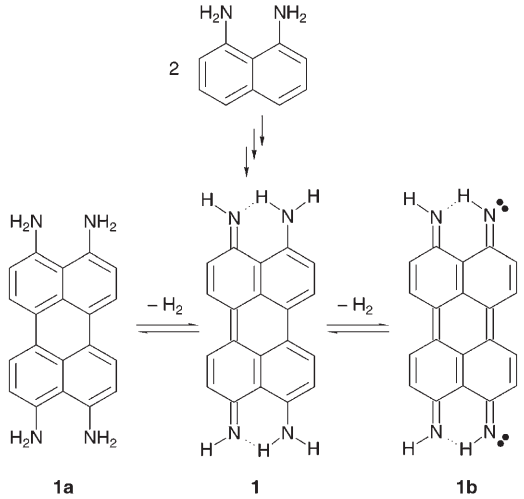
As the starting material for the surface studies, we chose a perylene derivative, 4,9-diaminoperylene-quinone-3,10-diimine (DPDI; **1**), which is readily obtained by oxidative coupling of two 1,8-diaminonaphthalene molecules[8] and displays a particularly rich redox chemistry.[9] The most stable form of this compound corresponds to the semiquinoidal structure displayed in Scheme 1, which on the one hand can



Scheme 1. The formation of DPDI (**1**) by oxidative coupling of two 1,8-diaminonaphthalene molecules, and its redox conversion into **1a** and **1b**.

be reversibly converted into the perylene **1a** by a two-electron reduction,[9] as previously shown for derivatives bearing bulky *N*-silyl groups, whereas a two-electron oxidation gives rise to the quinoidal redox state **1b**.[10] Because of this redox convertibility, **1** lends itself to chemical modification subsequent to its controlled deposition on metal surfaces and, thus, to significant changes in its intermolecular interactions.

Thin layers of **1** that range from submonolayer to monolayer (ML) coverage were prepared by thermal deposition onto a Cu(111) crystal and by subsequent annealing at 300 °C under ultra high vacuum (UHV) conditions (one monolayer of DPDI corresponds to the amount of molecules that is needed to cover the complete Cu surface and corresponds to 0.84 molecules nm^{-2}). The structures of the organic layers were characterized in UHV with room-temperature scanning tunneling microscopy (STM) and low-energy electron diffraction (LEED) before and after annealing. Before the annealing of submonolayer coverages of **1**, only a mobile phase and no ordered arrangement is found. The full monolayer assembles in an ordered aggregate with the monomers aligned in a rectangular unit cell of the size 0.92 nm × 1.3 nm,[11] an arrangement which is controlled by the molecular shape of **1**. The high mobility of **1** on the metal surface is unsurprising as there is no possibility of intermolecular hydrogen-bonding interactions in two dimensions, as the nitrogen functions are exclusively hydrogen-bond donors and there are no appropriate acceptor functionalities. As a result of the annealing process at 300 °C, the deposited molecules of **1** are chemically modified, as is reflected in the comparison of X-ray photoelectron spectroscopy (XPS) data before and after the thermolysis.[12] For surface coverages below 0.7 ML, the mobile monomers aggregate to give a well-ordered 2D honeycomb network (Figure 1 a, b). Based on the

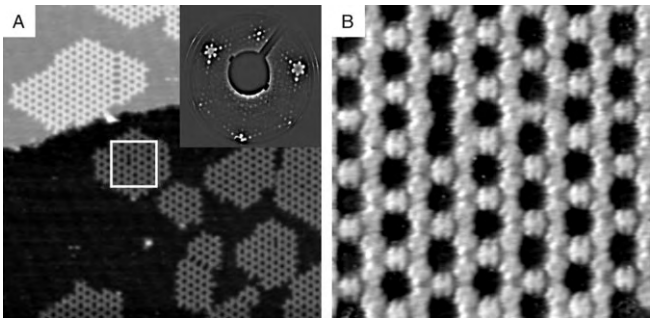


Figure 1. Self-assembly of 0.3 ML of DPDI on Cu(111) annealed at 300 °C. a) A large-scale STM image (100 nm × 100 nm, $I = 25$ pA, $U = -1.5$ V) of several DPDI islands that exhibit a honeycomb structure. Inset: LEED pattern that corresponds to this overlayer, as obtained at 52 eV primary energy representing a Cu(111)–p(10×10) DPDI lattice registry of the monomeric components. b) A high-resolution STM image (15 nm × 15 nm, $I = 25$ pA, $U = -2$ V) of the marked region, thus exhibiting the honeycomb network in detail and showing a vacancy defect.

STM data and the information obtained from the LEED pattern shown in the inset of Figure 1 a, a commensurate arrangement with regard to the Cu substrate of the DPDI monomers in a p(10×10) superlattice with a lattice constant of 2.55 nm is determined.

The assembly of these honeycomb networks can be readily explained by dehydrogenation of the DPDI monomers on the copper surface to provide the autocomplementary compound **1b**, in which the now-modified nitrogen functions may act as both hydrogen-bond acceptors and donors. The molecules, thus, link up through hydrogen-bonding interactions with each DPDI monomer binding to a total of four neighboring monomers to form the honeycomb network (Scheme 2). Hydrogen-bonding interactions between the nitrogen functions is consistent with the structural data from the STM and LEED experiments, from which a N···N distance between adjacent molecules of about 3.1 Å is derived.

The network itself exhibits an extraordinary stability, as is reflected by its inertness towards manipulation of individual monomers with the STM tip. Moreover, in LEED experiments performed while annealing the sample, the diffraction pattern of the overlayer persisted up to a temperature of 450 °C. Further increase in the temperature resulted in an irreversible destruction of the hexagonal perylene network. The considerable stability of this hexagonal network together with its commensurability with the Cu surface may be attributed to a combination of resonance-assisted hydrogen bonding[7,13] and a strong interaction with the Cu support. A similar case for a commensurate overlayer is reported for perylene tetracarboxdianhydride (PTCDA) adsorbed on a Ag(111) surface.[14]

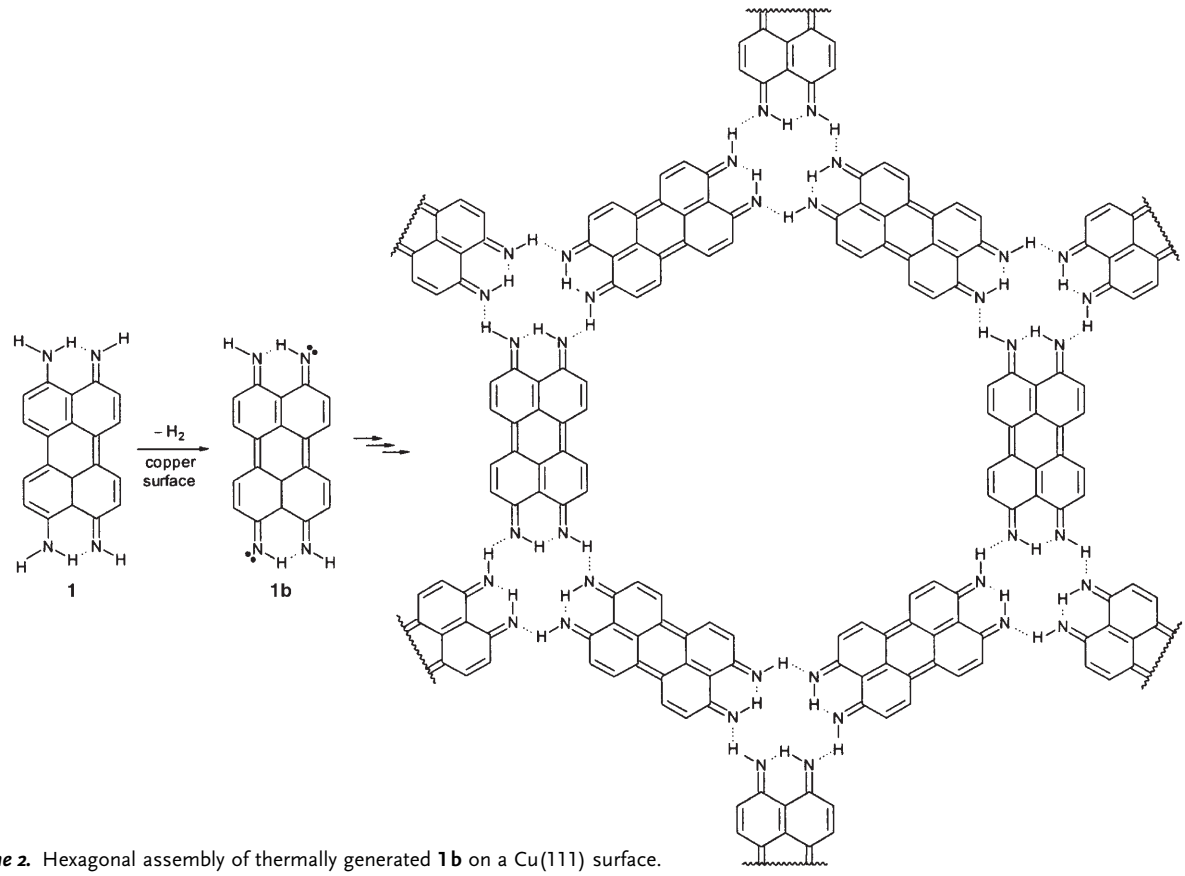

Scheme 2. Hexagonal assembly of thermally generated **1b** on a Cu(111) surface.

A key requirement for the formation of this highly ordered structure appears to be the free mobility of **1**, and subsequently **1b**, on the Cu(111) surface to attain the appropriate molecular arrangement and also the rather low molecular coverage on the metal support to accommodate the large hexagonal cavities in the 2D network. Thus, for geometrical reasons, the honeycomb structure corresponds to a maximum coverage of 0.7 ML. It was, therefore, of interest to assess if and how the polymer structure changed upon going to higher surface coverage.

Upon annealing a sample with a coverage of approximately 0.85 ML DPDI at 300 °C, trimeric structures in the form of rings are found (Figure 2

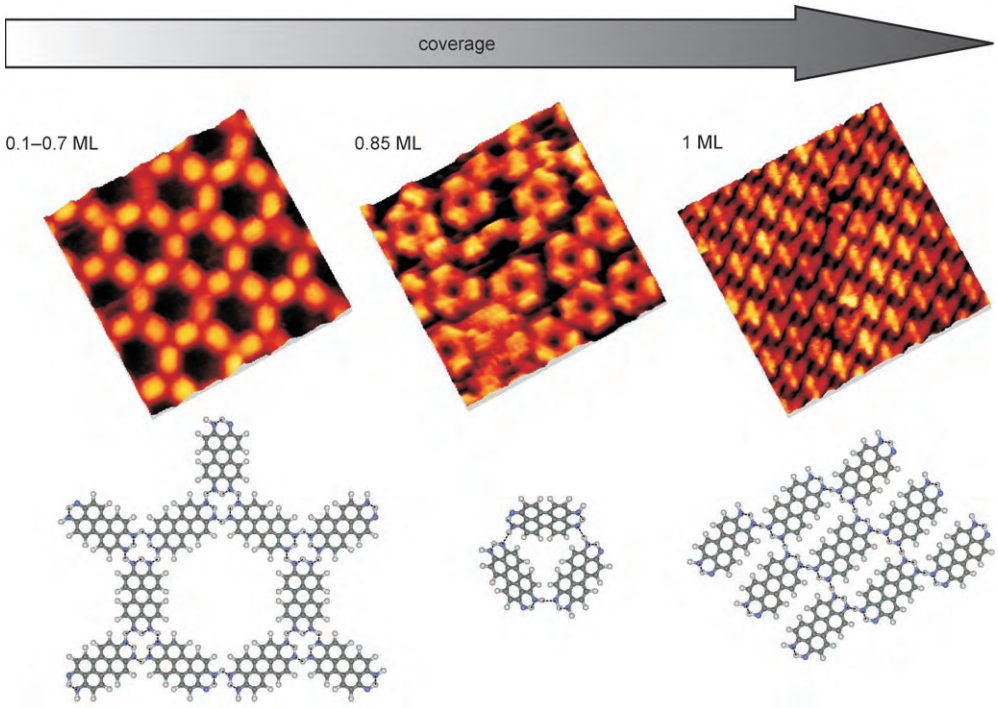

Figure 2. STM images (9 nm × 9 nm) and the corresponding chemical structures of the surface aggregates at variable coverage of **1**. All the polymeric islands were obtained by annealing the samples at 300 °C. For 0.1–0.7 ML of DPDI, an extended 2D honeycomb network is formed (left). Increasing the coverage to 0.85 ML yields a 0D trimeric structure (center), whereas at monolayer coverage a chain structure (right) is produced.

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

center), which are packed more densely on the surface than the honeycomb network discussed above. The formation of these trimers may be explained by the same dehydrogenation reaction as proposed for the honeycomb network that yields **1b**. This compound, activated for hydrogen-bond formation, then forms the observed cyclic hydrogen-bonded structure in a self-assembly process which is modified by a characteristic change of the diffusion length at the higher 2D molecular density. For the steric, repulsive interactions between the inwards-pointing hydrogen atoms of the perylene trimer, the overall structure is expected to deviate from a strictly planar arrangement and is expected to adopt an overall bowl-shaped form, a notion which is also supported by the STM images. Because of this steric interaction and because of the fact that each monomer is only hydrogen bonded to two neighboring monomers, a less robust structure of lower binding energy is expected in this case. This is evidenced by the observation of a dynamical equilibrium of "open" and "closed" structures (trimers, chains, and individual molecules) upon subsequent scanning of the same sample area at room temperature.[15] Furthermore, it was observed that only two preferred orientations of the trimers relative to the substrate exist, thus indicating that the structure of the Cu surface potentially contributes to the stabilization of the cyclic trimer.

For the final step of probing the concentration dependence of the polymerization pattern, we prepared full monolayers of DPDI on a Cu(111) surface. In contrast to the mobile submonolayer phases of the monomer, there is little room for molecular reorientation upon annealing of such a densely packed and highly ordered molecular array. The result of the thermal annealing of a DPDI monolayer on Cu(111) at 300 °C is displayed in Figure 2 on the right. STM analysis reveals a zigzag chain structure of the polymer with the chains packing one alongside the other. These chains derive from the regular monolayer structure of the monomer by an apparently concerted "shearing" movement, which is accompanied by shortening of the distance between adjacent molecular rows along the long molecular axis by approximately 1 Å. The same dehydrogenation reaction as for submonolayer coverage is thought to take place, thus resulting in each monomer being linked through hydrogen bonds to four adjacent monomers. The Moiré pattern in the STM images, as well as the LEED patterns, indicate that the molecular arrangement obtained in this annealing process is not commensurate to the underlying lattice of the Cu substrate.

Direct evidence for the importance of the conversion of **1** into **1b**, and thus for the formation of a monomer capable of the formation of 2D hydrogen-bonded networks, was obtained by deposition of the equivalent of approximately 0.15 ML of additional DPDI onto the previously prepared honeycomb network (Figure 3). These additional monomers in their initial, non-dehydrogenated form are not assembled into the existing honeycomb network at room temperature.[17] Instead, the additional monomer molecules are mobile on the metal surface, as found for submonolayer coverage prior to thermal treatment, and additional DPDI molecules are trapped in the hexagonal cavities of the honeycomb network, in which they are still mobile as can be deduced from their blurred appearance in the STM images. Extension of the honeycomb structure only occurs after a second annealing process. These findings indicate that the highly robust honeycomb network can be used as a template to arrange or trap molecules that are even larger than the DPDI monomers.

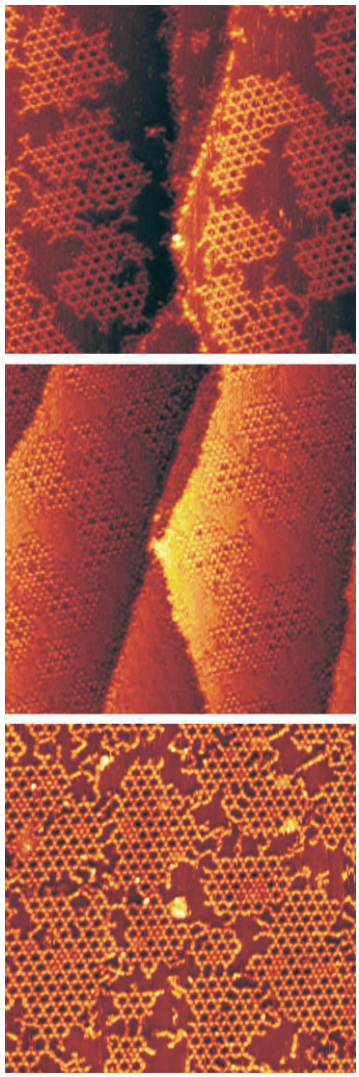

Figure 3. STM images (70 nm × 70 nm) of the same sample at different phases of sample preparation. First, the honeycomb network was prepared (top) and subsequently 0.15 ML DPDI were deposited (center). The additional DPDI molecules form a mobile phase on the bare Cu substrate and some are trapped in the pores of the honeycomb network. Annealing this sample at 300 °C converts the mobile phase into a solid phase because of dehydrogenation of DPDI, thus resulting in an enlargement of the honeycomb network (bottom). Individual molecules remain trapped within the network. However, the characteristic confined mobility disappears after annealing.

In conclusion, the deposition of 4,9-diaminoperylenequinone-3,10-diimine (**1**) on a metal surface provides highly mobile submonolayer phases because of the impossibility of significant intermolecular interactions in two dimensions. However, thermally activated dehydrogenation leads to **1b**, which is autocomplementary and serves both as an hydrogen-bond donor and acceptor. This behavior leads to well-defined polymeric structures that can be controlled by the typical diffusion length between the activation of the precursor and

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

its "polymerization", which in turn is controlled through different amounts of initial monomer coverage. This reactive self-assembly represents a "surface dilution principle" akin to the dilution principle in chemical synthesis.[18] The connectivity and the resulting dimensionality of the aggregates may be varied between 0D for the trimers and 2D for the hexagonal network. Once formed, these molecular surface assemblies are highly robust and, therefore, suitable for the construction of hierarchic structures by self-organization of subsequently deposited material at lower temperatures; such investigations are currently under way.

Experimental Section

The experiments were conducted in a UHV system composed of different chambers for sample preparation and characterization (base pressure: 10^{-10} mbar). The Cu(111) substrate was prepared by subsequent cycles of sputtering with Ar^+ ions and annealing at 870 K. Thermal evaporation from a homemade crucible at a rate of about 0.5 ML min^{-1} was used to prepare thin films of DPDI on the Cu(111) surface while the substrate was kept at RT. Annealing of the DPDI films was performed by radiative heating. The investigation of the samples was carried out with a homebuilt STM operated at room temperature, by LEED and by XPS.

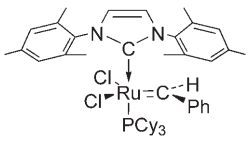
Efficient Mono- and Bifunctionalization of Polyolefin Dendrimers by Olefin Metathesis**

*Cátia Ornelas, Denise Méry, Jean-Claude Blais, Eric Cloutet, Jaime Ruiz Aranzaes, and Didier Astruc**

Olefin metathesis has recently transformed the way molecular chemists think about synthetic strategies.[1] Remarkable examples can be found in transition-metal architectures, such as ring-closing metathesis (RCM) of olefin-terminated ligands.[2,3] van Koten and Newkome have used stars for the nanofabrication of giant ring structures by using RCM,[4] and Zimmerman and co-workers have shown that RCM successfully allows molecular imprinting inside dendrimers and can be applied to the fabrication of nanotubes.[5] Indeed, RCM and ring-opening-metathesis polymerization (ROMP) are probably the most popular facets of olefin metathesis because of their considerable impact on the synthesis of biologically important cyclic compounds and polymers, respectively.[1] At first sight, cross metathesis (CM) is marred by the thermodynamic equilibrium that produces a mixture of compounds, but Blechert and co-workers showed that the excess of one olefin together with the Schrock Mo catalyst[1b] favors the formation of the cross product, whereas steric factors favor *E* stereoselectivity.[6] Grubbs and co-workers have shown that when a terminal olefin is metathesized with the second-generation Ru catalyst **A** (Cy = cyclohexyl) in the presence of another olefin bearing a strongly electron-withdrawing substituent, the stereoselectivity leads to high yields of the *E*-functionalized cross olefin.[7]



A

Despite the usefulness of this property in organic synthesis,[7] it has not been used in dendrimer chemistry.[8] Dendrimer functionalization is considerably more challenging than that of mono-olefin molecules, because it requires a clean and quantitative reaction to avoid the formation of mixtures among the branch termini.[8]

The $CpFe^+$-induced (Cp = cyclopentadienyl) activation of polymethylbenzenes under ambient or near-ambient conditions is known to efficiently produce polyolefin star and dendritic cores by reaction of such arene complexes with excess KOH and alkenyl halides in THF.[9] The reaction was extended to aryl ether complexes to yield to the phenol dendron p-$HOC_6H_4C(allyl)_3$ (**1**),[10a] which served as a brick for further dendrimer construction; for example, hydrosilylation of the polyolefin core with $HSiMe_2CH_2Cl$ followed by reaction of **1** yielded dendrimers with 3^n allyl branches ($n = 2$–10) starting from mesitylene.[10b] We now report that these star- and dendritic-shaped polyolefin dendrimers can be cleanly and stereospecifically mono- or bifunctionalized by CM or a combination of RCM + CM, respectively, using catalyst **A**. A quick, overall synthesis of water-soluble dendrimers from simple polymethylbenzenes, such as mesitylene and hexamethylbenzene, is therefore provided.

The reaction of $[CpFe(C_6Me_6)][PF_6]$ (**2**) with KOH + allyl bromide or 1-undecenyl iodide in THF, followed by visible-light irradiation in MeCN gives nearly quantitative yields of the known hexaolefin stars **4**[11a] and **5**,[11b] which give high yields of the new hexafunctionalized *trans* olefins **7** and **8** as the only reaction products upon reaction with $CH_2{=}CHCO_2R$ (R = H or Me) in the presence of 5 mol% of **A** (Scheme 1). The iron complex $[CpFe\{C_6(CH_2CH_2CH{=}CH_2)_6\}][PF_6]$ (**3**), the precursor of **4**, also gives hexafunctionalized iron complex **6a** upon metathesis with $CH_2{=}CHCO_2H$ using **A**, although partial decomplexation leads to reduced yields of the complexes.

In the case of mesitylene, complexation by the $CpFe^+$ species, reaction with KOH and allyl bromide in THF under ambient conditions, and decomplexation gives the known dendritic core $C_6H_3[C(CH_2CH{=}CH_2)_3]_3$ (**10**; generation 0 (G0)),[11c] whose metathetic reaction with $CH_2{=}CHCO_2R$ using **A** gives the new hetero-bifunctional compound **11**. This RCM + CM series of reactions inhibits the formation of the known capsule **12** formed from **10** in the absence of $CH_2{=}CHCO_2R$ with the same catalyst **A** (Scheme 2).[11d] As the tris-homofunctionalization of the triallylmethyl tripod is much less favored than RCM as an approach to form the cyclopentenyl group, we lengthened the dendritic tethers to prevent RCM. This lengthening of the tether was achieved by hydrosilylation of **10** with $HSiMe_2CH_2Cl$ followed by reaction with p-$OHC_6H_4O(CH_2)_9CH{=}CH_2$, thus giving the nonaolefin **13**. Contrary to **10**, the metathesis reaction of **13** with $CH_2{=}CHCO_2R$ only gives the CM product **14** (only *trans* isomers) which results from terminal-olefin functionalization (Scheme 2). Likewise, the tethers of the known 27- and 81-allyl dendrimers **15** and **18** (G1 and G2), which result from sequential hydrosilylation of **10** with $HSiMe_2CH_2Cl$,

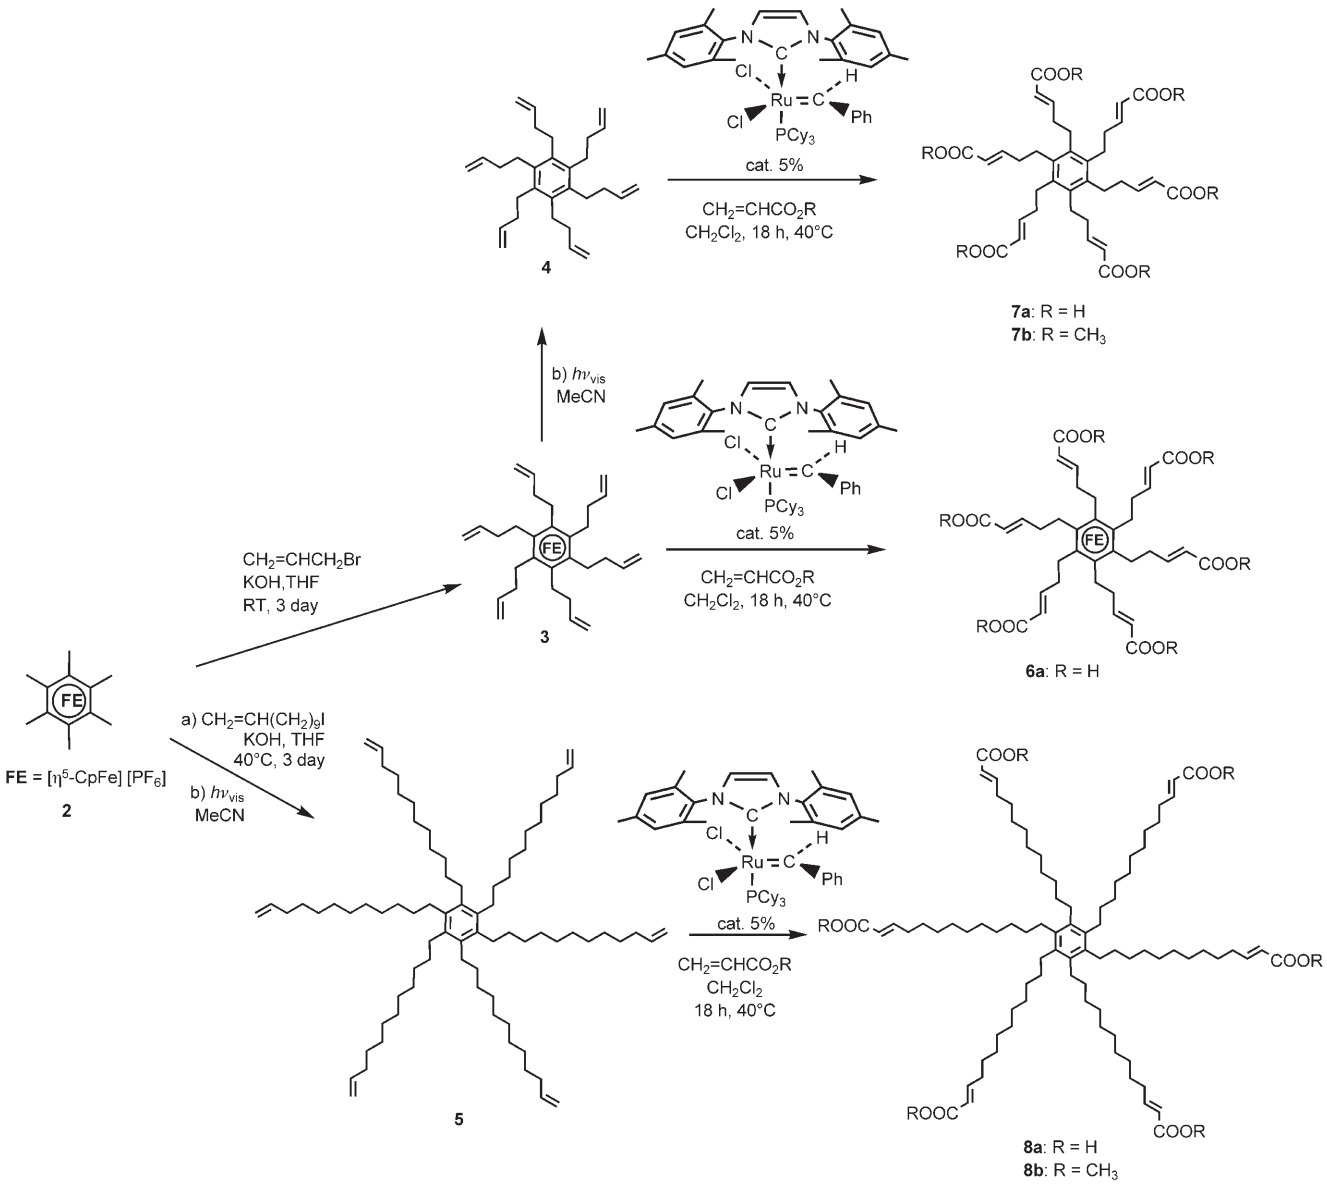

Scheme 1. Synthesis of hexafunctionalized *trans* olefins **7** and **8**.

reaction with NaI, and treatment with p-$HOC_6H_4C(allyl)_3$, were lengthened in the same way to give the new 27- and 81-olefin dendrimers **16** and **19**; their metathesis with CH_2=$CHCO_2R$ proceeded analogously with **A** to give the polyfunctional dendrimers **17** and **20** (Schemes 3 and 4). All the polyfunctionalized dendrimers were characterized by ^1H, ^{13}C, and ^{29}Si NMR spectroscopy and elemental analysis. In addition, the MALDI-TOF mass spectra of **8a**, **8b**, **14a**, and **14b** only show the molecular peaks (see the Supporting Information), and size-exclusion chromatography (SEC) showing Gaussian-type distributions (Figure 1) confirm the monodispersities of the three generations of polyallyl and polyester dendrimers.

The poly(carboxylic acid) dendrimers give water- or methanol-soluble sodium carboxylate salts upon contact with aqueous NaOH or NaOH in methanol. Water-soluble dendrimers are used for applications such as molecular micelles and cation binding and transport.[12] The poly(carboxylic acid) dendrimers are also very useful for their reactions with various amines, a further functionalization procedure. For example, reaction of the new amine dendron $N[(CH_2)_4Fc]_3$ (Fc = ferrocenyl; **21**) with **20a** quantitatively yields the 243-ferrocenyl dendrimer **22** (Scheme 4) that shows a single wave in cyclic-voltammetric studies (see the Supporting Information), which is a key feature for redox sensing—the large dendrimer size also being favorable for electrode modification.[13] The formation of the 81 ammonium carboxylate linkages is shown by the change in solubility, from **20a** that is insoluble in CH_2Cl_2 (but soluble in acetone) to **22** that becomes soluble in CH_2Cl_2. Moreover, the ^1H and ^{13}C NMR signals of the methylene groups attached to the carboxylate and amine groups, respectively, are strongly shifted as expected in **22** relative to the precursors **20a** and **21** (see the Supporting Information).

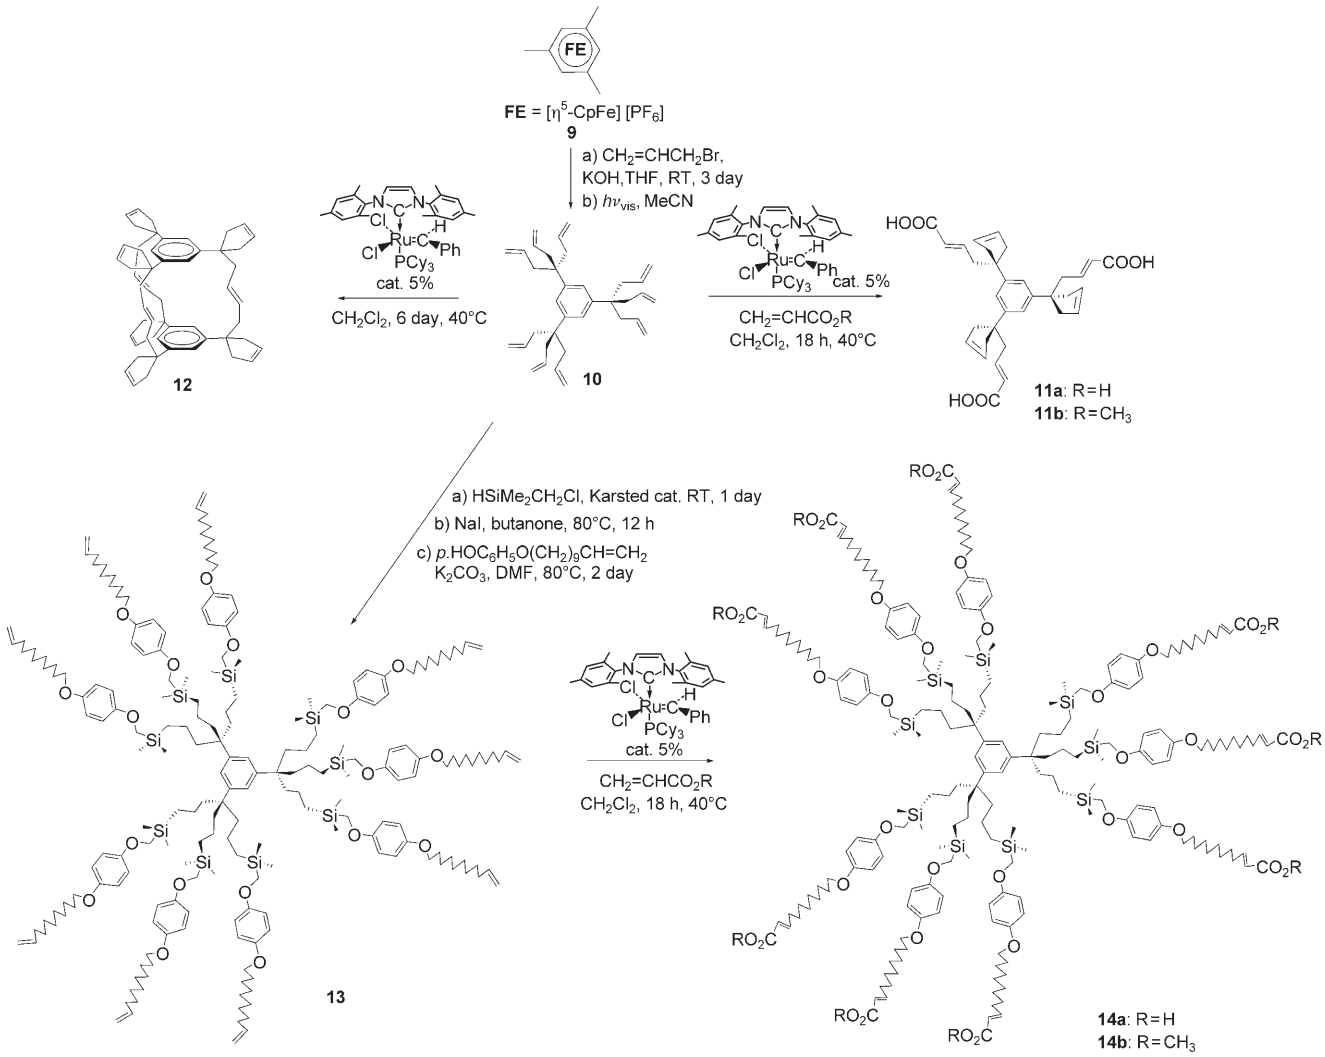

Scheme 2. Synthesis of the CM product **14**.

In conclusion, the finding of this remarkable quantitative chemio-, regio-, and stereoselective cross olefin metathesis with dendrimers using catalyst **A** provides a unique way to functionalize polyolefin-terminated dendrimers and to solubilize them in water and methanol. This reaction makes such useful dendrimers readily accessible on large scales from simple polymethylbenzenes in a few steps.[14]

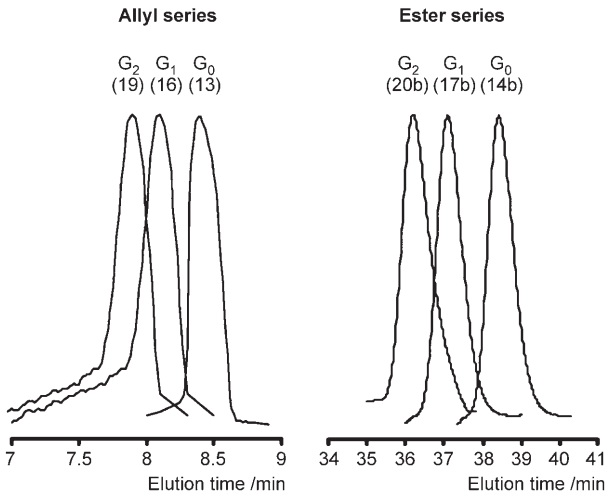

Figure 1. Size-exclusion chromatograms of the three generations of dendrimers (9, 27, and 81 tethers, respectively) before (left) and after (right) functionalization by cross metathesis with methylacrylate. The polydispersity indices obtained from these chromatograms have values between 1.00 and 1.02. Apparent molar masses of the dendrimers were determined by using two different size-exclusion chromatographic apparatus, both equipped with a refractive index (RI; Jasco) and UV/Vis (Varian 2550, $l = 254$ nm) detectors. The columns used were four TSK-gel columns (7.8×300 mm, G 2000, G 3000, G 4000, G 5000 with particle sizes of 5, 6, 6, and 9 mm, respectively) and one PL Poly Pore column (7.5×300 mm, particle size = 5 mm). The eluent was THF (0.7 mL min^{-1}) at 25 °C and calibration was carried out using linear polystyrene standards.

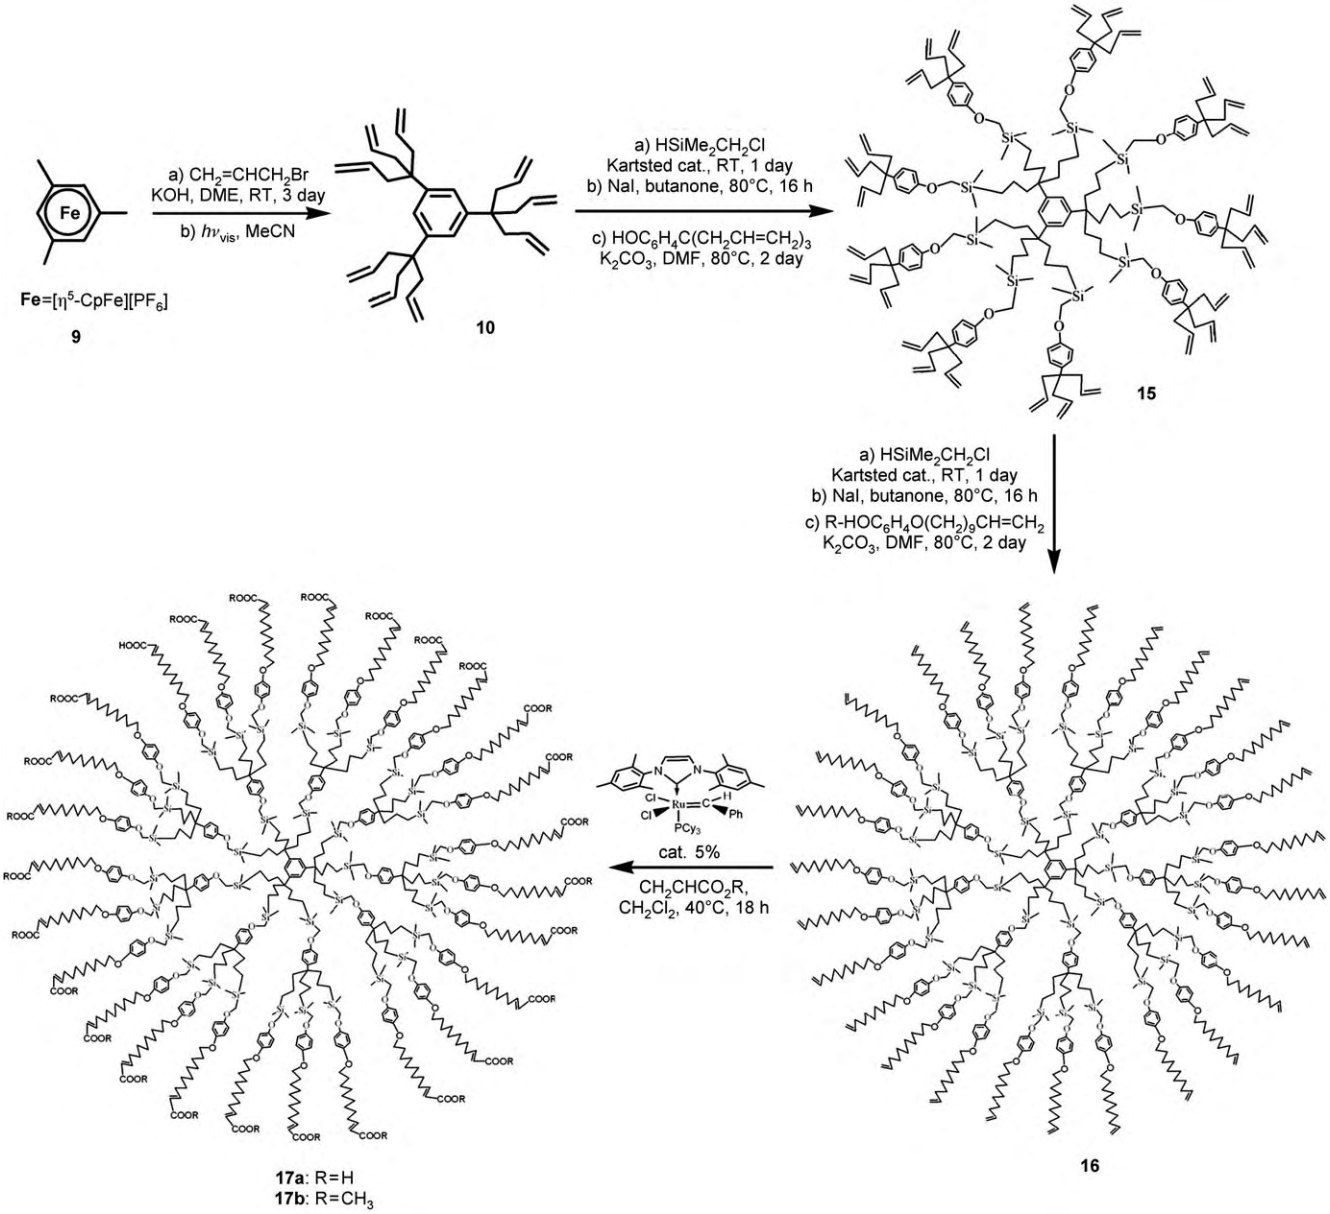

Scheme 3. Synthesis of the polyfunctional dendrimer **17**.

Experimental Section

General metathesis experiments: the polyolefin dendrimer (0.0418 mmol/n dendritic tethers), dry CH_2Cl_2 (10–50 mL), methyl acrylate or acrylic acid (0.221 mmol), and catalyst **A** (5 mol% equivalents per dendritic branch, 0.0114 g, 0.0134 mmol) were successively introduced into a Schlenk flask in an inert atmosphere. The reaction solution was warmed to 40 °C for 18 h. After removal of the solvent under vacuum, the product was washed with methanol and precipitated by addition of a tenfold excess of methanol to a solution of the polyester dendrimers in CH_2Cl_2 or to a solution of the polycarboxylic acid dendrimers in THF. The colorless waxy organic dendrimers were usually obtained in 95–99% yield and were characterized by ^1H, ^{13}C, and ^{29}Si NMR spectroscopy; MALDI-TOF-MS of **8a**, **8b**, **14a**, **14b**, **16**, **17a**, **17b**, and **21** (observation of the molecular peak and absence of other peaks); elemental analysis; and size-exclusion chromatography (SEC, Figure 1).

Difluoroallenyl Bromide as a Wide-Ranging Difluoromethylene Cation Equivalent: S_N2 Substitution of Difluoropropargyl Bromide through Sequential S_E2' and S_N2' Reactions**

*Bo Xu and Gerald B. Hammond**

Dedicated to Professor Chang N. Wu on the occasion of his 72nd birthday

Unlike the other halogens, the small size of fluorine, the strong bond it forms with carbon, and its high electronegativity make it an ideal substituent to produce compounds with unique stereoelectronic and biological properties.[1] In this regard, *gem*-difluoromethylene-containing compounds have been sought after because of their inhibition of HIV protease,[2] and protein tyrosine phosphatase,[3] together with their ability to mimic phosphate,[4] carbonyl,[5] and retropeptide[6] units. In addition, the anomeric effects of heteroatom substituents, such as α-fluorinated ethers, α-fluorinated thioethers, and α-fluorinated amines, have sparked a flurry of new applications.[7] Overall, the significance of the incorporation of fluorine in organic molecules has spurred the development of novel synthetic strategies.[8] Despite these advances, a fundamental synthetic challenge persists, namely, the S_N2 synthesis of RCF_2Nu from RCF_2X

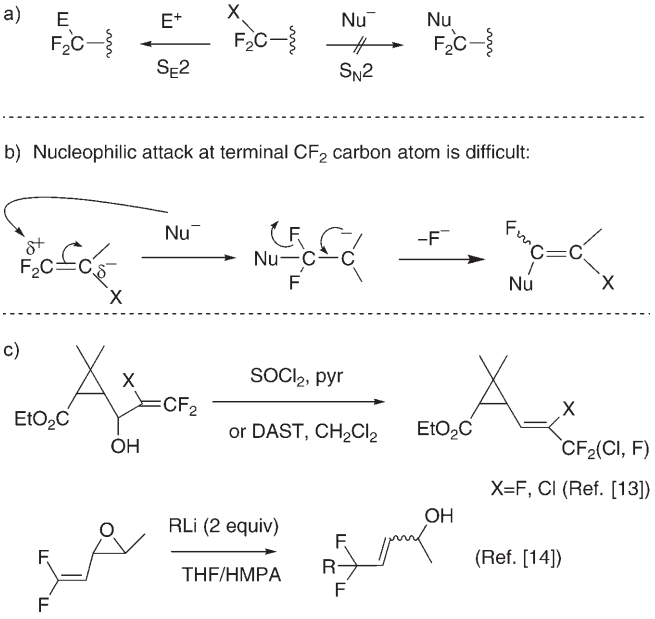
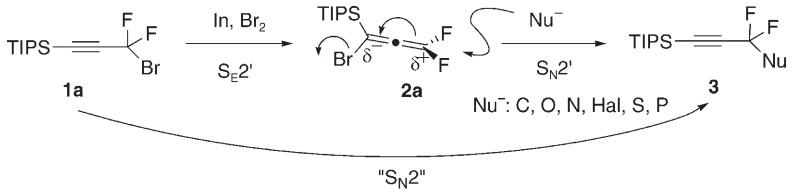
(Scheme 1a). Whereas potent methodologies exist for S_E2-type electrophilic substitution using either difluoromethylene mono-[9] or dianion equivalents,[10] the shielding of the carbon atom by the surrounding fluorine atoms impedes substitution by a nucleophile (Nu), except under exceptional circumstances.[11] In some cases, nucleophilic substitution has been shown to proceed through a radical anion radical ($S_{RN}1$) process triggered by single electron-transfer, rather than S_N2 displacement.[12] In principle, RCF_2Nu could be synthesized by a nucleophilic reaction on *gem*-difluoroolefins (Scheme 1b), thus taking advantage of the preferential attack of nucleophiles at the terminal sp^2 difluoromethylene carbon atom. However, this approach usually yields addition–elimination products that arise from the facile β-elimination of a fluoride ion. In a couple of examples, this problem has been circumvented by using either 1,1-difluoro-2-halo-1-alken-3-ols[13] or 3,4-epoxy-1,1-difluorobutenes[14] for the synthesis of polyfluorinated pyrethroids or allylic alcohols, respectively (Scheme 1c). We now report what is in effect a widely applicable two-step S_N2 conversion of RCF_2Br into RCF_2Nu, whereby an indium-mediated S_E2' bromide substitution converts **1a** into **2a**, which in turn reacts with a nucleophile in a S_N2' fashion to produce **3** in high yield (Scheme 2). An added advantage of this strategy is that the resulting product **3** is equipped with a triisopropylsilyl (TIPS)–acetylenic linkage suitable for further synthetic manipulation.



Scheme 1. a) S_N2 and S_E2 reactions; b) nucleophilic substitution on a sp^2 fluorinated carbon atom; c) synthesis of polyfluorinated pyrethroids and propargyl alcohols using nucleophiles. Nu = nucleophile, pyr = pyridine, DAST = diethylaminosulfur trifluoride, HMPA = hexamethylphosphoramide.



Scheme 2. Planned strategy for the synthesis of **3** from **1a** using a S_N2 substitution. Hal = halide.

targets.[15] We have recently shown that fluorine substitution imparts profound changes to the chemistry of allenes.[16] On the basis of ab initio calculations,[17] we postulated that a vinylogous *gem*-difluoro-olefin, such as fluoroallene **2a** (Figure 1), would be ideally suited to acting as a difluoromethylene-cation equivalent because of the opposite NBO charges in **2a** (+0.765 on C1 and −0.449 on C3). This charge distribution would favor a S_N2' nucleophilic attack at C1, with concomitant bromide elimination at C3; the isomerization of the allene to a propargyl group is favorable and acts as a driving force. Conversely, its non-fluorinated counterpart **2b** has the electronic charge concentrated on the carbon termini, which is a deterrent towards nucleophilic attack. The synthesis of **1a** was carried out by using our previously reported procedure[18] on a multigram scale (92% yield). We treated **1a** with both hard and soft nucleophiles, including sodium 2-methyl malonate, Grignard reagents, triphenylphosphine, or sodium ethoxide, to demonstrate the lack of reactivity of the $-CF_2Br$ moiety towards nucleophilic substitution. In all cases, we obtained either starting material or intractable, defluorinated mixtures.

Prior to the present work, γ-bromodifluoroallenes were unknown.[19] We had reported earlier that the preformed indium propargyl complex **4**[20] yielded fluoroallenyl alcohol **5** when treated with a reactive electrophile, such as aqueous formaldehyde (Scheme 3).[21] Less reactive electrophiles, such as benzaldehyde or imines, produced homopropargyl alcohol or amines. If this premise is correct, then the reaction between **4** and a reactive electrophile, such as Br_2, should produce the γ-bromodifluoroallene **2a**. To our satisfaction, the S_E2' reaction of **4** and bromine proceeded quite readily at −78 °C in THF to yield the desired **2a** in 81% yield. This compound can be stored neat for months at −5 °C without any noticeable decomposition; in solution, it reverted to **1a** most

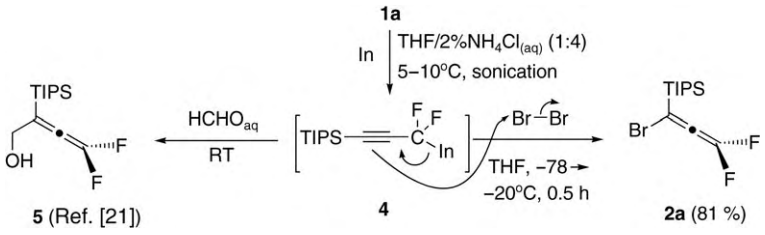
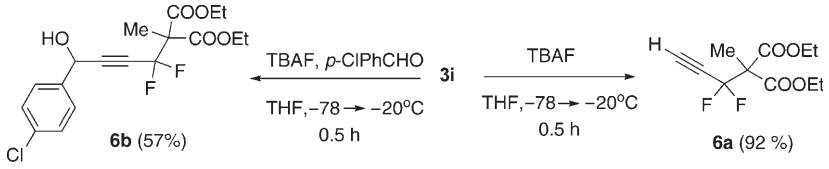


Scheme 3. Indium-mediated synthesis of **2a** via difluoropropargyl complex **4**.

likely through a S_N2' bromine displacement catalyzed by trace amounts of bromide. This proposition was later confirmed with the result obtained in entry **3g** in Table 1.

With a high-yielding synthesis of **2a** in hand, we proceeded to investigate its reactivity towards both soft and hard nucleophiles following the strategy depicted in Scheme 2. To our satisfaction, **2a** reacted readily with a wide range of weak and strong nucleophiles (P, O, S, C, N, and Br), in a S_N2' sense, thus furnishing **3** in good-to-excellent yields (Table 1). Aliphatic and aromatic amines produced complex mixtures. However, this problem was bypassed by using sodium azide as a nitrogen nucleophile, which produced a stable propargyl difluoroazide in almost 70% yield (entry **3h**). Notably, our new methodology also allowed the synthesis of hydrofluoroether **3c** in 68% yield by using trifluoroethanol as the nucleophile under very mild conditions. Prior to our disclosure, the synthesis of hydrofluoroethers could only be achieved under strongly basic conditions, which led to vinyl ether by-products, or through the very recently reported Pd^0-catalyzed hydroalkoxylation of hexafluoropropene.[22] In addition to the alkyne functionality present in **3**, the TIPS group is also a useful synthetic handle. It can be cleaved in excellent yield without loss of fluorine to yield **6a** by using TBAF. Alternatively, it can be further functionalized by using an electrophilic trap, such as *p*-chlorobenzaldehyde, to produce **6b** (see Scheme 4).

In conclusion, we have achieved a wide-ranging conversion of RCF_2Br into RCF_2Nu through a novel bromodifluoroallene **2a**, which is the synthetic equivalent of a difluoromethylene cation. We are currently exploring the use of other substituents appended to the γ-carbon atom and probing the synthetic usefulness of the diverse repertoire of $-CF_2Nu$ synthons which have been obtained through this novel reaction.



Scheme 4. Deprotection and functionalization of **3i** using tetrabutylammonium fluoride (TBAF).

One-Pot Tandem 1,4–1,2-Addition of Phosphites to α,β-Unsaturated Imines for the Synthesis of Glutamic Acid Analogues**

*Kristof Moonen, Ellen Van Meenen, Annelies Verwée, and Christian V. Stevens**

Amino phosphonates and their corresponding amino phosphonic acids are known as amino acid mimetics and, therefore, affect the physiological activity of the cell.[1] The synthesis of 1-alkylamino phosphonates by a reaction of a dialkyl phosphite and an imine under thermal conditions had been described in the early 1950s.[2] However, dialkyl phosphites are generally considered to be poor nucleophiles because they exist predominantly in a $\sigma_4\lambda_5$ configuration.[3] Dialkyl trimethylsilyl phosphites were presented by Afarinkia et al. as excellent mild phosphonylation agents because the more nucleophilic $\sigma_3\lambda_3$ form of the dialkyl phosphite reagent could be obtained by O-silylation with trimethylsilyl chloride (TMSCl) in dichloromethane and triethylamine as the base.[4] Furthermore, exclusive 1,2-addition to α,β-unsaturated imines containing a phenyl group was reported by the same authors using diethyl trimethylsilyl phosphite.[5] During our research into azaheterocyclic phosphonates,[6] we planned to use this phosphonylation reaction with α,β-unsaturated imines **5a–d** derived from cinnamaldehyde. The diethyl trimethylsilyl phosphite was prepared in situ, as described previously.[4] The reaction mixture consisted mainly of the 1,2-adduct **9a** (^{31}P NMR: $\delta = 24.44$ ppm) and residual starting material after 24 h of reaction with the imine **5a**. However, several small ^{31}P NMR signals were present and became more abundant upon prolonged reaction times. The minor peaks appeared as two doublets ($J = 9.7$ Hz) next to two singlets and could be assigned to be the double-addition product **6a** (two diastereomers, ratio: 27:73) after its isolation in very low yield by column chromatography. The same type of product was obtained using imines **5b–d** in increasing amounts proportional to the steric bulk of the *N*-substituent, which also explains the decreasing yields of 1,2-adducts when more sterically demanding *N*-substituents were used in the original

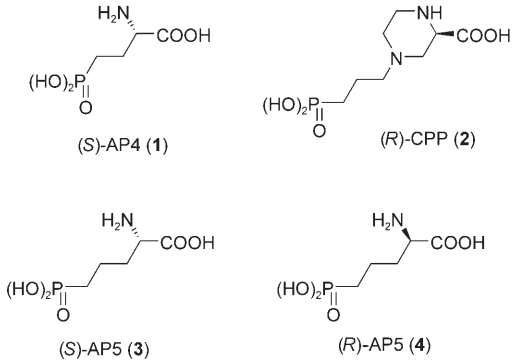
report.[5] With a *N*-phenyl substituent, however, only 1,2-addition was observed.

The obtained diphosphonates can be of major importance because of their high similarity to glutamic acid. (*S*)-Glutamic acid (Glu) is the main excitatory neurotransmitter in the central nervous system (CNS) and operates through two main heterogeneous classes of receptors: ionotropic and metabotropic Glu receptors (iGluRs and mGluRs, respectively). Both classes are further subdivided into several subclasses, but the number of functional receptors in the CNS is not known. Selective Glu agonists and antagonists are not only important for the characterization of different Glu receptor subtypes, but also for the treatment of CNS diseases, such as epilepsy, Huntington's disease, Parkinson's disease, dementia, chronic pain, and so forth. Therefore, the Glu receptor field has been, and continues to be, in a state of almost explosive development.[7] A number of phosphonic acid Glu analogues are known as potent selective Glu antagonists or agonists (Scheme 1). Substitution of the carboxylate group by a



Scheme 1. Selected examples of phosphonic acid Glu analogues with GluR-agonist or -antagonist activity.

bioisosteric phosphonic acid group is known to increase receptor selectivity. For example, (*S*)-AP4 (**1**) is shown as a group III mGluR agonist, some tenfold more potent than Glu.[9] (*S*)-AP5 (**3**) activates the same group III receptors, but with markedly lower potency and selectivity. (*R*)-AP5 (**4**) on the other hand can not be shown to interact with mGluRs, but is a potent and selective competitive *N*-methyl D-aspartate (NMDA; iGluR) antagonist.[8] The diphosphonic acid derivative of AP4 has been tested several times as a Glu analogue without any activity so far.[10] However, further research into new bioisosteres has been indicated as a fruitful path to new subtype-selective mGluR ligands.[7]

The previous results prompted us to look for appropriate reaction conditions to achieve higher yields of the desired Glu bioisosteres. When the imine **5b** was added to two equivalents of diethyl trimethylsilyl phosphite, prepared in situ, complete conversion of the imine into the 3-phosphonyl 1-alkylamino phosphonate (PAP) **6c** was achieved after 72 h at reflux. However, when the diethyl trimethylsilyl phosphite was filtered first to remove the triethylammonium salts, no reaction occurred at all when the imine was added. Also no reaction was observed on addition of LiCl or TMSCl, even though the latter was said to act as a catalyst in the reaction mechanism proposed by Afarinkia et al.[4] Addition of NH_4Cl led to approximately the same result as obtained before (complete conversion in 72 h) and acidification of the reaction medium was observed. Therefore, $(NH_4)_2SO_4$ was selected as a more acidic salt to replace the triethylammonium salts after filtration, thus leading to a remarkable acceleration of the reaction rate (complete conversion after 3 h of reflux). Moreover, when diethyl trimethylsilyl phosphite was mixed with an imine in dry dichloromethane, the reaction proceeded violently upon addition of one equivalent of concentrated sulfuric acid to yield **6c** as a single product in 30 minutes at room temperature. Also with other α,β-unsaturated imines, complete conversion into the corresponding PAP was observed.[11] Diastereomeric ratios were determined from ^{31}P and ^{1}H NMR integration measurements (see Table 1).

As the reaction of imine **5b** with diethyl trimethylsilyl phosphite catalyzed by sulfuric acid proceeds too rapidly to detect any reaction intermediates, triethylammonium chloride was selected as a less potent catalyst to monitor the reaction as a function of time. Rapid disappearance of **5b** was observed, whereas the amount of the 1,2-adduct grew accordingly to a maximum. The PAP **6c** was formed more slowly, however, finally becoming the only end product of the reaction (see Figure 1). This kind of behavior suggests that the imine is protonated first by the acid and becomes activated towards nucleophilic attack of the dialkyl trimethylsilyl phosphite (Scheme 2). 1,2-Addition is clearly the fastest reaction pathway and the *N*-trimethylsilyl 1-alkylaminophosphonate **9** is formed after nucleophilic attack of the nitrogen atom at the trimethylsilyl group of phosphonium salt **8**. These three steps all occur in an equilibrium which was demonstrated in a separate experiment (Scheme 3). When dimethyl (1-amino-1-phenylmethyl)phosphonate (**14**) was N-silylated using TMSCl and subsequently treated with a large excess of diethyl trimethylsilyl phosphite, diethyl phosphonate **15** was mainly recovered along with small amounts of **14**. When the same experiment was repeated without silylation and using diethyl phosphite, no exchange at all occurred. This clearly demonstrated the reversibility (**8**⇌**9**) of the reaction and the leaving-group capacity of the intermediate positively charged phosphonium group.

The initial equilibrium allows two possible routes to the PAP **6** (Scheme 2). The first (pathway A) is complete reversion into the iminium salt **7** followed by a slow 1,4-addition, whereas the second (pathway B) starts with an S_N'-like substitution of the phosphonium group. Both routes yield the same intermediate enamine **10**, which subsequently isomerizes to the imine **11**. A final 1,2-addition then yields PAP **6**, which only shows phosphonyl exchange at the 1 position.

However, enamine **10** or imine **11**, the suggested intermediates in this reaction mechanism (Scheme 2), were never observed. Furthermore, the proposed reaction mechanisms require an external proton source, as one equivalent of protons is incorporated in the final product **6**. Therefore, an experiment was performed using only 0.1 equivalents of sulfuric acid together with 2.0 equivalents of $P(OEt)_2OTMS$.

[a] Yield after column chromatography or acid–base extraction.

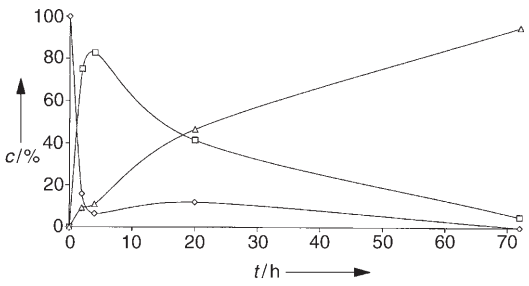

Figure 1. Composition (*c*) of the reaction mixture during the reaction of **5b** (◇) with $P(OEt)_2OTMS$ in the presence of $HNEt_3Cl$, measured by NMR spectroscopy. 1,2-Adduct **9** (□) appears as an intermediate in the reaction, whereas PAP **6c** (△) seems to be the final product.

The reaction proceeded very sluggishly under these conditions, and the formation of **6** was stopped completely after 3–4 h as expected. From that point, the concentration of **10** started to increase (^{31}P NMR: $\delta = \pm 27$ ppm in the reaction medium), while the rest of the imine **7** was slowly consumed (Figure 2). However, addition of water for the work-up led to the conversion of **10** into **6** and some of the imine **7** into the 1,2-adduct using the remaining phosphite in the reaction mixture. This result shows that water can also act as a proton source for this reaction. The structure of intermediate imine **11** was confirmed in a separate experiment (Scheme 4) using subequivalent amounts of sulfuric acid or the non-protic Lewis acid $AlCl_3$ as an activator, together with a limiting amount of diethyl trimethylsilyl phosphite (0.9 equivalents). Under these conditions, there was no free phosphite in the work-up and the intermediate 1,4-adduct **16** was obtained in a mixture of **6** and starting material **5**. The structure of **16** was confirmed after hydrolysis to the corresponding aldehyde **17** and comparison with literature data.[12]

From the evolution of the reaction intermediates as a function of the reaction time (Figure 2), it is clear that the 1,2-adduct **9** is not a real intermediate of the PAP formation. After the initial 1,2-adduct formation (which can also be noticed in Figure 1), the 1,2-addition is also blocked by the absence of protons. Furthermore, the observation that a considerably higher reaction rate results for imines bearing more sterically demanding *N*-substituents (tBu > iPr > Bn ≫ Ph) is in favor of the tandem addition, as the 1,2-addition should be slowed down by the steric bulk. One case of a

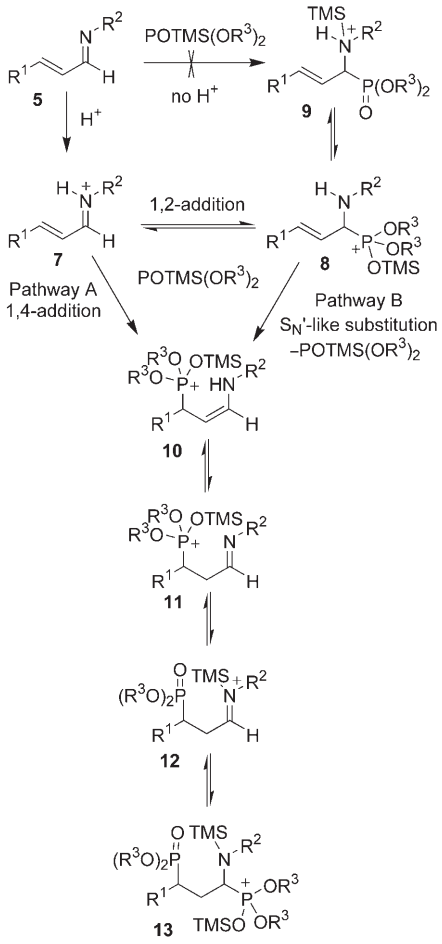
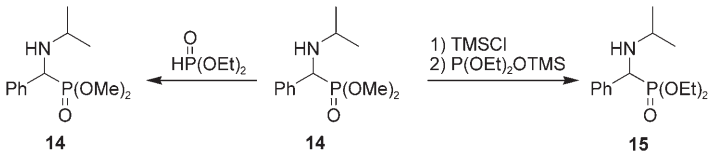


Scheme 2. Suggested reaction mechanisms.



Scheme 3. Phosphonyl exchange reactions.

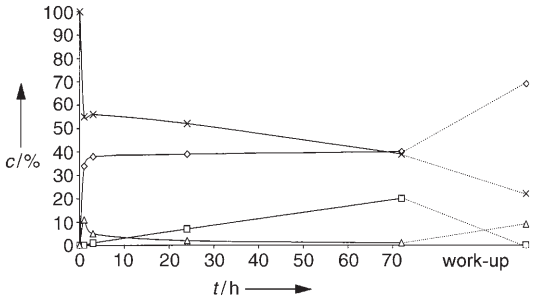


Figure 2. Composition (*c*) of the reaction mixture during the reaction of **5c** (×) with $P(OEt)_2OTMS$ in the presence of 0.1 equivalents of H_2SO_4, measured by NMR spectroscopy. Only a small amount of 1,2-adduct **9** (△) is formed, whereas PAP **6c** (◇) is formed initially very quickly. When the reaction stops because of a lack of protons, the concentration of intermediate enamine **10** (□) starts to increase.

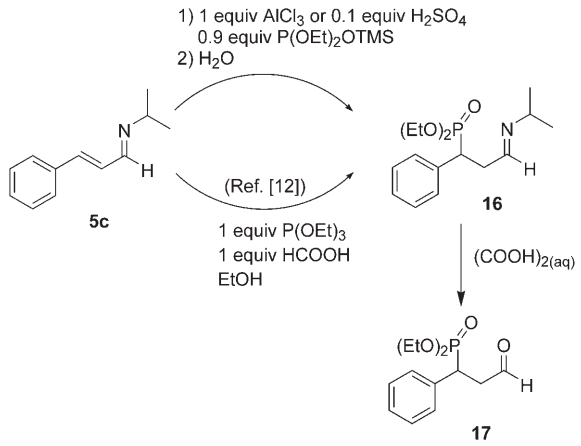

Scheme 4. Isolation and identification of the intermediate 1,4-adduct.

double addition of ketene silyl acetals to α,β-unsaturated imines has been reported, which also proceeded in a 1,4–1,2-tandem fashion.[14]

In summary, our observations in this field lead to a new insight regarding the use of dialkyl trimethylsilyl phosphite which contradicts earlier research:[5] when this reagent is present in its apparently most nucleophilic form, dialkyl trimethylsilyl phosphite fails to react either in a 1,2- or a 1,4-addition in the absence of a protic acid. Furthermore, it has been demonstrated that dialkyl phosphite itself is able to convert imines into the corresponding 1-aminoalkyl phosphonates with complete 1,2-regioselectivity.[2,13] However, in a sufficiently acidic medium, dialkyl trimethylsilyl phosphite is able to convert α,β-unsaturated imines **5** into diphosphonates **6** in one step through a sequential tandem 1,4–1,2-addition (pathway A of Scheme 2).[15] As the free phosphonic acids of diphosphonates[16] are potential Glu agonists or antagonists, our future research will be directed towards the synthesis of enantiopure PAP derivatives.[17]

Large-Scale Nonhydrolytic Sol–Gel Synthesis of Uniform-Sized Ceria Nanocrystals with Spherical, Wire, and Tadpole Shapes**

*Taekyung Yu, Jin Joo, Yong Il Park, and Taeghwan Hyeon**

In the last decade, nanocrystals have been intensively studied, not only for their fundamental scientific interest owing to their size-dependent properties, but also for their many technological applications.[1] Cerium oxide (ceria, CeO_2) is a rare earth oxide that has attracted a great deal of interest owing to its unique properties, including high mechanical strength, oxygen ion conductivity, and oxygen storage capacity. Because of these characteristics, ceria has been widely used as an oxygen ion conductor in solid oxide fuel cells, oxygen pumps, and amperometric oxygen monitors.[2] Ceria has also been used as a polishing agent for the chemical mechanical planarization (CMP) process, as a gate oxide in metal oxide semiconductor devices, and as a catalytic material for three-way catalysis (TWC) of exhaust gas from automobiles and fluid catalytic cracking (FCC).[3] Several methods have been employed to synthesize ceria nanoparticles. Deshpande et al. synthesized nanoparticles of CeO_2, ZrO_2, and $Ce_{1-x}Zr_xO_2$ by hydroxide coprecipitation of a precursor solution composed of cerium ammonium nitrate and zirconyl chloride.[4] Inoue et al. obtained a colloidal solution of 2 nm ceria particles by the solvothermal process.[5] Adachi and co-workers fabricated 2.6 and 4.1 nm ceria particles using reverse micelles.[6] Gedanken and co-workers synthesized 3.3 nm ceria nanoparticles using sonochemical treatment.[7] Zhu and co-workers also prepared 2.8 nm ceria nanoparticles by the sonochemical and microwave-assisted heating methods.[8] However, the ceria nanoparticles synthesized by these methods are often highly aggregated, and a very small quantity is usually produced. Recently, Yan and co-workers synthesized nanocrystals of ceria and other rare earth oxides with various shapes from the thermolysis of metal benzoylacetonate complexes in a solvent mixture composed of oleic acid and oleylamine.[9]

Nonhydrolytic sol–gel processes have been employed to synthesize various oxide materials.[10] Recently, they were

successfully applied to the synthesis of various nanocrystals of transition metal oxides. For example, Colvin and co-workers[11] synthesized TiO_2 nanocrystals by a nonhydrolytic alkyl halide elimination reaction. We employed a similar procedure[12] to produce uniform-sized tetragonal ZrO_2 nanocrystals on the multigram scale by high-temperature reaction of zirconium halides and zirconium isopropoxide. Recently, Brus and co-workers[13] further extended these synthetic methods to produce nanocrystals of HfO_2 and $Hf_xZr_{1-x}O_2$. Stucky and co-workers reported the synthesis of nanocrystals of various metal oxides from the reaction of metal chlorides and benzyl alcohol,[14] and Niederberger and co-workers developed a halide-free approach to synthesize nanocrystals of various oxides from the reaction of metal alkoxides and benzyl alcohol.[15]

One-dimensional (1D) nanocrystalline materials such as nanorods and nanowires have been intensively studied because of their unique properties, which are derived from their low dimensionality and possible quantum-confinement effects.[16] For extensive application of nanocrystals, an economical mass production method for the synthesis of uniform-sized nanocrystals must be developed. Recently, we reported the ultra-large-scale synthesis of monodisperse nanocrystals of many transition metal oxides and sulfides by thermolysis of metal–surfactant complexes.[17] Here we report on the large-scale synthesis of uniform-sized ceria nanocrystals with sphere, wire, and tadpole shapes by the nonhydrolytic sol–gel reaction of cerium(III) nitrate and diphenyl ether in the presence of appropriate surfactants. All of the ceria nanocrystals were produced on a scale of more than 10 g in a single reaction. In particular, we were able to synthesize ceria nanowires with the ultrasmall diameter of 1.2 nm on a multigram scale. The size and shape of the ceria nanocrystals were controlled by adjusting the experimental conditions such as the molar ratio of the surfactants, and the reaction time.

Spherical ceria nanocrystals with an average diameter of 3.5 nm were synthesized from the reaction of cerium(III) nitrate and diphenyl ether in oleylamine at 320 °C. A low-magnification transmission electron microscopy (TEM) image revealed uniform particles with an average size of 3.5 nm and a quasispherical shape (Figure 1 a). A high-resolution TEM (HRTEM) image of the ceria nanocrystals showed a cross-lattice pattern, which demonstrates their highly crystalline nature (Figure 1 a). The powder X-ray diffraction (XRD) pattern (Supporting Information) of the nanocrystals revealed that they have a cubic fluorite structure ($Fm3m$, $a = 5.41134$ Å, JCPDS Card No. 34-0394). The size of the ceria nanocrystals, calculated by using the Scherrer formula, was 3.65 nm, which matched very well with the TEM data. Larger ceria nanocrystals were synthesized by adding tri-*n*-octylamine (TOA) as a cosurfactant in addition to oleylamine. The TEM image showed that uniform quasispherical ceria nanocrystals with an average particle size of 5.2 nm were produced in this case (Figure 1 b). Under optimized synthetic conditions, we were able to synthesize both of these quasispherical ceria nanocrystals on a scale of more than 10 g in a single reaction in 200 mL of solvent (Supporting Information). The UV/Vis absorption spectrum of the 3.5 nm nanocrystals was significantly blue-shifted compared to that of the 5.2 nm nanocrystals (Supporting Information).

Recently, various anisotropic nanocrystals, including nanorods and nanowires, were synthesized by using two different kinds of surfactants.[18] In our synthesis, adding oleic acid as a cosurfactant in addition to oleylamine led to production of anisotropic wire- and tadpole-shaped ceria nanocrystals. When cerium nitrate (1.7 g, 4 mmol) dissolved in a mixture of oleic acid (3.39 g, 12 mmol) and oleylamine (20 mL, 60 mmol, 16.26 g) was treated with diphenyl ether and the resulting solution slowly heated and aged at 320 °C for 2 h, a mixture of ceria nanowires (1.2 nm in diameter and 71 nm in length) with 3.7 nm quasispherical nanocrystals was produced. The diameter of these nanowires is very similar to that of single-wall carbon nanotubes[19] and is among the thinnest of reported nanowires. Although nanowires with diameters of about 1 nm or less have been reported, they were generally produced in extremely small quantities.[20] The TEM image showed that the product was composed of about 70 % nanowires and about 30 % nanospheres (Figure 2). More careful investigation of the TEM images revealed that some nanowires were attached to nanospheres in a tadpolelike structure. The XRD pattern (Supporting Information) showed that the product had a cubic fluorite structure. The HRTEM image showed the {111} faces of a cubic fluorite structure of ceria grown along the [100] direction (Figure 2). By increasing the amount of oleic acid, while keeping the other experimental conditions unchanged, we were able to

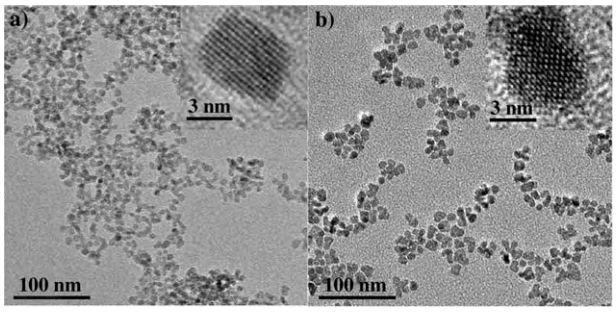

Figure 1. TEM images of a) 3.5 nm spherical ceria nanocrystals and b) 5.2 nm spherical ceria nanocrystals. Insets are their HRTEM images.

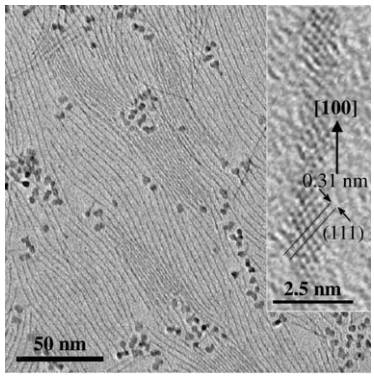

Figure 2. TEM images of 1.2 × 71 nm wire-shaped ceria nanocrystals. The inset is the HRTEM image of a wire-shaped nanocrystal.

synthesize longer nanowires without changing the diameter. By using different amounts of oleic acid, nanowires of various lengths with a nearly constant diameter of 1.2 nm were produced (Supporting Information). We were able to synthesize the nanowires in large quantities (> 10 g) in a single reaction in 200 mL of solvent (Supporting Information).

During a shape-evolution experiment with a relatively large amount of oleylamine, we determined the optimum conditions for predominant formation of the tadpole-shaped nanowires. Tadpole-shaped nanowires consist of a spherical head with a diameter of 3.5 nm and a wire-shaped tail with a diameter of 1.2 nm and length of 27 nm. The low-magnification TEM image revealed that most of these nanocrystals were tadpole-shaped and uniform in size (Figure 3). Recently,

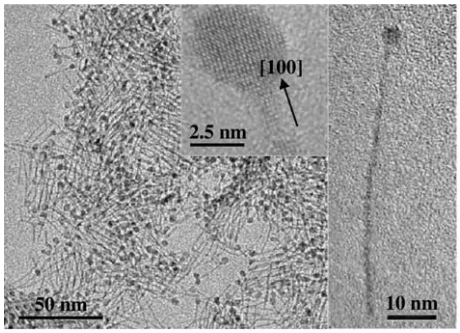

Figure 3. TEM images of the tadpole-shaped ceria nanocrystals. The inset is the HRTEM image of a tadpole shaped nanocrystal.

tadpole-shaped gold nanocrystals were produced.[21] The (HRTEM) image (Figure 3; see Supporting Information for further images) of a single tadpole-shaped ceria nanocrystal revealed that the spherical head and the wire-shaped tail grew epitaxially along the (200) planes with an interplanar distance of 0.27 nm. The XRD pattern showed that the tadpole-shaped ceria nanowires have a cubic fluorite structure (Figure 4).

In conclusion, uniform-sized ceria nanocrystals with quasispherical, wire, and tadpole shapes were synthesized from the nonhydrolytic sol–gel reaction of cerium(III) nitrate and diphenyl ether in the presence of appropriate surfactants. The synthetic procedures described in this study offer several important advantages for the production of ceria nanocrystals. First, this process allows uniform-sized nanocrystals to be obtained on a scale of tens of grams in a single reaction without the need for a further size-sorting process. When reactors are set up in parallel, several kilograms of monodisperse nanocrystals can be readily obtained. Second, ceria nanocrystals with various shapes can be produced simply by changing the experimental conditions. In particular, novel tadpole-shaped nanowires with an extremely small diameter of 1.2 nm were produced.

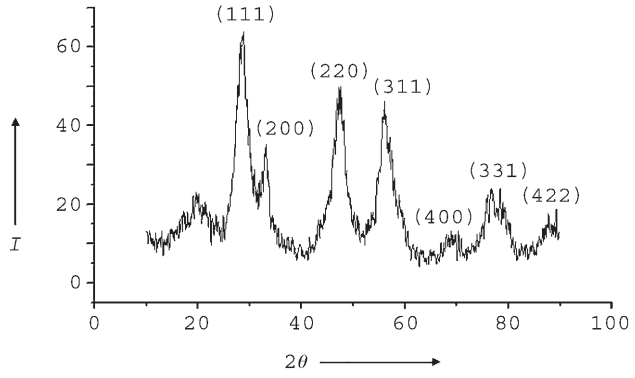

Figure 4. XRD pattern of the tadpole-shaped ceria nanocrystals.

Experimental Section

Synthesis of quasispherical ceria nanocrystals: Cerium(III) nitrate hexahydrate (1.7 g, 4 mmol) was added to oleylamine (technical grade, 20 mL, 16.26 g, 60 mmol) or a mixture of olyelamine (technical grade, 3.21 g, 12 mmol) and tri-*n*-octylamine (20 mL, 16.18 g, 45 mmol) at room temperature. The resulting solution was heated to 90 °C under vacuum, and a homogeneous, clear, black solution formed. Diphenyl ether (2 mL, 2.1 g, 12 mmol) was injected into the solution at 90 °C, and the observed increase in solution temperature to 120 °C demonstrated that the reaction between cerium nitrate and diphenyl ether did indeed occur. The resulting mixture was heated to 320 °C and aged at that temperature for 2 h to give a black colloidal solution. Ethanol (100 mL) was added to precipitate the CeO_2 nanocrystals. The precipitate was retrieved by centrifugation to give white-brown CeO_2 nanocrystals. The nanocrystals were dispersible in many organic solvents, such as toluene, hexane, and octane.

Synthesis of ceria nanowires: Cerium (III) nitrate hexahydrate (4 mmol, 1.7 g) was added to a mixture of oleylamine (technical grade, 20 mL, 16.26 g, 60 mmol) and oleic acid (3.39 g, 12 mmol) at 90 °C. The rest of the synthetic procedure was similar to that used for the synthesis of the spherical nanocrystals. Using 1.7, 3.39, 5.08, and 6.78 g (6, 12, 18, and 24 mmol) of oleic acid in the synthesis gave ceria nanowires with a uniform diameter of 1.2 nm and average lengths of 27.8, 71.1, 115.5, and 164.5 nm, respectively.

Synthesis of tadpole-shaped ceria nanowires: The synthetic procedure for the tadpole-shaped ceria nanowires was very similar to that used for the synthesis of the ceria nanowires. A reaction mixture composed of cerium (III) nitrate (0.85 g, 2 mmol), oleylamine (technical grade, 20 mL, 16.26 g, 60 mmol), of oleic acid (1.69 g, 6 mmol), and diphenyl ether (1 mL, 1.07 g, 6 mmol) was aged at 320 °C for 1 h.

UV/Vis spectra of 3.5 and 5.2 nm spherical nanocrystals, XRD patterns of 3.5 and 5.2 nm spherical nanocrystals and nanowires, TEM images of ceria nanowires of various lengths, and photographs of ceria nanocrystalline powders can be found in the Supporting Infomation.

metastable phase under atmospheric pressure according to the thermodynamic equilibrium phase diagram of carbon. However, it has been verified by experiments,[5–15] calculations,[16–19] and theory[20,21] that nanodiamonds with diameters of less than 5 nm are more stable than their graphitic counterparts. By calculating the structural energies (formation energies) of graphite, diamond, and fullerene on the basis of density functional theory, Barnard et al.[22] reported that the relative stability is dependent on the size of carbon clusters. For instance, diamond could be the stable phase of carbon clusters when the size is in the range of 1.9–5.2 nm. Thus, from the above studies, we conclude that a better understanding is required for two fundamental issues: 1) what relationship exists between size distribution and stability of nanodiamonds, and 2) what is the physical origin of the stability of nanodiamonds.

We have now studied the graphitization of nanodiamonds experimentally and theoretically. Interestingly, we found size-dependent graphitization of nanodiamonds, that is, the stability of nanodiamonds depends on size, and this implies that a nanosize effect is operative, remarkably similar to that of nanocavities.[23] Meanwhile, we established a thermodynamic model for the size effect on the basis of nanothermodynamic analysis.[20,24]

Commercial diamond nanoparticles with sizes of 5–6 nm and over 90% phase purity were annealed under a flow of Ar (purity $>99.99\%$) at atmospheric pressure and given temperatures. Annealing temperatures were in the range from room temperature (RT) to 1423 K, and annealing was performed for 2 h at each temperature. Transmission electron microscopy (TEM), selected-area electron diffraction (SAD), X-ray diffraction (XRD), Raman spectroscopy, and differential scanning calorimetry (DSC) were used to identify the graphitization of diamonds (for detailed analysis, see Supporting Information). The linewidth of the Raman spectrum as a function of nanodiamond size was calculated from the phonon-confinement model (Figure 1).[25] The inset to Figure 1 shows that the size of the residual nanodiamonds decreases from 5.5 to approximately 2.5 nm when the annealing temperature is elevated from RT to 1423 K. Figure 2a shows the bright-field TEM pattern of nanodiamonds annealed at 1423 K for 2 h. The size of the residual nanodiamonds is about 2.5 nm, and diamond nuclei are surrounded by an amorphous ring (see magnified view, top left in Figure 2a). These results indicate that graphitization starts at the surface region, on the basis of experiments by Enoki,[11] which are in good agreement with the above analysis. These experimental results reveal that the graphitization of nanodiamonds is size-dependent, and nanodiamonds smaller than 3 nm are more stable than graphite in graphitization at moderate temperature, that is, the phase stability of nanodiamonds is verified experimentally from the viewpoint of diamond-to-graphite transformation. This new size effect differs distinctly from the widely accepted nanosize and quantum-size effects that occur when the size confining a condensed-matter system is so small that it becomes comparable to the lattice distance.[26] A similar nanosize effect was reported for the shrinkage of nanocavities upon ion-beam irradiation.[23] A general symmetry relationship between nanoparticles and nanocavities can thus be established, as illustrated schematically in Figure 2b.

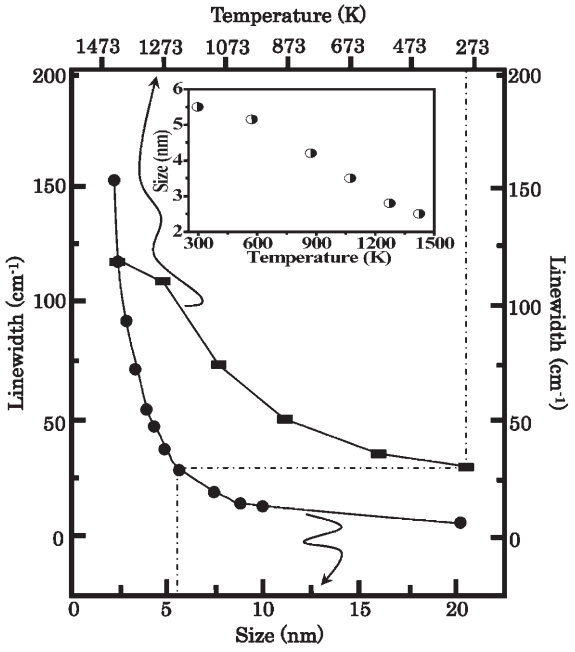

Figure 1. F_{2g} mode linewidth of Raman spectra versus annealing temperature (experimental values, ■) and variation of linewidth with particle sizes of 2.3, 2.5, 3.0, 3.5, 4.0, 4.5, 5.0, 5.7, 7.5, 8.8, 10.0, and 20.0 nm, based on the phonon-confinement model (calculated values, ●). The dash-dot line indicates the determination of particle size. The inset shows a plot of particle size versus annealing temperature.

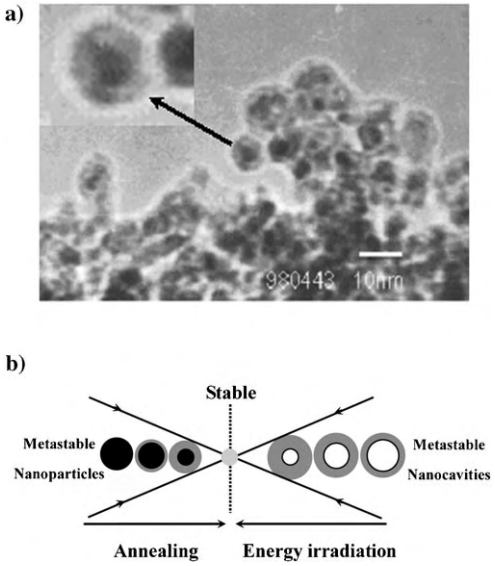

Figure 2. a) TEM images of 5–6 nm nanodiamonds after annealing at 1423 K for 2 h show that the size of the residual nanodiamonds is about 2.5 nm. b) The symmetry relationship between nanoparticles (left) and nanocavities (right) reveals that a similar nanosize effect operates in condensed-matter systems at the nanometer scale.

To provide a better understanding of the size effect in terms of thermodynamics, based on the equilibrium phase diagram of carbon[26] and thermodynamic analysis at the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

nanometer scale,[20,24] we performed a thermodynamic study, taking into account the capillary effect of the nanometer-sized curvature of diamond and graphite nanoparticles by the Laplace–Young equation. Under these assumptions of spherical and quasi-isotropic nanocrystals, the nanosize-curvature-induced interior pressure of the nanodiamonds, ΔP, is expressed by the Laplace–Young equation as $\Delta P = 4\gamma/d$, where γ and d are the surface tension and the diameter of spherical nanodiamonds, respectively. In view of the thermodynamic phase diagram of carbon,[27] the phase-equilibrium-line function $P(T)$ of the diamond–graphite phase transition in the bulk is approximately expressed by Equation (1).[20]

$$P^{be}(T)\ (\text{in Pa}) = 2.01 \times 10^6\, T + 2.02 \times 10^9 \quad (1)$$

$P^{be}(T)$ denotes the phase-equilibrium-line pressure (external pressure) in the bulk. On the basis of the liquid-drop model, the phase equilibrium line on the nanometer scale must be scaled taking into account the radius of curvature. This dependence is universal for all elements in the periodic table. Naturally, the phase equilibrium line on the nanometer scale is a function of temperature, pressure, and nanocrystal radius. The phase-equilibrium-line equation is expressed by Equation (2).[20]

$$P^{ne}(T,d)\ (\text{in Pa}) = 2.01 \times 10^6 T + 2.02 \times 10^9 - \frac{4\gamma}{d} \quad (2)$$

$P^{ne}(T,d)$ is the phase-equilibrium-line pressure (external pressure) under consideration of the radius of curvature of the nanodiamonds. In our case (under atmospheric pressure), if nanodiamonds are the stable phase, the functional relationship must fulfil the condition $4\gamma/d + 10^5 \geq 2.01 \times 10^6 T + 2.02 \times 10^9$. Thus, when $4\gamma/d + 10^5 = 2.01 \times 10^6 T + 2.02 \times 10^9$, we attain a new phase-equilibrium line for the size–temperature relationship, as shown in Figure 3a. These theoretical predictions of the nanodiamond stability are in good agreement with our experimental results. Furthermore, we calculated the Gibbs free energy of the graphitization of nanodiamonds by considering the nanosize-induced interior pressure. The Gibbs free energy is expressed as a function of radius r_g, pressure P, and temperature T [Eq. (3)].[20]

$$\Delta G(r_g,P,T)\ (\text{in J}) = \left(\frac{4}{3}\pi {r_g}^3\, \Delta g/V_{mg} + 4\pi {r_g}^2 \gamma_g\right) f(\theta) \quad (3)$$

V_{mg}, γ_g, and θ are the molar volume of graphite ($5.187 \times 10^{-6}\ m^3$), the surface energy of graphite ($0.55\ J\,m^{-2}$),[21a] and a contact angle,[20] respectively. Here, $f(\theta)$ is the so-called heterogeneous factor (in the range from 0 to 1) and can be expressed by $(1-\cos\theta)^2(2+\cos\theta)/4$, and Δg is the molar-volume Gibbs free energy, which is relative to dimension according to Equation (4), when the phase transition takes place near the phase-equilibrium line.

$$\Delta g\ (\text{in J}) = \Delta V\left(2.01 \times 10^6 T + 2.02 \times 10^9 - \frac{4\gamma}{d} - 1 \times 10^5\right) \quad (4)$$

ΔV ($1.77\ m^3\,mol^{-1}$)[20] is the molar volume difference between diamond and graphite. When $\frac{\partial \Delta G(r)}{\partial r} = 0$, the critical size of graphitization nuclei is obtained [Eq. (5)].

$$r_g^*\ (\text{in m}) = \frac{2\gamma}{\left(\frac{4\gamma}{d} + 1 \times 10^5 - 2.01 \times 10^6 T - 2.02 \times 10^9\right)\frac{V_{mg}}{\Delta V}} \quad (5)$$

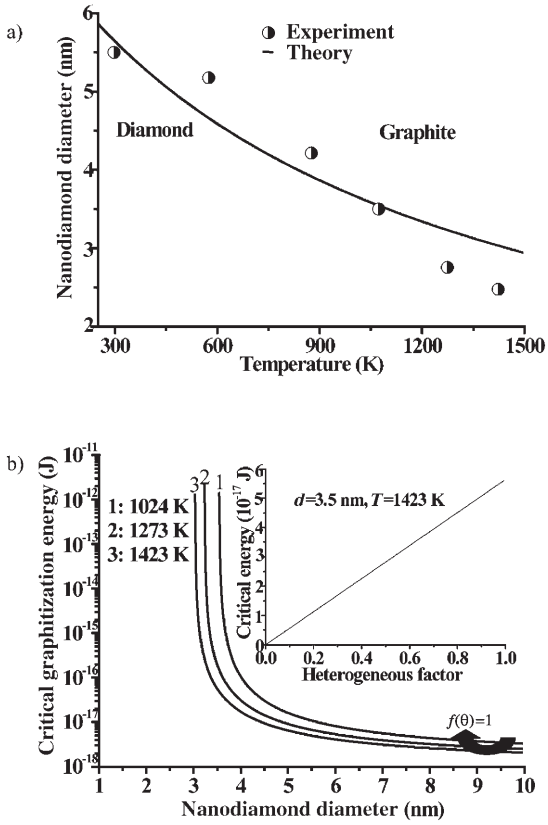

Figure 3. a) Phase-equilibrium line of diamond–graphite size–temperature relationship, which suggests that the stability of residual nanodiamonds is a function of size at a certain temperature. b) Relative curves of the diameters of nanodiamonds and the Gibbs free energy of the nanodiamond graphitization for various annealing temperatures and a given heterogeneous factor, which reveals that a definite threshold size exists for the graphitization of nanodiamonds at a given annealing temperature. The inset shows the relationship between the heterogeneous factor and the critical energy of graphitization.

Accordingly, we attain the relationship curve between size of the residual crystalline nanodiamond nuclei and the Gibbs free energy of graphitization for various annealing temperatures and heterogeneous factors (Figure 3b). Clearly, the Gibbs free energy of graphitization increases with decreasing nanodiamond size at a given temperature. For various annealing temperatures, there are corresponding thresholds of the size of residual nanodiamonds in graphitization, and this suggests that only the surface region of the nanodiamond particles is graphitized at a given temperature, and then graphitization proceeds inward on further elevation of annealing temperature at the expense of nanodiamond phase, as proved by the appearance of bands for graphitic structures in the Raman spectrum and X-ray diffraction (see Supporting Information). Thus, graphitization would display a staircase behavior with increasing annealing temperature,

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

due to the surface-curvature effect of the diamond and graphite nanoparticles. For example, the threshold diameters of the residual nanodiamonds are about 3.5 and 3 nm at annealing temperatures of 1073 and 1423 K. Therefore, graphitization hardly proceeds further when the size of the residual nanodiamonds reaches 3.5 and 3 nm at annealing temperatures of 1073 and 1423 K, respectively, which are consistent with our experiments. For comparison, the relationship curve between the graphitization energy and heterogeneous factor is shown as inset in Figure 3b. Similarly, we calculated the relationship curve between the annealing temperature and the probability of diamond-to-graphite transition. According to the general expression of the phase transformation probability,[28] the probability of graphitization is expressed as $f_g = \exp[-(E_a/RT)] - \exp[-(E_a - \Delta g)/RT]$, where R and E_a are the gas constant and the activation energy (212 kJ mol^{-1}),[29] respectively, and Δg is relative to dimension and defined by Equation (4). The resulting relationship curves between annealing temperature and graphitization probability are shown in Figure 4. Apparently, threshold

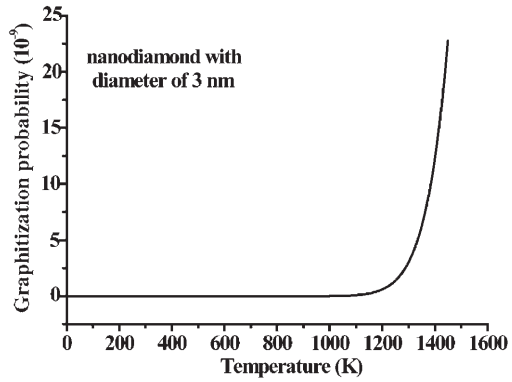

Figure 4. Dependence of the nanodiamond graphitization on annealing temperature for nanodiamonds of a given size. The transition from diamond to graphite almost stops for nanodiamonds with diameters of 3 nm at an annealing temperature of 1300 K.

temperatures exist for the graphitization of nanodiamonds of various sizes. For instance, graphitization of residual nanodiamonds with a size of 3 nm stops when the threshold temperature is about 1300 K. These theoretical results therefore indicate that the surface tension induced by the nanosized curvature of nanodiamonds is the physical origin of their stability and the size effect in nanodiamond graphitization. Accordingly, a thermodynamic approach on the nanoscale also seems applicable to the shrinkage of nanocavities.

In summary, nanodiamonds smaller than 3 nm were experimentally verified to be more stable than graphite from the viewpoint of nanodiamond graphitization. The relationship between the size of residual nanodiamonds and the critical energy of graphitization at given temperatures was studied theoretically on the basis of the size–temperature phase diagram, by taking into account the capillary effect of nanodiamonds, and revealed the dependence of graphitization on nanodiamond diameter and annealing temperature. Both experiment and theory suggested that the nanometer-sized curvature of nanodiamonds is the physical origin of the stability of nanodiamonds.

Carbon Dioxide Complexes

DOI: 10.1002/anie.200502400

Aluminum–Magnesium Complexes with Linearly Bridging Carbon Dioxide**

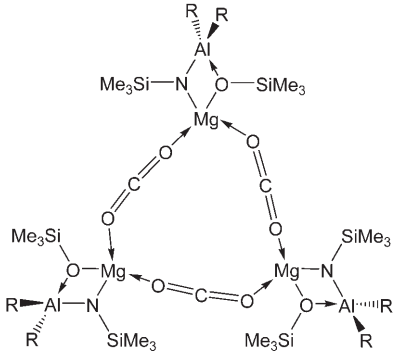
Chung-Cheng Chang, Min-Chun Liao, Tsu-Hsin Chang, Shie-Ming Peng, and Gene-Hsiang Lee*

Earlier, we found that an oxygen atom of carbon dioxide bonds to a metal atom when carbon dioxide is fixed by the Al–Mg mixed-metal compounds $[Me_2Al(\mu\text{-}NR_2)_2Mg(\mu\text{-}Me)]_n$ (R = *i*Pr, $n = 4$; R = Et, $n = 2$). Subsequently, the amino leaving group migrates from the attacked metal atom to the carbon atom of the carbon dioxide to form Al–Mg carbamato complexes.[1] The CO_2-ligated Mg compounds show a variety of bonding modes.[2] However, to date the linear $\mu(O,O')$-CO_2 coordination mode of carbon dioxide has not been observed, either in main group or in transition metal compounds.[3]

In accordance with earlier work by Sita et al.,[4] we presume that the reaction of $Mg[N(SiMe_3)_2]_2$ with carbon dioxide could also generate an oxo-transfer product, namely, $Mg(N(SiMe_3)_2)(OSiMe_3)$, and the expected $O{=}C{=}N(SiMe_3)$, instead of generating a carbamato complex.[5] In light of our previous experience with trialkylaluminum reagents and taking advantage of the oxo-transfer compound $Mg[N(SiMe_3)_2](OSiMe_3)$, we proposed a process for studying CO_2 fixation in a mixture of $Mg[N(SiMe_3)_2]_2$ and trialkylaluminum.

One equivalent of AlR_3 (R = Me, Et) was added to a solution of $Mg[N(SiMe_3)_2]_2$ in THF at room temperature, and an excess of carbon dioxide was bubbled through the stirred, ice-cooled mixture to yield compounds **1** (R = Me) and **2** (R = Et) [Eq. (1), Scheme 1].

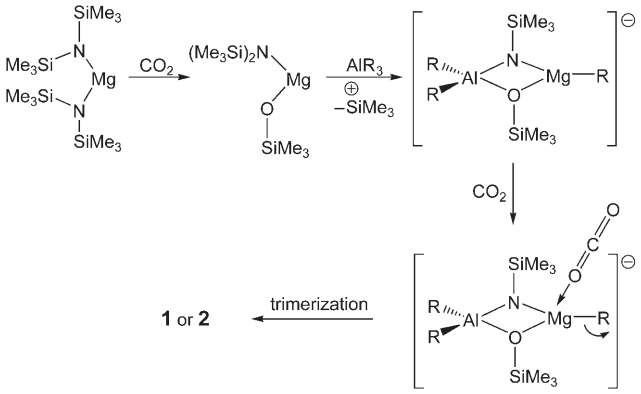
$$Mg[N(SiMe_3)_2]_2 + AlR_3 + CO_2 \xrightarrow[0\,^{\circ}C]{THF} [\{R_2Al(\mu\text{-}NSiMe_3)(\mu\text{-}OSiMe_3)Mg(thf)_2(\mu\text{-}O_2C)\}_3]\ (\mathbf{1}, \mathbf{2}) \quad (1)$$



1 R=Me
2 R=Et

Scheme 1. Schematic representation of **1** and **2**. Coordinated THF omitted for clarity.

Presumably, carbon dioxide reacted with $Mg[N(SiMe_3)_2]_2$ to give oxo-transfer product $Mg[N(SiMe_3)_2](OSiMe_3)$, which is assumed to form a bridged Al–Mg intermediate with AlR_3 (R = Me, Et); this subsequently loses a ligand from the magnesium center and is attacked by a second molecule of carbon dioxide with the oxygen atom as a weak electron donor (Scheme 2). Finally, the carbon dioxide acts as a



Scheme 2. Proposed reaction path for the formation of **1** and **2**.

bridging ligand to form a trimer. The products were characterized by elemental analysis, FTIR spectroscopy, and X-ray analysis. The single-crystal X-ray diffraction data confirmed the molecular structures (Figures 1 and 2).[6] The skeletons of **1** and **2** have a C_3 symmetry axis and can be viewed as composed of three equivalent motifs, each of which has a

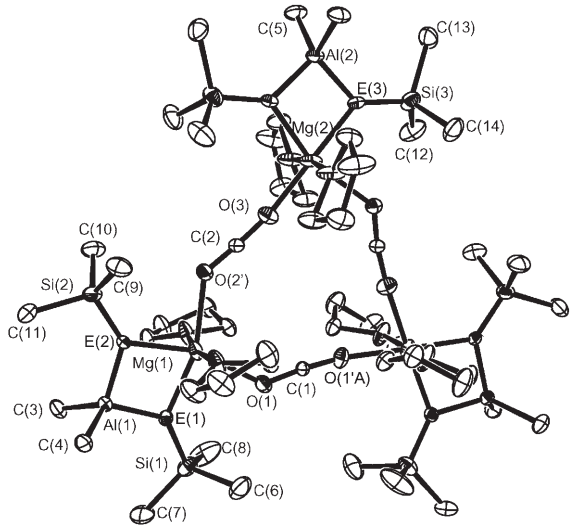

Figure 1. ORTEP view of **1** in the solid state. Thermal ellipsoids are drawn at the 20% probability level. Selected bond lengths [Å] and angles [°]: Mg(1)–O(1) 2.211(11), Mg(1)–O(2′) 2.232(12), Mg(2)–O(3) 1.944(10), O(1)–C(1) 1.208(10), O(2′)–C(2) 1.166(13), O(3)–C(2) 1.223(10); O(1′A)-C(1)-O(1) 173.6(10), O(2′)-C(2)-O(3) 175.3(8), C(1)-O(1)-Mg(1) 133.2(6), C(2)-O(2′)-Mg(1) 134.1(6), C(2′)-O(3)-Mg(2) 171.1(8), E(1)-Mg(1)-E(2) 75.53(12) E(1)-Mg(1)-O(1) 85.9(2) E(2)-Mg(1)-O(2′) 86.8(3), O(1)-Mg(1)-O(2′) 111.8(3). Atoms E(1), E(2), and E(3) were refined as mixed atoms (50% O and 50% N).

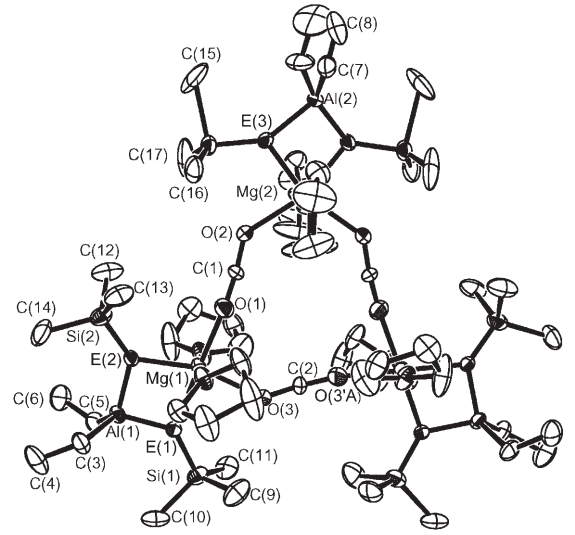

Figure 2. ORTEP view of **2** in the solid state. Thermal ellipsoids are drawn at the 20% probability level. Selected bond lengths [Å] and angles [°]: Mg(1)–O(1) 2.004(16), Mg(1)–O(3) 2.184(11), Mg(2)–O(2) 2.181(10), O(1)–C(1) 1.149(15), O(2)–C(1) 1.222(11), O(3)–C(2) 1.201(10); O(1)-C(1)-O(2) 173.3(9), O(3′A)-C(2)-O(3) 169.6(10), C(1)-O(1)-Mg(1) 171.3(11), C(1)-O(2)-Mg(2) 134.9(7), C(2)-O(3)-Mg(1) 136.9(7), O(1)-Mg(1)-E(2) 104.6(4), E(1)-Mg(1)-E(2) 76.03(13), O(1)-Mg(1)-O(3) 92.3(4), E(1)-Mg(1)-O(3) 86.9(3). Atoms E(1), E(2), and E(3) were refined as mixed atoms (50% O and 50% N).

bridged Al–Mg structure. The six-coordinate magnesium atom is linked to a four-coordinate aluminum atom by bridging $OSiMe_3$ and $NSiMe_3$ groups. Two alkyl groups are retained on each aluminum atom to attain a coordination number of four. The magnesium atoms of the three motifs are joined through three approximately linear carbon dioxide bridges to form a twelve-membered ring.

Atoms O(4)–O(6) of **1** and N(1)–N(3) of **2** were refined as mixed atoms (50% O and 50% N) due to their disorder in the $OSiMe_3$ and $NSiMe_3$ groups. The requirement for charge balance in the molecule and elemental analysis supported the assignment of these atoms. Compounds **1** and **2** have very similar skeletons.

In **1** and **2**, the Mg–O bond lengths of 1.944(10)–2.232(12) and 2.004(16)–2.184(11) Å, respectively, in the $MgCO_2$ moiety are within the range expected for such bonds (Mg←O (monodentate O donor ligand): 2.012–2.236 Å).[7] These bond lengths indicate that each oxygen atom donates a lone pair of electrons to the vacant p_z orbital of the electropositive magnesium atom in a dative bond. In other words, each carbon dioxide molecule links two magnesium atoms in a linear μ(O,O′) bonding mode. The C–O bond lengths of 1.166(13)–1.233(10) and 1.149(15)–1.222(11) Å, respectively, are very close to that of free carbon dioxide[8] and $Mn(HCOO)_3 \cdot {}^1/_2\,CO_2 \cdot {}^1/_4\,HCOOH \cdot {}^2/_3\,H_2O$,[9] and thus suggest the presence of C=O bonds. The O-C-O bond angles of 173.6(10)–175.3(8) and 169.6(10)–173.3(9)°, respectively, are close to 180° and suggest sp-hybridized C atoms. The Mg←O=C=O→Mg moieties show some disorder, with a shape like an hourglass.

The ^1H and ^{13}C NMR and IR spectroscopic data and the elemental analysis further characterized **1** and **2**.[10] The ^{13}C NMR spectra of **1** and **2** show peaks for the carbon atom of CO_2 at 120.87 and 120.76 ppm, respectively, shifted slightly upfield relative to free carbon dioxide.[11]

The IR spectra provided further strong evidence for the introduction of carbon dioxide into **1** and **2**. Compounds **1** and **2** showed strong absorption at 2267 and 2275 cm^{-1}, respectively, originating from stretching vibration of the bridging carbon dioxide. In comparison to free linear carbon dioxide (ν_{asym} 2348 cm^{-1})[12] and $Mn(HCOO)_3 \cdot {}^1/_2\,CO_2 \cdot {}^1/_4\,HCOOH \cdot {}^2/_3\,H_2O$,[9] the values are only slightly red-shifted. Decreasing CO_2 stretching frequency is an accepted measure of increasing negative charge on the Mg atom. Hence, the coordinated CO_2 molecules in **1** and **2** donate a small amount of electron density to the more electropositive Mg atoms.

In summary, we have reported a straightforward, one-pot synthetic pathway that leads to novel aluminum–magnesium complexes containing carbon dioxide in the heretofore-unknown linear μ(O,O′) bonding mode. The formation of **1** and **2** shows that interesting products can predictably be obtained when $Mg[N(SiMe_3)_2]_2$ and AlR_3 (R = Me, Et) are reacted with carbon dioxide. Investigations of the electronic and steric effects of substituents on the trialkylaluminum on the reaction with $Mg[N(SiMe_3)_2]_2$ and carbon dioxide under the same conditions are in progress.

Experimental Section

All experiments were carried out in an N_2-flushed glove bag, in a dry box, or under vacuum by using standard Schlenk techniques. All solvents were distilled and degassed prior to use. All ^1H and ^{13}C NMR spectra were measured on a Varian-500 spectrometer. Chemical shifts

are referenced to C_6D_6 (^1H, $\delta = 7.15$ ppm; $^{13}C\{^1H\}$, $\delta = 128.00$ ppm). FTIR spectra were obtained with a Bio-Rad model FTS-155 FTIR spectrometer.

1: $AlMe_3$ (2.0 M in toluene, 12 mL, 2.38 mmol) was added to a solution of $Mg[N(SiMe_3)_2]_2$ (8.21 g, 2.38 mmol) in THF (60 mL). The mixture was cooled in an ice bath, and an excess of carbon dioxide was bubbled through the stirred mixture for 2 h. An intermediate exothermic reaction ensued. The resultant solution was cooled in a freezer to give crystals of **1**. The preparation of complex **2** was similar to that of complex **1**.

1: Yield: 20%. M.p. > 112 °C (decomp). ^1H NMR (500 MHz, C_6D_6): $\delta = -0.36$ (s, 18H, $AlCH_3$), 0.34 ppm (m, 54H, $NSi(CH_3)_3$, $OSi(CH_3)_3$). $^{13}C\{^1H\}$ NMR (C_6D_6): $\delta = -5.75$ ($AlCH_3$), 3.24 ($NSi(CH_3)_3$; $OSi(CH_3)_3$), 120.87 ppm (CO_2). IR (Nujol): $\tilde{\nu} = 2267$(s), 1252(m), 1040(m), 890(s), 841(s) cm^{-1}.

Pd-Catalyzed Stereoselective Oxidation of Methyl Groups by Inexpensive Oxidants under Mild Conditions: A Dual Role for Carboxylic Anhydrides in Catalytic C–H Bond Oxidation**

*Ramesh Giri, Jue Liang, Jian-Guang Lei, Jiao-Jie Li, Dong-Hui Wang, Xiao Chen, Isaac Clement Naggar, Chengyun Guo, Bruce M. Foxman, and Jin-Quan Yu**

The selective oxidation of unactivated C–H bonds is a significant research goal because of its importance in synthesis and the chemical industry.[1] In the past few years, the development of stoichiometric σ-chelation directed C–H activation processes in catalytic reactions has met with remarkable success.[2] This approach has also yielded fruitful

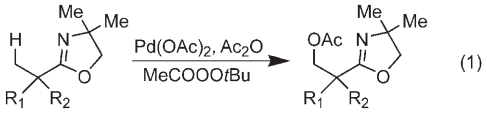
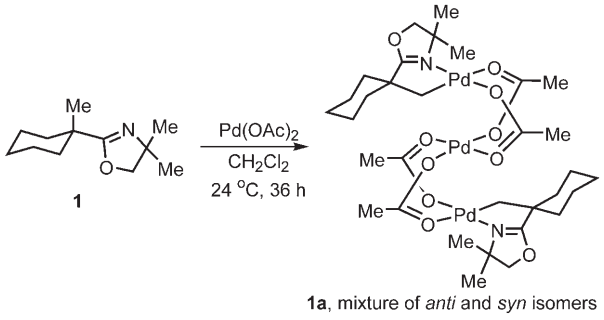
results in the oxidation of methyl groups catalyzed by transition-metal species.[3–5] Despite this significant progress, the development of practical catalytic methods to oxidize methyl groups using inexpensive oxidants under mild conditions remains an important task.

We have recently reported the use of a chiral oxazoline as the chelating group to iodinate prochiral sp^3 and sp^2 C–H bonds diastereoselectively.[6] The importance of the direct oxidation of methyl groups in synthesis turned our attention to the development of a catalytic system using inexpensive oxidants.[7] Pyridine and *O*-methyl oxime directed palladium-catalyzed acetoxylation has been recently reported using $PhI(OAc)_2$ as an oxidant.[8] Herein, we disclose a Pd-catalyzed oxidation of unactivated methyl groups using the peroxyester MeCOOO*t*Bu as the stoichiometric oxidant and Ac_2O as a crucial promoter [Eq. (1)]. Preliminary results on the diastereoselective oxidation of methyl groups using lauroyl or benzoyl peroxide as the stoichiometric oxidant are also described.



Our efforts began with the characterization of a Pd–alkyl complex formed from oxazoline directed C–H activation. The reaction of substrate **1** with 1.5 equivalents of $Pd(OAc)_2$ in CH_2Cl_2 at 24 °C for 36 h afforded a mixture of *anti* and *syn* trinuclear C(sp^3)–Pd complexes in a 3:2 ratio (Scheme 1).



Scheme 1. Formation of trinuclear C(sp^3)–Pd complex **1a**.

The molecular structure of the *anti* isomer **1a** determined by X-ray diffraction is related to a recently obtained C(sp^2)–Pd ferrocene derivative[9] and confirms earlier proposals based on ^1H NMR spectroscopic analysis (Figure 1).[6,10]

We envisioned that *tert*-butyl hydroperoxide (TBHP) would oxidize the Pd–C(sp^3) bond in **1a** to give Pd–OR complex **1b**, as TBHP/[$VO(acac)_2$] (acac = acetylacetonate) is known to insert an oxygen atom into the Pd–C(sp^2) bond of dimeric Pd–aryl complexes (Scheme 2).[11] We found that the reaction of **1a** with five equivalents of TBHP in CH_2Cl_2 at 24 °C for 36 h, followed by reduction with NH_2NH_2, afforded the hydroxylated product **1c** in 35% yield of isolated product (Scheme 2).

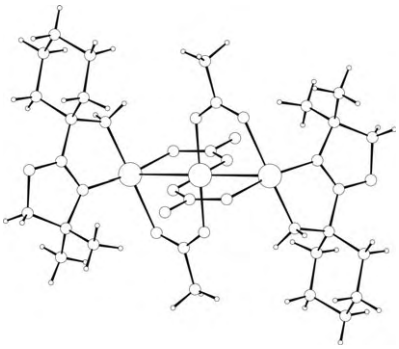


Figure 1. X-ray crystal structure of **1a**.

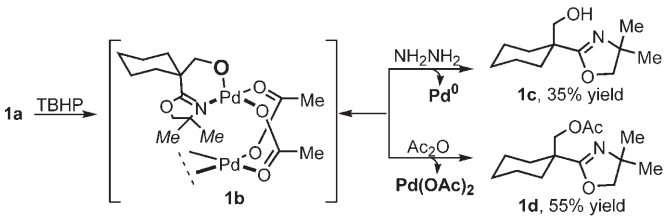

Scheme 2. Stoichiometric acetoxylation of methyl groups.

We further hypothesized that Ac_2O would acetylate the Pd–OR complex **1b** and regenerate $Pd(OAc)_2$, thereby rendering this reaction catalytic. Following the treatment of **1a** with TBHP in CH_2Cl_2 , addition of Ac_2O to the reaction mixture was found to give the product in the form of acetate **1d** and regenerate $Pd(OAc)_2$ (Scheme 2).

Carrying out this reaction with only a catalytic amount of $Pd(OAc)_2$ led us to discover that peroxyester MeCOOO*t*Bu, generated from the reaction of TBHP with Ac_2O, is an efficient oxidant for the oxidation of methyl groups. A combination of $Pd(OAc)_2$ (5 mol%) and MeCOOO*t*Bu (2 equiv) in Ac_2O was able to yield acetoxylate **1** in 71% yield.[12] A wide range of substrates are oxidized in good yields (Table 1): polar functional groups, such as ketals, imides, esters, and chlorides, are tolerated. Substrate **9** was used directly without protection of the hydroxy group, which was acetylated in the reaction. This oxidation protocol is potentially useful in the laboratory as MeCOOO*t*Bu is a cheap oxidant (TBHP: 5–6 M in hydrocarbon, $\$154\,mol^{-1}$; MeCOOO*t*Bu, 5–6 M in hydrocarbon, $\$14\,mol^{-1}$).[13]

Next, we attempted to extend this protocol to diastereoselective oxidation using a chiral oxazoline. MeCOOO*t*Bu is not compatible with a chiral oxazoline containing a hydrogen atom α to the nitrogen atom, as this hydrogen atom is readily oxidized, thus leading to the formation of an oxazole. We were delighted to find that this side reaction can be prevented by using inexpensive benzoyl or lauroyl peroxide as the oxidants (Table 2). Moderate diastereoselectivity (12–82% *de*) was observed with substrates containing prochiral methyl groups.

A chiral trinuclear C(sp^3)–Pd complex **16a** has also been obtained and characterized by X-ray studies (Figure 2). In sharp contrast to the 2:3 mixture of *syn* and *anti* complexes formed from nonchiral oxazoline **1** (Scheme 1), only the

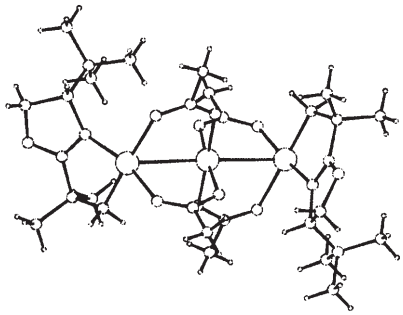

Figure 2. X-ray crystal structure of **16a**.

anti isomer was obtained from the chiral substrate **16** (Scheme 3). This result suggests that the asymmetric center on the oxazoline is crucial in the control of the geometry of the trinuclear complex. The exclusive formation of the *anti* isomer could be important for the rationalization of the observed stereoselectivity in the C–H activation step, as the *syn* isomer has a different symmetry and steric environment and could generate asymmetric centers of the opposite configuration in the C–H activation step. In future work, the crystal structures of $C(sp^3)$–Pd complexes derived from prochiral substrates, such as **15**, will be obtained and will shed further light on the stereoselectivity of the C–H activation step.

As reported previously, a mixture of $AcOH/Ac_2O$ has been used as the reaction media for Pd^{II}-catalyzed C–H activation reactions.[8,14] To the best of our knowledge, the role

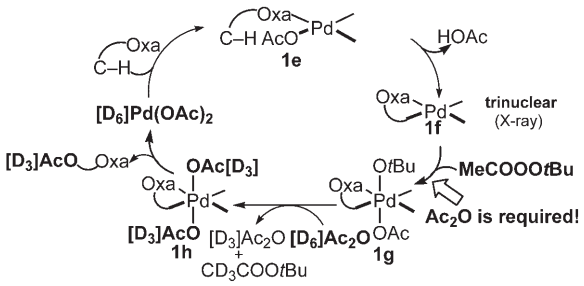
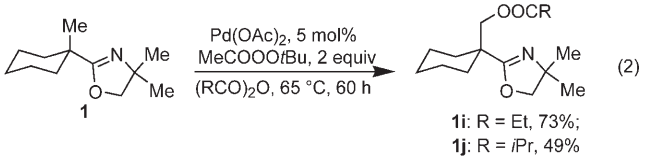
of Ac_2O remains obscure in C–H bond oxidation reactions. Isolation of the complex **1f** prompted us to investigate the influence of Ac_2O on the elementary steps of the reaction. Although no compelling evidence for the involvement of a Pd^{IV} species has been obtained in our experiments, previous characterization of a Pd^{IV} species formed upon the oxidative addition of benzoyl peroxide or aryl transfer from diphenyliodonium triflate to 2,2′-bipyridine-coordinated Pd^{II} and Pt^{II} centers allows the proposal of a plausible pathway (Scheme 4).[15] The formation of **1f** in CH_2Cl_2 was monitored



Scheme 4. Proposed catalytic cycle.

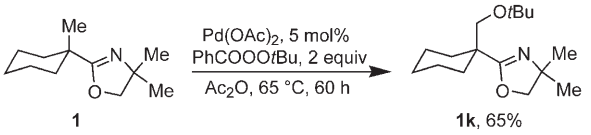
by ^1H NMR spectroscopy in the absence and presence of various amounts of Ac_2O (see the Supporting Information). The results showed that the rate was not affected by Ac_2O. The oxidative-addition step, however, was shown to require Ac_2O as no reaction of **1f** with MeCOOO*t*Bu was observed in CH_2Cl_2 at 50 °C. However, it is also possible that **1g** is in equilibrium with **1f**, largely in favor of the latter, and Ac_2O could scavenge $tBuO^-$ ions in **1g** to form **1h**, which undergoes reductive elimination.

We have also made a number of other observations that may be relevant to the mechanistic understanding of this catalytic reaction. The bridging acetate in complex **1f** undergoes rapid degenerate acetate exchange with $[D_6]Ac_2O$. The exchange process requires breaking of the μ-acetate bridge in the trinuclear complex **1f**, which could be related to the acceleration of the oxidative addition. The use of $[D_6]Ac_2O$ as a solvent also shows that the acetate or acetyl group from acetic anhydride, rather than from the oxidant, is incorporated predominantly into the product. The use of other anhydrides, such as propionic and isobutyric anhydrides, consistently affords the corresponding carboxylates [Eq. (2)].



(2)

This result further suggests that the acetate ligand at the apical position of the octahedral Pd^{IV} complex **1g** also rapidly exchanges with carboxylic anhydrides to give **1i** or **1j** prior to reductive elimination. Interestingly, when PhCOOO*t*Bu is used as an oxidant, the ether product **1k** was formed predominantly [Eq. (3)], which could be explained by assuming that the $PhCOO^-$ ion is less labile than the $tBuO^-$ ion in the octahedral intermediate analogous to **1g**.



(3)

The use of lauroyl peroxide or benzoyl peroxide as the oxidant has led us to identify a second role for Ac_2O. The reaction of **1f** with both peroxides proceeds to give the acetoxylated products in the absence of Ac_2O. However, the presence of Ac_2O is essential for the catalytic turnover. Measurement of the reaction rate by GC using 20 mol% $Pd(OAc)_2$ shows that the reaction in the first 10% conversion is not influenced by the addition of Ac_2O, but does not proceed further after 15% conversion in the absence of Ac_2O. This result suggests that Ac_2O is crucial for the regeneration of the reactive $Pd(OAc)_2$, as shown in Scheme 4.

In summary, the inexpensive oxidant MeCOOO*t*Bu is shown to oxidize unactivated methyl groups in the presence of a catalytic amount of $Pd(OAc)_2$ under mild conditions. The diastereoselective oxidation of methyl groups is also achieved in moderate diastereoselective excess (*de*) by using lauroyl or benzoyl peroxide as the oxidant. Investigations into the reactivity of the characterized trinuclear Pd–alkyl complex indicated a crucial dual role for anhydrides in C–H bond oxidation. Further efforts are being directed towards the characterization of crystal structures of $C(sp^3)$–Pd complexes derived from prochiral substrates to explain the stereoselectivity shown.

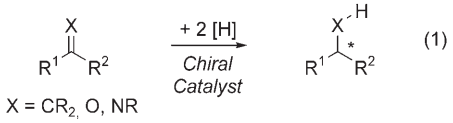
A Powerful Brønsted Acid Catalyst for the Organocatalytic Asymmetric Transfer Hydrogenation of Imines**

*Sebastian Hoffmann, Abdul Majeed Seayad, and Benjamin List**

The catalytic hydrogenation of alkenes, ketones, and imines is arguably one of the most important transformations in chemistry. Powerful asymmetric versions have been realized that require metal catalysts or the use of a stoichiometric amount of metal hydrides [Eq. (1)].[1]



Although effective and industrially relevant catalytic asymmetric hydrogenations and transfer hydrogenations of olefins and ketones have been developed, the corresponding imine reductions, although potentially highly useful for the synthesis of enantiomerically pure amines, are less advanced.[2] Living organisms employ organic dihydropyridine cofactors such as nicotinamide adenine dinucleotide (NADH) in combination with enzyme catalysts for the reduction of imines.[3] Chemical transition metal catalyzed asymmetric imine reductions have also been developed,[4] and are used, in at least one case, on an industrial scale.[5] However, with the exception of interesting Lewis base catalyzed asymmetric imine hydrosilylations,[6] organocatalytic and metal-free variants were not known. Recently, we and MacMillan and co-workers developed an asymmetric transfer hydrogenation of α,β-unsaturated aldehydes catalyzed by a chiral ammonium salt by using Hantzsch esters as a biomimetic hydrogen source.[7] Rueping et al.[8] very recently reported the development of a novel and elegant approach using Hantzsch esters as the reducing reagent for the catalytic asymmetric reduction of imines using a chiral Brønsted acid catalyst previously developed by Akiyama et al.[9,10] We now report parallel and independent studies from our laboratory

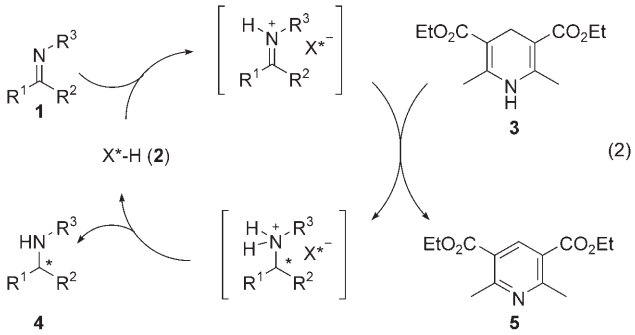
on the same reaction that resulted in the development of a significantly improved new catalyst for the highly efficient and enantioselective transfer hydrogenation of ketimines catalyzed by Brønsted acids.[11]

In pioneering studies, the research groups of Akiyama[10] and Terada[11] recently introduced relatively strong chiral phosphoric acid catalysts for asymmetric addition reactions to aldimines as a new strategy for organic catalysis.[12,13] Inspired by these studies, and the recent observation that imines are reduced with Hantzsch esters in the presence of achiral Lewis or Brønsted acid catalysts,[14] we envisioned a catalytic cycle which is initiated by protonation of ketimine **1** from a chiral Brønsted acid catalyst **2** [Eq. (2)]. The resulting iminium ion pair, which may be stabilized by hydrogen bonding, is chiral and its reaction with the Hantzsch dihydropyridine **3** could give an enantiomerically enriched amine **4** and pyridine **5**.



(2)

With this idea in mind, we synthesized and screened a variety of chiral phosphoric acid catalysts for the reduction of imine **1a** in the presence of Hantzsch ester **3** [Eq. (3), Table 1].[15]

Although the commercially available phosphoric acid **2a** clearly showed turnover, the enantioselectivity was low (entry 1). Increasing the steric bulk of the catalyst by adding aromatic substituents at the 3,3′-positions of the binaphthol core significantly increased the enatioselectivity but generally reduced the turnover (entries 2–9). The highest *ee* value (81%) was achieved with the new sterically congested phosphoric acid catalyst **2i**. Although the yield of **4a** was low (10% after 20 h), the only remaining material was the starting imine **1a**.

After further optimization of the reaction, which included changing the solvent from dichloromethane to toluene, increasing the temperature from RT to 35°C, and lowering the catalyst loading from 10 mol% to only 1 mol%, the *ee* value of the product **4a** could be further improved to 88% and with an excellent yield of 96% [Table 2, entry 1]. These conditions have been applied to several substituted aromatic ketimines **1a–j** and one aliphatic imine **1k** with good to excellent results [Eq. (4), Table 2].

Remarkably high yields were achieved in all cases, while the *ee* values were generally very good (80–93%). The highest yield was achieved with *p*-methyl-substituted imine **1f**, which provided amine **4f** in 98% yield (entry 6). *o*-Methyl-substituted imine **1h** gave the highest enantioselectivity and furnished amine **4h** with 93% *ee* (entry 8). Functional

groups (-NO_2, -F, -CN, -OMe) are tolerated well, although the full scope of the reaction has yet to be established. Remarkably, even an aliphatic imine (**1k**) could be used to give amine **4k** with high enantioselectivity (90% *ee*).

A similar study by Rueping's research group using Akiyama's phosphoric acid catalyst appeared during the preparation of this manuscript.[8,10b] However, our reaction times are generally shorter (42–71 h versus 72 h), our temperature is lower (35°C versus 60°C), our yields (80–98% versus 46–91%) and *ee* values (80–93% versus 68–84%) are higher, and most importantly our catalyst loading is much lower (1 mol% versus 20 mol%). Moreover, we can also reduce aliphatic ketimines highly enantioselectively while Rueping et al. only provided aromatic examples.

Imine generation and its reduction can also be performed in situ in the presence of molecular sieves. The *ee*-conserving

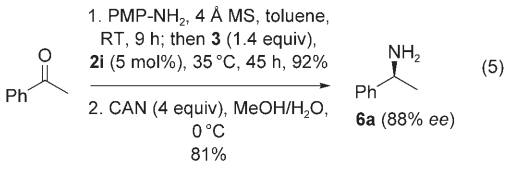
oxidative removal of the *p*-methoxyphenyl (PMP) group to give amine **6a** is well established [Eq. (5); CAN = cerium(IV) ammonium nitrate].[4i]



(5)

In summary we have developed an efficient organocatalytic asymmetric ketimine reduction using chiral phosphoric acid derivative **2i** in the presence of the commercially available Hantzsch ester **3**. Remarkable features of our process include a) its high yields and enantioselectivities, b) its scope, including both aliphatic and aromatic amines, c) its simplicity and practicability (in situ generation and reduction of imines), and d) the remarkably low catalyst loading, which so far is unprecedented in asymmetric Brønsted acid catalysis. Further extension of this methodology is ongoing and will be reported shortly.

Experimental Section

General procedure for the asymmetric transfer hydrogenation reaction**:** A mixture of imine **1** (0.4 mmol), Hantzsch ester **3** (142 mg, 0.56 mmol, 1.4 equiv), and phosphoric acid **2i** (3 mg, 0.004 mmol) in toluene (4 mL) was stirred at 35 °C in an argon atmosphere for 42–71 h. The solvent was evaporated at reduced pressure and the products were isolated by flash chromatography (SiO_2, ethyl acetate/hexane) to give pure amines **4**. The *ee* values were determined by using established HPLC techniques with chiral stationary phases.

enables their application in the development of immobilized enzyme processes[2] and the construction of magnetically controllable bio-electrocatalytic systems.[5,6] Herein, we demonstrate the use of immobilized enzymes in NMMs for magnetically switchable bio-electrocatalysis.

Magnetic mesoporous carbons, in which magnetic nanoparticles (MNPs) are incorporated into the mesoporous carbon matrix, have many desirable characteristics for preparation of immobilized enzymes for magneto-bio-electrocatalysis: large pore size and volume, the ability to be positioned with a magnet, and good electron conductivity. Herein, we synthesized magnetic mesocellular carbon foam by a simplified approach based on the in situ generation of MNPs during the synthesis of the mesocellular carbon. The resulting material, designated Mag-MCF-C, was found to possess large interconnected pores and well-dispersed MNPs. Glucose oxidase (GOx) was immobilized within the large cellular pores of Mag-MCF-C, and the resulting material was used for the construction of a magnetically switchable bio-electrocatalytic system.

The operating principle of magnetically switchable bio-electrocatalysis is illustrated in Figure 1a.[6a] When the enzymes in the Mag-MCF-C particles in a solution containing substrate (glucose) were brought into contact with the electrode by means of a magnet placed below the electrode, an anodic current was generated by electron transport from the enzyme reaction to the working electrode (switched "on"). Conversely, when positioned above the electrochemical cell, the magnet attracted the Mag-MCF-C particles away from the electrode, and the electron-transfer efficiency was significantly lowered, and the current decreased to the background level (switched "off"). By alternate positioning of an external magnet, the bio-electrocatalytic signal could be reversibly switched back and forth between the on and off states.

