recycled without loss of activity.[12k]

Using standard PVP-stabilized NP catalysts, parameters such as size and stability during the catalytic process have been examined. For instance, decreasing the PdNP size down to 3 nm in the Suzuki reaction improved the catalytic activity, suggesting that the low-coordination-number vertex and edge atoms on the particle surface are the active catalytic sites.[13] Many other polymers have recently been used as efficient supports for NP catalysis: polyurea (Scheme 2),[14a] polyac-



Scheme 2. Ring-opening hydrogenolysis of epoxides catalyzed by PdNPs (2 nm) microencapsulated in polyurea. The system can be recycled at least ten times with 97–99% yield.[14a]

rylonitrile and/or polyacrylic acid (Figure 2),[14b] multilayer polyelectrolyte films (Figure 3),[14c] polysilane micelles with cross-linked shells (Scheme 3),[14d] polysiloxanes (Scheme 4),[14e] oligosaccharides,[14f] copolymers synthesized by aqueous reversible addition–fragmentation chain-transfer polymerization,[14g] π-conjugated conducting polypyrroles,[14h] poly(4-vinylpyridine),[14h] poly(*N*,*N*-dialkylcarbodiimide,[14i] polyethylene glycol,[14j] chitosan[14k] and hyperbranched aromatic polyamides (aramids).[14l] Classic surfactants such as sodium dodecylsulfate (SDS) are also used as NP stabilizers for catalysis.[14m] Water-soluble polymers have been used with success for selective hydrogenation of cyclic versus noncyclic olefins.[5d]

A very important concept pioneered in the 1970s is that of catalysis using two different metals such as Au and Pd in the same NP.[15] This idea has been beautifully developed by Toshima's group who used PVP to stabilize core–shell bimetallic Au–PdNPs, that is, NPs in which the core is Au and the shell is Pd (Figure 4).[16] After co-reduction, the structure is controlled by the order of reduction potentials of both ions and coordination abilities of both atoms to PVP. The location of Au in the core and Pd on the shell was

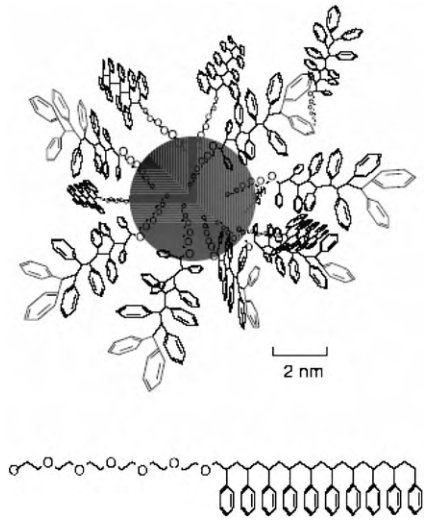


Figure 2. PdNP adsorbed on polyacrylic acid block copolymer as hydrogenation catalyst: the PdNP is stabilized through the block copolymer. Reprinted with permission from ref. [14c].

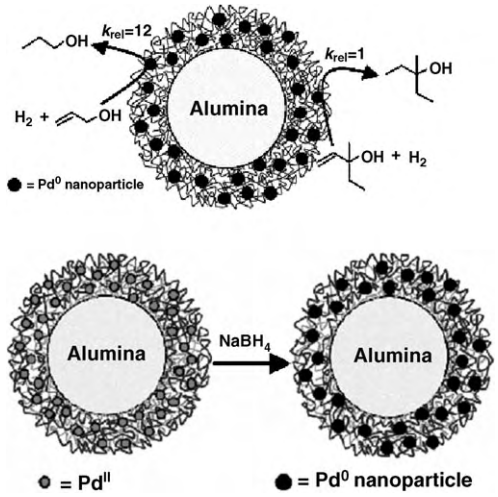

Figure 3. Principle of the formation of PdNPs in multilayer polyelectrolyte films for selective hydrogenation (the layer-by-layer deposition is both convenient and versatile). Reprinted with permission from ref. [14d].

demonstrated by extended X-ray absorption fine structure spectroscopy (EXAFS), and it was shown that such heterobimetallic Au-cored PdNPs are more active in catalysis than simple PVP-stabilized PdNPs. Thus, the Au core enhances the catalytic properties of PdNPs at the PdNP surface.[5f,g] Conversely, design strategies can lead to the opposite core–shell structure (Pd core, Au shell), and specific catalytic properties were obtained for methylacrylate hydrogenation.[16]

Cyclohexene hydrogenation was catalyzed with PdNPs stabilized by highly branched amphiphilic polyglycerol (75% esterified with palmitoyl chloride) and this system was used in a continuously operating membrane reactor to enable recovery and recycling of the PdNP catalyst.[16c]

3.2. Dendrimers

Dendrimers, like polymers, are macromolecules; but unlike polymers, there are perfectly defined on the molecular level with a polydispersity of 1.0.[17] Having shapes that resemble molecular trees or cauliflowers, they become globular after a few generations, and thus behave as molecular boxes[17c] that can entrap and stabilize metal NPs especially if there are heteroatoms in the dendrimer's interiors.[17d,18] The dendritic branches and termini can serve as gates to control the access of small substrates into the dendrimer and thus to the encapsulated NP. Finally, the dendrimer terminal groups can be chosen to provide the desired solubility in organic, aqueous, or fluorous medium. The formation of NPs stabilized by dendrimers for catalysis has been proposed in 1998 by the three research groups of Crooks,[18] Tomalia[19a,b] and Esumi.[19c–e] Metal NPs were introduced inside the dendrimers,[18,19a,b] or at the dendrimer periphery.[19c–e] The former strategy has proved very successful because of the molecular definition of dendrimers and their ability to serve as a box and generation-dependent filter of substrates.

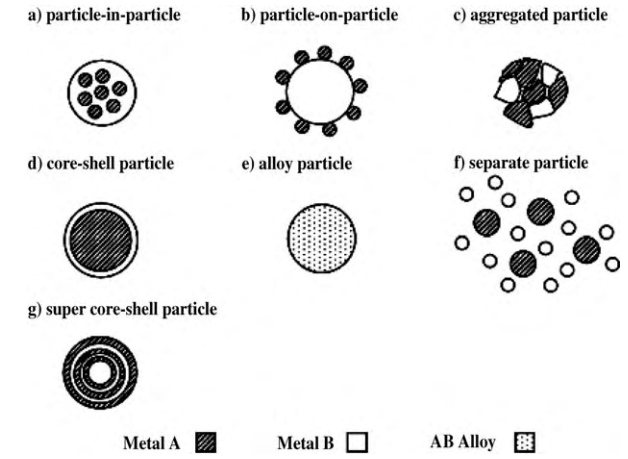

Figure 4. Representative morphologies of bimetallic nanoparticles. Reprinted with permission from ref. [16a].

Crooks and co-workers complexed metal ions (Cu^{2+}, Au^{3+}, Pt^{2+}, Pd^{2+}, Fe^{3+}, Ru^{3+}) to the inner nitrogen atoms of the tertiary amines of poly(amidoamine) (PAMAM) dendrimers. The reduction of the metal ions to M^0 by $NaBH_4$ provoked the agglomeration of the metal atoms to NPs inside the dendrimer.[18] When the terminal amino groups were protonated at pH 2 prior to complexation by metal ions, the metal ions proceeded selectively onto the inner nitrogen atoms resulting in water solubility of the dendrimer and subsequent catalytic activity in water. For example, the selective hydrogenation of allylic alcohol and *N*-isopropyl acrylamide was catalyzed in water by such PAMAM dendrimer–PdNPs (Figure 5 and Scheme 5). Terminal amino groups can be converted into amide groups by the addition of decanoic acid so that the dendrimer–NP catalyst becomes soluble in toluene. In this solvent the catalyst hydrogenates the substrates more rapidly than in water. Alternatively, a perfluorinated polyether "ponytail" can be covalently grafted to the PAMAM dendrimer PdNP catalyst making it soluble in supercritical CO_2. This catalyst was shown to perform classic palladium-catalyzed Heck coupling between aryl halides and methacrylate yielding predominantly (97%) *trans*-cinnamaldehyde. Oxidation[18] and reduction[20] catalysis could also be performed using such dendrimer-encapsulated NPs.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

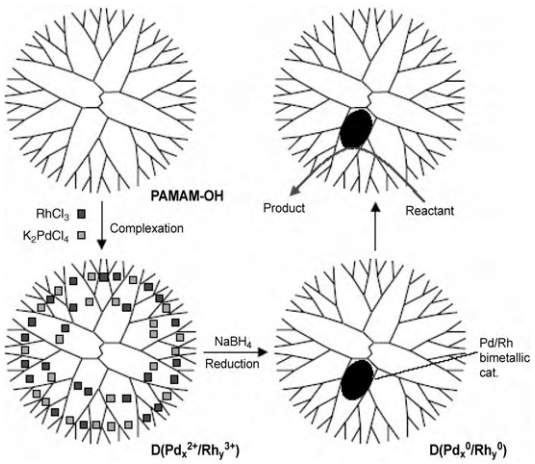

Figure 5. Strategy pioneered by Crooks for the catalysis by nanoparticles encapsulated in PAMAM or PPI dendrimers: complexation of a metal cation to the inner nitrogen atoms of tertiary amines, then reduction to metal(0) by $NaBH_4$, and aggregation giving the NPs inside the dendrimer. The use of PPI dendrimers requires control of the pH value before metal ion complexation to ensure protonation of the terminal amino groups ($pK_a = 9.5$), not the inner ones ($pK_a = 5.5$). In the PAMAM series, OH-terminated dendrimers are used.[18f] Specifically, the preparation of dendrimer-encapsulated bimetallic NPs is shown. Reprinted with permission from ref. [23].

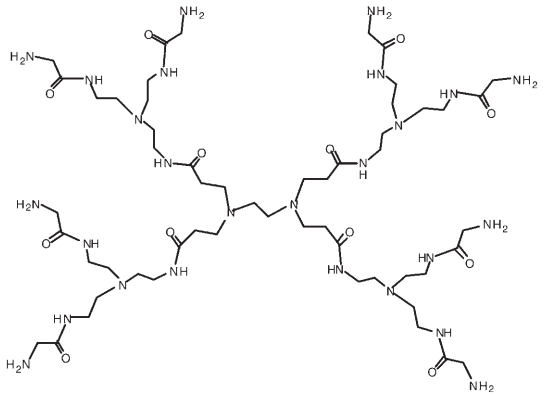
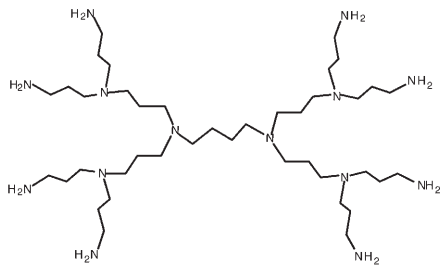


G1 PAMAM Dendrimer



G1 PPI Dendrimer

Scheme 5. The two families of commercial dendrimers considered as metal nanoparticle supports for catalysis (only the first generation (G1) is represented). PPI dendrimers are smaller then PAMAM (2.8 nm versus 4.5 nm for G4, respectively), but more stable (470 °C versus 100 °C respectively).[11b]

El Sayed and co-workers investigated the effect of the generation of the PAMAM dendrimer on the catalytic activity in the Suzuki C–C coupling reaction between phenyl iodide and phenylboronic acid at 80 °C.[21] Generations 3 and 4 were found to be good stabilizers (in contrast to generation 2). These dendrimers stabilize the metal NPs by preventing their agglomeration, but they do not fully passivate the metal surface. The PAMAM-dendrimer-stabilized PdNPs (1.3 ± 0.1 nm) were compared to PVP-stabilized PdNPs (2.1 ± 0.1 nm) for this Suzuki reaction carried out in MeCN:H_2O 3:1 at 100 °C. The mechanism was found to be similar in both cases with phenylboronic acid adsorption onto the NPs, but the turnover ratio for the 2nd cycle:1st cycle was higher for the dendrimer-PdNP catalyst.

Using a different mode of synthesis, 4th-generation (G4) PAMAM-dendrimer-stabilized PdNPs (3.2 ± 1 nm) where prepared by Christensen and co-workers.[22a] With this catalytic system Suzuki coupling occurs with iodobenzene in EtOH at 78 °C, whereas bromobenzene requires a temperature of 153 °C in DMF.[22a] The amount of catalyst was only 0.055 %, which is significantly smaller than traditional catalysts. It was suggested that, since the G4-dendrimer diameter is only 4.5 nm, the PdNPs are stabilized, rather than encapsulated, by the dendrimer.

In studies with 3rd to 5th-generation poly(propylene imine) (PPI) dendrimers that were functionalized by reaction with triethoxybenzoic acid chloride, the dendrimer-stabilized PdNP catalyst led to substrate specificity for the hydrogenation of polar olefins, owing to the strong interaction between polar substrates and the inner tertiary amino groups.[22b,c] For example, in competitive hydrogenation reactions of 3-cyclohexene-1-methanol and cyclohexene, G5-PdNPs gave only reduction of the 3-cyclohexene-1-methanol whereas the traditional Pd/C catalyst gave incomplete hydrogenation of both compounds under the same conditions (Figure 6). For third-generation PdNP-cored dendrimers catalytic activity has been found for the Heck reaction of iodobenzene with ethylacrylate in refluxing toluene (75 % yield) and Suzuki reactions of iodo- and bromobenzene with $PhB(OH)_2$ in refluxing ethanol (42–47 % yield) have been observed. No activity was obtained for hydrogenation reactions, however.[22d]

The encapsulation strategy has recently been extended to bimetallic NP catalysts,[23] evidence that these NPs are bimetallic being provided by single-particle X-ray dispersive spectroscopy (EDS).[17a,b] It was shown that the G4-PAMAM Pd–MNPs (M = Pt or Au) more efficiently catalyze allylic alcohol hydrogenation than the analogous monometallic Pt or Pd catalyst or a mixture of both (Scheme 6).[18i,k]

When a PdNP was located at the dendritic core of G3-TEBA dendrimer, Heck and Suzuki coupling could be obtained in 38 % to 90 % yield in refluxing toluene or ethanol for a day. The form of NPs within the dendrimer is not clear despite TEM studies. Are the NPs really completely inside the dendrimer? Is the dendritic core encapsulated in the NP? Are there several close NPs in the dendrimer cavities or are they connected? Likewise, more work is called for in order to understand the very nature of the catalytically active Pd species.

A different dendrimer-stabilizing strategy involves coordination of the NPs by the surface amino groups of PAMAM and PPI dendrimers,[19c–e] and these catalysts were used for various catalytic reactions including the reduction of 4-nitrophenol. In this case, the PdNPs may be surrounded by a number of dendrimers that can also bridge the nanoparticles.

In both situations, the dendrimers clearly stabilize small nanoparticles by a combination of polyligand and steric effects. Whether these dendrimer-stabilized PdNPs are the active species in palladium-catalysis or reservoirs of much smaller, very active palladium fragments, is unclear.

3.3. Ligands

The introduction of ligands as NP stabilizers is of special interest, because it focuses on the precise molecular definition of the catalytic materials. This strategy potentially allows optimization of the parameters that govern the efficiency in catalytic reactions, including enantioselective ones.

Gladysz showed that thermomorphic fluorous palladacycles act as PdNP catalyst precursors for the Heck reaction at 80–140 °C in DMF and gave very high turnover numbers.[24a] Molecular palladium complexes, such as palladacycles and other palladium salts, were also used as PdNP precursors. Treatment with CO in DMF or toluene at room temperature gave PdNPs that catalyzed nucleophilic substitution/carbonylation/amination affording *iso*-indolinones at room temperature.[24b] PdNPs capped with special ligands such as polyoxometallates[25] and cyclodextrins[26] were shown to be active for the catalysis of the hydrogenation of unsaturated substrates and for the Suzuki, Heck, and Stille reactions. For example, perthiolated β-cyclodextrin-PdNPs (1%), in the presence of K_2CO_3 or $Ba(OH)_2$, catalyze the coupling of iodo- and bromoarenes and iodoferrocene to phenyl boronic acid in refluxing in MeCN:H_2O, 1:1 (v/v).[26a] These 3 nm PdNPs are also active for the hydrogenation of water-soluble alkenes.[26b,c] The simplest dodecathiolate-PdNPs catalyze the Suzuki reaction of haloarenes including chloroarenes with phenylboronic acid even at ambient temperature, and the catalyst can be recycled several times.[27]

Another very simple mode of stabilization involves addition of silanes R_3SiH, such as *tert*-butyldimethylsilane, to PdX_2 ($X = Cl^-$, OAc^-) in *N*,*N*-dimethylacetamide. The black NP solution formed in this way catalyzes silane alcolysis of sugars[28a] and selective cross-coupling of the silane with phenyl and vinyl thioethers giving the corresponding thiosilanes and silthianes [Eq. (2); R and R′ = alkyl, aryl; DMA = *N*,*N*′-dimethylacetamide; $T = 25\,^{\circ}C$]:[28b]

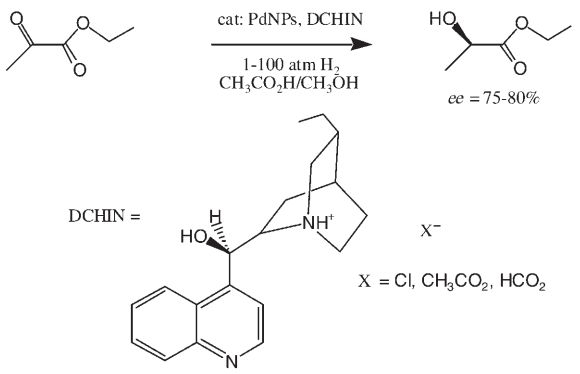
$$RSR' + HSi(t\mathrm{Bu})Me_2 \xrightarrow[DMA]{PdNPs} HSi(t\mathrm{Bu})Me_2 + R'H \qquad (2)$$

The synthesis of core–shell NPs that have a cheap-metal core, such as nickel, and a noble metal shell, such as palladium, has been achieved by the thermal decomposition (235 °C) of the Pd and Ni precursors ([$Ni(acac)_2$] + [$Pd(acac)_2$] + trioctylphosphine; acac = 2,4-pentanedione), the nickel complex decomposes before the palladium one. The nickel-cored PdNPs show a much better activity than PdNPs without nickel, but with the same amount of Pd atoms, for the Sonogashira coupling of *p*-bromoacetophenone with phenylacetylene in toluene at 80 °C, although *p*-chloroacetophenone was unreactive.[28c]

Enantioselective reactions have been carried out with metal NPs.[29–30] The first example of an asymmetric reaction catalyzed by metal NPs was reported by the group of Lemaire, Besson, and Galez in 1994 for the RhNP-catalyzed hydrogenation of 2-methylanisole *o*-cresol trimethylsilyl ether induced by a RhNP with a chiral amine, R-dioctylcyclohexyl-1-ethylamine, as ligand.[29] The hydrogenation of ethyl pyruvate was found by Bönnemann and co-workers[30a] to be efficiently catalyzed by Pt- or PdNPs with cinchonidine

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ligands (75–80% *ee*, Scheme 7). The *ee* value was later improved (up to 95–98%).[30b–d] Fujihara and co-workers reported 2,2′-bis(diphenylphosphino)-1,1′-binaphtyl (binap)—stabilized PdNPs with a diameter of 2.0 ± 0.5 nm



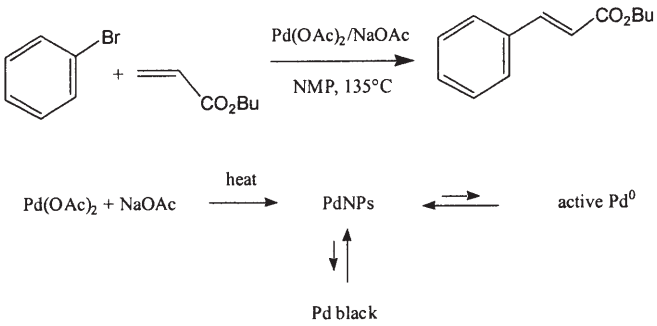
Scheme 7. Enantioselective hydrogenation of ethyl pyruvate catalyzed by cinchonidine-PtNP or cinchonidine-PdNPs.[30a]

and narrow size distribution. It was found that these binap–PdNPs catalyze the asymmetric hydrosilylation of styrene under mild conditions (*ee* 95% at 0°C), whereas mononuclear binap–Pd complexes are inactive.[30e] Recently, the Gomez and Chaudret groups reported enantioselective allylic alkylation reactions with 97% *ee* that were catalyzed by PdNPs stabilized by a chiral xylofuranide diphosphite.[30f] In the above mentioned reports it is suggested that the nanoparticles themselves are catalytically active. However, the nature of the catalytically active species (and even whether catalysis actually occurs on the NP surface) remains unclear. The catalytically active species could also be much smaller Pd fragments, that are leached from the NP, and to which the asymmetric ligand is bound. In any case, regardless of the mechanism, the selectivity obtained is remarkable.

3.4. "Ligand-free" Heck Reactions Using Low Palladium Loading and the Resulting Mechanistic Implications

The original work by Mizoroki et al.,[31a] then by Heck et al.[31b] on the palladium-catalyzed coupling reaction of aryl iodides with olefin used a palladium salt ($PdCl_2$ and $Pd(OAc)_2$, respectively), a base (NaOAc and NBu_3, respectively) and a solvent (methanol and *N*-methylpyrolidone, respectively), but no phosphine or other ligand. Beletskaya and co-workers reported a similar phosphine-free reaction of iodo- and bromoarenes in water, and the palladium loading was as low as 0.0005 mol% (for which the term "homeopathic dose" was used) in the case of 3-iodobenzoic acid.[31c] Likewise, the Reetz[31d,n] and de Vries[31e,n] groups reported extremely efficient Heck catalysis with similarly low palladium-loadings for the coupling between aryl bromides and styrene in organic solvents. Reetz also found that PdNPs are formed when $PdCl_2$, $Pd(OAc)_2$, or $Pd(NO_3)_2$ is warmed in THF in the presence of a tetrabutyl ammonium carboxylate that functions as a reducing and stabilizing agent.[31f] Heating $Pd(OAc)_2$ in polar solvents such as propylene carbonate also generated PdNPs. PdNPs generated in this way from $Pd(OAc)_2$[31d–f] or palladacycles[31g–i] are active catalysts in the Heck reaction, this was demonstrated by monitoring the reactions using TEM.[31j]

Very interestingly, it was found that the palladium catalyst "improves" upon lowering the palladium loading. The proposal to account for this observation was an equilibrium between small (monomeric or dimeric) catalytically active palladium species and the PdNPs which serve as a catalyst reservoir.[31d,h,k] When the catalyst concentration is too high, inactive palladium black forms (Scheme 8). This result



Scheme 8. Heck-type reactions catalyzed by extremely low loadings of palladium salts.[31d,f,j,n]

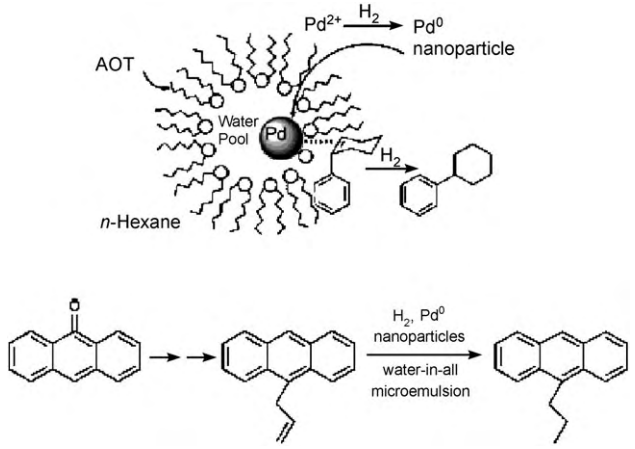
indicates that the rate of the catalytic reaction must be extremely high, since most of the palladium is in the form of PdNPs. This type of Heck reaction seems quite general for aryl bromides and has been scaled up by the firm DSM to kilogram scale to prepare a drug intermediate.[31e] Likewise, a range of enantiopure substituted *N*-acetylphenylalanines were obtained from methyl *N*-acetamido acrylate and various bromoarenes at very low palladium loading in the absence of other ligands, followed by rhodium-catalyzed hydrogenation.[31l] De Vries reported a similar behavior for the Suzuki reaction of aryl bromides with a turnover frequency (TOF) of up to 30000 mole of product per mole of catalyst per hour.[31m] The precise nature of the active species in these palladium-catalyzed C–C coupling reactions is not known, and it may well be an monomeric- or dimeric Pd^0 species to which an anionic ligand (Cl^- or OAc^-) is bound. This type of reaction is very important in terms of "Green Chemistry" as in it waste is minimized through the absence of added ligand and by such low palladium loadings.[31n] This concept could be extended to other types of catalysis, and indeed other examples of NP catalysts are known for platinum-catalyzed hydrosilylation[5c] and ruthenium-catalyzed hydrogenation.[31o–q] RuNPs have also been shown to catalyze the Heck reaction.[31r]

3.5. Micelles, Microemulsions and Surfactants

"Fluorous" strategies[32] have been used on various occasions for NP catalysis for instance by the Crooks[17] and Gladysz[3,24a] groups. Fluoro surfactants can also serve as micellar stabilizers for PdNPs in water-in-supercritical CO_2

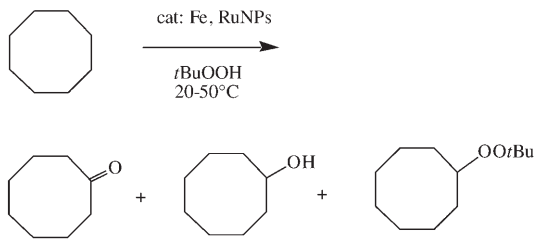
© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

($scCO_2$) microemulsions. Such systems were used as hydrogenation catalysts for simple olefins[32b–d] and citral.[32e] In these systems, hydrogen can work both as a reducing agent for palladium salts and for the unsaturated substrate. Ultrafine PdNPs in reverse micelles (KBH_4 used to reduce the Pd^{II} precursors) enabled the catalytic hydrogenation of allylic alcohol and styrene in the solvent isooctane, although the bis(2-ethylhexyl) sulfosuccinate surfactant inhibited the hydrogenation activity (Scheme 9).[32f] The oxidation of



Scheme 9. Hydrogenation of 10-(3-propenyl) anthracene catalyzed by PdNPs in water-in-oil microemulsion (the reaction is much faster than with Pd/C catalysts). AOT = sodium-5-14-diethyl-8,11-dioxo-7,12-dioxaoctadecane-2-sulfonate. Reprinted with permission from ref. [32f].

N,*N*,*N*′,*N*′-tetramethyl-*p*-phenylenediamine by $[Co(NH_3)_5Cl]^{2+}$ was catalyzed by PdNPs in an aqueous/AOT/*n*-heptane microemulsion.[32g] Functional olefins such as 4-methoxycinnamic acid were selectively hydrogenated in $scCO_2$ using PdNPs in a water-in-$scCO_2$ microemulsion, as was nitrobenzene (to aniline).[32h] Oxidation of cyclooctane by *tert*-butylhydroperoxide (*t*BHP) was catalyzed by FeNPs in reverse microemulsion or with RuNPs in biphasic water/cyclooctane solvent. The catalyst could be recycled without loss of activity (Scheme 10).



Scheme 10. Cyclooctane oxidation catalyzed by FeNPs in reverse microemulsions or by RuNPs in biphasic water–organic media.[49]

4. Ionic liquids as Media for Metal-Nanoparticle Catalysis

Ionic liquids (ILs) are valuable media for catalysis with PdNPs. The substituted imidazolium cation is bulky, favoring the electrosteric stabilization of NPs (as do tBu_4N^+ ions in Figure 1). The size of the imidazolium cation (that can eventually be tuned by the choice of the *N*-alkyl substituents) also has an important influence on the stabilization, size, and solubility of the NPs, factors which play a role in catalysis. However, ILs are non-innocent, at high temperatures they readily produce palladium-*N*-heterocyclic carbene complexes from PdNPs upon deprotonation of the imidazolium salt. Thus, these carbene ligands can be bound to the NP surface or form mononuclear mono- or biscarbene complexes with palladium atoms that have been leached from the PdNP surface.[33]

IrNPs in 1-*n*-butyl-3-methylimidazolium hexafluorophosphate ([BMIM][PF_6]) were used directly for the hydrogenation of olefins, and good results were obtained.[33b] Phenanthroline (phen) stabilized PdNPs prepared in [BMIM][PF_6] according to the method reported by Schmid and co-workers[33c] (but without using acetic acid as the solvent: $Pd(OAc)_2 + Phen{\cdot}H_2O + 1$ atm H_2 in the IL at room temperature), efficiently catalyzed the hydrogenation of olefins and the selective hydrogenation of cyclohexadiene to cyclohexene under mild conditions (1 atm H_2, 40 °C). Under these conditions, formation of palladium carbene complexes from the BMIM ions does not occur, thus the IL simply plays the role of a PdNP-stabilizing solvent. This catalyst could be reused several times,[33d] and it was much more active than phenanthroline-protected PdNPs supported on TiO_2 for the hydrogenation of 1-hexene.[6b] It was found that PdNPs, formed by reaction of $Pd(OAc)_2$ with tetrabutylammonium acetate dissolved in tetrabutylammonium bromide, efficiently catalyzed the stereospecific reaction of cinnamates with aryl halides to give β-aryl-substituted cinnamic esters.

As indicating in the beginning of this section, the role of the IL is crucial in both the PdNP formation and for the stereospecifity of C–C coupling that could not be obtained in previous studies of PdNP-catalyzed Heck reactions.[33e–g] Salts of *N*-butyronitrile pyridinium cation react with $PdCl_2$ to give dinitrile complexes that turn black upon addition of phenyltributylstannane, and the PdNPs formed catalyze Stille and Suzuki C–C coupling reactions. It is believed that the nitrile groups coordinate to the PdNP surface, which results in PdNP stabilization.[33h]

PdNPs are formed from palladium acetate in the presence of 1,3-dibutylimidazolium salts. It was suggested that N-heterocyclic palladium carbene complexes are generated which form the PdNPs that catalyze Suzuki coupling.[33i] Such carbene complexes were shown to form and catalyze the Heck reaction, and it is strongly suspected that the catalytically active species are in fact PdNPs which form under these conditions.[33e,j] Indeed, heating these N-heterocyclic palladium carbene complexes lead to PdNP formation after ligand loss (Scheme 11). The selectivity of the reactions in such IL media also depends on the solubility, and the solubility difference can be used for the extraction of the product.[33k–m]

Ionic liquids are favorable media for the electrostatic stabilization of preformed NPs at room temperature and subsequent catalysis. At high temperature they give palladium-carbene complexes upon deprotonation of the imida-

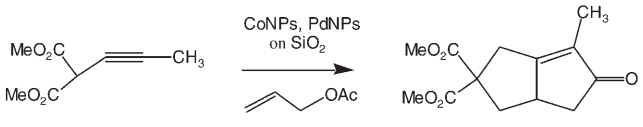
zolium cation, these carbene complexes in turn generate, PdNP catalysts.

5. Solid Supports for Metal Nanoparticles

5.1. Oxide supports

A large number of recent reports (for earlier reports, see refs [6] and [11]) focus on the catalytic properties of NPs supported on metal oxides, including oxides of Si,[34,35] Al,[36] Ti,[37] Zr,[43] Ca,[38] Mg,[39,43] and Zn.[39g] These oxides take various forms, such as SiO_2 aerogels or sol–gels such as Gomasil G-200, high-surface silica (for example, see Scheme 12), M41S silicates and alumimosilicates, MCM-41



Scheme 12. Sequential allylic alkylation and Pauson–Khand reactions for the one-pot syntheses of bicyclic enones. Both are catalyzed by CoNPs and PdNPs supported on silica.[35c]

mesoporous silicates such as HMS and SBA-15 silica, silica spheres,[35b] microemulsions (SiO_2), hydroxyapatite (Ca^{2+}),[38] hydrotalcite (Mg^{2+}, Al^{3+}),[39] zeolites (SiO_2, Al_2O_3),[40] molecular sieves (Figure 7)[41] and alumina membranes (Figure 8).[36a] Thus, despite the large variety of supports, the majority of them deal with a form of silica. The catalytic reactions examined with these supported NPs are hydrogenation reactions, including selective ones, of unsaturated substrates, Heck and other C–C coupling reactions, and oxidation of CO and alcohols using molecular oxygen. The heterogenization of polymer- or dendrimer-stabilized NPs on a solid supports such as silica brings the classic advantages of heterogeneous catalysis, that is, stability to high temperatures, easy removal from the reaction medium, and the bottom-up approach of NP synthesis. A few outstanding recent examples are discussed below, and Table 1 gathers references for each NP-catalyzed reaction.

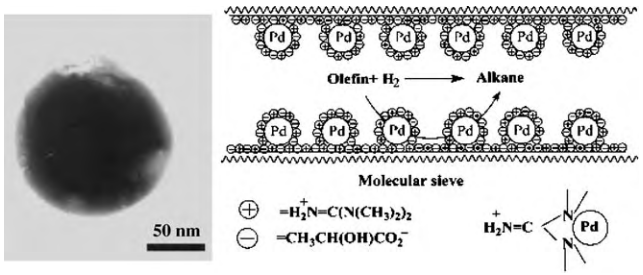


Figure 7. Transmission electron micrograph (left) of a molecular sieve with supported PdNPs (right). The catalyst, active in hydrogenation of olefins, contains 20 wt% ionic liquid as the stabilizer whose average layer thickness is 0.4 nm.[41b]

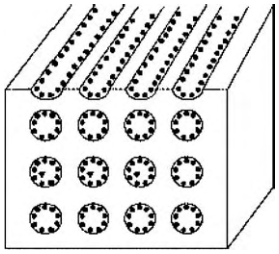

Figure 8. Schematic representation of a section of alumina membrane loaded with metal nanoparticles as would be used for the gas-phase catalysis of 1,3-butadiene hydrogenation (PdNPs) and CO oxidation (RuNPs).[36a]

PtNPs and bimetallic dendrimer-stabilized Pd–AuNPs were adsorbed onto a high-surface silica support and thermally activated to remove the dendrimers (Figure 9). The Chandler group showed that these NPs were smaller than 3 nm and highly active for CO oxidation catalysis near room temperature. The hydrogenation of toluene was also efficiently carried out.[34] The fabrication of uniform hollow spheres with nanometer to micrometer dimensions having tailored properties has recently been intensively studied using various procedures.[42] Monodisperse palladium nanospheres of 300 nm catalyzed Suzuki coupling of iodothiophene with phenylboronic acid using 3 mol% Pd catalyst in ethanol under reflux. Under the same conditions 15 mol% Pd catalyst was used to couple bromobenzene (Figure 9).[35b] Treating hydroxyapatite, $[Ca_{10}(PO_4)_6(OH)_2]$, with $[PdCl_2(CH_3CN)_2]$ gives a monomeric $PdCl_2$ species chemisorbed on the hydroxyapatite surface that, in the presence of alcohol, is readily transformed into supported PdNPs with narrow size distribution. These PdNPs catalyze the oxidation of 1-phenylethanol under atmospheric O_2 pressure in solvent-free conditions with very high turnover numbers of up to 236000 and a remarkable turnover frequency of 9800 h^{-1}. The work up is easy and the catalyst is recyclable without requiring additives to complete the catalytic cycles.[38]

Hydrotalcite anionic clays are layered double hydroxides of formula $M^{2+}_{1-x}M^{3+}_{x}(OH)_2(A^{n-})_{x/n}\cdot y\,H_2O$ (where A^{n-} is CO_3^{3-}, Cl^-, or NO_3^-) in which the anion can easily be exchanged. These materials, after calcination at temperatures over 723 K, serve as supports for noble-metal catalysts, for example, C–C coupling[39d] and selective semi-hydrogenation

Dehydrohalogenation of arylhalides	[44i,n]		

of alkynes[39e] have been obtained. Immobilization of a PdNP catalyst on a solid surface such as molecular sieves was achieved by using the ionic liquid 1,1,3,3-tetramethylguanidinium lactate. This system was used for solvent-free hydrogenation of alkenes and gave high activity and stability (for instance with a cyclohexene/palladium mol ratio of 12000:1, 100% conversion was obtained in 10 h at 20°C with a TOF of 20 min^{-1}).[41b] The PdNPs whose size remains unchanged (1–2 nm) during the catalysis, are stabilized by guanidinium ions.[33d] Ag–PdNPs prepared directly in ultrathin TiO_2 gel films by a stepwise ion-exchange/reduction method showed an activity in methyl acrylate hydrogenation 267-times higher than commercial palladium black and 1.6-times higher than PdNPs that did not contain Ag. This outstanding activity was explained by the large fraction of the surface-exposed palladium atoms.[37c] Polyelectrolyte multilayers serve as supports the PdNP catalysts for the selective hydrogenation of allylic alcohols, a reaction in which the isomerization is suppressed. To prepare this catalyst, polyacrylic acid and a polyethyleneimine palladium(II) complex were alternatively

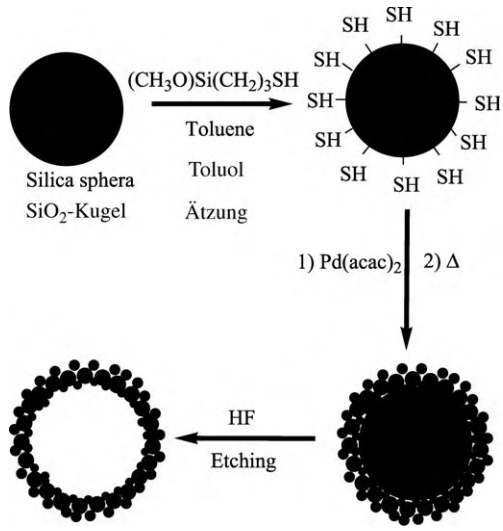

Figure 9. Principle of the formation of hollow PdNP spheres used for the catalysis of Suzuki reactions in refluxing ethanol with K_3PO_4 as a base. With 2-iodothiophene and phenylboronic acid (cat: 3% Pd spheres), at least seven cycles could be achieved with 95–97% yields, ref. [35b].

adsorbed on 150-mm diameter alumina particles, and subsequent reduction of Pd^{II} to PdNPs was carried out using $NaBH_4$.[14d]

The mechanisms of oxide-supported PdNP catalysis are a long way from being understood. The oxide support however has a strong influence on the activity. For instance, in the Heck reaction, the activity is dominated by the support in the order: C (84%) ~ H-Mordenite (83%) > ZrO_2 (49%) ~ TiO_2 (45%) > MgO (37%) = ZnO (37%) > SiO_2 (7%). The good activity of zeolites in this reaction is seemingly due to a better stabilization of the active species in the cavities and to a better dispersion of PdNPs on the oxide support. There are many heterogeneous-catalysis studies that discuss the influence of parameters (solvent, catalyst, base, temperature, recycling activity, NP size). Indeed, Djakovitch and Köhler have proposed that, since the results are often similar for homogeneous and heterogeneous systems in terms of selectivity, the "heterogeneous mechanism" proceeds by leaching of molecular palladium species into the solution (a phenomenon favored in DMF). On the other hand, dehalogenation is more favored on a heterogeneous support than with a homogeneous catalyst. Thus, it has been proposed that supported PdNPs are responsible for dehalogenation.[43]

The heterogeneous palladium-catalyzed Heck reaction has been extended to important α-arylated carbonyl derivatives, and the model arylation of diethylmalonate has been examined. The NaY-supported PdNP catalyst showed a limited activity, giving yields comparable to those obtained with the homogeneous ($Pd(OAc)_2$/4 PPh_3) system, but the palladium concentration used is only 2% and the recyclability is good. The amination of halogenoarenes has also been investigated with MgO-supported PdNPs and ZrO_2-supported PdNPs, the amphoteric supports give the best yields, which would indicate that they favor the rate-limiting C–N coupling in the reductive-elimination step. For this reaction, the zeolite supports give a better *para* selectivity presumably because of the "shape selectivity" properties of this material.[43]

The Heck and Suzuki reactions have also been catalyzed by alumina-supported RuNPs.[43c] Hydroxyapatite-supported RuNPs were recently found to be efficient and recyclable catalysts for *cis*-dihydroxlation and oxidative cleavage of alkenes.[43d] Supported RuNPs in the pores of mesoporous Al-MCM-41 materials were prepared by H_2 reduction of adsorbed $[Ru(NH_3)_6]^{2+}$. Their activity in benzene hydrogenation reactions was studied and found to be more efficient when 330 ppm H_2S was added to the H_2 than when H_2S was not present.[43d]

Little is known concerning the catalytically active species of oxide-supported NPs, and it is possible that the supported NPs are only reservoirs of much smaller catalytically active palladium fragments.

5.2. Carbon Supports

Charcoal is a classic commercial support for catalysts, (for example Pd/C). Using the general synthetic method developed by Bönnemann (the reduction of quaternary ammonium salts of metal cations in THF) the charcoal is impregnated simply by stirring in the NP suspension. These charcoal-supported metal NPs have been used for a variety of catalyzed reactions.[7,29a,35a,41a,c] This procedure was also used by Reetz et al. to support their electrochemically prepared metal NPs including catalytically active bimetallic NPs.[8,35a] Activated carbons that are suitable as support materials in catalytic processes need to be prepared and modified so that adequate surface area, porosity, and pore size distribution are obtained. Purification by acid treatment and elution processes are required to remove ash, extractable sp^3 material, and contaminants. Treating and conditioning supports leads to optimal interactions between the precious metal and the support during impregnation and ensures dispersibility in the reaction media.

The detailed identification of the specific properties of the surface atomic layers of carboneous supports used for the preparation of Pd/C catalysts has been studied recently by means of inelastic incoherent neutron scattering. This technique allows the behavior of activated carbons and carbon blacks in the presence of adsorbed hydrogen to be studied and the vibrational states of protons on and inside carbon-supported PdNPs and PtNPs to be identified.[44a] Well-known and typical applications of such materials are the hydrogenation reactions that are important for the synthesis of fine-chemicals intermediates, vitamins, and pharmaceuticals.[2,44b] Such Pd/C catalysts were also reported for the Suzuki and other C–C forming reactions.[44c–e]

It was shown that the catalysis proceeds with palladium dissolution/reprecipitation, the palladium concentration in solution being highest at the beginning of the reaction and minimal (< 1 ppm) at the end of the reaction. The mechanism is quasi-homogeneous, and small palladium species in solution act as the catalytically active species.[44f,g] The palladium

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

is leached and, at the end of the reaction redeposited, which provides an excellent recovery of the precious metal from the reaction mixture.[44f,g] The precipitation of the catalyst at the end of the reaction significantly changes its state and decreases its activity, however, making its reuse unattractive.[44f]

Köhler et al. also showed that optimization of the Pd/C catalyst (temperature, solvent, base, and palladium loading) for the Heck reaction of unactivited bromobenzene at 140 °C, allows turnover frequencies (TOFs) of up to 9000 mole of product per mole of catalyst per hour (the highest ever reported) to be reached and palladium concentration down to 0.005 mol % to be developed. The efficiency of this catalyst is far higher than, for instance, palladium on mesoporous silica and palladium on zeolites, and TOFs are higher than homogeneous palladium catalysts. The turnover numbers (TONs), however, are surpassed by those of the best homogeneous catalysts.[44f] As indicated above, the efficiency of the Pd/C catalyst strongly depends on the palladium dispersion, oxidation state in the fresh catalyst (in situ reduction of Pd^{II} to active Pd^0 under the Heck reaction conditions leads to the best dispersion and activity), impregnation method, and pre-treatment. Interestingly, exclusion of air and moisture is not necessary, however. The fact that no dehalogenation of bromobenzene to benzene is found confirms the homogeneous mechanism, whereas surface heterogeneous catalysis might be responsible for dehalogenation under different conditions.

Heterogeneous Ni/C catalysis[44h–o] is also mainly known for the hydrogenation of unsaturated compounds.[44h] Recent reports, however, concern hydrodehalogenation of aryl halides (including aryl chlorides),[44i,n] Kumada,[44j,k] Suzuki,[44l] and Negishi-type C–C coupling[44m] and aromatic amination.[44k–o] Whereas the mechanism for heterogeneous hydrogenation follows true surface chemistry with dihydrogen chemisorption onto the metal surface,[44p] C–C and C–N coupling reactions involve nickel bleed from the carbon support, a one-time event at the very beginning of the reactions. There is an equilibrium for between homogeneous nickel species located inside and outside the carbon pores which strongly favors the former. Thus, unlike in the Pd/C case, only traces of metal are detectable in solution. The nickel is completely recovered on charcoal, making this heterogeneous catalyst interesting for applications. These reactions appear to be due to a combination of heterogeneous and homogeneous catalysis.[44k,n]

Recently, new supports such as high-area carbon have been used to prepare bimetallic Pt–RuNPs that catalyze methanol electrooxidation with enhanced activities compared to commercial catalysts.[46i–l] Pd-, Rh-, and RuNPs, deposited onto functionalized carbon nanotubes by hydrogen reduction of metal-β-diketone precursors are effective catalysts for hydrogenation of olefins, such as *trans*-stilbene in $scCO_2$[32g]. Comparison of the properties of carbon nanotube and activated carbon supports were carried out for Heck and Suzuki reactions, aerobic alcohol oxidation, and selective hydrogenation.[44q]

6. The New Gold Rush

In the AuNP-catalyzed CO oxidation to CO_2 by O_2 that can occur down to 200 K, the oxide support (Fe_2O_3, TiO_2 or Co_3O_4) is indispensable.[9c,d] The mechanism is not clear, however.[45a] A new "gold rush"[9d,e,45] is now following Haruta's crucial work on catalysis with AuNPs.[9c,d] This finding of low-temperature catalysis of CO oxidation is of great interest, because the Pt/Pd catalysts that are currently used in cars for CO oxidation work only at temperatures above 200 °C. Thus, CO pollution essentially occurs during the first five minutes after starting the engine. The low-temperature, supported-AuNP-catalyzed CO oxidation clearly could solve this problem.

CO can be selectively oxidized by O_2 in the presence of H_2 which allows H_2 to be purified from residual CO. There are many other challenges in catalytic oxidation chemistry that can be addressed using this type of catalyst (see below). Of the various ways to prepare supported AuNP catalysts, it is considered that Haruta's deposition–precipitation procedure is the most suitable [Eq. (3)]:[9d]

$$\begin{aligned} &HAuCl_{4(aq)} + NaOH \rightarrow [Au(OH)_4]^- \; Na^+_{(aq)} \; (pH\,6-10) \rightarrow \\ &Au(OH)_3/Support \rightarrow wash,\ dry\ then \\ &calcinate\ at\ 563-673\ K \rightarrow AuNP/Support \end{aligned} \quad (3)$$

The optimum size of the AuNPs is 3 nm, stable hemispherical NPs, are formed, their size being controlled by the calcination temperature (optimum 570 K). The best support is TiO_2, for a good dispersion of the AuNPs the addition of Mg citrate is necessary during or after coprecipitation).

It has been shown that oxidation of CO by O_2 to CO_2 can also be catalyzed in the gas phase by the cluster Au_6^- (Figure 10),[45c] and calculations with Au_{10} predict CO oxidation by O_2 below room temperature.[45d] Although the mechanism was thus depicted with AuNPs alone[45c,d] (Figure 10), the activation by the oxide support is also

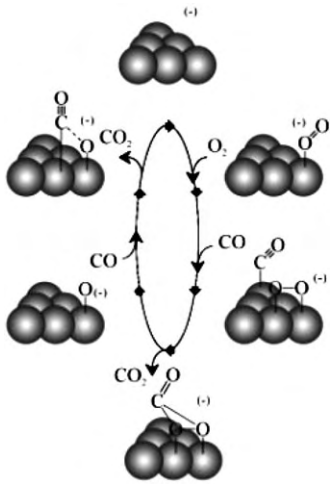

Figure 10. Proposed schematic mechanism of the Au_6^- catalyzed formation of CO_2 from CO and O_2 in the gas phase (Reprinted with permission from ref. [44c].

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

needed and must be involved in the mechanism. It is probable that the oxide favors the polarization of the adsorbed CO molecule to provoke electrophilic attack on the CO carbon atom by AuNP-support-activated O_2 (in the form of superoxide or a related nucleophilic oxygen species).[9d,e,45b] It is also suggested that CO adsorbs on the edge and step sites of AuNP surfaces and O_2 adsorbs on support surfaces.[50b]

Applications of supported AuNPs are expected both in the catalytic removal of CO produced at ambient temperature by engines and in the removal of CO traces from dihydrogen streams feeding the fuel cells. There has been a tremendous increase recently in the number of reports focusing on this area of supported AuNP-catalyzed CO oxidation, TiO_2 becoming the dominant support.[45] Besides CO oxidation, other supported-AuNP-catalyzed reactions have been disclosed, confirming that supported AuNPs are now a very popular means to catalytically activate dihydrogen and dioxygen. The following applications have been reported:

- Hydrogenation of 1,4-butadiene to butenes,[46a] acrylaldehyde to allylic alcohol,[46b] citral to geraniol and nerol,[46c] and benzalacetone to phenyl-3-butene-2-ol.[46d]
- Oxidation (using O_2 or air) of alcohols to aldehydes,[46c] *o*-hydroxybenzyl alcohol to salicylic aldehyde,[46d] ethane-1,2-diol to glycolate,[46c] other diols to hydroxymonocarboxylates,[46e] β-amino alcohols to β-amino-acids,[46e] aliphatic aldehydes to carboxylic acids,[46e] D-glucose to gluconic acid[46e] or oxalate,[46m] dihydrogen to hydrogen peroxide,[45f] aromatic amines (with CO) to carbamate,[46g] propene to propene oxide,[45h] and cyclohexane to cyclohenol and cyclohexanone.[46n–o] Alcohols, in particular methanol, are also oxidized electrochemically, with supported AuNPs being more active electrocatalysts than AuNPs alone.[47]

Other applications of supported AuNP-catalyzed reactions are numerous. They include:

- Oxidative decomposition by Fe_2O_3-supported AuNPs of bad-smelling alkylamines responsible for unpleasant atmosphere in toilets.[9d]
- Oxidative decomposition of dioxin coming from incinerator outlet gases by La_2O_3-supported AuNPs integrated with Pd/SnO_2 and Ir/La_2O_3.[9d]
- Direct epoxidation of propylene to propylene oxide by TiO_2(MCM48)-supported AuNPs.[9d]
- Sensors using Co_2O_3-supported AuNPs that are able to simultaneously detect H_2 and CO at low concentration levels.[9e]
- CO safety masks for efficient removal of CO from contaminated atmospheres.[9e,45f]
- Various liquid-phase synthetic processes.

7. Summary of Mechanistic Information

Hydrogenation of unsaturated substrates under ambient conditions can be catalyzed by a large variety of unsupported or supported metal NPs of 1 to 5 nm size and, in the mechanistically studied cases, proceeds by the classic heterogeneous surface mechanism involving dihydrogen chemisorption. The use of core–shell bimetallic NPs, where by the metal core activates the metal surface of the NP, improves the catalytic efficiency compared to the monometallic NPs. For soluble metal NPs active at room temperature, hydrogenation presumably proceeds on the edge of polyhedral NPs without leaching.

The finding that dehalogenation of halogenoarenes occurs in the course of heterogeneously catalyzed C–C bond-formation reactions is explained by a heterogeneous mechanism.[43] It has been proposed that defects on the PdNP surface are involved in the mechanism of C–C bond formation in the Heck reaction, that is, the activity should be related to the number of low-coordinate surface atoms.[83] It has also been suggested that flat π-adsorption of the aromatic ring of the aryl halide over a "large" PdNP is responsible of activation of the C–X bond prior to formation of a σ-aryl-palladium complex at the PdNP surface.[84] However, the homogeneous mechanism according which the catalytic activity is due to palladium species leaching from the heterogeneous catalyst (Pd/C or Pd/MO_x) into the solution is presently preferred. This "leaching mechanism",[43,85,86] first proposed by Julia et al. in 1973,[85] is now firmly established especially by the recent work by Djakovitch and Köhler using astute experiments in which the selectivities obtained in homogeneous and heterogeneous catalysis are compared.[43e] Charcoal-supported catalysts are superior to oxide-supported catalyst in terms of efficiency and selectivity. PdNPs on NaY zeolites are also very efficient catalysts, and the catalytically active Pd^0 species could be retained in the zeolite pores or re-adsorbed at the surface by dissolution–readsorption.[43e,f] The thermal treatment has an important influence on the mechanism, as Pd^{II} species surrounded by oxygen atoms in the zeolite pores could give leaching whereas Pd^0NP entrapped the zeolite pores would still react by a heterogeneous mechanism.[87a] The exact nature of these exceedingly reactive species involved in the homogeneous mechanism is not known: they could be mono- or bimetallic metal species[87b] or very small metal clusters containing only a few atoms. They could be neutral or be coordinated to an anionic ligand (for example, halide, acetate) making them anionic which could facilitate the oxidative addition of the aryl–halogen bond.[88]

The finding that unsupported palladium salts are active even under "homeopathic" (extremely low) concentration in the "absence" of ligand (except halide or acetate) was taken together with the facts that PdNPs were confirmed and that dilution improved the catalysis led Reetz to propose an equilibrium between PdNPs and catalytically active palladium fragments.[31j,n] Thus, in the Heck reaction, there is a good parallel between homogeneous catalysis and catalysis by supported PdNPs. In the homogeneous case, the PdNPs are the reservoir of active palladium species, and in the supported Pd/C catalysis, the charcoal or zeolite is the reservoir of palladium species that are also catalytically active in solution. These active species could be of similar nature in both supported and unsupported cases.

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Such a mixture homogeneous and heterogeneous catalysis was also found or Ni/C catalysis of a variety of C–C and C–N coupling reactions (Kumada, Suzuki, Negishi, Heck, amination of bromoarenes). The leaching of nickel species was demonstrated in all these cases. However, the amount of leached metal is much less important than in the palladium case; with nickel the amount of leaching remained essentially constant and extremely low throughout the reactions. Besides supported NP metal catalysts, some unsupported, but ligand-coordinated PdNPs are active and recyclable catalysts for the Suzuki C–C coupling reaction at room temperature.[27] It is possible that, under such mild conditions, the PdNPs do not loose palladium atoms or clusters of atoms in the solution, and that catalysis occurs at the edge of the polyhedral PdNP itself, but this remains to be ascertained.

It is clear that care should be exercised in classifying the NP-catalyzed reactions as homogeneous or heterogeneous as the frontier is fuzzy, as exemplified by the above homogeneous mechanism of reactions on heterogeneous supports.

Techniques that allow investigation of the leaching of metal species from the supported metal to the solution are crucial to mechanistic investigations and include transmission electron microscopy (TEM), energy dispersion X-ray analysis (EDX), and X-ray diffraction. Data are recorded from samples before and after catalytic runs for comparison. Sometimes, experiments carried out with and without PPh_3 or a polymer phosphine are compared to investigate the importance of such ligands on the activity of the leached metal species in solution. The metal content in solution can also be determined by inductively coupled plasma atomic emission spectroscopy (ICP-AES) after filtration of the hot or cooled reaction mixture. Comparison of the selectivities obtained with homogeneous and heterogeneous catalysts is also a powerful means to investigate whether heterogeneous catalysis proceeds by an active leached species.[43e]

Concerning the important AuNP catalysis of CO oxidation by O_2, recent studies by Haruta's group indicate that the TOF increases with decreasing AuNP diameter. The enhancing effect of moisture on the metal oxide support was demonstrated. Kinetic studies showed that the rate of CO oxidation is independent of the CO concentration and only slightly dependent on the O_2 concentration in the low concentration range down to 0.1 vol%. This result suggests that both CO and O_2 are adsorbed on the catalyst surface to near saturation and that the rate-determining step is the reaction between the two adsorbed species. Isotope effects also are a useful technique contributing to mechanistic investigations. Some logical mechanistic trends are apparent and have been proposed, in particular by Haruta, although the precise mechanism is unknown and still the subject of scrutiny. Adsorption of CO and O_2 must occur at the NP periphery on edges and corners. The Au-coordinated CO must be polarized ($C^{\delta+}$–$O^{\delta-}$) upon coordination, and the dioxygen molecule must also be polarized or reduced to the superoxide anion by AuNPs. Then $O_2^{\bullet-}$ could attack the positively polarized CO carbon atom. The role of the oxide support might be to facilitate the polarization of either molecule or both, this role however is more difficult to evaluate. The support may also have a crucial role in the cleavage of the superoxide species or negatively polarized oxygen atom of the O_2 molecule before, during, or after CO binding.[45] Haruta recently depicted his mechanistic proposal as follows [Eq (4)–Eq (6)]:[11j]

$$O_2 + Au_{NP}/TiO_2 \rightarrow Au_{NP}/TiO_2 \cdots O_2 \quad (4)$$

$$Au/TiO_2 \cdots O_2 + 2\,Au_{NP}CO \rightarrow OCAu_{NP}{=}O + CO_2 + TiO_2 \quad (5)$$

$$OCAu_{NP}{=}O \rightarrow Au_{NP} + CO_2 \quad (6)$$

Clarification should be provided by theoretical work involving not only AuNPs but all the four components of the reaction including the TiO_2 support. Intriguingly, the Corma group reported that Au^{3+} on CeO_2 catalyzed the homocoupling of phenylboronic acid, and the catalytic cycle was proposed to involve the interconversion of Au^{3+} and Au^{+}.[87c] Spectroscopic studies, by the same research group, of Au supported on nanocrystalline CeO_2 showed that CO was bonded to Au^{3+}, Au^{+}, and Au^{0} species, whereas the active form of O_2 was bonded to CeO_2 as superoxide η^1-O_2^-, confirming the nucleophilic attack on the electron-deficient carbon atom of CO by superoxide on the way to CO_2.[87d]

8. Prospects for Organic Synthesis

The discovery of the catalytic formation of C–C and C–N bonds by palladium catalysts has been a considerable advance for organic chemistry. It became possible to easily functionalize olefins, alkynes, and aromatics. Yet, the problems of catalyst recovery and pollution by phosphines were unsolved. These aspects are crucial for the pharmaceutical industry, because the presence of metal and phosphine contaminants in drugs is unacceptable. These problems are largely solved by the use of Supported NP catalysts which allows catalyst removal from the reaction mixture by simple filtration. The carbon and NaY zeolite supports (the best ones) are reservoirs of metal species that retain these metal species subsequent to reaction in solution. The amount of metal left in solution is in the ppm range. Moreover, such types of catalyst are phosphine free. The firm DSM employ this method for the synthesis on the kg-scale of pharmaceutical intermediates, and it is likely that this type of procedure will find use throughout the pharmaceutical and other industries.

The Heck reaction is a key reaction in the production of fine chemicals on multiton scale per year[89] for which the use of NP catalysts could be possible. It is used for the production of the herbicide prosulfuron,[90] the anti-inflamatory naproxen,[91] or the anti-asthma singulair.[92] On the other hand, in terms of "Green Chemistry", it is likely that procedures involving chemicals such as ionic liquids, micelles, surfactants, and other additives in homogeneous solution will be of interest.

Given the extraordinary recent advances in AuNP-catalyzed reactions, it is clear that many applications in oxidation catalysis will very soon penetrate the every-day world of organic chemists. In addition there is considerable interest from materials scientists for the reduction of car

pollution and in H_2 purification through the removal of residual CO.

9. Conclusion

The design and use of metal NP catalysis is now well advanced thanks to the efforts of pioneers and advent of modern characterization techniques. A large variety of NP preparation modes, a variety of materials that can serve as supports or grafting cores, and several media are available. Monodisperse, small (1–10 nm) supported metal NPs are available for many important reactions. Bi- and trimetallic NP catalysts are often more efficient than those containing only one type of metal. Compared surface studies on palladium single crystals and PdNP have even shown that alkene hydrogenation is only catalyzed by PdNPs.[32i] These advances have considerably improved the selectivity of NP-catalyzed reactions, especially the heterogeneously catalyzed hydrogenation of unsaturated substrates. High enantioselectivity has been obtained, although it has not yet been demonstrated that asymmetric induction occurs at the metal NP surface and not on more reactive leached monometallic complex fragments. For example, in the Pd/C and Ni/C catalyzed C–C and C–N bond forming reactions, the mechanism involves such a leaching pathway with recovery of the metal on the support at the end of the reaction. More mechanistic studies are called for to understand the nature of the very active metal species in solution. The activation of aryl chlorides for C–C coupling reactions still remains a key challenge because organometallic catalysts are presently more efficient than metal NP catalysts. A major recent finding was the removal of these NP catalysts by filtration, although recycling and efficient re-use many times of supported NP catalysts remains a challenge.

Altogether, the field of metal NP catalysis is a fascinating one, as exemplified by the new gold rush and its very attractive perspectives in oxidation chemistry and by the ligand-free palladium and nickel catalysts that are employed in "homeopathic" amounts. The metal NP field is presently expanding dramatically, and it is anticipated that these key challenges will be met in the near future, and that this area will find many more applications in tomorrow's laboratory and industry.

The UN_{21}^{3-} ion, which was characterized as the $(Bu_4N)_3[U(N_3)_7]$ salt, is not only the first homoleptic azide of an actinide but also the first structurally characterized heptaazide. For more information on this fascinating structure, see the Communication by M.-J. Crawford and co-workers on the following pages.

UN_{21}^{3-}: A Structurally Characterized Binary Actinide Heptaazide Anion**

Margaret-Jane Crawford, Arkady Ellern, and Peter Mayer*

Although the chemistry of uranium has been extensively investigated, many small, conceptually simple uranium compounds have not been unambiguously characterized, or are missing from the literature completely. The synthesis and characterization of such uranium compounds is particularly interesting, because uranium is the heaviest element that can be handled in the laboratory in small quantities without special techniques. Recent advances in computational chemistry have made the study of small uranium systems possible, thereby opening up a large and interesting aspect of actinide chemistry.[1] We recently reported the first structurally characterized actinide isocyanate,[2] which alerted us to the absence in the literature of any report describing the synthesis of a homoleptic uranium or actinide azide. Pyykkö et al. have recently reported computational investigations into the binary $Th(N_3)_4$ molecule,[3] which they predicted should possess linear azide units. However, despite this exciting prediction, to the best of our knowledge, no synthetic report describing a homoleptic thorium azide exists in the literature.

A few structurally characterized uranium azides have previously been reported, namely polymeric uranyl(VI) azide anions[4] and the $[UO_2\{(CF_3CO)_2CH\}_2N_3]^-$ ion,[5] as well as the uranium(IV) compound $[\{(ArO)_3tacn\}U(N_3)]$ ($(ArOH)_3tacn$ = 1,4,7-tris(3,5-di-*tert*-butyl-2-hydroxybenzyl)-1,4,7-triazacyclononane).[6] The $[UO_2(N_3)_4]^{2-}$ ion has been extensively investigated and unambiguously characterized by Beck and co-workers,[7] and we have recently reported the crystal structures of salts containing $[UO_2(N_3)_4]^{2-}$ and related anions.[8] However, in all of the above-mentioned compounds no binary U–N system was isolated. This is surprising because the synthetic chemistry of binary azides has undergone a renaissance.[9] In addition to the synthesis and structural characterization of IN_3 in the solid state,[10] many new main group and transition-metal anionic azide species have been synthesized.[11] The strategy of synthesizing salts containing binary azide anions in combination with large bulky cations has been used to prepare a wide range of binary azide anions, many salts of which could be structurally characterized in the solid state, and were usually found to be less explosive than neutral binary azides. Some examples include the $As(N_3)_6^-$,[11a,b] $Sn(N_3)_6^{2-}$,[11c,d] $Au(N_3)_4^{2-}$,[11e,f] $Si(N_3)_6^{2-}$,[11g] $Pd(N_3)_4^{2-}$,[11h] $Pt(N_3)_4^{2-}$,[11i] $B(N_3)_4^-$,[11j,k] $Ge(N_3)_6^{2-}$,[11l] $Pt(N_3)_6^{2-}$,[11i,m,n] $Te(N_3)_6^{2-}$,[11o] $Te(N_3)_5^-$,[11p] $I(N_3)_2^-$,[11q,r] $Sb(N_3)_6^-$,[11s] and $Ti(N_3)_6^{2-}$[11t] ions. Detailed discussions of the chemistry of covalent azides are available in excellent review articles by Dehnicke[12] and Klapötke et al.[9]

Since salts containing the binary azide anions are generally more thermally stable and less explosive, particularly when large bulky cations are employed, we set out to investigate the synthesis of a binary uranium azide anion. The convenient synthesis of the $(R_4N)_2[UX_6]$ (R = alkyl; X = Cl, Br) salts,[13] as well as the previous reports on the synthesis and structural characterization of salts of the octaisothiocyanatouranate anion $U(NCS)_8^{4-}$,[14] made the synthesis of a uranium(IV) azide a particularly interesting and promising target. Herein, we report on the synthesis and characterization including the single-crystal structure determination of the binary uranium(IV) heptaazide anion in the $(Bu_4N)_3[U(N_3)_7]$ salt.

The reaction of the uranium(IV) compound $(Bu_4N)_2[UCl_6]$ with two equivalents of Bu_4NBr and eight equivalents of silver azide at room temperature resulted in an immediate color change of the solution from pale green to emerald green. On leaving the reaction mixture to stir overnight (ca. 12 h), an extremely air-sensitive, clear emerald green solution was obtained which could be separated from the insoluble side products.

Large dark green crystals were obtained on cooling a solution of the crude product in $CH_3CN/CFCl_3$. X-ray diffraction revealed that these crystals were not the salt containing the octaazidouranate anion, $(Bu_4N)_4[U(N_3)_8]$, which was expected based on the stoichiometry used, but the heptaazide $(Bu_4N)_3[U(N_3)_7]$ (**1a**) [Eq. (1)]. It is worth mentioning, that to the best of our knowledge no structurally characterized octaazide of any element has been reported. Nevertheless, the isolation of the heptaazide was initially surprising, because preliminary results from our laboratory indicate that from a related reaction, the octaisoselenocyanatouranate anion can be prepared in the form of the $(Pr_4N)_4[U(NCSe)_8]\cdot 2\,CFCl_3$ salt,[8b] in analogy to the previously reported salts of the $U(NCS)_8^{4-}$ ion.[14]

$$(Bu_4N)_2[UCl_6] + Bu_4NBr + 7\,AgN_3 \xrightarrow{CH_3CN} (Bu_4N)_3[U(N_3)_7] + 6\,AgCl + AgBr \quad (1)$$

According to the X-ray structure determination **1a** crystallizes in the cubic space group $Pa\bar{3}$, with one uranium

atom and one of three crystallographically independent azide groups located on a C_3 symmetry axis. This results in a monocapped octahedron (1:3:3) arrangement of the azide ligands around the central uranium atom. The N_α atoms of six of the azide ligands are positioned at the corners of a trigonal antiprism, whereas the seventh azide group is located along the C_3 axis. The U–N bond lengths in **1a** range from 2.32(2) to 2.40(2) Å, and it is worth noting that the shortest anion–anion contact, between N6 and N3^i (with $i = y, {}^1/_2-z, -{}^1/_2+x$), is very long (6.72(3) Å; Figure 1) Despite several recrystallization attempts using this method, we did not obtain a better quality structure, therefore we decided to use CH_3CH_2CN as the solvent instead of CH_3CN, because the $(Bu_4N)_3(N_3)_7$ salt is less soluble in CH_3CH_2CN. The reaction using $(Bu_4N)_2[UBr_6]$ and CH_3CH_2CN as the solvent, proceeded analogously to that observed when $(Bu_4N)_2[UCl_6]$ and CH_3CN were used. Although eight equivalents of AgN_3 were used, again only the heptaazide was isolated [Eq. (2)].

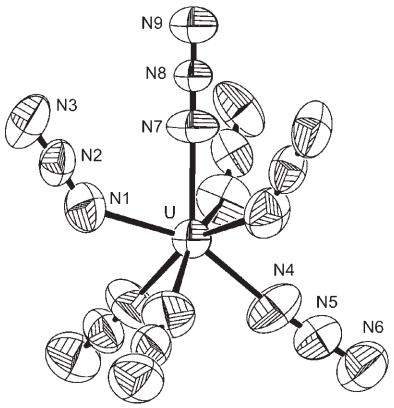

Figure 1. Molecular structure of the $U(N_3)_7^{3-}$ ion in **1a** as determined by single-crystal X-ray diffraction on crystals obtained from CH_3CN/$CFCl_3$ solution (thermal ellipsoids at the 25% probability level).

$$(Bu_4N)_2[UBr_6] + Bu_4NBr + 7\,AgN_3 \rightarrow (Bu_4N)_3[U(N_3)_7] + 7\,AgBr \quad (2)$$

After separation of the green solution from the insoluble solid, the solvent was removed under vacuum at room temperature to yield a sticky green solid **1b**, which was characterized by using IR spectroscopy and after recrystallization from CH_3CH_2CN, by using single-crystal X-ray diffraction (Figure 2). The single-crystal structure of the $U(N_3)_7^{3-}$ ion in **1b**, which was recrystallized from a saturated CH_3CH_2CN solution as the $(Bu_4N)_3[U(N_3)_7]$ salt, clearly shows a distorted pentagonal-bipyramid 1:5:1 arrangement of seven azide ligands around the central uranium(IV) atom. The U–N_α bond lengths of 2.323(6)–2.431(7) Å are significantly shorter than the U–N bond lengths observed in the related $U(NCS)_8^{4-}$ ion in $Cs_4[U(NCS)_8]$ (d(U–N) = 2.441(7)–2.446(5) Å),[14b] and are in reasonable agreement with those observed in $(Et_4N)_4[U(NCS)_8]$ (d(U–N) = 2.379 Å).[14a] Interestingly, the U–N bond lengths in the $U(N_3)_7^{3-}$ ion vary considerably (as was also observed for the Te–N bond lengths in the $Te(N_3)_6^{2-}$ ion),[11o] and can be separated into the five longer equatorial U–N distances (d(U–N) = 2.374(8)–2.431(7) Å) and two shorter axial U–N bond lengths (d(U–N) = 2.329(6) and 2.323(6) Å). The shorter axial U–N bond lengths are in good agreement with the VSEPR model, according to which the axial positions in a pentagonal bipyramid are sterically less crowded than the equatorial positions. The N_α–N_β bond lengths in the $U(N_3)_7^{3-}$ ion ($d(N_\alpha$–$N_\beta)$ = 1.162(8)–1.246(9) Å) are all longer than the corresponding N_β–N_γ bond lengths, as is to be expected ($d(N_\beta$–$N_\gamma)$ = 1.055(8)–1.150(7) Å), in nice agreement with the structures of various binary azide anions, such as $Ti(N_3)_6^{2-}$.[11t] The N_α-N_β-N_γ angles of the five equatorial azide groups (164(1)–168.1(8)°) deviate from linearity considerably more than the two axial N_α-N_β-N_γ angles, which are essentially linear (179.5(7) and 178.9(9)°).

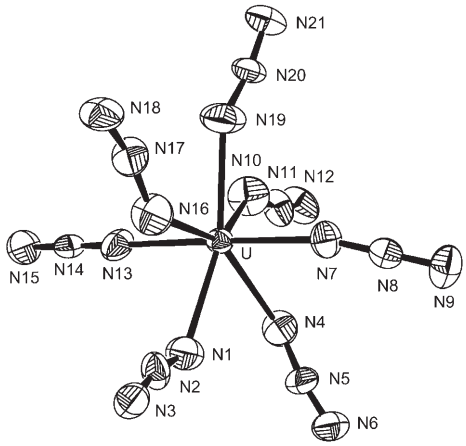

Figure 2. Molecular structure of the $U(N_3)_7^{3-}$ ion in **1b** as determined by single-crystal X-ray diffraction on crystals obtained from CH_3CH_2CN (thermal ellipsoids at the 25% probability level). Selected bond lengths [Å] and angles [°]: U–N1 2.431(7), U–N4 2.429(7), U–N7 2.329(6), U–N10 2.391(8), U–N13 2.323(6), U–N16 2.385(7), U–N19 2.374(8), N1–N2 1.223(8), N2–N3 1.081(7), N4–N5 1.239(9), N5–N6 1.085(8), N7–N8 1.172(7), N8–N9 1.150(7), N10–N11 1.174(9), N11–N12 1.055(8), N13–N14 1.162(8), N14–N15 1.133(8), N16–N17 1.246(9), N17–N18 1.093(8), N19–N20 1.20(1), N20–N21 1.093(7); U-N1-N2 130.5(5), N1-N2-N3 166.2(8), U-N4-N5 121.5(5), N4-N5-N6 168.1(8), U-N7-N8 162.0(5), N7-N8-N9 179.5(7), U-N10-N11 141.9(7), N10-N11-N12 164(1), U-N13-N14 178.6(7), N13-N14-N15 178.9(9) U-N16-N17 135.8(6), N16-N17-N18 165.0(9), U-N19-N20 140.2(8), N19-N20-N21 165.4(9), N4-U-N19 139.1(3), N7-U-N10 104.2(3), N7-U-N13 176.5(2), N7-U-N16 90.6(2), N4-U-N10 74.1(3), N10-U-N19 73.1(3), N16-U-N19 74.0(3), N1-U-N16 72.5(3), N1-U-N4 72.4(2).