Various nanoporous carbon materials have been prepared using nanostructured silica materials[7] as sacrificial templates.[8] The typical synthetic procedure for Mag-MCF-C is based on a template approach and is presented schematically in Figure 2a. MCF silica[9] was used as a template, and its surface area and pore volume were estimated by the BET method to be 574 $m^2 g^{-1}$ and 1.86 $cm^3 g^{-1}$, respectively. The cellular and window (percolation-path) pore sizes determined from the adsorption and desorption branch were 24.0 and 12.3 nm, respectively (see Supporting Information). After the polymerization of divinylbenzene (DVB), the main cellular pores of the MCF silica were partially filled by a poly(DVB) coating.[10] The BET surface area of the MCF/poly(DVB) composite was reduced to 138 $m^2 g^{-1}$, which indicates that complementary micropores in the walls of the MCF silica were filled with poly(DVB).[11] Also, the decreased cell size of 19.1 nm (see Supporting Information) indicates that poly(DVB) coatings of approximately 2.5 nm thickness were formed in the main cells of the MCF silica. The next step was impregnation of $Fe(NO_3)_3 \cdot 9H_2O$ dissolved in ethanol into the pores of the MCF/poly(DVB) composite. The Fe^{3+} ions present on the poly(DVB) surface were converted into magnetic nanoparticles during the carbonization at 800 °C. Finally, the dissolution of the MCF template in 1 M NaOH at

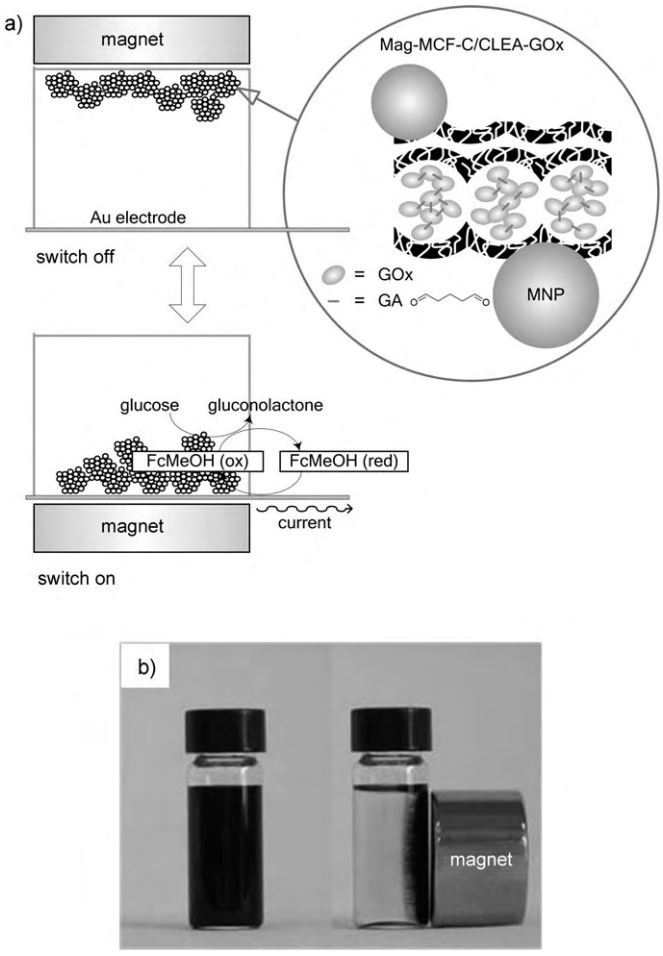

Figure 1. a) Working principle of the magnetically switchable bio-electrocatalytic oxidation of glucose by GOx immobilized in Mag-MCF-C. b) The separation of Mag-MCF-C/CELA-GOx particles by an applied magnetic field. The image shows a well-mixed suspension of Mag-MCF-C/CLEA-GOx in 0.1 M sodium phosphate buffer (ca. 10 mg mL^{-1}) before (left) and after (right) the application of a magnetic field.

100 °C yielded the magnetic mesocellular carbon foam Mag-MCF-C. The simplification of the synthetic procedure for Mag-MCF-C was attributed to the solid-state conversion of the impregnated iron salt into MNPs during the carbonization.[12] This method is in contrast with the recently reported multistep synthetic route to magnetic CMK-3 requiring separate steps for synthesis and postsynthetic deposition of the MNPs onto the carbon, and an additional carbonization step to cap the MNPs to prevent leaching.[13]

The field-emission scanning electron microscopy (SEM) image showed that the Mag-MCF-C particles had many large mesopores (see Figure 2b) open to the exterior, which was favorable for the quick incorporation of large biomolecules. The cellular mesopores were also observed in the transmission electron microscopy (TEM) image of Mag-MCF-C (Figure 2c). The cell sizes estimated from the adsorption branch of the argon isotherm were centered at 16.6 nm (Figure 3c). The window (percolation-path) sizes determined from the desorption branch were centered at 10.1 nm. The BET surface area and the single-point total pore volume were

AIBN = azobisisobutyronitrile.

revealed to be 865 $m^2 g^{-1}$ and 1.43 $cm^3 g^{-1}$, respectively. The MNPs formed in situ were found to be well dispersed over the Mag-MCF-C surface (see inset of Figure 2c). The TEM (Figure 2c) and SEM images at high magnification (Supporting Information) showed clearly that the magnetic nanoparticles were formed on the external surface of the MCF-C. The iron content of the Mag-MCF-C measured by inductively coupled plasma atomic-emission spectroscopy (ICP-AES) was 26.9 wt%. The X-ray diffraction (XRD) pattern of Mag-MCF-C showed that body-centered-cubic (bcc) iron (α-Fe) nanoparticles with an average diameter of 30 nm, estimated by using the Debye–Scherer equation, were well dispersed in the mesocellular carbon foam matrix (see Supporting Information). The XRD pattern also showed small peaks attributable to magnetite, which demonstrates that the iron was partially oxidized during the NaOH etching process. Further characterization by means of TEM, convergent-beam electron diffraction (CBED), and energy-dispersive X-ray spectroscopy (EDX) showed that the nanoparticles had an Fe/Fe_3O_4 core/shell structure. The formation of large, 30-nm sized particles, which are larger than the cell diameter of MCF-C, seems to be due to sintering of the initially synthesized small nanoparticles on the surface of the mesocellular carbon foam during the carbonization at high temperature.

The magnetization curves (see Supporting Information) exhibited hysteresis over the complete temperature range of the measurements from 325 K down to 2 K, which demonstrates the ferromagnetic character of Mag-MCF-C at room temperature. The zero-field cooled and field-cooled magnetization data measured in an applied field of 100 Oe also revealed that Mag-MCF-C is ferromagnetic at room temperature (Supporting Information). This ferromagnetic property, derived from the large size of the magnetic nanoparticles, turned out to be very important to the facile and fast migration of the nanoparticles to a desired position by means of an external magnetic field (see below). The saturation magnetization value was 8.5 emu g^{-1} at 300 K, which was sufficient for magnetic separation. Furthermore, the remnant magnetization was low (< 1 emu g^{-1}), which was important for the easy redispersion of the Mag-MCF-C particles when the magnet was removed.

To demonstrate the utility of Mag-MCF-C in the construction of a magnetically switchable bio-electrocatalytic system, glucose oxidase (GOx), which is a well-studied redox enzyme, was immobilized within the Mag-MCF-C particles. A schematic representation of Mag-MCF-C with immobilized and cross-linked GOx in the large mesocellular pores is presented in Figure 3a. From the molecular dimensions of GOx ($6.0 \times 5.2 \times 7.7$ nm^3),[14] it was expected that the enzyme molecules would easily enter the large cellular pores (16.6 nm) of Mag-MCF-C through the connecting windows (10.1 nm). In fact, the amount of argon adsorbed in Mag-MCF-C was found to be significantly decreased after loading with GOx (Figure 3b), which indicates that most of the GOx molecules were incorporated into the pores of Mag-MCF-C, especially into its large cellular pores (Figure 3c). The adsorption isotherm of GOx-immobilized Mag-MCF-C (see Supporting Information) shows a maximum loading of about 53% (w/w carbon). Equilibrium was reached after a 5 h incubation period (see Supporting Information). Notably, the isotherm obtained did not conform to the Langmuir-type with an almost-linear increase in loading with initial increase in enzyme concentration. The results suggest that the immobilization mechanism involves the entrapment of enzymes in the mesocellular pores of the Mag-MCF-C particles rather

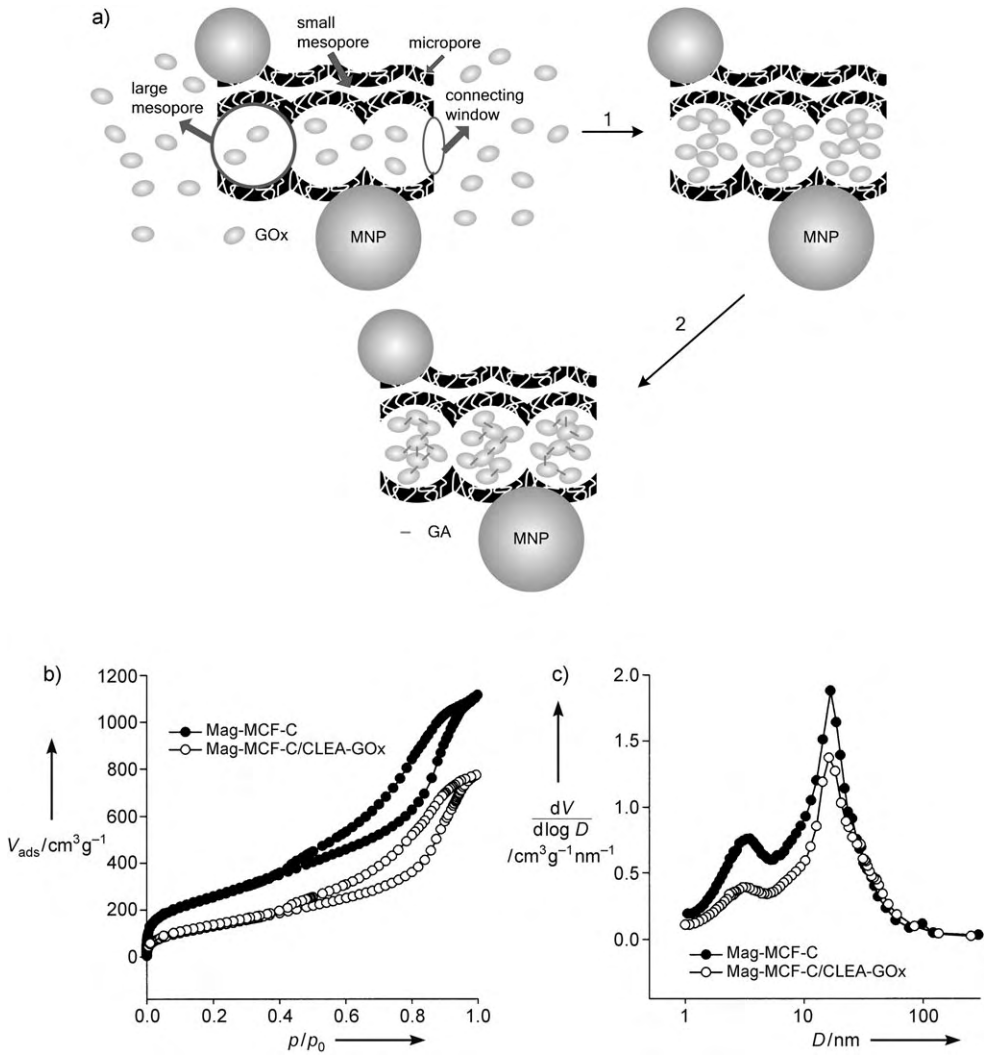

Figure 3. a) Schematic representation of Mag-MCF-C with immobilized and cross-linked GOx in large mesocellular pores. Also depicted are the incorporated MNPs and the small pores: adsorption of GOx in the mesocellular pores of Mag-MCF-C (1); cross-linking of GOx using glutaraldehyde to make enzyme aggregates (2). b) Argon-adsorption-desorption isotherms and c) pore-size distributions (PSDs) of Mag-MCF-C and Mag-MCF-C/CLEA-GOx. The PSDs were calculated from Ar adsorption data by using the Barrett–Joyner–Halenda (BJH) method. The amount of adsorbed argon was significantly reduced after loading of GOx.

than the adsorption of enzymes on the carbon surface. It was observed that the migration of the GOx-immobilized Mag-MCF-C (Mag-MCF-C/GOx) under the same strength of external magnetic field slowed down somewhat as the GOx loading increased. Consequently, Mag-MCF-C/GOx with a GOx loading of approximately 30% was used in this study to take into account the migration of Mag-MCF-C/GOx by a magnet.

The enzymes in the pores were stabilized through cross-linking with glutaraldehyde (GA).[15] As Mag-MCF-C consisted of 17-nm mesocellular pores connected with 10-nm window pores, we anticipated that the smaller size of the window pores would prevent the leaching of the cross-linked enzyme aggregates (CLEAs) and result in high enzyme loading and good enzyme retention (see Figure 3a).[15] As a result of the cross-linking, Mag-MCF-C/CLEA-GOx maintained more than 90% of its initial activity after 12 washings as well as after continuous incubation with vigorous shaking for 22 days, whereas only approximately 50% activity was retained for GOx immobilized in Mag-MCF-C without cross-linking after shaking for 22 days (see Supporting Information for experimental details). This observation suggests that the cross-linking of the enzyme was effective in improving its operational stability by preventing leaching of the enzyme from the Mag-MCF-C composite. On the basis of these results, cross-linked Mag-MCF-C/CLEA-GOx was used for the following experiments.

The specific activity of CLEA-GOx within Mag-MCF-C (45.8 ± 7.5 U per mg GOx) was estimated to be 29% of that of free GOx in buffer (155.5 ± 12.5 U per mg GOx). This 29% recovery of activity was quite impressive when the high concentration of GOx in the pores (384 mg mL^{-1}, see Supporting Information for the detailed calculation) and possible enzyme inactivation during cross-linking by GA is considered.

It was expected that the unique pore structure of the host Mag-MCF-C could relieve the mass-transport resistance: MCF-C had a variety of pore interconnections that facilitated the transport of substrate and products as shown schematically in Figure 3a. The small mesopores (diameters around 3.0 nm), which were generated by dissolution of the silica template, were too small to accommodate GOx but large enough to accommodate small molecules such as the substrate and products and thus provide "substrate transport channels". Micropores with an average diameter of around 0.7 nm (see Supporting Information) present throughout the carbon framework[16] might also provide a route for the transport of small molecules by connecting the small and the large mesopores.

Suspended Mag-MCF-C/CLEA-GOx particles were quickly attracted in the direction from which the external magnetic field was applied (see Figure 1b), which confirmed the utility of Mag-MCF-C in magnetically controllable sensing systems such as the one presented in Figure 1a. The heavily loaded, active, and stable Mag-MCF-C/CLEA-GOx composite was used for magnetically switchable bio-electrocatalysis (see Figure 1a). Figure 4a shows cyclic voltammograms obtained when the magnet was placed in the "up"

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

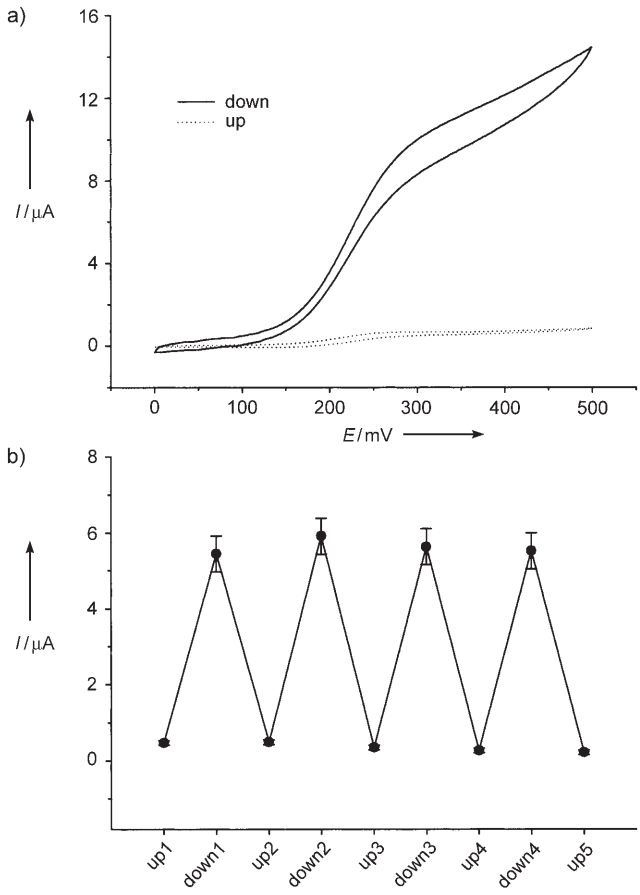

Figure 4. a) Cyclic voltammograms measured with the magnet in the "down" (Mag-MCF-C/CLEA-GOx near the electrode surface) and "up" (Mag-MCF-C/CLEA-GOx away from the electrode surface) positions. The voltammetry was performed in an electrochemical cell (4 mL) containing deoxygenated 0.1 M sodium phosphate buffer (pH 7.4) with 0.1 mM ferrocenemethanol and 5 mg of Mag-MCF-C/CLEA-GOx in the presence of 20 mM glucose. All the measurements were performed at room temperature with a scan rate of 5 $mV s^{-1}$. b) Current switching during the shuttling of the magnet between the "up" and "down" positions. The experimental conditions were the same as those described in (a).

(above the electrochemical cell) and "down" (below the electrode) positions, respectively, in the presence of 20 mM glucose. As expected, a significant increase in anodic current was observed when the Mag-MCF-C/CLEA-GOx particles were brought into contact with the electrode by a magnetic field. No such current was observed after the Mag-MCF-C/CLEA-GOx particles were pulled up by the magnet, even in the presence of glucose.

To check the reusability of Mag-MCF-C/CLEA-GOx and the reversibility of the current switching, bio-electrocatalytic oxidation of glucose was alternately repeated in the on and off states by cyclic placement of the magnet below and above the electrochemical cell. As shown in Figure 4b, anodic currents could be reversibly switched between the on and off states, and a constant signal was maintained in the on state. The magnetic capturing was also very quick; the positioning of most of the Mag-MCF-C/CLEA-GOx particles could be generally completed within 30 seconds. No catalytic current was observed even after the magnet was placed in the "up" position (off state) for several hours, which confirms that GOx was effectively retained within the Mag-MCF-C particles and leaching of the immobilized GOx was negligible, as observed earlier. The exceptional stability of the Mag-MCF-C/CLEA-GOx particles and the ability to easily control their placement by an external magnetic field allowed the construction of a highly effective magnetically switchable bio-electrocatalytic system showing a constant signal upon iterative switching.

In conclusion, we have demonstrated that the magnetic mesocellular carbon foam Mag-MCF-C can be synthesized through a simple synthetic method and used for the fabrication of a magnetically switchable bio-electrocatalytic system. The cross-linked GOx in the mesocellular pores of the Mag-MCF-C particles exhibited a high enzyme loading capacity and exceptional stability. Such advantageous characteristics of Mag-MCF-C/CLEA-GOx together with controlled positioning by an applied magnetic field were successfully utilized in the development of this system. From these results, it is anticipated that our approach will find various applications, such as bioconversion, reversible amperometric immunosensors, regeneration of enzyme electrodes, switchable biofuel cells, and site-specific immobilization of sensing elements in microsized sensing devices.

Harder than Diamond: Determining the Cross-Sectional Area and Young's Modulus of Molecular Rods

*Lior Itzhaki, Eli Altus, Harold Basch, and Shmaryahu Hoz**

The rapidly growing area of nanotechnology has provoked much interest in the various moduli of elementary building blocks at the nano/molecular level. Among these moduli, the most frequently discussed is probably Young's modulus, and we describe here the derivation of Young's modulus for two molecular rods, namely polyynes (**1**) and [*n*]staffanes (**2**, poly-1.1.1-propellanes; see Figure 1)[1].

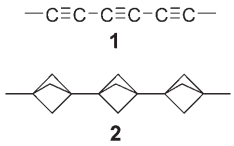

Figure 1. Sections from polyyne (**1**) and [*n*]staffane (**2**).

Given the force applied to a structure, Young's modulus (Y) can be calculated provided the area (A) to which force is applied is known. This, of course, is in addition to the deformation (ΔL) in the length (L) according to Equation (1).[2]

$$\frac{F}{A} = \frac{Y\,\Delta L}{L} \tag{1}$$

In the case of longitudinal compression of a solid homogeneous rod, the effective cross-sectional area (CSA) is the physical cross-sectional area of the rod. However, in the case of a unidimensional molecular rod such as polyyne, the effective cross-sectional area is not easily defined. The definition must rest heavily on our understanding of the nature of matter. In most cases, matter is associated with mass, therefore if the force is exerted on the mass, then the relevant dimension would be the cross-sectional area of the carbon nucleus. On the other hand, since any physical contact, including a punch thrown in a boxing ring, is in fact an interaction between electron clouds, one should consider the CSA of the electron cloud. It is, however, "already apparent from the nature of the wavefunction for atoms and ions that

they have no definite size."[3] Thus, the radius, like the partial atomic charge in polar molecules, although intuitively a very appealing concept, is not physically observable. Moreover, it is difficult to justify the use of any of the commonly applied radii such as the ionic, covalent, or the van der Waals radii for the electronic cloud in this context.

In the present work we have succeeded in calculating the effective cross-sectional area and the Young's modulus of a polyyne molecular rod using a combination of quantum mechanical and classical mechanical engineering tools. Our approach is based on the fact that longitudinal compression of a rod will eventually lead to its buckling. As we know that the larger the cross-sectional area of the rod the more it will resist buckling, there must be a correlation between the critical point of the collapse (buckling) and the surface area of the rod. This investigation was performed using the following procedure: In the first step, the structure and the energy of a given polyyne was calculated using the Gaussian 03 program at the B3LYP/6-31G level.[4] Next, the fixed distance between the two terminal carbon atoms was gradually reduced and the energy was optimized at each step with respect to the other structural parameters. These data were inserted into Equation (1), where F is the derivative of the energy (E) with respect to L (the distance between the two terminal carbons in the unconstrained system), and ΔL is the change of this distance upon going to the constrained structure, to give YA. This is the analog to a unidirectional loading of a rod in mechanical engineering terminology.

Further compression of the rod leads to buckling. At the onset of buckling we have the Euler relation [Eq. (2)],[5] which is the solution for a simply supported column under compression.

$$F = \frac{\pi^2 Y I}{L^2} \tag{2}$$

In this equation, I is the minimal static moment of inertia. YI can be calculated from this equation. The square root of the ratio YI/YA ($=I/A$) is equal to the radius of gyration, ρ, which in turn is equivalent to half of the radius, r, of the rod. r, Y, and I are given for a series of polyyne molecular rods in Table 1.

It should be pointed out that the values in Table 1 are not exact since they contain the approximations assumed in the mechanical engineering equations and the approximations used in the various definitions, in addition to the fact that the structure optimization was done using the default parameters of the Gaussian program. Regarding the definitions used, the buckling point was defined as the point at which one of the CCC angles decreased below 179°, and the energy before the critical point for Equation (1) was taken uniformly to be 0.1 % of the original length of the rod. The energy after the buckling was taken at a compression of 0.1 Å from this point. A change in these definitions, such as taking the buckling point as the geometry at which one of the CCC angles crossed the 178° value, rather than 179°, or varying the distances mentioned above by 50 %, changed the final value of the radius by less than 4 %. The direction of the buckling is governed by minor differences in the significant figures of the forces in the perpendicular directions.

It should be noted that the sensitivity to the basis set is rather low. The radius of the C_{10} polyyne was also calculated after addition of diffuse functions or d orbitals and the values obtained were 0.34 and 0.36 Å, respectively, instead of 0.35 Å.

An alternative method to calculate YI is by replacing the "buckling method" (first method in Table 1) with one based on a bending mode (Figure 2). Here, the two terminal carbons

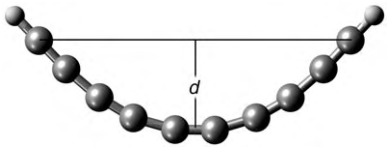

Figure 2. Bending mode for a C_{10} polyyne rod.

are restricted to a given axis and the center of the rod is forced to a point below this axis. The relation between YI and d for a small deformation is given by Equation (3)[6].

$$YI = \frac{F L^3}{48\, d} \tag{3}$$

Again, the aforementioned combination of YI and YA yields the effective radius of the rod. The data obtained using this procedure are also given in Table 1 (second method). The close resemblance of the two sets of values, in spite of the approximations involved in the mechanical engineering equations, is highly encouraging.

Thus, a physical parameter that was previously considered unobservable is quantitatively determined here. It is worth noting that we have obtained the cross-sectional area of the rod by interweaving two entirely different methodologies, none of which contains, either implicitly or explicitly, any value related to the effective radius of the rod. It is left for future studies to see how this value relates to the various π and σ components of the electronic wavefunctions.

An immediate outcome of this result is, of course, that if the cross-sectional area of a carbon atom in a nanotube, for example, is anywhere near that of our molecular rod the Young's modulus calculation for nanotubes[7] should be corrected accordingly.

Another interesting outcome of this study is the actual value of the Young's modulus of the acetylenic rod (Table 1). It turns out that our calculated Y is around 40 times larger than that of the hardest known material—diamond—whose Young's modulus is 1063 GPa ($Pa = N\,m^{-2}$).[8] The observed Young's modulus of a material is usually a result of the Young's modulus of the molecules of which it is comprised, their relative alignment, and the intermolecular voids. Since diamond can be viewed as a single molecule, having results for these two molecules provides, for the first time, an opportunity to examine the connection between Young's modulus and basic molecular parameters. A major difference between diamond and polyyne is the strength of the bonds involved. While the bonds in the latter are sp fortified by π bonding, the carbon atoms in diamond are interconnected by a series of much weaker sp^3-hybridized bonds. Although the issue is somewhat controversial, it seems that polyyne enjoys further strengthening due to conjugation, which is absent in diamond.[9] The hardness of the acetylenic rod stems, therefore, from the steeper potential functions of the bond, where a small compressional motion along its longitudinal axis results in a sharp rise in energy, namely higher resistance to a change in the position of the nuclei.

Since diamond has a three-dimensional network of bonds it is difficult to carve a unidirectional rod from it. One would like to simulate a rod of diamond in the sense of having a core repeating unit of the rod consisting of sp^3-hybridized carbon atoms, and [*n*]staffanes **2** seem to serve as a close model for this purpose. All carbons in the 1.1.1-bicyclopentane unit have a hybridization ranging from $sp^{3.3}$ to $sp^{2.5}$ for the internal C–C bonds, whereas the hybridization of the external bond has a somewhat lower p character ($sp^{2.1}$). Like in diamond, all four bonds of the carbon atoms along the axis of the rod participate in resisting deformation. The degree of flexibility that is acquired by bond-angle deformation in the bridges can also be found in diamond. Consequently, we have calculated the effective radius, Y, and I, using the compression/buckling method, for rods consisting of three and four bicyclopentane units, assuming that they will display a hardness similar to that of diamond.

Table 2: Radius, Young's modulus, and the static moment of inertia for [*n*]staffane rods.

n	Radius [Å]	$Y \times 10^{-12}$ [$N\,m^{-2}$]	$I \times 10^{41}$ [m^4]
3	0.78	4.9	2.9
4	0.73	5.6	2.3
Av.	0.76 ± 0.02	5.3 ± 0.3	2.6 ± 0.3

The data presented in Table 2 show, as expected, that the [*n*]staffanes' Young's modulus is close to that of diamond (around five times larger) and that its effective radius (approximating it to be a cylindrical rod) is, as expected, larger than that of a rod comprised of acetylene units.

As regards Young's modulus, one can conclude that, since among the sp-, sp^2-, and sp^3-hybridized bonds the sp^3 bond of diamond is the weakest one, some organic compounds may display a rigidity higher than that of diamond, although only along a single axis. The uniqueness of diamond stems from the fact that it displays the same strength in all directions. On the other hand, the uniqueness of polyyne is explained by the fact that it consists of the strongest bonds among the three groups of hybridization and therefore we expect that it will be very difficult to break its record in hardness, at least within the realm of carbon-based rods.

In light of the fact that no material significantly stronger than diamond has been synthesized up to now,[10] a very interesting option in three dimensions is a diamond in which two carbon atoms are connected not by a σ (sp^3) bond but by an acetylenic unit.[11] The building block of such a structure—triethynylmethane $C(C{\equiv}CH)_4$—was successfully synthesized[12] and studied computationally.[13] Although it is likely that the large voids in the "yne diamond" will take their toll on the overall hardness, it is possible that the large difference in the nature of the constituent bonds will more than overcome this deficiency. Although the hybridization of the corner carbon atoms remains sp^3, the sp^3–sp bond is significantly stronger than the sp^3–sp^3 bond and, as was shown recently by Schleyer and Houk,[9a] this bond is further stabilized by the neighboring triple bond. The internal radius of the adamantane cavity in the yne-diamond is about 2.16 Å (3.86 Å less the van der Waals radius of carbon). Chelation of an inert gas atom of the right size in this cavity will no doubt overcome the aforementioned problem of the internal voids. Based on its van der Waals radius, Xe ($r = 2.16$ Å) seems to be the element of choice (Figure 3). The synthesis of the yne-diamond is, however, an immense task to fulfill, and filling its yne-adamantane cavities with Xe, which will significantly increase its stiffness,[14] is also a colossal challenge.[15]

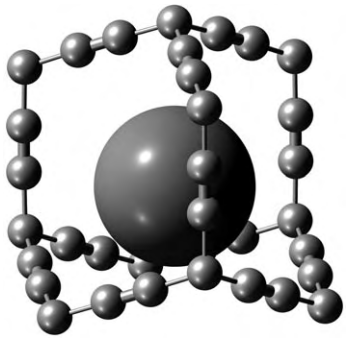

Figure 3. Yne-adamantane unit of yne-diamond containing a Xe atom. The size of the carbon atoms has been reduced to enable a better view.

[14] Young's modulus is, in fact, the measure of stiffness that is commonly referred to as hardness. However, in materials science, hardness is measured as the deformation caused by the indenting tip. Yet, hardness and Young's modulus are closely related, and diamond has the highest known Young's modulus.

"Hexacarboxytrindanes": Benzene Rings with Homotopic Faces as Scaffolds for the Construction of D_3 Chiral Architectures**

Giuseppe Borsato, Marco Crisma, Ottorino De Lucchi, Vittorio Lucchini,* and Alfonso Zambon*

The advantages offered by high-symmetry chiral molecules are largely recognized in asymmetric synthesis[1] and can be readily applied in several other fields (e.g., material science, liquid crystal technology, and nanoscience). For example, in asymmetric synthesis high symmetry can enhance chiral recognition because of the reduction in the number of the possible diastereomorphic transition states, the equivalence of the functionalities, and the improvement of the ratio between the functional groups and the chiral framework.[2] Other advantages are offered by the opportunities for metal multi-coordination or high metal loading, the simplification of the spectral features, high crystallinity, and so forth. These features can benefit the design of highly efficient catalysts.

Although C_2-symmetrically chiral molecules, exemplified by binaphthol and its derivatives,[3] are quite popular, and chiral structures that possess C_3 symmetry do not attract a lot of attention but are nevertheless numerous,[4] chiral compounds with D_3 or higher symmetry are less common. Within the field of organic chemistry, the following classes of D_3 chiral structures have been reported: perhydrotriphenylenes,[5] trishomocubanes,[6] cyclotriveratrylenes,[7] macrocyclic alkanes, polyethers and polyesters with three groups of strategically positioned substituents,[8] and fullerenes.[9] Other high-symmetry chiral molecules are represented by benzene rings joined (through at least three bonds) with six homotopic centers.[10] The symmetry of these molecules is C_6 or D_6 (from dynamic averaging).

We present herein the first examples of D_3 benzene rings with six directly bound homotopic groups. The homotopicity is attained exactly because of the proximity and the reciprocal steric interaction of the groups. The common structure is that

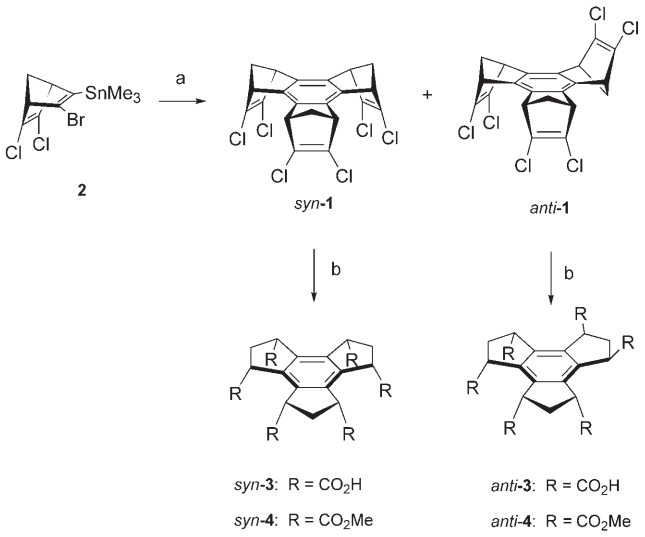
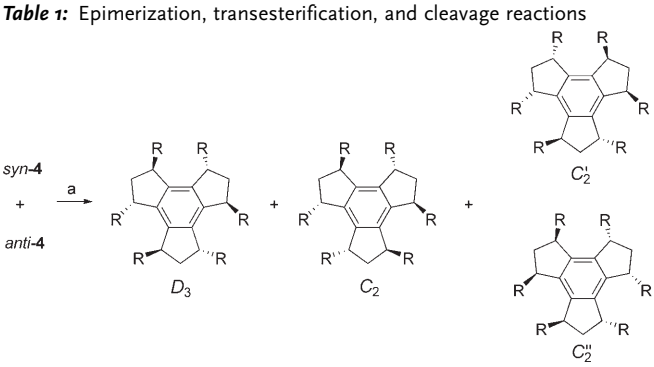
of 2,3,4,5,6,7,8,9-octahydro-1*H*-trindene-1,3,4,6,7,9-hexacarboxylic acid or ester ("hexacarboxytrindane"), which also, at variance from other D_3 molecules, is functionalized and thus amenable to further synthetic elaborations.

The access to these high-symmetry chiral molecules is described in Scheme 1 and Table 1 and originates from the recently synthesized cyclotrimers *syn*-**1** and *anti*-**1**, which are functionalized with three dichlorovinylene moieties on the edge.[11] These substrates could be obtained on multigram scales by cyclotrimerization of bromotrimethylstannylnorbornadiene (**2**) in the presence of copper(I) 2-thiophenecarboxylate (CuTC; Scheme 1). The oxidative cleavage of the three vinyl bonds of a mixture of *syn*-**1** and *anti*-**1** was carried out using $RuCl_3 \cdot 3H_2O/NaIO_4$,[12] thus leading to the quantitative and stereospecific formation of two isomeric trindane molecules *syn*-**3** and *anti*-**3**, in which the sets of the carboxylic groups reflect the same C_{3v} and C_s symmetries of the starting materials.



Scheme 1. Reagents and conditions: a) CuTC, NMP, −15 °C, 2 h, (>90%). b) 1. $RuCl_3 \cdot 3H_2O/NaIO_4$, CCl_4, CH_3CN, H_2O, 0 °C, 3 h, (**3**: 99%); 2. O_3/MeOH, RT, 1 h, (**4**: >95%); 3. **3**, PTSA, MeOH, reflux, 3 days (**4**: 10%). NMP = *N*-methylpyrrolidone, PTSA = *para*-toluenesulfonic acid.

Table 1: Epimerization, transesterification, and cleavage reactions



R	D_3	C_2	C_2''	D_3:C_2	Yield [%]
CO_2Me	D_3-(*R*,*S*)-**4**	C_2-**4**		1:2.1	70[a]
CO_2*i*Pr	D_3-(*R*,*S*)-**5**	C_2-**5**		1:1.2	60[a]
CO_2(−)ment	D_3-(*S*)-**6**		C_2''-**6** or C_2'-**6**	3:1	45[b]
CO_2H[c]	D_3-(*S*)-**3**			–	90
CO_2Cl[d]	D_3-(*S*)-**7**			–	>90
CO_2Me[e]	D_3-(*S*)-**4**			–	>90

[a] Yield determined spectroscopically. [b] Yield after flash-chromatographic purification. [c] Formed from CO_2(−)ment under conditions (b). [d] Formed from CO_2H under conditions (c). [e] Formed from CO_2Cl under conditions (d). Reagents and conditions: a) **4**: MeOLi, THF; **5**: *i*PrOLi, THF; **6**: (−)mentOLi, THF; b) Me_3SiI, CCl_4; c) $(COCl)_2$/DMF, CH_2Cl_2; d) MeOH. DMF = dimethylformamide, ment = menthyl.

The hexamethyl esters *syn*-**4** and *anti*-**4** can be obtained by two different synthetic approaches: oxidation by $RuCl_3$ to the corresponding acids *syn*-**3** and *anti*-**3**,[12] followed by esterification or direct oxidation of *syn*-**1** and *anti*-**1** by using ozone in methanol.[13] The first approach gives the hexaacids quantitatively, but Fischer esterification affords the esters in poor yield. As the second approach gives *syn*-**4** and *anti*-**4** directly in quantitative yield, we did not investigate any alternative to Fischer esterification.

The two base sensitive positions in *syn*-**4** and *anti*-**4**, that is, the benzylic proton and the carboxylic group, can be exploited in transesterification and epimerization processes.[14] The epimerization process may be governed by the steric hindrance between groups on the same five-membered ring or between facing groups on different rings.

The addition of MeOLi to a solution of either pure *syn*-**4** or *anti*-**4** in THF (Table 1) leads to only two out of the ten possible diastereomers, that is, D_3-(*R*,*S*)-**4** and C_2-**4**,[15] obtained in ratios of 1:2.0 (from *syn*-**4**) and 1:2.1 (from *anti*-**4**) in 70% overall yield. These results imply that the mixture of cyclotrimers, *syn*-**1** and *anti*-**1**, can be oxidized without previous separation and used in the rearrangement process. The ratios, measured from the integrated signals in the NMR spectra of the crude reaction mixture, are equal within the measurement error. When corrected for the statistical factor of 1:3, the ratio of D_3-(*R*,*S*)-**4**/C_2-**4** becomes 1:0.68, which is a thermodynamic ratio, as no change was observed from prolonged action of the base. Thus, D_3-(*R*,*S*)-**4** is somewhat more stable than C_2-**4**.

The effect of the steric hindrance of different esters was evaluated by changing the alcohol. A mixture of the isopropyl esters D_3-(*R*,*S*)-**5** and C_2-**5** was obtained from a mixture of *syn*-**4** and *anti*-**4** esters using *i*PrOLi as the base in 60% yield and in a ratio of 1:1.2, thus corresponding to a ratio of 1:0.40 after correction. The main steric hindrance is between ester groups located on the same five-membered ring, but also the steric hindrance between facing groups on different five-membered rings plays a role, which increases with the bulk of the group, thus favoring the D_3 structure.

The homotopicity of the six benzylic groups in the D_3 esters **4** and **5** allows recognition of the D_3-*R* and D_3-*S* enantiomeric forms in which the faces of the benzene ring are also homotopic.

Transesterification with a chiral alcohol allows the diastereomeric isolation of the pure enantiomers. Reaction of the mixture of *syn*-**4** and *anti*-**4** esters with lithium (−)-mentholate gives two isomers of **6** in a ratio of 3:1 and in 45% yield after flash-chromatographic purification.

The indane protons in D_3-(*S*)-**6** are represented by a unique AA′XX′ system, in the form of two pseudo triplets.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The detection of weak transitions at the triplet sides allowed second-order spin analysis.[15] The verification of three equivalent AA′XX′ spin systems provides a rigorous argument for D_3 symmetry. The diastereomeric purity of D_3-(*S*)-**6** can be determined by careful analysis of the ^{13}C NMR spectrum (Figure 1), in which only the signals of a single compound were detected. The dipolar interactions measured by NOESY or differential NOE spectroscopy allowed, together with HMQC spectroscopy, the unequivocal assignment of ^{1}H and ^{13}C NMR resonances.

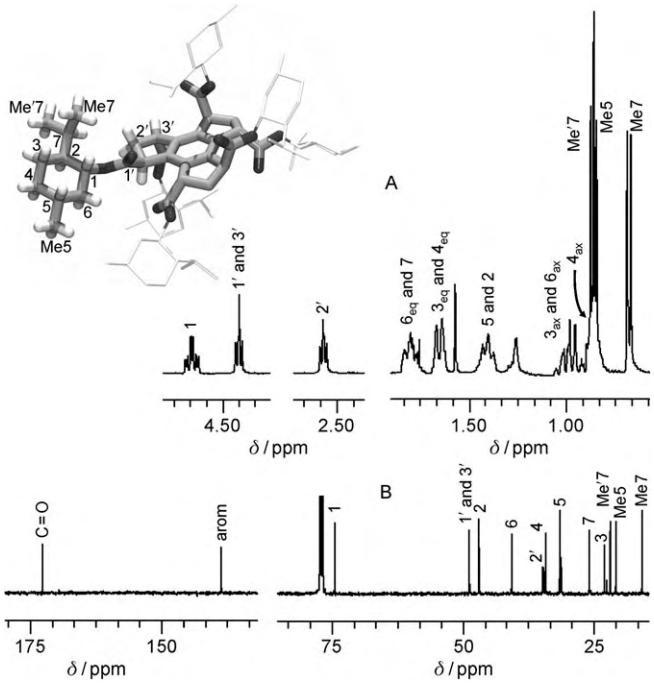


Figure 1. Complete assignment of NMR signals of D_3-(*S*)-**6** (only the relevant parts are shown). A) ^{1}H NMR (400 MHz), B) ^{13}C NMR (100 MHz) spectra.

The *S* configuration of the homotopic benzylic carbons in D_3-(*S*)-**6** was established unambiguously by single-crystal X-ray diffraction analysis[16] on the basis of the known 1*R*,2*S*,5*R* configuration of the menthyl ester units (Figure 2).

We could not find any indication of the formation of the D_3-(*R*)-**6** isomer. The isolated minor isomer displays the four protons of one five-membered ring in the form of two pseudo triplets, which is indicative of *trans* substitution, whereas the eight protons of the other rings present patterns similar to those of *syn*-**4** and *anti*-**4**, which is, therefore, indicative of *cis* substitution. Both the two C_2 structures, C_2'-**6** (more probable) or C_2''-**6**, can accommodate these features, and so we could not make an assignment.

It is appropriate to develop derivatization processes that will preserve the most valuable characteristics of the described hexaesters, particularly the up/down alternating substituents in D_3-**4**, D_3-**5**, and D_3-**6** and the enantiomeric purity of D_3-(*S*)-**6.** This possibility was verified by cleavage and esterification reactions.

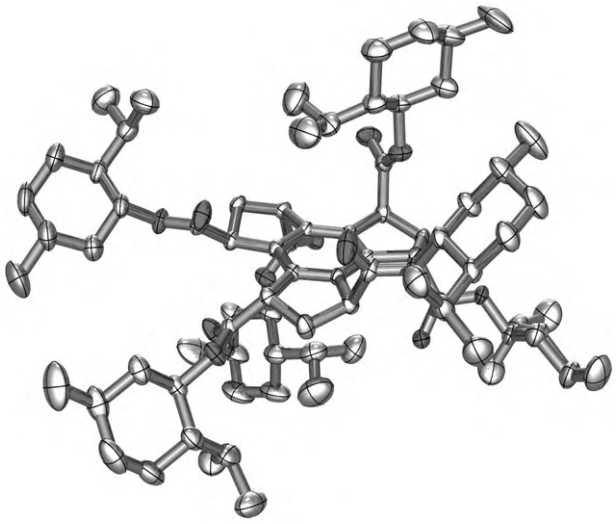

Figure 2. Structure of hexamenthyl ester D_3-(*S*)-**6** obtained by X-ray diffraction studies. Hydrogen atoms have been omitted for clarity. Ellipsoids drawn at 20% probability.

The removal of the chiral auxiliary in D_3-(*S*)-**6** gives the enantiopure hexaacid D_3-(*S*)-**3** ($[\alpha]_D^{20} = +18.16$, $c = 0.49$, dimethyl sulfoxide (DMSO)) in quantitative yield (Table 1). The cleavage reaction was carried out under neutral conditions using Me_3SiI in CCl_4.[17] The hexaacid D_3-(*S*)-**3** can be converted into the acid chloride D_3-(*S*)-**7** by using $(COCl)_2$/DMF,[17] and then esterified with MeOH giving D_3-(*S*)-**4** ($[\alpha]_D^{20} = +3.9$, $c = 0.23$, CH_2Cl_2). Compounds D_3-(*S*)-**3** and D_3-(*S*)-**4** are enantiopure, that is, the reactions occur with no rearrangement at the benzylic carbon atoms, as verified in the ^{1}H NMR spectra of the crude reaction mixture, in which no signal from the C_2 isomers could be detected.

Our approach suggests the following requirement for the generation of chiral D_3 molecules built around a benzene ring: a reversible epimerization process that will ensure the most stable configuration of the six substituents. However, in an open situation this process will lead to the alternation of *R* and *S* topicities in a molecule with C_3 symmetry (Figure 3 A). However, when the substituents with equal priority are forced toward each other by ring closures, a D_3 chiral molecule with six homotopic groups is produced (Figure 3 B).

The trindane framework with homotopic faces is the first example of an enantiopure D_3 molecule with six reactive units

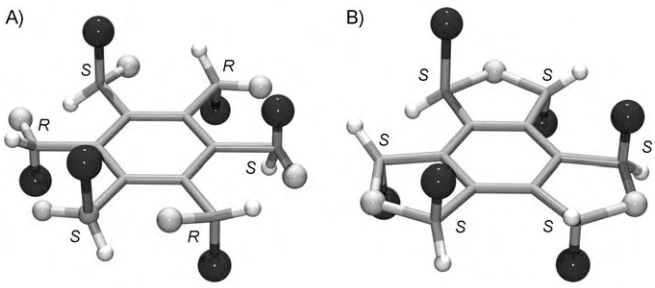

Figure 3. The effects of thermodynamic epimerization on A) open and B) ring-closed ("trindane") benzene structures.

joined directly in a rigid structure. This feature makes D_3-(*S*)-**7** an attractive core for the construction of new macromolecules, such as dendrimers,[18] liquid crystals,[19] supramolecular polymers,[10d,20] and molecular receptors,[21] in which asymmetric induction is not driven by the periphery of the molecule but by the center.

Experimental Section

D_3-(*S*)-**6**: A solution of *n*BuLi in hexanes (2.5 M, 24 mL, 59 mmol) was added dropwise to a solution of (−)-menthol (9.27 g, 59 mmol) in dry THF (80 mL) at room temperature under argon. A solution of *syn*-**4** and *anti*-**4** (3.24 g, 5.9 mmol) was added after 10 min at −78 °C. The dark solution was quenched after 2 days with saturated NaCl solution (100 mL), extracted with Et_2O (3 × 100 mL), the organic layers dried over $MgSO_4$, and concentrated in vacuo. The crude reaction mixture was purified by flash chromatography (CH_2Cl_2/hexane 1:1) to give the white solid D_3-(*S*)-**6** (2.5 g, 33 %; m.p. 78.8 °C) as the first product and C_2'-**6** or C_2''-**6** (0.89 g, 11 %; m.p. 101.7 °C) as the second product. D_3-(*S*)-**6** was recrystallized from CH_3CN/CH_2Cl_2 by slow solvent evaporation. 1H NMR ($CDCl_3$, 400 MHz): $\delta = 4.66$ (6H, H1, td, $J =$ 10.8, 4.2 Hz), 4.42 (6H, H1′ and H3′, pseudo t), 2.57 (6H, H2′, pseudo t), 1.82 (6H, $H6_{eq}$, m), 1.79 (6H, H7, m). 1.65 (12H, $H3_{eq}$ and $H4_{eq}$, m), 1.42 (6H, H5, m), 1.40 (6H, H2, m), 1.00 (6H, $H3_{ax}$, m), 0.89 (6H, $H4_{ax}$, m), 0.87 (18H, Me7, d, $J = 6.4$ Hz), 0.85 (18H, Me5, d, $J =$ 6.8 Hz), 0.68 ppm (18H, Me7, d, $J = 6.9$ Hz); 13C NMR ($CDCl_3$, 100 MHz): $\delta = 172.79$ (6C, carboxyl), 138.66 (6C, aromatic), 74.41 (6C, C1), 48.81 (6C, C1′ and C3′), 47.06 (6C, C2), 40.73 (6C, C6), 34.71 (3C, C2′), 34.27 (6C, C4), 31.42 (6C, C5), 25.93 (6C, C7), 23.13 (6C, C3), 22.01 (6C, Me′7), 20.94 (6C, Me5), 15.88 ppm (6C, Me7).

X-ray diffraction: The data were collected on a Philips PW1100 four-circle diffractometer. Single crystals suitable for X-ray diffraction analysis were grown by slow evaporation from a solution of CH_3CN/CH_2Cl_2.[16]

Nanoparticle Assemblies with Molecular Springs: A Nanoscale Thermometer**

*Jaebeom Lee, Alexander O. Govorov, and Nicholas A. Kotov**

Nanoparticle (NP) superstructures are important in the creation of smart materials with new functionalities. Most of the current examples of complex NP systems, such as bioconjugates[1–4] or hybrid nanocolloids[5] and their lattices,[6,7] are typically static: They show a limited response to environmental parameters and do not exhibit smooth reversible transitions of their three-dimensional organization or geometry in response to external stimuli. Dynamic NP superstructures with gradual structural adaptation to common physical parameters may reveal interesting analogies to biological entities of similar scale.[8,9] Additionally, such systems can find technological applications as optical devices. Herein we describe a reversible nanothermometer built from two types of NPs connected by a polymer acting as a molecular spring. The underlying microscopic mechanism of the nanothermometer involves plasmon resonance and exciton–plasmon interaction.

Poly(ethyleneglycol) (PEG) derivatives with *tert*-butoxycarbonyl (Boc) and *N*-hydroxysulfosuccinimide (NHS) groups at the terminal ends of the linear macromolecule (molecular weight 3400 Da, see *Experimental Section*) allow the sequential conjugation of one end to 20-nm Au NPs and of the other end to 3.7-nm CdTe NPs. This results in the superstructure depicted in the insert of Figure 1. The high-resolution transmittance electron microscopy (TEM) images of the product (Figure 2) confirm the formation of corona-like superstructures, although the density of the CdTe satellite particles distributed around the central gold core is lower than expected, probably owing to structural alterations during sample preparation. The CdTe colloid can be identified by the lattice plane spacing d of 0.352 ± 0.3 nm, which is typical for cubic CdTe.[10,11] The Au NPs show a d value of 0.23 ± 0.008 nm, which corresponds to the (111) planes of the Au crystal (see Supporting Information).

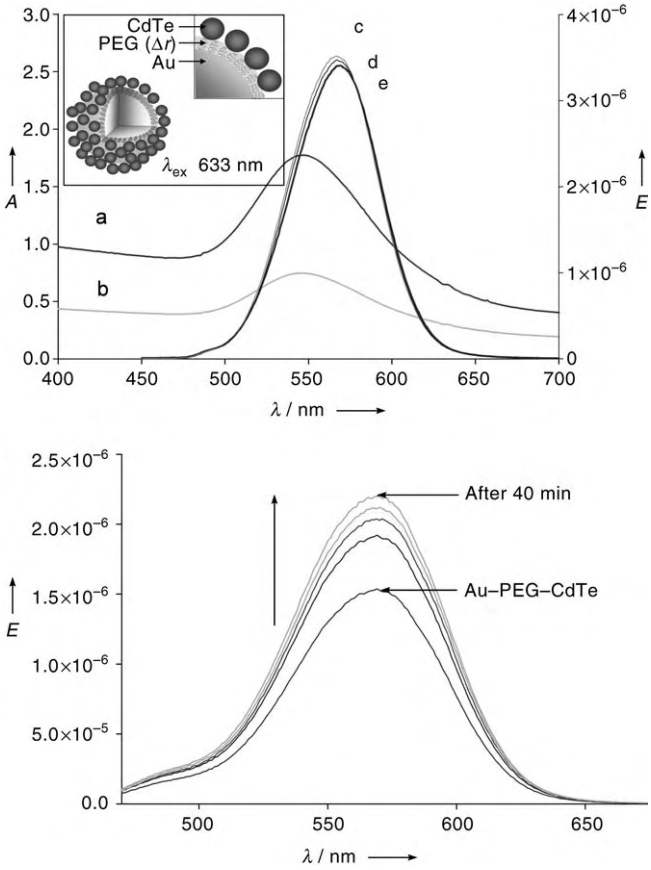

Figure 1. Top: Absorbance spectra of the PEG-conjugated Au NPs before (a) and after (b) removal of the Boc protecting groups; emission spectra of CdTe NPs after addition of EDC/NHS (c), after conjugation with Au–PEG (d), and of CdTe alone (e). Inset: Schematic drawing of the superstructure. Bottom: PL enhancement of the CdTe–PEG–Au superstructure after 40 min. A = absorbance, E = emission intensity.

The superstructure was excited with a He:Ne laser at 633 nm (20 mW, Uniphase, USA). The red light quanta result in efficient excitation of CdTe NPs, although these quanta are below the energy of the absorption threshold. This process is not as common as photoluminescence (PL) stimulated by light quanta with higher energy than the light emitted from

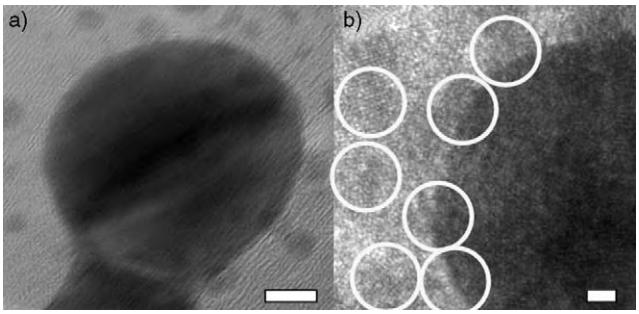

Figure 2. TEM images of the superstructure formed by conjugation of the CdTe NPs with the Au NPs: a) 5×10^5, and b) 10^6 magnification (in each case the bar represents 5 nm). The circles indicate the areas in which characteristic lattice fringes of 0.352 nm for the cubic zinc blende structure of CdTe can be seen after conjugation with PEG.

the NP, but it is well-documented for CdTe.[12,13] The mechanism of the excitation may include two-photon absorption as well as one-photon promotion of the charge carriers from thermally excited levels, yielding a complex curve with both second- and first-order dependence on the intensity of the incident light.[28] Regardless of the excitation pathway, luminescence induced by light below the absorption threshold is very useful for analytical applications because it allows effective elimination of the scattered light from the excitation source.

The similarity of the energies of the Au NP plasmon (549 nm) and the CdTe NP exciton (568 nm) results in resonance conditions in the superstructure (Figure 1). Once the exciton in the CdTe NP is generated, it induces oscillations of the electron density in the Au NP, that is, the plasmon. The resonance between them has two effects on the emission of CdTe: 1) It results in the enhancement of the luminescence intensity of the NPs at 568 nm, when the gap between the particles closes. In contrast to earlier reports on the fluorescence quenching of semiconductor colloids by gold particles,[14,15] we consistently observe a strong enhancement of the CdTe luminescence upon attachment of Au NPs, as long as certain geometrical rules are observed and the diameters selected match the resonance conditions.[16] The reasons behind this difference in observations can be understood from the theoretical description below. 2) The resonance conditions make the luminescence intensity very sensitive to the interparticle distance,[16] which is a convenient feature for analytical applications.[29,30] This complements the high signal-to-noise ratio that could result with two-photon emission. For a different geometrical arrangement—for instance, when a gold NP is attached to a CdTe nanowire, as described in our previous study[16]—a single Au NP may not produce any enhancement effect at all because of diffusion of the exciton along the nanowire. In this case, only the collective action of many NPs can provide a substantial enhancement of the emission.[16] Furthermore, the diameter of the Au NP also makes a substantial difference and, depending on the absorption peak of the Au colloid, one may not see any enhancement effect and even observe quenching of the semiconductor emission.

The temperature of the CdTe–PEG–Au dispersion was varied between 20 and 60 °C by a heating/cooling circulator (NESLAB, EX-111, USA). The conformation of the PEG can be altered as a response to the thermodynamic energy in the media. Despite the fact that PEG and PEO (poly(ethylene oxide)) have high critical temperatures, an increase in the temperature from 20 to 50 °C results in swelling of the PEG molecule and an increase in its diameter.[17,18] This alters the distance between the particles, which should produce a concomitant change in the luminescence output. Indeed, the superstructure shows a clear temperature dependence for the PL intensity. A high concentration of PEG segments attached to the Au surface can introduce additional differences compared to the classical case of diluted solutions of PEG.

A higher temperature leads to a decrease in the luminescence due to the more extended conformation of the PEG chain, and vice versa (Figure 3a, b). The non-PEG bonded system did not display any temperature dependence (see Supporting Information). Importantly, the process is totally reversible, showing less than 10% photodegradation with every temperature cycle (1500 s).

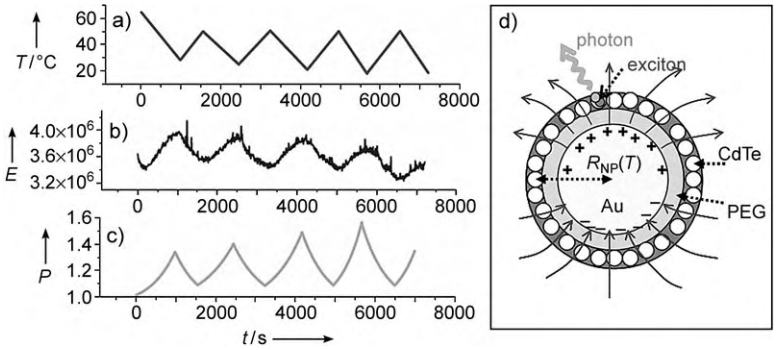

Figure 3. Variation in the PL intensity E (b) of the PEG-tethered Au and CdTe NPs depending on the temperature T (a); c) calculated photon-field enhancement factor P of the CdTe NPs as a function of time. d) Schematic representation of the dielectric model used for calculating the curve in (c) as well as the plasmon excitation with associated field lines; the plasmon excitation inside an Au nanosphere interacts with excitons in the CdTe NPs through electric fields. The distance $R_{NP}(T)$ varies with the temperature. The curve in (c) also represents a theoretical dielectric model of the NP assembly in which the CdTe NPs form a continuous spherical shell around the Au NP.

Calculations demonstrate that the change in the PEG-controlled distance between the NPs is the cause of the observed modulations in emission intensity. The photon-field enhancement factor P inside the CdTe NPs determines the probability of photon emission by an exciton trapped in a CdTe NP. Therefore, the emission intensity is proportional to the factor P [Eq. (1); where E_0 is the external electric field

$$P(\omega,R_{NP}) = \langle E^2\rangle_\Omega / E_0^2 \qquad (1)$$

inside a CdTe NP without the Au subsystem, E is the electric field in the presence of an Au NP averaged over the solid

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

angle Ω, R_{NP} is the position of the CdTe NPs with respect to the center of the superstructure (Figure 3d), and ω is the laser frequency].

We use here a simplified model which approximates a granular, molecular spring superstructure (Figures 1 and 2) as an Au sphere surrounded by polymer molecules and the CdTe shell (Figure 3d). We see no evidence of clustering of Au particles in the TEM images, which also supports the suggested theoretical model. Mathematical treatment of all CdTe NPs individually could be useful, but requires sophisticated numerical simulations. At the same time, a simple shell model reveals the physical essence of the phenomenon, which is important for the further development of similar superstructures. Note that the majority of Au NPs are faceted (see Supporting Information). While being mindful of the potential electric field aberrations caused by face edges, we consider them to be secondary effects in comparison to the model approximation.

Thus, treating an Au NP as a sphere and a collection of CdTe NPs as a spherical shell, we can analytically calculate the electric fields induced around the Au NP by matching the electrical boundary conditions and involving the first spherical harmonics.[19] After averaging over Ω, we obtain Equation (2), where B and C are complicated functions of the

$$P(\omega,R_{NP}) = \frac{|B| + 2|C^2|/R_{NP}^6}{E_0^2} \quad (2)$$

dielectric constants of the metal ($\varepsilon_m(\omega)$), PEG (ε_0), and CdTe ($\varepsilon_{CdTe} = 7.2$; see Supporting Information). In addition, the coefficients B and C are dependent on the radii of the spherical shells in our model. The function $\varepsilon_m(\omega)$ for the Au NPs was taken from reference [20]. Since the UV/Vis absorption of the Au NPs is dependent on the dielectric constant of the environment, the effective value of ε_0 of the surrounding media was taken as the dielectric constant of PEG (2.3).[21] Yun et al.[29] reported a $1/R^4$ dependence of fluorescence quenching by small Au NPs. The geometry of our system seems to be an even better match for $1/R^4$ distance dependence than that in reference [29], because the diameter of the Au NPs is large, and therefore the NP may behave like a surface. Nevertheless, Equation (2) (with $1/R^6$) was used because 1) a resonance process is better described by a dipole–dipole rather than a dipole–surface model, 2) it is a more general description, which could be applied for a variety of similar systems, and 3) expressions for corresponding coefficients are known, as opposed to those in the equation with $1/R^4$. R_{NP} was determined by the radius of gyration of PEG, R_{PEG}. On the basis of literature data,[22,23] R_{PEG} of PEG with a molecular weight of 3400 Da is 2–4 nm. The temperature-induced changes in the 20–60 °C range constitute 20–30 % of the polymer globule volume ratio, that is, changes in R_{PEG} of 0.6–1.2 nm.[24] In view of the fairly small change in the overall diameter of the Au–PEG–CdTe superstructure (ca. 26 ± 1.5 nm) caused by the conformational changes in PEG, the difference between the equations with $1/R^4$ and $1/R^6$ is not that essential here, except for the fact that a $1/R^6$ dependence should give stronger optical effects, which seems to be the case. Also note that light scattering plays a small role in the observed effect of luminescence enhancement. Assuming a linear dependence of $R_{PEG}(T) = 3\,\text{nm} + 1\,\text{nm}\,(T - 30\,°\text{C})/30\,°\text{C}$, one arrives at Equation (3). The high sensitivity of the NP

$$R_{NP}(T) = 11.8\,\text{nm} + R_{PEG}(T) = 14.8\,\text{nm} + (T - 30\,^o\text{C})/30\,^o\text{C} \quad (3)$$

emission to temperature in our superstructures arises from two factors: 1) The value of P rapidly decreases with Au–CdTe distance (approximately as R_{NP}^6), and 2) the exciton energy is very close to the plasmon resonance, which leads to a plasmon enhancement of emission. Equation (2) for the emission-enhancement factor has rather a complicated distance dependence caused by the multiple-shell structure. For $R_{NP} = 15$–16 nm, the plasmon-enhanced electric field and corresponding enhancement factor rapidly decrease with distance.

Compared with other approaches to sensing with nanocolloids,[4] the expansion and contraction of molecular springs represents a very sensitive transduction mechanism for chemical detection: Any change in the dimensions of the superstructure results in a shift of the plasmon resonance with respect to the exciton energy and subsequently in a reduction of the enhancement factor. Our theoretical analysis shows that, depending on the resonance conditions, the presence of Au can either increase or decrease the fluorescence of CdTe. For example, if the plasmon peak moves towards the exciton resonance with constriction of PEG, we may obtain the enhancement effect. If the plasmon peak is shifted away from the exciton energy, the fluorescence intensity can decrease. Substitution of $R_{NP}(T)$ into the equation for $P(\omega,R_{NP})$ for $\hbar\omega = 2.2$ eV, corresponding to a resonance wavelength of 568 nm, provides an analogue of the experimental $I(T)$ curve calculated in terms of photon-field enhancement factors (Figure 3c). The amplitude of the temperature zig-zag for $P(\omega,R_{NP})$ is about 30 %. This correlates very well with the variation of the emission intensity in our experiments (Figure 3a, b). The slightly lower amplitude registered in the experiment can be attributed to steric hindrance in the CdTe corona around the Au NP, preventing formation of the perfect CdTe NP shell assumed for our model. The linearity of the temperature response (Figure 3a) can be deceptive, because all the processes here are highly nonlinear. This becomes visible in the calculated results shown in Figure 3c.

Thus, the CdTe–PEG–Au system is an example of a nanoscale superstructure that undergoes a reversible structural change in response to the environmental conditions. The combination of this property with plasmon–exciton interactions that display a high sensitivity of the optical output on the distance modulations represents the foundation of a new family of sensing and optoelectronic devices.

Experimental Section

The CdTe NPs (3.7 nm in diameter with an emission at 568 nm) were synthesized according to the literature.[25] They were conjugated to the flexible spacer PEG and then linked to Au NPs (20 nm in diameter with a surface plasmon peak at 549 nm) to form molecular spring-type structures. The level of structural control necessary to produce molecular spring assemblies from NPs as shown in the insert

of Figure 1, rather than disorganized aggregates, was possible because the PEG oligomer had two different functional groups at the ends of the chain, NHS and Boc (Boc–NH–PEG–COO–NHS; molecular weight 3400 Da, Nektar, AL). The stabilizer, cetyltrimethylammonium bromide (CTAB, Aldrich, Milwaukee, WI) of the Au NPs was substituted with L-cysteine (Aldrich, Milwaukee, WI) in order to obtain the NH_2 functional group. The PEG (10 mg) was dissolved in deionized water (560 μL) and dimethyl sulfoxide (DMSO, 140 μL). This solution (700 μL) was mixed with the solution of the Au NPs (700 μL), and gently stirred at room temperature for 12 h. This procedure resulted in conjugation of the NHS terminus with NH_2 group of the NP stabilizer through a covalent amide linkage. Then the Boc protecting group was removed by treatment with trifluoroacetic acid (TFA, 5 μL) for 20 min.[26] The regenerated NH_2 terminus of PEG can be conjugated to a CdTe NP by standard conjugation techniques, that is, EDC/sulfo-NHS cross-linking,[16,27] resulting in covalent attachment of CdTe to the PEG chain on the end opposite to the Au NP.

Rate Enhancement by Ethylene in the Ru-Catalyzed Ring-Closing Metathesis of Enynes: Evidence for an "Ene-then-Yne" Pathway that Diverts through a Second Catalytic Cycle**

Guy C. Lloyd-Jones, Robert G. Margue, and Johannes G. de Vries*

The ring-closing metathesis (RCM) of enynes [**1**→**2**, Eq. (1)] was first reported by Katz and Sivavec in 1985.[1]

1 **2** (1)

A tungsten–alkylidene precatalyst was employed and, on the basis of mechanistic studies on alkene/alkyne metathesis copolymerization, a Chauvin-type[2] mechanism involving an "yne-then-ene" sequence was proposed (Scheme 1, cycle A).

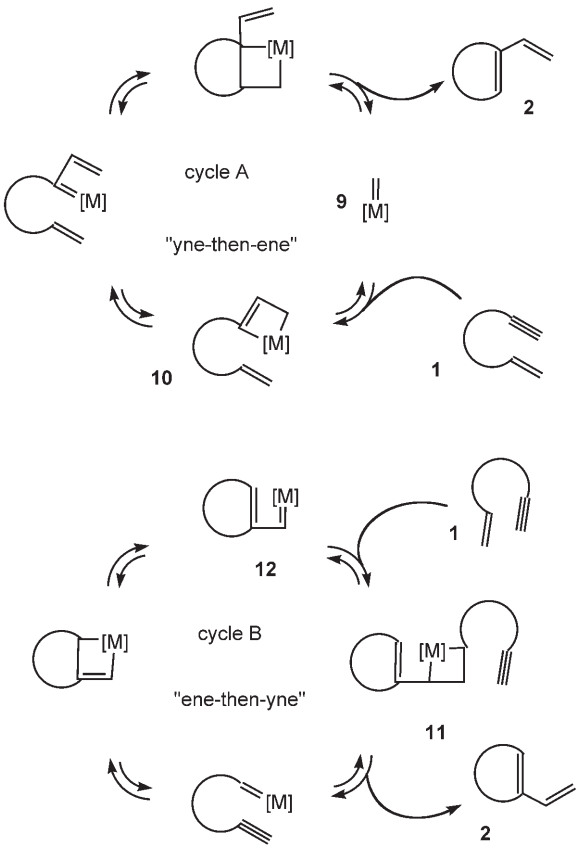
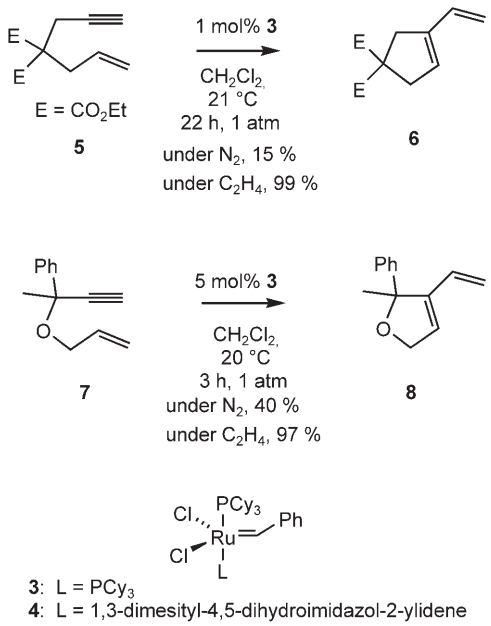


Scheme 1. The "yne-then-ene" (A) and "ene-then-yne" (B) mechanisms for RCM of enyne **1** proceeding intermolecularly via metal alkylidene intermediates.



Scheme 2. The effect of ethylene ("Mori's conditions"[10]) on the Ru-catalyzed RCM of enynes **5** and **7**.

Subsequent reports by Hoye and co-workers[3] and by Mori and co-workers[4] on analogous Mo- and Cr-based carbene precatalysts also invoked mechanism A, which neatly accounted for a number of side products, for example, vinyl cyclopropanes, by reductive elimination in the metallacyclobutane intermediate.

With the advent of Ru-based alkylidene precatalysts (for example, **3**[5] and **4**,[6] Scheme 2), both enyne RCM and alkene/alkyne co-metathesis have enjoyed rapidly increasing application.[7] Possibly as a legacy from the earlier work with catalysts based on Group VI elements,[1,3,4] the "yne-then-ene" mechanism (A) is commonly postulated for the Ru-catalyzed enyne RCM reaction.[8,9]

In 1998, Mori et al. reported that ethylene can have a dramatic effect on the yield of Ru-catalyzed enyne RCM reactions, for example, in the conversion of enyne **5** into diene **6** (Scheme 2).[10] We have recently been investigating the RCM of allyl propargyl ethers,[11] for example, **7**→**8**, which also improves under ethylene (Scheme 2). It is of note that the rate of RCM of **5** is increased by ethylene more than that of **7**.

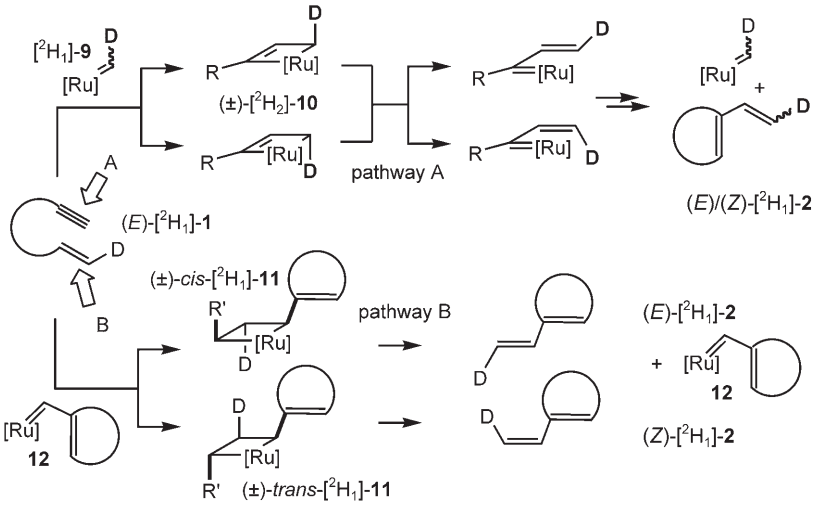
The beneficial effect of ethylene on some RCM reactions has led to "Mori's conditions"[10] being widely adopted[7a,12] to increase yields and inhibit side reactions such as epimerization,[12d] and substrate homo-cross-metathesis.[12c,g] The origin of the ethylene effect has been ascribed to the attenuation of unproductive resting states in equilibrium with the ruthenium methylidene **9** in cycle A.[10] However, such a "protective effect"[7a] would be expected to increase catalyst longevity rather than increase the reaction rate. Moreover, the effect should be operative across the full range of enynes,[12i–k] and it should extend to the RCM of the corresponding dienes.[13] An alternative explanation would be that ethylene acts as an initiator, which converts the precatalyst, for example, **3**, into the active intermediate **9** in cycle A by cross-metathesis. To test this supposition, we alternated the atmosphere above a RCM of enyne **5** (5 mol% **3**, CH_2Cl_2, 21°C) between N_2 (1 atm) and ethylene (1 atm) during the reaction. Irrespective of the extent of conversion of the substrate, catalysis always accelerated on switching to an ethylene atmosphere, and decelerated on returning to N_2, which refutes an initiation effect and emphasises that ethylene accelerates a net catalytic turnover.

An alternative mechanism for enyne RCM under standard conditions has also been proposed.[14] However, this "ene-then-yne" sequence (Scheme 1, cycle B) is seldom considered, despite a growing body of evidence.[14,15] Herein, we present ^{2}H- and ^{13}C-labeling strategies that probe the origin of the ethylene acceleration and its relationship to the mechanistic dichotomy (cycles A versus B) in Ru-catalyzed enyne RCM.

Starting with reactions conducted in the absence of ethylene, we focused on the steps in mechanisms A and B that generate the vinyl terminus (the methylene group) in the RCM product **2**. In cycle A this involves ring opening of ruthenacyclobutene **10** in which there are no C-based stereogenic centers in the ring. In cycle B, this involves ring opening of ruthenacyclobutane **11** in which there are two C-based stereogenic centers, and thus two diasteroisomeric forms. We have been able to probe for diastereoselectivity in this transient species[16] by use of stereospecifically labeled enyne substrate ((*E*)- and (*Z*)-[^{2}H]-**1**).[17]

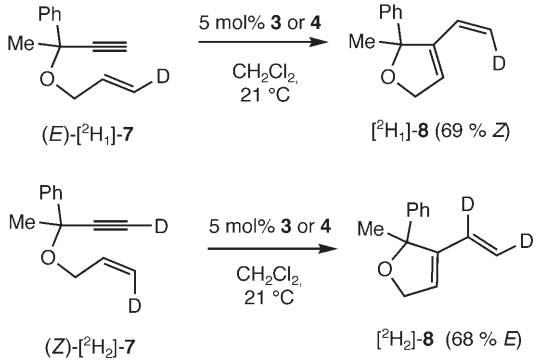
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

As illustrated for (*E*)-[^{2}H]-**1** in Scheme 3, pathway A is predicted to generate [^{2}H]-**2** with no *E*/*Z* selectivity at the CH=C(D)H group.[17] In contrast, in pathway B, any net diastereoselectivity in the formation and breakdown of [^{2}H]-**11**, will translate into *E*/*Z* selectivity, as the relative configuration of the CHD and CHR′ centers in **11** are determined by the geometry of the alkene substrate. Thus, isomeric substrate (*Z*)-[^{2}H]-**1** should give the opposite isomer of product [^{2}H]-**2**.



Scheme 3. The stereochemical outcome of RCM of stereospecifically labeled enyne ((*E*)-[^{2}H$_1$]-**1**) by mechanisms A and B. Note that the ruthenacyclobutane ring in **11** may well adopt a cyclobutane-like puckered structure. The deuterium atoms are marked in bold when they are derived from the alkylidene to differentiate them from those that are derived from the alkene.

Ru-catalyzed RCM reactions of enynes (*E*)-[^{2}H$_1$]-**7** and (*Z*)-[^{2}H$_2$]-**7** gave (*Z*)-[^{2}H$_1$]-**8** and (*E*)-[^{2}H$_2$]-**8**, respectively, with 68–69% selectivity irrespective of the precatalyst (Scheme 4). These results are consistent with pathway B operating in which the major flux is via the *trans* diastereomer of **11**.[18] Identical selectivities were found with the Fürstner–Ackermann catalyst system,[19] and also with an achiral analogue of (*Z*)-[1,7-^{2}H$_2$]-**7** in which the Me and Ph groups were replaced by a pentane-1,5-diyl system. The slower-reacting malonate substrate **5**, which has similar steric hindrance at the allylic and propargylic positions, proceeded with lower but analogous selectivity: (*Z*)-[^{2}H$_1$]-**5** gave (*E*)-[^{2}H$_1$]-**6** (55% (*E*)).



Scheme 4. Ru-catalyzed RCM of stereospecifically ^{2}H-labeled enynes. Note that the alkynyl ^{2}H label in (*Z*)-[^{2}H$_2$]-**7** arises from the synthesis and is present only as a spectator label.

The ene-then-yne sequence (cycle B) also provides a simple mechanistic rationale for the effect of ethylene (Scheme 5). The vinylalkylidene[20] complex **12**, which reacts with substrate **1** to liberate **2** via **11** on the primary cycle (B1), can also react with ethylene, as a surrogate alkene for **1**,[15] to liberate RCM product **2** via complex **13** (upper section of Scheme 5). The resulting ruthenium–methylidene complex **9**, which is identical to that found in the yne-then-ene sequence (cycle A), can rejoin the *primary* catalytic cycle (B1) by reacting with the substrate (**1**) and releasing ethylene, thereby creating a secondary cycle that is *catalyzed* by ethylene.

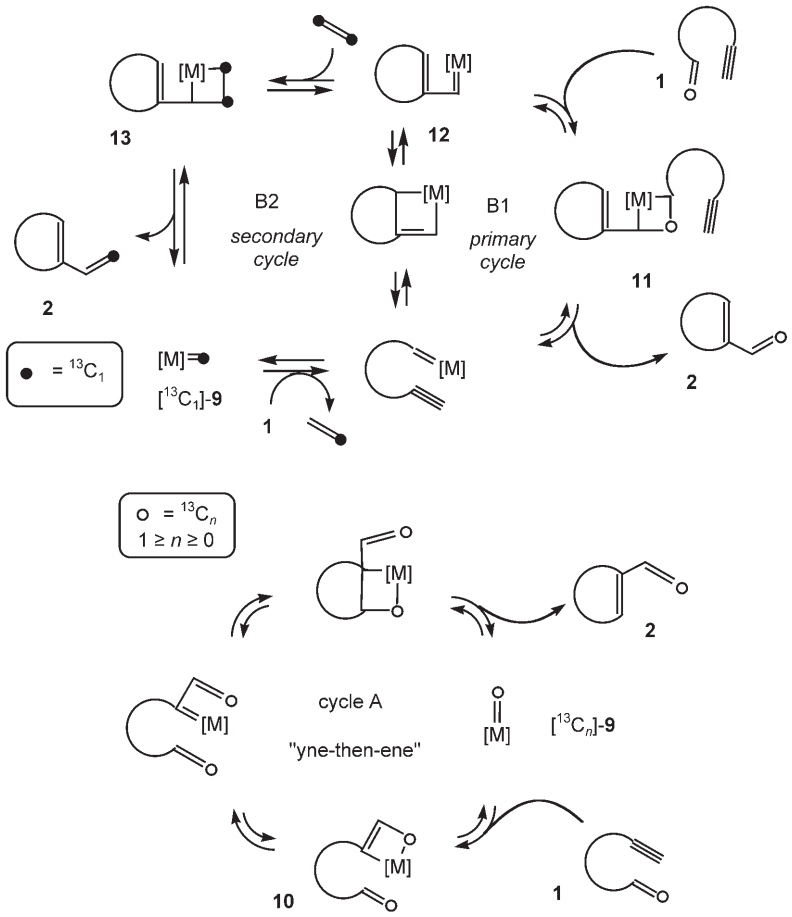
To investigate the possibility of turnover through a secondary cycle, we conducted RCM reactions under an atmosphere of [^{13}C$_2$]ethylene. In cycle A, cross-metathesis equilibration of [^{13}C$_2$]ethylene with Ru–methylidene **9** will lead to [^{13}C$_n$]-**9** ($n=0$ or 1). This labeled methylidene compound can then generate [^{13}C$_1$]-**2** and **9** by RCM, with the ^{13}C/^{12}C ratio in the terminal alkene of **2** being determined by the **9**/[^{13}C$_1$]-**9** ratio. In mechanism B, the primary cycle (B1) will generate unlabeled **2**, and the secondary cycle B2 will generate [^{13}C$_1$]-**2** (via [^{13}C$_2$]-**13**; see the filled circles in Scheme 5), with the ^{13}C/^{12}C ratio then being determined by B1/B2 partitioning. In addition, three more processes that can affect the ^{13}C/^{12}C ratio in **2** must be considered. Firstly, cross-metathesis of labeled methylidene [^{13}C$_1$]-**9** with the terminal alkene in **1** will generate [^{13}C$_1$]-**1**, which on RCM by pathway B1 will generate [^{13}C$_1$]-**2**. Secondly, cross-metathesis of product (**2**) with [^{13}C$_1$]-**9** will generate [^{13}C$_1$]-**2** by a non-RCM pathway. Finally, insufficiently rapid exchange of solution-phase ethylene with the bulk gaseous phase will result in temporary depletion of [^{13}C$_2$]ethylene, and enrichment of [^{13}C$_n$]ethylene ($n=0$, 1), in the solution phase. From the above analysis it is thus clear that the extent of ^{13}C incorporation in **2** cannot alone be used to distinguish mechanisms A and B.

To address this issue, we have designed a dual-substrate, dual-labeling strategy. The experiment involves RCM of a 1/1 mixture of two enynes (**5** and **7**) for which the accelerating effect of ethylene is different: the rate of RCM for the slower-reacting enyne **5** is increased 2.8 times over that of the faster-reacting enyne **7**.[21] This differential acceleration results in similar rates of RCM for **5** and **7** under ethylene (8.3×10^{-4} and 9.7×10^{-4} s^{-1}, respectively).

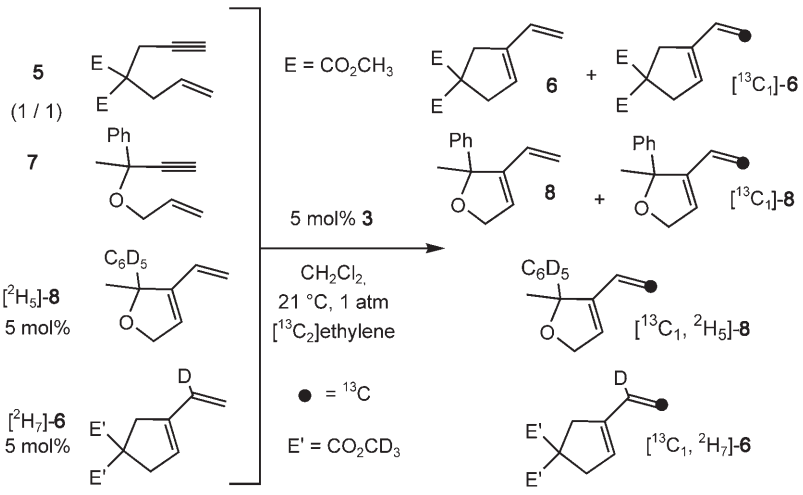
Conducting the reaction under [^{13}C$_2$]ethylene (1 atm, 930 mol%) gives [^{13}C$_1$]-**6**/**6** and [^{13}C$_1$]-**8**/**8.** As controls for the experiment, the reaction mixture also included 10 mol% of [D$_7$]-**6**/[D$_5$]-**8**, to allow estimation of the extent of ^{13}C$_1$ incorporation into **6** and **8** by non-RCM pathways, as well as any reversibility of the reaction (Scheme 6).

Samples taken over the entire course of the reaction were analyzed by GC and GCMS. The resulting incorporations of ^{13}C (%) in substrates **5** and **7**, products **6** and **8**, and reference products [D$_7$]-**6** and [D$_5$]-**8** as a function of conversion are shown in Figure 1.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 5. Adaptation of Scheme 1, to include a secondary cycle (B2) that is catalyzed by ethylene, as well as the ^{13}C-labeling patterns predicted for cycles A and B when reaction is conducted under [$^{13}C_2$]ethylene. Partial ^{13}C incorporation at the alkene terminus of enyne **1** arising from degenerate metathesis with [$^{13}C_n$]-**9** ($1 \geq n \geq 0$) is also shown.



Scheme 6. A dual-substrate/dual-labeling strategy for detection of preturnover/postturnover ^{13}C-label incorporation and distinction of enyne RCM through mechanisms A and B. $[\mathbf{5}]_0 + [\mathbf{7}]_0 = 0.08$ M.

The analysis demonstrates that non-RCM incorporation of ^{13}C into both the substrates and the products becomes increasingly competitive as the reaction evolves. Moreover, further control experiments showed that the rate of equilibration of [$^{13}C_n$]ethylene between the gas and solution phases under the reaction conditions ($t_{0.5} = 83 \pm 4$ s)[22] is only one order of magnitude faster than catalyst turnover, and thus all three factors outlined above affect the $^{13}C/^{12}C$ incorporation. Nonetheless, the dual-substrate, dual-labeling approach allows the distinction of mechanisms A and B as follows. In mechanism A, although the RCM reactions of **5** and **7** have been accelerated to different extents, the $^{13}C/^{12}C$ incorporation into **6** and **8** at any time in the reaction will be determined by the **9**/[$^{13}C_1$]-**9** ratio, and will thus be *equal*. In mechanism B, enyne **5**, whose RCM is accelerated by the ethylene more than **7**, will partition more through pathway B2, thus giving rise to a greater level of ^{13}C incorporation. The ratio of $^{13}C/^{12}C$ incorporation in **6** versus **8** should thus reflect the 2.8-fold difference in acceleration by ethylene for **5** versus **7**.

In the first half of the reaction an approximately linear relationship is found between the $^{13}C/^{12}C$ ratio at the vinyl terminus in **6** and **8** and the extent of the reaction (Figure 2). The steeper gradient observed for **6**, relative to that for **8**, arises from the more rapid non-RCM incorporation of ^{13}C, as revealed by the analyses in Figure 1. Extrapolating the two relationships in Figure 2 to 0% conversion, gives the initial ratio of $^{13}C/^{12}C$ incorporations for **6** and **8** as 2.3 ± 0.6:1, which is in good agreement with the ratio of 2.8:1 predicted by mechanism B,[23] and significantly greater than the ratio of 1.0:1 predicted by mechanism A. It can thus be concluded that the reaction of enyne **7** (→**8**) under ethylene does *not* proceed predominantly through pathway A. Moreover, the differential $^{13}C/^{12}C$ incorporation data strongly supports the proposal that both processes (**5**→**6** and **7**→**8**) proceed predominantly through pathway B2 under ethylene.[24]

In summary, isotopic labeling experiments (^2H and ^{13}C) of Ru-catalyzed enyne ring-closing metathesis reactions involving enynes **5** and **7** give results that are not compatible with the commonly proposed yne-then-ene mechanism (cycle A).[23] The results are however explained by the alternative ene-then-yne mechanism (cycle B) for which ethylene can *catalyze* the reaction by diversion of the vinylalkylidene intermediate **12** on the primary cycle B1[14] onto a *second cycle* B2.[15] The use of "Mori's conditions" (conducting Ru-catalyzed enyne RCM reactions under ethylene) is wide-

of the type [LRu(Cl_2)(η^2-$CHCH_2CH$)], where L = 1,3-dimesityl-4,5-dihydroimidazol-2-ylidene) has recently been observed by NMR spectroscopy at low temperatures: P. E. Romero, W. E. Piers, *J. Am. Chem. Soc.* **2005**, *127*, 5032 – 5033.

[17] The "low grade" -CH(D)- stereocenters are expected to exert negligible influence on the direction of ring opening, as evidenced by the complimentarity of the results obtained with (*E*)-[7-$^2H_1$]-**7** and (*Z*)-[1,7-$^2H_2$]-**7**. The magnitude of the selectivity is in vast excess over that expected from any secondary kinetic isotope effect in the addition of [^{2}H]-**9** to [^{2}H]-**1**.

[18] It should be noted that the observed 68.5 % (average) stereoselectivity for [^{2}H]-**7**→[^{2}H]-**8** is that at the end of reaction, during which control experiments indicate progressive scrambling of the *E*/*Z* stereochemistry in the [^{2}H]-**7** (ca. 20 % stereorandomization at 96 % conversion). The selectivity is thus consistent with the maximum range 63/37 to 0/100 A/B with 100 % to 68.5 % diastereoselectivity, respectively. For [^{2}H]-**5**, there is no scrambling during the reaction. The observed selectivity of 55 % is consistent with the range 90/10 to 0/100 A/B with 100 % to 55 % diastereoselectivity, respectively.

[19] A Fürstner, L. Ackermann, *Chem. Commun.* **1999**, 95 – 96.

[20] An η^3-coordination mode in vinylalkylidene complexes has been reported to attenuate the rate of metathesis: see T. M. Trnka, M. W. Day, R. H. Grubbs, *Organometallics* **2001**, *20*, 3845 – 3847.

[21] Reactions displayed reproducible pseudo-first-order kinetics. For **5** and **7**: under N_2: $k_{obs} = 1.1 \times 10^{-4}$ and $3.0 \times 10^{-3}\ s^{-1}$, under ethylene: $k_{obs} = 8.3 \times 10^{-4}$ and $9.7 \times 10^{-4}\ s^{-1}$; where k_{obs} was derived from a simulation of the parallel processes: 1) **1** + [Ru]→**2** + [Ru] (k), 2) [Ru]→inactive (k_{decomp}), where [Ru] = [**3**]$_0$ = 0.004 M and [**1**]$_0$ = [**5**]$_0$ or [**7**]$_0$ = 0.08 M and $k_{obs} = k \times$ [Ru]. For reactions under ethylene $k_{decomp} = 0$, for reactions under N_2, $k_{decomp} = 2 \times 10^{-4}\ s^{-1}$. Although bimolecular catalyst decomposition is probable, the model did not require this level of sophistication for satisfactory fit. The relative rate differential under ethylene = $[((k_{obs}^{5,C_2H_4} - k_{obs}^{5,N_2})/(k_{obs}^{5,N_2}))/((k_{obs}^{7,C_2H_4} - k_{obs}^{7,N_2})/(k_{obs}^{7,N_2}))] = 2.8$.

[22] After completion of the reaction, the liquid phase was replaced with an identical volume of CD_2Cl_2 and allowed to saturate with stirring in the [$^{13}C_n$]ethylene atmosphere. The CD_2Cl_2 was then transferred to an identical vessel containing [$^{12}C_2$]ethylene and the CD_2Cl_2 phase analyzed by ^{1}H NMR spectroscopy every 60 s until equilibrium was established (ca. 600 s). A plot of $-\ln([^{13}C_2]_t]/[^{13}C_2]_{eqm}])$ against t was linear, with the gradient = $(k_f + k_b) = 8.4(\pm 0.3) \times 10^{-3}\ s^{-1}$. The nonstatistical mixture of [$^{13}C_n$]ethylene (94.5 % $n = 2$, 4.9 % $n = 1$, 0.6 % $n = 0$) obtained at the end of co-RCM of **5** and **7** is qualitatively consistent with incomplete equilibration of the gas–solution phases during catalytic turnover.

[23] The $^{13}C/^{12}C$ ratios in **5** and **7** of 3.9:1 and 1.7:1 at "0 % conversion" (Figure 2) are ca. 63 % and 76 % of the predicted $^{13}C/^{12}C$ B2/B1 partitioning, which suggests that there may be an additional ethylene accelerating effect, for example, by ethylene acting as a spectator ligand, that increases the rate of pathway A or B1 slightly (for computational analysis of such effects see reference [15c]).

[24] It should be noted that in the absence of ethylene, cycles A or B may be dominant and either or both may be operative as nondominant pathways when the reaction is conducted under ethylene. However, with 1/1 mixtures of **5** and **7**, pseudo-first-order rate constants were identical under ethylene (1 atm) to those in the reactions of single components. Inconsistent with the yne-then-ene mechanism (A), the rate constant for reaction of **5**, but not of **7**, was somewhat attenuated under N_2 when mixed (1/1). Since the rate of reaction of **5** with **12**, will depend on whether **12** is derived from **7** or **5**, this further supports turnover by the primary ene-then-yne (B1) mechanism in the absence of ethylene.

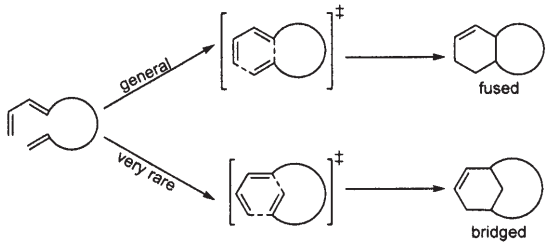
Complexation-Initiated Intramolecular [4+2] Cycloaddition: Construction of Bridged-Type Cycloadducts**

Nobuharu Iwasawa, Kennichi Inaba, Satoko Nakayama, and Masao Aoki*

Intramolecular cycloaddition reactions of linear substrates generally give fused-type adducts selectively, owing to the favorable straight alignment of the two reacting sites (Scheme 1). There have been many examples of fused-type



Scheme 1. The regioselectivity in the intramolecular [4+2] cycloaddition reaction.

intramolecular Diels–Alder reactions, but very few are known for the corresponding bridged-type Diels–Alder reaction.[1,2] Even in these cases, the bridged-type adducts were obtained as minor products along with the major fused-type products.[3,4]

We previously reported that alkynes bearing a furan diene and a dienophile unit on opposite ends, when complexed with $[Co_2(CO)_8]$, shift from a straight structure to a bent one (that is, the angle changes from 180° to around 140°). A subsequent intramolecular Diels–Alder reaction provides a mixture of the starting alkyne–$Co_2(CO)_6$ complex and the desired cyclized alkyne–$Co_2(CO)_6$ complex in equilibrium.[5] The important feature of this reaction is the ready formation of a seven-membered ring by the carbon tether. This is probably due to the rigid and planar structure of the alkyne–$Co_2(CO)_6$ moiety, compelling the two substituents at the alkyne to form an angle of about 140°,[6] which facilitates formation of the seven-membered ring.[7] We expected that this structural

feature of the alkyne–$Co_2(CO)_6$ moiety—namely, the wider angle of alkyne substituents compared to alkene substituents—might lessen the steric congestion in the transition state and allow formation of the bridged-type adduct. Thus, by the appropriate design of substrates in which orbital or electronic control favors the formation of bridged-type products, we could carry out a bridged-type cycloaddition reaction selectively, even with simple linear substrates. Here we describe the successful development of this novel bridged-type [4+2] cycloaddition reaction of silyloxydiene derivatives[8] utilizing alkyne–$Co_2(CO)_6$ complex formation.

First, the reaction was examined using the alkyne–$Co_2(CO)_6$ complex **1**, which contains a silyloxydiene and an electron-deficient dienophile [Eq. (1); TBS = *tert*-butyldimethylsilyl]. When the reaction was carried out in the presence of 2 equivalents of $BF_3{\cdot}OEt_2$ in CH_2Cl_2 at −78 °C, the desired [4+2]-cycloadduct was not obtained; instead **4**, the hydrolyzed product of the starting material, was isolated in 34 % yield (Table 1, entry 1). In contrast, when $AlCl_3$ was employed as a Lewis acid, the starting material disappeared at −78 °C, and the cycloadduct was isolated in 34 % yield along with the Michael-type adduct **3** and the hydrolyzed ketone **4** in 12 % and 26 % yields, respectively (entry 2). Among several aluminum-containing Lewis acids examined, $MeAlCl_2$ gave the best results (entry 4).[9]

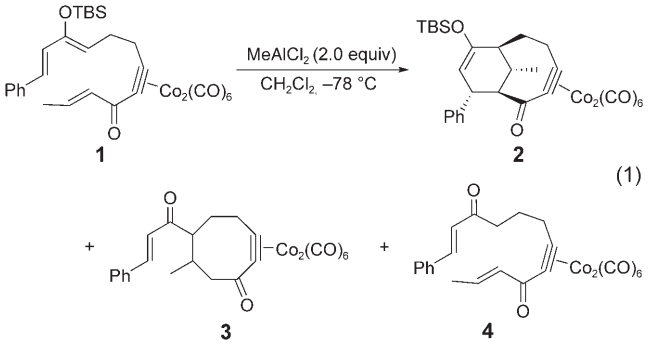

Table 1: Results of the intramolecular [4+2]-cycloaddition reaction in the presence of a Lewis acid [see Eq. (1)].

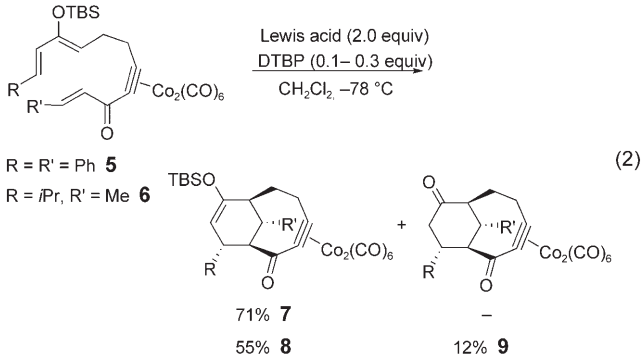
Entry	Lewis acid	*t* [h]	**2** [%]	**3** [%]	**4** [%]
1	$BF_3{\cdot}OEt_2$	0.5	0	0	34
2[a]	$AlCl_3$	25	34	12	26
3	Et_2AlCl	3.5	27	0	0
4[a]	$MeAlCl_2$	3.0	40	30	17
5[a,b]	$MeAlCl_2$	0.33	75	1	2

[a] Products **3** and **4** were obtained as an inseparable mixture. The yields were determined by ^{1}H NMR spectroscopy. [b] For this reaction 0.1 equivalent of DTBP was added.

Analysis of the NMR spectra of the cycloadduct obtained demonstrated that the product was not a normal fused-type adduct, but rather the bridged-type adduct **2** having a bicyclo[5.3.1]undec-3-yn-2-one skeleton. The product was isolated as a single stereoisomer, and the structure of the adduct was confirmed by X-ray crystal structure analysis of the corresponding hydrolyzed ketone.[10] This result proves that the cycloaddition is not a concerted Diels–Alder reaction, but a stepwise, double-Michael-type reaction giving the bridged-type [4+2]-cycloadduct.[11]

To prevent hydrolysis, we further examined the reaction in the presence of 2,6-di-*tert*-butylpyridine (DTBP), which is a well-known proton scavenger.[12] When the reaction was carried out employing 2 equivalents of $MeAlCl_2$ in the presence of 0.1 equivalents of DTBP in CH_2Cl_2 at −78 °C, formation of the hydrolyzed products was efficiently suppressed and the desired product **2** was obtained in 75 % yield (Table 1, entry 5).

We then extended the scope of the reaction using several substrates. As shown in Equation (2), the same type of substrates **5** and **6** gave the corresponding bridged-type [4+2] cycloadducts in good yield as a single stereoisomer when the reaction was carried with 2 equivalents of $MeAlCl_2$ in the presence of 0.1–0.3 equivalents of DTBP in CH_2Cl_2 at −78 °C. For the reaction with substrate **6**, the [4+2]-cycloadduct **8** was accompanied by a small amount of its hydrolyzed cycloadduct **9**. The configuration of the products were determined based on the analogy of the coupling pattern of their ^{1}H NMR spectra with that of **2**.

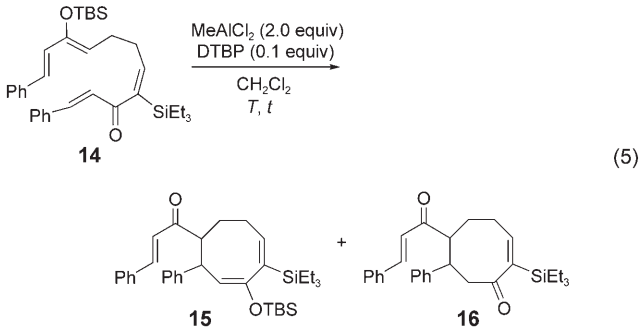


The reaction of substrate **10**, having an additional carbon atom in the tether, also gave the desired bridged-type adduct **11** with a bicyclo[6.3.1]dodec-3-yn-2-one skeleton as a single stereoisomer in reasonable yield [Eq. (3)]. The structure was again confirmed by X-ray crystal structure analysis of the corresponding hydrolyzed ketone.[10] Furthermore, the reac-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tion of substrate **12**, which has one less carbon atom in the tether than **1**, also proceeded albeit in moderate yield, probably due to the severe strain of the system. The desired adduct **13**, with the bicyclo[4.3.1]dec-3-yn-2-one skeleton, was obtained in 39% yield by carrying out the reaction with 5.25 equivalents of $MeAlCl_2$ in CH_2Cl_2 at room temperature [Eq. (4)].[13] Thus, this bridged-type [4+2] cycloaddition reaction shows reasonable generality with respect to the substituents and the number of carbon atoms in the tether.

We then examined the reaction of the corresponding olefinic substrate **14** to confirm the importance of the alkyne–$Co_2(CO)_6$ moiety for the formation of the bridged-type products. The vinylsilane substrate **14** was obtained in 63% yield by reduction of **5** with triethylsilane.[14] Treatment of **14** under several typical cycloaddition reaction conditions did not give the corresponding bridged-type cycloadduct, but instead the monocyclic Michael addition products **15** and **16** in high yield [Eq. (5), Table 2]. We believe that the wider bent angle of the alkyne–$Co_2(CO)_6$ complexes releases the steric congestion of the transition state and enables the smooth formation of the bridged-type cycloadduct. However, further examination is necessary to clarify the exact role of the alkyne–$Co_2(CO)_6$ moiety.



(5)

Table 2: Results of the reactions with the olefinic substrate **14** [see Eq. (5)].

Entry	*T*	*t* [min]	**15** [%]	**16** [%]
1	−78 °C	115	65	33
2[a]	−78 °C	50	45	44
3	RT	10	trace	80

[a] DTBP was not added.

Finally, we investigated the decomplexation of the alkyne–$Co_2(CO)_6$ moiety from the bridged-type cycloadducts (Table 3). The cycloadduct **2** and its hydrolyzed ketone **17** both underwent smooth hydrosilylation of the alkyne–$Co_2(CO)_6$ moiety to give vinylsilanes **18a** and **19a** in good yields upon heating of the complexes in the presence of triethylsilane (entries 1 and 2).[15] Furthermore, the reaction of **17** with sodium hypophosphite[16] proceeded smoothly to give enone **19b** (entry 3), while the same reaction using silyl enol ether **2** resulted in a complex mixture of products. To our surprise, simple heating of complex **2** in toluene/H_2O (5/1) with vigorous stirring gave the desired decomplexed enone **18b** in good yield without hydrolyzing the silyl enol ether moiety (entry 4). Although details of this demetalation reaction remain to be explored, this method affords a simple conversion of alkyne–$Co_2(CO)_6$ complexes into the corresponding alkenes.[17]

Table 3: Results of the demetalation reaction of bridged-type alkyne–$Co_2(CO)_6$ cycloadducts.[a]

Entry	Substrate	Reaction conditions	Product	Yield [%]
1	 **2**	Et_3SiH, BTMSA, DCE, 65 °C, 6.5 h	 **18a**	68
2	 **17**	Et_3SiH, BTMSA, DCE, 65 °C, 24 h	 **19a**	77
3	 **17**	$NaH_2PO_2 \cdot H_2O$, 2-methoxyethanol, 65 °C, 2 h	 **19b**	72
4	 **2**	H_2O, toluene, reflux, 2 h	 **18b**	66

[a] BTMSA = bis(trimethylsilyl)acetylene, DCE = 1,2-dichloroethane.

In conclusion, we have developed a method for the preparation of bridged-type [4+2]-cycloadducts utilizing alkyne–$Co_2(CO)_6$ complex formation. Synthetically useful bicyclo[*n*.3.1] skeletons with multiple functionalities could be prepared stereoselectively by this procedure.

Experimental Section

Cyclization of **1**: The alkyne–cobalt complex **1** was purified by PTLC (hexane/CH_2Cl_2 1/1) just before use. 2,6-Di-*tert*-butylpyridine (4.20 μL, 18.4 μmol) was added to a solution of **1** (125 mg, 0.187 mmol) in CH_2Cl_2 (19 mL) at −78 °C. After 5 min a solution of $MeAlCl_2$ (0.370 mL, 0.370 mmol) in hexane (1.0 M) was added, and the mixture was stirred for 20 min at −78 °C. Then the reaction was quenched with saturate aqueous $NaHCO_3$, and the product was extracted with ethyl acetate three times. The combined organic extracts were washed with brine, dried over anhydrous sodium sulfate, filtered, and concentrated under reduced pressure. The residue was purified by PTLC (hexane/CH_2Cl_2 1/1) to give **2** (93.0 mg, 0.140 mmol) in 75% yield as a dark red oil. Compounds **3**

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

and **4** were obtained as an inseparable mixture in a 1:2 ratio (3.10 mg, 5.60 μmol) in 3% yield as a dark red oil.

Rational Design and Synthesis of Highly Potent β-Glucocerebrosidase Inhibitors

*Xiaoxiang Zhu, Kamlesh A. Sheth, Shihong Li, Hui-Hwa Chang, and Jian-Qiang Fan**

β-Glucocerebrosidase (GCase or acid β-glucosidase) is a lysosomal hydrolase that catalyzes the hydrolytic cleavage of glucose from glucosylceramide.[1] A deficiency in GCase activity results in the progressive accumulation of glucosylceramide, a normal intermediate in the catabolism of globosides and gangliosides, in the lysosomes of macrophages. This deficiency leads to Gaucher disease, the most common lysosomal storage disorder.[2] The disease severity is based mainly on the level of the residual enzyme activity in the tissues of the affected patients.[3] Enzyme-replacement therapy is effective for type 1 Gaucher disease, the non-neuronopathic form; however, this therapy is not available for types 2 and 3 of Gaucher disease, the acute/subacute neuronopathic forms, because of the difficulty in delivering the replacement enzyme to the central nervous system.

We have reported that the residual enzyme activity can be increased in lymphoblasts from patients with Fabry disease, another lysosomal storage disease, when the cells were incubated with potent inhibitors of the mutant enzyme at subinhibitory concentrations.[4] The potent inhibitors serve as active-site specific chaperones (ASSCs) to assist the efficient folding process in the endoplasmic reticulum, thus accelerating the biosynthesis, processing, and maturation of the mutated protein.[5] A correlation demonstrated that the more potent inhibitors are the more effective ASSCs, because they retain high affinity with the catalytic domain of the

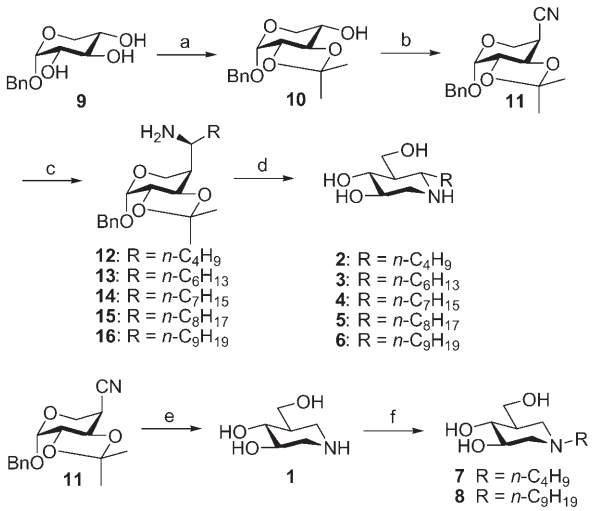
enzyme.[6] Sawkar et al. reported that the addition of an inhibitor of GCase to the culture medium of fibroblasts from patients with Gaucher disease led to a twofold increase in the activity of N370S GCase, which suggests that a potent inhibitor of GCase could be of therapeutic interest.[7] Therefore, an approach to the design and synthesis of potent inhibitors of GCase was undertaken.

The natural substrates for GCase are *N*-acylsphingosyl-1-*O*-β-D-glucosides, which have different fatty acid acyl and sphingosyl moieties depending upon the tissue source.[2] It is, therefore, reasonable to postulate that GCase may contain two substrate-binding sites in the catalytic domain: one that recognizes the glucosyl residue and the other that recognizes the hydrophobic ceramide moiety. Transition-state mimics are frequently potent inhibitors of the enzyme. Thus, our strategy to design potent GCase inhibitors focused on molecules that not only closely resemble both glucose and ceramide, but also mimic the transition state of enzymatic glycosidic cleavage. It is established that GCase cleaves the β-glycosidic bond to release glucose with the retention of the anomeric configuration via a covalent glucosyl enzyme intermediate with Glu340 acting as the nucleophile and Glu235 as the acidic/basic species.[8] Known as a potent inhibitor of sweet-almond β-glucosidase ($K_i = 110$ nM), isofagomine (IFG, **1**) closely resembles glucose with a nitrogen atom in the pseudo-anomeric position, thus presumably acting as a mimic of the glycosyl-enzyme intermediate.[9] The X-ray crystal structure of GCase indicated the existence of an annulus of hydrophobic residues around the entrance to the glucose binding site,[10] which could serve as a hydrophobic bind site. On the basis of these findings, derivatization of IFG with a hydrophobic group may lead to a highly potent inhibitor. We decided to synthesize a series of novel IFG analogues **2**–**6** with a hydrophobic alkyl group at C6 and IFG analogues **7**–**8** with an alkyl group at N1 in an attempt to demonstrate this concept and discover novel GCase inhibitors.

Numerous syntheses of IFG and its derivatives have been reported,[11] but the synthesis of 6-alkyl IFGs remains unexplored. As previously described,[11c] the synthesis of **1** was difficult because of the lack of a suitably branched carbohydrate precursor. In this regard, 6-alkyl IFGs with an additional chiral center might yet be more difficult to synthesize in a straightforward fashion. We envisaged a concise synthetic route for the preparation of **2**–**6** and disclose herein the success of our strategy with the stereocontrolled introduction of the 6-alkyl group by the addition of a Grignard reagent to the nitrile group.

Compounds **2**–**6** were synthesized from benzyl α-L-xylopyranoside (Scheme 1). Benzyl α-L-xylopyranoside was treated with 2-methoxypropene and *para*-toluenesulfonic acid (TsOH) in THF to afford **10** in 53% yield. Triflation of the free 4-hydroxy group of **10** and subsequent treatment with KCN in dimethylformamide (DMF) in the presence of [18]crown-6 led to nitrile **11** in 80% yield (two steps from **10**). The addition of *n*-C_4H_9MgCl to **11**, followed by reduction with $NaBH_4$, stereoselectively afforded a single stereoisomer **12** in 74% yield.[12] The same procedure was used for the synthesis of **13**–**16**, and the yield ranged from 65 to 74%. Catalytic hydrogenation of amine **12** in the presence of HCl



Scheme 1. Synthesis of IFG (**1**) and IFG derivatives **2**–**8**. a) CH_2=C(OMe)Me, TsOH·H_2O, THF, 1.5 h, 0°C (53%); b) Tf_2O, pyridine, CH_2Cl_2, 2 h, −78→0°C; then KCN, 18[crown]-6, DMF, 16 h, RT (80%); c) RMgX, Et_2O, 2 h, RT; then $NaBH_4$, overnight, RT (65–74%); d) H_2, 20% $Pd(OH)_2$/C, AcOH, MeOH, 50 psi, overnight, RT; then 1 N HCl (52–81%); e) H_2, 20% $Pd(OH)_2$/C, HCl (conc.), MeOH, RT (81%); f) aldehyde, $NaBH_3CN$, MeOH (79–83%). Tf=trifluoromethanesulfonyl.

over 20% $Pd(OH)_2$ on charcoal at atmospheric pressure gave **2** in 52% yield. Alternatively, amine **16** was hydrogenated in the presence of AcOH over 20% $Pd(OH)_2$ on charcoal under 50 psi, followed by acid hydrolysis of the protective group to afford **6** in 81% yield. The same procedure was successfully applied to **13**–**15** to give **3**–**5**. The hydrogenation of **11** over 20% $Pd(OH)_2$ on charcoal led to debenzylation, intramolecular cyclization, and concurrent deacetonation in one step to give **1** in 81% yield. In synopsis, although a number of methods have been reported for the synthesis of **1**,[11] the present method provides an efficient and short synthetic route for the synthesis of **1** in a total of four steps and an overall yield of 34%. In addition, *N*-alkyl IFGs **7** and **8** were prepared according to the previously reported procedure.[13]

The configuration of the newly formed stereogenic center in **12** was established based on 6-butyl IFG (**2**), whose stereochemistry was determined by 2D NMR spectroscopic analyses. The NOESY spectrum of **2** showed significant correlations of H6 with both H4 and H2a, and the coupling constant $J(5,6)$ was observed to be 10.5 Hz, thus confirming that H6 is situated at an axial orientation. Thus, the configuration of the new asymmetric center in **12** can be assigned as *S* (see the Supporting Information for the COSY, TOCSY, and NOESY spectra of **2**). Analysis of the ^{1}H NMR spectra of **2**–**6** indicates that they all possess the same configuration at the asymmetric C6 position.

The high stereoselectivity observed above can be explained by a chelation mechanism (Scheme 2). After addition of the Grignard reagent to the nitrile moiety, the magnesium atom of the magnesioimine could be chelated to the oxygen atom on the pyranose ring, thus resulting in the formation of a six-membered cyclic intermediate **17**. Further

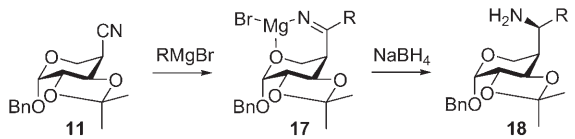

Scheme 2. Proposed mechanism for the stereoselective formation of amine **18**.

reduction of the ketimine function with $NaBH_4$ prefers an attack at the *Re* face to yield amine **18** with a *S* configuration.

The inhibitory activities of all compounds against human GCase was determined with 4-methylumbelliferyl β-glucoside (4MU-β-Glc) and are summarized in Table 1. To determine

Table 1: Inhibitory activity of **1** and derivatives **2**–**8** against GCase.

Inhibitors	IC_{50} [nM][a]	K_i [nM]
IFG (**1**)	56	25[b]
6-butyl IFG (**2**)	160	120[b]
6-hexyl IFG (**3**)	4.2	[c]
6-heptyl IFG (**4**)	1.8	[c]
6-octyl IFG (**5**)	0.8	[c]
6-nonyl IFG (**6**)	0.6	[c]
N-butyl IFG (**7**)	44000	n.d.
N-nonyl IFG (**8**)	>100000	n.d.

[a] All inhibitory activities were determined with 4MU-β-Glc at 3 mM. [b] The kinetic data were fit to a double-reciprocal plot and replotted to K_{mapp} versus [I]. [c] Data do not fit to a competitive-inhibition model by using lineal and nonlineal models (Prism GraphPad). n.d. = not determined.

the K_i values, a Lineweaver–Burk plot was used to calculate the K_{mapp} in the presence of an inhibitor at various concentrations and replotted against the concentrations of inhibitor (Figure 1). IFG (**1**) was a potent inhibitor against GCase with IC_{50} and K_i values of 56 and 25 nM, respectively. In contrast, modification of the imino group by a hydrophobic group

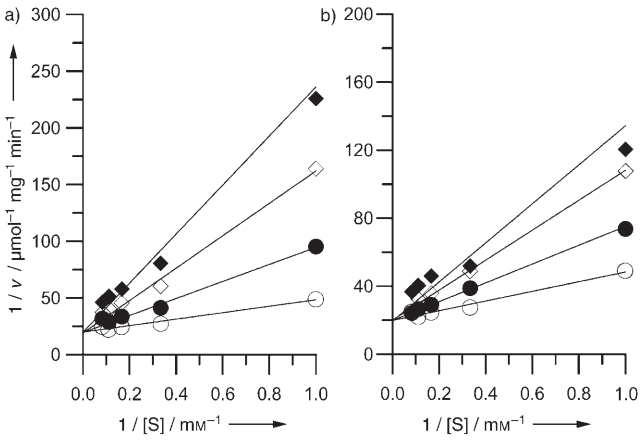

Figure 1. Lineweaver–Burk plots of **1** and 6-butyl IFG (**2**) for the inhibition of human GCase. The increasing concentrations of substrate were used to determine the K_{mapp} and K_i values and the data were plotted as $1/v$ versus 1/[S]. a) Concentrations of **1** were 0 (○), 20 (●), 50 (◇), and 150 nM (◆). b) Concentrations of **2** were 0 (○), 100 (●), 200 (◇), and 400 nM (◆).

greatly decreased the inhibitory activity ($IC_{50} \geq 44$ μM for **7** and **8**, respectively). The potent inhibitory activity of IFG is most likely attributed to the salt bridge between protonated **1** and the catalytic carboxylate of GCase.[9] The alkyl group attached to N1 might interfere with the formation of the salt bridge, thus resulting in less potent inhibitors. Incorporation of the 6-butyl group into **1** generated 6-butyl IFG (**2**), which did not exhibit a better inhibitory activity on GCase than **1**. However, 6-hexyl IFG (**3**) was apparently more potent than **1** with a 13-fold increase in potency. Further extension of the length of the alkyl chain improved the potency accordingly (**4**–**6**). The most potent inhibitor 6-nonyl IFG (**6**) displayed a remarkable IC_{50} value of 0.6 nM, which is 93-fold more potent relative to **1**. These data clearly indicate that a long alkyl chain (greater than four carbon atoms) is required to improve potency and a longer chain provides a higher potency, thus suggesting that there is a hydrophobic interaction between the alkyl group and enzyme and that an appropriate alkyl chain length is needed to bind the hydrophobic domain. In recent years, despite many efforts being directed towards the synthesis and study of IFG analogues, only weaker inhibitors have resulted from these investigations.[9,11] Based on the concept we have proposed and the x-ray crystal structure of GCase, we discovered highly potent GCase inhibitors **3**–**6**, which are between 13- and 93-fold more potent than the parent inhibitor **1**. The proposed binding of **6** with GCase is shown in Figure 2. The structural features of the potent inhibitors as described above can be applied further to find potent and selective inhibitors of GCase with an improved biopharmaceutical profile.

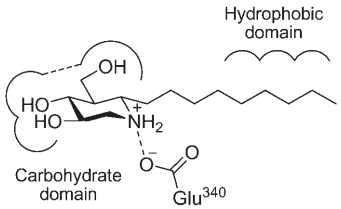

Figure 2. Proposed binding of **6** with human GCase.

The inhibition mode for **1** and **2** is competitive, with K_i values of 25 and 120 nM, respectively, using 4MU-β-Glc as the variable substrate (Table 1). The inhibition mode for the 6-alkyl IFG derivatives with longer chains was more complicated than being purely competitive but showed characteristics of a mixed-type inhibition. This difference may be explained on the basis that these inhibitors bind the enzyme through two distant binding sites: a carbohydrate binding site and a hydrophobic binding site (Figure 2). Whereas both inhibitory binding sites are likely to be competitive, the strong combination of both acts in a manner to provide a non-competitive-like inhibitory mechanism in some of the most potent 6-alkyl IFGs.

In conclusion, we have demonstrated an efficient and straightforward methodology for the synthesis of 6-alkyl IFGs, which represent a new class of highly potent inhibitors of human GCase. These inhibitors appear to utilize recog-

nition domains for both a carbohydrate and a hydrophobic binding site. As a result, the most potent GCase inhibitor 6-nonyl IFG (**6**) shows an IC_{50} value at subnanomolar concentrations. We have used these compounds as ASSCs for the rescue of misfolded mutant GCase in cells from Gaucher patients (results to be published elsewhere). As a consequence, they may be ideal candidates for further development as small-molecule drugs for the treatment of Gaucher disease, in particular for the neuronopathic disease form.

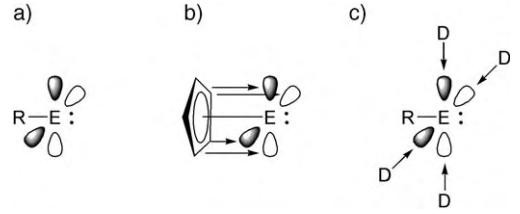
Crown Ether Ligation: An Approach to Low-Oxidation-State Indium Compounds**

*Christopher G. Andrews and Charles L. B. Macdonald**

In memory of Dennis G. Tuck

The chemistry of Group 13 elements in oxidation states lower than +3 has been a subject of increasing importance in main-group chemistry over the last 20 years. Particular attention has focused on the chemistry of compounds containing Group 13 elements in the +1 oxidation state (E^I) for both fundamental and practical purposes.[1–3] The presence of the "lone pair" of electrons on E^I (Scheme 1a) often makes the



Scheme 1. a) The "lone pair" of electrons on E^I. b) Electron donation to the formally vacant p orbitals on the E^I center resulting in stabalization. The postulated use of an appropriately shaped auxiliary donor to stabilize the vacant orbitals.

normally Lewis acidic Group 13 center behave as a Lewis base instead. Such altered reactivity means that compounds containing E^I centers can be used as ligands for main-group[4] and transition-metal acceptors;[5,6] some of the coordination complexes thus obtained have proven to be useful precursors for the formation of intermetallic and other materials.[6]

Although sterically demanding substituents such as terphenyl[7,8] and β-diketiminate[9–13] ligands have been used to obtain some examples, the vast majority of stable monomeric compounds containing E^I centers (apart from thallium[14]) have the Group 13 element bound to either a cyclopentadienyl (Cp) substituent[15] or to an isolobal tris(pyrazolyl)borate group.[16] These σ- and π-donating substituents stabilize

the low-oxidation-state center by providing sufficient electron density to fill the formally vacant p orbitals on the E^I center, as illustrated for a Cp group in Scheme 1b. We postulated that monomeric E^I species containing nonbulky, poorly or non-π-donating ligands could be stabilized by using an appropriately shaped auxiliary donor to stabilize the vacant orbitals (Scheme 1c). The shape and properties of the polydentate donor ligand are important in this context because, although coordination to E^I centers may appear to be trivial in theory, all previous attempts to coordinate donors to potentially monomeric E^I centers have resulted in the disproportionation of the Group 13 compound and the isolation of higher-oxidation-state products.[17–19]

Herein, we demonstrate that properly sized crown ethers are suitable ligands for this task; this approach has allowed us to isolate the first example of a monomeric adduct of a true $R–E^I$ compound with a Lewis base. Furthermore, the presence of the crown ether modifies the reactivity of the $R–E^I$ species. Lastly, we show that appropriate crown ethers can even be used to favor the formation of an $R–E^I$ environment from higher-oxidation-state precursors.

Recently, we reported syntheses for the salt $InSO_3CF_3$ (InOTf, **1**),[20] which is unusually soluble for an inorganic In^I salt. The solubility of this reagent in organic and particularly aromatic solvents has allowed us to conduct experiments using homogeneous solutions and to avoid the heterogeneous conditions often caused by the insolubility of In^I halides. Thus the reaction of **1** with 1,4,7,10,13,16-hexaoxacyclooctadecane ([18]crown-6; compounds labeled **a**) or 2,3,11,12-dibenzo-1,4,7,10,13,16-hexaoxacyclooctadecane (dibenzo[18]crown-6; compounds labeled **b**) in toluene resulted in the formation of a colorless solution. Concentration of the solution produced crystals of the 1:1 coordination complex **2a** or **2b**, as confirmed by spectroscopic and analytical methods. The colorless crystals of **2a** were subjected to a single-crystal X-ray diffraction experiment;[21] the molecular structure of **2a** is depicted in Figure 1, and there are no unusually short intermolecular contacts. There are

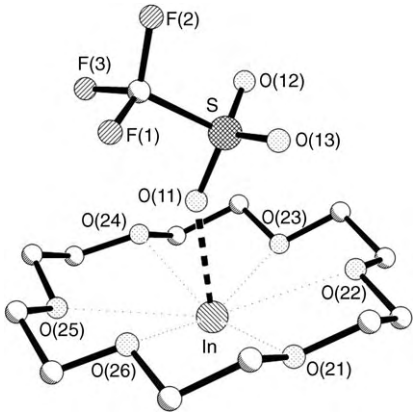

Figure 1. Molecular structure of **2a**. Hydrogen atoms are omitted for clarity. Selected bond lengths [Å] and angles [°]: O(11)-S 1.435(2), O(11)-In 2.370(2), O(12)-S 1.431(2), O(13)-S 1.426(2), O(21)-In 2.8690(18), O(22)-In 2.8492(18), O(23)-In 2.8299(18), O(24)-In 2.8513(18), O(25)-In 2.9292(18), O(26)-In 2.9167(19); S-O(11)-In 151.39(13).

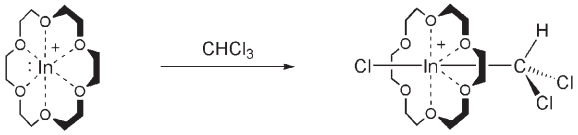
three important features in the structure of **2a**. Most noticeably, the complex still contains an In^I center, and **2a** is thus the only example of an intact monomeric In^I compound acting as a Lewis acid; every previous attempt to ligate bases to In^I salts has resulted in the disproportionation of the In^I compound.[18,19] Secondly, the In atom is situated essentially on the centroid of the O_6 ring, in marked contrast to the cationic In^{III} center in $[InI_2([18]crown-6)][InI_4]$.[22] Of further note is the relatively short In–O(11) distance of 2.370(2) Å, which is considerably shorter than the shortest distance of 2.579(6) Å found in **1**. Moreover, the crystallographic equivalence of the S–O bond lengths (1.435(2), 1.432(2), and 1.426(2) Å) is consistent with an ionic trifluoromethansulfonate (triflate) anion, thus, the data suggest that **2a** is best considered as an isolated contact ion pair in the solid state. Such an interpretation is also consistent with the ionic radii suggested for In^I (1.04 Å) and O^{2-} ions (1.40 Å).[23] All other metrical parameters are as one would predict, given the components of the adduct, and require no further comment.

Perhaps surprisingly, the analogous reactions of indium(I) chloride with [18]crown-6 or dibenzo[18]crown-6 result in the immediate deposition of In metal and the formation of products with In in a higher oxidation state. The disproportionation of In^ICl clearly contrasts with the behavior of **1** and suggests that the triflate anion confers benefits other than merely increased solubility to such low-oxidation-state reagents.

As well as providing monomeric compounds, the crown ethers appear to alter the reactivity of **1**. In particular, **1** is soluble in dichloromethane and chloroform but does not appear to react with the solvents at an appreciable rate. In contrast, **2a** and **2b** react rapidly with such chlorinated solvents through formal oxidative insertions into C–Cl bonds to form the compounds **3a** and **3b**, respectively, as outlined in Scheme 2. In the case of **3b**, crystalline material suitable for



Scheme 2. Oxidative addition of a C–Cl bond in chloroform to the In^I cation in **2** to produce the cation in **3**. Note: the crown ether is [18]crown-6 for **a** and dibenzo[18]crown-6 for **b**.

analysis by X-ray diffraction was obtained and the molecular structure obtained from the experiment is displayed in Figure 2.

The molecular structure of **3b** consists of distinct cations of the form $[In(CHCl_2)Cl(dibenzo[18]crown-6)]^+$ and triflate anions. There are no unusually short interionic distances and the metrical parameters of the anion are consistent with it being noncoordinating and ionic. The structural features of the cation, although unique, are predictable. For example, the smaller In^{III} ion is offset from the center of the O_6 ring to allow for four shorter In–O contacts (2.517(5) to 2.550(5) Å) and thus leaves two much longer In···O contacts (2.738(5) and 2.756(5) Å). The In–Cl bond length of 2.304(2) Å is one of the

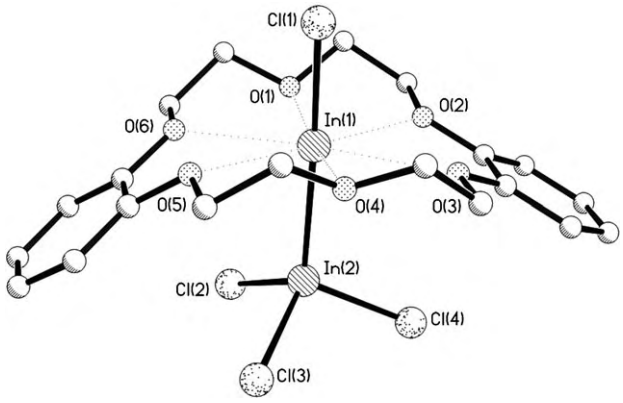

Figure 3. Molecular structure of **4b**. Hydrogen atoms are omitted for clarity. Selected bond lengths [Å] and angles [°]: In(1)-In(2) 2.7020(12), Cl(1)-In(1) 2.324(3), Cl(2)-In(2) 2.408(3), Cl(3)-In(2) 2.372(3), Cl(4)-In(2) 2.377(3), In(1)-O(1) 2.548(8), In(1)-O(2) 2.652(8), In(1)-O(3) 2.691(8), In(1)-O(4) 2.650(9), In(1)-O(5) 2.754(8), In(1)-O(6) 2.696(8); Cl(1)-In(1)-In(2) 177.12(9), Cl(3)-In(2)-Cl(4) 104.82(14), Cl(3)-In(2)-Cl(2) 102.52(12), Cl(4)-In(2)-Cl(2) 103.19(13), Cl(3)-In(2)-In(1) 116.77(9), Cl(4)-In(2)-In(1) 113.50(9), Cl(2)-In(2)-In(1) 114.47(9).

shortest such distances so far reported;[24] however, the In–C bond length of 2.174(7) Å is typical of such bonds[25,26] reported in the Cambridge Structural Database (CSD).[27] The minor deviation of the Cl-In-C angle from linearity (171.82(19)°) is consistent with the asymmetric ligation of the In center by the crown ether. All the other bond lengths and angles are typical and require no further comment.

Whereas the structural details of **3b** are unambiguous, the mechanism through which the oxidative addition occurs remains to be elucidated. Overall, we postulate that the enhanced reactivity of **2** with chlorocarbons relative to **1** may be attributable to the crown ether limiting the degree of agglomeration of **1** in solution. In this context, ligation of In^{I} species by crown ethers may possibly be used to significantly alter the reactivity of this important class of catalysts for certain organic transformations.[28]

Finally, crown ethers have provided us with a new method to generate In^{I} centers from In^{II} reagents. It is well-known that $[In_2Cl_4]$ disproportionates to form the In^{I}/In^{III} salt $[In][InCl_4]$ in the presence of certain arenes (Scheme 3, **A**);[29,30] however, the reactions of such salts with ethers or other donors yield complexes containing In^{II} (Scheme 3, **B**).[31] In contrast, the reaction of $[In_2Cl_4]$ with dibenzo[18]-crown-6 produces the In^{I}/In^{III} donor–acceptor complex **4b** (Scheme 3, **C**).[32]

Crystals of **4b** were obtained by slowly concentrating a solution of the reaction mixture in toluene; the molecular structure of the adduct is depicted in Figure 3. The structure of **4b** consists of a mixed-valent dinuclear indium core of the form Cl–In–$InCl_3$ that is symmetrically coordinated about the In^{I} center by the crown ether. Predictably, the In–In bond length of 2.7020(12) Å lies at the short end of the range of In–In bond lengths[33] compiled in the CSD and is shorter than the distance of 2.748(4) Å observed in the only other In–In donor–acceptor complex reported.[34] The In^{I}–Cl bond length of 2.324(3) Å is somewhat shorter than the In^{III}–Cl bond but still falls within the range typical for terminal bonds.[35] As observed in the structure of **2a**, the In^{I} center sits essentially at the centroid of the O_6 ring and the Cl-In^{I}-In^{III} angle of 177.12(9)° is consistent with the expected linear geometry.

We believe that the adoption of the donor–acceptor structure **4b** over the more common valence isomers (**A** and **B** depicted in Scheme 3) must be attributable to the size and shape of the crown ether. Overall, the crown ether alters the thermodynamic preference for the covalent In^{II}–In^{II} form[36] and has allowed us to isolate a homoleptic donor–acceptor isomer for the first time. Although the reaction of $[In_2Cl_4]$ with [18]crown-6 likely produces the analogous compound **4a**, we have not yet been able to obtain material suitable for single-crystal experiments.

In conclusion, we have discovered that crown ether ligation is a new, convenient, and mild method for the preparation and stabilization of In^{I} compounds. This approach has allowed for the first observation of two unprecedented structural types, and it is our hope that the stabilization or activation of low-oxidation-state centers by

cyclic, polydentate donors will increase the availability and practicality of such reagents for use by the larger chemical community. We are currently investigating the application of compounds such as **2** as ligands for main-group and transition-metal complexes and we are examining the use of the methods outlined herein to gain access to analogous compounds containing the lighter Group 13 elements.[37]

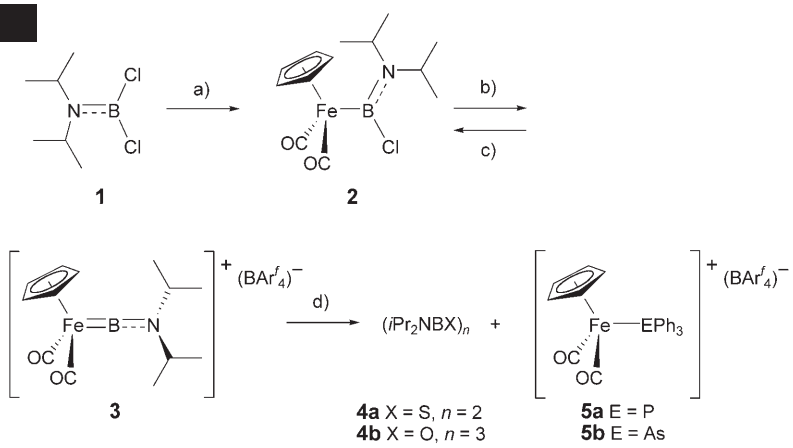
Cationic Terminal Borylene Complexes: A Synthetic and Mechanistic Investigation of M=B Metathesis Chemistry**

*Deborah L. Kays (née Coombs), Joanna K. Day, Li-Ling Ooi, and Simon Aldridge**

Metathesis reactions constitute a key component of modern synthetic chemistry; olefin metathesis, for example, provides a versatile and widely exploited carbon–carbon bond-forming methodology.[1] Such reactions are typically catalyzed by organometallic complexes that contain M=C bonds.[2] The synthesis of analogous complexes that contain M=Si bonds, for example, has led to an in-depth investigation of their reactivity towards unsaturated substrates.[3]

Synthetic approaches that lead to the isolation of related systems with M=B bonds have been developed only recently:[4–7] for example, halide-abstraction chemistry gives access to cationic terminal borylene complexes, $[L_nM{=}BX]^+$.[7] Consequently, reports of the fundamental chemistry of M=B bonds are somewhat limited (predominantly to metal–metal transfer reactions and addition/substitution reactivity towards nucleophiles).[4,6,7] Thus, the chemistry of $[Cp^*Fe(CO)_2(BMes)]^+$ (Mes = mesityl = 2,4,6-$Me_3C_6H_2$, Cp* = pentamethylcyclopentadienyl), for example, is dominated by the electrophilic character at both the Fe and B centers.[7] In an attempt to tune the reactivity of these highly unsaturated complexes we investigated the synthesis of cationic aminoborylene systems, $[L_nM{=}BNR_2]^+$.[5] Chloride abstraction from $[CpFe(CO)_2\{B(N{i}Pr_2)Cl\}]$ (**2**) (Cp = cyclopentadienyl) by $Na(BAr^f{}_4)$ (Ar^f = 3,5-$(CF_3)_2C_6H_3$) affords the thermally robust cationic B/N vinylidene analogue $[CpFe(CO)_2(BN{i}Pr_2)]^+$, which undergoes, with E=O and E=S bonds (E = P, As), the first reported examples of M=B metathesis chemistry.