The N_α-U-N_α angles between the N_α atoms of neighboring azide groups all lie between 72.4(2) and 74.1(3)°. Whereas the U-N_α-N_β angles are distinctly bent for six out of the seven ligands ($\sphericalangle$(U-N_α-N_β) = 121.5(5)–162.0(5)°), one of the axial azide ligands is bound to the uranium atom in an essentially linear array with a U-N_α-N_β angle of 178.6(7)°. The nitrogen atom N10 deviates the most (−0.457(9) Å) from the equatorial plane, which is defined by the atoms N1, N4, N10, N16, and N19. In addition, the axial U–N7 and U–N13 bonds are oriented 86.8(2)° and 88.4(3)°, respectively, to the equatorial plane. Interestingly, the packing diagram of **1b** indicates that the $U(N_3)_7^{3-}$ ions are surrounded on all sides by tetrabutyl-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ammonium cations. In addition, the shortest anion–anion contact, between N6 and N15^{i} (with $i = x, \frac{1}{2}-y, \frac{1}{2}+z$), was found to be very long (5.34(1) Å; Figure 3).

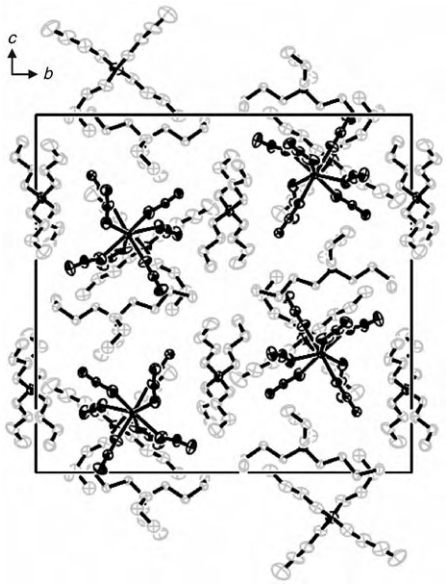

Figure 3. A view of the unit cell of **1b** along the *a* axis (crystals grown from CH_3CH_2CN solution). Thermal ellipsoids are drawn at the 25% probability level; hydrogen atoms are omitted for clarity.

We have not established the friction or impact sensitivity of solid $(Bu_4N)_3[U(N_3)_7]$, because of its extreme air sensitivity. Exposing the reaction mixture to air for a few minutes resulted in a rapid color change of the clear solution from green to yellow (which is indicative for the formation of a uranyl (uranium(VI)) species), and finally brown. Interestingly, for uranium(VI), the $[UO_2(NCS)_5]^{3-}$ ion possesses five SCN^- ligands in the equatorial plane,[15] whereas salts of the related uranium(VI) azide anions, $[UO_2(N_3)_4]^{2-}$ show only four azide ligands in the plane perpendicular to the uranyl axis.[7,8] For the homoleptic uranium(IV) anions, the eight-coordinate $U(NCS)_8^{4-}$ anion is formed,[14] whereas with azide ligands, the seven-coordinate $U(N_3)_7^{3-}$ ion was formed. Interestingly, the synthesis and characterization by IR spectroscopy of the uranium(VI) azide $[UCl_4(N_3)_2]$ has been reported,[16] however, the reaction of UF_6 with CsN_3 led to $CsUF_6$ and N_2.[17] However, the uranium(VI) hexakisamido complex $[U(dbabh)_6]$ (Hdbabh = 2,3:5,6-dibenzo-7-azabicyclo-[2.2.1]hepta-2,5-diene) has recently been described, in which the central uranium(VI) atom is coordinated by six amide nitrogen atoms.[18]

Although the $U(N_3)_7^{3-}$ ion is the first structurally characterized covalent heptaazide, the first covalent heptaazides to be synthesized and isolated were salts containing the highly shock-sensitive $Mo(N_3)_7^-$ and $W(N_3)_7^-$ anions reported by Christe et al., in which the central metal atom is in the +VI oxidation state.[19] In contrast to $Ph_4P[Mo(N_3)_7]$ and Ph_4P-$[W(N_3)_7]$, which were characterized by using low-temperature Raman spectroscopy and exploded violently when being warmed to room temperature, the $(Bu_4N)_3[U(N_3)_7]$ compound was found to be stable both in CH_3CH_2CN solution and in the solid state at room temperature for some time. In the previous report of the $Mo(N_3)_7^-$ and $W(N_3)_7^-$ ions, computational investigations on the $W(N_3)_7^-$ ion located two stable minima, namely the 1:5:1 and 1:4:2 structures, the former of which was calculated to be more favorable in energy by 3.3 kcal mol^{-1}.[19] This is in very good agreement with our experimental observations for the $U(N_3)_7^{3-}$ ion in compound **1b**, for which the 1:5:1 structure was observed. It should be noted however, that the calculated energy difference between the pentagonal bipyramid and monocapped trigonal prism for $W(N_3)_7^-$ was found to be very small.[19]

The synthesis and structural characterization of the homoleptic $U(N_3)_7^{3-}$ ion now raises the question whether further uranium azides can be synthesized, isolated, and structurally characterized, in which the central uranium atom is in an oxidation state other than +IV. In addition, an interesting investigation would be the synthesis and characterization of the neutral homoleptic azides $U(N_3)_4$ and $U(N_3)_6$, or related species such as $[U(N_3)_4L_x]$ (L = neutral coordinating ligand).

Experimental Section

$(Bu_4N)_2[UBr_6]$, $(Bu_4N)_2[UCl_6]$, and AgN_3 were prepared according to literature procedures.[13,20] Bu_4NBr (Fluka) was used as received. CH_3CN and CH_3CH_2CN were dried over P_4O_{10} and distilled twice immediately prior to use. The IR spectrum of the reaction product was recorded between KBr plates. The samples for IR spectroscopy were prepared in a glove-box under a nitrogen atmosphere and were recorded by using a Perkin Elmer FT-IR Spectrum One spectrometer. Standard procedures for working under inert gas atmospheres were used.

Caution! All covalent azides should be handled with extreme caution, because they can detonate unexpectedly due to friction or shock. Under no circumstances should AgN_3 or $(Bu_4N)_3[U(N_3)_7]$ be handled on larger scales, and the work should only be undertaken by experienced experimental chemists with the appropriate safety precautions (Kevlar gloves, leather jacket, face shield, earthing stripes, ear protectors, Teflon spatulas). Even using the above-mentioned precautions, violent explosions may occur, and disregarding the necessary stringent safety precautions can result in serious injury, even if reactions are carried out on a small scale.

1b: $(Bu_4N)_2[UBr_6]$ (0.601 g, 0.5 mmol), Bu_4NBr (0.322 g, 1.0 mmol), and AgN_3 (0.60 g, 4.0 mmol) were added to a 25-mL Schlenk flask under a nitrogen purge. On addition of rigorously dried CH_3CH_2CN (10 mL), a clear emerald green solution formed. The reaction vessel was covered in aluminum foil and the mixture was left to stir at room temperature for 5 h, after which time the insoluble side products were allowed to settle and separated from the green solution. The volume of the filtrate was reduced under vacuum and the vessel was then cooled, whereby emerald green crystals formed in moderate yield. The crystals were found to be stable for several hours when the vessel was maintained under an argon atmosphere in the dark at 4°C, but were extremely air-sensitive. IR (KBr plates, resolution 4 cm^{-1}): $\tilde{\nu}$ 3378 (w), 2961 (m), 2934 (m), 2874 (m), 2112 (m), 2055 (s), 2013 (m), 1983 (w), 1555 (w, br), 1471 (m. br), 1344 (m), 1333 (w), 1281 (w), 1262 (w), 1155 (m), 1066 (w), 1026 (w), 898 (w), 880 (w), 795 (w), 732 (w), 611 cm^{-1} (w).

Crystal data for $(Bu_4N)_3[U(N_3)_7]$ recrystallized from CH_3CH_2CN (**1b**): $C_{48}H_{108}N_{24}U$, $M_r = 1259.56$, yellow-green block, $0.20 \times 0.31 \times 0.42$ mm^3, monoclinic, space group $P2_1/c$, $a = 11.9064(1)$, $b = 24.1556(2)$, $c = 23.5762(2)$ Å, $\beta = 101.7397(6)°$, $V = 6638.8(1)$ Å^3, $Z = 4$, $\rho_{calcd} = 1.260$ g cm^{-3}, $\mu = 2.494$ mm^{-1}, $F(000) = 2624$, Nonius Kappa

CCD diffractometer, $Mo_{K\alpha}$ radiation, $\lambda = 0.71073$ Å, $T = 200$ K, $\theta = 4.0$–$27.5°$, $-15 \le h \le 15$, $-30 \le k \le 31$, $-30 \le l \le 28$, reflections collected: 75322, independent reflections: 15150 ($R_{int} = 0.058$), observed reflections: 10479, structure solution: Sir 97,[21] direct methods, $R1[I > 2\sigma(I)] = 0.0535$, Final w$R2$ (all data) = 0.1342, Goof = 1.048.

1a: An alternative procedure using $(Bu_4N)_2[UCl_6]$ instead of $(Bu_4N)_2[UBr_6]$ and acetonitrile instead of CH_3CH_2CN was also employed. After the volume of CH_3CN had been reduced in the reaction vessel under vacuum to form a saturated solution, $CFCl_3$ (20 mL) was added under an argon purge, and the vessel was then cooled to −28 °C, whereby emerald green crystals formed in low yield. The crystals were found to be stable for several weeks when the vessel was maintained under an argon atmosphere in the dark at 4 °C, but were extremely air-sensitive.

Crystal data for $(Bu_4N)_3[U(N_3)_7]$ recrystallized from $CH_3CN/CFCl_3$ (**1a**): $C_{48}H_{108}N_{24}U_1$, $M_r = 1259.56$, green block, $0.22 \times 0.24 \times 0.26$ mm^3, cubic, space group $Pa\bar{3}$, $a = 23.8368(3)$ Å, $V = 13543.9(3)$ Å^3, $Z = 8$, $T = 200$ K, $\rho_{calcd} = 1.235$ g cm^{-3}, $\mu = 2.445$ mm^{-1}, $F(000) = 5248$, Nonius Kappa CCD, $Mo_{K\alpha}$ radiation, $\lambda = 0.71073$ Å, $T = 200$ K, $\theta = 3.2$–$21.0°$, $-23 \le h \le 24$, $-24 \le k \le 24$, $-23 \le l \le 22$, reflections collected: 61063, independent reflections: 2409 ($R_{int} = 0.079$), observed reflections: 1599 [$I > 2\sigma(I)$], structure solution: Sir 97,[21] direct methods, final R indices: $R1[I > 2\sigma(I)]$: = 0.0718, final w$R2$ (all data) = 0.2142, Goof = 1.054.

CCDC-278412 and CCDC-278413 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

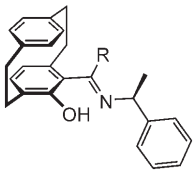
Asymmetric Conjugate Addition of Organozinc Compounds to α,β-Unsaturated Aldehydes and Ketones with [2.2]Paracyclophaneketimine Ligands without Added Copper Salts**

Stefan Bräse and Sebastian Höfener*

Dedicated to Professor Henri B. Kagan on the occasion of his 75th birthday

Asymmetric catalysis has established itself as a versatile method in modern synthetic chemistry. In particular, many transformations with almost complete enantioselectivity are possible today through the use of chiral ligands. One example is the conjugate addition of organometallic reagents to α,β-unsaturated carbonyl compounds, especially to ketones.[1] In the presence of copper additives different ligand systems give almost complete stereocontrol. The copper ions influence the electronic properties of the carbonyl group, they determine which alkyl or aryl residues are transferred, and they act as bridging units in the transition state.[2,3] As an extension of the non-enantioselective copper-free 1,4-addition to α,β-unsaturated aldehydes described previously by Knochel et al.,[4] we present here for the first time a highly enantioselective copper-free variant.



(R_p,*S*)-**1a**: R = Me
(R_p,*S*)-**1b**: R = Ph

Over the last few years we have been able to demonstrate that readily accessible, configurationally stable, planar and centrochiral ketimines **1** with a [2.2]paracyclophane framework[5] are highly suitable for the asymmetric addition of alkyl[6] and alkenyl residues[7] to aliphatic aldehydes. In addition, these ligands have proved to be useful in the addition of alkyl[8] and aryl residues[9] to *N*-acylimines.

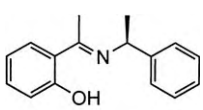
Since the addition to *N*-acylimines is comparable to a conjugate addition, we postulated that α,β-unsaturated aldehydes and ketones could also be suitable as substrates. Therefore different α,β-unsaturated aldehydes were tested under standard reaction conditions (2 mol% ligand **1**, 4 equiv $ZnEt_2$ or 2 equiv diisopropylzinc, −20 °C) (Table 1, entries 1–7). Unlike all previously described ligands,[10] the ketimines **1** also transformed α,β-unsaturated aldehydes **2** into the respective 1,4-addition products **3** in a highly enantioselective manner. This even takes place with a relatively small amount of catalyst, 2 mol%, without the addition[11] of compounds having a soft metal center (copper, nickel, or indium[12]). The 1,2-addition products **4** were also formed in most cases, but with only moderate enantioselectivity. The reason is that with α,β-unsaturated aldehydes, unlike, for example, benzaldehyde,[13] the uncatalyzed reaction also takes place. Other ligands (dimethylaminoethanol, 3-*exo*-(dimethylamino)isoborneol (DAIB)) gave, as described in the literature,[10] only 1,2-addition products **4**.

The ratio between 1,2- and 1,4-addition was temperature dependent: low temperatures increased the proportion of the more thermodynamically favorable 1,4 products. However, the reaction rate dropped to such an extent that a compromise between acceptable reaction rate and selectivity had to be found.

In the addition of diethylzinc to cinnamaldehyde (**2a**, entries 1–3 in Table 1) or its derivatives *o*-methoxycinnamaldehyde (**2b**, entry 5) and *p*-chlorocinnamaldehyde (**2c**, entry 6) and also 3-thiophen-3-yl-propenal (**2d**, entry 7) the yield of the 1,4 product was as high as 52% with enantiomeric excesses of between 96 and 98% *ee*. Better regioselectivity was obtained with 6-methoxy-2,2-dimethyl-2*H*-chromene-3-carbaldehyde (**2e**) after 62 h at 0 °C. Here both (S_p,*S*)-**1a** (Table 1, entry 9) and (R_p,*S*)-**1a** (entry 8) gave the 1,4 product in 78–80% yield and 97 and 96% *ee*, respectively. In both cases the *syn* diastereomers were formed preferentially (74% *de* with (S_p,*S*)-**1a**, 77% *de* with (R_p,*S*)-**1a**), which was confirmed by NOE experiments. The addition of diisopropylzinc to cinnamaldehyde (**2a**) was also successful; the 1,4 product was formed with a yield of 39% at 91% *ee* (entry 4).

Whereas in the 1,4-addition to aldehydes temperatures of −20 °C (or 0 °C) are of advantage for selectivity reasons, 1,4-additions to ketones such as benzylideneacetone (**2f**) and 3-octen-2-one (**2g**) can be carried out at room temperature (Table 1, entries 10–12). The 1,2-addition products were never formed as by-products, only the corresponding aldol addition products. However, in the case of benzylideneacetone their fraction could be reduced from 15 to 5% by increasing the amount of ligand from 2 to 4 mol% (Table 1, entries 10 and 11). The enantioselectivities varied between 73 and 90% *ee* for the ketones. Ketones were also successfully reacted with diisopropylzinc (see the Supporting Information).

The diastereomeric ketimine ligands (S_p,*S*)-**1a** and (R_p,*S*)-**1a** led in each case to the complementary main enantiomers of the 1,4- and 1,2-addition products. This pivotal influence of the planar chirality on product configuration confirms previous investigations on 1,2-additions to saturated aldehydes, which also indicated the strongly dominating effect of the planar chirality as opposed to the centrochirality of the ligands.[14]



(*S*)-**5**

The nonplanar analogue **5** of the paracyclophaneketimine ligand **1** also catalyzed conjugate addition, albeit

[a] See Experimental Section for details. [b] Determination by GC on an achiral stationary phase (HP1). [c] Determination by GC on a chiral stationary phase (CP-Chirasil-Dex for entries 1–8 and 11; Lipodex E for entries 9 and 10). [d] n.d. = not determined. [e] n.s. = no separation of enantiomers on chiral stationary phase. [f] The condensation product of the 1,2 product was also identified by GC-MS. [g] The aldol products were formed as by-products. [h] Amount of catalyst used: 4 mol%.

with a poorer ratio of 1,2- to 1,4-addition products and lower enantioselectivities. The reaction of cinnamaldehyde (**2a**) at −20 °C gave the 1,2 and 1,4 products in a ratio 2.3:1 (with 17% *ee* for the 1,4 product and 4% *ee* for the 1,2 product).

Here the first copper-free[11] asymmetric 1,4-addition of diethylzinc or diisopropylzinc to α,β-unsaturated aldehydes and ketones has been described. This methodology supplements the spectrum of synthetic methods for β-chiral aldehydes and ketones.[15] The application to the synthesis of biologically active compounds and the extension of the substrate spectrum represents further objectives of our investigations.

Experimental section

Variant A: The ligand (0.01 mmol) and the aldehyde (0.5 mmol) were placed in a 10-mL flask. The reaction vessel was purged with argon and cooled to −20 °C before a solution of diethylzinc (1M in toluene or hexane; 1 mL, 1 mmol) was added. The reaction mixture was stirred for 24 h at this temperature before more diethylzinc solution (1 mL) was added. The reaction mixture was then stirred at −20 °C for 38 h, warmed to room temperature, and stirred for a further 24 h. The reaction was quenched by the addition of semisaturated ammonium chloride solution (3 mL). The reaction mixture was treated with diethyl ether, filtered, and separated in a separating funnel. The organic phase was washed three times with deionized water and dried over magnesium sulfate. GC chromatograms were recorded for these solutions. The solution was then concentrated under reduced pressure, and the regioisomers were separated by column chromatography on silica 60 (eluent: cyclohexane/ethyl acetate).

Variant B: The same as variant A but the twice the quantities were used.

Variant C: The same as variant A, but the reaction was carried out at 0 °C (62 h) and not warmed to room temperature.

Variant D: The ligand (S_p,*S*)-**1a** (0.01 mmol) and cinnamaldehyde (0.5 mmol) were mixed. The reaction vessel was purged with argon and cooled to −20 °C before a solution of diisopropylzinc (1M in toluene; 1 mL, 1 mmol) was added. The reaction mixture was then stirred for 62 h at −20 °C before the reaction was quenched by the addition of semisaturated ammonium chloride solution (3 mL) and worked up as in variant A.

Variant E: (S_p,*S*)-**1a** (0.01 mmol) and the ketone (0.5 mmol) were placed in a 10-mL flask. The reaction vessel was purged with argon before diethylzinc or diisopropylzinc solution was added (1M in hexane or toluene; 1 mL, 1 mmol). After 62 h stirring at room temperature the reaction was quenched by the addition of semisaturated ammonium chloride solution (3 mL) and worked up as in variant A.

[11] According to ICPMS measurements the copper content of the commercial diethylzinc solutions used is (50 ± 5) μM or less. This gives a ligand/copper ratio of at least 100:1 and a zinc/copper ratio of at least 20000:1. We assume that these copper ions do not play any role in the catalyst cycle since other catalysts show no cuprate-like behavior. We thank Dr. Zsolt Berner, Institut für Mineralogie und Geochemie der Universität Karlsruhe (TH), for carrying out these measurements.

C–C Bond Activation by Octacarbonyldicobalt: [3+1] Cocyclizations of Methylenecyclopropanes with Carbon Monoxide**

*Takuya Kurahashi and Armin de Meijere**

The activation of carbon–carbon σ bonds under the influence of transition metals remains a fundamental challenge in organometallic chemistry.[1] Methylenecyclopropane and its derivatives were among the first substrates for which involvement of C–C single bonds in transition-metal-catalyzed cycloaddition reactions was observed.[2] In particular, the cycloadditions of methylenecyclopropanes as a C_3 component across C–C multiple bonds have been thoroughly investigated.[3] Surprisingly, only a limited number of transition metals such as Ni, Pd, and Pt have been explored. In recent years, cobalt complexes have been demonstrated to facilitate new types of C–H and C–C bond activation.[4,5] Alper et al. as well as other groups have shown that cobalt-catalyzed carbonylative ring expansions of epoxides and aziridines are useful and efficient procedures for the synthesis of β-lactones and β-lactams, respectively.[6]

In connection with our recently reported cobalt-catalyzed [5+1] cocyclization of vinylcyclopropanes with carbon monoxide leading to cyclohexenones, we found carbonylcobalt complexes to show the highest activity among the transition-metal complexes examined.[7] In view of the observed unique reactivity of the octacarbonyldicobalt complex, we have set out to further explore carbonylative ring-expansion reactions, and here we report a novel [3+1] cocyclization of methylenecyclopropanes with carbon monoxide under cobalt catalysis.

Initially, heptylidenecyclopropane (**1a**) was treated with one equivalent of octacarbonyldicobalt in THF at 50 °C for 12 h, and this led to a mixture of (2*E*)- and (2*Z*)-2-heptylidenecyclobutanone (**2a**) in 85 % yield (Table 1).[8] In other solvents such as toluene, dichloroethane, hexane, and acetonitrile the yields were lower. Among the carbonylmetal complexes examined, octacarbonyldicobalt gave the best

yield of this product. With $[Cr(CO)_6]$, $[Mo(CO)_6]$, $[W(CO)_6]$, and $[Fe(CO)_5]$ the yields were very low (5, 8, < 1, and < 1%, respectively). The reactivity of methylenecyclopropanes with an electron-withdrawing group in the 1′ position was lower, and the reaction of $[Co_2(CO)_8]$ with (phenylmethylene)cyclopropane (**1b**) at 50°C gave only a trace amount of the corresponding benzylidenecyclobutanone **2b**. However, at elevated temperature (100°C) **1b** furnished the product **2b** in 80% yield with a diastereomeric excess of 96%. More electron-deficient methylenecyclopropanes such as (bromomethylene)cyclopropane and *tert*-butyl methylenecyclopropane-1′-carboxylate did not react with $[Co_2(CO)_8]$ even at 100°C. Sterically encumbered 1′,1′-disubstituted methylenecyclopropanes such as **1c** and **1d** reacted sluggishly to give **2c** and **2d** in 5 and 27% yield, respectively. With the alkenyl-substituted methylenecyclopropane **1e**, $[Co_2(CO)_8]$ reacted at the methylenecyclopropane moiety selectively to give the corresponding cyclobutanone **2e** in moderate yield. Unsubstituted methylenecyclopropane and bicyclopropylidene also reacted with $[Co_2(CO)_8]$ even at 25°C, yet no low-molecular-weight products could be isolated.

Methylenecyclopropanes **3** with substituents at the 2- and 3-positions were also tested (Table 2). Indeed, 2-hexyl- (**3f**) and 2-phenylmethylenecyclopropane (**3g**) reacted with $[Co_2(CO)_8]$ to give the corresponding 3- and 4-substituted 2-methylenecyclobutanones **4f/5f** and **4g/5g** in 84 and 71% yield, respectively. In both cases, the regioisomer of type **4** predominated by a factor of about four. 2-Methyl-2-phenyl- (**3h**) and (2,2,3,3-tetramethyl)methylenecyclopropane (**3i**) also readily reacted to furnish the di- and tetrasubstituted 2-methylenecyclobutanones in good yields. The reaction tolerates ester functionalities and other C–C double bonds as exemplified by the successful transformations of **3j** and **3k** to **4j/5j** and **4k/5k**, respectively. Even the unprotected 4-(hydroxymethyl)methylenespiropentane (**3l**) reacted with $[Co_2(CO)_8]$ to give the regioisomeric methylenespiro[2.3]hexanones **4l** and **5l** in a ratio of 86:14 in 66% yield (Scheme 1).

These transformations of methylenecyclopropanes to 2-methylenecyclobutanones, which are essentially insertions of carbon monoxide into the proximal C–C single bonds of the methylenecyclopropanes **1** and **3**, also proceed in the presence of only 5 mol% of $[Co_2(CO)_8]$ [9] under an atmosphere of

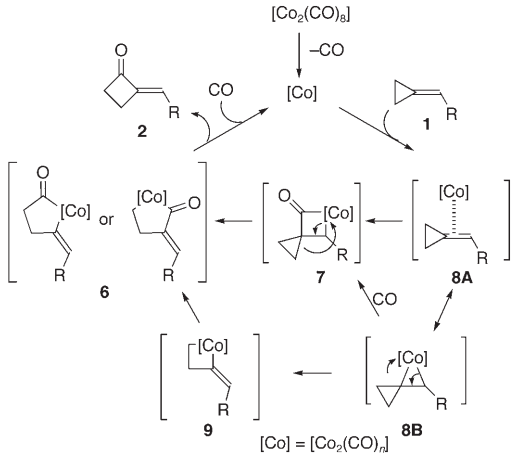
carbon monoxide (provided by a balloon). For example, **1a** thus reacted at 60 °C to furnish **2a** in 88 % yield.[8] 1′-Phenylmethylenecyclopropane (**1b**) did not yield the cyclobutanone **2b** at 60 °C under these conditions. Even at elevated temperature (100 °C in dioxane) only a trace amount of the product **2b** was identified. The 1′,1′-disubstituted methylenecyclopropane **1d** reacted sluggishly to give **2d** in 15 % yield. But 2-substituted and 2,3-oligosubstituted methylenecyclopropanes such as **3f** and **3g** did give the corresponding products **4f**/**5f** and **4g**/**5g**, respectively, in good yields. Even the tetrasubstituted methylenecyclopropane **3i** readily provided the product **4i** in 75 % yield.

Mechanistically, this formation of cyclobutanones **2** from methylenecyclopropane **1** is initiated by exchange of one or two CO ligands of the $[Co_2(CO)_8]$ complex with a methylenecyclopropane ligand. The resulting alkene complex, resembling a cobaltaspiropentane **8B**,[10] can either undergo migratory CO insertion to give the cobaltaspiro[2.3]hexanone **7** or a (cyclopropylmethyl)metal-to-homoallylmetal rearrangement[11] to yield an alkylidenecobaltacyclobutane **9**. Subsequent (cyclopropylmethyl)metal-to-homoallylmetal rearrangement[10] of **7** or migratory CO insertion in **9** leads to an alkylidenecobaltacyclopentanone **6**, which undergoes reductive elimination to give the alkylidenecyclobutanone **2** (Scheme 2).



Scheme 2. Mechanistic rationalization of the cobalt-catalyzed [3+1] cocyclization of methylenecyclopropanes with carbon monoxide.

In conclusion, a new cobalt-mediated and -catalyzed [3+1] carbonylative cocyclization of methylenecyclopropanes to give 2-alkylidenecyclobutanones under mild conditions has been developed. Thus, for the first time cobalt has been demonstrated to be an efficient transition metal for the activation of strained carbon–carbon σ bonds.[12] In comparison with rhodium, ruthenium, and nickel complexes, which are usually used for the activation of carbon–carbon bonds, octacarbonyldicobalt is significantly less expensive.

[8] Representative procedure: In an oven-dried Schlenk flask (250 °C) were placed $[Co_2(CO)_8]$ (17 mg, 0.05 mmol) and freshly distilled anhydrous THF (10 mL) under an argon atmosphere. To the resulting dark red solution was added **1a** (138 mg, 1 mmol), and the mixture was stirred at 60 °C under an atmosphere of CO provided by a balloon attached to the flask. The progress of the reaction was monitored by TLC. Upon completion, the initially dark green solution turned pale brown. The cooled reaction mixture was diluted with diethyl ether (20 mL) and stirred under air for 1 h. Filtration through a pad of Celite and purification by Kugelrohr distillation gave **2a** (146 mg, 0.88 mmol, 88 %) as a pale yellow oil. $R_f = 0.29$ (hexane/diethyl ether 10:1). ^{1}H NMR ($CDCl_3$, 500 MHz): $\delta =$ 6.26 (tt, $J = 7.6$, 2.8 Hz, 1H; CH), 2.91 (t, $J = 8.2$ Hz, 2H; CH_2CO), 2.58 (m, 2H; CH_2), 2.07 (m, 2H; CH_2), 1.47–1.39 (m, 2H; CH_2), 1.35–1.25 (m, 6H; 3 CH_2), 0.88 ppm (t, $J = 6.9$ Hz, 3H; CH_3); ^{13}C NMR ($CDCl_3$, 125 MHz): $\delta = 199.4$ (CO), 147.8 (C), 131.1 (CH), 43.3 (CH_2CO), 31.6 (CH_2), 29.0 (CH_2), 28.8 (CH_2), 28.2 (CH_2), 22.5 (CH_2), 20.2 (CH_2), 14.0 ppm (CH_3). IR (neat): $\tilde{\nu} = 2929$, 2857, 1757, 1670, 1457, 1394, 1222, 1098, 1006, 893, 727, 668 cm^{-1}; MS (EI): m/z: 166 ($[M]^+$, 2), 151 ($[M-Me]^+$, 1), 109 ($[M-Bu]^+$, 48), 81 (52), 68 (58), 55 (39), 43 (76), 41 (100); elemental analysis calcd (%) for $C_{11}H_{18}O$: C 79.46, H 10.91; found: C 79.16, H 10.68. Spectroscopic data of the minor diastereomer ($R_f = 0.41$): ^{1}H NMR ($CDCl_3$, 500 MHz): $\delta = 5.58$

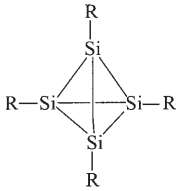
$Si_8(SitBu_3)_6$: A Hitherto Unknown Cluster Structure in Silicon Chemistry**

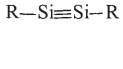
*Gerd Fischer, Volker Huch, Peter Mayer, Sham Kumar Vasisht, Michael Veith, and Nils Wiberg**

Dedicted to Professor Peter Paetzold on the occasion of his 70th birthday

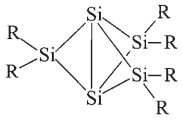
In a 1991 Review article on the then recent chemistry of cluster compounds of heavy elements of the fourth main group (Si, Ge, Sn, Pb) Masamune and co-workers[1] considered the synthesis of a tetrasilatetrahedrane, a disilyne, and a 1,1,1-pentasilapropellane (that is, a compound of strained anellated Si_3 rings, a compound with a Si–Si triple bond, and a compound with "inverse tetrahedral" Si atoms) as the greatest challenges of silicon chemistry.



tetrasilatetrahedrane



disilyne



1,1,1-pentasilapropellane

In 1993 we isolated the first tetrasilatetrahedrane with the orange-colored $Si_4R^*_4$ ($R^* = SitBu_3$; "supersilyl")[2] and in 2002 the first disilyne, which is metastable at room temperature, with the yellow $R^*_2MeSi\text{-}Si{\equiv}Si\text{-}SiMeR^*_2$. The latter compound was confirmed by mass spectrometry and NMR spectroscopy as well as chemically and by ab initio studies.[3] In the meanwhile Sekiguchi and co-workers synthesized in a similar way a second tetrasilatetrahedrane (Si_4R_4; $R = [(Me_3Si)_2CH]_2MeSi$) and a second disilyne (Si_2R_2; $R = [(Me_3Si)_2CH]_2iPrSi$), whose structure was elucidated experimentally by X-ray crystallographic analysis.[4] Herein we report the synthesis of a silicon cluster $Si_8R^*_6$ with "inverse

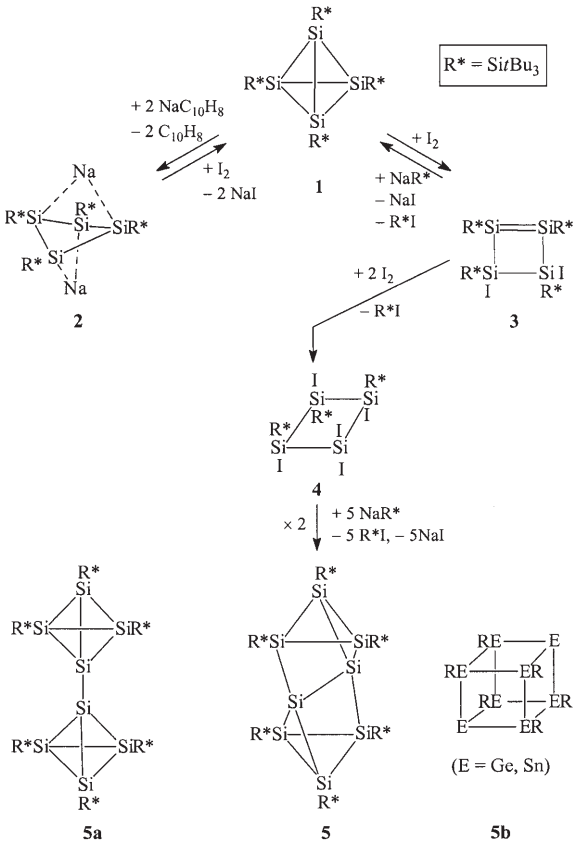
tetrahedral" Si atoms and thereby present a member of the third compound class mentioned at the outset.[5]

The high thermal stability of tetrasupersilyl tetrahedrotetrasilane $Si_4R^*_4$ (**1**)[2] led us to postulate the existence of a ditetrahedranyl $RR^*_3Si_4{-}Si_4R^*_3$ (**5a**), which should be accessible by metathesis from $MSi_4R^*_3$ and $R^*_3Si_4X$ (M = alkali metal, X = halogen). We found that the action of sodium



naphthalide ($NaC_{10}H_8$) on **1** in THF at −78 °C did not lead to the elimination of NaR* to the desired substitution product $NaSi_4R^*_3$. Furthermore, the reaction of **1** with iodine in benzene at 6 °C did not proceed with elimination of R*I to form $R^*_3Si_4I$. Instead, the reactions gave the addition products **2** (structure deduced from products of subsequent reactions with MeOH and Me_2SO_4) and **3**, respectively (structure elucidated by X-ray crystallographic analyis).[6] The compounds **2** and **3** readily revert back to **1** by reaction with I_2 and NaR*, respectively. Treatment of the cyclotetrasilene **3** with excess iodine in benzene at room temperature leads to the loss of R*I[7] to afford the pale yellow cyclotetrasilane *trans,trans*-$R^*_3Si_4I_5$ (**4**; Figure 1[8]), which in turn is iodinated to the cyclotetrasilane *trans*-$R^*_2Si_4I_6$ in boiling benzene.[9]

The complete deiodination of pentaiodide **4** with NaR* in THF resulted in a violet product with the sought-after composition $Si_8R^*_6$ (confirmed by mass spectrometry). However, X-ray crystal-structure analysis revealed that this cluster does not correspond to structure **5a**, but instead to **5** (Figure 2[10]). This structure exhibits the following features:

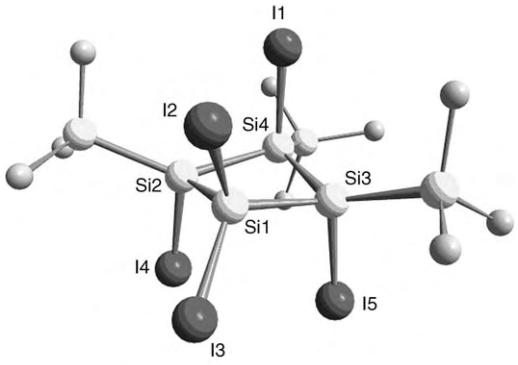


Figure 1. Molecular structure of **4** and selected bond lengths [Å] and angles [°] (methyl groups have been omitted for clarity): Si1-Si2 2.384(11), Si1-Si3 2.384(10), Si2-Si4 2.507(11), Si3-Si4 2.511(12), Si1-I2 2.466(9), Si1-I3 2.466(9), Si2-I4 2.487(9), Si3-I5 2.506(9), Si4-I1 2.485(9); Si2-Si1-Si3 97.2(4), Si1-Si2-Si4 84.2(4), Si1-Si3-Si4 84.1(3), Si2-Si4-Si3 90.9(4); Si1-Si2-Si4-Si3/Si2-Si4-Si3-Si1 14.0, Si4-Si3-Si1-Si2/Si3-Si1-Si2-Si4 14.9.

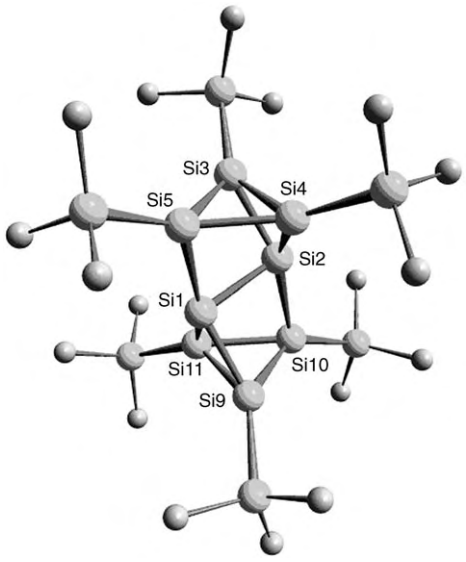

Figure 2. Ball-and-stick representation of the molecular structure of **5**. In the crystal Si1 and Si2 occupy three different positions A, B, and C, which can be approximately transformed into one another by rotation about a threefold noncrystallographic axis. The axis runs through the midpoint of the three-membered rings Si3,Si4,Si5 and Si9,Si10,Si11. Only position C is shown in the figure (methyl groups have been omitted for clarity). Selected bond lengths [Å]: Si3-Si4 2.40(1), Si4-Si5 2.40(1), Si3-Si5 2.39(1), Si9-Si10 2.39(1), Si10-Si11 2.41(1), Si9-Si11 2.40(1). Averaged bond lengths [Å] and angles [°]: Si1-Si2 2.29(1), Si1-Si(9, 11) and Si2-Si(3, 4) 2.33(2), Si1-Si5 und Si2-Si10 2.57(1); Si-Si-Si in the rings Si3,Si4,Si5 and Si9,Si10,Si11: 60.0(1), Si9-Si1-Si11 62.0(2), Si3-Si2-Si4 62.0(3), Si2-Si1-Si(9,11) 92.5(4), Si1-Si2-Si(3,4) 92.4(4), Si2-Si1-Si5 81.7(4), Si1-Si2-Si10 81.2(4), Si(9,11)-Si1-Si5 148.6(9), Si(3,4)-Si2-Si10 148.5(9).

1) **5** contains an unsubstituted Si_2 dumbbell with a short Si–Si single bond of only 2.29(1) Å (normally 2.34 Å). 2) The Si_2 dumbbell is embedded as in a sandwich compound between two almost parallel $Si_3R^*_3$ rings situated on a lattice vacancy where each Si atom of the dumbbell forms two Si–Si bonds of

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

normal length (2.33 Å) to one Si_3 ring and a long Si–Si bond (2.75 Å) to the other. 3) X-ray crystal-structure analysis showed that the atoms of the Si_2 dumbbell are distributed over six sites, which can be explained by a disorder of the molecules of **5** in the crystal. 4) The atoms of the Si_2 dumbbell are "inverse tetrahedrally" coordinated by four Si atoms.

Clearly the Si_2 dumbbell is not aligned vertically to the $Si_3R^*_3$ rings as in **5a,** although the atoms of the Si_2 dumbbell in such a structure would be arranged in the usual tetrahedral geometry of tetravalent Si atoms. It is noted in this context that the Ge and Sn atoms of the clusters Ge_8R_6[11] and Sn_8R_6,[12] homologues of $Si_8R^*_6$, are localized at the corners of a cube (in terms of the formulation of **5b**); however, the substituent-free Ge and Sn atoms are not "inverse tetrahedrally" coordinated as they bond only to three atoms (not four).

Theoretical studies[13] must now explain why the cluster $Si_8R^*_6$ adopts structure **5**, and not a bis(tetrahedranyl) structure **5a** or a hexahedranyl structure **5b** (E = Si), which would arise from **5** by stretching the Si–Si bond of the dumbbell. Steric effects do not play a role in this case, but clearly the Si–Si bond in the dumbbell is strong, as chlorination of **5** with CCl_4 does not give the dichloride of **5b** but the cyclotrisilane *cis*,*cis*-$R^*_3Si_3Cl_3$, and possibly Si_2Cl_6.[14]

Experimental section

4: A solution of iodine (0.660 g, 2.60 mmol) in benzene (20 mL) was added dropwise over 1 h, with ice cooling, to a suspension of **1** (0.740 g, 0.81 mmol) in benzene (50 mL) with the exclusion of light. The reaction mixture was allowed to warm to room temperature over about 12 h before the solvent and the excess iodine were removed under vacuum (oil pump). The pale yellow solid residue was washed five to six times with a little *n*-heptane to remove iodine residues and heptane-soluble by-products (e.g. tBu_3SiH), dried under vacuum, and then extracted for 5 h with benzene (25 mL) in a Soxhlet extractor. Pure **4** (0.846 g, 0.63 mmol, 77%) was obtained from the solution. ^{29}Si NMR (C_6D_6, 400 MHz, 23 °C): $\delta = 47.1$ (2 Si*t*Bu$_3$), 41.7 (Si*t*Bu$_3$), −39.0 ppm (3 SiIR*) (A signal for the SiI_2 group was expected in the upfield region, but could not be found owing to the poor solubility of the substance and the mostly low intensity of the ^{29}Si NMR signals for SiI_2 groups. The ^{29}Si NMR signals for two of the three SiIR* groups clearly appear at the same shift.); ^{1}H NMR (C_6D_6, 400 MHz, 23 °C): $\delta = 1.53$ (s; 2 Si*t*Bu$_3$), 1.47 ppm (s; Si*t*Bu$_3$); ^{13}C NMR (C_6D_6, 400 MHz, 23 °C): $\delta = 33.9$ (6 C*Me*$_3$), 33.4 (3 C*Me*$_3$), 27.8 (6 *C*Me$_3$), 26.7 ppm (3 *C*Me$_3$); MS (70 eV, DEI): *m*/*z* (%): 1344 (0.05) [M^+], 1287 (0.05) [$M-t$Bu]$^+$, 1145 (3) [M−R*]$^+$, 1018 (11) [$R^*_2Si_4I_4$]$^+$, 946 (100) [$R^*Si_4I_5$]$^+$, 889 (6) [$R^*Si_4I_5-t$Bu]$^+$, 819 (2) [$R^*Si_4I_4$]$^+$.

5: A solution of NaR* (1.25 mmol) in THF was added dropwise over 1 h to a vigorously stirred suspension of **4** (0.675 g, 0.50 mmol) in THF (50 mL) at −78 °C. The reaction mixture was allowed to warm to room temperature over about 12 h, a third of the solvent was removed under vacuum, and the residue was filtered. The orange-red filtrate contained, among other products, tBu_3SiI and the main component NaI. The violet residue was washed with *n*-heptane and dried under vacuum. Soxhlet extraction for one week with benzene (30 mL) gave pure **5** (0.272 g, 0.19 mmol, 77%); m.p. > 300 °C (lightening in color to yellow above ≈175 °C). ^{1}H NMR (D_8[toluene], 400 MHz, 60 °C): $\delta = 1.43$ ppm (br; Si*t*Bu$_3$) (Owing to the extremely low solubility of **5** in organic media the NMR spectra were recorded at 60 °C. Only one broad signal instead of the expected two appeared in the ^{1}H NMR spectrum; no ^{29}Si NMR signals were observed, even at 60 °C. Solid-state ^{29}Si NMR studies (MAS frequency 12 KHz, single pulse measurement) have thus far produced no meaningful results (signals at $\delta = 45.7$ and 32.0 ppm may possibly be assigned to Si atoms of 2 Si*t*Bu$_3$ and 1 Si*t*Bu$_3$, respectively.); MS (FAB$^+$, Xe, NBA): *m*/*z* (%): 1420.0 (4) [M^+], 1221.8 (21) [M−R*]$^+$, 1021.7 (9) [M−R*−R*H]$^+$, 821.4 (2) [$R^*_3Si_8$]$^+$, 737.7 (8) [$R^*_3Si_5$]$^+$, 709.7 (31) [$R^*_3Si_4$]$^+$, 681.7 (100) [$R^*_3Si_3$]$^+$.

reaction of **3** with iodine in boiling benzene gave *trans*-$R^*_2Si_4I_6$. ^{1}H NMR (C_6D_6, 400 MHz, 23 °C): $\delta = 1.39$ ppm (54 H; 2 Si*t*Bu$_3$); ^{29}Si NMR (C_6D_6, 400 MHz, 23 °C): $\delta = 37.5$ (2 Si*t*Bu$_3$), −58.0 ppm (2 SiIR*) (No signals were observed for SiI_2 groups.); ^{13}C NMR (C_6D_6, 400 MHz, 23 °C): $\delta = 26.7$ (6 *C*Me$_3$), 33.1 ppm (6 *Me*$_3$C); MS (70 eV, DEI): *m*/*z* (%): 1272 (0.4) [M^+], 1214 (4) [$M-t$Bu]$^+$, 1145 (0.4) [$M-$I]$^+$, 1173 (0.7) [$M-$R*]$^+$, 1018 (2) [$R^*_2Si_4I_4$]$^+$, 946 (100) [$R^*Si_4I_5$]$^+$, 889 (10) [$R^*Si_4I_5-t$Bu]$^+$, 819 (3) [$R^*Si_4I_4$]$^+$. For X-ray crystal-structure analysis of *trans*-$R_2Si_4I_6$, see reference [7].

[10] X-ray crystal-structure analysis of **5**: $C_{78}H_{168}Si_{14}$, violet crystals, $0.01 \times 0.05 \times 0.1$ mm^3, $M_r = 1499.38$ g mol^{-1}; triclinic, space group $P\bar{1}$; $a = 12.948(2)$, $b = 15.651(2)$, $c = 25.251(5)$ Å, $\alpha = 78.531(10)$, $\beta = 80.246(11)$, $\gamma = 75.450(10)°$, $V = 4815.1(14)$ Å^3, $Z = 2$, $\mu(Mo_{K\alpha}) = 0.222$ mm^{-1}, $T = 103(2)$ K, $F(000) = 1664$. On a Stoe-IPDS diffractometer, 33637 reflections were measured with $Mo_{K\alpha}$ radiation to $2\Theta_{max.} = 34.84°$ of which 6354 were independent and used for all calculations. The structure was solved by direct methods and refined anisotropically against F^2. Refinement of the H atoms was carried out with the Reiter model. $R1 = 0.068$, $wR2(F^2) = 0.1198$, GOF(F^2) = 1.034. CCDC-277488 (**5**) contains the detailed crystallographic data for this structure analysis. The data may be obtained free of charge from the Cambridge Crystallographic Data Centre under www.ccdc.cam.ac.uk/data_request/cif. Comments: a) No libration correction was carried out. However, the anisotropic temperature factors at the respective atoms are very small and have no pronounced preferred orientation (they are thus almost isotropic). Naturally, in the case of disorder, greater errors in the position parameters can be assumed. However, the deflection parameters did not indicate any excessive deviation. b)If the data set of **5** is expanded to a 2Θ value of 48.0° the R value deteriorates to $R1 = 0.0682$ ($wR2 = 0.11494$). The averaged values (see legend to Figure 2 are, however, not changed by this; thus the structure solution is indirectly confirmed. c) The comparably weak coordination of the Si_2 dumbbell could explain the small Si1–Si2 distance (the higher the coordination number of an atom, the longer are the bonds; Si1 and Si2 are the only atoms in **5** not to carry a R* ligand).

Photoactivatable Compounds

DOI: 10.1002/anie.200502411

Coumarinylmethyl Esters for Ultrafast Release of High Concentrations of Cyclic Nucleotides upon One- and Two-Photon Photolysis**

Volker Hagen, Brigitte Dekowski, Vasilica Nache, Reinhard Schmidt, Daniel Geißler, Dorothea Lorenz, Jenny Eichhorst, Sandro Keller, Hiroshi Kaneko, Klaus Benndorf, and Burkhard Wiesner*

Biologically inert, photoactivatable precursors ("caged" compounds) of cyclic nucleoside monophosphates (cNMPs) are powerful tools for studying the spatiotemporal dynamics of cyclic nucleotide dependent processes. Among these compounds, (coumarin-4-yl)methyl esters of cNMPs are most useful because they show no background bioactivity, are stable to solvolysis, and can be photolyzed efficiently and extremely quickly.[1,2] Recently, we introduced [7-(diethylamino)coumarin-4-yl]methyl (DEACM) esters of cNMPs as caged compounds.[3,4] Compared with other coumarinylmethyl-caged cNMPs, the DEACM esters photorelease cNMPs with higher photosensitivity at long-wavelength irradiation (up to 436 nm), thus minimizing or even preventing damage to cellular components and chromophores by photobleaching.

Herein, we describe the development of the 7-[bis(carboxymethyl)amino]-substituted coumarinylmethyl building blocks **1** and **2** (structures in Scheme 1) for the caging of phosphates and other functionalities. With the axial and the equatorial diastereomers of the {7-[bis(carboxymethyl)amino]coumarin-4-yl}methyl (BCMACM) esters of cAMP, cGMP, 8-Br-cAMP, and 8-Br-cGMP **3**–**6** (Scheme 1), we present new variants of the DEACM-caged cNMPs, which maintain their favorable properties and additionally have much higher aqueous solubility by virtue of their anionic

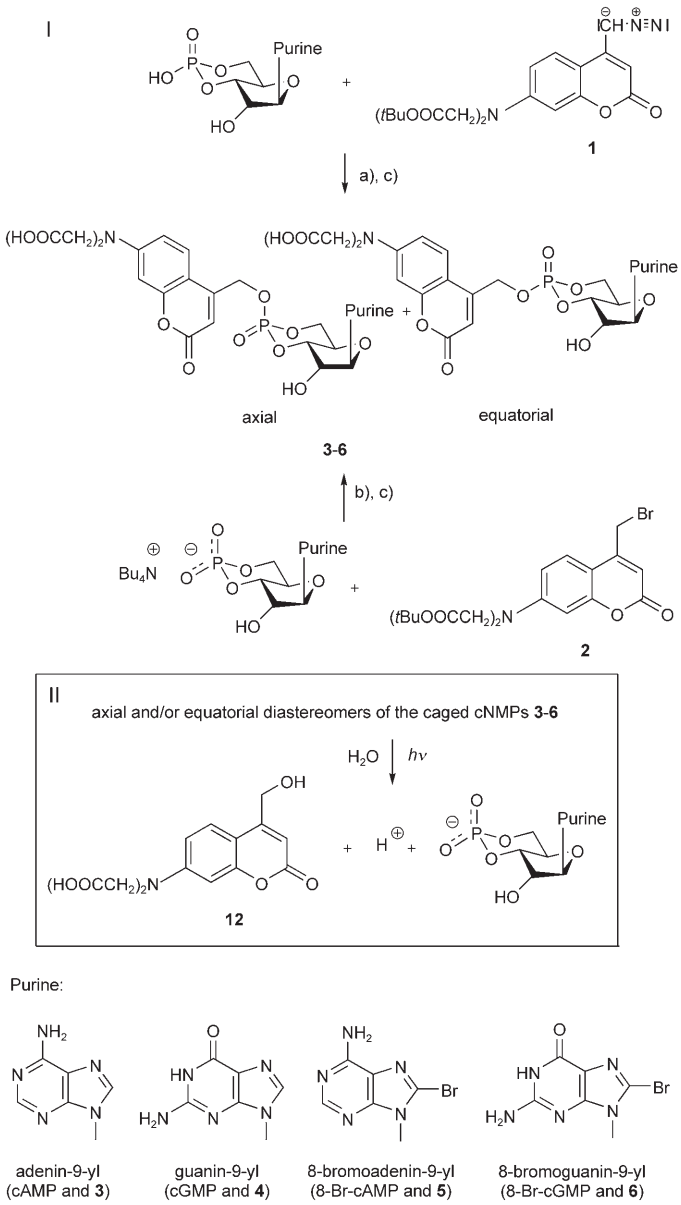

Scheme 1. Synthesis (I) and photolysis (II) of **3**–**6**: a) DMSO/CH_3CN (1:4), 60 °C, 24 h; b) CH_3CN, 85 °C, 5 h; c) TFA/CH_2Cl_2/H_2O (75:24:1), room temperature, 20 min.

centers. Furthermore, we show that the new caged compounds photorelease cNMPs upon one- as well as two-photon excitation and that it is possible to determine quantitatively the amount of cyclic nucleotide photoreleased inside a cell by fluorescence measurements.

The compounds **3**–**6** were prepared as shown in Scheme 1 I by alkylation of the free acid form of the respective cNMP with the 4-(diazomethyl)coumarin **1** (Method A) or by reaction of the tetra-*n*-butylammonium salts of the cNMPs with the 4-(bromomethyl)coumarin **2** (Method B) according to procedures described earlier for other coumarinylmethyl esters of cNMPs[5,6] and by subsequent removal of the *tert*-butoxy protecting groups with trifluoroacetic acid (TFA).

The synthesis of the key compounds **1** and **2** is outlined in Scheme 2. 7-Amino-4-methylcoumarin (**7**) was treated with an excess of bromoacetic acid *tert*-butyl ester in the presence of diisopropylethylamine to yield a mixture of **8** and **9**, which was separated by flash chromatography to provide the two products in yields of 27% and 31%, respectively. SeO_2 oxidation of **9** gave the corresponding aldehyde **10** in a yield of 80%. Condensation of **10** with tosylhydrazide furnished the corresponding hydrazone (84% yield), which was transformed into **1** by triethylamine-mediated Bamford–Stevens reaction (87% yield). Compound **2** was best prepared (81% yield) from the alcohol **11**, which was synthesized in 74% yield from **10** by reduction with $NaBH_4$, by mesylation and subsequent displacement of the mesyl group using LiBr in THF. Our attempts to convert **9** directly into **2** by utilizing *N*-bromosuccinimide were not successful as they resulted mainly in bromo substitution in position 3 of the coumarin ring.

Alkylation of the cNMPs using Method A gave relatively low product yields for the *tert*-butoxy-protected derivatives of **3** (12%) and **6** (7%) but an acceptable yield for the corresponding analogue of **4** (25%). The reaction of **1** with 8-Br-cAMP yielded only traces of **5**. However, the alternative esterification by Method B gave relatively high product yields for the *tert*-butoxy-protected derivatives of **3** (38%) and **5** (49%), an acceptable yield for the corresponding derivative of **6** (18%), and only negligible amounts of the analogue of **4**. Compared with the syntheses of other caged cNMPs,[2,3,7] **3**–**6** can be prepared with good yields by Method A for the synthesis of **4** and Method B for the preparation of **3**, **5**, and **6**, particularly because the product yields represent typical rather than optimal conditions.

Both synthetic procedures resulted in diastereomeric mixtures of the *tert*-butoxy-protected caged compounds. The ratios of the axial to the equatorial diastereomers were approximately 2:3 (Method A) and from 2:1 to 4:1 (Method B). The diastereomers were separated by reversed-phase HPLC on a preparative scale. In all cases, the axial isomers showed lower retention times than the equatorial isomers. TFA deprotection of the *tert*-butoxy-protected diastereomers of the esters resulted in the pure axial and equatorial isomers of **3**–**6** with approximately quantitative yields (see the Supporting Information for preparative details and analytical characterization). The isomers were assigned by ^{31}P NMR spectroscopy.[8,9]

Like other coumarinylmethyl-caged cNMPs, compounds **3**–**6** are highly resistant to spontaneous hydrolysis in the dark. HPLC monitoring of the pure diastereomers of the caged compounds in aqueous HEPES buffer at pH 7.2 during a 24-h period revealed no measurable formation ($<0.5\%$) of the free cNMPs at room temperature (HEPES = 2-[4-(2-hydroxyethyl)-1-piperazinyl]ethanesulfonic acid). All the compounds are readily soluble in aqueous HEPES buffer at pH 7.2 (Table 1), which is a prerequisite for the administration of large concentrations of phototriggers in cells or around membrane patches at the tip of glass pipettes when the patch–clamp technique is used. As expected, the hydrophilic caged cNMPs do not measurably partition into model lipid membranes at pH 7.2. This was demonstrated by the lack of reaction heats when compounds **3** and **5** were titrated with

lipid vesicles at different temperatures (see the Supporting Information for details). Nevertheless, the caged compounds rapidly enter live cells, probably using transport proteins or by endocytosis, and HEK293 cells could be loaded with **6** by incubation with a 50-μM buffered (pH 7.2) solution.

Photoactivation of the axial or equatorial diastereomers of the (coumarin-4-yl)methyl esters **3**–**6** by irradiation with wavelengths of 330–430 nm in aqueous buffer leads to the 7-[bis(carboxymethyl)amino]-4-(hydroxymethyl)coumarin **12**, a proton, and the respective "free" cNMP anion (Scheme 1 II). The photoreaction is efficient and clean and gives about 90–95% of the cNMP. Indications of a significant triplet-state population were not found. In fact, the lifetimes of the lowest excited singlet states S_1 are extremely short, about 0.1 ns (see Table 1). We assume that the photochemical conversion proceeds by means of a photochemical S_N1 mechanism (solvent-assisted photoheterolysis) from S_1 via a singlet ion pair. This ion pair decays mainly by recombination to the singlet ground state.[10] Competitively, separation of the ion pair by the polar solvent (formation of the cNMP anion) and subsequent hydrolysis of the coumarinylmethyl carbocation or, alternatively, direct reaction of a water molecule from the solvent cage of the ion pair with its carbocation followed by a very fast deprotonation step may take place.[10,11] Such a photolysis pathway implies that product formation is very fast. Indeed, time-resolved fluorescence measurements upon single-pulse excitation (0.5 ns half-width, 337 nm) of the axial diastereomers of **3** and **4** revealed fluorescence contributions from **12**. Because pure solutions of the caged compounds were irradiated, **12** must have been formed and excited during the photolysis pulse. Actually, deconvolution of the fluorescence signals with a biexponential decay function yielded rise times of the fluorescence of **12** of about 0.7 ns and 0.4 ns for the axial diastereomers of **3** and **4**, respectively. The rate constants of cNMP formation are the quotients of the efficiencies of product formation from the ion pairs and the fluorescence rise times of **12**.[10] Considering the corresponding efficiencies of product formation of 0.27 for **3** and 0.26 for **4**, we obtain for the rate constants values of $4 \times 10^8\ s^{-1}$ and $6 \times 10^8\ s^{-1}$, respectively. As the quantum yields, ϕ_{chem} and ϕ_f, do not vary much (Table 1), it is expected that the equatorial diastereomers of **3** and **4** as well the diastereomers of **5** and **6** photorelease the cNMPs with similar rates.

The photochemical characteristics of the BCMACM esters **3**–**6** in HEPES buffer (pH 7.2) are summarized in Table 1. The absorption and the fluorescence spectra show maxima at 382–387 nm and 479–487 nm, respectively, and correspond to those of the DEACM esters. The single-photon photochemical quantum yields, ϕ_{chem}, as well as the extinction coefficients, ε^{max}, are high for caged compounds, which results in excellent photosensitivity at long-wavelength irradiation. As a consequence, even moderate UV/Vis irradiation is sufficient to obtain large amounts of free cNMP.

The combination of the high photosensitivity and the good solubility of **3**–**6** also permits the generation of large instantaneous cNMP concentration jumps. This could be

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

demonstrated by means of cyclic nucleotide gated (CNG) ion channels of the rod photoreceptor, which are activated by cGMP. The CNGA1 subunit of these channels was expressed heterologously in *Xenopus* oocytes, and the current conducted by these channels was measured in inside-out patches with the patch–clamp technique. For example, with 400 μM **4** in the bath solution, a 150-μs light flash generated concentration jumps of free cGMP from zero to 72 μM. Figure 1

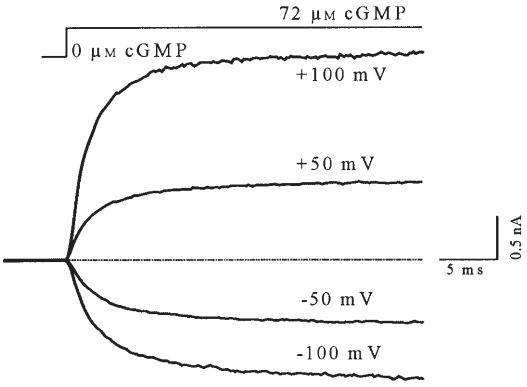

Figure 1. Activation of homotetrameric CNGA1 channels by jumps in cGMP concentration upon photolysis of **4** (axial isomer). The channels were expressed heterologously in *Xenopus* oocytes, and the recordings were performed in inside-out patches containing a high number of channels. The concentration of free cGMP was determined from the steady-state current of the traces referred to the steady-state current at saturating cGMP and the concentration–response relationship for these channels.[15] Before the flash, no current was present. The four traces at the indicated voltages were recorded from the same patch and were corrected for small leak currents by subtracting the respective traces recorded in the absence of cyclic nucleotide.

illustrates the resulting activation time courses at four transmembrane voltages. The time courses are highly resolved and are therefore most appropriate to give information on the molecular mechanisms underlying the activation gating of these channels. At maximum concentrations, **4** allowed us to elicit larger cGMP concentration jumps than the DEACM ester of cGMP.

BCMACM-caged cNMPs are highly sensitive not only to one-photon but also to two-photon excitation. Images obtained by confocal laser scanning microscopy (Figures 2 and 3) indicate that upon photolysis of **6**, 8-Br-cGMP mediates the entry of Ca^{2+} ions into HEK293 cells expressing the cGMP-gated ion channel of the cone photoreceptor (CNGA3). UV (argon laser, 364 nm) as well as IR light (Cameleon diode-pumped laser, 745 nm) evoked a saturable increase in the fluorescence intensity of the Ca^{2+} indicator FLUO-4, which indicates Ca^{2+}-ion influx through CNG channels. Addition of excess Mg^{2+} to the used Ca^{2+} buffer blocked Ca^{2+} influx, and neither UV nor IR irradiation in the absence of **6** led to changes in the fluorescence signal of the cells (not shown). High sensitivity to two-photon photolysis has been described earlier for (6-bromo-7-hydroxycoumarin-4-yl)methyl-caged compounds[2,12] and recently for (6,7-dimethoxycoumarin-4-yl)methyl diethyl phosphate as well as sodium [7-(dimethylamino)coumarin-4-yl]methyl sul-

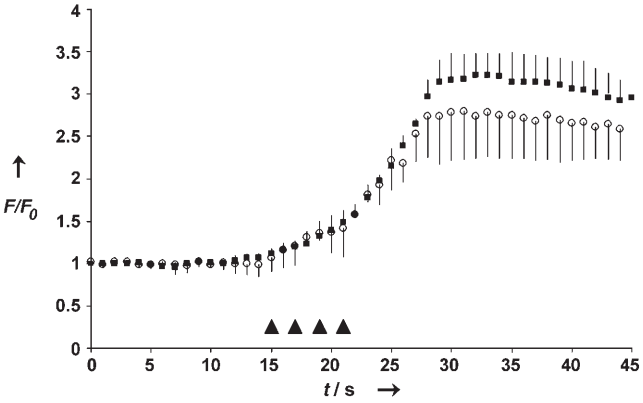

Figure 2. Time course of the Ca^{2+} influx through CNG channels into HEK293 cells expressing the CNGA3 channel after photorelease of 8-Br-cGMP from **6** (axial isomer) by exposure to UV light (364 nm, one-photon excitation, ■) and to IR light (745 nm, two-photon excitation, ○), respectively. The cells were preincubated with 4 μM FLUO-4/AM (30 min) and 50 μM **6** (20 min). The fluorescence intensity F of the Ca^{2+} indicator FLUO-4 was recorded before and after irradiation (▲). There was no significant difference between the two curves. F/F_0 = relative fluorescence intensity (mean values ± standard deviations obtained from three cells).

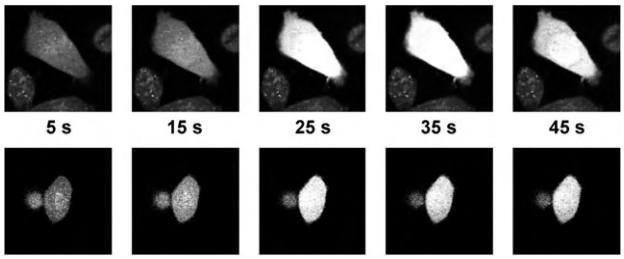

Figure 3. Fluorescence intensity of the Ca^{2+} indicator FLUO-4 in two CNGA3-transfected HEK293 cells before and after photorelease of 8-Br-cGMP from **6** (axial isomer) by exposure to UV (364 nm, upper row) or to IR light (745 nm, lower row). The cells were preincubated with 4 μM FLUO-4/AM (30 min)and 50 μM **6** (20 min). The indicated times correspond to those given in Figure 2. The fluorescence intensity is represented in an 8-bit gray scale.

fate.[13] Direct comparison of the time course for two-photon uncaging of **6** (axial isomer) with that of *N*-[(6-bromo-7-hydroxycoumarin-4-yl)methoxycarbonyl]-L-glutamic acid (Bhc-glu)[12] reveals that **6** photodecomposes initially 1.3 times faster than Bhc-glu under identical conditions (Figure 4). Because Bhc-glu displays a two-photon uncaging action cross-section, δ_u, at 740 nm of about 10^{-50} $cm^4 s\,photon^{-2}$, the two-photon action cross-section of **6** should be slightly larger than 10^{-50} $cm^4 s\,photon^{-2}$. Similar δ_u values are expected also for the equatorial isomer of **6** as well as for the diastereomers of **3**–**5**.

The fluorescence quantum yields ϕ_f of **3**–**6** are one order of magnitude smaller than that of the photoreleased alcohol **12** (Table 1). Compound **12** fluoresces also inside cells (see the Supporting Information), in contrast to 7-(diethylamino)-4-(hydroxymethyl)coumarin whose fluorescence is totally quenched inside HEK293 cells.[4] Thus, fluorescence spectro-

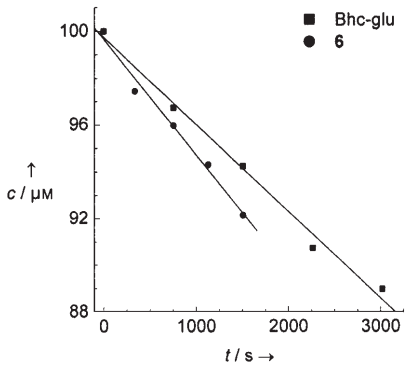

Figure 4. Initial time course of the two-photon photolysis of **6** (axial isomer) and Bhc-glu upon 740-nm irradiation in HEPES buffer, pH 7.2. The concentrations of **6** and Bhc-glu (starting concentrations 100 μM) were determined by RP-HPLC. Solid lines are linear regression lines. **6**: $c/\mu m = -0.0049t/s + 99.65$ ($R^2 = 0.987$); Bhc-glu: $c/\mu m = -0.0037t/s + 99.74$ ($R^2 = 0.991$). c = concentrations of the caged compounds.

scopic visualization of the progress of cNMP photorelease from BCMACM-caged cNMPs within cells becomes possible, as demonstrated in Figure 5. The generation of 8-Br-cGMP

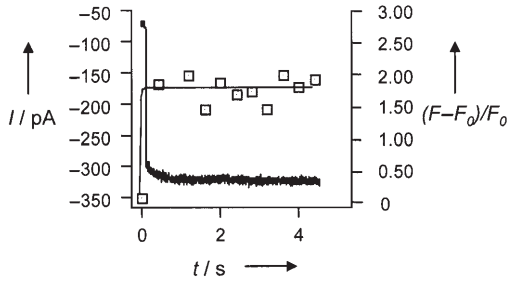

Figure 5. Monitoring the photorelease of 8-Br-cGMP from **6** within a CNGA3-transfected HEK293 cell by measuring the total whole-cell current and the fluorescence emitted from liberated **12** using excitation at 360 nm. The cell was loaded in the whole-cell configuration of the patch–clamp technique with 80 μM **6** and irradiated. The change in current amplitude and the fluorescence intensity increase (□) show photolytic liberation of 8-Br-cGMP.

from **6** in CNGA3-transfected HEK293 cells was monitored simultaneously by current recordings resulting from CNG-channel activation and by the fluorescence emitted from the liberated photoproduct **12** upon excitation at 360 nm. Since the fluorescence signal can be calibrated,[14] it is possible to quantify cNMP release from BCMACM esters of cNMPs using fluorescence spectroscopy. In addition to the high solubility of BCMACM-caged cNMPs in aqueous buffer, the possibility of visualizing and quantifying the release process within cells is a considerable advantage of BCMACM-caged cNMPs over the DEACM-caged analogues.

In conclusion, we have developed a photolabile coumarinylmethyl protecting group bearing a dianionic substituent and used this protecting group for the caging of cNMPs. The caged cNMPs exhibit high photosensitivities at long-wavelength irradiation and allow large and instantaneous cNMP concentration jumps upon one- and two-photon excitation within cells under physiological conditions. This approach can extend decisively the tools available for the study of space- and time-dependent aspects of cNMP-triggered processes. Finally, the novel protecting group should be useful in the caging and uncaging of other biomolecules with phosphate, carboxylate, and other functionalities. Exemplarily, the BCMACM ester of phenylacetic acid has already been prepared. The caged compound shows high solubility in aqueous buffer and can be photolyzed rapidly and efficiently ($\phi_{chem} = 0.02$, $\varepsilon^{max} = 20000$) in the visible-wavelength region.

Molecular Encoding at the Nanoscale: From Complex Cubes to Bimetallic Oxides**

Sebastian Polarz, Andrey V. Orlov, Maurits W. E. van den Berg, and Matthias Driess*

Nanoparticles,[1,2] in particular those of semiconducting metal oxides like ZnO, have received increasing attention because of their high potential as components in nanotechnological devices. In general, materials containing more than one type of metal should display higher complexity and a wider range of properties.[3] So far only little attention has been paid to bi- or multimetallic oxide nanostructures, although a diverse spectrum of properties can be envisioned for such oxides.[4] Multimetallic oxides have been known in solid-state chemistry for a long time, but the high processing temperatures typically applied make them less suitable for the preparation of nanoscaled materials.[5] In addition, optimum dispersity of the two metals inside the nanostructures would play a pivotal role for the rational synthesis and adjustment of properties of those systems. Optimum dispersity is ensured when the respective elements are distributed on the molecular level.[6] In this respect, the use of molecular single-source precursors could potentially solve this problem by the creation of molecular building blocks suitable for bottom-up formation of oxides or other materials. Correlated to the molecular design of the precursor are low thermolysis temperatures resulting in reduced particle growth.[7] However, the preparation of a specific precursor resulting in a specific oxide is difficult,[8] especially if bi- or multimetallic oxide nanostructures are targeted.[4,9] Some examples for such single-source precursors exist already.[10–16] In most cases these heterometallic precursors are alkoxides and are thus very moisture sensitive.[17–19]

Our goal is to identify a new precursor system that enables access to a large variety of nanoscaled bimetallic oxides, and at the same time is readily available and stable. One particular type of bimetallic oxide of current interest is metal oxide semiconductors (for instance ZnO) doped with paramagnetic metal ions like Mn^{2+} and Ni^{2+}. Since such metal-doped oxides are expected to display considerable magnetoresistivity, they are promising materials for "spintronics".[20,21] Heterometallic precursors for this type of materials are currently unknown.

Herein, we report on the intriguing properties of molecular clusters having heterocubane architecture $[M^1_{4-y}M^2_y(LH)_4]^{4+}(OAc)_{4-x}(ClO_4)_x$ ($\cong [M^1_{4-y}M^2_yO_4]$; see Scheme 1) with a singly deprotonated dipyridyldiol (LH) as a chelating ligand, and their exploitation for the preparation of metal-doped transition-metal oxides. We show that 1) monometallic $[M_4O_4]$ clusters are single-source precursors for nanoscaled oxides; 2) any combination and permutation of bimetallic clusters $[M^1_{4-y}M^2_yO_4]$ containing the metals $M^{1,2}$ = Mn, Co, Ni, Zn are easily accessible; and 3) these bimetallic clusters can be used to prepare nanoscaled bimetallic oxides. The oxo clusters introduced here are the smallest possible molecular building blocks for the desired bimetallic oxide nanostructures (see Scheme 1).