The synthesis of $[CpFe(CO)_2(BN{i}Pr_2)]^+(BAr^f{}_4)^-$ (**3**) is outlined in Scheme 1. The key precursor **2** was synthesized by the selective substitution of a chloride substituent in iPr_2NBCl_2 (**1**) by $[CpFe(CO)_2]^-$. The steric bulk of the amino substituents is a key point: the use of the smaller NMe_2 group results in the formation of a thermally fragile borylene product in the subsequent halide-abstraction step,[7b,8] whereas $[CpFe(CO)_2\{B(tmp)Cl\}]$ (tmp = tetramethylpiperamino) was inaccessible from $tmpBCl_2$. Compound **2** is a pale yellow sublimable crystalline solid, which was characterized by multinuclear NMR and IR spectroscopy, mass spectrometry, and X-ray crystallographic analysis (Figure 1).



Scheme 1. Synthesis and reactions of **3**. a) Na[CpFe(CO)$_2$] (1 equiv), toluene, 20 °C, 20 h.; b) Na(BAr$^f{}_4$), (1 equiv), dichloromethane, −78→20 °C, 30 min.; c) ppnCl (1.67 equiv), dichloromethane, 20 °C, 30 min.; d) $Ph_3P{=}S$ or $Ph_3As{=}O$ (1 equiv), dichloromethane, 20 °C, 30 min. ppn = bis(triphenylphosphoranylidene)ammonium.

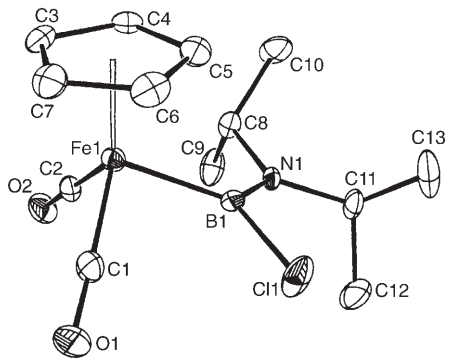


Figure 1. Structure of **2** (50% ellipsoids; H atoms omitted for clarity). Selected bond lengths [Å] and angles [°]: Fe(1)-B(1) 2.054(4), B(1)-Cl(1) 1.841(4), B(1)-N(1) 1.389(5); centroid-Fe(1)-B(1)-N(1) 83.7(4).

The reaction of **2** with Na(BAr$^f{}_4$) in dichloromethane results in a quantitative conversion (determined by ^{1}H and ^{11}B NMR spectroscopy) into **3**. The latter product (along with the C_5H_4Me analogue) is a colourless oil at (or close to) room temperature, but its formulation can be definitively established from spectroscopic and reactivity data. The measured ^{11}B chemical shift for **3** (δ_B = 93.5 ppm) is very close to that reported by Braunschweig et al. for neutral terminal-aminoborylene systems of the type $L_nM{=}BN(SiMe_3)_2$ (δ_B = 86.6–98.3 ppm).[5] The downfield shift upon chloride abstraction ($\Delta\delta_B$ = 38.1 between **2** and **3**) mirrors that found for $[Cp^*Fe(CO)_2\{B(Mes)Cl\}]/[Cp^*Fe(CO)_2(BMes)]^+$ (δ_B = 112.1 and 145.0 ppm, respectively) and for $[Cp^*Fe(CO)_2\{B(NMe_2)Cl\}]/[Cp^*Fe(CO)_2(BNMe_2)]^+$ (δ_B = 58.6 and 88.0 ppm, respectively).[7,8] The ^{1}H and ^{13}C NMR data are

consistent with the presence of Cp, N*i*Pr$_2$, and $(BAr^f_4)^-$ moieties in a 1:1:1 ratio, and the ES+ mass spectrum shows the presence of the $[CpFe(CO)_2(BN{\it i}Pr_2)]^+$ cation. The observation of equivalent *i*Pr substituents is consistent with the structure of the related neutral system $[CpV(CO)_3{=}BN(SiMe_3)_2]$[5c] and agrees with the results of DFT calculations for the model compounds $[(\eta^5\text{-}C_5R_5)Fe(CO)_2(BNMe_2)]^+$ (R = H, Me), for which a minimum-energy structure close to C_s symmetry [< centroid-Fe-N-C ≈ 90° (84.6° for R = Me)] and a low barrier to rotation about the Fe-B-N axis (≈ 2.2 kcal mol^{-1}) have been calculated.[7b,c] Furthermore, the IR spectrum of **3** shows carbonyl stretching frequencies ($\tilde{\nu}$ = 2070, 2028 cm^{-1}) that are significantly blue shifted with respect to **2** ($\tilde{\nu}$ = 2001, 1941 cm^{-1}) ($\Delta\tilde{\nu} \approx 50$ cm^{-1} for $[Cp^*Fe(CO)_2\{B(Mes)Cl\}]/[Cp^*Fe(CO)_2(BMes)]^+$) and are very similar to those reported for the archetypal Fischer carbene systems such as $[CpFe(CO)_2{=}CH(SPh)]^+(PF_6)^-$ ($\tilde{\nu}$ = 2073, 2034 cm^{-1}).[9] Further evidence for the nature of **3** was obtained: 1) from the reaction of **3** with ppnCl (see Supporting Information), which like the analogous reaction for structurally characterized cationic derivatives,[6b,7] generates a haloboryl complex (in this case **2**) by the addition of a halide at boron and 2) from the reaction of **3** with $Ph_3P{=}O$, which proceeds via the structurally characterized adduct $[CpFe(CO)_2\{B(N{\it i}Pr_2)(OPPh_3)\}]^+(BAr^f_4)^-$ (see below).

Although the reactivity of cationic aminoborylene complex **3** towards Cl^- is indicative of electrophilic character, its reactivity towards unsaturated substrates suggests a broader scope for its chemistry. Thus, the reaction of **3** with $Ph_3P{=}S$ in dichloromethane at room temperature leads to the formation of $[{\it i}Pr_2NB(\mu\text{-}S)_2BN{\it i}Pr_2]$ (**4a**) and $[CpFe(CO)_2(PPh_3)]^+(BAr^f_4)^-$ (**5a**) with a conversion of > 95% (as determined by ^{1}H, ^{11}B and ^{31}P NMR spectroscopy). The identities of the isolated products **4a** and **5a** were confirmed by comparison of NMR (^{1}H, ^{11}B, ^{13}C, ^{19}F, and ^{31}P) and IR spectra and mass spectrometry data with those reported for authentic samples.[10a–c] The similar reactivity of **3** towards $Ph_3As{=}O$ led to the isolation of $({\it i}Pr_2NBO)_3$ (**4b**) and $[CpFe(CO)_2(AsPh_3)]^+(BAr^f_4)^-$ (**5b**).[10c,d]

The reactions of **3** with $Ph_3P{=}S$ and $Ph_3As{=}O$ therefore represent, to our knowledge, the first examples of net metathesis reactions for a terminal borylene complex.[11] Although metathesis chemistry has been reported for isoelectronic vinylidene systems $[CpM(CO)_2{=}C{=}CH_2]$ (M = Mn, Re),[12] no such reactivity has been reported for neutral aminoborylene complexes.[5,6] The origins of the different reactivity of **3** and an idea of the likely mechanism can be gauged by examining of the analogous reaction with $Ph_3P{=}O$. This reaction proceeds at a significantly slower rate than those of $Ph_3P{=}S$ or $Ph_3As{=}O$ which presumably reflects the greater strength of the P=O bond. In this case, however, it is possible to identify a reaction intermediate, which was characterized by NMR signals at δ_B = 48.9 ppm and δ_P = 48.3 ppm. The former resonance is consistent with values previously reported for base-stabilized terminal borylene complexes (e.g. δ_B = 51.7–53.2 ppm for N-donor adducts of osmium aminoborylenes),[4b,c] whereas the ^{31}P chemical shift is as expected for donor/acceptor adducts of Ph_3PO with boron-centered Lewis acids (δ_P = 43.6–46.7 ppm).[13] Furthermore, the observations of inequivalent *i*Pr groups by ^{1}H and ^{13}C NMR and of significantly lower carbonyl stretching frequencies ($\tilde{\nu}$ = 2004, 1949 cm^{-1}) are consistent with the formation of a trigonal-planar boron center by coordination of a Lewis base. Confirmation that the intermediate species is indeed the B-bound Ph_3PO adduct $[CpFe(CO)_2\{B(N{\it i}Pr_2)(OPPh_3)\}]^+(BAr^f_4)^-$(**6**) was obtained by X-ray crystallographic analysis (Figure 2). Consistent with related complexes,[4b,c,14] the Fe–B bond length for **6** [2.057(4) Å] is more akin to that expected for a single bond than a double bond (2.054(4) and 1.792(8) Å for **2** and $[Cp^*Fe(CO)_2(BMes)]^+$, respectively).[7] Such a phenomenon has previously been ascribed to significant contributions from resonance forms that incorporate a formal M–B bond (Scheme 2),[4b,c] and a description of **6** as an amino(oxy)boryl species that features a pendant cationic phosphorus centre is probably most apt. Consistent with this, the P–O distance within **6** is significantly longer than that found in free Ph_3PO (1.540(2) vs. 1.493 Å (mean)).[15]

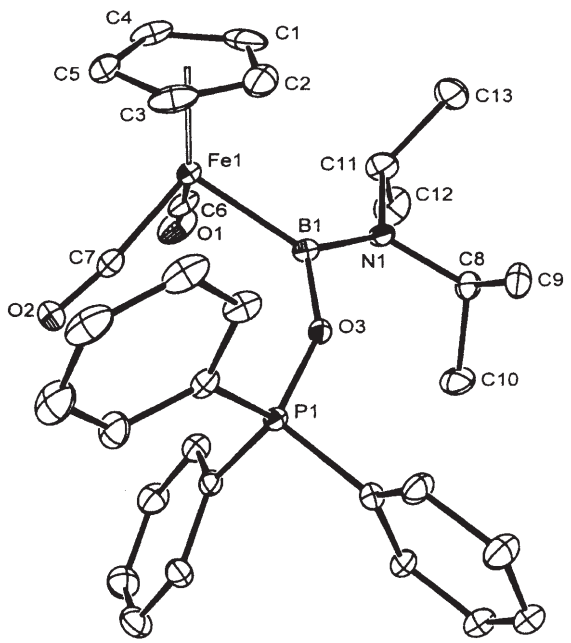

Figure 2. Structure of the cationic component of **6** (50% ellipsoids; H atoms omitted for clarity). Selected bond lengths [Å] and angles [°]: Fe(1)-B(1) 2.057(4), B(1)-O(3) 1.469(4), B(1)-N(1) 1.397(5), P(1)-O(3) 1.540(2); P(1)-O(1)-B(1) 148.0(2), centroid-Fe(1)-B(1)-N(1) 72.5(5).

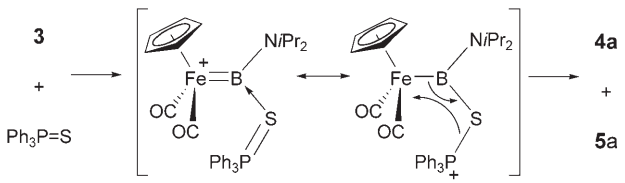
Given the isolation of **6**, it is plausible that the first step in the reaction mechanism involves coordination of $Ph_3E{=}X$



Scheme 2. Proposed addition/substitution pathway for the metathesis reaction of **3** (exemplified by $Ph_3P{=}S$).

(E = P, As; X = O, S) at boron, and that the overall metathesis chemistry of **3** therefore occurs through a combined addition/substitution pathway (Scheme 2). Further studies aimed at better understanding the reactivity of M = B bonds towards unsaturated substrates (including C = E multiple bonds) will be reported in a full account.[17]

Experimental Section

2: Reaction of **1** (1.199 g, 6.6 mmol) with Na[CpFe(CO)$_2$] (1.318 g, 6.6 mmol) in toluene (40 cm^3) at room temperature for 20 h, followed by filtration, removal of volatile compounds in vacuo, and extraction with hexanes ($\approx$40 cm^3) yielded crude **2** as an oily brown solid. Yellow crystals suitable for X-ray diffraction were obtained by sublimation under high vacuum (40 °C at 10^{-4} Torr). Yield (of sublimed material): 0.259 g, 12 %. ^{1}H NMR (400 MHz, C_6D_6): δ = 1.11 (d, J = 6.7 Hz, 6H; CH(CH_3)$_2$ of *i*Pr), 1.39 (d, J = 6.7 Hz, 6H; CH(CH_3)$_2$), 3.40 (sept, J = 6.7 Hz, 1H; CH(CH$_3$)$_2$), 4.44 (sept, J = 6.7 Hz, 1H; CH(CH$_3$)$_2$), 4.69 ppm (s, 5H; Cp-H); ^{13}C NMR (76 MHz, C_6D_6): δ = 21.2 (CH(*C*H$_3$)$_2$), 23.9 (CH(*C*H$_3$)$_2$), 47.8 (*C*H(CH$_3$)$_2$), 55.2 (*C*H(CH$_3$)$_2$), 88.2 (Cp), 215.6 ppm (CO); ^{11}B NMR (96 MHz, C_6D_6): δ = 55.4 ppm. IR (C_6D_6 soln); $\tilde{\nu}$ = 2001, 1941 cm^{-1} νCO; MS (EI): *m*/*z* (%): 295 (65) [*M*−CO]$^+$, 288 (weak) [*M*−Cl], 267 (10) [*M*−2CO]$^+$, 223 (100) [*M*−N*i*Pr$_2$]$^+$, *M*$^+$ not observed; MS: calcd for [*M*−CO]$^+$: 295.0592; found: 295.0595; calcd for [*M*−Cl]$^+$: 288.0853; found 288.0856. Crystal data: $C_{13}H_{19}BClFeNO_2$, orthorhombic, *Pbca*, a = 11.7410(4), b = 13.9170(4), c = 19.0830(7) Å, V = 3118.15(18) Å^3, Z = 8, ρ_{calcd} = 1.378 Mg m^{-3}, M_r = 323.40, T = 150(2) K. 22231 reflections collected, 3175 independent (R(int) = 0.1524), which were used in all calculations. R_1 = 0.0572, wR_2 = 0.1157 for observed unique reflections ($F^2 > 2\sigma(F^2)$) and R_1 = 0.1048, wR_2 = 0.1338 for all unique reflections. Max./min. residual electron densities 0.505/−0.537 e Å^{-3}.[16]

3: Reaction of **2** (0.259 g, 0.80 mmol) and Na(BAr$^f_4$) (0.710 g, 0.80 mmol) in dichloromethane (15 cm^3) from −78→20 °C over 30 min leads to a quantitative conversion (determined by ^{11}B NMR) of **2** (δ_B = 55.4 ppm) to **3** (δ_B = 93.5 ppm). Filtration, and recrystallization from dichloromethane/hexanes (or fluorobenzene/hexanes) at −30 °C leads to the isolation of **3** as a spectroscopically pure colourless oil. Yield of isolated material: 0.465 g, 50 %. ^{1}H NMR (400 MHz, CD_2Cl_2): δ = 1.39 (d, J = 6.6 Hz, 12H; CH(CH_3)$_2$), 3.32 (sept, J = 6.6 Hz, 2H; CH(CH$_3$)$_2$), 5.33 (s, 5H, Cp-H), 7.55 (s, 4H; BAr$^f_4{}^-$-H$_p$), 7.70 ppm (s, 8H; BAr$^f_4{}^-$-H$_o$); ^{13}C NMR (76 MHz, CD_2Cl_2): δ = 24.4 (CH(*C*H$_3$)$_2$), 51.0 (*C*H(CH$_3$)$_2$), 87.1 (C(Cp)), 117.6 (BAr$^f_4{}^-$-CH$_p$), 124.6 (q, $^1J_{CF}$ = 272 Hz, BAr$^f_4{}^-$-CF$_3$), 128.8 (q, $^2J_{CF}$ = 34 Hz, BAr$^f_4{}^-$-CH$_m$), 134.8 (BAr$^f_4{}^-$-CH$_o$), 161.8 (q, $^1J_{CB}$ = 49 Hz, BAr$^f_4{}^-$-C$_{ipso}$), 205.6 ppm (CO); ^{11}B NMR (96 MHz, CD_2Cl_2): δ = −7.7 (BAr$^f_4{}^-$), 93.5 ppm (b, fwhm $\approx$ 615 Hz, BN*i*Pr$_2$); ^{19}F NMR (283 MHz, CD_2Cl_2): δ = −62.6 ppm (CF$_3$); IR (CD_2Cl_2 soln): $\tilde{\nu}$ = 2070, 2028 cm^{-1} νCO; MS (ES): *m*/*z* (%): *M*$^+$ 288.1 (10).

Typical reaction: **3** (0.068 g, 0.06 mmol) and Ph$_3$P=S (1.0 equiv) were stirred together in dichloromethane for 30 min, after which the reaction was judged to be complete by ^{11}B and ^{31}P NMR (conversion of signals at δ_B = 93.5 ppm and δ_P = 43.7 ppm to δ_B = 35.6 ppm and δ_P = 60.8 ppm, respectively). Removal of volatile components in vacuo and extraction into hexanes gave *i*Pr$_2$NB(μ-S)$_2$BN*i*Pr$_2$ (**4a**), which was identified by comparison of ^{1}H, ^{13}C, and ^{11}B NMR spectroscopic and mass spectrometry data with those reported previously.[10a,b] ^{1}H, ^{13}C, ^{11}B, ^{19}F, and ^{31}P NMR and IR spectra of the hexane-insoluble product confirmed it to be [CpFe(CO)$_2$(PPh$_3$)]$^+$(BAr$^f_4$)$^-$ (**5a**).[10c] A similar procedure was adopted for the reaction of **3** with Ph$_3$As = O.[10c,d]

6: Reaction of **3** (0.199 g, 0.17 mmol) and Ph$_3$PO (0.048 g, 0.17 mmol) in dichloromethane (5 cm^3) at room temperature over a period of 30 min, followed by filtration and recrystallization from dichloromethane/hexanes at −30 °C led to the isolation of **6** as pale yellow crystals. Yield of isolated product: 0.105 g, 43 %. ^{1}H NMR (400 MHz, CD_2Cl_2): δ = 1.06 (d, J = 6 Hz, 6H; CH(CH_3)$_2$), 1.20 (d, J = 6 Hz, 6H; CH(CH_3)$_2$), 3.25 (sept, J = 6 Hz, 1H; CH(CH$_3$)$_2$), 4.10 (sept, J = 6 Hz; CH(CH$_3$)$_2$), 4.50 (s, 5H; Cp-H), 7.38–7.48 (m, 9H; Ph$_3$PO-CH_o and Ph$_3$PO-CH_p), 7.55 (s, 4H; BAr$^f_4{}^-$-H$_p$), 7.60–7.78 (m, 6H; Ph$_3$PO-H$_m$), 7.73 ppm (s, 8H; BAr$^f_4{}^-$-H$_o$); ^{13}C NMR (76 MHz, C_6D_6): δ = 22.4, 23.9 (CH(*C*H$_3$)$_2$), 47.2 (*C*H(CH$_3$)$_2$), 84.4 (C(Cp)), 117.5 (BAr$^f_4{}^-$-CH$_p$), 122.6 (Ph$_3$PO-C$_{ipso}$), 124.6 (q, $^1J_{CF}$ = 272 Hz; BAr$^f_4{}^-$-CF$_3$), 128.9 (q, $^2J_{CF}$ = 34 Hz; BAr$^f_4{}^-$-C$_m$), 130.1 (Ph$_3$PO-CH$_m$), 133.5 (Ph$_3$PO-C$_o$), 134.9 (BAr$^f_4{}^-$-CH$_o$), 135.9 (Ph$_3$PO-C$_p$), 161.8 (q, $^1J_{CB}$ = 49 Hz; BAr$^f_4{}^-$-C$_{ioso}$), 214.7 ppm (CO); ^{11}B NMR (96 MHz, CD_2Cl_2): δ = −7.7 (BAr$^f_4{}^-$), 48.9 ppm (b, fwhm $\approx$ 480 Hz, B-(OPPh$_3$)N*i*Pr$_2$); ^{19}F NMR (283 MHz, CD_2Cl_2): δ = −62.7 ppm (CF$_3$); ^{31}P NMR (121 MHz, CD_2Cl_2): δ = 48.3 ppm (Ph$_3$PO); IR (CD_2Cl_2 soln): $\tilde{\nu}$ = 2004, 1949 cm^{-1} ν(CO). Crystal data: $C_{63}H_{46}B_2F_{24}FeNO_3P$, triclinic, *P*$\bar{1}$, a = 13.0324(2), b = 13.9949(2), c = 19.1002(3) Å, α = 68.7080(10), β = 83.7430(10), γ = 87.4800(10)°, V = 3226.47(8) Å^3, Z = 2, ρ_{calcd} = 1.471 Mg m^{-3}, M_r = 1429.45, T = 150(2) K. 51247 reflections collected, 14704 independent (R(int) = 0.1118) which were used in all calculations. R_1 = 0.0718, wR_2 = 1791 for observed unique reflections ($F^2 > 2\sigma(F^2)$) and R_1 = 0.1223, wR_2 = 0.1992 for all unique reflections. Max./min. residual electron densities 1.086/−0.608 e Å^{-3}.[16]

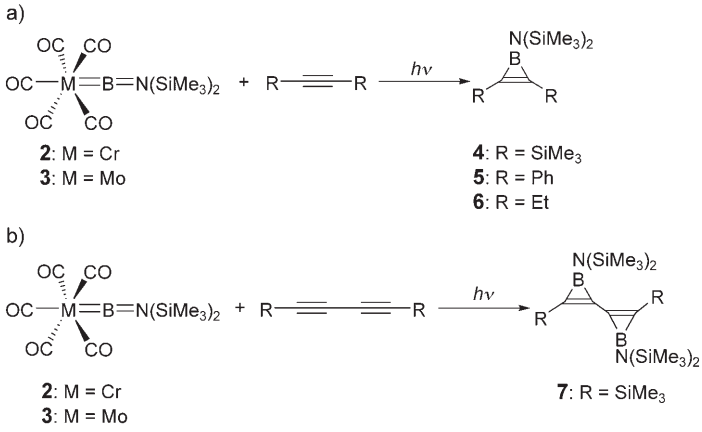
Synthesis of Borirenes by Photochemical Borylene Transfer from $[(OC)_5M{=}BN(SiMe_3)_2]$ (M = Cr, Mo) to Alkynes**

Holger Braunschweig, Thomas Herbst, Daniela Rais, and Fabian Seeler*

Boracyclopropene, or borirene, is isoelectronic with the cyclopropenylium cation and, as such, represents the simplest boron-containing cyclic system that might exhibit 2π aromatic stabilization.[1] A limited number of synthetic routes have been successfully applied to the generation of the borirene nucleus.[2–5] Among these, only two methods, although restricted in scope, yielded satisfactory amounts of the desired compounds: 1) the reaction reported by Pues and Berndt[3] of trimethylstannylalkynes with 1,2-di-*tert*-butyl-1,2-dichlorodiborane(4) which affords 1-*tert*-butylborirenes, and 2) the photoisomerization of diaryl(arylethynyl)boranes reported by Eisch et al.[5] The latter method, in particular, allowed the isolation and structural characterization of 2-(2,6-dimethylphenyl)-1,3-dimesitylborirene (**1**), thus providing experimental evidence for the theoretically predicted aromaticity of this class of compounds.

In 1984 Pachaly and West reported the formation of 1-triphenylsilyl-2,3-bis(trimethylsilyl)borirene upon reaction of the photochemically generated triphenylsilylborylene, B–$SiPh_3$, at −196 °C with bis(trimethylsilyl)ethyne. The compound was characterized by ^{1}H NMR and IR spectroscopy as well as mass spectrometry.[4] We recently demonstrated that the Group VI terminal borylene complexes $[(OC)_5M{=}B{-}N(SiMe_3)_2]$ (M = Cr, W)[6] are convenient sources of the borylene moiety $BN(SiMe_3)_2$, which can be efficiently transferred to different transition metals upon photolysis.[7] Following these important results, we turned our attention to the analogous borylene transfer to main-group-element compounds. Herein we report preliminary results of borylene transfer to alkynes which leads to borirenes in high yields.

Borirenes **4**–**6** were obtained upon photolysis of pale yellow solutions of $[(OC)_5M{=}BN(SiMe_3)_2]$ (M = Cr, **2**; M = Mo,[8] **3**) in the presence of the appropriate alkyne for 2–4 h at room temperature (Scheme 1). The reaction was monitored by multinuclear NMR spectroscopy, which revealed gradual consumption of the starting materials and quantitative formation of a new boron-containing compound, as indicated



Scheme 1. Synthesis of borirenes **4**–**6** (a) and **7** (b) by photochemically induced borylene transfer to alkynes and diynes.

by the presence of a singlet resonance in the $^{11}B\{^1H\}$ NMR spectrum at $\delta = 33.2$ ppm for **4** and $\delta = 25.0$ ppm for **5** and **6**. These values are in good agreement with those reported by Habben and Meller for a series of 1-bis(trimethylsilyl)aminoborirenes ($\delta = 26.5$–27.7 ppm), which were synthesized, albeit in very low yield (2–7%), by high-vacuum pyrolysis of an uncharacterized oligomeric product stemming from the reduction of suitable 1,2-dithia-3-bis(trimethylsilyl)aminoboroles with sodium.[2]

The trimethylsilyl derivative **4** was isolated in the form of pale yellow crystals by filtration of the reaction mixture and subsequent crystallization from hexane at −60 °C. The result of the X-ray crystal-structure analysis[9] on borirene **4** is displayed in Figure 1.

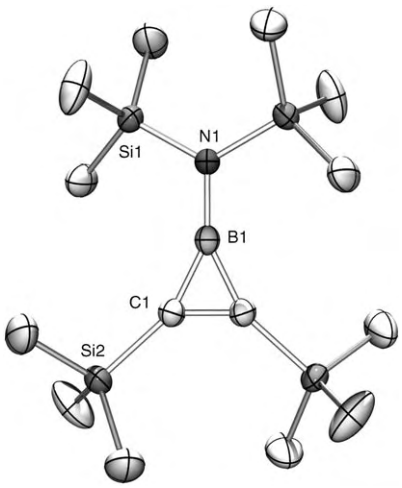


Figure 1. Molecular structure of **4**. Hydrogen atoms have been omitted for clarity. Selected bond lengths [Å] and angles [°]: N1-B1 1.421(4), C1-B1 1.485(3), C1-C1 1.376(4), C1-B1-N1-Si1 22.24(16). Ellipsoids drawn at the 50% probability level.

The C1–B1 bond length (1.485(3) Å) in **4** is comparable to those reported for 2-(2,6-dimethylphenyl)-1,3-dimesitylborirene (**1**, 1.450(10) and 1.464(11) Å)[5a] and so is the C–C bond length within the ring (**4**, 1.376(4) Å; **1**, 1.380(9) Å). In **1** such values were interpreted as indicative of extensive delocaliza-

tion of the two π electrons over a three-center bonding molecular orbital from the p atomic orbitals of boron and carbon.[5a] In **4**, such delocalization is likely to be attenuated by the presence of the amino substituent, which generally engages in a π-type interaction with the empty p orbital of boron. Interestingly, however, a tilt of the plane of the amino substituent with respect to the plane containing the boracyclopropene ring (C1-B1-N1-Si1 = 22.24(16)°) and a consequently elongated B1–N1 bond (1.421(4) Å) are observed in the molecular structure of **4**, possibly indicating a weaker π interaction between the boron and nitrogen centers as a result of the aromatic character of the boracyclopropene ring.

The versatility of the synthetic method was further probed in the reaction of $[(OC)_5Mo{=}BN(SiMe_3)_2]$ (**3**) with 1,4-bis(trimethylsilyl)-buta-1,3-diyne. Under analogous conditions to those applied for the synthesis of compounds **4**–**6**, complete consumption of the two starting materials was observed upon irradiation of the reaction mixture for 4 h, and clean formation of the unprecedented diborirene species **7** was confirmed by multinuclear and 2D NMR spectroscopy. A singlet is observed at $\delta = 28.0$ ppm in the $^{11}B\{^1H\}$ NMR spectrum of **7**. The ^1H NMR spectrum is characterized by the presence of only two singlets for the trimethylsilyl groups at $\delta = 0.29$ (36H) and 0.27 ppm (18H), implying free rotation around the B–N bond at room temperature. Cooling to −90 °C is necessary to observe two separate signals for the nitrogen-bound trimethylsilyl groups at $\delta = 0.36$ and 0.33 ppm. Most importantly, these results suggest a weak double bond character of the B–N bond in the room temperature structure of **7**, as a likely consequence of the strong conjugation of the boron atoms with the butadienyl unit.

In conclusion, the photochemical borylene transfer from $[(OC)_5M{=}BN(SiMe_3)_2]$ (M = Cr, Mo) to alkynes and diynes allows high-yielding, straightforward access to otherwise synthetically challenging borirene compounds. Furthermore, the ability of compounds **2** and **3** to act as convenient sources of the borylene moiety under standard conditions was demonstrated. Studies targeting the synthesis of polyborirene systems and the transfer of the borylene unit to different main-group-element compounds are currently underway.[10]

Experimental Section

NMR spectroscopic experiments were performed in quartz NMR tubes. The light source was a Hg/Xe arc lamp (400–550 W) equipped with IR filters, irradiating at 210–600 nm. Large-scale experiments were performed in a 150-mL Schlenk flask equipped with a quartz cooling jacket into which a Hg lamp (125 W) was inserted vertically.

4: A pale yellow solution of **2** (0.500 g, 1.38 mmol) and 1,2-bis(trimethylsilyl)ethyne (0.295 g, 1.73 mmol) in toluene (15 mL) was irradiated for 3.5 h at room temperature. After this time, the volatile components were removed under vacuum, and the remaining dark brown residue was extracted with hexane (2 × 10 mL). The orange-red filtrate was cooled to −60 °C overnight to yield pale yellow crystals of **4**. Evaporation of the filtrate afforded a second crop of analytically pure crystalline material (0.385 g, 82%). ^1H NMR (500 MHz, C_6D_6, 25 °C, TMS): $\delta = 0.32$ (s, 18H; $SiMe_3$), 0.30 ppm (s, 18H; $SiMe_3$); $^{13}C\{^1H\}$ NMR (125.8 MHz, C_6D_6, 25 °C): $\delta = 199.0$ (br s; =*C*-$SiMe_3$), 3.8 (s; $SiMe_3$), 0.7 ppm (s; $SiMe_3$); $^{11}B\{^1H\}$ (160.5 MHz, C_6D_6, 25 °C): $\delta = 33.2$ ppm (s); EI MS: *m*/*z*: 341 [M^+], 268 [$M-SiMe_3$]$^+$.

5: A pale yellow solution of **3** (0.070 g, 0.17 mmol) and 1,2-diphenylethyne (0.031 g, 0.17 mmol) in C_6D_6 (0.5 mL) was irradiated for 2 h at room temperature. After this time, the mixture was filtered over glass-fiber filter paper, and the filtrate was evaporated. The dark brown residue was taken up in hexane (5 mL). The hexane solution was stored at −30 °C for 2 weeks and yielded yellow crystals of **5** (0.051 g, 88%). ^1H NMR (500 MHz, C_6D_6, 25 °C, TMS): $\delta = 7.61$–7.59 (m, 4H; Ph), 7.16–7.13 (m, 4H; Ph), 7.07–7.04 (m, 2H; Ph), 0.36 ppm (s, 18H; $SiMe_3$); $^{13}C\{^1H\}$ NMR (125.8 MHz, C_6D_6, 25 °C): $\delta = 161.1$ (br s; Ph-*C*=), 135.0 (s; Ph), 132.4 (s; Ph), 129.3 (s; Ph), 129.3 (s; Ph), 3.7 ppm (s; $SiMe_3$); $^{11}B\{^1H\}$ (160.5 MHz, C_6D_6, 25 °C): $\delta = 25.0$ ppm (s); EI MS: *m*/*z*: 349 [M^+].

6: A pale yellow solution of **3** (0.046 g, 0.11 mmol) and 3-hexyne (0.016 g, 0.19 mmol) in C_6D_6 (0.5 mL) was irradiated for 3.5 h at room temperature. After this time, the reaction was judged to be complete by NMR spectroscopy, with quantitative formation of **6**, as ascertained by comparison of the NMR data with those reported in the literature.[2]

7: A pale yellow solution of **3** (0.160 g, 0.39 mmol) and 1,4-bis(trimethylsilyl)buta-1,3-diyne (0.067 g, 0.34 mmol) in C_6D_6 (0.5 mL) was irradiated for 4 h at room temperature. After this time, the reaction was judged to be complete by multinuclear NMR spectroscopy, with quantitative formation of **7** (>95% purity). The volatile components were then removed under vacuum, and the resulting brown residue was extracted with hexane (2 × 3 mL). The light brown filtrate was evaporated to yield crude **7** as a brown oil (>95% pure by multinuclear NMR spectroscopy). Sublimation at 100 °C/10^{-5} bar yielded **7** as an analytically pure colorless solid (0.020 g, 11%). ^1H NMR (500 MHz, [D_8]toluene, 25 °C, TMS): $\delta = 0.29$ (s, 36H; N-$SiMe_3$), 0.27 ppm (s, 18H; =C-$SiMe_3$); ^1H NMR (500 MHz, [D_8]toluene, −90 °C, TMS): $\delta = 0.37$ (s, 18H; =C-$SiMe_3$), 0.36 (s, 18H; N-$SiMe_3$), 0.33 ppm (s, 18H; N-$SiMe_3$); $^{13}C\{^1H\}$ NMR (125.8 MHz, [D_8]toluene, 25 °C): $\delta = 186.3$ (s, =*C*-$SiMe_3$), 156.1 (s, =*C*-C), 3.0 (s, N-$SiMe_3$), −0.3 ppm (s, =C-Si*Me*$_3$); $^{13}C\{^1H\}$ NMR (125.8 MHz, [D_8]toluene, −90 °C): $\delta = 186.5$ (s, =*C*-$SiMe_3$), 154.8 (s, =*C*-C), 2.8 (s, N-$SiMe_3$), 2.7 (s, N-$SiMe_3$), −0.4 ppm (s, =C-Si*Me*$_3$); $^{11}B\{^1H\}$ (160.5 MHz, C_6D_6, 25 °C): $\delta = 28.0$ ppm (s); EI MS: *m*/*z*: 536 [M^+].

Smooth Anodic TiO_2 Nanotubes**

*Jan M. Macak, Hiroaki Tsuchiya, Luciano Taveira, Saule Aldabergerova, and Patrik Schmuki**

In 1999 Zwilling et al. reported on the electrochemical formation of self-assembled TiO_2 nanotubes (π-TiO_2) by the anodization of Ti,[1] and other reports followed soon thereafter.[2,3] A factor limiting the application of this first generation of nanotubes was their production in hydrofluoric acid based electrolytes. As a result of the high rate of chemical dissolution of TiO_2 in these solutions, the nanotubes could be grown only up to a length of 500 nm. Recently, we have shown[4–7] and explained[4] how a second generation of nanotubes with lengths up to several micrometers and aspect ratios up to 50 can be formed by adjusting the pH gradient within the growing nanotube. Common to all these anodic approaches is that the side walls of the tubes show strong irregularities, that is, the side-wall profiles show considerable thickness variations (ripples) as shown in Figure 1a. In the present work we demonstrate how TiO_2 nanotubes with extremely smooth homogenous walls and aspect ratios up to 175 can be grown (as shown in Figure 1b). This third generation of nanotubes is formed by suppressing local concentration fluctuations and pH bursts during anodization by using highly viscous glycerol electrolytes.

In previous work it has been established that the length of the nanotubes is essentially the result of a steady-state situation between electrochemical formation of TiO_2 at the pore tip and the chemical dissolution of formed TiO_2 by fluorides from the electrolyte.[3,5] We showed how the pH at the pore tip is lowered by the hydrolysis reactions of the Ti^{4+} ions formed during anodization. As the Ti^{4+} flux can be controlled by the applied current, it was possible to adjust conditions that keep the pore tip sufficiently acidic while the pore walls dissolve much more slowly.[4] As a result, the nanotubes could be grown up to 2.5 μm in length, in contrast to the previous length of 500 nm (Figure 1a). Some other reports on these micrometer-length tubes[8,9] describe nanotubes with aspect ratios up to 44[8] and 58.[9] In all these reports it is apparent that relatively regular variations of the walls' thickness occur (Figure 1a).

To explain these variations one may examine the current transients of the electrochemical anodization of Ti (Figure 2). It is apparent that relatively regular current oscillations occur during anodization, for example in sulphate electrolytes. When the frequency of the current oscillations is converted into a length scale, it compares well to the distance between ridges on the side walls. Thus, the current transients are correlated with the variations in the wall thickness. This can be explained by the fact that every current transient is accompanied by a pH burst at the pore tip. This local acidification leads to a temporarily increased dissolution rate. Since diffusion is the main effect balancing local acidification,[4] a straightforward remedy to suppress pH bursts is to damp the fluctuations by decreasing the diffusion constant in the electrolyte. This can be achieved, for example, by using highly viscous electrolytes such as glycerol-based solutions. Clearly the current–time transient in a fluoride-containing glycerol electrolyte (Figure 2) shows much lower current densities than that in the purely aqueous electrolyte. This is in line with a diffusion-controlled process (considering the Stokes–Einstein relation, where the diffusion constant, D, is proportional to $1/\eta$, where η is the solution viscosity). But even more important than the lowering of the current by glycerol is that the curves in Figure 2 do not exhibit any detectable current fluctuations.

As a result, the tubes formed under these electrochemical conditions (Figure 1b) are entirely smooth over their entire

length. Additionally as a result of the change in the diffusion coefficients and the improved confinement of the acidic area at the pore tip, the tubes grow now to a length of 7 µm. The tubes are arranged in very tight bundles and are not connected with another; this is in contrast to all previous descriptions (Figure 1a). Figure 1c and d show scanning electron micrographic (SEM) images of self-assembled TiO_2 nanotubes from the top and bottom, respectively. It is apparent that the tubes are open on the top and closed with

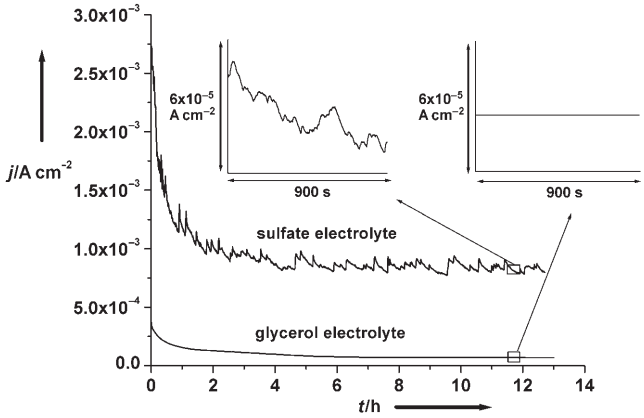

Figure 2. Current–time behavior during anodization of Ti samples at 20 V for 13 h. The samples were anodized in glycerol or in 1 M $(NH_4)_2SO_4$, in both cases with 0.5 wt% NH_4F. The insets show details of the current transients. Current fluctuations can be observed for the anodization in aqueous solution, while they are completely suppressed using the glycerol electrolyte.

a TiO_2 layer on the bottom of the layer of nanotubes. The inner diameters of the nanotubes are mostly around 40 nm; however, some tubes with diameters in the range between 30 and 60 nm can be found. In other words, tubes with aspect ratios between 233 and 117 are obtained. Figure 1e shows an SEM image of the lower part of the tubes and the interface between the TiO_2 nanotubes and the underlying Ti substrate. This image reveals that the convex shape of the closed ends of the nanotubes is reflected in the morphology of the surface of the Ti substrate. We reached a similar conclusion in our earlier work on the formation of nanotubular structures by anodization in aqueous fluoride-containing electrolytes:[4,5] We believe that the interface of the convex (nanotubes) and concave (Ti substrate) units plays a significant role for the good adhesion of both adjacent parts.

Figure 3 shows a transmission electron microscopic (TEM) image of several nanotubes (a), the TEM diffraction pattern (b), and a high-resolution TEM image of the single nanotube bottom (c). These TEM images confirm that the walls of the nanotubes are very smooth and straight over their entire length. The thickness of the walls is 12 nm, the thickness of the convex barrier oxide is 16 nm. If TEM

pictures from the side wall close to the pore bottom are compared to pictures close to the pore mouth, only minimal variations in thickness, (12 ± 2) nm, can be determined. This is also a clear improvement over previous syntheses, in which considerable thinning of the walls at the pore mouth was typically observed. The TEM diffraction pattern in Figure 3b was taken from the nanotube wall and shows clearly that the TiO_2 structure is amorphous. The high-resolution TEM image in Figure 3c additionally confirms the amorphous structure in the side wall and at the bottom of the tubes.

In summary, TiO_2 nanotubes prepared in glycerol solutions show an unprecedented degree of regularity and homogenity in comparison to the nanotubes described in earlier reports, in which thinning of the tube wall towards the mouth and ripples on the tube walls were observed.[1–9] In addition, the pore diameter is strongly affected by the electrolyte: in aqueous electrolytes it is about 100 nm, in glycerol it is about 40 nm. Besides the high aspect ratio, the smoothness of the nanotubes plays a crucial role in the improvement of various properties of the layers of self-assembled TiO_2 nanotubes. For instance, uniform depth profiles and flatter interfaces are essential from the point of view of optical devices, for example, waveguides and photonic crystals, where the light transmission is severely reduced by diffuse scattering at morphological inhomogeneities. Because of the high refractive index of TiO_2 (2.6), self-assembled nanotubular TiO_2 structures are viable candidates for applications in photonic crystals[10] and waveguides.[11]

We also note that layers of nanotubes with a tube length of 7 μm may be suitable for application in highly efficient dye-sensitized solar cells,[12] since the desired light absorption depth, nanoparticulate TiO_2 films with a thickness in the range of 5 to 10 μm yield optimum efficiency. In addition to dye sensitization,[13] several other applications have already been reported for the self-assembled TiO_2 nanotubes, for example, as a catalyst support for Pt/Ru nanoparticles for the electrooxidation of methanol[14] and as structures that can be modified with self-assembled monolayers of organic molecules to tailor surface wettability.[15]

Other potential applications of self-assembled TiO_2 nanotubular structures may be based on exploiting the specific properties of TiO_2, such as its catalytic properties,[16] self-cleaning,[17] and semiconductor properties.[18] The nanotubular structure could be also used to improve biocompatibility in biomedical applications.[19] Our results provide greatly improved nanotubular TiO_2 substrates for all these applications and represent a significant advancement towards the "ideal" tubular shape.

Experimental Section

Surface treatment: Ti samples (0.1-mm thick foils, 99.6% purity, Goodfellow, England) were degreased by sonicating in acetone, 2-propanol, and methanol, followed by rinsing with deionized water and drying in a nitrogen stream.

Electrochemical treatment: Titanium samples were contacted with a Cu plate and then pressed against an O-ring in an electrochemical cell, such that 1 cm^2 was exposed to the electrolyte. The setup consisted of a conventional three-electrode configuration with a platinum gauze as a counterelectrode and a Haber–Luggin capillary with Ag/AgCl (1M KCl) electrode as a reference electrode. Electrochemical experiments were carried out using a high-voltage potentiostat Jaissle IMP 88. Electrolytes were 0.5 wt% NH_4F in glycerol (1,2,3-propanetriol) with a dynamic viscosity of 1350 mPa s at 20 °C or in 1M $(NH_4)_2SO_4$. The electrolytes were prepared from reagent-grade chemicals. The electrochemical treatment consisted of a potential ramp from the open-circuit potential (OCP) to 20 V with a sweep rate of 1 $V s^{-1}$, after which the applied potential was held at 20 V for 13 h. The same treatment was used for reference samples produced in aqueous electrolytes. An estimate of the IR drop during experiments in glycerol electrolyte results in an error of less than 1 V on the effective potential. After the electrochemical treatment the samples were soaked with deionized water and dried in a nitrogen stream.

Surface characterization: Scanning electron microscopy (Hitachi FE-SEM S4800) was employed for the morphological characterization of the TiO_2 nanotubes. To gain information on thickness of the nanotubular layer, direct SEM cross-sectional thickness measurements were carried out on mechanically bent and cracked samples. This technique was also carried out to achieve bottom-view images of the nanotube layers. Transmission electron microscope Philips CM 30 T/STEM and high-resolution TEM Philips CM 300 UT were used for the morphological and structural characterization of the TiO_2 nanotubes.

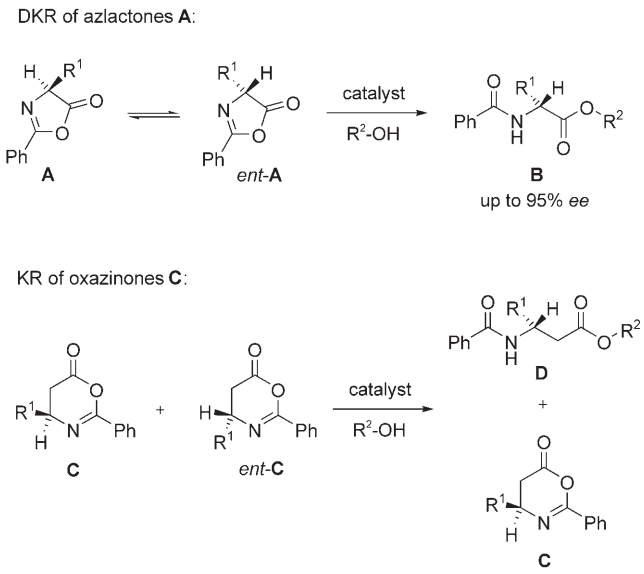
Kinetic Resolution of Oxazinones: An Organocatalytic Approach to Enantiomerically Pure β-Amino Acids**

Albrecht Berkessel, Felix Cleemann, and Santanu Mukherjee*

The development of new methods for the enantioselective synthesis of β-amino acids has been of considerable interest during the last years.[1–4] Owing to their unique pharmacological properties in the free form,[5] as cyclized β-lactams,[6] and as structural elements of naturally occurring compounds such as taxol[7] and the dolastatins,[8] there is a high demand in both academia and industry for enantiopure β-amino acids.[9] Besides chiral-auxiliary-based strategies[4] and catalytic asymmetric synthesis[1,10–13] the kinetic resolution of racemates is a well-established method for obtaining β-amino acids with high enantiomeric purity. The latter methodology is divided into "classical" chemical resolution processes, in which chiral resolving agents are used in stoichiometric amounts,[14] and enzymatic resolutions, which require acylases, amidases, or lipases.[15,16] Although the selectivity of enzymatic processes is in most cases excellent, the narrow substrate scope and thus the need for time-consuming enzyme engineering present a major drawback. To overcome these difficulties, we envisaged that the application of readily available modular organocatalysts[17] could greatly enhance the scope of these processes. Motivated by our success in the organocatalytic dynamic kinetic resolution (DKR) of azlactones *rac*-**A**, we set out to expand this methodology beyond the synthesis of (non-natural) α- to the even more challenging β-amino acids (Scheme 1).[18,19]

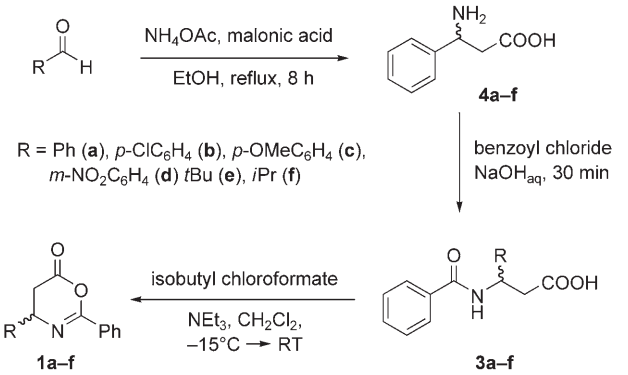
Azlactones **A** racemize readily and can be converted into the enantiomerically enriched N,C doubly protected α-amino acid derivatives **B**. By formally inserting a methylene group between the carbonyl group and the α-C atom of the azlactone, the nitrogen atom moves to the β position. The resulting compounds are known as 4,5-dihydro-1,3-oxazin-6-ones **C**, which are—in contrast to azlactones—configurationally stable. Although achiral and enantiomerically pure oxazinones **C** were utilized in peptide chemistry for coupling to amino acid esters,[20] no catalytic ring-opening reaction



Scheme 1. Alcoholytic DKR of azlactones (**A**, *ent*-**A**;top) and KR of oxazinones (**C**, *ent*-**C**; bottom).

appears to have been reported so far.[21] We considered these compounds to be promising substrates for organocatalytic asymmetric ring opening. It was hoped that the bifunctional thiourea catalysts **2a** and **2b** (Table 1), which proved to be highly effective in the alcoholytic DKR of azlactones,[19] would effect a kinetic resolution (KR) of racemic oxazinones.[22,23] If the selectivity of the catalyst is sufficiently high, a KR process will be of practical significance, provided that the racemate is obtained in an easy and cost-effective manner and that both the remaining and the converted substrate enantiomers are valuable compounds.[24] Oxazinones can be synthesized in a way similar to azlactones by cyclodehydration of the corresponding *N*-benzoyl amino acids **3** (Scheme 2).[25] We decided to use the one-step protocol of Tan and Weaver for the synthesis of racemic β-amino acids **4** from inexpensive aldehydes, malonic acid, and ammonium acetate (Scheme 2).[26]

The crude amino acids **4a–f** were converted directly into the *N*-benzoyl derivatives **3a–f** without the need for preceding purification. Condensation to give oxazinones **1a–f** was best effected by isobutyl chloroformate. Preliminary experi-



Scheme 2. Synthesis of the racemic oxazinones *rac*-**1a–f**.

ments indicate that **1** can also be obtained directly in a single step from β-amino acids **4** by treatment with excess benzoyl chloride. The first experiments with 4,5-dihydro-2,4-diphenyl-1,3-oxazin-6-one (*rac*-**1a**) as substrate and allyl alcohol as nucleophile in the presence of the bifunctional thiourea **2a** (5 mol%) already showed the potential of this process. As expected for a kinetic resolution, the enantiopurity of the remaining oxazinone **1a** and the product ester **5a** is a function of the conversion (Figure 1).

At 57% conversion, the *S* enantiomer of the oxazinone substrate *rac*-**1a** is completely consumed (99% *ee* in favor of the remaining *R* enantiomer), and the enantiomeric excess of the product ester (*S*)-**5a** is 86% (Table 1, entry 3). Calculated from these kinetic data, the selectivity factor *S* of the reaction is 68. At a conversion lower than 45%, the ester is produced with more than 94% *ee* (Figure 1 and Table 1, entries 1 and 2). Slightly lower selectivity and activity were observed when using 5 mol% of the cyclohexyl-substituted catalyst **2b** (Table 1, entry 4). As a consequence we chose catalyst **2a** for all further experiments. Because

[a] Conversions and enantiomeric excesses were determined by chiral HPLC. [b] This reaction was carried out with a substrate concentration of 0.5 M; 0.1 M concentration in other reactions.

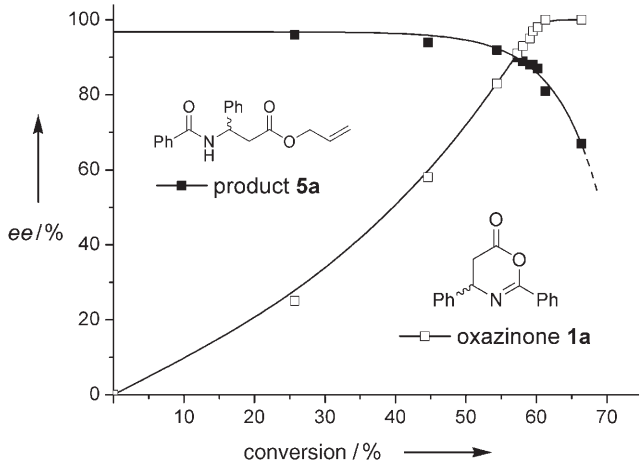

Figure 1. Time course of the kinetic resolution of *rac*-**1a** with allyl alcohol (1.0 equiv) and catalyst **2a** (5 mol% relative to *rac*-**1a**).

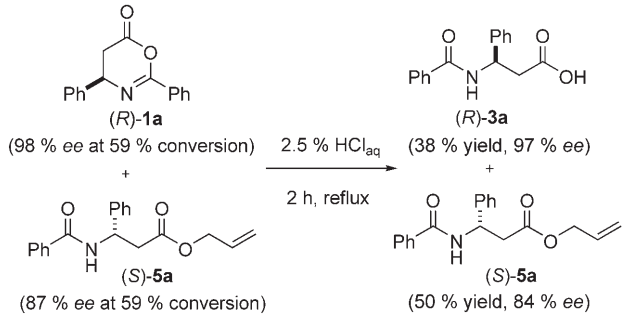
of the inherent difficulty in the accurate determination of selectivity factors when $S > 50$, we decided to characterize the quality of the kinetic resolution described herein solely in terms of conversion and *ee* values of the substrate and product, respectively (Table 1).[27]

The remaining oxazinone **1a** can be separated from the converted product ester **5a** by treating the reaction mixture with dilute aqueous HCl (Scheme 3; see Supporting Information for details). This hydrolytic procedure quantitatively converts the remaining oxazinone (*R*)-**1a** into the insoluble *N*-benzoyl β-amino acid (*R*)-**3a**. There is virtually no loss in



Scheme 3. Hydrolytic work-up procedure for the separation of the resolved oxazinone (*R*)-**1a** from the product ester (*S*)-**5a**.

enantiomeric purity during this hydrolysis reaction (Scheme 3). The filtrate contains the pure ester product (*S*)-**5a**.

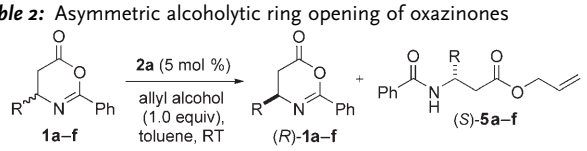
An increase in the catalyst loading to 10 mol% decreased the reaction time to 4.5 h, without affecting the selectivity (Table 1, entry 5). At a catalyst loading of 2.5 mol%, the reaction time is longer but the selectivity remains virtually unaffected (Table 1, entry 6). This decrease in the reaction rate could be compensated for by raising the concentration of the substrates from 0.1 to 0.5 M. Under these conditions, a catalyst loading of only 1 mol% was sufficient to catalyze the reaction effectively (Table 1, entry 7). Comparison with authentic samples prepared from enantiomerically pure (*S*)-3-amino-3-phenylpropanoic acid allowed us to determine the absolute configuration of both the oxazinone **1a** and the ester product **5a** by chiral HPLC.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

An increase in the solvent polarity, for example, by changing from toluene to THF or acetonitrile, retarded the reaction quite significantly (Table 1, entries 8 and 10). Based on the assumption that hydrogen bonds between the catalyst and the substrate are crucial for the activation of the latter, this effect can be rationalized by the ability of THF to act as a competing hydrogen-bond acceptor. In the case of acetonitrile, hydrogen bonds are weakened by dipolar interaction with the solvent. In dichloromethane (DCM) the reaction proceeded with a satisfying rate, but the selectivity was somewhat lower (Table 1, entry 9). Prolonged reaction times resulted from the variation of the alcohol nucleophile to methanol or 2-propanol (Table 1, entries 11 and 12). In the case of methanol, the reaction was still practically useful, although the selectivity was somewhat lower. In contrast, the sterically more demanding 2-propanol reacts much more slowly. Only 4% conversion was observed after 24 h (Table 1, entry 12).

To demonstrate the broad substrate scope of our KR process, we chose the electron-poor *p*-chlorophenyl- and *m*-nitrophenyl-substituted oxazinones **1b** and **1d** as well as the electron-rich *p*-methoxyphenyl-substituted oxazinone **1c** as substrates (Table 2, entries 2, 4, and 3). Furthermore, to show

Table 2: Asymmetric alcoholytic ring opening of oxazinones



Entry	Substrate (R)	*t* [h]	Conv. [%][a]	*ee* (**1**) [%][a,b]	*ee* (**5**) [%][a]

5	**1e** (*t*Bu)	48	54	97	82
6	**1f** (*i*Pr)	48	53	98	88

[a] Conversions were determined by chiral HPLC, the enantiomeric excesses either by chiral HPLC or chiral GC. [b] The absolute configurations of the products **1b–f** were assigned by analogy to **1a**.

that the method is not limited to oxazinones with aromatic substituents, we also included the *tert*-butyl derivative **1e** and the isopropyl derivative **1f** (Table 2, entries 5 and 6) in our study. We were pleased to see that all substrates were resolved with a high degree of enantioselectivity. In the presence of catalyst **2a** (5 mol%), the oxazinones **1a–f** were generally obtained with excellent enantiomeric excess (Table 2), whereas the esters were still produced with 80–90% *ee*.

Comparison of **1a** with the *p*-chlorophenyl-substituted oxazinone **1b** and the *p*-methoxy-substituted oxazinone **1c** reveals that the enantioselectivity is not significantly affected by the substituent on the aromatic ring (Table 2, entries 1–3). The same holds for the oxazinone **1d**, which bears a nitro substituent in the *meta* position (Table 2, entry 4). With the latter substrate, the reaction is complete within only 3 h. The sterically more-demanding *tert*-butyl residue and the isopropyl group of oxazinones **1e** and **1f** are also tolerated at reaction times of 48 h (Table 2, entries 5 and 6). The latter two examples demonstrate that the procedure is not limited to β-amino acids with aromatic substituents but can also be used equally well for the enantioselective synthesis of alkyl-substituted derivatives.

In summary, we have described a novel and practical organocatalytic method for the synthesis of enantiomerically pure β-amino acids. To the best of our knowledge, this is the first time that oxazinones were applied in a catalytic ring-opening reaction. The resolutions are carried out at ambient temperature; the applied catalyst is modular, readily available, and can be used at loadings as low as 1 mol%. This process provides efficient access to highly valuable protected β-amino acids from inexpensive bulk chemicals. The resolved starting material and the product can be separated by filtration in a simple workup procedure. It is particularly noteworthy that the remaining enantiomerically pure oxazinones are activated β-amino acid derivatives that can, in principle, be applied directly in coupling reactions, for example, in the synthesis of β-peptides. The scope of this novel resolution process and its mechanism are currently under investigation.

Experimental Section

All commercially available chemicals were used without further purification. (*S*)-3-Amino-3-phenylpropionic acid was a gift from Degussa AG, Hanau. Solvents were distilled prior to use and dried, if necessary, by using standard techniques. HPLC analysis was performed on Merck–Hitachi HPLC equipment with HPLC-grade solvents from Fisher Scientific. GC analysis was performed on Hewlett-Packard equipment. Catalysis runs were carried out under inert atmosphere.

Resolution of oxazinones: The alcohol nucleophile (1.00 equiv) was added to a solution of the catalysts **2a** or **2b** (8.33 μmol, 0.05 equiv) in absolute toluene (670 μL). After the addition of a solution of the oxazinone **1a–f** (167 μmol, 1.00 equiv) in absolute toluene (1.00 mL), the homogeneous reaction mixture was stirred at ambient temperature. For analysis, 50-μL samples were withdrawn and diluted with acetonitrile (450 μL). The conversion and enantiomeric excess were determined immediately by HPLC or GC (see Supporting Information). Quantification was based on UV detection at $\lambda = 230$ nm. The conversion was determined by comparison with the peak areas of stock solutions of the oxazinones **1** and the corresponding *N*-benzoyl amino acid esters **5–7** in dichloromethane.

Scaffolds for Microtubule Inhibition through Extensive Modification of the Epothilone Template**

*Frédéric Cachoux, Thomas Isarno, Markus Wartmann, and Karl-Heinz Altmann**

Cellular microtubules are important targets for the development of anticancer drugs, and a variety of microtubule-interacting agents are currently in clinical use for the treatment of human cancer.[1] Agents interfering with microtubule functionality may either stabilize or destabilize microtubules;[2] the most prominent examples of microtubule stabilizers are the clinical anticancer drugs taxol (paclitaxel) and docetaxel (taxotere).[3] While taxol and related compounds had long been the only structures known to stabilize microtubules and promote tubulin polymerization, a variety of other natural products have been recognized over the last ten years to exert their antiproliferative activity through a mechanism of action similar to that of taxol. These compounds include, for example, epothilones A and B (Epo A and B), discodermolide, laulimalide, and peloruside.[4]

Natural products have been the most productive source of potent microtubule stabilizers by far,[4] and the systematic screening of natural-product-based libraries (or perhaps libraries based on natural-product-like compounds) is likely to reveal additional templates for microtubule stabilization in the future.[5] Alternatively, such templates may be developed from existing microtubule stabilizers through extensive structural modification (and perhaps simplification), provided such modifications do not produce an unacceptable loss in the desired biological activity.

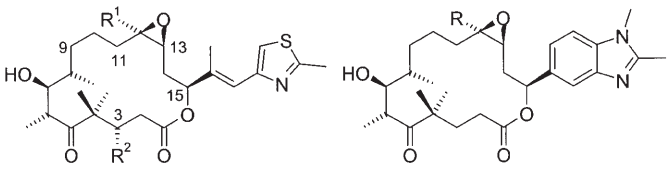
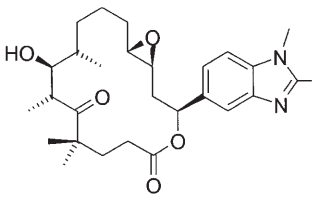
Of the various newly discovered microtubule-stabilizing agents mentioned above, the most extensively studied is Epo B,[6] for which numerous synthetic and semisynthetic variants have been prepared and subjected to biological profiling.[7] These efforts have produced an extensive database on structure–activity relationships (SAR) for epothilones and, most significantly, they have also led to the discovery of at least five analogues that are currently undergoing clinical evaluation in humans (in addition to Epo B).[7a] While the structures of these analogues are not significantly different from the original natural product lead, their biochemical and pharmacological properties appear to be distinct from that of Epo B, thus indicating that structural analogues closely related to Epo B may embody significant improvements in preclinical profile. Perhaps the most impressive examples are the 9,10-didehydro derivatives of Epo D,[8] which were recently described by the Danishefsky laboratory (and one of which has recently started phase I clinical trials).[9]

Notwithstanding these findings, it is still important to explore more extensive structural modifications of the epothilone scaffold that may lead to analogues with only limited or even no obvious structural resemblance to the starting natural product. Such analogues (if sufficiently potent) could be considered new templates for microtubule inhibition (in the same way a newly discovered natural product would be; vide supra). Here we provide a preliminary account of our synthetic and SAR work on a series of new epothilone analogues, which illustrates how iterative changes of the epothilone scaffold can lead to greatly modified ("hypermodified") structures that are still associated with potent tubulin-polymerizing and antiproliferative activity.

One of the strategic starting points for our development of hypermodified potent epothilone analogues was the removal of the hydroxy group in the 3-position of the epothilone scaffold. Rather surprisingly, the consequences of this simple modification have not been investigated explicitly to date, although other modifications at the 3-position have been described. Thus, formal dehydration at C2 and C3 (leading to 3-deoxy-2,3-didehydro derivatives) is well tolerated,[10] which is in agreement with an *anti*-periplanar conformation of the C2–C3 bond in the proposed bioactive conformation of Epo A.[11] Activity is also largely retained upon replacement of the (3*S*)-hydroxy group by a (3*S*)-cyano group,[10a] while inversion of configuration at C3 leads to a profound loss in biological potency (for both Epo A and Epo B[7d] as well as for the corresponding 3-deoxy-3-cyano analogues[10a]). Given the absence of biological information about simple 3-deoxy analogues of epothilones (with a single bond between C2 and C3), we have prepared 3-deoxy-Epo B (**1**) and assessed the biological activity of this compound. Scheme 1 summarizes our synthesis of **1**, which follows strategic principles similar to those we previously employed for the preparation of other types of epothilone analogues.[12]

Key steps are the aldol reaction between ketone **5** and aldehyde **6** (which proceeded with ca. 2.5:1 selectivity in favor of the desired aldol product **7** and was not optimized), the *B*-alkyl Suzuki coupling of **9** with vinyl iodide **10**, Yamaguchi macrolactonization, and finally epoxidation of the C12–C13 double bond in the deprotected macrolactone **12**. Unexpectedly, macrolactonization was accompanied by partial epimerization at C15 (!), which later necessitated purification of **12** by preparative HPLC.





4

The data summarized in Table 1 indicate that **1** exhibits potent tubulin-polymerizing and antiproliferative activity, such that its cellular activity against the human epidermoid cancer cell line KB-31 is only ca. 25 times lower than that of

Table 1: Tubulin-polymerizing and antiproliferative activity of 3-deoxyepothilone analogues.

Cmpd.[a]	% Tubulin polymerization[b]	IC_{50}(KB-31)[c] [nM]	IC_{50}(KB-8511)[c] [nM]

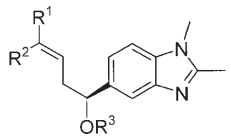
Epo B. The cellular potency of **1** is comparable with that of taxol, Epo A, and also 3-deoxy-2,3-didehydro-Epo B (data not shown), but in contrast to taxol the compound retains activity also against multidrug-resistant KB-8511 cells. The reduction in antiproliferative activity is somewhat larger at the level of deoxy compound **12**, which is roughly 40 times less potent than Epo D (12/13-deoxyEpo B).[8]

In the next step we asked whether at least some of the activity loss incurred by the removal of the 3-hydroxy group in Epo B could be recovered through additional and compensatory structural modifications. Based on our previous studies on potency-enhancing side-chain modifications,[12b] we designed compounds **2** and **3**, whose synthesis is summarized in Scheme 2. Starting from olefin **9**, Pd^0-catalyzed *B*-alkyl



13: R^1 = H, R^2 = I, R^3 = H
14: R^1 = CH_3, R^2 = I, R^3 = TES
15: R^1 = I, R^2 = H, R^3 = TES

Suzuki coupling with *cis*-vinyl iodides **13** (free OH group) and **14**[13] was followed by ester saponification, selective removal of the TES protecting group from O–C15 (only in the synthesis of **3**), Yamaguchi macrolactonization, and deprotection of O–C7 to produce 12/13-deoxy intermediates **16** and **17**, respectively (Scheme 2).

Again, macrolactonization produced two isomers (which we presume to be epimers at C15), but in both cases the major isomer was obtained in pure form at the stage of the 12/13-deoxy compound (i.e. after removal of the TBS group from O–C7). Epoxidation of **16** and **17** with H_2O_2/pyridine in CH_2Cl_2 and catalytic $MeReO_3$[14] gave the desired analogues of Epo A and B, compounds **2** and **3**, respectively, but profound differences in epoxidation selectivity were observed between the two substrates. Thus, epoxidation of **16** proceeded with only 2:1 selectivity (in favor of the desired epoxide isomer); in addition, the epoxidation products were difficult to separate and **2** could be obtained in only 16% yield after purification by preparative TLC. In contrast, epoxidation of **17** gave the desired isomer with >10:1 selectivity (85% yield for the mixture of isomers), and pure **3** was obtained in 54% yield after purification by preparative HPLC.

As can be seen in Table 1, the presence of the benzimidazole side chain in **3** leads to a significant potency increase over **1** against the drug-sensitive KB-31 cell line, while a smaller difference is observed for the multidrug-resistant KB-8511 line. In fact, compound **3** shows a small (three- to fourfold) but clearly detectable activity differential between the sensitive and the resistant cell line, indicating that it may be a weak substrate for the P-gp efflux pump. We have previously observed a similar decrease in activity against KB-8511 cells for the corresponding benzimidazole-based ana-

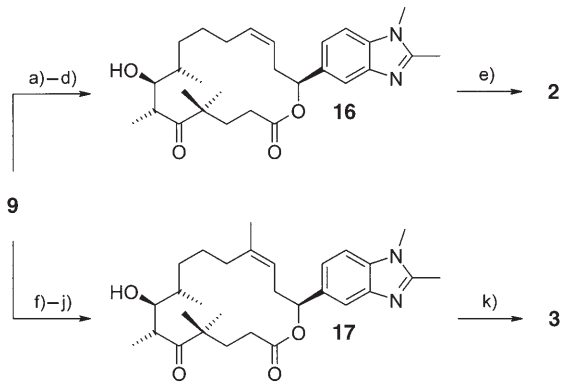
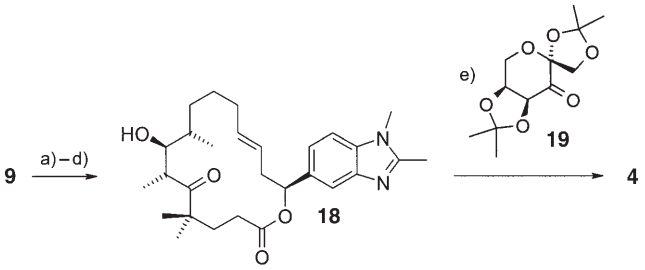


Scheme 2. a) 9-BBN (0.8 equiv), THF, RT, 100 min, then added to a mixture of Cs_2CO_3 (1.5 equiv), $[PdCl_2(dppf)_2]$ (0.2 equiv), Ph_3As (0.2 equiv), vinyl iodide **13**, DMF, 0 °C→RT, 75 min, 65%; b) LiOH (6 equiv), *i*PrOH/H_2O 4:1, 60 °C, 45 min, 87%; c) 2,4,6-$Cl_3C_6H_2C(O)Cl$, Et_3N, THF, 0 °C→RT, 30 min, then diluted with toluene and added to a solution of DMAP in toluene, RT, 2 h, 85% (4:1 mixture of epimers); d) HF·pyridine, CH_3CN, RT, 3 h, 68% (single isomer); e) $MeReO_3$, H_2O_2, pyridine, CH_2Cl_2, RT, 5 h, 16% (preparative TLC); f) 9-BBN, THF, RT, 2 h, then added to a mixture of Cs_2CO_3 (2 equiv), $[PdCl_2(dppf)_2]$ (0.2 equiv), Ph_3As (0.2 equiv), vinyl iodide **14** (1 equiv), DMF, 0 °C→RT, 2 h, 77%; g) LiOH (6 equiv), *i*PrOH/H_2O 4:1, 60 °C, 3 h, 90%; h) TBAF, THF, RT, 24 h, 75%; i) 2,4,6-$Cl_3C_6H_2C(O)Cl$, Et_3N, THF, 0 °C, 15 min, then diluted with toluene and added to a solution of DMAP in toluene, RT, 1 h, 85% (10:1 mixture of epimers); j) HF·pyridine, CH_3CN, RT, 3 h, 54% (single isomer; 87% for mixture of epimers); k) $MeReO_3$, H_2O_2/pyridine/H_2O, RT, 30 min, 64% (10:1 mixture of epoxide isomers). TBAF = tetrabutylammonium fluoride.

logue of Epo B.[12b] Moreover, we have repeatedly noted reduced activity against multidrug-resistant cells for structurally unrelated analogues, when they were more polar (reduced clogP) than the corresponding parent epothilone.[15] It is worth noting, however, that the activity of **3** against the KB-31 line is comparable with that of Epo B. Likewise, analogue **2** exhibits antiproliferative activity similar to that of Epo A and taxol, indicating that the presence of the dimethylbenzimidazole side chain can compensate for the removal of the 3-hydroxy group also in the epothilone A series. Similar conclusions can be derived from the data for 12/13-deoxy analogues **16** and **17**, which are only two times less potent antiproliferative agents than Epo C and D, respectively (Table 1; data for Epo C not shown).[8]

While the structures of compounds **2** and **3** deviate from those of Epo A and B, respectively, with regard to the core macrocycle as well as the heterocycle-bearing side chain, they are still characterized by a *cis*-configurated epoxide moiety at positions 12/13, which is a major structural hallmark of the natural products. However, we have previously shown that (12*S*,13*S*)-*trans* Epo A (but not the corresponding (12*R*,13*R*) isomer) is as potent as Epo A in terms of inducing tubulin polymerization and inhibiting cancer cell growth.[12a,16] In light of the potent biological activity of analogues **2** and **3**, the modification of (12*S*,13*S*)-*trans*-Epo A through removal of the hydroxy group at C3 and concomitant replacement of the natural side chain by a dimethylbenzimidazole moiety thus emerged as a promising approach for the creation of hypermodified but still potent epothilone analogues. These structural premises were realized in compound **4**, which was obtained from **9** by *B*-alkyl Suzuki coupling with vinyl iodide **15**,[13] elaboration of the coupling product into deoxy analogue **18**, and final epoxidation (Scheme 3).



Scheme 3. a) 9-BBN (0.8 equiv), THF, RT, 2 h, then added to a mixture of Cs_2CO_3 (1.5 equiv), $[PdCl_2(dppf)_2]$ (0.1 equiv), Ph_3As (0.2 equiv), vinyl iodide **15** (1 equiv), DMF, −10 °C→RT, 16 h, 58%; b) LiOH (6 equiv), THF/H_2O 7:1, RT, 24 h, 76%; c) 2,4,6-$Cl_3C_6H_2C(O)Cl$, Et_3N, THF, 0 °C, 15 min, then diluted with toluene and added to a solution of DMAP in toluene, RT, 1 h, 71%; d) HF·pyridine, THF, RT, 6 h, 94%; e) Oxone, ketone **19** (0.8 equiv), $Bu_4N(HSO_4)$ (cat.), K_2CO_3, MeCN/DME/0.05 M $Na_2B_4O_7\times10H_2O$ in 4×10^{-4} M Na_2EDTA 1:1:1.3, 0 °C, 3 h, 65% (86% based on recovered starting material; single isomer). DME = dimethoxyethane.

For the epoxidation of **18** to give **4**, the fructose-derived epoxidation catalyst **19** was employed,[17] and pure **4** was obtained in 65% yield after simple flash chromatography. This outcome represents a major advance over the epoxidation of *trans*-deoxyEpo A under similar conditions, which proceeded less efficiently (similar selectivity, but lower conversion); in addition, isolation of pure (12*S*,13*S*)-*trans*-Epo A required purification by preparative HPLC and provided the isolated target compound in only 13% yield.[12a]

Quite remarkably, compound **4** exhibits potent biological activity in spite of major structural differences to the native epothilone scaffold (Table 1). Thus, the tubulin-polymerizing and antiproliferative activity of **4** is virtually identical to that of Epo A and taxol. As for **2** and **3**, the growth inhibitory activity of **4** is slightly lower against the multidrug-resistant KB-8511 cell line than against the taxol-sensitive KB-31 line. However, given the high levels of P-gp expression by the KB-8511 line, this small difference in cellular potency would seem unlikely to be pharmacologically relevant in a clinical setting. I n fact, this minor shortcoming might even be correctable through the incorporation of other types of fused heteroaromatic side chains.[12b]

In summary, by employing an iterative approach for the modification of a natural-product structural scaffold, we have derived a new microtubule-stabilizing agent, which we consider to represent a novel structural scaffold for microtubule inhibition. As such, **4** and related compounds may offer the same potential for pharmacological differentiation from the original epothilone leads as various newly discovered natural-product microtubule inhibitors with macrolactone structure, such as laulimalide, peloruside, and dictyostatin.[4] This view is supported by preliminary data from similarity analyses, which indicate that **4** is as structurally dissimilar to Epo A or B as laulimalide and peloruside are.[20] Future work will focus on

synthesis scale-up and the extensive biological profiling of **4** and related structures in vitro and in vivo, in order to establish whether these compounds are in fact pharmacologically distinct from Epo A and Epo B. At the same time we will assess the effects of further structural modifications of **4** in the C8–C11 region and at the 2-position of the benzimidazole nucleus, which may or may not mirror the effects observed for analogous modifications of Epo A and Epo B.

Cationic Yttrium Methyl Complexes as Functional Models for Polymerization Catalysts of 1,3-Dienes**

*Stefan Arndt, Klaus Beckerle, Peter M. Zeimentz, Thomas P. Spaniol, and Jun Okuda**

As structurally defined catalyst precursors, isolated rare-earth-metal complexes allow the examination of factors that influence the activity and stereoselectivity associated with the polymerization of conjugated dienes.[1] Metallocenes of the lanthanides, for example, form living stereospecific polymerization catalysts.[2] Although Ziegler-type catalysts based on neodymium carboxylate/ethylaluminum chloride have long been employed in industry for stereospecific 1,3-diene polymerization,[3] it has been shown only recently that alkyl

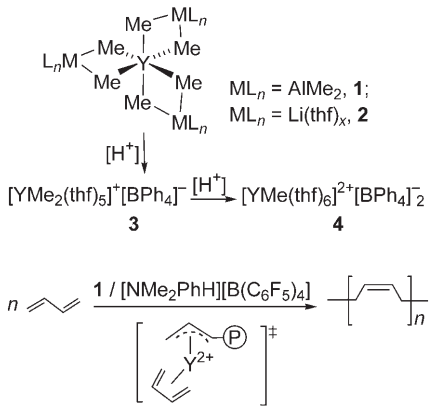
InterScience

species of the rare-earth metals play a pivotal role in this catalysis.[4a–c] The presence of chloride additives in these neodymium-based catalysts had been assumed to be essential for the generation of 1,4-*cis*-configured polymers.[4d] Taube et al., however, argued that rare-earth-metal allyl dications $[Ln(allyl)]^{2+}$ (Ln = La, Nd) should be considered as the active species during the 1,4-*cis*-selective polymerization of 1,3-butadiene.[5]

We report herein on cationic yttrium alkyl complexes $[YMe_{2-n}(solv)_x]^{n+1}$ ($n = 0$, 1), available from easily accessible precursors, that can be used as functional models for the industrially applied catalysts for the polymerization of 1,3-dienes. Yttrium complex cations are particularly amenable to being isolated with the tetraphenylborate counterion, and because of yttrium's diamagnetism and nuclear spin of $I = {}^1/_2$, can be characterized in solution by NMR spectroscopy. With the perfluorinated tetraphenylborate ion they catalyze the polymerization of 1,3-butadiene and isoprene.[6] These results support the hypothesis that the 1,4-*cis*-selective polymerization of 1,3-butadiene proceeds with allyl rare-earth metal dications $[Ln(allyl)]^{2+}$.

We recently reported on $[YMe(thf)_6]^{2+}[BPh_4]^-_2$ (**4**), prepared by protonolysis of the aluminate $[Y\{(\mu\text{-}Me_2)_2(AlMe_2)\}_3]$ (**1**) by $[NEt_3H][BPh_4]$ (Scheme 1), and characterized by single-crystal structure analysis.[6b] The laboriousness of the preparation of the aluminate motivated us to turn instead to the hexamethyl trianion $[LnMe_6]^{3-}$, which has been described with the $[Li(tmeda)]^+$ counterion by Schumann et al. (tmeda = N,N,N′,N′-tetramethyl-1,2-ethanediamine).[7] YCl_3 reacts with six equivalents of LiMe to form a series of equilibrating methyl species. A THF complex with the composition $[Li_3YMe_6(thf)]$ (**2**) could be isolated as a thermally stable solid. This compound was protonolyzed with five equivalents of $[NEt_3H][BPh_4]$ to give the methyl dication **4** in 65% yield (Scheme 1). Methyl dications $[LnMe(thf)_x]^{2+}[BPh_4]^-_2$ (**9**, Ln = Sc, $x = 5$; **10**, Ln = Lu, $x = 6$; **11**, Ln = Yb, $x = 6$; **12**, Ln = Ho, $x = 6$) were prepared similarly from the hexamethyl complexes $[Li_3LnMe_6(thf)]$ (**5**, Ln = Sc; **6**, Ln = Lu; **7**, Ln = Yb; **8**, Ln = Ho). The NMR spectroscopic data of the diamagnetic scandium and lutetium complexes **9** and **10** are consistent with the proposed structures. A crystal-structure analysis showed the holmium derivative **12** to be similar to yttrium complex **4**.[8]



Scheme 1. Synthesis of the mono- and dicationic yttrium methyl complexes **3** and **4** from yttrium aluminate **1** or hexamethylyttrium **2**, and polymerization of 1,3-butadiene by in situ generated methyl cations. Ⓟ polymer chain.

Dimethyl monocation $[YMe_2(thf)_x]^+$ that formed from **2** could not be isolated, owing to the difficulty in separating it from the $LiBPh_4$ generated in the reaction. However, the addition of [12]crown-4 allowed the isolation of the crown-ether adduct $[YMe_2([12]crown\text{-}4)(thf)_2]^+[BPh_4]^-$ (**3′**) as thermally robust colorless crystals in 80% yield. Protonolysis of the aluminate **1** in THF with one equivalent $[NEt_3H][BPh_4]$ gave the THF adduct $[YMe_2(thf)_5]^+[BPh_4]^-$ (**3**) in moderate yield.[9]

The coordinated THF in **3** is readily displaced by pyridine, as shown by NMR spectra recorded in $[D_5]$pyridine. In the ^1H NMR spectrum, the YMe group appears as a doublet at $\delta = 0.01$ ppm ($^2J(Y,H) = 1.2$ Hz); the ^{13}C NMR spectrum contained a doublet at $\delta = 17.7$ ppm ($^1J(Y,C) = 39.3$ Hz). The coordinated crown ether of **3′** is indicated in the ^1H NMR spectrum in $[D_5]$pyridine recorded at −20 °C as a broad resonance at $\delta = 3.75$ ppm in addition to the resonances arising from $[YMe_2([D_5]pyridine)_x]^+[BPh_4]^-$ and free [12]crown-4.[10] These results are consistent with a labile coordination of the crown ether of **3′** in pyridine.

The crystal-structure analysis of **3** revealed a pentagonal-bipyramidal coordination geometry around the yttrium center with *trans*-disposed methyl groups (Figure 1), whereas the ligands around the eight-coordinate metal center in **3′** adopt an square-antiprismatic arrangement with *cis* methyl groups.[8a] The yttrium–carbon bond lengths ranging between 2.508(2) and 2.526(2) Å in **3** are slightly longer than in the dication **4**,[6b] whereas the yttrium–oxygen bond lengths are similar to those in other cationic yttrium complexes.[6b,11]

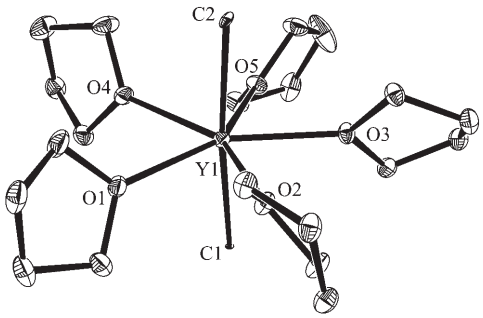


Figure 1. Molecular structure of the cation of **3**. Only one of the two crystallographic independent molecules is shown. Thermal ellipsoids are set at 30% probability, and hydrogen atoms are not shown for clarity. Selected bond lengths [Å] and angles [°]: Y1–C1 2.526(2), Y1–C2 2.508(2), Y1–O1 2.397(2), Y1–O2 2.399(2), Y1–O3 2.406(2), Y1–O4 2.395(2), Y1–O5 2.418(2); C1-Y1-C2 174.03(8).

Upon activation with $[PhNHMe_2][B(C_6F_5)_4]$, the precursors **1** and **2** both catalyzed the polymerization of 1,3-dienes (Table 1), whereas no polymerization was observed when activation of **1** and **2** was attempted with $[PhNHMe_2][BPh_4]$.[12] The in situ generated dication $[YMe(solv)_x]^{2+}$(**4a**, solv = toluene) gave 1,4-*cis*-polybutadiene in up to 97% selectivity at 100% conversion after 14 h (run 7). The in situ

[a] Conditions: 5 μmol Y; $T = 25\,^{\circ}C$. 1,3-Butadiene polymerization: $V_{butadiene} = 7.5$ mL (14 wt% in toluene); $V_{total} = 30$ mL. Isoprene polymerization: $V_{isoprene} = 1$ mL; $V_{total} = 30$ mL. [b] Ratio *cis*:*trans*:1,2 for 1,3-butadiene; ratio *cis*:*trans*:3,4 for isoprene. [c] $\times 10^3$ [g mol^{-1}]. [d] Molecular weight and microstructure not determined because of low conversion. [e] Microstructure not determined because of cross-linking; molecular weight determined for the soluble fraction.

generated monocation $[YMe_2(solv)_x]^+$ (**3a**, run 3) produced 1,4-*cis*-polybutadiene in only 90% selectivity and had a significantly lower polymerization activity (no polybutadiene was obtained after 30 min (run 2)) than the dications (18–26% conversion (runs 4 and 6)). These results show that the in situ generated monocation $[YMe_2(solv)_x]^+$ and the dication $[YMe(solv)_x]^{2+}$ have different activities and produce polybutadienes with different microstructures. The dication (Table 1, run 7) produced a polybutadiene with a molecular weight (M_n) twice as high as that obtained with the monocation (run 3). This result is consistent with an insertion mechanism assuming that the active species consists of, depending on the experimental conditions, either a dication with one growing chain or a monocation with two growing chains.[3b,13] In the absence of Al*i*Bu$_3$, cross-linked polybutadiene is isolated (runs 1, 2, and 5).

The in situ formed monocation $[YMe_2(solv)_x]^+$ polymerizes isoprene to 1,4-*cis*-enriched polyisoprene (Table 1, runs 8 and 9). In polymerization experiments with activated yttrium-aluminate **1** (run 9) as well as with the activated hexamethylyttrate **2**, polyisoprene with the same microstructure and similar molecular weight is obtained.[12b] Both catalyst precursors must therefore form the same THF-free monocationic species $[YMe_2(solv)_x]^+$.[12,14]

In the absence of Al*i*Bu$_3$, the dication forms (Table 1, run 10) polyisoprene with a molecular weight M_n that is twice as high as that formed with the monocation (run 8), analogous to the polymerization of 1,3-butadiene. In this case, however, a significant influence of the aluminum alkyl is seen. In the presence of Al*i*Bu$_3$, the dication (run 11) provides polyisoprene with a molecular weight significantly lower than that formed with the monocation (run 9). In both cases, the addition of Al*i*Bu$_3$ leads to a higher *cis*-selectivity. We are currently continuing our investigations into these effects in the polymerization of isoprene.

According to ^{1}H NMR spectra of the yttrium methyl cations in [D$_8$]THF, the cations with perfluorinated anions **3a** and **4a** are identical to the isolated model compounds **3** and **4** (see Supporting Information). The differences between the polymerization activities of the model compounds and the active compounds can be accounted for, on the one hand, by the different anions and, on the other hand, the presence of THF. Although, in principle, THF inhibits the polymerization, it can, in some cases, be trapped by Al*i*Bu$_3$.[6b,12b] The crystal structures of THF-free cationic lanthanide metallocenes with tetraphenylborate as the counterion typically show strong η^6-coordination of at least one of the phenyl groups to the metal center.[15] This bonding also occurs when these compounds are dissolved in aromatic solvents to give contact pairs, and is only removed by strong Lewis bases, such as THF, to give solvent-separated ions.[15b] From this result it may be concluded that tetraphenylborate complexes **3** and **4** form inactive contact pairs in toluene.[16] Cations with perfluorinated anions coordinate, in contrast, only very weakly,[17] and therefore form solvent-separated ion pairs in aromatic hydrocarbon solvents; as a result, in contrast to the tetraphenylborate complexes, they catalyze 1,3-diene polymerization.[16,18]

We could show that it is possible to specifically prepare the cationic yttrium methyl complexes $[YMe_2(solv)_x]^+$ and $[YMe(solv)_x]^{2+}$, which depending on the anion, could catalyze the homogeneous polymerization of 1,3-butadiene and isoprene. Further research into the systematic determination of the structure–activity relationship of this catalytic system and the polymerization behavior of the cationic methyl complexes is underway.

Experimental Section

4 and $[YMe([D_5]pyridine)_x]^{2+}[BPh_4]^-_2$: THF (150 mL) was added to a mixture of **2** (1.50 g, 5.51 mmol) and $[NEt_3H][BPh_4]$ (11.6 g, 27.6 mmol) at 25 °C; this resulted in the generation of gas. After the colorless suspension had been stirred at 25 °C for 30 min, the supernatant solution was removed by decantation. Drying in vacuo gave colorless microcrystals of **4** (4.24 g, 65%). ^{1}H NMR (200 MHz, [D$_5$]pyridine, 25 °C): $\delta = 0.67$ (d, $^2J(Y,H) = 2.0$ Hz, 3H, YCH_3), 1.61 (m, 6 × 4H, β-CH_2, THF), 3.65 (m, 6 × 4H, α-CH_2, THF), 7.08 (t, $^3J(H,H) = 7.0$ Hz, 2 × 4H, Ph-4), 7.25 (t, $^3J(H,H) = 7.4$ Hz, 2 × 8H, Ph-3), 8.02 ppm (br, 2 × 8H, Ph-2).

Polymerization of 1,3-butadiene with the in situ generated dication $[YMe(solv)_x]^{2+}$: A toluene solution of **1** (1 mL; 5 mmol L^{-1}) and a solution of $[PhNHMe_2][B(C_6F_5)_4]$ (2 mL; 5 mmol L^{-1}) were added to a 50-mL Schlenk tube containing toluene (19.5 mL; and, where appropriate, Al*i*Bu$_3$ (125 μL, 0.5 mmol)) under constant stirring. After the mixture had stirred at 25 °C for 10 min, 1,3-butadiene (7.5 mL of a 14 wt% solution in toluene) was added and the yellow reaction mixture was stirred for 30 min. The polymerization was subsequently terminated by the addition of methanol, and the reaction solution was poured into a mixture of 2,6-di-*tert*-

butylphenol and acidified methanol (300 mL). After filtration, the polymer was washed with methanol and dried in vacuo at 25 °C until it reached a constant weight.

MASAKATSU SHIBASAKI and YOSHINORI YAMAMOTO, (Eds.)

Multimetallic Catalysts in Organic Synthesis

This first book to comprehensively cover this hot topic presents the information hitherto scattered throughout smaller reviews or single book chapters to provide an introduction to this rapidly expanding field.
In ten chapters, the international team of expert authors treats asymmetric syntheses, new transformations, and organometallic reactions using homo- and hetero-bimetallic catalysts. Written for advanced researchers, this very timely publication is of significant benefit to organic and organometallic chemists in both academia and industry.

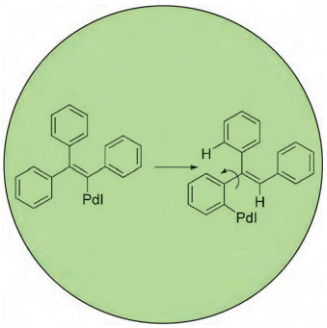
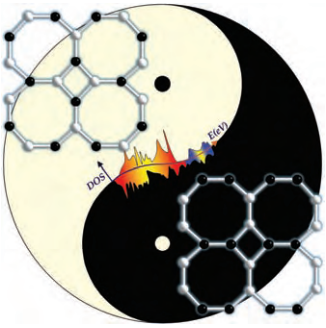
Ein Clathrat aus einem Zinkphthalocyanin hat eine ungewöhnliche Kristallstruktur mit großen solvensgefüllten Hohlräumen ($>8\ nm^3$). Der aufgefaltete Würfel auf dem Titelbild zeigt, wie sechs Phthalocyaninmoleküle einen Nanohohlraum aufbauen. Solvensmoleküle, auch Wasser, werden zwischen den Hohlräumen ausgetauscht, und die auf den Flächen befindlichen Metallzentren lassen katalytische Wirkungen erhoffen. Einzelheiten finden sich in der Zuschrift von N. B. McKeown et al. auf S. 7718 ff.



Katalysemechanismen
Bei manchen rhodium- und palladiumkatalysierten Reaktionen tritt als entscheidender Schritt eine 1,4-Wanderung des Metallzentrums auf. S. Ma und Z. Gu präsentieren einige Beispiele hierfür im Kurzaufsatz auf S. 7680 ff.

Atmosphärenforschung
Aerosole sind von zentraler Bedeutung für die Chemie und Physik der Atmosphäre, beeinflussen außerdem das Klima und können Erkrankungen auslösen. Im Aufsatz auf S. 7690 ff. fasst U. Pöschl den aktuellen Wissensstand zusammen.



Metallborcarbidphasen
Mithilfe von DFT-Rechnungen wurde das “Coloring-Problem” in MB_2C_2-Phasen gelöst. Einzelheiten dazu finden sich in der Zuschrift von X. Rocquefelte, J.-Y. Saillard, J.-F. Halet et al. auf S. 7714 ff.

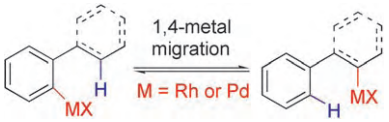
1,4-Migration of Rhodium and Palladium in Catalytic Organometallic Reactions



A key mechanistic step in a number of rhodium- and palladium-catalyzed reactions is the 1,4-migration of the metal center, which can be understood as the oxidative addition of the metal into a C–H or C–X bond followed by reductive elimination. Although concrete evidence for the transition state is lacking, the synthetic applications are numerous.

The question of coloring: Calculations present a definite solution to the "coloring problem" in the MB_2C_2 phases (M = Mg, Sc, Ca, Y, Ln; see picture of the four structure types). Electric-field gradient tensor components from NMR spectroscopy readily allow differentiation between the different B/C topologies and give support to the theoretical results.

A void apart! A clathrate based on zinc octa(2,6-diisopropylphenoxy)phthalocyanine contains solvent-filled voids of exceptionally large volume (> 8 nm^3; see picture for the packing arrangement). Each nanovoid is enclosed by a cubic assembly of six phthalocyanine molecules and contains 18 molecules of water and an estimated 65 molecules of acetone, which may be exchanged for methanol or water molecules without loss of order.

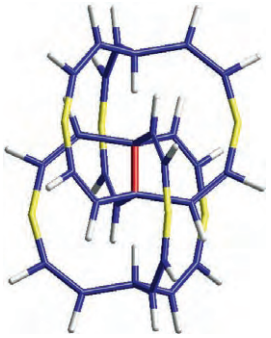
1804502_gu

It's not how short you make it, it's how you make it short! A diverse collection of compounds with short C–C single bonds whose lengths range from 1.32 Å to 1.46 Å have been theoretically designed (see structure of a "spiderane"). The strategies for squeezing the C–C bonds (encapsulation, strapping back, and stiffening) allow shorter bonds than hybridization and conjugative effects alone.

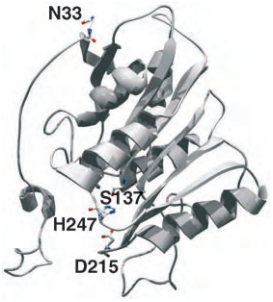


Carbon–Carbon Bonds

D. R. Huntley,* G. Markopoulos, P. M. Donovan, L. T. Scott, R. Hoffmann* ——— **7549 – 7553**

Squeezing C–C Bonds

A true convert: The carboxylesterase enzyme R.34 (see picture) can be converted into a triacylglycerol lipase without modification of the shape, size, or hydrophobicity of the substrate binding site. The substitution of Asn33 by Asp results in a salt bridge between the Asp33 and Arg49, which causes a distortion of the enzyme structure that makes the catalytic site more accessible to larger substrates but also more labile.

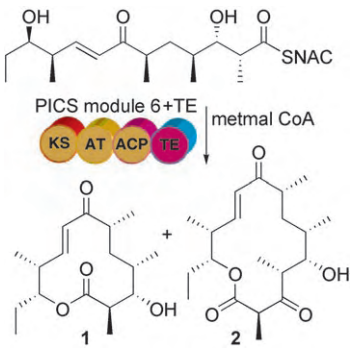


Enzyme Mutation

D. Reyes-Duarte, J. Polaina, N. López-Cortés, M. Alcalde, F. J. Plou, K. Elborough, A. Ballesteros, K. N. Timmis, P. N. Golyshin, M. Ferrer* ——— **7553 – 7557**

Conversion of a Carboxylesterase into a Triacylglycerol Lipase by a Random Mutation

---



Dual action: An analogue of a natural hexaketide thioester substrate is incubated with recombinant picromycin/methymycin synthase (PICS) module 6 with its attached thioesterase (TE). A mixture of 12- and 14-membered-ring macrolactones 10-deoxymethynolide (**1**) and narbonolide (**2**) are generated (see scheme) by competing chain elongation and direct lactonization of the substrate. KS = ketosynthase, AT = methylmalonyl transferase, ACP = acyl carrier protein, metmal CoA = methylmalonyl coenzyme A.

Biosynthesis

J. Wu, W. He, C. Khosla, D. E. Cane* ——— **7557 – 7560**

Chain Elongation, Macrolactonization, and Hydrolysis of Natural and Reduced Hexaketide Substrates by the Picromycin/Methymycin Polyketide Synthase

Molecular Motors

Cell motility, virus transport and developmental asymmetry are examples of biological processes related to the function or malfunction of the minute machinery of molecular motors. This handbook brings together current knowledge on the functionality, regulation, and interactions of cytoskeletal, DNA, and rotary motors. Leading experts present principles and applications ranging from atomic structure, biochemistry, and biophysics to cell biology, developmental biology and pathology - all set to become a "classic" in the years to come.

"...essential reading for graduate students in the field of cell motility and molecular motors... recommend it enthusiastically..."

Macromolecular Metal Complexes: Materials for Various Applications**

Dieter Wöhrle*

The variety of metals used by biological systems is very large and ranges from the alkali metals to the transition metals. They play an essential role in living systems, both in growth and metabolism. Examples include hemes as oxygen-carrier systems, chlorophylls as energy-conversion systems in photosynthesis, and metalloenzymes for various catalytic reactions. In living systems, metal ions can coordinate, or metal clusters are stabilized by a variety of biopolymers through covalent, ionic, or coordinative interactions. Nature shows how complicated it is to construct metal-containing macromolecules that are not only active but also selective with respect to a specific property. Therefore it is of great interest to synthesize artificial combinations of metal atoms/ions, ligands, and macromolecules with the aim to obtain new materials that exhibit a variety of properties. The first results on thermally stable polymer complexes and chelate-forming resins were published in the 1960s, while more intensive research began to stem from this towards the late 1970s/early 1980s. The first International Symposium on Macromolecule–Metal Complexes was held in 1985. In September 2005, the 11th IUPAC International Symposium organized by F. Ciardelli (University of Pisa) took place in Tirrenia (Pisa, Italy). Around 170 participants from 30 countries demonstrated the increasing interest and progress in this field, with contributions that focused on the different kinds of combinations of metal atoms/ions with organic or inorganic macromolecules.

As a result of the increasing number of new macromolecular metal complexes reported, a clear and simple classification is necessary.[1] Type I complexes consider the covalent, coordinative, or ionic binding of metal ions or complexes to linear or cross-linked macromolecules. In type II and type III complexes, the ligand or the metal, respectively, are integrated into a linear or cross-linked macromolecule thus giving the macromolecular backbone. Complexes of type IV include the physical incorporation of metal complexes or metal nanoparticles in macromolecules.

The groups of E. Tsuchida and H. Nishide (Tokyo, Japan) discussed the interaction of oxygen from air with metal porphyrins in macromolecules. Human serum albumin (HSA)—the plasma protein in our bloodstream—was modified by a proximal histidine in a subdomain, and then synthetic heme derivatives were incorporated. Dimeric and tetrameric clusters of this modified HSA can include 32 heme molecules. Tsuchida and T. Komatsu showed that this artificial hemoprotein binds and release O_2 in similar fashion to hemoglobin. This O_2-carrying plasma albumin is of importance not only for red-cell substitutes but also for O_2 therapeutic reagents (Figure 1).[2] Also, cobalt(II) porphyrin derivatives were coordinatively bound to poly(octyl methacrylate-co-vinylimidazole) or incorporated into Nafion (fluorinated sulfonic acid copolymers). Nishide demonstrated that membranes of these polymers containing the Co porphyrin act as oxygen carriers, transport oxygen through the membrane, and therefore can be used to separate O_2 from air. With one separation, O_2 in air was enriched from 21% to over 90%.[1]

The use of macromolecular metal complexes not only for binding of small molecules but also for their activation in catalytic reactions is of great industrial interest.[1] One of the promising trends in catalyst design is the use of water-soluble macromolecular metal complexes, as this allows the catalytic reaction to be carried out in a two-phase system, with the macromolecular catalyst in the aqueous phase and the reagents and reaction products in an organic phase. This process gives rise to catalytic activities that are similar to those observed in a homogeneous phase, with the added advantages of facile separation of reaction products and easy reuse of the aqueous solution of the catalyst. E. A. Karakhanov and A. Maksimov (Moscow, Russia) showed that water-soluble block copolymers of ethylene oxide–propylene oxide, dendrimers, or cyclodextrins are suitable carriers for transition-metal catalysts, as used successfully in oxidation, hydroxylation, hydrogenation, hydroformylation, and carbonylation reactions.[1] An interesting development is the use of natural macromolecules as carriers for artificial catalysts. One example is the cationic *meso*-tetrakis(4-*N*-methylpyridyl)porphyrin and its analogues, which are known to bind to DNA. H. Yamaguchi and A. Harada (Osaka, Japan) bound the Fe^{II} complex of this porphyrin to the monoclonal antibody 12E11G. This macromolecular metal complex displays remarkable activity in the oxidation of catechol, guajacol, and pyrogallol in the presence of H_2O_2 (Figure 2),[3] and exhibits a peroxidase activity that lies in the same order as that of horseradish peroxidase while

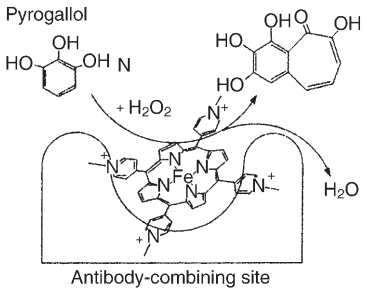

Figure 2. The complex between an antibody and a cationic Fe^{II} porphyrin, and its catalytic activity in the oxidation of pyrogallol.

showing a better stability than the natural system.

A more classical field of practical application is the binding of transition-metal ions to macromolecules for the cleaning of waste water, soils, and so on.[1] Several contributions pointed out improvements in the selectivity of metal-ion separation by using new ligands and better technologies for metal-ion binding. E. Rosenberg (Missoula, USA) optimized silica–polyamine composites by silylation of silica gel and subsequent reaction with polyamines. The average pore size of silica is critical for good performances of the gel, while the structure and the molecular weight of the polymer have a greater influence on the metal selectivity. Elsewhere, A. Kaledkowski (Wroclaw, Poland) introduced a calix[4]pyrrole[2]thiophene ligand. After binding the ligand to cross-linked polystyrene, the obtained resin shows distribution coefficients for noble-metal ions (Pt, Ag, Au) of two to four orders of magnitude greater than those observed for cations of other transition-metal ions. One of the most promising techniques for the removal of metal ions from waste water is by membrane ultrafiltration in a method known as liquid-phase polymer-based retention (LPR). Water-soluble polymers with different chelating groups of high affinity for transition-metal ions have been investigated by the LPR technique (B. L. Rivas, Concepcion, Chile; R. Molinari, Rende, Italy).[4]

With regards to type II macromolecular metal complexes, C. Lo Sterzo and co-workers (Teramo, Italy) have developed a multistep one-pot Pd-promoted synthetic strategy for the synthesis of poly(aryleneethynylene) copolymers of the general structure $[-C{\equiv}C-A-C{\equiv}C-B-]_n$, with A = 2,5-dialkoxy-substituted 1,4-phenylenes and B = substituted thiophenes, porphyrins, phenanthrolines, etc. Block A is in charge of the mechanical stability and processability, whereas block B is responsible for functional properties of the materials. Through appropriate choice of block B, functional materials that are interesting for sensoric and electronic applications have been obtained.[5]

Self-assembly to obtain type III polymers with one-dimensional architectures is a promising bottom-up strategy for nanocircuits. N. Kimizuka (Fukuoka, Japan) described supramolecular lipid Pt^{II}/Pt^{IV} complexes that spontaneously self-assemble in solution into 1D nanowires.[6] Also, the lipophilic triazole complexes $[M^{II}(\mathbf{1})_3](BF_4^-)_2$ (M = Fe, Co; **1** = azobenzene-substituted triazole moiety) self-assemble in solution in chloroform (Figure 3) and give heat-set gel-like networks. Nanofibers of the Fe complex have a width of 6 nm (the diameter of one chain) and a length of approximately 100 nm. Upon UV irradiation, reversible *trans* to *cis* isomerization of the azo group occurs and the fibrous nanostructures are transformed to irregular grains. This nanoswitching is interesting for the dynamic control of electromagnetic properties. S. Higuchi (Tsukuba, Japan) reported the self-assembly of polymers prepared from 1,4-bis(terpyridyl)benzene and Fe^{II} or Co^{II} to give metallosupramolecular polyelectrolytes, which are interesting for their reversible color change by oxidation/re-reduction processes.

Type IV polymers are used in bilayer photoreptor devices of laser printers, in which titanyl phthalocyanine clusters in polymers act as photoconductors (> 90% quantum yield of photocurrent). D. Wöhrle (Bremen, Germany) reported the preparation of thin films of polymers that contain carefully designed and monomolecular-distributed phthalocyanines. These metal complexes are among the most active known compounds for optical limiting (OL), which is a third-order nonlinear optical (NLO) property.[7] The transmission of light for an optical limiter is high at normal light intensities and low for intense beams which is interesting for the protection of eyes, optical elements, and optical sensors from intense laser pulses. It was recently found that the OL properties of phthalocyanines in multilayer films of PMMA and PVC are, in most cases, better than in solution. A field of increasing interest is metal nanoparticles in polymers, and progress in this area is described in recently published books.[8] P. A. G. Cormack (Glasgow, UK) described the synthesis of multicomponent particles in which dyes are first adsorbed onto silver colloidal nanoparticles. These modified particles are then encapsulated into cross-linked polystyrene beads followed by modification at the surface of the beads (diameter ≈ 1 μm) with functional groups (Figure 4).[9] After the binding of target oligonucleotides, a complementary DNA can interact with the modified surface. Surface-enhanced resonance Raman scattering (SERRS), which is a more sensitive technique than fluorescence by approximately three orders of magnitude, allows analysis of the DNA.

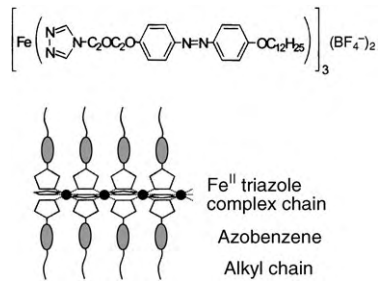

Figure 3. 1D chain of the photoresponsive iron(II) 1,2,4-triazole complex with azobenzene chromophores in the lipophilic chains.

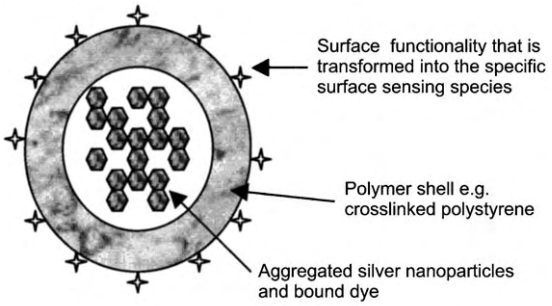

Figure 4. The encapsulation of dye-labeled Ag nanoparticles within a functionalized polymer core that allow detection by SERRS.

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The reports at the conference showed impressively the rapid development of this interdisciplinary field of material science. On the one hand, more classical applications such as metal-ion binding and catalysis have been further improved. On the other hand, new supramolecular structures that include the metal and display interesting properties are obtained by self-assembly. The main contributions of this conference will be published in a special volume of *Macromolecular Symposia* (Wiley-VCH) in 2006.

Extending Mechanistic Routes in Heterazolium Catalysis–Promising Concepts for Versatile Synthetic Methods**

*Kirsten Zeitler**

Keywords:
aldehydes · carbenes · nitrogen heterocycles · stereoselective catalysis · umpolung

In the development of sustainable chemical transformations, the discovery of new, efficient synthetic methods, especially for carbon–carbon bond formation, remains a great challenge. Organocatalytic processes mediated by small nucleophilic molecules have gained in importance enormously over the last few years.[1] Their benefits include not only atom economy and operational simplicity, but also the possibility of nontraditional retrosynthetic bond disconnections. A powerful example for such a strategy is the inversion of reactivity of functional groups (umpolung).[2] The catalytic version of this concept was first discovered in the context of benzoin reactions[3] and has led together with the extention to the Stetter reaction to highly valuable asymmetric methods, even for the construction of quaternary stereocenters.[4,5]

The use of functionalized aldehydes as donor substrates in N-heterocyclic carbene (NHC)-catalyzed umpolung reactions opens new mechanistic pathways and gives rise to new synthetic strategies (Scheme 1). Alkenes and other reducible functional groups have been employed successfully so far to generate subsequent electrophilic character at the previously umpoled carbonyl carbon.

The covalent activation of aldehydes and α-keto acids[6] as acyl anion equivalents through addition of nucleophilic, heterazolium-derived carbene **2** leads to the so-called Breslow intermediate **5** (Scheme 2).[3b,7] Depending on the kind of electrophile applied, benzoins or 1,4-dicarbonyls **15** (Stetter reaction) are formed (cycle **A**).[8]

Based on mechanistic considerations starting from the nucleophilic alkene **5**, the scope and utility of this umpolung can be extended by the use of further functionalized donor substrates that allow the subsequent formation of an acyl

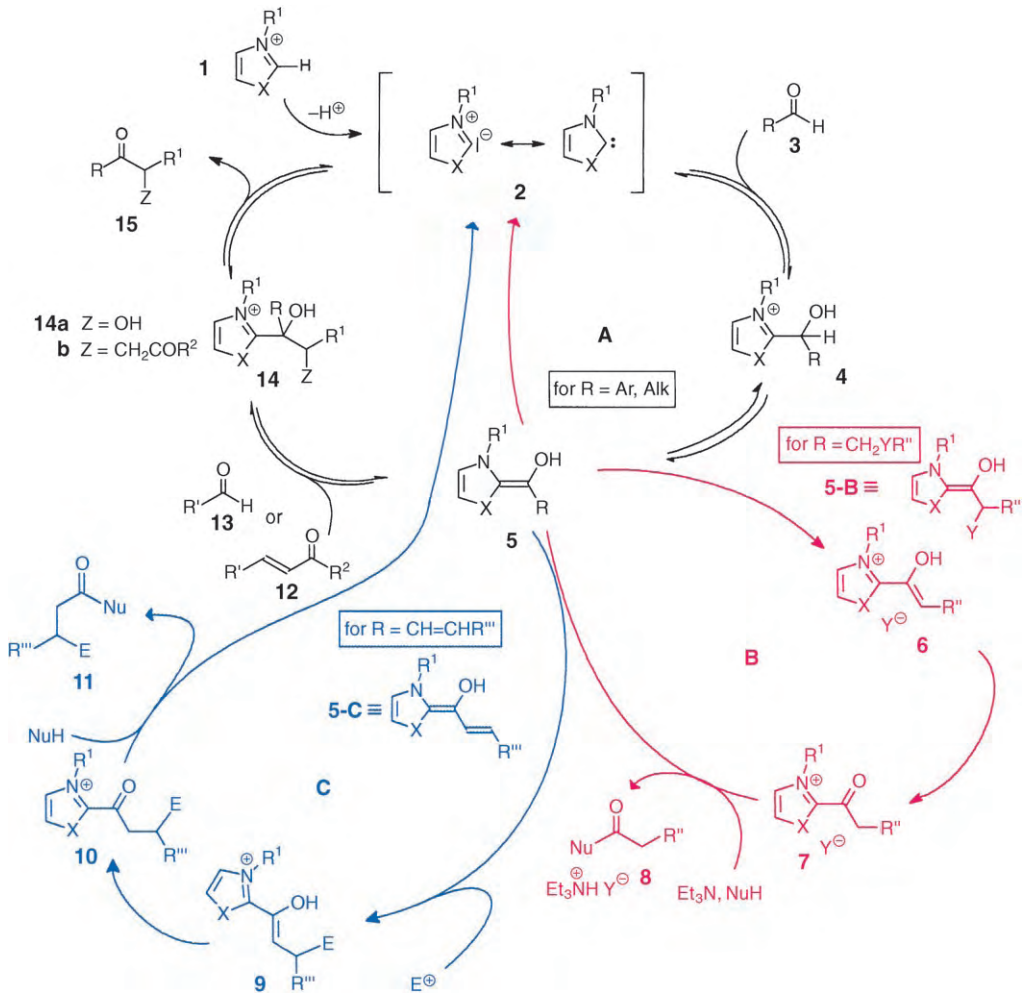

Scheme 2. Mechanistic considerations for extended reaction pathways.

azolium species, i.e. activated carboxylates **7** and **10**. This key intermediate can be formed by means of an internal redox reaction (cycle **B**) from α-heteroatomic aldehydes, such as α-halo aldehydes[11] and α,β-epoxy aldehydes[12] **5-B** by elimination of the leaving group Y through enol **6** followed by isomerization to give the corresponding acyl azolium tautomer **7**. Alternatively, the acyl azolium species arises from α,β-unsaturated aldehydes via a conjugated ("vinylogous") acyl anion equivalent **5-C** (cycle **C**).[11] This homoenolate **5-C** can undergo electrophilic trapping with subsequent tautomerization to form the pivotal catalyst-bound activated ester **10**. Reaction with appropriate nucleophiles (inter- or intramolecular) yields carboxylic acid derivatives **8** or **11**, and regenerates the catalyst **2**.

Bode et al. recently developed a direct stereoselective, catalytic method for the generation of *anti*-β-hydroxy esters from epoxy aldehydes using thiazolium precatalysts.[12] Aromatic and aliphatic epoxy aldehydes **16** react with alcohols to provide the desired esters **18** in good yield and stereoselectivity under mild conditions (Scheme 3). If one considers reaction pathway **B** (Scheme 2), the activated carboxylate **7** is formed by an epoxide-opening step from intermediate **5-B**. The synthesis of *N*-tosyl-β-amino esters from α,β-aziridinyl-aldehydes under similar conditions greatly extends the scope of this esterification approach.

Concurrently, Rovis et al. found that secondary and tertiary α-halo aldehydes provide access to dehalogenated acyl azolium species **7** (Scheme 2, pathway **B**) catalyzed by thiazolium- or triazolium-derived nucleophilic carbenes.[11] The possible nucleophiles for the interception of these acylation agents range from primary and secondary alcohols

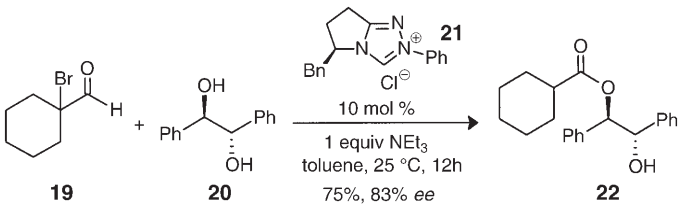
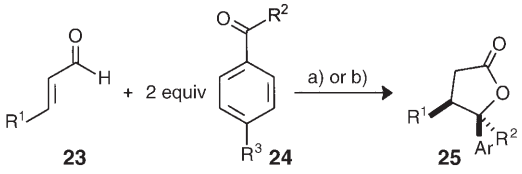


Scheme 4. Desymmetrization of *meso* diols.

(with tolerance of epimerizable stereocenters) to phenols and anilines. The use of chiral triazolium catalyst **21** allows the desymmetrization of *meso* diols **20** (Scheme 4). Interestingly, although they used reaction conditions similar to those for benzoin reactions, neither Bode nor Rovis could observe the formation of significant amounts of the corresponding benzoin or acyloin products.



Scheme 5. Organocatalyzed conjugate umpolung for the synthesis of γ-butyrolactones. Reaction conditions: a) R^1 = Ph; R^2 = H; R^3 = Br, CO_2Me; 8 mol% IMes·HCl, 7 mol% DBU, THF/*t*BuOH 10:1, >79%, d.r. >4:1. b) R^1 = Ph; R^2 = CF_3; R^3 = H. 5 mol% IMes·HCl, 10 mol% KO*t*Bu, THF, 84%, d.r. 2:1. Mes = 2,4,6-trimethylphenyl, DBU = 1,8-diazabicyclo[5.4.0]undec-7-ene.

The synthetic utility of the conjugated umpolung (Scheme 2, cycle **C**) as an alternative pathway in heterazolium catalysis was illustrated by Bode et al.[13a] and Glorius et al.,[13b] who independently developed a direct, organocatalytic annulation of enals **23** with aldehydes **24**. Under remarkably mild conditions the stereoselective synthesis of γ-butyrolactones **25** was achieved in a flexible one-step process via homoenolate intermediates generated by sterically demanding imidazolium ylides as catalysts (Scheme 5). The conjugated acyl anion equivalent **5-C** couples with an aldehyde to yield an alkoxide intermediate, which is trapped intramolecularly by the catalyst-bound activated ester. A survey of different catalysts showed the high preference for imidazolium salts; thiazolium precursors proved to be inefficient. Whereas a wide range of enals can be used as the nucleophile, the electrophilic partner has been limited to aromatic aldehydes and trifluoromethylaryl ketones. The configuration of the product is preferrably *cis* (d.r. up to 5:1), but the stereochemical outcome is influenced by substrate, reaction conditions, and catalyst structure. The generation of quaternary stereocenters from ketone electrophiles was catalyzed by a tricyclic imidazolium-derived NHC to give a diastereomeric ratio of 3:1 (like/unlike) with 12% and 25% *ee*.[13b]

The scope of the nucleophile-catalyzed generation of homoenolates from α,β-unsaturated aldehydes was only recently extended by Bode et al.[14] In a mechanistically similar process using imines as the electrophilic partner, the direct annulation of enals **23** with *N*-4-methoxybenzenesulfonylimines **26** followed by cyclization led to disubstituted γ-lactams **27** in good yield and good to moderate diastereomeric ratios (Scheme 6). It has to be noted that there is only a narrow range of suitable imine substrates (e.g. electron-rich *N*-sulfonyl imines) as they compete to react with nucleophilic catalyst. This one-pot procedure provides a fast access to the important class of γ-butyrolactams, and by nucleophilic ring-opening with alkoxides γ-amino acid derivatives are readily available.

Scheidt et al. have shown that the reactivity of these NHC-generated homoenolates is not restricted to the coupling with aldehydes and imines as electrophiles and the subsequent intramolecular nucleophilic attack of the resulting heteroanions (alkoxides and amides, respectively) on the acyl azolium species.[13c] The electrophilic and nucleophilic partners could be decoupled by using phenol derivatives as the proton source in combination with DBU and imidazolium salts in the presence of a second alcohol as nucleophile. In this context, Bode et al. only very recently reported on the product-determining effect of the base for the subsequent reactions of catalytically generated homoenolates **5-C**.[13d] While strong bases such as KO*t*Bu predominately lead to carbon–carbon bond formation, the use of weaker bases acting as a catalytic proton shuttle promotes in situ protonation of the homoenolate without an additional proton source (Scheme 7). Application of substoichiometric amounts of the triazolium precatalyst **28**, which is more readily deprotonated than other NHC precursors, leads to the catalytic, atom-economical redox esterification of a wide variety of enals **23** with alcohols R^2OH as nucleophiles in good to high yields (Scheme 7; optimized conditions).

Whereas the use of classical nitrogen-based nucleophiles (e.g. sulfonamides, azides, anilines) under Scheidt's conditions seems to be difficult in the complex balance of acid and base in this process, the use of chiral imidazolium salts allows enantiodiscrimination. With the participation of a chiral activated ester as a possible intermediate, the organocatalytic kinetic resolution of racemic 1-phenylethanol (**31**) was achieved with cinnamaldehyde (**32**) (Scheme 8).

In situ generated N-heterocyclic carbenes are also potent catalysts for trans-

esterifications[15] and ring-opening polymerization reactions. In these related processes, similarily activated carboxylates, formed from NHCs and ester or lactone precursors, are thought to be the pivotal intermediates.[16] An application of this concept to a nonenzymatic kinetic resolution has been published recently.[17,18] Chiral imidazolylidene catalysts **36** mediate a highly enantioselective transesterification of racemic secondary alcohols with vinyl esters without required stoichiometric amounts of base (Scheme 9).[18]

Not only the synthetic utility of the accessible products, but also the unique reactivity of these catalytically generated nucleophilic precursors and their subsequent electrophilic character should motivate chemists for further novel developments on this versatile mechanistic platform. Deeper insights into the mechanism and the possible combinations of electrophiles and nucleophiles should smooth the way for useful applications and further innovations in carbene-catalyzed reactions. These versatile concepts and the ample scope of possible substrates may lead to the catalytic, enantioselective, and sustainable synthesis of highly valuable, multifunctionalized molecules.

1,4-Migration of Rhodium and Palladium in Catalytic Organometallic Reactions

Shengming Ma and Zhenhua Gu*

Keywords:
1,4-migration · C–H activation · palladium · reaction mechanisms · rhodium

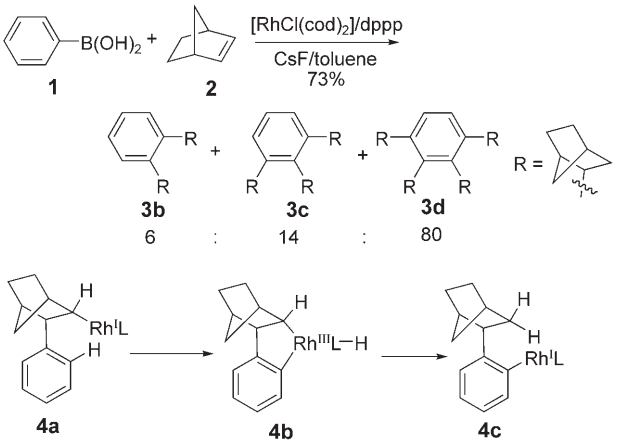
Mechanisms based on the 1,4-migration of metal centers have been proposed to explain some interesting transition-metal-catalyzed organic transformations. Despite the lack of solid evidence for the real nature of this process, the 1,4-metal migration reaction is proposed to proceed by the reductive elimination of trivalent intermediates for the Rh-involved reactions and of tetravalent intermediates for the Pd-catalyzed processes. These high-valent organometallic species would be formed by the oxidative addition to C–H and C–X bonds. This minireview summarizes the results in this area.

Introduction

Transition-metal-catalyzed reactions are among the most powerful tools in organic synthesis.[1] Four fundamental reactions of the transition-metal complexes—ligand substitution, oxidative addition/reductive elimination, insertion/elimination (retro-insertion), and nucleophilic/electrophilic attacks on coordinated ligands—are proposed to explain and predict these transition-metal-mediated or -catalyzed reactions.[2] Recently, several groups reported the 1,4-migration of palladium and rhodium in transition-metal-catalyzed multistep transformations. Some of the leading reports are summarized here.

The 1,4-Rhodium Migration

Miura and co-workers demonstrated that phenylboronic acid (**1**) and a strained alkene such as 2-norbornene (**2**), in the presence of a rhodium(I) catalyst, can afford the 1:4 product **3d** in 80% selectivity along with minor amounts of the 1:2 product **3b** and the 1:3 product **3c** (Scheme 1).[3] The authors give a plausible mechanism for the formation these 1:*n* (*n* = 2–4) products. The strained alkene is important to this reaction.



Scheme 1. Rhodium-catalyzed alkylation on an aromatic ring. cod = cycloocta-1,5-diene, dppp = 1,3-bis(diphenylphosphanyl)propane.

The key step is the intramolecular oxidative addition of the C–Rh bond in **4a** with the *ortho* C–H bond of the phenyl group to form the rhodium(III) intermediate **4b**,[4] which yields **4c** by means of reductive elimination.

Hayashi and co-workers reported the 1,4-migration of rhodium in the hydroarylation of alkynes, which was supported by two experimental observations.[5] The olefinic carbon atom in product **7a** does not have the deuterium label (Scheme 2). Instead, 98% incorporation of deuterium was found at the *ortho* position of the phenyl group. When **5** was treated with the pentadeuterated phenylboronic acid **6b**, 93% D-incorporation was found at the olefinic position.

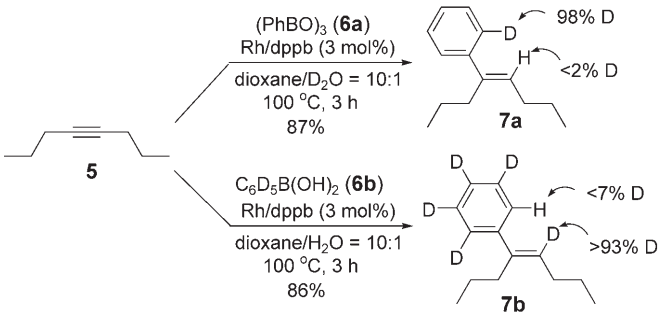
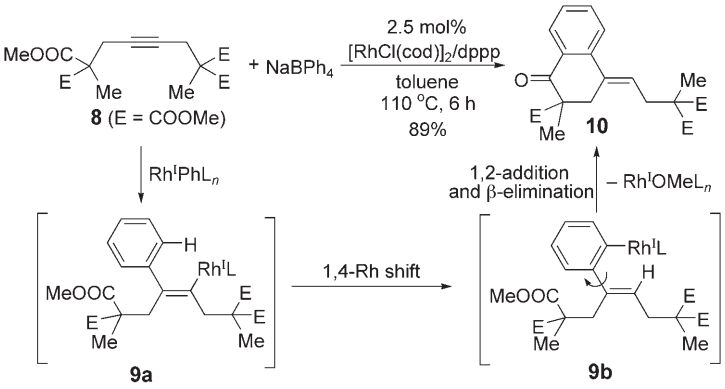


Scheme 2. Rhodium-catalyzed coupling reaction between an alkyne and boronic acid reagents. dppb = 1,4-bis(diphenylphosphanyl)butane.

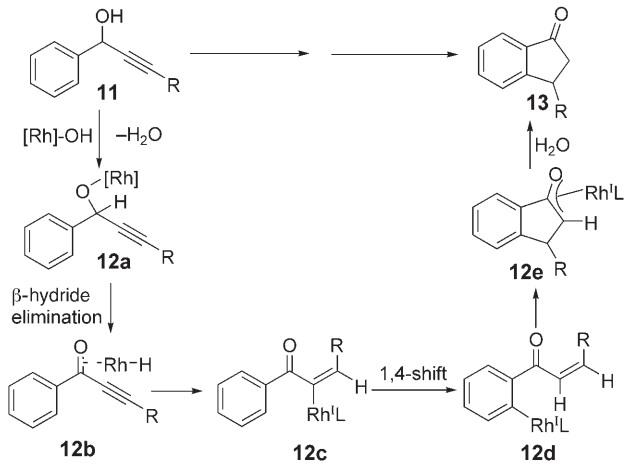
A rhodium-catalyzed acylation reaction to form the bicyclic ketone **10** was reported by Murakami et al. (Scheme 3).[6] The *syn* phenylrhodation of the C–C triple bond in **8** was proposed to give the intermediate **9a**, which underwent 1,4-rhodium migration to afford **9b**. Subsequent



Scheme 3. Intramolecular acylation of organorhodium(I) with ester.

intramolecular acylation of the C–Rh bond in **9b** with the ester group afforded the bicyclic product **10**.

Recently, the groups led by Hayashi and Iwasawa independently reported the rhodium-catalyzed isomerization of 1-arylpropargylic alcohols almost at the same time



Scheme 4. Rhodium(I)-catalyzed isomerization of 1-arylpropargylic alcohols.

(Scheme 4).[7] The alkoxyrhodium species **12a**, which was formed by ligand exchange between [Rh]-OH and propargylic alcohol **11**, generated the rhodium complex **12b** by means of β-hydride elimination. Then **12b** underwent a hydrorhodation of the conjugated C–C triple bond to form the vinylic rhodium intermediate **12c**. The 1,4-rhodium migration of **12c** affording the arylrhodium intermediate **12d** is the rate-determining step ($k_H/k_D = 2.8$). Subsequent intramolecular 1,4-addition and hydrolysis provide the benzocyclopentanone product **13**. The silyl substituent of the carbon–carbon triple bond is necessary for this isomerization reaction in most cases.

The 1,4-Palladium Migration and Its Application to Organic Synthesis

A similar 1,4-migration of palladium forming arylpalladium species from 2-phenyl-substituted alkenylpalladium was

Shengming Ma is originally from Zhejiang Province, China. He received a BS degree in Chemistry from Hangzhou University (1986), and an MS (1990) and a PhD degree (1990) from Shanghai Institute of Organic Chemistry, Chinese Academy of Sciences. After postdoctoral research at the ETH in Switzerland and Purdue University in USA, he joined the faculty of Shanghai Institute of Organic Chemistry (1997), where he is currently a Professor of Chemistry and the Director of the State Key Laboratory of Organometallic Chemistry. In February 2003 he received an additional appointment by the Department of Chemistry, Zhejiang University, as a Professor of the Cheung Kong Scholars Programme.

Zhenhua Gu was born in Jiangsu Province, China. He received a BS degree in Chemistry from Nanjing University (2002). He is currently conducting PhD research in the group of Prof. Shengming Ma at Shanghai Institute of Organic Chemistry, Chinese Academy of Sciences.

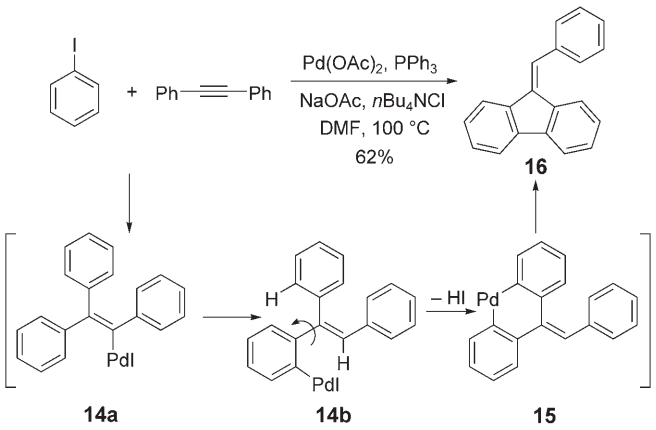
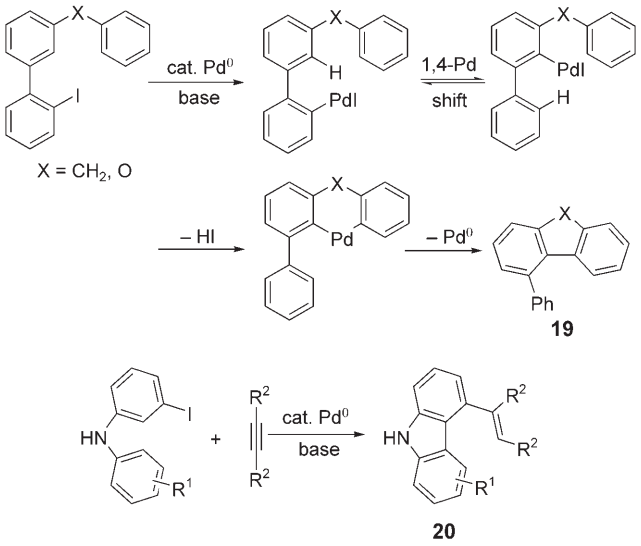


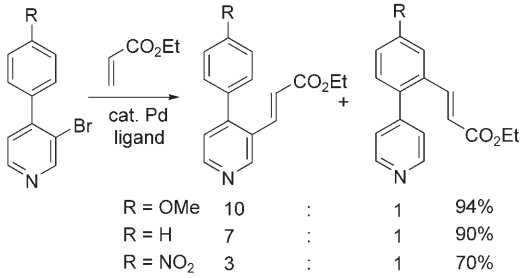
Scheme 5. Palladium-catalyzed synthesis of 9*H*-fluorene **16** from PhI and 1,2-diphenylacetylene.

reported by Larock et al. in the palladium-catalyzed synthesis of 9-alkylidene-substituted 9*H*-fluorene **16** (Scheme 5).[8] The reaction was also explained by a novel 1,4-palladium migration in alkenylpalladium intermediate **14a** to form the arylpalladium species **14b**. HI elimination afforded the palladacycle **15**, which underwent subsequent reductive elimination to afford the fluorene product **16** and regenerate the Pd^0 species.

Such a 1,4-palladium migration was also observed by Gallagher et al.[9] and Larock et al. [10] in the palladium-catalyzed reaction of *ortho*-halobiaryls (Scheme 6). The migration is increasingly favored when electron-deficient arenes are involved.[9] Furthermore, the 1,4-palladium migration can be switched by manipulating the reaction conditions.[10] Under the classical reaction conditions described by Jeffery et al.,[11] the normal product **18a** was obtained exclusively in quantitative yield, while with PPh_3 or bis(diphenylphosphanyl)methane (dppm) as the ligand the reaction afforded **18a** and **18b** in a 1:1 ratio (Scheme 7). The author successfully applied this type of 1,4-palladium migration to the synthesis of the fused polycycles **19** and **20** (Scheme 8).[12]



Scheme 8.

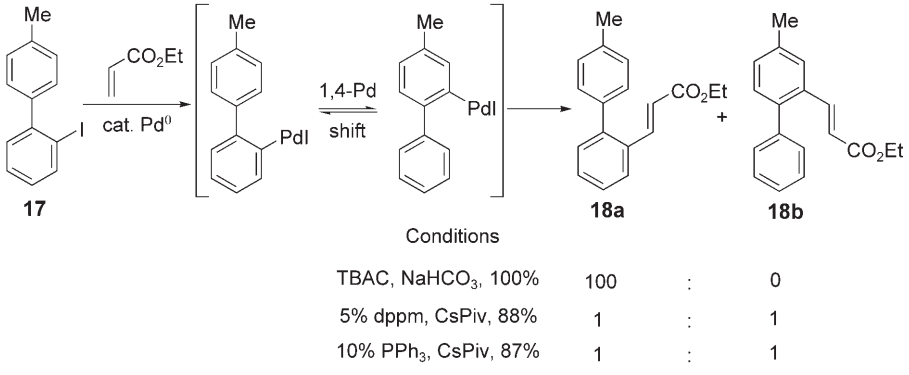


Scheme 6.