1) Preparation of nanoscaled oxides from $[M_4O_4]$ precursors. In order to probe the capacity of the described clusters as reliable precursors, the thermolysis behavior of the different monometallic compounds $[M_4O_4]$ was studied by thermogravimetric analysis (TGA) and powder X-ray diffraction (PXRD). The data for the $[Zn_4O_4]$ cluster shown in Figure 1 are representative. Since phase-pure zinc oxide is obtained both under argon as well as under oxidative (20 vol% O_2) conditions as proven by PXRD, $[Zn_4O_4]$ is a suitable single-source precursor for ZnO. The presence of oxygen facilitates the complete removal of the organic ligands as proven by TG analysis. Apart from the fact that one can obtain nanocrystalline ZnO, it is also possible to control the size of the ZnO particles by heating the $[Zn_4O_4]$ precursor to a particular temperature T_d and maintaining this temperature for 3 h in order to oxidize off the organic shell. Under these conditions, the size of the ZnO particles (determined by the Scherrer equation) depends nearly linearly on the thermolysis temperature T_d (similar to the Ni–ZnO system shown below). Similar behavior was found for the alternative monometallic precursors with the difference that the oxidation state of the resulting materials may be sensitive to the presence of oxygen during thermolysis [Eq. (1a–d)]. Oxidizing conditions were selected for the preparation of bimetallic oxides.

$$Zn^{II}O \xleftarrow{ox.} [Zn_4O_4] \xrightarrow{inert} Zn^{II}O \quad (1a)$$

$$Co^{II}O \xleftarrow{ox.} [Co_4O_4] \xrightarrow{inert} Co^{II}O \quad (1b)$$

$$Mn^{III}_2O_3 \xleftarrow{ox.} [Mn_4O_4] \xrightarrow{inert} Mn^{II}O \quad (1c)$$

$$Ni^{II}O \xleftarrow{ox.} [Ni_4O_4] \xrightarrow{inert} Ni^0 \quad (1d)$$

2) Preparation of bimetallic heterocubanes $[M^1_{4-y}M^2_yO_4]$ as precursors. Instead of employing pure metal acetates in the synthesis of the single-metal clusters, we used mixtures of metal acetates in order to synthesize bimetallic heterocubanes, which were hitherto unknown (Scheme 1). In fact, we could prepare all possible combinations and permutations of the mixed bimetallic clusters $[M^1_{4-y}M^2_yO_4]$ ($M^{1,2}$ = Mn, Co, Ni, Zn; see Scheme 1) in single-crystalline form (see the Supporting Information). Because of the cationic character of the

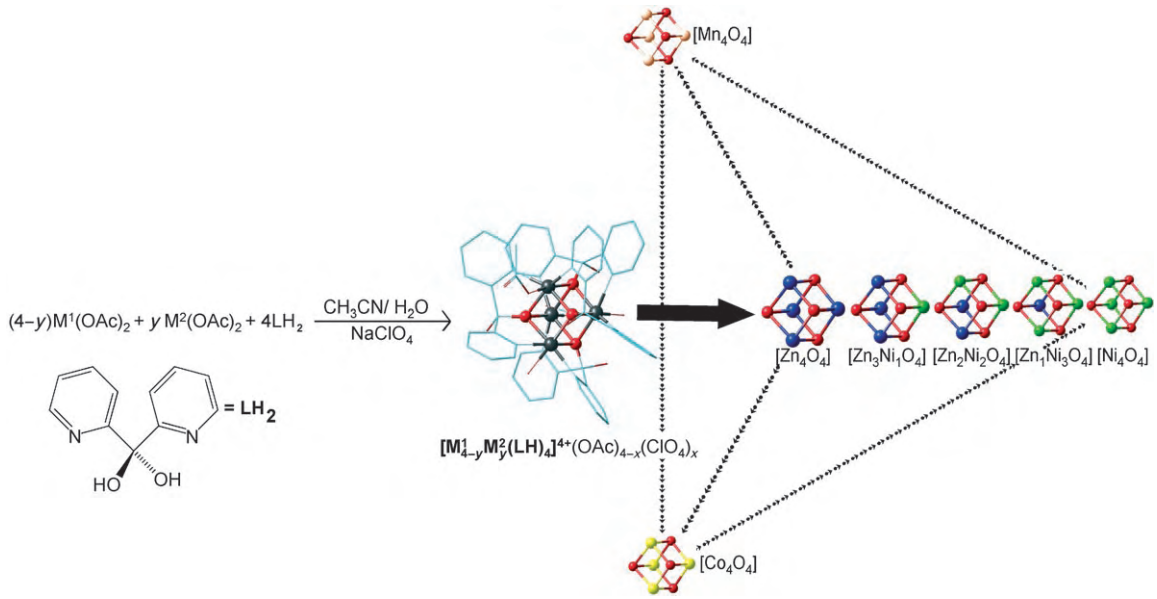

Scheme 1. Possible combinations and permutations of metals in bimetallic clusters. The chemical equation describes the general synthetic route to the heterometallic clusters. The central M_4O_4 motif is highlighted in the structural plot. (A structure determined by single-crystal X-ray analysis is shown in the Supporting Information.) The tetrahedron on the right outlines the possibilities for accessible precursor systems: monometallic clusters are located at the corners, bimetallic clusters along the edges, and trimetallic clusters (not shown) along the faces.

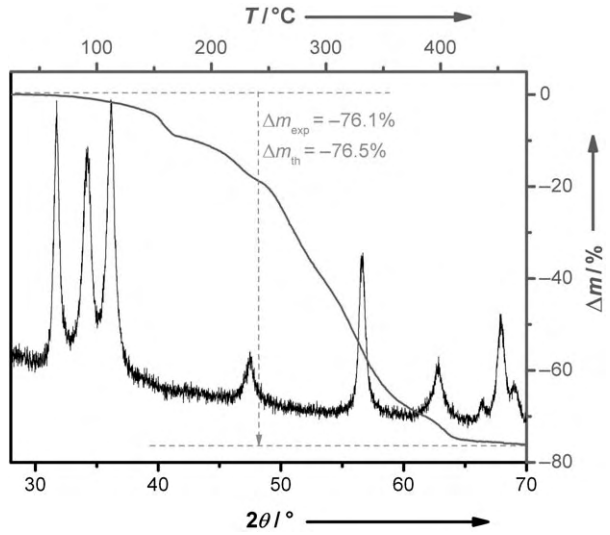

Figure 1. Powder X-ray diffraction pattern for the thermolyzed $[Zn_4O_4]$ cluster (black) and the thermogravimetric trace (gray) for its thermolysis. It is seen that the experimentally observed mass loss is very close to the theoretical mass loss for the transformation to ZnO.

oxo cluster core, the formation of the molecules can be followed by electrospray ionization mass spectrometry (ESI-MS). The spectra were recorded for acetonitrile solutions obtained from dissolving exactly one single crystal. ESI-MS gives a reliable picture of the true compositional distribution of the obtained clusters. The results are shown for the combinations Zn/Ni, Zn/Co, and Co/Ni as proof of principle (Figure 2). The most intensive signals in the spectra can be attributed to cluster ions of the type $[M^1_{4-y}M^2_y(LH)_2(L)_2]^{2+}$ (denoted as $[M^1_{4-y}M^2_yO_4]^{2+}$). Here, all counterions are solvent separated, but two dipyridyldiol functions in the cluster cations are additionally deprotonated, resulting in a net charge of +2. Signals related to singly charged species and complexes with different ratios of perchlorate to acetate were also seen in the spectra, but we focussed on the most intensive signal mentioned above. A broad signal centred around m/z 550 was observed (Figure 2a) when the synthesis mixture with the molar ratio of $Zn^{2+}/Ni^{2+} = 3:1$ was used. If one calculates the theoretical pattern expected for different cluster compositions, this signal is found to correspond to a superposition of several species. Deconvolution of the signal indicates that the solution contains roughly 73% $[Zn_3NiO_4]^{2+}$ as well as 22% $[Zn_4O_4]^{2+}$ and 5% $[Zn_2Ni_2O_4]^{2+}$. This is not surprising since the formation of clusters of different compositions is entropically favored. We also checked that there is no interchange equilibrium in solution. Pure $[Zn_4O_4]$ and pure $[Ni_4O_4]$ were dissolved together, and the ESI mass spectrum was recorded after two weeks. No formation of mixed clusters was found under these conditions. This and the fact that we used only one single crystal for each solution for ESI-MS measurement is clear proof that the bimetallic clusters are not an artifact but that they exist in solution as well as in the solid state.

Similarly, for the molar ratio $Zn^{2+}/Co^{2+} = 1:1$ (Figure 2b) not only the expected $[Zn_2Co_2]^{2+}$ but also the other permutations ($[Co_4O_4]^{2+}$, $[ZnCo_3O_4]^{2+}$, $[Zn_3CoO_4]^{2+}$) are observed in lower amounts as well. In principle all combinations of mixed-metal clusters ($M^{1,2}$ = Mn, Co, Ni, Zn) can be obtained. This is shown for the formation of mixed clusters starting from the molar ratio $Ni^{2+}/Co^{2+} = 1:1$ (Figure 2c). However, for addressing the mixed-metal clusters as precursors it would be even more desirable if one could obtain only one molecular species instead of a mixture of cluster compounds. To investigate this, the Zn/Ni system was chosen as a model

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

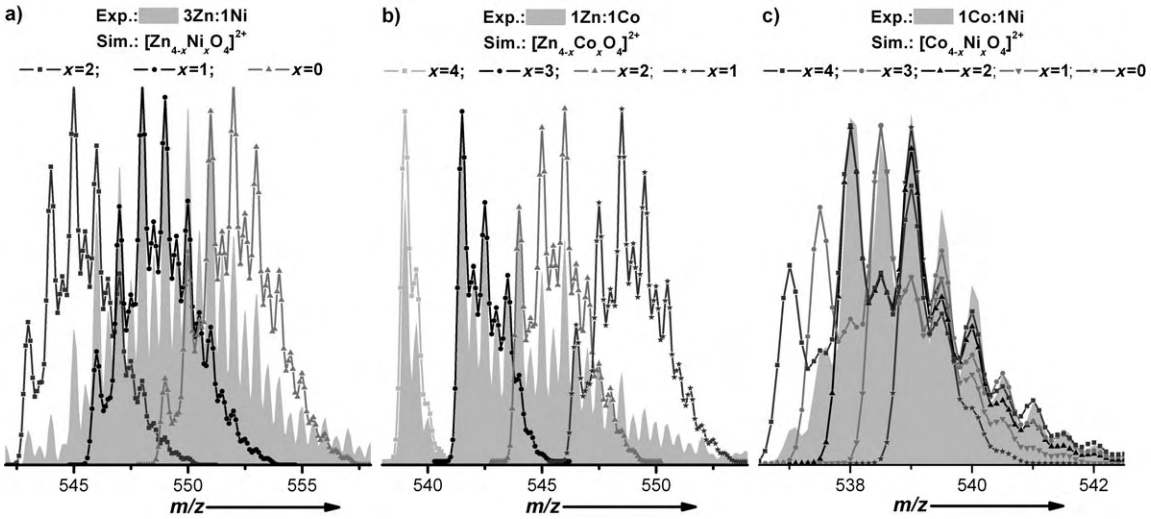

Figure 2. ESI mass spectra of mixed-metal clusters: a) Zn/Ni, b) Zn/Co, and c) Co/Ni. The light gray areas represent the measured spectra (Exp.), while the straight lines with symbols show the simulated patterns for a particular cluster composition (Sim.).

system. By changing the initial molar ratios of metal ions Zn^{2+}/Ni^{2+} from 3:1 to 1:1 (Figure 3a), the center of the cluster distribution can be moved towards clusters containing more Ni (cf. Figure 2a) but the width of the distribution is not affected.

Because the clusters are well soluble in acetonitrile as well as in water, we investigated whether the clusters of different compositions can be separated by chromatography. We performed HPLC on silica gel with a sodium acetate buffer as eluent. Indeed, fractions were collected with a narrower distribution of clusters (Figure 3b). The resulting pattern shows very good agreement with the pattern expected for a pure $[Zn_3NiO_4]^{2+}$ cluster (see Figure 2a).

3) Preparation of bimetallic oxide nanoparticles from mixed-metal clusters. The pure $[Zn_3NiO_4]$ compound obtained after chromatography was further used for the synthesis of oxidic materials. The formation of a nickel-doped zinc oxide is further complicated by the different coordination geometries (tetrahedral for Zn^{2+} in ZnO; octahedral for Ni^{2+} in NiO). Thermodynamically, this leads to a positive free mixing enthalpy. The formation of a spinell could be an alternative to the demixing, but spinells are not known for the Ni/Zn/O system. It is thus expected that for thermolysis of the $[Zn_3NiO_4]$ precursor demixing occurs resulting in a "zinc-saturated" NiO phase and a "nickel-saturated" ZnO phase. This is indeed the case as can seen from the XRD pattern of a sample where $[Zn_3NiO_4]$ had been decomposed at $T = 500\,^{\circ}C$ and tempered at this temperature for three hours (Figure 4a). The reflections can be attributed to $Ni_{0.7}Zn_{0.3}O$ (particle diameter $D_p = 44.1$ nm) and ZnO. The formation of the known $Ni_{0.7}Zn_{0.3}O$ phase is also very reasonable as Zn^{2+} can easily adopt octahedral coordination.

If, on the other hand, the precursor is thermolyzed at lower temperature, smaller particles result. It was already mentioned that under the described conditions the relationship between T_d and the particle size is practically linear (Figure 4c). Thus, particle size can be adjusted to a certain extent. Particles resulting from $T_d = 250\,^{\circ}C$ are only 10.1 nm

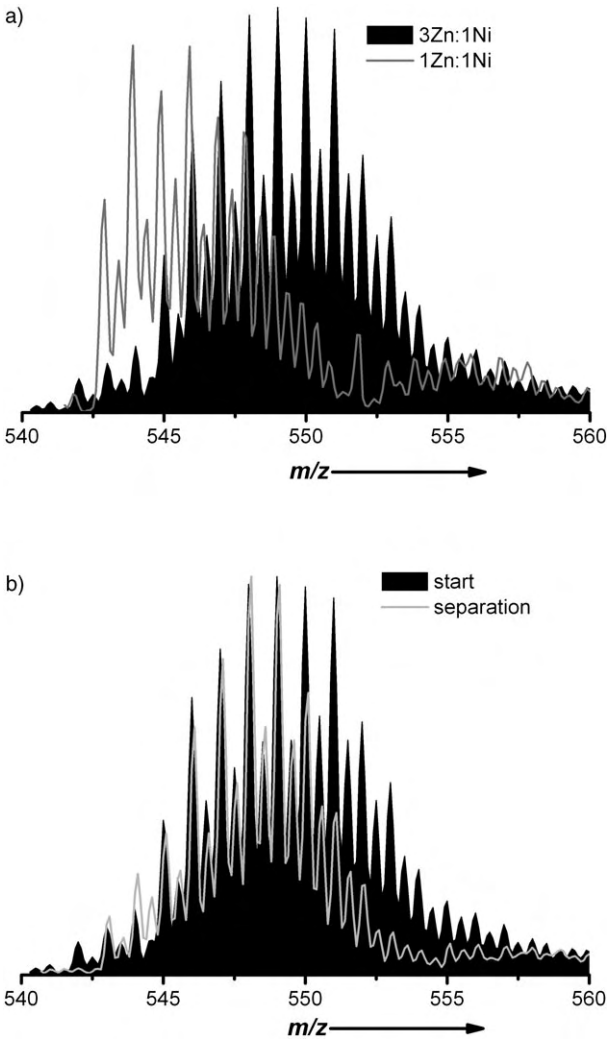

Figure 3. Change of the distribution of mixed Zn/Ni clusters from the initial distribution (black curve) a) upon adjustment of the initial ratio of metal acetates (gray line) and b) after chromatographic separation (gray line).

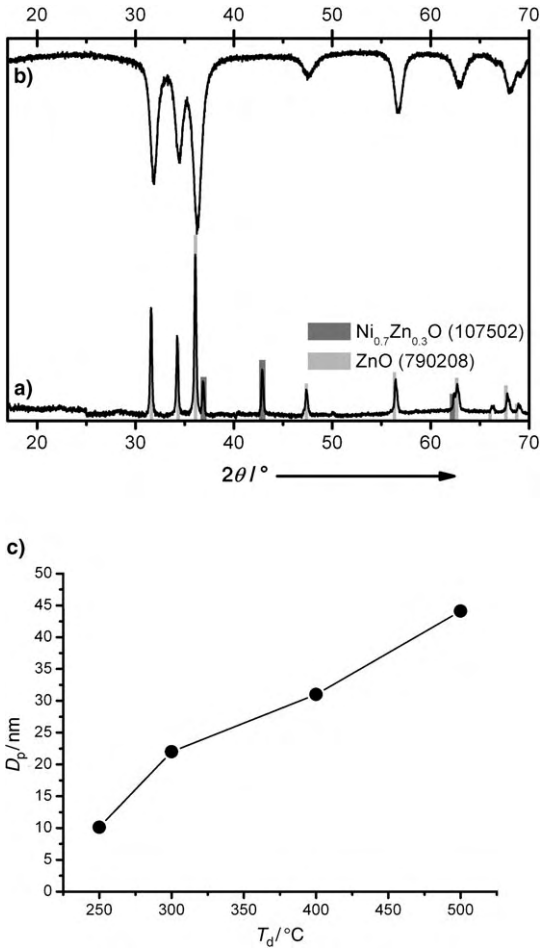

Figure 4. Powder X-ray diffraction patterns for material obtained by decomposition of $[Zn_3Ni]$ at a) $T_d = 500\,°C$ and b) $T_d = 250\,°C$. c) Dependence of particle size on decomposition temperature.

in size. Surprisingly, only the reflections of ZnO are found for the small particles, and a NiO phase is not detectable by X-ray diffraction (Figure 4b). EDX spectra (see the Supporting Information) recorded on agglomerates of such particles indicate that these particles contain $\approx 30\,\%$ nickel. However, it can not be excluded by EDX alone that the agglomerates do not contain particles of different composition. Nevertheless, TEM images indicate that these agglomerates are not amorphous and that the size of the constituent particles is very similar to that determined by means of X-ray scattering data (see SI2 in the Supporting Information). Therefore, it seems unlikely that an amorphous NiO phase, which would have been invisible in PXRD, is present in this material.

Another model which, at this point, can also not be excluded is that a thin NiO layer covers the ZnO nanoparticles. To consider this possibility in more detail, the local structures of the Zn and Ni centers were determined from K-edges (at 9659.0 and 8333.0 eV, respectively) by X-ray absorption spectroscopy (XAS) for the sample prepared at $T_d = 250\,°C$. Whereas from XRD results it is not possible to exclude small, amorphous NiO particles dispersed in ZnO, the XAS results indicate that the crystalline environment of Ni does not permit such an interpretation. The Ni–O distance fitted to the first feature in the Fourier transform of χ was found to be 2.07 Å, indicating a coordination number of Ni^{2+} of the order of 4. Furthermore, the Ni–Ni distance is clearly too small to be explained by the presence of a separate NiO phase (Figure 5). Small deviations in the Ni X-ray absorption

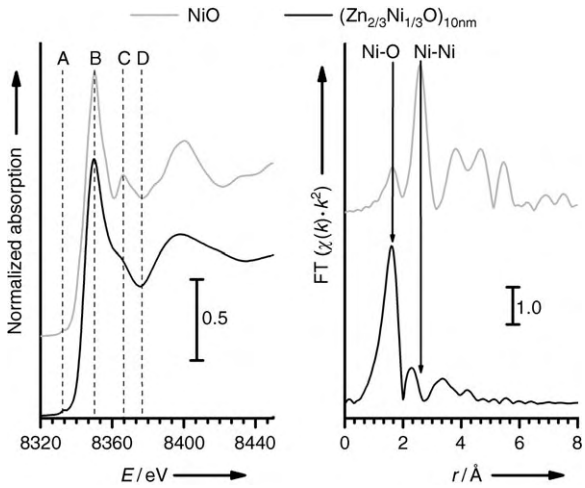

Figure 5. Ni K-edge XAS spectra of NiO and $[Zn_3NiO_4]$ ($T_d = 250\,°C$). Left: The XANES features A, B, C, and D. Right: The Fourier transform (not corrected for phase shifts).

near-edge spectrum (XANES) confirm this hypothesis. A NiO layer on top of the ZnO particles would have given a Ni–Ni distance close to the value expected for NiO. Therefore, we propose a model in which Ni^{2+} centers have replaced Zn^{2+} in the ZnO lattice. This assumption is further supported by modeling of the XAS data taking this model into account (see SI3 in the Supporting Information).

If one considers all the data together (the precursor architecture, the mild thermolysis conditions, TEM/EDX, PXRD, EXAFS), it appears that the molecular preorganization determined in $[Zn_3NiO_4]$ can lead to a Ni-doped ZnO but only for small particle sizes.

The findings reported here indicate that by forcing matter into the nanoscale, it is not only possible to manipulate the properties of ensembles of atoms (band gap) but also to alter the chemistry of individual atoms. It could be shown as soon as the particles are small enough, the chemical behavior of Ni^{2+} changes. It was possible to mix two species with each other that normally would segregate (demixing into ZnO and NiO).

The reason for this unusual behavior is presumably very simple. On the nanoscale, the total free energy of a system, ΔG_{tot}, is increasingly dependent on the free interface energy as particles become smaller, $dG \propto (\partial G/\partial A)\mathrm{d}A$, a relationship well established in colloid science. Thus, for the bulk (large particles) ΔG_{tot} is mainly determined by the free mixing energy, ΔG_{mix}, and free interface energy, ΔG_{if}, is negligible. However, the situation changes for the nanoscale: ΔG_{mix} and ΔG_{if} are antidromic in a certain sense. While a positive ΔG_{mix} results in demixing and thus the formation of two new particles, the formation of smaller particles from a larger one

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

is countered by ΔG_{if}, which is always positive. Therefore, under conditions where transport of matter is restricted, as under the moderate thermolysis temperatures used here for the preparation of the small oxidic nanoparticles, free interface energy overcompensates the free demixing energy, and thus demixing does not occur. This, in turn, leads to the formation of particles with unusual fine structure, for example, the ZnO particles doped with high content of tetrahedral Ni^{2+} atoms. Because the "game" of pitting ΔG_{if} against ΔG_{mix} is so fundamental, it can certainly be applied to many other systems as well.

Addressing the Metal Centers of [2 × 2] Co^{II}_4 Grid-Type Complexes by STM/STS**

Mohammad Sahabul Alam, Stefan Strömsdörfer, Viacheslav Dremov, Paul Müller, Jens Kortus, Mario Ruben,* and Jean-Marie Lehn**

The adsorption of functional molecules on solid substrates is increasingly becoming an important aspect of nanoscience and sensing technology. Molecular and supramolecular electronics, understood as the integration of molecular structures to supplement specific functionalities on an integrated circuit chip, is a promising alternative approach for reducing both the feature size and the cost per functional unit. Driven by its characteristic control of the self-assembly process with nanometer accuracy, supramolecular chemistry has a deep impact on the realization of new concepts in molecular electronics. In particular, it plays a leading role in the future development of electronic devices at the solid-state/air interface; the intrinsic physical properties of supramolecular nanostructures can be screened in view of potential applications in nanotechnology.[1]

Recent progress in supramolecular coordination chemistry allows access to a broad variety of transition-metal complexes of grid-type architecture comprising two-dimensional arrays of metal ions interconnected by a set of organic

ligands. They appear to be of particular interest as a basis for information storage functions, logic, sensing, and electrical switches.[2–5] Complexes of the $[n \times m]$ M^{II} type have been found to exhibit very interesting structural,[3] optical,[4] magnetic,[5] and, in particular the $[2 \times 2]$ Co^{II}_4 species, remarkable electronic properties.[6]

The synthesis and the structural characteristics of polypyridine-derived, multinuclear metal complexes of the $[2 \times 2]$ Co^{II} grid-type (Figure 1) have been reported earlier.[7] The

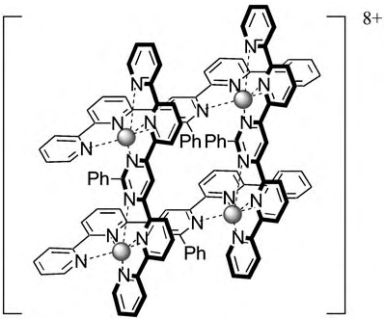

Figure 1. Representation of the $[Co^{II}_4L_4]^{8+}$ complex (L = 4,6-bis(2,2′-bipyrid-6-yl)-2-phenylpyrimidine). Each Co^{II} center is coordinated by six N donor atoms (dotted lines).[6,7]

central focus of the work presented here is to address two key challenges in the realization of composite solid-state molecule device architectures: the controlled deposition and organization of this class of molecules on solid surfaces and the addressing of individual subunits (here, metal centers) inside the $[2 \times 2]$ Co^{II} grid-type complex.

Experimentally, we applied scanning tunneling microscopy (STM) and scanning tunneling spectroscopy (STS) techniques to free-standing 1D and 2D ensembles as well as to single molecules of the $[2 \times 2]$ Co^{II}_4 type deposited onto highly oriented pyrolytic graphite (HOPG). STM studies of densely packed monolayers of $[Co^{II}_4L_4]^{8+}$ grid complexes on graphite have already been reported.[8,9] In order to study the specific features of the electronic properties at the single-molecule level, we concentrated our work on isolated, free-standing molecules. Related work on the investigation of specific functionalities of supramolecular nanostructures on surfaces was reviewed recently.[10,11]

Since the structural and electronic informations of STM measurements are strongly entwined,[12] the interpretation and analysis of the images of rather complex molecules is not straightforward. In addition, a pure topographical image of the van der Waals surface of $[2 \times 2]$ grid-like species would not be very useful as it would appear as a more or less featureless "blob" mapping the surface of a pile of more than 200 atoms. However, scanning tunneling spectroscopy (STS) measurements can provide direct information about the molecular energy levels, especially those close to the Fermi level. Functional units of atoms can be distinguished by selective mapping of certain energy regions, provided that their corresponding orbitals are well separated in energy. In general, such STS experiments are carried out under very rigorous conditions (metallic single crystals, ultrahigh-vacuum conditions with low temperatures) to minimize the coupling of the system with the environment.[13] However, it was also shown that under certain conditions room-temperature STM experiments could detect local changes in the electronic properties of molecules resulting, for example, from intramolecular acceptor–donor,[14a] intermolecular π–π,[14b] and charge-transfer interactions.[14c]

Using a homebuilt STM working under ambient conditions, we succeeded in combining high-resolution topography mapping with simultaneous measurement of current–voltage characteristics (STS) on single molecules deposited on HOPG surfaces. The electrical conductivity of molecules is not only of fundamental interest but is also of considerable significance in device applications.[15]

The investigated samples were prepared by depositing a drop of a solution of $[Co^{II}_4L_4]^{8+}$ molecules in acetonitrile (10^{-9} M). Different molecular arrangements of Co $[2 \times 2]$ grid complexes on the HOPG surface could be observed after repeated scanning under relatively mild tunneling conditions (Figure 2). At low coverage the grid complexes get trapped

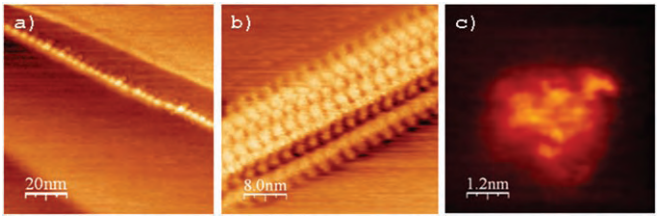

Figure 2. STM images of $[2 \times 2]$ Co^{II}_4 grid complexes deposited onto a HOPG surface. a) At low concentrations the $[Co^{II}_4L_4]^{8+}$ complexes are aligned along graphite steps into 1D chains (set point current 5 pA, set point voltage 100 mV). b) 2D crystal formed from $[Co^{II}_4L_4]^{8+}$ molecules along a graphite step (set point current 200 pA, set point voltage 100 mV). c) An isolated molecule with submolecular resolution (set point current 200 pA, set point voltage 500 mV).

along the step edges of HOPG, and it was possible to obtain continuous 1D chains several hundred nanometers in length (Figure 2a), as well as 2D arrays of densely packed grids (Figure 2b). The ordered 2D structures form spontaneously and start to grow from single nucleation points, which can be considered the 2D equivalent of a crystallization process. At very low coverage, a well-ordered distribution of isolated units is found, even at room temperature where thermal mobility becomes appreciable, which demonstrates the delicate adsorbate–substrate interactions in this system.[16]

In Figure 2c, we show a high-resolution STM image of a single $[2 \times 2]$ Co^{II}_4 complex. The image appears as a bright uniform spot with a cross-section of about 1.7 nm surrounded by a less defined halo, which can be caused by contributions from the BF_4 anions and solvent molecules, and corresponds to the molecular size extracted from single-crystal X-ray diffraction studies (1.65 nm).[7] Additionally, a quadratic set of slightly brighter spots can be observed on top of the structure anticipating the positions of the cornerstone metal ions. Besides these faint features, as expected, STM topography

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

cannot provide any further information on the intramolecular structure.

In order to investigate the electronic properties of the deposited $[Co^{II}_4L_4]^{8+}$ molecules, we applied current imaging tunneling spectroscopy (CITS) techniques to the molecule–substrate system. CITS techniques have been developed for scanning tunneling spectroscopy (STS) of a sample surface and consist in the recording of current–voltage (I–V) characteristics at every pixel position of the topography map while maintaining a constant tip to surface distance.[17–19] The I–V data set can be sorted such that it provides both a height (topography) map, taken at constant current, and several tens of current (CITS) maps, taken at constant voltage. The current contrast changes significantly when at certain bias voltages new molecular energy levels come into play. Although this technique has been applied successfully to semiconductor materials, its application to organic molecules is rather difficult because of mobility or instability of the molecules, drift, etc.[20] Nevertheless, if there would be energy regions where the molecular levels result exclusively from some functional subgroups of atoms, a selective screening of parts of the molecule would be possible.

We successfully applied CITS techniques to the [2 × 2] Co^{II}_4 grid-type complex. We confined our investigations to negative sample-to-tip bias voltages, that is, to the spectroscopy of occupied levels. Figure 3a shows a constant current topography imaging. Figure 3b shows the current map taken at a bias of −0.942 V in the same scan. The tunneling resistance was set to 1 GΩ. Thereby, the topographic image presents a rather featureless structure with a diameter of approximately 1.7 nm, while the CITS current map reveals a quadratic array of four bright spots representing sharp peaks of the tunneling current. In Figure 3c the set of I–V characteristics measured at 32 equidistant positions along a line between the two arrows in Figure 3b is shown. The background current arising from the graphite surface was subtracted. Two ridges are revealed which are approximately 0.7 nm apart. This is in accord to the distance between two neighboring Co ions.[7]

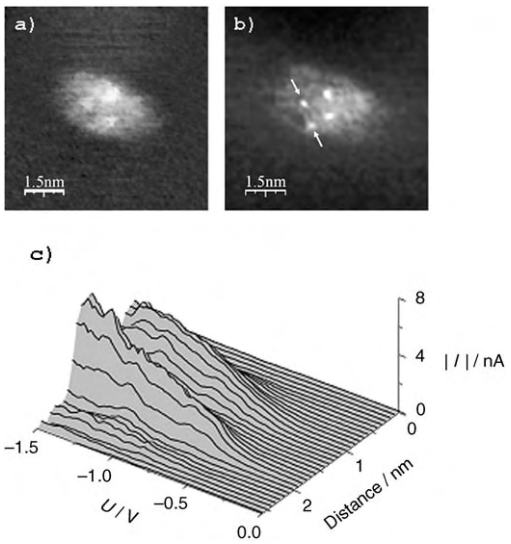

Figure 3. a) Topographic map of a [2 × 2] Co^{II}_4 grid. b) Simultaneously recorded current (CITS) image, taken at a voltage of −0.942 V. A quadratic array of bright spots can be detected with a spot-to-spot distance of approximately 0.7 nm. c) Representation of a set of I–V characteristics measured at positions between the two arrows in Figure 3b.

Since all distances between the peaks in the CITS pictures correspond to the Co–Co distances in the molecule, we conclude that we have mapped local maxima of the density of states situated at the positions of the Co ions. We note that in spite of the high resolution of the images no features arising from the bis(bipyridyl)pyrimidine ligands were observed. This can be expected because the electronic states of the ligands are located far from the Fermi level E_F.[19,21–24] As a consequence, these states do not play a significant role in the tunneling current at bias voltages down to −1.5 V. This is further confirmed by DFT calculations (vide infra).

Coming back to Figure 3c, we note that below a threshold of approximately −0.6 V the tunneling current at the positions of the bright spots increases drastically. This can be clearly seen in the set of 3D current maps presented in Figure 4.

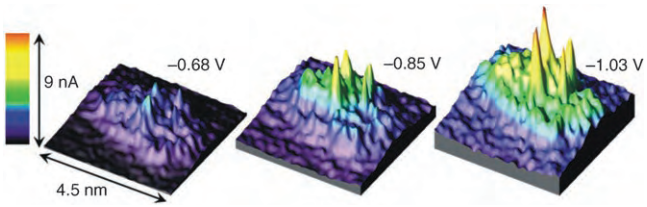

Figure 4. Set of 3D current images representing the central part of Figure 3b at different tunnel biases.

The DFT calculations show that the highest occupied molecular orbitals (HOMO) are build from Co d states. The energy gap between the highest occupied and the lowest unoccupied molecular orbital (LUMO) obtained from these calculations is 0.53 eV. The eightfold positively charged grid molecule is highly electronegative. Therefore it seems plausible that the Fermi level will be pinned at the energy position of the LUMO. This would explain the strong increase in tunneling current around −0.6 eV observed experimentally, because tunneling from the HOMO starts at this energy. In the following, all energies are given with respect to the Fermi level. The first three occupied orbitals are quasi degenerate in energy being separated in energy by only a few meV, followed by states at −0.55 and −0.60 eV and sets of states around −0.62 and −0.67 eV. Below −0.7 eV there is an energy gap of about 0.3 eV until the remaining states which exhibit d character are found around −1 eV. As evidenced by Figure 5a, all these states are localized near the position of the Co atoms. Figure 5a shows a superposition of the crystal structure, the above-mentioned orbitals in an energy window between the Fermi level and −0.7 eV (in red), and a color-coded contour plot of the electron density corresponding to these orbitals at a plane parallel to the Co atoms at a distance

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

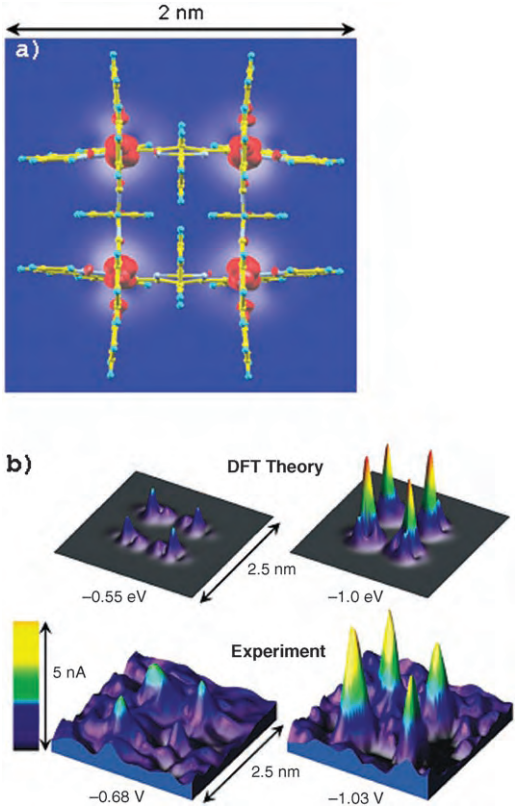

Figure 5. a) DFT calculation of occupied orbitals within an energy window between E_F and −0.7 eV and the electron density map in superposition with the crystal structure data. b) 3D representation of DFT-calculated electron density maps within an energy window between E_F and −0.55 eV and between E_F and −1 eV (upper row). Lower row: Central section of the measured CITS maps of Figure 4.

of 7 Å (white halo around the orbitals). A 3D representation of the electron density maps is repeated in Figure 5b, upper row, using the same coloring scheme as the experimental data. Two energy windows are shown: The first one covers the range between E_F and the HOMO (−0.55 eV), while the second one covers the full range between E_F and all states exhibiting 3d character (−1 eV). Considering that DFT usually underestimates band gaps, the HOMO–LUMO gap seems to be underestimated by 150 meV compared to experiment. If one assumes the validity of the Tersoff–Hamann approximation, the theoretical distribution at −0.55 eV should then conform to the map of tunneling currents at a bias of −0.7 eV, etc. The lower row of Figure 5b shows the central part of the CITS current maps of Figure 4 with subtracted background. The accordance with the electron density maps from the DFT calculation is striking. Of course, the DFT calculations do not include possible interactions between molecule and substrate. This might account for some of the discrepancies between theory and measurements.

Intuitively, one would assume that the weakest bonds, in other words, the supramolecular coordination interactions, should dominate the molecular orbitals near the Fermi level of the molecule. A comparison of our measurements with the DFT calculations confirms clearly this assumption. Thus, STS spectroscopy directly addresses the metal centers in a rather complex (supra)molecular entity. If this explanation can be applied also to other supramolecular species with metal centers, our method would allow a selective mapping of the functional units within the supramolecular architecture, even if these units are embedded into a complex set of organic ligands.

In conclusion, [2 × 2] Co^{II}_4 grid-type complexes on HOPG substrates were imaged using STM with submolecular resolution. At very low coverage, the molecules were shown to align preferably with the step edges of the HOPG surface. The size of the molecules observed is in agreement with the data determined by X-ray crystallography. STS measurements at room temperature allowed us to address directly the metal centers of the supramolecular architectures at the expected locations and in agreement with DFT calculations. It is to be expected that single-molecule spectroscopic techniques such as CITS, together with break junction techniques[25] or spin-polarized STM,[26] might constitute a significant part of the future tool kit needed for achieving the directed construction and controlled manipulation of fully electronically functional molecular designs.

Experimental Section

STM measurements: All measurements were carried out with a homebuilt low-drift STM head equipped with commercially available low-current-control electronics (RHK technology) under ambient conditions. For high-resolution STM studies a HOPG substrate was freshly cleaved. Afterwards, the substrate was imaged by STM to characterize the tip resolution. We calibrated distances in the STM images by observing atomic spacing on highly oriented pyrolytic graphite (HOPG). After imaging the graphite surface successfully, we deposited a droplet of a solution of the molecule under study and let the droplet run down the graphite surface. Concentrations were around 10^{-9} M. Typically for the STM measurements, tunneling currents between 5 and 200 pA were employed. The bias voltage was between ±50 and ±500 mV. The scan frequency was varied between 2 and 5 Hz. Resolution was 256 × 256 points for topography, and 128 × 128 in the STS measurements. In STS mode, current–voltage (*I–V*) curves were recorded simultaneously with a constant-current STM image with the interrupted-feedback loop technique. The scan range of voltages was typically from −1.5 to 0.1 V relative to the tip potential. Typically, tunneling resistances of the order of 1 GΩ were set. We used mechanically cut Pt–Ir (90:10) tips from wires with a diameter of 0.25 mm. Figures 2, 3a, b, 4, and 5 were produced using the program WSxM (Nanotec Electrónica, Madrid). The molecule $[Co^{II}_4L_4](BF_4)_8$ was synthesized as described previously.[7]

DFT calculations: The first-principles density functional theory (DFT) calculations have been carried out using the Naval Research Laboratory Molecular Orbital Library (NRLMOL) program package, which is an all-electron implementation of DFT. NRLMOL combines large Gaussian orbital basis sets, numerically precise variational integration, and an analytic solution of Poisson's equation in order to accurately determine the self-consistent potentials, secular matrix, total energies, and Hellmann–Feynman–Pulay forces.[27] Starting from the X-ray structure, we generated an isolated single Co [2 × 2] grid molecule without counterions for the calculation. This resulted in a cluster of 228 atoms used for the DFT calculation. To reduce the numerical cost we used a D_2 symmetry found in the isolated cluster. The basis set for each Co contained 11 s-like, 5 p-like, and 4 d-like contracted Gaussian orbitals with 20 exponents ranging from 0.048 to 4.2×10^6. Nitrogen and carbon had the same number of contracted orbitals (8 s, 4 p, and 3 d), with 13 bare Gaussians between 0.094 and 5.17×10^4 for N and 12 bare Gaussians between 0.077 and

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

2.22×10^4 for C. Finally, hydrogen had 6 s-like, 3 p-like, and 1 d-like orbital with six exponents between 0.074 and 77.84. For all orbitals not corresponding to an atomic orbital we used the longest ranged single Gaussians. This basis set resulted in a total number of 3372 orbitals for each symmetry representation of the complete cluster. The calculations have been carried out for the charged 8+ state using the generalized gradient approximation of Perdew, Burke, and Ernzerhof[28] to the exchange and correlation functional. The self-consistent charge density was obtained from a spin-polarized calculation with antiferromagnetic order of the Co ions on a dense real-space grid. The figure corresponds to a cut plane parallel to the Co atoms at a distance of 7 Å.

The Photochemistry of *o*-Nitrobenzaldehyde as Seen by Femtosecond Vibrational Spectroscopy**

*Stefan Laimgruber, Wolfgang J. Schreier, Tobias Schrader, Florian Koller, Wolfgang Zinth, and Peter Gilch**

Owing to their rich photochemistry, aromatic nitro compounds find applications wherever temporal and spatial control of chemical and biological activity is desired. The production of DNA chips relies on such compounds as photolabile protecting groups.[1] Composites of aromatic nitro compounds and bioactive molecules are used in experiments on photoactivatable ("caged") compounds.[2] Mechanistic studies of these reactions point to an initial hydrogen transfer from a residue situated in *ortho* position to the nitro group.[3] Secondary processes at the residue then lead to a bond fission which releases the molecule of interest. In the present study we supply firm experimental data on the mechanism of one of these reactions, the photochemical transformation of *o*-nitrobenzaldehyde (NBA) to *o*-nitrosobenzoic acid or the corresponding ester.

This intramolecular redox reaction first described by Ciamician and Silber in 1901[4] proceeds with a quantum yield of 50% nearly irrespective of the solvent properties.[5] It has been addressed twice by time-resolved techniques. In 1980 George and Scaiano[5] used laser flash photolysis with a time resolution of some nanoseconds and found transients with solvent-dependent lifetimes ranging from 50 ns to $\lesssim$ 1 ns. They associated these transients with the triplet state of NBA. A pump–probe experiment with a time resolution of 35 ps reported by Yip and Sharma[6] in 1989 revealed a transient with a lifetime of 74 ps for NBA in aqueous acetonitrile. Based on the strong solvent dependence and the observed spectroscopic signature, they argued that the transient should be assigned to a ketene intermediate and not to a triplet state. We here re-address this reaction with modern femtosecond (vibrational) spectroscopy. Thereby, we not only profit from an improved time resolution but also use the distinct features of vibrational spectroscopy to identify intermediates. Based on these results we will give clear-cut evidence for the involvement of the ketene intermediate and describe its formation dynamics and its transformation into further intermediates.

In the present experiments solutions of NBA were excited with laser pulses of 100–200 fs centered at a wavelength of approximately 260 nm, whereby the photoreaction is initiated. The spectral changes induced by this excitation were probed by three detection schemes: transient Vis absorption, transient IR, and (stimulated) Raman spectroscopy. The particulars of the IR experiment can be found in reference [7], the other techniques use well-known principles.[8–10] Details will be presented in a forthcoming publication. Since in alcoholic solution NBA is transformed into the respective hemiacetals on the timescale of a few hours,[11] sample solutions were always freshly prepared immediately before the measurements.

Transient Vis spectroscopy is best suited to study the kinetics of the process. Optical excitation of NBA results in an induced absorption centered around 500 nm which rises within the instrumental response time ($\approx$200 fs). This absorption evolves on multiple timescales (Figure 1a). A global analysis of the data affords three kinetic components with time constants of 0.4 ps (± 20%), 90 ps (± 30%), and 3 ns$^{+65\%}_{-35\%}$. Adding water reduces the second time constant, which goes down to 13 ps for ethanol/water 1:1 (v/v) (Figure 1b). The other time constants are virtually unaffected. As optical excitation results in the population of an excited singlet state, the 0.4-ps component must be associated

with the depletion of the excited state. The spectral signature of the 90-ps (in ethanol) component resembles that reported for a ketene intermediate (structure given in Scheme 1) obtained by matrix isolation spectroscopy.[12] This similarity and the water dependence suggest that the first intermediate is a ketene. However, as inspection of Figure 1a shows, the absorption signatures are not that discriminative, and intermediates that might respond to the water content are numerous.

Transient IR spectroscopy may deliver clear-cut evidence for the presence of a ketene intermediate. Ketenes feature a strong and very characteristic IR resonance centered around 2100 cm^{-1},[13] which is due to the stretching vibration of the ketene group. Matrix isolation spectroscopy of the ketene form of NBA delivers a resonance peaking at 2118 cm^{-1} for this vibration.[12] Upon 267-nm excitation of NBA a transient IR signal in the 2100-cm^{-1} range is observed (Figure 2). A

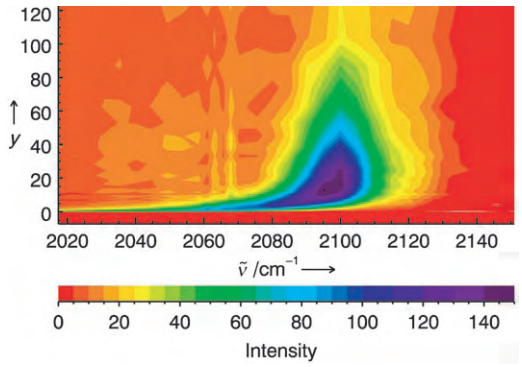

Figure 2. Contour representation of transient IR absorption of NBA in ethanol after excitation with 267-nm laser pulses. *y*: Delay time *t* in ps.

transient IR band rises rapidly within ≈400 fs. Immediately after its appearance the band peaks at 2040 cm^{-1} and then experiences a frequency up-shift to 2100 cm^{-1} proceeding with a characteristic time of ≈10 ps. Following that shift the signal decays with a time constant of 60 ps (± 20%), which is close to the time constant of 90 ps (± 30%) derived from the Vis experiment. Thus, in the course of the photorearrangement of NBA the ketene intermediate is formed within 0.4 ps. A frequency shift of an IR resonance is a marker for vibrational excitation (see, for example, reference [7]). The relaxation of this shift thus represents the vibrational cooling of the nascent ketene intermediate.

The ketene then reacts with a time constant of 60–90 ps. The presence of a further kinetic component in the Vis experiments (3 ns) indicates that the product of this reaction is *not* the final nitroso form but a second intermediate. The strong solvent dependence of the ketene lifetime (Figure 1b and reference [6]) could be interpreted as a signature for a reaction of the solvent and the ketene. The product of such a reaction could be a solvent adduct. Several tautomeric forms of this adduct are conceivable (referred to as **A**–**C** in Scheme 1). One suggested form, an enol tautomer (**A**),[5] would result from a formal addition of an ethanol to the C=O bond of the ketene. From a formal addition to the C=C bond (at least) two potential adduct forms may result (tautomers **B** and **C**). The solvent could also act catalytically promoting an intramolecular addition to the ketene function. The intramolecular reaction could also proceed by means of a C=C or a C=O addition. One potential product of a C=C addition is the lactone **D**. The IR experiments give a first indication for an addition to the C=C bond: In the spectral region of carbonyl stretching vibrations around 1700 cm^{-1} we observe the rise of an IR band (data not shown) concomitant with the decay of ketene. The second intermediate thus seems to bear a carbonyl group as contained in the ester function of the forms **B**, **C**, and **D**. A nonambiguous distinction between these forms based on the present IR data alone is not possible. Further information might be supplied by Raman spectroscopy.

Femtosecond stimulated Raman spectroscopy allows the recording of transient and stationary Raman spectra with a tremendous improvement in signal-to-noise ratio over that of conventional Raman spectroscopy.[8–10] The stationary stimulated Raman spectrum of the NBA sample is depicted in Figure 3, upper part. In these experiments the Raman pump

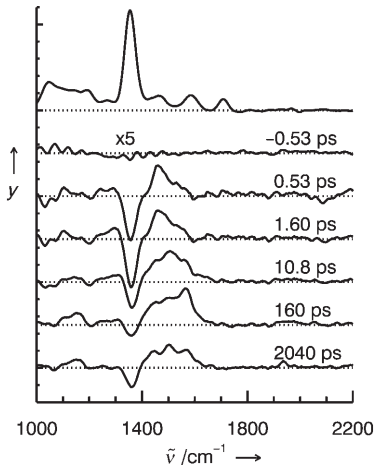

Figure 3. Steady-state and time-resolved stimulated Raman spectra of NBA in ethanol. *y*: Raman intensity *I* and change in Raman intensity Δ*I*. The uppermost trace is the spectrum of NBA (with the solvent contribution subtracted). The traces below are difference Raman spectra at the delay times given in the figure.

pulse had a wavelength of 388 nm, thereby fulfilling a (pre-) resonance condition for NBA and its products. The Raman spectrum of NBA is dominated by a strong peak at 1360 cm^{-1} due to the symmetric stretching vibration of the nitro group.[14] Upon photoexcitation at 260 nm this band experiences bleaching and adjacent to it new Raman resonances emerge (Figure 3, lower part). The bleaching is caused by the decrease of the concentration of ground-state NBA due to the photoexcitation. In the course of the reaction it partially recovers since the quantum yield of the reaction is only 50%

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

(see above). The emerging new bands are Raman resonances of intermediates. Strong resonances can be found between 1400 and 1700 cm^{-1}—a range characteristic for C=C and C=N stretching vibrations.[14]

To extract structural information from these Raman resonances, we compared them with results of DFT calculations (B3LYP, 6-311G** as implemented in Gaussian 98[15]). The spectra were calculated for geometry-optimized structures. In the case of NBA the initial geometry was based on a X-ray structure.[16,17] As the calculations do not include anharmonicities, solvent effects, and resonance Raman enhancements, only a *qualitative* agreement between experimental and calculated spectra is expected. Still, considering these shortcomings, the calculated spectrum of NBA rather nicely reproduces the experimental features (Figure 4, trace 1). For instance, the symmetric NO_2 stretching mode around 1350 cm^{-1} dominates both spectra, there is a close match of resonance frequencies, and the intensities agree qualitatively. This gives some confidence that this comparison may be used to draw conclusions on structures of intermediates. The experiment yields difference spectra of intermediates, whereas the output of calculations are absolute spectra. Prior to the comparison, the experimental spectra were therefore transformed into absolute spectra by correcting for the NBA bleaching. At a delay time of 10 ps the dominant intermediate is the (vibrationally relaxed) ketene form. The experimental spectrum at that instant (Figure 4, trace 2) is indeed in qualitative agreement with the calculated spectrum of the ketene intermediate. The DFT calculation tells us that the highest peak in the Raman spectrum is due to the *cis*-butadiene motif in the ketene intermediate. This type of vibration is also present on *o*-quinones and is known to have strong Raman intensities (see, for example, reference [18]). Thus, the presence of a strong resonance in that region of the spectrum recorded at a delay time of 160 ps is very telling.

Of the proposed structures (**A**–**D** in Scheme 1) for the second intermediate, we include only **B**–**D** in our comparison since IR spectroscopy rules out structure **A**. Among structures **B**–**D** the form **B** stands out as it contains an aromatic ring and not a *cis*-butadiene motif. The spectrum of form **B** (green dotted line in Figure 4, trace 3) shows the largest deviation from the experimental spectrum. For instance, it features strong bands at 1200 and 1670 cm^{-1} which are absent in the experimental spectrum. The agreement between forms **C** and **D** and the experiment—though not quantitative—is much better. The calculated spectra of **C** and **D** are so similar that a distinction between the two is not yet possible. Clearly, the data favor *cis*-butadiene-like structures (**C** and **D**) over aromatic ones (**B**). The second intermediate then supposedly transforms to the final nitroso product within $\approx$3 ns. The adduct **C** is expected to form the nitroso ester, whereas the lactone **D** should yield the acid. Both products are compatible with our spectroscopic results (Figure 4, trace 4).

Let us now summarize our spectroscopic findings and combine them with prior results to arrive at a comprehensive picture of the photoredox reaction of NBA (see Scheme 1). The photoexcited (singlet) state of

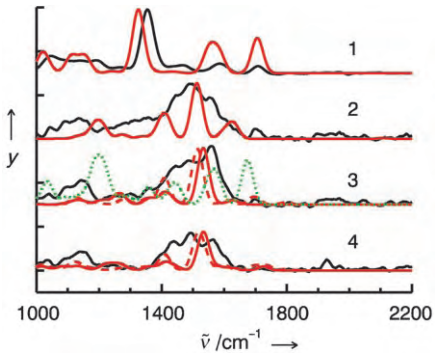

Figure 4. Experimental stimulated Raman spectra (black) in comparison with computed spectra (in color). y: Raman intensity *I*. The frequency axis for the computed spectra was scaled by 0.96,[22] the linewidths were adjusted to the experimental resolution, and the depolarization ratio was accounted for. 1: Steady-state spectra of NBA. 2–4: Experimental transient spectra (obtained by adding a properly scaled NBA spectrum to the difference spectra from Figure 3) are overlaid with computed spectra of suggested intermediates. 2: Ketene intermediate vs. 10-ps spectrum. 3: Second intermediate (structures **B** (green), **C** (red), **D** (red, dashed)) vs. 160-ps spectrum. 4: Nitroso ester product + structure **C** (red) and nitroso acid product + structure **D** (red, dashed) vs. 2-ns spectrum. Note that at 2 ns the product formation is not terminated and a mixture of the second intermediate and the final product has to be compared with the experimental spectrum.

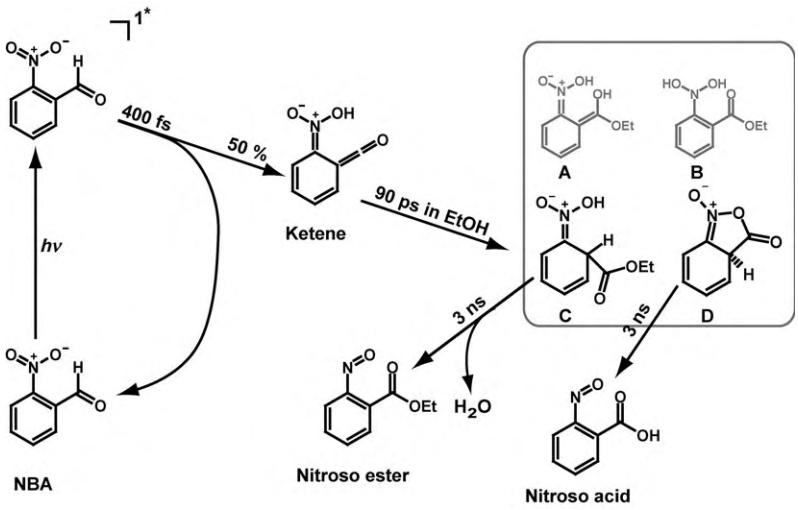
NBA is depopulated with a time constant of 400 fs. The product formed thereby is a ketene, which results from the transfer of a hydrogen atom from the aldehyde group to the nitro group. Comparison of the visible and IR femtosecond transients with matrix isolation experiments unequivocally shows that the ketene is formed in its electronic ground state. Furthermore, a biradical form often discussed[5,19] is not involved or if so its lifetime is considerably shorter than 400 fs. The transformation of NBA to the ketene intermediate calls for a considerable reorganization of the molecular



Scheme 1. Time constants and suggested intermediates of the photoredox reaction of NBA. The structures **C** and **D** and their reactions are compatible with our spectroscopic data.

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

structure. For instance, the C–O distance in the aldehyde is 1.208 Å, whereas it is 1.156 Å in the ketene (values from the DFT structures). This reorganization results in a high vibrational excitation of the stretching mode of the nascent ketene. That excitation is clearly seen in the IR experiment as an initial decrease of the ketene resonance frequency. As the ketene relaxes vibrationally, the resonance moves to its (higher) equilibrium value—a process which here takes about 10 ps. In the next step the ketene undergoes an addition reaction. The rate constant of this process depends on the nature of the solvent. In pure ethanol the reaction takes about 90 ps (± 30 %) and yields a second intermediate. The second intermediate results most likely from an addition to the C=C bond of the ketene. The addition of an ethanol solvent molecule as well as an intramolecular addition are in line with the present spectroscopic results. In either case, the most probable addition product bears an ester function and a *cis*-butadiene motif. During the last (3-ns) step the aromaticity of the phenyl ring is reestablished and the nitroso product formed. It has been found that NBA in ethanol photoreacts to give the nitroso ester.[4] This seems to point to the intermolecular reaction via the adduct form **C**. Yet, this product identification is based on a continuous-wave irradiation experiment. During the time it takes to phototransform the sample, NBA might also thermally react to give the hemiacetal. This is known to photoreact to give the nitroso ester.[21] Thus, a final decision cannot be based on the nature of the product.

Relying on our data, we will now address the quantum yield of the reaction. The quantum yield for the formation of the nitroso product is close to 50 % irrespective of the solvent.[5] As the lifetime of the ketene intermediate strongly depends on the solvent (13 ps in a 1:1 ethanol/water mixture and 24 ns in acetonitrile[6]), it can be excluded that the ketene intermediate is partially reconverted to the NBA starting material—otherwise the quantum yield would be strongly solvent dependent. So either the ground state is replenished during the decay of the electronically excited state or the adduct not only forms the nitroso product but also regenerates the starting material. The latter possibility can be excluded again on the grounds of the solvent independence of the overall quantum yield. Even in solvents like benzene where no addition product can be formed the quantum yield is $\approx$50 %. Thus, the branching must occur during an earlier stage—the decay of the electronically excited state. This decay is promoted by the motion of the hydrogen atom from the aldehyde moiety to the nitro group. The motion brings the ground- and excited-state surfaces in energetic vicinity and internal conversion takes place. Thereby, the ketene intermediate is formed and the ground state is partially recovered. Once formed, the ketene reacts to give the nitroso product with a high yield of $\approx$100 %.

The photoredox reaction of NBA was first described more than 100 years ago, and its study marked the beginning of modern photochemistry.[20] Previous experiments on its mechanism were limited by the time resolutions and the spectroscopic techniques used. Now with femtosecond experiments, particularly femtosecond vibrational spectroscopy, we can map out an "evidenced-based" mechanism based on a ketene intermediate for this reaction. It is foreseeable that this approach will shed light on the mechanisms of many other photoreactions.

On the Chemistry of Gold in Silicate Glasses: Studies on a Nonthermally Activated Growth of Gold Nanoparticles**

Maik Eichelbaum, Klaus Rademann, Ralf Müller, Martin Radtke, Heinrich Riesemeier, and Wolf Görner*

The history of gold-ruby glasses goes back to the Roman Empire. However, the first known written report about the manufacturing of these glasses was published in 1689 by the German pharmacist and alchemist Johannes Kunckel.[1] Colorless glasses containing the "magic" noble metal gold become characteristically ruby-colored after annealing because of the formation of gold colloids. The absorption of light is caused by an excitation of a collective oscillation of gold valence electrons. The quantum of this plasma oscillation is called the surface plasmon.[2] The surface plasmon resonance frequency mainly depends on the size, shape, topology, and dielectric environment of metal clusters.[3] By changing these parameters it should be possible to create materials that can be used in nanophotonic devices. A large nonlinear optical response with a fast response time is needed for applications in the field of optical computing. Plasmonic materials are exceptionally promising candidates for ultrafast optical switches and modulators because of their large third-order nonlinear susceptibility $\chi^{(3)}$. A second advantage is a response time in the range of picoseconds, which would therefore enable processors with terahertz frequencies.[4]

Another challenging problem is the chemical and mechanical stability of these materials. Gold clusters in glass matrices exhibit the extended stability required for the fabrication of nanodimensional optoelectronic circuits and optical memory with ultrahigh recording speed and storage density. With synchrotron radiation it is already possible to create very small devices, circuits, and even miniaturized lasers by UV and X-ray lithography. We have now succeeded in the spatial synthesis of gold nanoparticles of defined size and with a sharp size distribution by activation of gold silicate glasses with synchrotron radiation and subsequent heating of the samples. Understanding the chemical and physical processes of cluster formation is fundamental for the directed modification of the size, shape, and topology of gold clusters and hence for the creation of structures with a specific functionality. Therefore we have studied the activation caused by the reduction of gold ions to atoms as well as the nucleation and the growth of the gold nanoparticles in gold silicate glasses by UV/Vis spectroscopy, X-ray absorption near-edge spectroscopy (XANES), transmission electron microscopy (TEM), and high-resolution transmission electron microscopy (HRTEM).

Soda–lime–silicate glasses were doped with 0.02 mol% $AuCl_3$ by melting the component materials at 1450 °C. Selected samples were irradiated with a photon flux density of 10^{12} photons $mm^{-2}s^{-1}$ on a defined area with hard X-ray radiation (32 keV) for 300 s in the Berlin electron storage ring (BESSY II).[5] During this irradiation the activated area turned brownish (Figure 1a). Maxima at 315, 440, and 620 nm can be identified in the extinction spectrum of the activated sample (Figure 2, curve b). These peaks can be assigned to defect centers in the SiO_2 framework.

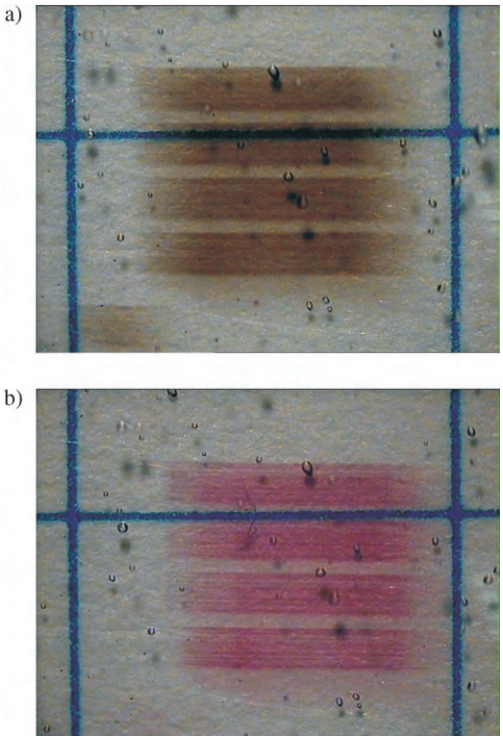

Figure 1. Light-microscopy images of a gold silicate glass after activation with 32-keV synchrotron radiation a) before thermal annealing, b) after annealing at 550 °C for 30 min. The pattern consists of spots with a size of 0.5×1.0 mm^2. The distance between the lines of the blue grid is 5 mm.

In general, the absorption at 315 nm in soda–lime–silicate glasses is caused by holes trapped in oxygen vacancies that neighbor alkali-metal ions (E′ centers).[6] This extinction is obviously much stronger in gold-doped samples than in undoped ones (Figure 2, curve a). Antonietti et al. recently reported TD-DFT (time-dependent density functional theory) cluster model calculations of optical transitions in

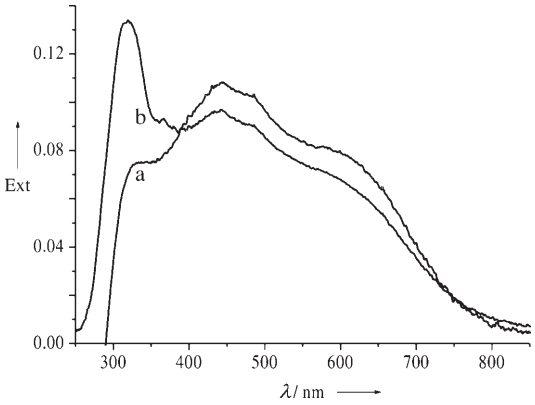

Figure 2. Extinction spectra of silicate glasses activated with 32-keV synchrotron radiation. a) Undoped glass sample; b) Au^{III}-doped (0.02 mol%) glass sample.

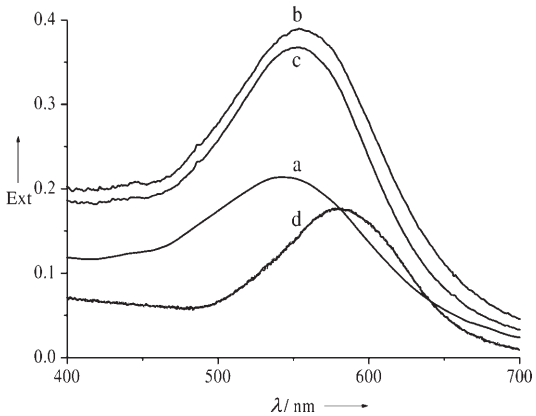

Figure 3. Extinction spectra of gold silicate glasses after activation with synchrotron radiation and subsequent annealing for a) 45 min at 550 °C, b) 45 min at 590 °C, and c) 15 min at 630 °C. d) Spectrum after only annealing for 240 min at 590 °C.

gold atoms bound to silicate defect centers.[7] The highest calculated oscillator strength of possible gold–defect bonds is predicted at 4.02 eV (308 nm) for gold atoms bound to E′ centers. Therefore the peak at 315 nm in the experimental spectrum could be assigned to gold atoms that were generated by activating the glass sample with X-rays.

Peaks at 440 and 620 nm can be attributed to the NBO (nonbridging oxygen) centers HC_1 and HC_2 (holes trapped in SiO_4 tetrahedrons with three or two nonbridging oxygen atoms, respectively).[6] These extinction maxima do not differ very much in doped and undoped samples (Figure 2). The irradiated glasses were subsequently annealed in a muffle furnace. After 10 min of thermal treatment at 450 °C the glasses became colorless again. Apparently the color centers consisting of electrons and holes recombine and their absorption vanishes. When the glass samples were annealed at a higher temperature of 550 °C, the color of the activated array changed to red within 30 min (Figure 1 b).

The red color corresponds to a peak at 540 nm in the extinction spectrum. This extinction can be attributed to the surface plasmon resonance (SPR) of gold nanoparticles.[2,8] When the activated gold silicate glass was annealed for 45 min at 550 °C instead of for 30 min, the extinction peak shifted to 549 nm (Figure 3, curve a). A remarkable red shift of the SPR with increasing duration of thermal treatment was also observed when samples were annealed at 590 °C (SPR peak after 10 min at 547 nm and after 45 min at 556 nm) and 630 °C (SPR peak after 5 min at 547 nm and after 15 min at 554 nm) (Figure 3, curves b and c, respectively).

The optical properties of spherical metal clusters can be described with the Mie theory using the complex dielectric function $\varepsilon^{\text{sphere}} = \varepsilon_1^{\text{sphere}} + i\,\varepsilon_2^{\text{sphere}}$ of the metal and the refraction index of the matrix material n_m.[2,9] For clusters with radii between 1 and 10 nm the extinction Ext can be formulated within a quasi-static approximation under the exclusive consideration of dipolaric excitations [Eq. (1)].[2] Fitting to

$$\text{Ext} = (\lg e)\, C\, d \frac{18\pi n_m^3}{\lambda} \frac{\varepsilon_2^{\text{sphere}}}{(\varepsilon_1^{\text{sphere}} + 2\,n_m^2)^2 + (\varepsilon_2^{\text{sphere}})^2} \quad (1)$$

the height of the extinction maximum in the experimental spectrum is achieved by varying the filling factor C. The refraction index of the glass matrix n_m is 1.52 and the thickness of the sample d is 1.00 mm.

The dielectric function of a metallic sphere $\varepsilon^{\text{sphere}}$ can be calculated from the dielectric function of the bulk material $\varepsilon^{\text{bulk}}$, if one considers its dependence on the sphere radius R caused by the effect of the limited mean free path of electrons ℓ_∞ as described by Equations (2) and (3).[2] Values for $\varepsilon_1^{\text{bulk}}$ and

$$\varepsilon_1^{\text{sphere}}(\omega,R) = \varepsilon_1^{\text{bulk}}(\omega) + \omega_p^2\left(\frac{1}{\omega^2+\Gamma_\infty^2} - \frac{1}{\omega^2+\Gamma(R)^2}\right) \quad (2)$$

$$\varepsilon_2^{\text{sphere}}(\omega,R) = \varepsilon_2^{\text{bulk}}(\omega) + \frac{\omega_p^2}{\omega}\left(\frac{\Gamma(R)}{\omega^2+\Gamma(R)^2} - \frac{\Gamma_\infty}{\omega^2+\Gamma_\infty^2}\right) \quad (3)$$

$\varepsilon_2^{\text{bulk}}$ were taken from ref. [10]. The Drude plasma frequency ω_p of gold is $1.37\times10^{16}\ \text{s}^{-1}$ and the halfwidth $\Gamma(R)$ is given by Equation (4) with the Fermi velocity being $\upsilon_{\text{Fermi}} = 1.40\times$

$$\Gamma(R) = \Gamma_\infty + \frac{\upsilon_{\text{Fermi}}}{R} = \frac{\upsilon_{\text{Fermi}}}{\ell_\infty} + \frac{\upsilon_{\text{Fermi}}}{R} \quad (4)$$

$10^6\ \text{m s}^{-1}$ and the mean free path of electrons being $\ell_\infty =$ 42 nm.

Transmission electron microscopy (TEM) was used to determine the mean cluster radius R of the gold nanoparticles in two samples to be 3.2 ± 0.9 nm (sample had been activated and annealed for 45 min at 550 °C) and 6.2 ± 1.5 nm (sample had been activated and annealed for 15 min at 630 °C). The shape of the curve and the halfwidth of SPR in the experimental UV/Vis spectra are very well described by calculating the extinction spectra for gold spheres with radii of 3.2 and 6.2 nm, respectively (Figure 4). The red shift of SPR with increasing cluster size cannot be explained with Mie theory for radii between 1 and 10 nm. Only for remarkably larger nanoparticles should red shifts and broadening of SPR caused by retardation effects be expected.[2,8a]

Equation (1) is valid only for spherical clusters. For the investigation of the shape of the gold particles, HRTEM images of the gold glass samples were made (Figure 5 a,b).

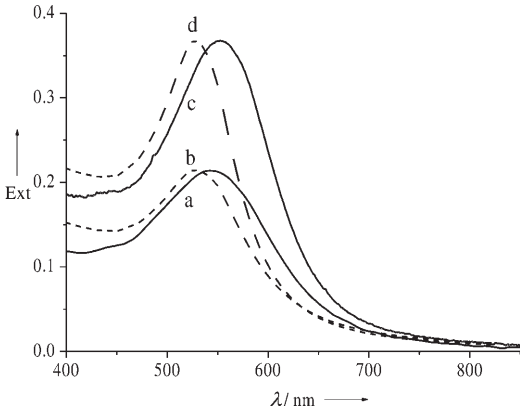

Figure 4. Experimental (solid lines) and calculated extinction spectra (dashed lines) of gold clusters in silicate glasses. a) Spectrum measured for a gold silicate glass that was activated with synchrotron radiation activated and subsequently annealed for 45 min at 550°C; b) spectrum calculated for gold spheres with $R = 3.2$ nm; c) spectrum measured for a gold silicate glass that was activated with synchrotron radiation and subsequently annealed for 15 min at 630°C; d) spectrum calculated for gold spheres with $R = 6.2$ nm.

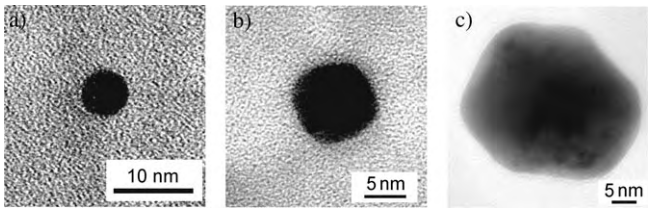

Figure 5. HRTEM images of characteristic gold clusters in gold silicate glasses. Samples were activated with synchrotron radiation and subsequently annealed for a) 45 min at 550°C and b) for 15 min at 630°. c) Sample was only annealed (240 min at 590°C).

Thus it appears that the shape of nanoparticles is approximately spherical. When the glasses were not activated by synchrotron radiation, a violet stain could be observed only after they had been annealed for 60 min at 590°C. The maximum of the observed SPR in the extinction spectrum was shifted from 574 nm (after annealing for 60 min) to 580 nm (after annealing for 240 min) (Figure 3, curve d). TEM images give a mean cluster radius of 27 ± 3 nm, and HRTEM images indicate a distinct deviation of particle shape from an ideal spherical symmetry (Figure 5c).

In 1951 Weyl tried to explain the violet stain of gold-ruby glasses after defined thermal treatment by a nonspherical shape of gold colloids. Thus the typical ruby color would be observed only for spherical particles.[1b] Experiments conducted by Doremus et al. confirm that the effect of particle size on the SPR frequency is marginal.[8c] They examined the growth of gold nanoparticles with radii between 3 and 6 nm in borosilicate glass and found a SPR wavelength of 525 nm. This value, which was independent of cluster size, is also in agreement with our calculations.

As a result of long annealing times of up to 150 h and the low diffusion constant in borosilicate glasses one can assume that the spherical nanoparticles are formed by a very slow growth process. Therefore red shifts of SPR observed in our samples could be explained by an increasing deviation of gold clusters from spherical shape. Studies on noble-metal ellipsoids in glass matrices would also confirm this thesis because of the observation of a red shift of SPR with increasing aspect ratio (and consequently an increasing deviation of spherical shape).[3] This property of our gold silicate glasses is very interesting because a shift of SPR can be achieved in unexpectedly small clusters within a very short period of time only by changing the annealing temperature and thus the optical properties can be modified very easily.

In activated glasses cluster growth occurs at a lower temperature and within a shorter period of time than in nonactivated samples. Light microscopy and TEM images show that the distribution of gold nanoparticles is more homogenous and cluster density is much higher than in exclusively annealed gold glasses. An explanation therefore could be that the activation with synchrotron radiation leads through a reductive process to a very high density of gold atoms, which can diffuse much easier through the glass matrix than bound, oxidized gold species. Thereby an effective cluster growth is facilitated when the samples are annealed at a temperature near the glass transformation temperature.

The chemistry of gold in glass is so far a mystery. The only certainty is that the glass compounds are doped with gold(III) before the melting process starts. Assumptions of the oxidation state in the resulting glass are contradictory. However, recent experiments come to the conclusion that the noble metal is mainly in cationic form before either annealing or activation.[11] Furthermore, one must assume that the gold cations undergo reduction to produce the coloring gold colloids.[2,8b–d]

We used Au L_{III}-edge XANES spectroscopy to study the effect of synchrotron radiation on the oxidation state. XANES spectroscopy is a reliable method for determining oxidation states and is also an established method for the qualitative analysis of gold nanoparticles.[12] In our studies a gold film with a thickness of 40 nm on silica glass, gold(I) cyanide, and gold(III) oxide were used as reference materials. Cationic gold standards show distinct white lines (caused by transitions of 2p electrons into vacant 5d states) at 11922 eV (Au^{III}) and 11926 eV (Au^{I}) and can be clearly distinguished from Au^0 samples, whose spectra do not show any white lines. A XANES spectrum was recorded for the activated area of a gold silicate glass. If the oxidation values $\pm$0, +I, and/or +III of gold exist in the sample, its spectrum should be composed additively of the reference spectra. Therefore the spectra of the gold film and gold(III) oxide were added in different proportions (Figure 6), and the L_{III} edges of the gold film and gold silicate glass were found to match up almost exactly. The white line at 11922 eV in the glass spectrum also indicates a minor fraction of gold(III).

XANES spectra of glass samples were furthermore compared with spectra obtained by combination of oxidation values $\pm$ 0 and +I (Figure 7). It is remarkable that the white line of AuCN at 11926 eV differs clearly from the white line of the activated glass sample. Indeed one cannot exclude a significant influence of ligands in the vicinity of Au^{I} on the XANES spectrum. This effect should be clarified by inves-

tigating further reference materials especially compounds with linearly coordinated oxygen ligands (e.g. CsAuO) as they would be expected in glass.

Although XANES measurements were conducted with photon flux densities (10^{10} photons $mm^{-2} s^{-1}$) well below activating densities (10^{12} photons $mm^{-2} s^{-1}$), occurrence of color centers could be observed in nonactivated samples, too, as a result of long measurement times. Hence it is not possible to get information about the oxidation state before synchrotron irradiation. In future work fast XANES spectroscopy must be used, because this method would provide a determination of oxidation values in a very short period.

In conclusion, activation of gold silicate glasses with synchrotron radiation allows spatial reduction of cationic gold. By subsequent annealing, gold clusters with a sharp size distribution can be synthesized within a short period of time. With increasing cluster size a red shift of surface plasmon resonance is observed in the extinction spectra. This effect can be explained by the increasing deviation from spherical symmetry with the increase in gold cluster size. Au L_{III}-edge XANES spectra of activated gold silicate glasses can be described best by a combination of the spectra of a gold film and an Au_2O_3 reference. This indicates that cationic gold species were found at least as minor compounds in the glass samples investigated. Because of the short wavelength used it should be possible to create nanostructures in glasses with X-ray lithography. This could provide an opportunity for developing nanophotonic devices in glass matrices for opto-electronic circuits, whose surface plasmon resonance could be tuned over a wide range of wavelengths by changing the size and shape of the gold nanoparticles.[13]

Experimental Section

Glasses composed of 70 SiO_2·20 Na_2O·10 CaO (values in mol %) were doped with 0.02 mol % $AuCl_3$·2 H_2O. Reagent-grade SiO_2, Na_2CO_3, $CaCO_3$, and $AuCl_3$·2 H_2O were used as starting materials. Approximately 35-g batches were mixed and melted at 1450 °C for 90 min in an electric furnace. The glass melt was then slowly cooled down to room temperature and cut, and samples were polished to sizes of 10 × 10 × 1.00 mm^3.

Selected samples were irradiated ("activated") on an area of approximately 2.0 × 1.5 mm^2 with synchrotron radiation from BESSY II with 32 keV for 300 s. In the subsequent thermal treatment the glass samples were placed into a platinum crucible and annealed in a muffle furnace. XANES spectroscopy was also recorded at BESSY II. Au L_{III}-edge XANES spectra were acquired in fluorescence mode (detection at the Au L_α line at 9707 eV) between 11 900 eV and 11 960 eV with an increment of 1 eV. Peak integration was determined with the program QXAS 3.5. The background spectra was corrected by subtracting the absorption value at 11 900 eV and normalizing the value at 11 960 eV to unity. Extinction spectra were acquired with a StellarNet EPP2000C-50 spectrometer and a Mikropack DH-2000 deuterium/halogen light source. For the activated samples a nonactivated area of the same glass was defined as the reference, and its spectrum was subtracted from the extinction spectrum of the activated area. For exclusively thermally treated samples an untreated glass with the same composition was defined as the reference, and its spectrum was subtracted from the extinction spectrum.

TEM measurements were made at Fritz-Haber-Institut der Max-Planck-Gesellschaft in Berlin with the microscope Philips CM 200 LaB_6 operating at an acceleration voltage of 200 kV.

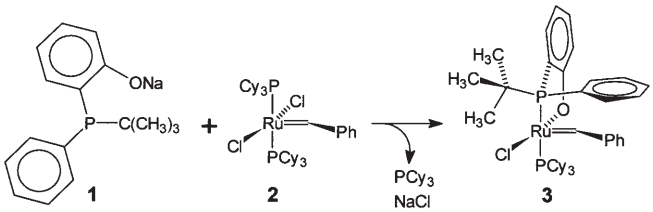
Mechanism-Based Design of a ROMP Catalyst for Sequence-Selective Copolymerization

*Marc Bornand and Peter Chen**

We report here the mechanism-based design of a ring-opening metathesis polymerization (ROMP)[1] catalyst which preferentially assembles a mixture of cyclooctene and norbornene into an alternating copolymer. While there have been reports of regular copolymerizations, highly selective examples are uncommon outside of free-radical polymerization, with the 1:1 alternating copolymers of ethylene and carbon monoxide,[2] or of epoxides and carbon dioxide,[3] being perhaps the most prominent examples. Given that the exemplary functional characteristics of biopolymers, for example, structural or catalytic functions in polypeptides, information storage and transmission in polynucleotides, and molecular recognition in polysaccharides, derive ultimately from sequence-selective copolymerization of simple monomer units, one can presume that synthetic polyolefins, as high-performance materials, would be substantially enhanced if even simple sequence-selective copolymerizations could be achieved routinely. Treating regular copolymerization more generally as a problem in metal-catalyzed organic synthesis, one sees that the issue is not stereoselectivity, or even regioselectivity. We seek to introduce into polymerization catalysts the element of chemoselectivity, which is the most basic kind of selectivity in organic synthesis. We encode the sequence information in the catalyst itself, and in this present study succeed in the most primitive, two-component, alternating sequence of ring-opening metathesis copolymerization.

Phosphine ligand **1** was prepared by sequential alkylation and arylation of phenyldichlorophosphine with *t*BuMgCl and *ortho*-methoxyphenyllithium, isolation by careful distillation, cleavage of the methyl ether by BBr_3, and then deprotonation with NaH. Reaction of one equivalent of **1** and $[(Cy_3P)_2RuCl_2(=CHPh)]$ (**2**, Scheme 1) resulted in phosphine exchange,



Scheme 1. Synthesis of the chemoselective ROMP catalyst **3**. Cy = cyclohexyl.

followed by elimination of NaCl. A similar approach has been reported by Hoveyda and co-workers for the preparation of a tethered, second-generation metathesis catalysts.[4] The resulting carbene complex **3** was purified by column chromatography under rigorous exclusion of oxygen, and checked by ^1H and ^{31}P NMR spectroscopy, as well as ESI-MS, to confirm that a single compound was prepared. Importantly, no other carbene species was present (analytical details and further information on the synthesis of **1** and **3** can be found in the Supporting Information). Polymerization of norbornene, cyclooctene, and mixtures thereof, together with 0.05 mol% catalyst, were conducted under dry N_2 at room temperature in either dichloromethane or cyclooctene as solvent. In experiments with cyclooctene as solvent, the norbornene is consumed quantitatively after 17 h. If a less-coordinating solvent, such as CH_2Cl_2, is used, then norbornene is consumed much more rapidly, with phenomenological rates comparable to those observed with catalyst **2** under the same conditions. The resulting polymer was isolated by removal of solvent at 0.01 mbar pressure until no further weight loss was seen. In copolymerizations with **3**, the weight of the dry polymer corresponded to the weight of norbornene, plus up to one equivalent of cyclooctene. The polymer samples were characterized by ^1H and ^{13}C NMR spectroscopy (Varian Gemini 300 MHz for ^1H, and 75.4 MHz for ^{13}C; $CDCl_3$) and gel

permeation chromatography (PL-GPC-220, 1,3,5-trichlorobenzene, 180 °C, PLgel 10 μm column) with refractive index and viscometry detection calibrated against polyethylene standards. Reference polymer samples were prepared analogously with $[(Cy_3P)_2RuCl_2(=CHPh)]$ (**2**) for comparison. The ^{13}C resonances were assigned with the help of group equivalents, which gave good predictions for the homopolymers. The relaxation time was set to $t_2 = 5$ s so that reliable integrations could be taken from the ^{13}C NMR spectra.

While the ordinary ruthenium carbene complex **2** polymerizes both norbornene and cyclooctene efficiently, complex **3** shows almost no reactivity with cyclooctene alone under the conditions of the experiment, but is nevertheless as active (qualitatively) as **2** in ROMP of norbornene. More interesting is the behavior with respect to copolymerization. Polymerization catalyzed by **3** in cyclooctene with various amounts of norbornene proceeds until the norbornene is exhausted and then stops, but the resultant polymer ($M_w \approx 10^6$, $M_w/M_n \approx 5$) contains increasingly long stretches of alternating copolymer as the ratio of norbornene to cyclooctene decreases. GPC analysis indicates that the polymer is not a physical mixture of the homopolymers of norbornene and cyclooctene. Both the viscosity and refractive index traces show a single, smooth, monomodal peak at the same retention time, which is significant because norbornene homopolymer would not appear in the latter trace, its refractive index being coincidentally the same as that of the 1,3,5-trichlorobenzene solvent. Moreover, the ^{13}C NMR spectra (Figure 1) of the homopolymers of norbornene and cyclooctene, as well as the copolymers with various ratios of the two monomers, demonstrate that alternate incorporation of cyclooctene and norbornene is preferred for complex **3** but not for ROMP catalyst **2**.

Catalyst **2** in norbornene/cyclooctene mixtures forms predominantly norbornene homopolymer until the norbornene is exhausted, and then proceeds to homopolymerize cyclooctene. As the norbornene is increasingly dilute, the ^{13}C NMR signals arising from its homopolymer disappear because of the increasing preponderance of cyclooctene polymer. Catalyst **3**, on the other hand, displays an increasing preference for the production of the alternating copolymer as the amount of norbornene, relative to cyclooctene, is decreased, with about two-thirds of the olefinic linkages in the copolymer comprising the alternating stretches in the best cases seen so far. Preliminary results for the negative control with a symmetrical analogue of **3** having two *tert*-butyl groups instead of one phenyl and one *tert*-butyl show that the symmetrical catalyst **4** (see Supporting Information for synthesis and characterization) homopolymerizes norbornene well and cyclooctene poorly. No alternating copolymer is formed in the negative control for mixtures of norbornene and cyclooctene.

The design concept for **3** derives from our earlier mechanistic work on olefin metathesis. Secondary deuterium isotope effects, measured in the gas phase, indicated that the structure of the rate-determining transition state for the metathesis reaction catalyzed by the first-generation ruthenium catalyst was a metallacyclobutane.[5] Computational work from our own research group,[6,7] as well as others,[8,9]

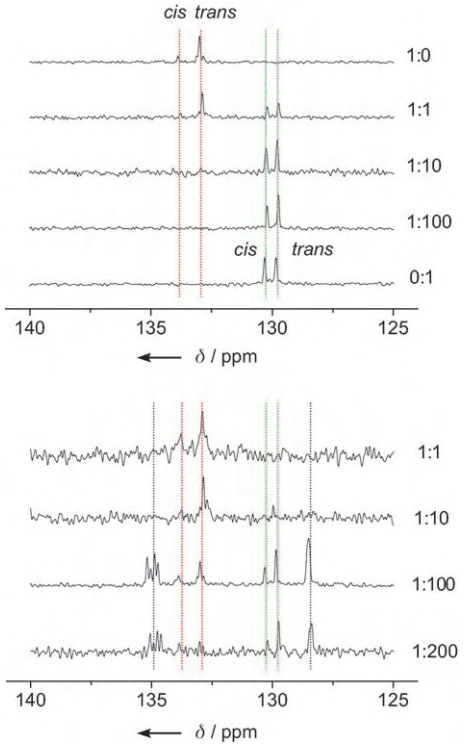

Figure 1. Olefinic regions of the ^{13}C NMR spectra of the polymer samples prepared from norbornene/cyclooctene mixtures at different mole ratios. The top spectra show results for catalyst **2**; spectra for catalyst **3** are at the bottom. The olefinic carbon resonances for the ring-opening metathesis polymer of norbornene are marked with red dotted lines, the resonances for the polymer from cyclooctene are marked in green. The black dotted lines mark the resonances for the alternating copolymer. There are at least two partially resolved signals in the high-field resonance, assigned to the end of the double bond derived from cyclooctene (*cis* and *trans*), whereas there are four signals in the low-field resonance, assigned to the end derived from norbornene. One presumes that, not only the *cis* and *trans* configuration of the double bond, but also the *cis* and *trans* configuration of the next double bond, causes the splitting.

however, found minima at the metallacyclobutane structure. Experimental observation of the olefin π complex by Snapper and co-workers[10] and a ruthenacyclobutane intermediate by Romero and Piers[11] supported the DFT calculations. In our computations, we did find, however, that the rate-determining transition step for olefin metathesis by **2** was a rotation of the tricyclohexylphosphine ligand in a metallacyclobutane structure,[6] which is in fact consistent with the isotope effect studies, the other computational work, and the solution-phase observations. For a degenerate metathesis reaction, the rotation is required by microscopic reversibility. If the rotation were, however, to be prevented, and, furthermore, the phosphine were to bear two different substituents, then the mechanism would require that the active site would swing back and forth with each productive metathesis step between two distinct states in a motion reminiscent of a windshield wiper. The two sites can be made sterically or electronically different enough so that chemoselectivity in an appropriate mixture of two substrates can be achieved. Scheme 2 depicts the catalytic cycle for ROMP of cycloalkenes by **3**. The carbene moiety in the propagating species can lie either on

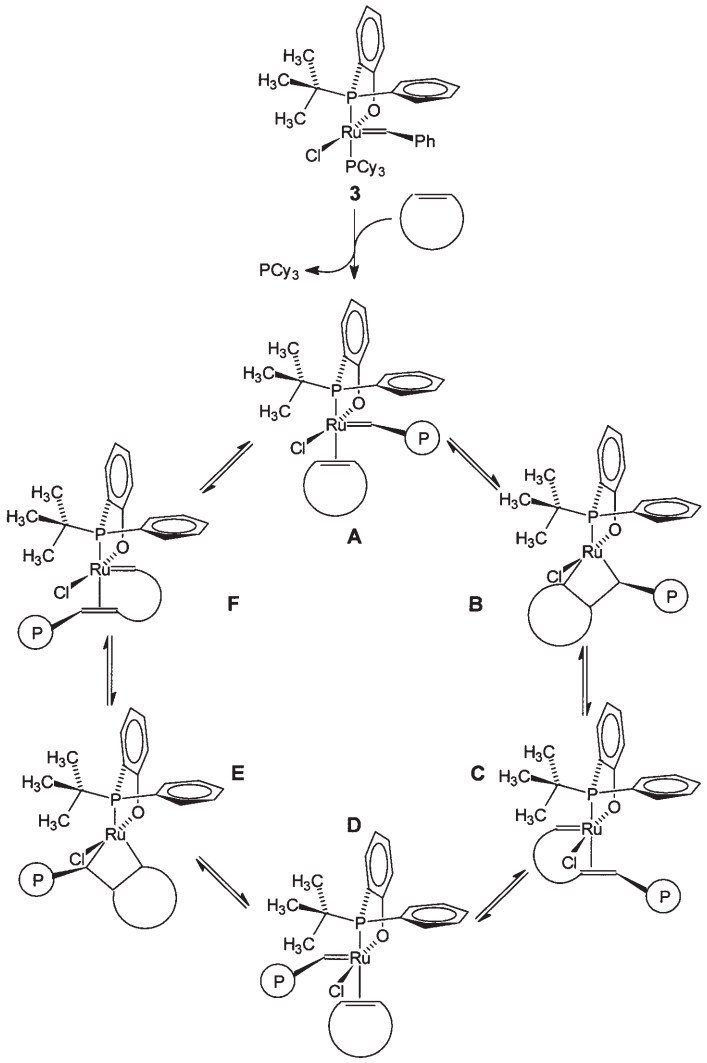

Scheme 2. Catalytic cycle for ROMP of cycloalkenes with catalyst **3**.

the right, as in species **A**, or on the left, as in species **D**. Molecular modeling studies indicate that **A** is much less sterically crowded than **D**, which breaks what would have been a degeneracy in the more usual case of a rotatable phosphine or a phosphine with at least two identical substituents.

If we consider the productive direction around the catalytic cycle for ROMP (**A**→**B**→**C**→**D**→**E**→**F**→**A**) with each step reversible, it would be expected that the forward reaction **A**→**B**→**C** would only occur if there is a large strain release in the **B**→**C** step so that the intermediate metallacyclobutane **B** would preferentially partition forward to **C** rather than return to **A**. On the other hand, the reaction **D**→**E**→**F** should proceed in the forward direction for any cycloalkene, strained or not, because the metallacyclobutane **E** should partition forward to the sterically less hindered carbene **F**. Consequently, the intermediate **A** can only incorporate norbornene into the growing chain, but intermediate **D** can take either norbornene or cyclooctene, the probability being largely determined by the relative concentrations. Accordingly, dilute concentrations of norbornene in a cyclooctene solution yields a largely 1:1 alternating copolymer.

Complex **3** is the simplest implementation of the general concept. It is a dual-site catalyst in which one site shows chemoselectivity and the other not, which, together with a concentration difference between the two monomers, constitutes the bare minimum case for an alternating copolymerization. Selectivity at both sites would eliminate the need for widely divergent concentrations of the two monomers, but even such a restriction can be easily accommodated by slow addition of one monomer into a neat solution of the other. One might expect similar behavior from an unsymmetrically substituted N-heterocyclic carbene complex reported by Mol and co-workers,[12] but the complex did not even polymerize norbornene well, presumably because of the much-too-large adamantyl substituent. One should note that a similar example of a dual-site catalyst can be found in the C_1- or C_s-symmetric metallocene catalysts for syndiotactic polypropylene.[13] In these systems, the activated catalyst alternately selects for the *re* and *si* face of the single monomer, propylene, but there is no documented case where selective copolymerization has been reported with these catalysts. The alternating selectivity has other potential uses as well. Selective oligomerization and selective ring-closing metathesis should be achievable with the new, designer catalyst architecture. Furthermore, while the designed structure demonstrates the target selectivity, no optimization of the catalyst has been attempted yet. Further work in this direction is underway.

Corrosion-Based Synthesis of Single-Crystal Pd Nanoboxes and Nanocages and Their Surface Plasmon Properties**

*Yujie Xiong, Benjamin Wiley, Jingyi Chen, Zhi-Yuan Li, Yadong Yin, and Younan Xia**

Corrosion can be broadly defined as "the damage to metal caused by reactions with its environment," and may take place in many different forms such as pitting, crevice etching, intergranular exchange, galvanic replacement, and dealloying.[1] Although corrosion is generally undesirable (automobile corrosion alone costs $16 billion annually!), it can be exploited as a versatile route to porous structures such as metal membranes.[2] While many solution-phase methods have been developed for synthesizing nanoparticles with well-controlled shapes,[3] it is still a great challenge to generate hollow nanostructures without involving exotic templates. We recently found that the galvanic replacement reaction between Ag templates and $HAuCl_4$ in an aqueous medium could lead to the formation of hollow nanostructures with controllable void size, wall porosity, and shell thickness.[4] More interestingly, the surface plasmon resonance (SPR) peaks of the resultant nanostructures could be continuously shifted from the blue (400 nm) to the near infrared (1200 nm) region by controlling the molar ratio of Ag to $HAuCl_4$ and thus the extent of replacement, alloying, and dealloying. Ideally, one would prefer a one-step synthesis that is able to tune the SPR properties of metal nanostructures without the requirement of templates made of a different metal. Here we demonstrate that corrosive etching of single-crystal Pd nanocubes could be used to transform them into nanoboxes and nanocages by controlling the reaction time.

As demonstrated in previous studies, Pd nanoparticles play an important role in hydrogen storage,[5] serve as the primary catalyst for the reduction of pollutants emitted from automobiles,[6] and facilitate organic reactions such as Suzuki, Heck, and Stille couplings.[7] Their performance could be tuned or improved for most of these applications by processing Pd nanostructures into hollow ones. For example, although solid Pd nanoparticles usually lose their catalytic activity after one round of Suzuki coupling reactions,[7a] hollow Pd spheres remained highly active for at least 24 rounds of reactions.[7b] While the SPR properties of Au and Ag have enabled many applications such as colorimetric sensing, nanoscale wave-guiding, and enhancement of electromagnetic fields and light transmission,[8] the SPR properties of Pd nanoparticles remain largely unexplored since Pd particles less than 10 nm in size give no resonance peak in the visible and near infrared regions.[9] Furthermore, the specific sensitivity of Pd towards hydrogen makes it especially interesting for fabricating SPR-based sensors for hydrogen gas.[10] We found by using discrete dipole approximation (DDA) calculations[11] that the resonant peak of Pd nanoshells with outer diameters of 48 nm could be tuned from 530 to 870 nm by tailoring their wall thickness from 6 to 3 nm. To demonstrate that Pd nanostructures with hollow interiors could indeed exhibit tunable SPR extinction peaks in the visible region we have synthesized single-crystal Pd nanoboxes and nanocages by a self-templating, corrosive pitting process.

The synthesis was conducted in a solution containing ethylene glycol, water, and poly(vinyl pyrrolidone) (PVP) with the addition of Na_2PdCl_4 as a precursor to Pd. The reaction can be divided into six distinctive stages based on both microscopic and spectroscopic observations. Reduction of $[PdCl_4]^{2-}$ to Pd atoms dominated up until $t = 18$ h (Figure 1a), with the Pd atoms nucleating and growing into nanocubes (with slightly truncated corners) with edge lengths of approximately 48 nm. Oxidative etching of the Pd nanocubes by O_2 (that is, corrosion) started to surpass the reduction process at $t = 20$ h. Small pits were observed in the surfaces of individual Pd nanocubes (Figure 1b), thus implying that the corrosion was initiated locally rather than uniformly over the entire surface of each cube. Over the next hour the interior of each cube became increasingly empty while the size of the hole in the surface started to shrink to form a box with relatively thick walls (Figure 1c). After another hour the void was further increased in size and each Pd cube evolved into a completely empty box with somewhat

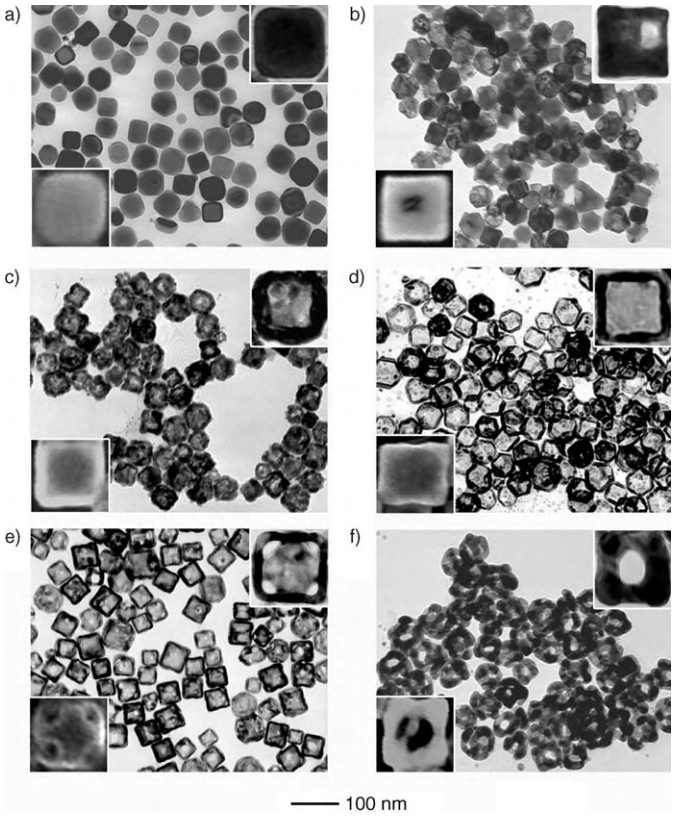

Figure 1. TEM images of the products at different reaction stages: a) $t = 18$ h; b) $t = 20$ h; c) $t = 21$ h; d) $t = 22$ h; e) $t = 24$ h; and f) $t = 28$ h. Note that the 100-nm bar applies to all images. The upper right and lower left insets show enlarged TEM and SEM images of an individual particle taken from each product, respectively.

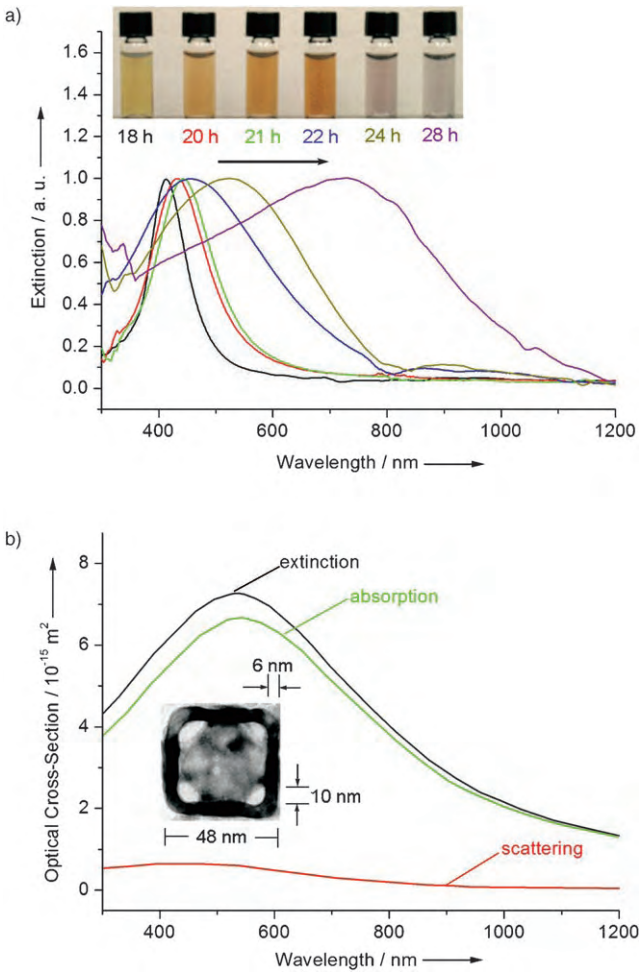

Figure 2. Surface plasmon properties of the Pd nanostructures shown in Figure 1: a) UV/Vis extinction spectra recorded from aqueous suspensions of the as-synthesized samples (see the inset, all spectra are normalized against the intensities of their strongest peaks); and b) DDA calculation of extinction, scattering, and absorption cross-sections of the Pd nanocage depicted in the inset.

truncated corners (Figure 1 d). Note that the hole in the surface had by now disappeared so that the nanobox was enclosed by a smooth, thin wall with a thickness of about 8 nm. Small holes appeared at the corners of each nanobox if the reaction was continued beyond this point. Holes of about 10 nm in diameter punctured each corner at $t = 24$ h (Figure 1 e), thus turning the nanobox into a cage. The Pd nanocage had an edge length of approximately 48 nm and was characterized by a uniform wall thickness of about 6 nm. It is worth noting that the outer diameter of the nanobox and nanocage exhibited no significant change relative to the initial Pd nanocube. The nanocage finally evolved into a ring (probably through additional etching and Ostwald ripening), thus causing the wall thickness to increase slightly from 6 to 10–20 nm (Figure 1 f).

The Pd nanostructures displayed distinctive colors since SPR is strongly dependent on wall thickness. As shown by the inset in Figure 2 a, the aqueous suspensions changed from yellow to orange to purple as the solid Pd nanocubes were transformed into hollow boxes and then porous cages. Figure 2 a shows the UV/Vis extinction spectra recorded from the six aqueous suspensions. The Pd nanocubes exhibited an SPR peak at 410 nm, which was consistent with the results of DDA calculations (see the Supporting Information).[11] The SPR peak was red-shifted to 430 nm as holes appeared in their surfaces. The formation of hollow structures with thick walls (and relatively rough inner surfaces) resulted in the sample exhibiting an SPR peak at 443 nm. The extinction peak was further shifted to 452 nm as the wall of the nanoboxes was thinned to 8 nm. Once the product had evolved into nanocages with an edge length of 48 nm and a wall thickness of 6 nm, the SPR peak was shifted to 520 nm, which matched the calculated spectra (Figure 2 b). The extinction (C_{ext}), absorption (C_{abs}), and scattering (C_{sca}) cross-sections are related by the following equation: $C_{ext} = C_{abs} + C_{sca}$.

Figure 3 a and b show typical SEM and TEM images of the Pd nanoboxes at relatively low magnifications which indicate that over 95% of the hollow structures inherited the truncated, cubic shape of the initial cubes. The fringes in the HRTEM images (Figure 3 c and d) showed a period of 2.0 Å, which was consistent with the {200} lattice spacing of face-centered-cubic Pd. These images also displayed well-resolved, continuous fringes with the same orientation, thus implying that the Pd nanobox, like the starting Pd nanocube, was a piece of single crystal. The inset of Figure 3 c shows a

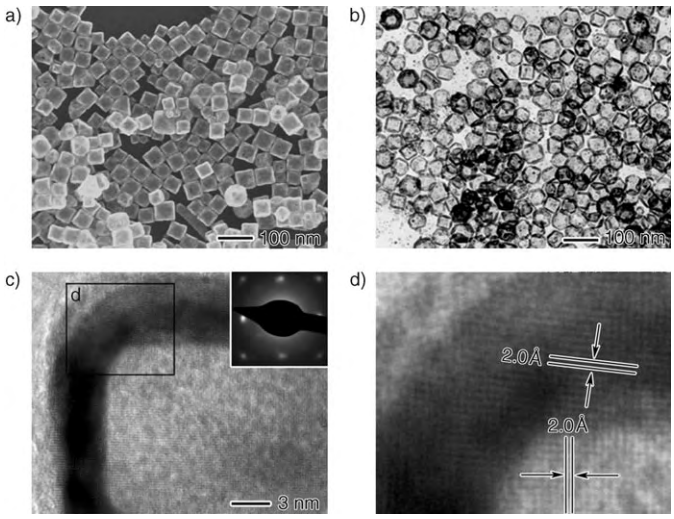

Figure 3. Electron microscopy characterization of the Pd nanoboxes obtained at $t = 22$ h: a) SEM image; b) TEM image; and c, d) high-resolution TEM images. The inset of (c) shows an electron diffraction pattern taken from the side surface of an individual Pd nanobox.

nanoprobe electron diffraction (ED) pattern obtained by aligning the beam perpendicular to one of the side faces of a cubic box. The spots could be indexed to the {200} diffraction of face-centered-cubic Pd. This diffraction pattern also suggests that the Pd nanobox was a single crystal with its symmetry similar to that of the initial Pd nanocube, which was enclosed by {100} facets. Both powder XRD and microprobe ED patterns (see the Supporting Information) further confirms the high phase purity and crystallinity of the Pd nanoboxes.

To analyze the corrosive etching process that transformed Pd nanocubes into nanocages we recorded UV/Vis spectra of the solution at different stages of the reaction (see the Supporting Information, the Pd nanoparticles were removed by centrifugation before the spectra were taken). The extinction peak at 242 nm (see the Supporting Information) corresponds to $[PdCl_4]^{2-}$ while that at 278 nm can be attributed to water-substituted $[PdCl_4]^{2-}$ ($[PdCl_{4-n}(H_2O)_n]^{(2-n)-}$) species.[12] The peak at 242 nm disappeared quickly when $[PdCl_4]^{2-}$ was reduced by ethylene glycol to generate Pd atoms and then nanocubes (see the Supporting Information). The concentration of water-substituted $[PdCl_4]^{2-}$ steadily increased as the nanocubes were etched by corrosive pitting. Similar to the corrosion of bulk metals,[13] O_2, Cl^- ions, and H_2O are all instrumental for the initiation of pitting on the surfaces of Pd nanocubes. As documented in the literature, corrosion most commonly occurs when the O_2 in air is dissolved in a thin film of water on the surface of a metal, thereby picking up electrons from the cathode to form hydroxide ions that then migrate towards the anode.[1] If the anode and cathode are located at different sites on the metal surface because of differences in the local environment (for example, surface heterogeneity and/or concentrations of ions), either pitting or crevice corrosion will take place.[1] Like the corrosion of bulk metals, adsorption of chloride ions can greatly increase the rate of surface diffusion and therefore expedite the pitting process.[13] On the other hand, the presence of a small amount of water can enhance the solubility of O_2 and profoundly increase the corrosion rate.[1] In addition to the augmentation by O_2, Cl^- ions, and H_2O, the amount of PVP was also found to be critical to the formation of hollow Pd nanostructures through a corrosion process. A large amount of PVP (with the ratio of PVP to Pd being 15:1) could ensure that the surface of each Pd nanocube was effectively covered by this polymer. In addition, the surface of each Pd nanocube is likely covered by a thin layer of palladium oxide.[13a] Both of these factors could make the surface of a Pd nanocube less reactive than the freshly exposed interior once the pitting process has started.[13b]

Figure 4 summarizes all the major steps involved in the corrosive etching process. Compared with the system without water (which produced Pd particles ca. 8 nm in size),[12b] the presence of water significantly accelerated the oxidative etching of Pd, and thus reduced the number of seeds formed in the nucleation step. As we have recently demonstrated in a case where Fe^{III} ions were added as the oxidative etchant,[14] a decrease in the number of seeds resulted in formation of Pd nanocubes with larger sizes when the concentration of the Pd precursor was maintained. As in the corrosion of bulk metals, the presence of water also facilitated the pitting process. Once a pit was formed at a specific site on the surface of a Pd cube (step a), further corrosion would occur preferentially inside

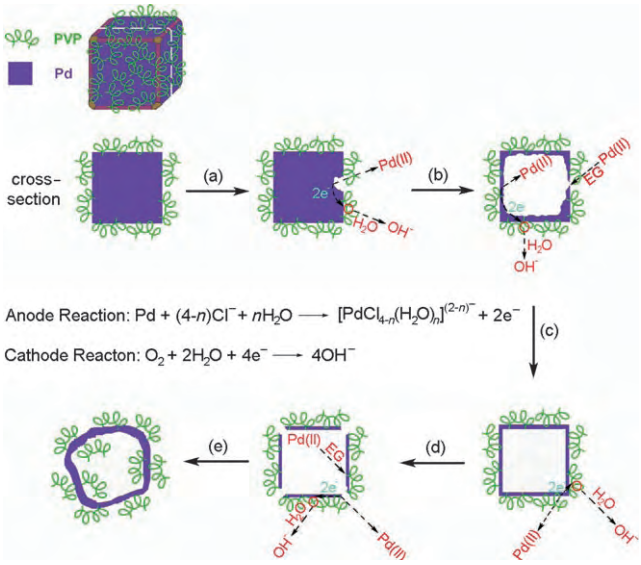

Figure 4. Schematic illustration summarizing all the major morphological changes involved in the synthesis of Pd nanoboxes and nanocages by corrosive etching: a) Pitting at a specific site on the surface of a nanocube where the O_2 dissolved in the solvent received electrons from the cathode and generated hydroxide ions that migrated towards the anode; b) formation of hollow structures after further etching of the interior of the nanocube, and the concentration of water-substituted $[PdCl_4]^{2-}$ increased; c) formation of a completely enclosed Pd nanobox by reducing the water-substituted $[PdCl_4]^{2-}$ species to form Pd atoms at the edge of each hole; d) formation of nanocages by dissolving Pd from the corners of the nanobox; and e) reconstruction of the nanocage by relocating all the holes from the corners to side faces and thickening of the wall as a result of additional reduction of the water-substituted $[PdCl_4]^{2-}$ species.

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the pit, thus leading to formation of a hollow nanostructure (step b). As etching was continued, the concentration of water-substituted $[PdCl_4]^{2-}$ sufficiently increased to allow the reduction by ethylene glycol to take place at the edge of a hole, thus causing it to gradually shrink in size. Since the reduction of water-substituted $[PdCl_4]^{2-}$ by ethylene glycol was minimal, most of these ionic species were retained in the solution rather than being reduced and deposited onto the outer surface of the Pd nanoboxes. This argument is supported by the UV/Vis spectra (see the Supporting Information), and it is for this reason why the outer dimensions of the Pd nanocubes, nanoboxes, and nanocages were essentially the same. It is the combination of continuous etching of the Pd nanocube from the interior and some reduction of the Pd^{II} species at the edge of the hole that resulted in the formation of Pd nanobox by $t = 22$ h (step c). It is worth pointing out that such a self-templating and self-etching process has also been observed in the solution-phase synthesis of ZnO microtubes.[15] The Pd nanoboxes were as unstable as the nanocubes when exposed to the corrosive environment. Under the illumination of light, the electric field intensity should concentrate at the corners, thus increasing the surface charge at these sites.[16] As a result, corrosive etching of the Pd nanoboxes preferentially occurred at the corners, thus leading to the formation of Pd nanocages with all eight corners being truncated (step d). This is different from the synthesis performed in the dark (see the Supporting Information). Further corrosion caused these holes to increase in dimension until the Pd nanocages evolved into rings. At the same time, continuous reduction of the water-substituted $[PdCl_4]^{2-}$ species occurred on the exterior surface of the nanocages, which led to the formation of nanorings (step e). This course of materials transfer resembles the conventional "Ostward ripening" process. Overall, the void size, shell thickness, and wall porosity of Pd hollow nanostructures were determined by the net difference between two opposite reactions: the reduction of the Pd^{II} precursor to form Pd^0 atoms, and the oxidation of Pd (both atoms and nanostructures) into Pd^{II} species.

In summary, metal corrosion is a familiar and common natural phenomenon that, while normally viewed as a detrimental process that destroys the usefulness of tools and machines, can also serve as a simple, elegant, and powerful method for the fabrication of hollow nanostructures with controllable optical properties. More specifically, corrosive pitting and etching could be combined to transform single-crystal Pd nanocubes into nanoboxes and nanocages in a one-pot synthesis without the involvement of exotic templates. The SPR peaks of Pd nanostructures could be tuned from 410 to 520 nm by empting their interiors. Our DDA calculations indicated that the SPR peak of the Pd nanocages with edge lengths of 48 nm could be further red-shifted to 870 nm by decreasing their wall thickness to 3 nm.

Experimental Section

In a typical synthesis, ethylene glycol (5 mL, J. T. Baker) was placed in a 3-neck flask (equipped with a reflux condenser and a teflon-coated magnetic stirring bar) and heated in air at 100 °C for 1 h. Meanwhile, palladium(II) sodium chloride (0.0486 g, Na_2PdCl_4, Aldrich) and poly(vinyl pyrrolidone) (0.2747 g, PVP, M.W. = 55000, Aldrich) were dissolved at room temperature in ethylene glycol (3 mL) and water (3 mL), respectively. These two solutions (with the molar ratio between Pd and the repeating unit of PVP being 1:15) were then injected simultaneously into the flask with a syringe pump at a rate of 45 mL h^{-1}. Heating of the reaction at 100 °C was continued in air for 28 h. A set of samples were taken over the course of a synthesis with a glass pipette. To minimize temperature perturbation during sampling, the glass pipette was held just above the solution and preheated for 30 s before immersion. For the argon-protected synthesis, all other experimental parameters were kept the same except for the continuous bubbling of argon. The samples were washed with acetone and then with ethanol several times before they were centrifuged at a rate of 6000 rpm for 10 min to remove most of the ethylene glycol and excess PVP. The samples were characterized by transmission electron microscopy (TEM), high-resolution TEM, scanning electron microscopy (SEM), electron diffraction (ED), and powder X-ray diffraction (PXRD).

TEM images and microprobe ED patterns were recorded on a Phillips 420 transmission electron microscope operated at 120 kV. HRTEM images and nanoprobe ED patterns were taken on a Jeol 2010 LaB6 high-resolution transmission electron microscope operated at 200 kV. PXRD patterns were recorded on a Philips 1820 diffractometer equipped with a $Cu_{K\alpha}$ radiation source ($\lambda = 1.54180$ Å). SEM images were taken on a FEI field-emission scanning electron microscope (Sirion XL) operated at an accelerating voltage of 20 kV. UV/Vis spectra were obtained using a Hewlett–Packard 8452A diode array spectrophotometer.

The calculation used in the article is based on the DDA method.[11] DDA is a computational method developed for studying both the scattering and absorption of electromagnetic radiation by particles with sizes on the order of or smaller than the wavelength of incident light. In the calculation, the particle is divided into an array of N polarizable point dipoles, each of which is characterized by a polarizability of $\boldsymbol{\alpha}_i$. When the system is excited by a monochromatic incident plane wave $\boldsymbol{E}_{inc}$, each dipole of the system will be subjected to an electric field that can be split in two contributions: 1) the incident radiation field $\boldsymbol{E}_{i,inc}$ and 2) the field radiated by all of the other induced dipoles $\boldsymbol{E}_{i,dip}$. The sum of both fields is the so-called local field at each dipole ($\boldsymbol{E}_{i,loc} = \boldsymbol{E}_{i,inc} + \boldsymbol{E}_{i,dip}$). Each dipole can be expressed as an oscillating polarization with the dipole moment being $\boldsymbol{P}_i = \boldsymbol{\alpha}_i \boldsymbol{E}_{i,loc}$. Both absorption and scattering cross-sections (C_{abs} and C_{sca}) can be obtained directly from $\boldsymbol{P}_i$. The refractive index of bulk Pd was used in all calculations reported in this article, and the nanoparticle was assumed to be surrounded by and filled with water (when it became porous).

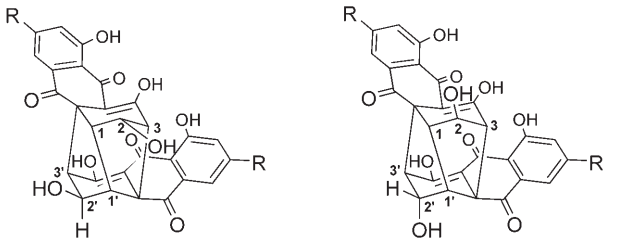
Natural Product Synthesis

DOI: 10.1002/anie.200503678

Total Synthesis of (+)-Rugulosin and (+)-2,2′-*epi*-Cytoskyrin A through Cascade Reactions**

K. C. Nicolaou, Yee Hwee Lim, Charles D. Papageorgiou, and Jared L. Piper*

We have previously reported[1] the development of the "cytoskyrin cascade" as a facile and efficient entry into the growing class of modified bisanthraquinones that includes cytoskyrin A (**1a**),[2] graciliformin (**1b**),[3] and rugulosin (**2b**; Figure 1).[1c,4] Isolated from a number of fungi and lichens,[4b]



R = OMe: (+)-cytoskyrin A (**1a**)
R = Me: (+)-graciliformin (**1b**)

R = OMe: (+)-2,2'-*epi*-cytoskyrin A (**2a**)
R = Me: (+)-rugulosin (**2b**)

Figure 1. Selected naturally occurring modified bisanthraquinones.

the latter compound (**2b**) was recently found to exhibit anti-HIV properties,[5] in addition to its originally reported cytotoxic activity[4b] that it shares with cytoskyrin A (**1a**).[2] Given the occurrence of both graciliformin (**1b**) and rugulosin (**2b**) in nature, it will not be surprising if 2,2′-*epi*-cytoskyrin A (**2a**) is someday discovered as a natural product, for its structural relationship to cytoskyrin A (**1a**) is the same as that of **2b** to **1b**. The multistep "cytoskyrin cascade" was demonstrated on a model system that differed from the

natural products by the absence of a hydroxy group at the C2 and C2′ positions (see Figure 1). The presence of these hydroxy groups was considered to be problematic for a total synthesis involving dimerization of two monomeric units, as their elimination was anticipated to be favored by aromatization, and hence facile. Although nature is probably carrying out this dimerization process with a hydroxy group in place, a recent report[1b] confirmed that attempts to synthesize the monomeric anthradihydroquinone featuring a benzyl-protected hydroxy group at the C2 and C2′ positions resulted in elimination of benzyl alcohol. Herein, we report the first biomimetic, asymmetric total synthesis of (+)-2,2′-*epi*-cytoskyrin A (**2a**) and (+)-rugulosin (**2b**) through the "cytoskyrin cascade", under conditions that successfully overcome the above-mentioned challenges.

There are four possible spatial arrangements (**A**–**D**) for the dimerization of the monomeric anthraquinones, two *endo* (**A**, **B**) and two *exo* (**C**, **D**) arrangements, which are further distinguished by the faciality of approach, the one from the top (**B**, **D**) and the one from below (**A**, **C**), as demonstrated in Figure 2. The two *endo* alignments (**A** and **B**) are equivalent and are unlikely, if not impossible, due to structural constraints. The *exo-syn* arrangement (**C**) would place the two substituted hydroxy groups (OR^1) in a *syn* arrangement resulting in the build-up of significant steric congestion and should, therefore, be disfavored. A pathway through such an arrangement would form *ent*-cytoskyrin (*ent*-**1a**) and *ent*-graciliformin (*ent*-**1b**) through the intermediacy of *O*-bridged dimers **3**. The alternative *exo-anti* arrangement (**D**), places these two interfering groups opposite to each other, hence minimizing the steric congestion and allowing the generation of 2,2′-*epi*-cytoskyrin A (**2a**) and rugulosin (**2b**). It is interesting to note that while the chirality of the monomeric anthraquinone is responsible for determining the absolute configuration of the cage, the diastereoselectivity of the dimerization step controls the relative stereochemistry of the C2 and C2′ centers relative to the rest (epimeric stereochemistry) in the final product of the cascade sequence (see also caption, Figure 2).

Reasoning that the nature of the groups (R^1) residing on the C2/C2′ hydroxy groups may make a difference in the outcome of the anticipated reactions, we proceeded to construct different monomeric units as starting materials for the cascade. Scheme 1 summarizes the synthesis of hydroquinones **11a**–**11c** featuring a Hauser annulation[6] to construct the requisite tricyclic system. Thus, protection of the known diacetate **5**[7] with MOMCl or TBSCl followed by desymmetrization using porcine liver esterase (PLE) at pH 8 afforded alcohols **6a**[8] or **6b**[7] in 95 and 90% yield, respectively, over the two steps. PCC oxidation under buffered conditions using NaOAc followed by brief (10 min) exposure to DBU at 25 °C furnished the desired enones **7a** or **7b** in 68 and 67% yield, respectively, over the two steps. The other partners for the Hauser annulation, nitriles **10a** and **10b** were synthesized as shown in Scheme 1. Thus, protection of the commercially available salicylic acids **8a** or **8b** with excess TBSCl followed by treatment with $(COCl)_2$ and a catalytic amount of DMF in CH_2Cl_2 at 0 °C afforded the corresponding acid chlorides, which were quenched with Me_2NH to furnish

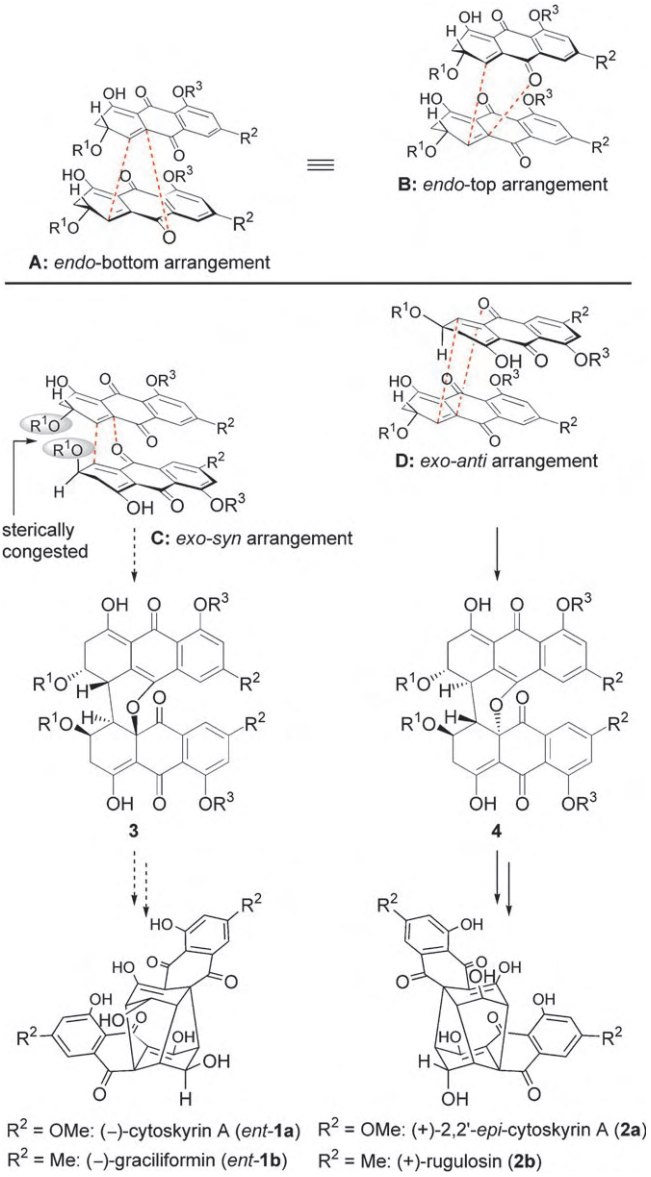

Figure 2. Stereoselectivity considerations for the dimerization step of anthradihydroquinones to modified bisanthraquinones. The shown enantiomers of the starting anthraquinones correspond to *ent*-**1a**, *ent*-**1b**, **2a**, and **2b**. Should the pathway involving arrangement **C** be possible, the opposite enantiomers would have been needed to obtain natural cytoskyrin A (**1a**) and graciliformin (**1b**).

amides **9a** or **9b** in 85 and 74% yield, respectively, over the three steps. *Ortho*-lithiation of amides **9a** or **9b** using *t*BuLi and TMEDA at −78 °C and subsequent quenching with freshly distilled DMF yielded the corresponding aldehydes. Exposure of the latter compounds to TMSCN, a catalytic amount of KCN, [18]crown-6, and AcOH afforded the deprotected nitrile compounds, which were finally treated with MOMCl and iPr_2NEt at 0 °C to furnish the required building blocks **10a** and **10b** in 64 and 50% yield, respectively, over the three steps.

With the two fragments in hand, the stage was now set for the synthesis of the requisite anthradihydroquinones **11a**–**11c**. Treatment of nitriles **10a** or **10b** with LHMDS in THF at

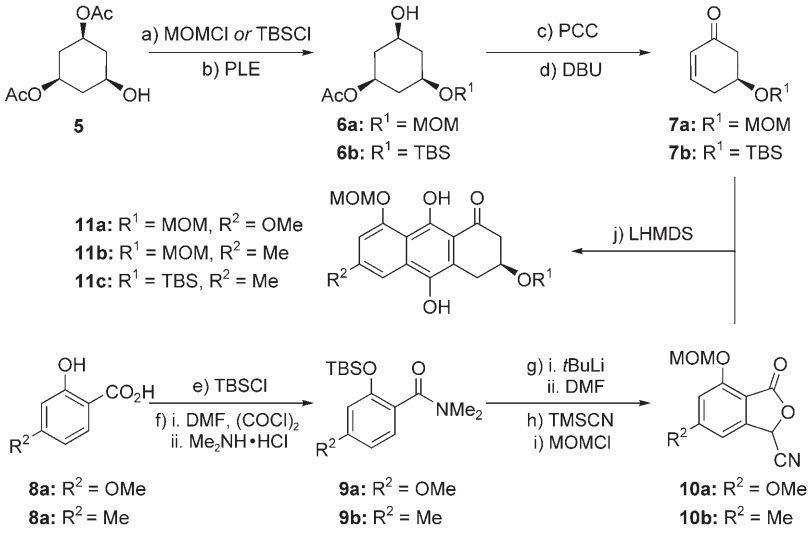


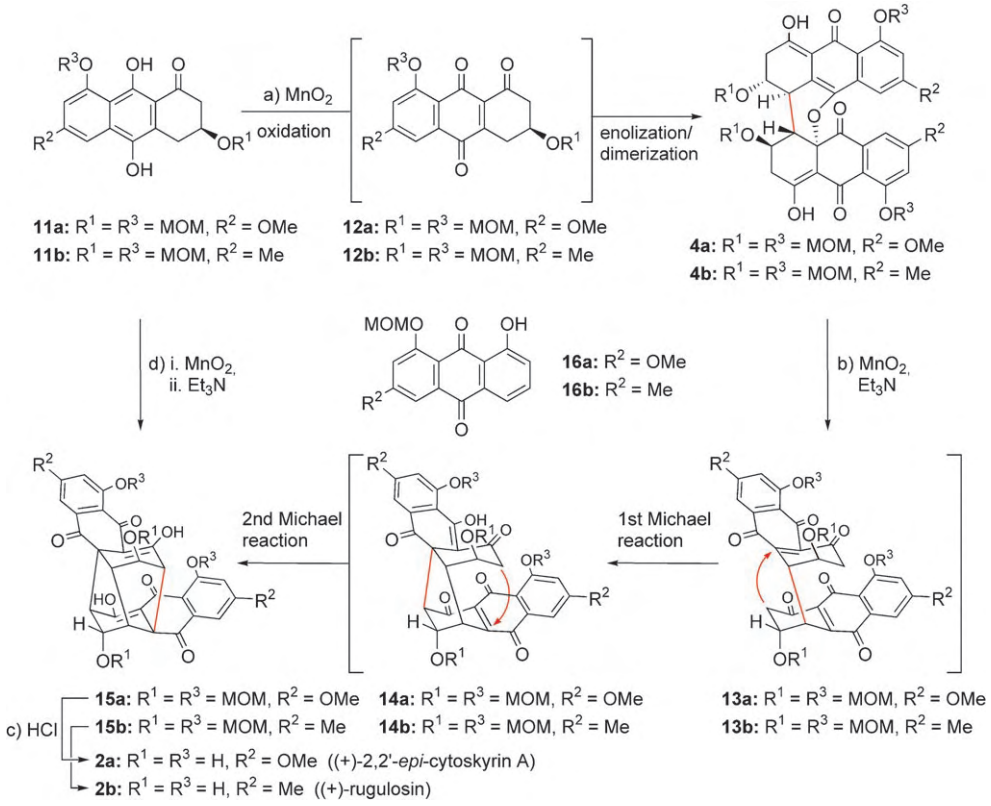
Scheme 1. Reagents and conditions: a) MOMCl (3.8 equiv), *i*Pr_2NEt (3.8 equiv), CH_2Cl_2, 25 °C, 1.5 h; TBSCl (3.8 equiv), imid (3.8 equiv), CH_2Cl_2, 25 °C, 48 h; b) PLE (1.0 equiv), buffer pH 8 (0.1 M), *t*BuOH (8% v/v), 25 °C, 4 h, 95% (**6a**), 90% (**6b**) over two steps;[8] c) PCC (3.0 equiv), NaOAc (3.0 equiv), CH_2Cl_2, 25 °C, 12 h; d) DBU (1.0 equiv), CH_2Cl_2, 25 °C, 10 min, 68% (**7a**), 67% (**7b**) over two steps; e) TBSCl (4.0 equiv), imid (6.0 equiv), DMF, 25 °C, 16 h; f) i. $(COCl)_2$ (1.25 equiv), DMF (cat.), CH_2Cl_2, 0 °C, 2 h; ii. $Me_2NH{\cdot}HCl$ (1.0 equiv), Et_3N (3.0 equiv), CH_2Cl_2, 0 °C, 30 min, 85% (**9a**), 74% (**9b**) over three steps; g) TMEDA (3.0 equiv), *t*BuLi (3.0 equiv), DMF (3.0 equiv), THF, −78→25 °C, 12 h; h) KCN (0.2 equiv), [18]crown-6 (0.2 equiv), TMSCN (1.4 equiv), CH_2Cl_2, 25 °C, 4 h; then AcOH, 12 h; i) MOMCl (1.5 equiv), *i*Pr_2NEt (1.2 equiv), CH_2Cl_2, 0 °C, 1 h, 64% (**10a**), 50% (**10b**) over three steps; j) **10** (1.1 equiv), THF, LHMDS (1.1 equiv), −78 °C; then **7** (1.0 equiv), −78→0 °C, 2 h, (submitted directly to the cascade). MOM = methoxymethyl; TBS = *tert*-butyldimethylsilyl; PLE = porcine liver esterase; PCC = pyridinium chlorochromate; DBU = 1,8-diazabicyclo[5.4.0]undec-7-ene; DMF = *N*,*N*′-dimethylformamide; TMEDA = tetramethylethylenediamine; THF = tetrahydrofuran; TMS = trimethylsilyl; LHMDS = lithium bis(trimethylsilyl)amide.

−78 °C, followed by addition of **7a** or **7b** (−78→0 °C) gave crude anthradihydroquinones **11a**–**11c**, which were directly subjected to the cytoskyrin cascade[1a] (Scheme 2). We had already established the facilitating role[1a] of MnO_2 and anticipated that the mild reaction conditions employed for the cascade coupled with the expected reluctance of the final compound to lose its alkoxy groups by virtue of Bredt's rule[9] would enable arrival at compounds **2a** and **2b**, provided that the feared elimination/aromatization pathway from the monomeric anthraquinones did not predominate. Indeed, exposure of **11a** or **11b** to MnO_2 (1.5 wt equiv) in a concentrated CH_2Cl_2 solution (0.35 M) at 25 °C for 30 min resulted in the formation of dimeric compounds **4a** or **4b** as single diastereoisomers in 64 and 32% yield, respectively, through a sequence featuring oxidation to the corresponding anthraquinone (**12a** or **12b**) and dimerization of its easily generated, under the reaction conditions, enol form. It was found that when crude **11a** or **11b** were used, the cascade was shutdown at the stage of **4a** or **4b**. This occurrence was attributed to an, as yet unknown, impurity[10] carried through from the Hauser annulation which hindered the oxidation of **4a** or **4b** to **13a** or **13b**, impeding the cascade. Prolonged exposure of the thus-obtained **4a** or **4b** to MnO_2 (12 h) resulted in quantitative formation of **16a** or **16b**, presumably through two successive retro-Michael reactions (see Scheme 3) followed by elimination and aromatization. However, treatment of purified **4a** or **4b** (flash column chromatography on silica gel) with MnO_2 (1.5 wt equiv) and Et_3N (5.0 equiv, added as soon as **14a** or **14b** were observed by thin layer chromatography (TLC), ca. 6 h) in CH_2Cl_2 at 45 °C for 12 h resulted in the formation of **15a** or **15b** in 71 and 81% yield, respectively, through the intermediacy of fleeting compounds **13a** or **13b** and **14a** or **14b**.

Use of carefully purified **11a** or **11b** (preparative TLC) enabled the realization of an impressive seven-step cascade sequence featuring the transformation of tricyclic monomers **11a** or **11b** into nonacyclic systems **15a** or **15b** in 60 and 50% yield, respectively, involving a sequence of alternating oxidations and double Michael reactions as shown in Scheme 2. The remaining mass was accounted for by the formation of aromatized monomers **16a** or **16b** in 40 and 50% yield, respectively. This cascade required treatment of **11a** or **11b** with MnO_2 (1.5 wt equiv) in CH_2Cl_2 (0.35 M) for 10 min at 25 °C, conditions that led to the formation of **4a** or **4b** as indicated by TLC, followed by tenfold dilution with CH_2Cl_2 and addition of a further 1.5 wt equiv of MnO_2 until the formation of **14a** or **14b** was complete (6 h). Finally, addition of Et_3N (5.0 equiv) and heating to 45 °C for 6 h furnished **15a** or **15b**. Exposure of the latter compounds (**15b** or **15b**) to concentrated HCl in a mixture of MeOH and THF (20:1) resulted in global deprotection, affording (+)-2,2′-*epi*-cytoskyrin A (**2a**) or (+)-rugulosin (**2b**) in 93 and 98% yield, respectively. The ^{1}H NMR spectrum of (+)-rugulosin (**2b**) in [D_6]DMSO was identical to that reported in the literature[4c] for the naturally occurring substance. Besides being anticipated on the basis of the above arguments (Figure 2), the stereochemistry of **2a** was firmly established through spectroscopic analysis. Thus, the ^{1}H NMR spectrum of synthetic (+)-2,2′-*epi*-cytoskyrin A (**2a**) exhibited doublets for H3/H3′ ($\delta = 2.85$, $J = 4.8$ Hz) and H2/H2′ ($\delta = 4.49$, $J = 4.8$ Hz), while in the spectrum reported for naturally occurring cytoskyrin A (**1a**)[2] both signals for H3/H3′ ($\delta = 2.85$) and H2/H2′ ($\delta =$ 4.00) appear as singlets. If **2a** was to have the same stereochemistry as cytoskyrin (**1a**) at C2/C2′, the dihedral angle of H1/H1′-H2/H2′ and H2/H2′-H3/H3′ would have been 78° and 85°, respectively (manual molecular models)[3] and hence the signals for H3/H3′ and H2/H2′ would have been singlets. Crystals of synthetic rugulosin (**2b**) obtained by slow crystallization from acetone containing 1% Et_3N over MeOH vapors yielded to X-ray crystallographic analysis (see ORTEP drawing,[11] Figure 3), proving unambiguously its structure and, indirectly, rendering further support for the assigned structure of (+)-2,2′-*epi*-cytoskyrin A due to the striking closeness of the ^{1}H NMR spectra of **2a** and **2b**.

Having established a viable pathway to 2,2′-*epi*-cytoskyrin A (**2a**) and rugulosin (**2b**) starting from **11a** or **11b**,

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 2. The cytoskyrin cascade: synthesis of (+)-2,2′-*epi*-cytoskyrin A (**2a**) and (+)-rugulosin (**2b**) from anthradihydroquinone **11a** or **11b**, respectively. Reagents and conditions: a) MnO_2 (1.5 wt equiv), CH_2Cl_2 (0.35 M), 25 °C, 1 h, 64% (**4a**), 32% (**4b**) over five steps; b) MnO_2, (1.5 wt equiv), Et_3N (5.0 equiv), CH_2Cl_2, 25→45 °C, 12 h, 71% (**15a**), 81% (**15b**) over three steps; c) conc. HCl, MeOH, THF, 60 °C, 12 h, 93% (**2a**), 98% (**2b**); d) MnO_2 (1.5 wt equiv), CH_2Cl_2, 25 °C, 10 min; then MnO_2 (1.5 wt equiv), Et_3N (5.0 equiv), 25→45 °C, 12 h, 60% (**15a**), 40% (**16a**), 50% (**15b**), 50% (**16b**).

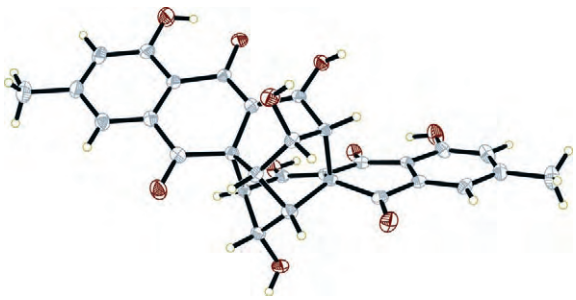


Figure 3. ORTEP drawing of rugulosin (**2b**) derived from X-ray crystallographic studies (O burgundy, C gray, H yellow). The molecule of Et_3N per molecule of **2b** is not shown. The crystallographic analysis did not reveal the absolute stereochemistry of **2b**, which was assigned as shown, on the basis of the absolute stereochemistry of the starting material and its positive optical rotation.[1c,4]

respectively, we then proceeded to investigate TBS-anthradihydroquinone **11c** as a substrate for the cytoskyrin cascade. It was reasoned that the sheer bulk of the TBS group as compared to the smaller MOM moiety was expected to retard both Michael reactions, an occurrence that could result in the isolation of some of the postulated intermediates of the cascade. Scheme 3 summarizes our findings, which indeed included the isolation of two of the reactive species involved, quinone **12c** and highly labile dimer **18**, both of which were characterized by ^{1}H NMR spectroscopy (see Table 1). Thus treatment of **11c** with MnO_2 (1.5 wt equiv) in a concentrated CH_2Cl_2 solution (0.35 M) at 25 °C for 30 min resulted in the slow formation of quinone **12c**, dimer **18**, product **4c**, and aromatized system **16b**. Moreover, compound **18**, upon standing in $CDCl_3$, slowly and quantitatively converted into **4c** and **16b** (**4c**/**16b** ≈ 1:3, as determined by ^{1}H NMR spectroscopy). This suggests that compounds **12c**, **17**, and **18** are in equilibrium with each other and that the rate of aromatization of **17** to **16b** is faster than the second Michael reaction within dimer **18** that leads to the desired compound **4c**. These observations were consistent with a stepwise mechanism for the cytoskyrin cascade involving two consecutive Michael reactions as shown in Figure 3, at least in the case of the TBS-protected derivative **11c**.

The described chemistry demonstrates the power of cascade reactions in chemical synthesis[12] and underscores the applicability of such processes in situations facing seemingly intransigent synthetic challenges. Further applications of these remarkable cascade reactions to the synthesis of other natural and designed members of the bisanthraquinone class should be forthcoming.

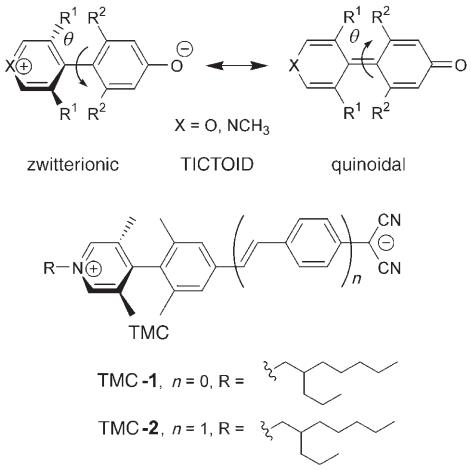
Exceptional Molecular Hyperpolarizabilities in Twisted π-Electron System Chromophores**

*Hu Kang, Antonio Facchetti, Peiwang Zhu, Hua Jiang, Yu Yang, Elena Cariati, Stefania Righetto, Renato Ugo, Cristiano Zuccaccia, Alceo Macchioni, Charlotte L. Stern, Zhifu Liu, Seng-Tiong Ho, and Tobin J. Marks**

Molecule-based electrooptic (EO) materials are of intense research interest for understanding how light interacts with matter and for applications in photonic technologies such as high-speed optical communications, integrated optics, and optical data processing and storage.[1] In such materials, the second-order susceptibility tensor governing EO response (r_{33}), is governed both by the net polar microstructural order and the microscopic molecular first hyperpolarizability tensor (β). Large β values are essential for large EO response, and the quest for higher performance EO chromophores presents a daunting challenge.[1] To date, effective chromophores have been designed according to similar principles embodied in the classical "two-level" model: conjugated π systems end-capped with donor (D) and acceptor (A) moieties.[2] Elegant efforts have sought maximum β by optimizing D and A strengths and conjugation pathways,[3] directed by "bond length alternation"[4] and "auxiliary donor and acceptor" models.[5] Such strategies utilize extended *planar* π-conjugation, resulting in chromophores that are inherently elaborate structurally, complicating synthesis and introducing potential chemical, thermal, and photochemical instabilities.[6] Alternative routes to very large-β chromophores would clearly be desirable, and there is growing evidence that simple two-level systems may not provide access.[7]

Recent theoretical work suggests that unconventional chromophores with *twisted* π-electron systems bridging D and A substituents (TICTOID = twisted intramolecular charge-transfer; Scheme 1) may exhibit unprecedented hyperpolarizabilities through non-classical mechanisms.[8] These would have relatively simple biaryl structures in which β is sterically tunable through R^1, R^2 modification of the interplanar dihedral angle (θ). Large β magnitudes are predicted at $\theta \approx 70$–$85°$,[8a] with twist-induced reduction in D–π–A conjugation leading to charge-separated zwitterionic ground states. The intriguing question is whether such molecules, with small numbers of π-electrons, could thereby exhibit far larger β values than conventional planar chromophores.



Scheme 1. Structures of TICTOID and TMC (twisted π-electron system molecular chromophore).

We report here the first realization of such TICTOID chromophores, that they have unprecedented hyperpolarizabilities on the order of 10–20× larger than previously observed,[1–5] and that these are not simple two-level systems. The new chromophores (Scheme 1) were designed according to the following criteria: 1) Synthetically challenging tetra-*ortho*-alkylbiaryl cores should enforce large interplanar angles, judging from bimesityl ($\theta \approx 90°$).[9] 2) Dicyanomethanide and pyridinium groups should be effective D and A substituents, with dicyanomethanide more stable than phenoxide.[10] 3) Pyridine alkylations should enhance solubility and processability (TMC-1 and TMC-2), with styrenic substitution further enhancing β (TMC-2).

TMC syntheses (Scheme 2) begin with precursor **1**, synthesized as reported elsewhere.[10] Pd-catalyzed $NaCH(CN)_2$ coupling affords **2**, which is then regioselectively quaternized[11] and deprotonated to afford TMC-1. Precursor **3** is synthesized by Pd-catalyzed coupling of 1-iodo-4-vinylbenzene with $NaCH(CN)_2$. Subsequent Heck-coupling of **1** and **3** affords precursor **4**, which is then alkylated and

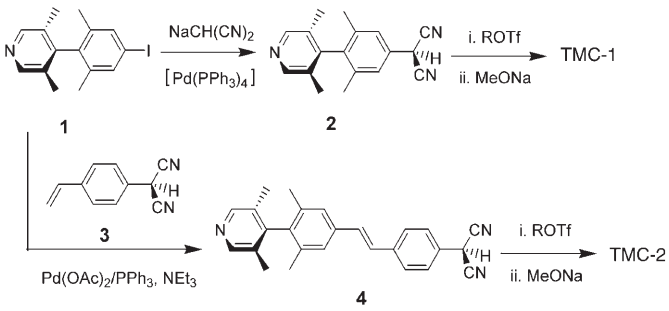

Scheme 2. Synthesis of twisted π-electron chromophores. Tf = trifluoromethanesulfonyl.

deprotonated to yield TMC-2. The new zwitterions are air- and moisture-stable, purifiable by column chromatography, and were characterized by conventional techniques.[12] Thermogravimetric analysis indicates very high chromophore thermal stability ($T_d \approx 306\,°C$ for TMC-1, $\approx 330\,°C$ for TMC-2),[12] while ^1H NMR indicates stability in [D$_6$]DMSO solution at 150 °C for periods of hours under air.