Besides the 1,4-palladium migration from an sp^2-hybridized carbon atom (vinylic, aryl) to an aryl carbon atom, Cámpora et al. reported a new palladium migration of an alkylpalladium intermediate to form an arylpalladium complex via palladacycles.[4,13] The π arene complex **21** was proposed to be the important intermediate, and it was further established by X-ray diffraction studies of the similarly structured **25**, in which the Pd–C1 distance is 2.39(1) Å (Scheme 9). The intramolecular oxidative addition of the aryl C–H bond in **21** would form **22**, which would undergo reductive elimination to afford **24**.

Larock and co-workers described a novel alkyl to aryl type 1,4-Pd migration in the successful synthesis of fused polycycles (Scheme 10).[14] Interestingly, the formed arylpalladium intermediate can also undergo standard organopalladium chemistry.[14] When aryl halide **32** was reacted with ethyl acrylate **33**, the chromene derivative **36** was generated in 62 % yield. The key step is the 1,4-palladium migration in the transformation of **35a** to **35c** (Scheme 11).

Larock et al. also reported an aryl to allyl type 1,4-palladium mi-



Scheme 7. Switched regioselectivity in the 1,4-palladium migration. TBAC = tetrabutylammonium chloride, Piv = Pivaloyl.

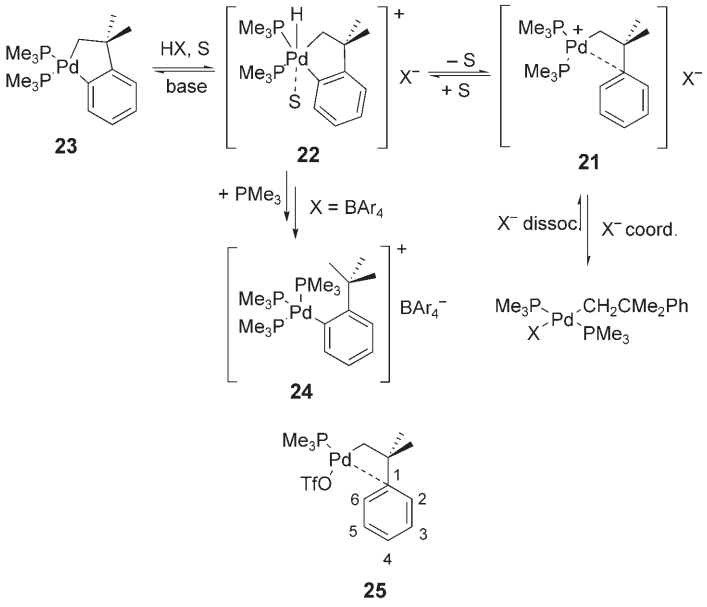
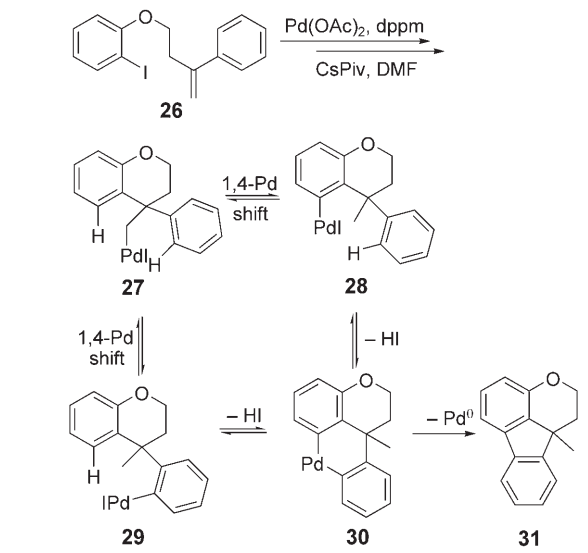
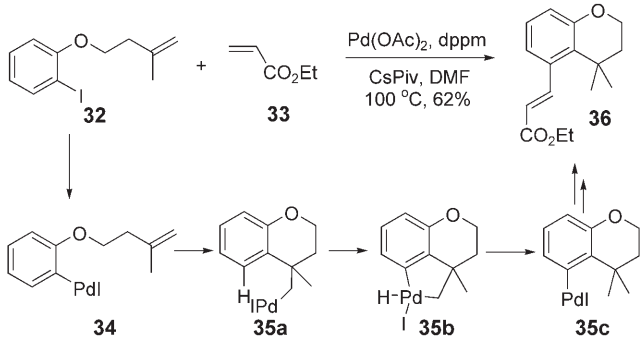


Scheme 9.



Scheme 10.

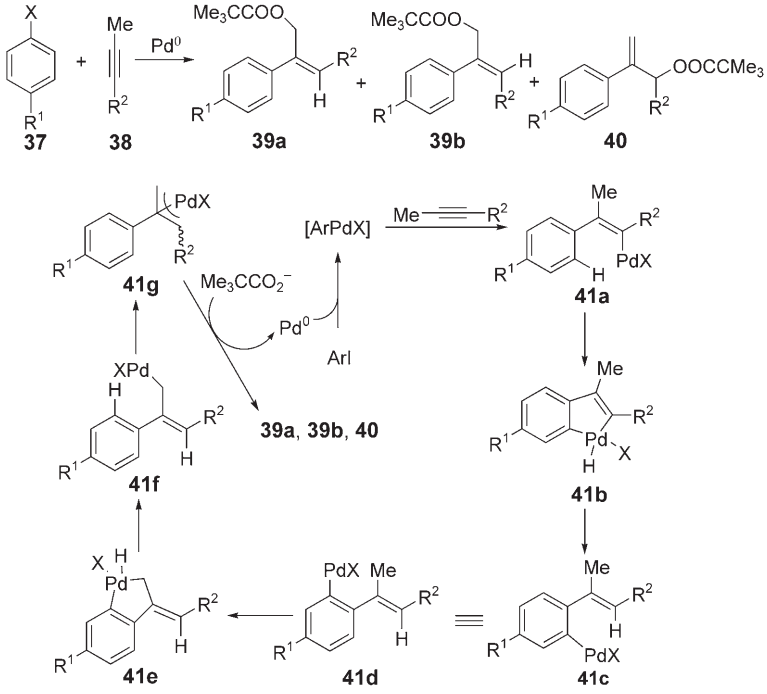


Scheme 11.

gration in the Pd^0-catalyzed coupling reaction of aryl halides with nonterminal alkynes.[15] The reaction proceeded by a double 1,4-palladium migration: 1) the isomerization of intermediate **41a** to the arylpalladium intermediate **41c**, and 2) the isomerization of intermediate **41d** to the allylic palladium intermediate **41f** via intermediate **41e** (Scheme 12).

Buchwald and co-workers reported that when the sterically hindered halide **42** was coupled with arylboronic acid **44**, a novel 1,4-palladium migration of arylpalladium intermediate **43a** was observed. The alkylpalladium intermediate **43c** formed would couple with **44** to afford product **46** (Scheme 13).[16]

Dyker proposed a similar mechanism for the 1,4-palladium migration of aryl intermediate **50a**. The reaction may proceed by the direct C–H activation of **50a** forming **50b**, which may undergo oxidative addition with **47** to afford intermediate **50c**. Subsequent reductive elimination would lead to the formation of **50d**, which would undergo HI elimination to afford **50e**.



Scheme 12.

Product **48** may be formed by reductive elimination of **50e**. The formation of compound **49** by the reductive elimination of **50b** was not observed (Scheme 14).[17]

Dyker also reported a similar 1,4-palladium migration of intermediate **54a**.[18] An aryl oxapalladacyclic intermediate **54b** was formed by direct C–H activation of the *ortho*-methoxy group of **54a**. Then **54b** may react with vinylbromide **52** to afford the palladium(IV) intermediate **54c**, which would form the palladium intermediate **54d**. Intramolecular carbopalladation and β-hydride elimination would form **53a**, which upon isomerization produces **53b** (Scheme 15).[18a]

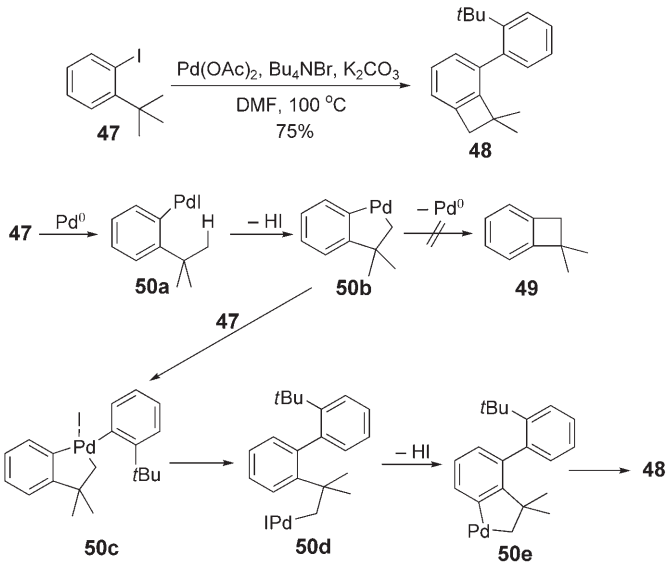

Scheme 14.

Conclusion and Outlook

In contrast to these successful experimental results, which may be explained by the 1,4-metal migration, there is currently no evidence for the exact transition state of these migrations.[19,20] The 1,4-migration of rhodium and palladium has been observed and applied in organic synthesis. The reaction may proceed by oxidative addition of a C–H bond or C–X bond followed by reductive elimination to furnish the 1,4-metal migration. Although the transition states of the migration have not been clearly known, these recent developments may open a new entry in the area of organometallic chemistry, providing powerful and efficient tools in transition-metal-catalyzed reactions.

Aerosols are of central importance for atmospheric chemistry and physics, the biosphere, climate, and public health. The airborne solid and liquid particles in the nanometer to micrometer size range influence the energy balance of the Earth, the hydrological cycle, atmospheric circulation, and the abundance of greenhouse and reactive trace gases. Moreover, they play important roles in the reproduction of biological organisms and can cause or enhance diseases. The primary parameters that determine the environmental and health effects of aerosol particles are their concentration, size, structure, and chemical composition. These parameters, however, are spatially and temporally highly variable. The quantification and identification of biological particles and carbonaceous components of fine particulate matter in the air (organic compounds and black or elemental carbon, respectively) represent demanding analytical challenges. This Review outlines the current state of knowledge, major open questions, and research perspectives on the properties and interactions of atmospheric aerosols and their effects on climate and human health.

1. Introduction

The effects of aerosols on the atmosphere, climate, and public health are among the central topics in current environmental research. Aerosol particles scatter and absorb solar and terrestrial radiation, they are involved in the formation of clouds and precipitation as cloud condensation and ice nuclei, and they affect the abundance and distribution of atmospheric trace gases by heterogeneous chemical reactions and other multiphase processes.[1–4] Moreover, airborne particles play an important role in the spreading of biological organisms, reproductive materials, and pathogens (pollen, bacteria, spores, viruses, etc.), and they can cause or enhance respiratory, cardiovascular, infectious, and allergic diseases.[1,5–7]

An aerosol is generally defined as a suspension of liquid or solid particles in a gas, with particle diameters in the range of 10^{-9}–10^{-4} m (lower limit: molecules and molecular clusters; upper limit: rapid sedimentation).[4,7] The most evident examples of aerosols in the atmosphere are clouds, which consist primarily of condensed water with particle diameters on the order of approximately 10 μm. In atmospheric science, however, the term aerosol traditionally refers to suspended particles that contain a large proportion of condensed matter other than water, whereas clouds are considered as separate phenomena.[8]

Atmospheric aerosol particles originate from a wide variety of natural and anthropogenic sources. Primary particles are directly emitted as liquids or solids from sources such as biomass burning, incomplete combustion of fossil fuels, volcanic eruptions, and wind-driven or traffic-related suspension of road, soil, and mineral dust, sea salt, and biological materials (plant fragments, microorganisms, pollen, etc.). Secondary particles, on the other hand, are formed by gas-to-particle conversion in the atmosphere (new particle formation by nucleation and condensation of gaseous precursors). As illustrated in Figure 1, airborne particles undergo various physical and chemical interactions and transformations (atmospheric aging), that is, changes of particle size, structure, and composition (coagulation, restructuring, gas uptake, chemical reaction). Particularly efficient particle aging occurs in clouds, which are formed by condensation of water vapor on preexisting aerosol particles (cloud condensation and ice nuclei, CCN and IN[+]). Most clouds reevaporate, and modified aerosol particles are again released from

the evaporating cloud droplets or ice crystals (cloud processing). If, however, the cloud particles form precipitation which reaches the Earth's surface, not only the condensation nuclei but also other aerosol particles are scavenged on the way to the surface and removed from the atmosphere. This process, termed "wet deposition", is actually the main sink of atmospheric aerosol particles. Particle deposition without precipitation of hydrometeors (airborne water particles)—that is, "dry deposition" by convective transport, diffusion, and adhesion to the Earth's surface—is less important on a global scale, but is highly relevant with respect to local air quality, health effects (inhalation and deposition in the human respiratory tract), and the soiling of buildings and cultural monuments. Depending on aerosol properties and meteorological conditions, the characteristic residence times (lifetimes) of aerosol particles in the atmosphere range from hours to weeks.[9,10]

The concentration, composition, and size distribution of atmospheric aerosol particles are temporally and spatially highly variable. In the lower atmosphere (troposphere) the total particle number and mass concentrations typically vary in the range of about 10^2–10^5 cm^{-3} and 1–100 $\mu g\,m^{-3}$, respectively.[9–12] In general, the predominant chemical components of air particulate matter (PM) are sulfate, nitrate, ammonium, sea salt, mineral dust, organic compounds, and black or elemental carbon, each of which typically contribute about 10–30 % of the overall mass load. At different locations, times, meteorological conditions, and particle size fractions, however, the relative abundance of different chemical components can vary by an order of magnitude or more.[1,4,9,13] In atmospheric research the term "fine air particulate matter" is usually restricted to particles with aerodynamic diameters ≤ 1 μm (PM1) or ≤ 2.5 μm (PM2.5). In air pollution control it sometimes also includes larger particles up to 10 μm (PM10).

Characteristic examples of particle number concentration, size distribution, and chemical composition of fine particulate matter in urban and high alpine air are illustrated in Figure 2. The displayed particle number size distributions (particle number concentration per logarithmic decade of particle diameter, $dN/d(\log d_p)$ plotted against particle diameter) were observed in the city of Munich (500 m above sea level; December 8–14, 2002) and at the Schneefernerhaus research station on Mount Zugspitze (2600 m above sea level; November 6, 2002) in Southern Germany. They correspond to total particle number concentrations of about 10^2 cm^{-3} in alpine air and 10^4 cm^{-3} in urban air, and to particle mass concentrations of about 1 $\mu g\,m^{-3}$ and 10 $\mu g\,m^{-3}$, respectively. The measurements were performed with a couple of complementary techniques, an electrical low-pressure impactor (ELPI, 10 nm–10 μm, flow rate 30 $L\,min^{-1}$, measurement interval 1 min) and a scanning mobility particle sizer (SMPS, 10–300 nm, flow rate 1 $L\,min^{-1}$, measurement interval 30 min).[14,15] The deviations at very low particle size can be attributed to wall losses by diffusion in the SMPS system. The dotted lines indicate characteristic particle size modes, which can be attributed to different sources, sinks, and aging processes of atmospheric particles: nucleation (Aitken), accumulation, and coarse modes.[4,7] In corresponding mass size distributions, which are obtained by multiplication with particle volume ($d_p^3\pi/6$) and density (typically around 2 $g\,cm^{-3}$), the nucleation mode is usually negligible whereas accommodation and coarse particle modes are of comparable magnitude. The composition pie charts are based on chemical analyses of PM2.5 filter samples from the same locations and literature data for urban and remote continental background air.[1,4,9,13,16–19]

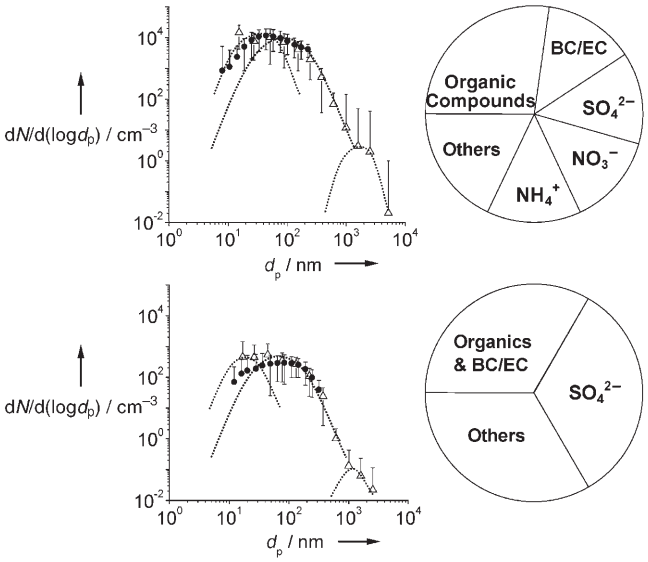

Figure 2. Characteristic examples of aerosol particle-size distribution and chemical composition in urban (top) and high alpine air (bottom). Graphs (left): number size distribution function $dN/d(\log d_p)$ (symbols and error bars: arithmetic mean values and standard deviations, △ ELPI, ● SMPS, ••••• characteristic particle size modes). Pie charts (right): typical mass proportions of main components.

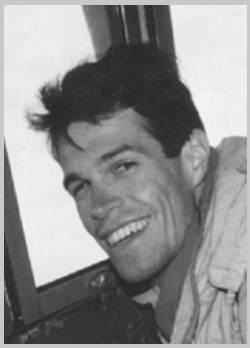
Figure 3 illustrates the interdependence of composition, composition-dependent properties, atmospheric interactions and transformation, climate and health effects, and aerosol sources. The resulting feedback loops are of central importance in the science and policy of environmental pollution and global change. Thus a comprehensive characterization (climatology) and mechanistic understanding of particle sources, properties, and transformation is required for the quantitative assessment, reliable prediction, and efficient control of



Ulrich Pöschl heads a research group at the MPI for Chemistry in Mainz (Biogeochemistry Dept., M. O. Andreae). He obtained his diploma and PhD at the TU Graz (1996) and then worked at MIT (M. J. Molina), at the MPI in Mainz (P. J. Crutzen), and at the TU Munich (R. Niessner). His research is focused on the properties and interactions of aerosols and their effects on the atmosphere, biosphere, climate, and public health. He initiated and is editor of the open-access journal Atmospheric Chemistry and Physics and is president of the Atmospheric Sciences Division of the European Geosciences Union.

natural and anthropogenic aerosol effects on climate and public health.

2. Composition and Analysis

A wide range of methods can be and have been applied for the physical and chemical analysis of aerosol particles and components.[1,20–22] Major analytical procedures and measurement techniques are outlined in Figure 4. In practice, the selection and combination of analytical methods depend on the sample type and target parameters (single particles or particle ensembles, suspended or deposited particles, physical properties or chemical composition, etc.) and requires a trade-off between sensitivity and selectivity, time and size resolution, and equipment and labor expenses.

The techniques most frequently applied for the physical characterization of atmospheric aerosol particles are: differential mobility analysis (DMA), inertial separation (impaction, time-of-flight), scanning and transmission electron microscopy (SEM, TEM), and light scattering (Mie) for particle size, structure, and density; β-ray attenuation, gravimetry, and oscillation of deposition substrates for particulate mass; spectrophotometry, photoacoustic spectroscopy, and nephelometry for absorption and scattering coefficients. Some advanced methods for the determination of physical and chemical aerosol properties involve multiple iterative steps of particle conditioning and sizing as indicated by the arrows in Figure 4. Examples are volatility and hygroscopicity tandem differential mobility analysis (V- and H-TDMA) or the online coupling of particle sizing, vaporization, and mass spectrometry with electron-impact (EI) or laser-desorption ionization (LDI). Detailed descriptions and explanations of these and related techniques can be found in recent monographs, reviews, and research articles.[1,20,22–28]

Accurate determination of the chemical composition of air particulate matter is a formidable analytical task. Minute sample amounts are usually composed of several main constituents and hundreds of minor and trace constituents. Moreover, the composition of the individual particles can be fairly uniform (internally mixed aerosols) or very different from the ensemble composition (externally mixed aerosols), depending on the particle sources and atmospheric aging processes involved (coagulation, gas–particle partitioning, chemical reactions). Especially in populated environments, air particulate matter can be pictured as the result of an "exploded pharmacy", comprising just about any non- or semivolatile chemical compound occurring in the biosphere, hydrosphere, and lithosphere, or released by human activity. Besides primary chemical components, which are directly emitted by natural and anthropogenic sources, air particulate matter mostly also contains secondary chemical components, which are formed by gas-phase reactions and subsequent gas-to-particle conversion or by chemical transformation of primary particle components in the atmosphere.

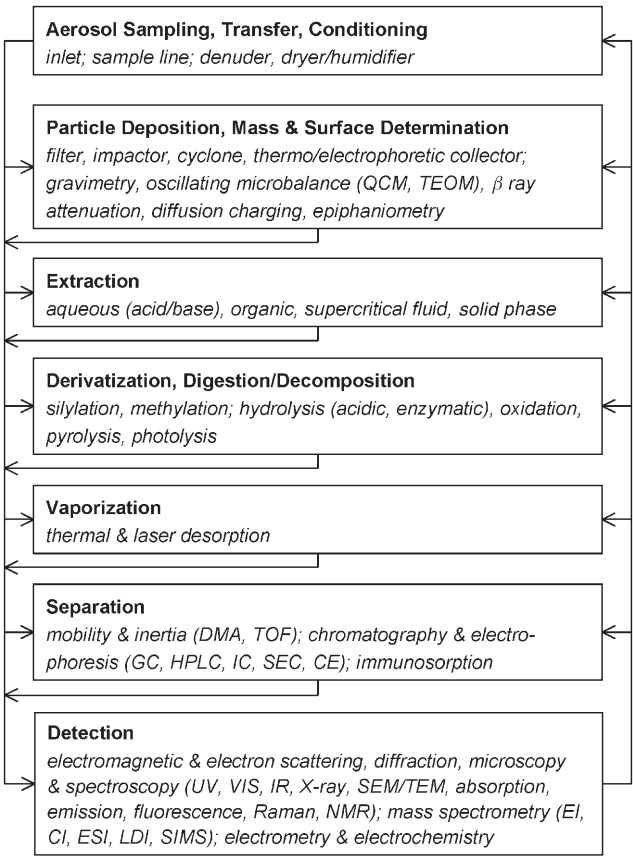

Figure 4. Major analytical procedures and techniques for the physical and chemical characterization of aerosol particles and components: arrows illustrate flexible combination and iterative application of individual steps and methods; acronyms are defined in the appendix.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

By definition, an aerosol is composed of particulate and gas-phase components, that is, the term aerosol component can refer to chemical compounds in condensed as well as in the gaseous state. In practice and in the remainder of this manuscript, however, the term aerosol component usually refers to semi- and nonvolatile particle components but not to volatile compounds residing almost exclusively in the gas phase.

Most traditional methods for the sampling and chemical analysis of air particulate matter are "offline" and involve the collection of the investigated particles on solid deposition substrates (membrane or fiber filters, inertial impaction plates, thermal or electrostatic precipitation plates) or in a liquid (wetted wall cyclone, impinger, or washing bottle) and intermediate steps of sample storage, transport, and preparation before chemical analysis.[1,20,22] These methods are prone to analytical artifacts caused by evaporation of particle components, adsorption or absorption of additional gas-phase components, and chemical reaction during sample collection, storage, transport, and preparation. The potential for measurement artifacts is particularly high for reactive and semivolatile organic aerosol components, and elaborate sampling techniques combining parallel or consecutive trains of denuders, filters, and adsorbent cartridges have been developed to minimize or at least quantify the effects outlined above.[1,19,20,29,30]

Besides the problem of sampling artifacts, offline techniques hardly allow the resolution of the high spatial and temporal variability of atmospheric aerosols. Over the past few years, however, substantial progress has been made in the development of aerosol mass spectrometers for real-time measurements of size-selected (single) particles. As the methods of vaporization, ionization, calibration, and data analysis are improved, these instruments promise reliable quantitative analyses, especially for chemical elements and inorganic species. Some of them also allow differentiation between surface and bulk composition, but the influence of matrix effects on vaporization and ionization efficiencies and thus on the interpretation of the measurement data still remains to be sorted out reliably. Advances in this rapidly moving field have been reported in a growing number of research and review articles.[20,25–28,31–40]

A particularly challenging application of aerosol mass spectrometry with high relevance for public health and security is the identification of biological particles and pathogens (bacteria, viruses, spores, etc.).[25,41,42] Alternative concepts for online monitoring of bioaerosols are based on aerodynamic sizing and fluorescence spectroscopy,[43] whereas most other applicable techniques are offline and highly labor intensive (cultivation, staining, fluorescence and electron microscopy, enzyme and immunoassays, DNA analysis, etc.).[18,44–52]

2.1. Carbonaceous Aerosol Components

Carbonaceous aerosol components (organic compounds and black or elemental carbon) account for a large fraction of air particulate matter, exhibit a wide range of molecular structures, and have a strong influence on the physicochemical, biological, climate- and health-related properties, and effects of atmospheric aerosols.[1,4,19,53–56]

Traditionally the total carbon (TC) content of air particulate matter is defined as the sum of all carbon contained in the particles, except in the form of inorganic carbonates. TC is usually determined by thermochemical oxidation and evolved gas analysis (CO_2 detection), and divided into an organic carbon (OC) fraction and a black carbon (BC) or elemental carbon (EC) fraction. Measurements of BC and EC are generally based on optical and thermochemical techniques, and OC is operationally defined as the difference between TC and BC or EC (TC = BC + OC or TC = EC + OC).[19] As illustrated in Figure 5, however, there is no real sharp

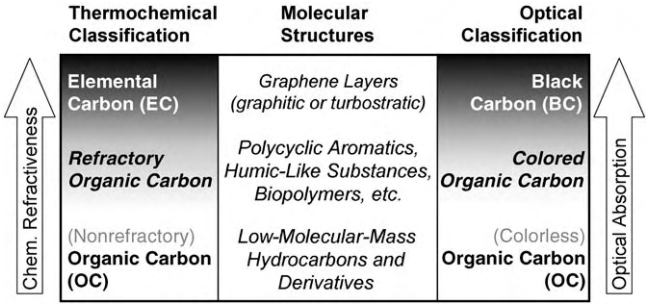

Figure 5. Optical and thermochemical classification and molecular structures of black carbon (BC), elemental carbon (EC), and organic carbon (OC = TC − BC or TC − EC).[57] Depending on the method of analysis, different amounts of carbon from refractory and colored organic compounds are included in OC and BC or EC.

boundary but a continuous decrease of thermochemical refractiveness and specific optical absorption going from graphite-like structures to nonrefractive and colorless organic compounds, respectively.[57] Both BC and EC consist of the carbon content of the graphite-like material usually contained in soot (technically defined as the black product of incomplete hydrocarbon combustion or pyrolysis) and other combustion aerosol particles, which can be pictured as more or less disordered stacks of graphene layers or large polycyclic aromatics.[58,59] Depending on the applied optical or thermochemical methods (absorption wavelength, temperature gradient, etc.), however, BC and EC measurements also include the carbon content of colored and refractory organic compounds, which can lead to substantially different results and strongly limits the comparability and suitability of BC, EC, and OC data for the determination of mass balances and physicochemical properties of air particulate matter.

Nevertheless, most information available on the abundance, properties, and effects of carbonaceous aerosol components so far is based on measurement data of TC, OC, and BC or EC.[19,56] These data are now increasingly complemented by measurements of water-soluble organic carbon (WSOC), its macromolecular fraction (MWSOC), and individual organic compounds as detailed in Section 2.2. Moreover, the combination of thermochemical oxidation with ^{14}C isotope analysis (radiocarbon determination in evolved

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

CO_2 by accelerator mass spectrometry) allows a differentiation between fossil-fuel combustion and other sources of carbonaceous aerosol components. Recent results confirm that the EC is dominated by fossil-fuel combustion and indicate highly variable anthropogenic and biogenic sources and proportions of OC.[60]

Characteristic mass concentrations and concentration ratios of fine air particulate matter (PM2.5) and carbonaceous fractions in urban, rural, and alpine air in central Europe are summarized in Table 1. The reported data have been obtained on an altitude transect through Southern Germany, from the city of Munich (500 m above sea level), via the meteorological observatory Hohenpeissenberg (1000 m above sea level), to the environmental research station Schneefernerhaus on Mount Zugspitze (2600 m above sea level) during 2001–2003. The sampling locations and measurement procedures have been described in detail elsewhere,[61,62] and the results are consistent with those of other studies performed at comparable locations.[9,11,13,16–19]

Table 1: Characteristic aerosol data for urban, rural, and high alpine air in central Europe.[a]

	Urban (Munich)	Rural (Hohenpeissenberg)	Alpine (Zugspitze)
PM2.5 [$\mu g\,m^{-3}$]	20 ± 10	10 ± 5	4 ± 2
TC in PM2.5 [%]	40 ± 20	30 ± 10	20 ± 10
EC in TC [%]	50 ± 20	30 ± 10	30 ± 10
OC in TC [%]	40 ± 20	70 ± 10	70 ± 10
WSOC in TC [%]	20 ± 10	40 ± 20	60 ± 20
MWSOC in WSOC [%]	30 ± 10	50 ± 20	40 ± 20

[a] Rounded arithmetic mean values ± standard deviation determined from about 30 filter samples collected at each location during 2001–2003.

On average, the total PM2.5 mass concentration decreases by about a factor of 2 from urban to rural and from rural to alpine air, whereas the TC mass fraction decreases from around 40% to 20%. The EC/TC ratios in PM2.5 are as high as 50% in the urban air samples taken close to a major traffic junction and on the order of approximately 30% in rural and high alpine air, demonstrating the strong impact of diesel soot and other fossil-fuel combustion or biomass-burning emissions on the atmospheric aerosol burden and composition. The water-soluble fraction of organic carbon (WSOC in OC), on the other hand, exhibits a pronounced increase from urban ($\approx$20%) to rural ($\approx$40%) and high alpine ($\approx$60%) samples of air particulate matter. This observation can be attributed to different aerosol sources (e.g. water-insoluble combustion particle components versus water-soluble biogenic and secondary organic particle components) but also to chemical aging and oxidative transformation of organic aerosol components, which generally increases the number of functional groups and thus the water solubility of organic molecules (Section 3).

Figure 6 illustrates a characteristic example of the size distribution of TC in air particulate matter sampled at the meteorological observatory Hohenpeissenberg. It exhibits an absolute maximum for particles with aerodynamic diameters on the order of approximately 300 nm, which is likely due to combustion and secondary organic aerosol (SOA) particles and another local maximum at 2.5 μm, which may be due to primary biological particles or soil dust.

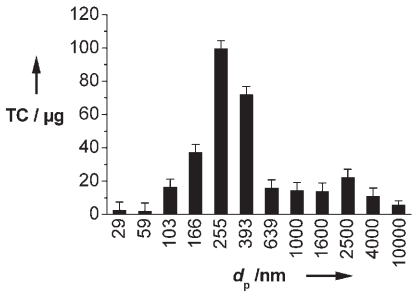

Figure 6. Total carbon content of a size-separated sample of rural air particulate matter plotted against the lower limits of the particle size classes (cut-off diameter of the impaction stages) of the applied electrical low-pressure impactor (ELPI, Hohenpeissenberg, May 27–June 6, 2002; error bars indicate TC measurement uncertainty).

Black or elemental carbon accounts for most of the light absorption by atmospheric aerosols and is therefore of crucial importance for the direct radiative effect of aerosols on climate.[63–65] Despite a long tradition of soot and aerosol research, however, there is still no universally accepted and applied operational definition of BC and EC. Several studies have compared the different optical and thermal methods applied by atmospheric research groups to measure BC and EC. Depending on techniques and measurement locations, fair agreement has been found in some cases, but mostly the results deviated considerably (up to 100% and more).[66–68]

Optical methods for the detection of BC are usually nondestructive and allow (near-)real-time operation, but on the other hand they are particularly prone to misinterpretation. They generally rely on the assumptions that BC is the dominant absorber and exhibits a uniform mass-specific absorption coefficient or cross-section. Although these assumptions may be justified under certain conditions, they are highly questionable in the context of detailed chemical characterization of aerosol particles ("How black is black carbon?").[57] Besides different types of graphite-like material, there are at least two classes of organic compounds that can contribute to the absorption of visible light by air particulate matter ("light-absorbing yellow or brown carbon"):[19] polycyclic aromatics and humic-like substances. Therefore, optically determined BC values must be considered as mass-equivalent values but not as absolute mass or concentration values. Moreover, most conventional optical methods such as aethalometry, integrating-sphere methods, and integrating-plate methods are based on the measurement of light extinction rather than absorption. As a consequence these methods require aerosol-composition-dependent calibrations or additional sample work-up processes to compensate for or minimize the influence of scattering aerosol components such as inorganic salts and acids on the measurement signal.[67,69,70] Alternatively, photoacoustic spectroscopy allows direct measurements of light absorption by airborne aerosol particles, and during the past years several photoacoustic spectrometers have been developed and applied for the measurement of aerosol absorption coefficients and BC equivalent concentrations.[71–73]

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Among the few methods available for the characterization of the molecular and crystalline structures of BC and EC (graphite-like carbon proportion and degree of order) are high-resolution electron microscopy, X-ray diffraction, and Raman spectroscopy.[59,74] These measurement techniques have revealed that the microstructure and spectroscopic properties of flame soot, diesel soot, and related carbonaceous materials depend on the processes and conditions of particle formation and aging. So far, however, these methods have been too labor-intensive for routine investigations of atmospheric aerosol samples, and their application in quantitative analyses remains to be proven.[59] Nevertheless, recently developed measurement systems show promise for the quantification of graphite-like carbon and soot in aerosol filter samples by Raman spectroscopy.[75,76]

2.2. Primary and Secondary Organic Aerosol Components

The total mass of organic air particulate matter (OPM), that is, the sum of organic aerosol (OA) components, is usually estimated by multiplication of OC with a factor of about 1.5–2, depending on the assumed average molecular composition and accounting for the contribution of elements other than carbon contained in organic substances (H, O, N, S, etc.).[19,77] The only way, however, to determine the overall mass, molecular composition, physicochemical properties, and potential toxicity of OPM accurately is the identification and quantification of all relevant chemical components. Also trace substances can be hazardous to human health, and potential interferences of refractive and colored organic components in the determination of BC or EC can be assessed only to the extent to which the actual chemical composition of OPM is known.[57,78]

Depending on their origin, OA components can be classified as primary or secondary. Primary organic aerosol (POA) components are directly emitted in the condensed phase (liquid or solid particles) or as semivolatile vapors, which are condensable under atmospheric conditions. The main sources of POA particles and components are natural and anthropogenic biomass burning (forest fires, slashing and burning, domestic heating), fossil-fuel combustion (domestic, industrial, traffic), and wind-driven or traffic-related suspension of soil and road dust, biological materials (plant and animal debris, microorganisms, pollen, spores, etc.), sea spray, and spray from other surface waters with dissolved organic compounds.

Secondary organic aerosol (SOA) components are formed by chemical reaction and gas-to-particle conversion of volatile organic compounds (VOCs) in the atmosphere, which may proceed through different pathways:

a) new particle formation: formation of semivolatile organic compounds (SVOCs) by gas-phase reactions and participation of the SVOCs in the nucleation and growth of new aerosol particles;
b) gas–particle partitioning: formation of SVOCs by gas-phase reactions and uptake (adsorption or absorption) by preexisting aerosol or cloud particles;
c) heterogeneous or multiphase reactions: formation of low-volatility or nonvolatile organic compounds (LVOCs, NVOCs) by chemical reaction of VOCs or SVOCs at the surface or in the bulk of aerosol or cloud particles.

The formation of new aerosol particles from the gas phase generally proceeds through the nucleation of nanometer-sized molecular clusters and subsequent growth by condensation of condensable vapor molecules. Experimental evidence from field measurements and model simulations suggests that new particle formation in the atmosphere is most likely dominated by ternary nucleation of H_2SO_4–H_2O–NH_3 and subsequent condensation of SVOCs.[79–81] Laboratory experiments and quantum chemical calculations indicate, however, that SVOCs might also play a role in the nucleation process (H_2SO_4–SVOC complex formation).[82] The actual importance of different mechanisms of particle nucleation and growth in the atmosphere has not yet been fully unraveled and quantified. In any case, the formation of new particles exhibits a strong and nonlinear dependence on atmospheric composition and meteorological conditions, may be influenced by ions and electric-charge effects, and competes with gas–particle partitioning and heterogeneous or multiphase reactions.[83] Among the principal parameters governing secondary particle formation are temperature, relative humidity, and the concentrations of organic and inorganic nucleating and condensing vapors, which depend on atmospheric transport as well as local sources and sinks such as photochemistry and preexisting aerosol or cloud particles.[54,56,79,80] The rate and equilibrium of SVOC uptake by aerosol particles depend on the SVOC-accommodation coefficients and on the particle surface area, bulk volume, and chemical composition (kinetics and thermodynamics of gas–particle partitioning).[84]

Most earlier studies of SOA formation were focused on pathways a and b. Several recent studies indicate, however, that heterogeneous and multiphase reactions may also play an important role and contribute substantially to the overall atmospheric burden of OPM.[19,85–88] The term "heterogeneous reaction" generally refers to reactions of gases at the particle surface, whereas the term "multiphase reaction" refers to reactions in the particle bulk involving species from the gas phase.

A variety of different reversible and irreversible mechanisms of acid-catalyzed condensation and radical-initiated oligo- or polymerization reactions involving organic and inorganic acids and photooxidants can lead to secondary formation of LVOCs and NVOCs of high molecular mass (SOA oligomers/polymers; Table 2). The actual atmospheric relevance and contributions of the different SOA formation pathways and involved chemical reaction mechanisms, however, still remain to be clarified.[19,56]

Depending on local sources, meteorological conditions, and atmospheric transport and thus on location, season, and time of day, the composition of OPM can be dominated by POA or by SOA components. Recent studies indicate high abundance of POA in tropical air masses owing to intense biomass burning, whereas SOA from biogenic and anthropogenic emissions of precursor VOCs seems to dominate in

Table 2: Prominent organic aerosol components.

Substance Classes	Proportions[a]	Sources
aliphatic hydrocarbons	10^{-2}	biomass, fossil-fuel combustion
aliphatic alcohols and carbonyls	10^{-2}	biomass, SOA/aging
levoglucosan	10^{-1}	biomass burning
fatty acids and other alkanoic acids	10^{-1}	biomass, SOA/aging
aliphatic dicarboxylic acids	10^{-1}	SOA/aging
aromatic (poly-)carboxylic acids	10^{-1}	SOA/aging, soil/dust
multifunctional aliphatic and aromatic compounds (OH, CO, COOH)	10^{-1}	SOA/aging, soil/dust
polycyclic aromatic hydrocarbons (PAHs)	10^{-3}	fossil-fuel combustion, biomass burning
nitro- and oxy-PAHs	10^{-3}	fossil-fuel combustion, biomass burning, SOA/aging
proteins and other amino compounds	10^{-1}	biomass
cellulose and other carbohydrates	10^{-2}	biomass
secondary organic oligomers/polymers and humic-like substances	10^{-1}	SOA/aging, soil/dust

[a] Characteristic magnitudes of the mass proportion in fine OPM.

mid-latitude air masses. On a global scale, the formation of SOA appears to be dominated by oxidation of biogenic VOCs (mostly by ozonolysis of terpenes)[89] and to amount to at least 50% of POA emissions.[56,90] In the atmosphere, POA and SOA components are mixed with each other, with BC/EC, and with inorganic aerosol components (externally and internally mixed aerosols).[91] Moreover, both POA and SOA components can be efficiently transformed upon interaction with reactive trace gases and solar radiation (chemical aging, Section 3).

Hundreds of organic compounds have been detected in air particulate matter. Even in the most comprehensive investigations, however, only 10–40% of the OPM content estimated from OC measurements have been unambiguously identified on a molecular level. Prominent organic substance classes, characteristic magnitudes of their proportion in fine OPM (approximate upper limit of mass fraction), and their main sources are summarized in Table 2.[1,4,19,29,56,92–96]

Several studies have shown that macromolecules such as cellulose and proteins (molecular mass $\geqslant 1$ kDa) and other compounds with relatively high molecular mass ($\geqslant 100$ Da) such as humic-like substances (HULIS) account for large proportions of OPM and WSOC.[19,62,97–101] Evidently, biopolymers and humic substances are emitted as POA components (soil and road dust, sea spray, biological particles), which may be modified by chemical aging and transformation in the atmosphere (e.g. formation of HULIS by oxidative degradation of biopolymers). On the other hand, organic compounds with high molecular mass can also originate from SOA formation by heterogeneous and multiphase reactions at the surface and in the bulk of atmospheric particles as outlined above (SOA oligomers/polymers).

For the identification and quantification of individual organic compounds, filter and impactor samples are usually extracted with appropriate solvents, and the extracts are analyzed by advanced instrumental or bioanalytical methods of separation and detection: gas and liquid chromatography; capillary electrophoresis; absorption and fluorescence spectroscopy; mass spectrometry; immunosorbent, enzyme, and dye assays; etc.[29,57,62,92,95,102–105] Alternatively, deposited or suspended particles can be partially or fully vaporized by thermal or laser desorption and directly introduced into a gas chromatograph or spectrometer.[1,20,25,26,32]

In recent studies nuclear magnetic resonance,[16] Fourier-transform infrared spectroscopy,[77] scanning transmission X-ray microscopy,[106] and aerosol mass spectrometry[107] were applied for efficient characterization and quantification of functional groups in OPM (alkyl, carbonyl, carboxyl, and hydroxy groups; C–C double bonds and aromatic rings). These methods give valuable insight into the overall chemical composition, oxidation state, and reactivity of OPM, but they provide only limited information about the actual identity of the individual compounds, which are present in the complex mixture. The molecular mass and structure of organic compounds, however, are crucial parameters for their physicochemical and biological properties and thus for their climate and health effects (volatility, solubility, hygroscopicity, CCN and IN activity, bioavailability, toxicity, allergenicity; see Sections 3 and 4).

3. Chemical Reactivity and Water Interactions

Chemical reactions proceed at the surface and in the bulk of solid and liquid aerosol particles and can influence atmospheric gas-phase chemistry as well as the properties of atmospheric particles and their effects on climate and human health.[1,4,84,108–116,117]

For example, aerosol chemistry leads to the formation of reactive halogen species, changes to reactive nitrogen compounds, and depletion of ozone—especially in the stratosphere, upper troposphere, and marine boundary layer.[118–128] On the other hand, chemical aging of aerosol particles generally changes their composition, decreases their reactivity, increases their hygroscopicity and cloud condensation activity, and can change their optical properties.[19,114,115,129–134]

Because of their high surface-to-volume ratio, fine aerosol particles can be very efficiently transformed upon interaction with solar radiation (photolysis) and reactive trace gases (oxidation, nitration, acid–base reactions, hydrolysis, condensation or radical-initiated oligomerization, etc.). For example, oxidation and nitration reactions lead to the formation or degradation of hazardous aerosol components,[6,61,78,101] they cause artifacts upon collection and analysis of air particulate matter,[1,19,30] and they play a major role in technical processes and devices for the control of combustion aerosol emissions.[74,135–137] Moreover, the interaction with water can lead to structural rearrangements of solid aerosol particles, to the

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

formation of highly concentrated aqueous solution droplets (hygroscopic growth), and to the formation of cloud droplets and ice crystals (Section 3.2).

Atmospheric aerosol transformations and gas–particle interactions generally involve multiple physicochemical processes such as mass transport, phase transition, and chemical reactions at the interface or in the bulk of gas, liquid and solid phases, as illustrated in Figure 7. These multiphase processes are pivotal for the aerosol and cloud interactions and feedback loops outlined in Figures 1 and 3, and thus for the climate and health effects of atmospheric aerosols detailed below (Section 4).

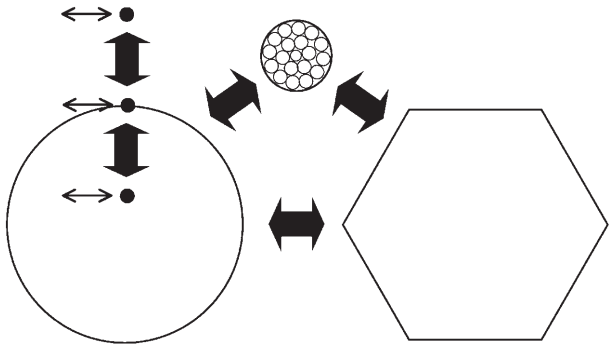

Figure 7. Schematic illustration of multiphase aerosol and cloud processes: mass transport and phase transitions of (semi-)volatile molecules between gas phase, aerosol particles, cloud droplets, and ice crystals (bold arrows); chemical reactions in the gas phase, at the particle surface, and in the particle bulk (thin arrows).

Efficient investigation, elucidation, and description of the interactions between multiple phases and chemical components of aerosols and clouds by laboratory experiments, field measurements, remote sensing, and model studies require consistent terminologies and universally applicable mathematical formalisms and physical parameters. However, the current understanding of the mechanisms and kinetics of mass transport, phase transitions, and chemical reactions in atmospheric aerosols and clouds is very limited. Besides a lack of experimental data, one of the limitations is that the formalisms applied in different studies have mostly been restricted to specific systems and boundary conditions: liquid water, ice, acid hydrates, soot, or mineral dust; fresh or aged surfaces; low or high reactant concentration levels, transient or (quasi-) steady-state conditions; limited selection of chemical species and reactions.[84] The different and sometimes inconsistent rate equations, parameters, and terminologies make it hard to compare, extrapolate, and integrate the results of different studies over the wide range of reaction conditions relevant for the atmosphere, laboratory experiments, technical processes, and emission control.

A comprehensive kinetic model framework for aerosol and cloud surface chemistry and gas–particle interactions was recently proposed by Pöschl, Rudich, and Ammann (PRA).[84] It allows the description of mass transport and chemical reactions at the gas–particle interface and the linking of surface processes with gas-phase and particle bulk processes in aerosol and cloud systems with unlimited numbers of chemical components and physicochemical processes. The key elements and essential aspects of the PRA framework are:

a) a simple and descriptive double-layer surface model (sorption layer and quasi-static layer);
b) straightforward and additive flux-based mass balance and rate equations;
c) clear separation of mass transport and chemical reactions;
d) well-defined rate parameters (uptake and accommodation coefficients, reaction- and transport-rate coefficients);
e) clear distinction between different elementary and multi-step transport processes (surface and bulk accommodation, etc.);
f) clear distinction between different elementary and multi-step heterogeneous and multiphase reactions (Langmuir–Hinshelwood and Eley–Rideal mechanisms, etc.);
g) mechanistic description of complex concentration and time dependence;
h) flexible inclusion or omission of chemical species and physicochemical processes;
i) flexible convolution or deconvolution of species and processes;
j) full compatibility with traditional resistor model formulations.

Figure 8 illustrates the PRA model compartments and elementary processes at the gas–particle interface. The individual steps of mass transport are indicated by bold

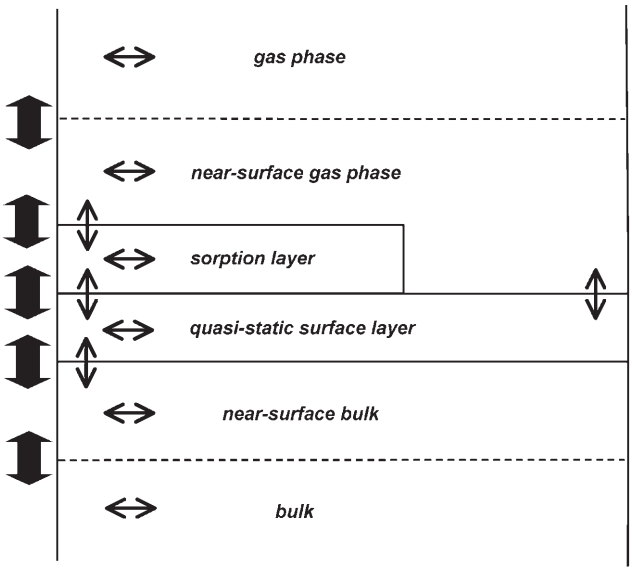

Figure 8. PRA framework model compartments, transport processes, and chemical reactions at the gas–particle interface (double-layer surface model): fluxes of diffusion in the gas phase and particle bulk, adsorption and desorption, transfer between sorption layer and quasi-static surface layer and between quasi-static surface layer and near-surface particle bulk indicated by vertical bold arrows on the left side; elementary chemical reactions between species in the same or in different model compartments indicated by horizontal and vertical thin arrows, respectively.[84]

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

arrows beside the model compartments: gas-phase diffusion; reversible adsorption; mass transfer between sorption layer, quasi-static surface layer, and near-surface particle bulk; diffusion in the particle bulk. The thin arrows inside the model compartments represent different types of chemical reactions: gas-phase reactions; gas-surface reactions; surface-layer reactions; surface-bulk reactions; particle-bulk reactions.[84] Exemplary practical applications and model calculations demonstrating the relevance of these aspects were presented in a companion paper.[138]

The PRA framework is meant to serve as a common basis for experimental and theoretical studies to investigate and describe atmospheric-aerosol and cloud-surface chemistry and gas–particle interactions. In particular, it should support the following research activities: planning and design of laboratory experiments for the elucidation and determination of elementary processes and rate parameters; the establishment, evaluation, and quality assurance of comprehensive and self-consistent collections of kinetic parameters; and the development of detailed master mechanisms for process models and the derivation of simplified but yet realistic parameterizations for atmospheric and climate models in analogy to atmospheric gas-phase chemistry.[89,139–143]

3.1. Chemical Transformation of Carbonaceous Aerosol Components

Organic aerosol components as well as the surface layers of BC or EC can react with atmospheric photooxidants (OH, O_3, NO_3, NO_2, etc.), acids (HNO_3, H_2SO_4, etc.), water, and UV radiation. The chemical aging of OA components essentially follows the generic reaction pathways outlined in Figure 9 and tends to increase the oxidation state and water solubility of OC. In analogy to atmospheric gas-phase photochemistry of VOCs (methane, isoprene, terpenes, etc.),[89,140,141] oxidation, nitration, hydrolysis, and photolysis transform hydrocarbons and derivatives with one or few functional groups into multifunctional hydrocarbon derivatives. The cleavage of organic molecules and release of SVOCs, VOCs, CO, or CO_2 can also lead to volatilization of OPM. On the other hand, oxidative modification and degradation of biopolymers may convert these into HULIS (analogous to the formation of humic substances in soil, surface water, and groundwater processes). Moreover, condensation reactions and radical-initiated oligo- or polymerization can decrease the volatility of OA components and promote the formation of SOA particulate matter (SOA oligomers or HULIS; Table 2; Section 2.2).

The actual reaction mechanisms and kinetics, however, have been elucidated and fully characterized only for a small number of model reaction systems and components. So far, most progress has been made in the kinetic investigation and modeling of chemical reactions in cloud droplets.[144,145] For the reasons outlined above, very few reliable and widely applicable kinetic parameters are available for organic reactions at the surface and in the bulk of liquid and solid aerosol particles.[19,27,84,114,146,147]

Several studies have shown that surface reactions of organic molecules and black or elemental carbon with gaseous photooxidants such as ozone or nitrogen dioxide tend to exhibit nonlinear concentration dependence and competitive coadsorption of different gas-phase components, which can be described by Langmuir–Hinshelwood reaction mechanisms and rate equations.[84,109,114,138,148]

An example of such reactions is the degradation of benzo[*a*]pyrene (BaP) on soot by ozone. BaP, a prominent air pollutant, is a polycyclic aromatic hydrocarbon (PAH) with the chemical formula $C_{20}H_{12}$ and consists of five six-membered aromatic rings. It is one of the most hazardous carcinogens and mutagens among the 16 priority PAH pollutants defined by the US Environmental Protection Agency (EPA). The main source of BaP in the atmosphere are combustion aerosols, and it resides to a large extent at the surface of soot particles.[30,78,115]

Figure 10 shows pseudo-first-order rate coefficients for the degradation of BaP on soot by ozone at gas-phase mole fractions or volume mixing ratios (VMR) up to 1 ppm under dry conditions and in the presence of water vapor (relative humidity (RH) 25 %, 296 K, 1 atm). These and complementary results of aerosol flow tube experiments and model calculations indicate reversible and competitive adsorption of O_3 and H_2O, followed by a slower, rate-limiting surface reaction between adsorbed O_3 and BaP on the soot surface. The kinetic parameters determined from the displayed non-

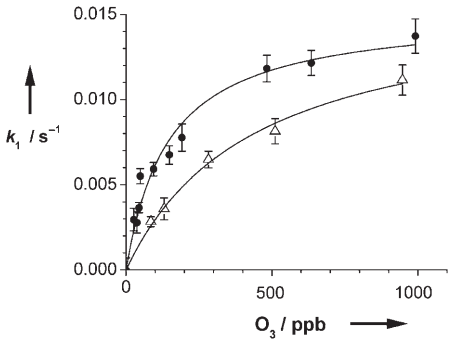

Figure 10. Pseudo-first-order rate coefficients (k_1) for the degradation of benzo[*a*]pyrene (BaP) on soot by ozone: measurement data from aerosol flow tube experiments under dry and humid conditions (symbols and error bars: arithmetic mean ± standard deviation; full circles: RH < 1 %; open triangles: RH ≈ 25 %) and nonlinear least-squares-fit lines based on Langmuir–Hinshelwood rate equation.[115]

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

linear least squares fits (maximum pseudo-first-order rate coefficients and effective Langmuir adsorption equilibrium constants) allow the prediction of the half-life (50% decay time) of BaP on the surface of soot particles in the atmosphere. At typical ambient ozone VMR of about 30 ppb it would be only around 5 min under dry conditions and 15 min at 25% RH.

Figure 11 illustrates the recovery ratio (RR) of BaP from fine air particulate matter (PM2.5) collected with a regular

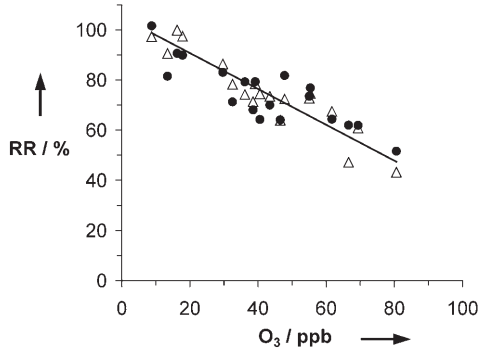

Figure 11. Recovery ratio for benzo[*a*]pyrene, BaP (full circles), and the sum of all particle-bound five- and six-ring US EPA priority PAH pollutants, PAH(5,6) (△), plotted against ambient ozone volume mixing ratio upon filter sampling of urban air particulate matter: measurement data points and linear least-squares fit.[30]

filter sampling system from urban air at ambient ozone VMRs of up to 80 ppb (Munich, 2001/2002). The plotted recovery ratios refer to filter samples collected in parallel with a system that removes ozone and other photooxidants from the sample air flow by means of an activated carbon diffusion denuder.[30] Thus deviations from unity represent the fraction of BaP degraded by reaction with ozone and other photooxidants from the sampled air during the sampling process, that is, the BaP loss by filter reaction sampling artifacts. The BaP recovery ratio is nearly identical to the recovery ratio of the sum of all particle-bound five- and six-ring US EPA priority PAH pollutants, PAH(5,6), and exhibits a negative linear correlation with ambient ozone. It decreases from 100% at low ozone levels to 50% at 80 ppb O_3, which is a characteristic concentration level for polluted urban air in summer. Similar correlations have been observed in experiments performed at different locations and with different filter sampling and denuder systems.[30]

With regard to chemical kinetics, the linear correlation between PAH recovery ratio and O_3 VMR can be attributed to the near-linear dependence of the PAH degradation rate coefficient on O_3 at low VRMs (VMR $\ll$ inverse of effective adsorption equilibrium constant; Figure 10).[84,109,115,138] Moreover, it indicates efficient protection and shielding of the PAH on deposited particles from further decay by coverage with subsequently collected particulate matter (build-up of "filter cake") on time scales similar to the half-life of PAH at the surface. Otherwise, the PAH recovery should be even lower and the ozone concentration dependence should be less pronounced.

In any case, the sampling artifacts observed by Schauer et al. (2003) and illustrated in Figure 11 imply that the real concentrations of particle-bound PAH in urban air are up to 100% higher than the measurement values obtained with simple filter-sampling systems (without activated carbon diffusion denuder or equivalent equipment) as applied for most atmospheric research and air-pollution-monitoring purposes.[30,78,115] Clearly also other OA components with similar or higher reactivity towards atmospheric oxidants (e.g. alkenes) are prone to similar or even stronger sampling artifacts, which have to be avoided or at least minimized and quantified for accurate and reliable determination of atmospheric aerosol composition and properties. These and other potential sampling and analytical artifacts caused by reactive transformation of fine air particulate matter have to be taken into account not only in atmospheric and climate research activities, but also in air-pollution control. In particular, the control and enforcement of emission limits and ambient threshold level values for OA components which pose a threat to human health (Section 4.2) require the development, careful characterization and validation, and correct application of robust analytical techniques and procedures.[78]

As far as atmospheric aerosol cycling and feedback loops are concerned (Figures 1 and 3), chemical aging and oxidative degradation of organic compounds present on the surface and in the bulk generally makes aerosol particles more hydrophilic or hygroscopic and enhances their ability to act as CCN. Besides their contribution to the water-soluble fraction of particulate matter, partially oxidized organics can act as surfactants and influence the hygroscopic growth, CCN, and IN activation of aerosol particles (Section 3.2).

The chemical reactivity of carbonaceous aerosol components also plays an important role in technical applications for the control of combustion aerosol emissions. For example, the lowering of emission limits for soot and related diesel exhaust particulate matter (DPM) necessitates the development and implementation of efficient exhaust-treatment technologies such as diesel particulate filters or particle traps with open deposition structures. These systems generally require regeneration by oxidation and gasification of the soot deposits in the filter or catalyst structures. Usually the regeneration is based on discontinuous oxidation by O_2 at high temperatures ($>500\,^{\circ}C$) or continuous oxidation by NO_2 at moderate exhaust temperatures (200–500 °C).[74,135–137,149] Efficient optimization of the design and operating conditions of such exhaust-treatment systems requires comprehensive kinetic characterization and mechanistic understanding of the chemical reactions and transport processes involved. Recent investigations have shown that the oxidation and gasification of diesel soot by NO_2 at elevated concentrations and temperatures (up to 800 ppm NO_2 and 500 °C) follow a similar Langmuir–Hinshelwood reaction mechanism as the oxidation of BaP on soot by O_3 at ambient concentrations and temperature (up to 1 ppm O_3 and 30 °C).[115,148,149]

3.2. Restructuring, Phase Transitions, Hygroscopic Growth, and CCN/IN Activation of Aerosol Particles upon Interaction with Water Vapor

When water vapor molecules interact with aerosol particles, they can be adsorbed to the surface of the particles or absorbed into the bulk of the particles. For particles consisting of water-soluble material, the uptake of water vapor can lead to aqueous solution droplet formation and a substantial increase in the particle diameter (hygroscopic growth) even at low relative humidities (RH < 100 %; atmospheric gas phase water partial pressure < equilibrium vapor pressure of pure liquid water).[8]

At water vapor supersaturation (RH > 100 %) aerosol particles can act as nuclei for the formation of liquid cloud droplets (cloud condensation nuclei, CCN). For the formation of water droplets from a homogenous gas phase devoid of aerosol particles supersaturations of up to several hundred percent would be required (thermodynamic barrier for the homogenous nucleation of a new phase). In the atmosphere, however, water vapor supersaturations with respect to liquid water generally remain below 10 % and mostly even below 1 %, because aerosol particles induce heterogeneous nucleation, condensation, and cloud formation. At low temperatures or high altitudes clouds consist of mixtures of liquid water droplets and ice crystals, or entirely of ice crystals. The formation of ice crystals is also induced by preexisting aerosol particles, so-called ice nuclei (IN), as detailed below. Ice nucleation in clouds usually requires temperatures well below 0 °C, which can lead to high water vapor supersaturations with respect to ice.[8,150–155]

The minimum supersaturation at which aerosol particles can be effectively activated as CCN or IN, respectively, is called critical supersaturation. It is determined by the physical structure and chemical composition of the particles and generally decreases with increasing particle size. For insoluble CCN the critical supersaturation depends on the wettability of the surface (contact angle of liquid water), and for partially or fully soluble CCN it depends on the mass fraction, hygroscopicity, and surfactant activity of the water-soluble particulate matter.[8,53,55,156,157]

The nucleation of ice crystals on atmospheric aerosol particles can proceed through different pathways or modes. In the deposition mode, water vapor is adsorbed and immediately converted into ice on the surface of the IN (deposition or sorption nuclei). In the condensation freezing mode the aerosol particles act first as CCN and induce the formation of supercooled aqueous droplets, which freeze later on (condensation freezing nuclei). In the immersion mode the IN are incorporated into preexisting aqueous droplets and induce ice formation upon cooling (immersion nuclei). In the contact mode, freezing of a supercooled droplet is initiated upon contact with the surface of the IN (contact nuclei). Obviously, the IN activity of aerosol particles depends primarily on their surface composition and structure, but condensation and immersion freezing can also be governed by water-soluble bulk material.[8,154,158–164]

Most water-soluble aerosol components are hygroscopic and absorb water to form aqueous solutions at RH < 100 %. The phase transition of dry particle material into a saturated aqueous solution is called deliquescence and occurs when a substance-specific RH threshold value (deliquescence relative humidity, DRH) is exceeded. The reverse transition and its RH threshold value are called efflorescence and efflorescence relative humidity (ERH), respectively. The hygroscopic growth and CCN activation of aqueous solution droplets can be described by the so-called Köhler theory, which combines Raoult's law or alternative formulations for the activity of water in aqueous solutions and the Kelvin equation for the dependence of vapor pressure on the curvature and surface tension of a liquid droplet.[8,24,53,55,156,165–169]

Figure 12a shows a typical example of the hygroscopic growth of water-soluble inorganic salts contained in air particulate matter: the hygroscopic growth curve (humidogram) of pure NaCl aerosol particles with dry particle diameters of 100 nm measured in a hygroscopicity tandem differential mobility analyzer (H-TDMA) experiment at relative humidities of up to 95 %. Upon hydration (increase of RH) the crystalline NaCl particles undergo a deliquescence transition at DRH ≈ 75 %. The water uptake and dependence of the aqueous solution droplet diameter on RH agree very well with Köhler theory calculations, which are based on a semiempirical ion interaction parameterization of water activity and account for the effects of particle-shape transformation (cubic crystals and spherical droplets, mobility and mass equivalent diameters).[24] The hysteresis branch measured upon dehydration (decrease of RH) is due to the existence of solution droplets in a metastable state of NaCl supersaturation (ERH < RH < DRH). The efflorescence transition, that is, the formation of salt crystals and evaporation of the liquid water, occurs at ERH ≈ 40 %.

Figure 12b displays the hygroscopic growth curve of aerosol particles composed of pure bovine serum albumin (BSA) as a model for globular proteins and similar organic macromolecules. The hygroscopic growth is much less pronounced than for inorganic salts but still significant, with deliquescence and efflorescence transitions at DRH ≈ ERH ≈ 40 % (conversion of dry protein particles into saturated aqueous solution or gel-like droplets, v.v.) and no significant deviations between hydration and dehydration (no hysteresis effect). The dependence of the deliquesced particle diameter on RH is in good agreement with Köhler theory calculations based on a simple osmotic pressure parameterization of water activity, which has been derived under the assumption that the dissolved protein macromolecules behave like inert solid spheres.[24]

Figure 12c shows the hygroscopic growth curve of internally mixed NaCl–BSA particles (mass ratio 1:1) with dry particle diameters of approximately 100 nm. The mixed aerosol particles have been generated in full analogy to the pure NaCl and pure BSA particles (nebulization of an aqueous solution). Upon hydration, however, the particles exhibit a significant decrease of the measured (mobility equivalent) diameter as the relative humidity approaches the deliquescence threshold (DRH ≈ 75 %). The observed minimum diameter is about 10 % smaller than the initial diameter, indicating high initial porosity of the particles (envelope void

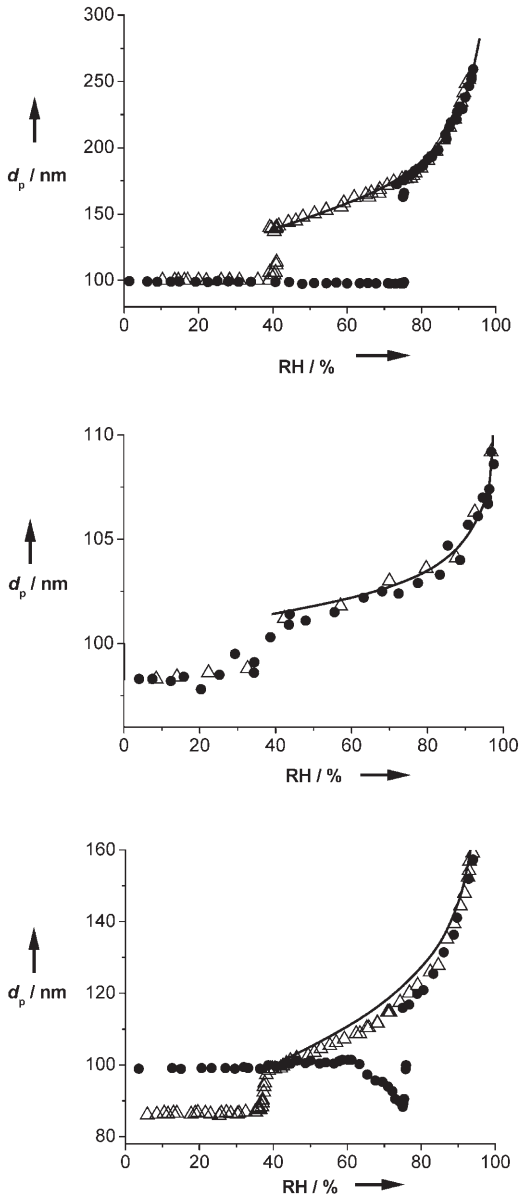

Figure 12. Hygroscopic growth curves for a) pure NaCl salt particles, b) pure BSA protein particles, and c) internally mixed BSA–NaCl protein–salt particles: data points measured upon hydration (●) and dehydration (△) in H-TDMA aerosol experiments; solid lines represent Köhler theory calculations based on NaCl ion interaction and BSA osmotic pressure parameterizations for water activity.[24]

fraction ≈30%) and strong restructuring upon humidification. Upon dehydration the efflorescence threshold is lower than for pure NaCl (ERH ≈37% vs. 40%), indicating that the protein macromolecules inhibit the formation of salt crystals and enhance the stability of supersaturated salt solution droplets. The particle diameters observed after efflorescence essentially equal the minimum diameter observed prior to deliquescence. The hygroscopic growth of the deliquesced particles (aqueous solution droplets) is in fair agreement with Köhler theory calculations based on the observed minimum diameter rather than the initial diameter and on the assumption of simple solute additivity (linear combination of NaCl ion interaction and BSA osmotic pressure parameterizations of water activity).[24] These and complementary measurement and modeling results can be explained by the formation of porous agglomerates due to ion–protein interactions and electric charge effects on the one hand, and by compaction of the agglomerate structure due to capillary condensation and surface tension effects on the other.

Depending on their origin and conditioning, aerosol particles containing inorganic salts and organic (macro-) molecules can have complex and highly porous microstructures, which are influenced by electric charge effects and interactions with water vapor. Proteins and other surfactants tend to be enriched at the particle surface and form an envelope that can inhibit the access of water vapor to the particle core and lead to kinetic limitations of hygroscopic growth, phase transitions, and CCN and IN activation. Formation and effects of organic surfactant films on sea salt particles have recently been discussed by O'Dowd et al.[170] These and other effects of (nonlinear) interactions between organic and inorganic aerosol components have to be elucidated further and considered for consistent analysis of measurement data from laboratory experiments and field measurements and for reliable modeling of atmospheric aerosol processes (Figures 1 and 3).

Structural rearrangements, hygroscopic growth, phase transitions, and CCN and IN activation of aerosol particles interacting with water vapor are not only important for the formation and properties of clouds and precipitation (number density and size of cloud droplets and ice particles; temporal and spatial distribution and intensity of precipitation). They influence also the chemical reactivity and aging of atmospheric particles (accessibility of particle components to reactive trace gases and radiation), their optical properties (absorption and scattering cross-sections), and their health effects upon inhalation into the human respiratory tract (deposition efficiency and bioavailability). Therefore, the water interactions of particles with complex chemical composition are widely and intensely studied in current aerosol, atmospheric, and climate research. So far, however, their mechanistic and quantitative understanding is still rather limited, especially with regard to carbonaceous components.[3,8,19,55,56,154,169,171–176]

4. Climate and Health Effects

Anthropogenic emissions are major sources of atmospheric aerosols. In particular, the emissions of particles and precursor gases from biomass burning and fossil-fuel combustion have massively increased since preindustrial times and account for a major fraction of fine air particulate matter in polluted urban environments as well as in the global atmosphere (carbonaceous components, sulfates, etc.).[1,2,4,9,177–183] Numerous studies have shown that both natural and anthropogenic aerosols have a strong impact on climate and human health. Due to the limited knowledge of aerosol sources, composition, properties, and processes outlined above, however, the actual effects of aerosols on climate and health are still far from being fully understood and

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

quantified. Some of the most important aspects and recent developments will be addressed in the following sections.

4.1. Direct and Indirect Aerosol Effects on Climate

Aerosol effects on climate are generally classified as direct or indirect with respect to radiative forcing of the climate system. Radiative forcings are changes in the energy fluxes of solar radiation (maximum intensity in the spectral range of visible light) and terrestrial radiation (maximum intensity in the infrared spectral range) in the atmosphere, induced by anthropogenic or natural changes in atmospheric composition, Earth surface properties, or solar activity. Negative forcings such as the scattering and reflection of solar radiation by aerosols and clouds tend to cool the Earth's surface, whereas positive forcings such as the absorption of terrestrial radiation by greenhouse gases and clouds tend to warm it (greenhouse effect).[2] Figure 13 illustrates the distinction between direct and indirect aerosol effects and some major feedback loops in the climate system. Direct effects result from the scattering and absorption of radiation by aerosol particles, whereas indirect effects result from their CCN and IN activity (influence on clouds and precipitation), or from their chemical and biological activity (influence on aerosol and trace gas emissions and transformation).

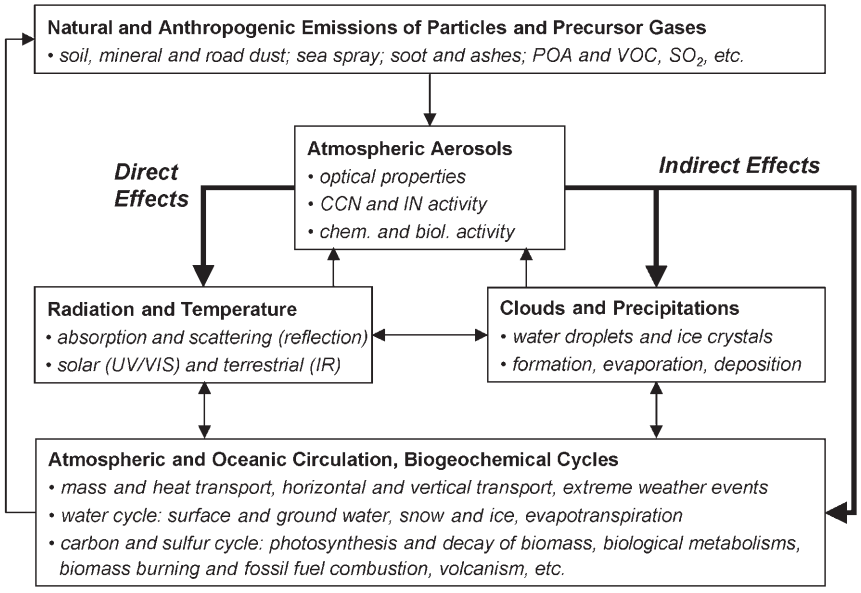

Figure 13. Direct and indirect aerosol effects and major feedback loops in the climate system.

The optical properties relevant for the direct effects (scattering and absorption coefficient or extinction cross-section and single scattering albedo, etc.) as well as the CCN, IN, chemical and biological activities relevant for indirect effects are determined by aerosol particle size, structure, and chemical composition. Thus they are strongly influenced by the atmospheric processes outlined above (coagulation, chemical transformation, water interactions).

The climate feedback loops illustrated in Figure 13 involve the interaction of atmospheric aerosols with solar and terrestrial radiation, clouds and precipitation, general circulation and hydrological cycle, and with natural and anthropogenic aerosol and trace gas sources on global and regional scales. On microscopic and molecular scales, each of the interactions outlined in Figure 13 comprises a multitude of physicochemical processes that depend on atmospheric composition and meteorological conditions and are largely not quantitatively characterized. Thus the actual climate system responses and feedback to natural or anthropogenic perturbations such as industrial and traffic-related greenhouse gas and aerosol emissions, volcanic eruptions, etc. are highly uncertain. In many cases, even the sign or direction of the feedback effect is unknown, that is, it is not clear whether a perturbation will be reinforced (positive feedback) or dampened (negative feedback).

For example, enhanced deposition and uptake of aerosol particles and trace gases on vegetation, soil, or surface water can lead to an increase or decrease in biogenic POA and SOA precursor emissions, depending on the fertilizing, toxic, or reproductive biological activity of the aerosol and trace gas components. The increase in atmospheric CO_2 and global warming is expected to enhance photosynthesis, biogenic emissions of VOC, and the formation of SOA particles, which may act as CCN, increase cloudiness, and lead to a cooling effect (negative feedback).[54] On the other hand, the negative feedback mechanism could be counteracted by temperature-related biological stress and eutrophication effects which may lead to a decrease in photosynthesis, biomass production, VOC emissions, SOA formation, and cloudiness, and further enhance global warming (positive feedback). In any case, feedback effects of this kind and the influence of SOA formation on CCN and IN concentration are determined not only by VOC emissions but also by the photochemical transformation of VOCs into SVOCs and LVOCs/NVOCs, respectively, and their contribution to the growth of preexisting particles or to the formation of new particles. As outlined above, these processes strongly depend on atmospheric composition and meteorological conditions.

An increase in atmospheric CCN and IN concentrations in the atmosphere can have different effects on the formation and properties of liquid water, ice, and mixed-phase clouds and precipitation. Among them are the so-called cloud albedo or Twomey effect (more-numerous and smaller cloud particles reflect more solar radiation), cloud lifetime effect (smaller cloud particles decrease the precipitation efficiency), thermodynamic effect (smaller cloud droplets delay the onset of freezing), and glaciation effect (more IN increase the precipitation efficiency). These and related effects of aerosol, cloud, precipitation, and radiation interactions influence the regional and global radiative energy balance and hydrological cycle as well as the temperature, dynamics, and general

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

circulation of the atmosphere and oceans.[2,184–187] Moreover, they can promote extreme weather events (intense rain, hail, and thunderstorms).[188] A recent review article by Lohmann and Feichter (2005)[3] provides an overview of indirect aerosol effects, their estimated magnitude, and climatic implications.

Overall, the current aerosol radiative forcing relative to that in preindustrial times is estimated to be around -1 to $-2\ \mathrm{W\,m^{-2}}$, as opposed to a greenhouse gas forcing of about $+2.4\ \mathrm{W\,m^{-2}}$.[2,3,187] Owing to the limited understanding of the underlying physicochemical processes, however, it is still unclear if clouds provide a positive or negative feedback to an increase in atmospheric carbon dioxide and other greenhouse gases. The uncertainties of aerosol, cloud, and precipitation interactions and feedback effects are among the main reasons for the high uncertainty of climate sensitivities and for the projected global mean surface temperature increase over the next century (1–6 °C or more).[2,3,56]

4.2. Aerosol Health Effects and Air Quality

Numerous epidemiological studies show that fine air particulate matter and traffic-related air pollution are correlated with severe health effects, including enhanced mortality, cardiovascular, respiratory, and allergic diseases.[5,189–192] Moreover, toxicological investigations in vivo and in vitro have demonstrated substantial pulmonary toxicity of model and real environmental aerosol particles, but the biochemical mechanisms and molecular processes that cause the toxicological effects such as oxidative stress and inflammatory response have not yet been resolved. Among the parameters and components potentially relevant for aerosol health effects are the specific surface, transition metals, and organic compounds.[5,193–195] Some of the possible mechanisms by which air particulate matter and other pollutants may affect human health are summarized in Table 3.

Table 3: Possible mechanisms by which aerosol particles and other air pollutants may cause adverse health effects.[5]

pulmonary inflammation induced by PM or O_3
free radical and oxidative stress generated by transition metals or organic compounds (e.g. PAHs)
covalent modification of key intracellular proteins (e.g. enzymes)
inflammation and innate immune effects induced by biological compounds such as endotoxins and glucans
stimulation of nocioreceptor and autonomic nervous system activity regulating heart-rate variability and airway reactivity
adjuvant effects in the immune system (e.g. DPM and transition metals enhancing responses to common environmental allergens)
procoagulant activity by ultrafine particle accessing the systemic circulation
suppression of normal defense mechanisms (e.g. suppression of alveolar macrophage functions)

Ultrafine particles ($d_p < 100$ nm) are suspected to be particularly hazardous to human health, because they are sufficiently small to penetrate the membranes of the respiratory tract and enter the blood circulation or be transported along olfactory nerves into the brain.[196–198] Neither for ultrafine nor for larger aerosol particles, however, it is clear which physical and chemical properties actually determine their adverse health effects (particle size, structure, number, mass concentration, solubility, chemical composition, and individual components, etc.).

Particularly little is known about the relations between allergic diseases and air quality. Nevertheless, traffic-related air pollution with high concentration levels of fine air particulate matter, nitrogen oxides, and ozone is one of the prime suspects besides non-natural nutrition and excessive hygiene practices, which may be responsible for the strong increase of allergies in industrialized countries over the past decades.[5,199–201] The most prominent group of airborne allergens are protein molecules, which account for up to 5% of urban air particulate matter. They are not only contained in coarse biological particles such as pollen grains (diameter $>10\ \mu$m) but also in the fine fraction of air particulate matter, which can be explained by fine fragments of pollen, microorganisms, or plant debris and by mixing of proteins dissolved in rain water with fine soil and road dust particles.[98,101,202]

A molecular rationale for the promotion of allergies by traffic-related air pollution has been proposed by Franze et al. (2003; 2005),[101,102] who found that proteins including birch pollen allergen Bet v1 are efficiently nitrated by polluted urban air. The nitration reaction converts the natural aromatic amino acid tyrosine into nitrotyrosine and proceeds particularly fast at elevated concentrations of NO_2 and O_3 (so-called photosmog or summer smog conditions), most likely involving nitrate radicals (NO_3) as reactive intermediates. From biomedical and immunological research it is known that protein nitration occurs upon inflammation of biological tissue, where it may serve to mark foreign proteins and guide the immune system. Moreover, conjugates of proteins and peptides with nitroaromatic compounds were found to evade immune tolerance and boost immune responses, and post-translational modifications generally appear to enhance the allergenicity of proteins.[101] Thus the inhalation of aerosols containing nitrated proteins or nitrating reagents is likely to trigger immune reactions, promote the genesis of allergies, and enhance the intensity of allergic diseases and airway inflammations. This hypothesis is supported by first results of ongoing biochemical experiments with nitrated proteins.[203]

By means of newly developed enzyme immunoassays, nitrated proteins have been detected in urban road and window dust as well as in fine air particulate matter, exhibiting degrees of nitration of up to 0.1%. Upon exposure of birch pollen extract to heavily polluted air at a major urban traffic junction and to synthetic gas mixtures containing NO_2 and O_3 at concentration levels characteristic for intense summer smog, the degrees of nitration increased up to 20%. The experimental results indicate that Bet v1 is more easily nitrated than other proteins, which might be an explanation why it is a particularly strong allergen.[101] If the ongoing

biochemical experiments and further studies confirm that protein nitration by nitrogen oxides and ozone is indeed an important link between air pollution, airway inflammations, and allergies, the spread and enhancement of these diseases could be counteracted by an improvement in the air quality and a decrease in emission limits for nitrogen oxides and other traffic-related air pollutants. Moreover, it might be possible to develop pharmaceuticals against the adverse health effects of nitrated proteins.

Efficient control of air quality and related health effects requires a comprehensive understanding of the identity, sources, atmospheric interactions, and sinks of hazardous pollutants. Without this understanding, the introduction of new laws, regulations, and technical devices for environmental protection runs the risk of being ineffective or even of causing more harm than good through unwanted side effects.

For example, epidemiological evidence for adverse health effects of fine and ultrafine particles has led to a lowering of present and future emission limits for soot and related DPM.[137,198,204–206] For compliance with these emission limits, different particle filter or trapping and exhaust-treatment technologies have been developed and are currently being introduced into diesel vehicles. Depending on the design of the particle filter or trap and catalytic converter systems, their operation can lead to substantial excess NO_2 emissions.[148] If, however, elevated NO_2 concentrations and the nitration of proteins indeed promote allergies, such systems could reduce respiratory and cardiovascular diseases related to soot particles but at the same time enhance allergic diseases. Moreover, elevated NO_2 concentrations and incomplete oxidation of soot in exhaust filter systems could also increase the emissions of volatile or semivolatile hazardous aerosol components such as nitrated PAH derivatives.[61,78] Thus an effective mitigation of the adverse health effects of diesel engine exhaust may require the introduction of advanced catalytic converter systems that minimize the emissions of both particulate and gaseous pollutants (soot, PAH and PAH derivatives, nitrogen oxides, etc.) rather than simple particle filters.

In any case, comprehensive investigations, understanding, and control of aerosol health effects need to consider both the particulate and gaseous components of aerosols as well as their chemical reactivity and aging.[78]

5. Summary and Outlook

Scientific investigations and reports of atmospheric aerosols date back as far as the 18th century, and since then it has become increasingly clear that aerosol particles are of major importance for atmospheric chemistry and physics, the hydrological cycle, climate, and human health.[207] Motivated by global change and adverse health effects of traffic-related air pollution, aerosol research has been intensified increasingly over the past couple of decades.

These activities have led to a fairly comprehensive conceptual understanding of atmospheric aerosol sources, composition, properties, interactions, and effects on climate. The parameters required for a quantitative description of the underlying physicochemical processes, however, are generally still uncertain by factors of two or more, which implies uncertainties of an order of magnitude for most effects involving multiple competitive or sequential processes.

In some cases (e.g. particle nucleation and reactive gas uptake), even the basic parameters are uncertain by orders of magnitude. Consequently, model calculations of atmospheric aerosol effects on future climate have to be regarded as sensitivity studies with more or less reliable qualitative and semiquantitative results and implications, rather than reliable quantitative predictions. In particular, interactions and feedback responses between aerosols and clouds, the hydrological cycle, and the biosphere are difficult to quantify with the currently available information. Regardless of the rapid increase in numerical simulation capacities, this situation can hardly change before the basic physicochemical processes and properties of atmospheric aerosol particles have been elucidated to an extent comparable to the present state of knowledge of atmospheric gas-phase chemistry (universally applicable and validated master mechanisms, rate coefficients, structure–reactivity relationships, etc.).

Outstanding open questions and research aims for the elucidation of aerosol effects relevant to the science and policy of global change have been outlined in several recent monographs, reviews, and research articles.[2,3,54,79,80,84] Among these are the quantification, mechanistic elucidation, and kinetic characterization of the following processes: formation of new particles and secondary organic aerosols; emission of primary organic aerosol components and black or elemental carbon; aging and deposition of aerosol particles; activation of cloud condensation and ice nuclei. As far as chemical transformations, heterogeneous and multiphase reactions, and gas–particle interactions of aerosols and clouds are concerned, one of the most important prerequisites for efficient further investigation and scientific progress is the establishment of a common basis of consistent, unambiguous, and universally applicable terminologies, model formalisms, and kinetic and thermodynamic parameters.

With regard to atmospheric aerosol effects on human health not only the quantitative but also the qualitative and conceptual understanding is very limited. Epidemiological and toxicological studies indicate strong adverse health effects of fine and ultrafine aerosol particles as well as gaseous air pollutants, but the causative relations and mechanisms are hardly known.[5,192] Their elucidation, however, is required for the development of efficient strategies for air-quality control and medical treatment of related diseases that will enable the minimization of adverse aerosol health effects at minimum social and economic costs.

Particularly little is known about the relationship between allergic diseases and air pollution and the interactions between natural aeroallergens and traffic-related pollutants. Several studies have shown synergistic and adjuvant effects of diesel particulate matter, O_3, NO_2, and allergenic pollen proteins, but the specific chemical reactions and molecular processes responsible for these effects have not yet been clearly identified. Recent investigations indicate that the nitration of allergenic proteins by polluted air may play an important role. Nitrated proteins are known to stimulate

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

immune responses, and they could promote the genesis of allergies, enhance allergic reactions, and influence inflammatory processes, which is confirmed by the results of ongoing biochemical investigations.[101,203]

For efficient elucidation and abatement of adverse aerosol health effects, the knowledge of atmospheric and biomedical aerosol research should be integrated to formulate plausible hypotheses that specify potentially hazardous chemical substances and reactions on a molecular level. These hypotheses have to be tested in appropriate biochemical and medical studies to identify the most relevant species and mechanisms of interaction and to establish the corresponding dose-response relationships. Ultimately, the identification and characterization of hazardous aerosol components and their sources and sinks (emission, transformation, deposition) should allow the optimization of air-pollution control and medical treatment of aerosol effects on human health.

6. Appendix

List of Abbreviations, Acronyms, and Symbols

BaP	benzo[*a*]pyrene
BC	black carbon
BSA	bovine serum albumin
CCN	cloud condensation nucleus
CE	capillary electrophoresis
CI	chemical ionization
d_p	particle diameter
$dN/d(\log d_p)$	particle number size distribution function
DMA	differential mobility analyzer
DPM	diesel exhaust particulate matter
DRH	deliquescence relative humidity
EC	elemental carbon
EI	electron impact ionization
ELPI	electrical low-pressure impactor
EPA	Environmental Protection Agency
ERH	efflorescence relative humidity
ESI	electrospray ionization
HC	hydrocarbon
H-TDMA	hygroscopicity tandem differential mobility analyzer
HULIS	humic-like substances
IC	ion chromatography
IN	ice nucleus
k_1	(pseudo-)first-order rate coefficient
LDI	laser desorption ionization
LVOC	low-volatility organic compound
MWSOC	macromolecular water-soluble organic carbon
NVOC	nonvolatile organic compound
OA	organic aerosol
OC	organic carbon
OPM	organic particulate matter
PAH	polycyclic aromatic hydrocarbon
PAH(5,6)	polycyclic aromatic hydrocarbons consisting of five or six aromatic rings
PM	particulate matter
PM2.5 (1 or 10)	particulate matter of particles with aerodynamic diameters ≤ 2.5 μm (1 or 10 μm)
POA	primary organic aerosol
PRA	Pöschl, Rudich, Ammann (2005)
QCM	quartz crystal microbalance
RH	relative humidity
RR	recovery ratio
SEC	size exclusion chromatography
SEM	scanning electron microscopy
SIMS	secondary ion mass spectrometry
SMPS	scanning mobility particle sizer
SOA	secondary organic aerosol
SPE	solid-phase extraction
SVOC	semivolatile organic compound
TC	total carbon
TEM	transmission electron microscopy
TEOM	tapered element oscillating microbalance
VMR	volume mixing ratio
VOC	volatile organic compound
WSOC	water-soluble organic carbon

I thank my colleagues at the Technical University of Munich, Institute of Hydrochemistry, and my research partners for personal and scientific collaboration, discussions, and good times—in particular M. Ammann, S. Bhowmik, A. Duschl, T. Fehrenbach, T. Franze, C. Huber, L. Krämer, R. Leube, T. Letzel, S. Mahler, A. Messerer, U. McKeon, E. Mikhailov, R. Niessner, D. Rothe, Y. Rudich, A. Sadezky, C. Schauer, M. Weller, and A. Zerrath. The German Federal Ministry of Education and Research (BMBF, AFO2000 young scientist group CARBAERO), the Bavarian Research Foundation (BFS, project PM-Kat), and the Bavarian State Ministry for Regional Development and Environmental Affairs (BayStMLU, project SCAVEX) are gratefully acknowledged for financial support. Moreover, I thank my mentors, partners, and supporting organizations of earlier and other scientific activities for encouragement, insight, and cheerful experiences, in particular P. Crutzen, J. Jayne, D. Worsnop, M. Molina, T. Koop, K. Carslaw, R. Sander, B. Sturges, A. Richter, the Austrian Science Foundation (FWF), the Max Planck Society (MPG), and the European Geosciences Union (EGU). J. Huth, B. Graham, and G. Helas are gratefully acknowledged for electron micrographs. Last but not least I thank my family and personal friends for sharing my life, interests, and pleasures.

Full geometric optimizations have been applied to metal boron carbide (MB_2C_2) phases. The respective positions of the B and C atoms (the so-called "coloring problem") have been definitely solved for trivalent metals by using DFT calculations. For further details, see the Communication by J.-Y. Saillard, J.-F. Halet, X. Rocquefelte, and co-workers on the following pages.

Structural Preference versus Metal within the MB_2C_2 (M = Mg, Sc, Ca, Y, Ln) Phases: The Coloring Problem Revisited by DFT Calculations**

Xavier Rocquefelte, Salah Eddine Boulfelfel, Mouna Ben Yahia, Josef Bauer, Jean-Yves Saillard,* and Jean-François Halet**

The chemistry of boron-containing compounds is particularly rich and offers an extremely broad variety of topologies.[1] In the case of the MB_2C_2 phases (M = alkaline-earth or rare-earth metal), for instance, the recent discovery of various potentially interesting properties has revived the interest of the scientific community. For example, CeB_2C_2 is known to exhibit antiferromagnetic ordering at low temperature,[2] and antiferroquadrupolar transitions have been measured for DyB_2C_2[3] and HoB_2C_2.[4] Akimitsu et al. reported that CaB_2C_2 is a high-temperature ferromagnet,[5] although it was shown later by Mori and Otani that this ferromagnetism is due to the presence of an iron impurity.[6,7] Superconductivity at low temperature has also been reported for YB_2C_2, LuB_2C_2, and doped MgB_2C_2.[8] Although the properties of this family of compounds have been widely investigated, some of their structures are still debated, especially with respect to the position of B atoms versus C atoms (the so-called "coloring problem"[9]). Indeed, when the metal is a heavy element, it is not easy to differentiate between these two atoms, either by using X-ray or neutron-diffraction techniques.[10] Indeed, all the known MB_2C_2 structures consist of the stacking of two-dimensional (2D) B/C layers, with metal atoms in between. Four different 2D B/C topologies have been reported so far: fused six-membered rings in the 6^3 net of MgB_2C_2[11] (Figure 1a), fused five- and seven-membered rings in the 57^2 net of ScB_2C_2[12] (Figure 1b) and two different colorings of fused four- and eight-membered rings in the 48^2 net (Figure 1c,d). LaB_2C_2 (Figure 1c) has been proposed by Bauer and Bars[13] to adopt coloring I (BBCC), thus contradicting an earlier study of Smith et al. who suggested coloring II (BCBC; Figure 1d). More recently, neutron-diffraction structures of various lanthanide derivatives were solved assuming the model of Smith et al.[14] On the other hand, Albert et al.[10,15,16] have shown that CaB_2C_2 also adopts coloring II, but with a different stacking of the 2D layers (Figure 1d). Thus, among the 48^2 nets three B/C orderings with two different in-plane colorings have been proposed so far, thereby leading to controversial reports concerning these structures.[17,18]

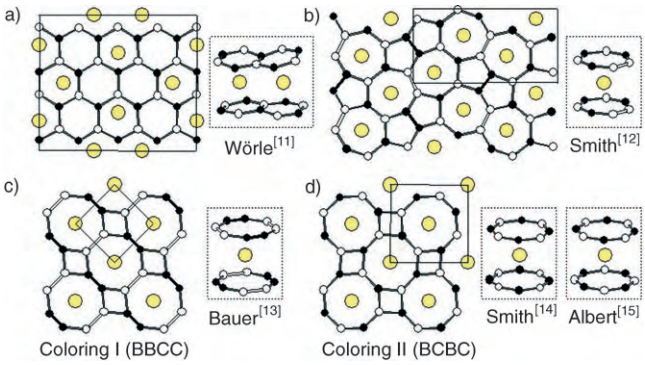

Figure 1. Schematic representation of the MB_2C_2 structure types. a) 6^3 net of MgB_2C_2 (*Cmca*) and b) 57^2 net of ScB_2C_2 (*Pbam*). Three models corresponding to the 48^2 net: c) Bauer model ($P4_2/mmc$) and d) Smith ($P4/mbm$) and Albert ($I4/mcm$) models. The insets show the corresponding stackings.

About 20 years ago, a very elegant theoretical tight-binding investigation of the 2D $B_2C_2^{2-}$ network by Burdett et al.[19] led to the conclusion that coloring II is more stable than coloring I for this formal dianionic charge. Indeed, coloring II allows a band gap at the Fermi level to open, whereas coloring I does not. This prediction was experimentally confirmed later for CaB_2C_2 (formally $[Ca^{2+}, B_2C_2^{2-}]$) by Albert et al.[10,15,16] However, the question of the coloring remains open with one more electron per formula unit (f.u.), that is, when the metal is a trivalent metal. Indeed, the presence of an extra electron occupying antibonding states is expected to destabilize coloring II.

We report herein the first quantitative theoretical analysis of the structural preference of MB_2C_2 (M = Mg, Ca, Sc, Y, La, Ce, and Lu) phases, including the answer to the coloring question for trivalent metals. Full geometric optimizations of the five structure types shown in Figure 1 were carried out for each metal at the DFT level.[20] The cohesive energies estimated from the optimized structures are given in Table 1. The stability of MgB_2C_2 and ScB_2C_2 in their experimentally characterized structures is well reproduced. This result supports our theoretical approach to estimating the relative stability of the models based on the 48^2 nets. Regardless of the metal, coloring II is significantly more stable than coloring I. CaB_2C_2 is found to be more stable in its experimental structure.[15] In the case of the trivalent metals (Y, Ce, and La), coloring II is also found to be the most stable B/C arrangement, with little energy difference between the Albert and Smith models, as observed with Ca. The Smith and

La^{3+}	1.22	437	592	625	0	6

[a] Bauer model. [b] Albert model. [c] Smith model.

Albert models differ only by long-distance interactions between the B/C planes and so are expected to be very close in energy. This result suggests the possibility of defaults in the stacking of the 2D B/C nets, which should render the differentiation between B and C by diffraction techniques even more difficult. On the other hand, the ScB_2C_2 structure type is found to be preferred when M = Lu,[25] thus indicating that the B/C topology is related to the ionic size of the metal. Although the structure of LuB_2C_2 in the 48^2 net was recently reported,[18e] it appears from the present calculations that it should also be possible to stabilize this metal in the 57^2 network as well.

The agreement between the most stable computed structure and the corresponding experimentally characterized structure is excellent. Interatomic distances, for example, differ by less than 0.3, 1.3, and 1.5 % in the cases of M = Mg,[11] Ca,[15] and Ce,[18c] respectively. For M = Sc, they differ by less than 1.2 %, except for the B–B distance, which is 5.8 % longer than in the rather inaccurate X-ray structure.[12]

The density of states of CaB_2C_2 is shown in Figure 2 with both coloring I and II (Smith) structure types. As initially qualitatively predicted by Burdett et al.[19] and confirmed recently by Albert et al.,[15] coloring II allows the opening of a energy band gap at the Fermi level. This gap disappears in the case of the less stable coloring I. A rather similar situation occurs for LaB_2C_2, but with one more electron per f.u. In the case of coloring II, this electron occupies the conduction band above the pseudo band gap. Our results (Table 1) show clearly that this extra electron does not destabilize coloring II with respect to coloring I. From this point of view, it is noteworthy that identical B–C distances (short: 1.525 Å; long: 1.603 Å) are computed for CaB_2C_2 and YB_2C_2 in the Smith model despite of their different electron counts.

None of the trivalent metals led to the opening of an energy gap at the Fermi level in any structure type. Band gaps were found only with divalent metals and for the MgB_2C_2 structure type (1.31[26] and 0.41 eV for Mg and Ca, respectively) and the Albert CaB_2C_2 structure type (1.13 and 0.58 eV[26] for Mg and Ca, respectively).

Magishi et al.[28] recently deduced the components of the electric-field gradient (EFG) tensor of CeB_2C_2 from ^{11}B NMR spectroscopic experiments to elucidate its magnetic properties. Such measurements combined with calculated EFG data can also be used to characterize the local environment of the probed atoms. This approach is exemplified by the ^{11}B and ^{139}La EFGs computed for different MB_2C_2 phases using the WIEN2k code[24] (Table 2). A very good agreement between the experimental data of CeB_2C_2 and the calculated data for coloring II is obtained. However, this agreement is not the case for coloring I. Note that, the EFGs are nearly the same in the Albert and Smith models. Such a result is expected because of the similar local environments of the boron atoms in these two models. For the other metals, calculations show that the EFG values, as in the case of Ce, allows differentiation between the two different colorings I and II but not between the Smith and Bauer models.

These calculations provide a clear theoretical answer to the coloring problem in these MB_2C_2 phases. As this problem is experimentally difficult to solve unambiguously by using diffraction techniques (particularly with heavy metals), we suggested EFG measurements from NMR spectroscopy instead. Indeed, our calculations show that EFGs are very sensitive to atomic local environment, and therefore should easily discriminate between colorings I and II.[31]

A Phthalocyanine Clathrate of Cubic Symmetry Containing Interconnected Solvent-Filled Voids of Nanometer Dimensions**

Neil B. McKeown, Saad Makhseed, Kadhum J. Msayib, Li-Ling Ooi, Madeleine Helliwell, and John E. Warren*

Dedicated to Professor Clifford C. Leznoff

Since the middle of the last century, the crystal structures of a vast number of organic inclusion compounds (namely, clathrates) have been determined.[1] In most cases, only one or two guest molecules reside at well-defined sites within the unit cell of the crystal; however, for a number of structures, such as those derived from urea,[2] thiourea,[2] or tris(*o*-phenylenedioxy)cyclotriphosphazene,[3] extended channels are formed within which the guest molecules, usually the solvent of recrystallization, are contained. Recent extensive research that involves rigid and extended organic components linked through hydrogen-bonding interactions[4] or by coordination to metal ions (namely, metal–organic frameworks (MOFs))[5] has resulted in structures in which solvent-filled channels occupy over 70% of the total volume of the crystal. Furthermore, there are now numerous examples of MOFs for which the removal of the included solvent does not result in loss of crystalline order, but instead gives microporous materials that resemble zeolites.[5,6] However, to offer practical advantages over conventional microporous materials, such as the zeolites and activated carbons, it is desirable that these organic-based microporous materials possess in-built functionalities for selective heterogeneous catalysis, adsorption, and separations. In this context, numerous crystalline porphyrin-based clathrates[7,8] and nanoporous coordination network polymers[8,9] have been reported which may ultimately allow the exploitation of the well-established homogeneous catalytic activity of metal-containing porphyrins in well-defined heterogeneous systems.[10]

Following on from the preparation of amorphous phthalocyanine-based microporous polymers,[11] we have become interested in the possibility of using the highly functional phthalocyanine macrocycle as a building block for the assembly of crystalline nanoporous materials. In analogy to the porphyrins, suitable transition-metal ions held in the central cavity of a phthalocyanine unit can induce catalytic behavior. Unlike porphyrins, for which large-scale production is unfeasible, the structurally related phthalocyanines are made routinely and cheaply by industry for use as stable blue colorants, photoconductors in xerography, and IR dyes, as well as for application to homogeneous oxidation catalysis in the removal of sulfurous compounds from crude petrochemicals (the Merox process).[12] Unfortunately, the extended planar shape of the phthalocyanine unit results in a strong tendency to form densely packed cofacial aggregates (e.g., stacked crystals,[13] columnar liquid crystals,[14] etc.), and this behavior must be prohibited to engineer open nanoporous structures that allow access to such active metal centers.

Our general strategy to avoid cofacial self-association involves the use of substituents that can introduce severe steric crowding adjacent to the phthalocyanine core.[15] Molecular modeling helped to identify that 2,6-diisophenoxy groups placed on the peripheral positions of the phthalocyanine ring would be perfectly suited for this purpose. Hence, a novel zinc 2,3,9,10,16,17,23,24-octa(2′,6′-diisopropylphenoxy)phthalocyanine (**1**) compound was prepared by using a simple two-step high-yielding synthesis from the commercially available 4,5-dichlorophthalonitrile and 2,6-diisopropylphenol via 4,5-di(2′,6′-disopropylphenoxy)phthalonitrile (**2**) by following a literature procedure (Scheme 1).[16]

Slow recrystallization by the diffusion of acetone into a solution of **1** in $CHCl_3$ gives large crystals (up to 1 mm^3) with a cubic morphology, for which a surprising molecular packing arrangement was revealed by single-crystal X-ray diffraction (XRD) analysis (Figure 1). The crystal structure is cubic and belongs to the exceptionally rare space group $Pn\bar{3}n$,[17] with 12 phthalocyanine molecules in the unit cell ($a = 3.77$ nm). The phthalocyanine core of **1** is a shallow cone-shape with the central Zn^{2+} ion and the oxygen atom of its axial ligand protruding from the molecular plane (probably from a water ligand as the acetone used for the recrystallization was not anhydrous). As predicted, the 2,6-diisopropylphenoxy substituents lie out of the plane of the macrocycle and thereby prohibit the formation of columnar stacks. Instead, the molecules pack to form cubes, with an equivalent of two per unit cell and a molecule of phthalocyanine comprises each of the six faces. The macrocycles are arranged so that their Zn^{2+} ion and its axial ligand point towards the center of the cube. Based upon the distance between the protruding Zn^{2+} ions on opposite sides of the cube, the minimum diameter of the cube is 2.33 nm, which gives a cavity volume of at least 8 nm^3, even if the width, calculated from the sum of the van der Waals radii, of the phthalocyanine unit (0.33 nm) is taken into account. In addition to the axial water ligand attached to the Zn^{2+} center of **1**, there are a further

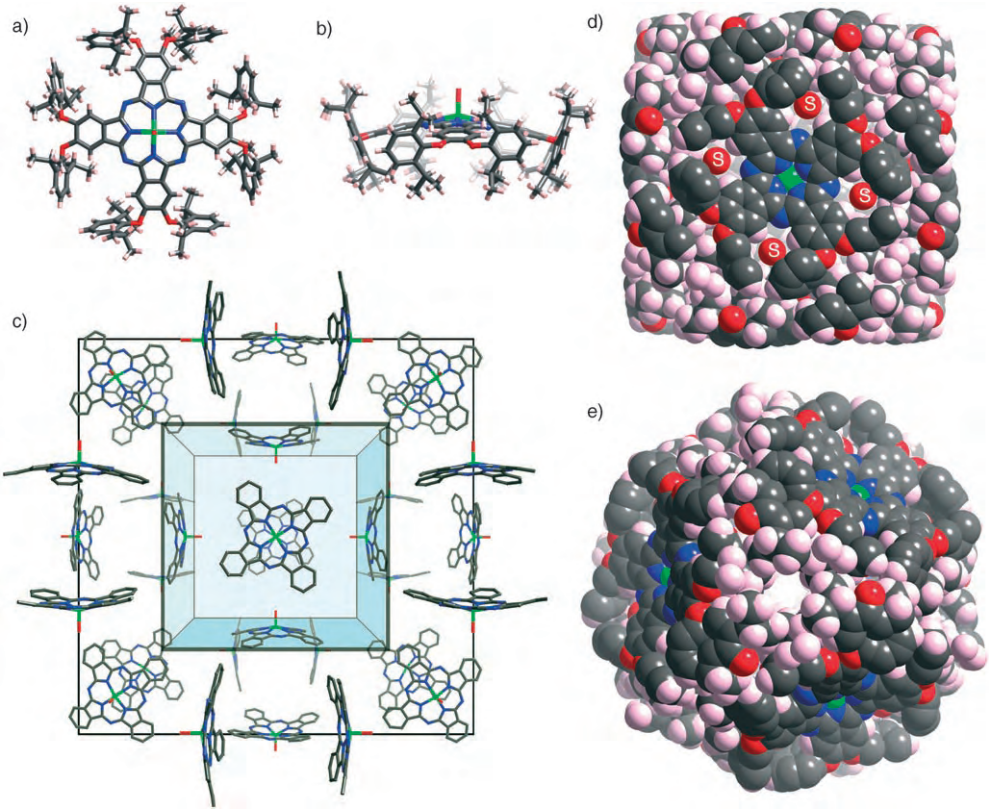

Figure 1. The molecular and crystal structure of **1**. a) Face-on and b) edge-on molecular views of **1** which show the orthogonal and square conformation of the eight peripheral 2′,6′-diisopropylphenoxy substituents relative to the phthalocyanine core, which prohibits cofacial molecular self-association. c) The cubic packing arrangement of **1** shown with the phenoxy substituents removed for clarity. The outer cube represents the unit cell, with dimensions of 3.77 nm, which contains 12 molecules of **1**. The inner cube represents one of the two voids of volume 8 nm^3 found in each unit cell. In this view, the second nanovoid is distributed at each corner of the unit cell in 8×1 nm^3 portions. d) Side-view of a space-filling representation of the central cubic subunit showing the location of the oxygen atoms (S) of the solvent (water or methanol) hydrogen bonded to the *meso* nitrogen atoms of the phthalocyanine unit. e) Corner view of the cubic subunit showing one of the 0.4-nm cylindrical openings, which interconnect the 8-nm^3 voids contained within the cubes.

24 water molecules per unit cell that appear to be associated through hydrogen-bonding interactions to the *meso* nitrogen atoms of the phthalocyanine ring (Figure 1d). No further solvent could be located within the crystal structure.

The calculated density of the crystal of **1** is only 0.75 $g\,mL^{-3}$, which when compared to that of the densely packed crystal of its phthalonitrile precursor **2** (approximately 1.15 $g\,mL^{-3}$), suggests a total void volume of 35% (namely, approximately 18 nm^3 per unit cell). Calculations with the PLATON program[18] indicate a solvent-accessible void volume of 20.5 nm^3 per unit cell (namely, 38.2% of the total volume). Thermal analysis of a freshly recrystallized sample of **1** with thermogravimetric analysis (TGA) shows a mass loss of 25.5% on heating up to 120 °C, for which the water of solvation observed in the crystal structure can account for only 1.6%. Assuming that the additional loss of mass observed by TGA is because of included, but disordered, solvent of recrystallization, it can be estimated that there is a molar ratio of **1**/acetone/H_2O of approximately 1:11:3. ^1H NMR spectroscopic analysis based on the peak integration for the clathrate dissolved in $CDCl_3$ provides a very similar molar ratio. This result is consistent with filling both of the two 8-nm^3 void spaces within the unit cell with approximately 132 molecules of acetone at a density of 0.77 $g\,mL^{-3}$ (density of acetone at 20 °C = 0.79 $g\,mL^{-3}$).

The crystal is not stable on removal from the crystallization solvent because of solvent loss, as indicated by XRD analysis, although the macroscopic appearance of the crystals is unchanged. Over half of the included solvent is lost within one hour (12% by mass remains, as determined by TGA) when placed in a dry stream of nitrogen at room temperature. A close inspection of the structure of each cubic subunit reveals that the void space appears almost fully

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

enclosed by the six phthalocyanine units and their 2,6-diisopropylphenoxy substituents (Figure 1d). The largest apertures are situated at each corner of the cube, and these provide narrow cylindrical channels (approximately 0.4 nm in diameter) that connect the voids (Figure 1e). Preliminary solvent-exchange experiments were performed by submergence of the clathrate crystals in [D_6]acetone, followed by NMR spectroscopic analysis of the crystals dissolved in $CDCl_3$. These experiments show that nearly all of the included acetone (approximately 98%) is exchanged within two hours. A similar experiment using methanol indicates that all of the included acetone can be replaced to give a crystal that contains a molar ratio of **1**/MeOH/H_2O of 1:20:2, thus giving approximately 120 molecules of methanol in each void at a calculated density of 0.8 g mL^{-3} (density of methanol at 20 °C = 0.79 g mL^{-3}). XRD analysis shows that the solvent exchange does not alter the basic crystal structure, although the water molecules hydrogen bonded to the *meso* nitrogen atoms of **1** (Figure 1d) are replaced by methanol, and several other localized, but highly disordered, methanol molecules can be tentatively assigned within the crystal structure.

Remarkably, even water can be used to achieve almost complete exchange of acetone without loss of crystalline order. NMR spectroscopic analysis of the dissolved clathrate which had been previously submerged in water gives a molar ratio of **1**/acetone/H_2O of 1:0.5:30, which indicates each void is filled with approximately 180 water molecules at a calculated density of 0.65 g mL^{-3}. The apparent low density of the included water may be related to the predominately hydrophobic nature of the voids. It has been recognized that a narrow depletion layer, composed of water in the vapor phase, forms at the interface between a hydrophobic surface and water because of the disruption of hydrogen-bonding interactions.[19] At first sight, it seems surprising that water can gain access to the voids through the narrow interconnecting channels, which are lined with isopropyl groups (Figure 1e). However, the recent observation of water transport through the extended hydrophobic channel of a carbon nanotube of similar diameter provides a close analogy.[20]

The cubic packing of **1** is clearly related to the fourfold symmetry of the phthalocyanine molecule and allows the number of weak intermolecular interactions to be maximized by the interleaved phenoxy substituents along each of the 12 vertices of the cubic subunit. Relative to reported hydrogen-bonded clathrate structures, the proportion of included solvent within the crystal structure of **1** is unremarkable; however, its distribution into such large well-defined cavities is unprecedented. Molecular enclosure on the subnanoscale may be achieved within the voids of discrete molecular cages,[21] crystalline clathrates,[4] and network coordination polymers;[22] however, only a few examples approach,[23] and fewer exceed,[24] an enclosed volume of 1 nm^3. Of interest, is the potential for the exploitation of the functionalities present in the phthalocyanine unit to provide catalytic sites that would be embedded in the wall of the cavities and accessible only through the narrow size-selective channels. Hence, we envisage a clathrate that exhibits similar size and shape selectivity to that of the channel inclusion complexes (e.g., urea) but with intrinsic catalytic activity. Studies on the preparation of similar clathrates that contain catalytically active transition-metal ions (e.g., Co^{2+}, Fe^{3+}, etc.) are in progress, as are attempts to stabilize the structure through the placement of polar and hydrogen-bonding substituents on the 2,6-diisopropylphenoxyl units. Furthermore, the unique crystal structure of **1** suggests an approach to novel inorganic or organic nanoparticles by their assembly within the enclosed voids.[25]

Experimental Section

1: A mixture of 4,5-di(2,6-diisopropylphenoxy)phthalonitrile (0.5 g, 1.04 mmol; prepared by using an adapted literature procedure)[16] and an excess of anhydrous zinc acetate (20 mg) in dry NMP (6 mL) was stirred at 150 °C under nitrogen for 24 h. The reaction mixture was added to stirred distilled water (200 mL) on cooling, and the solid product was collected by filtration and washed with water and MeOH. The crude product was purified by column chromatography on silica gel with dichloromethane as the eluent and recrystallized from acetone to afford a bright green crystalline solid. Yield: 0.32 g (65%). M.p. 286 °C, elemental analysis (%) calcd for $C_{128}H_{144}O_8N_8Zn$: C 77.33, H 7.30, N 5.63; found: C 76.98, H 7.14, N 5.44; ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 1.35 (96H, br s), 3.48 (16H, sept), 7.51 (16H, d), 7.62 (8H, t), 8.20 ppm (8H, s); IR (KBr disc): λ_{max} (CH_2Cl_2, nm): 680, 362, 280 cm^{-1}; MALDI-MS (*m*/*z*) 1988 ([M^++H$^+$]).

X-ray structural analysis: Data were collected at 150 K using synchrotron radiation at Daresbury SRS, UK (Station 9.8) with a Bruker-Nonius APEX11 CCD diffractometer (λ = 0.6934 Å), and the structure was solved by direct methods. All calculations were carried out using the SHELXTL package.

Crystal data for **1**·3H_2O·11C_3H_6O: crystal size 0.7 × 0.4 × 0.4 mm^3, cubic, space group $Pn\bar{3}n$, $a = b = c$ = 3.76973(2) nm, V = 53.571.1(5) nm^3, Z = 12, R_1 = 0.0915. The asymmetric unit contains a quarter of **1** together with half a water molecule. A number of the carbon atoms were disordered over two sites, whose occupancies were constrained to sum to unity. The components of the disordered phenyl group were constrained to be regular hexagons. Non-hydrogen atoms were refined anisotropically, with restraints on the thermal motion of the carbon atoms, except those that were disordered. Hydrogen atoms were included in calculated positions, except those bonded to the axial oxygen atoms, which were omitted. CCDC-279644 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Carbon–Carbon Bonds

DOI: 10.1002/anie.200502721

Squeezing C–C Bonds**

Deborah R. Huntley, Georgios Markopoulos, Patrick M. Donovan, Lawrence T. Scott, and Roald Hoffmann**

Making C–C bonds long is a going enterprise; dozens of bonds that are 0.10–0.15 Å longer than a normal 1.54 Å C–C bond are known. It is possible to weaken a bond through electronic effects, but strain is the major factor. What about short C–C bonds? Single bonds between two- and three-coordinate carbon atoms (e.g., the central C–C bonds in 1,3-butadiyne and 1,3-butadiene) are certainly short—a phenomenon usually interpreted in terms of hybridization. However, short single bonds between two four-coordinate carbon atoms are rare. Two examples that have caught the attention of the community are the π-acceptor-substituent-influenced bond in a bridged bicyclobutane **1**, with a C–C bond length of 1.41 Å,[1] and the external bonds between two bicyclobutane bridgeheads in **2** and **3** with lengths of near 1.44 Å.[2] An interesting theoretical discussion of these and the related bonds in the bitetrahedryl and bicubyl molecules, **4** and **5**,[3a] has appeared.[3b–g] Recently, Tanaka and Sekiguchi published the synthesis and structure of the hexakis(trimethylsilyl) derivative of **4**, which contains a very short exocyclic C–C bond (1.436 Å).[4]

One might think that the normal shape of a molecular potential argues against a short C–C single bond: Aren't all such potentials anharmonic, with elongation less costly energetically than contraction? For "small" deviations (ca. 0.05 Å) it really doesn't matter that much. Single-point calculations on D_{3d} ethane (Figure 1) are indicative: it takes 2.8 kJ mol^{-1} to stretch the C–C bond by 0.05 Å from its equilibrium value and only 3.5 kJ mol^{-1} to squeeze it by the same amount; on the other hand, stretching and squeezing by 0.15 Å requires 21.9 and 37.7 kJ mol^{-1}, respectively.[5]

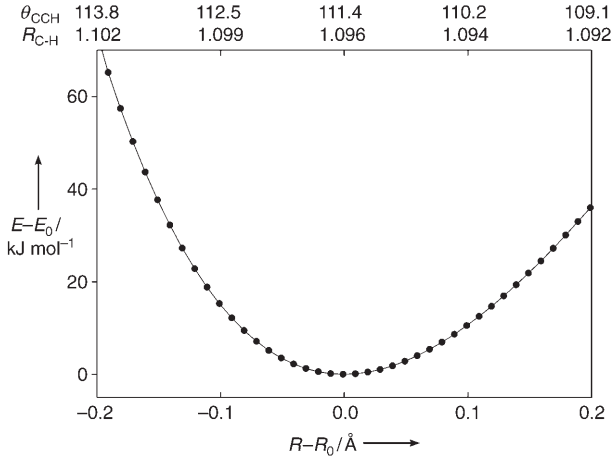

Figure 1. Computed potential-energy curve for ethane showing the energetic cost of bond stretching ($R-R_0 > 0.0$) and compression ($R-R_0 < 0.0$). At each fixed distance, the C–H bond length (R) and C-C-H angle (θ), as shown at the top of the graph, were optimized within a D_{3d} constraint.

So why do we see so few shortened C–C bonds? We think it is because strain dissipates in a multitude of ways. It is not easy to concentrate stress into a specific bond or in a single phase of the stretching motion. Herein, we report our attempts to design such squeezed C–C single bonds, making use of the reliability of contemporary computational methods to monitor how well we do. In doing so, we are responding to a question raised 29 years ago by Henning Hopf.[6] He asked "*Wie kurz kann eine Einfachbindung werden? Wie stark lässt sie sich stauchen?*" (How short can a single bond be? How strongly can it be compressed?)

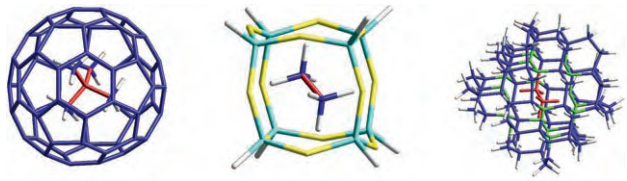
We constrained ourselves (arbitrarily) to C–C bonds in which the carbon atoms involved are tetracoordinate. Also, for the initial moves in the game,[7] we did not allow substitution at either of the tetracoordinate carbon atoms by atoms other than hydrogen or carbon. Also, to rely on well-understood electronic effects (as are operative in **1**) was deemed "unsporting."

Computational Methods

Structures were optimized with the B3LYP hybrid functional and the 6-31G(d) basis set as implemented in the Gaussian 03 program.[8] This functional has been shown to be reliable for the determination of normal and anomalous C–C bond lengths using both 6-31G(d) and 6-31G(d,p) basis sets above.[3g,9] In a few cases (indicated in footnotes), a smaller basis set (6-31G) was used. Frequency calculations were performed to confirm that every structure represents a true energy minimum. Many of the structures were also optimized using the BLYP functional and triple-zeta Slater orbital basis set (TZ2P) with the Amsterdam Density Functional Program,[10] and effectively identical results were obtained. Our structures are color-coded as follows: C atoms blue; N atoms green; O atoms yellow; H atoms white; and Si atoms cyan (one exception will be specified later); the shortened bonds are highlighted in red.

Caging

The simplest strategy for applying pressure to one C–C single bond (or a group of such) is to encapsulate it in a reasonably inert cage, a game that is easier to play theoretically than experimentally. In the examples pictured here, **6** puts a molecule of neopentane inside C_{60}, **7** puts ethane in silsesquioxane $(SiH)_8O_{12}$, and **8** puts a molecule of ethane into a



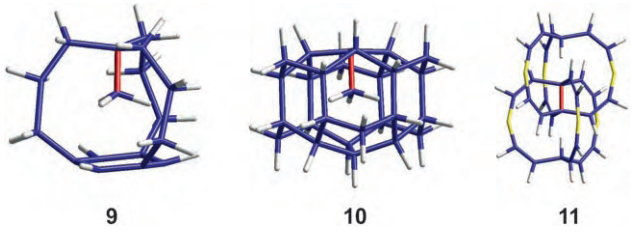
6 7 8

"diamond skin." (This last structure requires further explanation: Begin with an extended cubic diamond structure. Discard from it a C_2 unit as well as the six attached carbon atoms. Place C_2H_6 inside that space, then sculpt the outside to form a thin diamondoid layer around the molecule of ethane, and "heal" the inside cavity by replacing the 18 carbon atoms that face the ethane by nitrogen atoms. The outside of the diamond skin is passivated with hydrogen atoms.[11]) This kind of brute-force pressure leads to optimized C–C bond lengths of 1.36 Å in **6**,[12] 1.40 Å in **7**, and 1.46 Å in **8**.[13,14]

Capsule and encapsulated entities can also be combined in a single molecule. Cyclophane **9** presses a methyl group towards the aromatic ring, in a similar manner to the "iron maidens" recently reviewed by Pascal.[15] The steric congestion at the center of this molecule leads to a shortened bond length of 1.43 Å.[16] Song, Ho, and Pascal recently synthesized related in-cyclophanes with short C–Me bonds of 1.475 and 1.495 Å.[17] Tightening the cage around such an in-methyl

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

group, as in **10**, leads to a corresponding C–C bond length of just 1.41 Å.



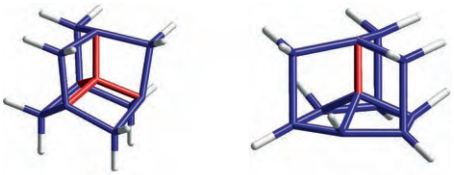
9 **10** **11**

The Spiderane

A unique topology (a spiderane) is demonstrated by **11**,[12] in which the above principle is applied twice. This "back-strapped" structure with two intertwined cages has a central C–C bond length of 1.44 Å. The hydrogen atoms pointing towards the short C–C bond are essential; replacing the CH groups with nitrogen atoms leads to a more typical bond length of 1.51 Å.

Shortening a Bond without Pushing on It

Though the spiderane **11** is sui generis, van der Waals repulsion has been crucial in our strategy so far. Many other variations are possible in which shortened bonds are achieved solely by covalent means. For example, **12** forces a carbon



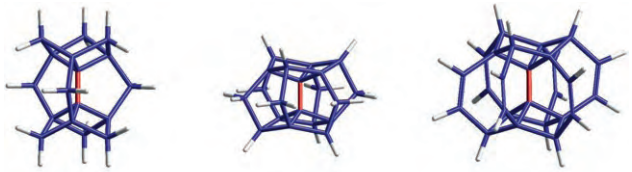
12 **13**

atom into the adamantane framework, removing the bridgehead hydrogen atoms along the way. A set of four equally shortened C–C bonds (1.44 Å) arises as a result of the small covalent cage. Next, we replaced the six bridging methylene groups with NH groups, resulting in a more compressed structure that has a central bond length of 1.39 Å.[18]

Rotation around one of the eclipsed C–C bonds in **12** and reconnection of the "bridges" in a staggered manner leads to the closely related structure **13** (bridging group $X = CH_2$). Here, we observed that one bond becomes even shorter (1.38 Å), while the three basal C–C bonds relax to a normal C–C bond length (1.54 Å). Still, the squeeze comes at a cost: the surrounding bond angles are very distorted, and the bonds to the methylene carbon atoms (1.70 and 1.84 Å) are very elongated. The use of longer bridges ($X = C_2H_2$, C_2H_4, C_3H_4, C_3H_6) reduces the distortions but also leads to a gradual lengthening of the short bond to 1.48 Å for the trimethylene species ($X = C_3H_6$).

Stiffened and Strapped, Eclipsed and Staggered

A different look at **12** opens the door to another variation: the lower part of the molecule is comprised of three fused cyclobutane rings. This connectivity provides a highly strained but rigid framework at one end of an eclipsed ethane unit. If that fused-ring system were repeated at the other end, we would have molecules that are reminiscent of bicubyl or bis(bicyclo[1.1.1]pentyl), which are known to have short central bonds.[3] Those bonds should get even shorter if we impose further geometric constraints. Implementing this idea, with three bridging methylene groups, leads to a central bond of length of 1.37 Å in **14**.



14 **15a** **15b**

Application of this concept to the "staggered" system **13** allows six bridging methylene units and leads to the shortest carbon–carbon single bond observed in the course of this study: 1.32 Å in **15a**. Although this molecule is highly congested and very, very strained, a single-bond distance in the regime of double-bond lengths is quite remarkable. The other C–C bonds in the molecule all fall in the range of 1.60–1.64 Å. Replacement of the methylene bridges in **15a** with ethyleno groups (C_2H_2) results in slight elongation of the central C–C bond to 1.35 Å (**15b**).

Tied-Up Bicycloalkanes

Clearly, stiffening both ends of an ethane unit and tying them together is a promising approach to obtain short bonds. Other examples include interior propellanes formed by strapping bicyclo[*n.n.n*]alkane units together. Many variations in the bridges are possible; herein, we show only the use of *exo* double bonds (1.37 Å in **16a**) and ethano bridges

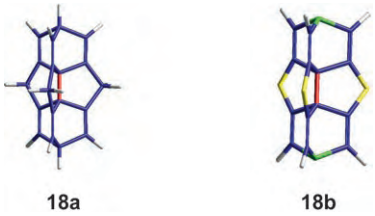
16a **16b** **17**

(1.39 Å in **16b**). The triply methylene-bridged analogue of **16a** has a central C–C bond of 1.35 Å, but some external bonds are quite long (1.74 Å).[19] Merging the strategies of **15** (hexuple straps) and **16b** (linking bicylic units) leads to **17**, which has a central C–C bond length of 1.34 Å, again with some long C–C bonds in the bicyclic systems (1.74 Å).

Less-strained frameworks, which might be more easily synthesized, were also tested and still show significantly shortened bonds. System **18a** has a shortened bond of 1.46 Å.

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Introduction of heteroatoms leads to a stronger squeeze, as shown for **18b** (1.41 Å).



Not Just s Character

In the course of this stroll into the largely neglected land of short bonds, we have developed a menagerie of molecules that are predicted to have very short bonds between coupled four-coordinate carbon atoms. Is it simple hybridization that drives this bond shortening, as others have rather convincingly argued for bicubyl **5**, the bicyclobutane dimers **2** and **3**, bitetrahedryl **4**, and Tanaka's derivative?[3,4] We don't think so. In Figure 2, we have used natural bond orbital (NBO)

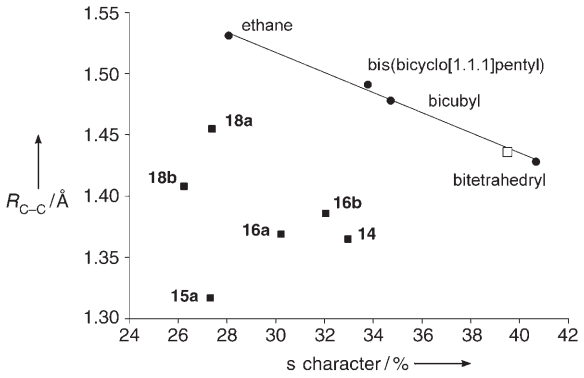


Figure 2. Percentage s orbital character (from an NBO analysis) and optimized C–C bond lengths for some selected molecules. The open square corresponds to Tanaka and Sekiguchi's hexakis(trimethylsilyl)bitetrahedryl. The squeezed bonds in the molecules proposed by us are shorter by approximately 0.1 Å or more than the lengths expected on the basis of hybridization arguments.

analysis[20] to determine the hybridization in our short bonds. The C–C bond lengths are plotted as a function of the percentage s orbital character in the bond for selected[21] molecules discussed herein as well as for some of the dimers previously studied. It is clear from Figure 2 that our molecules have C–C single bonds that are shorter by approximately 0.1 Å or more than what would be expected from hybridization alone. The additional strain caused by the threefold symmetric geometry constraints is responsible for this effect. Our short bonds simply cannot achieve "typical" lengths without wreaking havoc elsewhere in the molecule.

[5] In D_{3d} or D_{3h} ethane, there are three structural parameters that may be chosen as the C–C and C–H bond lengths, and a C-C-H (or H-C-H) angle. In Figure 1, the energy is plotted as a function of the C–C bond length, with the other structural parameters optimized. Schleyer and Bremer[3b] performed a similar optimization, in which the C–C bond length was plotted versus the C-C-H angle in the optimized geometries.

Enzyme Mutation

DOI: 10.1002/anie.200502461

Conversion of a Carboxylesterase into a Triacylglycerol Lipase by a Random Mutation**

*Dolores Reyes-Duarte, Julio Polaina, Nieves López-Cortés, Miguel Alcalde, Francisco J. Plou, Kieran Elborough, Antonio Ballesteros, Kenneth N. Timmis, Peter N. Golyshin, and Manuel Ferrer**

Lipases and esterases are enzymes of increasing importance for classical and new industrial applications.[1,2] The most significant properties of these enzymes are that they are very stable and active, especially in organic solvents, and they possess regio- and stereospecificity.[2] Esterases (also called carboxylesterases, EC 3.1.1.1) preferentially hydrolyze water-soluble "simple" esters and usually only triglycerides bearing fatty acids shorter than C_6, whereas lipases (also known as triacylglycerol lipases, EC 3.1.1.3) prefer water-insoluble substrates, typically triglycerides composed of long-chain fatty acids.[1] Despite their close relationship in sequence and structure, these enzymes differ in their profile for chain-length specificity. In fact, substrate specificity is the only completely valid criterion for distinguishing between carboxylesterases and lipases, because several exceptions exist for the other criteria used previously: the existence of a *lid*, interfacial activation, and hydrophobicity of the scissile acyl-binding site of the substrate.[1,3,4]

Lipases and esterases have already been improved by methods such as medium engineering, immobilization on suitable supports, and rational protein design. Moreover, it has been demonstrated that directed evolution can lead to enzymes with thermal stability[5] and inverted or improved enantioselectivity.[6] A few examples also showed that the chain-length specificity of lipases can be achieved.[7] Notably, in all cases the original lipase showed activity toward long-chain fatty acid esters, and laboratory evolution was used to improve and thereby modify its hydrolytic activity. Clearly, the transformation of a "true carboxylesterase" into a "true lipase" seems to be difficult, as no examples of this change have been reported. Two hypotheses may explain the supposed difficulty: 1) the active center in esterases is smaller than that in lipases, so it can only accommodate short-chain fatty acid esters;[8] or 2) the esterase requires a hydrophobic mobile *lid* to facilitate its interfacial activation, and that has only been found in lipases.[9] Whatever the case, both situations seem to be critical for a high-performance lipase. Herein, we describe the conversion of a "true esterase" into a triacylglycerol lipase by directed evolution; the significance of this study is also discussed. Enzyme R.34, retrieved from the metagenome library of bovine rumen microflora,[10] was chosen as the test enzyme.

The data in Figure 1 a and b support the notion that R.34 is a true carboxylesterase, which acts preferentially on *p*-nitrophenyl (*p*-NP) esters and the triacylglycerol of short-chain fatty acids ($\leq C_4$), and is optimal for C_3 acids (up to 240 units mg^{-1}). One round of error-prone PCR was used to create a mutant with higher activity toward long-chain fatty acid esters.[12a] Potential improved variants were identified on agar plates by using α-naphthyl laurate (αNL) and an azo dye (Fast Blue RR) that reacts with the released 2-naphthol to generate an insoluble brown product.[13] Under these conditions, *Escherichia coli* colonies expressing wild-type R.34 did not produce brown halos on αNL plates, but did produce them on α-naphthyl acetate (αNA) plates.[12b] Approximately 8200 colonies were screened in the first round, and only one clone (EL1) was identified. Such a low frequency of improvement was surprising, and may reflect the fact that long-chain esters are very inefficient substrates for R.34. Both R.34 and EL1 were produced as a fusion with a hexahistidine (His_6) tag at the C terminus,[12a] and their biochemical properties were investigated. Although the optimal pH, temperature, and

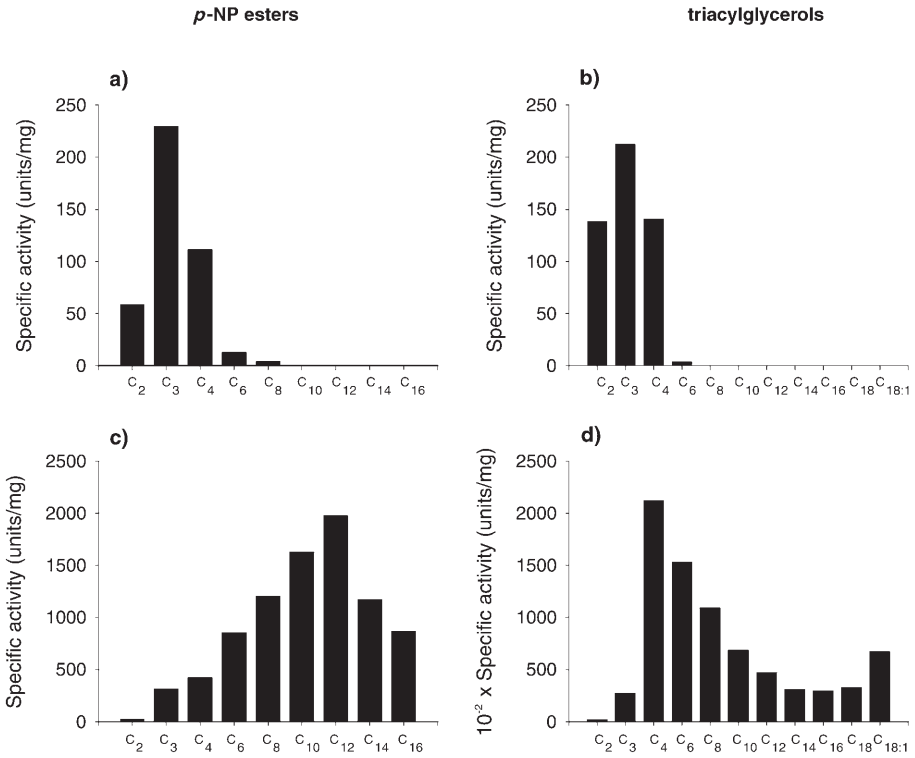

Figure 1. Relative activity of the wild-type R.34 esterase (top) and EL1 mutant (bottom) to *p*-NP esters (a and c) and triacylglycerols (b and d). Specific activities are given in units mg^{-1} pure protein. R.34 and EL1 enzymes were purified by using a Ni-Sepharose column after expression with a carboxyl-terminated His_6 tag.[12a] To exclude any influence of the His_6 tag on activity, the R.34 protein was expressed in and purified from *E. coli* XLOLR cells harboring pBKR.34 plasmid.[10] The enzyme obtained by this method did not show relevant differences in substrate specificity.

subunit composition were essentially the same for both proteins,[12c] several significant differences were found (see below).

First, the optimal acyl chain for *p*-NP esters switched to *p*-NP laurate (C_{12}) with a nearly one order of magnitude increase in specific activity ($\approx$2000 units mg^{-1}; Figure 1c). Interestingly, the specificity switched >1000-fold toward short-chain triacylglycerols (Figure 1d). Tributyrin (C_4) was the optimal substrate for EL1 (214000 units mg^{-1}), but the enzyme was also able to efficiently hydrolyze typical lipase substrates such as trilaurin, tripalmitin, and triolein (>67000 units mg^{-1}).

Encouraged by this finding, we assessed the susceptibility of EL1 to several fatty acid sulfonyl fluorides (SFs), which are potent serine-specific inhibitors. As shown in Figure 2a, R.34 was strongly inhibited by phenyl methyl sulfonyl fluoride (PMSF); however, it was partially inhibited by capryl sulfonyl fluoride (C_6SF), and was not affected by the longer lauroyl (C_{12}SF) and palmitoyl (C_{16}SF) derivatives. On the other hand, EL1 mutant was equally inhibited by all the SFs tested, which suggests that the serine residue at the active site is more accessible in this mutant compared with the wild-type enzyme.

Next, we examined the susceptibility of the EL1 variant to detergents and solvents. As illustrated in Figure 2b, the stability of the mutant was very similar to that of the wild-type enzyme upon addition of acetonitrile. This result suggests that solvent-exposed residues were, most likely, not changed by the mutation and that they were similarly exposed in both variants. However, when both enzymes were incubated at different concentrations of the ionic detergent Triton X-100, we observed that the EL1 variant was more affected than the wild-type enzyme (Figure 2c). Thus, R.34 showed maximal activity at 0.6% (w/v) detergent and retained more than 50% of the maximum activity at a 5% (w/v) concentration, whereas the EL1 mutant was strongly inhibited above 0.06% (w/v). The mutation may have induced a conformational change, whereas the catalytic residues became exposed to the large detergent micelles.

We further analyzed the secondary structure content, and found that the CD spectra for R.34 and EL1 mutant measured at 25°C were similar, with minima at 208 and 222 nm (Figure 3a), which is consistent with an α-helical protein. The thermal unfolding of each protein was determined by fitting the ellipticity at 222 nm (θ_{222}) versus temperature. As shown in Figure 3b, the melting temperature (T_m) shifted from 63.7°C (for R.34) to 51.3°C (for EL1). This result was somewhat unexpected, and indicates a lower stability for the EL1 mutant.

The creation of a lipase (EL1) prompted us to examine its positional specificity. The transesterification of the structured lipid 1,3-dipalmitoyl-2-oleoyl glycerol (POP) with ethanol[12a] was used to unambiguously identify the regiospecificity and to minimize acyl migration artifacts. When using lipase EL1 immobilized on Sepabeds EC-EP3, 2-methyl-2-butanol, and a water activity (a_w) of 0.22 (predetermined to be optimal), the reaction reached a conversion of $\approx$98% after 4 h at 30°C (Figure 4). EL1 showed a preference for the sn2 position, as deduced from the significantly higher concentrations of ethyl oleate and 1,3-dipalmitoyl glycerol over those of ethyl palmitate (Figure 4) and 1-*O*-palmitoyl- and 1(3)-palmitoyl-2-oleoyl glycerol,[12d] respectively.

The sequence analysis of EL1 mutant revealed a single amino acid substitution, N33D. The question that arises from this finding is, why does this single amino acid substitution in the EL1 mutant have such a profound effect on the substrate specificity? To understand the significant differences observed in the substrate specificity profile mediated by this substitution, we produced a three-dimensional model of the R.34 structure (Figure 5a), in which the esterase sequence was aligned with that of *Alicyclobacillus acidocaldarius*.[14]

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

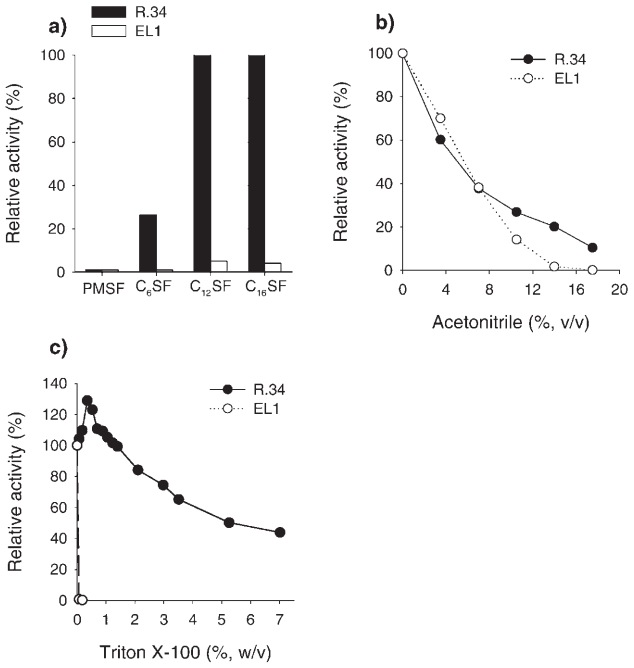

Figure 2. Parameters affecting the activities of R.34 and EL1. a) Inactivation by irreversible active-site inhibitors. Purified enzymes were incubated with 1 mM PMSF, C_6SF, C_{12}SF, and C_{16}SF. After incubation for 20 min, an aliquot was withdrawn and the hydrolytic activity was monitored. b) Effect of acetonitrile on esterase activity. c) Effect of Triton X-100 on esterase activity. Hydrolytic activity was monitored spectrophotometrically by following the increase in absorbance at 410 nm as a result of hydrolysis of *p*-NP propionate at 40 °C in HEPES buffer (100 mM, pH 7.5). The relative activity is normalized as 1.

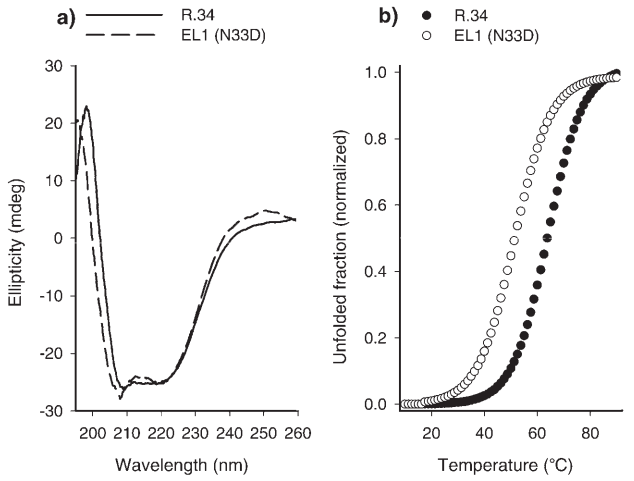

Figure 3. Circular dichroism studies. a) Far-UV CD spectra of R.34 and the EL1 mutant. b) Unfolding profiles of proteins. The samples were heated from 15 to 90 °C at 1 °C min^{-1} and the ellipticity was recorded at 222 nm. The T_m values were calculated by a nonlinear least-squares fit of the transition temperatures.

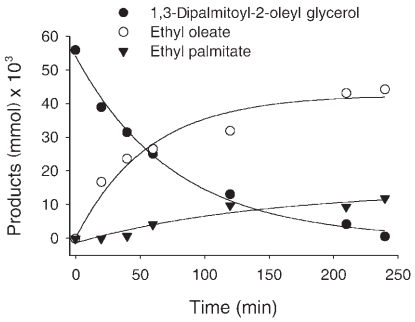

Figure 4. Time course of the transesterification reaction of POP with ethanol in 2-methyl-2-butanol using immobilized EL1 lipase (as determined by GC).[12a] Initial conditions: POP (0.056 mmol), ethanol (0.58 mmol), immobilized EL1 lipase (a_w = 0.22, 5 mg), 30 °C, 2-methyl-2-butanol (a_w = 0.22, 1 mL). Conditions as described in Ref. [12a]. The data are not fitted to any model; each point represents the mean of three experiments.

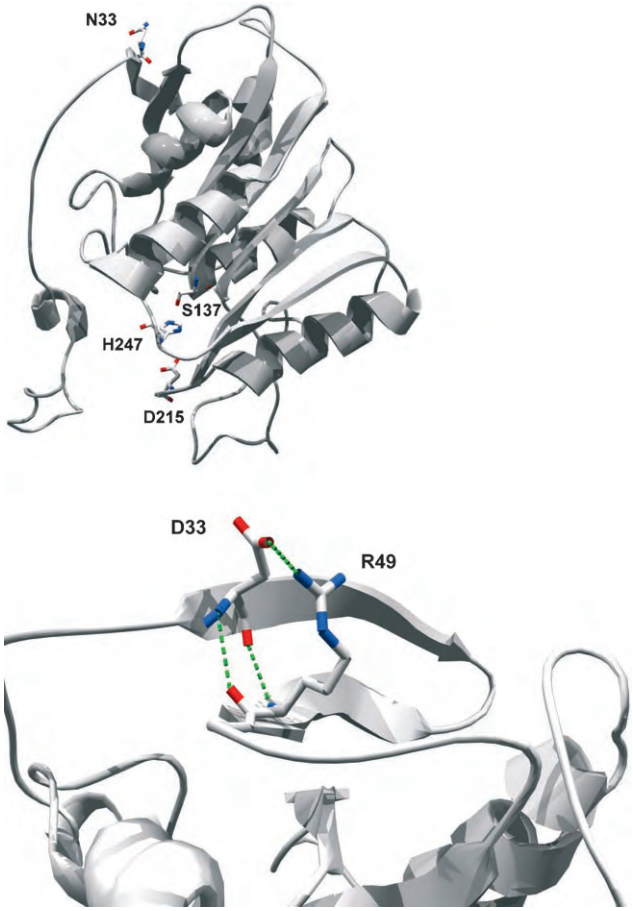

Figure 5. a) Overall three-dimensional structure of R.34, as obtained by homology modeling. Residues belonging to the catalytic triad and N33 are explicitly shown. b) Schematic representation of the putative salt-bridge binding residues D33 and R49 in the EL1 mutant.

The analysis of the *A. acidocaldarius* EST2 esterase structure indicates the existence of an ion pair between the two residues (Glu and Arg) present at positions equivalent to those of Asn33 and Arg49 in the R.34 sequence. This finding prompted us to suggest that the substitution of Asn33 by Asp leads to the formation of a salt bridge between the newly introduced Asp33 and Arg49 (Figure 5b). Most likely, this may cause a distortion of the enzyme structure (proof of which awaits 3D structure determination), which would make

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the catalytic site more accessible to larger substrates, but also more labile. This argument was supported experimentally by the analysis of the substrate-specificity profile (Figure 1), in which it was clear that the active site accommodated longer fatty acid esters, and by the higher susceptibility of EL1 to chemical inactivation and denaturation (Figure 2). In addition, the midpoint of unfolding was 12 °C lower. To prove the supposed interaction between D33 and R49, and the fact that this interaction affects the catalytic activity of the mutant enzyme toward triacylglycerols, single R49D and R49N mutant variants of the enzyme were generated by site-directed mutagenesis. Mutations at R49 produced variants with no activity on αNL plates, but they did hydrolyze αNA.[12e] Furthermore, we also introduced a reversed mutation N33R-R49D in R.34 and obtained the lipase phenotype in both αNL[12f] and rhodamine–triolein plates.[12g] These results unambiguously confirm that the interaction between residues 33 and 49 exists, and that it is essential for the substrate preference of the R.34 enzyme.

In summary, we have provided clear proof that the substrate specificity of a true carboxylesterase can be modified toward insoluble substrates, that is, turned into a true triacylglycerol lipase, without modification of the shape, size, or hydrophobicity of the substrate-binding sites that are considered to be essential for chain-length specificity.[1,7,8] Moreover, minimal changes in the structure are sufficient for enhancing the acyl chain-length preference of esterases. More significantly, compared with other lipases,[17,18] the EL1 mutant may constitute an important step toward the synthesis of structured lipids[19] and may have other lipase applications, which are under investigation.

[10] Wild-type esterase was retrieved from the bacteriophage lambda-based expression library created from DNA extracted from bovine rumen fluid, after screening in NZY soft agar containing α-naphthyl acetate (αNA), and expressed from the pBK-CMV phagemid pBKR.34 in *E. coli* XLOLR. Sequence analysis of R.34 is consistent with a 273 amino acid protein of $M_r = 34\,173.99$ Da and an isoelectric point of 5.03. It belongs to the ester hydrolase of family II of the Arpigny and Jaeger classification,[11] according to the conserved motif GDS(L); the catalytic triad was deduced to be formed by Ser137, Asp215, and His247. For details, see: M. Ferrer, O. V. Golyshina, T. N. Chernikova, A. N. Khachane, D. Reyes-Duarte, V. A. P. Martins Dos Santos, C. Strömpl, K. Elborough, G. Jarvis, A. Neef, M. M. Yakimov, K. N. [13] V. Khalameyzer, I. Fischer, U. T. Bornscheuer, J. Altenbuchner, *Appl. Environ. Microbiol.* **1999**, *65*, 477 – 482.
[14] a) Sequence alignment of R.34 esterase and other xylanases and esterases is shown in the Supporting Information; b) The structure of esterase EST2 from *A. acidocaldarius* (PDB Acc. number 1EVQA) was chosen as the most suitable template to generate a model for R.34. See G. De Simone, S. Galdiero, G. Manco, D. Lang, M. Rossi, C. Pedone, *J. Mol. Biol.* **2000**, *303*, 761 – 771. The degree of sequence identity between these two proteins is 19%. Ramachandran plots of both model and template proteins (see the Supporting Information) were obtained to assess the overall stereochemical quality of the model. The model is not reliable at the N-terminal part of the structure (first 32 residues of esterase R.34), where the sequence similarity between the model and template is very low. However, the results of threading[16] indicate a consistent structural similarity in the region starting at residue 33.

Chain Elongation, Macrolactonization, and Hydrolysis of Natural and Reduced Hexaketide Substrates by the Picromycin/Methymycin Polyketide Synthase**

*Jiaquan Wu, Weiguo He, Chaitan Khosla, and David E. Cane**

Macrolide polyketides are a structurally diverse group of natural products, widely used for their pharmaceutically important antimicrobial, antitumor, and immunosuppressant properties.[1] The picromycin/methymycin synthase (PICS) of *Streptomyces venezuelae*, which is responsible for the formation of the 12- and 14-membered-ring antibiotics methymycin and picromycin,[2,3] is a typical modular polyketide synthase (PKS), in which each module is responsible for a single round of polyketide-chain elongation and functional-group modification.[4–6] Each module is in turn made up of a specific combination of fatty acid synthase-like domains that catalyze the individual biochemical steps of polyketide biosynthesis.

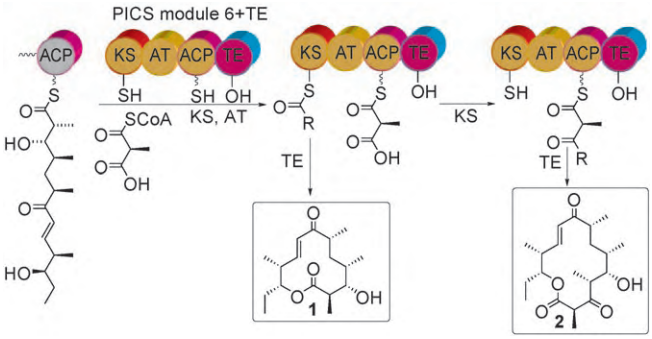
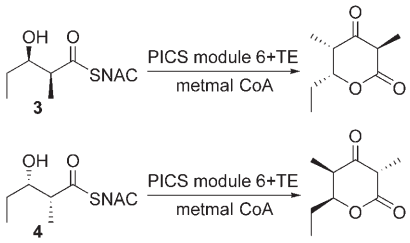
PICS module 6, a homodimer of subunit $M_w = 142$ kDa encoded by *pikAIV*, is organizationally one of the simplest known PKS modules, as it only consists of a ketosynthase (KS), a methylmalonyl transferase (AT), and an acyl carrier protein (ACP) domain as well as a C-terminal thioesterase (TE; Scheme 1). In spite of this apparent structural simplicity, PICS module 6(+TE) is one of the catalytically most intriguing PKS modules, on the basis of its demonstrated role in the formation of both 10-deoxymethynolide (**1**)[7] and narbonolide (**2**), the parent macrolide agylcones of methymycin and picromycin, respectively.[4,6,8–10]



Scheme 1. Conversion of hexaketide into 10-deoxymethynolide (**1**) and narbonolide (**2**) by PICS module 6+TE.

We have reported the expression and purification of recombinant PICS module 6+TE from *Escherichia coli* and have investigated its relative substrate specificity by using *N*-acetylcysteamine (SNAC) thioesters of 2-methyl-3-hydroxypentanoic acid as diketide analogues of the natural hexaketide chain-elongation substrate.[11] It was found that PICS module 6+TE processed both *syn*-diketide diastereomers (2*S*,3*R*)-**3** and (2*R*,3*S*)-**4** with a modest 2.5:1 preference in k_{cat}/K_m for **4**, but did not process either of the two *anti* diketides (Scheme 2). Similar findings were reported independently by Sherman and co-workers,[9] who also described extensive in vivo and in vitro investigations of the biochemical basis for the competition between elongation of the natural hexaketide substrate by PICS module 6 to give **2** and direct cyclization to **1**, with the final macrolactonization being controlled in both cases by the C-terminal TE domain.[8,12] Although active KS6, AT6, and ACP6 domains were found to be essential for the formation of **1**, the precise role of these



Scheme 2. Conversion of diketide-SNAC analogues into triketide ketolactones by PICS module 6+TE. metmal CoA = methylmalonyl coenzyme A.

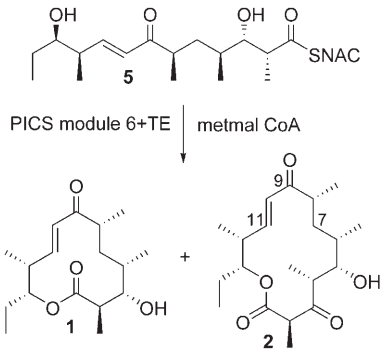
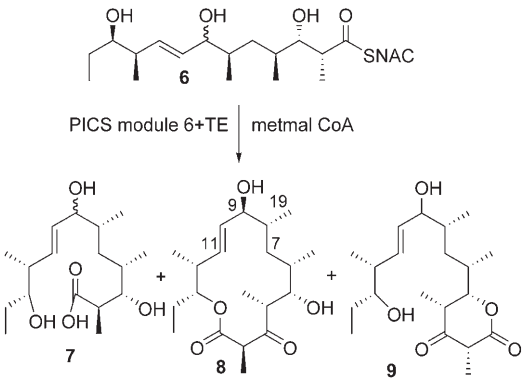
domains in the delivery of the hexaketide substrate to the active site of the TE domain remains to be established. Investigations, both by us and Sherman and co-workers, have recently established that recombinant PICS TE alone can efficiently catalyze the macrolactonization of synthetic *seco*-hexaketide acyl SNAC **5** to **1** while catalyzing the exclusive hydrolysis of the corresponding 7-dihydro-*seco*-SNAC thioester **6**.[13,14] Most recently, Sherman also reported that PICS module 6+TE can convert the *seco*-SNAC thioester **5** and methylmalonyl coenzyme A (CoA) into **2**, although they did not monitor the competing direct lactonization to **1** and reported only a
k_{cat}/K_m value for the chain elongation and the lactonization reaction.[15] We now report that in the presence of the cosubstrate methylmalonyl CoA PICS module 6+TE catalyzes competing macrolactonization and chain elongation of **5**, which is converted into a 4:1 mixture of **1** and **2** (Scheme 3).



Scheme 3. Conversion of hexaketide *seco*-SNAC thioester **5** into **1** and **2** by PICS module 6+TE.

PICS module 6+TE is also shown to convert **6** and methylmalonyl CoA into a mixture of the direct hydrolysis product **7** and the isomeric chain-extended heptaketide lactones **8** and **9** (Scheme 4).

The requisite substrates **5** and **6** were each prepared by degradation and semisynthesis from **1**, as previously described.[13] The *seco*-SNAC thioester **5** is in equilibrium with approximately 50–60% of the corresponding 3,7-hemiacetal



Scheme 4. Hydrolysis and lactonization of 7-dihydro-*seco*-SNAC-thioester **6** by PICS module 6+TE.

in $CDCl_3$.[13,15] Incubation of **5** with recombinant PICS module 6+TE and [2-^{14}C]methylmalonyl CoA produced a 4:1 mixture of **1** and **2**, as monitored by RP-HPLC with concatenated inline UV/Vis and flow-scintillation detection (Scheme 3). The identities of the enzymatic reaction products were confirmed by carrying out a preparative-scale reaction over 0.5 hours with **5** (2 mM) and methylmalonyl CoA (2 mM) in the presence of PICS module 6+TE (13.2 μM).[16] The resulting macrolide aglycones, purified by preparative RP-HPLC, displayed ^{1}H NMR and HR-ESI mass spectra that were identical to authentic samples of **1** as well as literature values for **1** and **2**.[17] The steady-state kinetic parameters for the formation of both **1** and **2** were determined by carrying out a series of incubations at concentrations of **5** that ranged from 0.5 to 4.0 mM, with the yields of **1** and **2** determined by HPLC/diode-array UV (230 nm) and phosphorimaging with TLC, respectively. The corresponding k_{cat} and K_m values were calculated by direct fitting of the plots of v versus [S] to the Michaelis–Menten equation (Table 1).[17] The relative values

[a] Formation of **1** in the absence of methylmalonyl CoA.

of k_{cat} showed the expected 4:1 preference for the formation of the macrolactonization product **1** over chain extension and cyclization to **2**. The observed K_m values were not corrected for the presence of the corresponding hemiacetal form of **5**, as the concentration of this species in the reaction buffer was not determined and all of the substrate was consumed in the preparative-scale reaction. Interestingly, incubation of **5** with PICS module 6+TE under identical conditions but in the absence of methylmalonyl CoA gave exclusively **1**, but with approximate 2.2-fold increases in both k_{cat} and k_{cat}/K_m values relative to the cyclization to **1** in the presence of the methylmalonyl CoA cosubstrate.

We previously reported that incubation of **6** (7*S*/7*R* 3:1) with the recombinant PICS TE alone results exclusively in hydrolysis to the corresponding diastereomeric mixture of *seco* acids **7**.[13,14] By contrast, preparative-scale incubation of **6** (2 mM) and methylmalonyl CoA (1 mM) with PICS module 6+TE (10 μM) gave **7**, **8**, and **9** in a 6:3:4 mixture that could be readily separated by flash chromatography (Scheme 4). The NMR spectroscopic and chromatographic properties of **7** were identical to those previously determined.[13] The structure and stereochemistry of **8** and **9** were determined by ^{1}H and ^{13}C NMR spectroscopy, including HMQC and NOESY analysis.[17] Both compounds exhibited HR-ESI mass spectra consistent with the molecular composition $C_{20}H_{34}O_5$ expected for the isomeric lactones. The

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

^{1}H NMR spectrum of **8** closely resembled that of **2**, with several key differences. Thus, the two olefinic protons exhibited the expected upfield shift and change in multiplicity relative to the enone double bond of **2**: H10 ($\delta = 5.34$ ppm, dd, $J = 15.4$, 7.8 Hz) coupled to H11 ($\delta = 5.42$ ppm, dd, $J = 15.4$, 7.7 Hz), with similar changes in the ^{13}C NMR spectrum (C10 $\delta = 134.1$; C11 133.6 ppm). The presence of only a single resonance for allylic H9 in both the ^{1}H NMR ($\delta = 3.47$ ppm, t, $J = 8.5$ Hz—correlated to both H10 and H8 in the ^{1}H COSY spectrum) and ^{13}C NMR spectra ($\delta = 78.8$ ppm) is consistent with the formation of a single diastereomer of **8**. The configuration of **8** was readily assigned as the 9*S* isomer, as based on the NOESY spectrum, which showed crosspeaks between H9 and the H19 methyl protons ($\delta = 1.03$ ppm) as well as between H9 and both the olefinic H11 proton ($\delta = 5.42$ ppm) and one of the H7 methylene protons ($\delta = 0.74$ ppm), but not with either H8 or H10 (Figure 1). Compound **9** was assigned the isomeric δ-lactone structure based on comparison with the spectra of **8**. Thus, the ^{13}C NMR resonance for the lactonic C5 ($\delta = 82.4$ ppm) appeared downfield of the corresponding signal for C5 in **8** ($\delta = 71.7$ ppm), with the expected differences in the attached H5 protons as well (**9**: $\delta = 4.32$ ppm, dd, $J = 9.8$, 2.0 Hz; **8**: $\delta = 4.02$ ppm, dd, $J = 5.4$, 2.4 Hz). The signals for C13 (**9**: $\delta = 76.8$; **8**: 80.1 ppm) and H13 (**9**: $\delta = 3.44$ ppm, td, $J = 8.4$, 3.5 Hz; **8**: $\delta = 4.77$ ppm, td, $J = 10.3$, 3.1 Hz) also showed the expected complementary changes in chemical shift. Although **9** is most likely a single diastereomer (H9 $\delta = 3.44$ ppm, t, $J = 5.1$ Hz; C9 $\delta = 75.9$ ppm), the configuration at C9 was not assigned. The steady-state kinetic parameters for the formation of **8** and **9** (lactonization) as well as **7** (hydrolysis) were also determined (Table 1).

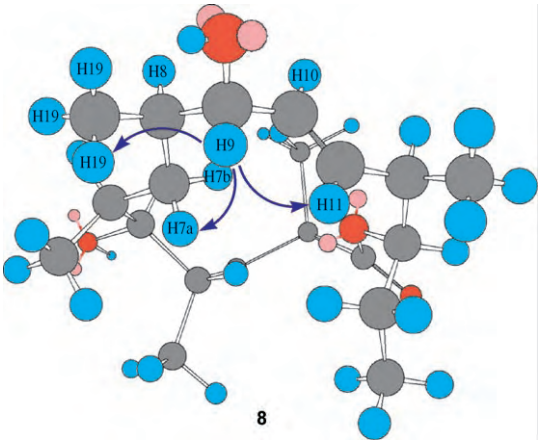

Figure 1. Key NOESY correlations for (9*S*)-9-dihydronarbonolide (**8**). (Energy-minimized conformation calculated by using the MM2 module of Chem3D.)

The observed k_{cat} and k_{cat}/K_m values for chain-elongation/cyclization of **5** to **2** (Table 1) are nearly two orders of magnitude greater than the corresponding steady-state parameters previously determined for the diketide analogue (2*R*,3*S*)-**4** ($k_{cat} = 0.057 \pm 0.003$ min^{-1} and $k_{cat}/K_m = 0.027$ M^{-1} s^{-1}); some of the difference in the k_{cat}/K_m values rises from an approximate tenfold decrease in the K_m value relative to (2*R*,3*S*)-**4** (35 ± 4 mM).[9,11] It would be expected that the natural hexaketide intermediate, which is delivered to PICS module 6 as the corresponding acyl thioester bound to the ACP of PICS module 5, would have an even lower native K_m value.[18] Although both the KS6 or ACP6 domains have been reported to be essential for in vivo macrolactonization of the hexaketide produced by PICS module 5,[8] it is not clear whether the observed dominant macrolactonization of **5** by PICS module 6 + TE involves mandatory transfer to the TE domain by way of transient covalent attachment to either the KS6 or ACP6 domains. Irreversible formation of the acyl-KS species has been shown to be the sole determinant of the k_{cat}/K_m value for the processing of substrates by PKS modules.[19] The fact that the k_{cat}/K_m values measured for lactonization and for chain-elongation of **5** are different may suggest that these two reactions do not involve partitioning of a common hexaketide KS intermediate. Indeed, recombinant PICS TE alone catalyzes the efficient conversion of **5** into **1**.[13,14] Interestingly, the observed steady-state kinetic parameters for the conversion of **5** into **1** by PICS module 6 + TE in the absence of methylmalonyl CoA are effectively the same as those that we previously determined for the macrolactonization of **5** by recombinant PICS TE ($k_{cat} = 54.4 \pm 5.8$ min^{-1}, $K_m = 4.1 \pm 0.8$ mM, $k_{cat}/K_m = 221 \pm 50$ M^{-1} s^{-1}).[13] The k_{cat} value for the formation of **1** by PICS module 6 + TE in the absence of methylmalonyl CoA is larger than the combined k_{cat} value for both the lactonization and chain elongation by the PICS module 6 + TE in the presence of methylmalonyl CoA, thus suggesting that the presence of a methylmalonyl thioester attached to the ACP of module 6 may inhibit access of the hexaketide substrate to the active site of the downstream TE domain. Alternatively, it may reflect slower cyclization of the heptaketide substrate than of the hexaketide substrate by the TE domain.

The chain elongation/lactonization of **6** into **8** and **9** by PICS module 6 + TE also takes place at rates comparable to those observed for the processing of **5**, the analogue of the natural hexaketide substrate. Interestingly, although a mixture of isomeric lactones is observed, chain elongation appears to be diastereoselective. The formation of the two lactones from **6** is in contrast to the exclusive hydrolysis of the same substrate by recombinant PICS TE alone,[13,14] thus indicating that both the PICS KS6 domain and the TE domain can process reduced hexaketide and heptaketide subtrates, respectively.

In summary, we have shown that recombinant PICS module 6 + TE is capable of mediating both chain elongation and lactonization as well as competing lactonization or hydrolysis of both the natural hexaketide substrate **5** and the reduced 7-dihydro analogue **6** and have established the full set of steady-state kinetic parameters for both sets of reactions. The observed 4:1 ratio of lactonization to chain elongation for the processing of **5** may represent the intrinsic ratio of these two processes that leads to the characteristic formation of 12- and 14-membered-ring macrolides, thereby definitively excluding the necessity for N-terminal truncation

of PICS module 6 for formation of the hexaketide macrolactonization product 10-deoxymethynolide (**1**), as has been suggested at one time.[12]

Nickel-Catalyzed Oligomerization

DOI: 10.1002/anie.200502532

Ethylene Oligomerization at Coordinatively and Electronically Unsaturated Low-Valent Nickel**

*Zhiqiang Weng, Shihui Teo, Lip Lin Koh, and T. S. Andy Hor**

Research in nickel-catalyzed olefin oligomerization and polymerization continues to progress at an accelerating pace.[1] With the synthesis of new Ni^{II} catalysts that are highly tolerant towards polar substrates and are less oxophilic,[2] we are now able to target specific functional products. This advancement has brought along a host of new ligands, catalysts,[3] and mechanistic data.[4] It has also spilled over into scientific breakthroughs in new nickel chemistry, among which the recent isolation of low-valent coordinatively unsaturated Ni^{I} is particularly noteworthy.[5,6] This immediately gave rise to some pertinent questions, such as how Ni^{I} compares to the classical Ni^{II} and the sensitive Ni^{0} in catalytic performance or whether a coordinatively and electronically unsaturated Ni^{I} center might exhibit enhanced activity.

To address some of these questions, we need to design, prepare, and isolate close counterparts for direct structural and catalytic comparisons. We herein report our preliminary findings in using a ferrocenediyl iminophosphane supporting ligand. The flexibility of the ferrocenyl backbone,[7,8] coupled with the hemilability of the donors,[9] allows the metal to "pick and choose" its donors, and tune its receptivity to the substrates. It also raises our chances of isolating catalytically important intermediates for structural verification. The use of iminophosphanes as ligands for late transition metals for olefin polymerization has been demonstrated.[10]

$NiCl_2$(DME) (DME = dimethoxyethane) reacts with [{η-$C_5H_4CH{=}N(C_6H_5)$}Fe{η-$C_5H_4P(t\mathrm{Bu})_2$}] to give the Ni^{II} complex [{[η-$C_5H_4CH{=}N(C_6H_5)$]Fe[η-$C_5H_4P(t\mathrm{Bu})_2$]}$NiCl_2$] (**1**). Addition of one equivalent of MeLi to **1** in THF at −30 °C resulted in a one-electron reduction to [{[η-$C_5H_4CH{=}N(C_6H_5)$]Fe[η-$C_5H_4P(t\mathrm{Bu})_2$]}$Ni^{I}Cl$] (**2**; Scheme 1), with no evidence of methylnickel(I/II) products similar to the result from bis(imino)pyridylcobalt(II) with methylaluminoxane (MAO).[11] Ligand replacement of [$Ni(cod)_2$] (cod = 1,5-cyclooctadiene) with [{η-$C_5H_4CH{=}N(C_6H_5)$}Fe{η-

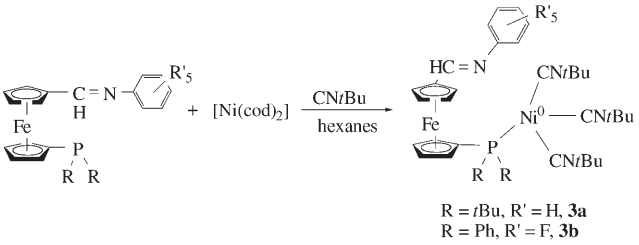
$C_5H_4P(tBu)_2$}] and [{η-$C_5H_4CH{=}N(C_6F_5)$}Fe{η-$C_5H_4PPh_2$}], in the presence of CN*t*Bu in hexane, yields dark-red solids of [{[η-$C_5H_4CH{=}N(C_6H_5)$]Fe[η-$C_5H_4P(tBu)_2$]}$Ni^0(CNtBu)_3$] (**3a**) and [{[$C_5H_4CH{=}N(C_6F_5)$]Fe[η-$C_5H_4PPh_2$]}$Ni^0(CNtBu)_3$] (**3b**), respectively (Scheme 2). All the products were isolated and characterized spectroscopically.



Scheme 2.

Single-crystal X-ray diffraction[12] revealed that **2** crystallizes with two independent molecules (A and B) per unit cell (molecule A is shown in Figure 1). It shows a trigonal planar (mean plane deviation 0.0045 Å) Ni^I center with three heteroatom donors, namely N, P, and Cl. There is no evidence of significant intermolecular contacts. This 15-electron, three-coordinate Ni^I is thus an unusual coordinatively exposed and electronically unsaturated paramagnetic complex. Despite the apparent electronic deficiency and coordinative exposure, there is no evidence of any electron donation by obvious means, such as dimerization, hydride formation, agostic Ni···H (Fc or Bu) interactions, π–imine coordination, or Fe→Ni dative bonding. This type of low-coordinate, low-valent Ni^I complex is rare but not unprecedented (e.g. β-diketiminatonickel(I)[5] and diphosphane-supported alkylnickel(I) complexes[6]). The Ni–N bond length (1.995(2) Å) is between that to Ni^I (1.876(1) Å)[5a] and the iminophosphanenickel(II) (2.043(6) Å),[10c] whereas the Ni–P bond (2.2251(8) Å) is also intermediate between the P,N-bound Ni^0 complex [$(iPr)_2PCH_2CH_2NMe_2$)Ni(PhC≡CPh)] (2.1565(10) Å)[13] and a Ni^{II} complex (2.338(2) Å).[10c] The Ni–Cl bond (2.1929(9) Å) is similar to those in a P,N-chelating tetrahedral Ni^{II} complex (2.191(1) and

opts for the stronger π-accepting environment provided by isonitrile, especially in its angular mode [C(23)–N(2)–C(24) = 148.7(4)°]. This is facilitated by the lability of the imine donor and the ability of the ferrocenyl ligand to sustain a unidentate mode with a dangling functional entity. The Ni–P bond (2.2001(10) Å) is slightly shorter than that of **2** (2.2251(8) Å). The Ni–C bond of bent isocyanide (1.821(4) Å) is slightly stronger than that of the other two Ni–C bonds (1.843(4) and 1.842(4) Å), with the latter being similar to that of the ethylene polymerization active Ni^{II}–isocyanide complex $[NiBr_2(CNAr)_2]$ (1.846(2) Å)[15] and the Ni^0–isocyanide complex $[Ni(C_6H_5N{=}NC_6H_5)(CN\textit{t}Bu)_2]$ (1.841(5) Å).[16]

Isolation of **1**–**3** pointed to some valuable features of iminophosphane as a ligand. It supports a metal (Ni) in its normal, intermediate, and low valency, it is sensitive to the coordinative change of the metal, and it uses its hemilability to adjust the electronic donation. These are essential qualities that could raise the catalytic performance and enable us to isolate catalytically important intermediates. It also enables us to directly compare the activity of Ni^{II}, Ni^{I}, and Ni^0 in ethylene oligomerization through the use of **1**, **2**, **3a**, and **3b**. Some preliminary results under ambient conditions are summarized in Table 1. Using MAO as the cocatalyst with an Al/Ni ratio of 1000, the ethylene oligomerization activity (TOF) decreases in the order $\mathbf{2} \gg \mathbf{3a} > \mathbf{1}$ which reflects the activity order of $Ni^{I} \gg Ni^0 > Ni^{II}$ (entries 1–3). The 1-butene selectivity for Ni^{II} is, however, higher. All of them give insignificant amounts of high molecular weight polymeric products. We should add, however, that the electronic effect of the iminophosphane ligand could override the metal effect. This is best exemplified in the higher TOF of **3b** (75000), which contains a pentafluorophenyl imine and phenylphosphane, compared to **3a** (10667) (entries 3 and 4, respectively). These residues raise the electrophilicity of the central metal, thus promoting substrate attack.[17]

We have also studied the effect of cocatalyst, temperature, and pressure using **3b** as the catalyst. $EtAlCl_2$ performs better than MAO (entries 5–8), possibly due to facile formation of alkylnickel species in situ, which leads to active nickel hydrides by β-elimination, consistent with the observations of Braunstein and co-workers.[14] A TOF of 119400 (entry 6) is achieved at 30 °C. There is no clear advantage from using a higher temperature (compare entries 5 and 7) or pressure (compare entries 6 and 8). The oligomerization performance depends more on catalyst design and cocatalyst support. With a metal that can attract ethylene efficiently and promote detachment through a β-hydride elimination, one would expect a good yield at ambient conditions with reasonable selectivity. Complex **2** and the reported $(N,N)Ni^{I}$ complex[5c] are both three-coordinate but they present two different assemblies in catalyst design, namely, the use of an anionic chelating ligand (diketiminato) with a terminal neutral ligand (phosphane) and a neutral ferrocenediyl iminophosphane with an anionic halide. The former relies on the lability of the phosphane, whereas the latter relies on anion (e.g. Cl→R, to give alkylnickel(I) species[6a]) or hydride exchange (Cl→H) for activation.

Complex **1** (Ni^{II}) would not survive under the reducing (and basic) conditions generated by excess MeLi. Could it, however, be active and persistent in a catalytic mixture that contains $AlMe_3$ or MAO? Experiments on the reaction of **1** with two equivalents of $AlMe_3$ or MAO at room temperature led to the isolation of the Ni^{I} complex $[\{[\eta\text{-}C_5H_4CH{=}N\text{-}(C_6H_5)]Fe[\eta\text{-}C_5H_4P(\textit{t}Bu)_2]\text{-}\textit{CN},\textit{P}\}Ni^{I}Cl]$ (**4**) (Scheme 1), which can also be independently prepared from **2** and $AlMe_3$ or MAO (1:2). Single-crystal X-ray diffraction analysis[12] revealed that **4** is related to **2** but, significantly, coordination at the N site has slipped to C=N, thus activating the π functionality, while maintaining a planar Ni^{I} (mean plane deviation 0.0147 Å; Figure 3). This lengthens and weakens the C–N bond from 1.288(3) in **2** to 1.435(9) Å in **4**. Accordingly, the Ni–P bond is shorter and presumably stronger (2.169(2) Å) than that in **2** (2.2251(8) Å), while the Ni–Cl bond is correspondingly weaker (2.231(2) Å) than that in **2** (2.1929(9) Å). The fragility of the Ni–Cl bond and the strengthening of the other protective ligands appear to support and "prepare" the metal for its catalytic function. Oligomerization experiments using **4** as the catalyst demonstrate that it is active. Upon activation with excess MAO (1000-fold), it gives a TOF of 14666 in ethylene oligomerization.

We have shown that a hemilabile iminophosphanylferrocene ligand can stabilize catalytically active low-valent nickel and the resulting complexes can be used directly to catalyze ethylene oligomerization. This highlights the potential use of Ni^0 and Ni^{I} rather than the more popular Ni^{II} in similar catalysis.[18] In Ziegler–Natta-type polymerization, the cata-

lytically active species is widely believed to be a cationic alkyl–metal complex L_nMR^+.[19] Olefin oligomerization by Ni^{II} is also widely acknowledged to proceed via L_nNiR^+, which readily gives $L_nNi^{II}(H)(alkene)^+$ as a key intermediate.[20] Use of Ni^I complexes, such as **2** and **4**, or Ni^0 complexes, such as **3a** and **3b**, suggests that we can enter the catalytic cycle with non-alkyls and electronically neutral species. The key here is the use of a coordinatively exposed metal in a low oxidation state and a hemilabile ligand. These are features that are usually advantageous to catalytic pathways, such as Suzuki coupling, that hinge on the complementary oxidative addition and reductive elimination, but not olefin oligomerization. They offer new opportunities in catalyst design for polymerization, but they also pose some pertinent questions. For example, does this necessarily require a different mechanistic pathway? Do Ni^I and Ni^0 offer a better prospect in olefin oligomerization? Does the use of mononuclear paramagnetic Ni^I necessarily demand a free radical pathway, such as the one shown in other four-coordinate Ni^I complexes?[21] Our ongoing experiments are driven by these curiosities.

Asymmetric Hydrogenations

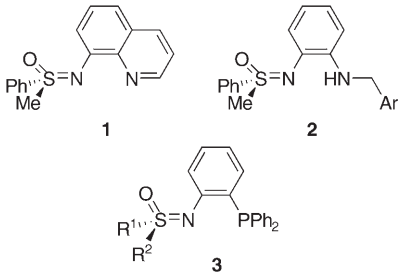
DOI: 10.1002/anie.200502482

Diphenylphosphanylsulfoximines as Ligands in Iridium-Catalyzed Asymmetric Imine Hydrogenations**

*Christian Moessner and Carsten Bolm**

Chiral amines are ubiquitous in natural products and drugs, and their synthesis by asymmetric hydrogenation of carbon–nitrogen double bonds has attracted much attention.[1] However, the search for and development of efficient catalysts for enantioselective C–N double bond hydrogenations with high enantioselectivity at a reasonable catalyst loading proved much more difficult than for the reduction of C=C and C=O groups.[2–5] Furthermore, most of those catalysts are only suitable for asymmetric hydrogenations of cyclic substrates, whereas acyclic imines still represent challenging compounds.[6] In this case, one of the major problems for achieving a high enantiomeric excess is the equilibrium between the *E* and *Z* isomer of the imine,[7] which makes it difficult for the catalyst to convert all stereoisomers in a uniform and selective manner. Consequently, the first successful chiral catalysts for this important transformation have only recently been described. Among them, homogenous Ir complexes with chiral P,P- or P,N-ligands, which are structurally analogous to Crabtree's catalyst,[8] have attracted particular attention. For example, Zhang and co-workers reported enantioselective hydrogenations of *N*-aryl imines (with up to >99% *ee*) by applying an iridium catalyst bearing a chiral 1,1′-bisphosphanylferrocene (f-binaphane).[9] Phosphanyloxazoline complexes with noncoordinating anions have been used by several group to afford products with up to 90% *ee*.[10] Industrially relevant in this context is the asymmetric hydrogenation of an acyclic *N*-aryl imine as key step in the synthesis of the herbicide (*S*)-metolachlor by Syngenta.[11] Although only moderate enantioselectivities are achieved, the exceptionally high turnover numbers (TON) and turnover frequencies (TOF) of the iridium-ferrocenylphosphine catalyst allowed this imine reduction to become one of the largest catalytic enantioselective industrial processes to date.

Chiral sulfoximines are versatile ligands for asymmetric catalysis,[12] and highly enantioselective hetero-Diels–Alder reactions,[13] Mukaiyama-type aldol,[14] and carbonyl-ene reactions[15] with sulfoximine-based catalysts have recently been described. In all these catalytic reactions, dinitrogen chelates such as **1** or **2** with sulfoximine units linked to quinoline or aniline moieties were applied. We thus focused our attention on the synthesis and use of phosphine-substituted sulfoximines **3**, which on the basis of conclusions from solution and solid-state studies[13c,16] were expected to be good metal binders through their P and N donor sites.



For the preparation of diphenylphosphanyl sulfoximines **3**, phosphine oxide **4**, which can be obtained by palladium-catalyzed cross-coupling of 2-bromo-1-iodobenzene with diphenylphosphane, served as starting material.[17] Application of the newly developed copper-mediated *N*-arylation reaction[18] afforded products **6a–f** from **4** and sulfoximines **5a–f**, respectively, in moderate to good yields (Scheme 1). Reductive deoxygenation of **6** with trichlorosilane gave diphenylphosphanylsulfoximines **3** as solid, air-stable products in 55–81% yield.

Guided by the successful applications of other P,N-ligands as effective hydrogenation catalysts,[3–5,19] the novel sulfoximine derivatives **3** were tested in Ir-catalyzed asymmetric imine hydrogenations. For the initial screening and optimizing process, acetophenone-derived imine **7a** was selected as substrate. To our delight we found that the catalyst generated by mixing [{Ir(cod)Cl}$_2$] (0.5 mol%) with sulfoximine **3a** (1.1 mol%) followed by the addition of iodine (2.0 mol%) led to full conversion of **7a** under H_2 into **8a** with rather encouraging 79% *ee* (Scheme 2).

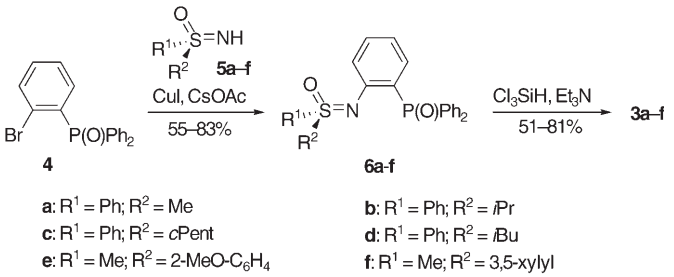
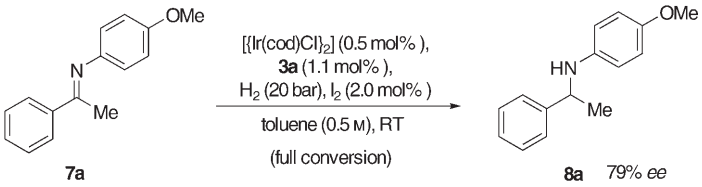
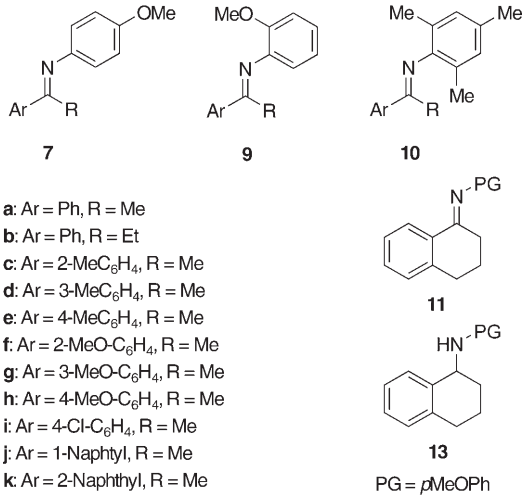


Scheme 1. Synthesis of the diphenylphosphanylsulfoximines **3**.



Scheme 2. Ir-catalyzed asymmetric imine hydrogenation.

Subsequent experiments revealed that no reaction occurred in the absence of iodine, which indicated that the Ir^I complex formed in situ was only a precatalyst, which most likely was further oxidized by iodine.[20] Hydrogenations of analogous substrates showed that the aryl group on the imine nitrogen atom had a strong effect on the reactivity and selectivity of the catalyst. The best result was achieved with the imine bearing the *N*-(*p*-methoxy)phenyl (PMP) group, which can easily be removed by oxidative methods. Use of the *N*-(*o*-methoxy)phenyl-protected substrate **9a** led to lower reactivity and enantioselectivity (58% *ee* after 20 h). No reaction occurred with imine **10a** bearing the *N*-mesityl group.



Next, the influence of the ligand structure on the catalyst performance in the test reaction depicted in Scheme 2 was studied. Increasing the steric bulk of the alkyl substituent of the sulfoximine α to the sulfur atom drastically lowered both the activity and the enantioselectivity of the resulting catalysts. Thus, use of **3b** and **3c** bearing *S*-isopropyl or *S*-cyclopentyl groups resulted in low conversions of **7a** (<40%), even after extended reaction times, to give **8a** with 66 and 10% *ee*, respectively (Table 1, entries 2 and 3). Surprisingly, however, the effect of branching at the β position of the sulfoximine alkyl group was opposite, and the catalyst efficiency increased remarkably! Thus, with isobutyl-substituted sulfoximine **3d** an excellent conversion of **7a** was achieved after only 4 h, and the enantioselectivity of the resulting amine **8a** reached an unprecedented 96% *ee* (Table 1, entry 4). Sulfoximines **3e** and **3f**, which have modified *S*-aryl groups, led to active catalysts as well (99% conversion after 12 h; Table 1, entries 5 and 6), but in these cases the enantioselectivities were lower (50 and 88% *ee*, respectively) than those attained with **3d**.

As the Ir catalyst with sulfoximine ligand **3d** performed exceptional well in the test reaction (Scheme 2), we briefly studied its catalytic behavior under modified reaction conditions. A decrease in the catalyst loading to 0.5 mol% did not result in any change in the enantioselectivity. With 0.1 mol% of catalyst, the hydrogen pressure had to be increased to 50 bar to achieve full conversion.[21] Toluene was the solvent of choice, and lowering the reaction temperature led to a slight increase in enantioselectivity (97% *ee* at 0°C).[22]

Table 1: Influence of the ligand structure on the asymmetric hydrogenation of imine **7a**.[a]

Entry	Sulfoximine	*t* [h]	Conv. [%][b]	*ee* [%][c]
1	(*S*)-**3a**	4	99	79 (−)
2	(*S*)-**3b**	8	40	66 (−)
3	(*S*)-**3c**	20	<20	10 (−)
4	(*S*)-**3d**	4	99	96 (−)
5	(*R*)-**3e**	12	99	50 (+)
6	(*R*)-**3f**	12	99	88 (+)

[a] Reaction conditions: imine **7a** (0.5 mmol), [{Ir(cod)Cl}$_2$] (0.0025 mmol), sulfoximine **3** (0.0055 mmol), iodine (0.01 mmol), H_2 (20 bar), toluene (0.5 M), room temperature. [b] Determined by ^{1}H NMR spectroscopy. [c] The enantiomer ratios were determined by HPLC by using a column with a chiral stationary phase (Chiralcel OD-H). The direction of the optical rotation of **8a** is given in parenthesis.

To explore the scope of the Ir-catalyzed asymmetric hydrogenation with the catalyst based on sulfoximine **3d**, a series of imines with 4-methoxyphenyl groups on the imine nitrogen atom were reduced under the optimized reaction conditions (Table 2).

The data can be summarized as follows: Substrates with *meta*- or *para*-substituents on the arene (e.g. **7d**, **7e**, **7g–i**) reacted equally well as unsubstituted **7a** to afford the corresponding aryl-protected amines with enantioselectivities in the range 93–96% *ee* (Table 2, entries 4, 5, 7–9). Although *ortho*-substituted imines **7c**, **7f**, and **7j** were applied as mixtures of double-bond isomers, they also gave products with excellent enantioselectivities (90–98% *ee*; Table 2, entries 3, 6, and 10). Imine **7b**, which was derived from propiophenone (and isolated as a 7:1 mixture of *E*/*Z* isomers),

[a] Reaction conditions: imine **7** (0.5 mmol), $[\{Ir(cod)Cl\}_2]$ (0.0025 mmol), sulfoximine **3d** (0.0055 mmol), iodine (0.01 mmol), H_2 (20 bar), toluene (0.5 M), room temperature. In all cases, full conversion was achieved. [b] The enantiomer ratios were determined by HPLC using a column with a chiral stationary phase (Chiralcel OD-H). The directions of the optical rotations of amines **8** are given in parentheses. [c] Mixture of isomers; for details see the Supporting Information.

was hydrogenated to the corresponding amine with 92% *ee* (Table 2, entry 2). Interestingly, the two isomeric naphthyl-substituted imines **7j** and **7k** afforded products with very different enantiomeric excesses. Whereas the first led to the corresponding amine with 98% *ee*, the latter gave the product with only 69% *ee* (Table 2, entries 10 and 11). Even when the alkyl group was incorporated into a cyclic structure, a high enantioselectivity was attained, as illustrated by the asymmetric hydrogenation of tetralone-derived imine **11** (91% *ee*; Table 2, entry 13). Also with the catalyst bearing sulfoximine **3d** as ligand, switching the substituent at the imine nitrogen atom from the *para*- to the *ortho*-substituted arene led to a significant lower enantioselectivity (Table 2, entry 12).

In conclusion, we introduced a novel class of C_1-symmetric sulfoximines, which can effectively be used in Ir-catalyzed asymmetric hydrogenations of acyclic *N*-aryl imines. Under optimized reaction conditions, high enantioselectivities and reaction rates have been attained for a variety of *N*-(4-methoxy)phenyl imines. Currently, the application of these novel sulfoximines in other catalytic asymmetric processes is under investigation.

Experimental Section

3d: In an oven-dried Schlenk flask under an argon atmosphere sulfoximine **6d** (446 mg, 0.94 mmol) was dissolved in toluene (3 mL). The solution was cooled to 0 °C, and NEt_3 (655 μL, 4.70 mmol) and trichlorosilane (470 μL, 4.70 mmol) were added. The heterogenous mixture was stirred for 12 h at 105 °C. The reaction mixture was then cooled to room temperature, and degassed water (3 mL) was added. The solid was filtered through a small plug of celite and thoroughly rinsed with ethyl acetate. The organic phase was dried ($MgSO_4$) and evaporated to dryness. The pure product was obtained as a colorless solid (344 mg, 81%) after flash chromatography (SiO_2; pentane/acetone 10:1). For analytical data, see the Supporting Information.

General procedure: Under an argon atmosphere $[\{Ir(cod)Cl\}_2]$ (1.7 mg, 0.0025 mmol) and sulfoximine **3d** (2.5 mg, 0.0055 mmol) were placed in a 10-mL test tube equipped with a stirrer bar. After the addition of dry toluene (0.5 mL), the yellow solution was stirred for 30 min. Iodine (2.5 mg, 0.010 mmol) was then added, and the solution turned red within 30 min. To this catalyst solution was added the imine (0.5 mmol) and additional toluene (0.5 mL). The test tube was placed in an argon-filled steel autoclave, which was purged three times with hydrogen (5 bar) and finally pressurized to 20 bar. The reaction mixture was stirred for the indicated period of time. Then, the hydrogen gas was released and the reaction quenched by addition of pentane (3 mL). The product was filtered through a short plug of silica (3 cm) and eluted with pentane/acetone (20:1).

The conversions were determined by ^1H NMR spectroscopy, and the enantiomer ratio analyzed with analytical HPLC by using chiral columns. For details, see the Supporting Information.

S-Heterocyclic Carbene with a Disilane Backbone**

Hidefumi Nikawa, Tsukasa Nakahodo, Takahiro Tsuchiya, Takatsugu Wakahara, G. M. Aminur Rahman, Takeshi Akasaka, Yutaka Maeda, Michael T. H. Liu, Akira Meguro, Soichiro Kyushin, Hideyuki Matsumoto,* Naomi Mizorogi, and Shigeru Nagase**

Recently, Wiberg and co-workers reported the preparation of tetrathiofulvalene (TTF) analogue **1** with a disilane backbone (see Scheme 1), obtained from the reaction of the isolable disilene **2** with carbon disulfide.[1] Compound **1**, with a Si–Si bond instead of a C=C bond in the TTF ring, may be potentially useful as a new electron donor because of the intriguing electronic properties of the silicon σ-conjugate system (Si–Si), which resembles the carbon π-conjugate system (C=C). Apparently, **1** was formed by the dimerization of the S-heterocyclic carbene (SHC) **3** as the proposed

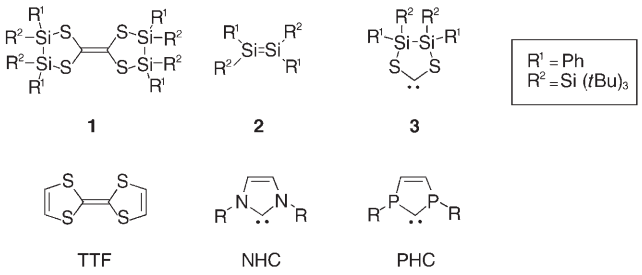

Scheme 1. TTF analogue **1** and S-heterocyclic carbene **3** with a disilane backbone.

intermediate. Meanwhile, since the discovery of the first stable carbenes by Arduengo and co-workers,[2] heterocyclic carbenes have attracted special attention as ligands, catalysts, and spin sources because of their unique coordination properties based on good σ-donor and poor π-acceptor properties.[3] A large variety of stable N-heterocyclic carbenes (NHC) have been reported so far which have various substitution patterns,[4] ring sizes that vary from four to six,[5] and inorganic backbones;[6] furthermore, a P-heterocyclic carbene (PHC) has also been reported.[7] To the best of our knowledge, only theoretical investigations into the formation of SHCs by a [2+3] cycloaddition of an alkyne with CS_2 and subsequent dimerization have been reported.[8] In this context, the generation of a carbene by the reaction of disilene with CS_2 would be a new synthetic approach to SHCs. The reactivity of a SHC with a disilane backbone and the properties of a TTF analogue with a disilane backbone prompted us to investigate the reaction of the disilene with CS_2. We have reported the photochemical generation of cyclotetrasilene **4** (see Scheme 2), which has a higher reactivity than **2**,[9] and the use of C_{60} as a probe, which is a nonspectroscopic method to confirm the formation of a carbene.[10,11] We report herein the generation of SHC **6** with a cyclotetrasilane backbone by a [2+3] cycloaddition of cyclotetrasilene, prepared by the photolysis of *anti*-dodecaisopropyltricyclo[4.2.0.0^{2,5}]octasilane[12] (**5**), with CS_2. Carbene **6** then reacts with C_{60} to result in the formation of methanofullerene **7** (Scheme 2).

Irradiation of a solution of *anti*-dodecaisopropyltricyclo[4.2.0.0^{2,5}]octasilane **5** in toluene in the presence of C_{60} and CS_2 in a degassed sealed tube at room temperature using a high-pressure mercury arc lamp resulted in the formation of the corresponding adduct $C_{60}(C_{19}H_{42}S_2Si_4)$ (**7**) in 20% yield. Compound **7** was then purified by preparative HPLC. The MALDI-TOF mass spectrum of **7** exhibits a molecular ion peak at *m*/*z* 1172–1166 and a peak at *m*/*z* 723–720 (C_{60}) because of the loss of the substituent $C_{19}H_{42}S_2Si_4$ (**8**). The UV/Vis absorption peak of **7** appears at 433 nm, which is indicative of the formation of a 6,6-adduct of C_{60}.[13]

The ^{13}C NMR spectrum of **7** shows 32 signals for the C_{60} cage, of which four peaks are at half intensity and 28 peaks are at full intensity. These results are consistent with the appropriate number and ratio of peak intensities for the C_{60} adduct with C_s symmetry. The signals at $\delta = 83.36$ and 80.63 ppm, assigned to the sp^3 carbon atom on the fullerene cage, indicate a methanofullerene structure.[13] The signal at $\delta = 58.54$ ppm is assigned to the sp^3 carbon atom on the spiro ring system. The carbon atoms in the isopropyl group on cyclotetrasilane may be observed at $\delta = 23$–14 ppm. The ^{29}Si NMR spectrum of **7** shows two signals at $\delta = 20.36$ and 0.31 ppm.

X-ray crystallographic analysis[14] unambiguously confirms the structure of **7** (Figure 1) as having a *cis*-fused bicyclic structure and a spiro ring system, which has C_1 symmetry in the crystalline state. The dithiadisilolane ring possesses a half-chair structure, and the cyclotetrasilane ring has a moderately holded structure with hold angles of 18.9 and 19.2°. (The Si–Si bond lengths range from 2.358(3) to 2.407(3) Å with an average of 2.378 Å.) As the Si(3)–Si(4) bond is within the bicycle ring, its length (2.358(3) Å) is the shortest among the others (2.362(3)–2.407(3) Å). The

Si-Si-Si bond angles of the {Si_4} rings range from 88.2(11) to 90.8(11)°, with an average of 89.2°.

Table 1 shows the redox potentials of **7** and C_{60},[15] together with the 6,6-adduct of C_{60}-adamantylidene (6,6-C_{60}-Ad)[10] as a reference compound. Compound **7** exhibits three

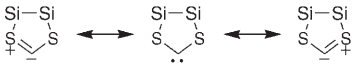
Table 1: Redox potentials[a] (V) of $C_{60}(C_{42}H_{18}Si_4)$, 6,6-C_{60}-Ad,[10] and C_{60}[15].

Compound	oxE_1	redE_1	redE_2	redE_3
$C_{60}(C_{42}H_{18}Si_4)$	+1.04[d,e]	−1.16	−1.52	−2.01
6,6-C_{60}-Ad	+1.07[d,e]	−1.21	−1.58	−2.06
C_{60}	+1.21[d,e]	−1.12	−1.50	−1.95

[a] Versus Fc/Fc^+ in 1,2-dichlorobenzene with 0.1 M $(n\text{Bu})_4NPF_6$ at a Pt working electrode; scan rate = 20 mV s^{-1}. [b] Irreversible. [c] Values were obtained by differential pulse voltammetry: pulse amplitude = 50 mV; scan rate 20 mV s^{-1}.

one-electron reversible reduction waves and one irreversible oxidation wave, as observed for C_{60} and 6,6-C_{60}-Ad. The salient feature is that the redox potentials of **7** are cathodically shifted, thus indicating that the introduction of substituent **8** results in a decrease in the electron-acceptor property.

To characterize carbene **6**, generated by a [2+3] cycloaddition of cyclotetrasilene with CS_2, theoretical calculations were carried out.[16] The singlet state of **6** was calculated to be 23.4 kcal mol^{-1} more stable than the triplet state. The dithiadisilolane ring of **6** in the singlet state has an envelope structure with a dihedral angle of 1.6°, and the cyclotetrasilane ring has a moderately holded structure with hold angles of 8.8 and 8.9°. The carbon–sulfur bond lengths are 1.678 and 1.679 Å, which are considerably shorter than typical C–S single bond lengths (1.758–1.854 Å).[17] These bond lengths are ascribed to the conjugative donation of the lone-pair electrons on the sulfur atoms into the vacant p_π orbital at the carbene center (Scheme 3). Because of its dipolar character, **6** has a high nucleophilicity; therefore, it is not surprising that **6** reacts readily with the electrophilic C_{60}, as in the reaction of the dimethoxy carbene[18] and C_{60}.[19]



Scheme 3. Resonance structure of S-heterocyclic carbene **6**.

We have demonstrated that carbene **6** can be generated by the [2+3] cycloaddition of cyclotetrasilene **4** with CS_2 by trapping **6** with C_{60} as a chemical probe. NMR spectroscopic measurements and X-ray crystallographic analysis verify that **7** is a methanofullerene (a 6,6-adduct of C_{60}). Theoretical calculations show that **6** has a high nucleophilicity in the singlet ground state. This method to generate SHC **6** may be applied to prepare novel compounds, such as TTF analogue **1**.

Experimental Section

Irradiation of a solution of *anti*-dodecaisopropyltricyclo[4.2.0.$0^{2,5}$]octasilane (**5**; 5.1 mg, 6.9×10^{-3} mmol) in toluene in the presence of C_{60} (5.0 mg, 6.9×10^{-3} mmol) and CS_2 (0.4 mL, 6.9×10^{-3} mol) in a degassed sealed tube at room temperature using a high-pressure mercury arc lamp (cut off < 300 nm) resulted in the formation of the adduct $C_{60}(C_{20}H_{42}Si_4S_2)$ (**7**) as a dark-brown solid in 20% yield, which was purified by preparative HPLC with a Buckyprep column (ϕ20 × 250 mm; Cosmosil, Nacalai Tesque Inc.). A MALDI-TOF mass spectrum was measured on a BIFLEX III (Bruker, Germany) with 1,1,4,4-tetraphenyl-1,3-butadiene as a matrix. UV/Vis–NIR spectra were measured on a UV 3150 instrument (Shimadzu, Japan) in toluene. ^1H, ^{13}C, and ^{29}Si NMR and 2D NMR (HMQC and HMBC) spectra were recorded on Bruker AVANCE 500 spectrometer with a CryoProbe system and Bruker AVANCE 300 spectrometer in CS_2 and $CDCl_3$ (3:1). Cyclic voltammograms were measured on a potentiostat/galvanostat (BAS CW-50) in *o*-dichlorobenzene with 0.1 M $(n\text{Bu})_4NPF_6$ at a Pt working electrode.

Spectra data of **7**: ^1H NMR (500 MHz Cyroprobe, $CS_2/CDCl_3$ (3:1), 20 °C) δ = (sep, J = 7.4 Hz, 2H; CH), 1.75 (sep, J = 7.5 Hz, 2H; CH), 1.69 (sep, 2H, J = 7.4 Hz, 2H; CH), 1.38 (d, J = 7.3 Hz, 6H; CH_3), 1.36 (d, J = 7.4 Hz, 12H; CH_3), 1.35 (d, J = 7.4 Hz, 12H; CH_3), 1.31 ppm (d, J = 7.5 Hz, 6H; CH_3); ^{13}C NMR (125 MHz Cyroprobe, $CS_2/CDCl_3$ (3:1), 20 °C) δ = 148.2 (s, 2C; C_{60}), 147.6 (s, 2C; C_{60}), 145.3 (s, 2C; C_{60}), 144.9 (s, 2C; C_{60}), 144.9 (s, 2C; C_{60}), 144.8 (s, 2C; C_{60}), 144.8 (s, 2C; C_{60}), 144.7 (s, 2C; C_{60}), 144.5 (s, 2C; C_{60}), 144.4 (s, 4C; C_{60}), 144.3 (s, 1C; C_{60}), 144.3 (s, 1C; C_{60}), 144.2 (s, 2C; C_{60}), 143.8 (s, 2C; C_{60}), 143.6 (s, 4C; C_{60}), 142.9 (s, 2C; C_{60}), 142.8 (s, 2C; C_{60}), 142.7 (s, 2C; C_{60}), 142.7 (s, 2C; C_{60}), 142.6 (s, 2C; C_{60}), 141.9 (s, 4C; C_{60}), 141.9 (s, 4C; C_{60}), 140.6 (s, 4C; C_{60}), 138.5 (s, 2C; C_{60}), 138.3 (s, 2C; C_{60}), 83.3 (s, 1C; CC_{spiro}), 80.6 (s, 1C; CC_{spiro}), 58.5 (s, 1C; C_{spiro}), 22.4 (q, 3C; CH_3), 22.2(q, 3C; CH_3), 22.2(q, 3C; CH_3), 21.2 (q, 3C; CH_3), 21.1 (q, 3C; CH_3), 20.7 (q, 3C; CH_3), 17.0 (d, 3C; CH), 15.4 (d, 3C; CH), 14.5 ppm (d, 3C; CH); ^{29}Si NMR (59.6 MHz, $CS_2/CDCl_3$ (3:1), 20 °C) δ = 20.4, 0.3 ppm; MALDI-TOF mass (negative mode, matrix: 1,1,4,4-tetraphenyl-1,3-butadiene): *m/z* 1166(M), 720(C_{60}); MALDI-TOF mass (positive mode, matrix: 1,1,4,4-tetraphenyl-1,3-butadiene): *m/z* 1166[*M*], 1123; UV/Vis–NIR (toluene) $\lambda_{max}(\varepsilon)$ 694 (190), 478 (1400), 433 (2100), 330 (35000) cm^{-1}.

Stereoselective Palladium-Catalyzed Four-Component Cascade Synthesis of Pyrrolidinyl-, Pyrazolidinyl-, and Isoxazolidinyl Isoquinolines**

H. Ali Dondas, Colin W. G. Fishwick, Xinjie Gai, Ronald Grigg, Colin Kilner, Nuethip Dumrongchai, Boonsong Kongkathip, Ngampong Kongkathip, Chatchwan Polysuk, and Visuvanathar Sridharan*

One-pot multicomponent reactions (MCRs) provide a rapid and elegant means for the preparation of complex molecular architectures from readily available building blocks.[1–5] Among the advantages of MCRs are yields that are higher than almost any sequential synthesis of the same target, a single purification step, and easy adaptation to combinatorial synthesis.

In recent years, allenes have become useful building blocks in palladium catalyzed processes.[6,7] We have demonstrated that carbon monoxide and allenes are powerful relay switches in palladium-catalyzed cyclization–anion-capture

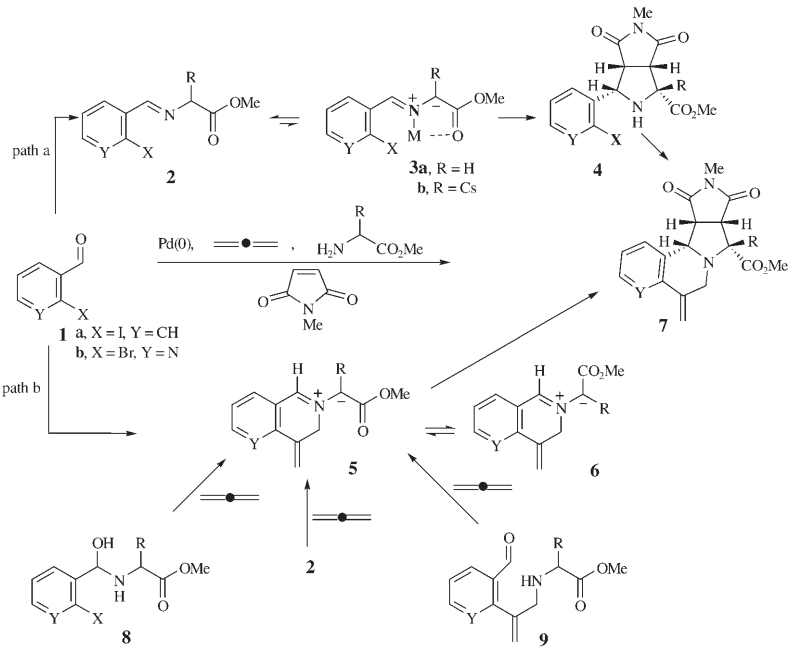
cascades.[1,6,7] As part of our ongoing interest in the design of palladium-catalyzed allenylation processes in a tactical combination with core reactions, we have explored combinations that have 1,3-dipolar cycloaddition processes as the key step in the synthesis of heterocycles.[8] Herein we report four-component cascades with 2-iodoaryl aldehyde **1a** or 2-bromoaryl aldehyde **2b** (Scheme 1) that generate azomethine ylides, azomethine imines, and nitrones as integral parts of the cascade.

Aldehydes **1a** and **b** react, through path a or path b, with an allene, an α-amino acid methyl ester, and *N*-methyl maleimide (NMM) in the presence of Pd^0 to afford **7** (Scheme 1). Path a involves the formation of imine **2**, which undergoes 1,3-dipolar cycloaddition via azomethine ylide **3a** or **3b** (*endo* transition state) to give **4**.[9] Successive palladium-catalyzed allene/nucleophile incorporations then afford **7**. Path b proceeds by initial palladium-catalyzed allene/nucleophile incorporation to generate azomethine ylide **5**, which then undergoes 1,3-dipolar cycloaddition to afford **7**. Azomethine ylide **5** could arise through the precursors **2**, **8**, or **9**.

Our hope was that, if successful, the configuration of the product could be used to distinguish between paths a and b (Scheme 1) as the cycloaddition of *N*-alkylated azomethine ylides **5**/**6** has a different stereochemical outcome to those of **3a**/**3b**.[9]

2-Iodoaldehyde **1a** or 2-bromoaldehyde **1b** (1 mmol) were treated with allene (1 bar), alanine methyl ester hydrochloride (1.2 mmol), NMM (1 mmol), $[Pd_2(dba)_3]$ (2.5 mol%), tris(2-furyl)phosphane (TFP) (10 mol%), and Cs_2CO_3 (4 equiv) in toluene at 100°C for 24 h (48 h for **1b**) to afford **10a** and **10b** in 69% and 57% yield, respectively (Table 1, entry 1). The configuration of **10a**, **b** was established by NOE studies. Phenylalanine methyl ester, aspartic acid



Scheme 1. Four-component cascade that begins with 2-iodoaryl aldehyde **1a** or 2-bromoaryl aldehyde **2b** and generates azomethine ylides, azomethine imines, and nitrones as integral parts of the cascade.

Entry	α Amino acid methyl ester	*t* [h]	Product	Yield [%]
1		24	 **10a,b**	69 (**10a**, Y = CH) 57[b] (**10b**, Y = N)
2		24	 **11a,b**	54 (**11a** Y = CH) 59[b] (**11a**, Y = N)
3		24	 **12**	57
4		24	 **13**	57
5		24	 **15** 1.0  **14** 3.5	64
6		24	 **16** : **17** 1 : 1	53

[a] All reactions were carried out in toluene at 100°C. [b] Reaction time 48 h.

methyl ester, and methionine methyl ester were successfully employed in the cascade reaction to give **11**–**13** in 54–57% yield (Table 1, entries 2–4). Interestingly phenylglycine methyl ester, under the same conditions, afforded **14**/**15** as a 3.5:1 mixture in 64% yield (Table 1, entry 5). The configuration of **14** and **15** was established by NOE studies and, in the case of the major isomer **15**, by an X-ray crystal structure (Figure 1). When the reaction was carried out at 100°C for 12 h, the crude product comprised a 12:12:1 mixture of cycloadducts **4** (R = Ph, X = I, Y = CH), **14**, and **15**. This indicates that **15** might

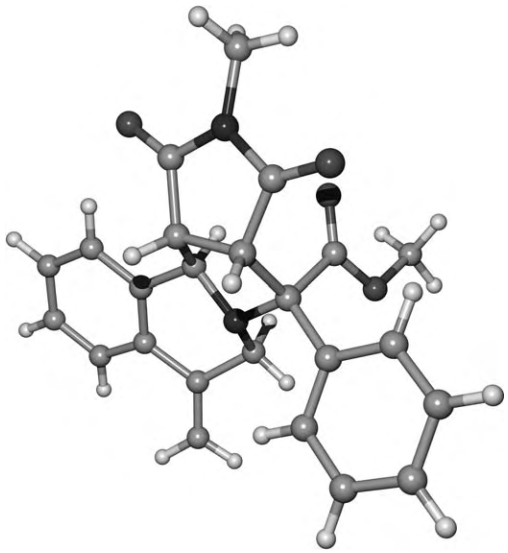

Figure 1. X-ray crystal structure of **15**.[15]

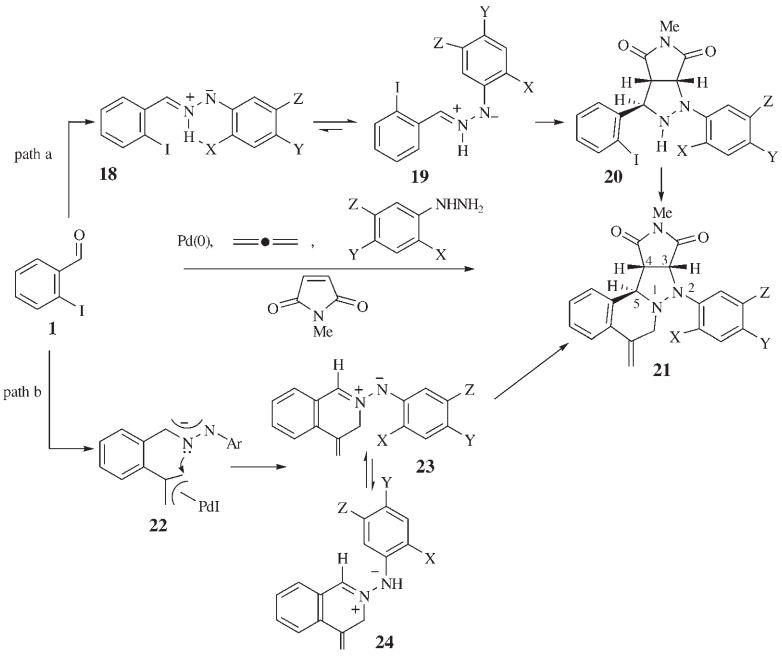
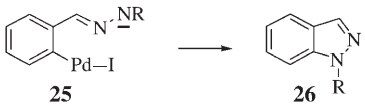
arise through epimerization of **14**, or alternatively, that **14** might undergo a slow retro-1,3-dipolar cycloaddition reaction to generate a new *syn* azomethine ylide **5** (R = Ph, Y = CH) in which the isoquinoline ring is present. The *syn* **5** ylide then equilibrates with *anti* azomethine ylide **6** (R = PH, Y = CH) followed by a 1,3-dipolar cycloaddition reaction through an *exo* transition state to give **15**. Similar results were obtained when the glycine methyl ester was employed in the above cascade (Table 1, entry 6). After 24 h, **16** and **17** were obtained as a 1:1 mixture. Further studies are clearly required to delineate the precise order and nature of the steps involved in this four-component cascade. Current evidence favors path a, which passes through compound **4**, as the configuration of the product conforms to that expected for processes that proceed via **3a**/**3b**.

In seeking to extend the cascade to azomethine imines, through the utilization of hydrazines in place of α-amino esters, we were cognizant of the fact that 1,2-prototropy in hydrazones generally requires temperatures of 120–150 °C.[10] We therefore evaluated a strategy that utilized intramolecular hydrogen bonding to proximal fluorides to stabilize the azomethine imine **18** (Scheme 2). Such hydrogen bonding appears to be weak (ca. 0.2 kcal mol^{-1}),[11] but might be enhanced by electrostatic effects.

Initially we surveyed the reactions of 2,5-difluorophenyl hydrazine and 2-fluorophenylhydrazine with **1**, NMM, and allene in toluene in the presence of a catalyst system that comprises $Pd(OAc)_2$ (10 mol%), PPh_3 (20 mol%), and Cs_2CO_3 (2 equiv). The four-component cascade products **21a** and **b** were obtained in 68 and 72% yield, respectively (Table 2, entries 1 and 2), but their configuration signaled that an *exo* transition state was involved. Azomethine imines impart an imperfect memory of dipole stereochemistry to the product owing to the absence of a fixed configuration at N2 in **21**. A similar pattern was displayed by 2-trifluoromethylphenyl hydrazine which afforded **21c** in 70% yield (Table 2, entry 3). In this case, hydrogen bonding would involve a seven-membered ring in **18**. Evaluation of other hydrazines (Table 2, entries 4–8) showed that the cascade proceeded in the absence of a proximal halogen (Table 2, entries 4 and 7) and that phenyl vinyl sulfone gave the four-component cascade product **21h** both regio- and stereoselectively (Table 2, entry 8). The structure of **21h** was unequivocally determined by X-ray crystallography (Figure 2). The phenyl and the 2,5-difluorophenyl rings are essentially parallel and approximately 3.5 Å apart, which suggests π stacking. AM 1 calculations of the activation energies for the cycloadditions of **18**, **19**, **23**, and **24** show that *exo* cycloadducts via **18** and **23** are favored, with the latter ($E_a = 19.11$ kcal mol^{-1}) favored over the former ($E_a = 22.75$ kcal mol^{-1}).[12] Hydrazones ArCH=N-NH-EWG (EWG = CO_2R, SO_2R) do not give four-component cascade products under our conditions, nor do we observe the formation of indazoles by cyclization of the palladium complex **25** to **26**.[13]



Scheme 2. The use of hydrazines in the extension of the cascade to azomethine imines.



Oxime anions exhibit ambident character (O versus N) with alkylating agents,[14] which prompted a study of their use in multicomponent cascade reactions. The example shown in Scheme 3 parallels the hydrazine case and affords **27** in 62% yield.

Table 2: Four-component azomethine imine cycloaddition/allene insertion/nucleophile incorporation cascades with hydrazines.[a]

Entry	Hydrazines	*t* [h]	Product	Yield [%]
1		24	 **21a**	68
2		24	 **21b**	72
3		24	 **21c**	70
4		24	 **21d**	63
5		24	 **21e**	66
6		24	 **21f**	58
7		24	 **21g**	53
8		24	 **21h**	55

[a] All reactions were carried out in toluene at 100 °C.

In conclusion, we have demonstrated novel four-component palladium catalyzed 1,3-dipolar cycloaddition/allene insertion/nucleophile incorporation cascades that proceed via intermediate azomethine ylides, azomethine imines, and nitrones. Imines undergo cycloaddition through an *endo* transition state prior to incorporation of the allene. The precise order of events in the case of hydrazines and hydroxylamines is not clear but may involve an initial incorporation of the allene followed by trapping of the π-allylpalladium species by the ambident hydrazone and oxime anions and finally cycloaddition through an *exo* transition state. Such a reversal in the relative rates of allene incorporation/cycloadduct formation would be consistent with the slower cycloaddition rates of hydrazones and oximes. These four-component cascades result in a substantial increase in molecular complexity with formation of five new bonds, two rings and two–four stereocenters.[16]

tics.[1] Silica-based mesoporous materials, prepared by the assembly of periodic inorganic and surfactant-based structures, have received considerable attention because of the diverse collection of possible pore sizes and shapes.[2] More recently, this concept has been extended to include lyotropic liquid crystalline assemblies,[3] ionic liquids,[4] cyclodextrin-based materials,[5] triphenylene as an electron donor (charge-transfer agents),[6] phthalocyanine-based amphiphiles,[7] and block copolymers[8] as structure-directing agents. Block copolymers have the advantage of fine-tuning the polymer/solvent/silica phase behavior through variation of the monomer type, volume composition, or macromolecular architecture.[9]

We have recently described the generation of nanoporous organosilicates by using block copolymers that exhibit unimolecular self-organization within a vitrifying organosilicate matrix. This process requires an environmentally responsive, star-shaped macromolecule that organizes the organosilicate vitrificate into nanostructures through a matrix-mediated collapse of the interior core of the core–corona polymeric structure. The insoluble core is rendered compatible in the thermosetting matrix and dispersed through the outer corona designed to be miscible with the matrix.[8c,g] The unimolecular nature of the amphiphile eliminates the complex dynamic assembly that characterizes most amphiphiles, and the curvature constraints of this architecture generate non-interconnected spherical pores up to high volume fractions (approximately 50%) upon porogen burn out. Herein, the synthesis of amphiphiles that are between conventional surfactants and block copolymers, with the shape of the former and the size of the latter, is described with the objective of templating a wide variety of porous morphologies through an amphiphile, organosilicate self-assembly process. Amphiphilic dendrons as described by Percec et al.[10] are an example of a system that self-assembles into a variety of nanostructures. Alternatively, dendritic linear hybrid AB amphiphilic block copolymers are also likely candidates, as Frechet, Meijer, Stupp, Hawker, and others[11] have shown that such architectures respond to changes in their environment through changes in the type and shape of micelles formed. In addition, these copolymers assemble into well-defined Langmuir–Blodgett monolayers that are capable of the formation of nanostructured materials with unusual properties and morphologies.[12] Wiesner and co-workers used such amphiphilic dendrimers as structure-directing agents for aluminosilicate-based materials and generated hybrids with a wide variety of nanostructured morphologies.[13] As the shape of low-molecular-weight surfactants has a pronounced effect on the type of aggregate structure formed in silica-surfactant self-assembly, we felt that a dendritic linear amphiphilic copolymer provides an excellent platform from which to tailor the size and shape of the copolymer. Herein, the responsiveness to change in the environment of the copolymer can be tuned by the type, surface functionality, and dendrimer generation together with the structure and molecular weight of the linear component.[14] Herein, we describe the use of amphiphilic dendritic linear copolymers, based on poly(ethylene oxide) (PEO) and a dendron derived from 2,2′-bis(hydroxymethyl)propionic acid (bis(MPA)),[15] as structure-directing agents for organosilicates to generate a unique, oriented perforated porous lamellar morphology.

PEO hydroxy-functionalized oligomers ($M_w = 4800$ and 9800 g mol^{-1}; polydispersity indices (PDI) = 1.03 and 1.05, respectively) were chosen as the linear component of the copolymer, as PEO has been shown to be miscible with the methyl silsequioxane (MSSQ) prepolymer over wide compositional and molecular-weight ranges.[8c,g] Dendrons derived from bis(MPA) were chosen as they decomposed cleanly and quantitatively upon thermolysis;[16] furthermore, they can be prepared by both divergent and convergent methods and provide exquisite NMR spectroscopic handles to follow the various chemical transformations.[17] Frechet and co-workers showed that hydroxy-terminated PEO is an excellent scaffold for the divergent growth of dendrons using acetal-protected anhydride derivatives of bis(MPA) and also importantly demonstrated that the PEO facilitates product purification through precipitation.[18] This divergent-growth approach was employed using acetonide-protected bis(MPA) anhydride, prepared from the self-condensation of the acetonide-protected bis(MPA) using *N*,*N*′-dicyclohexylcarbodiimide (DCC), in the presence of dimethylaminopyridine (DMAP; 0.25 mol% with respect to the anhydride) in a solvent mixture of CH_2Cl_2/pyridine (90:10). An approximate 2–4-fold excess of anhydride was used to insure quantitative conversion of the terminal hydroxy groups, and the reaction was performed at room temperature (approximately 15–18 h) under nitrogen (Scheme 1). Upon completion, the excess anhydride was treated with methanol to facilitate purification as the by-products generated are soluble in diethyl ether and the PEO copolymers do not allow polymer precipitation. Deprotection of the acetonide groups was accomplished by using Dowex 50W-X2 acidic ion-exchange resin in methanol at 54 °C for 5 h. This general procedure was repeated for each generation and for both poly(ethylene) glycol (PEG) molecular weights surveyed, thus ultimately producing up to six generations of bis(MPA) dendron "block length" in the copolymers. These transformations were followed using ^{13}C NMR spectroscopy, as the quaternary carbon atom of bis(MPA) is sensitive to the substitution of the neighboring hydroxy groups, and the spectra associated with dendritic, linear, and terminal substitution have been identified by model-compound studies. The functionalization and deprotection steps are quantitative irrespective of the generation (Figure 1). The quaternary carbon atom of the acetonide-protected first generation occurs at $\delta \approx 42$ ppm, which on deprotection shifts to $\delta \approx 50.5$ ppm. Subsequent functionalization of the first generation produces the acetonide-protected second generation ($\delta \approx 42$ ppm) and the inner first generation ($\delta \approx 46$ ppm); incomplete transformations are readily detected. The surface hydroxy groups of the dendrons for the fourth to sixth generations were subsequently functionalized by esterification with either protiated or deuterated heptanoic acid in CH_2Cl_2 using DCC/pyridinium 4-toluenesulfonate (DPTS)/DMAP.[19,20] ^{13}C NMR spectroscopy of the terminal quaternary carbon atoms of bis(MPA) clearly showed quantitative conversion into the esterification product (Figure 1). Functionalization of the polymer chain with acetonide–bis(MPA) ($\delta \approx 42$ ppm), followed by its deprotection ($\delta \approx 50.5$ ppm), is

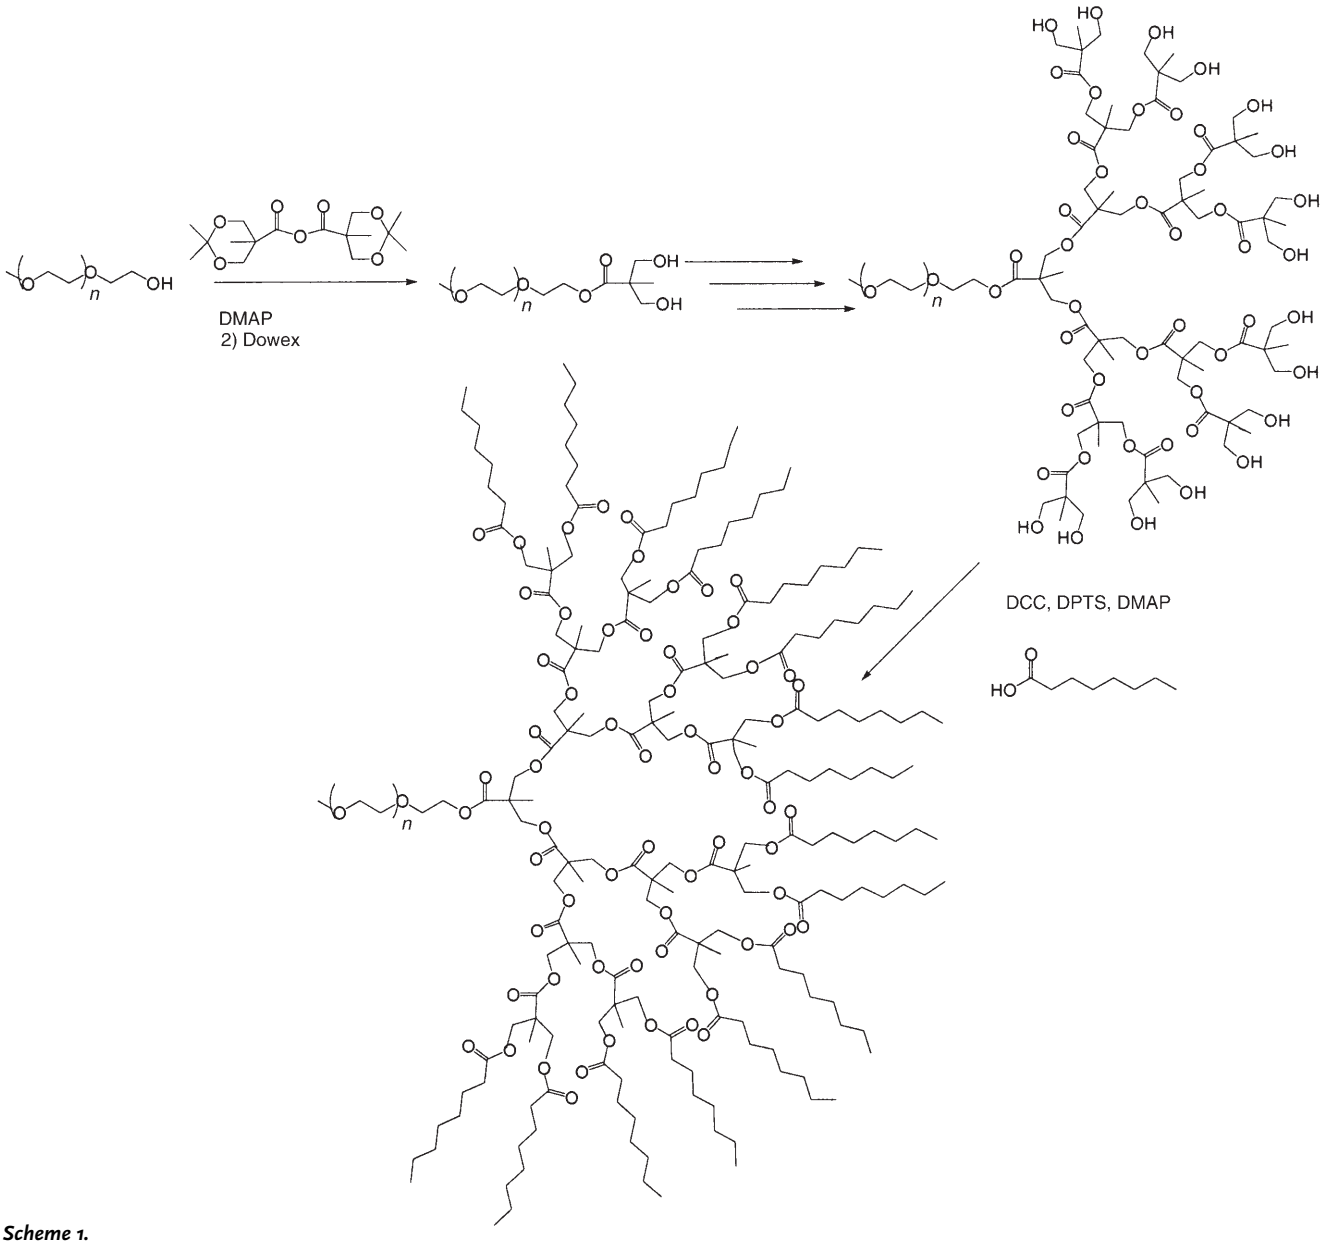

Scheme 1.

clearly seen for each generation (up to generation 5). The fifth generation is then deprotected and functionalized with heptanoic acid ($\delta \approx 46$ ppm). The general characteristics of the fourth–sixth generation copolymers prepared from each of the PEG oligomers, including the molecular weight and weight fraction of the dendron and the molecular weight and polydispersity of the entire copolymer, are given in Table 1. The size-exclusion chromatograms of the fourth–sixth generation copolymers **1a–c** (see Figure 1 and the Supporting Information) and (**2a–c**) clearly demonstrate monomodal, narrowly dispersed products (Figure 2). Thin films of these block copolymers show microphase-separated morphologies, as evidenced by the presence of two T_g values in the dynamic mechanical analysis (DMA) spectra for the third–sixth generation copolymers (Figure 3). Wiesner and co-workers studied the morphologies of similar macromolecular architectures in detail.[21]

The amphiphilic polymers were dissolved in a solution containing the MSSQ prepolymer in 1-methoxy-2-propanol, and the resulting solution was spun on a silicon wafer to produce thin films that were cured to 430 °C to effect the first network formation of the MSSQ and decomposition of the sacrificial copolymer template. Representative tan δ curves obtained from DMA for the **1a**/MSSQ hybrid (40 wt. % copolymer loading) after curing to 80 °C (minimal advancement in MSSQ molecular weight) and 150 °C (significant advancement in molecular weight of MSSQ, that is, network formation) are presented in Figure 3 (also see the Supporting Information) together with the copolymer for comparison. Irrespective of the cure temperature, a two-phase structure is clearly evident in the hybrid. The retention of the T_g value at −25 °C associated with the bis(MPA) dendron phase and the disappearance of the PEO transition (approximately −55 °C) supports the hypothesis that a two-phase structure is present

even prior to cure. Although it is difficult to assign with certainty, we believe it is likely that the T_g value at 50 °C is the mixed T_g values of the PEG and MSSQ phase as they are miscible. Small-angle neutron scattering (SANS) measurements of **1a** (in which the chain ends are selectively decorated with deuterated heptanoic acid) confirm the two-phase structure of the hybrid containing 40 wt.% copolymer (see the Supporting Information). This structure, generated upon spin coating, is thought to occur through a self-assembly process facilitated by the selective solubilization of the PEO by MSSQ and subsequent collapse of the dendron (namely, the structure-directing agent). Further heating of hybrid samples to 430 °C removes the block-copolymer template to create a porous thin film. For example, a porous film derived from a hybrid containing 40 wt.% **1a** has a refractive index of 1.24 and a dielectric constant of 2.00, in comparison to the dense MSSQ matrix with values of 1.37 and 2.85, respectively. Irrespective of the PEG block length or dendron generation surveyed, all refractive indices and dielectric constants were comparable for similar loading levels.

Cross-sectional transmission electron micrography (TEM) images of MSSQ mixtures containing 20, 40, and 60 wt.% of **1b** are shown in Figure 4. The sample of 20 wt.% shows a porous structure (pore sizes: 4–5 nm) with a shape that resides at the interface between the spherical and cylindrical morphologies. Conversely, mixtures that contain the higher volume fractions of copolymer manifest a nanoporous lamellar structure that is oriented parallel to the surface, and this morphology is maintained over a wide compositional range (approximately 35–70%). Small-angle X-ray scattering (SAXS) measurements on the porous films show an increasing scattering intensity with porogen volume

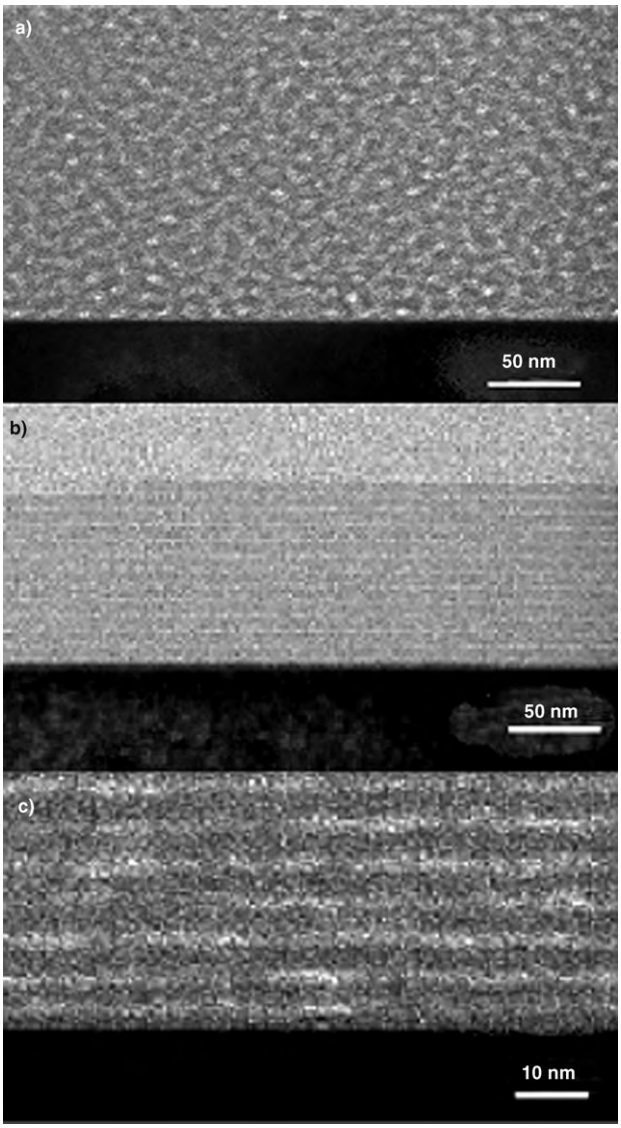

Figure 4. TEM images of copolymer **1b** with mixtures of MSSQ containing a) 20, b) 40, and c) 60 wt.% copolymer.

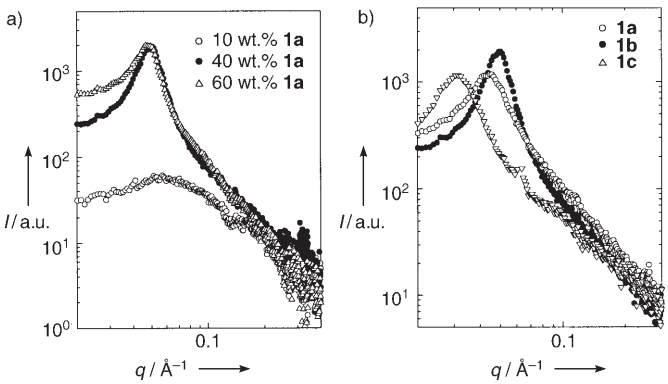

Figure 5. SAXS profiles of porous organosilicates: a) SAXS profiles as a function of weight fraction of G4-PEO5K; b) SAXS profiles of porous films generated with 40 wt.% of copolymer. The samples were prepared by thermal heating to 450 °C after spin-casting.

fraction of **1a** (Figure 5). At a loading of 40 wt.% and above, a strong interpore correlation is observed with peaks that correspond to approximately 129 Å ($2\pi/q$), and no significant change was observed by increasing the copolymer loading to 60 wt.%. Figure 5b shows the effect of PEO molecular weight and dendron generation on the pore structure. An increase in interpore distance from 129 to 137 Å was observed for a loading of 40 wt.% with increasing PEO molecular weight from 5000 to 10000. The SAXS profiles for **2a** and **2b** show the interpore distance increases from 137 to 197 Å as the dendron generation is varied from the fourth to the fifth. Although a porous morphology was observed for all calcined samples, the well-defined lamellar structure oriented parallel to the surface was observed only for the copolymer that contained the fifth generation dendron, irrespective of the PEO block length. The lamellar morphology oriented parallel to the surface was further confirmed by X-ray reflectivity (XR) by the strong scattering that satisfies the Bragg condition (40 wt.% loading of **1b**), thus indicating a layered structure with porosity oriented parallel to the substrate (Figure 6). The first-order Bragg peak corresponds to a period of approximately 107 Å ($2\pi/q$). The higher-order peaks correspond to periods of approximately 56 and 38 Å, respectively.

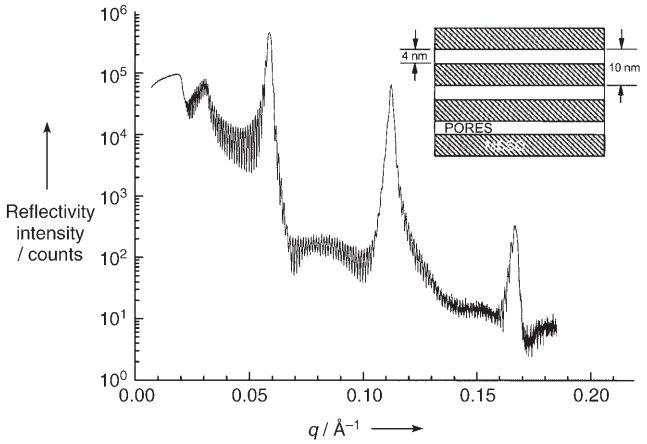

Figure 6. XR profile of porous organosilicate thin films generated with 40 wt.% **1b**. The samples were prepared by thermal heating to 450 °C after spin-casting.

In summary, environmentally responsive, topologically unsymmetrical dendritic linear diblock copolymers with a compatiblilizing linear component were used to organize a MSSQ vitrificate into nanostructures through a matrix-mediated collapse of the interior core. DMA and SANS measurements strongly suggest that the dendron is phase separated in the as-cast film, and serves as the macromolecular template for a porous lamellar morphology (XR and SAXS) at copolymer compositions above 35% volume fraction. The bulky nature of the dendron may also affect their ability to pack efficiently into the traditional spherical micelles that can form from diblock copolymers in selective solvents. The formation of elongated micellar structures, or

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

"worm-like micelles", would help relieve some of the packing constraints of the dendrons and may require less distortion of the molecules from their single-molecule conformation.[11b,12c] This outcome, in turn, may explain the porous lamellar structure (4 nm) obtained between organosilicate sheets (6–9 nm) that persist over a wide temperature range. Moreover, the substrate surface SiO_2 causes the lamellar structure to orient in a parallel fashion over the entire substrate. Although inorganic hybrids with well-defined lamellar morphologies have been reported and are well characterized, this structure, although observed before,[22] is largely unstable at calcination temperatures.[8h,j,22,23]

A DNA-Templated Aldol Reaction as a Model for the Formation of Pentose Sugars in the RNA World**

*Michael Oberhuber and Gerald F. Joyce**

An early stage in the history of life on Earth is thought to have involved RNA genomes and RNA catalysts, an era commonly referred to as the "RNA world".[1,2] RNA-based life would have required substantial amounts of the building blocks of RNA, such as the sugar ribose. The formation of ribose and other pentoses from simple precursors involves a substrate-specific cross-aldol reaction of glyceraldehyde and glycolaldehyde.[3] Without enzymatic control, however, a network of competing pathways, including self-aldol, isomerization, and retro-aldol reactions, gives rise to a complex mixture of compounds that includes only a small amount of pentoses and challenges even the most advanced analytical techniques.[4] While several laboratories have reported conditions that can lead to an increased yield of ribose and other pentoses from simple aldehydes,[5–9] a chemical system that allows direct and systematic investigation of the reaction of glyceraldehyde and glycolaldehyde has remained elusive. Such a system would enable examination of the kinetic and mechanistic features of this reaction, setting the stage for the development of RNA catalysts that can be used to synthesize ribose, analogous to those that may have existed in an RNA world.

The present study demonstrates a DNA-templated model system that allows the selective formation of pentoses by a cross-aldol reaction of glyceraldehyde and glycolaldehyde. DNA-templated chemistry parallels nature's approach to selectivity by exploiting the molecular recognition properties of biological macromolecules to direct the reactivity of small molecules.[10] The reactivity of the aldehydes was controlled by linking them to oligonucleotide "handles", which were recognized by Watson–Crick pairing to a complementary

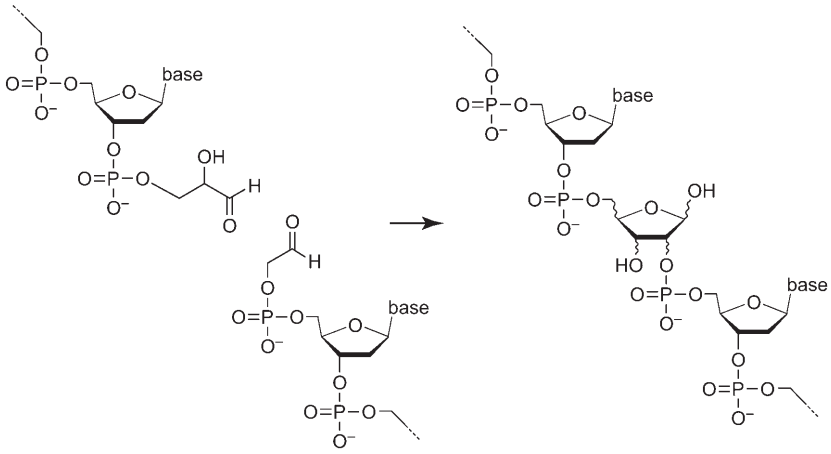
DNA template. These handles also made it possible to use sensitive detection methods available for nucleic acids to overcome the analytical challenges. Each aldehyde was linked to a different synthetic oligonucleotide (Scheme 1), allowing



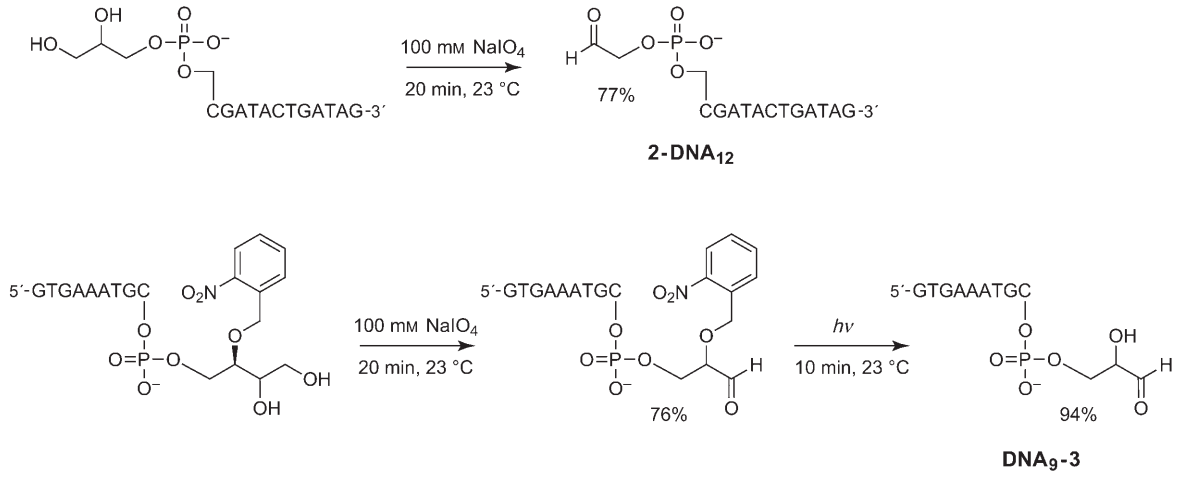
Scheme 1.

the two to be co-aligned in the desired orientation through binding to a common template. The template was designed to promote the cross-aldol reaction by increasing the effective concentration of the two juxtaposed aldehydes, at the same time suppressing undesired reactions. Over the past few years DNA templates have been shown to promote a remarkably diverse set of organic reactions.[10,11] A DNA-directed aldol reaction, however, has not yet been described.

A new class of oligonucleotide–aldehyde conjugates was synthesized by using a phosphoramidite-based approach. The synthetic strategy involved vicinal diols as aldehyde synthons, which were incorporated during solid-phase DNA synthesis and converted to the corresponding aldehyde through periodate oxidation.[12] The 5′-glyceryl-DNA conjugate was synthesized in the 5′-to-3′ direction, purified by denaturing polyacrylamide gel electrophoresis (PAGE), and oxidized to the glycolaldehyde-bearing DNA (**2-DNA$_{12}$**; Scheme 2, top).

The design of the diol precursor for the glyceraldehyde-DNA conjugate (**DNA$_9$-3**) involved a photolabile protection scheme to prevent formation of glycolaldehyde. The hydroxy group vicinal to the phosphate was protected with an *o*-NO_2-benzyl moiety, which is stable under the conditions of DNA synthesis and deprotection, and can be cleaved by irradiation with UV light following periodate oxidation.[13] The diol precursor for **DNA$_9$-3** was prepared by standard DNA synthesis using a glyceraldehyde synthon as the 3′-terminal residue. The precursor was purified by PAGE and converted to the corresponding aldehyde by oxidation and photolysis (Scheme 2, bottom). The identities of **DNA$_9$-3** and **2-DNA$_{12}$** were verified by matrix-assisted laser desorption time-of-flight (MALDI-TOF) mass spectrometry (see Supporting Information) and by DNA-templated reductive amination[11] (data not shown).

By employing the same approach, longer versions of the two DNA–aldehyde conjugates were synthesized and used to explore different formats for the template-directed reaction. The compound 5′-T_{15}GTGAAATGC-3′-glyceraldehyde (**DNA$_{24}$-3**) was efficiently [5′-^{32}P]-labeled by using [γ-^{32}P]-ATP and T4 polynucleotide kinase. It was mixed with an excess of glycolaldehyde-5′-CGATACTGATAGGACGAAGAGAT-GGCACC-3′ (**2-DNA$_{29}$**) and a complementary template that contained an unpaired thymidylate opposite the site of the juxtaposed aldehydes. Following incubation at pH 8.5 and 23 °C, the reaction mixture was analyzed by PAGE, which demonstrated formation of products with the electrophoretic mobility expected for the pentose-linked DNA (**DNA$_{24}$-5-DNA$_{29}$**) (Figure 1; lanes 2, 3, and M). There was no detectable reaction in the absence of the template or in the presence of a mismatched template (Figure 1; lanes 6 and 7, respectively). If an analogue of **DNA$_{24}$-3** was used that contained glycerol instead of glyceraldehyde, no product formation was observed (Figure 1; lane 8). Similarly, replacing **2-DNA$_{29}$** by



Scheme 2.

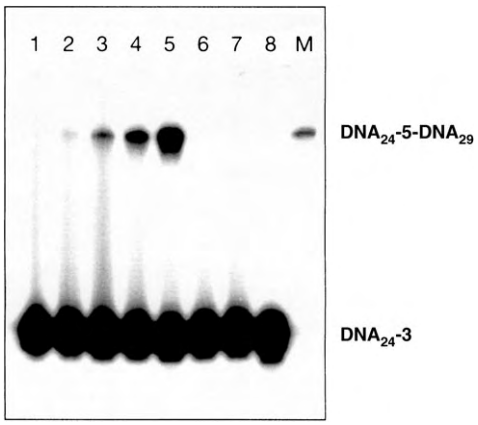

Figure 1. DNA-templated cross-aldol reaction. Reaction of 5 nM labeled **DNA_{24}-3** and 2 μM unlabeled **2-DNA_{29}** in the presence of 1 μM complementary template (lanes 2–5), no template (lane 6), or 1 μM mismatched template (lane 7). Lanes 2 and 3 correspond to reaction in the absence of L-Lys for 6 and 48 h, respectively; lanes 4 and 5 correspond to reaction in the presence of 50 mM L-Lys for 6 and 48 h, respectively; lanes 6 and 7 correspond to reaction in the absence of L-Lys for 48 h. Lane 1 contains unreacted labeled **DNA_{24}-3**; lane 8 corresponds to a control reaction (48 h) employing a labeled DNA-glycerol conjugate instead of **DNA_{24}-3**, and lane M contains a marker of the same composition as **DNA_{24}-5-DNA_{29}** but with thymidine in place of the newly-formed pentose. All reaction mixtures contained 10 mM $MgCl_2$, 100 mM NaCl, and 50 mM TAPS (pH 8.5). Reaction products were separated by denaturing 20% PAGE, an autoradiogram of which is shown.

the corresponding glycerol-containing DNA eliminated the observed reaction (data not shown).

In order to carry out mass-spectrometric analysis of the products, unlabeled **DNA_9-3** was incubated with a slight excess of **2-DNA_{12}** in the presence of a complementary template. MALDI-TOF mass spectrometry of the PAGE-purified products gave a mass consistent with the formation of a pentose linking the two substrate oligonucleotides (see Supporting Information). The **DNA_{24}-5-DNA_{29}** products were prepared similarly and analyzed by a primer extension reaction, which employed a 17 mer oligonucleotide that hybridized to the 3′ end of the product molecules and was extended by reverse transcriptase. A minor pause with substantial read-through was seen at the aldol junction (see Supporting Information), similar to the behavior of an abasic site,[14] and excluding the possibility of an unusual connectivity such as would result from the reaction of an aldehyde with a nucleobase. It was not possible to obtain sufficient material to determine the relative amounts of the four pentose sugars and their respective enantiomers. The 2′,5′-phosphodiester linkage that is formed at the aldol junction (Scheme 1) allows read-through by reverse transcriptase,[15] but the minor pause that occurs at the junction cannot be taken to indicate the presence of any particular sugar.

The rate of the DNA-templated aldol reaction was measured as a function of pH (Figure 2). Consistent with a base-catalyzed reaction, the observed pseudo-first-order rate constant increased at alkaline pH, but was nearly unchanged at neutral to acidic pH. At elevated pH and temperatures a degradation product of **DNA_{24}-3** also was detected, presumably arising from elimination of glyceraldehyde-2,3-cyclic-phosphate (data not shown). Mildly alkaline pH (8.5) and ambient temperature (23 °C) were chosen as the standard reaction conditions, for which the observed rate of reaction was about 4×10^{-6} min^{-1}.

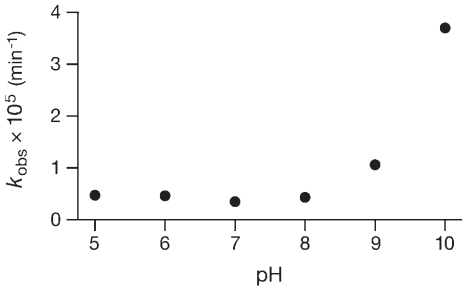

Figure 2. pH dependence of the DNA-templated aldol reaction. Reaction conditions were as described in the legend to Figure 1, except for differences in pH.

In view of the well-established role of amines as organocatalysts,[16] and with regard to their potential role as cofactors in RNA catalysis, the DNA-templated aldol reaction was studied in the presence of various amines and amino acids. A family of biological aldolases, as well as catalytic antibody aldolases that have been reported, utilize a lysine residue to catalyze aldol reactions via a Schiff-base intermediate.[17,18] This provided the impetus for experiments identifying L-Lys as a potential catalyst for the DNA-templated aldol reaction (Figure 1; lanes 4 and 5). Elevated concentrations of L-Lys accelerated the reaction up to 20-fold, but concentrations below 10 mM had no significant effect (Figure 3), suggesting a slow second-order rate of formation of the Schiff base.

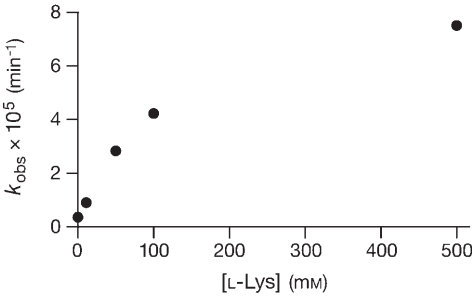

Figure 3. DNA-templated aldol reaction in the presence of varying concentrations of L-Lys. Reaction conditions were as described in the legend to Figure 1, except for the addition of 0–500 mM L-Lys.

The dipeptide Lys–Lys was similarly effective as L-Lys, but L-Pro, a well-known catalyst of aldol reactions in organic solvents,[16] was ineffective in the DNA-templated format, even at high concentrations (Figure 4). The aldol reaction also was accelerated by small aliphatic diamines, especially putrescine (Figure 4), suggesting the need for an extended aliphatic primary amine. As a negative control, the reaction was analyzed in the presence of 1M NaCl, excluding the possibility that the enhanced rate with certain amines was due to the high ionic strength of these solutions.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

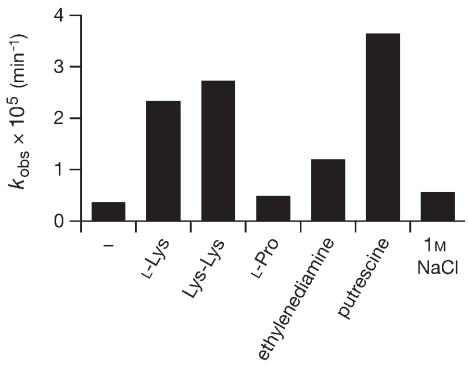

Figure 4. DNA-templated aldol reaction in the presence of various amine-containing cofactors. Reaction conditions were as described in the legend to Figure 1, except for the addition of no cofactor (lane –), 50 mM cofactor (indicated), or 1 M NaCl.

The influence of the template architecture on the aldol reaction was examined by replacing the unpaired thymidylate opposite the aldol junction with a hexaethylene glycol linker, or by placing the two aldehydes at the same end of hybridized DNA strands. Consistent with the reduced frequency of substrate encounter in these formats, the reaction rate decreased by about threefold compared to the standard format, but was similarly accelerated by the addition of 50 mM L-Lys. A variety of other template architectures were tested, but none resulted in an increased rate of reaction compared to the standard format.

In summary, this first reported example of a DNA-templated aldol reaction demonstrates how nucleic acids can selectively promote the cross-aldol reaction of glyceraldehyde and glycolaldehyde. This model system allows kinetic and mechanistic investigation of the template-directed formation of pentoses, relevant to the corresponding biosynthetic reaction in an RNA world. Aliphatic amines, such as L-Lys, were found to accelerate the reaction, emphasizing their role as potential cofactors in the RNA-catalyzed synthesis of ribose. The observed requirement for high amine concentrations may reflect the slow formation of a Schiff-base intermediate, indicating that precise positioning of the cofactor in the active site will be a crucial feature of enzymatic catalysis. A recent report by Famulok and colleagues[19] described the first example of an aldolase ribozyme, obtained by in vitro evolution, which catalyzes the reaction of a levulinic acid modified RNA and benzaldehyde-4-carboxamide. The ribozyme employs a Zn^{2+} cofactor, analogous to biological class II aldolases.[20] That work, together with the present study, suggest the plausibility of evolving aldolase ribozymes that catalyze the biosynthesis of ribose.

Experimental Section

Oligonucleotides were prepared by using a PerSeptive Biosystems Expedite 8909 Nucleic Acid Synthesis System, employing standard methods. Diol-containing oligonucleotides were synthesized by using either 3′-glyceryl CPG (Glen Research) or a solid-supported glyceraldehyde synthon (see Supporting Information). Oligonucleotides were cleaved from the solid support and deprotected by using either concentrated aqueous NH_3 at 55 °C for 2–20 h for standard DNA or 10 M $MeNH_2$ in H_2O:EtOH (1:1 v/v) at 23 °C for 14–20 h for diol-bearing DNA. All oligonucleotides were purified by PAGE. Diol precursor oligonucleotides were adsorbed on a Sep-Pak C18 resin (Waters) and oxidized with 100 mM $NaIO_4$ (ca. 3 mL), which was allowed to drip slowly through the cartridge at 23 °C over 15–20 min. After washing with H_2O (5 mL), then 10 % (v/v) MeOH (1.5 mL), the aldehyde-bearing DNA was eluted with 50 % (v/v) acetonitrile (5 mL). Photolysis was carried out at 23 °C for 10–15 min using a 100-W long-wavelength UV lamp.

DNA-templated reactions were carried out in the presence of 10 mM $MgCl_2$, 100 mM NaCl, and 50 mM 3-[(2-hydroxy-1,1-bis(hydroxymethyl)ethyl)amino]propanesulfonic acid (TAPS, pH 8.5) at 23 °C, unless otherwise stated. Aliquots were taken at 4–10 different time points and stored at −80 °C in the presence of 90 mM Tris-borate (pH 8.0), 20 mM Na_2EDTA, 10 % (w/v) sucrose, and 8 M urea. The samples were analyzed by denaturing PAGE, using a Molecular Dynamics PhosphorImager to quantify the radiolabeled material.

Supporting Information describes additional experimental procedures, including synthesis of the solid-supported glyceraldehyde synthon (Scheme S1), radiolabeling of oligonucleotides, mass-spectrometric analysis of the substrates and products of the DNA-templated aldol reaction (Figure S1), and primer extension analysis of the pentose-linked DNA (Figure S2).

Ion Selectivity

DOI: 10.1002/anie.200501625

A Highly Active Anion-Selective Aminocyclodextrin Ion Channel**

*Nandita Madhavan, Erin C. Robert, and Mary S. Gin**

Ion-channel proteins are molecular devices found in nature that mediate the transport of charged species across cell membranes. Various functions in the human body, such as nerve and muscle excitation, hormonal secretion, cell proliferation, and homeostasis, are regulated by ion channels.[1] The efficient functioning of ion-transport machinery in nature has led to considerable interest in understanding the mechanisms by which these proteins mediate selective, regulated transmembrane ion transport.[2] Furthermore, the ability of ion channels to effect electrical signaling under aqueous saline conditions has inspired their use as biosensors,[3] therapeutic agents,[4] and other useful materials.[5] Despite the potential utility of controlled ion transport, the relative instability of proteins in vitro will likely prohibit their use in commercial applications. Advances in the synthesis of more robust artificial channels provide a viable solution to the problem of ion-channel stability, thus enabling the construction of biomimetic signaling components.

An important feature that dictates the physiological function of ion channels is ion selectivity. Ion channels can be classified as cation or anion selective on the basis of the differential permeability of ions through the channel pore. Ion channels selective for cations over anions have been widely studied, and several synthetic analogues that use β-cyclodextrin,[6] crown ethers,[7] peptides,[8] and calixarenes[9] are among the molecular scaffolds that have been developed to date. In contrast, there have been far fewer examples of synthetic channels that are selective for anions over cations. Peptidic synthetic channels developed by Gokel[10] and Matile[11] and sterol mimics developed by Regen[12] have been shown to preferentially transport anions over cations upon self-assembly within phospholipid membranes. Reported herein is a highly active, monomeric cyclodextrin-based ion channel (**1**, Figure 1) that displays not only selectivity for anions over cations but also discriminates among halide anions ($I^- > Br^- > Cl^-$).

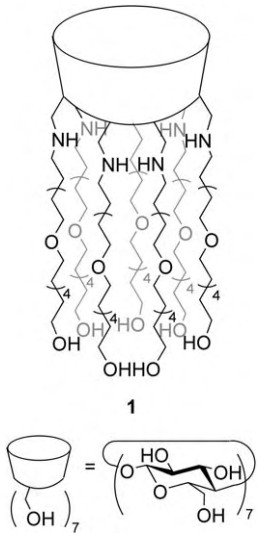

Figure 1. Structure of aminocyclodextrin channel **1**.

Channel **1** comprises a β-cyclodextrin head group with oligoether chains attached to the primary face of the cyclodextrin through amine linkages. The chains are sufficiently hydrophobic to promote insertion into a phospholipid bilayer membrane[13] and possess a length that should allow the channel to span the entire membrane.[14] Channel **1** was synthesized (Scheme 1) from pentabutylene glycol (**2**), which is readily accessible in five steps from commercially available 2,5-dimethoxytetrahydrofuran.[15,16] Conversion of **2** into the monotosylate **3** was achieved using *p*-toluenesulfonyl chloride (TsCl) and pyridine (pyr). Monotosylate **3** was heated with sodium azide at 80 °C to give the oligoether azide, which was reduced to the corresponding amine **4** using triphenylphosphine and water. N-Alkylation of neat amine **4** with the activated heptaiodocyclodextrin **5**[17] afforded channel **1**.

Initial ion-channel activity was assessed by using ^{23}Na NMR spectroscopy to study Na^+ transport across vesicle membranes (Figure 2a),[18] on the basis that other cyclodextrin-based ion channels were cation selective.[6] In the NMR experiment, a Dy^{3+} complex was used as a shift reagent to differentiate the extravesicular Na^+ ions from the internal Na^+ ions.[19] Ion transport can be visualized and quantified by the line broadening observed for the Na^+ resonances because of the exchange of the internal and external Na^+ ions. The rate of exchange is directly proportional to the line broadening observed for the internal Na^+ signal [Eq. (1)], in which ν and

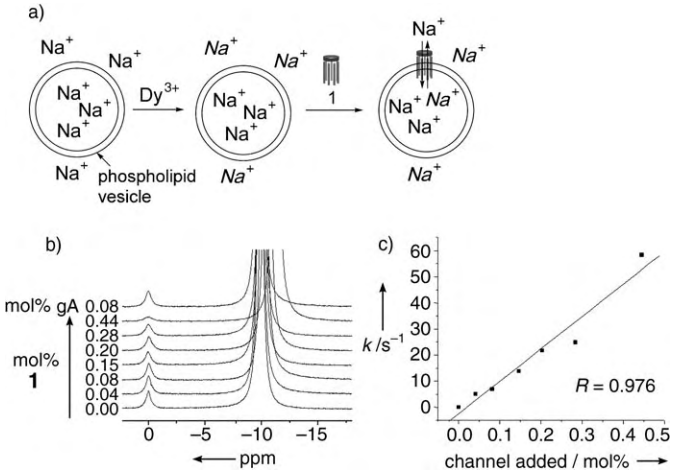

Figure 2. a) Schematic representation of the ^{23}Na NMR spectroscopic experiment (the italicized Na^+ ions represent external ions with shifted NMR peaks owing to the presence of the Dy^{3+} shift reagent). b) Stacked NMR plots that indicate line broadening observed with an increase in the channel concentration (mol% relative to phospholipid); as a comparison gramicidin A (gA) was also added. c) Linear correlation between the Na^+ exchange rates and the concentration of channel added, thus indicating that channel **1** is monomolecular.

$$k = 1/\tau = \pi(\nu - \nu_0) \quad (1)$$

ν_0 are the line widths in the presence and absence of the exchange, respectively. For the ^{23}Na NMR experiment, large unilamellar vesicles of egg-yolk phosphatidylcholine (EYPC) lipids were prepared by multiple extrusions through 0.4-μm polycarbonate membranes.[16] The vesicles were determined to be approximately 200 nm in diameter using dynamic light scattering. Addition of the $DyPPi_3$ shift reagent to the vesicle suspension followed by a solution of **1** led to significant line broadening of the internal Na^+ peak (Figure 2b), thus indicating the channel-mediated exchange of Na^+ ions across the vesicle membrane.[20] The dependence of the observed rate of Na^+ exchange (k_{obs}) on the concentration of **1** can be used to determine the aggregation state of the channel, or the number of **1** monomers that form the active structure [Eq. (2)].[21] A linear correlation ($n = 1$) between the

$$k_{obs} \propto [\text{channel}]^n \quad (2)$$

Na^+ exchange rate and the concentration of the channel indicated that the active structure formed from **1** was monomolecular (Figure 2c). Also, a comparison of the Na^+ transport rate through **1** with that for the natural ion-channel gramicidin A revealed that **1** was 36% as active as gramicidin A, thus indicating that **1** formed a highly active monomolecular ion channel.[22] This result is particularly noteworthy in light of the net charge of **1**. The multiple positive charges associated with previously studied hepta-amino, -hydroxyethylamino, and -alkylamino cyclodextrin derivatives at physiological pH values have been widely exploited for binding negatively charged phosphates to the cyclodextrin cavity.[23] In view of the similar charge densities imparted by the ammonium groups of **1** to the channel pore, it is remarkable that sodium transport is observed through the channel.

To expand the range of ions that could be assessed for transport activity, transmembrane ion-transport properties of **1** were also studied with fluorescence spectroscopy, in which the fluorescence of the pH-sensitive dye 8-hydroxypyrene-1,3,6-trisulfonic acid trisodium salt (HPTS) was used as the probe.[24] In the fluorescence assay, the HPTS dye was encapsulated inside small unilamellar vesicles (Figure 3a) approximately 50–80 nm in diameter, which were prepared by using the detergent dialysis method.[16] A pH gradient of 0.6 units was introduced by addition of a solution of NaOH (2N) to the vesicle solution, which also introduced a Na^+ concentration gradient. A solution of **1** was added to the vesicles and the activity of the channel was gauged by monitoring the change in the fluorescence intensity of the deprotonated dye. Finally, gramicidin A was added to the

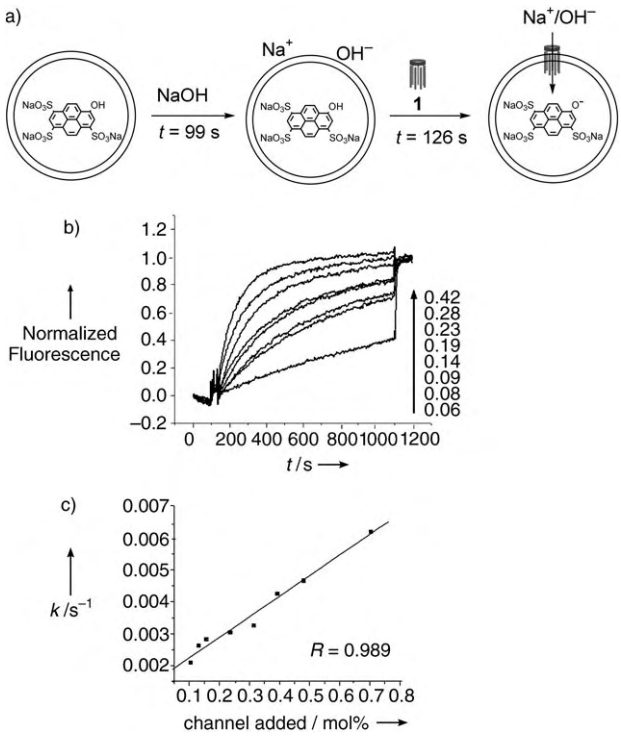

Figure 3. a) Schematic representation of the fluorescence experiment. b) Change in the fluorescence intensity of the deprotonated dye with a change in the concentration of the channel (mol%). c) Linear correlation between the rate of transport and the concentration of the channel.

vesicles to ensure complete equilibration of the HPTS dye between the protonated and deprotonated states. Upon addition of a solution of **1** to the vesicles, an increase in the concentration of the deprotonated dye was observed, thus indicating a Na^+/H^+ antiport or Na^+/OH^- symport through **1**. Moreover, variation in the concentration of **1** induced a corresponding change in the ion-transport rate (Figure 3b). A linear correlation was observed upon plotting the rates for ion transport against the amount of **1** added, thereby confirming that **1** indeed formed a monomolecular ion channel (Figure 3c).[25]

Having established that channel **1** mediates the rapid transport of Na^+ ions through a monomolecular pore, the fluorescence assay was used to probe its ion selectivity.[26] Cation selectivity was tested by repetition of the fluorescence experiment with different alkali hydroxides (Figure 4a). The differences in rate observed for the different cations (Li^+, Na^+, and K^+) were relatively small, which is characteristic of channels with little or no selectivity among cations. Anion selectivity was investigated by variation of the counteranion (Cl^-, Br^-, and I^-) for the Na^+ ion. In this case, a consistent difference in the fluorescence profile was observed that was dependant on the nature of the anion added (Figure 4b). In all cases, the fluorescence of the deprotonated dye decreased, which indicated either an X^-/H^+ symport or X^-/OH^- antiport through the channel. For NaBr and NaI, a rapid decrease in the fluorescence intensity indicative of X^- transport was followed by a steady increase to the fully equilibrated state, thus suggesting a slower rate of Na^+ influx. A gradual decrease in fluorescence intensity was observed for NaCl, thereby indicating comparable rates for Na^+ and Cl^- transport. The curves obtained for the NaX salts were fit to exponential equations to corroborate this hypothesis. The curves obtained with NaBr and NaCl were fit to Equation (3),

$$\text{Rate} = A + Be^{-k_1 t} - Ce^{-k_2 t} \quad (3)$$

in which k_1 and k_2 represent the competing rates for ion transport.[16] However, the curve for NaI was fit to Equation (4), in which an extra term was required because of the

$$\text{Rate} = A + Be^{-k_1 t} - Ce^{-k_2 t} + De^{-k_3 t} \quad (4)$$

significant rate of I^- transport through the lipid membrane (k_3).[27] In all cases, the second exponential terms bore negative coefficients consistent with an increase in fluorescence intensity, and the k_2 values were within the same range as the rates determined for the addition of NaOH. These data are indicative of a slower increase in fluorescence intensity because of Na^+ transport. The rates (k_1) that correspond to the rapid decrease in fluorescence intensity because of X^- transport were found to vary considerably depending on the nature of the anion. The k_1 value obtained for NaCl ($0.0097\ s^{-1}$) was comparable with the rate of Na^+ transport ($k_2 = 0.0097\ s^{-1}$), the k_1 value obtained for NaBr ($0.018\ s^{-1}$) was approximately 2.7 times faster than the rate of Na^+ transport ($k_2 = 0.0066\ s^{-1}$), and the k_1 value obtained for NaI ($0.071\ s^{-1}$) was found to be significantly higher than that obtained for Br^- transport (ca. 9.5 times faster than k_2 ($0.0075\ s^{-1}$)). In addition, the k_3 value obtained for NaI ($0.002\ s^{-1}$) matched well with the rate observed for the influx of I^- ions into vesicles without channels.[28] The necessity of including a third term for membrane-permeable I^- ions corroborates the assertion that anions do indeed travel through the pore formed by **1**. Only two terms would be necessary to fit the data if anion transport only occurred through the membrane in response to Na^+ transport through the channel.

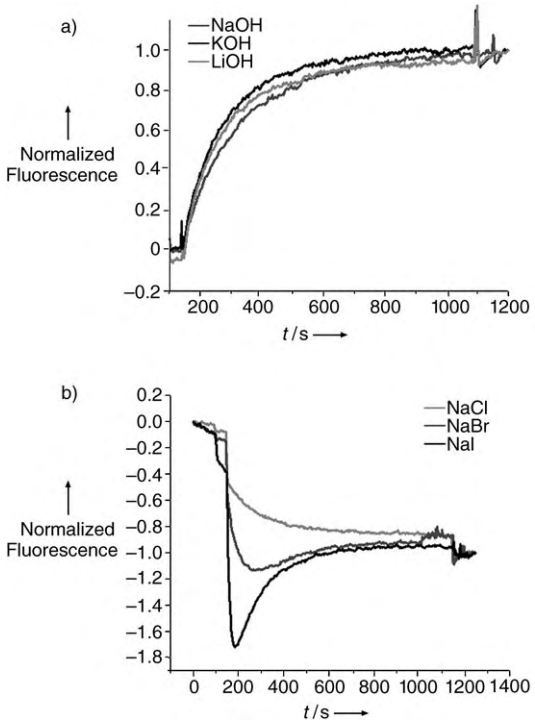

Figure 4. a) Fluorescence change of deprotonated HPTS for different cations (Li^+, Na^+, and K^+) upon addition of 1.1 mol% channel **1**. b) Fluorescence change of deprotonated HPTS for different anions (Cl^-, Br^-, and I^-) upon addition of 0.4 mol% channel **1**.