Single-crystal diffraction data for TMC-1[13] reveal a large arene–arene dihedral twist angle (89°; Figure 1). The fact that twisting is governed primarily by tetra-*ortho*-methylbiaryl

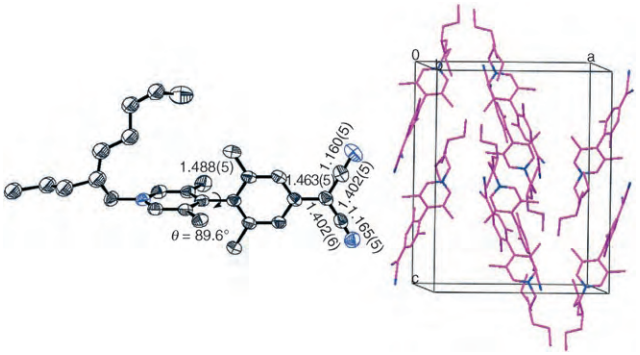

Figure 1. Left: ORTEP drawing (50% probability ellipsoids) of the TMC-1 molecule. Hydrogen atoms are omitted for clarity. Right: Packing diagram.

steric interactions and is independent of chromophore architecture is argued by nearly identical angles in several other TMC-type molecules.[10] The TMC-1 (ring)C–C(ring) distance (1.488(5) Å) is close to that in typical biphenyls ($\approx$1.487 Å),[14] indicating steric crowding, consequent reduction in inter-ring π-conjugation, and departure from quinoidal structures where (ring)C=C(ring) $\approx$ 1.349 Å.[14] The phenylenedicyanomethanide fragment displays different bond length patterns than in typical TCNQs;[14,15] the (NC)$_2$C-bound phenylene ring has less quinoidal character, and the (dicyanomethanide)C–C(aryl) distance (1.463(5) Å) lacks TCNQ C=C(CN)$_2$ exocyclic character ($\approx$1.392 Å).[14] This metrical pattern indicates negative charge localization on the C(CN)$_2$ group, also evident from C–CN bond shortening and C≡N bond elongation (TCNQ distances are 1.427 Å and 1.144 Å, respectively).[14] Finally, there is significant pyridinium aromatic character, with molecular dimensions paralleling those in *N*-methyl-*p*-phenylpyridinium salts[16] rather than in cyclopentadienylidene-1,4-dihydropyridines.[17] Together, these metrical parameters confirm a charge-separated zwitterionic TICTOID ground state. Importantly, close correspondence between solid-state ^{13}C NMR and optical spectra and those recorded in solution[12] argue that this structure persists essentially unchanged in solution.[18] As might be expected, the present zwitterion packs centrosymmetrically in pairs (Figure 1), likely a result of electrostatic dipole–dipole interactions (reasonable considering the large computed dipole moments).[19]

Optical spectra further support a zwitterionic ground state, with oscillator strengths unexceptional for two-level chromophores.[1–5] Thus, TMC-1 exhibits two fairly short wavelength maxima, assigned to pyridinium and phenyl subfragment high-energy intra-ring excitations, and one low-energy inter-subfragment charge-transfer (CT) excitation (Figure 2a).[8] The TMC-1 CT bands exhibit strong negative

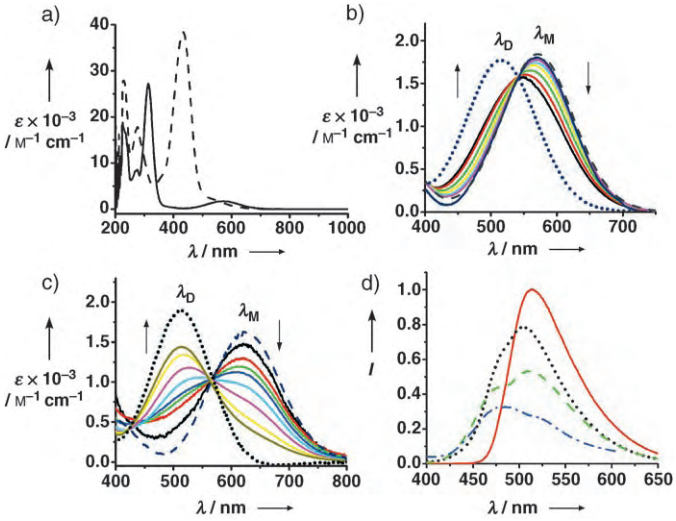

Figure 2. a) Optical absorption spectra of TMC chromophores in CH_2Cl_2 solution. Solid line: TMC-1; dashed line: TMC-2. b, c) Concentration-dependent TMC-1 spectra in CH_2Cl_2 solution (b) (3.0×10^{-3}–2.0×10^{-5} M) and in $CHCl_3$ solution (c) (5.6×10^{-4}–4.5×10^{-6} M). Arrows indicate changes in CT bands upon dilution. The monomer (dashed line) and dimer (dotted line) spectra were derived from the data at two different concentrations and $K_{dimerize}$. d) Variable-concentration fluorescence spectra (λ_{ex} = 300–350 nm) of TMC-2 in CH_2Cl_2. Intensities are normalized. I = fluorescence intensity. Solid line: 5×10^{-4} M, dotted line: 5×10^{-5} M, dashed line: 5×10^{-6} M, dash-dotted line: 2.5×10^{-6} M.

solvatochromism – large blue-shifts with increasing the solvent polarity (Table 1), indicating that the ground state dipole moment is substantially larger than in the excited state, consistent with the dominant zwitterionic ground state (and a negative β). TMC aggregation observed in the solid state is further evidenced in CH_2Cl_2 solution by concentration-dependent optical spectra (Figure 2b), exhibiting a red-shift and increase of CT band intensity upon dilution in the range of 10^{-3}–10^{-4} M (H-aggregation), with an isosbestic point supporting well-defined aggregation equilibria.[20]

To estimate binding energetics, the TMC-1 extinction coefficient was analyzed[20] as a function of concentration,

Solvent (E_T)	TMC-1			TMC-2		
	λ_{max} (ε)[b]	λ_{max} (ε)[c]	$\Delta\mu$[d]	λ_{max} (ε)[b]	λ_{max} (ε)[c]	$\Delta\mu$[d]
MeOH (0.76)	297	451		397	–	
DMF (0.40)	310	478		427	–	
			64			151
CH_2Cl_2 (0.31)	314 (27200)	569 (1840)		433 (38400)	540[e] (2090)	
THF (0.21)	320	592		451	578[e]	

[a] λ_{max} in nm, ε in $M^{-1}cm^{-1}$, $\Delta\mu$ in 10^{-30} C m. Solvent polarity given by the normalized E_T parameter. [b] Assigned to intra-subfragment excitation. Another high-energy subfragment excitation overlaps with the solvent (except CH_2Cl_2) and is not tabulated here. [c] Assigned to low-energy inter-subfragment charge-transfer (CT) excitation. [d] DFT-derived change in dipole moment from ground to excited state. [e] Deconvoluted from the subfragment excitation band and assigned to inter-subfragment CT.

assuming a simple dimerization model, and yields $K_{dimerize} = 250 \pm 30\,M^{-1}$ and $\Delta G^{o}_{dimerize} = -13.6 \pm 0.3\,kJ\,mol^{-1}$ in CH_2Cl_2. Concentration-dependent TMC-1 studies (Figure 2c) in less polar $CHCl_3$ yield larger $K_{dimerize}$ and $\Delta G^{o}_{dimerize}$ values of $13300 \pm 1420\,M^{-1}$ and $-23.5 \pm 0.3\,kJ\,mol^{-1}$, respectively, not unexpectedly indicating that the aggregation is weaker in more polar solvents and also somewhat stronger than in typical planar merocyanine zwitterions.[20]

The TMC-2 spectrum features an intense band at 433 nm in CH_2Cl_2 doubtless involving stilbenyl subfragment excitation,[8b] overlapping a weaker CT band centered at 540 nm (Figure 2a). Both subfragment and CT bands again exhibit negative solvatochromism (Table 1). Variable-concentration TMC-2 fluorescence spectra (Figure 2d) reveal a clear transition from dimer (515 nm) to monomer (485 nm) in the range of 5×10^{-4}–2.5×10^{-6} M, providing confirmation of aggregation.

Additional quantitative information on the state of TMC chromophore aggregation is provided by PGSE (pulsed field gradient spin-echo) NMR spectroscopy (Figure 3).[21] Here, experimentally determined translational self-diffusion coefficients (D_t), hydrodynamic radii (r_H), volumes (V_H), and the ratio between V_H and the van der Waals volume afford aggregation numbers (N) readily identifying the aggregation level in solution ($N = 1.0$, 1.5, or 2.0 means 100% monomer, 50% monomer + 50% dimer, or 100% of dimer, respectively).[21c] The trends in N versus $\log c$ (Figure 3) clearly show that monomer predominates in [D$_6$]DMSO (ε_r^{25} = relative permittivity at 25 °C = 46.45) for both TMC-1 and TMC-2 over the entire concentration range (see Supporting Information). In CD_2Cl_2 ($\varepsilon_r^{25} = 8.93$), TMC-1 is exclusively monomeric only at the lowest concentrations examined (4×10^{-6} M, Supporting Information) while dimers (see Supporting Information) and even larger aggregates (Figure 3, Supporting Information) are present at the highest concentrations (Figure 3). TMC-2 exhibits a greater aggregation tendency and is not exclusively monomeric even at 5×10^{-6} M (see Supporting Information). For TMC-2, aggregates larger than dimers are present at the highest concentrations (Figure 3, Supporting Information).

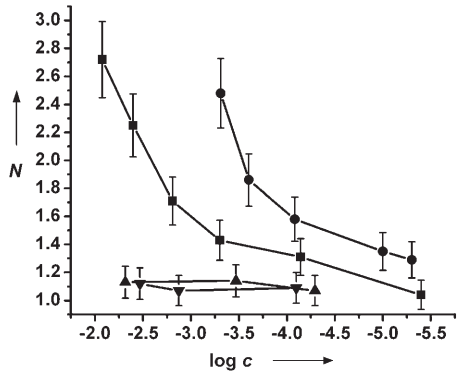

Figure 3. PGSE NMR-derived aggregation numbers (N) as a function of concentration for chromophores TMC-1 in CD_2Cl_2 (●) and [D$_6$]DMSO (▲), and TMC-2 in CD_2Cl_2 (■) and [D$_6$]DMSO (▼). Lines are drawn as guides to the eye. c = concentration [M].

Hyperpolarizabilities were measured at 1907 nm in CH_2Cl_2 by electric field-induced second harmonic generation (EFISH)[22] and track the same concentration-dependence as observed in the optical and PGSE spectra. Thus, the TCM-1 and TCM-2 $\mu\beta$ values show pronounced concentration dependence due to the aforementioned aggregation effects (Figure 4). The TCM-1 $\mu\beta$ rapidly increases as concentration falls, with $\mu\beta$ saturating at a very large[1–5] $-24000 \pm 4320 \times 10^{-48}$ esu at 5×10^{-6} M. The increase with dilution indicates dissociation of (presumably centrosymmetric) aggregates, paralleling the PGSE data, as expected. Note that $\mu\beta$ approaches a maximum at concentrations where the PGSE measurements indicate the presence of more than 80% monomer. TCM-2 deaggregation occurs at somewhat lower concentrations (10^{-5}–10^{-6} M), in good agreement with the PGSE data, with an unprecedented $\mu\beta$ value of $-488000 \pm 48800 \times 10^{-48}$ esu at 8×10^{-7} M.[23] From the reliably computed μ[19] we estimate $\beta_{0.65eV} \approx 9800 \times 10^{-30}$ esu. To our knowledge, these are the largest off-resonance $\mu\beta$ and β values ever achieved for any molecule.[1–5]

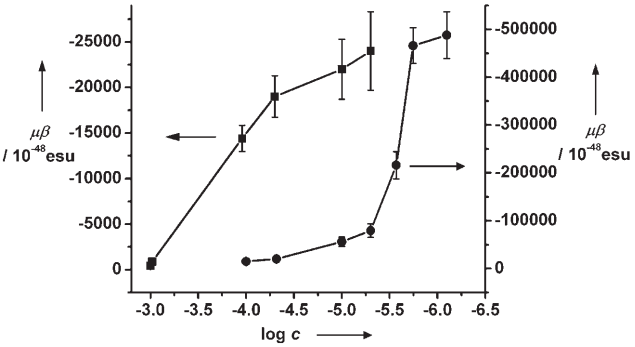

Figure 4. EFISH-derived $\mu\beta$ data for chromophores TMC-1 (■) and TMC-2 (●) versus concentration in CH_2Cl_2 at 1907 nm. Lines are drawn as guides to the eye. c = concentration [M].

Preliminary Teng and Man[24] measurements on poled TMC-1 and TMC-2 containing guest–host polymers reveal very large EO coefficients (r_{33}) at 1310 nm. Poly(vinylphenol) films containing 10 wt % TMC-1 and 5 wt % TMC-2, poled at 100 $V\,\mu m^{-1}$, exhibit nonresonant r_{33} responses of 48 and 320 $pm\,V^{-1}$, respectively. Lower EO responses are observed in less polar matrices, presumably due to the aggregation. These results suggest obvious molecular and macromolecular modification strategies, currently under investigation, to address the aggregation issue and to further enhance r_{33}.

In summary, twisted π-electron system chromophores have been prepared and exhibit exceptional molecular hyperpolarizabilities, with nonresonant $\mu\beta$ values as high as -488000×10^{-48} esu, while preliminary poled guest–host experiments indicate promise for EO applications. An interesting observation here is that the ultralarge hyperpolarizabilities exhibited by these unconventional chromophores seem far beyond classical two-level behavior. Kuzyk argues that the β responses of all organic chromophores prepared to date fall far short of the theoretical quantum limits, for reasons that are presently not entirely clear.[25] Twisted π-electron system chromophores may provide new insight into the reasons.

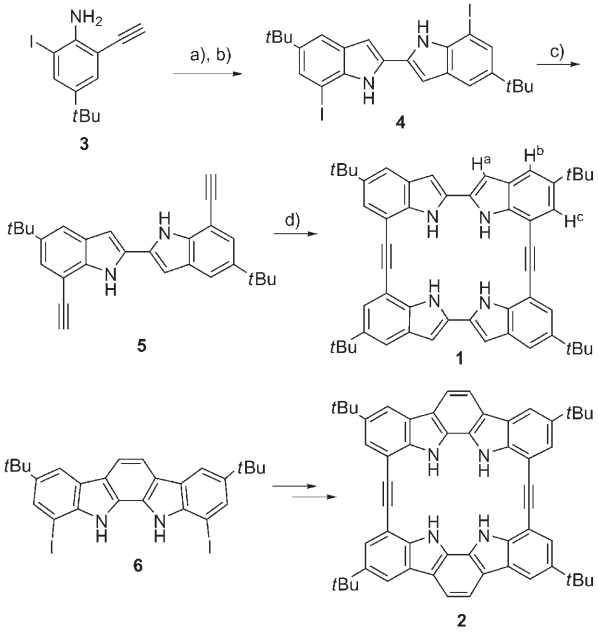
Indole-Based Macrocycles as a Class of Receptors for Anions**

*Kyoung-Jin Chang, Dohyun Moon, Myoung Soo Lah, and Kyu-Sung Jeong**

The development of synthetic receptors and chemosensors for anions[1] has attracted much attention in recent years as the fundamental role of anions in biological and chemical processes has become increasingly understood. Biomacromolecules such as sulfate-binding proteins and a CIC chloride channel make use of hydrogen bonds as a major driving force to bind or transport anions through cell membranes.[2] Similarly, hydrogen-bonding interactions are widely implemented for the construction of artificial receptors, and amido and ureido groups have frequently been incorporated for this purpose.[1,3,4] Furthermore, the pyrrolic NH group has also been used as a hydrogen-bond donor to an anion, as demonstrated in calixpyrroles,[5] expanded porphyrinoids,[6] and amidopyrroles.[7]

Herein, we describe the synthesis and binding properties of indole-based macrocycles **1** and **2**, which can function as a new class of synthetic receptors for anions.[8] The macrocycles contain a well-defined internal cavity surrounded by four indole NH hydrogen atoms, thus are capable of binding anions strongly through hydrogen-bonding interactions. More interestingly, **1** and **2** showed separate sets of ^{1}H NMR signals for the free macrocycles and their complexes at room temperature in all cases and thus can serve as chemosensors for anions based on ^{1}H NMR chemical shifts.

The synthesis of **1** and **2** is outlined in Scheme 1. The key molecular building block 7,7′-diiodo-2,2′-biindole (**4**) was prepared by oxidative dimerization ($Cu(OAc)_2$, 95%)[9] followed by double indolization (CuI, 81%)[10] of 4-*tert*-butyl-2-ethynyl-6-iodoanilne (**3**).[11] In turn, **4** was converted into a diethynyl derivative **5**. After numerous unsuccessful attempts,[12] the coupling reaction of **4** and **5** under the copper-free conditions described by Soheili et al. gave **1** in a reasonable yield (64%).[13] Similarly, the ethynylene-bridged macrocycle **2** was synthesized from compound **6**,[11] and the yield for the final coupling step was 73%. The structures of **1** and **2** were elucidated by elemental analyses, ^{1}H NMR spectroscopy (including ^{1}H-^{1}H NOESY experiments), and FAB mass spectrometry.



Scheme 1. Reaction conditions: a) $Cu(OAc)_2 \cdot H_2O$, pyridine, RT, 95%; b) CuI, DMF, 100–110°C, 81%; c) $[Pd(dba)_2]$, CuI, PPh_3, TMS-acetylene, Et_3N/THF, 54–55°C, 80%, then K_2CO_3, MeOH, RT, 90%; d) $[(allylPdCl)_2]$, P(*t*Bu)$_3$, DABCO, CH_3CN/toluene, RT, 64%. dba = *trans*,*trans*-dibenzylidineacetone, TMS = trimethylsilyl, DABCO = 1,4-diazabicyclo[2.2.2]octane.

Computer modeling studies show that **1** and **2** are highly rigid, flat structures[14] as a result of full conjugation of all the indole rings without any flexible bonds (see the Supporting Information). The cavity sizes of **1** and **2** are nearly identical; the diagonal distances between the NH hydrogen atoms in the internal cavities are 3.7 Å for **1** and 3.6 Å for **2**. The widths and heights of the cavities of **1** and **2** are 2.5 and 2.7 Å, and 2.8 and 2.3 Å, respectively. These structural features were confirmed by single-crystal X-ray diffraction analysis[15] of the complex formed between **2** and $Bu_4N^+Cl^-$ (Figure 1). The chloride ion is located in the middle of four indole NH groups and stabilized by four hydrogen bonds with N···Cl$^-$ distances of 3.14(±0.01) Å. The chloride ion is only partially inserted into the cavity of **2**, which implies that the internal size is slightly too small for the chloride ion. It is also worth mentioning that the tetrabutylammonium countercation sits in the plane of the aryl rings, possibly as a consequence of cation–π interactions.The binding properties of **1** and **2** in solution were studied first by ^{1}H NMR spectroscopy. The symmetrical nature of **1** and **2** results in the ^{1}H NMR spectra being very simple; for example, **1** exhibits only five singlets at $\delta = 10.9$ (NH), 7.15 (H_c), 7.01 (H_b), 6.56 (H_a), and 1.24 ppm (*t*Bu) in CD_3CN. Addition of an anion (0.5 equiv) resulted in a new set of ^{1}H NMR signals corresponding to its complex

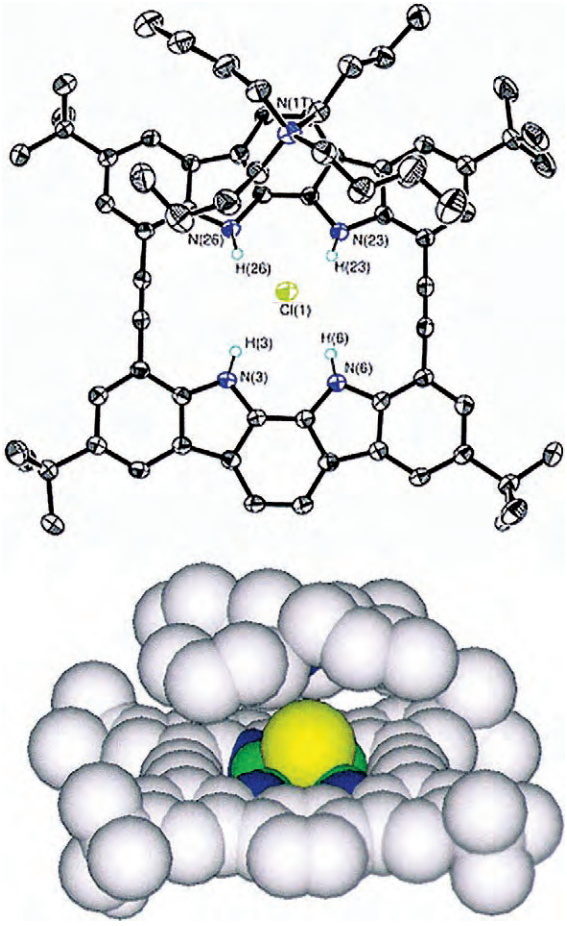

Figure 1. Crystal structures of the complex formed between **2** and $Bu_4N^+Cl^-$: Ortep plot (top) and CPK representation (bottom). Displacement ellipsoids represent 50% probability. Hydrogen-bonding distances and angles between the indole nitrogen atoms and chloride ion are 3.13–3.15 Å and 149–153°, respectively.

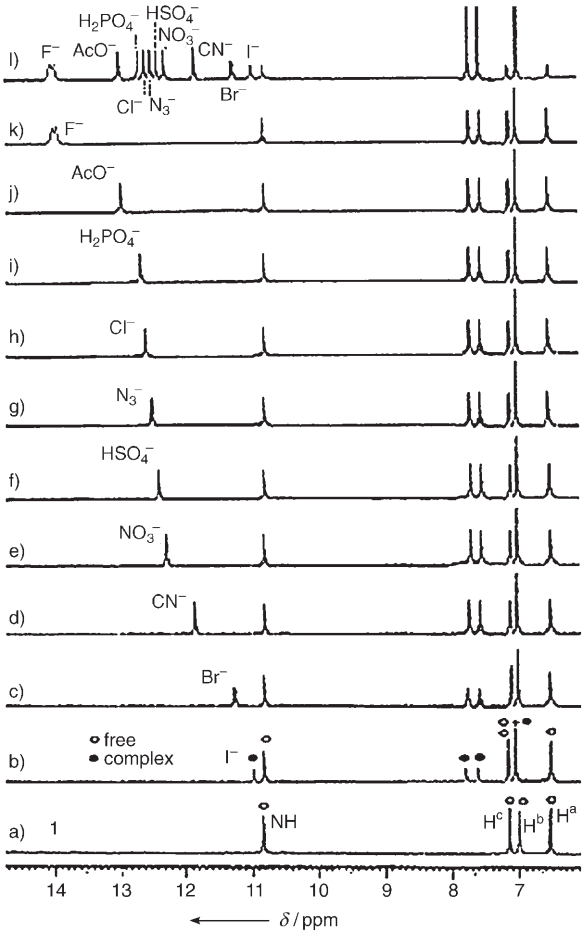

Figure 2. Partial ^{1}H NMR spectra (500 MHz, CD_3CN, 298 K) of a) **1** (1.0×10^{-4} M); b–k) **1** containing approximately 0.5 equivalents of I^-, Br^-, CN^-, NO_3^-, HSO_4^-, N_3^-, Cl^-, $H_2PO_4^-$, AcO^-, and F^-, respectively, and l) **1** (2.0×10^{-4} M) containing approximately 0.1 equivalents of each of 10 different anions. The anions were used as their tetrabutylammonium salts.

that appear at the expense of those of the free macrocycles **1** and **2**, as a consequence of slow exchange on the NMR time scale at ambient temperature (Figure 2). In particular, the NH signals of the complexes were significantly shifted downfield as a result of the formation of hydrogen bonds between the macrocycle and the anions. It should be mentioned that separate sets of ^{1}H NMR signals were observed even with the weakly binding anions Br^- and I^- at room temperature. This type of slow exchange is quite unusual for macrocycles, regardless of the binding strength.[16] All the anions studied gave different chemical shifts for the NH protons of the complexes, and ranged from $\delta = 10.7$ (I^-) to 13.9 ppm (F^-; Table 1).

The NH signals of the complexes appear as a sharp singlet in all cases except for **1**·F^-, which split into a doublet as a consequence of coupling between the NH protons and the bound fluoride nucleus. These NH signals have allowed us to identify and analyze an anion at a micromolar concentration (for example, 5.0×10^{-6} M for Cl^-) by ^{1}H NMR (500 MHz) spectroscopy. Furthermore, the NH signals of all 10 complexes were nicely resolved at room temperature when 10 different anions were added at the same time to a solution of **1** (2.0×10^{-4} M) in CD_3CN. The macrocycle **2** also showed identical spectroscopic behaviors when complexed with anions, but the NH chemical shifts of the complexes were slightly different from those derived from **1** (see the Supporting Information). As a result, the presence of an anion can be detected qualitatively and even quantitatively from the NH chemical shifts and ^{1}H NMR integrals. Therefore, **1** and **2** can be considered as chemical shift based chemosensors capable of sensing and analyzing anions in solution.

The association constants between the macrocycles and anions were determined by UV/Vis titration experiments in CH_3CN at 295 ± 1 K. Incremental addition of an anion to a solution of the macrocycle in CH_3CN (2.0×10^{-5} M) led to gradual changes in the UV absorption spectra, with isosbestic points at several different wavelengths. The association constants (K_a) were determined by nonlinear fitting analyses of the titration curves (Table 1).[17] Job's plots[17b] showed that **1** and **2** formed 1:1 complexes with all of the anions except Br^- and I^-. These larger halides form 2:1 macrocycle/anion complexes, possibly sandwich-type complexes as observed in

Table 1: Association constants (K_a, M^{-1}) and NH chemical shifts of complexes (CD_3CN) formed between **1** and **2** and anions.

Anion	NH chemical shift[a] (δ, ppm)		Association constant (K_a, M^{-1})[b]	
	1	**2**	**1**	**2**
F^-[c]	13.9	13.9	2.0×10^8	5.6×10^8
AcO^-	13.0	12.8	5.9×10^6	6.5×10^6
$H_2PO_4^-$	12.7	12.5	2.1×10^6	3.2×10^6
Cl^-	12.6	12.3	1.5×10^6	2.1×10^6
N_3^-	12.5	12.1	8.8×10^5	9.1×10^5
HSO_4^-	12.4	12.0	6.5×10^5	6.8×10^5
NO_3^-	12.3	11.8	3.9×10^5	3.9×10^5
CN^-	11.9	11.5	6.5×10^4	7.5×10^4
Br^-	11.3	10.9	$K_1=1.9\times10^3$	$K_1=1.9\times10^3$
			$K_2=10$	$K_2=14$
I^-	11.0	10.7	$K_1=3.1\times10^2$	$K_1=3.0\times10^2$
			$K_2=6$	$K_2=5$

[a] The NH chemical shifts of the free macrocycles **1** and **2** are $\delta=10.9$ and 10.6 ppm, respectively. [b] Titrations were all duplicated in CH_3CN at 295 ± 1 K and the errors in the K_a values were within $\pm6\%$. The CH_3CN containing less than 0.05% water was used directly as purchased. [c] The association constants between macrocycles and fluoride ions were determined by competition experiments with chloride by using ^1H NMR spectroscopy.

the binding mode of alkali metals with crown ethers having small cavities.[18] As anticipated from the cavity size, macrocycles **1** and **2** generally show similar binding affinities toward anions. The association constants for a series of halides decrease dramatically in the order $F^- > Cl^- \gg Br^- > I^-$. This large difference is probably attributed to the charge density of the anion surfaces and to the size complementarities of the anions and the internal cavity. Finally, it should be noted that there is a good linear relationship between the binding affinities and the NH chemical shifts of the complexes (see the Supporting Information).

In conclusion, macrocycles **1** and **2** strongly bind various anions through hydrogen-bonding interactions and function as chemosensors capable of distinguishing between anions on the basis of the ^1H NMR chemical shifts of the complex. We are currently developing more practical and selective chemosensors for anionic species by incorporating a chromophore or a fluorophore and by tuning the cavity size.

monochromator. Cell constants and orientation matrices for data collection were obtained from least-squares refinement with a set of 45 narrow-frame (0.3° in ω) scans. The SMART and SAINT software packages were used for data collection and integration, respectively. Collected data were corrected for absorbance by using SADABS based upon Laue symmetry using equivalent reflections. The structure was solved by direct methods and refined by full-matrix least-squares calculations with the SHELXTL-PLUS software package (version 5.1). All non-hydrogen atoms were refined anisotropically; hydrogen atoms except those on the nitrogen atoms were assigned isotropic displacement coefficients U(H) = 1.2U (C) or 1.5U (C_{methyl}), and their coordinates were allowed to ride on their respective atoms. Four hydrogen atoms on the nitrogen atoms could be found in the difference Fourier map and refined with isotropic displacement coefficients. Crystal data for **2**·Cl^- at 173 K: $C_{72}H_{88}N_5Cl$, $0.38 \times 0.33 \times 0.30$ mm^3, orange crystal, monoclinic, space group $P2_1/c$, $a = 15.664(2)$ Å, $b = 19.343(2)$ Å, $c = 20.201(2)$ Å, $\beta = 92.752(2)°$, $V = 6114(1)$ Å^3, $Z = 4$; $M_r = 1058.92$, $\rho_{calcd} = 1.150$ g cm^{-3}, $\mu(Mo_{K\alpha}) = 0.109$ mm^{-1}, final R1 = 0.0554 for 14549 reflection of $I > 2\sigma(I)$, $R1 = 0.1111$, $wR2 = 0.1633$ for all 37737 reflections. Characteristics of Boron Nitride Nanotube–Polyaniline Composites**

Chunyi Zhi, Yoshio Bando, Chengchun Tang, Susumu Honda, Kazuhiko Sato, Hiroaki Kuwahara, and Dmitri Golberg*

Significant efforts have been made to design and fabricate nanotube-based composites since the pioneering report on carbon nanotube (CNT)–polymer composites by Ajayan et al.[1] These composites are expected to have useful electrical and optical properties, thermal conductivity, and superior mechanical strength compared to unprocessed polymers.[2,3] Polyaniline (PANI), a typical electroconductive polymer, is a promising candidate for the fabrication of nanotube-based composites due to its stability and redox properties. Significant progress has been achieved with respect to the processing and property improvements of PANI–CNT composites.[4] For real-device applications, the two important factors—functionality and processability—should be considered. These parameters primarily depend on the efficiency of interactions between the nanotubes and polymer chains within a composite material. To enhance these interactions, the PANI–CNT composites are typically fabricated by in situ polymerization.

Boron nitride nanotubes (BNNTs), which are structurally similar to CNTs, have been predicted to behave like wide-band-gap semiconductors independent of radius, chirality, and the number of tubular shells.[5] Interestingly, the electrical polarization induced by broken symmetry along the BNNT axis has been predicted in a theoretical study; this is quite distinct from the case of CNTs.[6] Moreover, BNNTs have superb mechanical properties, thermal conductivity, and resistance to oxidation at high temperatures.[7–11] These factors may promote effective BNNT usage in nanocomposites. However, to the best of our knowledge, no BNNT–polymer composites have been reported to date. Studies of BNNTs–polymer composites are absent because it is extremely difficult to obtain a highly pure BNNT phase with a yield high enough to fabricate and test a composite

material, although many methods have been probed to synthesize BNNTs.[12–16]

In the study presented herein, large quantities of highly pure BNNTs were synthesized by chemical vapor deposition with boron and metal oxide as the reactants.[17,18] PANI–BNNTs composites were fabricated by simple solution mixing to give self-organized composite films. Detailed comparative characterization of the composite samples and initial materials constituting them was then carried out. The morphology of the composites was analyzed by using scanning and transmission electron microscopy (SEM, TEM), which both revealed uniform coverage of a BNNT surface with PANI. Additional characterization was performed by using Raman spectroscopy, UV/Vis absorption, and X-ray diffraction (XRD). All results indicated strong interactions between PANI and BNNTs within the composites.

BNNTs and a nonconducting soluble emeraldine-based form of PANI (EB) were mixed and sonicated in *N*,*N*-dimethylformamide to form a solution. The solution was then left at room temperature for over 12 h during which a self-organized composite film formed at the bottom of the reaction vessel. It is worth noting that when the same process was carried out with a solution of CNT and EB, no film was deposited. This result indicates that BNNTs display stronger interactions with EB than CNTs. A BNNT–EB film was removed from the reaction vessel and mounted on a silicon wafer for further characterization and testing.

Figure 1 depicts typical SEM images of a composite film. Figure 1a shows the BNNTs embedded in an EB matrix; some BNNTs are out of the matrix because the film broke during its mounting on a silicon wafer. During the long irradiation times, the film shrank and broke, thus allowing the BNNTs to become clearly visible (Figure 1b). The morphology of BNNTs within the composites is similar to that of pure BNNTs, as revealed by SEM. However, notable differences were observed by TEM. Figure 2a shows a low magnification TEM image of a composite. Although the BNNTs are covered by EB, they still retain a perfect crystalline structure, as revealed by a high-resolution TEM image (Figure 2b). Typically, BNNTs are not wetted by most materials (see Supporting Information). In contrast, in the present experiments all BNNTs were well covered by EB, although some BNNTs protruded from the matrix during SEM observations. This coverage indicates strong interactions between BNNTs and EB. The origin of these interactions may be analogous to that found in a solution of BNNT/poly(*m*-phenylenevinylene-co-2,5-dioctoxy-*p*-phenylenevinylene):[19] the PANI ring units may come sufficiently close to a hexagonal BNNT surface to lead to efficient π–π interactions.[4] The interactions between BNNT and PANI are stronger than between CNT and PANI due to electrical polarization in BNNTs induced by broken symmetry.[6]

Raman spectroscopy was used to gain insight into the origin of the strong interactions between EB and BNNTs. As shown in Figure 3, two dominant peaks at 1350 and 1579 cm^{-1} are present in the Raman spectrum of pure EB. Only one peak at 1365 cm^{-1} is visible in the spectrum of BNNTs. It is surprising that the marked peak shifts are observed in the Raman spectrum of the composite. The BNNT-related peak

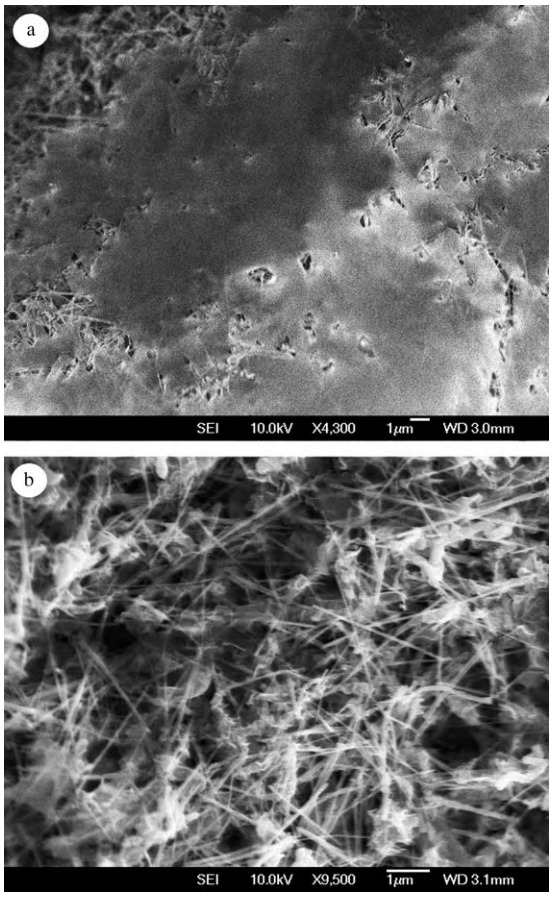

Figure 1. SEM images of an EB–BNNT composite a) before and b) after a long period (10–15 s) of electron-beam irradiation inside the scanning electron microscope.

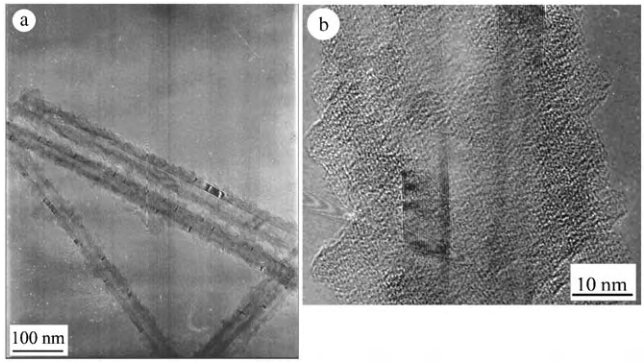

Figure 2. a) Low magnification TEM image and b) high-resolution TEM image of an EB–BNNT composite.

shifts to 1352 cm^{-1}, while the EB-related peak at 1579 cm^{-1} shifts to 1589 cm^{-1} (the peak at 1350 cm^{-1} cannot be identified in the spectrum because it is too weak and overlaps with the BNNT-related peak). Raman peak shifts have not been observed during studies of CNT–PANI composites. It is well known that the Raman spectra of CNTs consist of a G band (in-plane stretching, E_{2g} mode) and a D band induced by the disordering or an amorphous C residue. For single-walled

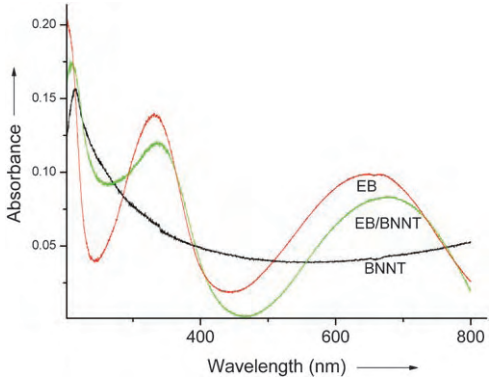

Figure 4. UV/Vis absorption spectra of BNNTs, EB, and an EB–BNNT composite film.

CNTs, evidence of a radial breathing mode (RBM) can also be observed, which is associated with a symmetric movement of all C atoms in the radial direction. The D and G bands are usually not changed in the Raman spectra of CNT–polymer composites, whereas the RBM may shift to somewhat lower frequencies. This fact is supposed to highlight that the breathing mode of single-walled CNTs is largely affected by the particular surrounding of an individual tube.[20] It is clear that a different mechanism should be assigned to explain the large Raman shifts observed in our experiments. Raman spectra are associated with the lattice vibrations. These vibrations are affected by the atomic structure, chemical bonds, and/or electronic structure through electron–phonon coupling. For BNNTs, the shifts may be caused by the prominent variations of the electronic structure rather than the atomic structure. The BNNTs are structurally stable, and it is doubtful that EB, which only covers the BNNT surface, may affect the entire atomic structure of the nanotube. For EB, the shift may be caused by conformation-induced changes in the electronic structure. Generally, given the fact that this phenomenon has not been observed for the CNT composites, we suggest that the peak shift may be related to the electrical polarization solely peculiar to BNNTs.[6] Nevertheless, strong interactions between EB and BNNTs have been demonstrated here by these Raman studies. These interactions may facilitate the charge-transfer processes between the two components. A detailed mechanism of the prominent Raman shifts for the novel composites is still not clear and is the subject of on-going research.

To reveal the influence of the interactions within the composites on the electronic structures of the constituting EB and BNNTs, we performed UV/Vis absorption measurements. Figure 4 shows the UV/Vis absorption spectra of EB, a composite film, and a BNNT film retracted from the composite film by heating the sample at 700 °C in air. For EB, two broad peaks are visible with maximums at 332 nm and 650 nm, which correspond to the π–π^* transitions centered at the benzenoid unit of EB and on the quinoid exciton band, respectively.[21] The peak at 332 nm shifts to 338 nm and that at 650 nm shifts to 673 nm for the composite. For BNNTs, the peak corresponding to a band-gap transition shifts from 214 nm (pure BNNT film) to 210 nm (composite film). This shift implies that BNNTs may have a dopant effect, which was first mentioned for CNT–PANI composites.[4b] However, it is hard to expect a drastic improvement in the conductivity of the present EB–BNNT composites as EB is a nonconducting form of PANI and BNNT is a wide-band-gap semiconductor. In CNT–PANI composites, CNTs can act as conducting bridges, which leads to an increase in conductivity, whereas the present BNNTs cannot. Further investigations on the dopant effect within the composites by using luminescence experiments are underway.

The strong interactions in the EB–BNNT composites may influence the conformation of EB.[4a] Consequently, the ordered structures of a EB–BNNT composite were investigated by XRD, as shown in Figure 5. For BNNTs, the peaks

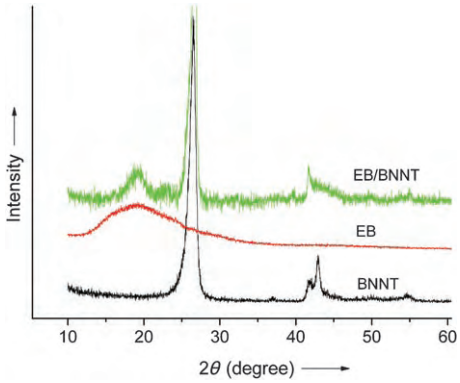

Figure 5. XRD of BNNTs, EB, and an EB–BNNT composite powder.

at $2\theta = 26°$, 41°, 43°, and 54° correspond to the (002), (100), (101), and (004) reflections, respectively. Pure EB displays only a very broad peak centered at 19°. However, for the composite, the EB-related peak becomes much sharper (the full-width half maximum decreases from 10 to 3°). This peak sharpening indicates that the structure of EB within a composite becomes more ordered. The strong nanotube–polymer interactions may lead to such ordering. The above-mentioned EB Raman shifts may be another reflection of this ordering.

In summary, BNNTs–EB composites were fabricated by using simple solution mixing. A composite film can be obtained through self-organization, which is indicative of the strong interactions between BNNT and PANI. Proof of this interaction is given by Raman, UV/Vis absorption, and XRD experiments. BNNT may exhibit a dopant effect to PANI due to charge transfer. PANI becomes more ordered in a composite with respect to its pure form. The present studies reveal that mechanically tough BNNTs may find application as an effective composite additive in EB in order to improve the polymer processing and handling due to the strong BNNT–polymer interactions. In addition, the optical properties of the newly fabricated EB–BNNT composites may be of significant interest.

Experimental Section

An induction furnace was used to synthesize BNNTs. In a typical experimental run, a mixture of MgO, FeO, and boron powder was heated in a boron nitride crucible to 1400 °C. Ammonia gas was then introduced into the system to react with gaseous Mg and Fe and gaseous B_2O_2 was produced. After two hours, a white product was collected from a BN tube attached to the reaction chamber. The BNNT–PANI composites were fabricated by simple mixing and sonication of BNNTs and EB in the *N*,*N*-dimethylformamide. A self-organized composite film was recovered from the bottom of the reaction vessel. An SEM (JEOL SM67F) was used to characterize the products. The microstructure was investigated by using a JEOL-3000F high-resolution field-emission TEM operated at 300 kV. A Reinshaw 2000 Micro-Raman system with a 30 mW Ar^+ laser of wavelength of 514 nm was used to study the lattice vibrations of the fabricated composites. The UV/Vis absorption experiments were performed by using a HITACHI U-4100 spectrometer. XRD patterns of the samples were recorded on a RINT2200 X-ray diffractometer with standard $Cu_{K\alpha}$ radiation.

Covalent Functionalization: Towards Soluble Multiwalled Boron Nitride Nanotubes**

Chunyi Zhi, Yoshio Bando, Chengchun Tang, Susumu Honda, Kazuhiko Sato, Hiroaki Kuwahara, and Dmitri Golberg*

In many respects, a boron nitride nanotube (BNNT) has advantageous properties when compared to a standard carbon nanotube (CNT). For example, BNNTs are stable wide-band-gap semiconductors, independent of diameter and chirality.[1] In contrast, the electrical performance of a CNT is a complex function of many structural parameters, which are difficult to control.[2] BNNTs exhibit excellent mechanical properties, high thermal conductivity, and superb resistance

to oxidation.[3–8] Therefore BNNTs are thought to be primarily useful in nanoscale semiconductors working in oxidative or hazardous environments at high temperatures, and as an additive in composites that leads to the improvement of mechanical properties and thermal conductivity of the matrix.

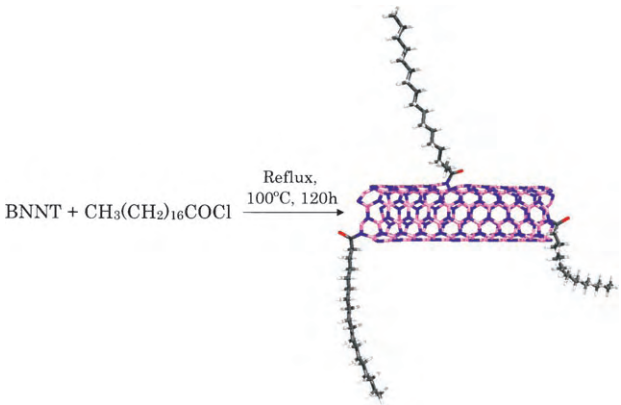
However, to date there has been a lack of notable progress in the above-mentioned fields. Many unanswered questions, such as how to adjust the electronic structure of BNNTs, how dispersible BNNTs are in a solvent, and how to produce clean BNNTs in high yield, has hampered the expected breakthroughs.

The functionalization of CNTs is a vital tool in tailoring their properties and engineering devices, and significant efforts have been undertaken with respect to this functionalization. Intense research has been carried out on soluble CNTs, CNT composites, and CNT compatibility with biological systems.[9–13] As for the BNNT system, only recently Xie et al. have obtained good BNNT dispersion through their functionalization with amine-terminated oligomeric poly(ethylene glycol).[14] The functionalized BNNTs were easily retracted, which indicates that the interactions between the amino groups and the BNNTs are noncovalent. In addition, contamination with carbon was a major concern as the BNNTs were produced by a CNT substitution reaction.[8] To date, the covalent-bond chemistry of BNNTs and related functionalization has long been awaited but not reported. The ability to functionalize BNNTs with covalently bonded groups should allow the tailoring of their properties and of the materials made out of them.

Herein, we report how pure multiwalled BNNTs are synthesized in high yield by carbon-free chemical vapor deposition (CVD).[15,16] A mixture of boron and metal oxide served as the reactant during the synthesis and an original approach was then developed to functionalize BNNTs with an organic residue through the formation of a covalent bond. This method led to highly soluble products. Cathodoluminescence (CL) and UV/Vis absorption experiments revealed variations in the electronic structure of the BNNTs after functionalization, which may pave a way to tune the band gap of the BNNTs.

The functionalization methodology is based on the chemical reaction between the COCl group of stearoyl chloride and amino groups on the BNNTs, as shown in Scheme 1. A similar reaction has been widely applied to modify CNTs.[9] In contrast to the starting material (multiwalled BNNTs), which is insoluble in organic solvents, the functionalized BNNTs (f-BNNTs) are soluble in solvents such as chloroform, *N*,*N*-dimethylacetamide, tetrahydrofuran, *N*,*N*-dimethylformamide, acetone, toluene, and ethanol. The solubility of f-BNNTs in *N*,*N*-dimethylacetamide is $>0.5\,g\,L^{-1}$. Very dilute BNNT solutions are almost totally transparent and white concentrated BNNT solutions are visually nonscattering. No precipitation was observed when the sample was kept over a long period under ambient conditions.

Transmission electron microscopy (TEM) was used to confirm the presence of BNNTs in solution and to check the morphology of the f-BNNTs. The results are shown in Figure 1. f-BNNTs in solution are well dispersed and retain



Scheme 1. Schematic representation of the designed reaction to give a functionalized nanotube.

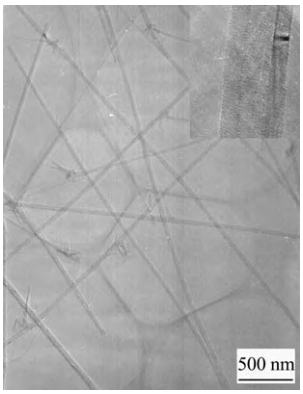


Figure 1. TEM images of f-BNNTs. Inset: a high-magnification TEM image revealing a tubular structure of the f-BNNT and an amorphous layer on its surface.

a characteristic 1D tubular morphology. An amorphous layer can be observed on their surface. On average, the f-BNNTs are slightly shorter than the original BNNTs, which is caused by stirring of the reaction mixture for a long period during functionalization.

To reveal the functionalization mechanism, Fourier-transformed infrared (FTIR) spectroscopy was used to compare the original BNNTs with f-BNNTs (Figure 2. The absorptions corresponding to C=O (1774 and 1630 cm^{-1}) and C–H bonds (bending vibrations: 1016, 1078, 1163, and 1193 cm^{-1}, stretching vibrations: 3033 2959 and 2925 cm^{-1}(weak)) can be clearly identified in the FTIR spectrum of f-BNNTs, which indicates that long alkyl chains are bonded to the BNNTs. It is worth noting that for stearoyl chloride, the peaks related to C=O appear at 1712 and 1807 cm^{-1}, while they appear at 1774 and 1630 cm^{-1} for the f-BNNTs. This shift implies that the COCl functional group participates in the chemical reaction. As a reductive NH_3 gas is used during the CVD synthesis of BNNTs from boron and metal oxide,[15,16] we assume that there are some amino groups present on the side walls of the BNNTs, as well as at their open ends. Their presence ensures that long alkyl chains can bond through the chemical reaction between COCl and the amino groups. The effect is similar to that observed in CNTs, whose defects can be oxidized to form

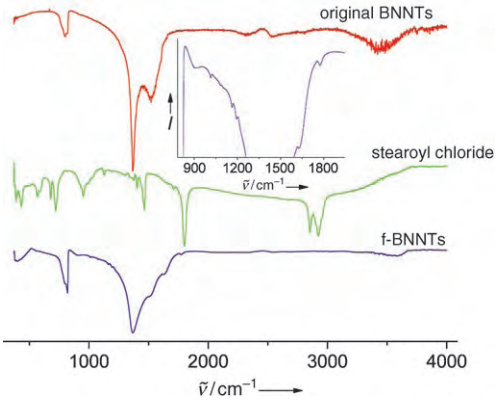

Figure 2. Comparative FTIR spectra of original BNNTs, stearoyl chloride, and f-BNNTs. Inset: an enlarged profile of additional peaks that only appear in the spectrum of f-BNNTs.

reactive groups, and subsequently long-chain alkyl amines can be coupled to carboxy groups activated with $SOCl_2$.[17] In addition, the chemical reaction also induces notable variations in BNNT-related FTIR peaks, namely, the disappearance of peaks corresponding to multiphonon processes (2313 and 2530 cm^{-1}) and abatement of splitting of the E_{1u}(TO) and E_{1u}(LO) modes (TO: transverse optic; LO: longitudinal optic).[18] An investigation into the detailed mechanism that causes these changes is underway.

Given that variations in the optical properties have also been observed for CNTs after functionalization[19,20] and that UV emission has been observed for BNNTs,[18] we performed CL measurements on the f-BNNTS. A f-BNNTs powder was chosen as the sample to be analyzed as solutions are not suitable for CL experiments. Figure 3 compares the room-

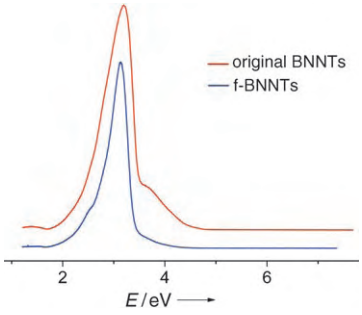

Figure 3. Comparative CL spectra of original BNNTs and f-BNNTs.

temperature CL spectrum of original BNNTs with that of f-BNNTs. As previously reported, the spectrum of original BNNTs shows a dominant peak at about 3.25 eV and a shoulder at about 4.05 eV, which is thought to originate from B or N vacancies.[18] Peaks related to the band transition should appear at about 5.5 eV, which can only be observed from low-temperature CL experiments. In the spectrum of the f-BNNTs, there is a new shoulder at about 2.50 eV. One possible explanation for this emission is that a new defect-related band is introduced into the energy gap of BNNTs. This, in turn, implies that a long alkyl chain protruding from a side wall or open end of a BNNT may lead to a dopant effect. The dopant effect may be induced by a charge transfer between the BNNT and the alkyl chain.[9] Another possibility is that the shoulder at about 2.50 eV may solely originate from the long alkyl chains, which means that we detect a kind of surface-state luminescence. If so, the intensity of the shoulder emission may provide a way to estimate the density of alkyl chains on the surface of a BNNT.

To probe the influence of long alkyl chains on the electronic structure of BNNTs, UV/Vis absorption experiments were performed. A solution sample cannot be used for these experiments as most organic solvents are totally opaque to wavelengths shorter than 250 nm (4.96 eV), and a BNNT has an even larger band gap according to a previous study.[1] Therefore, BNNT films were used as samples. Figure 4

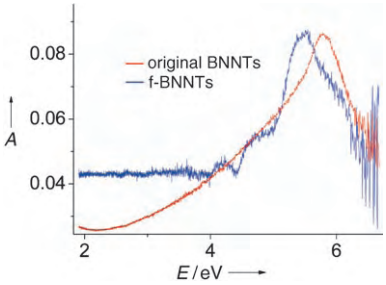

Figure 4. Comparative UV/Vis absorption spectra of original BNNTs and f-BNNTs.

compares the UV/Vis absorption spectrum of BNNTs with that of f-BNNTs. The peak at 5.80 eV dominates the BNNT spectrum; it corresponds to the band-gap transition and indicates a band gap in the range of 5.2 to 5.5 eV.

More features appear in the spectrum of the f-BNNT. First, the dominant peak shifts to about 5.45 eV and displays a shoulder at 5.8 eV. This shoulder clearly corresponds to the peak of the band-gap transition mentioned above. Second, new peaks at about 4.68 and 4.20 eV appear. The shift of the main peak indicates that some new electronic states are present in the energy-gap region of the f-BNNTs. If the long alkyl chain acts as a carbon dopant, it may be that the additional electronic states appear in the top of the valence band and the bottom of the conduction band. It was reported that in boron carbonitride (BCN) nanotubes, the carbon content may affect the band gap. Typically in BCN nanotubes, the width of the band gap decreases with an increase in carbon concentration.[21] However, it is difficult to control precisely the atomic concentration of carbon within BCN nanotubes at the stage of tube growth.

In contrast, the process of postsynthesis chemical modification of BNNTs may be easily controlled. Specifically, the density of alkyl chains on the BNNT surface can be adjusted by controlling the reaction time and temperature. Alternatively, a defunctionalization process could be developed to further adjust the alkyl-chain density as with CNTs.[22] The peaks at 4.68 and 4.20 eV imply that the dopant effect of alkyl chains on BNNTs is real. This doping is crucial for the engineering of the wide band gap. Chen et al. have used a long alkyl chain to decorate single-walled CNTs.[9] Variations in the band structure of the decorated CNTs have indeed been observed in absorption experiments. The influence of an alkyl chain on BNNTs may be even larger than that on CNTs as

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

carbon atoms are already present in CNTs but are heteroatomic for BNNTs. This factor makes the modification of BNNTs with organic groups highly promising.

In summary, an original methodology has been developed to functionalize multiwalled BNNTs with long alkyl chains and the resultant functionalized BNNTs are soluble in many organic solvents. The CL and UV/Vis absorption experiments indicate that long alkyl chains may induce drastic changes in the band structure of BNNTs. These findings may be the beginning of significant progress in the chemistry of BNNTs and their functionalization paves the way to controllable tailoring of their electronic structure and to band-gap engineering.

Experimental Section

An induction furnace was used to synthesize multiwalled BNNTs. The detailed procedure is described elsewhere.[15,16] The as-prepared BNNTs were heated to about 1900 °C in nitrogen to remove impurities and metal catalysts. For functionalization, the BNNTs were immersed in stearoyl chloride, the mixture was stirred, heated to 100 °C, and annealed over 120 h. After centrifugation, the remaining solid was washed with chloroform and *N*,*N*-dimethylformamide repeatedly to afford f-BNNTs.

The microstructure was analyzed by using a JEOL-3000F high-resolution field-emission TEM operated at 300 kV. FTIR spectra were collected by using a Perkin Elmer FTIR spectrometer with a laser wavelength of 1024 nm. The CL spectra were recorded in a charge-coupled device (spectra view 2D; Jobin Yvon, France).

The UV/Vis absorption experiments were performed by using a Hitachi U-4100 spectrometer. The f-BNNTs were dissolved firstly in chloroform, a few drops of the solution were dripped onto a clean quartz wafer, then the solvent was allowed to evaporate. A uniform compact film suitable for UV/Vis absorption experiments was thus obtained. For the original BNNTs, a technique developed in our previous studies was used to make a film.[23] Briefly, a conjugated polymer, poly(*m*-phenylenevinylene-*co*-2,5-dioctoxy-*p*-phenylenevinylene), was used to wrap the BNNTs, which allows them to be dissolved. Composite films were first made by dripping a solution of the BNNTs onto a quartz wafer; the original uniform BNNT film was obtained by heating the composite film to 700 °C in air to remove the polymer.

Dynamic Combinatorial Libraries of Dye Complexes as Sensors**

*Andrey Buryak and Kay Severin**

Mixtures of compounds which are formed by the combinatorial assembly of molecular building blocks under thermodynamic control are generally referred to as "dynamic

combinatorial libraries" (DCLs).[1,2] DCLs are adaptive chemical networks. The addition of a target molecule that selectively interacts with some members of the library may result in a re-equilibration, and this adaptation can be used to identify library members with a high affinity for the respective target molecule. So far, DCLs have mainly been used to study receptors, catalysts, enzyme inhibitors, and new materials.[1,2] Herein, we describe a different application: the utilization of DCLs as sensors.[3]

The relative concentrations of the members of a DCL depend on the environment (solvent, pH, absence or presence of target molecules etc.). A certain library composition is thus a characteristic feature of the environment. It is possible to use the DCL as a sensor if the DCL composition can be transduced into a specific signal output. Up to now DCLs have mainly been analyzed by HPLC, mass spectrometry, and NMR spectroscopy.[1,2] For sensing purposes, however, a fast and cheap analysis method such as fluorescence or UV/Vis spectroscopy would be advantageous. To use the latter technique, we have constructed a DCL of metal–dye complexes in which the library members have a different color. Any re-equilibration will, therefore, result in a variation in the UV/Vis spectrum of the mixture (Figure 1). We show herein that such a library can be used to identify dipeptides in aqueous solution with high selectivity.

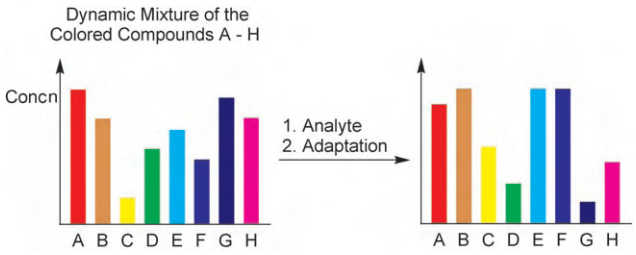

Figure 1. The adaptive behavior of a DCL upon addition of an analyte can be used to identify this analyte by UV/Vis spectroscopy given that the library members possess a characteristic color.

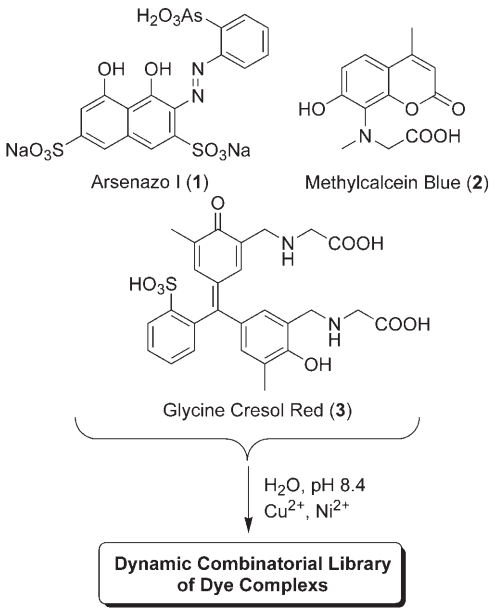
We have used the commercially available dyes arsenazo I (**1**), methylcalcein blue (**2**), and glycine cresol red (**3**) in combination with the metal salts $CuCl_2$ and $NiCl_2$ to generate a DCL in which the library members have a characteristic color (Scheme 1). The dyes form stable complexes with Cu^{2+} and Ni^{2+} ions in buffered aqueous solution (2-(*N*-cyclohexylamino)ethanesulfonic acid (CHES) buffer, pH 8.4), as evidenced by UV/Vis titration experiments. This result is in agreement with reports on the high affinity of these dyes for metal ions.[4–6] Job plot analyses[7] revealed that complexes with more than one ligand per metal ion were formed for several combinations in addition to 1:1 complexes (see the Supporting Information).

The individual metal–dye complexes are able to undergo ligand-exchange reactions. This was evidenced by the fact that the UV/Vis spectra of solutions containing a mixture of two dyes and one metal were different from the sum of the spectra of the individual metal–dye mixtures. The same was true for



Scheme 1. Generation of a DCL of metal–dye complexes by mixing arsenazo I, methylcalcein blue, and glycine cresol red with $CuCl_2$ and $NiCl_2$ in buffered aqueous solution.

the experiments with two metal ions and one dye molecule (see the Supporting Information).

This data confirmed that solutions of the dyes **1**–**3** and the two metal salts contain a complex mixture of metal–dye complexes and that these complexes are in a dynamic equilibrium with small amounts of free metal ions and dye molecules. Any disturbance of this equilibrium by addition of an analyte was expected to result in a characteristic change of color.

We decided to use dipeptides as analytes to demonstrate this proposal.[8] Dipeptides are known to form stable complexes with Cu^{2+} and Ni^{2+} ions[9] and may therefore displace some of the dyes from the metal ions.[10] This process should lead to an increase in the free dye concentration as well as to a re-equilibration of the remaining metal–dye complexes. In a first experiment we added aqueous solutions of the dipeptides Val-Phe, Gly-Ala, His-Ala, Ala-His, Phe-Pro, and Pro-Gly to a mixture of the three dyes and the two metal salts (final [peptide] = 1.0 mM; [**1**] = [**2**] = [**3**] = 75 μM; [Cu] = [Ni] = 75 μM; 35 mM CHES buffer, pH 8.4). The changes in the UV/Vis spectra upon addition of the respective peptide are shown in Figure 2.

All six dipeptides can be easily distinguished by UV/Vis spectroscopy. An experiment of this kind can therefore be used to identify the dipeptide. It is interesting to note that His-Ala gave rise to a spectrum which was very different from that of the other peptides. This result can be explained by the fact that the side chain of the N-terminal His residue is able to coordinate to the metal ions. The spectrum of Ala-His, on the other hand, was more similar to the spectra found for simple dipeptides such as Val-Phe. This observation suggests that the side chains of a His residue at the C terminus is less important for metal coordination. Another distinctive spectrum was found for Phe-Pro, with rather weak color changes being

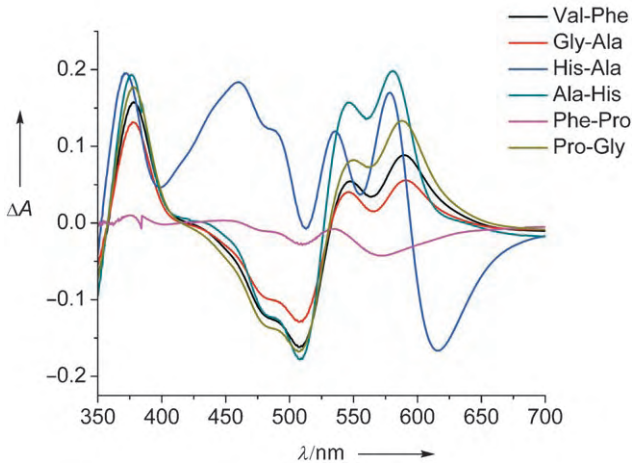

Figure 2. The changes in the UV/Vis spectra upon addition of different dipeptides (1.0 mM) to an aqueous solution containing a DCL sensor composed of the dyes **1**–**3** and the metal salts $CuCl_2$ and $NiCl_2$ ([**1**] = [**2**] = [**3**] = 75 μM, [Cu] = [Ni] = 75 μM, 35 mM CHES buffer, pH 8.4).

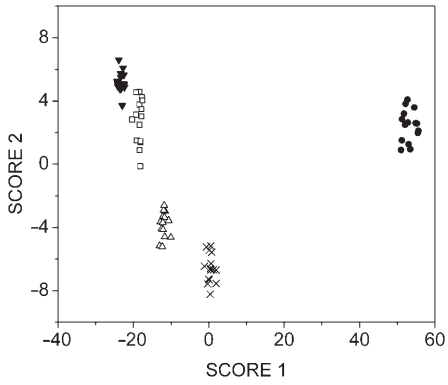

Figure 3. Two-dimensional LDA score plot for the analytes Gly-Ala (●), Val-Phe (□), Ala-Phe (▼), Phe-Ala (△), and D-Phe-Ala (×).

observed. This result highlights the importance of the amide bond for metal coordination.[9]

To test the scope of the DCL sensor we performed a second set of experiments with dipeptides which were structurally more closely related (Gly-Ala, Val-Phe, Ala-Phe, Phe-Ala, and D-Phe-Ala). As expected, the UV/Vis difference spectra were similar to each other, and we therefore used chemometrics[11] to classify the analytes. Fifteen UV/Vis measurements were performed for each dipeptide. To verify that the discrimination between the analytes did not arise from small differences in the concentrations of the peptide stock solutions we varied the peptide concentration for each analyte by ±5%. Thus, five measurements were performed with a peptide concentration of 1.00 mM, five with a concentration of 0.95 mM, and five with a concentration of 1.05 mM (the sensor composition was the same as that described in Figure 2). Data analysis was carried out with the help of the commercial statistics program SYSTAT (version 11.0).[12] A preselection was performed using an automatic variable selection algorithm (see the Supporting Information) to determine which wavelengths in the region between 350 and 700 nm were most relevant for the identification of the peptide. The data from the eight selected wavelengths were then classified by a linear discriminant analysis (LDA).[13] A graphical representation of this analysis in the form of a score plot is shown in Figure 3.

A 100% discrimination was achieved for a "jack-knifed" classification matrix, in which one measurement at a time was treated as an unknown and the rest of the data was used as the training set.[14] This result is quite remarkable, given the fact that none of the dipeptides contain coordinating side chains and that closely related analytes such as the regioisomers Ala-Phe and Phe-Ala as well as the stereoisomers L-Phe-Ala and D-Phe-Ala were used. The discriminative power of the sensor was lower when the complexity of the DCL was reduced by omitting one of the two metal salts: 7 out of the 75 measurements were misclassified for a DCL containing the dyes **1**–**3** and only $CuCl_2$, and 17 misclassifications were obtained for a DCL containing the dyes **1**–**3** and only $NiCl_2$ (see the Supporting Information). This observation shows that a certain library complexity is required to obtain a good differentiation.

The results described above clearly demonstrate the potential of DCLs as sensors. The present library was obtained by mixing commercially available dyes with two transition-metal salts. Despite this simplicity, it was possible to differentiate closely related analytes such as the steroisomers Phe-Ala and D-Phe-Ala. It should be noted that other adaptive systems which show a detectable response upon addition of an analyte can easily be envisioned. DCLs based on compounds with a distinct redox potential or fluorescence, for example, are potentially well suited. The response could then be used to identify a single component or to classify a complex matrix. The modular nature of a DCL makes it easy to optimize the response for a particular sensing problem by variation of the nature, the number, and/or the relative amount of its constituent building blocks. Given these advantages, it seems likely that DCL sensors may find various applications in analytical chemistry.

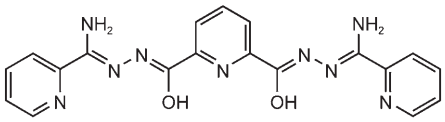
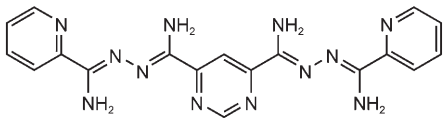
some exhibit spin-transition behavior[7] or manifest catalytic activity.[8] Like metal-template techniques,[9] self-assembly[10] can be used to build up beautiful molecular architectures,[6,11–13] often containing paramagnetic ions and endowed with unique properties.[14] A few octanuclear copper(II) complexes have been reported,[8,15–21] mostly synthesized in an "uncontrolled" assembly process starting from a large number of components in the presence of small bridging ligands such as hydroxide, oxide, methoxide, or halide.[21] A more attractive approach is the use of tailored single-stranded ligands for self-assembly, which makes the involvement of small bridging fragments unnecessary.[21,22] Two remarkable recent examples, reported by Thompson et al.[23] and Matthews et al.,[21] relied on linear ligands, one of which, $2poapH_2$, is tritopic, and the other, L′, tetratopic. Here we use a ditopic single-stranded thiocarbohydrazone ligand and show that further unusual multinuclear systems can be formed.



$2poapH_2$



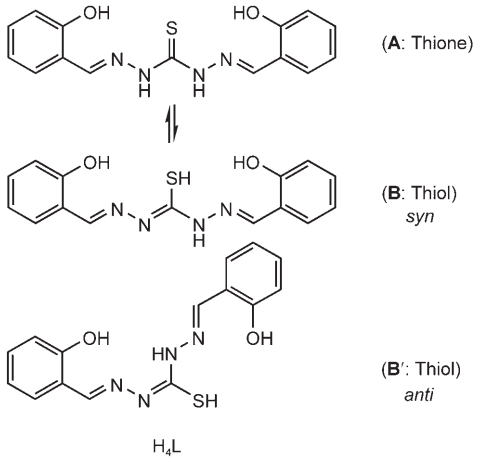
L′

Thiocarbohydrazones have previously served as building blocks in the self-assembly of tetranuclear molecular square structures. In particular, mixed-valent iron(II)–iron(III), nickel(II), zinc(II), and cadmium(II) clusters have been synthesized starting from 1,5-bis(2-acetylpyridine)thiocarbohydrazone or related derivatives.[24–26] Reactions of the same ligands with copper(II) produced dimers of dinuclear units held together by extraneous bridging ligands.[26,27]

We discovered that 1,5-bis(2-hydroxybenzaldehyde)thiocarbohydrazone (H_4L) reacts with copper(II) acetate monohydrate or copper(II) sulfate in dimethylformamide (DMF)/ethanol (1:10) in the presence of triethylamine to give the green-brown complex $[Cu_8L_4(DMF)_8(H_2O)]\cdot 3.5\,DMF\cdot 3\,H_2O$ (**1**·3.5 DMF·3 H_2O) with absorbance features at λ_{max} (ε_M) = 320 (118285), 413 (114660), 437 (136860), and 461 nm (113610 $M^{-1}cm^{-1}$). Recrystallization of the reaction product from dimethyl sulfoxide afforded the complex $[Cu_8L_4(dmso)_7]\cdot 6\,DMSO\cdot 1.32\,H_2O$ (**2**·6 DMSO·1.32 H_2O).

As for the parent thiocarbohydrazide, two tautomeric forms are possible for H_4L: thione form **A** and thiol form **B**, which are in equilibrium.[28] The thiol tautomer can adopt a syn (**B**) or anti (**B′**) configuration as a consequence of the double-bond character of the central N–C linkage.

X-ray diffraction studies showed the metal-free compound to crystallize in the thione form **A**.[29] Both thiol forms have been observed in metal complexes: in $[MoO_2(H_2L)(dmso)]$ the dianionic ligand adopts the *syn* configuration



(**A**: Thione)

(**B**: Thiol) *syn*

(**B′**: Thiol) *anti*

H_4L

B,[28] while the *anti* configuration **B′** was found in $[MoO_2(H_2L)(CH_3OH)]$.[30] X-ray diffraction[31] revealed that in **1**·3.5 DMF·0.7 H_2O the four thiocarbohydrazone ligands adopt the thiol *anti* configuration **B′** and thus provide two contiguous tridentate pockets, one with NNO and the other with ONS donor atoms, each of which can accommodate one copper(II) ion (Figure 1). Thus, six of the seven donor atoms of a fully deprotonated ligand L^{4-} are linked with two metal ions to give a dicopper(II) unit $\{Cu_2L\}^0$. The assembly of four such units into a metallomacrocyclic array takes place by coordination of the seventh donor atom of each $\{Cu_2L\}$ unit to the copper(II) atom of the adjacent unit which resides in the ONS

ligand pocket to achieve a square-planar geometry. In the resulting architecture (see Figure 1) four copper(II) atoms, Cu1, Cu3, Cu5, and Cu7, are four-coordinate, with two ligands L^{4-} filling all four coordination positions, while the other four copper(II) centers, Cu2, Cu4, Cu6, and Cu8, each accommodated in an ONN ligand pocket, require additional ligands (DMF or DMF and H_2O) to complete their coordination spheres, as shown for Cu2 in Figure 2. The coordination polyhedron for Cu2 is a trigonal bipyramid, while those for

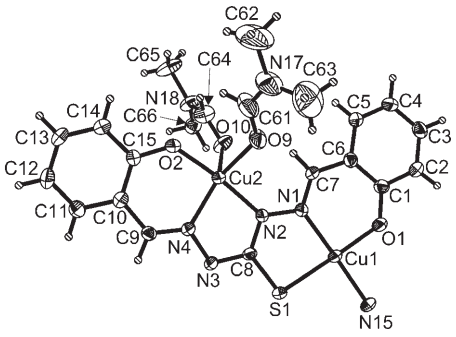

Figure 2. Structural representation of the $\{Cu_2L(dmf)_2\}$ fragment in **1**·3.5 DMF·0.7 H_2O. The atom N15 belongs to the second $\{Cu_2L\}$ unit, which is arranged perpendicular to the N1–Cu1 vector. Selected bond lengths [Å]: Cu1–O1 1.908(4), Cu1–N1 1.970(4), Cu1–S1 2.2527(15), Cu1–N15 2.007(4), Cu2–O2 1.887(4), Cu2–N2 1.965(4), Cu2–N4 1.957(4), Cu2–O9 2.109(4), Cu2–O10 2.159(4).

Cu4 and Cu8 can be better described as distorted square pyramids. Depending on the positions of the disordered components of DMF and H_2O molecules around Cu6 its coordination geometry changes between distorted trigonal-bipyramidal and distorted octahedral. In both cases a water molecule is involved in coordination to Cu6. The charge balance is in agreement with formation of species **1**. Sixteen negative charges provided by four fully deprotonated ligands are balanced by the sixteen positive charges of eight copper(II) ions. This unique assembly of eight copper(II) centers, four of which are four-coordinate and the other four five-coordinate, into an azine-bridged 24-membered metallomacrocycle is to our knowledge the first example in copper(II) coordination chemistry. It requires four heptadentate ligands which use their donor capacity in an unprecedented manner for thiocarbohydrazone coordination chemistry to bind eight metal ions with the number of solvent molecules required to fully satisfy the coordination preferences of the eight copper(II) centers. We note that **1**·3.5 DMF·3 H_2O has an insular molecular structure in which the shortest intermolecular copper–copper separation is about 7.6 Å.

Unlike **1**, the molecule of **2** has C_2 symmetry. Of four independent copper(II) atoms two (Cu1 and Cu3) are square-planar coordinated like in **1**, whereas the coordination polyhedra of Cu2 and Cu4 can be described as distorted trigonal-bipyramidal with DMSO molecules occupying the "axial" positions. While both DMSO molecules at Cu2 are bound through oxygen atoms (Cu2–O5 2.002(5), Cu2–O6 2.346(6) Å), the coordination behavior of the two DMSO ligands at Cu4 is different. One of them coordinates to Cu4 through the oxygen atom (Cu4–O8 1.948(6) Å), whereas the second is disordered over two positions, coordinating through O7 (Cu4–O7 2.378(11) Å) or S5 with a weak contact (Cu4–S5 at 3.257(2) Å) in an alternating fashion. As a result, this DMSO acts as a bridging ligand leading to association of the molecules of **2** in one-dimensional chains along [100] (Figure 3).

The magnetic behavior of a polycrystalline sample of **2**·6 DMSO·1.32 H_2O in the temperature range 2–290 K in a field of 1 T is shown in Figure 4. The value of $\chi_M T$ decreases from 1.48 $cm^3 K mol^{-1}$ at 300 K and reaches a plateau of 0.02 $cm^3 K mol^{-1}$ below 20 K. As the room-temperature value of $\chi_M T$ for an octanuclear unit of eight noninteracting $S = {}^1/_2$ Cu^{II} ions with $g = 2.0$ would be 3.00 $cm^3 K mol^{-1}$, this clearly reflects that the major interactions in **2**·6 DMSO·1.32 H_2O are antiferromagnetic in nature. To extract the magnitude of exchange interaction between the Cu^{II} ions we applied the spin Hamiltonian $\mathscr{H} = -2J \sum_{i=1}^{8} S_i S_{i+1}$. Best fits to the experimental data down to low temperature were obtained by using g values of 2.2 for the Cu^{II} ions and a coupling constant of $J = -145\ cm^{-1}$, taking additionally into account 0.66% of a paramagnetic impurity ($R = 1.6 \times 10^{-4}$). Since the formation of a dinuclear transition metal species with a related ligand

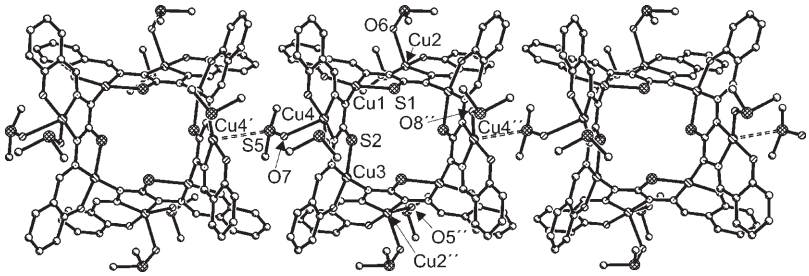

Figure 3. One-dimensional chain of molecules of **2** in **2**·6 DMSO·1.32 H_2O. The second position of the disordered bridging DMSO ligand is omitted for clarity; S5 atoms lie on special positions on twofold axes.

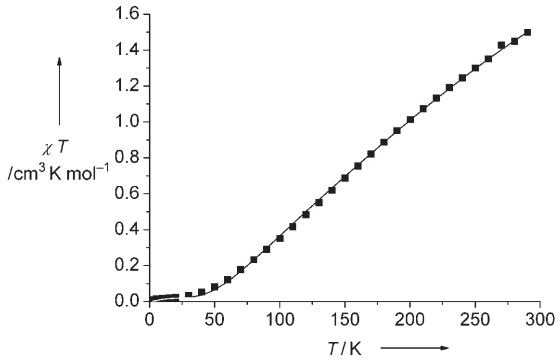

Figure 4. Magnetic data for **2**·6 DMSO·1.32 H_2O (see text for fitting parameters).

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

has been observed,[32] the low-temperature behavior of the molar susceptibility was regarded not as a simple paramagnetic impurity but rather as 0.3% of a weakly coupled dimer of two copper ions in comparable ligand environments, and hence presumably having the same g values as in the main compound. The simulation of $\chi_M T$ versus T with these data is shown in Figure 4 as a solid line. The magnetic behavior of **1**·3.5 DMF·0.7 H_2O is very similar: the g value is 2.14, and the intramolecular coupling $J = -128$ cm^{-1}. Also here an impurity had to be considered. The preparation of **1** is very sensitive, and contributions of between 1 and 7% of a coupled side product were experimentally found. Independent of whether DMF or DMSO completed the coordination sphere for the copper atoms in **1**·3.5 DMF·0.7 H_2O and **2**·6 DMSO·1.32 H_2O, respectively, alternation of the bridging between the metal ions is not reflected in the magnetic measurements. In all cases the fitting of the data with a model containing only one exchange interaction constant was good. This seems reasonable, since all torsion angles Θ_{CuNNCu} (av. 176°) are very close to 180°. Interestingly, the intermolecular arrangement as a one-dimensional chain for **2**·6 DMSO·1.32 H_2O does not influence the magnetic properties of the octanuclear compound; it behaves magnetically like **1**·3.5 DMF·0.7 H_2O, which has shortest intermolecular contacts of about 7.6 Å.

In conclusion, the unprecedented octanuclear clusters **1** and **2** are formed by a unique heptadentate ligand that exhibits particular conformational and configurational flexibility, appropriate spatial arrangement of metal-binding sites, coordination ability, and acid–base properties which allow full use of its donor capacity to satisfy maximally the stereochemical demands of the metal ions with minimum strain energy. The assembled metallomacrocyclic array of eight azine-bridged copper(II) ions, four of which are square-planar and four of which are distorted square-pyramidal or distorted trigonal-bipyramidal, is also unique in copper(II) coordination chemistry. The isolation of **1** and **2** opens up exciting opportunities to construct multinuclear systems with a number of other redox active metal ions with similar stereochemical preferences. The construction of heteronuclear clusters is also a challenge. Substitution of solvent molecules by suitable bridging ligands will also permit the assembly of oligomeric or even polymeric chains of HSNC units. This work is underway in our laboratories.

Experimental Section

All reagents were used as received from Aldrich. 1,5-Bis(2-hydroxybenzaldehyde)thiocarbohydrazone[29] was prepared according to reported procedures.

1·3.5 DMF·3 H_2O: $Cu(CH_3COO)_2 \cdot H_2O$ (0.2 g, 1.0 mmol) in ethanol (20 mL) and triethylamine (3 mL) was added to a hot solution of 1,5-bis(2-hydroxybenzaldehyde)thiocarbohydrazone (0.16 g, 0.5 mmol) in DMF/ethanol (1:10, 22 mL). The resultant brown solution was heated at 100 °C for 1 h and allowed to cool to room temperature. The green-brown crude product was collected by filtration, washed with diethyl ether, and then dissolved in hot DMF (10 mL) and filtered. After 5 d the brown product crystallized from this solution at room temperature, was collected by filtration, washed with diethyl ether, and dried in air. Yield: 0.06 g, 19%. Elemental analysis (%): calcd for $C_{94.5}H_{144.5}N_{27.5}Cu_8O_{23.5}S_4$: C 42.38, H 5.44, N 14.38, S 4.79; found: C 41.99, H 5.60, N 14.09, S 4.92. IR (CsI): $\tilde{\nu} = 1651$, 1599, 1537, 1361, 1331, 1199, 757, 571, 527, 495, 472, 364, 323 cm^{-1}. Brown cubic crystals of 1·3.5 DMF·0.7 H_2O suitable for X-ray diffraction were obtained by recrystallization of **1**·3.5 DMF·3 H_2O from anhydrous DMF.

2·6 DMSO·1.32 H_2O: Recrystallization of the green-brown crude product (obtained as described above) from DMSO (5 mL) afforded green-brown prisms suitable for X-ray diffraction. Yield: 0.04 g. Elemental analysis (%): calcd for $C_{86}H_{120.67}N_{16}Cu_8O_{22.33}S_{17}$: C 37.03, H 4.32, N 8.03; found: C 37.03, H 3.97, N 8.11.

IR spectra were recorded on a Bruker FTIR VERTEX70 instrument in the region 4000–150 cm^{-1}. UV/Vis spectra were recorded on a Perkin-Elmer Lambda 20 UV/Vis spectrophotometer on samples dissolved in DMF. Magnetic susceptibility measurements were carried out with a Quantum Design MPMS SQUID magnetometer between 2 and 290 K in an applied field of 1 T. Diamagnetic corrections of -1370×10^{-6} and -1340×10^{-6} cm^3 mol^{-1} for **1**·3.5 DMF·3 H_2O and **2**·6 DMSO·1.32 H_2O, respectively, were estimated from Pascal's constants.[33]

[31] Crystal data for **1**·3.5 DMF·0.7 H_2O: $C_{94.5}H_{139.9}Cu_8N_{27.5}O_{21.2}S_4$, $M_r = 2620.83$, monoclinic, space group $P2_1/c$, $a = 19.431(4)$, $b = 28.279(6)$, $c = 26.838(9)$ Å, $\beta = 129.48(2)°$, $V = 11383(5)$ Å^3, $Z = 4$, $\rho_{calcd} = 1.529$ g cm^{-3}, $Mo_{K\alpha}$ radiation ($\lambda = 0.71073$ Å, $\mu = 1.615$ mm^{-1}), $T = 120$ K, $R = 0.0588$ ($F^2 > 2\sigma$), $R_w = 0.1746$ (for 22343 data and 1466 refined parameters). Crystal data for **2**·6 DMSO·1.32 H_2O: $C_{86}H_{120.67}Cu_8N_{16}O_{22.33}S_{17}$, $M_r = 2789.35$, monoclinic, space group $P2/c$, $a = 14.228(3)$, $b = 13.863(3)$, $c = 29.827(6)$ Å, $\beta = 102.75(3)°$, $V = 5738(2)$ Å^3, $Z = 2$, $\rho_{calcd} = 1.614$ g cm^{-3}, $Mo_{K\alpha}$ radiation ($\lambda = 0.71073$ Å, $\mu = 1.833$ mm^{-1}), $T = 120$ K, $R = 0.0820$ ($F^2 > 2\sigma$), $R_w = 0.2562$ (for 11279 data and 723 refined parameters). Data were collected on a Nonius Kappa CCD diffractometer. Single crystals were placed at 50 mm from the detector and 1267 and 942 frames were measured, each for 60 and 80 s over a 0.75 and 1° scan width for **1**·3.5 DMF·0.7 H_2O and **2**·6 DMSO·1.32 H_2O, respectively. The data were processed using Denzo-SMN software. The structure was solved by direct methods and refined by full-matrix least-squares techniques. Non-hydrogen atoms were refined with anisotropic displacement parameters. H atoms were placed at calculated positions and refined as riding atoms in the subsequent least-squares model refinements. Two DMF ligands coordinated to Cu6, as well as one of two DMF molecules coordinated to Cu4 and Cu8, were disordered over two positions, which could be resolved with close 0.5:0.5 occupancy. On the other hand, by taking into account the increased values of the thermal anisotropic factors, one of the DMF molecules of solvation was localized in a single position with 0.5 occupancy. Structure solution and refinement were performed with the SHELX program. CCDC-270851 (**1**·3.5 DMF·0.7 H_2O) and -281722 (**2**·6 DMSO·1.32 H_2O) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.
[32] The reaction of $CuCl_2$ with 1,5-bis(2-hydroxybenzaldehyde)carbohydrazone (H_4L'') in 2:1 molar ratio in DMF/H_2O with subsequent recrystallization of the resulting precipitate from DMSO afforded the dinuclear complex $[Cu_2(HL'')Cl(dmso)_2]$·DMSO.

Interpenetrating Copper–Silver Cyanometallate Networks: Polymorphs and Topological Isomers**

Ann M. Chippindale, Simon M. Cheyne, and Simon J. Hibble**

Transition-metal cyanides have a long and fascinating history and exhibit a diverse and interesting range of chemical and physical properties leading to technological applications.[1] Many complex cyanometallate can be viewed as supramolecular compounds[2,3] constructed from $M(CN)_x$ structural building blocks that have independent existence. These include simple ions, for example, square planar $[Ni(CN)_4]^{2-}$ and octahedral $[Fe(CN)_6]^{4-}$, but can also include larger

fragments, for example, -{CuCN}- chains. Such units are relatively robust, have well-defined topology and geometry, and can be assembled in at least a semirational manner to form new solids by combining with themselves, other complex metal ions, or organic species such as amines to generate 1-, 2-, and 3-dimensional frameworks.[2,4,5]

We have been investigating the use of CuCN, both as a source of infinite -{CuCN}- chains and as a precursor to other Cu^I cyano species, for use as alternative structural building blocks in the construction of new cyanide complexes. We have found that monatomic species, such as halide ions, are capable of producing new zeolitic and interpenetrating frameworks when alkali-metal halides and CuCN react under modest conditions.[6,7] Urban et al. recently achieved similar results using silver cyanide and cesium halides.[8] An extension of this approach is to replace the halides, which form bridges between copper–cyanide building units, with complex cyanide anions in the hope of producing framework materials with larger pore sizes. We selected $[Ag(CN)_2]^-$ as a bridging unit because it has been successfully used in the past to link other metal ions, for example, Mn^{II} and Cd^{II}, into 3D networks.[2,9,10] Employing $[Ag(CN)_2]^-$ has the additional attraction of providing a synthetic route to mixed Cu^I/Ag^I cyanides, which, despite the similarity in the chemistry of copper and silver in the +1 oxidation state, surprisingly remained unknown before this work. The Cu^I/Ag^I cyanide materials have the formula $A[Ag_2Cu(CN)_4]$ (A = K, Rb, Cs) and contain remarkable interpenetrating anionic networks assembled from $\{Cu(CN)_4\}^{3-}$ and $\{Ag(CN)_2\}^-$ units. These units are connected in different ways in the Rb and Cs compounds to produce two-dimensional (form I) and three-dimensional (form II) networks of the same formula. These materials challenge our views of what constitutes and distinguishes polymorphs and topological isomers.

Reaction of excess $K[Ag(CN)_2]$ with CuCN under hydrothermal conditions produced single crystals of $K[Ag_2Cu(CN)_4]$ (**1**, form I).[11] This material can also be made at room temperature by adding an aqueous solution of $K_3[Cu(CN)_4]$ to $AgNO_3$ in a 1:2 molar ratio. The Rb and Cs analogues $Rb[Ag_2Cu(CN)_4]$ (**2**, form I) and $Cs[Ag_2Cu(CN)_4]$ (**3**, form I) were also produced in hydrothermal reactions, but in each case, a second form, $Rb[Ag_2Cu(CN)_4]$ (**4**, form II) and $Cs[Ag_2Cu(CN)_4]$ (**5**, form II), predominated.[11]

Although form I of $A[Ag_2Cu(CN)_4]$ (**1**–**3**) has a two-dimensional network, and form II (**4**, **5**) a three-dimensional network, a good starting point for describing the structures is to view them both as derived from a (4,4)-connected net. Figure 1 shows the two different sheets found in these forms, both of which have this connectivity. Copper atoms are located at the 4-connected nodes in both forms.

In form I, all the copper atoms are identical and are linked by almost-linear bridging -{NC-Ag-CN}- units. In form II, there are two types of copper atoms: one type (Cu(1)) occurs at the nodes of the (4,4)-connected net and the second (Cu(2)) occurs within the -{NC-Cu(2)-NC-Ag(1)-CN}- unit that links the Cu(1) nodes. As a consequence of the tetrahedral coordination around the copper center, the sheets in both forms I and II are buckled. Neither of the resulting sheets fills the space very efficiently, and the

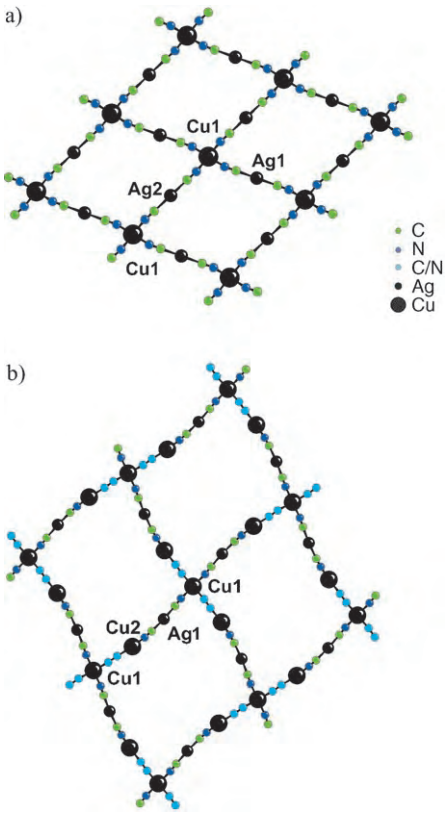

Figure 1. Portions of the sheets derived from a (4,4)-connected net for a) $A[Ag_2Cu(CN)_4]$ (form I, A = K, Rb, Cs) and b) $A[Ag_2Cu(CN)_4]$ (form II, A = Rb, Cs). The bridging cyanide groups bond through the carbon atom to silver, but are disordered when they bridge Cu(1) and Cu(2) atoms in (b).

structures formed from isolated sheets of these types, if they could be produced, would have very large free volumes. This situation is not the case in these materials. Instead, further copies of the sheets occupy the space (Figure 2). In form I, the structure consists of AAA-stacked layers of three identical interpenetrating sheets. In form II, four sheets can interpenetrate because the longer internode linkers (-{NC-Cu(2)-NC-Ag(1)-CN}- units) produce a larger mesh size than that found in form I. Figure 3 shows two layers formed from these interpenetrating sheets and clearly shows the buckling of the layers for each compound. In form I, the layers are sufficiently close together that the potassium ions within the layers also interact with cyanide groups in neighboring layers. The layers in form II, which stack in an ABAB pattern, are well separated, but, in contrast to form I, there are coordinatively unsaturated copper atoms on the outside of the layers. These Cu(2) atoms complete their tetrahedral coordination by forming bonds to two -{NC-Ag(2)-CN-Ag(3)-CN}- units external to the sheet. These units link sheets in adjacent layers to form a three-dimensional framework consisting of four identical interpenetrating networks. As in form I, the alkali-metal cations lie within the layers of buckled sheets.

Threefold parallel interpenetration of (4,4)-connected nets to form layers, as observed in form I, is very rare for coordinatively bonded networks[16,17] and this is the first

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

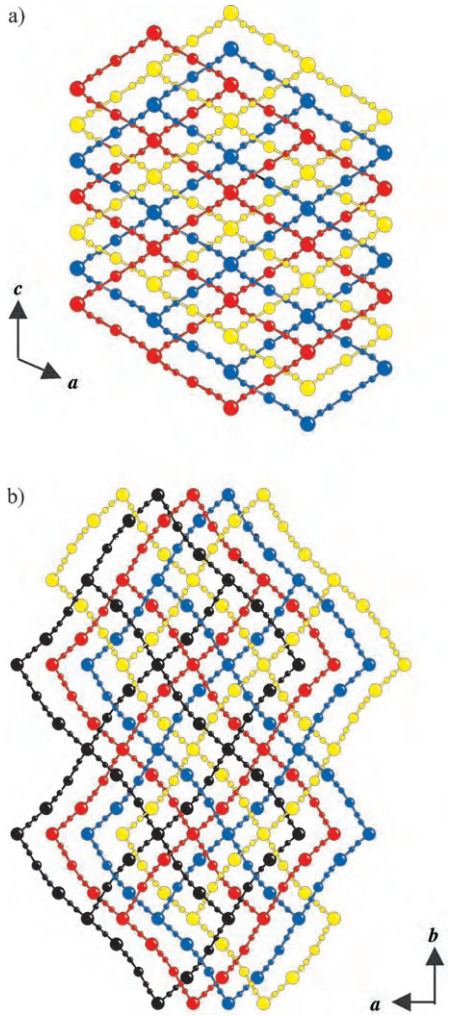

Figure 2. Layers derived from parallel interpenetration of a) three of the sheets shown in Figure 1 a) for $A[Ag_2Cu(CN)_4]$ (form I) and b) four of the sheets shown in Figure 1 b) for $A[Ag_2Cu(CN)_4]$ (form II). The different independent networks are shown in black, red, blue, and yellow.

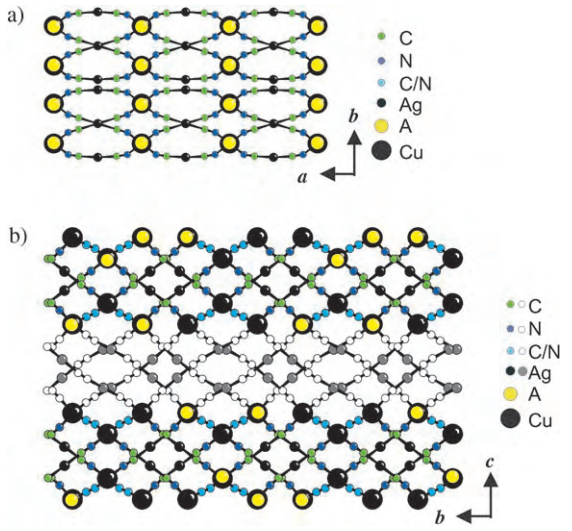

Figure 3. Side view showing the buckled sheets in a) $A[Ag_2Cu(CN)_4]$ (form I) forming a layered structure and b) $A[Ag_2Cu(CN)_4]$ (form II) forming a three-dimensional structure. The open and gray circles in (b) correspond to -{NC-Ag(2)-CN-Ag(3)-CN}- units that interlink the layers shown in Figure 2 b) to form the 3D structure containing four independent networks.

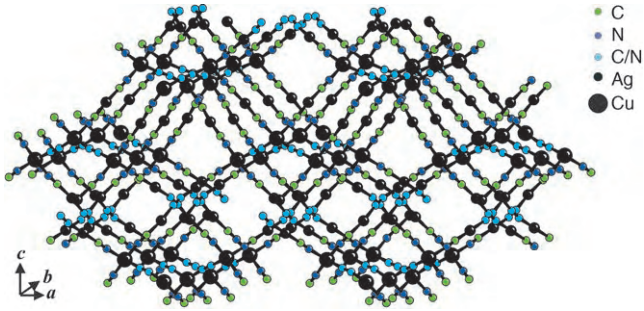

Figure 4. View of a single network found in $A[Ag_2Cu(CN)_4]$ (form II) showing self interpenetration.

totally inorganic example. Previous examples all have organic spacers between the metal centers at the nodes.[18–20] Form II, according to the recent classification of interpenetrating 3D networks by Blatov and co-workers,[21,22] belongs to Class Ia, which means that the four identical three-dimensional networks are related by simple translations ([1/2, 1/2, 1/2] (19.26 Å) and the symmetry-related operations). The 3D network found in form II[23] is, to the best of our knowledge, of a previously unknown type.[17,24,25] Moreover, this new network is self-penetrating (Figure 4) as rings containing six and eight copper atoms catenate within the structure. Interpenetration of self-penetrating networks is a rare combination[26] and, as is observed here, can lead to very complicated entangled structures.

It is remarkable that compounds of $A[Ag_2Cu(CN)_4]$ (A = Rb and Cs) form two distinct types of interpenetrating solid. These exceptional materials are true topological isomers because not only do they have frameworks of the same composition constructed from the same units, but their overall compositions are also identical. Most quoted examples of topological isomerism found in supramolecular chemistry involve the inclusion of different guest molecules, typically the solvent used in preparation,[27] and the overall compositions of the related compounds are therefore different. As the compositions of forms I and II are identical, and both are extended solids, they can also be classified as polymorphs according to the normal usage of that term.

Our experiments show that form II is the thermodynamically more stable phase of $Cs[Ag_2Cu(CN)_4]$ both under hydrothermal conditions and at atmospheric pressure at 300 K. Form I is the kinetically favored product, being formed immediately upon reaction between solutions containing A^+ (A = K and Cs), $Cu(CN)_4^{3-}$, and Ag^+, and also it appears as a minor phase in shorter hydrothermal reactions. It is interesting that $K[Ag_2Cu(CN)_4]$ has only been found in form I and does not convert to a form II analogue even on prolonged hydrothermal reaction. A further illustration of the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

thermodynamic stability of $Cs[Ag_2Cu(CN)_4]$ (form II) is that it can be formed by stirring a polycrystalline sample of $K[Ag_2Cu(CN)_4]$ in an aqueous solution of $CsNO_3$.

In summary, the first family of Cu^I/Ag^I cyanides has been prepared. The compounds of general formula $A[Ag_2Cu(CN)_4]$ (A = K, Rb and Cs) form curious interpenetrating two- and three-dimensional networks, the latter of which is also self penetrating. The two forms of the Rb and Cs compounds are both topological isomers and polymorphs. Further work will include analysis of the correlation between the uniaxial negative thermal expansion and the contraction of this axis upon increasing radius of the alkali-metal cation in all these materials. We are also attempting the preparation of $A[M_2M'(CN)_4]$ materials using other metals.

Experimental Section

$K[Ag_2Cu(CN)_4]$ (**1**, form I): Colorless rectangular plates[11] (IR: $\tilde{\nu} = \nu$(CN) 2135(vs), 2120(vs) cm^{-1}) were obtained by heating CuCN (0.09 g, 1 mmol) with $K[Ag(CN)_2]$ (1.39 g, 7 mmol) in H_2O (5 mL) in a teflon-lined autoclave at 453 K for 24 h and could be easily separated from a fernlike growth of metallic silver. A polycrystalline sample of **1** was prepared at 300 K by adding a solution of $K_3[Cu(CN)_4]$ (1.42 g, 5 mmol) in H_2O (5 mL) to $AgNO_3$ (1.75 g, 10 mmol) dissolved in H_2O (5 mL). A dark-gray precipitate formed immediately. In contrast, addition of the $AgNO_3$ solution to the $K_3[Cu(CN)_4]$ solution resulted in significant contamination by AgCN.

$Rb[Ag_2Cu(CN)_4]$ (**2**, form I and **4**, form II): Hydrothermal reaction of CuCN (0.09 g, 1 mmol), NaCN (0.15 g, 3 mmol), $RbNO_3$ (0.44 g, 3 mmol), and $AgNO_3$ (0.34 g, 2 mmol) in H_2O (5 mL) at 413 K for 3 days produced a mixture of colorless crystals—a majority of rectangular needles (**4**) and a minority of rectangular blocks (**2**)—which were easily separated for diffraction studies.[11]

Polycrystalline **2** was prepared at 300 K by adding $RbNO_3$ (0.44 g, 3 mmol) to a solution of $Na_3[Cu(CN)_4]$ (0.24 g, 1 mmol) in H_2O (2.5 mL). The resulting solution was then added to a solution of $AgNO_3$ (0.34 g, 2 mmol) in H_2O (2.5 mL) and a gray precipitate formed immediately. Compound **2** was the major component, together with a significant amount of AgCN. Allowing the precipitate to sit in the mother liquor at room temperature for 14 days led to the growth of single crystals of **2** (IR: $\tilde{\nu} = \nu$(CN) 2130(s), 2110(vs), 2089(s) cm^{-1}). Compound **4** was not produced in either room temperature reaction.

$Cs[Ag_2Cu(CN)_4]$ (**3**, form I and **5**, form II): Hydrothermal reaction of CuCN (0.23 g, 2.5 mmol), KCN (0.49 g, 7.5 mmol) $CsNO_3$ (1.46 g, 7.5 mmol), and $AgNO_3$ (0.85 g, 5 mmol) in H_2O (10 mL) at 413 K for 3 days produced colorless needles of **5** (IR: $\tilde{\nu} = \nu$(CN) 2168(vs), 2139(vs), 2115(vs), 2094(vs) cm^{-1}) as the major phase, together with a small quantity of colorless rectangular blocks of **3** (IR: $\tilde{\nu} = \nu$(CN) 2136(vs), 2114(vs), 2091(s) cm^{-1}).[11] Heating an identical mixture for 8 days produced a pure sample of **5**. Polycrystalline **3** was prepared at 300 K by adding $CsNO_3$ (1.46 g, 7.5 mmol) to $K_3[Cu(CN)_4]$ (1.42 g, 5 mmol) in H_2O (5 mL). The resulting solution was then added to $AgNO_3$ (0.85 g, 5 mmol) in H_2O (5 mL) and a gray precipitate formed immediately. Compound **3** was the major component, together with a small amount of AgCN. There was no evidence for the formation of **5** in this reaction.

Reactions of $K[Ag_2Cu(CN)_4]$ (**1**, form I): Stirring **1** (0.30 g, 0.70 mmol) in a solution of $CsNO_3$ (0.68 g, 3.5 mmol) in H_2O (5 mL) for 9 days at 300 K produced a change in the $[Ag_2Cu(CN)_4]^-$ framework to give $Cs[Ag_2Cu(CN)_4]$ (**5**, form II) as the major phase, together with small amounts of AgCN and Ag. The original $[Ag_2Cu(CN)_4]^-$ framework was, however, retained in a similar reaction in which $CsNO_3$ was replaced by KNO_3 (0.35 g, 3.5 mmol), although again some degradation to form AgCN occurred.

Mild and Chemoselective Peptide-Bond Cleavage of Peptides and Proteins at Azido Homoalanine**

Jaap Willem Back, Olivier David, Gertjan Kramer, Géraldine Masson, Piotr T. Kasper, Leo J. de Koning, Luitzen de Jong, Jan H. van Maarseveen, and Chris G. de Koster*

The chemical cleavage of amide (peptide) bonds usually requires harsh conditions.[1] As a result, side reactions and the lack of specificity of chemical amide-bond hydrolysis limits its scope in chemical biology and synthetic applications. Herein, we disclose our results on the selective cleavage of amide bonds in peptides and proteins that is milder than any previously reported chemical method.

The azide functional group is well suited for the in vivo labeling of biomolecules.[2] Azides combine a high chemical stability under physiological conditions with a unique reactivity that enables mild and selective organic transformations, such as the Staudinger ligation[3] and the azide–alkyne [3+2] cycloaddition.[4] Azido-functionalized amino acids[5] and azido sugars[4e] have been introduced into biomacromolecules and have subsequently been derivatized with specific labels to enable their detection, thereby demonstrating full bioorthogonality.[2] It has been shown that azido homoalanine (**1**) is effectively incorporated into proteins by the native methionyl tRNA synthetase of *E. coli*, thus allowing specific modification reactions.[5a] Azides, however, are susceptible to reduc-

tion to amines with, for example, phosphines[3,6] and (di)thiols,[7] which are amongst the most widespread reagents to promote reduction in samples of biological origin, or that are present intracellularly (e.g., in the form of glutathione).

In our investigations into Cu^{I}-catalyzed [3+2] "click" cycloadditions of several different alkynes to peptides containing **1**,[4a–c] with the in situ reduction of Cu^{II} to Cu^{I}, we discovered that aside from the expected products smaller fragments were produced. Control experiments in which Cu^{II} or the alkyne moiety, or both, were omitted and a reducing agent was added showed a marked increase in peptidolysis, and so were chosen to investigate the underlying mechanism.

Two products were formed when the model octadecapeptide **P** (sequence: PPHHHHHHPPRGFG**1**GFR, synthesized by standard Fmoc chemistry) was incubated in buffers containing either tris(carboxyethyl)phosphine (TCEP), 2-mercaptoethanol (2ME), or dithiothreitol (DTT). As expected, a peak corresponding to the reduction of **1** to 2,4-diaminobutyrate (DAB) at *m*/*z* 2108.0 was observed under these conditions. Surprisingly, an additional product at *m*/*z* 1729.8 was observed. Low-energy collision-induced dissociation (CID) of this product in an ESI-Q-FT mass spectrometer revealed an N-terminal fragment of **P** that resulted from cleavage of the peptide bond C-terminal to element **1** together with the loss of the azide group.

To test the general occurrence of this cleavage reaction in proteins that contain **1** instead of methionine,[5a] we have produced His-tagged recombinant photoactive yellow protein (PYP) from *Ectothiorhodospira halophila* in methionine-auxotrophic *E. coli* grown on media containing **1**. A pure preparation of azido PYP (AzPYP), in which all six methionine residues have been replaced by **1**, was obtained, as detected by ESI mass-spectrometric analysis of the intact protein (see the Supporting Information) and MALDI-TOF mass-spectrometric analysis of a tryptic digest (data not shown). Reduction and cleavage of purified AzPYP by TCEP, 2ME, or DTT was analyzed by sodium dodecylsulfate polyacrylamide gel electrophoresis (SDS-PAGE) and mass spectrometry (Figure 1 a, b). It was found that TCEP was able to cleave the protein under all the conditions investigated, whereas both the rate and yield of the cleavage with DTT and 2ME increased drastically under denaturing conditions (4 M urea). Fragments N- or C-terminal to all positions of **1** in reductively treated AzPYP were detected (Figure 1 c).

All fragments, except for the C-terminal peptide that ends in valine, have a C-terminal residue with a mass of 83 Da which corresponds to **1** minus a HN_3 moiety, as confirmed by CID ESI Fourier Transform tandem mass spectroscopy (FTMSMS). Peptides with "missed cleavages" have masses that are in accordance with a reduction of the internal azidohomoalanine residues. The fact that reduction-induced cleavage occurs C terminal to all positions of element **1** in AzPYP indicates that the cleavage reaction apparently poses no special prerequisites to the residue C terminal to the scissile bond. This result underscores the high specificity and general applicability of this mild chemical cleavage reaction of peptide bonds C terminal to **1**.

Next, we carried out cleavage of peptide **P** by tris(carboxy ethyl)phosphine (TCEP) in 50% ^{18}O-enriched water, which

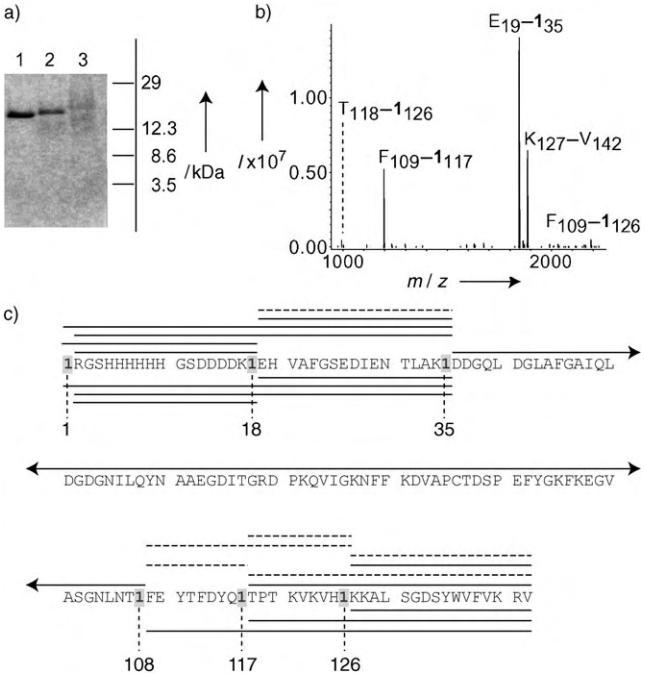

Figure 1. Recombinant AzPYP is cut by TCEP. a) Coomassie Blue stained gel containing equal amounts (23 μg) of AzPYP incubated without (lane 1) and with 10 mM (lane 2) and 100 mM (lane 3) TCEP at pH 5; the intact protein disappears and is cut into smaller fragments that do not resolve on the polyacrylamide gel. b) Deconvoluted ESI FTMS spectrum of TCEP-cleaved AzPYP. c) Sequence of His-tagged PYP from *E. halophila*. Intact molecular-mass and tryptic-peptide mapping confirmed >95% incorporation of **1** at methionine-coded residues. A coverage map obtained with TCEP (above the sequence) and DTT (below the sequence) is presented. Solid lines indicate peptides that result from cleavage that were detected with MALDI-TOF MS; dashed lines indicate peptides that were detected with ESI FTMS.

confirmed that the peptide bond C terminal to **1** is cleaved by hydrolysis, and indicated that only one ^{18}O atom is incorporated into the resulting C-terminal residue of the N-terminal peptide fragment (see the Supporting Information).

The C-terminal residue is considered to have a homoserine lactone structure based on the following observations: 1) When the cleavage product of peptide **P** was incubated under basic conditions, the mass of the product increased by 18 Da, which was added to the C-terminal residue as confirmed by CID; this addition could be reversed by incubation for one hour in anhydrous TFA.[8] 2) Incubation of the cleaved product of peptide **P**, or the cleaved products of AzPYP in butylamine, led to full conversion with an irreversible increase in the mass of the cleavage products by 73 Da, which is consistent with the addition of a C-terminal butylamine group,[8] as verified by CID. 3) It was found that both RP-HPLC retention times and CID MSMS analysis (see Figure 2 and the Supporting Information) of the presumed homoserine lactone ending peptides from TCEP-cleaved AzPYP and the corresponding homoserine lactone ending peptides from CNBr cleaved PYP were identical.

With TCEP, the reaction runs to completion in 100 min at 50 °C and pH 5, based on the disappearance of starting

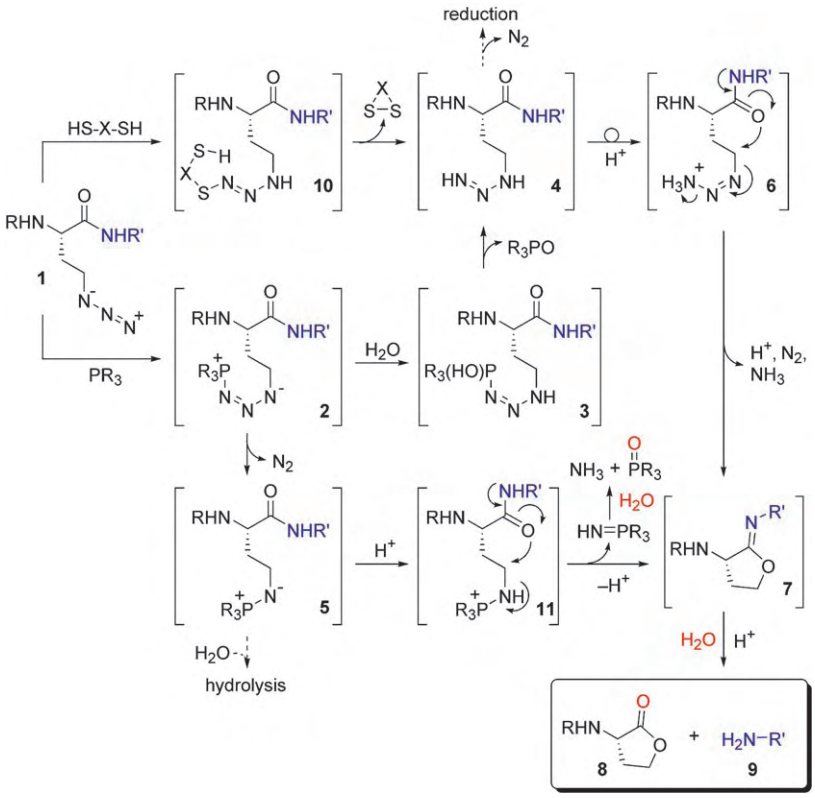
material. The ratio of cleaved/reduced product varied little as a function of pH value (the range of pH 3–11 was tested) or temperature, as quantified from RP-HPLC followed by MALDI-TOF-MS identification of the collected peak fractions. A maximized ratio at room temperature was accomplished at pH 5, thus resulting in 55% (±5%) cleavage, whereas at pH 9 approximately 40% (±5%) was cleaved (sum total of homoserine and homoserine lactone cleavage products).

With thiol reagents, the reaction only became significant at pH > 7, which is indicative of the requirement for the more nucleophilic thiolate anion. The peptide was significantly cleaved under these conditions, and a 30% (±8%) cleaved product was obtained with DTT within 16 hours with full conversion, whereas 84% of the azide compounds were still intact after 48 hours with 2ME. These results are consistent with the previously reported efficiencies of dithiols versus monothiols for azide reduction.[7a,9] In the case of 2ME, reduction into DAB (14%) predominated over cleavage (1%) as well. Cleaved peptides were mainly recovered with homoserine C termini, as could be expected at pH 9.2. Cleavage of AzPYP with thiols required unfolding of the protein with 4 M urea, which was not necessary for TCEP.

Peptide-bond hydrolysis that resulted in lactone formation can be rationalized by the mechanism depicted in Scheme 1. Phosphines attack at the electrophilic terminal nitrogen atom of azide **1**, initially forming intermediate **2**.[10] Water may add to **2** to give the postulated intermediate **3**, which fragments into the triazene **4** or lose dinitrogen to yield aza-ylide **5**.[10] It has been shown previously that triazenes may be substituted by suitable nucleophiles of either intra- or intermolecular origin.[9] It is worth mentioning that at elevated pH values conversion of **1** into homoserine without peptide cleavage occurs, which is indicative of direct hydroxide attack. The protonated triazene **6** may cyclize to imido ester **7** via an energetically favorable five-membered transition state, a pathway analogous to the cyanogen bromide induced cleavage of the methionine peptide bond.[11] Finally, hydrolysis of **7** liberates the homoserine lactone **8** and amine **9**.[1,8,11] This mechanism is supported by the above-discussed ^{18}O-labeling experimental results, which allow the carbonyl oxygen atom to be conserved in the lactone.

Alternatively, **5** can be hydrolyzed to an amine or may become protonated to generate intermediate **11**, which, through intramolecular S_N2 displacement involving the amide oxygen atom, yields the common imido ester intermediate **7**, which will then again hydrolyze to give **8** and **9**. The cleavage induced by (di)sulfides is presumed to be



Scheme 1. Mechanism for peptide cleavage C terminal to **1**. Initiation of the reaction is by reduction of the azide **1** into triazene **4**. Intramolecular S_N2 reaction of the carbonyl oxygen atom displaces the reduced azide to yield imido ester **6**, which is hydrolyzed and liberates a homoserine lactone ending peptide **8** and a peptide with an N-terminal free amine **9**. X denotes a three- or four-carbon spacer that can be substituted (e.g., X = -CH_2-CHOH-CHOH-CH_2- for DTT).

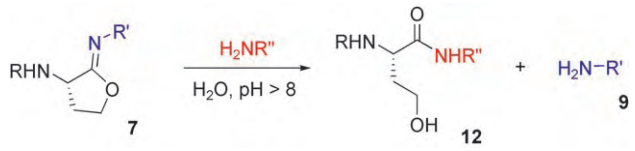
initiated by attack of the thiolate anion at either the α- or, as depicted, the γ-azide nitrogen atom (intermediate **10**).[7a] Loss of a cyclic disulfide from **10** gives the triazene **4**, which follows the pathway to **7** or fragments into DAB.

Lactones are amenable to further derivatization, for example, with amines in near quantitative yields,[8] as we have shown above for the cleaved peptide **P** and butylamine. As the cleavage reaction is not significantly affected by pH value, we were able to perform the cleavage reaction at elevated pH values (8–9) in the presence of amines. Under these conditions, we obtained products that were verified to be **P** cleaved C terminal to **1**, followed by addition of the selected amines (see the Supporting Information) and propose that the reaction proceeds as depicted in Scheme 2.



Scheme 2. Transamidation by exogeneous amines added to the reaction. Nucleophilic attack of an amine at the carbon atom of imido ester **7** may directly provide amide **12** while liberating amine **9**.

Other desired functionalities may similarly be installed with selected amines in a "one-pot" procedure. It is noteworthy that the stereocenter at C_α remains conserved, as is evident from the protein semisynthesis experiments with cyanogen bromide cleaved protein fragments.[12]

For optimal yield, however, the two-step alternative, in which first lactones are harvested and homoserine residues are closed by acid incubation,[8] may be preferred, as the initial yield of the TCEP-induced cleavage is higher at pH 5.

To our knowledge, this new cleavage reaction is milder than any chemical proteolysis described so far and, in contrast to I_2-induced allyl glycyl cleavage,[13] is directly applicable to overexpressed recombinant proteins. This report is also the first description of the use of an aza ylide as a leaving group amenable to intramolecular displacement by an amide group followed by hydrolysis to obtain an acid and amine. Until now, activated carboxylic acids were converted into amides using aza ylides and amidines were formed from amides,[3,14] the latter mainly in cyclization reactions. Performing this reaction in water has opened up a new pathway with far-reaching potential.

Direct application may be found in the preparation of isotope-labeled peptides by recombinant techniques, similar to the method described by Lindhout et al.[15] or protein semisynthesis from homoserine lactone,[8,12] but then after mild reduction-induced cleavage instead of CNBr. The yield of the cleavage reaction can be up to 60%; furthermore, a C-terminal function may be installed in a single step: an amine of choice elongates the cleaved polypeptide chain, thus providing the desired functionality.

Another powerful possibility lies in the targeted degradation of biopolymers.[16] However, as it is evident from earlier studies on azidothymidine (AZT) metabolism[9,17] and our findings that thiols reduce azides into highly reactive intermediates, one must remain conscious that the long-term intracellular presence of azides can lead to unintentional decomposition into unexpected products. On the other hand, methionines are often buried inside the protein core, and we have shown that degradation by thiols is accelerated under denaturing conditions, so at least for short-term experiments the azide function may be considered bio-orthogonal in vivo.

However, when phosphines or other reducing agents are added in subsequent reactions for the purpose of Staudinger ligations or to promote the in situ reduction of Cu^{II} to Cu^{I} for the catalysis of [3+2] azide–alkyne cycloadditions, it is conceivable that competitive nucleophilic substitutions at the (formerly) azide functionalized carbon atom may take place. The fate of intermediates **2** and **5** in Scheme 1, for example, will depend on the availability of suitable nucleophiles towards the phosphorane or the carbon nucleophilic center.[18] The proposal of using ultrapure Cu^{I} salts instead of the in situ reduction of Cu^{II} to catalyze the cycloadditions of azides and alkynes in biological samples[5c] may suppress reductive cleavage when this is not desired.

Synthetic Substrates for an Endoplasmic Reticulum Protein-Folding Sensor, UDP-Glucose: Glycoprotein Glucosyltransferase**

*Kiichiro Totani, Yoshito Ihara, Ichiro Matsuo, Hiroyuki Koshino, and Yukishige Ito**

Proteins destined for secretory pathways are transported to the lumen of the endoplasmic reticulum (ER). The ER lumen is a machine for post-translational modifications that is equipped with a quality-control system.[1] It assists with the folding of proteins and prevents aggregation and transport to the Golgi apparatus of misfolded glycoproteins. Protein glycosylation with an Asn-linked (N-linked) oligosaccharide is a co-translational process that occurs in the ER. N-linked glycan is attached to nascent protein as a tetradecasaccharide (Glc3Man9GlcNAc2; Glc = D-glucose, Man = D-mannose, GlcNAc = *N*-acetyl-D-glucosamine), and is trimmed sequentially by glucosidase I (G-I) and glucosidase II (G-II) to tridecasaccharide (Glc2Man9GlcNAc2), dodecasaccharide (Glc1Man9GlcNAc2), and then to undecasaccharide (Man9GlcNAc2; Figure 1).

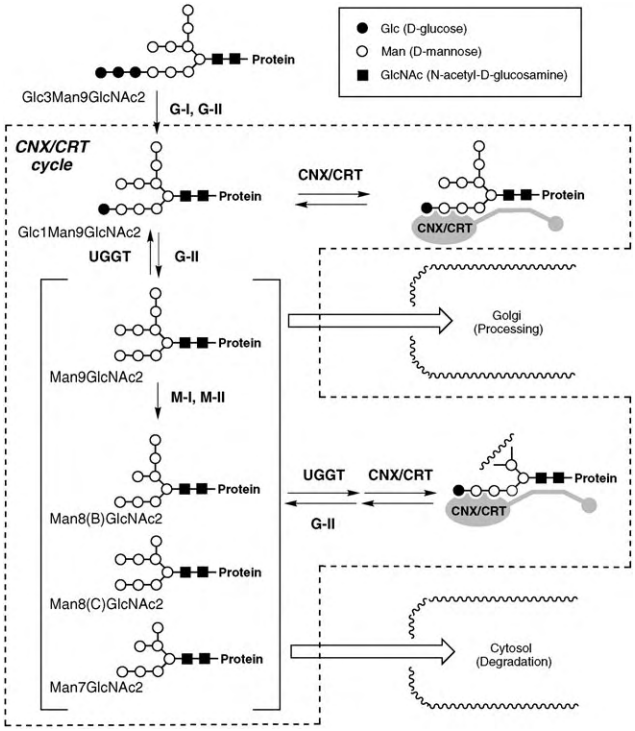

Figure 1. Processing of N-linked oligosaccharides in the ER.

The calnexin (CNX) cycle plays a central role in glycoprotein folding (Figure 1).[1] CNX and its soluble homologue calreticulin (CRT) are lectin chaperones, which have a similar specificity for monoglucosylated high-mannose-type glycans, such as the Glc1Man9GlcNAc2 of N-linked glycoproteins, as primary ligands. These chaperones assist with the folding of glycoproteins by recruiting the disulfide isomerase-like protein ERp57.[2] Clearly, CNX/CRT and G-II compete for the same glycan, and a certain proportion of glycoproteins may reach the nonglucosylated stage (Man9GlcNAc2) without being folded correctly.

Uridine 5′-diphosphate (UDP)-glucose:glycoprotein glucosyltransferase (UGGT) plays an important role in the CNX/CRT cycle as the "folding sensor".[3] It glucosylates the Man9GlcNAc2 of incompletely folded glycoproteins that arise from immature deglucosylation, and regenerates the CNX/CRT ligand Glc1Man9GlcNAc2. With repeated attempts at folding (CNX/CRT), deglucosylation (G-II), and reglucosylation (UGGT), this system maximizes the chance that newly formed glycoproteins will attain the correct structure. Successfully folded proteins escape from this cycle

and are transported to the Golgi apparatus for further processing and secretion, while misfolded proteins are retrotranslocated to the cytosol for degradation.[4] ER-resident α-mannosidases may digest Man9GlcNAc2 to Man8GlcNAc2, Man7GlcNAc2, and possibly Man6-5GlcNAc2.[5] UGGT also converts these glycans to monoglucosylated forms that can be CNX/CRT ligands, when protein folding is incomplete, thus constituting an intricate fail-safe system.

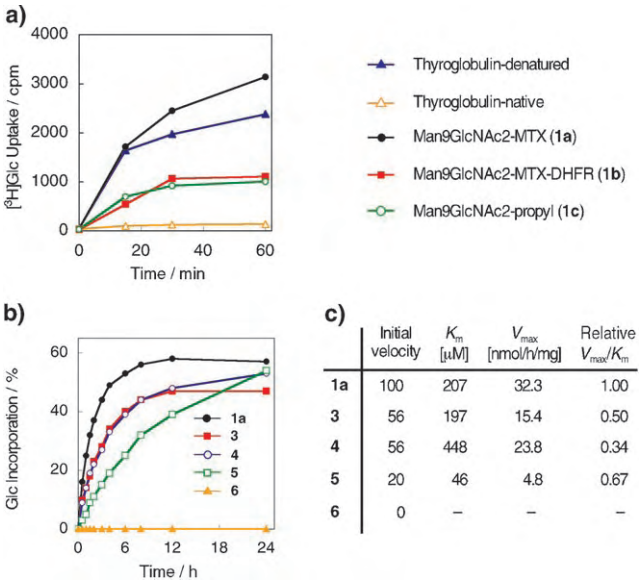
The detailed analysis of UGGT has been problematic because of its unusual specificity; it accepts unglucosylated high-mannose-type glycans only when they are covalently bound to incompletely folded proteins. Remarkably, UGGT rejects folded as well as severely misfolded glycoproteins, and prefers a native-like, compact, molten-globule-type conformation.[3,6,7] Previous studies of UGGT have been conducted using artificially denatured glycoproteins,[6,8] their tryptic digests,[8f] or neoglycopeptides.[7] The development of a simpler and better-defined substrate of UGGT is challenging, because this enzyme requires the coexistence of three separate elements: an acceptor (Manα1→2Man) element, a GlcNAcβ1→Asn element, and a cluster of hydrophobic amino acids exposed on the protein surface. Herein, we describe the first analysis of UGGT-catalyzed glucose transfer, by using chemically synthesized, fully defined, nonpeptidic substrates.

We have recently reported oligosaccharide–methotrexate conjugates (CHO-MTX) as the precursor of artificial glycoproteins having homogeneous carbohydrates.[9] MTX and its derivatives have been investigated as anticancer and antimicrobial drug candidates,[10] because of their inhibitory activity toward dihydrofolate reductase (DHFR), a key enzyme in the biosynthesis of nucleotide precursors of DNA. *Escherichia coli* DHFR is a relatively small (≈18 kDa) protein, which has been used as a tag for induced protein dimerization[11] and the in vitro labeling of proteins.[12] CHO-MTX can be converted to a tight-binding complex with DHFR, by virtue of the strong affinity ($K_A \approx 10^{10}\,M^{-1}$) between MTX and DHFR.[13] In the course of preparing a series of complexes of CHO-MTX and DHFR (Figure 2), we observed that CHO-MTX conjugate **1a** was an excellent acceptor substrate of UGGT.

The synthesis of Man9GlcNAc2-MTX (**1a**) was conducted as shown in Scheme 1. Thus, the protected undecasaccharide **7a**,[14] which was prepared from synthetic blocks **A**, **B**, and **C**, was deprotected to **8a** and converted to glycosylamine under the conditions proposed by Kochetkov et al.[15] Subsequent reaction with FmocGlyCl and removal of Fmoc afforded Man9GlcNAc2-Gly **9a**. Coupling with MTX-(α-*t*Bu)[9,16] was conducted under the conditions reported by Kunishima et al.[17] and cleavage of the *t*Bu ester afforded **1a**. Compound **1a** retained affinity for DHFR, which was confirmed by inhibition experiments[18] and lectin (Con A) binding experiments (see the Supporting Information). The expected UGGT product Glc1Man9GlcNAc2-MTX (**2**) was prepared from the protected dodecasaccharide **7b** in a similar manner.

Rat liver UGGT[19] and UDP-[^{3}H]Glc were used for the efficient glucosylation of **1a** (Figure 3a). Under the assay conditions (50 μM substrate), the reactivity of the synthetic substrate **1a** was at least comparable to that of denatured thyroglobulin, which has been used in conventional UGGT assays.[8a,19] Native thyroglobulin was completely inactive, as reported previously.[19b] We speculate that MTX mimics the property of unfolded proteins, and presumably has an exposed hydrophobic patch. In fact, Man9GlcNAc2 linked to a simpler and less hydrophobic aglycon (**1c**) was much less active, as was the complex Man9GlcNAc2-MTX-DHFR (**1b**).



c)

	Initial velocity	K_m [μM]	V_{max} [nmol/h/mg]	Relative V_{max}/K_m

3	56	197	15.4	0.50
4	56	448	23.8	0.34
5	20	46	4.8	0.67
6	0	–	–	–

Figure 3. Reaction of UGGT with the synthetic substrates. a) Time course of [^{3}H]Glc uptake; Man9GlcNAc2-MTX (**1a**), Man9GlcNAc2-MTX-DHFR (**1b**), Man9GlcNAc2-propyl (**1c**), denatured thyroglobulin, and native thyroglobulin. b) Time course of Glc incorporation; Man9-GlcNAc2-MTX (**1a**), Man8(B)GlcNAc2-MTX (**3**), Man8(C)GlcNAc2-MTX (**4**), Man7GlcNAc2-MTX (**5**), and Man8(B)GlcNAc1-MTX (**6**). c) Initial velocity (calculated from the value at 1 h incubation on (b)), K_m, and V_{max} values of **1a**, **3**, **4**, **5**, and **6**.

In the latter case, MTX may be buried in the folded protein, which makes it less accessible to UGGT.

The enzymatic transformation of **1a** to Glc1Man9GlcNAc2-MTX (II) was readily traced by HPLC and the characteristic UV absorption of MTX (Figure 4a). The product II was separated by preparative HPLC to achieve its characterization. Enzymatically produced II was identical to synthetic **2**, judging from MALDI-TOF mass spectrometry and ^{1}H NMR spectroscopy (1D, differential NOE, 2D TOCSY; see Figure 4b–d and the Supporting Information). Furthermore, when measured by isothermal titration calorimetry (ITC),[20] UGGT-generated II had a binding affinity for CRT with a K_A value ($5.17 \times 10^6\,M^{-1}$) essentially identical to that of the authentic **2** and previously reported Glc1Man9GlcNAc2-propyl[14,21] ($5.26 \times 10^6\,M^{-1}$). These results provided proof of the glycan structure of the UGGT product Glc1Man9GlcNAc2.

We then prepared a series of high-mannose glycan–MTX conjugates, Man8(B)GlcNAc2-MTX (**3**), Man8(C)GlcNA2-MTX (**4**), Man7GlcNAc2-MTX (**5**), and Man8(B)GlcNAc1-MTX (**6**; Figure 2), to examine the specificity of UGGT. As shown in Figure 3b and c, the order of reactivity was Man9 > Man8 > Man7, with relative values of initial velocity of 100, 56, and 20, respectively. These values were in good agreement with previously reported values that were estimated by using protease-digested thyroglobulin.[8a] The B and C isomers of Man8GlcNAc2-MTX had a similar reactivity. The K_m and V_{max} values for **1a**, **3**, **4**, and **5** (calculated from Lineweaver–Burk plots, see the Supporting Information) are provided in Figure 3c, and show that **1a** was the most reactive substrate. Interestingly, compound **6**, which had a single GlcNAc instead

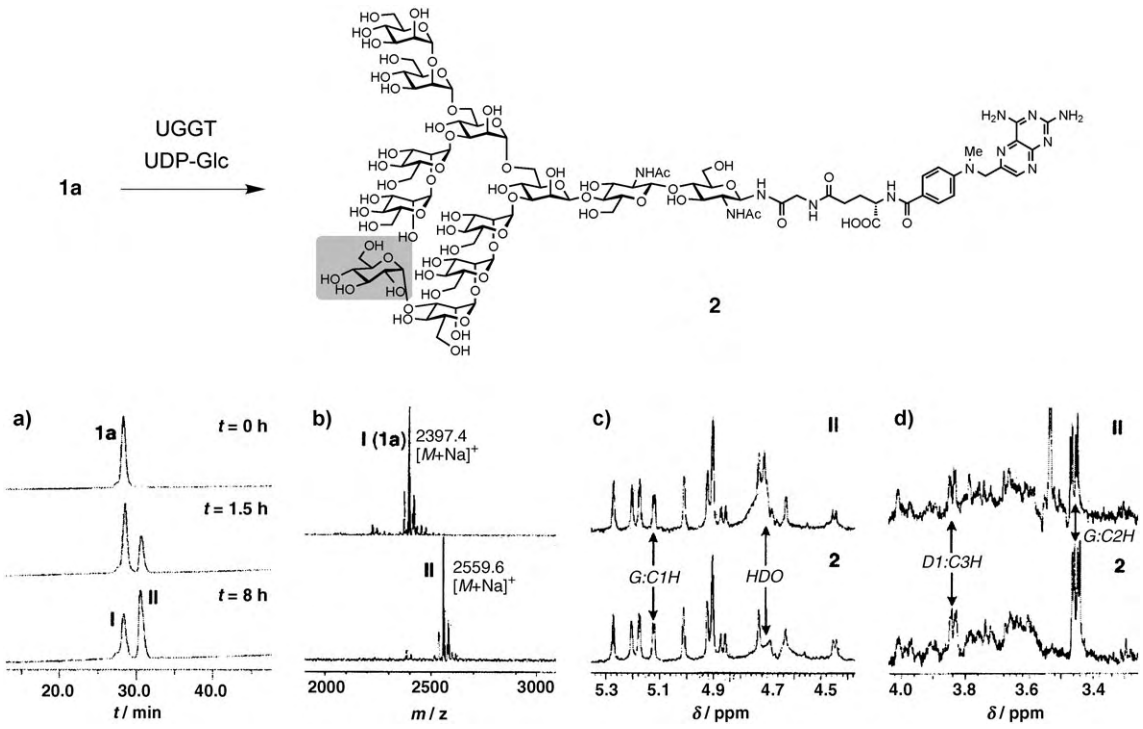

Figure 4. Characterization of the UGGT product. a) HPLC analysis of the glucosylation of Man9GlcNAc2-MTX (**1a**): TSK-GEL Amide-80 column (4.6 mmφ × 25 cm), mobile phase CH_3CN/3% AcOH-Et_3N, pH 7.3, linear gradient from 65:35 to 50:50 in 50 min, flow rate 1.0 mL min^{-1} at 40 °C. b) MALDI-TOF mass spectra of HPLC peaks of compounds **I** (**1a**) and **II** (corresponds to Glc1Man9GlcNAc2-MTX (**2**)). c) ^{1}H NMR spectra of synthetic **2** and the resulting UGGT product **II** in D_2O. The HDO signal was suppressed by DANTE (delays alternating with nutations for tailored excitation) presaturation. d) Differential NOE spectra (trace through the G:C1H resonance) of **2** and **II**.

of chitobiose ($GlcNAc_2$), was completely devoid of activity. UGGT was reported to recognize the innermost GlcNAc moiety,[8b] so the fact that **6** was not accepted might reflect an insufficient distance between the acceptor site Man and innermost GlcNAc.

Although Man7-9GlcNAc2-MTX were all accepted as substrates of UGGT, the glucosylation stopped at 50–60% conversion in every case. Addition of alkaline phosphatase had no effect, which suggests that the result was not caused by accumulated UDP. Interestingly, when recombinant CRT[22] (25 mol%) was added to the incubation mixture well after the reaction reached its plateau (150 h), the glucosylation was boosted (Figure 5a). We speculate that there was inhibition by glucosylated products; CRT trapped the products, segregated them from UGGT, and alleviated the inhibition. In line with this conjecture, a lectin-deficient CRT mutant (D135A)[23] had no effect (Figure 5b). For all the substrates examined (**1a**, **3**, and **4**), enhancement of the conversion (up to >70%) was observed in a dose-dependent manner (Figure 5c).

In summary, we have developed efficient substrates of UGGT that are completely synthetic. An unambiguous characterization of the UGGT product and the quantitative analysis of the specificity of UGGT for glycan were achieved with these substrates. Studies are in progress to systematically prepare various CHO-MTX conjugates. These compounds are expected to be valuable tools with which to investigate the

Predictions, Synthetic Strategy, and Isolation of a Linear Tetrametallic Triple-Stranded Lanthanide Helicate**

Kornelia Zeckert, Josef Hamacek, Jean-Michel Senegas, Natalia Dalla-Favera, Sébastien Floquet, Gérald Bernardinelli, and Claude Piguet**

Dedicated to Professor Jean-Claude G. Bünzli

The majority of self-assembled linear multi-stranded helicates are bimetallic, with some extensions toward trimetallic analogues,[1] whilst those with four or more metal centers remain rare.[2] Although the regular arrangement of several metal ions in a single direction, thus forming a discrete chain, may induce novel and unusual electrochemical,[3] photophys-

ical,[4] or magnetic[5] properties, multimetallic linear helicates have been mainly investigated for their structural aspect, which is indebted to their undeniable aesthetic appeal. The recent expansion of (supra)molecular chemistry toward the nanosciences dramatically revealed the very limited quantitative predictions available for the design of large multicomponent assemblies,[6] despite the remarkable reports of major successes based on qualitative symmetry matching and stereochemical restrictions.[7] In this context, the assembly of simple mono-dimensional multimetallic helicates can bring some valuable contributions to the fundamental understanding and rationalization of thermodynamically driven multicomponent complexation processes. In two seminal reports,[8] Lehn and co-workers first proposed a thermodynamic model that accounted for the formation of trimetallic double-stranded helicates. Scatchard plots based on the classical two-parameter site-binding model,[9–11] which considers the total free energy of formation of the final complex as the sum of the connection energies of each metal ion to a single receptor modulated by intermetallic pair interactions, suggested the occurrence of thermodynamic complexation processes driven to completion by positive cooperativity—a landmark that deeply influenced the rationalization of metallosupramolecular self-assembly processes for more than a decade.[10] The recent reanalysis of these original data by Ercolani indicates that helicate formation cannot be modeled with pure intermolecular interactions and entropic corrections must be considered for adequately rationalizing intramolecular metal–ligand connections, which occur during the self-assembly processes.[11] An explicit treatment, which combines metal–ligand connections (intra- and intermolecular) and pair interactions (intermetallic and interligand) has been recently proposed, and the macroscopic formation constant $\beta_{m,n}^{M,L}$ of any supramolecular complex $[M_mL_n]$ [Eq. (1)] can be modeled with four microscopic parameters [Eq. (2), extended site-binding model]:[12]

$$m\,M + n\,L \rightleftharpoons [M_mL_n]\ \beta_{m,n}^{M,L} \quad (1)$$

$$\beta_{m,n}^{M,L} = \sigma_{chir}^{M,L}\,\omega_{m,n} \prod_{i=1}^{mn} (f_i^{M,L}) \prod_{i=1}^{mn-m-n+1} (c_i^{eff}) \prod_{i<j}{}'' (u_{ij}^{MM}) \prod_{k<l}{}''' (u_{kl}^{LL}) \quad (2)$$

1) $f_i^{M,L}$ represents the intermolecular microscopic affinity constant that characterizes the connection of a metal M to the binding site i of a ligand L (including desolvation); 2) $u_{ij}^{MM} = \exp(-\Delta E_{ij}^{MM}/RT)$ is the Boltzman factor that accounts for the intermetallic interaction ΔE_{ij}^{MM} (in terms of free energy), which occurs when two metal centers occupy two adjacent binding sites i and j of the same ligand; 3) $u_{kl}^{LL} = \exp(-\Delta E_{kl}^{LL}/RT)$ is the Boltzman factor that accounts for the interligand interactions ΔE_{kl}^{LL}, which results from the connection of two binding sites k and l to the same metal center; 4) $c_i^{eff} = \exp((\Delta S_{i,intra}^{M,L} - \Delta S_{i,inter}^{M,L})/R)$ is the "effective concentration" used for the correction of the entropy change observed between inter- and intramolecular binding processes; 5) the term $\sigma_{chir}^{M,L}\omega_{m,n}$ represents the degeneracy of the microscopic state, which must be evaluated for each microspecies by using standard statistical methods.[9–12] Finally, the two last products $\prod''$ and $\prod'''$ run over all the pairs of intermetallic (u^{MM}) or interligand (u^{LL}) interactions that occur in the $[M_mL_n]$ microspecies.[12] Obviously, the reliable estimation of these four parameters requires a large amount of independent macroscopic constants that characterize comparable complexation events, a situation which is met when the thermodynamic equilibria relevant to the formation of the bimetallic $[Eu_2(\mathbf{L1})_3]^{6+}$ and $[Eu_2(\mathbf{L2})_3]^{6+}$ and trimetallic $[Eu_3(\mathbf{L3})_3]^{9+}$ triple-stranded helicates are simultaneously considered (only two different tridentate binding units N_2O and N_3 are involved in these complexes; Scheme 1). A complete set of microscopic parameters $f_{N_2O}^{Eu}$, $f_{N_3}^{Eu}$, u^{EuEu}, u^{LL}, and c^{eff} results,[13] and Equation (2) can be then used to predict the stability constant of the unknown tetrametallic homologue $[Eu_4(\mathbf{L4})_3]^{12+}$ [Eq. (3)].

$$\beta_{4,3}^{Eu,L4} = 2\,(f_{N_2O}^{Eu})^6\,(f_{N_3}^{Eu})^6\,(u^{LL})^{12}\,(u^{EuEu})^{4.33}\,(c^{eff})^6 \quad (3)$$

We calculate $\log(\beta_{4,3}^{Eu,L4}) = 42.5$ for the saturated triple-stranded helicate $[Eu_4(\mathbf{L4})_3]^{12+}$ [Eq. (3)], which is much larger than $\log(\beta_{3,3}^{Eu,L4}) = 35.5$, $\log(\beta_{3,2}^{Eu,L4}) = 27.4$, and $\log(\beta_{4,2}^{Eu,L4}) = 31.5$ predicted for its decomposition products, respectively, in excess of ligand ($[Eu_3(\mathbf{L4})_3]^{9+}$) or in excess of metal ($[Eu_3(\mathbf{L4})_2]^{9+}$ and $[Eu_4(\mathbf{L4})_2]^{12+}$; detailed calculations are given in the Supporting Information). The associated predicted distribution curves for a total ligand concentration

$|\mathbf{L4}|_{tot} = 10^{-3}$ M show that $[Eu_4(\mathbf{L4})_3]^{12+}$ corresponds to > 95% of the solution species for the stoichiometric ratio Eu/**L4** = 1.33, despite its high 12+ charge (see the Supporting Information). With this encouraging prediction in mind, we embarked upon a program to prepare the first stable tetrametallic lanthanide-containing triple-helical complex. Our ultimate goal is concerned with the exploration of the exact dependence of u^{MM} and c^{eff} on the intersite separation d, which is responsible for 1) the potential programming of local intermetallic dielectric constants (through $\Delta E^{MM} \propto 1/\varepsilon_r d$) and 2) the quantitative description of preorganization in self-assembled processes (through $c^{eff} \propto 1/d^n$).[6,11,12] Herein, we present the synthetic strategy, isolation, and structural and thermodynamic characterizations of the first tetrametallic lanthanide triple-stranded helicate $[Eu_4(\mathbf{L4})_3]^{12+}$. Following the original synthetic strategy developed for the preparation of **L3**,[14] we attempt to react the unsymmetrical *o*-nitroaminoarene **3**[14] with the diacid **2** (Scheme 2).[15]

However, **3** proved to be such a poor nucleophile that it does not react with the activated dicarbonyl chloride **2**-$(COCl)_2$ (Scheme 2, left). The remarkable C-shaped molecular structure of **3** observed in the solid state[16] may help to rationalize its poor nucleophilicity because 1) one face of the incriminated secondary ethyl amine N1 is blocked by the distal diethylcarboxamido group bound to the pyridine ring and 2) the H1 proton is involved in an intramolecular hydrogen bond with the adjacent nitro group N1–H1···O1 (N1···O1: 2.634(3) Å, ∢ N1–H1···O1: 130(2)°; Figure 1). Removing the terminal *N*,*N*-diethylcarboxamide pyridyl group in **1** sufficiently improves the nucleophilicity of the secondary amine to react with **2**-$(COCl)_2$ to give the bis(*o*-nitroaminoarene) **4**, which can be further successfully converted into **L4** (Scheme 2, right).

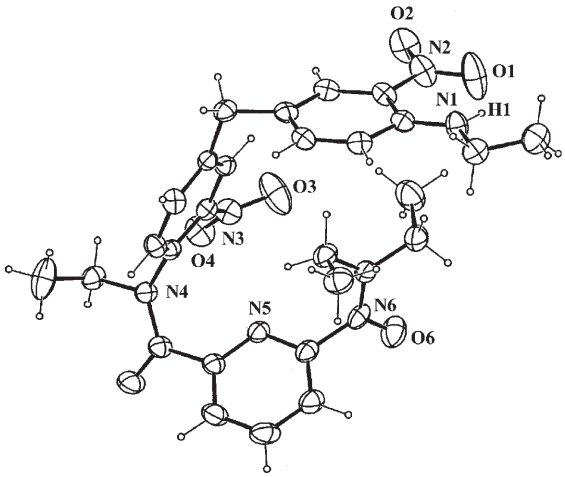

Figure 1. Perspective view of the C-shaped molecular structure of the *o*-nitroaminoarene synthon **3** with partial numbering. Ellipsoids are shown at the 50% probability level.