The role of electrostatics in ion selectivity has been observed with natural ion channels, wherein the charges of the amino acid residues at the pore dictate the preference of the channel for different ions.[29] Anion selective channels have a net positive charge owing to the presence of positively charged amino acids that line the pore of the channel. Channel **1** possesses a positive charge at the pore opening because of the basic amine groups at the chain-functionalized rim of the cyclodextrin. This positive charge likely leads to electrostatic interactions that favor the transport of anions over cations. The selectivity among the anions ($I^- > Br^- > Cl^-$) follows the Hofmeister series, in which various phenomena, such as protein precipitation, enzymatic activity, and polymer conformation, are influenced by the polarizability of the environmental anions.[30] The more polarizable I^- ion should face a lower activation barrier to entry into the hydrophobic interior of **1**, thus resulting in a faster rate of transport.[31]

In conclusion, the ability of aminocyclodextrin ion channel **1** to mediate transport of anions in preference to

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

cations at rates that compare with, or even exceed, those of natural channel proteins is reported. The ability of this robust synthetic channel to effect conductance across a hydrophobic barrier is an important first step toward devices that take advantage of biomimetic electrical signaling under aqueous saline conditions. Investigations into the basis of anion selectivity, the range of ions that are permeable, and pH effects on ion-channel activity are currently underway.

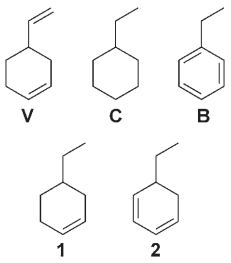
"Hydrogen-Catalyzed" Dehydrogenation: A Supercritical Conundrum**

Jason R. Hyde, Ben Walsh, and Martyn Poliakoff**

In recent years there has been increasing interest in organic reactions in supercritical carbon dioxide ($scCO_2$). These reactions have included Friedel–Crafts alkylations,[1–4] hydroformylation,[5–9] oxidation,[10–15] etherification,[16–18] and especially hydrogenation.[19–24] Apart from the environmental acceptability, the attractions of $scCO_2$ for hydrogenation are improved mass transport, ease of continuous operation, and potentially improved selectivity.[25] Much of this work has involved continuous reactors, which simplify scale-up. However, we show herein, that these reactors can produce apparently misleading results which, when correctly interpreted, can open up new routes to compounds which are difficult to synthesize otherwise.

The starting point for this paper was a report[26] of the attempted selective hydrogenation of 4-vinylcyclohex-1-ene (**V**; Scheme 1), in a small-scale (5 mL) continuous reactor. Unexpectedly, this approach resulted in the formation of ethyl benzene (**B**; which is a dehydrogenation product) even in the presence of a large excess of H_2 and at temperatures apparently as low as 40 °C. This report was significant firstly because the dehydrogenation of **V** is industrially important[27–31] and secondly because the reactor design is one which is very widely used for supercritical chemistry.



Scheme 1. Structures of ethyl cyclohexane (**C**) and ethyl benzene (**B**) formed during the dehydrogenation of 1-vinyl cyclohex-4-ene (**V**); **1** and **2** are the intermediates detected in the course of this reaction and were identified by NMR spectroscopy (see Supporting Information).

The dehydrogenation of cyclohexyl compounds to the corresponding benzene derivatives is an attractive route to aromatic compounds from cheap, plentiful biologically derived feedstocks. In batch reactors, this appears to be an overall disproportionation reaction, producing two mole of **B** for each mole of **C**. So, a surprising aspect of the reported dehydrogenation of **V** in $scCO_2$ was that **C** was not observed, making a simple disproportionation unlikely. The results presented herein provide an explanation of this conundrum and include the identification of two previously unsuspected intermediates, **1** and **2** in Scheme 1.

Initially, we investigated the effect of passing **V** + $scCO_2$ through the reactor in the absence of H_2. Our automated reactor (Figure 1)[16] was therefore programmed to ramp the temperature of the catalyst bed (Pd 2 %) from 80 °C to 200 °C over a period of 8 h at a constant pressure of 150 bar, analyzing the products by GLC every 5 minutes. Figure 2, shows that 1) in the absence of H_2, a reaction does occur; 2) this reaction yields both **B** and **C**, unlike the reaction in the presence of H_2 where **C** is not observed; 3) the ratio of **B** to **C** was found to be 2:1 close to the ratio expected for disproportionation;[27–31] 4) there are two additional products, **1** and **2**; 5) the reaction displays "light-off"[32] (i.e. there is an ignition over a small temperature interval of only 2–3 °C; similar behavior was also observed at 100, 200, and 250 bar) and 6) the reaction switches-off equally suddenly.

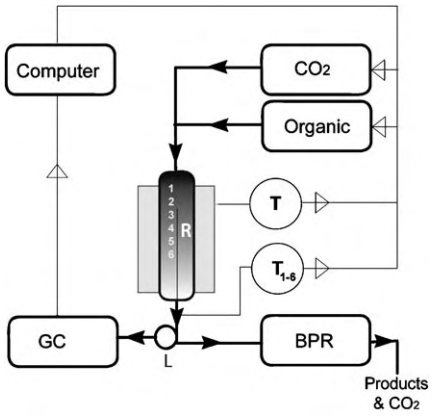


Figure 1. Schematic diagram of the automated apparatus. The organic substrates and CO_2 are delivered by HPLC pumps (Jasco PU–980 and CO_2–1580, respectively); system pressure in the reactor (R) is maintained by a Jasco Back Pressure Regulator (BPR) which also facilitates product separation. Samples of product are collected in-line by a sample loop (L; Valco/Vici) and injected into a gas chromatograph (GC) and the results are downloaded automatically to the computer. The high-pressure lines are designated by heavy filled arrowed lines, whilst data lines and the direction of data are depicted by light unfilled arrowed lines. T_{1-6} are optional thermocouples placed within the reactor.

Analysis of the product stream by off-line GC/MS showed that **2** had a parent ion with m/z 108, identical to that of **V**. By contrast **1**, had m/z 110, consistent with a partially hydrogenated product. Further experiments, detailed in the ESI, provided sufficient NMR spectroscopic data to identify the structures of **1** and **2** (see Scheme 1).

Estimating the residence times in these reactors is straightforward but slightly convoluted.[33] However, once the relationship between flow rate and residence time has

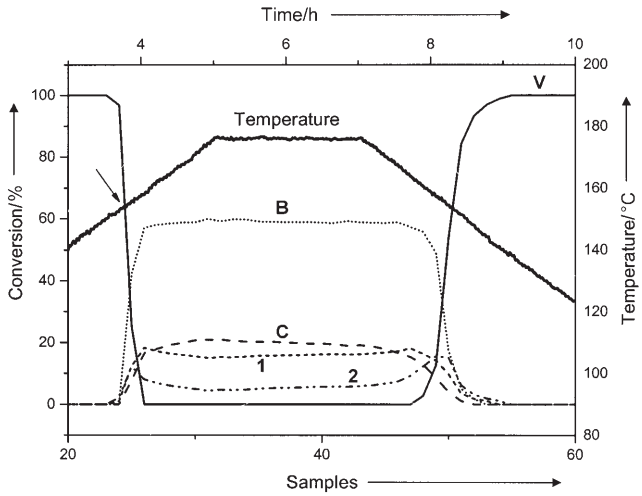

Figure 2. Plot of the product distribution observed whilst the catalyst bed is heated (bold line) between 140 and 180 °C. Note the arrowed auto-thermal ignition point at around 150 °C, and the presence of intermediates **1** and **2**. Flow rates: CO_2 1 mL min^{-1}, **V** 0.2 mL min^{-1}. The product composition was sampled every 15 minutes over the 10-hour period.

been established, it is relatively simple to investigate the variation of reaction products with residence time. Figure 3 shows that 1) reaction products are detected at residence times longer than 2 s; 2) the yields of **B** and **C** grow steadily with increasing residence time, confirming that **B** and **C** are final products; 3) the yields of **1** and **2** reach maxima and then decrease, suggesting that **1** and **2** are intermediates, and 4) the initial rates of formation of **2** and **B** are similar, suggesting that **2** is not an intermediate in the formation of **B**.

However, additional evidence for the relative positions of the different species in the reaction scheme can be obtained

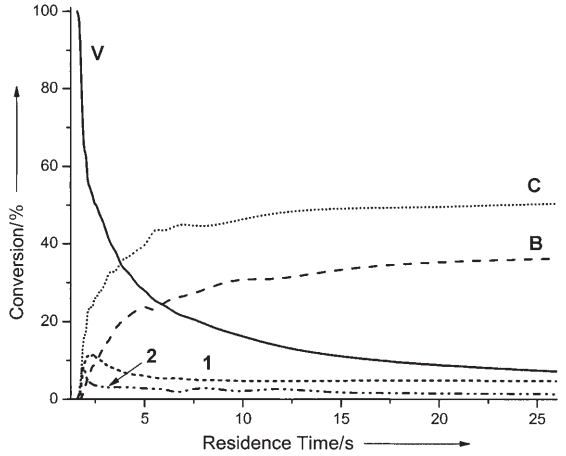

Figure 3. Plot of the product distribution for the dehydrogenation of **V** in the absence of H_2 as the residence time is varied. The traces are labeled **1**, **2**, **V**, **C**, **B** as in Scheme 1. In principle, such data can be used to model the kinetics of the reaction and hence to extract rate constants for the different stages. However, we are limited in this case by the fact that H_2 is a key component in the reaction but its concentration is unknown and indeed, will vary at different points in the reactor.

by analyzing the GC data with the new analytical technique, 2DCOR-GC,[1,34] which is an extension of the generalized correlation function to chromatographic data.[34] The 2DCOR-GC maps shown in Figure 4, are calculated from

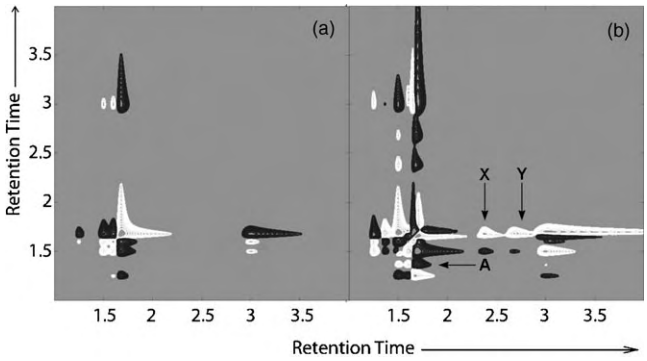

Figure 4. 2D-correlation analysis of the complete GC data from the experiment illustrated in Figure 3. This analysis is mathematically similar to the 2DCOS methodology for FTIR.[38] The principle of analysis for GC and FTIR are the same. The sequence in which the various compounds occur in response to a perturbation (in this case residence time) is obtained by comparing the signs (white positive, black negative) of the off-diagonal peaks in the synchronous and asynchronous plots and applying Noda's Rules.[38] a) Synchronous map showing the simultaneous relationships between products; b) asynchronous map showing the "out-of-phase" relationships. In this plot, further products, **A**, **X**, and **Y**, have been highlighted. High-resolution color copies are available in the Supporting Information.

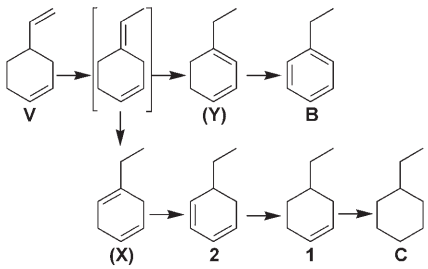
the same experiment that gave the data in Figure 3. The off-diagonal peaks in Figure 4 a show that the formations of all of the products are correlated to **V** but not necessarily to each other, reflecting the existence of two parallel reaction pathways, namely hydrogenation and dehydrogenation. Together, the two maps can be used to deduce the sequence of formation of **B**, **C**, **1**, and **2**, see Scheme 2. The 2DCOR-GC maps provide evidence for two additional intermediates, **X** and **Y**, which are difficult to discern in the 1D chromatograms but are easily seen in the maps. **X** and **Y**, correlate with **2** but are formed before it. Although **X** and **Y** were not identified spectroscopically, a simple GC structural–elution simulation[35] suggests that they may have the structures shown in Scheme 2. An additional weak peak, **A** in Figure 4, was



Scheme 2. Postulated mechanism for the dehydrogenation/hydrogenation of **V** to form **B** and **C**. Compounds **1** and **2**, have been identified by NMR spectroscopy, and **X** and **Y** have been tentatively identified by elution–structure relationships.

identified as vinyl cyclohexane, by comparison with an authentic sample. Compound **A** does not correlate synchronously with any other species and is probably the product of a side reaction.

We now return to the original conundrum, namely why H_2 apparently catalyzes the dehydrogenation of **V** at temperatures close to ambient.[26] Figure 5 shows thermal images of the reactor, which reveal that H_2 causes a highly exothermic reaction and the generation of a distinct hot spot. A separate experiment with an internal thermocouple, deliberately located in the region of the hot spot, indicated that the temperature of the catalyst bed rose to approximately 200 °C. A further experiment with a series of six thermocouples positioned at regular intervals down the length of an 8 cm reactor showed that over 24 h the hot spot gradually moves down the catalyst bed; presumably the catalyst gradually becomes deactivated through charring or coking.[36] Thus, the explanation of the "catalysis" by H_2 is that hydrogenation of **V** rapidly heats a thin layer at the top of the catalyst bed to a temperature well above the light-off temperature for dehydrogenation of **V**. Since the dehydrogenation is itself exothermic, the reaction becomes almost self-sustaining and therefore can continue with almost 100% yield of **B** without the formation of **C**.

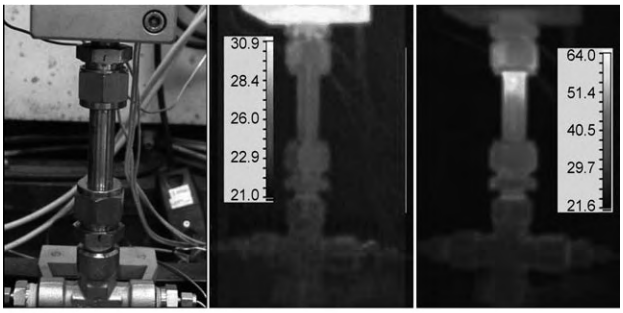

Figure 5. Evidence for hot spots during the dehydrogenation of **V** in the presence of H_2. a) photograph of the reactor; b) and c) thermal images of the same reactor with b) the pre-heater set to 40 °C, and CO_2 and **V** both flowing through it. Note the maximum temperature is 31 °C and c) with H_2 flowing and all other conditions unchanged. Note that the reactor skin has now reached nearly 65 °C. A thermocouple place at the center of the reactor reads over 200 °C. The exit temperature remained close to ambient. High-resolution color copies are available in the Supporting Information.

It is possible to suppress the dehydrogenation completely by deliberately cooling the reactor to 10 °C, although the catalyst bed itself is presumably at a higher temperature. This approach was used to generate sufficient quantities of **1** and **2** for their identification by NMR spectroscopy (see Supporting Information). Note that this low-temperature hydrogenation of **V** is a much simpler route to **2** than the original synthesis by Trost and co-workers,[37] which involved a Diels–Alder or cycloaddition reaction, and thus opens up the possibility of manufacturing this compound on a larger-scale if required.

The apparent catalytic effect of H_2 in the dehydrogenation **V** is the result of thermal hot spots generated in the catalyst bed by an initial exothermic hydrogenation "light-off" forcing the dehydrogenation reaction. The important point is that the possible presence of such hot spots in small-scale reactors should not be overlooked in other exothermic reactions in fixed bed reactors. Clearly it will be worth investigating the effects of different supercritical solvents on hot spots since different fluids can have significantly different thermal properties. In addition our study has resulted in the isolation of the diene, **2** by a potentially much simpler route than that previously reported.[37]

Many of our experiments would not have been possible on manually operated equipment because it was necessary to collect large amounts of data over a whole series of different reaction conditions, a process which would be impractically long without automation. However, handling such large volumes of data in itself presents problems and herein we have demonstrated again the value of 2DCOR-GC for presenting these data in a more easily interpretable form. Overall, one of the more important lessons from this work is that even apparently simple catalytic reactions are in reality quite complex, but that current techniques for supercritical chemistry are now capable of unraveling these complexities.

Experimental Section

Our automated continuous supercritical apparatus has recently been described in detail elsewhere.[16] Figure 1 shows a schematic of the design. Computer controlled HPLC pumps (Jasco CO_2–1580 and Jasco PU–980) deliver the CO_2 and organic substrate. The preheated CO_2/organic mixture is passed over the catalyst bed (2% $Pd/SiO_2/Al_2O_3$ supported: Johnson Matthey), which is heated by cartridge heaters and aluminum blocks. The temperature of the catalyst bed is controlled by a programmable Eurotherm. After the reaction has occurred and left the catalyst bed, the mixture of products and gases are passed through a HPLC 4-port sample loop (Valco/Vici), which samples 0.06 μL periodically into a GLC (Shimadzu GC17–A v.4), whereupon product separation and analysis is carried out. The system pressure and product separation is facilitated by a programmable Back Pressure Regulator (Jasco BPR BP-1580-81). Data analysis is performed off-line after the experimental is completed.

Molecular AND Logic Gate Based on Electric Dichroism of a Photochromic Dihydroindolizine**

Joakim Andréasson, Yuichi Terazono, Bo Albinsson, Thomas A. Moore,* Ana L. Moore,* and Devens Gust**

Molecular switches that perform Boolean logic operations are scientifically interesting and may have technological potential.[1–4] A variety of molecule-based logic switches (AND gates, OR gates, etc.) have been reported.[5–9] In the vast majority of cases, at least one of the gate inputs requires physical addition of a chemical species. We have reported several molecular switches that employ photochromes, and function with only optical or thermal inputs.[9–12] Orientation of molecules by electric fields can lead to optically detectable electric linear dichroic phenomena.[13] The ability to control solution absorbance by using either photochromism or electric fields suggests that molecular logic gates switched by these two inputs might be realizable. Here, we report a molecular AND gate based on photochromic dihydroindolizine **1** (Scheme 1) whose two inputs are light at 366 nm and an electric field, and whose output is the electric linear dichroism (ELD) of **1**.

The dihydroindolizine[14] photochrome **1** exists in two isomeric forms. The closed, thermally stable spiro form **1c** does not absorb light significantly in the visible region (Figure 1); its longest-wavelength absorption band is at 415 nm. Irradiation of **1c** with ultraviolet light causes isomerization to the open, zwitterionic form **1o**, which absorbs in the visible region ($\lambda_{max} = 585$ nm). Compound **1o** is isomerized back to **1c** by heat or visible light. Irradiation ($\approx 1.5\ mW\,cm^{-2}$) of a solution of **1c** in 2-methyltetrahydrofuran at 366 nm at 20.5 °C, produces a photostationary state greatly enriched in **1o** with a time constant of 10.6 s. This

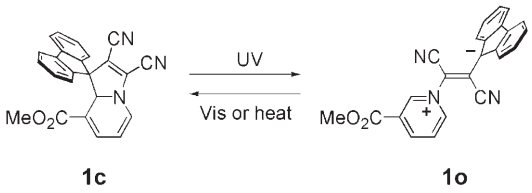

Scheme 1. Structures of the closed (**1c**) and open (**1o**) isomers of the dihydroindolizine. The thermally stable **1c** may be photoisomerized to **1o** with UV light of wavelength 366 nm and **1o** may be isomerized to **1c** with visible light or heat.

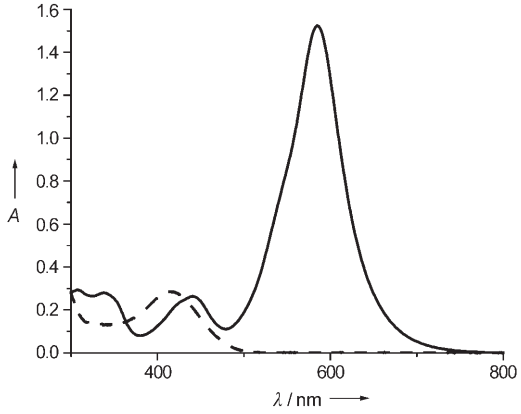

Figure 1. Absorption spectra of solutions in 2-methyltetrahydrofuran of the open (**1o** ——) and closed (**1c** -----) forms of the photochrome.

sample thermally isomerizes slowly back to **1c** ($\tau = 580$ min) in the dark. Irradiation of a sample in the **1o** state with visible light ($580\text{ nm} < \lambda < 900\text{ nm}$, $\approx 50\text{ mW cm}^{-2}$) leads to photoisomerization back to **1c** ($\tau = 9.8$ min).

ELD is the change in absorbance of plane-polarized light by a substance caused by an applied electric field. Isotropically oriented achiral molecules in an isotropic solvent have the same absorbance of plane-polarized light, regardless of the polarization. In the presence of an electric field, a molecule with a permanent dipole moment, such as **1o**, will partially align with the field. This causes orientation of the transition moment for absorption, and anisotropic behavior results. The magnitude of the absorbance change observed upon application of a field depends upon, among other things, the dipole moment and the isotropic extinction coefficient. Molecule **1o** is relatively polar, which favors alignment with an external field. It has an absorption maximum at 585 nm and could exhibit a significant ELD effect. Isomer **1c** does not absorb in the visible spectral region and is not expected to have a significant ELD response.

The ELD response for **1** was observed by using the apparatus detailed in the Experimental Section. The sample of **1** was placed in a cuvette containing two parallel, flat-plate metal electrodes separated by 1.6 mm. A beam of monochromatic plane-polarized light was passed through the sample between the electrodes, such that its plane of polarization was parallel to the electric field generated by application of a voltage across the electrodes. The intensity of the transmitted light was monitored with a photomultiplier tube. A voltage was applied across the electrodes to observe the ELD response. A 1.5 kV ac electric field (50 Hz, 940 kV m^{-1}) was used, and the change in light intensity induced by the field was measured by using lock-in detection. An ac signal from the lock-in amplifier reflects the change in absorption of the sample caused by the field (ELD response).

Figure 2 shows the ELD response (decrease in the intensity of transmitted light) for a sample of **1** that has been irradiated at 366 nm, and thereby converted into a

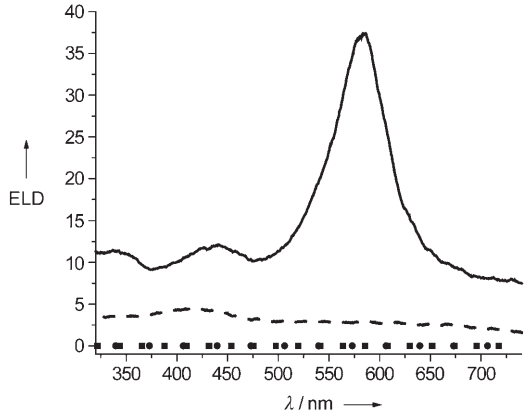

Figure 2. ELD response (arbitrary units) of a solution of **1** in 2-methyltetrahydrofuran: ——: following irradiation at 366 nm and with the application of the electric field; -----: following red light irradiation and with the application of the electric field; ●: following irradiation at 366 nm and in the absence of the electric field; and ■: following irradiation with red light and in the absence of the electric field. Note that the two data sets in the absence of the electric field overlap.

photostationary state consisting mainly of **1o**. The large band at approximately 583 nm is associated with the absorption of **1o** (Figure 1). The signal-to-noise ratio at 583 nm is very high, and the ELD response is easily observable. The ELD response and the absorption spectra are not expected to match exactly, as the ELD signal has not been corrected for the (wavelength-dependent) incident intensity nor converted into a logarithmic form. However, the lamp output as a function of wavelength is reasonably constant in this spectral region.

A similar experiment carried out with the closed form **1c** (obtained by irradiation with red light) yields a small electric-field response at the absorption maximum of approximately 416 nm (Figure 2). The response of **1c** is much smaller than that of **1o** because of differences in the dipole moment, extinction coefficient and orientation of the transition dipole. The small response in regions where **1** does not absorb is ascribed to the solvent, and it was observed even in the absence of molecule **1**. Figure 2 also shows the ELD response for **1o** and **1c** in the absence of the electric field. The response is essentially zero in both cases.

A Boolean AND logic gate requires two inputs, A and B, and an output. In the initial state with no inputs, the gate does

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

not generate an output. No output is produced when either input A or input B is switched on. However, if both inputs are on, then the gate produces an output. On the basis of the ELD effects noted above, a solution of **1** can function as a molecule-based AND gate. Inputs A and B are UV irradiation at 366 nm and the application of an electric field, as discussed above. The output of the gate is the ELD signal, monitored at 583 nm.

In the initial state of the AND gate, the molecule is set in the thermally stable **1c** form. This solution does not generate an ELD response in the absence of an electric field, and the output of the gate is off (Figure 3a). Irradiation of this solution at 366 nm (input A on) generates a photostationary state containing mainly **1o**. However, in the absence of an electric field (input B off), no ELD response is observed, and the gate remains off. If, on the other hand, the original solution of **1c** is subjected to the 50 Hz electric field (input B on), only a small ELD response caused by the solvent is obtained. If a suitable threshold level is chosen, the gate in this case remains off. Alternatively, when the solution of **1c** is subjected to both irradiation at 366 nm and the electric field, photoisomerization to **1o** occurs, and **1o** gives a strong ELD response at 583 nm. The gate is switched on. Thus, the conditions for the AND function are met. After applying any combination of inputs, the gate may be reset to **1c** by irradiation with red light.

Although the purpose of this research has been to investigate a new approach to molecular gates rather than to make practical devices, the stability of **1** is important for any future applications. Figure 4a shows the ELD response of

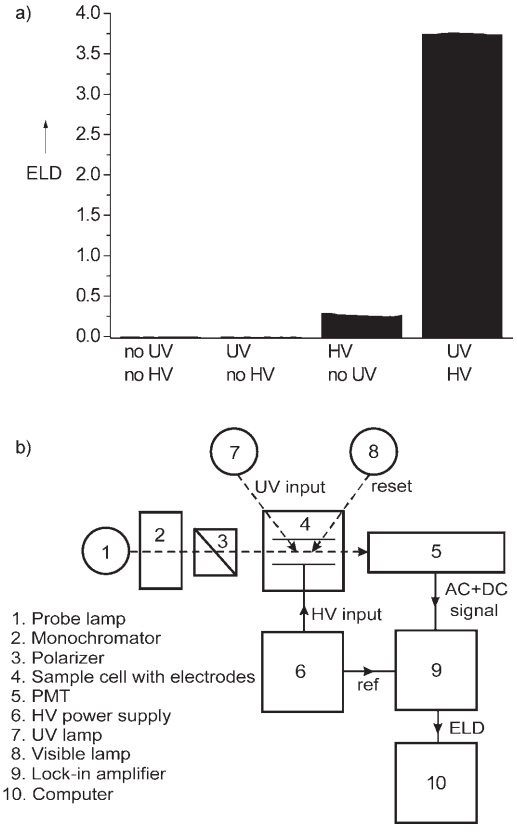

Figure 3. a) ELD response (arbitrary units) at 583 nm of **1** in 2-methyltetrahydrofuran following combinations of light (UV) and electric field (HV) inputs for the AND logic gate. Prior to the indicated inputs, the sample was in the **1c** state. The signal-to-noise ratio (variation of the ELD signal with time during a 4 s collection period, 20 data points) is shown by the small height variations within each bar. b) Schematic diagram of the experimental apparatus.

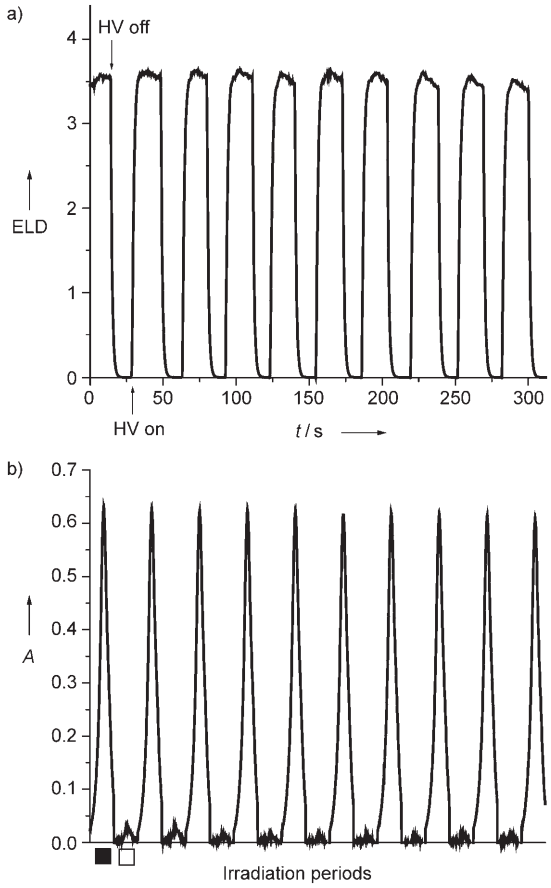

Figure 4. Cycling of the AND gate switching operations. a) The ELD signal at 583 nm from **1** in 2-methyltetrahydrofuran, measured for ca. 15 s after each switching operation, as a function of cycling of the applied voltage (HV) between 1.5 kV (HV on) and 0 V (HV off). b) Variation of the absorbance of **1**, recorded between 500 and 700 nm (where the zwitterionic isomer **1o** absorbs): after UV irradiation (■), and after red-light irradiation (□), as described in the text.

1o during application of 10 on–off cycles of the electric field. There is no degradation of the signal. Figure 4b reports the absorption between 500 and 700 nm (absorption from **1o**) after each of ten 40-s exposures to light at 366 nm alternated with nine 40-min exposures to red light. Only a small amount of photodegradation occurred after these cycles. The sample was degassed prior to the experiment with six freeze–pump–thaw cycles to a final pressure of approximately 1×10^{-4} Torr to reduce photodegradation.[15]

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

This molecular AND gate does not require the addition of chemicals or translational diffusion of molecules. The times required for the photoisomerizations involved in one input and in the resetting operation are determined by the light-flux applied. The light intensities used here were chosen for convenience, rather than switching speed. The photoisomerization reactions themselves occur in ns or less. The time required for readout is ultimately limited by the time required to align the molecular dipoles sufficiently, and will be on the order of rotational diffusion times. If ac detection is employed, the frequency of the applied ac field and time constant of the cell circuit will determine the time required for detection.

The UV photonic input to the AND gate may be applied at any time prior to readout and the system will "remember" that this input was turned on because of the photoisomerization. The gate will persist in the **1o** state until thermal reversion eventually occurs. However, the second input, the ac high voltage, must be on during readout or no ELD will be detected. This behavior differs from that of photonic gates in which both inputs are photoisomerization reactions and the final state of the gate may be read out at any convenient time after the inputs have been applied and turned off.[9,12]

In summary, a solution of photochrome **1** functions as a molecule-based AND Boolean logic gate with inputs of light of 366 nm and an ac electric field. The output is the electric linear dichroism response. Resetting the gate to the initial state is accomplished by irradiation with red light. The signal-to-noise ratio is more than ample for observation of gate switching, and the sample can be cycled many times before photodegradation interferes. The apparatus is relatively simple, requiring only UV, visible, and plane-polarized light, a light-sensitive detector, an ac voltage source, and, for high sensitivity, lock-in detection.

Experimental Section

Dihydroindolizine **1** was synthesized as reported.[14] The solvent for all measurements was freshly distilled 2-methyltetrahydrofuran. Photoisomerizations of **1** were achieved by using a UVP UV lamp UVGL-25 (366 nm, ca. 1.5 $mW\,cm^{-2}$) or a 1000 W Xe/Hg-lamp at 450 W. The light from the Xe/Hg-lamp was filtered with two hot mirrors (each having $A = 1.8$ at 900 nm) to reduce the IR intensity and a long pass filter (> 580) nm. The power density at the sample was approximately 50 $mW\,cm^{-2}$.

The electric linear dichroism (ELD) measurements (Figure 3b) were performed on a JASCO J-500 A CD spectropolarimeter with the photoelastic modulator disconnected, so that the incident light was linearly polarized parallel to the applied electric field. The silica cuvette (10×10 mm) was equipped with two planar stainless-steel electrodes (9.5 mm×22 mm) connected to a 50-Hz ac high-voltage power supply. The gap between the electrodes was 1.6 mm, and the voltage was 1.5 kV, which gave a maximal field strength of 940 $kV\,m^{-1}$. The light passing between the electrodes was detected with a photomultiplier tube (PMT) connected to a lock-in amplifier (LIA; EG&G Model 124A) equipped with a differential preamplifier (EG&G Princeton Applied Research Model 116). The LIA received a 50 Hz reference signal from the high voltage power supply. The LIA detects only the ac component of the PMT response in phase with the high voltage. The output of the LIA, which represents the raw ELD response, is shown in the Figures.

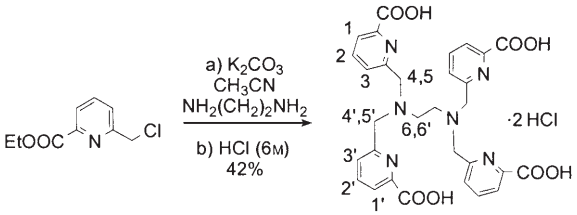
An Efficient Design for the Rigid Assembly of Four Bidentate Chromophores in Water-Stable Highly Luminescent Lanthanide Complexes**

*Nicholas Chatterton, Yann Bretonnière, Jacques Pécaut, and Marinella Mazzanti**

The unique electronic properties of lanthanide ions (long-lived luminescence and sharp emission spectra) make them particularly suitable for the development of diagnostic tools in medical analysis.[1,2] Lanthanide complexes are increasingly used for sensor development[3] and as luminescent probes in time-resolved high-throughput assays and fluorescence imaging because of their ability to discriminate between background fluorescence and the target signal.[4–8] Numerous studies have been directed to design efficient luminescence probes containing the long-lived visible emitters Eu^{III} and Tb^{III}[9–14] and more recently near-infrared (NIR) emitters (Pr^{III}, Er^{III}, Yb^{III}, Nd^{III}).[15–18]

As the Laporte-forbidden 4f–4f transition prevents direct excitation of lanthanide luminescence, lanthanide ions require sensitization by suitable organic chromophores. Furthermore, for practical applications under physiological conditions, the lanthanide ion should be incorporated into highly stable complexes. The efficiency of ligand-to-lanthanide energy transfer, which requires compatibility between the energy levels of the ligand excited states and the accepting levels of lanthanide ions, is crucial in the design of high-performance probes.[19] Moreover, high quantum yield cannot be obtained without the prevention of nonradiative deactivation of the lanthanide excited states by O–H oscillators of coordinated or closely diffusing water molecules. The incorporation of suitable chromophores in carefully designed polydentate ligands leads to increased stability of the lanthanide chelate in solution and allows for the metal center to be well protected from water molecules. However, the tendency of lanthanide ions to adopt high coordination numbers and their lack of stereochemical preferences make the design of such ligands very challenging.[20] A successful strategy adopted by several investigators relies on tripodal architectures for the organization of three tridentate binding units in nine-coordinate Ln^{III} complexes.[21–25] The design of polydentate ligands that allow the arrangement of four bidentate moieties around a lanthanide ion has received less attention in spite of the excellent luminescent properties observed for tetrakis complexes of bidentate chomophores, such as quinolinates[26] or tropolonates.[27] Recently, octadentate ligands incorporating four bidentate chromophores have been shown to yield lanthanide complexes with very efficient emissions in the visible or NIR regions.[15,28] The structures of these complexes have not been elucidated, but the highly flexible structure of the backbone that connects the bidentate units suggests nonoptimal protection of the metal center in such systems.

Herein, we describe a new and particularly efficient way of assembling four picolinate chromophores around a lanthanide center with a multidentate ligand that yields highly luminescent and water-stable lanthanide complexes. The decadentate ligand *N*,*N*,*N*′*N*′-tetrakis[(6-carboxypyridin-2-yl)methyl]ethylenediamine (H_4tpaen) is readily obtained in five steps from commercially available pyridine-2,6-dicarboxylic acid and ethylenediamine in a yield of 26% (Scheme 1).



Scheme 1. Synthesis of the ligand $[H_6tpaen]^{2+}$, and its numbering scheme for NMR spectral assignment.

The water-soluble complexes of tpaen were isolated in 50–60% yield by treating the ligand with $LnCl_3{\cdot}6H_2O$ (Ln = Ce, Eu) and adjusting the pH value to approximately 6. Five deprotonation constants ($pK_{a,1} = 2.8(1)$, $pK_{a,2} = 3.2(1)$, $pK_{a,3} = 3.9(2)$, $pK_{a,4} = 5.1(1)$, and $pK_{a,5} = 7.8(1)$) were determined for the $[H_6tpaen]^{2+}$ ions by potentiometric titration as well as the stability constants of the resulting Eu^{III} and Ca^{II} complexes ($\log\beta_{EuL} = 15.3(3)$) and Ca^{II} ($\log\beta_{CaL} = 8.5$ (5); see the Supporting Information). The values of pEu = 15.7, pGd = 15.0, and pCa = 8.5 ($-\log[M]_{free}$ at pH 7.4, $[M]_{total} = 1\,\mu M$, and $[tpaa]_{total} = 10\,\mu M$) relative to the value of pEu = 14.0 for ethylenediaminetetraacetate (edta) indicate that the tpaen ligand forms lanthanide complexes of sufficient stability for potential biomedical applications and shows a good selectivity for europium with respect to calcium.

The crystal structure of the complexes [{Eu(tpaen)}K$(H_2O)_3$]·$4H_2O$ (**1**; Figure 1) and [{Ce(tpaen)}K-

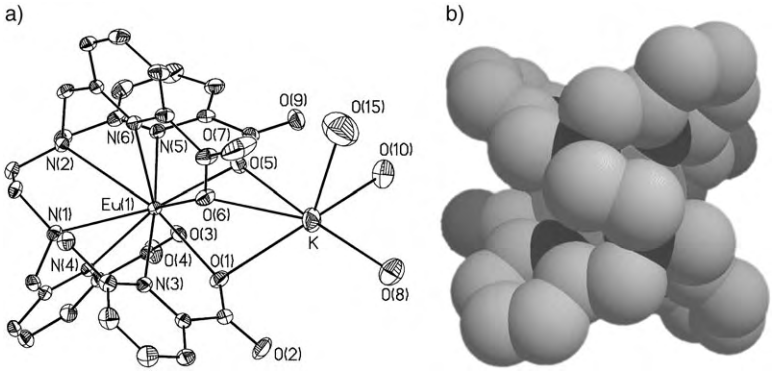

Figure 1. a) Molecular structure of $[\{Eu(tpaen)\}K(H_2O)_3]\cdot 4H_2O$ (**1**) (30% probability level). b) CPK (or space-filling) model of $[Eu(tpaen)]^+$ in **1**.

$(H_2O)_3]_2\cdot 16H_2O$ (**2**; see the Supporting Information) were analyzed by X-ray diffraction. In both complexes, the Ln^{III} ion is ten-coordinate with the four oxygen atoms (mean values of the M–O distances: 2.42(1) Å for Eu and 2.50(4) Å for Ce) and the six nitrogen atoms (mean values of the $M–N_{pyridine}$ distances: 2.65(4) Å for Eu and 2.72(1) Å for Ce, and mean values of the $M–N_{amine}$ distances: 2.91(1) Å for Eu and 2.91(4) Å for Ce) of the ligand. The bridging mode of the six-coordinate K^+ counterion differs in the two structures, thus leading to a monomeric structure for the Eu complex and to a dimeric structure for the Ce complex. The picolinate arms of the tpaen ligand wrap around the metal ion in a pseudo-C_2-symmetric helical arrangement that results in a chiral complex. Both complexes crystallize as a racemic mixture of Λ and Δ enantiomers in a centrosymmetric space group.

The ^{1}H NMR spectra of the Eu (Figure 2) and Ce complexes of tpaen in a solution of D_2O at room temperature and at pH 7 is consistent with the presence of rigid C_2-

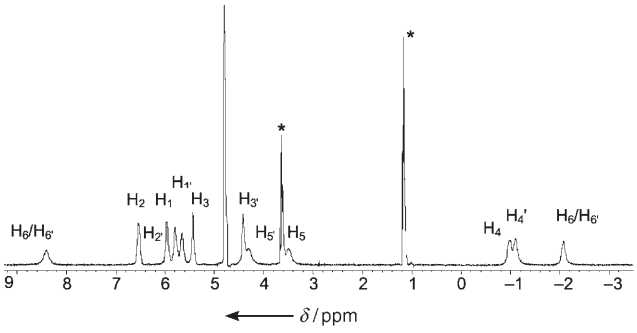

Figure 2. ^{1}H NMR spectrum at 298 K of [Eu(tpaen)]K in D_2O at pD = 6.9 (* denotes EtOH).

symmetric species in solution, in which the four chelating arms remain coordinated to the metal center on the NMR timescale. The observed symmetry is in agreement with a chiral helical solution structure, as found in the solid state. The complexes maintain their rigid structure in the temperature range 298–363 K. The presence of similar rigid C_2-symmetric species was also observed in the range 298–363 K for solutions of the tpaen complexes of La and Tb in D_2O prepared in situ. The high rigidity of these complexes in solution, rarely observed for lanthanide complexes with high denticity,[29] indicated that the arrangement of the ten donor atoms provided by the simple ethylenediamine backbone is very well adapted to lanthanide complexation, thus providing highly effective protection of the metal center from interaction with solvent molecules.

As a result, the Eu^{III} and Tb^{III} complexes of tpaen showed a bright and long-lived luminescence in solutions of both H_2O and D_2O. The observed lifetimes of the $Eu(^5D_0)$ and $Tb(^5D_4)$ levels for the $[Tb(tpaen)]^-$ and $[Eu(tpaen)]^-$ ions are in agreement with the presence of 0.04 ± 0.2 and 0.03 ± 0.2 coordinated water molecules in the Eu and Tb complexes, respectively. The luminescent properties of the visible-light emitting lanthanide ions Eu and Tb are efficiently sensitized by the ligand tpaen (Figure 3). An efficient ligand-to-metal energy transfer is

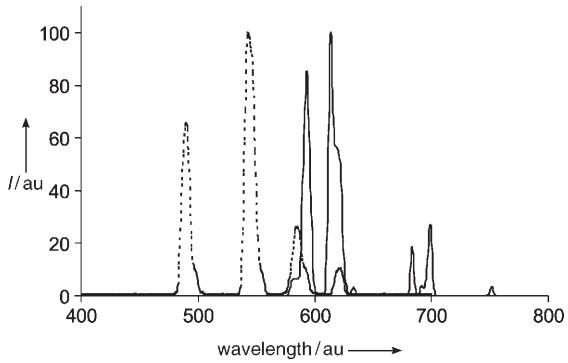

Figure 3. Normalized emission spectrum of $[Tb(tpaen)]^-$ (-----) and $[Eu(tpaen)]^-$ (——) upon ligand excitation at 274 nm.

suggested by close matching of the excitation and absorption spectra of the Eu and Tb chelates (Figure 4). The value of the quantum yield of the $[Tb(tpaen)]^-$ complex ($\Phi = 45\%$) measured relative to $[Tb(dpa)_3]^{3-}$ in aerated 0.1M tris buffer with an experimental error of 15% is one the highest reported to date.[28,30–32] The tpaen chromophore also efficiently sensitize the Eu ion to lead to a quantum yield value $\Phi =$ 7%, which is lower than that of the Tb^{III} complex but still

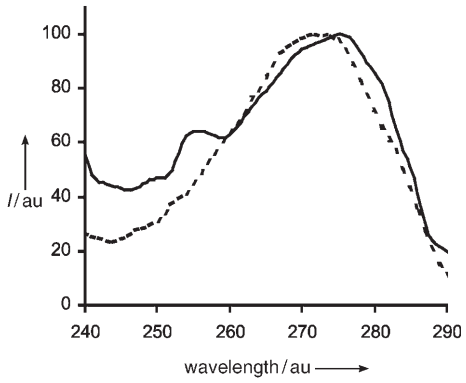

Figure 4. Absorption (•••••) and excitation spectrum (——) of [Tb-(tpaen)]$^-$ in tris Buffer.

significantly larger than the quantum yield of lanthanide-based commercial luminescent probes.[33,34] The very intense luminescence of these ions is a result of efficient (Table 1)

Table 1: Lifetime and absolute quantum yields in tris buffer (pH 7.4; 298 K) relative to $[Eu(dpa)_3]^{3-}$ and $[Tb(dpa)_3]^{3-}$ ions.

Compound	λ_{exc} [nm]	ε [$M^{-1}cm^{-1}$]	τ_{H_2O} [ms]	τ_{D_2O} [ms]	Φ_{H_2O}
tpaen	270	15800			
[Eu(tpaen)]	274	21600	1.70(2)	3.30(1)	0.07
[Tb(tpaen)]	274	21600	3.0(1)	3.75(1)	0.45

ligand-to-metal energy transfer and effective shielding of the metal ion from radiationless deactivation. The long luminescence lifetime observed for the terbium complex in H_2O rules out the presence of a de-excitation pathway that involves back transfer from the excited state of the metal center to the ligand. This leads to a high luminescence quantum yield. The synthesis of the ligand tpaen is simple, can be performed on large scales, and can be readily modified to anchor the complex with functions capable of binding biomolecules so that highly luminescent labels for time-resolved luminescence imaging can be developed.[32]

The straightforward approach used to organize four bidentate chromophores in the decadentate ligand tpaen has yielded lanthanide chelates that are highly soluble and stable at physiological pH values. Moreover, the ligand architecture leads to a rigid structure in solution, in which the metal center is effectively protected from interaction with the solvent molecules. This approach opens a wide variety of perspectives on the development of stable visible-light or NIR emitting luminescent probes for biomedical applications from suitable chromophores; investigations towards extending this approach to other chromophores are currently in progress.

Experimental Section

A detailed description of the synthesis of the ligand *N*,*N*,*N*′*N*′-tetrakis[(6-carboxypyridin-2-yl)methyl]ethylenediamine (H_4tpaen) and of the cerium and europium complexes is given in the Supporting Information. The complexes were prepared as follows: A solution of $CeCl_3{\cdot}7H_2O$ or $EuCl_3{\cdot}6H_2O$ (0.138 mmol) in water (0.5 mL) was added to a solution of H_4tpaen (0.138 mmol) in water (6 mL) at pH 5, adjusted by the addition of KOH (0.2 M). The resulting solution was then stirred at room temperature for 2 h and its pH value was readjusted to 6 by the addition of further KOH (0.2 M). The water was then evaporated and the resulting solid was suspended in EtOH (5 mL). The insoluble salts were removed by filtration and the filtrate was evaporated. Slow evaporation of a solution of the resulting solid in water (1 mL) yielded the tpaen complexes as yellow ([Ce(tpaen)]K) or white ([Eu(tpaen)]K) crystals after 5 days in 50–60% yield. Elemental analysis (%) calcd for $[Ce(tpaen)]K{\cdot}4.5H_2O$ ($C_{30}H_{33}N_6O_{12.5}CeK$): C 42.05, H 3.88, N 9.81; found: C 41.85, H 3.67, N 9.77; elemental analysis (%) calcd for$[Eu(tpaen)]K{\cdot}6H_2O$ ($C_{30}H_{34}N_6O_{13}CeK$): C 40.22, H 4.05, N 9.38; found: C 40.03, H 4.03, N 9.19.

[Ce(tpaen)]: ^{1}H NMR (D_2O, 400 MHz, 298 K, pD = 5.4): δ = −2.03 (sbr, 2H, H6/H6′), 0.09 (sbr, 2H, H5′), 1.18 (sbr, 2H, H6/H6′), 3.25 (d, 2H, H4′), 3.51 (d, 2H, H4), 5.44 (sbr, 2H, H5), 7.97 (d, 2H, H3), 8.10 (d, 2H, H3′), 8.45 (d, 2H, H1), 8.91 (t, 2H, H2), 8.94 (d, 2H, H1′), 9.04 ppm (t, 2H, H2′).

[Eu(tpaen)]: ^{1}H NMR (D_2O, 400 MHz, 298 K, pD = 6.9): δ = −2.07 (sbr, 2H, H6/H6′), −1.11 (sbr, 2H, H4′), −0.99 (sbr, 2H, H4), 3.48 (sbr, 2H, H5), 4.28 (sbr, 2H, H5′), 4.41 (dbr, 2H, H3′), 5.43 (dbr, 2H, H3), 5.65 (sbr, 2H, H1′), 5.79 (sbr, 2H, H1), 5.96 (br, 2H, H2′), 6.53 (br, 2H, H2), 8.40 ppm (br, 2H, H6/H6′).

Crystal data for $[\{Eu(tpaen)\}K(H_2O)_3]{\cdot}4H_2O$ (**1**): $C_{30}H_{38}EuKN_6O_{15}$, M_r = 913.7, monoclinic, space group $P2(1)/n$, a = 11.995(2), b = 14.539(3), c = 21.407(5) Å, β = 106.186(3), V = 3585.2(12) Å^3, Z = 4, ρ_{calcd} = 1.693 g cm^{-3}, μ = 1.944 mm^{-1}, T = 298 K. Of the 12504 reflections collected, 5133 were unique (R_{int} = 0.0192). Refinement on all data converged at R_1 = 0.0296, wR_2 = 0.0667. Max/min residual density 0.693 and −0.528 e Å^{-3}.

Crystal data for $[\{Ce(tpaen)\}K(H_2O)_3\}_2]{\cdot}16H_2O$ (**2**): $C_{30}H_{46}CeKN_6O_{19}$, M_r = 973.95, monoclinic, space group $P2(1)/c$, a = 11.7615(10), b = 14.5931(12), c = 22.965(2) Å, β = 101.640(1), V = 3860.7(6) Å^3, Z = 4, ρ_{calcd} = 1.676 g cm^{-3}, μ = 1.374 mm^{-1}, T = 193 K. Of the 12929 reflections collected, 7459 were unique (R_{int} = 0.0310). Refinement on all data converged at R_1 = 0.0430, wR_2 = 0.1340. Max/min residual density 1.055 and −2.462 e Å^{-3}.

Data were collected using a Bruker SMART CCD area detector three-circle diffractometer $2\theta_{max}$ = 59.38° (ω scans, $Mo_{K\alpha}$ radiation, λ = 0.71073 Å, graphite monochromator). CCDC-275838 (**1**) and -275839 (**2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

The number of coordinated water molecules present in solution q were determined from lifetime measurements by using the equation of Parker and co-workers ($q = A_{Ln}(1/\tau H_2O - 1/\tau D_2O - \alpha_{Ln})$ with A_{Tb} = 5 ms, A_{Eu} = 1.2 ms, α_{Tb} = 0.06 ms^{-1}, and α_{Eu} = 0.25 ms^{-1}).[35] Quantum yields Q have been calculated by using the equation $Q_x/Q_r = A_r(\bar{\nu})n_x^2D_x/A_x(\bar{\nu})n_r^2D_r$, in which x refers to the sample, r to the reference, A to the absorbance, $\bar{\nu}$ to the excitation wavenumber used, n to the refractive index, and D to the integrated emitted intensity. The tris(dipicolinate) complexes $[Eu(dpa)_3]^{3-}$ (dpa = pyridine-2,6-dicarboxylate; Φ = 13.5%, 7.5×10^{-5} M in tris buffer 0.1 M) and $[Tb(dpa)_3]^{3-}$ (Φ = 26.5%, 6.5×10^{-5} M in tris buffer 0.1 M) were used as references for the determination of the quantum yields of Eu- and Tb-containing samples, respectively.[36] The consistency of data was checked by measuring the quantum yield of the tris(dipicolinate) complexes against rhodamine 101 (Q_{abs} = 100% in ethanol) and cresyl violet (Q_{abs} = 54% in methanol).[37]

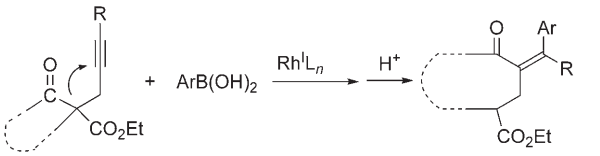
Acyl 1,3-Migration in Rhodium-Catalyzed Reactions of Acetylenic β-Ketoesters with Aryl Boronic Acids: Application to Two-Carbon-Atom Ring Expansions**

*Tomoya Miura, Masahiko Shimada, and Masahiro Murakami**

Rhodium(I)-catalyzed carbon–carbon bond-forming reactions with organometallic reagents have recently attracted significant attention in organic chemistry.[1] We report herein a new acyl 1,3-migration catalyzed by rhodium(I) and its extension to a two-carbon-atom ring-expansion reaction [Eq. (1)].



(1)

We recently reported that a cyclopentanol derivative can be synthesized from a 5-alkyn-1-one by intramolecular nucleophilic addition of an intermediate organorhodium(I) species to the ketone carbonyl group in a 5-*exo*-trig cyclization.[2] We next examined the possibility of an equivalent 4-*exo*-trig cyclization, although such a four-membered-ring formation would suffer from developing ring strain.[3] The desired 4-alkyn-1-one substructure was incorporated into the model substrate **1a**, which was readily synthesized by the alkylation reaction of a β-ketoester with 1-bromo-2-butyne. The 4-alkyn-1-one **1a** was treated with phenylboronic acid (**2a**, 2.0 equiv) in the presence of [{Rh(OH)(cod)}$_2$] (0.05 equiv of Rh) in dioxane/H_2O (100:1) at room temperature under a nitrogen atmosphere. The substrate **1a** was consumed in 16 h, and subsequent chromatographic isolation on silica gel afforded not the expected cyclobutanol derivative **3**, but rather the α,β-unsaturated ketone **4aa** in 69% yield (Scheme 1).

The following mechanism explains the production of **4aa**: A phenylrhodium(I) species is initially generated by trans-

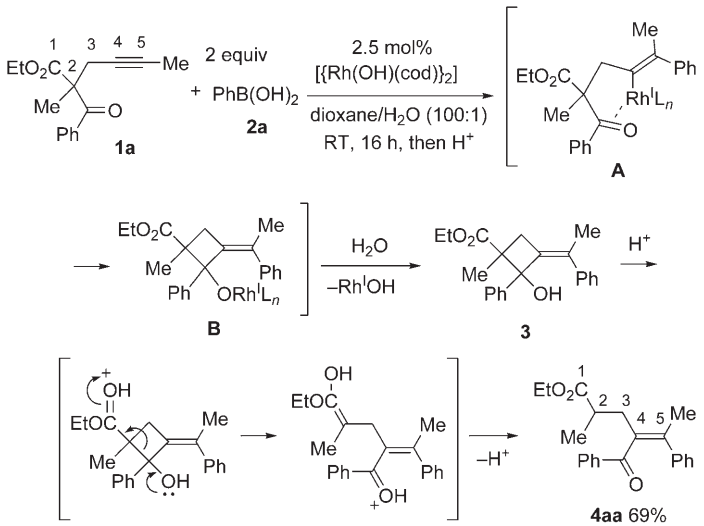
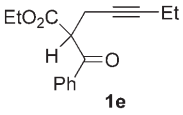


Scheme 1. Rhodium(I)-catalyzed reaction of acetylenic β-ketoester **1a** with phenylboronic acid (**2a**).

metalation of hydroxorhodium(I) with phenylboronic acid (**2a**), which then undergoes *cis*-1,2-addition to the carbon–carbon triple bond[4] in a regioselective manner directed by the ketone carbonyl group.[5] We propose that the resulting alkenyl rhodium(I) intermediate **A** undergoes intramolecular nucleophilic addition to the benzoyl group[6] in a 4-*exo* mode despite the development of ring strain. As a result, the four-membered ring carbocycle **B** is furnished as a rhodium(I) alkoxide. Hydrolysis produces the cyclobutanol **3** with regeneration of the catalytically active hydroxorhodium(I). Cleavage of the cyclobutane ring through a retro-aldol reaction is promoted by the acidic nature of silica gel during purification[7,8] to afford acyl 1,3-migration product **4aa**.

During the transformation of **1a** into **4aa**, a phenyl group was introduced at C5 of **1a**, and the resulting alkenyl rhodium intermediate facilitated migration of the benzoyl group from C2 to C4.[9] This 1,3-migration reaction was generally applicable to a variety of combinations of acetylenic β-ketoesters **1** and aryl boronic acids **2** (Table 1). Both electron-rich and -deficient aryl boronic acids were suitably reactive (Table 1, entries 1–4). *o*-Tolylboronic acid, however, failed in the acyl 1,3-migration reaction probably owing to steric reasons.[10] A better yield was obtained with 1b having an ethyl-substituted alkyne than with 1a (Table 1, entry 5).[5,6c] Methyl ketone **1c** also underwent acetyl 1,3-migration (Table 1, entry 6). The reaction of trimethylsilyl-substituted alkyne **1d** suffered from lower regioselectivity of the initial 1,2-addition and gave the product **4da** in only 25% yield (Table 1, entry 7).[11] Acetylenic β-ketoester **1e** without an α-substituent failed to undergo the cyclization reaction, probably because of the presence of a stable enol tautomer.



We next envisioned that if a β-ketoester moiety was installed in a cyclic skeleton, an analogous acyl 1,3-migration process would expand the ring by two carbon atoms to serve as a synthetic method for the preparation of medium-sized-ring carbocyclic skeletons.[12,13] Thus, we prepared the cyclopentanone substrate **5a** by the reaction of 2-(ethoxycarbonyl)cyclopentanone with 1-bromo-2-butyne. The cyclic substrate **5a** was treated with phenylboronic acid (**2a**) in the presence of [{Rh(OH)(cod)}$_2$] (0.05 equiv of Rh) in dioxane/H$_2$O (100:1) at room temperature for 6 h under a nitrogen atmosphere, and the resulting reaction mixture was then treated with aqueous NH$_4$Cl for 24 h to promote the retro-aldol process. As expected, the cycloheptanone **6a** was produced in 63% yield through phenyl addition and ring expansion [Eq. (2)].

7	**1d**	Ph	TMS	**2a**	Ph	**4da**	25

[a] Reaction conditions: **1** (0.2 mmol), **2** (0.6–1.0 mmol), [{Rh(OH)(cod)}$_2$] (0.05 equiv of Rh) in dioxane/H$_2$O (2.0 mL/20 μL); then treatment with aqueous NH$_4$Cl. [b] Yields of isolated products. cod = cyclooctadiene.

As listed in Table 2, the catalytic ring-expansion process worked well with substrates of five-, six-, and eight-membered-ring structures to give the seven-, eight-, and ten-membered-ring products, respectively, in yields ranging from 49% to 66%.[14] Cyclic 1,3-diketones **5f** and **5g** also underwent the analogous ring-expansion reaction. The ring opening of intermediate cyclobutanols formed from substrates **5c**, **5d**, and **5f** under the weakly acidic conditions proceeded more slowly than that of **5a** and thus required longer times for completion (see Supporting Information).

In summary, a new rhodium(I)-catalyzed acyl 1,3-migration reaction of acetylenic β-ketoesters was developed in which an intermediate organorhodium(I) species undergoes intramolecular nucleophilic addition to a ketone carbonyl group in a 4-*exo* process, which is followed by cyclobutane cleavage through a retro-aldol reaction. On the basis of this new 1,3-migration reaction, medium-sized carbocyclic rings

Oxygen Storage at the Metal/Oxide Interface of Catalyst Nanoparticles**

Tobias Schalow, Mathias Laurin, Björn Brandt, Swetlana Schauermann, Sebastien Guimond, Helmut Kuhlenbeck, David E. Starr, Shamil K. Shaikhutdinov, Jörg Libuda, and Hans-Joachim Freund*

Numerous processes in chemical industry, in emission control, and in energy technology involve the application of heterogeneous catalysts consisting of nanometer-sized metal particles on high-surface-area oxides.[1,2] Often, it is found that the activity of these so-called supported catalysts critically depends not only on the size and morphology of the metal particles, but also on the support itself. At the microscopic level, the origins of such effects are poorly understood in most cases. The situation turns out to be particularly intricate for the case of oxidation reactions on supported transition-metal particles. Here, many different oxygen species may be present under reaction conditions, for example, different types of chemisorbed oxygen, subsurface oxygen, surface oxides, and bulk oxides (see e.g. Refs. [3–16] and references therein). On some transition metals such as Ru, it has indeed been shown that not the metal surface itself but surface oxides formed under reaction conditions may represent the active phase of the catalyst.[17] Also for Pd surfaces strong changes in activity have recently been observed at higher partial pressures and have been related to surface oxidation processes (Ref. [18], see also Refs. [19,20]). In most cases, however, it is unclear what the role of the different oxygen species may be during oxidation reactions.

In this contribution, we suggest a new mechanism for oxygen storage and oxidation on oxide-supported metal catalysts: For a Pd/Fe_3O_4 model catalyst it is shown that large amounts of oxygen can be reversibly accumulated in form of a thin Pd oxide layer at the metal/oxide interface. From this interface oxide layer, which is stabilized by the support, oxygen is released and migrates back onto the metallic Pd surface, where it then is available for oxidation reactions. This storage mechanism may play an important role for the kinetics of oxidation reactions, in particular under non-steady-state conditions.

The experimental approach leading to these insights is summarized in Figure 1: Briefly, we employ well-defined supported model catalysts, which are characterized in detail by surface-science methods. These systems are then probed with respect to their reactivity using molecular beam techniques. The use of model systems is motivated by the high degree of complexity of real catalysts and by experimental restrictions concerning the application of surface-science methods to these systems. Both points often preclude detailed insights into the surface chemistry and structure of real catalysts. Supported model catalysts, on the other hand, provide clean and well-defined surfaces with strongly reduced complexity and are easily accessible for most experimental techniques available in surface science.[21–23]

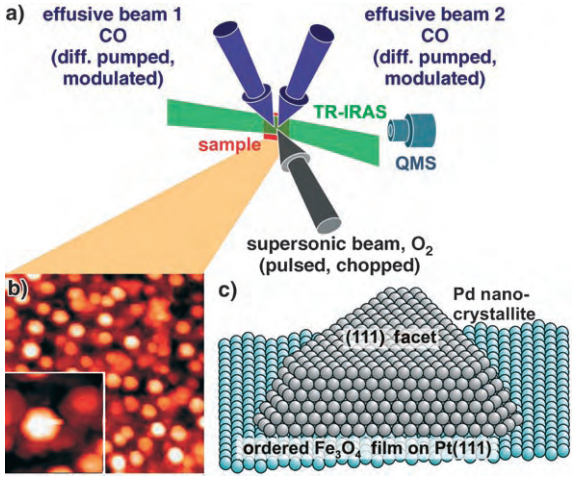

Figure 1. a) Representation of the molecular beam setup; b) STM image (100 nm × 100 nm, inset: 20 nm × 20 nm) of the Pd nanoparticles on Fe_3O_4/Pt(111) (after annealing at 600 K and oxidation and reduction at 500 K); c) model of the Pd nanoparticles.

In this study, we used Pd nanoparticles grown by metal-vapor deposition on a thin, well-ordered Fe_3O_4 film on Pt(111). The model catalyst was prepared in situ under ultrahigh-vacuum (UHV) conditions. Structure, morphology, and adsorption properties of both the Fe_3O_4 support[24,25] and the Pd particles were previously investigated in detail.[26] In Figure 1b a scanning tunnelling microscopy (STM) image of the Pd particles is shown as well as a model schematically illustrating their morphology. The three-dimensional particles have an average diameter of approximately 7 nm and contain around 3000 Pd atoms per particle. They are characterized by a well-defined crystalline shape, grow in (111) orientation with respect to the substrate, and expose a majority of (111) as well as a smaller fraction of (100) sites.

In order to study the interaction of the supported model catalyst with oxygen, we employed molecular beam (MB) methods. Molecular beams are well-established among the major experimental tools to study surface kinetics and dynamics[27–29] (for some recent examples in model catalysis see Refs. [30–32]). In this work, the technique is utilized to

quantitatively determine the oxygen uptake and release under exactly controlled and isothermal conditions. The MB apparatus used allows us to superimpose up to three independent reactant beams on the sample surface and facilitates simultaneous gas-phase detection (quadrupole mass spectrometry, QMS) and surface spectroscopy (time-resolved IR reflection absorption spectroscopy, TR-IRAS, see Figure 1 a).[33]

To quantitatively probe the oxygen uptake and release we performed pulsed CO titration experiments as shown in Figure 2: First, the model surface was exposed to a pulse of oxygen. After a defined delay time, short pulses of CO were applied in order to probe oxygen release by means of oxidation of CO to CO_2. The latter desorbs immediately and can be detected in the gas phase. In all experiments a supersonic beam of $^{18}O_2$ was employed in order to minimize the background signal. Experimentally, this type of pulsed titration technique allows an exact quantification of the CO_2 yield, even at very low reaction rates.

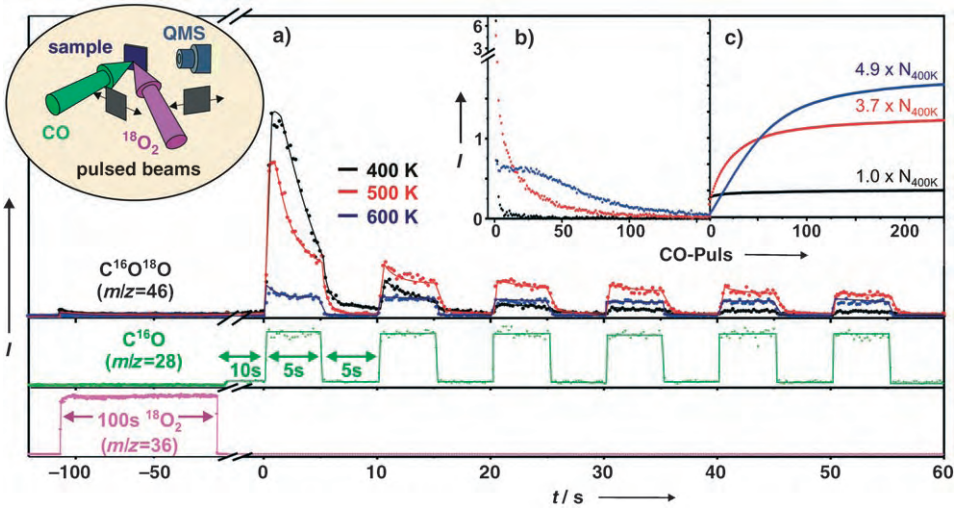

Figure 2. Pulsed CO titration experiment on the Pd/Fe_3O_4 model catalyst after oxygen exposure at different sample temperatures. Initially the model surface is exposed to a pulse of $^{18}O_2$ (100 s). After a delay time (10 s), pulses of CO (on-time 5 s, off-time 5 s) are applied to remove oxygen stored on the catalyst surface in form of CO_2: a) CO_2 formation rate; b) CO_2 yield per CO pulse; c) total CO_2 yield.

Pulsed titration experiments were performed as a function of surface temperature. At 400 K we find very high initial reaction rates, which drop to the background level within few CO pulses. The observations indicate high initial reaction probabilities and low oxygen uptake. This type of behavior is consistent with the presence of solely chemisorbed oxygen on the Pd particles and agrees well with what is expected on the basis of previous studies.[34–36] (The expected coverages of atomic oxygen would be around 0.25 monolayers (ML) on Pd(111) and around 0.5 ML on Pd(100), see Refs. [9,12] and references therein).

With increasing oxidation temperature (500–600 K) a surprising behavior is observed: The CO_2 formation rate in the first CO pulse decreases, but subsequently the rate remains finite for a long time, that is, up to 50 to 100 CO pulses. Simultaneously, the total CO_2 yield, obtained by integrating over all pulses (see Figure 2 b, c), increases drastically, indicating a nearly fivefold increase in the total oxygen release between 400 K and 600 K. Two conclusions can be drawn from these observations:

a) Partial surface oxidation of metal particles: The large oxygen release cannot be explained by surface chemisorption only. Alternatively, oxygen uptake and release by means of oxidation and reduction of the Fe_3O_4 support could be invoked. However, titration experiments on isotopically labeled supports show that oxygen exchange with the support is very slow under the experimental conditions applied in this work.[37] Therefore, we attribute the storage effect to the formation of a thin oxide layer on the Pd particles. It is well established that on Pd single crystals surface oxides can be formed under similar conditions.[10–16] Recently detailed structure models for surface oxides on both Pd(111)[13] and Pd(100)[14] were suggested on the basis of combined theoretical and experimental work. The oxygen densities in surface oxides drastically exceeds those in chemisorbed layers, allowing oxygen storage and subsequent release.[38] It is expected, however, that the oxidation behavior of small supported particles may differ from the behavior observed on single-crystal surfaces. Differences may arise, for example, from the simultaneous presence of different types of facets and low coordinated sites, from lattice distortions, and from the particle support interface. As will be discussed in a forthcoming publication,[37] the process of surface oxidation can be monitored and analyzed in detail by means of IRAS using CO as a probe molecule. For the work discussed here, the most important point to note is that metallic and oxidized surface areas coexist on the Pd particles over a large temperature region, ranging from approximately 450 K to 600 K. Within this temperature region the fraction of the metallic part decreases with increasing oxidation temperature.

b) Reactivity of partially oxidized metal particles: The low initial reaction rate after oxidation at 600 K shows that the CO reaction probability on the surface oxide is drastically lower than on the metallic surface. Consequently, for a partially oxidized surface the CO_2 yield of the first CO pulse can be interpreted as the amount of chemisorbed oxygen adsorbed on the metallic part of the Pd particles. With increasing oxidation temperatures, the amount of chemisorbed oxygen decreases as a result of the increasing fraction of the surface covered by the oxide. This result fits well with IRAS work mentioned above, showing that after oxidation at 600 K a major fraction of the particle surface is covered by surface oxides, whereas after oxidation at

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

500 K only a minor part is oxidized. Accordingly, the CO_2 yield of the following CO pulses can be assigned to CO oxidation involving oxygen originating from the oxide layer. Two points are noteworthy here: Firstly, the amount of oxygen stored at 500 K is large in spite of the small degree of surface oxidation (see Figure 2c)). As shown below, this effect can be attributed to a preferential oxidation of the particle/support interface. Secondly, the CO_2 yield per pulse is initially higher at lower surface oxide coverage (500 K oxidation) than at higher coverage (600 K oxidation). This finding indicates that CO does not react directly with surface oxide. Instead, we suggest that the reduction mechanism proceeds predominantly by slow decomposition of the oxide, releasing oxygen onto the metallic Pd parts, where it readily reacts with coadsorbed CO. This model is in agreement with a detailed analysis of the transient behavior of pulsed CO titration experiments.[37] We conclude that the surface oxide layer, covering part of the particle surface, acts as an oxygen reservoir allowing storage and release of oxygen in a reversible fashion.

In view of the above results showing partial oxidation of the Pd surface, the question arises which parts of the nanoparticle are initially oxidized and, therefore, are primarily responsible for the oxygen-storage mechanism. To address these questions we have performed high-resolution photoelectron spectroscopy (PES) using synchrotron radiation (see Figure 3). For the clean Pd particles before exposure to oxygen, the Pd $3d_{5/2}$ region contains two features: a Pd bulk signal (binding energy, BE = 335.0–335.1 eV) and a surface- and interface-derived component (BE = 335.3–335.6 eV) (compare e.g. Refs. [13,14]). The surface sensitivity of the experiment can be varied by changing the photon energy. With increasing photon energy ($h\nu$) the kinetic energy of the photoelectrons increases and so does the electron escape length λ ($h\nu = 465$ eV, $\lambda \approx 4$ Å; $h\nu = 840$ eV, $\lambda \approx 9$ Å[39]). As a result, the bulk feature becomes more prominent at higher photon energy, that is, at a lower degree of surface sensitivity.

After oxidation at 600 K (at similar oxygen doses as those in MB experiments), components at higher BE are observed, which are characteristic for oxygen chemisorption and surface oxidation. Based on high-resolution PES work on single-crystal surfaces,[13,14] the Pd $3d_{5/2}$ region can be qualitatively decomposed into three regions: 1) a low BE component (335.0–335.1 eV) related to bulk Pd metal, 2) an intermediate BE region (around 335.7 eV) containing contributions from metallic Pd coordinated to chemisorbed oxygen and from specific Pd atoms in thin oxide layers, and 3) a high BE region (around 336.6–336.7 eV) due to Pd atoms in thin oxide layers only. A more detailed assignment is precluded by the large number of nonequivalent Pd atoms, exposed by the supported particle system.

Two main conclusions can be drawn from the spectra. First, the constant BE of the Pd bulk feature upon oxidation indicates that the metallic nature of the particle core is preserved and rules out significant dissolution of oxygen in the Pd lattice, the latter result being in agreement with recent theoretical studies.[16] The most surprising observation, however, is the decreasing intensity of the metallic bulk signal with increasing photon energy (similar effects also observed at other photon energies and oxidation temperatures). This finding indicates that the Pd oxide layer is not preferentially formed on the outer particle surface, that is, at the Pd/vacuum interface, but rather below the particles, that is, at the metal/support interface. As a driving force for preferential formation of a Pd interface oxide we suggest that the oxide film is stabilized by interaction with the iron oxide support. Further evidence for this hypothesis is derived from transient MB experiments showing that there is a dynamic equilibrium between chemisorbed oxygen on the metallic Pd and the interface oxide, strongly favoring formation of the latter.[37] This observation is in contrast to the oxidation behavior of Pd single crystals, on which surface-oxide formation occurs at high oxygen coverage only.[16] Finally, it should be noted that the formation of a Pd interface oxide is in agreement with the MB and IRAS experiments discussed above, showing that at 500 K substantial oxygen storage occurs without a pronounced loss of the metallic Pd surface.

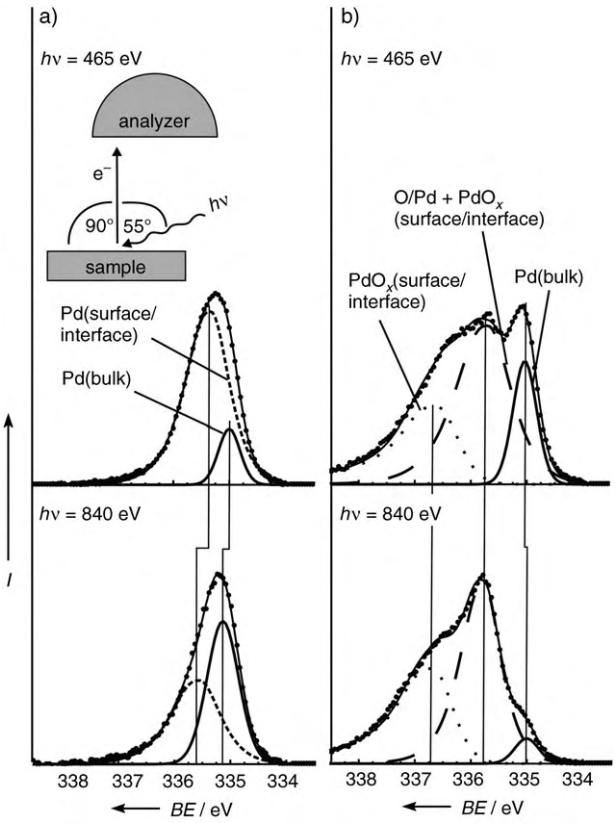

Figure 3. High-resolution core-level spectra of Pd $3d_{5/2}$ region after preparation of the model catalyst at different photon energies: a) immediately after Pd deposition and annealing in UHV to 600 K; b) after oxygen exposure at 600 K (oxygen dose: 3×10^{17} molecules cm^{-2}).

A schematic summary of our proposed oxygen-storage and CO-oxidation mechanism is depicted in Figure 4: We have shown that for a Pd/Fe_3O_4 model catalyst reversible oxygen storage and release occurs at 500 K and above through formation of thin Pd oxide layers. Preferentially the

oxide layer forms at the particle/support interface due to stabilization by the Fe_3O_4 support, before—under more drastic conditions—oxidation of the complete particle surface occurs. A dynamic equilibrium is established between oxygen chemisorbed on the metal and oxygen incorporated into the interface or surface oxides. As a result, the oxide layers can act as an oxygen reservoir for oxidation reactions. For the specific case of CO oxidation, the reaction with chemisorbed oxygen on metallic Pd is fast, whereas the reaction probability on the surface oxide is low. Thus CO oxidation occurs by release of oxygen from the interface oxide onto the metal surface, where it subsequently reacts with coadsorbed CO. Large amounts of oxygen can be stored and released by this mechanism, without substantial changes of the metal surface available. It may be anticipated that similar storage mechanisms might be active for other dispersed metal catalysts on reducible or irreducible oxide supports as well.

Experimental Section

MB and IRAS experiments were performed in a UHV apparatus at the Fritz-Haber-Institut (Berlin) which allows up to three beams to be crossed on the sample surface.[33] The CO beam (Linde, 99.997%, further purified by a gas filter (Mykrolis)) was generated by a doubly differentially pumped effusive multichannel array source and modulated by a motorized shutter. The $^{18}O_2$ beam (Campro Scientific, 95% ^{18}O, 99.7% purity) was generated from a triply differentially pumped supersonic expansion and modulated using a solenoid valve. Typical intensities of the beams were 2.1×10^{14} molecules $cm^{-2}s^{-1}$ for CO and 4.6×10^{14} molecules $cm^{-2}s^{-1}$ for O_2. For measuring the reaction rate, an automated QMS system (ABB Extrel) was employed. PES was performed at BESSY II, Beamline UE52-PGM1 with a 200-mm hemispherical energy analyzer (Scienta SES200). The energy resolution was approximately 100 meV at $h\nu = 465$ eV and 160 meV at $h\nu = 840$ eV.

The thin ($\approx$100 Å) Fe_3O_4 film was grown on Pt(111) by repeated cycles of Fe (>99.99%, Goodfellow) deposition and subsequent oxidation (see Refs. [24–26] for details). Cleanliness and quality of the oxide film was checked by IRAS of adsorbed CO (for MB experiments) and low-energy electron diffraction. Pd particles (>99.9%, Goodfellow) were grown by physical vapor deposition (Pd coverage: 2.7×10^{15} atoms cm^{-2}, sample temperature: 100 K) using a commercial evaporator (Focus, EFM 3, flux calibrated by a quartz microbalance). The particles were stabilized by annealing to 600 K in UHV and subsequent oxidation/reduction cycles at 500 K.

Short De Novo Synthesis of Fully Functionalized Uronic Acid Monosaccharides**

*Mattie S. M. Timmer, Alexander Adibekian, and Peter H. Seeberger**

Dedicated to Professor Albert Eschenmoser on the occasion of his 80th birthday

The biological importance of carbohydrates in a host of fundamental cellular processes has dramatically increased the demand for pure, synthetically derived oligosaccharides.[1] Over the past 100 years, chemical methods for the assembly of all classes of carbohydrates have been developed. This has resulted in sophisticated glycosylation reactions that allow the formation of even the most difficult glycosidic linkages with a high degree of selectivity.[2] More recently, automated methods for the rapid combination of monosaccharide building blocks on a solid phase were reported.[3] The time required to assemble an oligosaccharide has been reduced more than 100-fold, and as a result, the need for substantial quantities of and rapid access to fully functionalized building blocks has increased.

A typical monosaccharide building block used in oligosaccharide assembly is equipped with different protecting groups that mask the hydroxy and amine functions and an anomeric leaving group that can be activated to induce the formation of a glycosidic linkage. These differentially protected and functionalized monosaccharides have traditionally been accessed from naturally occurring sugar starting materials through a series of protection-deprotection maneuvers. Such a process establishes the desired protecting group pattern and typically requires 6–20 steps depending on the sugar, the protecting group pattern, and the anomeric leaving group.[4]

To avoid these lengthy procedures for producing building blocks for the assembly of larger structures, efforts have been directed at the synthesis of orthogonally protected hexose monosaccharides from noncarbohydrate precursors.[5] The landmark syntheses of hexoses by Masamune, Sharpless, and co-workers[6] were enabled by the ability of new synthetic methods to introduce specific stereogenic centers selectively. The aldol reaction has also proved to be a particularly useful tool in the creation of hexoses from simple precursors. Mukaiyama and co-workers[7] reported a stereoselective synthesis of pentoses and hexoses through the use of silyl enol ethers in aldol condensations to furnish partially protected pentoses and hexoses. Unfortunately, these fundamental explorations were not investigated further than the initial proof of concept. Recently, proline-catalyzed aldol reactions were used to fashion aldo- and ketohexose precursors for Mukaiyama-type aldol reactions, which were then used to synthesize partially protected glucose, mannose, and allose monosaccharides.[8] The yields and selectivities reported for these transformations, although excellent, were highly dependent on the specific protecting groups that were chosen.

Oligosaccharide assembly requires monosaccharide building blocks that contain orthogonal protecting-group patterns and a readily activated anomeric leaving group. Herein we report a convergent route to orthogonally protected D-glucuronic and L-iduronic acid thioglycoside building blocks, which are commonly used in the assembly of heparin oligosaccharides.[9] This approach relies on the selective Mukaiyama-type aldol reaction[10] that unifies a silyl enol ether and a thioacetal-containing aldehyde (derived from the chiral pool).

Retrosynthetic analysis of the uronic acids **A** (Scheme 1) revealed that the fully protected uronic acid thioglycosides could be obtained through cyclization of the linear hexoses **B**. The open-chain hexoses can be formed, in turn, through a Mukaiyama-type aldol reaction of an appropriately protected ketene acetal **C** with a thioacetal-containing aldehyde **D**.

Synthesis of the key thioacetal aldehydes **8** and **9** commenced with readily available L-arabinose (**1**; Scheme 2). The aldehyde was converted into the corresponding thioacetal by reaction with ethanethiol in the presence of hydrochloric acid.[11] Subsequent protection of the 4,5-diol with 2,2-dimethoxypropane furnished the crystalline acetonide **2**.[12] At this stage, the protecting-group patterns for the C2 and C3 hydroxy groups were selected. The reaction of **2** with NaH, in the presence of excess benzyl bromide, afforded

dibenzylarabinoside **3**, whereas formation of a tin ketal of the diol **2** and subsequent monobenzylation gave **4**. After acetylation of the remaining hydroxy group in **4**, selectively protected **5** was isolated in 46% overall yield together with 45% of the 2-*O*-benzyl-3-*O*-acetyl regioisomer. Deprotection of the acetal groups in **3** and **5** was followed by sodium periodate mediated cleavage of the resulting vicinal diols to form the desired aldehydes **8** and **9** in very good overall yields. Notably, these two key intermediates are derived from cheap, commercially available starting materials (L-arabinose) through straightforward and high-yielding transformations that are readily scalable.

After this efficient route for the synthesis of thioacetal aldehydes was established, the aldol reaction/cyclization sequence was explored (Scheme 3). The $BF_3{\cdot}Et_2O$ mediated aldol reaction[13] of aldehyde **8** with silyl enol ether **10**[14] gave a 1:1:1 mixture of three products as was determined by analysis of the ^1H NMR spectrum of the crude product mixture. The three individual aldol products were isolated by column chromatography and identified after conversion into the corresponding thiopyranosides. The free hydroxy groups of **11**, **14**, and **17** were first transformed into 9-fluorenylmethyl carbonates followed by cleavage of the silyl ether in the presence of pyridine·HF to obtain the alcohols **12**, **15**, and **18**, respectively, in good overall yields. Although initial attempts to effect cyclization under various acidic conditions proved to be challenging, NIS-promoted activation of the thioacetal led to the formation of pyranose carbohydrates **13**, **16**, and **19**, respectively, in quantitative yields.

At this stage, the absolute configurations of the pyranoses were established by the ^1H NMR coupling patterns of the carbohydrate ring protons. For compound **13**, the large coupling constants ($J = 8$–10 Hz) between 2-H, 3-H, 4-H, and 5-H provided the evidence to assign the *gluco* configuration. The *ido* configuration of **16** was assigned based on the characteristically small coupling constants ($J = 1$–3 Hz) for protons 2-H to 5-H. This configuration was further corroborated by the W coupling, $^4J_{2,4} = 1.0$ Hz, which is typical of a 2,4-diaxial-substituted pyranose. The coupling pattern for the less common altruronic acid **19** was in full accordance with the reported coupling constants for altroses.[15] Notably, no trace of the *galacto* uronic acid, the fourth possible isomer, was found. This absence can be rationalized through the assumption of a nonchelating, open-chain transition state that allows only the three C–C bond formations observed and not the sterically demanding *Si*, *Si* attack that would lead to the *galacto* isomer.

Once the absolute configurations of the aldol products had been determined, the selectivity of the aldol reaction was

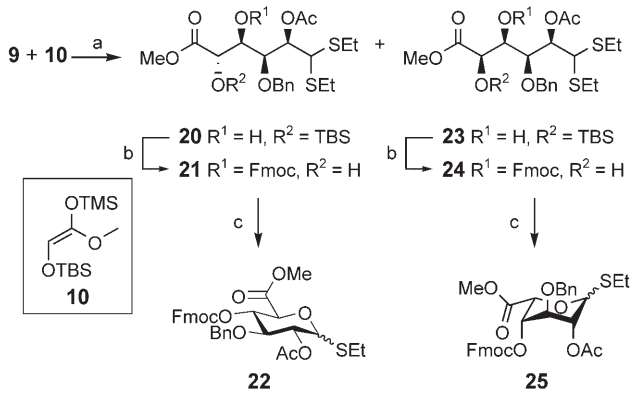
Scheme 3. explored further. It has been shown previously that stereoselectivities can be significantly improved by the use of metal Lewis acids in a chelation-controlled Mukaiyama-type aldol reaction.[13] We envisaged that Felkin–Anh addition of a silyl enol ether to a aldehyde, in an open transition state, should preferentially furnish a glucuronic acid. Indeed, the $MgBr_2{\cdot}Et_2O$-promoted aldol reaction of the aldehyde **8** and the silyl enol ether **10** (Method B, Scheme 3) afforded glucuronic acid **11** in quantitative yield as a single diastereomer.

The $BF_3{\cdot}Et_2O$-mediated aldol reaction between the selectively protected aldehyde **9** and ketene acetal **10** was also examined (Scheme 4). Surprisingly, analysis of the crude



Scheme 4. Synthesis of selectively protected D-glucuronic and L-iduronic acid building blocks. a) Method A: $BF_3{\cdot}Et_2O$, CH_2Cl_2, 0 °C, 15 min, 95% (**20**/**23** = 3:2); Method B: $MgBr_2{\cdot}Et_2O$, toluene, −78 → −30 °C, 1 h, 98% (only **20**); b) 1. FmocCl, pyridine, 2 h; 2. HF·pyridine, THF, 16 h, **21**: 79%, **24**: 76% (two steps); c) NIS, CH_2Cl_2, 15 min, quant. (**22** and **25**), (α/β = 1:1).

reaction mixture by ^1H NMR spectroscopy showed a 3:2 ratio of two diastereomers, and only traces of a third. Separation of the individual isomers followed by protecting-group manipulations and NIS-mediated cyclization led to the isolation of the pyranoses **22** and **25**. Through comparison of the ^1H NMR coupling constants with those of the pyranosides **13** and **16**, thioglycoside **22** was identified as D-glucuronic acid and **25** as L-iduronic acid. Finally, the $BF_3{\cdot}Et_2O$-mediated aldol reaction between **9** and **10** (analogous to the reaction of **8** and **10**) led to the formation of the *gluco*-configured product as the only detectable diastereomer (Method B, Scheme 4).

In conclusion, a highly convergent route to orthogonally protected D-glucuronic and L-iduronic acid thioglycoside building blocks has been developed. Rapid access to substantial quantities of monosaccharides that contain practical protecting group patterns and a readily activatable anomeric leaving group will greatly facilitate oligosaccharide assembly by using automated methods. The construction of heparin analogues and the development of efficient routes to further carbohydrate building blocks are currently under investigation.

A High-Throughput Investigation of the Role of pH, Temperature, Concentration, and Time on the Synthesis of Hybrid Inorganic–Organic Materials**

Paul M. Forster, Norbert Stock, and Anthony K. Cheetham**

Since their discovery in the 1940s, synthetic aluminosilicate zeolites have become a major research focus owing to their commercially important catalytic, ion-exchange, and sorption properties.[1] Because many of the commercially important zeolites may be synthesized without organic templates by altering simple variables such as temperature, reaction time, Si/Al ratio, and pH,[2] a detailed understanding of the role that these variables play in zeolite synthesis[3] remains one of the most important advancements in the field. Similar studies, to date, are rare for hybrid inorganic–organic systems. Instead, as a result of the remarkable success of reticular chemistry,[4] the field has focused on understanding the role of the organic molecules in determining the overall structures that hybrid materials adopt.[5] Consequently, while more than 13000 metal–organic frameworks (MOFs) have been described,[6] there are very few combinations of metal centers and ligands[+] for which more than two or three structures have been identified.[7]

The existence of five well-characterized phases of cobalt succinates containing water and/or hydroxide ions[8] offers a rare opportunity to examine the role of various reaction variables in determining which structure forms. Moreover, this family includes one-, two-, and three-dimensional systems, several of which contain infinite Co-O-Co networks,-which may display interesting magnetic[9] or catalytic[10] properties in addition to relatively high thermal stability.[11] However, since these cobalt succinate phases have been prepared by different research groups and by different procedures, a retrospective examination of the effect of the reaction conditions on the product formation is difficult.

Previously, we discovered that a very simple reaction of stoichiometric amounts of cobalt hydroxide and succinic acid in water could be used to produce the five known phases when we varied only the reaction temperature. We found that that less hydrated and increasingly dense phases form at higher temperatures.[8b] While our previous investigation was very successful in studying the role of temperature as an isolated variable, simultaneous study of additional reaction variables should provide additional insights into the chemistry of the system. Unfortunately, each increase in the number of variables raises the number of necessary reactions exponentially. The serial investigation of a large parameter spaces is impractical and most often infeasible. Recent progress in high-throughput materials science has led to the incorporation of parallel reactor systems that allow the investigation of hydrothermal syntheses. The methodology is characterized by low reagent consumption, and a complete set of parallel reactors can be set to work under identical reaction conditions. Thus, synthesis regions for various phases can be efficiently established. The application of the methodology has recently lead to a number of systematic investigations in the field of phosphonate-based inorganic–organic hybrid compounds with a focus on the role of the pH on the reaction product.[12–15] Here, we use high-throughput hydrothermal synthesis to elucidate the role of four variables in the cobalt succinate system: temperature, pH, concentration, and reaction time.

In analogy to our previous studies on the cobalt succinate system,[8b] we examined reactions of the $Co(OH)_2/C_4H_6O_4/H_2O$ system. One significant advantage is that the number of reactants is held to a minimum since the cobalt source contains the hydroxide ions necessary to deprotonate the dicarboxylic acid. Inclusion of the base in the cobalt source is also advantageous for reactions in dilute solution since weighing errors inherent to the small scale could translate into very large pH changes with other bases, such as alkali hydroxides. A second advantage is that this method does not generate salt by-products, preventing the complications from having to consider the role of different bases, additional phases that may incorporate cations from these bases,[8c] and the salt concentrations' influence on the reaction.[16] One disadvantage of this approach is that the pH cannot be determined quantitatively due to the insolubility of cobalt hydroxide, although reaction mixtures with excess metal hydroxide and succinic acid are clearly basic and acidic, respectively.

The reactions were carried out in a teflon-lined 48-reactor block with a sample volume of approximately 400 μL per reactor. We initially selected eight $Co(OH)_2/C_4H_6O_4$ ratios, six concentrations, and six temperatures, for a total of 288 reactions. The quantity of water was fixed at 200 μL, such that the vessels were filled to the same extent for most reactions. Except for reactions at very high concentrations and acidity, the amount of reactants added did not change the total volume appreciably. The reaction temperatures ranged from 75–200 °C at intervals of 25 °C. To keep the total number of

reactions reasonable, the role of time was tested by setting up identical sets of 48 reactions for 5, 25, and 75 h at 150 °C, which added a further 96 reactions. The reaction parameters investigated are summarized in Table 1.

Table 1: Summary of the temperatures, concentrations, and acid/base ratios simultaneously explored in this work.

T [°C]	75	100	125	150	175	200		
$H_2O/Co(OH)_2$	200	150	110	75	50	25		
succinic acid/$Co(OH)_2$	0.2	0.4	0.6	0.8	1	1.2	1.5	2

Of the reaction parameters investigated, the $C_4H_6O_4$/$Co(OH)_2$ ratio and temperature proved to be the most important. For concentrations and reaction times similar to those used in our previous study ($H_2O/Co^{2+} = 110$, 75 h), variation of temperature the $C_4H_6O_4/Co(OH)_2$ ratio allowed us to synthesize four of the five phases reported in the previous paper on temperature[*] as well as two new phases, summarized in Table 2. The new phases F and G both occur

Table 2: Summary of phases of cobalt succinate. For dimensionality, the overall dimensionality is given followed by the metal–oxygen–metal dimensionality in parenthesis.

Code	Phase	Dimensionality	Ref.
A	$[Co(H_2O)_4(C_4H_4O_4)]$	1 (0)	[8a]
B	$[Co(H_2O)_2(C_4H_4O_4)]$	1 (0)	[8b]
C	$[Co_4(H_2O)_2(OH)_2(C_4H_4O_4)_3]\cdot 2H_2O$	2 (2)	[8c]
D	$[Co_6(OH)_2(C_4H_4O_4)_5]\cdot 2H_2O$	3 (2)	[8d]
E	$[Co_5(OH)_2(C_4H_4O_4)_4]$	3 (2)	[8e]
F	$[Co_7(H_2O)_3(OH)_6(C_4H_4O_4)_4]\cdot 7H_2O$	2 (1)	[18]
G	"$[Co_7(H_2O)_2(OH)_{12}(C_4H_4O_4)]$"	2 (2)	[19]

under considerably more basic conditions than those in the original investigation, and they contain much more hydroxide. The powder diffraction diagram of the first of these new cobalt succinates, F, matched the simulated powder diffraction pattern for a nickel succinate material previously described by Guillou et al. using ab initio structure solution from synchrotron powder diffraction.[17] We have subsequently obtained single crystals of the cobalt analogue and will publish a complete description of the structure elsewhere.[18] The second new phase, G is easily recognized by its bright blue color, whereas the rest of the known cobalt succinates vary between pink and dark purple. Despite a significant amount of additional work using conventional autoclaves, we were unable to obtain single crystals or phase-pure powder samples of this material. However, given its color (which is indicative of the presence of tetrahedral Co^{2+} ions), the conditions under which it forms, and the position and high intensity of its first powder diffraction peak, this material is likely to be a layered hydroxide material with cationic brucite-like sheets and succinate anions between the layers. We believe that this phase is related to $[Co_7(H_2O)_2(OH)_{12}$ (ethanedisulfonate)], which forms from a similar reaction and contains both tetrahedral and octahedral Co^{2+} ions.[19]

We have constructed a crystallization diagram for temperature and $C_4H_6O_4/Co(OH)_2$ ratio (Figure 1) by choosing a fixed concentration (molar ratio $Co(OH)_2/H_2O = 1{:}110$, as used in the original study). The results are very similar for other concentrations, but deviations will be discussed shortly. Co_3O_4 and unreacted $Co(OH)_2$ have been omitted for simplicity.

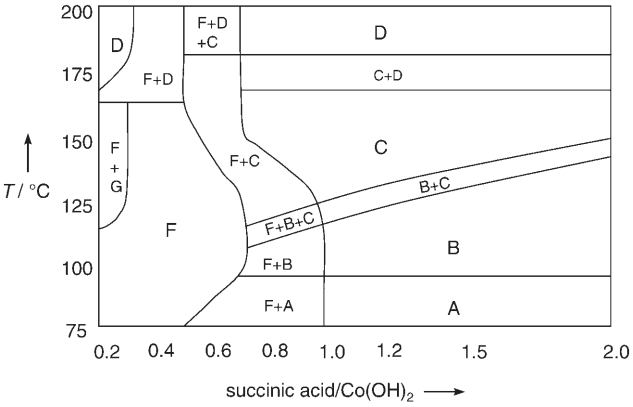

Figure 1. Crystallization diagram for the parameters reactant ratio (succinic acid/$Co(OH)_2$))and temperature at the fixed molar ratio $Co(OH)_2/H_2O = 1{:}110$. The phases are indicated by their letter code as assigned in Table 2. Unreacted $Co(OH)_2$ as well as Co_3O_4 have been omitted for clarity.

It is evident from Figure 1 that once sufficient succinic acid has been added to neutralize the hydroxide ions of $Co(OH)_2$, additional acid plays a very limited role in determining the phase. The only clear exception occurs at the boundary between the B ($[Co(H_2O)_2(C_4H_4O_4)]$) and C ($[Co_4(H_2O)_2(OH)_2(C_4H_4O_4)_3\cdot 2H_2O]$) regions, where higher concentrations of succinate were observed to favor B, while lower concentrations favored C. Since C contains hydroxide and B does not, it is reasonable that the additional amounts of acid would hinder the formation of C.

The two new phases, F ($[Co_7(H_2O)_3(OH)_6(C_4H_4O_4)_4\cdot 7H_2O]$) and G ("$[Co_7(H_2O)_2(OH)_{12}(C_4H_4O_4)]$"), encountered in this survey both occur on the basic (left) side of the phase diagram. It is surprising, given the number of groups that have studied cobalt succinates and the wide range of conditions for which F forms, that this phase has not been identified previously. More surprisingly, while the highly condensed Co–O ribbons and moderately high number of Co^{II} atoms per carboxylate group in the structure of F are more typical of hydrothermal phases, it is evident from Figure 1 that the structure forms most readily at lower temperatures. This suggests that more basic conditions may also be used to favor more condensed structures in the same

[*] Since the high-throughput autoclaves can be operated at temperatures only up 200 °C , we could not reach sufficiently high temperatures to prepare $[Co_5(OH)_2(C_4H_4O_4)_4]$ (phase E, Table 2). However, since all the other phases were obtained at the corresponding reaction conditions, we are confident that this phase would have formed at higher temperatures in this study as well.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

way that temperature does. The blue phase G described above occurs only under the most basic conditions studied at temperatures between 100 and 150 °C.

We have summarized the seven cobalt succinate phases in a ternary plot based on composition (Figure 2). It is interesting to note that the five original phases (A–E) occur along an approximate line on the left-hand side of the triangle while the two new phases (F and G) lie closer to the more basic corner of the diagram. We have added arrows indicating the effect of temperature and more basic conditions on the formation of cobalt succinate phases.

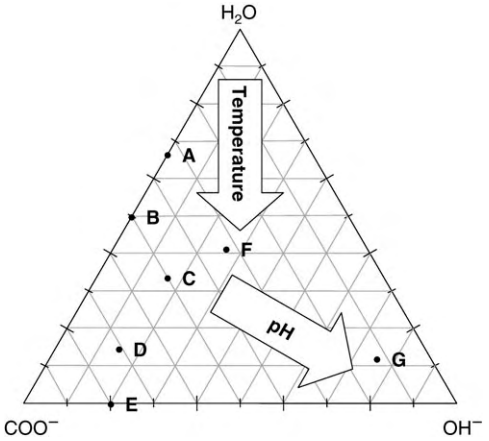

Figure 2. Ternary composition map for the seven known forms of cobalt succinate. The direction that temperature and reactant composition (indicated pH) tend to shift a reaction are indicated with arrows.

The role of reaction time, which was investigated for 150 °C only, indicated that reactions are more or less complete after one day. Corresponding crystallization diagrams for different molar ratios $H_2O/Co(OH)_2$ and $C_4H_6O_4/Co(OH)_2$ are presented in Figure 3 for the products obtained after 5, 25, and 75 h. Under strongly acidic conditions, the shortest reaction time produced phase B, which is normally found at lower temperatures, while longer reactions led almost exclusively to phase C. It is likely that some crystallites of B would form while the reactor block is heating, and that this phase may persist for some time before C, the more thermodynamically favorable phase for these conditions, forms. It is also possible that much smaller crystallites of C formed during the short reaction time, but dissolved and recrystallized as phase B while the autoclave cooled (ca. 1 h).

For intermediate acid/base ratios between 0.6 and 1.2, mixtures of phases F and C form over a wide range for the 5-h reaction, while mixtures of the two phases were observed only for the molar ratio $C_4H_6O_4/Co(OH)_2 = 0.6$ for the longer two reaction times. The most likely explanation is that F forms initially by reaction between the cobalt hydroxide and succinic acid, and that excess succinic acid then reacts with F to produce C.

Finally, under the most basic conditions (acid/base ratios of 0.6 and less), there were no differences in the phases that formed, although it was qualitatively evident that, for longer reaction times, the X-ray peaks corresponding to products

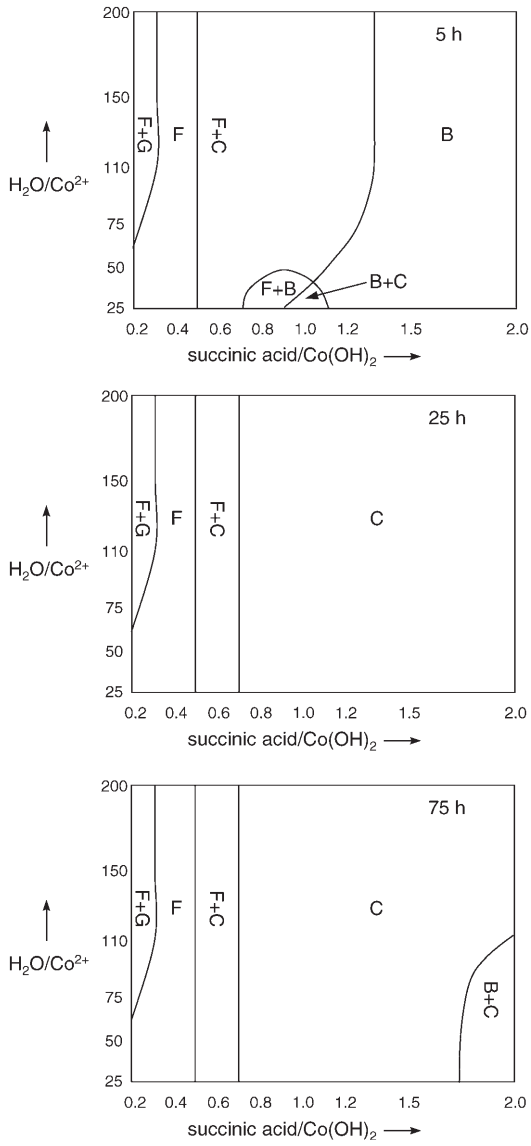

Figure 3. Crystallization diagrams for three sets of reactions carried out for 5, 25, and 75 h. These figures plot the phases observed by varying reactant composition and concentration at a fixed temperature of 150 °C.

increased in intensity relative to $Co(OH)_2$ peaks between the three time intervals. Further experiments, particularly in situ studies, will undoubtedly help to further clarify these observations.

Finally, concentration proved to be relatively unimportant. The most prominent instance where it influenced a reaction involved the formation of G. At high concentrations, G did not form at all. At lower concentrations, an increase of the relative peak height for G relative to F was noticeable as concentration dropped. Qualitatively, concentration appeared to influence crystal size. Although the effect varied considerably from reaction to reaction, the most concentrated reaction mixtures often led to the smallest crystallites for a given set of reaction conditions.

Several different groups have studied cobalt succinates during the seven years since the first example, $[Co_5(OH)_2$-

$(C_4H_4O_4)_4]$ (phase E), was described by Livage et al. Here, we show that a simple, systematic, examination of parameter space resulted in the discovery of two additional phases in this already diverse family of materials. Furthermore, our approach shows the roles that temperature, acid/base ratio, time, and concentration play in determining which structure forms. Thanks to the rapid development of high-throughput hydrothermal methods, systematic studies such as this may be carried out in a matter of weeks, opening the door to the discovery of fascinating new compounds and an improved picture of the role that synthesis parameters play in their formation.

Experimental Section

Newly machined teflon liners for the autoclaves were used for these experiments. The machined liners were washed five times with deionized water, heated for 1 h in freshly prepared aqua regia, rinsed five times with water, heated in water to boiling for 90 min, rinsed five times with acetone, and dried at 60 °C. A similar procedure (without the acetone rinse and with an overnight soak in aqua regia) was used to clean liners for subsequent uses to insure that no nucleation centers were present.

Cobalt hydroxide (Alfa Aesar, 99.9 %) was weighed directly into the teflon liner inside an enclosed balance. The liners were handled with plastic tweezers in order to minimize weighting errors and contamination. Succinic acid (Aldrich, 99 + %) was then weighed on a piece of wax paper and added to the liner. Doubly deionized water was added as a final step using an Eppendorf pipette. The pipette was calibrated beforehand to deliver 200 μg (as verified by balance) with a consistency of better than ±1 μg. The reaction mixtures were not stirred, but sealing and moving the reaction vessel obviously resulted in some agitation.

Reactions were carried out immediately after the addition of water. Reactions were run for 75 h with two exceptions, those at 100 °C and 200 °C, which were run for 25 h. Based on our study of the kinetics, it is unlikely that this deviation affected the results. The reaction vessels were then cooled in air on a metal surface, and the mixtures were filtered as soon as possible in order to prevent dissolution of any phases stable at higher temperatures but not favored at lower temperatures. The reaction products were removed by pipette, rinsed with water followed by acetone, and dried in air at room temperature.

X-ray powder diffraction patterns were collected on a high-throughput X-ray powder diffractometer STADI P from STOE (monochromated $Mo_{K\alpha}$ radiation) equipped with a PSD detector and a horizontal *xy* stage for automated analysis without individual sample manipulation. Each sample was measured in 8 min in the range between 2 and 22° (2θ). X-ray powder diffraction patterns were compared to calculated patterns of known reaction products using Powdercell.[20] Comparisons were made for $Co(OH)_2$[21] as well as other known cobalt succinate structures.

Quantum Dots as Efficient Energy Acceptors in a Time-Resolved Fluoroimmunoassay**

Niko Hildebrandt, Loïc J. Charbonnière,* Michael Beck, Raymond F. Ziessel, and Hans-Gerd Löhmannsröben*

Dedicated to Professor Herbert Dreeskamp on the occasion of his 76th birthday

The last decade has witnessed the emergence of semiconductor nanoparticles as very attractive building blocks for nanotechnology. Spherically or ellipsoidally shaped nanoparticles, also called quantum dots (qdots), display size-dependent optical properties with extremely large absorption cross sections.[1] When appropriately protected from the surrounding media by a covering shell, they display narrow and symmetric emission bands with quantum yields approaching unity in some cases.[2] The inorganic cores of qdots are also more robust than organic dyes or luminescent proteins toward photobleaching.[3,4] Recent accounts have reported on the possibility of derivatizing qdot surfaces,[5] thereby offering a broad scope of opportunities for chemical and biological interactions.[6] These combined features make qdots excellent tools in analytical techniques associated with fluorescence spectroscopy, reaching sensitivity limits going down to the single particle.[4] Qdots display extremely high extinction coefficients over a wide range of wavelengths as a result of the absorption of photons with energies higher than the band gap of the semiconductor material. The resulting excitons (electron–hole pairs) recombine to generate photons with narrow emission bands. These properties make qdots excellent energy donors in fluorescence (or Förster) resonance energy transfer (FRET) experiments,[7] a technique that is ideally suited for events occurring at the nanometer scale, such as numerous biological processes. For instance, a homogeneous maltose sensor has been described in which the maltose concentration can be monitored by the recovery of qdot luminescence concomitant to the displacement of a quencher dye.[8]

Importantly, if qdots are to be used as energy acceptors, significant direct excitation may be undesirable as it limits the extent of resonance transfer and results in spurious fluorescence emission. The use of qdots as energy acceptors has proven possible in a few solid-state devices based on semiconductor quantum wells,[9] with smaller-sized qdots,[10] and with a blue-emitting polymer[11] as the energy donor, but very rarely in discrete molecular systems in solution.[12,13] Mattoussi and co-workers explained low energy-transfer efficiency from organic or inorganic donors to the qdot acceptors by the fact that the rate of FRET is much slower than the fast radiative decay rates of the donors.[12]

In the present work, we report that CdSe/ZnS core shell qdots are excellent energy acceptors in a time-resolved fluoroimmunoassay system in which a terbium chelate with long-lived luminescence lifetime is the energy donor and the strong biotin–streptavidin interaction is used for the recognition process.

The TbL chelate consisted of a terbium cation embedded in a ligand made of two 6-carboxybipyridyl arms organized on a glutamate framework (Figure 1). The terminal carboxylate function of the glutamic residue was activated with the sodium salt of *N*-hydroxysulfosuccinimide in the presence of EDC·HCl (EDC = *N*-ethyl-*N*′-(3-dimethylaminopropyl)carbodiimide hydrochloride) according to an existing procedure.[14] The activated ester, TbL*, was incubated with streptavidin in PBS buffer (pH 7.4) overnight at room temperature, and the unreacted complex was removed by extensive dialysis of the protein. The absorption spectrum of TbL-Strep is a quasi-perfect linear combination of the spectra of streptavidin and 3.5 TbL complexes (Figure 2). Material with this labeling ratio was used in all further experiments (schematically simplified by four TbL labels on streptavidin in Figure 1).

The MALDI-TOF mass spectra of the labeled tetrameric streptavidin protein show that the labeling is not simply localized on one site of each monomeric unit (see Supporting Information). While a single marker per monomer is the major species observed, monomers containing zero, two, and three labels (trace amount) are also evident in the spectrum, pointing to at least two different environments for the Tb complexes. Upon excitation in the $\pi \rightarrow \pi^*$ transitions centered on the bipyridine moities at 308 nm, the emission spectrum of TbL-Strep displays the typical emission lines of the Tb^{3+} $^5D_4 \rightarrow {}^7F_J$ ($J = 0$–6) electronic transitions (Figure 3). Excitation of the ligand resulted in an efficient energy transfer to the lanthanide cation. The labeling process did not greatly perturb the Tb environment and, in pure water, the luminescence lifetime of TbL-Strep shows a bi-exponential behavior with a major long-lived component of 1500 ± 10 μs (97 %) and

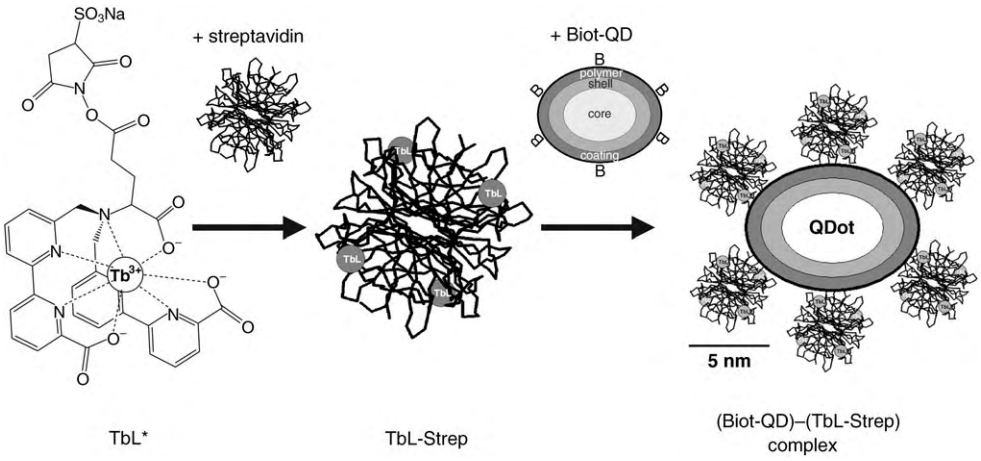

Figure 1. Schematic representation of the assembly of the Biot-QD/TbL-Strep complex. TbL-labeled streptavidin binds to biotin on the polymer surface of the qdot.

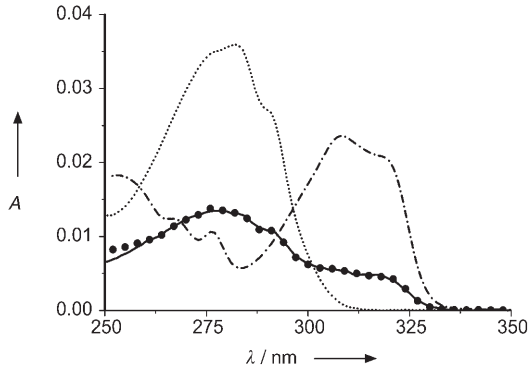

Figure 2. UV/Vis absorption spectra of streptavidin (••••, $c = 4.25 \times 10^{-7}$ M), TbL* (–•–•, $c = 2.27 \times 10^{-6}$ M), and TbL-Strep (——, $c = 1.55 \times 10^{-7}$ M) and a linear combination of streptavidin and TbL* (●).

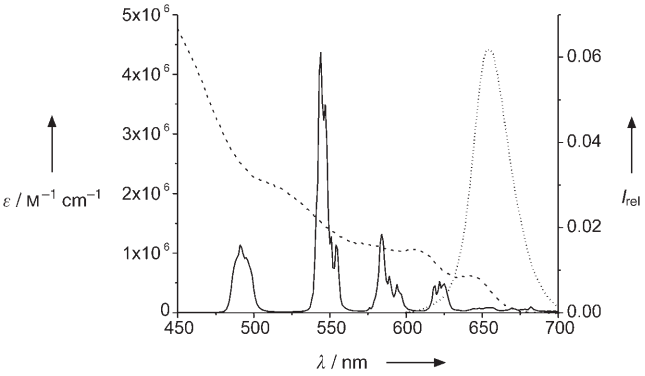

Figure 3. Normalized emission spectrum (intensity *I*) of TbL-Strep (——) and emission (·····) and absorption (-----) spectra of Biot-QD.

a minor, shorter one of 200 ± 30 μs (3%) (see Supporting Information). The longer lifetime is comparable to the value of pure TbL in water (1.48 ms).[14] In a 50 mM borate buffer containing 2% bovine serum albumin (BSA) at pH 8.3,[15] the luminescence intensity decay profile of TbL-Strep shows two exponential components. The main component remains the long-lived TbL decay with 1500 ± 50 μs (60%), and the second, with a decay time of 450 ± 30 μs (40%), results from TbL species quenched by nonspecific interactions with BSA. In this buffer, also used in the experiments, two distinct donor species are then present. The overall quantum efficiency of the system in this buffer is 14.5% (31% for pure TbL in water[14]).

As the energy-acceptor component of our fluoroimmunoassay system, an ellipsoidally shaped multilayer CdSe semiconductor core coated with a ZnS protective shell was used. The complete qdot was coated in a polymer–biotin complex, providing five to seven biotin molecules per qdot (Figure 1), with an average long axis of 10–12 nm for the biotinylated qdots (Biot-QD).[16] These nanoparticles display characteristic absorption and emission spectra with an emission maximum at 655 nm (Figure 3). Their luminescence decay profile in the borate buffer is deconvoluted with nanosecond-order multiexponential components (see Supporting Information), associated to the dispersion of the qdot in shape and size.[17]

Following Förster's theory for resonance energy transfer[18] with a refractive index of $n = 1.4$ for biomolecules in aqueous solution,[19] and assuming that the long-lived excited state lifetime of the Tb donor allows for a statistical distribution of the donor–acceptor dipoles (orientation factor $\kappa^2 = 2/3$), we calculated the Förster radius to be $R_0 = 81$ Å. This value represents the mean donor–acceptor distance at which half of the energy of the donor is transferred to the acceptor. As a result of the particularly high $\varepsilon(\lambda)$ parameters of qdots, this R_0 value is large compared to those of conventional donor–acceptor pairs (with distances ranging from 21–61 Å)[20] or pairs containing qdots as donors (47–65 Å).[7a,c]

To induce the recognition process and to probe the energy transfer, increasing amounts of Biot-QD were added to a solution of TbL-Strep ($c = 1 \times 10^{-9}$ M). Each sample was excited with a Xe-Cl excimer laser at 308 nm, and the emission was measured at 545 and 665 nm, which are the optimum spectral regions for emission from TbL-Strep and Biot-QD, respectively. Biot-QD emission was measured at 665 nm instead of 655 nm (maximum) in order to minimize the weak TbL-Strep background luminescence present at the latter wavelength (Figure 3). Emission was measured in time-resolved mode, using gated acquisition with a time window ranging from 250 to 1000 μs after the excitation pulse, which resulted in two long-lived intensities I_{665} and I_{545}. In this way

the autofluorescence of the sample and buffer and interference associated with light scattering in the apparatus are drastically reduced.[21] Figure 4 shows the dependence of the intensity ratio R collected at two channels ($R = I_{665}/I_{545}$) as a function of Biot-QD added at varying incubation times.

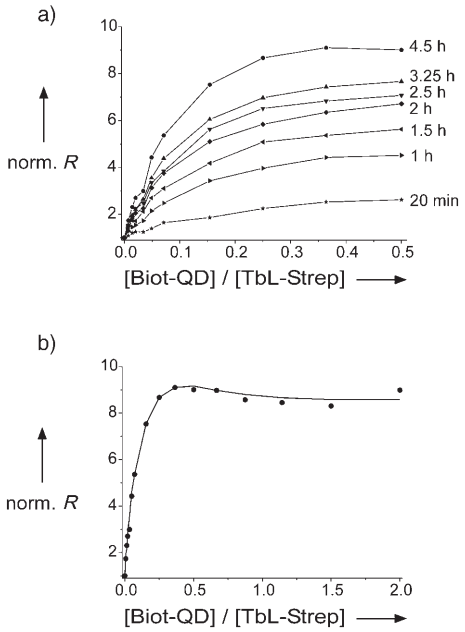

Figure 4. a) Intensity ratio R as a function of [Biot-QD]/[TbL-Strep] between values of 0 and 0.5 at varying incubation times (20 min to 4.5 h). b) R after 4.5 h (equilibrium) for [Biot-QD]/[TbL-Strep] = 0–2. Initial concentration: [TbL-Strep] = 1×10^{-9} M. In both graphs R was normalized to unity for [Biot-QD]/[TbL-Strep] = 0.

Addition of Biot-QD to TbL-Strep led to a strongly increased R for low qdot concentrations ([Biot-QD]/[TbL-Strep] < 0.2) which leveled off at higher qdot concentrations. The phenomenon evolved slowly with time (Figure 4a), reaching equilibrium after 4.5 h (Figure 4b).[22] Then, the first part of the curve, corresponding to low qdot concentrations ([Biot-QD]/[TbL-Strep] < 0.1), displayed a marked rise, mainly originating from a large long-lived qdot emission increase. At [Biot-QD]/[TbL-Strep] > 0.4, the emission ratio became almost constant. Extrapolation of the linear rising part at low concentrations led to an intersection with the plateau region at [Biot-QD]/[TbL-Strep] ≈ 0.13–0.16. This value is in excellent agreement with the number of biotin fragments per qdots mentioned by the supplier (5–7), suggesting that all biotin molecules remain accessible at the surface of the nanoparticle.

In a control experiment, dynamic energy transfer between TbL and qdots could be ruled out, as the weak linear increase of R with [Biot-QD]/[pure TbL] resulted from a stronger decrease of I_{545} compared to I_{665} (see Supporting Information). We thus take the strong increase of R with [Biot-QD]/[TbL-Strep] (Figure 4b) as clear evidence for FRET from TbL to qdots in the streptavidin-biotin complex.

Further evidence of a sensitization of qdot emission by energy transfer from terbium was obtained by measuring the decay profiles at 665 nm for various [Biot-QD]/[TbL-Strep] ratios (Figure 5). In the presence of TbL-Strep, the qdot

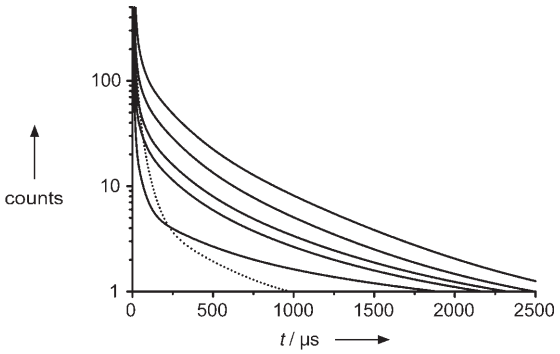

Figure 5. Intensity decay profiles at 665 nm ($\lambda_{exc} = 308$ nm) for various values of [Biot-QD]/[TbL-Strep] (0, 0.014, 0.034, 0.071 and 0.25, full lines from bottom to top, [Biot-QD] = 0–2.0×10^{-10} M) and pure Biot-QD (dotted line, [Biot-QD] = 1.0×10^{-10} M).

emission profile displays two new long-lived components of 560 ± 40 µs and 170 ± 20 µs, originating from energy transfer from the two Tb donor components. Given that the intrinsic Biot-QD decay is very prompt,[17] the long-lived components observed for Biot-QD in the presence of TbL-Strep can safely be attributed to the luminescence decays of the donors in the presence of acceptor, τ_{DAi}.[20] Calculation of the energy transfer rate and the average distance r between donor and acceptor pairs with multiexponential-decay donors gave a mean distance of $r = 72$–76 Å depending on the amount of added Biot-QD (see figure and theoretical treatment in the Supporting Information).[19] These distances reflect the assumed system configuration depicted in Figure 1 and resulted in energy-transfer rates of $k_{ET1} = (1.1 \pm 0.3) \times 10^3\ s^{-1}$ and $k_{ET2} = (3.9 \pm 0.6) \times 10^3\ s^{-1}$ as well as an efficiency of $E = 63 \pm 4\%$. It is worth pointing out that this treatment is valid for a spherically symmetric system consisting of point dipoles and does not take into account the geometric anisotropy of the ellipsoidal qdot particles and the nonrandom distribution of Tb acceptors around the nanocrystals.[24]

In short, these results show that the TbL-qdot pair is a very promising couple for FRET experiments. The use of long-lived excited state donors provides two advantages. First, efficient energy transfer to qdots becomes feasible, and the competition between radiative deactivation of the donor and energy transfer[12] swings the balance in favor of the latter. Second, the increased decay time of the qdot acceptor (up to some hundred µs) permits the use of a time-resolved acquisition mode that greatly enhances the sensitivity of the detection procedure. Under our experimental conditions, a detection limit of 3.3×10^{-12} M was estimated. The large R_0 value, which results from the very high qdot absorption,

expands the scope of applications of energy-transfer experiments to very big proteins without the need to use large fluorescent proteins as energy donors or acceptors. Further work along these lines is currently in progress.

Experimental Section

TbL was prepared according to the literature procedure.[14] Synthesis and characterization of TbL*: [TbL]Na·4 H_2O (45 mg, 55 μmol) was suspended in 10 mL of dimethyl sulfoxide (DMSO). *N*-hydroxysulfosuccinimide sodium salt hydrate (14 mg, 60 μmol) and EDC·HCl (12 mg, 63 μmol) were added, and the solution was stirred at room temperature for 92 h, resulting in the complete dissolution of the starting complex. THF was added to precipitate the product. Upon centrifugation and drying under vacuum, [TbL*]·5 H_2O (45 mg, 81 %) was isolated as a yellow powder. Elemental analysis: calcd for $C_{33}H_{24}N_6NaO_{13}STb\cdot 5H_2O$ (%): C 38.99, H 3.37, N 8.27; found: C 39.20, H 3.56, N, 8.39; FAB$^+$-MS: m/z: 682.2 ([TbL*−$C_5H_3NNaO_7S$]$^+$, 95 %), 727.2 ([TbL*−$C_4H_3NNaO_5S$+H]$^+$, 55 %); IR (KBr): $\tilde{\nu}$ = 3447 (s), 1735 (w), 1624 (m), 1388 (w), 1231 (w), 1043 (w) cm^{-1}.

TbL-Strep labeling was performed by mixing 0.5 mg of TbL* (dissolved in 2 μL DMSO) with 1 mg of streptavidin in 200 μL PBS buffer (pH 7.4). After 1 day of incubation on a shaker at room temperature the solution was diluted in purified water (Millipore) and dialyzed.

Biotinylated qdots (Qdot 655 biotin conjugate-trial size lot no. 0603-0050) were supplied by Quantum Dot Corp. (Hayward, CA, USA). FRET measurements were performed on a modified Kryptor system (Cezanne, Nîmes, France) for time-resolved integrated single-photon counting at two channels (545 nm and 665 nm; filter-based wavelength separation) with 2-μs integration steps over 8 ms, with an OPTex XeCl excimer laser (Lambda Physik AG, Göttingen, Germany) excitation source at 20 Hz repetition rate. Qdot lifetime measurements were performed on an Andor iStar ICCD setup with monochromator and spectrograph wavelength separation (LOT-Oriel, Darmstadt, Germany) with XeCl excimer laser excitation.

[22] Preliminary studies on Tb excited-state lifetimes have shown that introduction of BSA in the buffer plays a significant role. Nonspecific binding interactions of BSA and streptavidin that are able to compete with biotin-streptavidin recognition have previously been reported.[23] In our case, this nonspecific binding results in slow equilibration of the system. The interaction of BSA with streptavidin must first be disrupted before the thermodynamically favorable TbL-Strep/Biot-QD interaction can take place. Peeling off the BSA from the Tb emitting species eliminates the associated quenching processes and is probably the origin of the rising Tb emission for [Biot-QD]/[TbL-Strep] < 0.25 (see Supporting Information).

Fibrous Red Phosphorus**

Michael Ruck, Diana Hoppe, Bernhard Wahl, Paul Simon, Yuekui Wang, and Gotthard Seifert*

According to general chemistry textbooks, three basic allotropic modifications of elemental phosphorus exist, namely, white, red, and black phosphorus, which differ considerably in their chemical and physical properties. When white phosphorus is heated or exposed to radiation, it is transformed to amorphous red phosphorus. The structure of red phosphorus is considered to be a polymeric network of different building units, which are well-known from various compounds containing polymeric phosphorus structures.[1,2] While this network features only short or intermediate range order, further heating or irradiation leads to crystallization. Different crystalline allotropes were reported to form in this way, for example, red phosphorus IV and red phosphorus V, which were characterized by X-ray powder diffraction.[3]

Already in 1865 Hittorf found that phosphorus can also be crystallized from a melt of lead, giving red-to-violet colored platelets.[4] In 1969 Thurn and Krebs determined the structure of this crystalline type of phosphorus, called violet or Hittorf's phosphorus.[5] Up to now, it is the only structurally characterized crystalline form of red phosphorus. This modification consists of pentagonal tubes formed by covalently bonded phosphorus atoms. By comparison of the powder diffraction patterns it can be equated with red phosphorus V described earlier.

Furthermore, Thurn and Krebs reported in their work on the structure of Hittorf's phosphorus: "When white phosphorus is annealed at temperatures between 545 and 580 °C for several months, in addition to platelike crystals of Hittorf's phosphorus bunches of capillary parallel lying fibers form. […]".[5] From X-ray rotation photographs of the fibers, they proposed an arrangement of tubes of the same kind as in Hittorf's phosphorus but linked to parallel double tubes. Furthermore, they considered the constitution to be energetically stable but estimated the density to be lower than the density of Hittorf's phosphorus. Later Böcker and Häser showed in their theoretical investigations on phosphorus structures that Hittorf's phosphorus and the proposed structure of the fibrous type are energetically equivalent and the most favored of all the possible phosphorus chains.[6]

We have now confirmed the assumed structure of the fibrous type of red phosphorus using single-crystal X-ray diffraction as well as transmission electron microscopy methods. The iodine-catalyzed recrystallization of red phosphorus in a small temperature gradient yields dark red needles. In most cases the crystal quality of the fibrous phosphorus is very poor due to agglomeration and stacking faults. Frequently radial growth of fiber bunches upon the ampule wall was observed. Furthermore, needles and platelets often share edges, indicating an intergrowth of crystals of Hittorf's phosphorus and of the fibrous type. The two types can hardly be distinguished visibly; both show a bright red to deep red color and a more or less platelike shape. However, under mechanical stress crystals of the fibrous type split into thin filaments, whereas the crystal platelets of the Hittorf phosphorus type just break up into smaller platelets. In addition, the crystallization of red phosphorus from a lead melt[4,5] was carried out in order to examine whether crystals of the fibrous type can be obtained. But exclusively crystals of the Hittorf type formed by this means.

Powder diffraction patterns of sublimation products show reflections that can be assigned to Hittorf's phosphorus and numerous additional reflections. These can be assigned entirely to the fibrous type after comparison to the theoretical pattern calculated based on structural data. On comparison of the powder diffraction pattern of fibrous phosphorus with powder diffraction patterns given in ref. [3], it becomes clear that the so-called form IV of red phosphorus corresponds to the fibrous type presented here.

Under the transmission electron microscope the two crystalline forms can be differentiated easily: In Figure 1 a the high-resolution micrograph of perpendicular strands is indicative of Hittorf's phosphorus; Figure 1 b in contrast shows exclusively strands lying parallel to each other, which

corresponds to fibrous phosphorus. Fast Fourier transform (FFT) of the micrographs of Hittorf's phosphorus gives images with orthogonal rows of pseudo-Bragg reflections (plane $hk0$) and reciprocal lattice parameters of $a^* \approx b^* \approx (920\,\text{pm})^{-1}$. The FFT images of fibrous phosphorus (plane $(h,2h,l)$) give lattice parameters of $|\boldsymbol{a}^* + 2\boldsymbol{b}^*| \approx (440\,\text{pm})^{-1}$ and $c^* \approx (580\,\text{pm})^{-1}$; the included angle amounts to 55.5°. The c^* axis is perpendicular to the visible fiber direction.

The crystal structure of the fibrous type of crystalline red phosphorus is closely related to the structure of Hittorf's phosphorus. Both consist of tubes with pentagonal cross section, which in turn are a regular sequence of three different building units (Figure 2). The subunits are cages of eight or nine phosphorus atoms, which we denote as *[P8]* and *[P9]* in keeping with ref. [6], and dumbbells of two phosphorus atoms, *P2*.

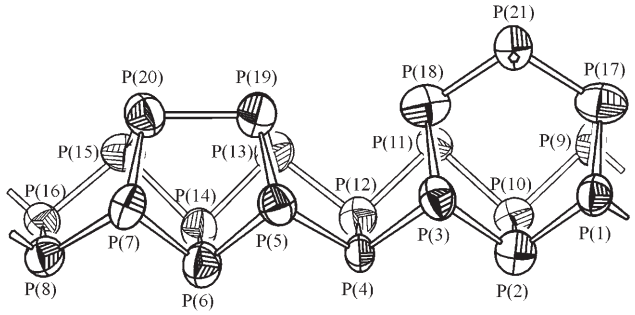

Figure 2. Repeating unit of the tubes in fibrous and in Hittorf's phosphorus (numbering of atoms in analogy to ref. [5]). Thermal ellipsoids enclose 90% probability for atomic displacement. Bond lengths are between 219(1) and 231(1) pm; the mean bond length is 221.9 pm.

The tubes can be interpreted alternatively as zigzag-shaped double chains, which form a corrugated ladder. Free valences are saturated by "roofs" of two or three phosphorus atoms. These single tubes feature the symmetry of the rod group $p2mm$ (no. 18).[7] At the medial roof atoms of the *[P9]* cages, denoted as P(21) and P(21^{i}) (Figure 3), two tubes are each connected to form double tubes with $p112/m$ symmetry (no. 11).[7] Covalent bonds of the atoms P(21) and P(21^{i}) are arranged in staggered conformation, and the corresponding lone pairs are aligned antiparallel. The arrangement resembles the energetically most favored conformation of methyl groups in 2,3-dimethylbutane.

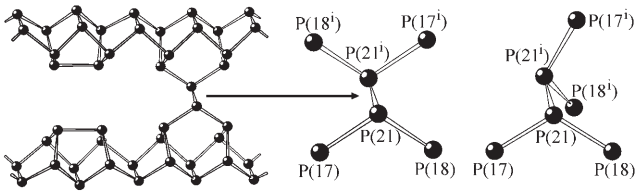

Figure 3. Linkage of the tubes in fibrous phosphorus (left; i: $-x$, $1-y$, $-z$) vs. Hittorf's phosphorus (right; i: $-x$, y, $0.5-z$). Bonding lengths and angles in the structures of fibrous and Hittorf's phosphorus[8] that differ by more than 3 SD: P(21)–P(21^{i}) 222.4(8)/217.3(1) pm; P(17)-P(21)-P(18) 111.9(3)/115.98(3)°, P(17)-P(21)-P(21^{i}) 94.7(3)/96.71(4)°, P(18)-P(21)-P(21^{i}) 93.6(3)/108.23(2)°.

In contrast, the connected tubes of Hittorf's phosphorus run perpendicularly, forming double layers of two interpenetrating but independent tube systems. These double layers are stacked in the c direction and held together by van der Waals forces. As a result of the perpendicular arrangement of two linked tubes, the described staggered conformation of the atom groups P(17)-P(21)-P(18) and P(17^{i})-P(21^{i})-P(18^{i}) cannot be attained (Figure 3, right). The consequence is a higher tension, expressed in expanded bonding angles at the atom P(21) in Hittorf's phosphorus.

The double tubes of the fibrous-type structure are stacked in the a direction with a displacement of $^{1}/_{8}\,b$ and in the c direction with a displacement $^{1}/_{4}\,b$. A distorted hexagonal pattern for the single tubes results (Figure 4). As a consequence of the packing, the $p112/m$ symmetry of the double tubes is not transferred to the crystal lattice, and the space group symmetry is $P\bar{1}$. The packing density of the tubes in Hittorf's and in fibrous phosphorus is very similar, although the arrangements of the tubes differs considerably. In contrast to the assumption in ref. [5], the calculated X-ray densities of fibrous phosphorus and Hittorf's phosphorus both amount to 2.37 g cm^{-3}. The shortest van der Waals distance in Hittorf's phosphorus is 306 pm, between atoms P(14) and P(14^{ii}) [ii: $-1-x$, $-1-y$, $-z$];[8] in fibrous phosphorus the shortest van der Waals distance is 315 pm, also between atoms P(14) and P(14^{ii}) [ii: $1-x$, $-y$, $-z$]. The observation of diffuse X-ray scattering in the diffraction pattern of many phosphorus fibers indicates alternative stacking sequences.