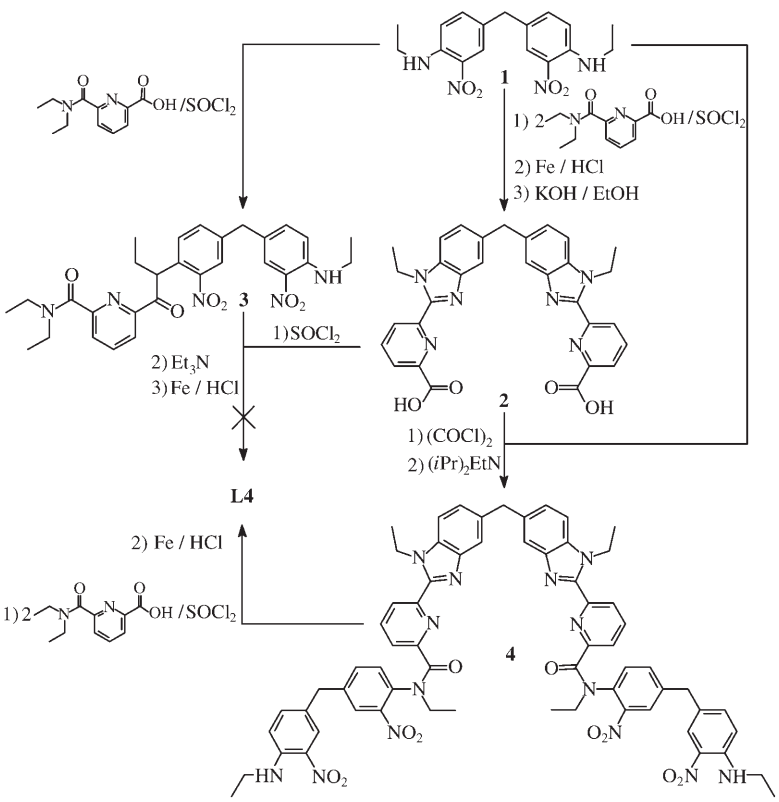

Scheme 2. Synthetic strategy for the preparation of **L4**.

ESI-MS titrations of **L4** (10^{-3} M) with $[Ln(CF_3SO_3)_3]\cdot x H_2O$ ($x = 3$–5) in acetonitrile (Ln = La, Eu, Lu) are dominated by the signals of the saturated species $[Ln_4(\mathbf{L4})_3(CF_3SO_3)_n]^{(12-n)+}$ ($n = 3$–9) together with minor signals (< 10%) that arise from the unsaturated intermediates $[Ln_3(\mathbf{L4})_3(CF_3SO_3)_n]^{(9-n)+}$ (excess of ligand, Ln/**L4** < 1.33) and $[Ln_3(\mathbf{L4})_2(CF_3SO_3)_n]^{(9-n)+}$ and $[Ln_4(\mathbf{L4})_2(CF_3SO_3)_n]^{(12-n)+}$ (excess of metal, Ln/**L4** > 1.33; see the Supporting Information). Parallel ^{1}H NMR titrations in CD_3CN/CD_2Cl_2 (9:1, $|\mathbf{L4}|_{tot} = 8 \times 10^{-3}$ M) confirm this behavior with the stepwise conversion of free **L4** into $[Ln_4(\mathbf{L4})_3]^{12+}$, which largely dominates the speciation in solution (only very weak signals are detected for some low-symmetrical intermediates; see the Supporting Information). The only species detected in solution for Ln/**L4** = 1.33 are $[Ln_4(\mathbf{L4})_3]^{12+}$, and their ^{1}H NMR spectra are compatible with D_3-symmetry (six equivalent half-ligand strands that lead to 15 different CH signals, an enantiotopic central methylene signal for H16,16′, and six diastereotopic methylene protons H17,17′–H22,22′; Figure 2). Finally, preliminary-batch spectrophotometric titrations show complicated variations of the absorption spectra for Eu/**L4** in the range 0.1–4.0 ($|\mathbf{L4}|_{tot} = 10^{-4}$ M, CH_3CN + 5% CH_2Cl_2; see the Supporting Information), which can be satisfyingly fitted with the four absorbing complexes $[Eu_3(\mathbf{L4})_3]^{9+}$, $[Eu_4(\mathbf{L4})_3]^{12+}$, $[Eu_3(\mathbf{L4})_2]^{9+}$, and $[Eu_4(\mathbf{L4})_2]^{12+}$. The associated macroscopic constants $\log(\beta_{3,3}^{Eu,L4}) = 36.2(1.9)$, $\log(\beta_{4,3}^{Eu,L4}) = 42.1(1.9)$, $\log(\beta_{3,2}^{Eu,L4}) = 27.9(1.4)$, and $\log(\beta_{4,2}^{Eu,L4}) = 32.0(1.7)$ match our predictions within experimental errors.

The diffusion of diethyl ether into a concentrated solution of $[Ln_4(\mathbf{L4})_3]^{12+}$ in methanol provides white microcrystals in 70–85% yield; the elemental analyses were shown to be compatible with $[Ln_4(\mathbf{L4})_3](CF_3SO_3)_{12}\cdot x H_2O\cdot y CH_3OH$ (Ln = La: $x = 8.1$,

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

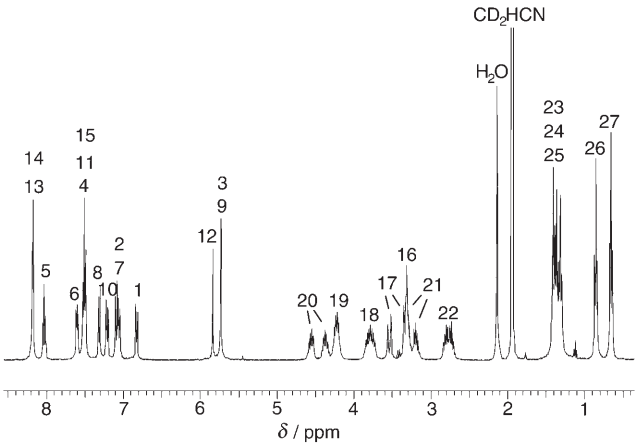

Figure 2. ^{1}H NMR spectrum of the D_3-symmetrical complex $[La_4(\mathbf{L4})_3]^{12+}$ in CD_3CN (298 K, numbering given in Scheme 1).

$y = 1.6$; Ln = Eu: $x = 5.0$, $y = 2.3$; Ln = Lu: $x = 9.6$, $y = 4.7$; see the Supporting Information). Their ESI-MS and ^{1}H NMR spectra obtained after redissolution in acetonitrile are identical with those obtained during the original titration processes (except for an extra peak in the ^{1}H NMR spectrum corresponding to CH_3OH), and slow recrystallization from methanol/diethyl ether gives prisms of $[Eu_4(\mathbf{L4})_3](CF_3SO_3)_{12}\cdot 5H_2O\cdot 5CH_3OH$ (**5**) suitable for X-ray diffraction studies.[17] The crystal structure of **5** is composed of the expected tetrametallic $[Eu_4(\mathbf{L4})_3]^{12+}$ cations together with 12 non-coordinated triflate anions and 10 interstitial solvent molecules. The pseudo-D_3-symmetrical triple-helical cation $[Eu_4(\mathbf{L4})_3]^{12+}$ shows only minor disorder that affects two peripheral ethyl groups, and its molecular structure (Figure 3a) can be best described as the packing of two terminal $\{EuN_6O_3\}$ and two central $\{EuN_9\}$ pseudo tricapped trigonal prismatic building blocks along the approximate threefold axis defined by the metal ions, as previously reported for $[Eu_3(\mathbf{L3})_3]^{9+}$.[14] The Eu–N and Eu–O bond lengths are standard, as are the bond angles (see the Supporting Information).

The four europium atoms are aligned along the pseudo threefold axis (∢Eu1···Eu2···Eu3: 170.71(1), ∢Eu2···Eu3···Eu4: 172.03(1)°) and regularly spaced by approximately 9.3 Å (Eu1···Eu2: 9.312(1), Eu2···Eu3: 9.054(1), Eu3···Eu4: 9.405(1) Å; Figure 3a). A detailed analysis of the 11 successive helical portions delimited by the 12 parallel facial planes containing the coordinated donor atoms (see Figure 3b and the Supporting Information) shows the usual tightening of the helical pitch about the complexed metal centers, and its relaxation within the intermetallic domains (see the Supporting Information). The total length of the helix amounts to 31 Å (3.1 nm according to modern semantics) for 2.22 turns (Figure 3c), which translates into an average helical pitch of 14.0 Å, comparable with 13.6 Å previously reported for the trimetallic analogous complex $[Eu_3(\mathbf{L3})_3]^{9+}$.[14]

We thus conclude that the incorporation of an additional central tridentate N_3 segment into **L3** to form **L4** is not deleterious for the extension of the helicate series and, in agreement with theoretical thermodynamic predictions, the tetrametallic complex $[Eu_4(\mathbf{L4})_3]^{12+}$ indeed dominates the speciation in solution for concentrations within the millimolar range. Its isolation in the solid state eventually demonstrates the formation of the expected linear triple-stranded helicate. Interestingly, the considerable intermetallic separation in these complexes limits destabilizing intramolecular intercationic repulsions, thus allowing the preparation of stable highly charged polymetallic cations. Although further work is required to address the exact dependence of u^{MM} and c^{eff} on the intersite separation, our novel synthetic strategy for the stepwise extension of the ligand strand offers remarkable perspectives for the design of higher homologues, a crucial

ation energy of the corresponding cation. Examples include the autoionization of alkali metals M on reaction with crown ethers to give complexed M^+ as well as alkalides and electrides,[2] and the autoionization of main-group and transition-metal chlorides to give cationic crown ether complexes and metal chloro anions.[3] We report herein the reaction of TiF_4 and [15]crown-5 to give $[TiF_2([15]crown\text{-}5)][Ti_4F_{18}]\cdot 0.5\,MeCN$ (**1**). This is, as far as we are aware, the first autoionization of a metal fluoride on reaction with a crown ether, and suggests that this is a viable preparative route to other related binary fluoro metal anions. $[Ti_4F_{18}]^{2-}$ (Figure 1) has overall T_d symmetry and is the second example

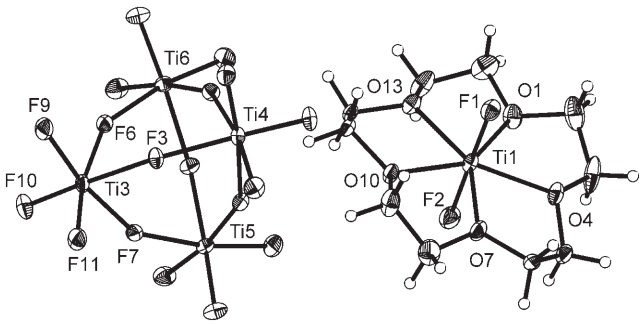

Figure 1. One of the two crystallographically independent dications and dianions in **1** (ellipsoids represent 30% thermal probability). Selected distances [Å] and angles [°]: dication: Ti1–F1 1.769(3), Ti1–F2 1.821(3), Ti1–O1 2.084(3), Ti1–O7 2.089(3), Ti1–O10 2.101(3), Ti1–O13 2.103(3), Ti1–O4 2.113(3); dianion: av $Ti-F_{terminal}$ 1.768 Å, av $Ti-F_{bridging}$ 1.987 Å, av $F_{bridging}$-Ti-$F_{bridging}$ 97.12 °, av $F_{terminal}$-Ti-$F_{terminal}$ 82.84 °.

of such a binary $[M_4X_{18}]^{2-}$ cage (M = metal, X = halogen), the first being $[W_4F_{18}]^{2-}$.[4] Its structure is related to the more-elaborate oxo complexes, for example, $[Ti_4F_{12}O_6]^{4-}$,[5] and $[Ti_4O_6(OSMe_2)_{12}]^{4+}$.[6] The related $[Ti_2F_9]^-$ ion was claimed to exist in solution,[7] and the salts $M[Ti_2F_9]$ (M = Cs, NF_4) have been reported,[8] although their X-ray crystal structures were not determined. We predict, on the basis of estimates of the corresponding energetics, that all monocation salts, with the possible exception of those having small cations, favor $[Ti_2F_9]^-$ ions, and salts of dications favor $[Ti_4F_{18}]^{2-}$ ions.

The structurally characterized binary Ti^{4+} fluorides are $[TiF_4]$,[9] $[TiF_6]^{2-}$,[10] $[TiF_7]^{3-}$,[11] $[Ti_2F_{11}]^{3-}$,[12] $[Ti_2F_{10}]^{2-}$,[13] $\{[Ti_8F_{33}]^-\}_n$,[14] and $\{[Ti_7F_{30}]^{2-}\}_n$.[15] Excess [15]crown-5 and titanium tetrafluoride react in MeCN to form $[TiF_2([15]crown\text{-}5)][Ti_4F_{18}]\cdot 0.5\,MeCN$ (**1**) in 90% yield according to reaction (1), thus effecting the autoionization of $[TiF_4]$ to $[TiF_2]^{2+}$ (stabilized by [15]crown-5) and $[Ti_4F_{18}]^{2-}$. This product is formed in contrast to the neutral adduct isolated from the reaction of $[TiF_4]$ with [18]crown-6, which yielded $[(TiF_4)_2([18]crown\text{-}6)]$.[16] This difference may be because [18]crown-6[17] has a cavity diameter of about 2.9 Å, which is large relative to the ionic diameter of Ti^{4+} (1.4 Å).[18] The diameter of the [15]crown-5 cavity is about 1.95 Å,[17] that is, slightly larger than the ionic diameter of Ti^{4+}, and hence, [15]crown-5 is well suited to promoting the formation of cationic and anionic titanium complexes.

$$5\,TiF_4 + [15]crown\text{-}5 \xrightarrow{MeCN} [TiF_2([15]crown\text{-}5)][Ti_4F_{18}]\cdot 0.5MeCN \quad (1)$$

The ^{19}F NMR spectrum of **1** formed in situ from the reaction of $[TiF_4]$ (4.2 equiv) and [15]crown-5 (1 equiv) in MeCN showed the resonance of the $[TiF_2([15]crown\text{-}5)]^{2+}$ ion at $\delta = 246.8$ ppm.[19] The X-ray crystal-structure determination (Figure 1) showed discrete $[TiF_2([15]crown\text{-}5)]^{2+}$ ions, with structure identical to that found in $[TiF_2([15]crown\text{-}5)][SbF_6]_2$,[19] and $[Ti_4F_{18}]^{2-}$ ions. This $[Ti_4F_{18}]^{2-}$ ion has almost T_d symmetry, with the four titanium atoms situated at the vertices of a tetrahedron, connected by six bridging fluorine atoms and capped by three terminal fluorine atoms each. The $Ti-F_{terminal}$ bond lengths (1.754(3)–1.777(3) Å, av 1.768 Å, 0.98 v.u. (valency units)[20]) and $Ti-F_{bridging}$ bond lengths (1.965(3)–2.010(3) Å, av 1.987 Å, 0.54 v.u.) are similar to those found in oligomeric Ti^{IV} fluoride complexes.[21] The $F_{terminal}$-Ti-$F_{terminal}$ angles (94.94(12)–98.03(13)°, av 97.12°) in **1** are greater than the $F_{bridging}$-Ti-$F_{bridging}$ angles (81.88(10)–83.40(10)°, av 82.84°), as expected from a VSEPR[22] and a ligand–ligand repulsion model.[23]

Consistent with the latter model, the $F_{bridging}\cdots F_{bridging}$ contacts (2.596(4)–2.641(3) Å) are almost equal to the $F_{terminal}\cdots F_{terminal}$ contacts (2.609(5)–2.671(4) Å) in $[Ti_4F_{18}]^{2-}$. We note that the F···F nonbonding distances in other oligomeric Ti–F complexes are very similar (e.g., $[TiF_4]$ ($F_{bridging}\cdots F_{bridging}$ 2.553–2.670 Å, $F_{terminal}\cdots F_{terminal}$ 2.603–2.638 Å),[9] $[Ti_7F_{30}]^{2-}$ ($F_{bridging}\cdots F_{bridging}$ 2.567–2.669 Å, $F_{terminal}\cdots F_{terminal}$ 2.631–2.744 Å),[15] $[TiF_6]^{2-}$(2.636 Å);[10e] the F-Ti-F angles are determined by the almost equal nonbonding F···F distances, in a similar way to various second and third row main group fluorides.[23]

To answer the question as to why $[Ti_4F_{18}]^{2-}$ and not $[Ti_2F_9]^-$ was formed, the optimized structures, vibrational spectra, and ^{19}F NMR shifts of $[Ti_2F_9]^-$ and $[Ti_4F_{18}]^{2-}$ were calculated (see Supporting Information). Unfortunately, the calculated spectroscopic properties were very similar for both anions. The similarity of spectroscopic properties is related to the similarity in the structures of $[Ti_2F_9]^-$ and $[Ti_4F_{18}]^{2-}$ from the perspective of the environments around the titanium and fluorine atoms, and a completely unambiguous distinction between the two is only possible experimentally by X-ray diffraction.

The calculated values of ΔH^{298} and ΔG^{298} for reactions (2)–(5) are given in Table 1. The formation of two $[Ti_2F_9]^-$ ions is favored in the gas phase over dimerization to the $[Ti_4F_{18}]^{2-}$ ion. The situation is less clear for solutions in acetonitrile and dichloromethane, and most likely both anions exist in equilibrium. The energetics in the solid state were estimated by using the equation of Jenkins et al. and applying the "volume-based" thermodynamic (VBT) approach.[24,25] Dimerization to the $[Ti_4F_{18}]^{2-}$ ion and formation of $[TiF_2([15]crown\text{-}5)][Ti_4F_{18}]$ is strongly favored in the solid state over the hypothetical $[TiF_2([15]crown\text{-}5)][Ti_2F_9]_2$ salt of the $[Ti_2F_9]^-$ ion, thus the $[Ti_4F_{18}]^{2-}$ ion is lattice-stabilized in the solid state.[26]

To investigate which conditions promote the formation of a stable salt of $[Ti_2F_9]^-$, the $\Delta H^{298}{}_{(s)}$ ($\approx \Delta G^{298}{}_{(s)}$) values of reactions (6) and (7) for salts containing mono- and dications of different sizes were compared (Figure 2).

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Table 1: Calculated and estimated thermodynamic enthalpies and free energies [kJ mol^{-1}] of the $[Ti_2F_9]^-$ and $[Ti_4F_{18}]^{2-}$ ions for the gas-phase, solid-state (as salts of $[TiF_2([15]crown-5)]$),[a,b] and solution dimerization[c] reactions.[d]

	Reaction	$\Delta G(n)^{298}$	$\Delta H(n)^{298}$
(2)	$2\,[Ti_2F_9]^-_{(g)} \rightarrow [Ti_4F_{18}]^{2-}_{(g)}$ [e]	215	160
(3)	$[TiF_2([15]crown-5)][Ti_2F_9]_{2(s)} \rightarrow [TiF_2([15]crown-5)][Ti_4F_{18}]_{(s)}$		−216
(4)	$2\,[Ti_2F_9]^- \rightarrow [Ti_4F_{18}]^{2-}$ (in MeCN)	−4[c]	
(5)	$2\,[Ti_2F_9]^- \rightarrow [Ti_4F_{18}]^{2-}$ (in CH_2Cl_2)	19[c]	

[a] $U_{lattice}\{[TiF_2([15]crown-5)][Ti_2F_9]_{2(s)}\}$ 1289 ± 5 kJ mol^{-1} (see Supporting Information). [b] $U_{lattice}\{[TiF_2([15]crown-5)][Ti_4F_{18}]_{(s)}\}$ 1665 ± 6 kJ mol^{-1} (see Supporting Information). [c] C-PCM solvation model. [d] Details for the estimation of the energetics in all three phases are included in the Supporting Information. [e] We note that the number of bridging and terminal bonds in $2\,[Ti_2F_9]^-$ and $[Ti_4F_{18}]^{2-}$ are the same. Thus the reaction is isodesmic and therefore the calculated energy is of good accuracy, ± ca. 10 kJ mol^{-1}. It is not trivial to establish the absolute error in such calculations. However, borderline cases of this kind can be used to obtain upper or lower limits of the gas phase calculated values, e.g. in the dimerization of $2\,S_2^+$ to S_4^{2+}.[35]

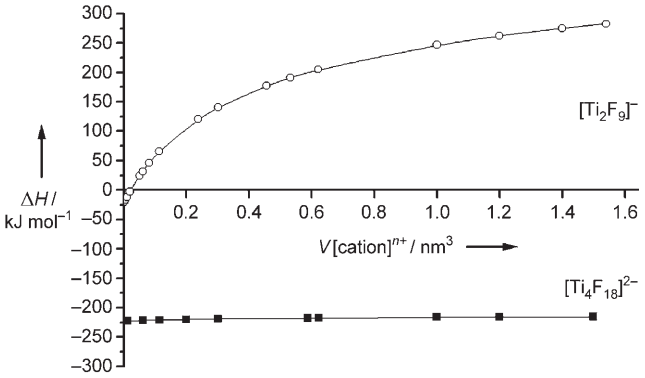

Figure 2. Plot of ΔH ($\approx \Delta G$) versus $V([cation]^{n+})$ for reactions (6) (○, $n=1$) and (7) (■, $n=2$). The data used in the calculation of this plot are included with the Supporting Information.

$$2\,[cation]^+[Ti_2F_9]^-_{(s)} \rightarrow [cation]^+_2[Ti_4F_{18}]^{2-}_{(s)} \quad (6)$$

$$[cation]^{2+}[Ti_2F_9]^-_{2\,(s)} \rightarrow [cation]^{2+}[Ti_4F_{18}]^{2-}_{(s)} \quad (7)$$

The VBT approach suggests that the monocations generally favor the formation of [cation][Ti_2F_9] (since $\Delta H(6)$ ($\approx \Delta G(6)$) is usually >0), whereas dications favor [cation]-[Ti_4F_{18}] (since $\Delta H(7)$ ($\approx \Delta G(7)$) <0, i.e., negative and almost independent of the size of the cation). We predict that the previously reported $[NF_4][Ti_2F_9]$ salt[8] ($\Delta G(6) = 32 \pm (10 + x)$ kJ mol^{-1} [x = uncertainty in the calculated dimerization energy of $2[Ti_2F_9]^-_{(g)}$ according to reaction (2)]) probably contains $[Ti_2F_9]^-$ ions; for $Cs[Ti_2F_9]$[8] ($\Delta G(6) = -3 \pm (10 + x)$ kJ mol^{-1}), however, with its slightly smaller Cs^+ ion, it is still an open question as to which anion is present. Notwithstanding borderline cases, this approach has the potential for rationalizing the underlying thermodynamics of related systems and to guide the synthesis of hitherto unknown anions.

Experimental Section

1: A solution of [15]crown-5 (0.54 g, 0.49 mL, 2.5 mmol) in MeCN (20 mL) was added to a solution of $[TiF_4]$ (1.244 g, 10.0 mmol) in MeCN (20 mL). Concentration of the resulting transparent mixture to approximately 20 mL and storage at room temperature for a period of several hours afforded colorless crystals (1.58 g, 90%). Elemental analysis (%): calcd for $C_{22}H_{43}F_{40}NO_{10}Ti_{10}$: C 15.34, H 2.50, Ti 27.90, F 44.14, N 0.81; found: C 15.47, H 2.40, Ti 27.10, F 43.54, N 0.82. Decomposition occurred above 120 °C without melting; ^{1}H NMR (400 MHz, MeCN, RT): $\delta = 4.61$ ppm (s, *trans*-$[TiF_2([15]crown-5)]^{2+}$); ^{19}F NMR (376.3 MHz, MeCN, RT): $\delta = 262.8$ (m, $12\,F_{terminal}$, $[Ti_4F_{18}]^{2-}$), 246.8 (s, 2F, *trans*-$[TiF_2([15]crown-5)]^{2+}$), −21.6 ppm (m, $6\,F_{bridging}$, $[Ti_4F_{18}]^{2-}$).

Data were collected on a Bruker AXS P4/SMART 1000 diffractometer ($\lambda(Mo_{K\alpha}) = 0.71073$ Å) by using ω and θ scans. The structure was solved by direct methods and refined against F^2 with non-hydrogen atoms anisotropic and hydrogen atoms in a riding model. The data were reduced (SAINT)[27] and corrected for absorption (SADABS).[28] All calculations were carried out with SHELXTL software,[29] and the structural drawing was prepared by using Diamond.[30] Crystallographic data for **1** ($C_{11}H_{21.50}F_{20}N_{0.50}O_5Ti_5$) at 198 K: $M_r = 860.29$, crystal dimensions $0.30 \times 0.275 \times 0.275$ mm^3, monoclinic, space group $P2_1/c$, $a = 8.3335(9)$, $b = 41.887(5)$, $c = 16.4117(18)$ Å, $\beta = 103.927(2)°$, $V = 5560.4(11)$ Å^3, $Z = 8$, $\rho_{calcd} = 2.055$ Mg m^{-3}, $\mu = 1.531$ mm^{-1}, of 28675 reflections measured ($2.33 < \theta < 25.00°$), 9761 were independent ($R_{int} = 0.0277$), $wR2 = 0.1445$ (all data), $R1 = 0.0482$ (for 7181 reflections with $I > 2\sigma(I)$), 734 parameters, GOF = 1.073. CCDC-272157 contains the supplementary crystallographic data. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

All theoretical calculations were performed by using the Gaussian 03 program[31] and the MPW91PW91 DFT functional[32] with the NASA AMES cc-pVTZ basis set[33] for titanium and the aug-cc-pVDZ basis set[34] (aug-cc-pVTZ for energy calculations) for fluorine. Solution energetics in acetonitrile and dichloromethane were calculated by using the C-PCM solvation model as implemented in Gaussian 03.[31] Details for all calculations are included in the Supporting Information.

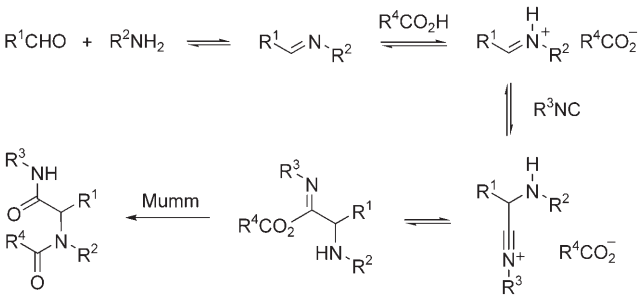
Phenol Ugi–Smiles Systems: Strategies for the Multicomponent N-Arylation of Primary Amines with Isocyanides, Aldehydes, and Phenols

Laurent El Kaïm, Laurence Grimaud,* and Julie Oble*

Since the pioneering work of Passerini and Ugi, the use of isocyanides has been strongly associated with the success achieved by multicomponent reactions (MCRs) in the creation of molecular diversity.[1] The high efficiency of isocyanides in MCRs lies in their ability to create bonds in a reversible manner by extending their valence. In the Ugi four-component reaction (U-4CR), equilibria between primary amines, isocyanides, carbonyl compounds, and carboxylic acids are displaced by a final irreversible Mumm-type rearrangement (Scheme 1).



Scheme 1. Ugi reaction mechanism.

The replacement of the carboxylic acid by other acidic compounds has found limited success since the discovery of the reaction. The ideal surrogate for the carboxylic acid should be sufficiently acidic to activate the imine toward the moderately nucleophilic isocyanide, and its counter anion should give a reversible addition to the nitrilium intermediate and induce an irreversible rearrangement in the final step. Ultimately, the acidic compound has to be integrated in the structure so that the final adduct retains sufficient stability (to heat, and for compounds of biological interest, to enzymatic hydrolysis).

Besides carboxylic acids, the most useful acidic components (water, hydrazoic acid, carbonic acid monoesters,

hydrogen sulfide, hydrogen selenide, cyanate,[2] thiocyanate,[2] and thiosulfate[2])[3] were examined by Ugi shortly after his description of the U-4CR process. Recently, in analogy to the formation of carbonic acid from CO_2 and alcohols, COS and CS_2 have also been employed for the preparation of thio derivatives.[4] More significantly, the use of thio acids has led to some elegant heterocyclic syntheses.[5] There has since been no major development in this direction.

The scope of MCRs using isocyanides has been widely extended through the intramolecular trapping of the nitrilium intermediates. Among the most recent and useful examples, the [4+1] cycloaddition of 2-iminopyridines[6] and the formation of isoxazole from isocyanoacetamides[7] are worth noting. In these cases, intramolecular conditions and final aromatization allow good yields even with nucleophiles that perform poorly in the normal U-4CR process (oxygen atoms of amides for instance). However, their intramolecular nature limits the scope of these reactions to three-component couplings with a consequent lower molecular diversity.[8] Herein, we report a highly flexible multicomponent reaction between electron-deficient phenols, amines, carbonyl compounds, and isocyanides to form *N*-aryl amines in phenol Ugi–Smiles systems.

While searching for new acidic partners in the Ugi reaction, we thought that a suitable electron-withdrawing group on a phenol could trigger both the imine activation and the irreversible rearrangement in the key step of the reaction. Indeed, we were delighted to find that *o*-nitrophenol reacts with cyclohexyl isocyanide (1 equiv), *p*-chlorobenzylamine (1 equiv), and propionaldehyde (1 equiv) by a very efficient four-component reaction. This reaction proceeds smoothly at 40 °C in methanol (1 M) within a few hours to provide the desired *N*-aryl amine **1** in 74 % yield (Scheme 2).

The high yield, simple reaction protocol, and originality of this tandem process prompted us to explore the reaction more widely (Table 1). Aliphatic aldehydes are good substrates for this process and react with various amines and isocyanides. Aromatic aldehydes give the expected adducts in moderate

Table 1: The reagents used in the multicomponent reactions and the resulting products.

Entry	RCHO	Amine	RNC	Phenol	Reaction time	Product	Yields[%][a]

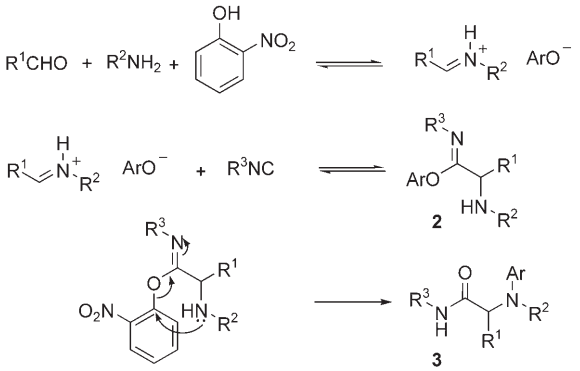
yields under these conditions. However, the use of a catalytic amount (15 mol %) of magnesium perchlorate improves the yield considerably (entries 4 and 5, Table 1). *p*-Nitrophenol, which has a comparable acidity, undergoes this coupling process equally efficiently (entries 6 and 7, Table 1). Ketones are less reactive than aldehydes and need much longer reaction times to afford the desired products in moderate yield (entries 8 and 9, Table 1).

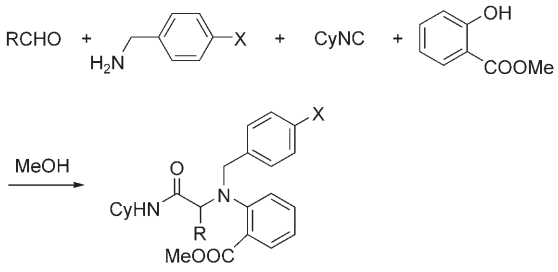
Although no detailed mechanistic studies have been carried out, a reaction sequence leading to *N*-aryl amines can be proposed (Scheme 3). It seems that the acidity of nitrophenols (pK_a values from 7 to 9) provokes sufficient



Scheme 3. Proposed mechanism for the phenol Ugi–Smiles reaction.

protonation of the imine to induce isocyanide addition. The phenoxide is nucleophilic enough to trap the resulting nitrilium intermediate, thus forming imidate **2**. At 40 °C, the latter undergoes a Smiles rearrangement[9] to provide the more stable *N*-aryl amine **3** (Scheme 3). This last rearrangement probably constitutes the only irreversible step in the whole process, and drives all the preceding equilibria toward the desired product in high yields.

Imidates are known to undergo a Mumm-type rearrangement or an electrocyclic reaction (in the case of hydrazoic acid).[10] However, to the best of our knowledge, this reaction constitutes the first example of a Smiles rearrangement intervening in an Ugi-type reaction. Moreover, the reaction can be extended to other weak phenolic acids. As an example, the reaction of methyl salicylate, propionaldehyde, cyclohexyl isocyanide, and *p*-chlorobenzylamine provides the desired *N*-aryl amine in 74 % yield (Scheme 4). The reaction proceeds smoothly in methanol at 60 °C within 2 days. This result indicates that a wide range of phenols could participate successfully in this new four-component reaction.



R = Et	X = Cl	40°C, 16h	38%
		40°C, 48h	57%

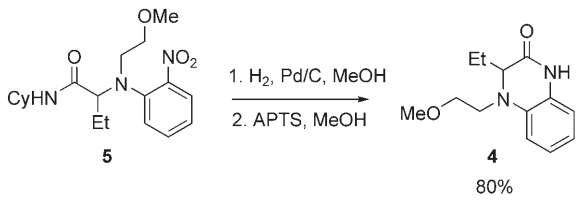
Scheme 4. Salicylic ester as the phenol in the Ugi–Smiles reaction. Cy = cyclohexyl.

The presence of the nitro or ester group on the final adduct allows interesting applications to heterocyclic synthesis. Thus, we accomplished an efficient one-pot synthesis of benzopyrazinone **4** by hydrogenolysis (H_2, Pd/C, methanol) and subsequent acidic cyclization (*para*-toluenesulfonic acid (TsOH), methanol) of the aryl amine **5** (Scheme 5).



Scheme 5. Application to the synthesis of benzopyrazinone. Cy = cyclohexyl.

In conclusion, we have developed a novel and very efficient four-component reaction from readily available substrates. The creation of four bonds that should be reasonably resistant to hydrolysis makes this process particularly attractive for the design of pharmaceutical and agrochemical libraries. Moreover, a straightforward elaboration of these adducts gives easy access to various heterocyclic structures. Further studies are under way to examine more thoroughly the scope and limitations of this MCR system.

Experimental Section

Synthesis of benzopyrazinone **4**: 2-Methoxy-1-ethylamine (1.0 equiv), cyclohexyl isocyanide (1.0 equiv), and *o*-nitrophenol (1.0 equiv) were added to a solution of propionaldehyde in methanol (1 M). The resulting mixture was stirred at 40 °C under an inert atmosphere for 20 h and concentrated in vacuo. The crude product was then purified by flash chromatography on silica gel.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

A catalytic amount of Pd/C (10%) was added to a solution of the resulting aryl amine in methanol (0.3 M), and the mixture was stirred at room temperature (RT) under a hydrogen atmosphere for 24 h. Hydrogen was then replaced by argon and a catalytic amount of *p*-toluenesulfonic acid was added. The resulting mixture was stirred at RT for 24 h. After addition of a saturated aqueous solution of $NaHCO_3$, filtration, and extraction with diethyl ether, the combined organic layers were washed with brine, dried over anhydrous $MgSO_4$, filtered, and concentrated in vacuo. The crude product was purified by flash chromatography on silica gel (80:20 ether/petroleum ether) to give the desired benzopyrazinone **4** in 81% yield. ^{1}H NMR ($CDCl_3$, 400 MHz): $\delta = 8.62$ (br s, 1H), 7.02–6.96 (m, 1H), 6.80–6.70 (m, 3H), 3.86 (t, 1H, $J = 6.8$ Hz), 3.73–3.63 (m, 1H), 3.57 (t, 2H, $J = 6.8$ Hz), 3.37 (s, 3H), 3.41–3.31 (m, 1H), 1.72–1.60 (m, 2H), 0.95 ppm (t, 3H, $J = 7.3$ Hz). ^{13}C NMR ($CDCl_3$, 100.6 MHz): $\delta = 168.9$, 134.2, 126.7, 124.5, 119.1, 115.9, 113.5, 70.5, 64.6, 59.4, 50.1, 24.1, 10.4 ppm. Gelation of Helical Polypeptide–Random Coil Diblock Copolymers by a Nanoribbon Mechanism**

Kyoung Taek Kim, Chiyoung Park, Guido W. M. Vandermeulen, David A. Rider, Chulhee Kim, Mitchell A. Winnik, and Ian Manners**

The polypeptide poly(γ-benzyl-L-glutamate) (PBLG) serves as a model rod-like polymer in solution and in the solid state because of its rigid α-helix conformation.[1,2] The stiff rod-like conformation of the PBLG helix is a crucial prerequisite for its unique solution behavior such as liquid crystalline ordering[3,4] and thermoreversible gelation.[5] Nematic ordering (orientational order of rod-like molecules) is responsible for the thermoreversible gelation of PBLG in dilute solution. Diblock copolymers of PBLG and flexible organic polymers are unable to form a nematic phase due to the presence of a block with a bulky random-coil conformation. Here we report the discovery of thermoreversible gelation of diblock copolymers of PBLG in dilute solution which has not been observed previously despite many studies of such materials.[6] We also explain the gel formation of PBLG-based diblock copolymers in solution by a mechanism which is distinct from the current understanding of PBLG self-assembly.[7] Based on our findings, we describe the formation of self-assembled functional scaffolds with precisely aligned fluorescent labels. The results illustrate a novel and general mode of self-assembly for block copolymers of PBLG and presumably other helical polypeptides and demonstrate an attractive new approach to nanostructured supramolecular materials derived from biological and synthetic polymers.

Our initial studies involved the synthesis of poly(ferrocenylsilane)-*b*-poly(γ-benzyl-L-glutamate) (PFS-*b*-PBLG), conjugates of an organometallic polymer and polypeptides with narrow molecular weight distributions (Figure 1a, Table 1).

[f] Calculated length of the PBLG helix of the block copolymers. L_{helix} (in nm) = $N_{PBLG} \times 0.15$ nm where N_{PBLG} is the average number of residues in the PBLG helix determined by ^{1}H NMR. [g] The width of the ribbon in the dried gels measured by SAXS.

These materials were synthesized by ring-opening polymerization (ROP) of γ-benzyl-L-glutamate-*N*-carboxyanhydride (γ-Bz-L-Glu-α-NCA) with amine-terminated PFS (amino-PFS) as a macroinitiator.[8] Amino-PFSs were prepared by living anionic ROP of a strained [1]-silaferrocenophane monomer.[9,10] The PFS-*b*-PBLG block copolymers were very soluble in common organic solvents such as chloroform and tetrahydrofuran (THF), but only sparingly soluble in hot *N*,*N*-dimethylformamide (DMF).

We found that PFS-*b*-PBLG block copolymers are soluble in hot toluene and, to our surprise, form optically transparent gels upon cooling to ambient temperature. The gelation was thermally reversible in all cases. The apparent critical concentration for the gelation (C_{gel}), below which the solution exists as a viscous fluid (Figure 1b), strongly depends on the chain length of the PBLG block (see Experimental Section for details of the measurement). For example, block copolymers **1** and **2**, which differ only in the number of γ-Bz-L-Glu residues (69 for **1** and 98 for **2**) in the PBLG block, have a considerably different C_{gel} (3.3 wt% for **1** and 0.2 wt% for **2**). This result indicates that the interaction between the PBLG helices is a crucial factor in the gelation process. The lower C_{gel} of block copolymer **3** as compared to that of **1** (Table 1) suggests that the chain length ratio between the PFS and the PBLG blocks might also be a factor in the gelation process. In addition, for PFS_{38}-*b*-$PBLG_{133}$ (38.5 kDa), where the chain length ratio between the PFS and the PBLG exceeds 1:3, incomplete gelation was observed (macroscopic phase separation into a dense block copolymer gel and the free solution phase) regardless of the concentration of the block copolymer in toluene. Significantly, the gels retained their shape and thermoreversibility on the addition of methanol (5 vol% to toluene). This suggests that there is no end-to-end intermolecular hydrogen bonding between the PBLG blocks, as methanol can readily disrupt the hydrogen bonding between the PBLG chains.[11,12] This result indicates that hydrogen bonding is not a key factor for the gelation.

PBLG homopolypeptide is known to form thermoreversible gels in various solvents such as toluene and benzyl alcohol,[13] which has led to challenging questions on the origin of this phenomenon.[14] PBLG differs from other gel-forming polymers[15] because its rigid-rod conformation does not allow the formation of chain–chain entanglements. One aspect of the current understanding of the gelation of PBLG in solution is based on phase separation.[16] The PBLG homopolypeptide undergoes microscopic phase separation when a warm homogeneous solution in the dilute concentration regime (< 2 wt%) is cooled. Phase separation increases the concentration of PBLG locally, and the increased concentration forces the rods to order in a liquid crystalline phase where PBLG rods align parallel to the long axis of the phase-separated domains. Strong dipolar π–π interactions between the phenyl groups of the PBLG rods consequently stabilize the microfibers that are intertwined into a 3-D network structure.

Based on the mechanism described above, it is difficult to imagine that block copolymers of PBLG and a random-coil polymer could form a gel since the block copolymers can not be ordered in a liquid crystalline phase in dilute solution due to the presence of the bulky random-coil polymer chain at the end of PBLG helix. Our findings reported here imply that a different mechanism of gelation is required to explain the self-assembly behavior of PBLG–random coil diblock copolymers in solution. Therefore, we studied the detailed structure of the gels of PFS-*b*-PBLG in toluene with transmission electron microscopy (TEM), atomic force microscopy (AFM), and small-angle X-ray scattering (SAXS). TEM images of the dried gel of **2** formed in toluene (Figure 1c)

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

show a network of fibrous structures, where each individual fiber has a width of about 20 nm. Energy- dispersive X-ray spectroscopy (EDX) clearly evidenced the presence of both the PBLG block and PFS block in the structure (Figure 1d). AFM experiments were carried out to determine the lateral dimension and the height profiles of the fiber (Figure 2a and b). Analysis of the AFM height profiles (Figure 2b) revealed

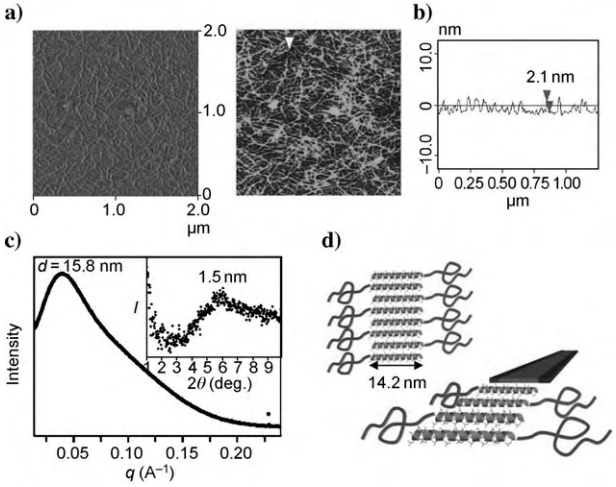

Figure 2. a) AFM phase (left) and height (right) images of the toluene gel of **2** (0.1 wt%). b) AFM height profile of the nanoribbons. c) SAXS profile of the dried gel of **2** showing the width of the ribbon (15.8 nm). The inset denotes the diffraction at 1.5 nm indicating the distance between two PBLG helices obtained by PXRD. d) A schematic presentation of the nanoribbon formed in the network structure of the toluene gel of **2**. 14.2 nm indicates the calculated length of the PBLG helix.

a height of 2.1 ± 0.2 nm, and a lateral dimension of about 23 nm. This suggests that the individual fibrous structure is not cylindrical but has a ribbon or tape-like morphology. SAXS measurements were carried out on the dried gel because all gels showed strong birefringence when examined by polarized optical microscopy, indicating the presence of regular structures (Figure 2c). The results corroborated TEM and AFM observations of the width of the individual fibers by showing a diffraction peak at 15.8 nm. This lateral dimension of the fiber obtained on SAXS has not been observed in the gels of the PBLG homopolypeptide due to the lack of order in the diameters of fibers.[17] Powder X-ray diffraction (PXRD) of the dried gels of PFS-*b*-PBLG also showed a diffraction peak at 1.5 nm, which indicates the distance between PBLG helices.[4]

Based on the TEM, AFM, SAXS, and PXRD results, a mechanism for the gelation of **2** was conceived. From the experimental data and the molecular dimensions of block copolymer **2**, containing a PBLG helix of 14.2 nm length and 1.5 nm diameter, we propose that the observed fibers are nanoribbons assembled from the 1-dimensional stacking of the block copolymers in a monolayer fashion (Figure 2d).[18] This self-assembly mechanism is reminiscent of that proposed for nanoribbons derived from dendron rod-coil molecules[19] but with two differences. First, in our case, the self-organizing motifs are high molecular weight block copolymers, and second, hydrogen bonding interactions, which have been shown to be essential for dendron rod-coil self-assembly, are not involved. We propose that strong dipolar π–π interactions involving phenyl groups between the PBLG helices stabilize the structure and could be the driving force for the self-assembly.[20] The long axis of the PBLG helix is parallel to the plane of the ribbon. The PFS block protrudes outside of the ribbon due to its high solubility in toluene and prevents the aggregation between nanoribbons in the solution. In the nanoribbon, the PBLG chains are most probably oriented in an anti-parallel fashion. In this orientation the dipole moments of the PBLG helices are oriented in a favorable manner, and the steric repulsion between the PFS chains is minimized.[21] The nanoribbon mechanism proposed here explains the dependence of C_{gel} of the block copolymers on the length of the PBLG helix and the independence of gelation on the presence of hydrogen bonding disrupting solvents such as methanol.

The proposed mechanism is potentially applicable to other diblock copolymers when the appropriate structural requirements are met: a stable α-helical conformation of the PBLG polypeptide block and a random-coil block which is soluble in the given solvent. To establish the generality of the mechanism, we prepared two block copolymers, polystyrene-*b*-PBLG (PS-*b*-PBLG) **4** and poly(ethylene glycol)-*b*-PBLG (PEG-*b*-PBLG) **5**. We chose PS and PEG because these polymers possess a random-coil conformation in solution and are readily soluble in toluene. In addition, amino-functionalized PS and PEG are commercially available, and the block copolymers, PS-*b*-PBLG and PEG-*b*-PBLG, have been previously synthesized.[22,23] Both diblock copolymers formed stable transparent thermoreversible gels in toluene at concentrations as low as 0.3 wt% (Figure 3a and c). A detailed structural characterization of gels in toluene of both block copolymers also showed structures of the fibers identical to those described for the PFS-*b*-PBLG gels. TEM observations and SAXS experiments revealed that both block copolymers self-assemble in a manner that is consistent with the nanoribbon mechanism described above (Figure 3b and d). In addition to our work, diblock copolypeptides containing both random-coil and α-helical peptide blocks have been shown by Deming and co-workers to form hydrogels in aqueous solution.[24] Our results together with those of Deming strongly suggest that the gelation of the diblock copolymers with an α-helix and a random-coil block in an appropriate solvent (toluene for the PBLG block copolymers) is a general phenomenon, and the concept could be expanded to numerous block copolymers containing a helical polypeptide block other than the PBLG.

The ROP of α-NCA yields an amino end group at the polypeptide chain. This amino group could be further functionalized by reacting guest molecules such as fluorescent dyes, nanoparticles, and other functional species. The resulting self-assembled structures of the labeled block copolymers would then be functional scaffolds with precise alignment of the labels in the nanostructures. To test this idea, we labeled PEG-*b*-PBLG with a pyrene (Py) chromophore using an *N*-hydroxysuccinimide activated pyrene derivative (Figure 4a

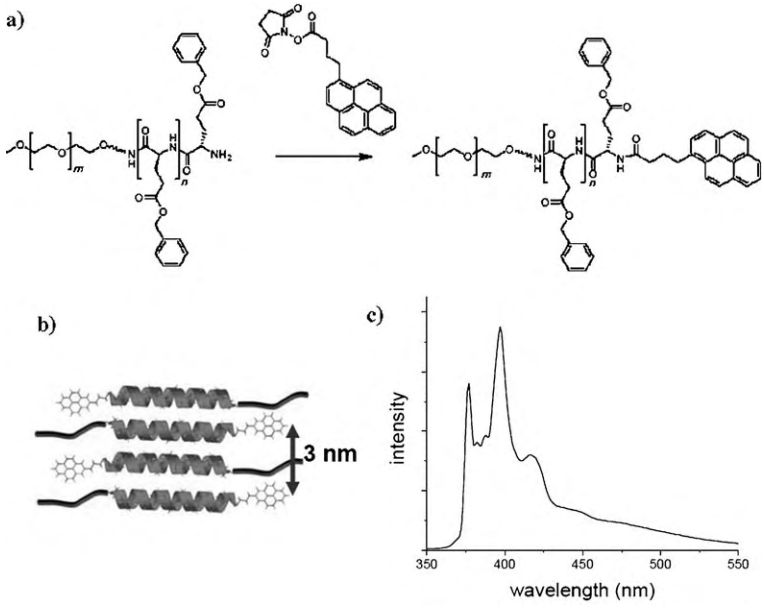

Figure 4. a) N-terminal labeling of PEG-*b*-PBLG. b) Graphic representation of the self-assembled nanoribbon of pyrene-labeled PEG-*b*-PBLG. c) Fluorescence emission spectrum (excitation at 340 nm) of toluene gel of pyrene-labeled PEG-*b*-PBLG.

and Experimental Section).[25] The functionalized PEG-*b*-PBLG formed a transparent thermoreversible organogel at 2.5 wt% in toluene. This indicates that the incorporation of bulky guest molecules such as pyrene does not hamper the self-assembling ability of the block copolymer and the self-assembled structure can accommodate numerous functional molecules and nanoparticles with 1-D alignment at the defined location. For Py, the fluorescence emission spectrum reveals information about its micro-environment. Based on the mechanism proposed here, Py groups would be segregated in the nanoribbon structure by a 3 nm distance and shielded from one another by flexible PEG chain. Despite the high local concentration of Py groups, the structural model predicts that excimer formation should be strongly inhibited (Figure 4b). The excimer sandwich requires close proximity of two Py molecules (ca. 4 Å), achieved either through pre-association or diffusive motion of Py groups in the medium.[26] The fluorescence emission spectrum of the organogels of pyrene-labeled PEG-*b*-PBLG shows only characteristic monomeric emission peaks of pyrene (377 nm, 397 nm, and 416 nm) and no noticeable excimer emission at about 480 nm. This result provides strong support for the proposed mechanism. In addition, the unique self-assembly mechanism allows labeling species to be incorporated in the block copolymer without interfering with the self-assembly process. The labeled organogels based on random coil–helical polypeptide block copolymers could be utilized as scaffolds for catalysis.

The studies described here show that synthetic polymers with a defined conformation can play a role as well-defined building blocks for self-assembly. It is remarkable that the random coil–helical polypeptide diblock copolymers behave with the same precision as well-defined small molecules that form organogels (organogelators)[27] although the size of the block copolymer building blocks is orders of magnitude larger. This dimension regime is comparable to that of proteins that form elaborate 1-D structures such as F-actin.[28] Our findings could facilitate the development of synthetic polymeric systems that self-assemble precisely into well-defined nanostructures by adopting stable polymer conformations. Furthermore, fine-tuning of the properties and chemical functionality of organogels made of helix–random coil diblock copolymers should be possible based on the mechanism proposed here. The potential development of PFS-*b*-PBLG gels as magnetic and redox-active scaffolds where the additional functionality arises from the presence of metal atoms is particularly attractive.[29,30]

Experimental Section

Synthesis of the block copolymers, gel characterization, and labeling experiments: Amino-PFSs and block copolymers of PBLG were synthesized as previously reported.[8] Amino-polystyrene ($M_n = 10500\ g\,mol^{-1}$, PDI = 1.05) and amino-poly(ethylene glycol) ($M_n = 10000\ g\,mol^{-1}$, PDI = 1.08) were purchased from Polymer Source. For organogels, block copolymers and toluene were mixed in a sealed vial and heated until the mixture became a homogeneous solution. The homogeneous solution was stored at 22 °C for 24 h. After 24 h, the organogel was subjected to gravity for 24 h. When no flow was observed, we defined the state as a gel. The lowest concentration of gelation in this condition was determined as C_{gel}. T_{gel}

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

was measured by the procedure reported by Hirst et al.[31] All C_{gel} and T_{gel} values were measured three times. Pyrene labeling of the block copolymer was achieved by means of an amidation reaction between PEG-*b*-PBLG and *N*-hydroxysuccinidal pyrene butyric acid (fivefold excess to the block copolymer) in THF at room temperature for 24 h. The completion of the reaction was monitored by ^{1}H NMR integration. Labeled block copolymer was purified by repeated precipitations in diethyl ether and washings over acetone until the washings show no presence of pyrene by UV/Vis absorption. Organogels of the labeled block copolymer were prepared in sealed quartz cells. Fluorescence emission spectrum of the organogel were taken on a Flurolog 322 fluorescence spectrophotometer with a 340 nm excitation wavelength.

Microscopy and X-ray experiments: Transmission electron microscopy (TEM) images were obtained on a Philips CM200 microscope operated at an acceleration voltage of 80 kV. The TEM specimen was prepared by gently placing a carbon-coated copper grid on the fraction of organogel. The TEM grid was removed after 30 sec and air-dried for 1 h. When necessary, the sample specimen was shadowed with Au/Pd (7–8 Å thickness at 20° tilting angle). Zero-loss bright field images were obtained on the energy-filtering TEM microscope Carl Zeiss Leo 912 Omega at an acceleration voltage of 120 kV. Small angle X-ray scattering (SAXS) experiments were carried out at the 4C1 X-ray beamline of Pohang Accelerator Laboratory (Pohang, Korea). The scattered data were collected using a 2-D CCD detector and the X-ray wavelength was 1.608 Å ($Co_{K\alpha}$ radiation). Powder X-ray diffraction data were collected on a Rigaku RINT-2000 counter diffractometer with a $Cu_{K\alpha}$ radiation source (operated at 40 kV, 40 mA). For X-ray experiments, organogels were slowly dried under air for 24 h. Atomic force microscopy was performed on a NanoScope III in the tapping mode. The sample preparation for AFM measurement was identical to the preparation of the TEM specimen. Fresh cleaved mica was used as a substrate. The height and width values of the fiber were determined from ten different locations.

Springlike Nanohelical Structures in Chiral Block Copolymers**

Yeo-Wan Chiang, Rong-Ming Ho, Bao-Tsan Ko, and Chu-Chien Lin*

Helical structures are probably the most fascinating morphologies in nature, and they have been intensively studied as a result of their specific functions in the formation of biological architectures. Helical-chain conformations, such as single-strand α-helical peptides and double-stranded DNA, are regarded as the fundamental motifs for the hierarchical organization of proteins. A variety of origins for the formation of helical structures, such as hydrogen bonds,[1] solvophobic interactions,[2] π–π interactions,[3] cholesteric liquid crystal formation,[4] relative incompatibility,[5] and chirality,[6] have all been demonstrated. Biomimicking nature, helical morphologies have been obtained on different length scales by the interplay of noncovalent bonding interactions (that is, secondary forces). Block copolymers that consist of two chemically different components are able to self-assemble into various ordered nanostructures, such as spheres, cylinders, gyroids, and lamellae, as a consequence of the incompatibility of the constituent blocks.[7] Therefore, the self-assembled nanostructures in block copolymers appear promising in applications that employ the bottom-up approach.[8] In contrast to the helical superstructures in the hierarchical organization of chiral molecules, helical nanostructures have been obtained from the self-assembly of block copolymers that consist of achiral and chiral blocks, for example, polystyrene-*b*-poly(isocyanopeptide), in buffer solutions.[6a] However, a three-dimensionally packed nanohelical structure phase was found in the self-assembled chiral diblock copolymer, polystyrene-*b*-poly(L-lactide) (PS-PLLA), in the bulk.[9] Contrary to the conventional phase morphology of diblock copolymers, the formation of a nanohelical structure phase is attributed to the chirality of the constituent PLLA block.[9] Furthermore, a significant change, from long-pitch to short-pitch nanohelices, was found in the nanohelical phase upon annealing.[10] Thus, the structural geometries of the nanohelices might be strongly affected by applying stimulation. Herein, we report the internal and external stimuli, such as crystallization and shearing, respectively, which act on the nanohelical morphology so that the microphase-separated PLLA nanohelices exhibit springlike behavior in a PS matrix in response to the applied stimulus. Consequently, switchable nanostructures can be obtained by interplay of vitrification, crystallization, and microphase separation as well as shearing.

Bulk samples of block copolymers were prepared by solution casting of PS280-PLLA127 ($f^{v}_{PLLA} = 0.35$) in dichloromethane (CH_2Cl_2; 10 wt%) at room temperature. As evidenced by transmission electron microscopy (TEM) and small-angle X-ray scattering (SAXS), a nanohelical structure phase quenched from microphase-separated melt at 165 °C (melting point of PLLA, ca. 160 °C) can be obtained from the self-assembly of PS-PLLA, and is packed in a hexagonal lattice.[9] In contrast to the racemic block copolymer, polystyrene-*b*-poly(D,L-lactide) (PS-PLA),[11] the formation of the nanohelical structures in PS-PLLA is attributed to the interplay of chirality and immiscibility of the constituent blocks.[9] As a result, the self-assembly of helical curvature is induced by the formation of specific conformations of PLLA chains arising from the interactions of chiral entities.

Considering their origin, the self-assembled nanohelical structures are expected to be affected by the changes of PLLA chain conformation. Notably, the PLLA component is intrinsically a crystallizable polymer as a result of the regularity of the chiral configuration. The crystallization of PLLA in PS-PLLA might give rise to significant changes in the self-assembly morphology and is thus considered as a driving force (namely, an internal stimulus) for manipulating the intrinsic nanohelical structure. The final morphology of crystalline block copolymers is strongly dependent on the experimental temperature, with respect to the order–disorder transition temperature (T_{ODT}), the crystallization temperature of the crystallizing block (T_c^c), the glass transition temperature of the amorphous block (T_g^a), and the crystallization rate.[12] Consequently, the microphase-separated morphology is determined by the crystallization temperature of PLLA that also justifies the degree of vitrification of the confined environment (that is, the PS matrix). The dividing confined environments—hard confinement ($T_c^c < T_g^a$) and soft confinement ($T_c^c \geq T_g^a$)—dictate the final morphology of crystallized PS-PLLA. For a system with $T_c^c < T_g^a$, the ordered nanostructure can be preserved because of the vitrified microdomains of the PS blocks. By contrast, if $T_c^c \geq T_g^a$, the effect of crystallization may lead to a change of microphase-separated morphology.

To examine the crystallization effect, the amorphous nanohelices (intrinsic nanohelices) of PS-PLLA were crystallized from hard ($T_{c,PLLA} < T_{g,PS} = 99.2$ °C) to soft ($T_{c,PLLA} \geq T_{g,PS}$) confinement. The nanohelical morphology remained

while PLLA crystallization was carried out under hard confinement (for instance, $T_{c,PLLA} = 80\,^{\circ}C$; see Figure 1a). The microdomains of the PS component became dark after staining with RuO_4, whereas those of the PLLA component appeared light. The crystallization of PLLA was restricted within confined microdomains because of the vitrification of the PS matrix, which preserved the helical morphology. Also, as evidenced by the one-dimensional (1D) SAXS profile (Figure 2a and b), the diffraction peaks occurred at q^* ratios of $1:\sqrt{4}:\sqrt{7}:\sqrt{13}$, consistent with the hexagonally packed phase structure. As a result, the packing geometry of the crystalline nanohelices remained as a hexagonal lattice under hard confinement.

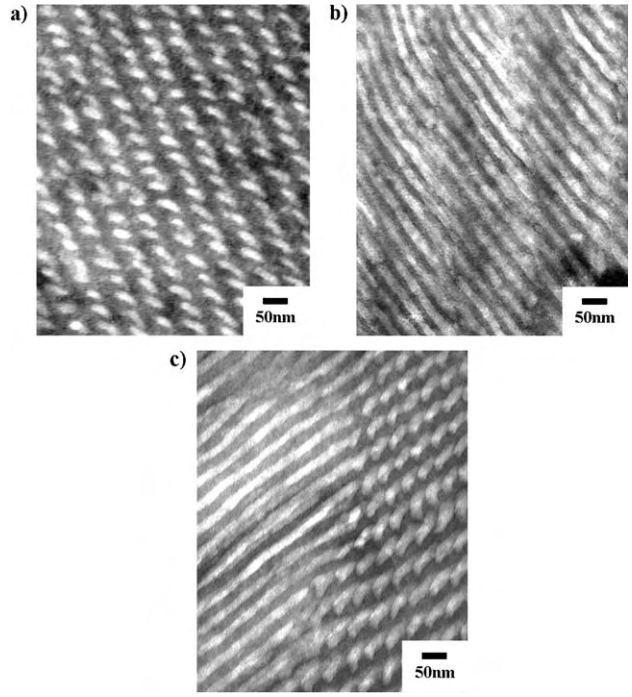

Figure 1. TEM micrographs of nanohelical structures in PS280-PLLA127 ($f^{v}_{PLLA} = 0.35$) bulk samples quenched from microphase-separated melt (165 °C), then a) crystallized at 80 °C for 120 min and b) crystallized at 110 °C for 120 min. c) TEM micrograph for phase transformation from helices to cylinders during crystallization at 110 °C.

By contrast, the nanohelices were transformed into a cylindrical phase when crystallization was carried out under soft confinement, while $T_{c,PLLA} > T_{g,PS}$ (for instance, $T_{c,PLLA} = 110\,^{\circ}C$; see Figure 1b). The developing stage of phase transformation can be clearly observed (Figure 1c). The helical structure was stretched and transformed into a crystalline cylinder along the long axes of the helices (or cylinders), so that the hexagonal packing remained regardless of the transformation (Figure 2c). The significant effect of crystallization on the microphase-separated phase is attributed to the stress-induced structural change when crystallization is carried out above $T_{g,PS}$.[12] As a result, the nanohelical structure behaves like a spring in response to a crystallization event, and the springlike PLLA microdomain can be modified as a crystalline spring under hard confinement, or a fully extended spring under soft confinement, by tuning the crystallization temperature.

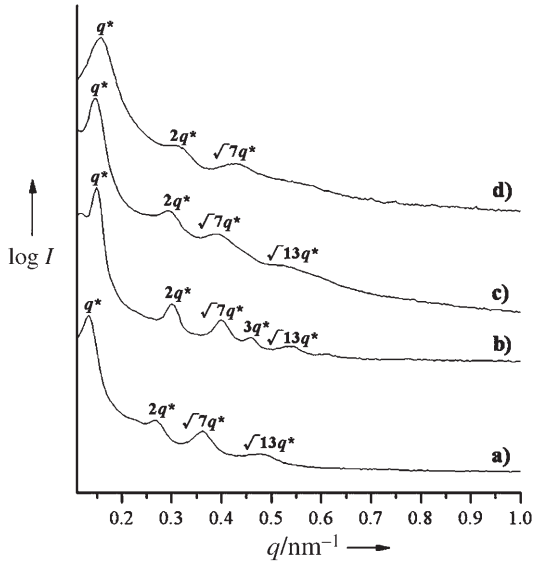

Figure 2. One-dimensional SAXS profiles for self-assembly of PS280-PLLA127 ($f^{v}_{PLLA} = 0.35$) with different geometries. a) Intrinsic nanohelices; b) crystalline nanohelices under hard confinement; c) stretched nanohelices (crystalline cylinders) under soft confinement; d) stretched nanohelices (amorphous cylinders) after shearing.

It is well-known that shear-induced orientation of block copolymers is one of the most convenient ways to generate a well-oriented morphology for bulk samples in practical applications.[13] Considering the springlike behavior of the nanohelical phase, shearing (an external stimulus as compared to crystallization) is expected to achieve the orientation of nanohelices and modify the morphology. Flow-induced alignment of the nanohelical phase was thus conducted by using a lubricated-channel die based on the design of Khan and Larson.[14] Molding and shearing of the intrinsic nanohelices were performed on a microphase-separated melt at 180 °C for 1 min, and then the processed strip was held in the die at the shearing temperature for 1 min before quenching with liquid nitrogen to eliminate the residual shear stress. The shear (velocity), vorticity, and velocity gradient directions were assigned as the x, y, and z directions, respectively. After quenching from the shearing melt, a hexagonally packed cylinder morphology was found in the y–z plane (Figure 3a). Also, a longitudinal cylinder morphology was observed along the y direction (Figure 3b), whereas the 2D SAXS pattern along the y direction appeared as a well-defined diffraction from oriented microdomains (inset of Figure 3b). The 1D SAXS profile indicated the unchanged hexagonally packed structures after shearing (Figure 2d). Thus, oriented cylinders were obtained, and the nanohelices also exhibited springlike behavior in response to shearing. Contrary to crystallization-induced cylinders, the shear-induced cylinders appeared as an amorphous entity.

The nanohelical phase with PLLA helices embedded in the PS matrix acted with springlike behavior upon internal and external stimulation. The stress-induced phase trans-

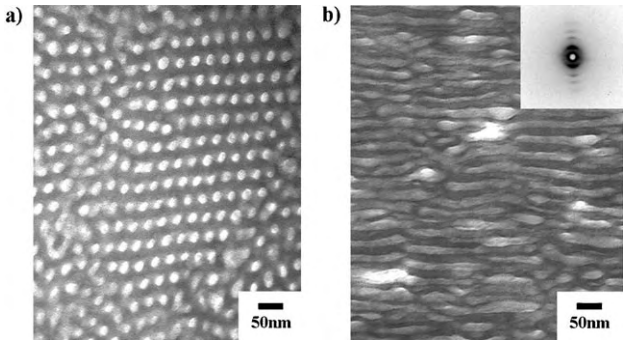

Figure 3. TEM micrographs of nanohelical structures in PS280-PLLA127 ($f^{v}_{PLLA}=0.35$) bulk samples after shearing at 180 °C (above the m.p. of PLLA (≈160 °C) and $T_{g,PS}$ (99.2 °C)) viewed a) parallel, and b) perpendicular to the shear axis. The inset shows the 2D SAXS pattern normal to the cylindrical axis.

formation from nanohelices to cylinders was driven either by crystallization or shearing. Considering the springlike behavior, a reversible process comprising transformation from stretched nanohelices (that is, cylinders) to intrinsic nanohelices would be expected once the stress-induced morphology was thermally treated to release the built-in stress. Figure 4 shows the reversible morphology at which the

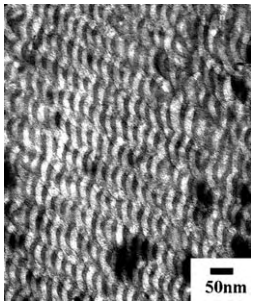

Figure 4. TEM micrograph of crystalline cylinders of PS280-PLLA127 ($f^{v}_{PLLA}=0.35$) bulk samples after annealing at 130 °C for 60 min from 165 °C (microphase-separated melt).

crystalline cylinders gradually revert to the original nanohelical structures through undulation, once the crystallized samples are remelted (at 165 °C) and then annealed at a temperature (130 °C) above the glass transition temperature of PS ($T_{g,PS}=99.2$ °C). Similar results can also be obtained in shear-induced, amorphous cylinders, which progressively transform into an intrinsic structure once the shearing samples are annealed at a temperature (130 °C) above the glass transition temperature of PS (see the Supporting Information).

In conclusion, a variety of self-assembled nanohelices in chiral block copolymers were observed by applying internal and external stimuli (that is, crystallization and shearing). The amorphous nanohelices in the bulk transform into crystalline nanohelices and cylinders by crystallization, and into amorphous cylinders by shearing. The crystallization-induced cylinders were thermally reversible, and able to revert to the original nanohelices upon remelting and annealing. In contrast to crystallized nanohelices, the reversible phase behavior can also be found in shear-induced cylinders by simple thermal annealing. As a result, the hexagonally packed nanohelical structure of the PLLA in the PS matrix of chiral PS-PLLA block copolymers has springlike behavior in response to the applied stimulus. This unique phase behavior thus might provide a technique for manipulating tunable nanohelical structures in practical applications. Consequently, switchable nanohelices from chiral block copolymers can be manipulated by the interplay of vitrification, crystallization, and microphase separation as well as shearing.

Experimental Section

PS-PLLA samples were prepared by using living free radical and ring-opening polymerizations in sequence. Detailed synthetic routes were described in our previous paper.[9]

The number-average molecular weight of PS and polydispersity index (PDI) of PS-PLLA were obtained by gel permeation chromatography. The molecular weight of the PLLA block was measured by ^{1}H NMR analysis. On the basis of molecular weight and volume ratio, the PS-PLLA is designated as PSx-PLLAy ($f^{v}_{PLLA}=z$); x and y represent the numbers of repeating units of PS and PLLA, respectively, and z indicates the volume fraction of PLLA calculated by assuming that the densities of PS and PLLA are 1.02 and 1.18 g cm^{-3}, respectively. The number-average molecular weights of PS and PLLA and the PDI of PS280-PLLA127 ($f^{v}_{PLLA}=0.35$) were 29400 g mol^{-1}, 18300 g mol^{-1}, and 1.21, respectively.

The thermal behavior of PS-PLLA was examined by differential scanning calorimetry (DSC). The sample was first heated to 165 °C and then cooled to −50 °C at a rate of 150 K min^{-1}. The glass transition temperatures of the PLLA and PS blocks were clearly identified as 51.4 and 99.2 °C, respectively.

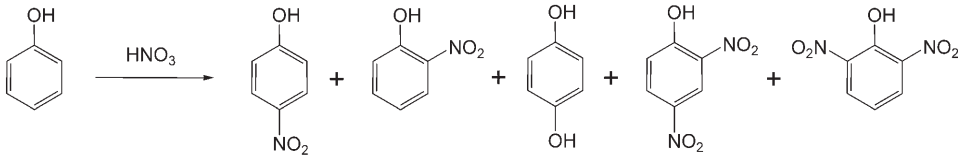
Controlled Autocatalytic Nitration of Phenol in a Microreactor

Laurent Ducry and Dominique M. Roberge**

Nitration reactions can often show extremely exothermic behavior, and this, combined with the decomposition or explosion potential of many nitro compounds, places them amongst the most hazardous industrial processes.[1] In this context, continuous processes are attractive for safety reasons because of the much smaller reaction volumes used.[2] Continuous production is of commercial importance for very fast nitrations, such as that of phenol (Scheme 1).[3] Moreover, microreactors[4] should allow better control of the reaction thanks to their efficient mixing and heat transfer, as already described for nitration reactions.[5] The nitration of phenol (**1**) was chosen as a model reaction to investigate the potential of microreactors from both a chemical and a safety point of view.

The general mechanism for the acid-catalyzed nitration of aromatic compounds is electrophilic and involves the nitronium ion (NO_2^+) as the reactive species.[6] The nitration of phenol (**1**) and other aromatic substrates activated toward electrophilic substitution is, however, essentially different in that it is catalyzed by nitrous acid.[7] The rate of phenol nitration by nitric acid in water was first reported by Martinsen, who showed that the reaction is autocatalyzed by the nitrous acid it produces.[8] The importance of the presence of HNO_2 could suggest that the nitrosonium ion (NO^+) acts as the reactive species. Catalysis by nitrous acid can not, however, involve a nitrosation followed by an oxidation by HNO_3, since nitrosation is *para*-selective whereas nitration affords a mixture of *ortho*- and *para*-nitrophenols.[9] Evidence has since been gained that phenol nitration mainly occurs by a radical mechanism involving a single electron-transfer reaction.[10]

The autocatalytic nature of phenol nitration was first verified by carrying out the reaction in a Mettler RC1 calorimeter (Table 1, entries 1 and 2). The addition of 65% HNO_3 to a 23% phenol solution in CH_3CO_2H (6%, used to increase the phenol solubility) and water (71%) was carried out in two portions (Figure 1). Essentially no reaction took place during the addition of the first HNO_3 portion (corresponding to 0.67 equiv). The small heat signal observed during this addition corresponds to the slightly exothermic dilution of the acid. A first exothermic reaction (35 kJ mol^{-1}) was observed shortly after the first addition. Once this reaction was over, the HNO_3 addition was resumed; again, the reaction did not start immediately. It was only towards the end of the second addition (2.0 equiv HNO_3 added in total) that the strongly exothermic reaction took place (170 kJ mol^{-1}; 115 °C total adiabatic temperature rise). It is important to note that despite the relatively small reaction volume (< 1 L) and the efficient cooling system of the calorimeter, a significant temperature rise occurred (55 °C). Scaling-up such a semibatch reaction would almost certainly be impracticable for safety reasons. Analysis of the final organic phase by differential scanning calorimetry (DSC) showed a small exotherm starting at 104 °C (30 J g^{-1}) followed



Scheme 1. Nitration of phenol (**1**) affords the mononitro isomers **2** and **3** as main products. Some hydroquinone (**4**), dinitrophenols (**5** and **6**), and polymeric side-products are also formed. *para*-Nitrophenol (**2**) is the most valuable regioisomer commercially.

[a] The nitrated solution was analyzed by GC (quantitative results for **1**, **2** and **3**, area% for the side-products). The yield (calcd) and purity correspond to the total amount of mononitro products **2** and **3**. The water concentration does not take into account the water contained in nitric acid.

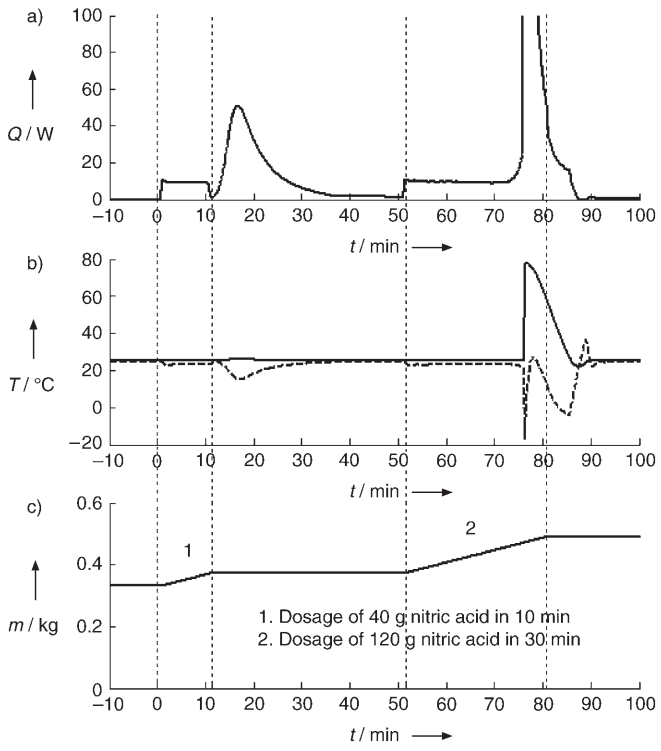

Figure 1. Semibatch nitration of phenol at 25 °C with acetic acid (Table 1, entry 2): a) heat signal (Q, positive values denote exothermic reactions); b) reaction temperature (T, ——) and temperature of the cooling system (T, -----); c) addition rate (m) versus reaction time (t).

by a large one at 185 °C (1500 $J\,g^{-1}$), which actually corresponds to a thermal runaway scenario.

A glass microreactor with a 10×0.5-mm channel width and 2.0 mL internal volume was next used for the nitration experiments (entries 3–8). The phenol solution (23%) in a mixture of CH_3CO_2H (6%) and water (71%, feed 1) and the 65% HNO_3 solution (feed 2) were continuously pumped through the mixer at a total flow rate of approximately 21 $g\,min^{-1}$ (phenol throughput of 3.7 $g\,min^{-1}$). The split between the phenol (**1**) and the nitric acid solutions was varied between 3.9:1 and 2.3:1, which corresponds to 1.1 to 1.8 equivalents of HNO_3. The efficient cooling of the microreactor allowed safe control of the exothermic reaction. With 1.5 equivalents of HNO_3, a one-minute delay was observed at 45 °C before the start of the autocatalysis (Figure 2). The autocatalysis started immediately at a higher temperature with 1.5 equivalents of HNO_3 (entry 8), whereas at lower temperatures the autocatalysis did not start at all, was extinguished, or partially took place outside the microreactor. Similar trends were also observed on variation of the amount of HNO_3: the nitration was completed within the microreactor with 1.8 equivalents of HNO_3 (entry 7), while the reaction proved slower and occurred partially outside the reactor (residence time: 7 s) at a lower stoichiometry. One advantage of a glass microreactor is the possibility to observe the reaction as it takes place. After the start of the autocatalysis, the violent evolution of a colorless gas suggests that gaseous nitrogen dioxide (N_2O_4) is formed in the catalytic cycle. However, the true reactive species for this reaction is presumably the dissociated nitrogen dioxide radical ($NO_2^{\bullet}$) which couples with the radical cation from the phenol in a single electron-transfer mechanism.[10]

Reduced amounts of polymeric side-products, increased purities, and up to 20% higher yields were obtained when performing the reaction continuously in a microreactor. Only

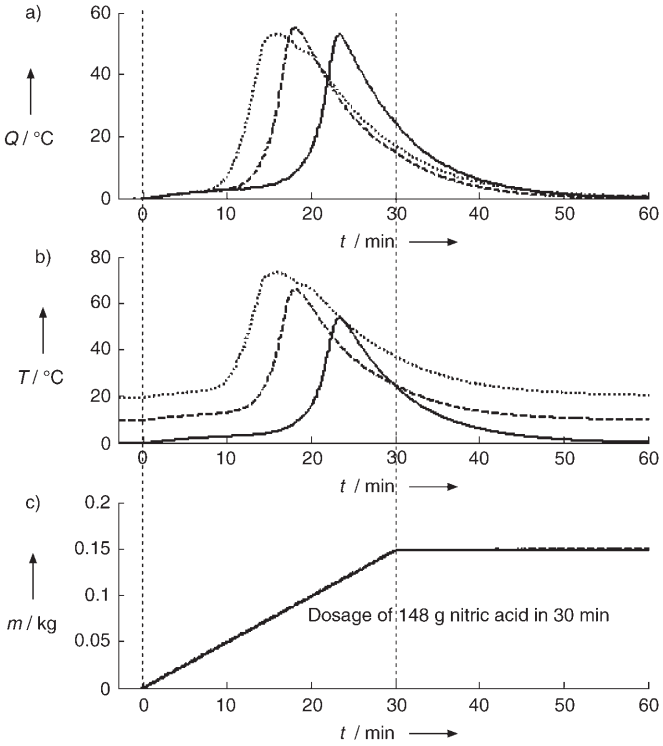

Figure 3. Batchwise phenol nitration at 0 (——), 10 (-----), and 20 °C (•••••) without acetic acid (Table 1, entries 9–11): a) heat signal (*Q*) obtained from the difference of the reactor and jacket temperatures; b) reaction temperatures (*T*); c) mass of nitric acid added (*m*) versus reaction time (*t*).

about 9 % of polymers were formed when 1.6 and 1.8 equivalents of HNO_3 were used (entries 7 and 8). Lower HNO_3 stoichiometries resulted in intermediate amounts of polymers, possibly reflecting the part of the nitration which took place outside the microreactor (batch instead of flow reaction). While the *para* isomer **2** was slightly favored in batch reactions, especially at lower temperature, no significant regioselectivity was observed with the microreactor.

In a second set of experiments, phenol nitration was studied without CH_3CO_2H. For comparison purposes, the reaction was again first performed batchwise in a jacketed 100-mL reactor. Continuous addition of 65 % HNO_3 to a 24 % aqueous phenol solution was carried out at various temperatures (Figure 3). These conditions correspond to a liquid–liquid biphasic system where the phenol (**1**) is dispersed as a fine emulsion. The reactions only started after a delay of 15, 18, and 24 minutes at 20, 10, and 0 °C, respectively, as judged by the heat signal. Not surprisingly, the lower the temperature, the longer the time required to start the autocatalysis. In each case, the exotherm was such that a 50 °C temperature rise occurred. These conditions led mainly to polymer formation and only 21–32 % yield of nitrophenols **2** and **3** (entries 9–11).

The phenol nitration without CH_3CO_2H was next investigated using the microreactor. The phenol concentration was increased to 90 % (feed 1) because of the difficulty to continuously dose a liquid–liquid emulsion. The HNO_3 solution (feed 2) was first diluted with water to obtain the same concentration as in the batch experiments. Based on the good temperature control obtained with the microreactor, the concentration of the nitric acid solution was increased stepwise and commercial 65 % HNO_3 solution was finally used (entries 12–20). Thus, these experiments were performed solvent-free, except for the 10 % water used to liquefy the phenol and the water present in the nitric acid. The flow rate was reduced to about 8 $g\,min^{-1}$ (1.6:1 split, phenol throughput of 2.8 $g\,min^{-1}$). Under these concentrated conditions the autocatalysis always started spontaneously in the mixing zone of the microreactor, thus allowing safe control of the reaction. The amount of polymeric components decreased by a factor of 10 compared to batch experiments, with the yield of the mononitro products **2** and **3** increasing correspondingly. However, the amount of hydroquinone (**4**) and of dinitro compounds **5** and **6** also increased. The best yield (77 %) and purity (74.6 %) of nitrophenols **2** and **3** were obtained with 1.4 equivalents of nitric acid at 20 °C (entry 12). Some unreacted phenol remained at lower stoichiometries, presumably a consequence of HNO_3 consumption in overnitration and oxidation reactions. In contrast to the series with acetic acid, *ortho* isomer **3** was slightly favored.

The results described above indicate that higher yields of nitrophenols are obtained when the nitration of phenol is performed in a microreactor (both with and without CH_3CO_2H). Enhanced heat exchange, good mixing properties, and very rapid radical propagation in a confined volume account for this result. In addition to the small reacting volumes present at any given time, continuous phenol nitration in a microreactor allows for better control of the exothermic reactions. Running the nitration under more concentrated conditions, almost solvent-free and without H_2SO_4 or CH_3CO_2H, is important to ensure that the nitration takes place within the microreactor. Thus, the resulting improved yields and enhanced process safety make micro-

Phase-Transfer-Catalyzed Asymmetric Aza-Henry Reaction Using *N*-Carbamoyl Imines Generated In Situ from α-Amido Sulfones**

Francesco Fini, Valentina Sgarzani, Daniel Pettersen, Raquel P. Herrera, Luca Bernardi,* and Alfredo Ricci*

Nucleophilic addition to the C=N bond of imine derivatives is of paramount importance in organic chemistry for the synthesis of functionalized amines and related nitrogen-containing compounds.[1] In this transformation, the substituent on the nitrogen atom of the imine often plays a crucial role, thus strongly affecting the electrophilicity.[2] In principle, as well as guaranteeing sufficient reactivity, this *N*-substituent should be easily removable after the reaction has taken place. Both requirements are fulfilled by carbamoyl groups, such as *tert*-butoxycarbonyl (Boc) or benzyloxycarbonyl (Cbz).[3] However, because of their inherent high reactivity, *N*-carbamoyl imines are rather sensitive to moisture, their purification (though often not necessary) is rather troublesome, and their storage requires some precautions. Furthermore, the isolation of *N*-carbamoyl imines derived from aliphatic enolizable aldehydes has not been reported, as they readily tautomerize to the corresponding ene carbamate,[4] thus resulting in a considerable limitation to the generality of their applications. A possible way to overcome these drawbacks is the in situ generation of the imine through the use of carbamates with a good leaving group at the carbon atom α to the nitrogen atom. Among the suitable imine precursors available, α-amido sulfones **1** are particularly attractive as they are bench-stable solids and can be very easily obtained by the condensation of a carbamate and a sodium aryl sulfinate with the appropriate aldehyde.[5] As α-amido

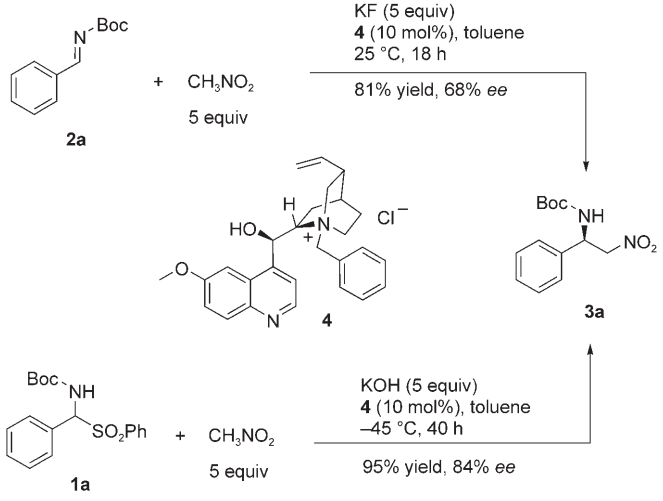
sulfones **1** furnish the corresponding imine when treated with a base,[6] they have been widely used in combination with hard organometallic reagents or metal-stabilized enolates.[7] The formation of the imine in situ can also be achieved by using a phase-transfer catalyst in combination with an inorganic base. Despite the considerable benefits of the latter approach, which combines the operational simplicity and the mild reaction conditions typical of phase-transfer catalysis (PTC)[8] with the convenience and the generality of the use of α-amido sulfones **1** as imine surrogates, this reaction has been only occasionally reported.[9]

Bearing in mind the impressive applications of PTC in enantioselective transformations,[8] we decided to employ this strategy in the catalytic asymmetric nucleophilic addition of nitromethane to *N*-carbamoyl imines (aza-Henry reaction) generated in situ from α-amido sulfones **1**[10] using cinchona-derived quaternary ammonium salts as catalysts.[11] The aza-Henry reaction,[12] and especially its catalytic asymmetric variants,[13] has received a lot of attention in recent years, the resulting β-nitroamines being readily converted into highly valuable chiral compounds, such as α-amino acids and vicinal diamines. After the first pioneering reports on metal-catalyzed asymmetric aza-Henry reactions,[14] a few organocatalytic protocols have been reported.[15] Despite the remarkable results in terms of enantioselectivity and catalytic efficiency, all methods show a considerable limitation in the variability of the imine partner because preformed imines are employed. We felt that our approach could significantly extend the scope of the reaction, besides providing a new and convenient protocol for this asymmetric transformation.[16]

To test the feasibility of our approach, we thought it convenient to first explore the capability of phase-transfer catalysts derived from cinchona alkaloids to impart an appreciable asymmetric induction in the addition of nitromethane to *N*-carbamoyl imines. For this purpose, *N*-Boc imine **2a** was treated in the presence of catalytic amounts of several cinchona-derived quaternary ammonium salts and KF as a base under the solid–liquid PTC conditions used for the enantioselective addition of nitromethane to chalcones and for the Henry reaction (Scheme 1).[17] Among the catalysts tested (see the Supporting Information), the commercially available *N*-benzyl quininium chloride **4** proved to be the most effective, thus furnishing the corresponding β-nitroamine **3a** after 18 h in good yield of isolated product and with moderate, but promising, enantiomeric excess (Scheme 1). Encouraged by this result, we turned our attention to the possibility of using **1a** directly in the reaction with nitromethane. After a thorough screening of different



Scheme 1. PTC aza-Henry reaction using imine **2** and α-amido sulfone **1a**.

reaction conditions (see the Supporting Information), we found that the reaction proceeded smoothly even at low temperature when a stronger base, such as solid KOH, was used, thus furnishing the product **3a** directly from **1a** at −45 °C in good yield and with useful enantiomeric excess (Scheme 1).

We next investigated the generality of this new catalytic enantioselective addition of nitromethane to *N*-carbamoyl imines generated in situ from **1** by varying both the substituent of the starting compound **1** and the protecting group (PG) on the nitrogen atom (Table 1). A few α-amido sulfones **1a–e** derived from aromatic and heteroaromatic

aldehydes were treated with nitromethane under the optimized reaction conditions, thus furnishing the corresponding optically active *N*-Boc β-nitroamines **3a–e** in fairly good yield and enantiomeric excess (entries 1–5). It is noteworthy that **3a** and **3c** could be obtained in essentially enantiopure form after a single crystallization (entries 1 and 3). Moreover, we found that this new strategy for the catalytic enantioselective aza-Henry reaction was particularly effective for the synthesis of *N*-Boc α-alkyl β-nitroamines, which cannot be obtained by the previously reported methods. As a matter of fact, **1f–j**, derived from both linear and branched aliphatic aldehydes, all gave the corresponding β-nitroamines **3f–j** in very good yields and enantioselectivities (entries 6–10). The efficiency of the present method for this class of substrates is well accounted for by the high enantiofacial discrimination in the imine derived from **1j** (entry 10) bearing a proton and a small methyl group. Variation of the protecting group on the nitrogen atom was then shortly investigated using **1k** and **1l** bearing a Cbz moiety (entries 11 and 12), thus demonstrating that the present method is not restricted to obtaining *N*-Boc-protected β-nitroamines. Also in this case, **1l**, derived from an aliphatic aldehyde, gave better results with respect to **1k**.

The absolute configuration of the products was determined by comparison of the HPLC retention time and optical rotation of **3a** with reported values[15b,c] and by reduction of **3h** (see the Supporting Information) to the known diamine derivative.[18] Attack on the *Si* face of the intermediate imine by the nitronate and quininium ion pair accounts for the *R* configuration at the stereogenic centre observed in both cases.

In summary, we have developed a new catalytic enantioselective approach to the asymmetric nucleophilic addition of nitromethane to *N*-carbamoyl imines generated in situ from α-amido sulfones. The chiral phase-transfer catalyst acts in a dual fashion,[19] first promoting the formation of the imine under mild reaction conditions and then activating the nucleophile for asymmetric addition. The potential of this approach was demonstrated in the reaction of nitromethane with α-amido sulfones, which could be efficiently catalyzed by a simple and commercially available quininium salt. Besides the mild reaction conditions and the operational simplicity, this new method allows *N*-carbamoyl imines derived from enolizable aldehydes in a catalytic asymmetric aza-Henry reaction to be used for the first time, thus extending the generality of this asymmetric transformation.

Quasi-Homogeneous Methanol Synthesis Over Highly Active Copper Nanoparticles**

*Sascha Vukojević, Oliver Trapp, Jan-Dierk Grunwaldt, Christoph Kiener, and Ferdi Schüth**

Heterogeneously catalyzed methanol synthesis from synthesis gas over $Cu/ZnO/Al_2O_3$ is one of the most important processes in the chemical industry, with a world production capacity of more than 28 million tons per year.[1] Despite the enormous number of publications on methanol synthesis over copper-based catalysts, however, the nature of the active site(s), the reaction mechanism, the role of Cu and ZnO in the solid catalyst,[2] and further issues remain highly controversial. This is partly due to the problems associated with the analysis of a complex solid catalyst. However, a homogeneous model system for the methanol synthesis catalyst, which would help to address these questions, is lacking so far.[3] We have now succeeded in the development of a quasi-homogeneous version of the process which uses aluminum-stabilized copper colloids with a size of about 5 nm. This catalyst, rather surprisingly, has a productivity that is very high in spite of the absence of ZnO. Consequently, the intrinsic activity of copper in this reaction is much higher than previously thought. Mechanistic studies suggest that the reaction proceeds in a similar manner as on the solid catalyst, which opens new roads for a detailed understanding of one of the most important commercial catalytic systems.

There are several reports in the literature on homogeneously catalyzed methanol synthesis;[4] they typically use catalysts based on transition metals such as Ru,[5,6] Ni,[7,8] or Re.[7] However, these catalysts bear no resemblance to the technically used $Cu/ZnO/Al_2O_3$ system. The homogeneous analog of this process—methanol synthesis over copper-based catalysts—has not been described up to now. Indeed, our attempts with simple copper complexes in solution did not result in the formation of methanol from synthesis gas. However, copper nanoparticles synthesized by reduction of copper acetylacetonate with trialkylaluminum were found to be highly active in this reaction. This shows that copper can have a very high intrinsic activity for methanol synthesis, and opens the door to mechanistic studies of the process with techniques known from homogeneous catalysis.

In the present study colloidal copper nanoparticles were obtained by reduction of copper acetylacetonate in THF with a triorganoaluminum reagent.[9] The organoaluminum compounds also stabilizes the colloid by forming an organometallic protecting shell around the nanoparticles.[10] The resulting copper nanoparticle solutions were deep-red and stable for months in the absence of air. The copper particle size can be tuned in the 3–5 nm range, with a narrow size distribution, by varying the alkyl groups of the aluminum reagent. Figure 1 a shows a TEM image of roughly spherical, isolated copper nanoparticles with sizes of (4.5 ± 1.5) nm. The nano-

particles are protected against aggregation by a layer of condensed triorganoaluminum molecules. High-resolution TEM images (Figure 1b) revealed that the nanoparticles are crystalline, and upon closer inspection some of the particles were found to consist of one single-crystal domain, while others seemed to be composed of several domains. Lattice fringes with a lattice spacing of about 2.17 Å, which corresponds to the Cu (111) plane, can be resolved in the HRTEM images of Cu nanocrystals (Figure 1b).

The Cu nanoparticles were also subjected to a Cu K-edge EXAFS analysis to obtain complementary insight into the structure of the Cu nanoparticles in solution, especially the oxidation state and the Cu–Cu distance. Figure 2 displays the extracted EXAFS functions at the Cu K-edge and the corresponding radial distribution functions of trioctylaluminum-stabilized copper colloids compared with that of copper foil.

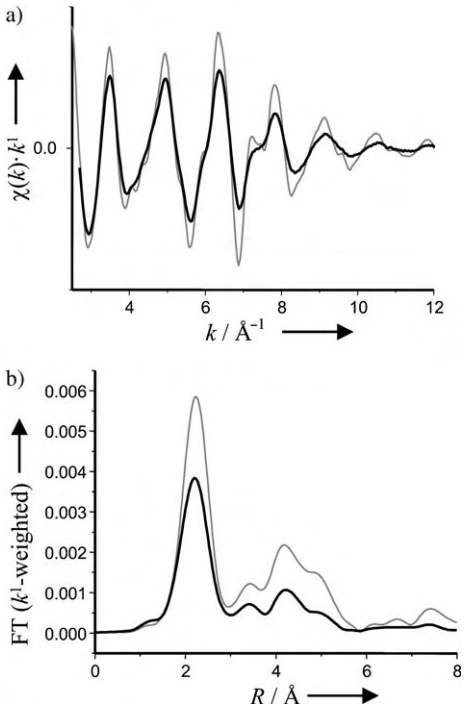

Figure 2. EXAFS function at the Cu K-edge in terms of a) the k^1-weighted $\chi(k)$-function and b) the corresponding radial distribution functions (Fourier-transformed k^1-weighted EXAFS spectra, not corrected for the phase shift) of trioctylaluminum-stabilized copper colloids (black line) in comparison to copper foil as reference (gray line).

The EXAFS experiment confirmed the zero-valent state of copper in the colloids. In the $\chi(k)$-extracted EXAFS functions the same frequency was observed for Cu foil, as reference, and the Cu colloids. The relatively lower amplitude of the function representing the Cu colloids is due to the small size of the Cu nanoparticles (Figure 2a). The Fourier-transformed EXAFS spectra show mainly the first Cu–Cu shell (Figure 2b). Fitting of the EXAFS spectra resulted in a Cu–Cu distance of 2.53 Å, compared to 2.55 Å in bulk copper, which is shorter because of the small size of the Cu nanoparticles.[11,12] This is also supported by the fact that the next nearest neighbors ($R > 4$ Å) give a smaller contribution in the Fourier-transformed EXAFS spectrum. No oxygen shells were detected. The coordination number is significantly lower than in bulk copper (10.9 for trioctylaluminum-stabilized copper colloids and 12 for copper foil) and corresponds to a particle size of about 3 nm.

Freshly synthesized copper colloids dissolved in THF were tested for methanol formation in a laboratory-made, high-pressure, stainless-steel autoclave in a quasi-homogeneous phase. Quantitative online analysis of the reaction mixture was performed with a gas chromatograph coupled directly to the high-pressure autoclave. The ratio of gases in the reaction gas mixture was adjusted to correspond to the typical gas-phase composition ($H_2/CO/CO_2 = 74:20:6$), although the different solubility of the reaction gases in THF resulted in a gas-phase composition with a different molar ratio ($H_2/CO/CO_2 = 86:10:4$). In a typical procedure, the high-pressure autoclave was charged with copper colloid solution (40 mL, 9.8 mM Cu) followed by sequential pressurization with synthesis gas (H_2/CO) and CO_2 at room temperature. The reaction mixture was heated with a ramp of 0.5 K min^{-1} to the desired reaction temperature. Surprisingly, methanol formation started already at 130 °C. The results of the methanol formation under these reaction conditions at temperatures with trioctylaluminum-stabilized copper colloids as catalyst are summarized in Figure 3.

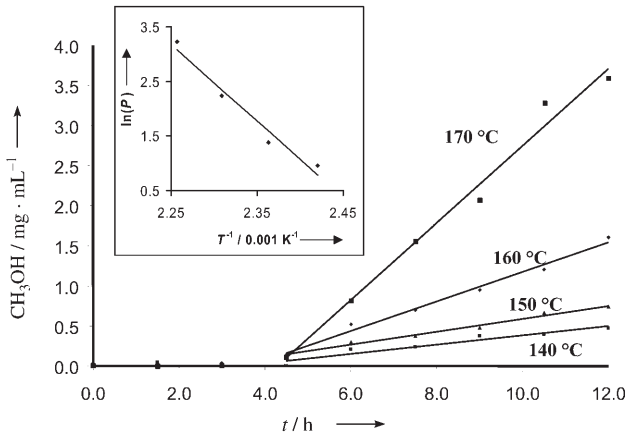

Figure 3. Formation of methanol at temperatures between 140 and 170 °C. Inset: Arrhenius plot for the determination of the apparent activation energy.

The productivity of the methanol formation ($mol_{methanol}/(kg_{Cu}\,h)$) was obtained from the slope of the linear regression of these data points (the first three data points show the methanol formation during the heating period and were not considered in the linear regression). Productivities, P, as high as 25.2 $mol_{methanol}/(kg_{Cu}\,h)$ were observed at elevated reaction-gas pressure and temperature. The results of the temperature-dependent catalytic experiments over trioctylaluminum-stabilized copper colloids are summarized in Table 1 and show an increase in productivity with increasing reaction temperature. From these, turnover

Table 1: Catalytic performance of trioctylaluminum-stabilized copper colloids at different temperatures.

T [°C]	P [$mol_{methanol}/(kg_{Cu}\,h)$]	TOF [$10^{-4}\ s^{-1}$]
140.0	2.6	3.2
150.0	4.0	4.9
160.0	9.3	11.3
170.0	25.2	30.7

frequencies (TOF) were calculated assuming spherical Cu particles with a diameter of 5 nm and approximately 800 Cu surface atoms per particle. From the temperature-dependent experiments an apparent activation energy of 116 $kJ\,mol^{-1}$ was calculated from the slope of an Arrhenius plot (see inset in Figure 3).

An isotope-labeling experiment with deuterium instead of hydrogen was performed to confirm methanol formation from the reaction gases and to gain further information on the catalytic process. At 150 °C and a gas-phase composition of $D_2/CO/CO_2 = 86:9:5$ at an initial pressure of 11.2 MPa a productivity of 6.8 $mol_{methanol}/(kg_{Cu}\,h)$ was determined. GC-MS analysis revealed the formation of deuterated methanol (CD_3OH; -OD to -OH exchange occured during the separation process) and perdeuterated methyl formate. Methyl formate is often observed as a by-product in the heterogeneously catalyzed synthesis of methanol. It has to be noted, though, that after an initial increase the concentration of methyl formate remained constant throughout the entire run in all experiments. This indicates that methyl formate reaches a steady-state concentration and may therefore not be a by-product but rather an intermediate. To elucidate the role of the methyl formate, the following experiments were conducted: 1) catalysis was performed with synthesis gas only, excluding CO_2. In this experiment, only negligible formation of methanol was observed ($P = 0.4$ $mol_{methanol}/(kg_{Cu}\,h)$); 2) the reaction was carried out with H_2 and CO_2 only, which gave initial methanol formation with the production dropping to zero after 10 h. The initial productivity was determined to be 1.7 $mol_{methanol}/(kg_{Cu}\,h)$ at 140 °C; 3) the reaction was performed with synthesis gas and a trace amount of methyl formate (50 μL in 40 mL of Cu colloid solution), which gave fast initial formation of methanol ($P = 4.2$ $mol_{methanol}/(kg_{Cu}\,h)$). The concentration of methyl formate reaches a steady state due to hydrogenolysis of methyl formate and simultaneous conversion of synthesis gas into methanol via methyl formate. It should be noted that the stability of the Cu colloids in experiment 3 was greater than in experiments where CO_2 was present in the gas phase. Productivity differences were within a margin of error of ± 1.6 $mol_{methanol}/(kg_{Cu}\,h)$.

These experiments with our model Cu catalyst suggest that the reduction of CO_2 to methyl formate is the initial step for methanol formation. However, more detailed studies are necessary to distinguish between different mechanistic pathways.

To exclude the remote possibility that methanol is formed from the acetylacetonate ligands of the copper precursor some of the experiments were repeated with copper colloids synthesized from copper bis(hexafluoroacetylacetonate) by reduction with trioctylaluminum. The resulting Cu colloids were less stable than those synthesized from the non-fluorinated Cu precursor, but were also active in methanol production, although with a reduced productivity $P =$ 2.0 $mol_{methanol}/(kg_{Cu}\,h)$ at 150 °C. No fluorinated by-products or fragments beside hexafluoroacetylacetonate were detected, which, together with the results of the experiments with deuterium as a synthesis gas component, proves that methanol is indeed formed from the synthesis gas.

In an effort to compare these data with the results for a commercially available methanol synthesis catalyst (ICI Katalco 51-8, powder, < 125 μm, same copper amount as in colloidal solution), this catalyst was reduced under H_2 at 250 °C, following the prescribed protocol, and suspended in THF solution. Catalytic testing was performed in a stainless-steel reactor in batch mode at 150 °C with the same reaction conditions as described above. A methanol productivity of 5.5 $mol_{methanol}/(kg_{Cu}\,h)$ was determined after a reaction time of 20 h. This is higher than with the Cu colloids described here. However, it should be kept in mind that the Cu colloids do not contain any Zn species, which are thought to improve the catalytic activity.[2b] Studies of the catalytic activity of commercial catalysts cannot be compared directly to the value measured here for the $Cu/ZnO/Al_2O_3$ system (ICI Katalco 51-8) since these investigations are typically performed at appreciably lower pressures at different temperatures and in the gas phase.

Our study shows that copper nanoparticles are remarkably active catalysts in the quasi-homogeneous phase for methanol synthesis from synthesis gas without any solid support. Similar results have been obtained in independent studies on colloidal Cu/ZnO particles by Fischer.[13] Our results show, in particular, that the ZnO component of the technical catalyst is not absolutely necessary to induce high activity for methanol synthesis, since the colloids without a Zn compound display similar activities as the commercial catalyst, which is in agreement with surface science studies on polycrystalline or single-crystal copper surfaces.[14–16]

Experimental Section

All preparations were carried out in anhydrous THF as solvent under an argon atmosphere.

Organoaluminum-stabilized Cu colloids were synthesized by the dropwise addition of Al(*n*-octyl)$_3$ (7.3 mL, 16.5 mmol) or Al(*n*-butyl)$_3$ (6.7 mL, 27.5 mmol) in THF (30 mL) to a solution of [Cu(acac)$_2$] (1.45 g, 5.5 mmol) in THF (400 mL) at room temperature with mechanical stirring. After 2–3 h the deep-red solution was filtered through a glass frit and stored under argon.

To determine the effective copper concentration an aliquot of the copper colloid solution was dissolved in hydrochloric acid and titrated with ethylenediaminetetraacetic acid solution (0.1M) using murexide as indicator at pH 8.0.

Safety warning: Experiments using large amounts of compressed gases, especially CO, are potentially hazardous and must only be carried out with the appropriate equipment and safety precautions.

The catalytic experiments were carried out in a laboratory-built, stainless-steel, high-pressure autoclave connected to a microvolume high-pressure valve system (0.2 μL) and an online GC analysis setup equipped with a fused-silica column coated with poly(dimethylsiloxane) SE30 (ID 250 μm, film thickness 500 nm). Typically, the Cu colloid solution (40 mL) was placed under argon in the 225-mL,

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

window-equipped autoclave together with *n*-heptane (50 μL) as internal standard. A preformed H_2/CO gas mixture (molar ratio 9:1) was prepared in a 5-L autoclave at 25.0 MPa and used throughout the experiments. The reactor was pressurized to the desired starting pressure (10.0–14.0 MPa) whilst stirring vigorously and CO_2 gas (0.6 MPa) was added. The pressurized system was heated to the reaction temperature with a ramp of 0.5 K min^{-1} (pressure at reaction temperature was 17.5–21.5 MPa). Samples were automatically analyzed every 90 min. After the reaction, the reactor was vented to ambient pressure and the collected samples were analyzed by GC, GC-MS, and TEM.

XAS data were collected at the European Synchrotron Radiation Facility (ESRF, Grenoble, France, beamlines SNBL and DUBBLE) using a specially designed cell for liquid samples. The XAS data were obtained in transmission geometry using a Si(111) channel-cut monochromator. For XAS measurements at the Cu K-edge (8.980 keV) the incident and transmitted X-rays were recorded with ionization chambers. Three ionization chambers, located before and after the spectroscopic cell as well as after a Cu foil for energy calibration, were used to measure the incident and output X-ray intensities. The colloidal solution, prepared as above, was introduced into the liquid cell under argon. Kapton windows allowed transmission of the X-rays, and due to appropriate sealing the cell could be dried and evacuated before filling with exclusion of air (for details see ref. [17]). The EXAFS spectra were extracted after background correction, normalization, and energy correction with the WINAXS 3.1 software.[18] Fourier transformation was applied in the region 3 to 12.5 $Å^{-1}$ (the distance scale in the Fourier-transformed EXAFS spectra was not phase-shift corrected) and data fitting was performed in R-space using theoretical phase and amplitude functions calculated with the FEFF 6.0 code.[19]

TEM studies were performed with a Hitachi 7500 and Hitachi HF2000 microscope. Samples were prepared by placing a drop of the dispersed colloidal solution onto a carbon-coated Ni grid. The samples were prepared in a glove box to prevent exposure to air.

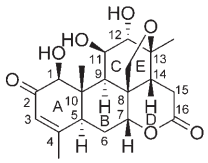
Quassinoids, a group of heavily oxygenated terpenoid bitter compounds isolated from the *Simaroubaceae* plant family, display a wide range of biological activities[1] and have attracted interest with respect to their synthesis during the past decades.[2] (−)-Samaderine Y (**1**), a pentacyclic quassinoid isolated from *Quassia indica*, was shown to exhibit in



(−)-samaderine Y (**1**)

vitro cytotoxicity ($IC_{50} = 0.10\ \mu g\,mL^{-1}$) against KB cells[3] and contains stereogenic centers common to many pentacyclic quassinoids as well as structural requirements and functionalities that are essential for cytotoxicity and solid tumor selectivity.[1] Herein, we report the first short, efficient, and enantiospecific total synthesis of (−)-samaderine Y (**1**) from (*S*)-(+)-carvone (**2**).

On the basis of our previous synthetic endeavors toward pentacyclic quassinoids, we reasoned that the hydroxy group at C11 in ring C of **1** should be secured before the construction of the pentacyclic skeleton.[4] The known enone **3**, which is readily available from (*S*)-(+)-carvone (**2**) in two steps that involve an aldol reaction with formaldehyde and acetonation in an overall yield of 75%,[4] was considered a good starting material for our synthesis (Scheme 1). After extensive experimentation, enone **3** was oxidized regioselectively with CrO_3 and 3,5-dimethylpyrazole[5] at the allylic position at C11 (quassinoid numbering scheme) to give ene-dione **4**. Regio- and stereoselective hydride reduction of the less congested keto group in **4** under Luche conditions[6] from the less hindered α face provided a β-alcohol, which was silylated to give silyl ether **5** in good overall yield. Alkaline hydroperoxide epoxidation of enone **5** at the less hindered α face afforded the α-epoxide, which was subjected to chelation-controlled hydride reduction of the remaining keto group to yield epoxy alcohol **6**. Acid-catalyzed shift of the acetonide diol protecting group accompanied by epoxide-ring opening with an internal hydroxy function in a one-pot procedure furnished ether-bridged **7**. The structure of **7** was confirmed by an X-ray crystallographic study,[7] and the stereocenters in rings C and E were thereby established. Protection of the hydroxy group at C12 in **7** gave disilyl ether **8**. Acid hydrolysis of the acetonide in **8** followed by TPAP-catalyzed[8] oxidation of the resultant 1,3-diol gave rise to keto-aldehyde **9** in 78% overall yield from **7**.

Construction of the AB ring system involved the addition of a six-carbon-atom diene to aldehyde **9** to form the Diels–Alder precursor (Scheme 2). Addition of Grignard reagent **10**[4] to aldehyde **9** generated the 1,4-diene **11** as a single diastereomer (the 1,3-cycloadduct). The stereochemistry of the hydroxy group in **11** was confirmed at a later stage. Fortunately, subsequent [1,3]-sigmatropic rearrangement[9] of 1,4-diene **11** furnished the desired 1,3-diene **12** also as a single diastereomer, in which the alcohol group at C7 was then protected as an acetate to give **13**. The AB ring was constructed by an intramolecular Diels–Alder reaction. Heating triene **13** in toluene at 180 °C afforded *trans*- and *cis*-fused tetracyclic keto-acetate **14** in 2:1 ratio based on ^{1}H NMR spectroscopic studies.[10] Variation of the reaction temperature (140–220 °C), reaction time (48–150 h), and solvent (benzene and benzonitrile) did not affect the ratio of *trans* and *cis* isomers. The two diastereomers could not be separated by column chromatography at this stage but were separated later. Our next aim was to invert the configuration at C7 to the desired α-acetate—the stereochemistry found in natural (−)-samaderine Y (**1**). Base-catalyzed hydrolysis of β-acetate **14** afforded alcohol **15**, which was esterified to give triflate **16**. Nucleophilic substitution of triflate **16** with nBu$_4$NOAc[11] provided α-acetate **17**. No *cis*-fused tetracyclic acetate was obtained. Instead, *cis*-fused tetracyclic 1,4-diene **18** was

isolated, attributable to hindrance imposed by ring A in which substitution could not proceed smoothly. At this stage, compounds **17** and **18** could be separated by column chromatography.

The construction of ring D was our next objective. Intramolecular aldol reaction of acetate **17** gave lactone **19**. The chirality at C14 was introduced in a three-step sequence. Dehydration of the alcohol in **19** afforded α,β-unsaturated lactone **20**. Conjugated reduction[12] of **20** gave rise to the corresponding lactol, which was subjected to acid-catalyzed acetalization with methanol in a one-pot procedure to yield methyl acetal **21** (Scheme 3).

Our remaining task was the functionalization of ring A, and tetracycle **17** was used for model studies (Scheme 4). Oxidation of **17** with classic chromium reagents[13] did not afford enone **28**. After several trials, allylic oxidation of tetracycle **17** did furnish enone **28**.[14] α-Keto acetoxylation[15] of enone **28** gave diacetate **29**, whose structure was confirmed by X-ray crystallography.[7] Following the successful functionalization of ring A of tetracycle **17**, the same procedure was applied to pentacycle **21**.

Allylic oxidation[14] of **21** provided enone **22**, which was subjected to α-keto acetoxylation[15] to give α-acetate **23** as anticipated. The stereogenic center at C1 in **23** had to be inverted before further manipulation could take place. Base hydrolysis of acetate **23** gave alcohol **24**. Acid- or base-catalyzed epimerization of **24** from OH1α to OH1β were unsuccessful. After extensive experimentation, we investigated an oxidation–reduction sequence. Dess–Martin oxidation[16] of alcohol **24** yielded an unstable diketone **25**. Regio- and stereoselective hydride reduction of the carbonyl at C1 in diketone **25** afforded β-alcohol **26**. Acid hydrolysis of acetal **26** gave rise to the corresponding lactol, which was oxidized with Ag_2CO_3 on celite[17] to yield lactone **27**.

Our last objective was the removal of the two silyl ethers, however, conventional desilylation conditions were unsuccessful. After extensive experimentation, the use of concentrated HCl with TFA as the solvent at room temperature led to the smooth removal of the silyl ether groups and gave the target molecule (−)-samaderine Y (**1**) in 61% yield. The physical and spectral data of synthetic **1** were in full accordance with those reported in the literature in all respects.[3]

In summary, (−)-samaderine Y (**1**) was constructed in 21 steps from (*S*)-(+)-carvone (**2**), with an average yield of 81% for each step. This relatively short synthesis opens feasible avenues for the preparation of other optically active pentacyclic quassinoids and analogues for biological evaluation. Research aimed in this direction is in progress.

High-Temperature Synthesis of the Surprisingly Stable C_1-$C_{70}(CF_3)_{10}$ Isomer with a *para*^{7}–*meta*–*para* Ribbon of Nine $C_6(CF_3)_2$ Edge-Sharing Hexagons**

Ivan E. Kareev, Igor V. Kuvychko, Alexey A. Popov, Sergey F. Lebedkin, Susie M. Miller, Oren P. Anderson, Steven H. Strauss, and Olga V. Boltalina**

With one exception, isolable $C_{70}X_{10}$ derivatives, which include $C_{70}H_{10}$,[1] $C_{70}Me_{10}$,[2] $C_{70}Ph_{10}$,[3] $C_{70}Ph_9(OH)$,[4] $C_{70}Ph_8(OH)_2$,[4] $C_{70}Cl_{10}$,[5] and $C_{70}Br_{10}$,[6] have the "equatorial-belt" C_s structure shown in Figure 1, with the ten substituents[7] positioned on a closed loop of ten edge-sharing hexagons, nine of which are *para*-C_6X_2 fragments and one of which is an *ortho*-C_6X_2 fragment (p^9o(loop)).[8–10] The exception is the recently described compound $C_{70}(t\text{BuOO})_{10}$, which has the C_2 structure also shown in Figure 1 with an all-*para* ribbon of nine edge-sharing $C_6(t\text{BuOO})_2$ hexagons (p^9), presumably because the *t*BuOO groups are too large to be on adjacent cage C atoms.[11]

We recently reported the synthesis of batches (more than 10 mg) of a single isomer of $C_{70}(CF_3)_{10}$ at 470 °C in 27 % overall yield based on converted C_{70}.[12] A combination of 1D- and 2D-COSY ^{19}F NMR spectroscopy showed that this derivative has C_1 symmetry and, by analogy with the structure of a spectroscopically similar C_1 isomer of $C_{60}(CF_3)_{10}$, most probably has its ten CF_3 groups arranged in the form of a ribbon of nine *meta*-$C_6(CF_3)_2$ and/or *para*-$C_6(CF_3)_2$ edge-sharing hexagons.[12] We now report an X-ray diffraction study of this high-yield, high-temperature C_1-$C_{70}(CF_3)_{10}$ isomer, which demonstrates that the ribbon of hexagons is the

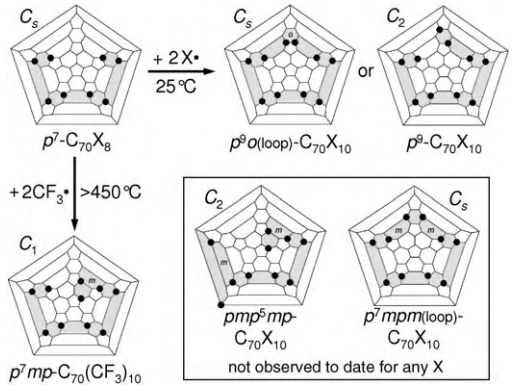

Figure 1. The transformation of C_s-p^7-$C_{70}X_8$, the structure of which has been proven by single-crystal X-ray diffraction (XRD) for X = Me, into either C_s-p^9o(loop)-$C_{70}X_{10}$ (proven by XRD for X = Br; proven by ^{13}C NMR for X = H, Cl, and Ph), C_2-p^9-$C_{70}X_{10}$ (proven by ^{13}C NMR for X = *t*BuOO), or C_1-p^7mp-$C_{70}(CF_3)_{10}$ (proven by XRD; this work). The inset shows the structures of two $C_{70}X_{10}$ isomers that have not yet been observed for any isolable compound. See text for references.

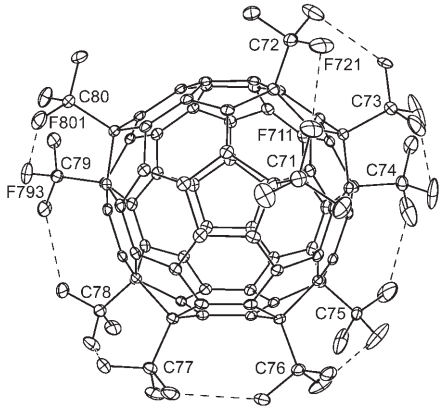

Figure 2. Drawing of C_1-$C_{70}(CF_3)_{10}$ looking down the former C_5 axis of the empty C_{70} cage (50% probability ellipsoids; only one of the two disordered CF_3 conformers is shown for each of the C73 and C74 CF_3 groups). Starting with the C80 CF_3 group, the CF_3 groups are arranged on a *para*^{7}–*meta*–*para* ribbon of $C_6(CF_3)_2$ edge-sharing hexagons. Atoms C71–C80 are connected to the fullerene cage at C25, C10, C1, C4, C19, C41, C60, C69, C66, and C49, respectively. The F801···F793 and F711···F721 distances are 2.570(2) and 2.744(2) Å, respectively.

unprecedented C_1-symmetric p^7mp ribbon shown in Figure 1. Like the hypothetical C_s-p^9o(loop)- and C_2-p^9-$C_{70}(CF_3)_{10}$ structures, the C_1-p^7mp-$C_{70}(CF_3)_{10}$ structure includes the C_s-p^7-$C_{70}X_8$ motif that has been observed for $C_{70}Me_8$[13] and $C_{70}Ph_8$.[3]

A thermal-ellipsoid plot, excluding the molecule of lattice-bound toluene, is shown in Figure 2. The poly(trifluoromethyl)fullerene itself is not disordered. The CF_3 groups containing C73 and C74 each exhibit a two-fold librational disorder; the other CF_3 groups, including the four CF_3 groups on the two *p*-$C_6(CF_3)_2$ hexagons at opposite ends of the ribbon, exhibit unexceptional F-atom thermal ellipsoids. Distances and angles within the ordered CF_3 groups are normal. The estimated standard deviations (esds) for individual C–C and C–F distances in this structure are all 0.003 Å (except for the C–F distances in the two disordered CF_3 groups), making this one of the most precisely determined C_{70}-containing structures reported to date (the ranges of esd's for C–C bonds within the cage of known structures include 0.002–0.004 Å for two Diels–Alder monoadducts,[14] 0.004–0.006 and 0.006–0.007 Å for $C_{70}(CH_3)_8$[13] and $C_{70}F_{38}$,[15] respectively, and 0.02–0.03 Å for $C_{70}Br_{10}$,[6] $C_{70}(IrCl(PPh_3)_2)$,[16] and $C_{70}(Ru_3(CO)_9)$[17]).

In addition to further supporting[12] our earlier conclusion[18] that fullerene$(CF_3)_n$ compounds in general have their CF_3 groups arranged on *m*- and *p*-$C_6(CF_3)_2$ hexagons (most of which form a continuous ribbon through edge sharing) and are not arranged on adjacent (i.e., *ortho*) cage C atoms as suggested by others,[19–21] the structure of C_1-$C_{70}(CF_3)_{10}$ has revealed several interesting and unanticipated aspects of $C_{70}X_n$ stereochemistry. In 1999, Clare and Kepert predicted the relative ΔH_f^0 values for a (necessarily) limited number of isomers of $C_{70}X_{10}$ at the AM1 level of theory, including the C_s-p^9o(loop) and C_2-p^9 isomers for X = H, F, Br, Ph, and *t*Bu.[10] They did not consider any $C_{70}X_{10}$ isomer with one or more *m*-C_6X_2 hexagons. Except for X = *t*Bu, the C_s-p^9o(loop) isomer was found to be more stable than the C_2-p^9 isomer for these substituents (Table 1; Schlegel diagrams for the five isomers are shown in Figure 1). However, all isolable C_s-p^9o(loop)-$C_{70}X_{10}$ compounds[1,3–6] and the one isolable C_2-p^9-$C_{70}X_{10}$ compound, $C_{70}(t\text{BuOO})_{10}$,[11] were prepared at 25 °C and may, at least in some cases, be a kinetically stable isomer and not the isomer with the lowest ΔH_f^0 value. On the other hand, C_1-$C_{70}(CF_3)_{10}$ was prepared at 470 °C,[12] a temperature that may be high enough for facile CF_3 migration to occur on the fullerene surface, a process that could conceivably result in the transformation of a less stable isomer to a more stable

Table 1: AM1 relative enthalpies ΔH_f^0 [kJ mol^{-1}] of formation of $C_{70}X_{10}$ isomers.[a]

X	C_s-p^9o(loop)	C_2-p^9	C_1-p^7mp	C_s-p^7mpm(loop)	C_2-pmp^5mp

[a] All values from this work except values in square brackets, which are from reference [10]. The lowest relative ΔH_f^0 value for each composition is underlined. [b] The principal or only isomer observed by X-ray crystallography or ^{13}C NMR spectroscopy. [c] The next most stable structure reported in reference [10], $p^4opopop$(loop)-$C_{70}H_{10}$, had a relative ΔH_f^0 value of 46.4 kJ mol^{-1}.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

one. The facile migration of F atoms on the surface of $C_{60}F_n$ isomers at 300–350 °C is well documented.[22]

The relative stabilities of various fullerene$(CF_3)_n$ isomers are determined by at least four factors: 1) the degree of delocalization/aromatization of the remaining fullerene π bonds; 2) the presence or absence of double bonds in pentagons; 3) steric repulsions between proximate substituents; and, in the case of nonlinear polyatomic substituents such as CF_3 groups, 4) the rotational conformation of each substituent with respect to its underlying cage C–C bonds. To examine the possibility that C_1-p^7mp-$C_{70}(CF_3)_{10}$ is truly more stable than the alternative C_s-p^9o(loop) and C_2-p^9 isomers, we also carried out calculations at the AM1 level of theory. The AM1-predicted relative ΔH_f^0 values for five isomers of $C_{70}(CF_3)_{10}$ and selected $C_{70}X_{10}$ derivatives (X = H, F, Cl, Br, Ph, *t*BuOO, and *t*Bu) are also listed in Table 1. (We also optimized the geometry of C_1-p^7mp-$C_{70}(CF_3)_{10}$ at the DFT level of theory for comparison with the X-ray structure.) Note that C_1-p^7mp-$C_{70}(CF_3)_{10}$ is predicted to be 36 kJ mol^{-1} more stable than the C_s-p^9o(loop) isomer and 22 kJ mol^{-1} more stable than the C_2-p^9 isomer, despite the fact that the C_s and C_2 isomers do not have any double bonds in pentagons and the C_1 isomer has several (the three shortest 6–5 junctions in C_1-p^7mp-$C_{70}(CF_3)_{10}$ are C8-C9 (1.347(3) Å X-ray, 1.357 Å DFT), C6-C7 (1.397(3) Å X-ray, 1.403 Å DFT), and C11-C29 (1.391(3) Å X-ray, 1.399 Å DFT)).

The difference in energy between the C_1 and C_2 isomers may be explained by the fact that two bulky CF_3 groups can be farther apart on a *p*-$C_6(CF_3)_2$ hexagon in the more highly curved polar region of the C_{70} cage than on a relatively flat equatorial hexagon. For example, the $F_3C\cdots CF_3$ distance is 4.412(3) Å for the end-of-ribbon polar *p*-$C_6(CF_3)_2$ hexagon (i.e., C71···C72) and 3.935(3) Å for the end-of-ribbon equatorial *p*-$C_6(CF_3)_2$ hexagon (C79···C80); the corresponding DFT distances are 4.502 and 3.992 Å, respectively. Consistent with this, the X-ray and DFT results reveal that every other CF_3 group on the equatorial part of the ribbon of *p*-$C_6(CF_3)_2$ edge-sharing hexagons in C_1-p^7mp-$C_{70}(CF_3)_{10}$ is partially or very-nearly eclipsed, in contrast to the [60]fullerene derivative C_1-pmp^3mpmp-$C_{60}(CF_3)_{10}$, in which all but one of the CF_3 groups along the ribbon are staggered or nearly so.[12] Note that both of the CF_3 groups on the end-of-ribbon polar hexagon in the structure of C_1-$C_{70}(CF_3)_{10}$ adopt the staggered conformation.

Surprisingly, the relative ΔH_f^0 results in Table 1 suggest that the isolable and well-characterized C_s-p^9o(loop) isomers of $C_{70}Br_{10}$ and $C_{70}Ph_{10}$ may only be kinetically stable with respect to their respective, thermodynamically more stable, C_1-p^7mp isomers. Even more surprisingly, it appears that C_2-p^9-C_{70}(*t*BuOO)$_{10}$[11] may be a kinetic isomer with respect to *both* C_1-p^7mp-C_{70}(*t*BuOO)$_{10}$ and C_s-p^9o(loop)-C_{70}(*t*BuOO)$_{10}$, and would ultimately rearrange to C_s-p^9o(loop)-C_{70}(*t*BuOO)$_{10}$ if sufficient activation energy were available (and if the compound did not decompose when that activation energy was added). It is also possible that C_2-p^9-$C_{70}(CF_3)_{10}$, like C_2-p^9-C_{70}(*t*BuOO)$_{10}$, is formed during the reaction of C_{70} and the X· precursor (CF_3I or *t*BuOOH) and rearranges to the high-yield product C_1-p^7mp-$C_{70}(CF_3)_{10}$ at 470 °C.[12] These and other issues relating to the mechanisms of multiple additions to C_{70}, including the kinetic vs. thermodynamic importance of the density of unpaired spins on the various C atoms of putative $C_{70}X_9$· radical intermediates,[9] will be addressed in future experimental work and with additional calculations at the DFT level.

It is significant that the stability of C_1-p^7mp-$C_{70}(CF_3)_{10}$ relative to the hypothetical isomers C_s-p^9o-$C_{70}(CF_3)_{10}$ and C_2-p^9-$C_{70}(CF_3)_{10}$ would not have been discovered were it not for the fact that poly(trifluoromethyl)fullerenes are thermally stable at 400–500 °C,[12,18] a property that is unparalleled in exohedral fullerene chemistry except for a few fluorofullerenes.[23] Therefore, we expect that the study of poly(perfluoroalkyl)fullerenes at high temperatures will reveal additional unanticipated aspects of kinetically vs. thermodynamically controlled addition reactions for C_{60} and higher fullerenes.

We have also calculated ΔH_f^0 values at the AM1 level for two loop/ribbon $C_{70}X_{10}$ isomers that have not been observed experimentally, the equatorial C_s-p^7mpm(loop) isomer and the "pole-to-pole" C_2-pmp^5mp isomer. The C_s-p^7mpm(loop) isomer is $\geq$140 kJ mol^{-1} less stable than the most stable isomer listed in Table 1 for X = H, F, Cl, Br, Ph, and CF_3. This extreme instability is because the formation of C_s-p^7mpm-(loop)-$C_{70}X_{10}$ from C_s-$C_{70}X_8$ requires the pyramidalization of two triple-hexagon junctions, the most planar C atoms in C_{70}.[24] In the structure of C_s-p^7-$C_{70}Me_8$,[13] for example, the triple-hexagon-junction C atoms are only 0.19 Å above the least-squares planes formed by their three nearest-neighbor cage C atoms. Other sp^2 C atoms involved in forming the four other isomers in Table 1 are displaced 0.26–0.31 Å from their respective nearest-neighbor planes (the largest values in this range are for the C atoms that comprise the polar pentagons). For comparison, out-of-plane displacements for the sp^3 cage C atoms are 0.58–0.59 Å in $C_{70}Me_8$ and are 0.583(3) and 0.561(3) for C25 and C49 in C_1-$C_{70}(CF_3)_{10}$. The high energy cost involved in adding X groups to the triple-hexagon junctions of C_{70} was previously noted.[10] The pole-to-pole isomers C_2-pmp^5mp-$C_{70}(CF_3)_{10}$ and -$C_{70}Ph_{10}$ are marginally more stable than the all-*para*, all-equatorial ribbon isomers C_2-p^9-C_{70}-$(CF_3)_{10}$ and -$C_{70}Ph_{10}$. They are not more stable than the C_1-p^7mp isomers, possibly because the formation of the pole-to-pole isomer would disrupt the polar corannulene-like π system of C_1-p^7mp-$C_{70}(CF_3)_{10}$.

The two *p*-$C_6(CF_3)_2$ hexagons at opposite ends of the ribbon of edge-sharing hexagons in C_1-$C_{70}(CF_3)_{10}$ give rise to two different F···F distances between nearest-neighbor CF_3 groups, 2.744(2) Å for the polar end-of-ribbon hexagon and 2.570(2) Å for the equatorial end-of-ribbon hexagon. These F···F distances are fully consistent with different through-space Fermi-contact $^7J_{FF}$ values reported earlier for the two terminal CF_3 groups in C_1-$C_{70}(CF_3)_{10}$, 10.3 and 15.9 Hz,[12] which can now be assigned to the polar and equatorial end-of-ribbon CF_3 groups, respectively. Note that one of the end-of-ribbon *p*-$C_6(CF_3)_2$ hexagons in C_1-$C_{60}(CF_3)_{10}$ exhibited an F···F distance of 2.640(3) Å and a $^7J_{FF}$ value of 12.8 Hz,[12] both intermediate values when compared with the above-listed values for C_1-$C_{70}(CF_3)_{10}$. The conclusions reached by others, that through-space J_{FF} coupling in fullerene$(CF_3)_n$ derivatives is unimportant[19,20] and that, in general, 1,4-addition of CF_3 groups to C_{70} "does not account for the large coupling

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

constant variations" (i.e., $J_{FF} = 9.1–17.7$ Hz),[19,21] are not supported by the data presented here.

In summary, the precise structure of C_1-$C_{70}(CF_3)_{10}$ and the new computational results have added significant new information to the small but growing fullerene$(CF_3)_n$ and $C_{70}X_{10}$ databases. More importantly, it has shown that low-temperature exohedral addition on C_{70} may frequently produce kinetic, not thermodynamic, products.

Experimental Section

The compound C_1-$C_{70}(CF_3)_{10}$ was prepared as previously described (no other isomers of this composition were obtained).[12] Crystals suitable for X-ray diffraction were grown by slow evaporation of a toluene solution. Diffraction data from a single crystal were recorded on a Bruker SMART CCD diffractometer employing MoK_α radiation (graphite monochromator). Unit cell parameters were obtained from a least-squares fit to the angular coordinates of all reflections. An empirical absorption correction was applied by using SADABS.[25] The structure was solved by using direct methods and was refined (on F^2, using all data) by a full-matrix, weighted least-squares process.[26] All C and F atoms were refined using anisotropic atomic displacement parameters. Two of the CF_3 groups (C73, C74) were treated as disordered by rotation about the C–C bond connecting them to the fullerene cage. The disorder model allowed for variation of the C-F distance within each disordered group while preserving the tetrahedral geometry about the C atom. Standard Bruker software was employed for structure solution, refinement, and graphics.[27]

The DFT-optimized structure of C_1-p^7mp-$C_{70}(CF_3)_{10}$ was determined with the PRIRODA package[28] using the GGA functional of Perdew, Burke, and Ernzerhof (PBE)[29] and the TZ2P {6,1,1,1,1,1/4,1,1/1,1} basis set. Semi-empirical AM1 calculations were performed with the PC version[30] of the GAMESS(US) package.[31]

Photofunctional Materials

DOI: 10.1002/anie.200502514

An Unexpected Photoelectronic Effect from $[Co(en)_3]_2(Zr_2F_{12})(SiF_6)\cdot 4H_2O$, a Compound Containing an H-Bonded Assembly of Discrete $[Co(en)_3]^{3+}$, $(Zr_2F_{12})^{4-}$, and $(SiF_6)^{2-}$ Ions**

Yu Du, Min Yang, Jihong Yu, Qinhe Pan, and Ruren Xu**

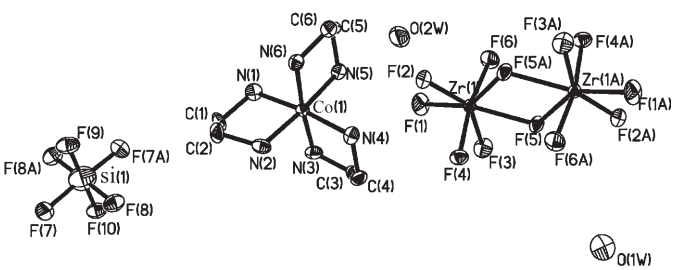

Figure 1. Thermal ellipsoid plot (50%) of $[Co(en)_3]_2(Zr_2F_{12})(SiF_6)\cdot 4H_2O$ (**1**).

Photofunctional materials are important because of their unique optical and electrical properties and are widely used in solar-energy conversion, semiconductor surface sensitization and modification, and nanoelectronics.[1–5] In recent decades, much effort has been directed toward the synthesis of pnictide- and chalcogenide-based inorganic semiconductor materials such as GaN,[6] SiC,[7] ZnO_2,[8] and SnO_2[9] because of their comparatively wide HOMO–LUMO gaps. There has been little investigation, however, of the photoelectronic properties of molecular solids.

Recently, by using an optically pure or a racemic mixture of a chiral cobalt complex such as $[Co(en)_3Cl_3]$ or $[Co(dien)_2Cl_3]$ as the template, we prepared a series of open-framework metal phosphates and oxides with chiral structure characters.[10,11] In order to explore new metal fluorides formed with a chiral cobalt complex as the template, we prepared a new cobalt complex-containing zirconium–silicon compound, namely $[Co(en)_3]_2(Zr_2F_{12})(SiF_6)\cdot 4H_2O$ (**1**), which contains an H-bonded network of discrete $[Co(en)_3]^{3+}$, $[Zr_2F_{12}]^{4-}$, and $[SiF_6]^{2-}$ ions. Unexpectedly, this new compound exhibits intriguing photoelectronic effects in the near-UV region.

A single-crystal X-ray diffraction analysis[12] indicated that **1** crystallizes in a monoclinic unit cell with space group *C*2/*c* (no. 15). Each asymmetric unit (Figure 1) contains one unique Co atom, one unique Zr atom, and one unique Si atom that is located on the two-fold axis. Two $[ZrF_7]^{3-}$ units share edges through difluoro bridges to form a $[Zr_2F_{12}]^{4-}$ pentagonal-bipyramid cluster with Zr–F bond lengths in the range of 1.988(4)–2.213(3) Å. The $[Co(en)_3]^{3+}$ cation and $[SiF_6]^{2-}$ anion display a disordered and a near regular octahedral geometry, respectively, with the Co–N and Si–F distances in the range of 1.965(6)–1.984(5) and 1.660(6)–1.742(6) Å, respectively. Each asymmetric unit also contains two H_2O molecules. As seen in Figure 2a, an extensive H-bonding network exists connecting the discrete $[Zr_2F_{12}]^{4-}$, $[Co(en)_3]^{3+}$, and $[SiF_6]^{2-}$ ions, in which the N atoms serve as H-bond donors and the F atoms as H-bond acceptors. As seen in Figure 2b, each $[Zr_2F_{12}]^{4-}$ unit interacts with six nearby complex cations through H-bonds. The N···F distances are in the range of 2.766(7)–3.106(7) Å, with angles in the range of 111.60–170.83°, both of which are typical values for H-bonding interactions between F and N atoms observed in a variety of metal fluorides.[13] The six complex cations are three pairs of enantiomers of the chiral $[Co(en)_3]^{3+}$ ion with *C*2 point symmetry; they are related by an inversion center.

The UV/Vis absorption spectrum of **1** shows three bands with maxima at approximately 237, 337, and 465 nm (Fig-

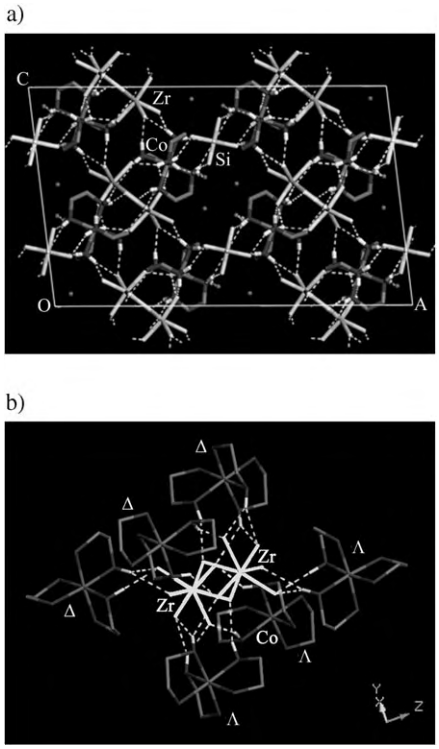

Figure 2. a) H-bonding network of discrete $[Co(en)_3]^{3+}$, $[Zr_2F_{12}]^{4-}$, and $[SiF_6]^{2-}$ ions viewed along the *b* axis. b) One $[Zr_2F_{12}]^{4-}$ unit interacts with six complex cations through H-bonds.

ure 3a). The two absorptions at 337 and 465 nm are d–d transitions characteristic of the $[Co(en)_3]^{3+}$ complex cation,[14] whereas that at about 237 nm, which is absent in $K_4Zr_2F_{12}$ but is commonly found in many zirconium-containing compounds,[15] is tentatively assigned to a ligand-to-metal charge-transfer (LMCT) from the fluoride to the zirconium center. As $K_4Zr_2F_{12}$ itself does not absorb at wavelengths longer than 200 nm, the absorption at about 237 nm in **1** suggests that the HOMO–LUMO gap of $[Zr_2F_{12}]^{4-}$ in **1** may be smaller than that in $K_4Zr_2F_{12}$.

Studies by surface photovoltage spectroscopy (SPS) revealed that compound **1** possesses unusual photoelectronic properties (Figure 3b). When illuminated in absence of an external electric field, **1** shows a signal for the surface photovoltage (SPV) at 337 nm that is coincidental with one of the UV/Vis adsorption transitions of the $[Co(en)_3]^{3+}$ ions (Figure 3a). In contrast, no photovoltage response is generated when either $[Co(en)_3Cl_3]$ or $K_4Zr_2F_{12}$ are illuminated by photons with wavelengths longer than 300 nm. It is supposed that the electrons of the $[Zr_2F_{12}]^{4-}$ ion in $K_4Zr_2F_{12}$ are unable to transfer from the HOMO to the LUMO energy levels upon illumination by light of 337 nm. In $[Co(en)_3Cl_3]$, even though the $[Co(en)_3]^{3+}$ ion can be excited by light of this wavelength, electron–hole pairs cannot be effectively separated because no perfect energy band is formed, and, as a result, no photovoltage signal is generated. Furthermore, the fact that the intensity of the SPV response increases with increasing positive electric-field strength is indicative of its *n*-type conduction character[8] (inset of Figure 3b).

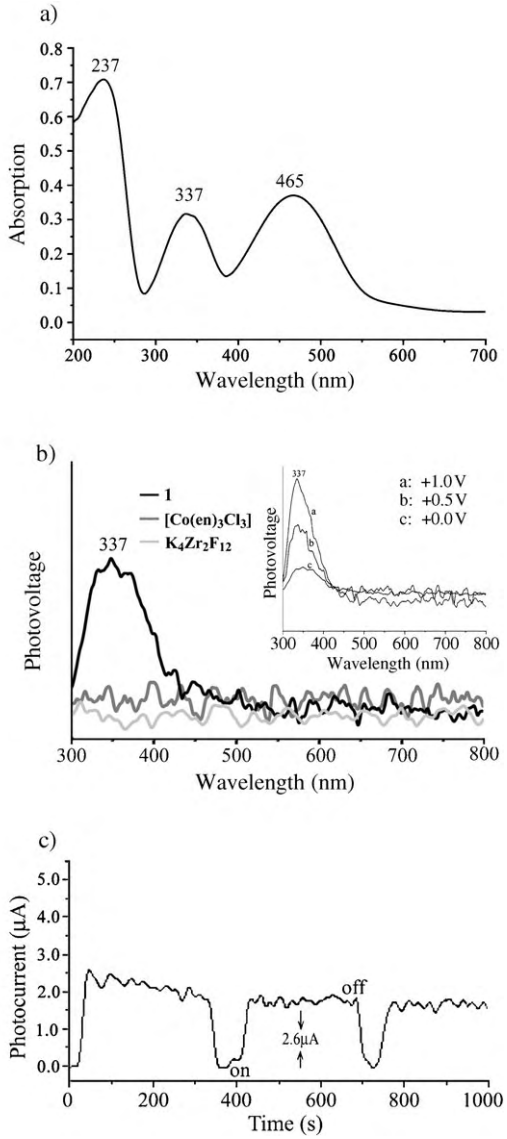

Figure 3. a) UV/Vis absorption spectrum of **1**. b) SPS of $[Co(en)_3Cl_3]$ (dark gray line), $K_4Zr_2F_{12}$ (light gray line), and **1** (black line). Inset: FISPS of compound **1** under positive field. c) Transient photocurrent response of compound **1** at 0.4 V versus SCE. (↑ and ↓ indicate when the light was turned on and off).

Figure 3c shows the transient photocurrent response of **1** recorded for several on–off cycles of illumination. The current reaches a steady-state value in approximately 300 s. The trace shows that an anodic photocurrent of about 2.6 μA is generated at a constant applied voltage of 0.4 V versus SCE, which is much higher than that of $(ZnO)_2(UO_2)_3(NA)_4(OAC)_2$ (0.2 μA) under the same measurement conditions.[16] In contrast to conventional oxide semiconductors,[17] the current density of compound **1** is very low. However, the lower current density, in combination with its lower electrical conductivity ($< 10^{-5}$ S cm^{-1}), suggests that compound **1** might contain a controlled carrier density[18] similar to that of $(ZnO)_2(UO_2)_3(NA)_4(OAC)_2$.

We believe that a cooperative behavior between discrete $[Co(en)_3]^{3+}$ and $[Zr_2F_{12}]^{4-}$ ions through interionic interactions might be responsible for this unexpected photoelectric phenomenon in **1**. As expected, we have also observed an interesting photoelectric phenomenon in another cobalt complex-containing zirconium fluoride compound, namely $[Co(chxn)_3](ZrF_6)Cl{\cdot}3.5\,H_2O$ (**2**; chxn = 1,2-diaminocyclohexane).[19] Compound **2** is built up from discrete $[Co(chxn)_3]^{3+}$ and $[ZrF_6]^{2-}$ ions (see Supporting Information). As with **1**, there are extensive H-bonds between the $[Co(chxn)_3]^{3+}$ and $[ZrF_6]^{2-}$ ions in **2**. Upon illumination in absence of an external electric field, **2** shows a signal for the surface photovoltage at 357 nm, which is also coincidental with one of the UV/Vis adsorption transitions of the $[Co(chxn)_3]^{3+}$ ions (see Supporting Information).

In summary, compounds **1** and **2** both exhibit unusual photoelectric properties. The fact that the signal of the surface photovoltage is coincident with one of the UV/Vis absorption transitions of the cobalt complex implies that a charge transfer from the excited cobalt complex cation to the zirconium fluoride anion may occur upon illumination. The successful synthesis of compounds **1** and **2** and the discovery of their unusual physical properties as a result of the cooperative behavior between their component species will open-up new vistas in the search for materials with useful photoelectric properties. Further investigation of the mechanism of this intriguing photoelectric effect is ongoing.

Experimental Section

In a typical hydrothermal synthesis of **1**, zirconium tetrachloride (0.233 g, 1.00 mmol) was dissolved in distilled water (10 mL) and

tris(ethylenediamine)cobalt(III) chloride (0.172 g, 0.50 mmol) and phosphoric acid (0.272 mL, 85 wt.%, 4 mmol) were added whilst stirring. Finally, hydrofluoric acid (HF, 0.5 mL, 40 wt.% aqueous solution, 10 mmol) and tetraethylorthosilicate (0.10 mL, 97 wt.% aqueous solution, 0.43 mmol) were added to the above reaction mixture. After stirring for 30 min, the final reaction mixture with a pH value of about 1.0 was transferred into a Teflon-lined, stainless-steel autoclave (20 mL) and heated at 130 °C for six days. The resulting orange, rod-like crystals were isolated by filtration, washed with deionized water, and dried in the air. The phase purity of **1** was checked by recording its X-ray powder diffraction pattern, which was consistent with that simulated on the basis of the single-crystal structure data. XRD studies indicated that compound **1** is thermally stable below 200 °C. Inductively coupled plasma (ICP) analysis indicated a Zr:Co:Si molar ratio of 1:1:0.5 for **1**.

[19] Compound **2** was obtained from a reaction mixture with a molar composition of $1\,ZrCl_4{:}3\,H_3PO_4{:}0.5\,Co(chxn)_3Cl_3{:}10\,HF{:}404\,H_2O$ at 110 °C for six days. The resulting orange-yellow, block-shaped crystals were isolated by filtration, washed with deionized water, and dried under ambient conditions.

Book and Website Reviews

For book reviews authors/editors, book titles, and reviewers are given, for website reviews subjects and reviewers.

Books

Autobiography/Biography

Stoltzenberg, D.	Fritz Haber: Chemist, Nobel Laureate, German, Jew	Friedrich, B.	3957
Hargittai, I.	Our Lives	Schroth, W.	5169
Büttner, J.	The Life and Work of Friedrich Wöhler (1800–1882)	Hopf, H.	5168

Encyclopedia/Handbook/Reference Book

Enghag, P.	Encyclopedia of the Elements	Fink, G.	3174
Blümich, B.	Essential NMR	Lützen, A.	6445
Hartmann, R. K., Bindereif, A., Schön, A., Westhof, E.	Handbook of RNA Biochemistry	Saenger, W.	5367

Industrial Chemistry

Lawrence, S. A.	Amines	North, M.	2053
Sundmacher, K., Kienle, A., Seidel-Morgenstern, A.	Integrated Chemical Processes	Cornils, B.	6807
Larsen, R. D.	Organometallics in Process Chemistry	Bröring, M.	360
Hawthorne, F.	The Merck Druggernaut	Kleemann, A.	4834

Monograph/Research Report in Analytical Chemistry

Kellner, R., Mermet, J.-M., Otto, M., Valcárel, M., Widmer, H. M.	Analytical Chemistry	Bettmer, J.	4286
Duer, M. J.	Introduction to Solid-State NMR Spectroscopy	Baldus, M.	2473
Noble, R. D., Terry, P. A.	Principles of Chemical Separations with Environmental Applications	Frimmel, F. H.	183
Kambhampati, D.	Protein Microarray Technology	Eppinger, J.	5770

Monograph/Research Report in Biochemistry/Bioorganic Chemistry

Breslow, R.	Artificial Enzymes	Meldal, M.	7829
Buchholz, K., Kasche, V., Bornscheuer, U. T.	Biocatalysts and Enzyme Technology	May, O.	5367