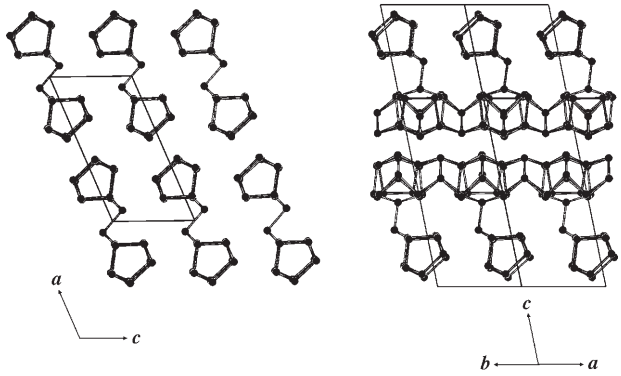

Figure 4. Left: Arrangement of the double tubes along the fiber axis in fibrous phosphorus. Right: Stacking of the layers in Hittorf's phosphorus.

Since the calculations of Böcker and Häser had focused on phosphorus clusters,[6] we have performed density functional based calculations for the bulk phases at the DFTB level[9] to investigate the relative stability of Hittorf's and fibrous phosphorus. The energy contributions of the van der Waals interactions were considered in a semiempirical a posteriori treatment.[10] Periodic boundary conditions were imposed on the systems in all calculations. Comparisons between the DFTB-optimized bond parameters and the experimental values can be found in the Supporting Informa-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tion. Clearly, for both allotropes the calculated bond parameters are in quite good agreement with the experimental findings. For bond lengths, the standard deviations (SD) are about 1%, and the maximum deviations (MD) are less than 2%. The deviations in bond angles are SD = 0.8° and MD = 1.4° for Hittorf's phosphorus, and SD = 1.8° and MD = 3.6° for the fibrous structure. The results show that the energy differences for the two structures are all less than 0.003 eV per atom, regardless of which bond lengths (experimental or optimized) are used and whether the van der Waals interactions are included. Therefore no preferred structure could be figured out. The conclusion that neither structure is energetically preferred is in agreement with the findings of Böcker and Häser.[6]

For a better understanding of the bonding characteristics of fibrous and Hittorf's phosphorus, especially the short bridging bond P(21)–P(21^{i}) in the latter structure, we performed further calculations, using cluster models (Figure 5) at

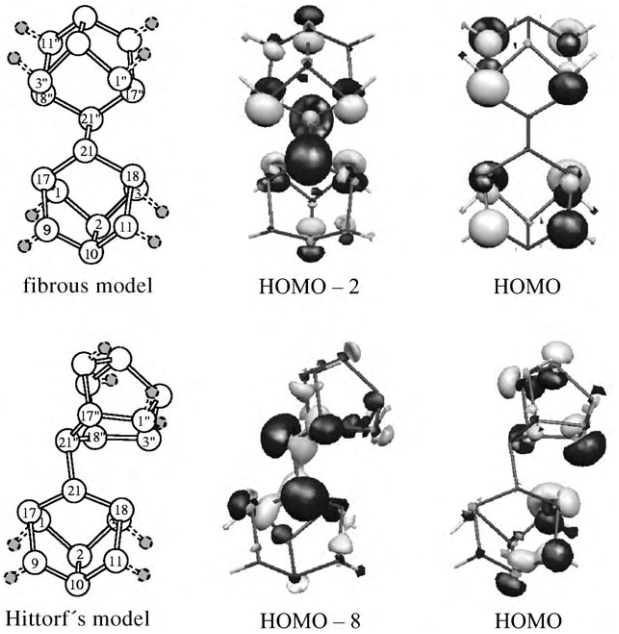

Figure 5. The cluster models ($P_{18}H_8$) used to simulate the bridge between the *[P9]* units in fibrous and in Hittorf's phosphorus (left). The highest occupied molecular orbitals (HOMO) and the orbitals close to the HOMO with dominant "lone-pair" character on the bridge atoms are shown on the right side. Note that in the configuration corresponding to Hittorf's phosphorus the orbital HOMO−8 exhibits some π-bonding characteristics between the bridge atoms, while in the fibrous structure no such contribution can be traced (see orbital HOMO−2).

the DFT/LSD/DZVP level. The fixed (X-ray) geometries of fibrous and Hittorf's phosphorus were used in these calculations. The free valences in these clusters were saturated with hydrogen (P−H = 142 pm). The results indicate that the orbitals around the HOMO show significant lone-pair character. In the fibrous structure one of these orbitals (HOMO−2), dominated by the lone-pair electrons located on the bridge atoms P(21), is only about 0.1 eV below the HOMO. In Hittorf's phosphorus the corresponding orbitals are at lower energy (1 eV below the HOMO). It seems that the twist structure in Hittorf's model is favorable to lower the energy of "lone-pair" electrons on the bridge atoms due to some π-bonding contribution, while in the fibrous structure the inversion symmetry prohibits such an effect. This accounts for the unusually short bridging bond in Hittorf's phosphorus and corresponds to the expanded bonding angles. In addition, a DFT geometry optimization of the Hittorf cluster model was also performed at the LSD/DZVP level, which confirmed that the bridging bond P(21)−P(21^{i}) is the shortest one (experimental 217.8 pm, calcd 219.5 pm).

As a general conclusion it can be stated that the fibrous type of crystalline red phosphorus bears strong structural resemblance to Hittorf's phosphorus. It represents a new crystalline modification of phosphorus. Both types of red phosphorus can be obtained in the same way. The growth mechanism is still unknown, yet experimental results indicate that homogeneous nucleation, for instance in a lead melt, leads only to Hittorf's phosphorus, whereas the growth of phosphorus fibers is preferred in case of heterogeneous nucleation. The structure model given by Thurn and Krebs as well as the theoretical predictions for the existence and stability of a fibrous type of phosphorus by Böcker and Häser thus could be confirmed.

Phosphorus tubes of similar architecture were identified in numerous compounds, such as polyphosphides (e.g. MP_{15}, M = Li–Cs;[11] M′M″P_{14}, M′ = Zn, Cd, Hg, M″ = Sn, Pb[12]); they represent quite stable possibilities of connecting phosphorus atoms.[6,11,13] Other compounds that contain exclusively polymeric tubular structures of phosphorus atoms embedded in copper halide matrices were scrutinized over the past decades.[14] Moreover, two of these phosphorus structures were extracted from their matrices.[15] The phosphorus architectures found in copper halide matrices differ from those obtained from pure amorphous red phosphorus, in all probability because the pentagonal tubes in Hittorf's and fibrous phosphorus are energetically more stable and can be arranged more densely in a crystal than the corrugated or helical phosphorus rods forming in the matrices.

Experimental Section

Synthesis: Amorphous red phosphorus (Fluka 99%; purified according to ref. [16]) was sublimed in evacuated fused-silica ampules using iodine (Merck; sublimed twice on barium oxide) as a catalyst.[17] Best results were achieved with approximately 1.0 g of phosphorus and 40 mg of iodine in an ampule of 17 cm^3. Hittorf's phosphorus and a fibrous solid were obtained. The latter showed increasing crystallinity when the temperature was increased and the temperature gradient decreased within the ampule. Sufficiently large crystals could be grown in a temperature gradient of about 10 K in the temperature range between 590 and 570 °C over several days (see also ref. [18]). At higher temperatures the phosphorus vapor pressure increases rapidly due to the increasing formation of white phosphorus in the gas phase. Therefore the samples were not heated above the given temperatures. Sublimation of red phosphorus also succeeds without catalysts. However, the generation of a gas phase is kinetically hindered, and autosublimation requires much more time.

Transmission electron microscopy: Crystallites of fibrous red phosphorus and of Hittorf's phosphorus were examined by high-resolution transmission electron microscopy (HRTEM). The inves-

tigations were performed at the Speziallabor für Elektronenmikroskopie Triebenberg with a Philips CM200 FEG\ST Lorentz electron microscope, equipped with a field emission gun and at an acceleration voltage of 200 kV. Point resolution amounts to 2.4 Å and information limit to about 1.2 Å. A TEM Philips CM30 FEG UT/Special Tübingen at an acceleration voltage of 300 kV also equipped with a field emission gun was also used. In this case, point resolution amounts to 1.7 Å and information limit to about 0.9 Å. TEM images were processed by Digital Micrograph (Gatan, USA).

X-ray crystal structure determination: systematic name: phosphorus (*aP*42); triclinic, space group $P\bar{1}$ (no. 2), $a = 1219.8(8)$, $b = 1298.6(8)$, $c = 707.5(7)$ pm; $\alpha = 116.99(7)$, $\beta = 106.31(7)$, $\gamma = 97.91(7)°$, $V = 911(2) \times 10^6$ pm^3, $\rho_{calcd} = 2.37$ g cm^{-3}, absorption coefficient $\mu = 1.89$ mm^{-1}, $2\theta_{max} = 42.5°$, $Mo_{K\alpha}$ radiation, $\lambda = 71.073$ pm, $T = 293(2)$ K. The diffraction data were collected on an imaging plate diffraction system IPDS-I (Stoe). Numerical absorption corrections were applied. The structure was solved with SHELXS97 and refined against F_o^2 using SHELXL97.[19] All atoms were refined using anisotropic displacement parameters. Final R values: $R_1(F_o > 4\sigma(F_o)) = 0.028$, wR_2(all F_o^2) $= 0.042$; $GooF = 0.934$ for 4048 (1932 unique) reflections and 190 parameters; min./max. residual electron density ± 1.38. Atom parameters are listed in Table 1. Further details

Table 1: Atomic coordinates and equivalent displacement parameters U_{eq} of fibrous phosphorus.[a]

of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen, Germany (e-mail: crysdata@fiz-karlsruhe.de; fax: (+49) 7247-808-666) on quoting the depository number CSD-391323.

Computational methods: The initial geometries were taken from the X-ray crystal data of Hittorf's[5] and fibrous phosphorus. To investigate the relative stability of these allotropes in the bulk phase, the initial structures were optimized using the density functional based tight-binding method (DFTB)[9] and the Γ-point approximation, as implemented in the program package *deMon*.[20] The experimental lattice constants were kept fixed during the geometry optimizations, and the convergence criterion 10^{-6} atomic units for the energy gradient was used. The validity of the gamma approximation was checked with different *k*-point sets and different sized supercells. The energy contribution of van der Waals interactions for the allotropes was calculated for fixed (X-ray) and optimized geometries. The optimized bond lengths, bond angles, and dihedral angles are given together with the corresponding experimental values in Tables 2–5 of the Supporting Information. The calculations of the clusters as models for the *[P9]* units were also performed with the program package *deMon*[20] within density functional theory (DFT) method and the local density approximation (LDA) for the exchange-correlation (XC) energy, using a DZVP basis set.

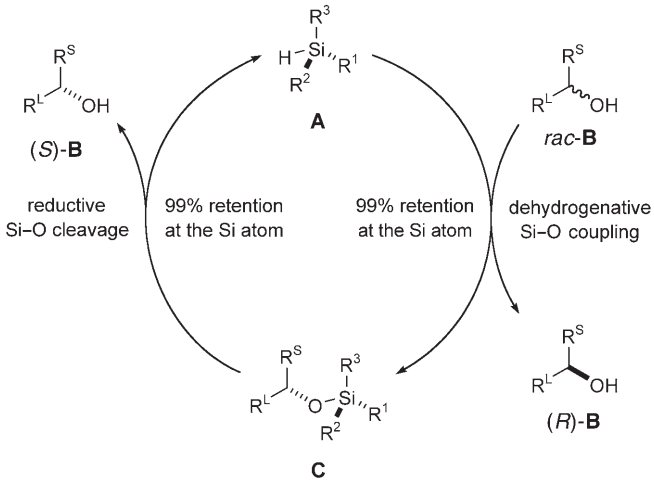
Kinetic Resolution of Chiral Secondary Alcohols by Dehydrogenative Coupling with Recyclable Silicon-Stereogenic Silanes**

*Sebastian Rendler, Gertrud Auer, and Martin Oestreich**

Non-enzymatic kinetic resolution[1] of racemic mixtures is a competitive strategy in asymmetric synthesis for the preparation of chiral building blocks.[2,3] The general approach relies on either a chiral reagent to undergo or a chiral catalyst to promote a stereoselective reaction of one enantiomer over the other. Within the theme of the former scenario, we devised a novel concept based on an unprecedented diastereoselective transition-metal-catalyzed dehydrogenative silicon–oxygen coupling of silicon-stereogenic silanes **A** and racemic alcohols *rac*-**B** (Scheme 1).[4]

We envisioned that if a preferential reaction of **A** with (*S*)-**B** to produce diastereoenriched **C** were viable, the optical antipode (*R*)-**B** would remain in enantioenriched form. Moreover, stereospecific reductive cleavage of the silicon–oxygen bond in **C** would allow complete recovery of the resolving reagent **A**. Importantly, both silicon–oxygen bond formation and cleavage would have to proceed without any erosion of stereochemical information at the silicon atom. Herein, we describe this novel concept of utilizing silicon-stereogenic silanes **A** in a kinetic resolution reaction.



Scheme 1. Kinetic resolution with recyclable silicon-stereogenic silanes ($R^1 \neq R^2 \neq R^3$, R^L = large R, and R^S = small R groups).

We initially sought suitable reaction conditions for silane alcoholysis with a particular emphasis on the stereochemical course at the silicon atom. Several heterogeneous and homogeneous catalysts are available,[5,6] and we selected the copper(I)-catalyzed dehydrogenative coupling introduced by Lorenz and Schubert.[7] Oxygen-sensitive $[\{(Ph_3P)CuH\}_6]$[8] is effectively replaced by a robust precatalyst (CuCl, Ph_3P, NaO*t*Bu) reported by Buchwald and co-workers[9] which also enables simple variation of the phosphine ligand.

We then screened this catalyst in the methanolysis of several asymmetrically substituted silanes[10] **1**–**3** (Figure 1) followed by stereoretentive reduction with aluminum hydrides.[11] To our delight, **1**–**3** were invariably recovered with complete retention of configuration, thereby verifying the stereospecificity of the copper(I)-catalyzed dehydrogenative silicon–oxygen coupling at the asymmetrically substituted silicon atom.[12] These experiments secured the pivotal preservation of the stereochemical integrity at silicon throughout this two-step process.[13]

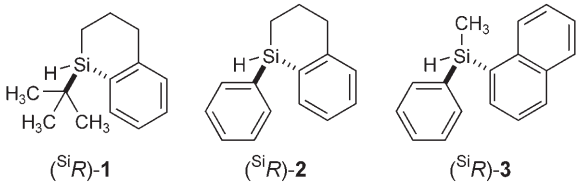


Figure 1. Silanes with silicon-centered chirality.

We then addressed the stereoselectivity of the dehydrogenative silicon–oxygen coupling of racemic alcohols with privileged silane (^{Si}R)-**1**.[14] A selected experiment (*rac*-**4**→(^{Si}S,*S*)-**5**, Scheme 2) showed that unfunctionalized secondary alcohols are essentially ineffective (d.r. ≤ 60:40). These discouraging observations led us to consider the introduction of a pendant donor (Do) in the substrate (Do = CH in **4**, Do = N in **6**), which provides a temporary residence site for the copper catalyst. We reasoned that alcohols capable of two-point binding would create more rigidity around the copper center, which in turn could be beneficial to diastereoselectivity. Consistent with our hypothesis, we were pleased to find that dehydrogenative coupling of *rac*-**6** and (^{Si}R)-**1** proceeded with substantially improved diastereoselectivity and enhanced reaction rate (*rac*-**6**→(^{Si}S,*S*)-**7**, Scheme 2).

The ideal phosphine ligand for this transformation, tri(3,5-xylyl)phosphane (**L1f**), was identified in an extensive screening of mono- and bidentate phosphine and N-heterocyclic carbene ligands (**L1**, **L2**, and **L3**, Table 1). We aimed to elucidate the influence of the ligand on the reaction rate and diastereoselectivity of the dehydrogenative coupling of *rac*-**6**

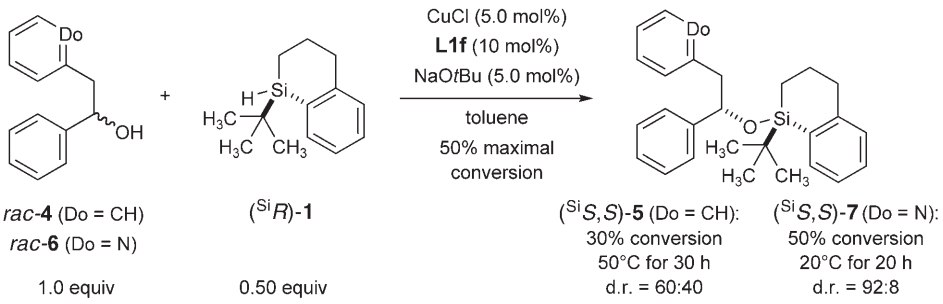
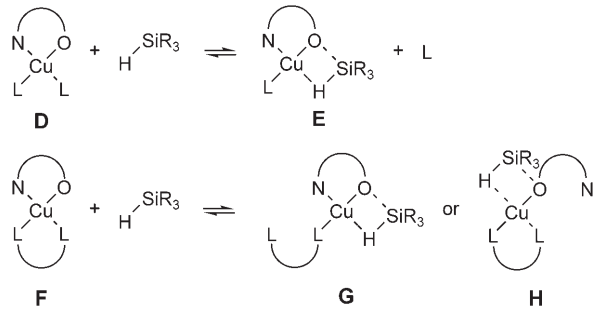


Scheme 2. Control of diastereoselectivity: Beneficial two-point binding. **L1f** = tri(3,5-xylyl)phosphane.

and (^{Si}R)-**1**.[15] A ligand/copper(I) ratio of 2:1 is usually needed to stabilize the catalyst. We began with triphenylphosphane (**L1a**), which gave ($^{Si}S,S$)-**7** under mild conditions with good diastereoselectivity (Table 1, entry 1). The reactivity decreased significantly in the presence of electron-poor phosphines **L1b–d**,[4a] yet the diastereoselectivity remained almost unaffected (Table 1, entries 2–4). Steric hindrance was not tolerated, and 2-tolyl-substituted phosphine **L1e** failed to stabilize the catalyst (Table 1, entry 5). Conversely, 3,5-xylyl-substituted phosphine **L1f** combined high reactivity with excellent diastereoselectivity at complete conversion (Table 1, entry 6). Electron-rich phosphines **L1g** and **L1h** (Table 1, entries 7 and 8), N-hetereocyclic carbene ligands[16] **L2a** and **L2b** (Table 1, entries 9 and 10), and Buchwald biaryl phosphines (not shown) were less effective. Interestingly, bidentate phospines **L3a–d** generated unreactive catalysts and led merely to moderate levels of diastereoselectivity (Table 1, entries 11–14).

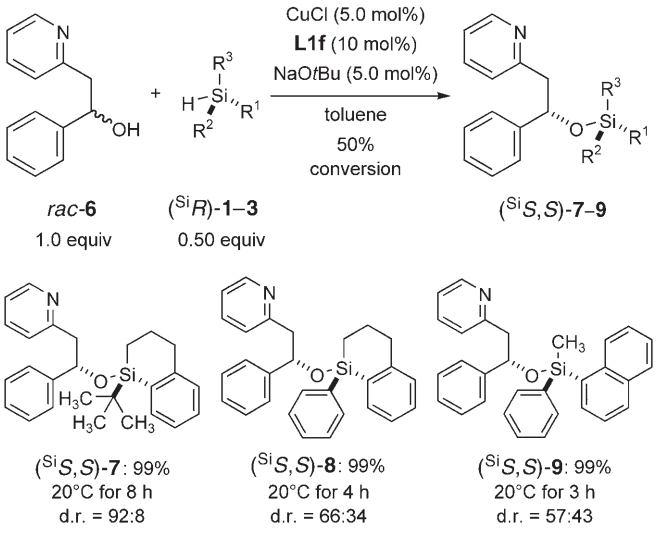
These findings can be roughly rationalized by the model outlined in Scheme 3. In the rate-determining step, one of the ligands L at the copper(I) center is replaced by the weakly



Scheme 3. Model for the postulated rate-determining step.

coordinating silane. This requires ligands with distinctly tuned σ-donor and π-acceptor strength as well as steric demand at electron-rich copper(I). In the case of monodentate ligands, a ligand must dissociate to generate a vacant coordination site (**D**→**E**). In the case of bidentate ligands, one of the chelates must open in an energetically clearly unfavorable step: 1) **F**→**G**, leaving the N,O-chelate intact, or 2) **F**→**H**, without two-point binding. The exact mechanism of the actual silicon–oxygen bond formation is still not completely understood, but is likely to involve—at least in a transition state—a pentacoordinated silicon of unknown configuration. Remarkably, a conceivable pseudorotation[17] and, hence, racemization are not observed, which indicates a concerted σ-bond metathesis.[10c]

We conducted our investigations with rationally yet empirically designed (^{Si}R)-**1**.[14] A comparison with less sterically encumbered cyclic or even acyclic silanes (^{Si}R)-**2** and (^{Si}R)-**3** impressively demonstrated once again the importance of steric demand and of three truly different substituents at the silicon atom (Scheme 4).[10c] Whereas less-hindered silanes were expectedly more reactive, diastereoselectivity collapsed in the case of cyclic (^{Si}R)-**2** (d.r. = 66:34) and was hardly observed with (^{Si}R)-**3** (d.r. = 57:43).



Scheme 4. Probing the steric demand and substitution pattern at the silicon atom.

This preliminary insight set the stage for an investigation of the kinetic resolution itself. As a starting point, we resolved our standard substrate *rac*-**6** by using optically enriched (^{Si}R)-**1** (96% *ee*). Both silyl ether ($^{Si}S,S$)-**7** and alcohol (*R*)-**6**[18] were isolated in quantitative yields, the latter with an encouraging 84% *ee* at 56% conversion (Table 2, entry 1). Importantly, the diastereomeric ratio of ($^{Si}S,S$)-**7** decreases with increasing conversion (d.r. = 92:8 at 50% conversion versus d.r. = 86:14 at 56% conversion). The stereoselectivity factor *s*[1] can only be estimated at larger than 10,[19] as this kinetic resolution involves an enantiomerically impure resolving reagent.[20] Indeed, we were able to verify experimentally this interesting

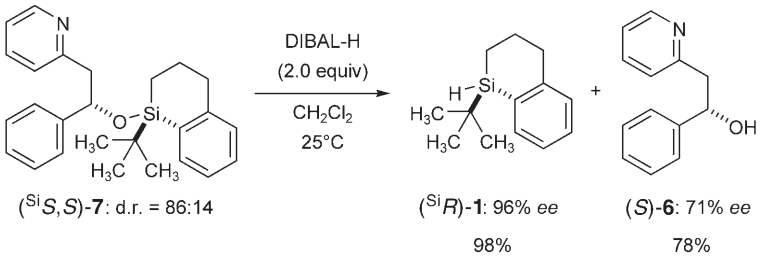
[a] Unless otherwise noted, all reactions were conducted with CuCl (5.0 mol%), **L1 f** (10 mol%), NaO*t*Bu (5.0 mol%) with a substrate concentration of 0.1 M in toluene at 25 °C. [b] HPLC analysis using a Daicel Chiralcel OJ-R column (EtOH/H_2O 80:20 at 20 °C) provided baseline separation of enantiomers. [c] Absolute configurations of (^{Si}R)-**1**[10c] and (*R*)-**6**[18] and, therefore, **7** are known. The absolute configurations of enantioenriched alcohols **10**–**15** as well as silyl ethers **16**–**21** were assigned by analogy. [d] Yield of analytically pure product isolated by flash chromatography on silica gel. [e] Determined from the ^{1}H NMR spectra of the crude reaction mixtures by integration of the baseline-separated resonance signals of the diastereomers. [f] Monitored by ^{1}H NMR analysis and determined by integration of the baseline-separated resonance signals of the alcohol and silyl ether. [g] HPLC analysis using a Daicel Chiralcel OD-H column (*n*-heptane/*i*PrOH 90:10 for **6**, **10**, **12**, and **13** and 98:2 for **11** at 20 °C) or Daicel Chiralcel AD-H column (*n*-heptane/*i*PrOH = 98:2 for **14** and **15** at 20 °C) provided baseline separation of enantiomers. [h] *c* = 0.22–0.55 in $CHCl_3$ at 20 °C. [i] Reaction accompanied by partial *Z*-selective alkyne reduction: ($^{Si}S,S$)-**19** contaminated with 7% *Z* alkene and (*R*)-**13** contaminated with 21% *Z* alkene in 57% *ee*. [j] (^{Si}R)-**1**: 0.65 equiv. [k] The reaction was performed with CuCl (10 mol%), **L1 f** (20 mol%), NaO*t*Bu (20 mol%), and (^{Si}R)-**1** (1.2 equiv) at 110 °C. [l] High diastereomeric ratio at conversion below 50% and, therefore, moderate enantiomeric excess.

effect (Table 2, entry 2), whereas the efficiency decreased with less sterically demanding vinyl (*rac*-**11**) and cinnamyl groups (*rac*-**12**) (Table 2, entries 3 and 4). For alkynyl substitution (*rac*-**13**), we probed the efficiency at higher conversion and obtained good enantiomeric purity; however, this reaction was accompanied by partial reduction of the triple bond (Table 2, entry 5). When methyl derivative *rac*-**14** was employed, the kinetic resolution was least efficient (Table 2, entry 6). Dehydrogenative coupling of branched, *t*Bu-substituted alcohol *rac*-**15** was highly diastereoselective, but conversion did not proceed beyond 50%, even at elevated temperatures (Table 2, entry 7).

Finally, our concept would only come full circle with complete recovery of the resolving reagent without racemization at the silicon atom. Reductive cleavage of the silicon–oxygen linkage in ($^{Si}S,S$)-**7** in quantitative yield liberated (^{Si}R)-**1** with an unchanged 96% *ee* (Scheme 5).



($^{Si}S,S$)-**7**: d.r. = 86:14 (^{Si}R)-**1**: 96% *ee* 98% (*S*)-**6**: 71% *ee* 78%

Scheme 5. Recycling of the resolving reagent. DIBAL-H = diisobutylaluminum hydride.

In conclusion, we have developed a novel kinetic resolution based on a diastereoselective dehydrogenative coupling of racemic alcohols and asymmetrically substituted silanes. Two-point binding of the substrates emerged as the pivotal feature for stereoselectivity. The efficiency of this strategy was exemplified by resolving a family of 2-pyridyl-substituted alcohols. Apart from the recyclability of the silicon-stereogenic silane, this two-step reaction sequence

involves the simple separation of compounds with substantially different polarity. Further optimization and extension of substrate scope are currently underway in our laboratories.

Synthetic Vaccines Consisting of Tumor-Associated MUC1 Glycopeptide Antigens and Bovine Serum Albumin**

*Sebastian Dziadek, Danuta Kowalczyk, and Horst Kunz**

The identification of cell-surface components that occur only on tumor but not on healthy cells is essential for a selective immunological attack on tumor tissue. About 30 years ago, Springer[1] described membrane glycoproteins containing the Thomsen–Friedenreich T antigen and the monosaccharide Tn antigen side chains as tumor-associated antigens on epithelial tumors. These T and Tn glycoproteins were described to be structurally related to the N-terminal region of asialoglycophorin. Based on this structural information, we synthesized a vaccine consisting of N-terminal glycopeptides from asialoglycophorin of M blood group specificity conjugated with bovine serum albumin (BSA)[2] and employed it in the immunization of mice. Although the monoclonal antibody (82-A6) obtained from these experiments showed affinity to epithelial tumor cells, the selectivity for tumor cells was not sufficient.[3] However, the antibody 82-A6 was capable of distinguishing clearly between asialoglycophorin of M and N

blood groups,[3] indicating that not only the saccharide, but also the peptide sequence, contributed to the recognized epitope. From this observation we inferred that apart from tumor-associated saccharides, tumor-selective peptide structural elements are required to render an antigen sufficiently tumor-selective.

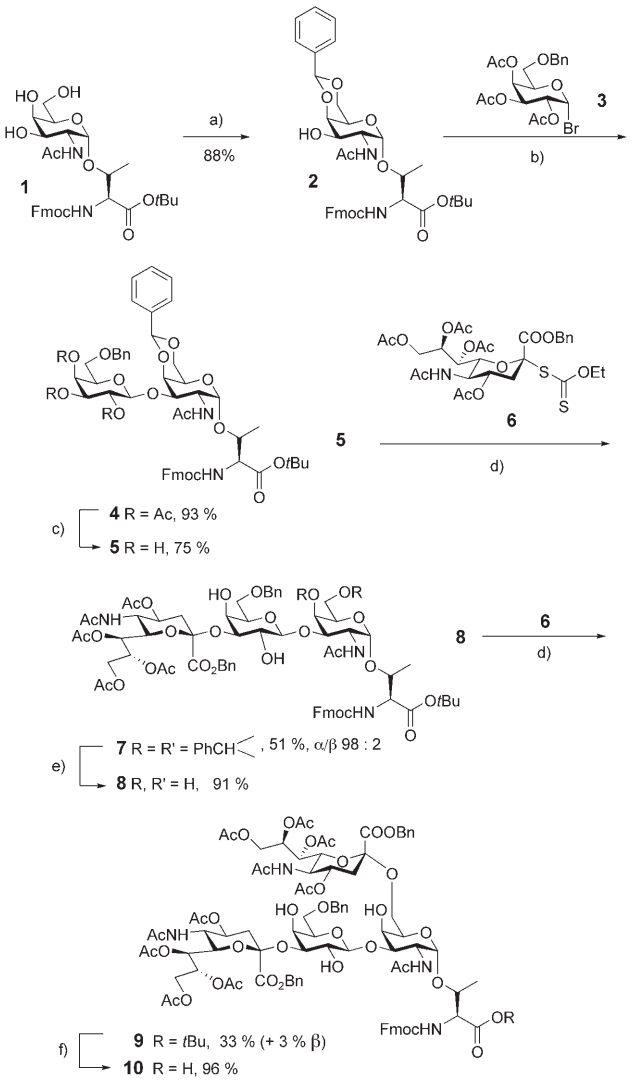
Structural leads for the design of tumor-selective glycopeptide antigens are obtained from analyses of the tumor-associated epithelial mucin MUC1,[4] which is extensively over-expressed on tumor cells. The extracellular portion of MUC1 contains numerous repeating units of the amino acid sequence HGVTSAPDTRPAPGSTAPPA.[5] Most *O*-glycosylation sites are located within these tandem repeats. Owing to the down-regulation of a glucosaminyl transferase (C-2GnT-1) and the concomitant overexpression of sialyl transferases,[6] MUC1 on tumor cells carries short, prematurely sialylated saccharide side chains. Antibodies induced with MUC1 isolated from tumor tissues[4,5] were used to identify the peptide motif PDTRPAP as an immundominant epitope within the MUC1 tandem repeat.[7] The specificity of these anti-MUC1 antibodies was verified with synthetic Tn- and T-antigen glycopeptides.[8,9] Moreover, saturation transfer difference NMR analyses revealed the conformation of a Tn antigen pentapeptide from MUC1 bound to a monoclonal antibody.[10]

In contrast to such studies, which proved valuable for analytical purposes, immunizations with MUC1 extracted from tumor tissues as a vaccine appear not to be promising, because MUC1 from biological isolates generally displays microheterogeneity and contains structural elements that also occur on healthy cells.

For this reason we focused our attention on the development of anticancer vaccines based on defined synthetic Tn, T, and sialyl–Tn glycopeptides[11,12] from MUC1.[13] A construct, in which a glycopeptide sequence from the MUC1 tandem repeat carrying a sialyl–Tn side chain is conjugated through a polar spacer amino acid with a partial T-cell epitope from tetanus toxoid, was used to induce the proliferation of cytotoxic T cells in cell cultures of peripheral blood lymphocytes (PBLs).[14] This effect occurred exclusively in the presence of antigen-presenting cells. Apart from cytotoxic T-cell response, strong T-helper-cell-dependent antibody production is of crucial importance for the development of an efficient antitumor vaccine and requires the use of glycopeptide antigens conjugated with carrier proteins such as BSA or KLH (keyhole limpet hemocyanine).

Herein we describe the synthesis of a series of glycopeptide antigens that bear the sialyl-Tn, (2,6)-sialyl-T, (2,3)-sialyl-T, or the glycophorin (2,3-2,6-bissialyl)-T antigens and contain the partial or complete tandem repeat sequence of MUC1. We also report methods to couple these tumor-selective cell surface structures to carrier proteins or to bind them to microtiter plates. The synthetic strategy relies on the synthesis of the corresponding *O*-glycosyl amino acids, followed by sequential solid-phase glycopeptide synthesis and subsequent conjugation to proteins or immobilization.

A range *O*-glycosyl amino acids were synthesized according to a biomimetic strategy[15] starting from the same precursor. Scheme 1 illustrates the preparation of the most



Scheme 1. a) α,α-Dimethoxytoluene, cat. *p*-TsOH, CH_3CN, 3 h; b) $Hg(CN)_2$, CH_2Cl_2/CH_3NO_2 (2:3), 4-Å molecular sieves; c) 1. NaOMe, MeOH, pH 8.5–9, 8 h; 2. Fmoc-OSu, dioxane/H_2O (1:1), NMM; d) MeSBr, AgOTf, CH_3CN/CH_2Cl_2 (2:1), −68 °C, 3-Å molecular sieves; e) 80% AcOH (aq), 80 °C; f) CF_3COOH, anisole (10:1), 2 h.

complex of the tumor-associated MUC1 saccharide antigens, the (2,3-2,6-bissialyl)-T–threonine conjugate. The *N*-Fmoc protected Tn antigen threonine *tert*-butyl ester **1**[16] deprotected at its glycan moiety served as common starting material for the synthesis of all tumor-associated mucin carbohydrate antigens. The base and acid sensitivity of the Fmoc group and the *tert*-butyl ester must be carefully taken into account in all protecting-group manipulations and glycosylation reactions. The precursor **1** was treated with α,α-dimethoxy toluene in acetonitrile in the presence of catalytic *p*-toluenesulfonic acid at pH 4 to give 4,6-benzylidene acetal **2**. Although activation of a glycosyl trichloroacetimidate[17] with trimethylsilyl trifluormethanesulfonate for 3-β-galactosylation is usually very efficient, in this case the benzylidine acetal and *tert*-butyl ester were cleaved or, after addition of sufficient amounts of molecular sieves, predominantly gave the corresponding orthoester.[18] The most successful route involved activation

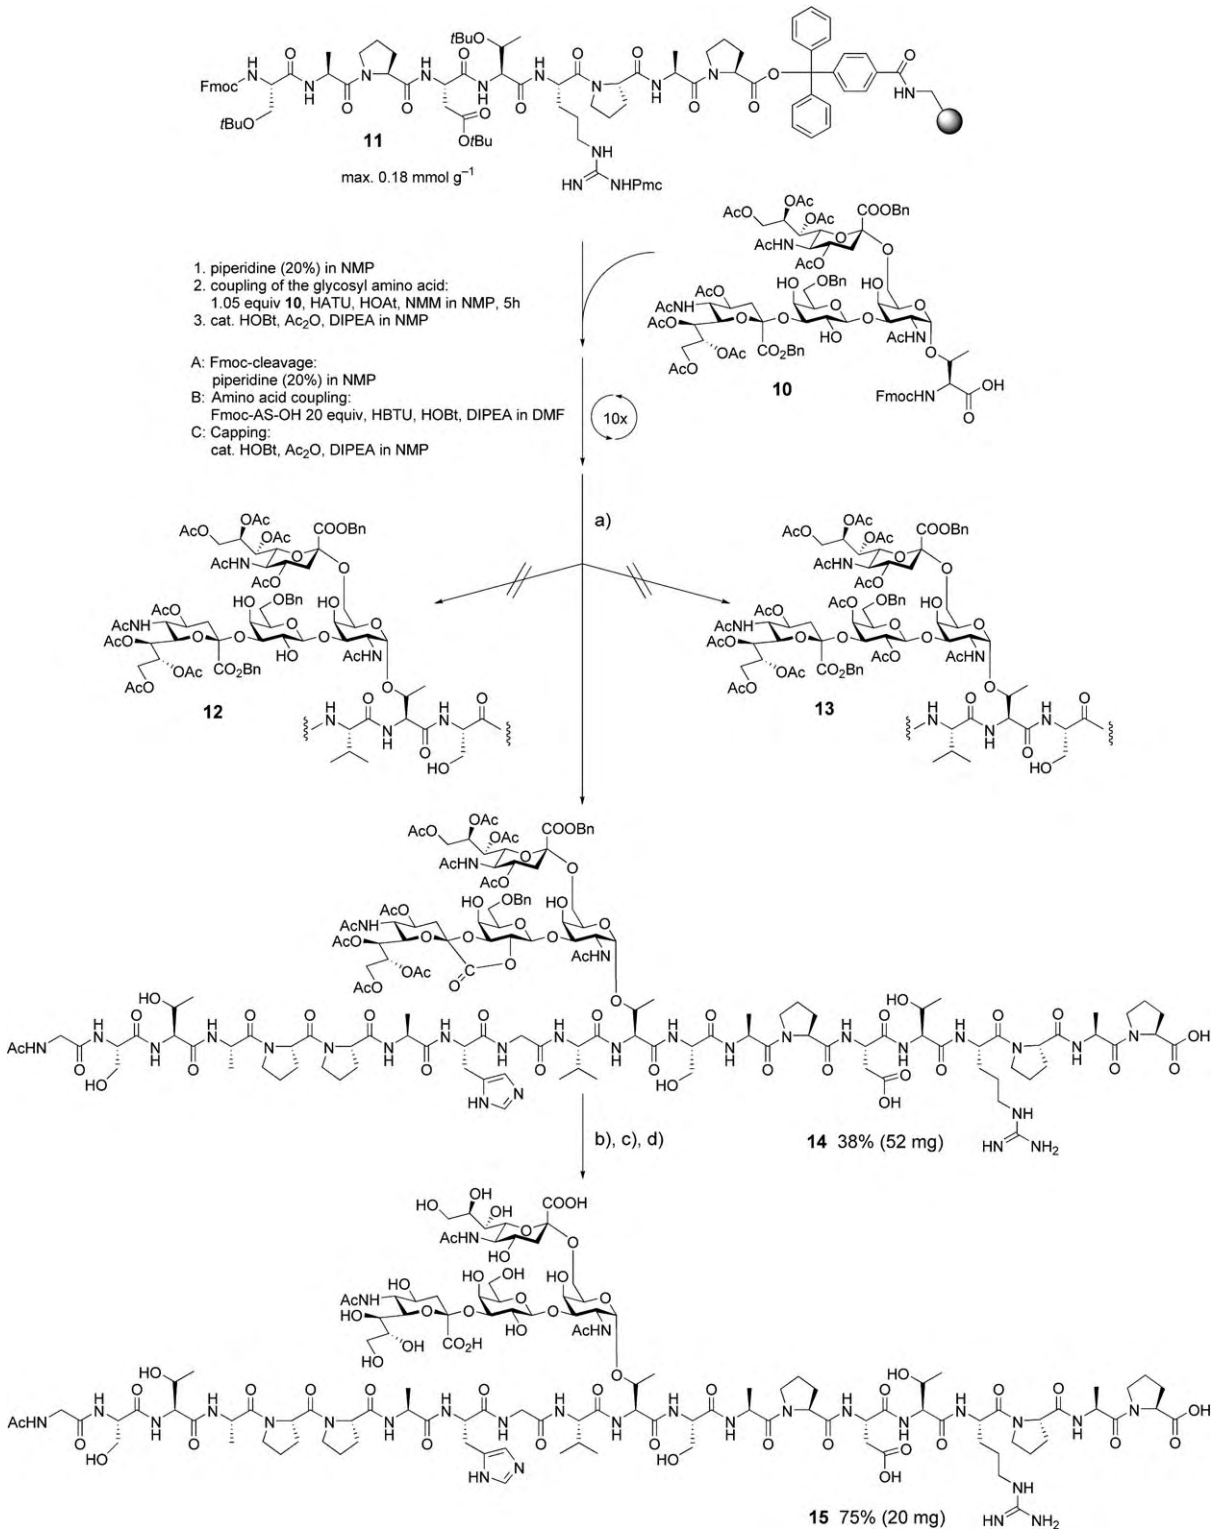


Scheme 2. a) TFA, TIS, H_2O (15:0.9:0.9); b) H_2, Pd/C (10%), MeOH; c) NaOMe/MeOH, pH 9.5; d) NaOH (aq), pH 11.5, 1 h; then AcOH. DIPEA = diisopropylethylamine.

of the 6-*O*-benzyl protected galactosyl bromide **3**[19] with mercury cyanide (according to the procedure of Helferich and Wedemeyer[20]) in nitromethane/dichloromethane which stereoselectively furnished the T-antigen–threonine conjugate **4** in high yield.

The selective *O*-deacetylation of **4** proved to be particularly challenging. On a 1-g scale, use of catalytic NaOMe in methanol under careful adjustment of the pH value to 8.5 furnished **5** in 62% yield. On a larger scale (5 g) and at pH 8.6–9, not only **5** (39%) but also the *N*-deprotected

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

conjugate (46%) were formed. Subsequent *N*-acylation of the latter with 9-fluorenyl-methoxycarbonyl-*N*-hydroxy-succinimide gave more of the desired product (36%), resulting in an overall yield of 75% of **5**. Sialylation of **5** with xanthate **6** of the peracetylated sialic acid benzyl ester[14] activated with methylsulfenyl triflate[21] gave **7** with nearly complete regio- and stereoselectivity. After selective cleavage of the benzylidene acetal with aqueous acetic acid (80% *v*/*v*) at 80 °C[22] to afford **8**, a second sialylation step under identical conditions gave the bissialyl-T-antigen–threonine conjugate **9**. Although the conversion remained incomplete after 3.5 h, **9** (33%) as well as some of the corresponding β-anomer (3%) were isolated by preparative HPLC.[23] Acidolysis of the *tert*-butyl ester with trifluoroacetic acid/anisole (10:1) furnished the Fmoc-protected bissialyl-T–threonine building block **10**,[24] which was incorporated into the solid-phase synthesis without further *O*-acetylation.[25] Of the other tumor-associated glycosyl amino acid antigens, the Tn antigen **1**, T antigen **4**, and 2,3-sialyl-T antigen **7** are directly accessible by the synthetic route shown in Scheme 1, while the sialyl-Tn antigen is obtained by regioselective sialylation of **1**[14,16] and the 2,6-sialyl-T antigen through regioselective sialylation after cleavage of the benzylidene acetal in **4**.[15,26]

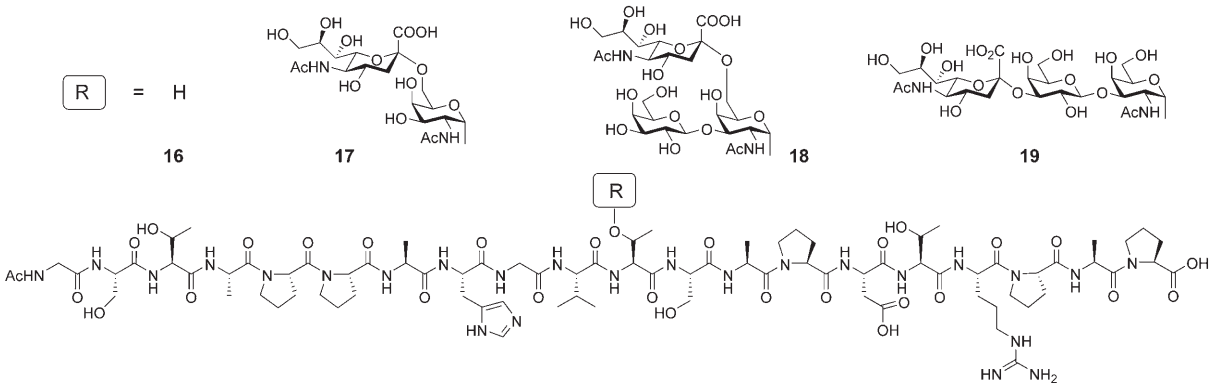
These building blocks were all subsequently applied in the solid-phase glycopeptide synthesis of various MUC1 tandem repeat glycopeptides, as illustrated in Scheme 2 for the bissialyl-T antigen MUC1 glycopeptide. Fmoc-proline was coupled through a trityl linker[27] to a Rapp-Tentagel polymer[28] and used to assemble the protected nonapeptide **11** from MUC1 according to the Fmoc strategy.[29] After cleavage of the Fmoc group with piperidine/*N*-methylpyrrolidone (NMP) (1:4), the *O*-glycosyl amino acid **10** (1.05 equiv) was coupled through activation with *O*-(7-azabenzotriazol-1-yl)-*N*,*N*,*N*′,*N*′-tetramethyluronium hexafluorophosphate (HATU), 1-hydroxy-7-azabenzotriazole (HOAt),[30] and *N*-methylmorpholine (NMM) in NMP. All non-glycosylated Fmoc-protected amino acids were coupled with *O*-(1H-benzotriazole-*N*,*N*,*N*′,*N*′-tetramethyluronium hexafluorophosphate (HBTU)/1-hydroxybenzotriazole (HOBt),[31] and Hünig base (*i*Pr$_2$NEt) in DMF. The remaining free amino components were capped with acetic anhydride/HOBt/*i*Pr$_2$NEt after each coupling cycle.[31c]

After completion of the peptide sequence, the trityl linker and the acid-labile side-chain protecting groups were cleaved simultaneously with trifluoroacetic acid (TFA), triisopropylsilane (TIS), and small amounts of water.[32] This cleavage procedure liberated neither the expected glycoeicosapeptide **12** with unaltered carbohydrate side chain nor the completely *O*-acetylated analogue **13** formed through the capping reactions. Instead, glycopeptide **14**,[33] which bears a lactone structure formed between the 2,3-linked sialic acid and the 2-OH group of the galactose moiety, was isolated in an overall yield of 38% after approximately 40 steps. Subsequent hydrogenolysis of the benzyl ester and benzyl ether, transesterification with NaOMe/methanol (pH 9.5), opening of the lactone with aqueous NaOH (pH 11.5), neutralization with acetic acid, lyophilization, and purification by semipreparative HPLC furnished the desired MUC1 tandem repeat glycopeptide **15**[34] in 75% yield (based on **14**).

In analogous procedures, the MUC1 eicosapeptide **16** as well as the complete tandem repeat glycopeptides from MUC1 carrying the other important tumor-associated sialyl saccharide antigens, sialyl-Tn (**17**), 2,6-sialyl-T (**18**), and 2,3-sialyl-T (**19**), were synthesized in significantly higher overall yields (Scheme 3). No formation of a lactone was observed during the acidolysis of the trityl linker in any of these syntheses.

According to the procedure illustrated in Scheme 2, the dodecapeptide **20** equipped with a triethylene glycol spacer with an amino group[14] as well as the analogous sialyl-Tn dodecapeptide **21** from MUC1 were synthesized to serve as model compounds for conjugation with bovine serum albumin (BSA) and for immobilization on microtiter plates (Scheme 4).[35] For this purpose, the N-terminal Fmoc group was removed from the resin-bound peptide and all acid-labile side-chain protecting groups were cleaved during the acidolysis of the trityl anchor. The synthesis of sialyl-Tn glycopeptide **21** required the additional removal of the carbohydrate-protecting groups by hydrogenolysis and transesterification catalyzed by NaOMe after cleavage from the resin.

To conjugate the synthetic MUC1 peptides and glycopeptides with proteins, recourse was made to the procedure described by Tietze et al.[36] for the conjugation of a lactosamine phenyl glycoside. The amino groups of the spacers of **20**



Scheme 3. Eicosapeptide **16** and the complete tandem repeat glycopeptides from MUC1 carrying sialyl-Tn (**17**), 2,6-sialyl-T (**18**), and 2,3-sialyl-T (**19**).

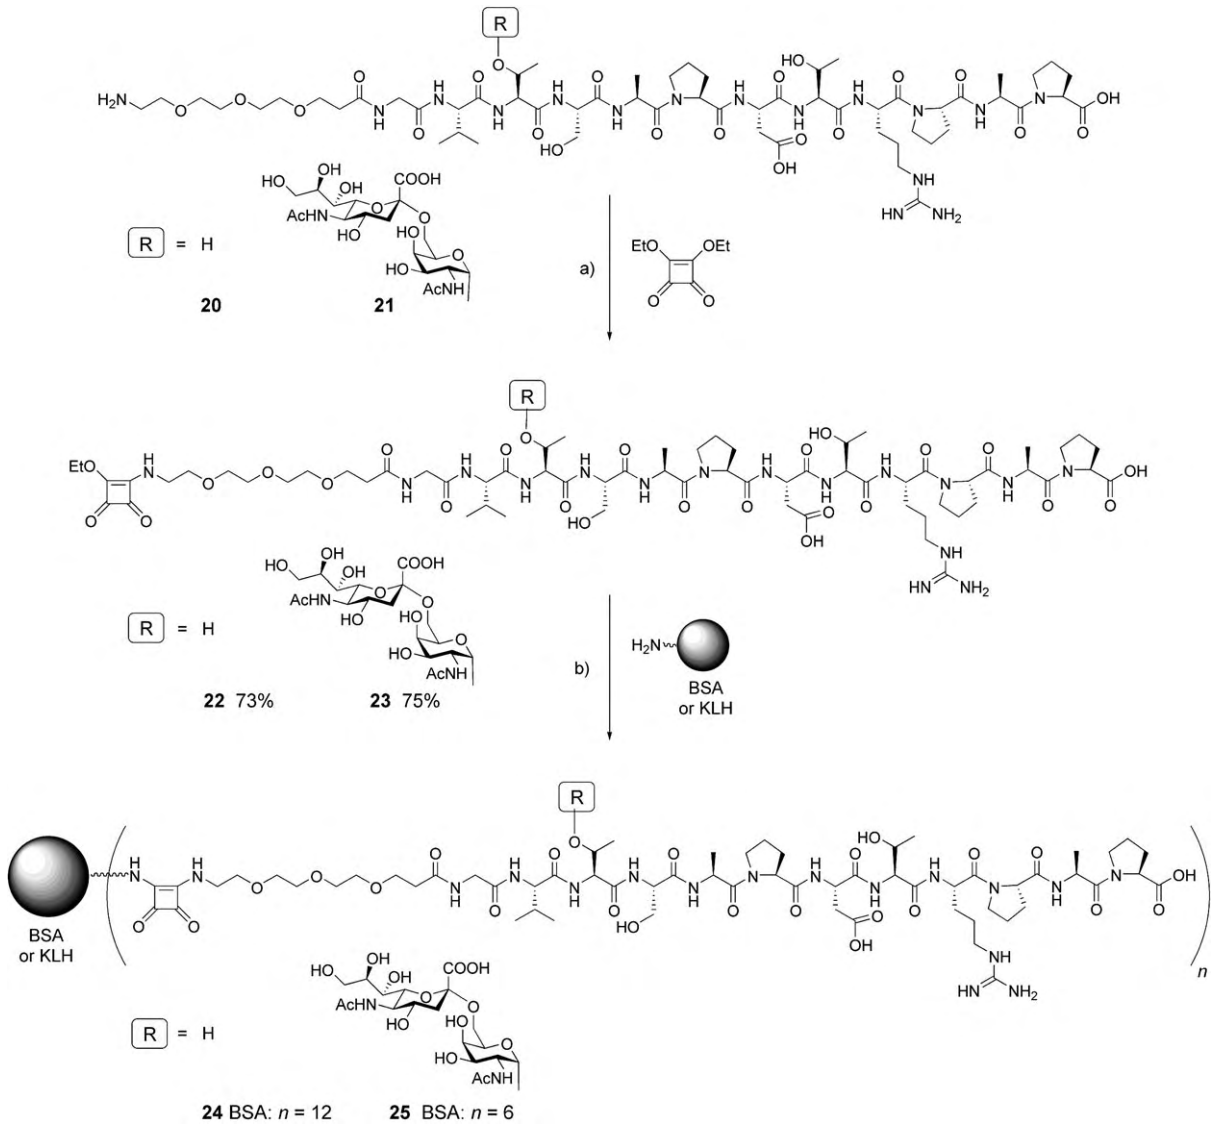

Scheme 4. a) Ethanol/water (1:1), Na_2CO_3, pH 8.0, 2 h, preparative HPLC; b) sodium borate (0.07 M), $NaHCO_3$ (0.035 M), pH 9, 24 h, gel filtration chromatography (Sephadex-G25 PD10 column), dialysis against H_2O.

and **21** were converted into the corresponding squaric monoamides **22** and **23**[37] by using diethyl squarate (3,4-diethoxy-3-cyclobutene-1,2-dione) in ethanol/water at pH 8. After purification by preparative HPLC, the activated peptide structures were coupled to BSA in a sodium borate buffer at pH 9.

Conjugation of peptide **22** resulted in a coupling yield of approximately 60% within 24 h and furnished vaccine **24** with an average degree of incorporation of 12 peptide molecules per molecule of protein as determined by MALDI-TOF MS. In the case of glycopeptide **23** the coupling to furnish **25** proceeded more slowly, and led to the incorporation of only half as many antigen molecules. Furthermore, the glycopeptide antigen equipped with the spacer was covalently immobilized on microtiter plates[38] functionalized with a secondary amine **26** (Scheme 5). The covalent linkage of the MUC1 antigen to the microtiter plates (see **27**)[39] prevents the loss of material in ELISA tests when washing with water, which had previously caused difficulties while working with glycopeptide antigens.

The immobilized and conjugated MUC1 glycopeptide antigens not only provide vaccines with a highly defined structure representing tumor-selective surface antigens but also provide tools for the verification of the structural selectivity of an immune response. The initial results are promising[40] and encourage further exploration of the entire spectrum of structures characterized by the synthetic glycopeptide antigens such as **17**, **18**, **19**, **21**, **23**, and **25** for the development of antitumor vaccines.

Antitumor Agents

DOI: 10.1002/anie.200501594

A Fully Synthetic Vaccine Consisting of a Tumor-Associated Glycopeptide Antigen and a T-Cell Epitope for the Induction of a Highly Specific Humoral Immune Response**

*Sebastian Dziadek, Alexandra Hobel, Edgar Schmitt, and Horst Kunz**

Tumor therapy based on nontoxic anticancer vaccines would be a valuable alternative to treatments such as chemotherapy and irradiation, which are often accompanied by significant side effects.[1] As a prerequisite for selective immunotherapy it is essential to identify antigenic target structures that distinguish a normal cell from a tumor cell as clearly as possible. In this context, glycopeptides from the tandem repeat region of the extracellular domain of the tumor-associated epithelial mucin MUC1 appear to be particularly attractive target structures.[2] MUC1 isolated from epithelial tumor cells, however, is not suitable for the induction of a tumor-selective immune response. This is due to the micro-heterogeneity of the carbohydrate moieties of these glycoproteins, which contain tumor-associated saccharide antigens but also saccharide side chains that occur in normal cells. Moreover, immunosuppressive mechanisms often prevent the organism from attacking and eliminating foreign antigens of this kind. Therefore, a further aim of antitumor vaccination is to break this tolerance by the induction of a strong immune response. With respect to tumor selectivity, apart from the initiation of a cytotoxic T cell response,[3] the induction of a selective T-helper-cell-mediated antibody production is crucial. Specific antibodies contribute decisively to the immune defense of tumors by initiating a complement-dependent lysis of both stationary as well as circulating tumor cells.

The specificity of a humoral immune response relies on the specific binding of an antigen to the membrane-bound immunoglobulin receptor of a B cell. However, in the case of the tumor-selective but only moderately immunogenic MUC1 glycopeptides, this binding itself is not sufficient to stimulate a

naive B cell to proliferate and to differentiate into an antibody-secreting plasma cell. Additional stimulation by activated $CD4^+$ T helper cells is required. In turn, the T_H cells are activated when their receptor (TCR) binds to a T-cell peptide antigen presented by the major histocompatibility complex (MHC II) on the surface of a cell.[4]

We describe herein a concept for the construction of antitumor vaccines **1** in which a tumor-associated sialyl-Tn glycopeptide antigen from the tandem repeat region of MUC1 is connected to a T_H-cell peptide epitope from ovalbumin ($OVA_{323-339}$)[5] through a polar, nonimmunogenic amino acid spacer (Figure 1a). Such a synthetic vaccine should be taken up by antigen-presenting cells (APCs). After processing of construct **1**, the ovalbumin T-cell epitope[5] should be presented by MHC II complexes on APCs and recognized by the T-cell receptor (TCR). This results in the activation and differentiation of naive T cells. The activated T_H cells then stimulate those B cells that also present the corresponding T-cell epitope. It is anticipated that, according to the mechanism illustrated above (Figure 1b), recognition of the tumor-associated MUC1 glycopeptide antigen in **1** by the immunoglobulin receptor of a B cell and subsequent processing of construct **1** in the same B cell combined with additional co-stimulatory signals will initiate a strong production of specific antibodies directed against the MUC1 glycopeptide antigen.

The glycopeptide–T-cell-epitope conjugate **1** was constructed by fragment condensation on a solid phase. The MUC1 glycopeptide antigen of the sequence GVT*SAPDTRPAP chosen as the target structure contains the immunodominant motif PDTRP,[6] which is masked in MUC1 on normal cells by the large glycan side chains. The sialyl-Tn antigen, which has been identified in mammary, stomach, and colon carcinomas,[7–9] was incorporated into the peptide sequence at Thr^3 as the tumor-associated saccharide component. Examination of the aberrant glycosylation of mucines in tumor cells[10,11] reveals that the sialyl-Tn antigen may not be the most abundant, but is certainly a highly important structure in terms of tumor selectivity.

The sialyl-Tn glycopeptide from MUC1 was assembled as a protected fragment by solid-phase synthesis on the 2-phenyl-2-trimethylsilylethyl ester (PTMSEL) linker[12] (Scheme 1). For this purpose, *O*-(benzotriazol-1-yl)-*N*,*N*,*N*′,*N*′-tetramethyluronium hexafluorophosphate (HTBU)[14] and 1-hydroxybenzotriazole (HOBt) were utilized for condensing the Fmoc-protected amino acids, whereas the 7-aza analogues HATU/HOAt[16] of these reagents served for coupling the protected sialyl-Tn–threonine building block **3**.[3,12b,15] To detach side-chain-protected glycopeptide **4** from the resin, the PTMSEL anchor was cleaved with tetrabutylammonium fluoride (TBAF) trihydrate in dichloromethane.[12]

Under these almost neutral conditions, the hydrate shells of the fluoride ions remain intact, thus leaving even very sensitive protecting groups untouched. In this way, **4** could be isolated in 45% yield based on **2** after purification by preparative HPLC (Scheme 1, see Supporting Information for analytical data).

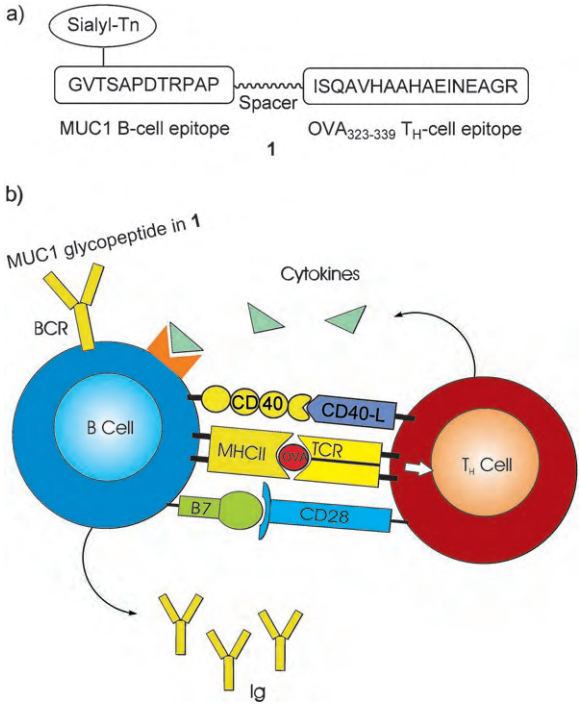

Figure 1. a) MUC1-$OVA_{323-339}$ vaccine conjugate **1**. b) T_H-cell-stimulated humoral immune response.

Parallel to this, the $OVA_{323-339}$ heptadecapeptide fragment was synthesized on a TentaGel-bound Wang linker[13,17] (**5**). After completion of the target sequence and N-terminal

deprotection, the Fmoc-protected triethylene glycol spacer–amino acid **6**[3] was coupled and deprotected at the N terminus to give **7** (Scheme 2).

Subsequently, the sialyl-Tn–MUC1 glycopeptide **4** activated with HATU/HOAt was coupled to the polymer-bound conjugate **7**; the excess of the carboxy fragment component **4** used was only 5% relative to the starting material **5**. The Wang linker was cleaved with a mixture of trifluoroacetic acid, triisopropylsilane, and water, and all acid-sensitive protecting groups were simultaneously removed. The construct **8** still protected in its carbohydrate moiety was isolated after purification by preparative HPLC in a yield of 42% based on **5**. Hydrogenolysis of the NeuNAc benzyl ester and removal of the *O*-acetyl groups by transesterification in methanol with catalytic NaOMe at pH 9 furnished the fully synthetic vaccine **1**, which was isolated after purification by preparative HPLC in 43% yield. Purity was confirmed by analytical HPLC and NMR spectroscopy (see Supporting Information). In the 500-MHz ^{1}H NMR spectrum of **1**, only three signals that correspond to the α-H atoms of proline were detected, thus ruling out any considerable epimerization of the *C*-terminal proline during the fragment condensation.

For the induction of a strong humoral immune response against the tumor-associated MUC1 glycopeptide antigen

incorporated in vaccine **1**, transgenic mice (DO11.10), whose T cells express a receptor specific for the ovalbumin T-cell epitope ($OVA_{323-339}$) presented by MHC-II molecules ($I\text{-}A^d$),[5] were immunized with **1**. For this purpose, the synthetic vaccine **1** (10 μg) in combination with complete Freund's adjuvant (CFA) were initially injected into the footpads of three transgenic mice (mouse 4–6). Booster immunizations were performed after 21 days: vaccine **1** (10 μg) was administered intraperitoneally together with incomplete Freund's adjuvant (IFA). As a control, three DO11.10 mice received identical vaccine formulations that contained a phosphate buffer instead of the synthetic vaccine (mouse 1–3, PBS group). Five days after each immunization, blood was drawn from the tail vein of each mouse, and serum was isolated for antibody analysis. Detection of MUC1-specific antibodies in the sera of the mice was conducted by ELISA.[18] For this purpose, the wells of an ELISA plate were coated with the MUC1–sialyl-Tn glycopeptide[19] from **1** conjugated with bovine serum albumin (BSA). This neoglycoprotein unspecifically binds to the polymer surface, thereby immobilizing the highly hydrophilic glycopeptide antigen[2a] on the microtiter plate. The sera were titrated at increasing dilutions (abscissa) in a phosphate buffer (PBS), and the antibody concentration was detected photometrically by using a secondary anti-mouse antibody conjugated to horseradish peroxidase (HPO).[18] Comparing the extinctions after the

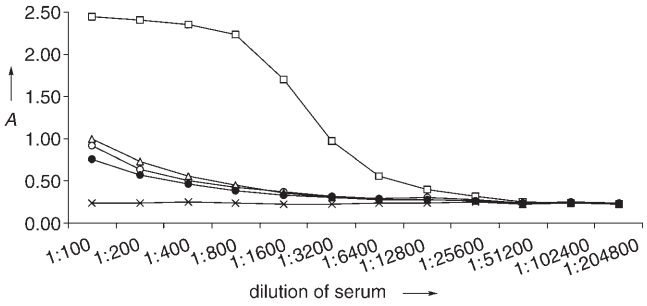

Figure 2. ELISA of sera isolated from mice immunized with **1** (after third immunization, coating of the microtiter plate with MUC1–BSA conjugate[19]): *A* at $\lambda = 414$ nm; ○: mouse 4, □: mouse 5, △: mouse 6, ●: control mouse, ×: negative control.

third immunization, a significant effect was observed (Figure 2): One of the mice (mouse 5, open squares) immunized with the synthetic MUC1-$OVA_{323-339}$ vaccine **1** exhibited a considerably elevated MUC1-specific antibody concentration, whereas the control mice (PBS mice) showed only minor unspecific reaction. Although the DO11.10 mice are genetically mostly identical, their immune responses differ individually, so it is not uncommon that only one of the three immunized mice reacted with a significantly enhanced antibody response.

When observing the development of the MUC1-specific antibody titer of mouse 5 during the immunization experiment (Figure 3), the significant increase in antibody concentration between the second and the third immunization is

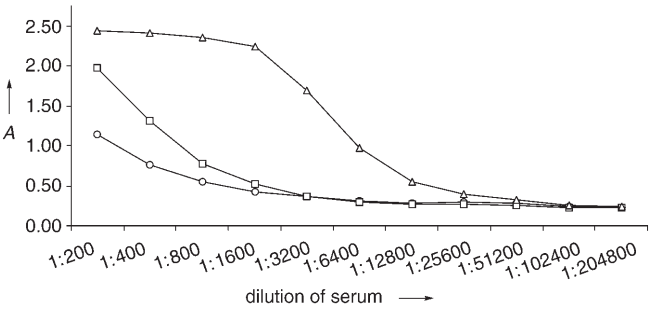

Figure 3. Development of MUC1-specific antibody titer of mouse 5. *A* at $\lambda = 414$ nm; ○: first immunization, □: second immunization, △: third immunization.

striking, clearly indicating the establishment of an immunological memory (specific IgG response).

To verify the specificity of the antibodies in the serum isolated from mouse 5, neutralization experiments with different (glyco)peptide antigens were performed at three concentration stages (1:4000, 1:8000, 1:16000) (Figure 4). In contrast to the untreated serum (open circle), incubation with the tumor-associated sialyl-Tn glycopeptide antigen **9**[2a,3,12b] contained in **1** led to nearly complete neutralization of the MUC1-specific antibodies in the isolated serum (filled squares in Figure 4a). Neither the unglycosylated dodecapeptide **10** with the same sequence from MUC1[2a,3,12b] nor the glycohexadecapeptide **11** from the tandem repeat region of MUC4[15] with identical sialyl-Tn carbohydrate component as in **9**, nor the MUC4 peptide **12**[15] were capable of neutralizing the antibody induced with vaccine **1** (Figures 4b–d).

The immunization of mice with the fully synthetic vaccine **1** consisting of a tumor-associated sialyl-Tn glycopeptide antigen from MUC1 and a T-cell epitope from ovalbumin resulted not only in the generation of a strong but also a highly specific humoral immune response directed against the tumor-associated structure. The antibody induced in this way exclusively recognizes structure **9**, consisting of peptide as well as carbohydrate components, which is contained in vaccine **1**, but not the corresponding peptide sequence **10** alone or the sialyl-Tn carbohydrate structure in combination with a different peptide sequence (**11**). This high specificity of the antibody induced with the synthetic vaccine **1** is an encouraging result for the development of efficient antitumor vaccines. Such a selective activation of the immune system directed against glycoprotein structures that only occur on tumor but not on normal cells can only be achieved with pure, preferably fully synthetic antigens that become accessible through modern chemical methodologies available today.[2a,20]

Microarray technology allows the analysis of a large number of different parameters simultaneously by using a variety of readout systems based on fluorescence, chemiluminescence, electrochemistry, radioactivity, or mass spectrometry (MS).[1] Of these readout systems mass spectrometry is unique, since it provides information on an intrinsic physical parameter of the analyte, its molecular weight. Such a readout system is especially useful to determine protein expression levels by using surface enhanced laser desorption ionization (SELDI), to determine enzyme activity through peptide-based approaches such as SAMDI (self-assembled monolayers for MALDI), and for the direct detection of cross-hybridization on DNA chips.[2–7] Particularly important is the capability of mass spectrometry to unequivocally identify specific protein–protein interactions by providing the exact molecular weight of the binding partner.[7]

To develop a microarray-based assay that combines the reversible immobilization of proteins with readout by MALDI mass spectrometry, we have utilized protein–DNA conjugates (DNA-directed immobilization, DDI). This method achieves highly specific but noncovalent and therefore reversible binding of protein–DNA conjugates to com-

plementary, surface-attached oligonucleotides. DDI combines efficient in-solution binding of protein–DNA conjugates with spatially encoded detection in microarray format.[8–10] This approach is an addition to the widely used antibody-based immobilization of capture proteins on microarrays.[11,12]

As a model system for detecting specific protein–protein interactions by DDI and mass spectrometry, the protein pair Ras and the Ras-binding domain (RBD) of its effector molecule cRaf-1 was selected because of its medicinal relevance.[13] In addition a second protein pair, Ras and a Ras-specific antibody, was chosen. The Ras protein plays a vital role in signal transduction by cycling between its activated, GTP-bound state and its inactive, GDP-bound state.[14] The affinity of Ras:GTP for the RBD is approximately 160 nM, whereas the affinity of Ras:GDP for the RBD is around 200-fold weaker.[15] Mutations in Ras can lead to constitutive activation of the signaling cascade and occur in 30% of all solid human cancers.[16] An important reason for selecting this system was the observation that no antibody exists that can distinguish between Ras:GTP and Ras:GDP.

Functional immobilization of proteins in a controlled manner was achieved by synthesizing protein–DNA fusion proteins based on the expressed-protein ligation technique.[17,18] Similar approaches have been described for peptide–DNA and protein–PNA conjugates.[9,19,20]

The DNA-directed immobilization of protein–DNA fusion constructs through hybridization on oligonucleotide-modified microarrays is a mild procedure that combines high efficiency of adsorption and reversibility with high specificity. The immobilization strategy was initially tested with Ras–DNA and RBD–DNA conjugates on glass microarrays. The glass surface was modified with a dendritic intermediate layer and 5′-amino-modified oligonucleotides were covalently attached.[21] Three different DNA sequences were used for capturing the Ras–DNA and RBD–DNA conjugates. Two of these were fully complementary to the DNA attached to the proteins but differed in the number of nucleobases (**1**, **2**). In addition, a non-complementary capture DNA (**3**) served as a control for the specificity of DNA hybridization.

Synthesis of protein–DNA conjugates was achieved by expression of Ras and RBD in *E. coli* fused to an Mxe intein and a chitin-binding domain (CBD), which was used for affinity purification.[22] Treatment of the purified fusion proteins with mercaptoethanesulfonic acid (MESNA) liberated the corresponding C-terminal thioesters of Ras (**4**) and RBD (**5**) (see Supporting Information). These were ligated with an oligonucleotide carrying a cysteine residue at its 5′ end. The 5′-modification of the oligonucleotide was accomplished by two different routes. In the first approach a modified thymidine phosphoramidite (**6**) was introduced into the oligonucleotide (**7**) during solid-phase synthesis. Compound **6** carried a 5′-cysteine residue and was synthesized from 5′-amino thymidine (Figure 1). The second method utilized a 5′-amino oligonucleotide, covalently linked to the solid phase (**8**). The oligonucleotide was treated with an (9H-fluoren-9-ylmethoxy)carbonyl (Fmoc) protected cysteine residue (Fmoc-Cys(SBu)-OH) to produce the 5′-cysteine modified oligonucleotide **9** (see Supporting Information).[23] The oligonucleotides **7** and **9** were treated with Ras (**4**) and RBD (**5**) thioesters and produced the protein–DNA conjugates **10** and **11** (Figure 1 a–c).[19,24,25]

In initial tests conventional fluorescence readout was used to detect Ras:GppNHp–DNA (GppNHp is a nonhydrolyzable GTP analogue) on glass microarrays after incubation with a Cy5-labeled Ras-specific antibody. Specific interaction between a fully complementary surface-attached oligonucleotide **1** and the Ras–DNA conjugate **10** was clearly demon-

strated by the strong fluorescence signal (Figure 1d). A complementary but truncated oligonucleotide **2** produced a much weaker signal (Figure 1d). The non-complementary oligonucleotide **3** did not produce a signal (Figure 1d) and was used as a negative control in all experiments to exclude any influence of the surface-attached oligonucleotide on the readout.

For the detection of analyte proteins by MALDI-MS, a different solid support had to be chosen because glass slides, owing to their poor electrical conductance properties, are inappropriate as a support. Silica wafers are easily available, have an adequate electric conductance and offer similar surface chemistry to that of glass slides. Arrays were produced in object-holder format, and contained five subarrays (18 × 9 mm) per wafer. Each subarray contained 18 to 36 spots with a diameter of approximately 200 μm (Figure 2b). In initial experiments, three different capture oligonucleotides (**1**–**3**) were spotted in rows of six spots each and the silica chips were washed and blocked with an albumin containing buffer (see Supporting Information). Subsequently the capture molecules RBD–DNA or Ras–DNA were immobilized on the surface, there then followed several washing steps and incubation with the analyte proteins (Ras:GppNHp/Ras antibody). Finally a layer of organic matrix (sinapinic acid) was deposited on the microarrays and dried (Figure 2a).

MALDI measurements were performed with a home-built post source decay (PSD) MALDI mass spectrometer (Aladim II) that allowed adjustment of the microarray plate in x, y, and z directions.[26,27] Multiple controls were performed by including a row of non-complementary oligonucleotide **3** in every subarray, as well as by measuring subarrays not treated with capture or analyte molecules and a subarray treated only with the capture molecule RBD–DNA. In the case of surface-attached, non-complementary oligonucleotide no signal, for either capture or analyte molecules, was detected. Measurement of subarrays with immobilized RBD–DNA or Ras–DNA did not produce a signal, thus demonstrating that either the conjugates were not detached from the surface or, more probably, that they were not ionized efficiently under these conditions (Figure 2c). Measurements in negative-ion mode also did not give a signal for the capture molecules.

Incubation of an RBD–DNA-loaded subarray with a 3-μM solution of C-terminally truncated Ras:GppNHp, however, produced a MALDI signal at 18862 Da for the Ras protein after only 2–20 laser pulses (calculated M_W: 18853 Da, Figure 2d). Incubating the arrays with Ras:GDP did not produce a signal, thus demonstrating that the immobilized RBD–DNA selectively binds activated Ras:GppNHp and not its inactive form (Ras:GDP). Positive results were only obtained from spots on the array that carried the oligonucleotides **1** and **2** but never for the non-complementary oligonucleotide **3**, emphasizing the specificity of the method for immobilization of both capture and analyte proteins.

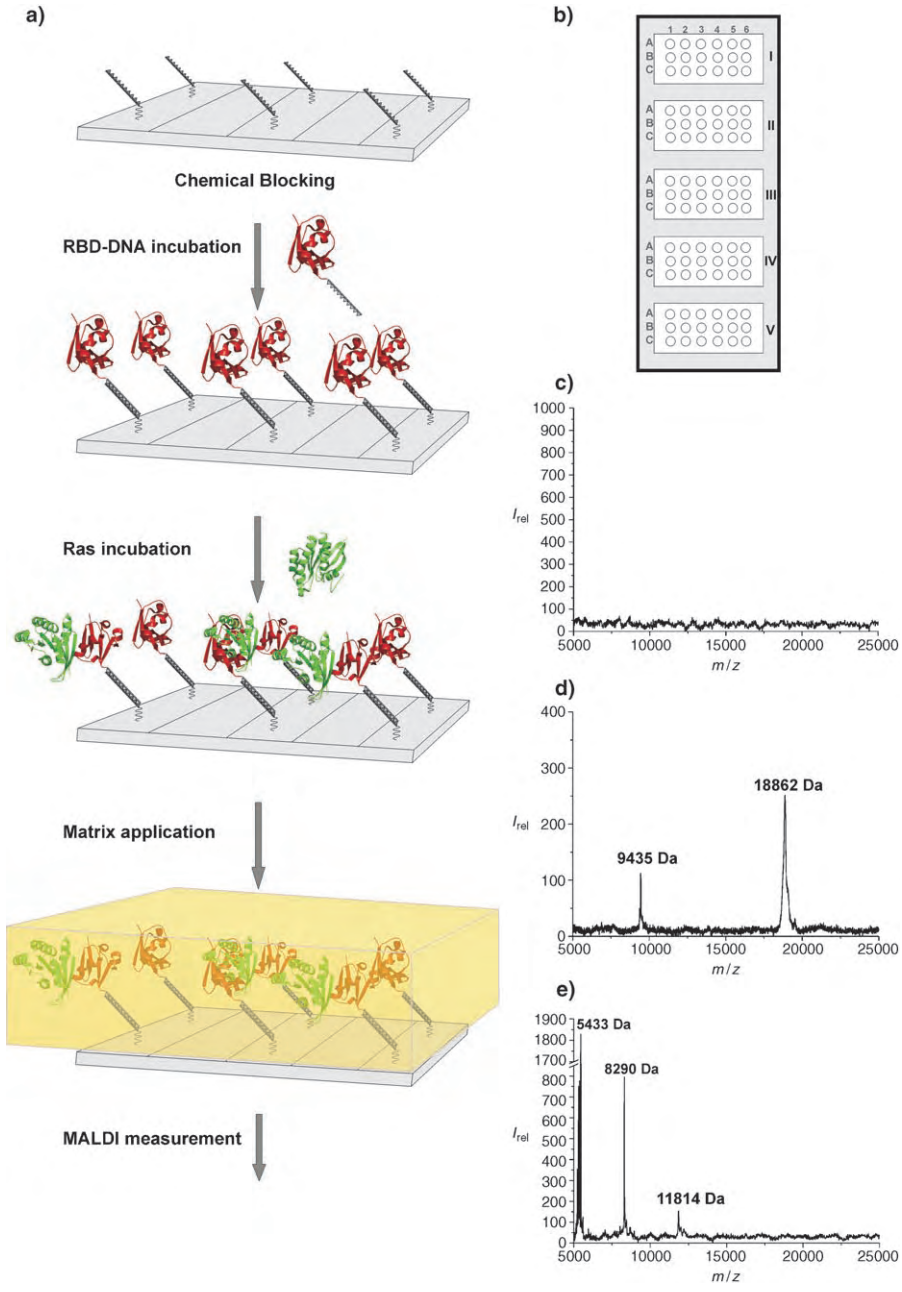

Figure 2. a) Microarray preparation. Chemical blocking of the surface after covalent attachment of oligonucleotides; DNA-directed immobilization of the capture molecule (RBD–DNA conjugate); incubation with analyte (Ras:GppNHp); matrix application; typical MALDI spectra of captured Ras:GppNHp. b) Microarray in object holder format; c) Typical MALDI spectrum of background signal (only capture molecule on the surface); d) MALDI spectrum of microarray incubated with 3-μM solution of Ras:GppNHp; e) MALDI spectrum of microarray spots with Ras–DNA as capture molecule and Ras-specific antibody as analyte.

An important advantage of this approach is its spatial resolution. Peaks in the mass spectrum were only observed for equidistant areas on the subarray that correlated very well with the spots of immobilized oligonucleotide which were brought onto the surface by an automated spotter. Based on this observation we conclude that the applied matrix solution did not fully dissolve and dislocate the analyte molecules.

To determine the scope of the method, a second protein pair was used. Ras–DNA was immobilized on one subarray and incubated with a solution of Cy5-labeled Ras-specific antibody. The corresponding mass spectrum (Figure 2e) showed a signal at 11814 Da, which can be attributed to one of the light chains of the Fab antibody. Other signals observed in this spectrum did not interfere with the identification of the analyte. Negative controls similar to those described above gave no signal.

An important aspect of analyzing protein–protein interactions is the affinity, which can be the limiting factor for measurements in physiological contexts. For the Ras–RBD interaction, which can be regarded as of intermediate affinity, the detection limit was determined by incubation of the five subarrays on one silica wafer with solutions containing 3 μM, 300 nM, 30 nM, 3 nM, and 0.3 nM Ras:GppNHp. In all cases, 80 single-laser-pulse spectra were averaged (see Supporting Information). Ras:GppNHp was detected down to an incubation concentration of 3 nM, which is 50-times below the K_D value determined for the Ras:GppNHp–RBD interaction (160 nM) in solution-phase experiments.[15] This result suggests that measurements at sample concentrations considerably below the K_D value for the interaction are possible and thus that the identification of weakly binding molecules is also possible. In addition, quantification of the analyte protein by MALDI-MS could provide information on affinities between capture and analyte protein as well as the concentration of the analyte.[28]

The successful measurement of low concentrations of activated Ras enabled the detection of activated Ras in complex mixtures originating from cell lysates. A mammalian cell line, Madine Darby canine kidney (MDCK) cells and a closely related MDCK-f3 cell line (virally transformed with the *H-Ras* gene[29–31]) were chosen to obtain fractionated cell lysates. MDCK-f3 cells express elevated levels of Ras and therefore activated Ras should be present at concentrations in amounts typical for cancer cells. After cell lysis the cytoplasmic and membrane fractions were separated. Cytoplasmic fractions were used as obtained, whereas the membrane fractions were extracted with TritonX100-containing buffer and only the soluble fraction was used.

Four subarrays were individually incubated for 30 min with the cytoplasmic fraction and the membrane extract of MDCK and MDCK-f3, then came the washing steps and application of matrix. For both membrane extracts, only a series of equidistant signals between 500 and 2000 Da was observed that arose from detergent molecules left on the surface during sample preparation, possibly impairing the detection of activated Ras. However, the cytoplasmic fraction of MDCK-f3 cells produced a broad signal, ranging from 21050 to 21700 Da, with a maximum at 21329 Da, which is in good agreement with unmodified full-length Ras (M_W 21298 Da;[32] Figure 3). This result demonstrates that activated Ras can be detected in cell lysates at concentrations well below the K_D of the Ras–RBD interaction. An increase in spectral resolution will allow the distinction of post-translationally modified isoforms of Ras in different cellular environments.

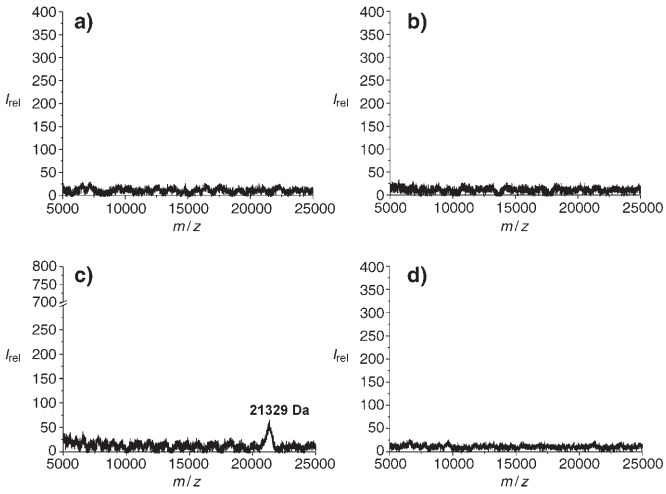

Figure 3. Microarray with RBD–DNA as capture molecule incubated with cytosolic fractions and membrane-extracts of MDCK and MDCK-f3 cells. MALDI spectrum of subarray incubated with a) cytosolic fraction of MDCK cells; b) membrane extract of MDCK cells; c) cytosolic fraction of MDCK-f3 cells showing a signal around 21329 Da; d) membrane extract of MDCK-f3 cells.

Herein we have shown that the modification of proteins by easily accessible cysteine-modified oligonucleotides using an expressed-protein ligation approach is straightforward and allows direct functional as well as highly selective immobilization of protein–DNA conjugates. A combination of the resulting DDI-based protein microarrays and MALDI mass spectrometry leads to the identification of protein–protein interactions at concentrations far below the K_D value of the chosen interaction. The selectivity and sensitivity is sufficient to identify Ras proteins in complex mixtures such as cell lysates, without interfering signals.

An additional benefit of the reversible immobilization strategy is the reusability of these microarrays with different capture molecules (e.g. protein–DNA conjugates). The advantage of MALDI detection over conventional systems such as fluorescence is the molecular-weight information obtained. In combination with proteolytic cleavage and advanced MALDI techniques, such as post source decay or composition-based sequencing FT-ICR-MS, it should be possible to identified analyte molecules directly with this approach.[33] Finally, the method described herein will permit analysis of protein–protein interactions, screening for new or unknown binding partners, or monitoring the influence of third components (drugs) on the binding event.

$[Tl_8]^{6-}$ in Cs_8Tl_8O: A Naked Eight-Vertex *closo*-Deltaeder as a Cluster Anion**

*Andrey Karpov and Martin Jansen**

Dedicated to Professor Herbert W. Roesky on the occasion of his 70th birthday

Using NaTl as an example, Zintl developed the concept[1] that was later named after him, and which was subsequently generalized by Klemm.[2] The Zintl–Klemm approach allows a reliable and qualitative analysis of the chemical bonding in intermetallics near the ionic–metallic border-line to be performed. The classical formulation assumes that the electropositive component, for example, of a binary intermetallic phase, transfers all valence electrons to the electronegative component. The resulting anions interconnect by two-electron-two-center (2e2c) bonds to form oligomeric or polymeric substructures. Thus the anions achieve closed-shell electron configurations, which show similar structural motives to the elements with the same valence electron concentration (8-*N* rule or concept of the effective atomic number (EAN)).[3] Since then, a huge number of oligomeric and polymeric thallium anions has been discovered.[4] It may be perceived as a curiosity that among them virtually none fulfills the Zintl rules. This fact reflects some peculiarities of thallium. In accordance with its position in the periodic table, the thallium 6s orbital is contracted and energetically stabilized. In addition, the oxidation state −I is somewhat favored, because the corresponding ground state $(p_{1/2})^2$ can be considered closed-shell as a result of lifting the degeneracy of the 6p orbital through spin-orbit splitting.[5] As a consequence of the larger radial extension of the orbitals contributing to the Tl–Tl bonds, delocalized bonds play an important role in these clusters. Because of this complex interplay, completely different bonding descriptions have been considered for the thallium polyanions reported. $(Tl^-)_n$[1] and $[Tl_4]^{8-}$[6] can be classified as Zintl ions, $[Tl_5]^{7-}$[7] and $[Tl_6]^{8-}$[8] obey Wade's rules,[9] whereas $[Tl_6]^{6-}$,[10] $[Tl_7]^{7-}$,[11] $[Tl_9]^{9-}$,[7] $[Tl_{11}]^{7-}$[12] cannot be explained using any known system, and are denoted as hypoelectronic.[4] Beside these closed-shell (diamagnetic) clusters, open-shell (paramagnetic) species are also known,

for example, $[Tl_{13}]^{10-}$ (with the shape of a centered icosahedron).[13]

In the context of our investigations on aurides[14] and platinides,[15] the Tl^- ion is of particular interest to us. As part of our synthesis attempts we have also added oxygen as a third component to the binary system Cs/Tl. In this way, a further degree of freedom is introduced, thus opening additional options for the formation of appropriate compositions and packings. In the course of these studies, we discovered Cs_8Tl_8O, which contains previously unknown $[Tl_8]^{6-}$ oligoanions.

Cs_8Tl_8O was prepared from Cs, Tl, and Cs_2O, by reaction at 773 K and subsequent slow cooling to room temperature. The educts contained the required stoichiometric Tl/O ratio, however with an excess of Cs. In a second procedure the mixture was rapidly quenched from 773 K to room temperature and then heated at 473 K for 1000 h. The excess of cesium was subsequently removed by evaporation. Cs_8Tl_8O is a dark-gray brittle crystalline powder, and can be isolated as a single phase (shown by powder X-ray diffraction) in this manner. However, the products often contain an admixture of Cs_8Tl_{11},[12] as detected by powder X-ray diffraction (ca. 1–5 wt.%). The compound is extremely air- and moisture-sensitive, and thermally stable up to approximately 498 K. At this temperature, it decomposes, leaving a solid residue of Cs_8Tl_{11}. The compound Cs_8Tl_8O is formed in a wide concentration range of the constituent components (the surplus reactants do not react) and shows practically no homogeneity range. The magnetic susceptibility is temperature independent in the region 50–300 K (-72.3×10^{-10} m^3 mol$^{-1}\pm2.5\%$) and agrees fairly well with the sum of the diamagnetic core corrections $(8\chi(Tl^+)+8\chi(Cs^+)+\chi(O^{2-})=-67.1\times10^{-10}$ m^3 mol^{-1})[16] and the Larmor susceptibility of the cluster orbital electrons (-18.8×10^{-10} m^3 mol^{-1}).[17] The temperature dependence of the electrical conductivity has a gradient $(1/\rho)\,\partial\rho/\partial T=-0.36\%$ K^{-1} in the region 50→300 K (ρ(50 K) = 0.085, ρ(273 K) = 0.023 Ohm cm), which is characteristic for a semiconductor.[18] The measurement of the diffuse reflectance shows a clear absorption edge at $\lambda=465$ nm which corresponds to an optical band gap E_g of 2.7 eV, thus confirming the semiconducting nature of the sample (Figure 1).

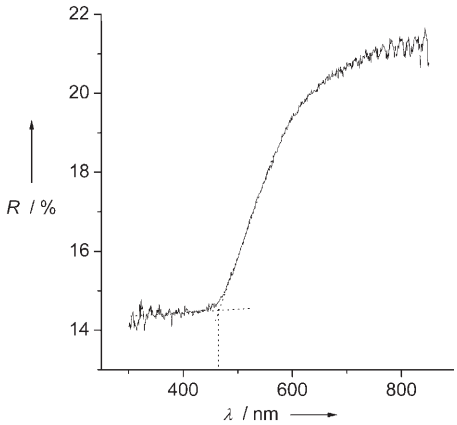

Figure 1. Diffuse reflectance spectrum of Cs_8Tl_8O. The optical band gap is defined by the intersection of the extrapolated steep rise with the base line.

According to the results of X-ray single-crystal structure analysis[19] Cs_8Tl_8O crystallizes in a novel structure type (Figure 2). The oxygen atoms are surrounded by an octahedral arrangement of six cesium atoms at a distance of 290.0(1) pm (Cs–O in Cs_2O: 287 pm).[20] Two further Cs atoms are located at a distance of 533.1(1) pm above and below each oxygen atom on the $\bar{3}$ axis of space group $R\bar{3}$. The resemblance of the Cs–O separations in Cs_8Tl_8O to those in Cs_2O is indicative for a full ionization of the Cs atoms with a charge transfer to oxygen atoms and formation of cationic $[OCs_{6+2}]^{6+}$ groups. The electrons released are accommodated by isolated ("naked") $\{Tl_8\}$ groups (point group D_{3d}, Figure 3). The Tl–Tl separations within the $[Tl_8]^{6-}$ cluster range from 311 to 326 pm, and thus are comparable to the corresponding values in other known thallium clusters. The intercluster Tl–Tl separations are clearly larger ($\geq$ 577 pm).

Topologically, the $\{Tl_8\}$ units can be regarded as being generated by condensation of an octahedron with two

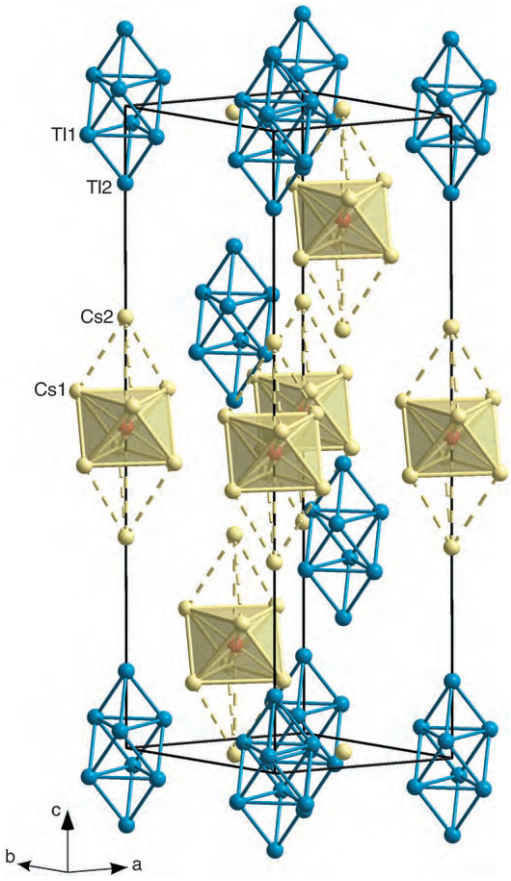

Figure 2. Crystal structure of Cs_8Tl_8O. Black lines mark the unit cell edges; $\{Tl_8\}$ clusters are blue, $\{O(Cs1)_6(Cs2)_2\}$ polyhedra are yellow.

tetrahedra (bicapped octahedron). The somewhat larger Tl–Tl distances are found in the common faces. The $\{Tl_8\}$ and $\{OCs_{6+2}\}$ groups belong to the same point group (D_{3d}), which favors the formation of a simple and highly symmetric packing. The $\{Tl_8\}$ clusters are arranged analogous to a cubic-closed packing, with the octahedral holes completely occupied by $\{OCs_{6+2}\}$ groups. The structure can therefore be

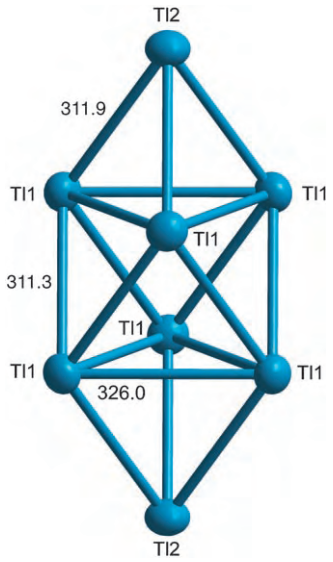

Figure 3. The $\{Tl_8\}$ cluster (thermal ellipsoids set at 50%). Interatomic distances [pm] and angles [°]: Tl1–Tl1 311.3(1) ×2, Tl1–Tl2 311.9(1), Tl1–Tl1 326.1(1) ×2, Tl2–Tl1 311.9(1) ×3; Tl1-Tl1-Tl1 63.16(3), Tl1-Tl1-Tl2 116.90(2) ×2, Tl1-Tl1-Tl1 58.42(1) ×2, Tl1-Tl1-Tl1 90 ×2, Tl1-Tl1-Tl2 58.48(1) ×2, Tl1-Tl1-Tl1 60.00, Tl1-Tl2-Tl1 63.03(3) ×3.

understood as an NaCl derivative, with one of the threefold axes of the originally cubic crystal system elongated.

Cs_8Tl_8O is the first example of a compound with an eight-vertex anionic framework in the shape of a bicapped octahedron. The earlier examples of bicapped octahedra were limited to transition metals.[21] The lack of such clusters within the boron or carbon chemistry was ascribed to the high strain of only four orbitals (per atom) contributing to the bonding.[22] When moving to the higher homologues, d orbitals are available which might reduce the angular strain. Accordingly, the first ligand-stabilized, eight-vertex, main-group-element cluster with the shape of a distorted bicapped octahedron (C_i) has recently been isolated for indium ($[In_8(2,6\text{-}Mes_2C_6H_3)_4]$, Mes = 2,4,6-$Me_3C_6H_2$).[23] Other topologies for eight-vertex cages are a distorted dodecahedron (ca. D_{2d}; $[B_8H_8]^{2-}$),[24] a distorted cube (ca. D_{2d}; $[In_8]$),[25] a rhombic prism (ca. D_{2d}; $[Sn_8]$),[26] and a square antiprism (D_{4d}; $[Sn_8]^{6-}$).[27] The latter example ($[Sn_8]^{6-}$) was the only representative of an eight-vertex, "isolated" anionic cluster known, until now.

Thirty valence electrons are available in the $[Tl_8]^{6-}$ cluster. This value is much less than the number of electrons required for 2e2c bonds within the Zintl–Klemm concept (18 edges × 2e + 8 inert pairs = 52e). The classical Wade's rules also fail at the description of this cage: in this case, for a *closo*-$[Tl_8]^{6-}$ cluster, 34 electrons would be necessary (2 × 8 + 2 skeletal electrons + 8 inert pairs = 34e). Only when employing the extended Wade–Mingos concept,[28] does the number of the electrons available correspond to the number of electrons required (electrons of the octahedron + 2 × {electrons of the tetrahedron − electrons of the common triangular face} = (4 × 6 + 2) + 2 × {(2 × 6 + 8) − (2×3+3×4)} = 30e). In this view, the two capping thallium atoms serve as electron donors for the stabilization of the electron-deficient octahedron framework ($2n \rightarrow 2n + 2$) [Eq. (1)]. As an alternative possibility of stabilizing the $[Tl_6]^{6-}$ octahedron by a strong axial compression has also been observed and discussed.[10]

$$2\,Tl^0 + [Tl_6]^{6-} = (Tl^+)_2[Tl_6]^{8-} \quad (1)$$

The closed-shell character of the $[Tl_8]^{6-}$ cluster is also qualitatively confirmed by extended Hückel calculations.[29] The bonding skeletal orbitals and the LUMO are shown in Figure 4. The LUMO (e_u) is separated from the HOMO (a_{1g}) by a remarkable band gap (0.6 eV). The band gap value is clearly underestimated, because the stabilization influence of the relativistic effects[5] is not considered.

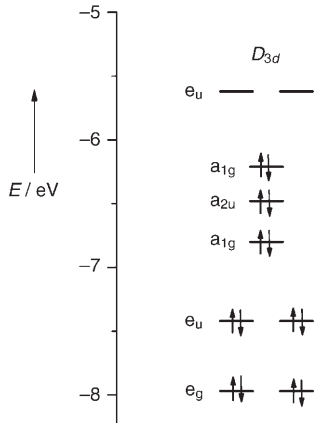

Figure 4. The MO diagram of the $\{Tl_8\}$ cluster calculated using the extended Hückel approximation.

The cluster compound reported herein provides a well defined setting for the discussion of the bonding relations. In the past, when analyzing complex compounds of oligomeric homoatomic thallium anions, incomplete charge transfer was often taken into account, as a possible correction parameter. In contrast, the details of the Cs/O substructure in Cs_8Tl_8O allows an assignment following the ionic bonding model, and therefore reasonable conclusions about the total charge of the $\{Tl_8\}$ cluster can be drawn. Although in this case neither the Zintl–Klemm concept nor Wade's rules (in their strict interpretation) apply, achieving a closed-shell electron structure appears to be the driving force for the formation of this specific structure. It is clear that for strongly delocalized bonding systems the otherwise so useful heuristic interpretation patterns are not adequate. Even only a qualitative understanding, would require an analysis of the MO term scheme of the cluster.

Experimental Section

All operations were performed under dried argon (Schlenk technique or glove-box: M.Braun, H_2O, $O_2 < 0.1$ ppm). Cs_8Tl_8O was prepared by reaction of cesium (synthesized from CsCl by a reduction with Ca and distilled twice in vacuum)[30] with thallium (Sigma-Aldrich, 99.9+ %, dried before use at 423 K in vacuum at 10^{-6} bar) and Cs_2O (synthesized from Cs by oxidation with a slight deficiency of oxygen

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

followed by distillation of the excess Cs)[31] in the ratio Cs:Tl:Cs_2O 6:8:2. The mixture (1–2 g) was sealed under Ar in a tantalum ampoule, heated for 1 day at 773 K and subsequently cooled to room temperature with a rate of 1.5 K h^{-1}. In an alternative procedure, the mixture of Cs:Tl:Cs_2O in the ratio 7.5:8:1.25 was homogenized at 773 K for 1 day, quenched to room temperature and annealed at 473 K for 1000 h. The cesium excess was distilled at 363 K in both cases. Besides pure Cs_8Tl_8O, the samples often contained the thermal decomposition product Cs_8Tl_{11}. Cs_8Tl_8O is extremely sensitive to air and moisture. The atom ratio of heavy elements was additionally confirmed by energy dispersive X-ray spectroscopy (EDX) analysis (XL30TMP, Philips). The thermal stability was studied using high temperature X-ray powder diffraction (Stoe & Cie GmbH, $Mo_{K\alpha1}$, $\lambda =$ 70.93 pm, $4° < 2\theta < 40°$, T from room temperature to 623 K at 25 K intervals). The magnetization was measured using a SQUID Magnetometer (MPMS5.5, Quantum Design) in the temperature range 5–300 K at a field of 5 T. The specimen (0.1434 g) was sealed in a quartz tube under helium. The raw data were corrected for the holder contribution. The electrical conductivity measurement was performed using the four points technique (cylindrical sample, 6 mm diameter × 1 mm thickness, van der Pauw[32]) in the temperature region 5–300 K. Diffuse reflectance was recorded on a spectrophotometer (Perkin-Elmer Lambda 9) in the wavelength region 250 nm < λ < 850 nm. The sample as a finely ground powder was filled under argon into a flat quartz cuvette.

The Supporting Information contains an X-ray powder diffraction pattern of Cs_8Tl_8O and its comparison with a pattern as calculated from single-crystal data as well as the temperature dependences of the magnetization and of the electrical resistivity.

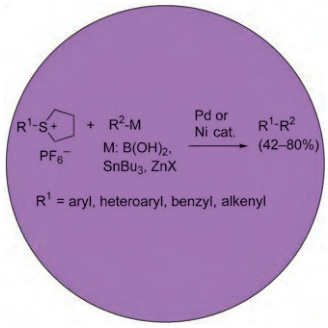
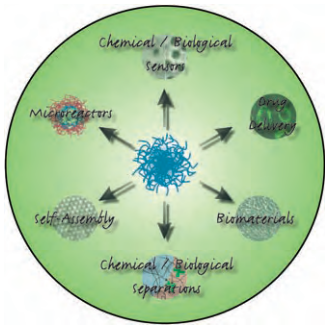
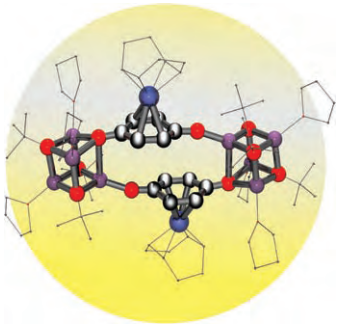
Diruthenium complexes with optically active thiolate-bridged ligands promote the catalytic propargylic substitution of propargylic alcohols with acetone as the nucleophile. The use of novel chiral ligands bearing a phenyl ring that can engage in a π–π interaction with a phenyl ring of the ruthenium–allenylidene moiety lead to high enantioselectivities in these processes. For more details, see the Communication by Y. Nishibayashi and co-workers on page 7715 ff.



Organosulfur Reagents
In their Minireview on page 7674 ff., P. Vogel and S. R. Dubbaka describe how recent developments in the area of ligands and additives allow the cross-coupling of a large variety of reactants, including inexpensive and readily available sulfonyl chlorides.



Soft Nanotechnology
Hydrogel nanoparticles are promising materials for nanotechnological and biotechnological applications. In their Review on page 7686 ff., L. A. Lyon and S. Nayak describe the advances made with these swellable materials.



Lithium Alkoxide Cubanes
A dimeric, doubly bridged complex in which Li_4O_4 cubane units are connected by a transition-metal complex is presented by D. A. Sweigart and co-workers in their Communication on page 7710 ff.

Reviews

A swell idea: Research on hydrogel nanoparticles confirms the huge application potential of soft nanomaterials. Such nanoparticles can be made to swell and contract in response to changes in their environment. They could find uses as bioresponsive sensors, drug-delivery systems, implantable biomaterials, biotesting, and targetable chemotherapy agents. The picture shows HeLa cells containing core–shell nanoparticles as fluorescent markers.

Ringing the changes for organopalladium catalysts. A new nucleophilic reactivity of organopalladium species has been revealed. The reaction between aryl isocyanates and terminal alkynes in the presence of a palladium catalyst produces oxindoles through the intramolecular vinylpalladation of isocyanates (see scheme; dppe = 1,2-bis(diphenylphosphanyl)ethane).

WILEY-VCH is an international science publisher and part of the John Wiley & Sons Publishing Group.

STM Chemistry has a position available for an

Assistant Editor (f/m)

Applicants should be self-motivated, innovative and have the desire to contribute to the development of ***Small*** – an exciting new micro- and nanoscience journal. You will be involved in all aspects of the editorial procedures, such as the reviewing process, the development of journal content, editing and proof reading manuscripts, coordination of freelance work, and contact with authors from all over the world.

Excellent organizational and communication skills, diplomacy, and flexibility are needed. A broad education in biology, medicine, chemistry, materials science or physics with an emphasis on nanoscience or technology is essential. You should be fluent in English (native speaker preferred) and be familiar with text and graphics PC programs.

The editorial office is based at WILEY-VCH in Weinheim, a pleasant small town near Heidelberg in southwest Germany.

Applicants should send their full CV with a covering letter describing their suitability for the post to:

Wiley-VCH Verlag GmbH & Co. KGaA
Human Resources
Christiane Rabe
Boschstraße 12
D-69469 Weinheim

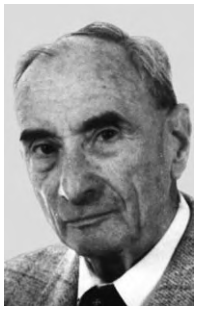
Leopold Horner (1911–2005): Nestor of Preparative Organic Chemistry

Leopold Horner, Professor Emeritus at the Institute of Organic Chemistry at the Johannes Gutenberg-Universität Mainz, passed away at his home in Mainz-Bretzenheim on October 5, 2005, at the age of 94. He was fully engaged with science until his unexpected death; just a week before, he had guided Polish guests through the institute and had enquired about the seminar and lecture program for the coming winter semester.



Leopold Horner was born on August 24, 1911, in Kehl am Rhein. He came into contact with chemistry at a young age as his parents ran a dyers. He endured much hardship during his childhood and adolescence: His father returned from the first world war in poor health and died in 1919. His mother, who had to raise the children and guide the company on her own through the difficult post-war years and the period of inflation, died five years later, leaving Leopold and his sister orphans. Fortunately, the children were taken in by an uncle and an aunt, who also took over the running of the dyers.

Through family solidarity and frugality, it was made possible for the young Leopold Horner, whose talent was recognized early, to attend the Oberrealschule and then to study chemistry in Heidelberg (1931). After the first Verbandsexam (known today as the Vordiplom), he moved to the Universität München where he passed the second Verbandsexam in 1935. The years of his postgraduate studies with Heinrich Wieland (Nobel Prize winner, 1927), who introduced him to the fascination of natural product chemistry, were particularly influential for Horner with regards to his research interests and his future career path as a young scientist. He obtained his doctorate in 1937 for work on vomicine—a relative of strychnine—and was appointed assistant lecturer by Heinrich Wieland. During his Habilitation, he was responsible for the preparation and execution of experiments in both organic and inorganic chemistry, which perhaps explains the remarkably wide scientific interests that were a feature of his career.

After his habilitation work on oxindoles in Munich in 1942, Horner moved to the Plastics Research Institute (Forschungsinstitut für Kunststoffe) in Frankfurt am Main. There he met his future wife, Gerda. The apartment of the young couple, and later the young family with their three children Christoph, Michael, and Irene, was frequently the venue for many friends and colleagues who were fighting for their survival during the extremely difficult time immediately before and after the end of the war. The provision of an open house and immediate aid for friends and those in need distinguished Horner and his family.

As a young assistant professor in Frankfurt, he was deeply involved in the reconstruction of the destroyed chemical institute of the university. His research concentrated on the mechanisms of polymerization induced by single-electron transfer from amines and later by two-electron transfer from phosphines. The results of this work lead to his calling to the Universität Mainz in 1953 as professor of organic chemistry. They were also the starting point of Leopold Horner's scientific work, which was characterized by a broad professional knowledge, bold interpretation, and an interdisciplinary approach.

In Mainz he carried out comprehensive studies on the chemistry of orthoquinones that included model reactions on melamine and pupurogallin formation.[1] The photochemistry of diazo compounds[2] and [2s + 2a] cycloadditions to β-lactams[3] were also investigated, as were electrochemical and catalytic hydrogen transfers of different types. Horner was also ahead of his time in the investigation of surface processes, in the process of corrosion and the reaction at silicate surfaces.[4] Organophosphorus chemistry was, however, central to his work. The principle of condensation and substitution reactions with tertiary phosphines and soft electrophiles, today known as the Appel, Mukaiyama, and Mitsunobu reactions, had already been described by Horner and his co-workers in 1959 with triphenylphosphine dihalides.[5]

The electrochemical cleavage of quaternary phosphonium salts[6] led to the unexpected discovery that tertiary phosphines with three different substituents are chiral.[7] This knowledge formed the basis of the pioneering work of Horner on enantioselective catalysis, and especially enantioselective homogeneous hydrogenation,[8] which was published independently in the same year as the work of W. S. Knowles—work that was honored by the Nobel Prize and which was also based on the chiral phosphines discovered by Horner.

Probably of even greater significance for the arsenal of preparative methods in chemistry is a previous masterly achievement of Horner: the development of PO-activated olefination.[9] In the second of his reports on this topic, Horner described the use of phosphonic acid esters as CH acidic olefination reagents as well as phosphine oxides, and was published two and three years, respectively, before Emmons et al. reported their initial experiments of this type in 1961. Without fear of contradiction, the Horner reaction can be regarded as an essential tool in the demanding field of preparative chemistry, and especially in the total synthesis of natural products and active compounds.

Horner was awarded many honors for his outstanding scientific work. He received an honorary doctorate from the Universität Karlsruhe and the Hanuš Medal of the Czech chemical society, he was also a member of the Deutsche Akademie der Naturforscher Leopoldina zu Halle and received its gold Cothenius medal. He was honored with the Liebig Commemorative Medal of the Gesellschaft Deutscher Chemiker (GDCh, German chemical society), and another particular honor for him was the conferment of Honorary Membership of the Gesellschaft Deutscher Chemiker at the 2005 Chemiedozententagung.

Horner selflessly served his university and the chemistry world in many different senior positions. He also remained especially close to his colleagues, students, and pupils and listened to their progress at congresses, seminars, and colloquia with youthful curiosity

Novartis is pleased to announce the 2005 recipients of the

Novartis Young Investigator Award in Chemistry

Prof. Benjamin List
Max Planck Institute
Mülheim, Germany

for his outstanding contribution towards the development and application of new synthetic methodology in the area of organocatalysis

Prof. Dirk Trauner
University of California
Berkeley, USA

for his outstanding contribution towards the development of new synthetic methodology, natural product synthesis and bioorganic chemistry

The Novartis Young Investigator Award in Chemistry was created in 2002 to mark Novartis' commitment to science and innovation. The award is presented annually to outstanding scientists under the age of 40 who are active in the areas of organic or bioorganic chemistry in the broadest sense. Two winners are identified, one from Europe and one from North America, each of whom receives an unrestricted research grant.

Past winners:
Bernhard Breit, University of Freiburg (2002)
Thomas Carell, Philipps University, Marburg (2002)
Thorsten Bach, Technische Universität München (2003)
J Stephen Clark, University of Nottingham (2004)
Jonathan P Clayden, University of Manchester (2004)

All the Rave in Microwaves**

C. Oliver Kappe* and Mats Larhed*

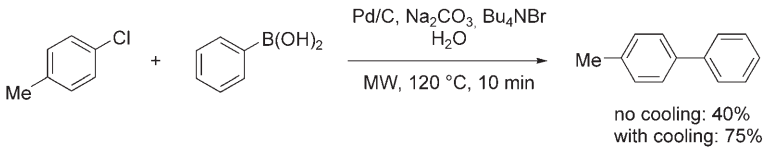
Over the past several years, there has been a significant growth in the area of "microwave chemistry", in particular applied to synthetic organic chemistry, drug discovery, and polymer chemistry.[1] This nonclassical heating technique has slowly moved from a laboratory curiosity to an established method that is heavily used in both academia and industry. Today, the availability of dedicated microwave reactors for chemical synthesis has removed many of the safety and reproducibility issues faced by the early pioneers in the field who employed domestic kitchen microwave ovens. Nevertheless, there is still a considerable debate on the existence of "special or nonthermal microwave effects" and a generally accepted rationalization of many of the observed effects in microwave chemistry remains elusive.

Given this background, the Gesellschaft Deutscher Chemiker (GDCh) decided to organize the first ever Symposium on Microwave-Accelerated Synthesis (M.A.S.-05) at the Heinrich-Heine University in Düsseldorf (Germany). The scientific committee, chaired by Helmut Ritter (University of Düsseldorf), put together a well-balanced interdisciplinary program that consisted of 11 invited lectures, 10 contributed oral presentations, and a poster session. During the one-and-a-half day meeting, a broad range of microwave applications in chemistry were discussed, including organic and medicinal chemistry, solid-phase peptide synthesis, oligonucleotide synthesis, polymer chemistry, microwave-assisted extractions, and the use of microwave heating in material sciences. The meeting was attended by 130 scientists, roughly two thirds of whom came from industry with the remaining one-third from academia.

The opening lecture of the symposium was given by Michael J. Collins (CEM Corporation, Matthews, USA). From the standpoint of an instrument manufacturer, Collins shared with the audience new developments and innovations in the field of microwave chemistry. The lecture focused on the controversial topic of the so-called "simultaneous cooling" technique, whereby microwave synthesis is carried out under microwave irradiation with simultaneous cooling of the reaction vessel by either compressed air or with the aid of a cooling fluid. Citing recently published work by Arvela and Leadbeater,[2] Collins presented examples of aqueous Suzuki coupling reactions of aryl chlorides using palladium-on-charcoal as the catalyst, where yields were significantly increased from 40% to 75% using the simultaneous cooling technique (Scheme 1). Another part of the lecture dealt with the important aspect of scaling up microwave chemistry. According to Collins, the preparation of kilogram quantities of products per day is technically feasible nowadays by using batch or stop-flow microwave reactors, whereas larger continuous-flow instruments for the production-scale level may be available within five years.

Following a short presentation on the use of microwave heating for the synthesis of modified oligonucleotides on controlled pore glass (cpg) surfaces by Clemens Richert (University of Karlsruhe, Germany), Hans-Georg Frank (AplaGen GmbH, Baesweiler, Germany) detailed the experiences of his laboratory in the field of microwave-assisted solid-phase peptide synthesis. While many traditional peptide chemists would be afraid of "cooking peptides" in a microwave oven through fear of side reactions, the group at AplaGen has achieved spectacular success in employing microwave heating in peptide chemistry. According to Frank, the synthesis of an otherwise problematic model peptide that mimicks the action of erythropoietin (H_2N-GGTYSCHFFGPLTWVCKPQGG-COOH) can be achieved within one day by using microwave irradiation for both the coupling and deprotection steps, as opposed to 10 days with the conventional protocol. More importantly, the peptide was obtained in significantly higher yield and purity without any racemization by using carefully controlled microwave conditions that involved intermittent cycles of short pulses of microwave irradiations and ice-bath cooling of the reaction mixture.

In the following presentation, Ulrich S. Schubert (Eindhoven University of Technology and the Dutch Polymer Institute, The Netherlands) discussed the advantages, automation issues, and scale-up possibilities of microwave irradiation for a variety of polymerization reactions, in particular for living/controlled polymerization techniques. In many instances, such polymerization reactions can be carried out much more efficiently under con-



Scheme 1. The effect of the simultaneous cooling technique on a Suzuki reaction (internal temperature measurement with fiber-optic probe). MW = microwave.[2]

trolled microwave heating in sealed vessels than by using conventional reflux conditions.[1b] However, the involvement of special "microwave effects" in many of these reactions is unclear. For the atom-transfer radical polymerization (ATRP) of methyl methacrylate, for example, it was demonstrated by carefully conducted kinetic studies that the obtained results were exactly the same as those obtained using oil-bath chemistry at the same reaction temperature.[3]

The contribution by Mats Larhed (Uppsala University, Sweden) described some high-speed microwave approaches for the synthesis and rapid optimization of novel hepatitis C virus NS3 and HIV-1 protease inhibitors, making extensive use of transition-metal-catalyzed carbon–carbon and carbon–heteroatom bond-forming reactions.[4]

After the lunch break, C. Oliver Kappe (University of Graz, Austria) highlighted several applications of controlled microwave heating in the area of heterocyclic chemistry. Examples included the automated synthesis and scaffold decoration of a library of dihydropyrimidones, involving multicomponent and transition-metal-catalyzed chemistries. In his lecture, Kappe emphasized the potential of high-speed microwave synthesis for the rapid testing of new ideas and for reaction optimization. In addition, he argued that microwave chemistry should not only be used as a last resort when all other options have failed (as is still the case in many laboratories) but rather as a first choice for all transformations that require heating. This is well demonstrated for the synthesis of a 4-arylquinolin-2-one derivative in which all six steps of the synthesis were successfully carried out using high-speed microwave conditions (Scheme 2).[5]

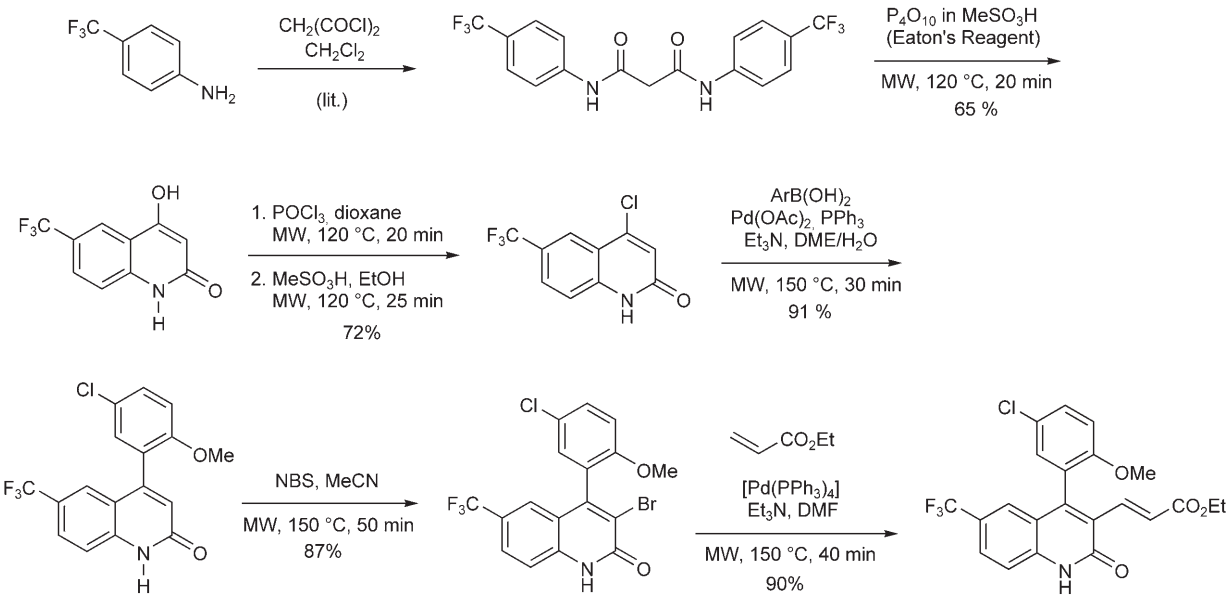
In his lecture, Joachim C. Burbiel (University of Bonn, Germany) presented several examples of microwave-assisted ring-closure and nucleophilic substitution reactions facilitating the preparation of adenosine receptor ligands of the xanthine type. In all cases, the reported ring-closure reactions were significantly faster when performed under sealed vessel microwave irradiation conditions at higher temperatures compared to the corresponding oil-bath experiments carried out at reflux temperatures. The yields, however, remained essentially unchanged.

The remainder of the afternoon session featured a series of talks on the use of microwaves in organic synthesis (Thomas J. J. Müller, University of Heidelberg, Germany; Bert U. W. Maes, University of Antwerp, Belgium), polymer chemistry (Kolio Troev, Bulgarian Academy of Sciences, Sofia, Bulgaria; Lionel L. Delaude, University of Liège, Belgium; Frank Wiesbrock, Eindhoven University of Technology and the Dutch Polymer Institute, Eindhoven, The Netherlands), as well as a presentation by Sandra Uy (University of Auckland, New Zealand) on microwave-assisted seaweed extractions.

The day ended with a poster session (32 presentations) followed by the conference dinner, which featured an Irish folk band, and allowed informal discussions among the conference participants.

Andreas Greiner (Philipps-University of Marburg, Germany) opened the Friday morning session with a short account of microwave-heated polymerization reactions.[1b] He then described systematic investigations of styrene and methyl acrylate radical (co)polymerizations under microwave irradiation and with classic heating. It was found that the choice of solvent and radical initiator is essential for microwave-assisted free radical polymerization. Despite the impressive scope of the study, no evidence for monomer selectivity or a clear correlation between microwave power and molecular weight was found.

Another highlight of the symposium was the lecture by Rainer Schobert (University of Bayreuth, Germany) with the title "Solid-Phase and Domino



Scheme 2. Six-step "all microwave" synthesis of a 4-aryl-2-quinolinone maxi K^+ channel opener.[5] DME = 1,2-dimethoxyethane; NBS = *N*-bromosuccinimide; DMF = *N*,*N*-dimethylformamide.

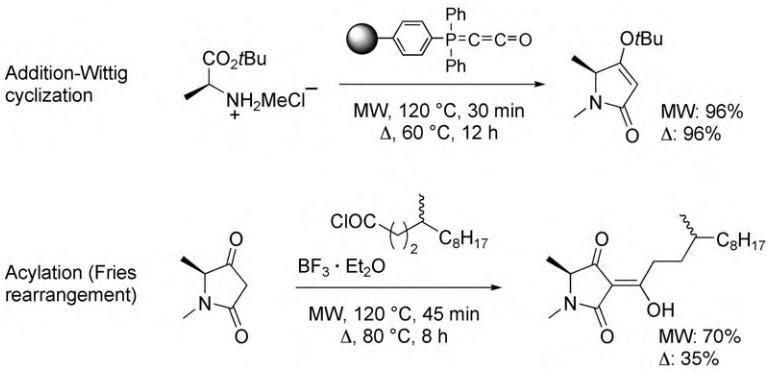
Synthesis in the Microwave—Bioactive Heterocycles in No Time". Schobert demonstrated that through careful choice of reaction parameters, a large number of 5–7 membered O and N heterocycles can be selectively prepared under controlled microwave irradiation. Among different reaction types used in his synthesis of melophlin B, both addition-Wittig cyclizations and Fries rearrangements were successfully microwave-accelerated (Scheme 3).[6]

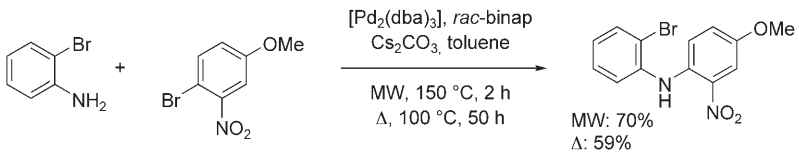


Scheme 3. Microwave-mediated improvements in the synthesis of the 3-acyltetramic acid melophlin B.[6]

Although a great variety of assembly methods and an impressive diversity of structures was established, it was also pointed out that premature linker cleavages and unwanted racemizations had been observed with high-temperature microwave heating.

Another important subject area of the symposium concerned microwave-induced inorganic materials. In a lecture by Dieter Wöhrle (University of Bremen, Germany), impressive results in microwave synthesis of structurally uniform and dye-loaded molecular sieves were presented. These novel composite materials may find use as optical switches, microlasers, and optical sensors, and in energy-transfer applications. By taking advantage of microwave heating, dye molecules were encapsulated undestroyed into molecular sieves after only 15–45 minutes of hydrothermal synthesis. Furthermore, dye-free molecular sieves were quickly and smoothly prepared using microwave conditions.

Interest in the generation of alkoxyl radicals by microwave irradiation was the topic of a lecture by Jens Hartung (Technische Universität Kaiserslautern, Germany), who showed how *N*-(alkoxy)-thiazolethiones can act as useful precursors for oxygen-centered radicals in synthetic chemistry. Hartung's work furnished two decisive results: a) regardless of the initiation source in oxyl radical chemistry (microwaves, oil-bath heating, or UV irradiation), there was no difference in the product selectivity; b) microwave heating consistently provided the shortest reaction times and highest yields.



Scheme 4. Acceleration of a palladium-catalyzed intermolecular Buchwald–Hartwig *N*-arylation by single-mode microwave heating.[7] dba = dibenzylidineacetone.

In agreement with Schobert, Uwe Beifuss (University of Hohenheim, Stuttgart, Germany) stressed the beneficial use of microwave heating in heterocyclic chemistry. In the strategy employed for the synthesis of biologically active phenazines, inter- and intramolecular palladium-catalyzed *N*-arylation reactions were accelerated by microwave irradiation from days to hours (Scheme 4).[7] It was further found that a number of Brönsted and Lewis acid catalyzed cyclizations responded positively to microwave flash heating both with respect to yield and selectivity.

In addition to the invited speakers on Friday morning, Richard Hoogenboom (Eindhoven University of Technology and Dutch Polymer Institute, The Netherlands) gave an oral presentation on the scale-up of microwave-promoted polymerizations and Steven Tierney (Merck Chemical Ltd, Southampton, UK) presented novel methods for the synthesis of semiconducting polymers under high-density microwave irradiation. The final talk concerned the delicate problem of measuring reaction temperatures correctly under microwave heating. In his talk, Wilfried M. Braje (Abbott GmbH & Co. KG, Ludwigshafen, Germany) stressed that proper control experiments and measurement of reaction temperatures are of utmost importance not only for the outcome of reactions but also for the reproducibility of results.

The conference closed with the presentation of the best poster awards and the farewell comments by the chairman, Helmut Ritter. Most of the participants—if not already "riding the microwave"—will probably have gone away from this conference with a strong desire to try their next reaction under microwave conditions, although the controversial question on the existence of nonthermal microwave effects could not be resolved. As announced by the chairman, there will probably be another microwave conference organized by the GDCh in the future.[8]

Stephacidin B, The Avrainvillamide Dimer: A Formidable Synthetic Challenge**

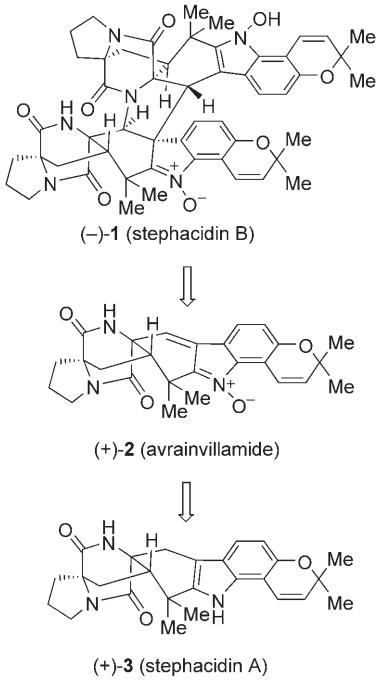
*Carmen Escolano**

Keywords:
alkaloids · avrainvillamide · natural products · stephacidin · total synthesis

Nature capriciously provides us with a considerable number of alkaloids with structures that result from a combination of two identical molecules. Such a rearrangement of two molecules to create a new complex entity with different architectures, properties, and biological activity may be an intelligent energy-saving natural strategy, and thus the biosynthetic pathway to these dimeric alkaloids provides a model for a good synthetic approach.

One particularly outstanding dimeric alkaloid, in terms of its complexity, is stephacidin B. The story of stephacidin B (**1**) began a few years ago, after its isolation from the fungi *Aspergillus ochraceus* WC76466 by Qian-Cutrone et al. at Bristol-Myers Squibb (Scheme 1). Later on, the same group unambiguously elucidated the structure of this new alkaloid by a combination of NMR spectroscopy and X-ray crystallography studies.[1] The molecular architecture of **1** revealed a complex dimeric prenylated *N*-hydroxyindole alkaloid that contains 15 rings and nine stereogenic centers, but its absolute configuration remained unknown.

N-hydroxyindole and indole nitrone alkaloids, which may play important biological roles, are interesting entities rarely found in nature. In particular, the novel antitumor antibiotic stephacidin B exhibits an unusual mechanism of action. This new alkaloid has already been discussed by von Nussbaum[2] with respect to its biogenetical aspects and the mechanism of the late-stage putative biomimetic dimerization from avrainvillamide (**2**)[3] to stephacidin B (**1**). Recently, two groups of researchers led by Myers and Baran, respectively, achieved the enantioselective total synthesis of stephacidin B.[4] Furthermore, Baran et al. determined its absolute configuration as (−)-**1** and those of the biogenetically related monomeric alkaloids stephacidin A ((+)-**3**) and avrainvillamide ((+)-**2**). In this Highlight, both syntheses are compared and the most relevant aspects and the new methodology developed are discussed.



Scheme 1. Absolute chemistry of stephacidin B and related alkaloids from *Aspergillus ochraceus*.

The first synthetic concern of both groups was the total synthesis of avrainvillamide (**2**), an alkaloid with a unique oxidation pattern (3-alkylidene-3*H*-indole-1-oxide). Then, stephacidin B (**1**) was envisioned to form by dimerization of two identical units of **2**, presumably involving a Michael-like addition process. The putative dimerization was pointed out by Quian-Cutrone et al.[1] and supported by von Nussbaum[2] as well as Myers and Herzon.[4]

Myers' Approach to (−)-Avrainvillamide

In previous work, Myers and Herzon had developed a sequence to access the original 3-alkylidene-3*H*-indole-1-oxide moiety present in **2** and demonstrated the capability of this nucleus to act as a Michael acceptor.[5] Their retrosynthetic analysis is outlined in Scheme 2. The most remarkable features are 1) the simplification of avrainvillamide (**2**) by cleavage of the dihydropyrano[2,3-*g*]indole-1-oxide moiety, 2) the addition of an aminoacyl radical to a γ-phenylthiyl-substituted enamine to construct the diketopiperazine ring, 3) a Strecker-like reaction involving the addition of cyanide to an *N*-Boc-protected enamine, and 4) the use of a Corey–Bakshi–Shibata (CBS) catalyst to generate the first stereocenter and thereby set the total configuration in the final target.

The starting point of the synthesis (Scheme 3) was the enantioselective preparation of the protected allylic alcohol **8** by enantioselective reduction of the corresponding α,β-unsaturated ke-

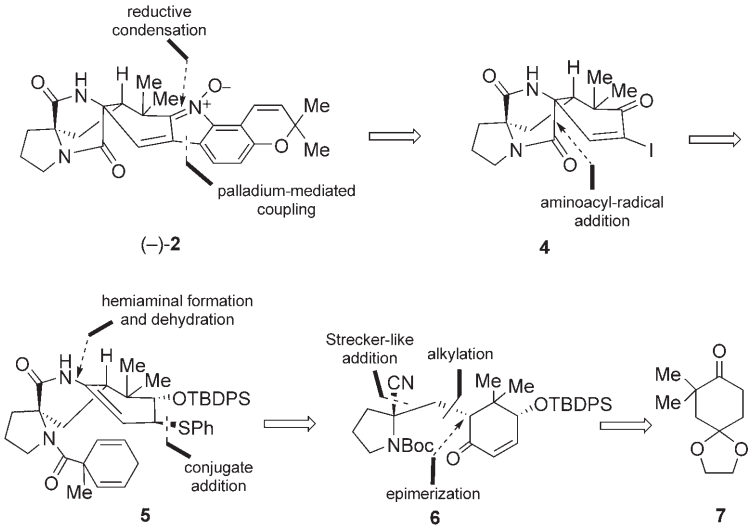
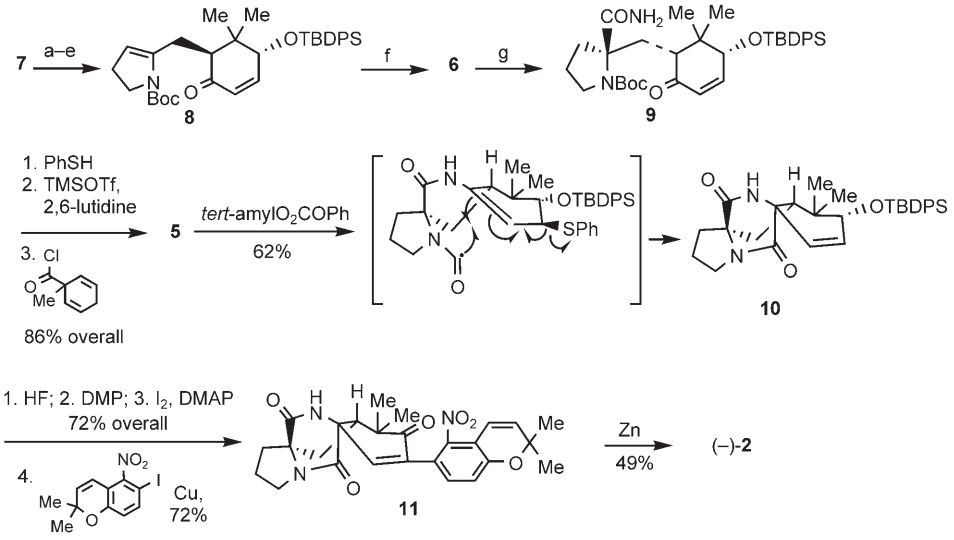


Scheme 2. Retrosynthesis of (−)-avrainvillamide by Myers and Herzon. Boc = *tert*-butyloxycarbonyl.

tone using an (*S*)-CBS catalyst. The stereochemistry of the catalyst was chosen randomly, as the absolute configuration of the final targets was still unknown. The side chain was installed by an alkylation reaction and required subsequent epimerization to give the required relative 1,3-*cis* stereochemistry. Note the unprecedented Strecker-like addition of a cyano group in the presence of hexafluoroisopropyl alcohol to an *N*-Boc enamine, and the hydrolysis under essentially neutral conditions of the resulting major *N*-Boc nitrile **6** (4:1 diastereomeric ratio) to the corresponding amide **9** using a homogeneous platinum phosphinito catalyst.[6] Conjugate addition of thiophenol with concomitant formation of a cyclic hemiaminal, followed by dehydration, cleavage of the *N*-Boc protecting group, and acylation of the pyrrolidine ring with 1-methyl-2,5-cyclohexadiene-1-carbonyl chloride furnished intermediate **5**, setting the stage for the radical-mediated elaboration of the diketopiperazine ring. This step illustrates the application of the tin-free methodology recently developed by Walton and co-workers to generate aminoacyl radicals.[7] From the advanced tetracyclic intermediate **10**, the completion of the synthesis was straightforward. After conversion of **10** into an α-iodoarene in a three-step sequence, an Ullmann-like coupling allowed the benzopyran moiety to be assembled to give *o*-nitroaryl ketone **11**, which was converted into the target heptacyclic nitrone (−)-**2** by reductive condensation with activated zinc.[8] The synthesized material was shown to be levorotatory ($[\alpha]_D = -35.1$, $CHCl_3$, 25 °C) while a dextrorotatory value ($[\alpha]_D = +10.6$, $c = 0.17$, $CHCl_3$) was described for natural **2**.[3a]

Baran's Approach to (−)-Avrainvillamide

The approach of Baran and coworkers relied on the fact that stephacidin A (**3**), a reduced monomer which is biogenetically related to stephacidin B (**1**), can be oxidized to avrainvillamide (**2**). Their retrosynthetic analysis (Scheme 4) fundamentally differs from that of Myers in that 1) the indole nucleus is already present in the starting



Scheme 3. a) LiHMDS, TMSCl, $Pd(OAC)_2$; b) BH_3·DMS, (*S*)-CBS catalyst; c) TBDPSOTf, 2,6-lutidine; d) 1 N H_2SO_4; e) KHMDS, *N*-(*tert*-butoxycarbonyl)-2-isopropylsulfonatemethyl-4,5-dihydropyrrole, 64% (5 steps); f) TMSCN, HFIPA, KHMDS, pivalic acid, 65%; g) [PtH(PMe_2OH)($PMe_2O)_2$H], 75% (2 steps). HMDS = hexamethyldisilazide; TMS = trimethylsilyl; DMS = dimethyl sulfide; CBS is short for Corey–Bakshi–Shibata, the catalyst is (*S*)-1-methyl-3,3-diphenylhexahydropyrrolo[1,2-*c*][1,3,2]oxazaborole; TBDPSOTf = *tert*-butyldiphenylsilyl trifluoromethylsulfonate; HFIPA = 1,1,1,3,3,3-hexafluoro-2-propanol; DMP = 1,1,1-triacetoxy-1,1-dihydro-1,2-benziodozol-3(1*H*)-one; DMAP = 4-(dimethylamino)pyridine.

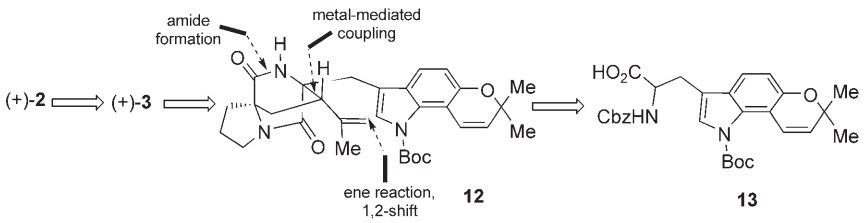


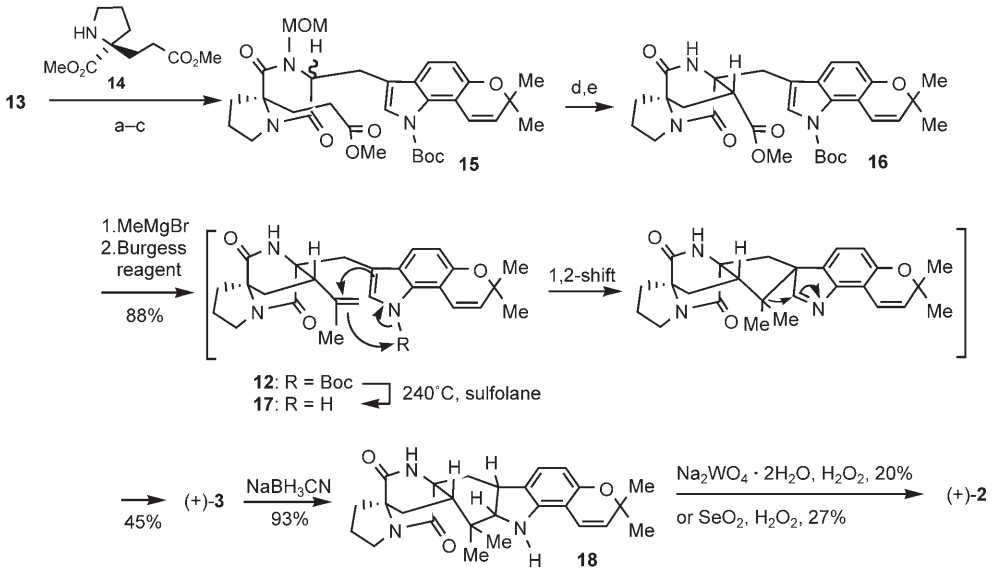
Scheme 4. Retrosynthesis of (+)-avrainvillamide by Baran et al. Cbz = carbobenzyloxy.

material, 2) one stereocenter is already fixed in one of the starting products whereas the other two stereocenters present in **2** are simultaneously installed in a rare stereocontrolled intramolecular metal-mediated oxidative coupling of enolates, and 3) the last step involves an oxidation, rather than a reduction, that leads to the unsaturated nitrone. However, a common feature of both strategies is that the configuration of the final products is determined by the absolute stereochemistry of one of the chiral reagents used in the initial steps (CBS catalyst or proline).

Guided by their previous success in the synthesis of (−)-stephacidin A[9] from an (*S*)-proline derivative, and now with a dextrorotatory natural sample of stephacidin A in hand, Baran et al. realized that their synthetic material was the unnatural enantiomer. Thus, by using (*R*)-proline they secured the preparation of the natural (+)-stephacidin A. Their synthetic pathway (Scheme 5) starts with the peptide coupling of an (*R*)-proline diester derivative **14** with the racemic tryptophan derivative **13**. The Cbz group was chemoselectively removed and the diketopiperazine ring was formed in a single step, which avoided the intramolecular cyclization to form a γ-lactam. Next, the metal-mediated oxidative coupling of enolates, a reaction that is seldom used in synthesis and never for such challenging natural targets, was envisaged to gain access to the bicyclo[2.2.2]-diazaoctane moiety in a stereocontrolled manner. Subsequent reaction with a Grignard reagent allowed the introduction of all the carbon atoms present in stephacidin A (**3**). Heating the intermediate **12** removed the Boc protecting group, and a new thermal indole annulation gave (+)-**3** ($[\alpha]_D = +68.5$, $c = 0.35$, 1:1 CH_2Cl_2/MeOH; natural (+)-**3**: $[\alpha]_D = +61.5$, $c = 0.26$, 1:1 CH_2Cl_2/MeOH). The latter transformation can be mechanistically explained by an ene reaction followed by a 1,2-shift of the spirocyclic intermediate. At that point, Somei's tungstate method which permits access to 1-hydroxyindoles from 2,3-dihydroindoles was considered.[10] In this manner, reduction of the indole ring led to indoline **18**, which surprisingly underwent chemoselective oxidation to directly give the unsaturated nitrone present in (+)-avrainvillamide (**2**) in a single step ($[\alpha]_D = +11$, $c = 0.1$, $CHCl_3$).

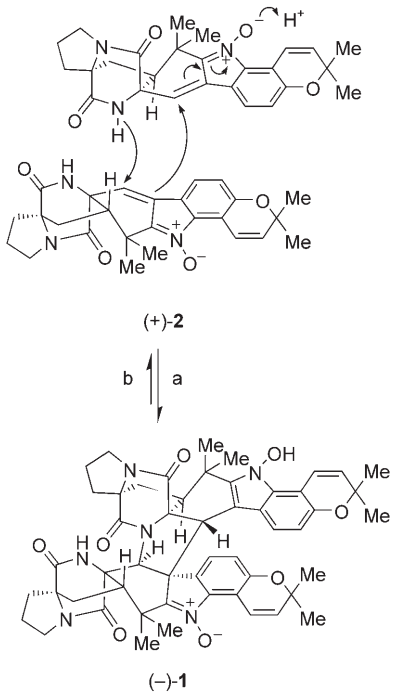
Biomimetic Dimerization

Preparative TLC (SiO_2, EtOAc), treatment with Et_3N/CH_3CN, or even simple evaporation of DMSO from a solution of **2** entails dimerization and furnishes the final target **1** (Scheme 6; natural sample from Bristol-Myers Squibb: $[\alpha]_D = -21.1$, $c = 0.19$, $CDCl_3$; Myers' synthetic sample: $[\alpha]_D = +91$, $c = 0.25$, CH_3CN; Baran's synthetic sample: $[\alpha]_D = -33$, $c = 0.1$, $CDCl_3$). The mechanism most probably involves a novel Michael-like 1,5-addition, which leads to the stereocontrolled formation of a new pyrrolidine connecting ring.



Scheme 5. a) (*R*)-methyl-2-[(2-(methoxycarbonyl)ethyl]pyrrolidine-2-carboxylate, HATU, *i*Pr_2EtN, DMF; b) $[Pd(dba)_3]\cdot CHCl_3$, Et_3SiH, Et_3N, CH_2Cl_2; then DMF/MeOH; c) NaHMDS, MOMCl, 62% (3 steps); d) LDA; $[Fe(acac)_3]$; e) *B*-bromocatecholborane, 48% (2 steps). HATU = *O*-(7-azabenzotriazol-1-yl)-*N*,*N*,*N*′,*N*′-tetramethyluronium hexafluorophosphate, DMF = *N*,*N*-dimethylformamide; dba = dibenzylideneacetone; MOM = methoxymethyl; LDA = lithium diisopropylamide; acac = acetylacetonate; Burgess reagent = $MeO_2CN^-SO_2N^+Et_3$.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 6. Proposed dimerization mechanism from (+)-**2** to (−)-**1**: a) preparative TLC; or NEt_3 (excess), CH_3CN, 25 °C, 1 h; or DMSO/solvent removal; b) chromatography. DMSO = dimethyl sulfoxide.

Likewise, the retrodimerization to give **2** occurs spontaneously by addition of molecular sieves to a solution of **1** in $[D_6]$DMSO/CD_3CN or during chromatography of this dimeric material. In fact, reversible additions had already been observed by Myers and Herzon[5] when oxygen- and sulfur-centered nucleophiles reacted with α,β-unsaturated nitrones that are structurally related to **2**.[11]

Owing to the observed equilibration of both compounds **1** and **2** under mild conditions, Myers and Herzon[4a] cast some doubts over which compound is responsible for the biological action, suggesting that the activity observed for stephacidin B may be attributable to avrainvillamide (**2**) formed from **1** in vivo. Moreover, the possibility that stephacidin B may be an artefact in the isolation of **2** is considered. Accordingly, Baran et al. found that a solution of a natural sample of stephacidin A in DMSO contained 20% of stephacidin B, although a natural solid sample was found to be stable.[4b] The ready equilibration of avrainvillamide (**2**) and stephacidin B (**1**) illustrates the difficulty in distinguishing if the original structure of a determinate compound has been modified when extracted from its natural source or during biological testing involving chemicals and solvents.[12]

The enantioselective syntheses discussed herein have not only tackled formidable synthetic challenges but also paved the way for a series of medicinally attractive stephacidin analogues. Moreover, both sequences have expanded the arsenal of protocols for the organic chemistry community, especially in the relatively unexplored area of the chemistry of 1-hydroxyindoles.

Organosulfur Reagents

Organosulfur Compounds: Electrophilic Reagents in Transition-Metal-Catalyzed Carbon–Carbon Bond-Forming Reactions

*Srinivas Reddy Dubbaka and Pierre Vogel**

Keywords:
cross-couplings · homogeneous catalysis · sulfonamides · sulfonyl chlorides · transition metals

Transition-metal-catalyzed carbon–carbon bond-forming reactions are among the most powerful methods in organic synthesis and play a crucial role in modern materials science and medicinal chemistry. Recent developments in the area of ligands and additives permit the cross-coupling of a large variety of reactants, including inexpensive and readily available sulfonyl chlorides. Their desulfitative carbon–carbon cross-coupling reactions (Negishi, Stille, carbonylative Stille, Suzuki–Miyaura, and Sonogashira–Hagihara-type cross-couplings and Mizoroki–Heck-type arylations) are reviewed together with carbon–carbon cross-coupling reactions with other organosulfur compounds as electrophilic reagents.

1. Introduction

Transition-metal-catalyzed C–C[1] and C–heteroatom[2] bond-forming reactions are among the most powerful methods in organic synthesis.[3] They have many applications in medicinal chemistry[4] and materials science.[5–7] Their popularity stems from their tolerance of many different functional groups which allows their application in the synthesis of highly complicated molecules.[8] For C–C bond-forming reactions, one denotes two main classes: 1) reactions with a nucleophilic metallic reagent [Eq. (1)] and 2) reactions of alkene or alkyne C–H reagents with electrophilic partners RX, ArX [Eqs. (2) and (3)].

$$R\text{-}X + R^1\text{-}M \xrightarrow{\text{catalyst}} R\text{-}R^1 + MX \qquad (1)$$

M = B : Suzuki–Miyaura[1,9]
M = Sn : Stille[1,10]
M = Si : Hiyama[1,11]
M = Zn : Negishi[1,12]
M = Mg : Kumada[1,13]

$$Ar\text{-}X + \underset{R}{\diagup\!\!=} \xrightarrow{\text{cat.}} Ar\underset{R}{\diagup\!\!=} + HX \qquad (2)$$

Mizoroki–Heck[1,14]

$$Ar\text{-}X + H\text{—}\equiv\text{—}R \xrightarrow{\text{cat.}} Ar\text{—}\equiv\text{—}R + HX \qquad (3)$$

Sonogashira–Hagihara[1,15]

There have been many recent developments in the area of ligands and additives that permit the cross-coupling of a large variety of reactants[1–4,9–16] in the presence of late-transition metals (i.e. pincer complexes with Ir, Pt, Pd, and palladacycles). Other recent developments include immobilized metal catalysts that allow the easy recovery and reuse of the catalyst[17] and the use of ionic liquids.[18] The efficiency of a synthetic procedure can be improved dramatically by the use of multiple metal-catalyzed transformations, either in a domino process or in a sequential fashion.[19] There has been much progress in enantioselective palladium-catalyzed C–C bond formations.[20] It is now possible to couple inexpensive, less reactive organic chlorides by using highly active catalysts[21] or by use of microwave irradiation.[22] In the continuing search for more-economical procedures, there is more and more emphasis to avoid the formation of by-products.[23]

We have shown previously that readily available sulfonyl chlorides (RSO_2Cl, R = aryl, alkenyl, benzyl, 2-methallyl[24]) undergo desulfitative Suzuki–Miyaura,[25] Stille and carbonylative Stille,[26] Mizoroki–Heck,[27] Sonogashira–Hagihara,[28] and Negishi[29] cross-coupling reactions. We review these

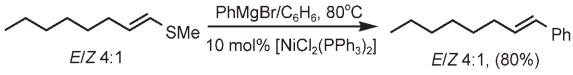
reactions herein together with those involving other organosulfur compounds as electrophilic reagents.

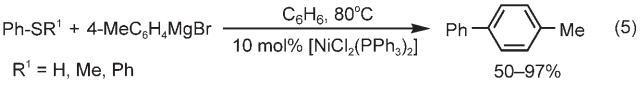
2. Reactions of Thiols, Sulfoxides, Thioethers, Aryl Sulfones, and Sulfoximines with Grignard Reagents

Wenkert and co-workers[30a–f] reported that the reactions of alkenyl sulfides, [Eq. (4)], vinyl 2-pyrimidyl sulfides,[30g] and aryl thiols and sulfides [Eq. (5)] with methyl-, phenyl-, and *p*-tolylmagnesium bromides, mediated by $[NiCl_2(PPh_3)_2]$, lead to alkenes (predominantly with retention of configuration), toluenes, and biaryl compounds, respectively.

The displacement of sulfur is faster for alkenyl sulfides than for aryl sulfides, a reactivity pattern that is similar to that



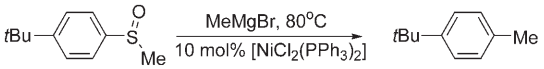
(4)



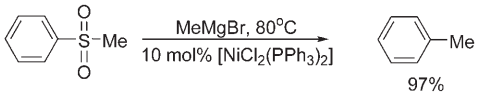
(5)

observed for enol and aryl ethers.[30e] The carbon–sulfur bond of sulfoxides[30a,f] [Eq. (6)] and sulfones[30a] [Eq. (7)] can also be replaced by a carbon–carbon linkage through nickel-catalyzed reactions with Grignard reagents. Gais and co-workers showed that alkenyl sulfoximines can also be cross-coupled either with Grignard or zinc reagents in the presence of $[NiCl_2(dppp)]$ (8 mol %) [Eq. (8)] (dppp = 1,3-bis(diphenylphosphanyl)propane).[31a–c]

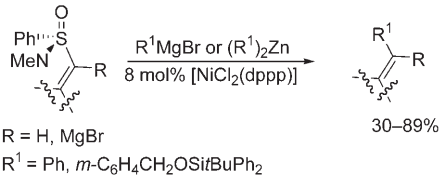
Independently, Takei and co-workers showed that alkenyl and aryl sulfides can be coupled with Grignard reagents in the presence of $[NiCl_2(PPh_3)_2]$ (3 mol %) [Eq. (9)].[32] It was



(6)

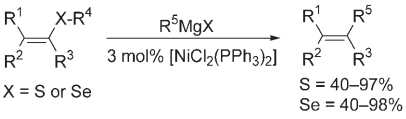


(7)



(8)

confirmed that the reactions do not occur in the absence of the Ni catalyst and that organolithium reagents are not suitable for such reactions.



(9)

In 1980, the same group demonstrated that alkenyl, aryl, and allylic selenides also couple with Grignard reagents in the presence of catalytic amounts of $[NiCl_2(PPh_3)_2]$ or $[NiCl_2(dppp)_2]$ to give the corresponding unsaturated compounds.[33] The reactivity order of these Kumada-type cross-coupling reactions of BuMgBr, with PhSeMe, PhSMe, and PhCl catalyzed by $[NiCl_2(dppp)]$ was found to be PhSeMe $\gg$ PhCl $>$ PhSMe. The application of *ortho*-, *meta*-, and *para*-bis(alkylthio)benzenes in these reactions led to selective monoarylation and -alkylation. This allows the introduction of two different aryl or alkyl groups into the benzene ring by sequential substitution of the two substituents. Steric factors play a decisive role in the chemoselectivity of these reactions.[34]

3. Reaction of Aryl tert-Butyl Sulfones, Alkyl Arene Sulfonates, and Arene Sulfonamides with Grignard Reagents

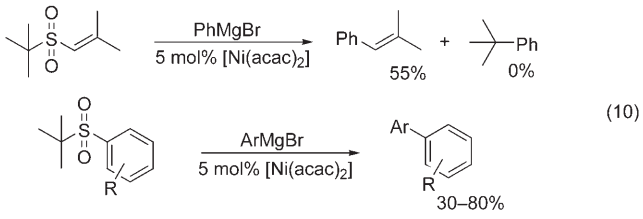
Julia and co-workers showed that the cross-coupling reactions between vinyl *tert*-butyl sulfones[35a–c] and aryl *tert*-butyl sulfones[35d,e] with Grignard reagents take place in the presence of $[Ni(acac)_2]$ catalyst through desulfonylation [Eq. (10)] (acac = acetylacetonate). The Ni^0 species (pro-

Pierre Vogel completed his PhD at the University of Lausanne (Switzerland) in 1969 with Prof. Horst Prinzbach. After two years at Yale University with Prof. Martin Saunders, he joined the research laboratory of Syntex (Mexico City) and worked with Prof. Pierre Crabbé. He returned to the University of Lausanne and became full professor in 1977. Since 2001, he has chaired the Laboratory of Glycochemistry and Asymmetric Synthesis of the Ecole Polytechnique Fédérale de Lausanne. He obtained the Novartis lectureship (2003) and was Boehringer-Ingelheim Distinguished Lecturer for 2005.

Srinivas Reddy Dubbaka was born in MachiReddy Pally (India) in 1979. He obtained his BSc from the Kakatiya University in 1999 and MSc from the Central University of Hyderabad, India in 2001. Since 2001, he has been working towards his PhD under the supervision of Professor Pierre Vogel at the Swiss Federal Institute of Technology, Lausanne. His research focuses on the development of new organic reactions based on sulfur dioxide.

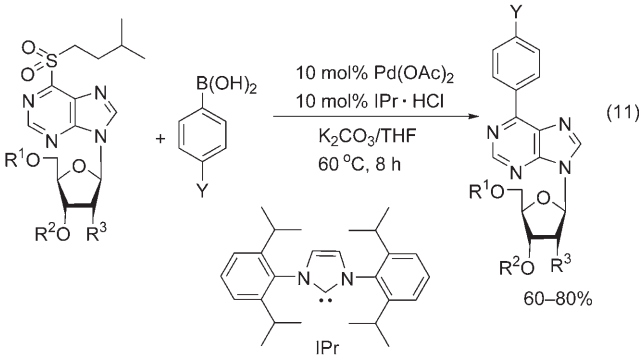
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

duced from the Ni^{II} catalyst by transmetalation with two Grignard molecules and reductive elimination to form biphenyl and active Ni^0 catalyst) inserts into the vinyl or aryl $C(sp^2)$–S bond. The resulting aryl nickel(II) sulfonate complex[30b] undergoes ligand exchange with the Grignard reagent to give an unsymmetrical bisaryl complex. Finally, reductive elimination generates the C–C coupling product.[36] Notably, the $C(sp^3)$–S bond of the *tert*-butyl sulfone is never cleaved under these conditions [Eq. (10)].



(10)

Before 2004, aryl and alkyl sulfones were not known to undergo C–C cross-coupling reactions with nonpolar nucleophiles such as boronic acids and organotin and organosilicon reagents in the presence of palladium or nickel catalysts (for polar nucleophiles, see [Eq. (10)]). However, Liu and Robins recently showed that the palladium-catalyzed Suzuki–Miyaura cross-coupling reaction of arene boronic acids and 6-[(3-methylbutyl)sulfonyl]purine nucleoside does occur with desulfonylation under suitable conditions [Eq. (11)].[37]



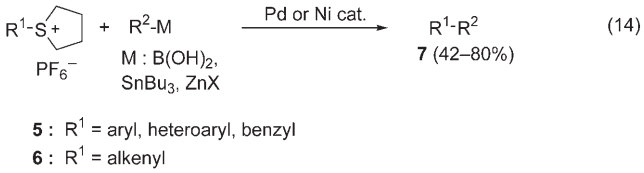
(11)

Recently, Park and co-workers found that unsymmetrical terphenyls of type **4** can be prepared in high yields by the nickel-catalyzed cross-coupling of biphenyl sulfonates **2** with aryl Grignard reagents **3** [Eq. (12)] (dppf = 1,1′-bis(diphenylphosphanyl)ferrocene).[38] Unsymmetrical biaryl compounds can also be prepared under similar conditions by reaction of alkyl arene sulfonates with aryl Grignard reagents **3**. Neopentyl arene sulfonates **1** are thus useful sources of electrophilic aryl groups. In this case, the nickel catalyst prefers to insert into the C–S rather than the C–O bond of **1** or **2**.[39] Milburn and Snieckus[40] reported the Ni^0-catalyzed C-C cross-coupling reactions between arylsulfonamides and Grignard reagents through desulfamoylation in toluene at 100 °C. As sulfonamides do not undergo Negishi coupling with aryl zinc derivatives, the method has been applied to generate unsymmetrical teraryls of type **4** [Eq. (13)].

The cross-coupling of sulfonamides and Grignard reagents represents a new variant of the Corriu–Kumada–Tamao protocol.[41] It offers the advantage of directed *ortho* metalation[42] and thus enhances its synthetic utility.[43]

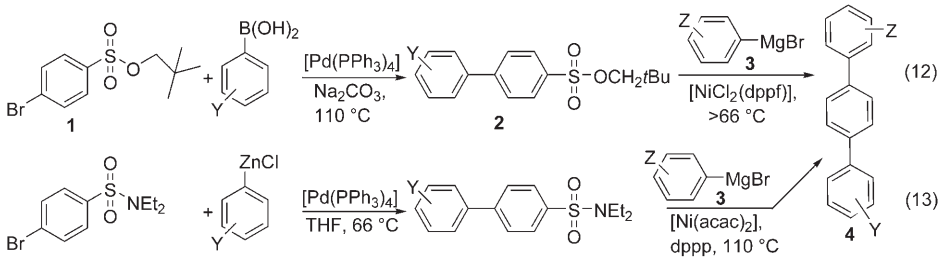
4. Reaction of Sulfonium Salts, Thioethers, and Thiol Esters with Nonpolar Organometallic Compounds

Several biotransformations employ metalloenzyme-induced cleavage of carbon–sulfur bonds. The metals used by Nature are Ni, Co, Cu, and Fe.[44] Aryl and heteroaryl sulfonium salts **5** are prepared readily either by the reaction of thiolane with the corresponding halides in the presence of HPF_6, NH_4PF_6, or $NaClO_4$, or by the reaction of the corresponding thiols with 1,4-dibromobutane in the presence of NH_4PF_6.[45] Alkenyl sulfonium salts **6** can be prepared from alkenes upon reaction with Br_2/thiolane followed by the elimination of HBr and counterion exchange.[45] Liebeskind and co-workers[45] reported that electrophiles **5** and **6** undergo smooth cross-coupling reactions [Eq. (14)] with organotin reagents (Stille-type couplings), arene and heteroarene



(14)

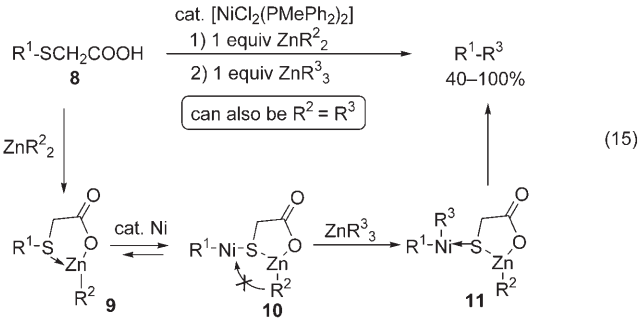
boronic acids (Suzuki–Miyaura-type couplings), and (2-thienyl)zinc chloride (Negishi-type couplings) in the presence of a Pd or Ni catalyst to give the corresponding products of C–C coupling **7**. The same group later found that triphenylphosphite, a supporting ligand for the palladium catalyst that is not readily alkylated, is uniquely effective as a ligand in hetero-



© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

benzylic cross-coupling reactions with aryl tin, heteroaryl tin, alkenyl tin, and organozinc compounds.[46]

Inspired by the mechanism of methane production from methyl coenzyme M ($CH_3SCH_2CH_2SO_3^-$) mediated by methyl coenzyme M reductase[44c,47] (a process involving a nickel hydrocorphinoid cofactor (F_{430}) that cleaves the CH_3–S bond of $CH_3SCH_2CH_2SO_3^-$ with the generation of a CH_3–Ni intermediate, which subsequently undergoes protonation to methane), Liebeskind and co-workers developed Ni-catalyzed cross-coupling reactions of thioglycolic acids **8** with organozinc reagents [Eq. (15)].[48]

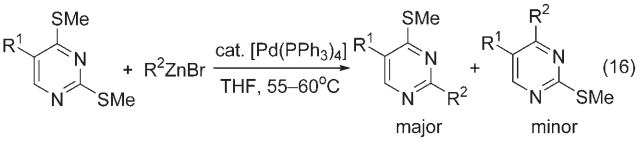


(15)

R^1 = aryl, heteroaryl, benzyl, alkenyl
R^3 = alkyl, aryl, benzyl

Experiments suggested that intermediates **9** in which the zinc center is chelated by the carboxylate moiety and the β-thioether group has a favorably activated C–S bond for nickel oxidative addition, which leads to **10**. It was also proposed that intramolecular transfer of R^2 from the zinc to the nickel center of **10** does not occur, but that an external zinc reagent interacts with the nickel center of **10** to generate the intermediate **11.**[48]

Casalnuovo and co-workers found that benzyl zinc reagents undergo Pd-catalyzed cross-coupling reactions with methylthio-substituted N-heterocycles in moderate to good yields.[49] 2-(Methylthio)pyrimidines are particularly reactive substrates for this reaction. The regioselectivity of the reactions of 2,4-bis(methylthio)pyrimidines **12** [Eq. (16)] is

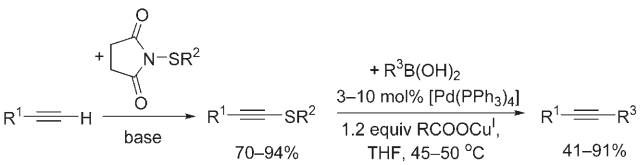


(16)

12: R^1 = H, Me
R^2 = Bn, *m*-$CF_3C_6H_4$

opposite to that of their 2,4-dichloropyrimidines analogues. This offers the possibility to prepare important heterocyclic compounds.

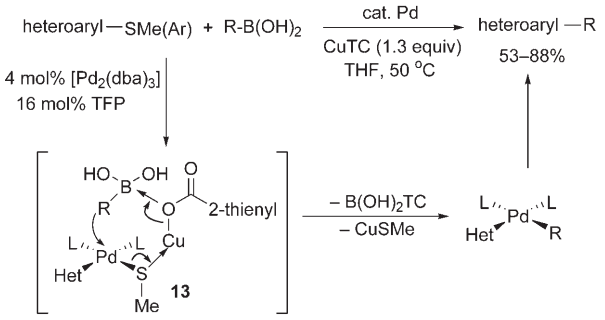
A new method for the preparation of substituted alkynes was reported by Liebeskind and co-workers.[50] In the presence of copper(I)–thiophene-2-carboxylate (CuTC) or copper(I)–3-methylsalicylate (CuMeSal), the Pd-catalyzed cross-coupling of thioalkyne derivatives with boronic acids affords functionalized alkynes in moderate to good yields. Thus, disubstituted alkynes can be prepared under mild, nonbasic conditions [Eq. (17)].



(17)

R^1 = Bu, Ph, $MeOCH_2$, *m*-$CF_3C_6H_4$, *p*-$MeOC_6H_4$, *m*-$NO_2C_6H_4$
R^2 = *p*-tolyl, Me

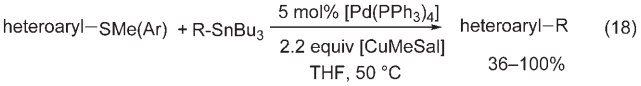
The same protocol was applied successfully to methylthio-substituted heterocyclic compounds and allows the synthesis of heterocyclic compounds that are important in medicinal chemistry. The proposed mechanism of this Suzuki–Miyaura-type cross-coupling reaction is shown in Scheme 1.[51] It



Scheme 1. Proposed mechanism by Liebeskind and Srogl for the Cu^I/Pd-catalyzed cross-coupling of heteroaromatic thioethers with boronic acids under neutral conditions.[51]

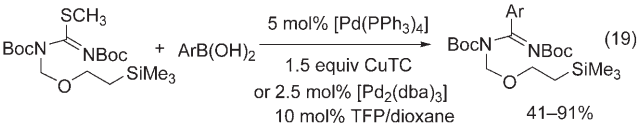
implies the formation of intermediate **13** from the oxidative addition of the C(sp^2)–S bond, rather than of the C(sp^3)–S bond, to palladium. Coordination with the copper carboxylate and the boronic acid provides the activation for the next step.

Heteroaromatic thioethers and aryl, heteroaryl, and alkenyl stannanes participate in Pd-catalyzed, Cu^I-mediated cross-coupling reactions at 50 °C in THF [Eq. (18)].[52,53] A



(18)

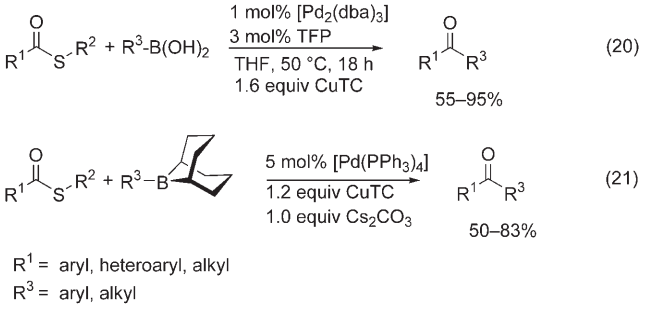
similar method was proposed for the synthesis of protected benzamidines [Eq. (19)].[54]



(19)

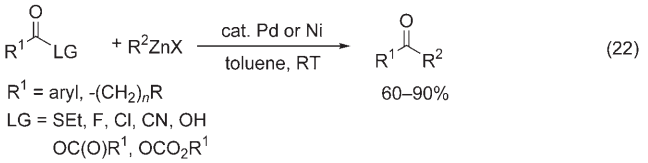
Liebeskind and Srogl designed a mild and general method for the Pd-catalyzed, Cu^I-mediated coupling of thiol esters and boronic acids under base-free conditions that produces ketones [Eq. (20)].[55] Thiol esters and *B*-alkyl-9-borabicyclo-[3.3.1]nonane derivatives also undergo smooth cross-couplings under similar conditions [Eq. (21)]. In such cases, the addition of Cs_2CO_3 facilitates the reaction.[56] A similar

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



synthesis of ketones relies on the Pd-catalyzed, copper diphenylphosphinate-mediated coupling of thiol esters with organostannanes under neutral conditions.[57]

A large variety of ketones can be prepared through Fukuyama coupling. The coupling reaction between aryl esters and ethanethiol esters with organozinc derivatives and other nucleophiles (e.g. alkynes, boronic acids) takes place at ambient temperature to give the corresponding ketones [Eq. (22)].[58a–c] Ketones are also prepared by the Ni-catalyzed

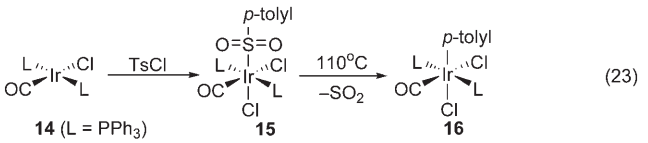


cross-coupling of organozinc and carboxylic acid fluorides, chlorides, anhydrides, and thiol esters.[58d]

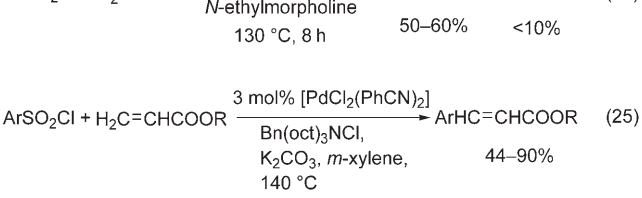
5. Desulfitative C–C Cross-Coupling of Sulfonyl Chlorides

Arene and alkane sulfonyl chlorides are inexpensive and readily available compounds. They have been used for more than a century in materials science and medicinal chemistry. For instance, both α- and β-naphthalenesulfonyl chlorides obtained from naphthalene, the most abundant compound derived from coal, have been used in industry for the manufacture of drugs, pesticides, dyes, polymers, and other goods.[59] Hence it is logical to use sulfonyl chlorides as reagents in transition-metal-catalyzed C–C bond-forming reactions. However it is only recently, that this has come into practical use.

In 1966, Collman and Roper[60] reported the preparation of the iridium(III) *S*-sulfinate complex **15** by treating $[IrCl(CO)(PPh_3)_3]$ with *p*-toluenesulfonyl chloride (TsCl). They also found that upon heating to 100 °C, loss of SO_2 from **15** leads to the formation of complex **16** [Eq. (23)].

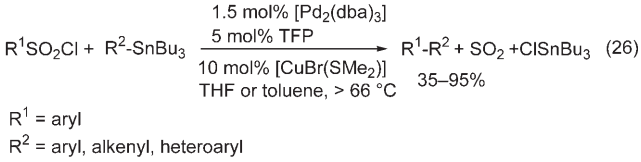


The year thereafter, Cook and Jauhal[61] reported a similar reaction sequence with $[Pt(PPh_3)_4] + TsCl \rightarrow [PtTsCl(PPh_3)_2] \rightarrow SO_2 + [Pt(C_6H_4Me)Cl(PPh_3)_2]$. In 1970, the catalytic desulfonylation of arene sulfonyl chlorides and bromides by various Rh, Ir, Ru, Pt, and Pd catalysts were investigated and proposed to proceed mainly by a metal-center-promoted mechanism and, to a smaller extent, through homolytic decomposition.[62] The first reports of transition-metal-catalyzed C–C bond-forming reactions with arene sulfonyl chlorides as reagents were those of Kasahara et al.[63] [Eq. (24)] in 1988 and of Miura and co-workers[64] [Eq. (25)]

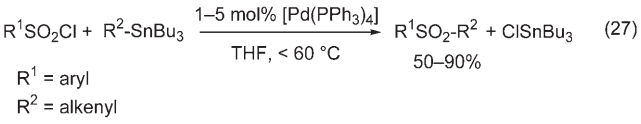


in 1989. These authors disclosed for the first time the possibility of performing desulfitative carbon vinylations (Mizoroki–Heck-type reactions) with arene sulfonyl chlorides and various alkenes in the presence of palladium catalysts.

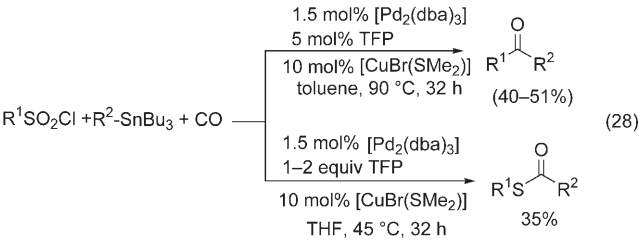
Arene sulfonyl chlorides have also been employed in carbon carbonylation[65] and C–C homocouplings.[66] In 2003, we reported for the first time that arene and phenyl methanesulfonyl chlorides can be cross-coupled [Eq. (26)]



with aryl, heteroaryl, and alkenyl stannanes with concomitant loss of SO_2 in the presence of palladium and copper catalysts at temperatures above 66 °C.[26a,67] When the reaction was carried out in the presence of catalytic $[Pd(PPh_3)_4]$ in THF at 40–60 °C, the corresponding sulfones were obtained [Eq. (27)].[68]



When the amount of the copper complex $[CuBr(SMe_2)]$ was increased, a rate enhancement was observed but the major product was that arising from the self-coupling of the organostannane.[69] We also examined the palladium-catalyzed carbonylative Stille cross-coupling reaction of arene



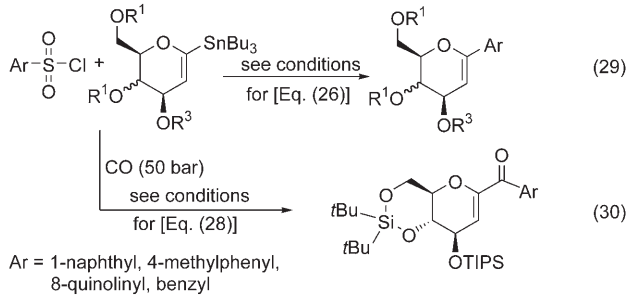
© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

sulfonyl chlorides and organostannanes in the presence of carbon monoxide (60 bar) at 110 °C in toluene. The carbonylative cross-coupled products [Eq. (28)] were obtained in moderate yields.

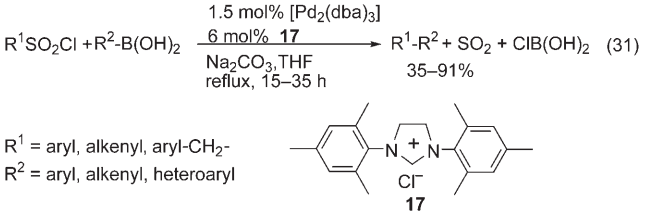
When we used THF instead of toluene as solvent at 45 °C in the carbonylative Stille reaction, $R^1SC(O)R^2$ products were obtained in low yield [Eq. (28)]. The amount of thiol ester product increased with the amount of tri-2-furylphosphane (TFP) ligand, indicating that their formation resulted from the reduction of the sulfonyl chlorides to sulfenyl chlorides, which then underwent aryl carbonylation.[26a] This process is analogous to the known $[Co_2(CO)_8]$-catalyzed carbonylation of thiols[70] and to the thiocarbonylation of acetylenes with thiols and carbon monoxide catalyzed by palladium[71] or platinum complexes.[72]

When TsCl was mixed with $[PdCl_2(PhCN)_2]$ (1 equiv) and triethylamine (2 equiv) in $[D_8]$THF at 45–60 °C, a signal typical for a C–Pd bond[73a] appeared in the ^{13}C NMR spectrum after 10 min ($\delta = 145.2$ ppm). Pd^0 is generated[64,73b] in situ and undergoes oxidative addition to *p*-toluenesulfonyl chloride, thereby inserting into either the SO_2–Cl bond or the C–SO_2 bond. Subsequent rapid loss of SO_2 gives the same aryl palladium chloride in either case which in turn undergoes cross-coupling with the organostannane, in a way similar to intermediates derived from aryl halides or triflates in Stille couplings.[10] In Stille reactions, and under our conditions, the sulfonyl chloride is more reactive than the corresponding chloride or bromide. However, sulfonyl chlorides proved to be less reactive than the corresponding iodides.

Aryl and arylmethane C-glycosides have been obtained through desulfitative Stille [Eq. (29)] and carbonylative Stille [Eq. (30)] cross-coupling of tin glycals and sulfonyl chlorides.[26b]



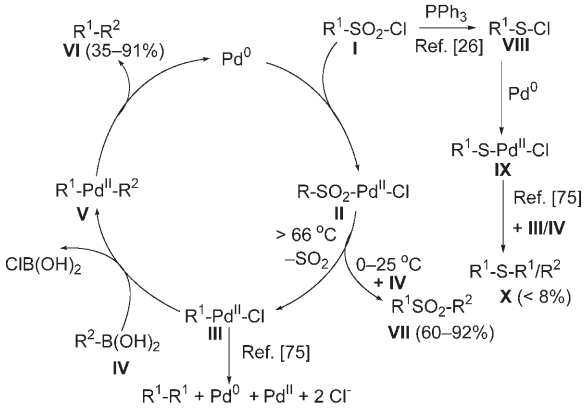
Arene, aryl methane, and alk-2-ene sulfonyl chlorides undergo Suzuki–Miyaura cross-coupling with arene, heteroarene, and alkene boronic acids in THF at reflux [Eq. (31)]. In this case too, the reactivity order is ArI > $ArSO_2Cl$ > ArBr > ArCl.[25]



Na_2CO_3 proved to be the best activator for the boronic acids (without destroying the sulfonyl chloride) relative to other bases such as Et_3N, Cs_2CO_3, NaOAc, K_3PO_4, K_2CO_3, or Li_2CO_3. In the presence of Cs_2CO_3, we failed to observe any trace of the cross-coupling product (α-naphthalenesulfonyl chloride + 4-methylbenzeneboronic acid), even though all the starting sulfonyl chloride was consumed.

A wide range of electronically and structurally diverse sulfonyl chlorides and boronic acids were examined and proved to undergo efficient cross-coupling under our conditions. Thus, electron-rich, electron-neutral, and electron-poor arene sulfonyl chlorides reacted with boronic acids to provide the corresponding biaryl products. Self-coupling of boronic acids was observed concurrently in some cases.[74] The proportion of the latter was lower in boiling THF than in boiling dioxane, acetonitrile, 1,2-dimethoxyethane, or *p*-xylene.

The postulated mechanism of the reaction is shown in Scheme 2. Palladium(0) species arises either from $PdCl_2$ or



Scheme 2. Proposed catalytic cycle for Suzuki–Miyaura cross-coupling of sulfonyl chlorides and boronic acids.

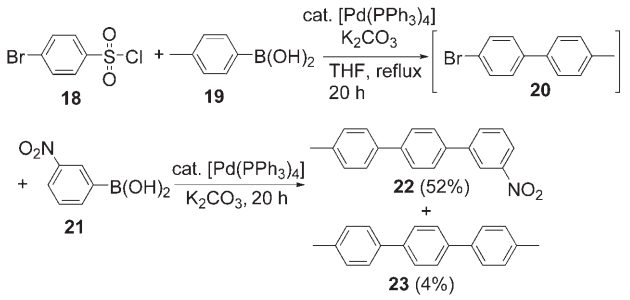
from the addition of sterically hindered or electron-rich ligands to $[Pd_2(dba)_3]$. The O_2S–Cl bond of the arene sulfonyl chloride undergoes oxidative addition to the Pd^0 species to give first a chloro palladium(II) sulfinate of type **II**. At higher temperatures (> 66 °C) loss of SO_2 occurs rapidly and a Ar–Pd–Cl complex of type **III** forms which then undergoes cross-coupling with the arene boronic acids **IV**,[25] in a way similar to aryl halides or triflates in Suzuki–Miyaura condensations.[1,9]

In the presence of $[Pd(PPh_3)_4]$ catalyst, traces of diaryl sulfide were frequently observed. For instance, treatment of *p*-toluenesulfonyl chloride with 4-methoxybenzeneboronic acid in the presence of $[Pd(PPh_3)_4]$ and K_2CO_3 (3 equiv) led to Tol-S-Ar **X** (Ar = 4-methoxyphenyl), which was isolated in 8% yield. The formation of this by-product probably results from the reduction of the sulfonyl chloride to the corresponding sulfenyl chloride **VIII** by PPh_3.[26a] The Pd^0 then inserts into the S–Cl bond followed by coupling with the boronic acid **IV** (Scheme 2). In contrast, when carbenes and sterically hindered or electron-rich ligands are employed, the aryl palladium chloride intermediates **III** can give the corresponding homocoupled products[75] (Scheme 2).

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

At 0–25 °C, loss of SO_2 does not occur in chloro palladium(II) sulfinate **II** and, following transmetalation with arene boronic acid **IV**, yields a palladium(II) complex, which undergoes reductive elimination of the product sulfones **VII** with concomitant regeneration of the active palladium(0) catalyst.[25,76] These results show that the palladium(0) species undergoes SO_2–Cl rather than C–SO_2 oxidative addition of an arene sulfonyl chloride.

The reaction of 4-bromobenzenesulfonyl chloride (**18**) and 4-methylbenzene boronic acid (**19**) gives the corresponding bromobiaryl compound **20**, which reacts with 3-nitrobenzeneboronic acid (**21**) to generate unsymmetrical teraryl **22** in 52% yield, together with 4% of **23** (Scheme 3).



Scheme 3. Chemoselective sequential Suzuki–Miyaura cross-couplings.

When the above reactions were carried out at 0–25 °C, sulfones were formed instead of the products of Suzuki–Miyaura cross-coupling. Good yields of unsymmetrical diaryl sulfones were obtained when using $PdCl_2$ as catalyst and K_2CO_3 as base [Eq. (32)].[76]

$$\mathrm{ArSO_2Cl + Ar'\text{-}B(OH)_2} \xrightarrow[\text{acetone/H}_2\text{O (3:1)},\ \text{N}_2,\ 0\text{–}25\ ^\circ\text{C}]{2\ \text{mol\%}\ \mathrm{PdCl_2},\ \mathrm{K_2CO_3}} \mathrm{ArSO_2Ar'}\ (60\text{–}92\%) \qquad (32)$$

Ar, Ar' = aryl, heteroaryl

Preliminary results from our laboratory suggest that Negishi-type couplings can be carried out between arene sulfonyl chlorides and zinc reagents in the presence of a catalytic amount of $[Pd(PtBu_3)_2]$ in THF at reflux [Eq. (33)].[29]

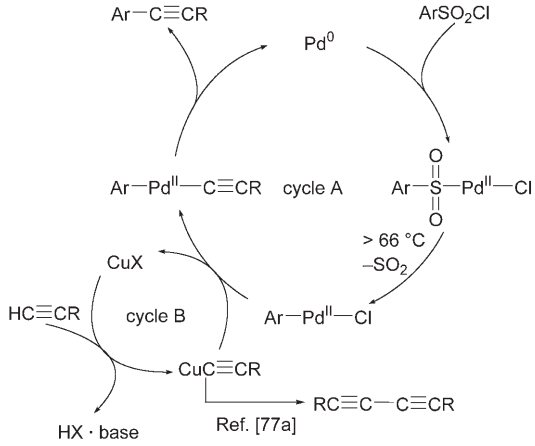
$$\mathrm{R^1SO_2Cl + R^2\text{-}ZnX} \xrightarrow[\text{THF, reflux, 15 h}]{\text{cat. } [\mathrm{Pd\{P}t\mathrm{Bu_3\}_2}]} \mathrm{R^1\text{-}R^2 + SO_2 + ZnXCl} \qquad (33)$$

We reported conditions for the first palladium-catalyzed desulfitative carbon–carbon cross-coupling of arene sulfonyl chlorides with aryl and alkyl acetylenes [Eq. (34)].

$$\mathrm{ArSO_2Cl + HC{\equiv}CR} \xrightarrow[\text{15 mol\% CuI, } \mathrm{K_2CO_3}\text{, THF, 66 °C}]{\text{3 mol\% } [\mathrm{Pd_2(dba)_3}],\ \text{10 mol\% } \mathrm{P}t\mathrm{Bu_3}} \mathrm{ArC{\equiv}CR + SO_2 + HCl}\ (40\text{–}72\%) \qquad (34)$$

$[Pd_2(dba)_3]$/$PtBu_3$ and CuI proves to be the best catalyst system for the reactions in refluxing THF and in the presence of K_2CO_3.[28]

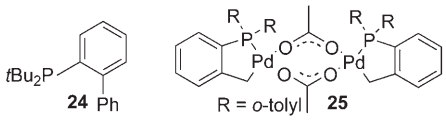
In the presence of $[PdCl_2(PhCN)_2]$ catalyst and CuI cocatalyst (5 mol% each), the reaction of TsCl with phenylacetylene leads to the desulfitative cross-coupled product in low yield ($\leq$10%). The major product was the undesired diphenylbuta-1,3-diyne (Glaser reaction).[77] However, the required cross-coupling could be seen in the presence of $[\{(\pi\text{-allyl})PdCl\}_2]$ and $PtBu_3$ (4:15 mol%). In this case, K_2CO_3 is a better base than Et_3N as it improves the competition between the desired cross-coupling and undesired homocoupling reactions. To our surprise, diaminocarbene ligands generated by α elimination of HCl from **17** (and analogous salts) led to no cross-coupling at all. Among several phosphine ligands tested, $PtBu_3$ gave the best results. It was also found that boiling THF is better than toluene or acetonitrile. A possible mechanism for these reactions is shown in Scheme 4.



Scheme 4. Proposed catalytic cycle for the desulfitative Sonogashira–Hagihara cross-coupling of sulfonyl chlorides and terminal alkynes.

Since copper cocatalyst promotes the homocoupling of acetylenes (Glaser reaction[77]) and inhibits their cross-coupling reactions,[78] conditions have been proposed for copper-free palladium-catalyzed Sonogashira–Hagihara couplings.[79] Under the latter conditions, arene sulfonyl chlorides do not undergo desulfitative cross-couplings with acetylenes. Thus presently, CuI is still necessary as cocatalyst.

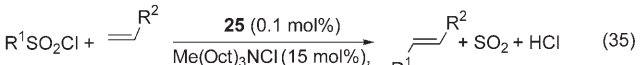
As a continuation of the work of Kasahara et al.[63] and Miura and co-workers work,[64] we explored catalysts other than $[PdCl_2(PhCN)_2]$, $Pd(OAc)_2$, $PdCl_2$, Pd black, and $[PdCl_2(PPh_3)_2]$ in the desulfitative Mizoroki–Heck type reactions



with electron-rich [Eq. (24)] and electron-poor alkenes [Eq. (25)]. We were inspired by numerous recent advances made in classic Mizoroki–Heck reactions (with aryl halide reagents in the presence of phase-transfer catalysts[80] and palladium complexes containing electron-rich ligands such as

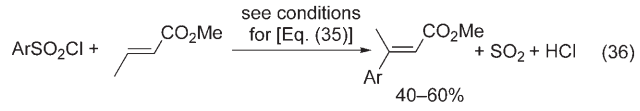
© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

17,[21a] P*t*Bu$_3$,[21b–c] and **24**[81] or the palladacycle **25**[82]). We found new conditions for the desulfitative Mizoroki–Heck arylation and trifluoromethylation of mono- [Eq. (35)] and



(35)

R^1 = aryl, CF_3
R^2 = COO*n*Bu, Ph, SO_2Ph

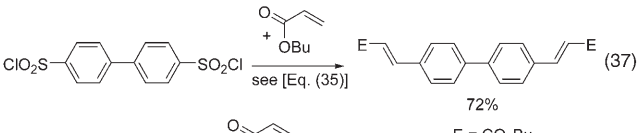


(36)

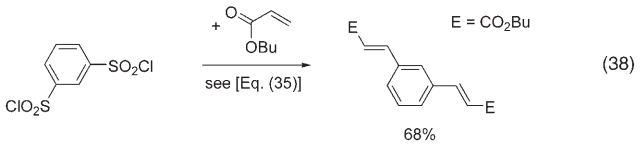
Ar = 4-F-C_6H_4, 4-NO_2-C_6H_4, 4-MeO-C_6H_4, 3-NC-C_6H_4

disubstituted olefins [Eq. (36)] with arene sulfonyl and trifluoromethanesulfonyl chlorides. *E*-1,2-Disubstituted alkenes were obtained with high stereoselectivity and 1,1,2-trisubstituted alkenes were prepared with 12:1 to 21:1 *E*/*Z* stereoselectivity. The Herrmann palladacycle **25** (0.1 mol%) is sufficient to catalyze these reactions for which electron-rich or electron-poor sulfonyl chlorides and alkenes are suitable.

Double desulfitative Mizoroki–Heck couplings have also been carried out [Eqs. (37) and (38)]. Important polymer precursors[83] have been produced in this way.

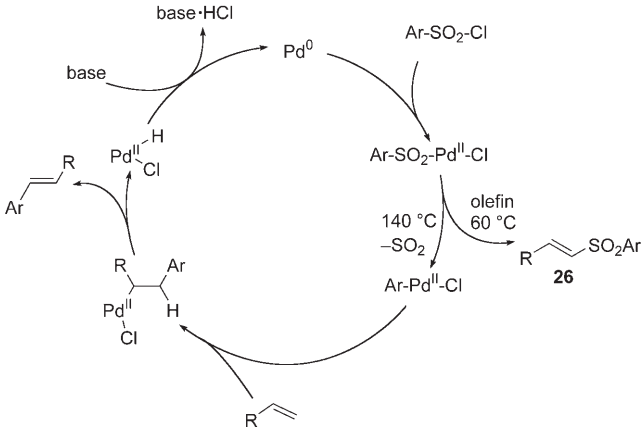


(37)



(38)

The reaction of arene sulfonyl chlorides with styrene in the presence of a catalytic amount of $PdCl_2$ or [$Pd(PPh_3)_4$] in benzene or in THF at 60 °C (instead of 140 °C) and in the presence of K_2CO_3 or NEt_3 produces the corresponding α,β-unsaturated sulfones **26**. Heating of sulfone **26** in boiling xylene in the presence of **25** (1 mol%) or [{$RhCl(C_2H_4)_2$}$_2$] (1 mol%) did not produce any traces of products of SO_2 loss after 24 h. This observation shows that sulfones **26** (Scheme 5) are not intermediates in these Heck-type reactions [see Eqs. (35)–(38)]. Kamigata and co-workers[84f] reported that [$RuCl_2(PPh_3)_2$] catalyzes the addition of sulfonyl chlorides to alkenes with the formation of the corresponding sulfones. These reactions imply $RSO_2^{\bullet}$ radical intermediates that are scavenged by the galvinoxyl free radical. This was not the case with our reactions [Eqs. (35)–(38)] catalyzed by [$Pd(PPh_3)_4$]/Et_3N because these were neither inhibited by galvinoxyl nor by 2,2,6,6-tetramethylpiperidine 1-oxyl radical (TEMPO).[27] These observations can be interpreted by the mechanism shown in Scheme 5. A palladium(0) species such as [$Pd(PPh_3)_4$] or one arising from **25**[82d] first undergoes oxidative addition into the SO_2–Cl bond of an arene sulfonyl chloride.

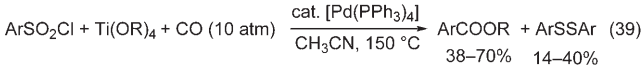


Scheme 5. Proposed catalytic cycle for sulfone synthesis and desulfitative Mizoroki–Heck type reaction between sulfonyl chlorides and olefins.

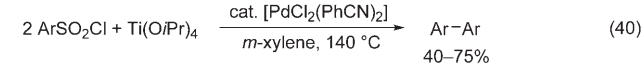
[($Pd(PPh_3)_4$] was chosen because it is known that this catalyst facilitates the reaction of arene sulfonyl chlorides with organostannanes[68] and arene boronic acids,[76]) and the alkene insertion generates the corresponding sulfone **26**. At 60 °C, loss of SO_2 does not occur, whereas at higher temperature (140 °C) SO_2 loss is rapid and forms an Ar-Pd-Cl complex, which then undergoes β addition to the olefin, followed by β elimination of chlorohydridopalladium to afford the final product of Heck coupling together with the active Pd^0 catalyst.

If phosphine- and base-free conditions are required, [{$RhCl(C_2H_4)_2$}$_2$] can be used to catalyze the desulfitative Mizoroki–Heck reactions [Eqs. (32)–(35)]. The mechanisms of these rhodium(I)-catalyzed reactions are probably similar to those for the Pd^0-catalyzed reactions (Scheme 5). We verified that the Rh-catalyzed reactions were not inhibited by radical-scavenging agents such as the galvinoxyl free radical.

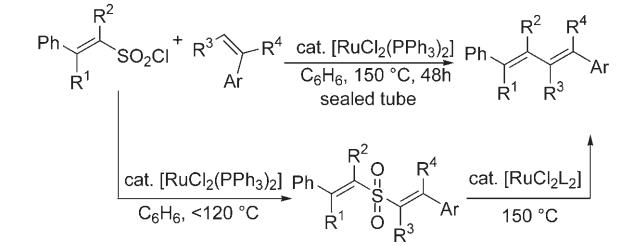
Miura and co-workers reported that arene sulfonyl chlorides can be desulfitated and carbonylated with $Ti(OR)_4$ and carbon monoxide (10 atm) in the presence of palladium in acetonitrile at 150 °C to give the corresponding arene carboxylic esters [Eq. (39)].[65] They also found that, in the absence of carbon monoxide, desulfitative homocouplings



(39)



(40)



Scheme 6. Ru^{II}-catalyzed reactions of alkene sulfonyl chlorides with alkenes.

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

occur in *m*-xylene at reflux to give symmetrical biaryl species [Eq. (40)].[66]

Perfluoroalkene- and benzenesulfonyl chlorides add to alkenes in the presence of $[RuCl_2(PPh_3)_2]$ catalyst.[84] When the reactions are carried out at high temperature, SO_2 is eliminated and Mizoroki–Heck-type products are obtained (Scheme 6) instead of the corresponding sulfones. The process works with alkenes, arenes, and thiophene.[84c,d] The same reactions can be applied to prepare 1,3-dienes (Scheme 6).[84e,f]

6. Summary and Perspective

Organosulfur compounds are versatile electrophilic reagents for C–C cross-coupling reactions with organometallic compounds in the presence of transition-metal catalysts. Recent discoveries herald a renaissance for sulfonyl chlorides as versatile reagents for C–C coupling reactions. As arene sulfonyl chlorides are often less expensive and more reactive than corresponding aryl chlorides,[25–26] their importance in materials science and medicinal chemistry should grow in the future. Other organosulfur compounds such as sulfones, sulfoxides, sulfoximines, sulfonates, and sulfonamides can be synthesized on larger scales and engaged in Negishi- or Kumada-type cross-coupling reactions in the presence of less-expensive nickel catalysts. The reaction of substituted ketones with enantiomerically pure $LiCH_2SO(NMe)Ph$ through asymmetric elimination[31d–e] provides easy access to alkenyl sulfoximines. The latter were successfully employed in Kumada-type cross-coupling reactions, thus realizing the key step in the synthesis of important biologically active compounds.[31a–c] Based on these recent developments, organosulfur compounds should find even broader applications as coupling partners in the area of target synthesis.[85]

This work was supported by the Swiss National Science Foundation (Grant No. 2000-20100002/1). We are grateful to M. Thresen, Dr. M. Turks, Dr. Ana T. Carmona, R. Mimna, and N. Jagan Mohan Rao for their critical reading of this manuscript and suggestions.

The last decade of research in the physical sciences has seen a dramatic increase in the study of nanoscale materials. Today, "nanoscience" has emerged as a multidisciplinary effort, wherein obtaining a fundamental understanding of the optical, electrical, magnetic, and mechanical properties of nanostructures promises to deliver the next generation of functional materials for a wide range of applications. While this range of efforts is extremely broad, much of the work has focused on "hard" materials, such as Buckyballs, carbon nanotubes, metals, semiconductors, and organic or inorganic dielectrics. Meanwhile, the soft materials of current interest typically include conducting or emissive polymers for "plastic electronics" applications. Despite the continued interest in these established areas of nanoscience, new classes of soft nanomaterials are being developed from more traditional polymeric constructs. Specifically, nanostructured hydrogels are emerging as a promising group of materials for multiple biotechnology applications as the need for advanced materials in the post-genomic era grows. This review will present some of the recent advances in the marriage between water-swellable networks and nanoscience.

1. Introduction

In a sense, the earliest investigators of synthetic and natural polymers were practicing nanoscience, that is, they were studying structures with spatial dimensions on the order of a few nanometers up to many microns. A similar statement could be made regarding the advent of research in molecular biology, as the dimensions of peptides, proteins, and oligonucleotides span the nanoscale. Thus, the nanometer length scale was as important in the early days of macromolecular science as it is today for nanoscientists. Many researchers in nanoscale phenomena rigidly define the nanoscale as that dimension where things become "different" (e.g. quantum confinement, dipolar plasmon oscillations, quantum conductance, etc.). Early polymer scientists may have also appreciated this philosophy, as they struggled to understand why certain arrangements of small molecules behaved in such a different fashion than their isolated molecular precursors. Indeed, polymers could be considered as the first demonstration of synthetic materials where the details of their length scale made them "different".

How then, in this modern age of nanoscience, do we define polymeric nanomaterials if most polymer chains are indeed nanometric? We could attempt to apply the above definition of differentness to some physical property of the polymer. That is, define, for a particular material, the point at which a decrease in macromolecular size leads to a discontinuity in some physical property. However, most scaling laws for polymer solution behavior begin to break down only when the polymer length approaches the persistence length of the chain, that is, the point where solutions begin to look "molecular" and not "macromolecular". While interesting physics arise from such situations, many of the desirable properties of polymers also disappear at this point. It seems then that this is a poor guideline for defining polymer nanoscience if functional materials are the overriding goals of our work. Given this conundrum, it may be the case that the redundant term "polymeric nanomaterials" cannot be rigorously defined. With this in mind, the goal of this Review is simply to explore current research in polymeric hydrogel particles, where the specific arrangement of the polymeric matter at the nanoscale imparts new properties that are not attainable from simple polymer solutions. The focus on polymer particles is important, as these discrete structures bridge the gap between more traditional areas of nanoscience and the world of soft matter. The focus on hydrogels arises from the growing need to understand how hydrophilic polymers can influence emerging areas of biotechnology.

1.1. Definition of Hydrogels

As a state of matter, gels are somewhat difficult to define, as they combine the properties of solids and fluids. They have structural integrity and do not flow appreciably when removed from their container. However, for molecules that are significantly smaller than the gel pore size, the transport of material through a gel is similar to mass transport in a fluid. Hydrogels are simply gels that swell strongly in aqueous media, and are typically composed of a hydrophilic organic polymer component that is cross-linked into a network by either covalent or noncovalent interactions.[1–3] It is the cross-linking that provides for dimensional stability, while the high solvent content gives rise to the fluid-like transport properties. The particular physical properties that result from this unusual state of matter make hydrogels ideal candidates for a number of applications. Perhaps the most widespread use

comes in the form of simple superabsorbent materials, which act to absorb and entrap water in applications where large volumes of aqueous media must be rapidly removed from a localized source. However, to have an impact in areas such as in vivo diagnostics, drug/gene delivery, chemical separations, chemical and biological sensors, and optical materials, many groups have pushed towards the synthesis of more complex polymer architectures to obtain highly functional nanomaterials. Such materials may be designed for biocompatibility, biodegradation, encapsulation, biorecognition, environmentally switchable payload release, or directed self-assembly. A number of creative synthetic methods have thus been brought to bear on this problem. In this Review, we will focus on a wide variety of approaches towards nanostructured hydrogel materials. For example, tremendous progress has been made in the assembly of amphiphilic block copolymers into dimensionally stable micellar particles. We will also address the use of stimuli-sensitive polymers in such materials, as these polymers offer new routes to hydrogels that can sense and respond to local environmental conditions. For example, it is possible to imagine the creation of a hydrogel particle that encapsulates and protects a pharmacologically active protein, only releasing it when the particle "senses" the presence of a particular disease state.

1.2. Classification of Hydrogels

Hydrogels can be classified in many ways but in this Review we will deal mostly with the classification based on type of cross-links. Cross-links are important to maintain the network structure of the hydrogels and to prevent dissolution of the hydrophilic chains. Based on the type of cross-links there are two classes of hydrogels.[4] For more detailed information on noncrystalline polymer networks, see the excellent review by Dušek and Prins.[5]

1.2.1. Physically Cross-Linked Hydrogels

The synthetic and natural hydrogels in this class have led to the concept of reversible or degradable hydrogels that undergo a transition from the three-dimensionally stable structure to a polymer solution. Most often these hydrogels have been used to encapsulate proteins,[6] cells,[7] or drugs[8] and then release them through the dissolution of the hydrogel structure. The cross-links in this class of hydrogels arise from noncovalent attractive forces between the polymer chains (Figure 1). These forces are often hydrophobic interactions, hydrogen bonding, or ionic interactions.

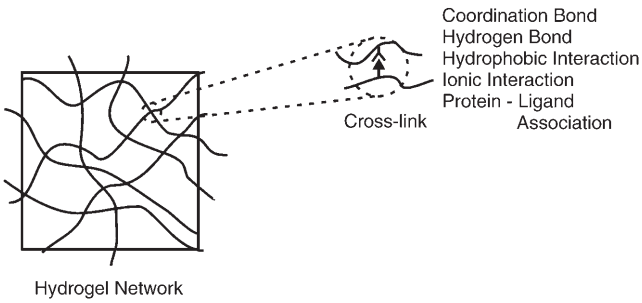

Figure 1. Physical cross-linking in hydrogels, in which the cross-links are formed by noncovalent interactions.

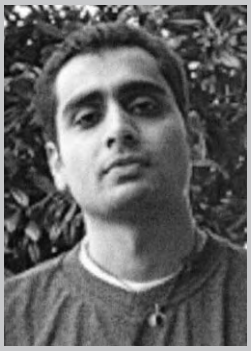
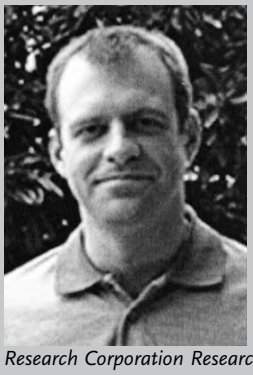
Alginate is a polysaccharide composed of mannuronic acid and gluconic acid, which can be cross-linked by divalent calcium ions.[4,9] The hydrogel can then be dissolved by using a chelating agent that binds to calcium ions. Alginate hydrogels have been used for encapsulating proteins and also as a matrix for the encapsulation of cells, and they often allow growth and proliferation of the cells within the encapsulating gel. Another example of cross-linking by ionic interactions is that of dextran, which lacks charged regions, but forms hydrogels in the presence of potassium ions. The reason for the cross-linking is that the ionic radius of potassium ions is such that it fits perfectly in the cage formed by six oxygen atoms of glucose units on three adjacent polymer chains.[10]

Noncovalent cross-links can also be formed in blends and interpenetrating networks of two dissimilar polymers. For example, poly(acrylic acid) and poly(methacrylic acid) form hydrogen bonds with poly(ethylene glycol), which results in formation of hydrogels. The hydrogen bond is formed between the oxygen of the poly(ethylene glycol) and carboxylic group of the poly acids. The hydrogen bonds are formed only when the acid groups are protonated, hence the hydrogel formation is pH dependent.[11,12] Oligonucleotides have also been used in the formation of hydrogels. Nagahara et al.



Satish Nayak received his BSc in chemistry from Ramnarain Ruia College, Mumbai and his MSc in analytical chemistry from the Institute of Science, Mumbai. He started his doctoral work on synthesizing and characterizing various types of hydrogel nanoparticles at Georgia Institute of Technology in 2000 under the supervision of Prof. L. Andrew Lyon. He successfully defended his thesis in 2004 and is currently working as a postdoctoral fellow at the University of Chicago.



Andrew Lyon received his PhD at Northwestern University under the direction of Professor Joseph T. Hupp (1996) and was a postdoc with Professor Michael J. Natan at Penn State (1997–1998). He began his career at Georgia Tech in 1999 and was promoted to Associate Professor in 2003. His current research involves the design of stimuli-sensitive hydrogel nanoparticles, as well as the assembly of these particles into higher order structures such as photonic crystals. His awards include the NSF CAREER Award, Beckman Young Investigator Award, Research Corporation Research Innovation Award, and the Camille Dreyfus Teacher-Scholar Award.

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

coupled water-soluble poly(*N*,*N*-dimethylacrylamide-*co*-*N*-acryloylsuccinimide) to a single-stranded DNA.[13] At room temperature and in presence of complementary DNA, hydrogels are formed, which dissolve at temperatures above the DNA melting point.

1.2.2. Chemically Cross-Linked Hydrogels

These types of hydrogels are usually more stable than the physically cross-linked hydrogels because the cross-links are formed by covalent bonds.[4] The hydrogels formed by such cross-links have a permanent structure unless chemical labile bonds have been intentionally added to the network.

Chemically cross-linked gels are usually formed by polymerizing monomers in the presence of cross-linking agents. Poly(2-hydroxyethyl methacrylate) is a well studied hydrogel-forming polymer. It is typically synthesized by polymerizing 2-hydroxy methacrylate ($H_2C{=}C(CH_3)COOCH_2CH_2OH$) with ethylene glycol dimethacrylate ($H_2C{=}C(CH_3)COOCH_2CH_2OCO(CH_3)C{=}CH_2$) as a cross-linker. Various physical properties, such as the swelling capacity of the hydrogels are controlled by the amount of cross-linker used.[4] Hydrogels can also be formed by cross-linking of the various functional groups present on the polymer backbone. Polymers containing hydroxy, amine, or hydrazide groups can be cross-linked by using glutaraldehyde, which forms covalent bonds with each of these functionalities.[4,14,15]

Enzymes have been used in the formation of cross-linked hydrogels. In one interesting example, Sperinde et al. employed tetrahydroxy PEG (PEG = poly(ethylene glycol)) functionalized with glutaminyl groups. This polymer forms hydrogels in the presence of the enzyme transglutaminase and poly(lysine-*co*-phenylalanine), where by the enzyme catalyses the reaction between the γ-carboxyamide group of the PEG-glutaminyl polymer and ε-amine group of the lysine to form an amide bond.[16,17]

1.2.3. Other Classifications

Hydrogels can also be classified based on their size as either macrogels or microgels. Macrogels[18–20] are bulk gels where the size can be anywhere from millimeters and larger, while microgels[21,22] are colloidally stable hydrogels, and their size can vary from tens of nanometers to micrometers. Perhaps the earliest report of microgel synthesis was by Staudinger in 1935,[23] so as with most of macromolecular science, the nanoscale has been the focus for a very long time. However, given the recent interest in such materials across multiple disciplines, as well as the continued efforts in all things "nano", microgels or hydrogel nanoparticles will be the central topic of this Review.

Hydrogels can be further classified as stimuli-responsive or non-responsive gels. Non-responsive gels, as the name suggests, are merely materials that swell upon water absorption. On the other hand stimuli-responsive gels have been called "smart" materials because they respond by a change in swelling to subtle changes in the environment.[24,25] These hydrogels can be made responsive to temperature,[19] pH value,[22,26] ionic strength,[27–29] light,[30–34] electric field,[35] and biomolecules.[36–40] The responsive behavior of the hydrogels is inherited from the type of the polymer used in making the gel and/or any post-polymerization modifications that are made.

1.3. Stimuli-Sensitive Polymers

The use of stimuli-sensitive polymers in fabricating hydrogels has led to many interesting applications; in this section we illustrate a few examples. One of the most widely studied stimuli-sensitive polymers is poly(*N*-isopropylacrylamide) (pNIPAm) formed from the monomer *N*-isopropylacrylamide ($H_2C{=}CHCONHCH(CH_3)_2$). to facilitate the understanding of some of the later parts of this Review, and as most of our group's work is based on pNIPAm, it is appropriate to provide a brief background on this polymer. For an in depth understanding see the very comprehensive review by Schild.[41]

One of the earliest studies on the solution properties of PNIPAm was carried out by Heskins et al.,[42] in which they observed that the phase transition of pNIPAm is endothermic and entropy driven. Owing to this striking thermal behavior in aqueous media, pNIPAm has been widely used to make responsive hydrogels. As with most olefin-based monomers, pNIPAm has been synthesized by a variety of techniques: redox initiation, free radical initiation, ionic initiation, and also by using radiation.[41] Various functional groups have also been added to the polymer by copolymerization and post-polymerization modification, thereby giving multiresponsive and multifunctional polymers.

The behavior of any polymer in a solvent is related to the balance between solvent–solvent, solvent–polymer, and polymer–polymer interactions. For stimuli-sensitive polymers, the polymer solvation can be "switched" by strengthening one of these interactions or by weakening another. Figure 2 illustrates this concept schematically. For the case of pNIPAm in water, the polymer hydrogen bonds to water through the amide side chains. However, the isopropyl group on the side chain induces hydrophobic structuring of the water. This structured water leads to entropically driven polymer–polymer interactions by the hydrophobic effect.[41] Under the conditions where pNIPAm has a random-coil structure, the solvent–polymer interactions are stronger than the polymer–polymer interactions. At higher temperatures, the hydrogen bonds to the water molecules break and there is an entropi-

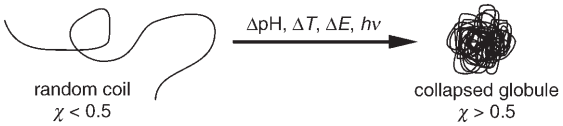


Figure 2. A stimuli-sensitive polymer undergoing phase transition as a result of a change in the solvent properties. Factors such as pH value, temperature, electric field, and light can cause these phase transitions depending on the polymer composition.

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

cally favored release of bound and structured water, leading to the formation of a globular polymer conformation. In this case the polymer–polymer hydrophobic interactions become stronger than the polymer–solvent interactions, and the polymer phase separates. The temperature at which this phase separation occurs is called the lower critical solution temperature (LCST). It is this behavior that makes pNIPAm a very attractive candidate for the fabrication of stimuli-responsive hydrogels. Note, however, that more than just the hydrophilic and hydrophobic side-chain contributions to polymer solvation must be considered when describing LCST behavior. For example, the polymer formed from *N*-isopropylmethacrylamide ($H_2C{=}C(CH_3)CONHCH(CH_3)_2$),[43–48] which differs from NIPAm by only a single methyl group, has a higher LCST in water, which suggests that it is more hydrophilic despite having a greater organic content. Apparently, this "increased hydrophilicity" does not arise from an increase in polymer polarity, but instead comes from a decrease in chain flexibility. This feature changes the entropic contribution to the free energy of mixing, and thus increases the LCST.

The LCST behavior of pNIPAm has been studied by a variety of techniques including UV-Vis spectroscopy, differential scanning calorimetry (DSC), light scattering, viscometry and fluorescence spectroscopy.[49–57] Wu et al. have extensively studied the phase transition of pNIPAm, where they observed that the transition is not first order, that is, the polymer does not directly go from a random coil state to a globular state, but there are other intermediate thermodynamically stable conformations (Figure 3).[52,54,58]

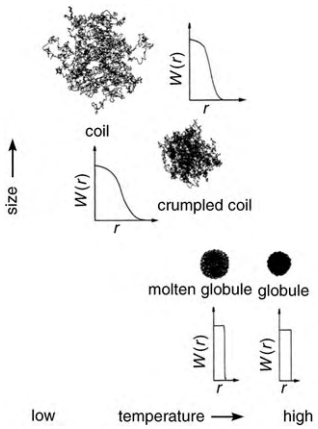

Figure 3. The thermodynamically stable states present during the phase transition of pNIPAm and the corresponding chain-density distribution along the radius for each state. Reprinted with permission from ref. [58].

There are other classes of thermoresponsive polymers that show an upper critical solution temperature (UCST). In this case the polymer is phase separated at low temperatures owing to inter- or intramolecular interactions, while at high temperatures these interactions break and the polymer dissolves or swells. Most often these interactions are hydrogen bonding or electrostatic. In one example Laschewsky and co-workers have synthesized a block copolymer of pNIPAm and 3-[*N*-(3-methacrylamidopropyl)-*N*,*N*-dimethyl]ammoniopropane sulfonate (SPP), which exhibits both LCST and UCST behavior.[59] The pNIPAm segment confers temperature sensitivity by the mechanism described above. On the other hand, SPP is a polyampholytic polymer, which at low temperatures displays strong electrostatic interactions between the oppositely charged regions of the polymers, whereas these interactions are broken at high temperatures.

Using this understanding of polymer solvation, Irie and co-workers have synthesized photoresponsive polymers by incorporating azobenzene side chains in pNIPAm.[60] Azobenzenes undergo *trans* to *cis* isomerization on UV irradiation; the transition is reversed by irradiation with visible light or by thermal relaxation. Furthermore, the dipole moment and hence the hydrophilicity of azobenzene is dependent on the isomerization state. In this fashion, the investigators were able to change the phase-transition temperature of pNIPAm by inducing isomerization of the azobenzene side chains, which in turn changed the free energy of mixing. Figure 4 shows the change in transmittance of poly-[*N*-isopropylacrylamide-*co*-*N*-(4-phenylazo-phenyl)-acrylamide] as a function of temperature before and during irradiation with UV light.

1.4. Swelling Properties of Hydrogels

The nature of hydrogels is dependent on the type of the monomers used to synthesize them. In case of hydrogels synthesized from pNIPAm, the thermoresponsivity of the parent polymer is inherited by gels made from it. These hydrogels exhibit volume phase transition temperature (VPTT)[61] at around the LCST of pNIPAm. At temperatures higher than VPTT the hydrogel goes from a swollen (hydrophilic) state to a compact (relatively hydrophobic) state. The VPTT of the gels is dependent on several factors including cross-link density, hydrophobic-hydrophilic balance, ionic strength, and solvent composition. Correspondingly, hydrogels fabricated from titratable ionic monomers show pH-dependent swelling. The most common ionic monomers used are acrylic acid and methacrylic acid. At $pH > pK_a$ of the acid comonomer, the gel swells because of Coulombic repulsion

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

between the charged monomer units and the more favorable solvation of the deprotonated monomer by the solvent. The equilibrium gel-swelling volume is a balance between the osmotic pressure of the polymer network, which is governed by polymer–solvent interactions, and the elasticity of the network.[5]

In ground-breaking work, the group of Tanaka showed that ionic thermoresponsive gels, when heated, display a discontinuous transition, while non-ionic gels undergo a continuous transition. They have also shown that the shrinking rate of the gel is inversely proportional to the square of the smallest dimension of the gel.[20,35,62–64] Taking advantage of the diffusion length scale, Yan and Hoffman have shown that polymerizing pNIPAm gels at temperatures higher than the LCST of the polymer results in gels that have large pore sizes, which in turn have faster swelling rates.[65] Reporting all the properties of hydrogels is beyond the scope of this Review; hence we have mentioned just a few important properties, and some others will be discussed in the later Sections.

The swelling behavior of hydrogels has made them useful in some interesting applications. Thermosensitive pNIPAm gels have been used in controlling the activity of enzymes. Park and Hoffman demonstrated that by immobilizing an enzyme in the gel, the diffusion of the substrate to the enzyme could be controlled by changing the pore size of the gel, which in turn depends on the temperature of the system. In this way they were able to switch the enzyme on or off by controlling the temperature.[66] Kim and Healy have synthesized pNIPAm gels with peptide cross-links. These gels can be used as an extracellular matrix mimic, where the peptide can be cleaved by a metalloproteinase, which subsequently leads to gel erosion. Figure 5 shows a schematic depiction of this process.[67]

1.5. Microgels and Nanogels

Colloidally stable particles made from hydrogels, also referred to as micro- or nanogels, have properties similar to those of their macrogel counterparts, that is, a pNIPAm microgel, just like the bulk gel, will also undergo a VPTT near the LCST of the polymer.[68,69] In addition to these properties, microgels have other characteristics of colloidal dispersions, such as zeta potentials,[69–71] and can also form ordered colloidal phases.[72–75]

Some very important studies have focused on the differences between macro- and microgels with respect to their phase behavior. For example, Wu et al. have shown that the VPTT of the microgels is slightly higher than the LCST of pNIPAm (Figure 6), and also that the transition region is less

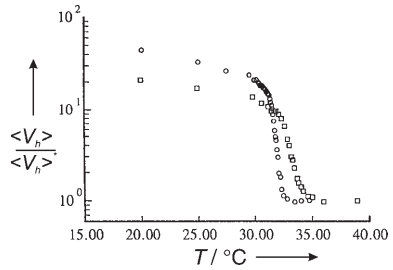

Figure 6. Deswelling ratio of linear pNIPAm chains (○) and cross-linked microgels (□) in water. Owing to the heterogeneity of the cross-links, microgels have a broader phase-transition region than the linear pNIPAm chains. Reprinted with permission ref. [76].

sharp than that of bulk gels.[76] The reason for this continuous transition is due to a greater heterogeneity in the subchain lengths of the microgels than in the traditionally prepared macrogels. When the microgels are subjected to $T >$ VPTT, the regions of the particle with longer subchain lengths collapse at a lower temperature than the regions with shorter subchains. Thus the observed phase transition for a microgel can be thought of as being the summation of the phase transitions of the different sub-networks in the particle. We have also observed this behavior in core–shell structured microgels by using fluorescent probes to interrogate cross-linker gradients.[77]

PNIPAm microgels show interesting behavior in mixed solvents owing to the cononsolvency of pNIPAm (i.e., the non-linear dependence of solvation on solvent volume fraction).[78] For example, the LCST of linear pNIPAm decreases with increasing methanol concentration until 55% methanol, beyond which the LCST increases sharply.[79] The same effect has been observed by McPhee et al. for microgels.[80] The mechanism for cononsolvency is explained by clathrate formation. Cosolvents such as water and methanol form clathrate structures, which compete with pNIPAm for the water molecules that hydrate the polymer. Hence the deswelling of the polymer is observed as the water molecules are removed from the interior of the gel by the other solvents. In related work, Daly and Saunders have studied the

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

effect of added electrolyte on the stability of the microgels. It was observed that at a particular temperature particles flocculate at higher ionic strength. The swelling ability of the particles also depends on the ionic strength of the salt and its position in the Hoffmeister series, which relates to the effect of ions on the activity of water.[70] An interesting study by Greinert and Richtering involved the modulation of polyelectrolytic pNIPAm microgels by the adsorption of oppositely charged polyelectrolytes in solution.[81] The charge compensation and bridging effect of the polyelectrolyte adsorption have a profound effect on the LCST behavior of the microgels. These studies may offer insight into the swelling phenomena observed in microgel-based polyelectrolyte multilayers,[82–85] which are discussed in Section 3.1.

Many researchers have carried out electrophoretic mobility measurements for charged particles. One of the first reports was from Pelton et al., they studied the electrokinetic behavior of pNIPAm microgels as a function of temperature and salt concentration.[86] They observed that at $T < \mathrm{VPTT}$, mobility was nearly zero owing to a low charge density on the particles, but at $T > \mathrm{VPTT}$ a sharp increase in mobility was observed. This change was attributed to the increase in charge density on the smaller deswollen particle. Since the charge per particle is constant, smaller (deswollen) particles will have a higher charge density than swollen particles. Daly and Saunders carried out a similar study and found that the onset of the increase in electrophoretic mobility was about 5–6 K higher than the VPTT of the particles. This behavior was proposed to result from a three-stage phase transition in the microgels (Figure 7).[70]

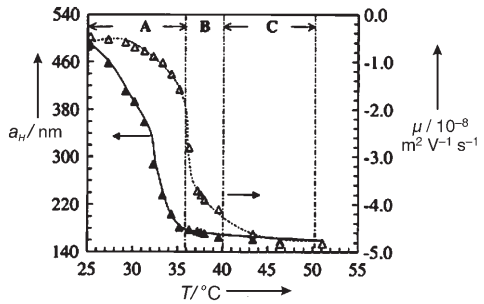

Figure 7. Electrophoretic mobility (△) and hydrodynamic radius (▲) as a function of temperature for pNIPAm microgels. The regions A, B, and C represent the three stages in the collapse of the particle. Reproduced with permission from ref. [70].

Surfactants can have a strange effect on the swelling of pNIPAm microgels. Tam et al. have observed that the microgels swell in presence of anionic surfactant.[87] They attributed this property to the interaction of the hydrophobic tail of the surfactant with the polymer network. However, in the presence of a cationic surfactant of the same chain length, no such effect was observed. Wu et al. carried out similar studies and observed by NMR spectroscopy that at concentrations less than the critical micelle concentrations (CMC), the anionic surfactants form micelles in the polymer network owing to a higher effective concentration in the network.[88] The cationic surfactants failed to form micelles in the polymer network even at very high concentration, and hence no microgel swelling was observed.

Understanding the structure of hydrogel nanoparticles is important for explaining their detailed phase-transition behavior, mass-transport through the network, and colloidal stability. Light scattering is one of the most common techniques used for structural analysis of hydrogel nanoparticles. Both dynamic and static light scattering have been used extensively and remain the standard techniques for particle characterization.[69,76,89–91] However, other techniques have allowed for even greater insight into the structure of microgels. Guillermo et al. used NMR spectroscopy to determine the cross-linker distribution in microgel particles and confirmed that these particles have a heterogeneous structure, wherein the periphery of the microgel is more loosely cross-linked than the interior.[92] Similar studies were carried out by Saunders, in which small-angle neutron scattering (SANS) was used to investigate the structural details of pNIPAm microgels synthesized by surfactant-free polymerization.[93] This study again revealed that the microgels prepared by precipitation polymerization have a heterogeneous structure, in this case it was also determined that a thin layer of loosely cross-linked chains was present at the particle periphery. Woodward et al. used DSC to determine the influence of cross-linking density on the phase transition of the particles. They observed an overall decrease in phase-transition enthalpy with increase in cross-linker density.[94] In addition to DSC they also used pulsed-gradient spin echo (PGSE) NMR spectroscopy to study the mobility of the solvent in the particle as a function of cross-linker density and observed that the diffusion of solvent is reduced with the increase in the cross-linker density, hence the particles are more rigid at high cross-linker density. Figure 8 depicts the change in relative diffusion coefficient of water in the microgels, measured by PGSE-NMR spectroscopy, for samples with different cross-linker densities.

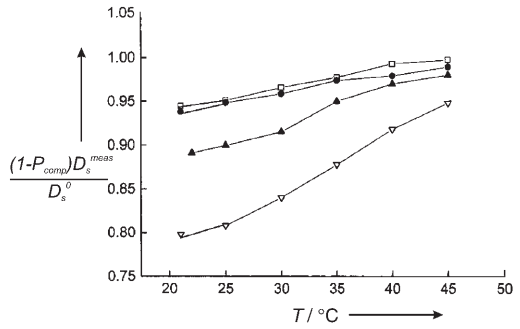

Figure 8. Relative diffusion coefficient of water inside the polymer network for 0.25% (□), 0.5% (●), 5% (▲), and 30% (△) cross-linked pNIPAm microgels as a function of temperature. The diffusion coefficient of water within the particle decreases with an increase in the cross-link density. Reprinted with permission from ref. [94].

Senff et al. have used rheometry to understand the phase behavior of microgels and to determine the effective "softness" of microgel particles.[73,95,96] This group has also carried out studies aimed at determining the internal structure of

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

microgels.[97,98] Again, it was determined that the cross-link density is highest at the center of the particle and decreases gradually to the surface. They also found that the internal structure of the microgels depends on the manner in which they are synthesized. A semibatch reaction (reactants are added gradually over a certain time) gives more homogeneous morphology than a simple batch reaction (all the reactants are added at the start) This effect is attributed to the faster reactivity of the cross-linker, which gets incorporated at a faster rate during the early stages of a batch reaction. Similar behavior has also been reported by Pelton.[68,99]

2. Synthesis of Hydrogel Nanoparticles

Hydrogel Nanoparticles have been synthesized by numerous approaches. In this Section we will discuss some of the commonly used methods, where the synthetic technique being employed is typically dictated by the desired application or the type of study to be carried out.

2.1. Emulsion and Precipitation Polymerization

Surfactant-free emulsion polymerization (SFEP), or precipitation polymerization, is the most common technique to synthesize thermosensitive hydrogel particles. Although pNIPAm microgel synthesis by this method was not reported until 1986, the technique was apparently first utilized by Philip Chibante in 1978.[68,100] If carried out carefully, this method can afford particles with very narrow size distribution. In this method all the monomers, NIPAm, and the cross-linker (typically *N*,*N*′-methylenebisacrylamide (BIS)), are dissolved in water. The solution is purged with N_2 and heated to a temperature above the pNIPAm LCST (usually around 70 °C), then an initiator such as ammonium persulfate (APS) or potassium persulfate (KPS) is added.

Microgels synthesized by this method are formed by homogenous nucleation. There are good reasons for carrying out the polymerization at high temperature: the sulfate radicals, which initiate the polymerization need to be formed. After initiation the NIPAm monomer is attacked by the sulfate radical, there then follows radical propagation and chain growth. Once the chain reaches a critical length, it collapses upon itself producing precursor particles. The chain collapses because the polymerization temperature is higher than the LCST of the polymer, hence the name precipitation polymerization. The precursor particles grow by aggregation with the other precursor particles, by being captured by existing particles, by capturing growing oligoradicals, and by monomer addition. The charge imparted by the initiator stabilizes the microgels once they have reached a critical size. Figure 9 shows the proposed mechanism for precipitation polymerization. This method is extremely versatile from the standpoint of particle size control. For example, to synthesize smaller microgels, the precursor particles must be stabilized earlier in the reaction. Since there is not enough charge available from initiator fragments to stabilize small precursor particles, an ionic surfactant can be added to impart colloidal stability earlier in the reaction. Similarly, larger particles can be obtained by decreasing the surfactant concentration. Precipitation polymerization can also be used to incorporate comonomers in the microgel. We and others have copolymerized ionic monomers with pNIPAm to create pH-responsive microgels.[22,29,101–105] We have also copolymerized a hydrophobic comonomer *N*-*tert*-butylacrylamide (TBA, $H_2C{=}CHCONHC(CH_3)_3$) to give pH and temperature responsive microgels; these particles exhibit phase transitions at lower temperatures owing to the increase in hydrophobicity of the gel while retaining a pH-tunable VPTT.[105] Similarly, other functionalities can also be copolymerized into these particles by this method.

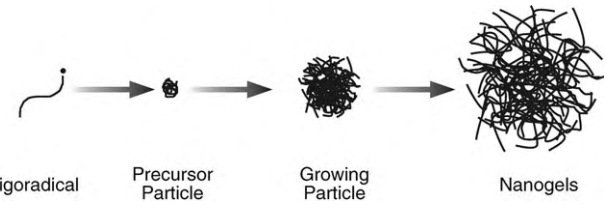

Figure 9. Precipitation polymerization of colloidal micro or nanogels from phase-separating polymers.

The presence of a cross-linker is critical in preventing the dissolution of the polymer particle as it is cooled below the LCST. However, Gao and Friskin have reported that it is possible to make pNIPAm microgels by precipitation polymerization, without using a cross-linker.[106,107] They attributed this effect to "self cross-linking" of pNIPAm chains by a chain-transfer reaction occurring at either or both of two possible sites: the hydrogen atom attached to the tertiary carbon atom on the pendant isopropyl group and the hydrogen atom on the tertiary carbon atom of the main-chain backbone. These results indicate that in precipitation polymerization the cross-link density might be higher than expected on the basis of the cross-linker concentration used in the reaction.

Precipitation polymerization has a few drawbacks. First, the method is useful only for materials that are stable at high temperatures and hence cannot be used to incorporate biological macromolecules. Also the method is best for materials which are hydrophobic so that they can attach to the collapsed precursor particle easily. Hence, if a hydrophilic comonomer is to be copolymerized, only a certain wt % can be incorporated. Beyond that wt % the growing oligomer will be too hydrophilic to undergo efficient chain collapse, thereby resulting in a very polydisperse microgel dispersion, or the complete lack of particle formation. To overcome these hurdles many researchers have used inverse microemulsion polymerization. In this method an aqueous solution of all the monomers is added to an appropriate amount of oil and surfactant and is stirred to form thermodynamically stable microemulsions. Polymerization can be initiated by having the initiator in the aqueous or in the oil phase. This method has been used to synthesize hydrogel particles with high wt % of ionic monomers; Neyret and Vincent used microemulsion polymerization to prepare zwitterionic pNIPAm microgels.[108] In this case they used a UV-activated photoinitiator

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

dissolved in the organic phase. McAllister et al. used the same technique to synthesize a highly cationically charged hydrogel. These particles were able to bind to DNA and can potentially be used in gene delivery.[109] One other method for preparing microgels, which is similar to microemulsion polymerization, utilizes lipids to form liposomes inside which the particle is formed. Kazakov et al. have demonstrated that liposomes can form a "nanoreactor" inside which microgels can be polymerized.[110] Figure 10 illustrates the general procedure.

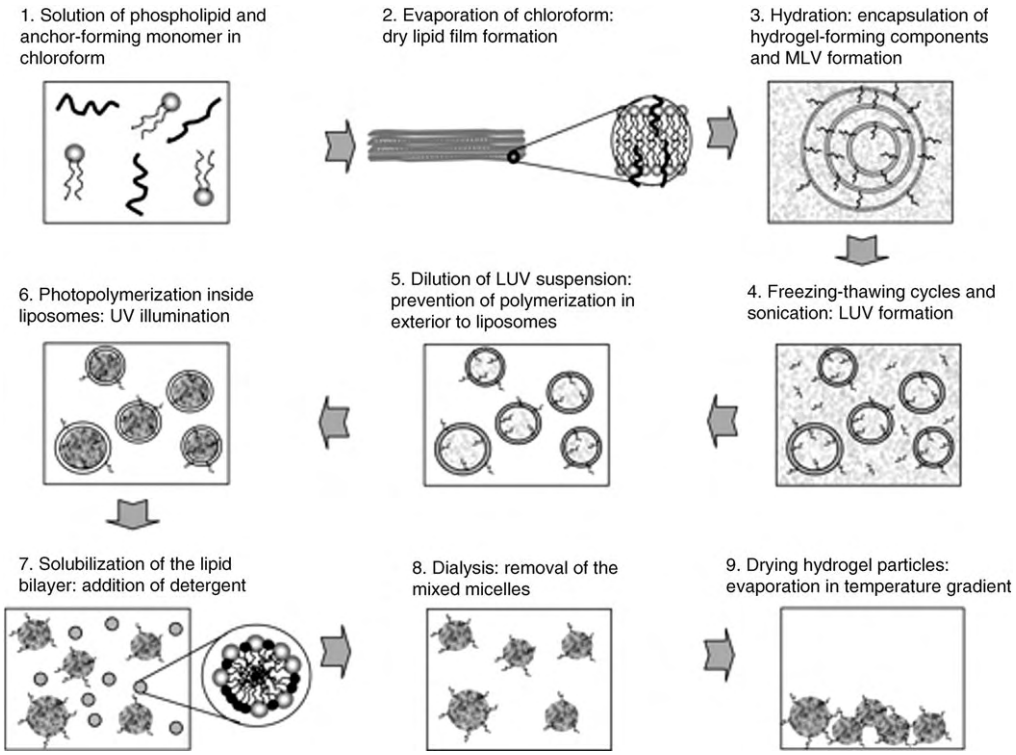

Figure 10. Hydrogel particle synthesis in liposomes. Reprinted with permission from ref. [110].

2.2. Core–Shell Structured Materials

Core–shell hydrogel particles can broadly be divided in two classes: 1) where the core is made from non-hydrogel material and the shell is made from hydrogel and 2) where both the core and the shell are made of a hydrogel-like material. In the first class of materials the core is usually made of solid material, such as polystyrene, silica or gold nanoparticles. Dingenouts et al. synthesized a polystyrene core with small amount of NIPAm as a co-monomer by SFEP.[111] The polystyrene-*co*-pNIPAm particles were stabilized by the sulfate groups from the initiator. These cores were then used as seeds for polymerizing a cross-linked shell of pNIPAm. For the shell synthesis the reaction was carried out at 80 °C, which provided a core particle with a deswollen pNIPAm-rich periphery, onto which pNIPAm polymerizing in solution aggregated by a precipitation polymerization mechanism. Xiao et al. synthesized similar particles in which pNIPAm chains were grafted onto the polystyrene core resulting in a "hairy" particle.[112]

In another example, Zha et al. have used silica particles prepared by the Stöber method[113] as a core material.[114] Vinyl groups were introduced to the surface of the particles by a silane coupling reaction. These particles were then used as seeds for precipitation polymerization of pNIPAm, which resulted in the formation of silica-core pNIPAm-shell particles. This approach allowed the synthesis of hollow pNIPAm capsules by dissolution of the silica with HF. Similarly, Kim and Lee have synthesized gold-core pNIPAm-shell particles by SFEP. The size of these citrate-stabilized gold nanoparticles was approximately 60 nm. The gold nanoparticles were then treated with oleic acid, which helps in attaching the pNIPAm hydrogel shell to the gold core during SFEP.[115]

The second type of core–shell materials is the one which has hydrogel in both the core and the shell. Our group first reported the synthesis of this type of hydrogel particles by two-stage precipitation polymerization.[22] In this method a polymer shell with the same or different structure or functionality as the core, is added onto preformed core particles thereby allowing control over the radial distribution of the functional groups in the particle. In a typical synthesis, preformed pNIPAm core particles are heated to approximately 70 °C, then the shell monomer solution is added, and polymerization is initiated. The reaction is carried out for around 4 h and then the mixture is cooled and separated by filtration. This method gives core–shell particles with no increase in polydispersity, as all the oligomers formed in solution precipitate onto the preformed core particles. To prevent heteronucleation there are several important parameters that should be controlled, including the concentration of the core, initiator, surfactant, and the shell monomer. The mechanism by which this reaction takes place is somewhat similar to that for the core microgels. Since the reaction temperature is well above the VPTT of the core particles, the particles are in a collapsed state. The collapsed particles are hydrophobic and hence they tend to capture the growing oligomers, which results in the formation of the shell.

Core–shell particles prepared in this fashion can exhibit very interesting properties.[21,43,44,77,116–119] Since the shell can be synthesized using different comonomers to the core, the particles can show multiple phase-transition behavior with

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

temperature.[22,43,44] Furthermore, depending upon the cross-linker density of the shell, compression or "shrink-wrapping" of the core can be observed resulting from a cross-link gradient in the shell.[116,117,119] We have also used this synthetic method to make hollow hydrogel capsules, Figure 11.[120] To

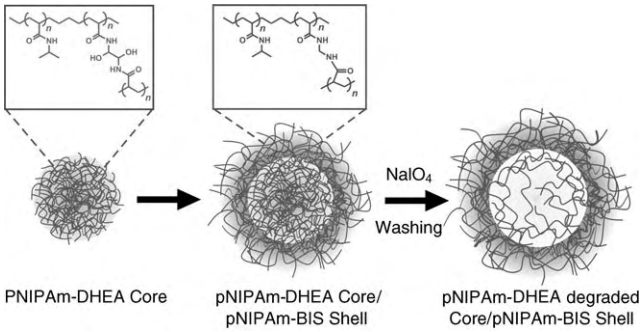

Figure 11. Preparation of thermosensitive hollow microgels by oxidation of the core cross-links. Reprinted with permission from ref. [120].

accomplish this, the core is fabricated with a degradable cross-linker and the shell with a non-degradable one. The degradable cross-linker that we have used contains a vicinal diol, which can be degraded by stoichiometric addition of periodate. After core degradation, the particles were cleaned extensively by centrifugation, after which DLS and fluorescence were used to confirm the hollow structure.

Berndt and Richtering have also synthesized core–shell particles which have two different polymers in the core and the shell.[43] In their demonstration, the core was made of pNIPAm and the shell consisted of poly(*N*-isopropylmethacrylamide) (pNIPMAm), which has a LCST of 45 °C. They studied the thermoresponsivity of these particles and found, in a similar fashion to previous work from our group, that the particles had two transitions corresponding to the LCSTs of the two polymers (Figure 12).

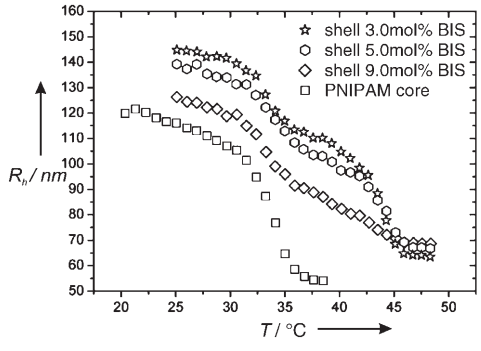

Figure 12. Hydrodynamic radius as a function of temperature for pNIPAm-core/pNIPAMAm-shell microgels with different shell cross-linker concentrations. The sample containing 3.0 mol% BIS clearly shows that the particle is undergoing two phase transitions, the first transition corresponding to the LCST of pNIPAm and the second to that of pNIPMAm. Reprinted with permission from ref. [43].

2.3. Block-Copolymer Micelles

Hydrogel nanoparticles can also be formed by using the ability of block copolymers to self-assemble into micelles.[121] Most often block copolymers are like surfactants in that they have a hydrophobic and a hydrophilic block. Depending on the polarity of the solvent and the concentration of the polymers, block copolymers can form spherical micelles. In hydrophilic solvents the hydrophobic block forms the core and the hydrophilic block is exposed to the solvent. In some cases these micelles can be cross-linked to form stable nanoparticles. For example, Zhu and Napper used pNIPAm-*b*-PEO (PEO = poly(ethylene oxide)) to form microgels.[122,123] Initially the block copolymer was synthesized using the ceric ion redox system in nitric acid at 50 °C, then addition of the cross-linker BIS formed cross-linked microgels. It was observed that the size of the microgels, as measured by DLS, was dependent on the concentration of NIPAm and PEO, and also on the rate of heating during polymerization.

The Wooley group has extensively studied cross-linked block-copolymer micelles, which they refer to as shell cross-linked knedels (SCK).[121,124–137] The size range for SCKs is around 5–200 nm. They are prepared from amphiphilic block copolymers, which self-assemble into polymeric micelles. The micelles are further stabilized by cross-linking of the side-chain functional groups in the shell of the micelles (Figure 13). The first SCK reported was fabricated from a

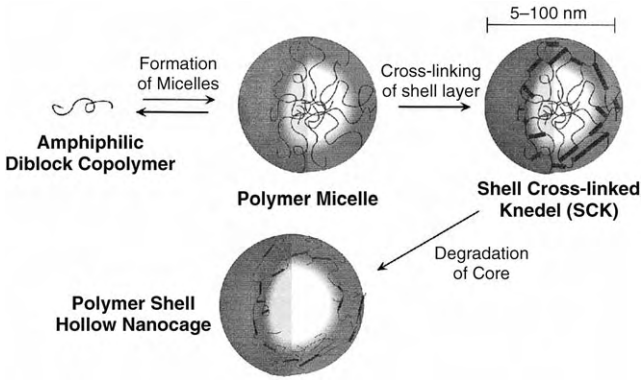

Figure 13. General synthetic approach for synthesizing SCK nanoparticles. The degradation step is used for the preparation of hollow particles. Reprinted with permission from ref. [131]

polystyrene and poly(4-vinylpyridine) block copolymer.[124] Before self-assembling the polymer into micelles, the pyridyl nitrogen was quaternized by reaction with *p*-chloromethylstyrene to impart hydrophilicity to the polymer. Once the polymer formed micelles the styrene moiety in the shell was polymerized to give the cross-linked structure. The dimensions and topologies of the particles can be controlled by varying the length of the hydrophilic and hydrophobic blocks.

The Wooley group has also prepared hydrogel-coated particles by using a polystyrene-*b*-poly(acrylic acid) copolymer.[137] The polymer self-assembled into a polystyrene core and acrylic acid shell micelle. The acrylic acid groups were

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

then cross-linked by using variety of bifunctional amine cross-linkers. They have also prepared SCKs with degradable cores. In one example they used poly(ε-caprolactone)-*b*-poly(acrylic acid) copolymers. This polymer forms micelles with the caprolactone core and acrylic acid shell. The shell is cross-linked by the methods mentioned above to form SCKs, the core is then dissolved by acid or base hydrolysis.[130] In a second demonstration, they have used poly(isoprene-*b*-acrylic acid) to form hollow SCKs.[126] The micelles formed by this polymer have isoprene groups in the core and the acid groups on the periphery. The acid groups in the shell were cross-linked by amidation and the core was dissolved by isoprene oxidation, resulting in hollow capsules. The Wooley group has also synthesized an entirely hydrophilic SCK, which was pH responsive.[134] The polymer was poly(acrylic acid)-*b*-poly(methyl acrylate), which forms an acrylic acid shell and a methyl methacrylate core micelle. The shell was cross-linked, subsequent hydrolysis of the core using LiOH, which converted acrylate into acid groups, made the entire particle hydrophilic. The acid groups in the core and the shell made the SCK pH responsive.

Akiyoshi et al. have found that polysaccharides partly modified by hydrophobic groups, such as cholesterol, can form nanoparticles in water.[138] The sizes of these particles typically range from 20–30 nm with excellent monodispersity, according to size-exclusion chromatography, DLS, and TEM. These particles are not true block-copolymer micelles but are closely related to this class of particles, since the association forces are similar. These particles were first prepared in 1993 by using hydrophobized pullulan having 1.6 cholesterol groups per 100 glucose units,[138] which aggregated intermolecularly to form nanoparticles. These nanoparticles are considered to be hydrogels in which the cross-links are provided by the associated hydrophobic groups. The size of the particles can be controlled by the number of the hydrophobic groups and also by the structure of the polymers. The Akiyoshi group has also made particles in which pNIPAm was incorporated to create thermoresponsive pullulan particles. These particles can capture and entrap macromolecules, such as proteins, in the gel network.[139–142] The self-assembly of these polymers can be controlled from the molecular level (association of hydrophobic groups) to the nanoscale level (association of hydrophobized polymers) and macroscopic level (association of nanoparticles). The hierarchy of pullulan assembly is shown in Figure 14.

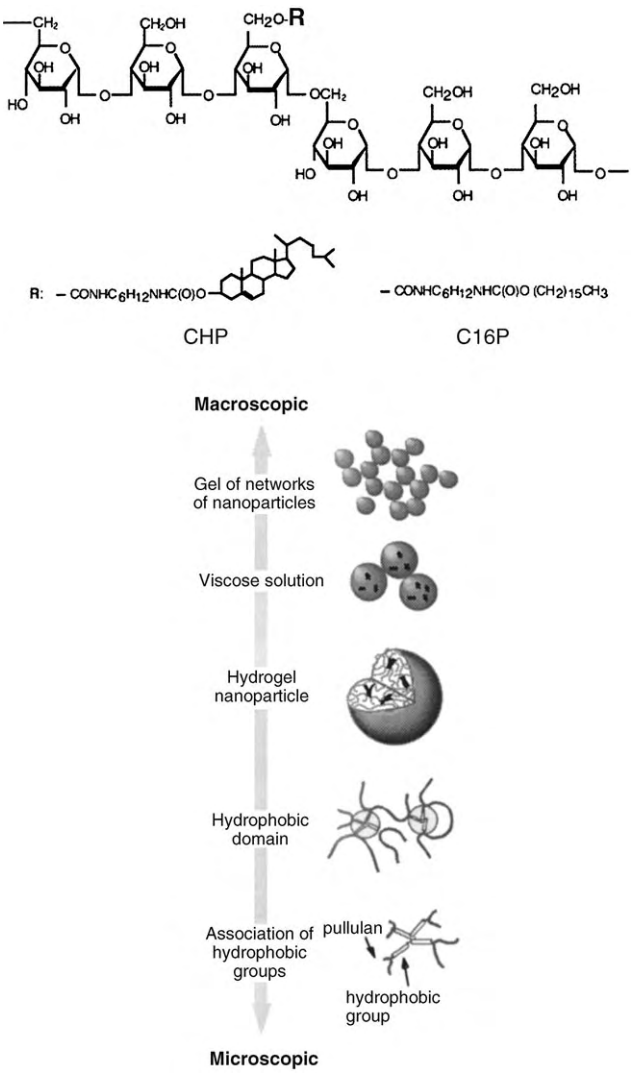

Figure 14. Chemical structure and the hierarchical self-assembly of hydrophobically modified pullulan. Reprinted with permission from ref. [142].

2.4. Post-Polymerization Modification of Hydrogels

For certain applications not all of the desired hydrogel functional groups can be added during the polymerization step. There are several reasons for this: the desired functional groups may not be stable during the polymerization step or the molecules are simply not polymerizable. This situation is true for most biomolecular structures from which hybrid gels would be prepared. To allow further functionalization of hydrogels, most often a small amount of comonomer with acidic or basic functional groups is copolymerized during the polymerization step. These functional groups are then used for the attachment of molecules that could not be directly incorporated by polymerization. This particular class of syntheses encompasses a large variety of particles, of which only a few will be mentioned in this Review.

We have created photoresponsive microgels by post-polymerization modification.[143] An amine comonomer was copolymerized in the pNIPAm microgels. This amine group was then used for attaching malachite green isothiocyanate to the microgels. Malachite green is a temperature-jump dye molecule that converts light ($\lambda_{max}^{abs} = 620$ nm) to thermal energy by nonradiative relaxation. Since the polymer is thermoresponsive, the microgels undergo deswelling when irradiated with a HeNe laser. Photoresponsive microgels exhibit dye-concentration dependent deswelling, that is, for the same laser intensity, microgels having higher concentration of malachite green deswell to a larger extent than microgels with lower concentration of the dye.

The Kawaguchi group has used post-polymerization modifications extensively for making particles with variety

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

of functions.[144] For example, to synthesize a tetra-functional particle, they first synthesized standard microgels using acrylamide, BIS, methacrylic acid, and *p*-nitrophenyl acrylate as the co-monomers. The thus introduced ester side chain can be hydrolyzed to give acidic particles, or after hydrolysis can be treated with ethylene diamine to give amphoteric particles. The acid groups were also coupled with a long-chain alkyl amine to form hydrophobic particles. Finally the acid groups were coupled to an immunoglobulin G (IgG) to form bio-functionalized microgels. This particular example illustrates the tremendous versatility in microgel structure and function that is offered by post-polymerization modification.

Another interesting system involved the synthesis of pNIPAm chains bearing terminal carboxyl groups, which were then grafted to microgels. Some of the carboxy termini were then used to attach the enzyme trypsin, resulting in a particle having two different kinds of pNIPAm chains on the surface; one with trypsin and the other without it. Surprisingly, it was found that the two chains had different transition temperatures. The free chains collapsed at a lower temperature than the trypsin-conjugated chains, thereby exposing the enzyme for substrate binding. Hence by this simple construct it was possible to control the enzyme activity by controlling the temperature (Figure 15).[145]

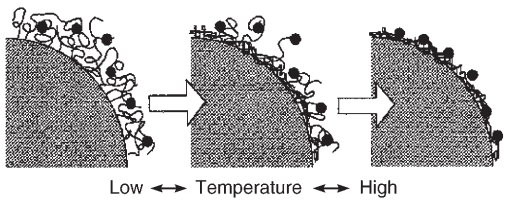

Figure 15. Changes in the surface of the particle conjugated with two different types of pNIPAm chains (filled circles depict the enzyme trypsin) with temperature. These types of phase transitions enable thermally modulated enzyme activity. Reprinted with permission from ref. [145].

Delair, et al. described the immobilization of DNA on microgels by post-polymerization modification. PNIPAm microgels with an amine comonomer were synthesized. Single-stranded DNA with an amine group at the 5′-end was treated with 1,4-phenylene diisocyanate in 1:2 ratio so that one of the isocyanates was coupled to the DNA, while the other one remained free. After purification, the DNA was coupled to the pNIPAm microgels by allowing the free isocyanate to react with the amines on the surface of the particles. The DNA particles were then used for detection of viral DNA and also for formation of two-dimensional arrays on planar substrates.[146]

Post-polymerization modification can not only be used for coupling biomolecules but also for grafting synthetic polymer chains. Hu et al. synthesized pNIPAm microgels and grafted pNIPAm chains on these particles by reversible addition fragmentation chain transfer (RAFT).[147] They then used these particles to study the thermal behavior of the grafted polymer. In another example Hu and Wu grafted PEO chains onto the microgel particles. The hydrophilic PEO chains were observed to stretch from the particle surface as the particles size decreased with increasing temperature.[148]

3. Hydrogel Particles in Nanotechnology

The synthetic methods described in the previous Sections have enabled the field to advance towards the application of hydrogel nano- and microparticles in more complex biotechnology and nanotechnology applications. In this Section, we will describe some of these applications, highlighting systems where the ability to create synthetically and topologically complex hydrogels has led to successful incorporation into advanced nanosystems.

3.1. Drug and Gene Delivery

Recently, significant efforts have been put into devising colloidal drug carriers. It has been hypothesized that an actively targeted particulate drug carrier will increase the therapeutic efficacy of a drug by delivering that drug to the diseased site, while also reducing systemic side-effects of the drug. An ideal drug carrier should be able to target and deliver only to the diseased sites, it should not induce immune response, and it should be degradable and produce nontoxic degradation products.[149]

The particulate carriers that have been most widely studied are liposomes and polymer nanoparticles. Liposomal drug carriers have been studied extensively, and a few liposomal formulations are currently available in the market, while many others are in the development "pipeline". One important drawback of liposomes is payload leakage. Since the boundary of the liposomes is a simple lipid bilayer, performance can be hampered by passive diffusion of drugs across that boundary.[150]

Among polymer particles, the most widely studied are poly(lactic acid-*co*-glycolic acid) (PLGA) particles.[151] The popularity of this material largely stems from its degradation into nontoxic by-products, which can be removed from the body by the renal system. However, this construct suffers from numerous drawbacks, as it is a very hydrophobic, immunogenic polymer with acidic degradation products. The increase in acidity associated with polymer degradation can induce nonspecific inflammatory responses, which can be very detrimental in targeted delivery applications. Non-viral gene-delivery systems have been proposed as a safer alternative to viral vectors, since they will induce host immune response to a lesser extent than viral vectors. Several cationic polymers, such as polyethyleneimine, polyamidoamine, and polylysine, have been used for non-viral gene delivery, but they all lack the biocompatibility needed for in vivo use.[152] Conversely, hydrogel nanoparticles, are a potentially useful class of materials in drug-/gene-carrier systems, but have been studied much less extensively. Herein we report a few examples of recent efforts involving nanoparticulate hydrogel delivery vehicles.

In an effort to employ naturally occurring polymers as delivery vehicles, Wang and Wu used agarose gel particles for

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

protein delivery.[153] A model protein, ovalbumin was encapsulated in approximately 500-nm diameter, spherical agarose gel particles. After protein loading, it was demonstrated that the particles released ovalbumin in a temperature-dependent fashion, where the rate of protein release was higher at elevated temperatures. This effect is due to the higher swellability of agarose at higher temperature, which facilitates mass transport.

Another example of protein delivery was reported by Li et al.,[154] who demonstrated that poly(vinyl alcohol) hydrogel nanoparticles could be used for this application. These particles were prepared by an emulsion technique without incorporating any cross-linker. The model protein, bovine serum albumin (BSA) was incorporated during the particle formation. As with the previous example, the rate of release of BSA increased with temperature. The authors attribute this behavior to the decrease in the number of cross-links in the polymer network at higher temperature, thereby making the gel more "open" for the transport of BSA. Using this methodology, they were able to demonstrate release of BSA over 30 h.

Biodegradable hydrogel nanoparticles have been prepared by Kim et al. using glycidyl methacrylate dextran as the major comonomer and dimethacrylate poly(ethylene glycol) as a covalent cross-linker.[155] In this case, the particles were prepared by free-radical polymerization and a hydrophobic drug, clonazepam, was then loaded in the particles. It was found that the release rate was dependent on the pH value as well as the concentration of the enzyme dextranase, which degraded the dextran and eroded the particles.

Na and Bae have used self-assembled hydrogel particles of pullulan acetate and sulfonamide conjugates to study the release of the drug adriamycin.[156] In this case the pullulans had a pH-responsive polymer incorporated into their structure, which caused the particles to shrink and aggregate at $pH < 7$. The shrinking of the particles in turn caused the expulsion of the drug into the surrounding medium.

An interesting example of the controlled release of a drug from a microgel comes from Needham et al.[157] They used approximately 6.5-μm diameter methacrylic acid microgels as a matrix for drug encapsulation and release. While these particles are by no means in the nanoscale-range, they illustrate an interesting concept that could be extended to the nanoscale. Under conditions where the particles are deprotonated, and hence swollen (as a result of Coulombic repulsion between the negatively charged regions), the particles could be loaded with the anticancer drug doxorubicin. Upon reducing the pH value of the medium below the acid pK_a, the particles condensed. To prevent leakage of the drug from the polymer, the particles were then coated with a lipid bilayer. These lipid-coated particles were then suspended in a medium of $pH > pK_a$. Surprisingly, no gel swelling was observed and hence no drug was observed to leak from the construct. To release the drug, a series of voltage pulses was applied to electromechanically disrupt the bilayer and cause the swelling of the particle. Thus, it was illustrated that the drug could be protected and then be released on demand using a subtle stimulus. The concept is illustrated in Figure 16.

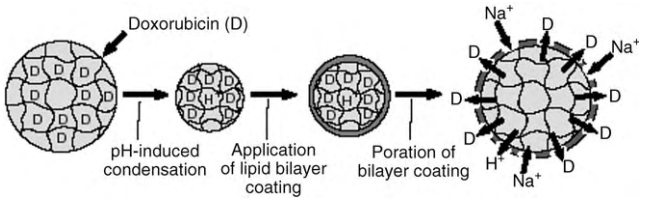

Figure 16. Loading and release of doxorubicin from lipid-coated microgels. Reprinted with permission from ref. [157], Copyright 1998 Macmillan Magazines Limited.

A similar example was published by Moore and coworkers. Again, in this example the polymer constructs are not at the nanoscale level but nonetheless provide an interesting concept.[158] A pH-sensitive gel was photopolymerized in a cylindrical shape. The gel was fabricated from 2-hydroxyethyl methacrylate, acrylic acid, and ethyleneglycol dimethacrylate. Palmitoyl chloride was then covalently bound to the surface of the gel. This modification of the gel created an ion barrier that enabled the pH-sensitive gel to remain in a condensed state even in media with a high pH value. Only when this barrier was disrupted by a surfactant did the gel swell (Figure 17). The ability of the fatty acid layer to maintain a sharp chemical gradient is analogous to the function of a cell membrane and shows the promise of creating highly non-equilibrium systems from well-designed nanomaterials.

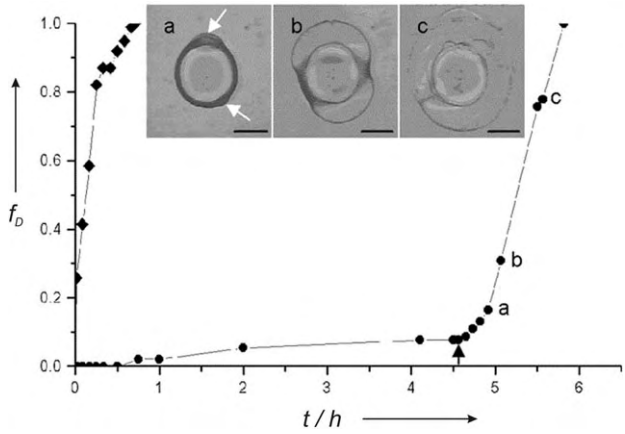

Figure 17. Lipid-modified pH-responsive gels. When the lipid-modified gel (●) is exposed to a buffer solution at pH 12, it resists swelling for a significant time, whereas the unmodified gel swells immediately (◆). The photographs show the effect of SDS on the lipid–modified gel in pH 12 buffer. The arrows indicate the points at which instabilities are first observed; swelling propagates from these points. The scale bar is 250 μm. Reprinted with permission from ref. [158].

While the previous examples were simple demonstrations of ex vivo controlled release from hydrogel particles, others have applied nanoparticulate hydrogels to in vivo delivery. For example, Hsiue et al. have used pNIPAm nanoparticles for ocular delivery.[159] Two formulations were used, one was composed of a solution of linear pNIPAm, the other was a mixture of linear pNIPAm and pNIPAm particles. The drug-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

release and cytotoxicity studies were carried out on rabbits. The drug epinephrine, which reduces intraocular pressure, was then delivered from each of the two formulations. It was observed that the intraocular pressure was decreased for around 24 h when the linear pNIPAm system was used, while the mixed system extended the therapeutic effect to about 32 h. Systems such as these are therefore potentially interesting for the clinical treatment of glaucoma.

As mentioned above, an ideal drug carrier should not induce an immune response in the host. This property is commonly achieved by making the surface of the particle hydrophilic, which can prevent opsonization (i.e. adhesion enhanced phagocytosis) by macrophages.[160] For example, Gaur et al. synthesized cross-linked poly(vinylpyrrolidine) hydrogel nanoparticles ($\approx$100 nm diameter).[161] The surface of these particles was then made hydrophilic by attaching poloxamers and poloxamines, which are PEG/poly(propylene glycol) block copolymers. In vivo studies in mice indicated that less than 1% of the dose was retained by the macrophages in the liver, and even after 8 h of injection around 5–10% of these particles were still circulating in the vasculature. This enhanced circulation time, and the lack of liver accumulation, could enable the use of such particles in drug delivery. They also reported that an increase in size and hydrophobicity of the particles increased the uptake by reticulo-endothelial system, suggesting that both factors may play a role in the ability of the body's defense mechanisms to recognize the particles as foreign invaders.

Targeting is an important property for a drug carrier, as potentially, the uptake and retention of the nano-carrier at the site of disease can be enhanced by active targeting. We have synthesized a folic acid labeled pNIPAm core–shell microgel that can target cancer cells.[162] Folic acid is a well known ligand for targeting cancer cells because most tumors overexpress folate receptors. In this demonstration, pNIPAm core–shell hydrogel particles were synthesized, in which the pNIPAm core was fluorescently labeled and the pNIPAm shell contained a small amount of a comonomer containing a primary amine. We then covalently coupled folic acid to the amine-containing hydrogel shell to localize the targeting ligand on the shell surface. When these particles were incubated with cancer cells that were overexpressing the folate receptor, the hydrogel nanoparticles were taken up by receptor-mediated endocytosis (Figure 18). It was also observed that the particles exhibited thermal cytotoxicity above the phase-transition temperature. The exact reason for this effect is not known but is suspected to be intracellular aggregation and protein adsorption onto the deswollen, hydrophobic pNIPAm particles. Since these particles apparently retain their thermoresponsivity in the cytosol, it was hypothesized that they could enable thermally triggered delivery of chemotherapeutic payloads, thereby enabling both active targeting and triggered delivery in one vehicle.

In another example of active targeting, Choi et al. used pNIPAm microgels for targeting liver cells.[163] They used pNIPAm-*co*-acrylic acid microgels that were tagged with fluorescein, while the targeting moiety in this case was galactose, which is a ligand for asialoglycoproteins. Through this ligand–receptor interaction the galactosylated microgels

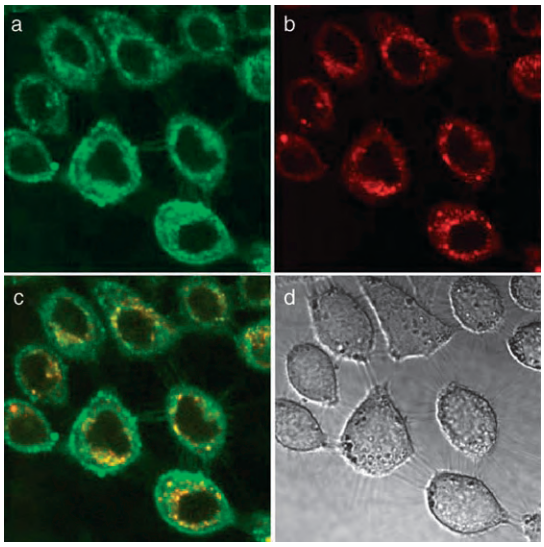

Figure 18. Confocal images of HeLa cells incubated with folate-conjugated nanoparticles. a) Green-fluorescent particle channel, b) lysotracker red-dye channel, c) overlap of both the channels and d) transmittance image of the cells. Experiments performed in collaboration with Jean Chmielewski at Purdue University.

were internalized in the cells. Furthermore, because these particles are thermoresponsive, their temperature-dependent uptake was studied. The uptake efficiency increased with the increase in temperature, which was suggested to arise from the enhanced uptake efficiency of smaller particles, although the increase in particle hydrophobicity could also enhance uptake. The Wooley group has investigated SCKs with targeting ligands such as folic acid, integrins, and peptides.[164–166] They have also demonstrated that nanoparticles coupled with a short peptide belonging to the protein transduction domain of HIV exhibited targeting ability for CHO and HeLa cell lines.

Synthetic–viral composite systems have also been explored. For example, Jana et al. prepared poly(vinylpyrrolidone) nanoparticles and encapsulated them in a reconstituted Sendai viral envelope containing only the fusion proteins.[167] These particles were incubated with human hepatoblastoma cell lines, which resulted in internalization of the polymer particles, as confirmed by fluorescence spectroscopy. Na et al. have used self-assembled polysaccharide (curdlan) particles for targeting.[168] Curdlan was hydrophobically modified with a carboxylated sulfonylurea derivative. The targeting ligand was lactobionic acid, which targets HepG2 cells. As expected, the degree of nontargeted uptake was significantly diminished relative to that for particles targeted to HepG2 cells.

Many groups have used cationic polymers, such as chitosan, for gene delivery. Chitosan is a natural cationic polysaccharide consisting of D-glucosamine and *N*-acetyl-D-glucosamine. This polymer has been shown to be biocompatible, non-immunogenic, and degradable, thereby making it potentially suitable as a delivery vehicle. In the presence of polyanions, chitosan can form hydrogel nanoparticles by complex coacervation. For example, chitosan–DNA nano-

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

particles have been widely studied for their application in gene delivery.[152] Targeting agents, such as transferrin, have also been conjugated to these particles to increase the internalization, while drugs such as chloroquine have been encapsulated within these particles to investigate controlled release. Mitra et al. have used chitosan to encapsulate doxorubicin, a highly toxic chemotherapeutic drug.[169] For encapsulation they first conjugated doxorubicin with dextran. This drug–dextran conjugate readily formed particles when mixed with chitosan. In vivo studies then showed that the chitosan–drug conjugate circulated in the blood longer and decreased the size of tumor to a larger extent than the free drug.

We have developed a technique to fabricate microgel thin films, which can potentially be used as drug-delivery implant devices.[85] The films are made by assembling charged microgels on a surface by a traditional layer-by-layer approach.[170] The microgels incorporated in these films retain their pH- and thermoresponsive properties.[83,85] In one example, we have loaded the microgels with insulin before assembling them into films.[82] The films then release insulin when subjected to a temperature above the microgel VPTT. The data shown in Figure 19 illustrate that this release can be thermally modu-

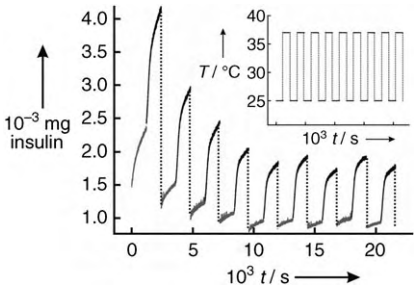

Figure 19. Insulin release during each thermal pulsing of 30-layer microgel film. Inset: the time–temperature wave form used for temperature modulation. The *x*-axis of the inset is identical to that of the main panel.

lated by alternating between heating and cooling cycles. Such films were extremely stable over extended periods of continuous thermal cycling. In addition to the release of macromolecules, these films have also been used for releasing small drug molecules such as doxorubicin.[84] Unlike in the insulin case, these films were first fabricated and then loaded with doxorubicin by thermal cycling. Similar results were obtained for the doxorubicin loaded films, where film deswelling resulted in the expulsion of the drug over many thermal cycles. These initial experiments provide a basis for creating constructs that can release therapeutic agents in a pulsed fashion when prodded by an external signal.

3.2. Encapsulation and Microreactors

The large internal free volume and hydrophilicity of hydrogels makes them useful in encapsulation of various species, such as DNA, RNA, small molecules, and proteins. When encapsulated, the hydrogel network can protect these species or release them in a controlled manner, as discussed in section 3.1. In this Section we will discuss the encapsulating property of microgels for applications other than drug delivery.

It has been observed that mass-transport rates of small molecules in hydrogels depend on the pore size, where larger pore sizes make it easier for the molecules to diffuse in the gel. In case of thermoresponsive microgels, a temperature-dependent diffusion is observed. At $T < \mathrm{VPTT}$ higher diffusion rates are observed than at $T > \mathrm{VPTT}$, owing to a decrease in the pore size of the polymer network at higher temperatures. Also, the charge on the polymer network is an important parameter, because it is easier to encapsulate molecules that are oppositely charged with respect to the polymer. In addition, a hydrophobic polymer network will enhance the encapsulation of a hydrophobic moiety.

Akiyoshi et al. have used cholesterol-bearing pullulans to encapsulate various proteins and peptides, for example, insulin, for which they observed the conformational stability of the macromolecule using circular dichroism (CD) spectroscopy.[139,140] No spontaneous release of insulin was observed from the nanoparticle, suggesting a very strong complexation in the macromolecular assembly. They observed that free insulin aggregated when subjected to heating but the encapsulated protein resisted such aggregation. They further studied the insulin stability against α-chymotrypsin activity, which degrades insulin. The pullulan-insulin complex resisted degradation to a much larger extent than the free insulin. Hence this system can potentially be used for the protection of the species of interest. Similarly, pullulans have been used as molecular chaperones for an enzyme.[141] Carbonic anhydrase B is an enzyme that denatures and aggregates at high temperature. The enzyme, in its denatured state, was complexed with the pullulans. The complex was cooled and the enzyme was released from the particles. The enzyme refolded in its native state and again became active.

SCKs have also been used for encapsulation and release of various entities. Murthy et al. have synthesized a polystyrene-*b*-poly(acrylic acid) SCK which has a thermally labile linkage at the core–shell interface.[136] After self-assembly and cross-linking of the shell, the particles were heated to 125 °C, which cleaved the bond between the polystyrene block and the poly(acrylic acid) block. The resulting release of the hydrophobic polystyrene chains occurred as a function of the cross-link density in the shell, with more heavily cross-linked shells releasing a smaller amount of hydrophobic polymer. In a further study, SCK particles were fabricated with poly(ε-caprolactone)-*b*-poly(acrylic acid).[129] Poly(ε-caprolactone) is a semicrystalline polymer with a lamellar lattice structure. In this case it was observed that at room temperature the core crystallizes and forces the particle to adopt a disc-shaped structure, which was confirmed by AFM. When the particles were heated above the melting point of the crystal, the particles adopted a spherical structure. Hence by using this novel construct it was possible to study the crystallization of poly(ε-caprolactone) in a confined system. SCKs have also been used to package DNA and thus offer protection against enzymatic degradation.[171]

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Soft nanomaterials have potential for being used as reaction vessels, which can then control the volume in which a specific reaction can take place. Liu et al. reported the use of self-assembled triblock copolymers, which they refer as shell cross-linked micelles, for preparation of gold nanoparticles.[172] The block copolymer that they used was composed of poly(ethylene oxide)-*b*-poly(glycerol monomethacrylate)-*b*-poly(diethylamino)ethyl methacrylate (PEO-GMA-DEA) as well as a second version in which the middle block was replaced by hydroxyethyl methacrylate (PEO-HEMA-DEA). These triblock copolymers form "onion like" micelles, where the core is made of DEA, the middle shell is of HEMA/GMA, and the outer shell is of PEO. After micellization, the middle shell was cross-linked with divinyl sulfone to make the structure stable. The DEA in the core was protonated by $HAuCl_4$ and subsequent in situ reduction of Au^{III} to Au^0 using $NaBH_4$. The mean size of the resultant gold nanoparticles was around 1–5 nm. The gold particles formed were not very monodisperse since each "nanoreactor" contained several gold particles and also the size was not controllable. This technique has one main advantage, that the dimensions of the nanoreactors are preserved during the reduction step as a result of the cross-linked shell. Zhang et al. have also synthesized inorganic nanoparticles in microgels.[173] They used pNIPAm-*co*-acrylic acid-*co*-2-hydroxyethyl acrylate microgels cross-linked with BIS. First the acid groups were deprotonated at high pH value and then, depending upon the type of nanoparticles desired, different precursor cations were introduced into the microgels. Three different types of nanoparticles were synthesized within the microgel matrix: CdS (a solution of Na_2S was added to a Cd^{2+}/microgel solution), Ag (an Ag^+/microgel solution was reduced by $NaBH_4$), and Fe_3O_4 (an aqueous Fe^{2+}/microgel solution was oxidized by $NaNO_2$). Most importantly, the size and polydispersity of the nanoparticles could be controlled by controlling the composition and the structure of the microgels.

3.3. Analytical Applications

Given the ability to synthesize a variety of responsive hydrogel structures, chemical and biological sensing applications remains an intriguing application. One of the earliest types of hydrogel nanoparticle employed in "sensing" was a pH-responsive particle. The simplest method of fabrication involves the use of a pH-responsive moiety, such as a weak acid, which can be copolymerized into the polymer network. At low pH value, the acid groups are protonated and the particles will be in a somewhat condensed form, while at a higher pH values at which the acid groups are deprotonated, the particles adopt a swollen structure because of Coulombic repulsion among the negatively charged regions and a change in the free energy of mixing with water. Similarly, charged microgels are responsive to ionic strength, where an oppositely charged ion neutralizes the charge and causes the gel to shrink. Similar approaches have enabled the fabrication of cross-linked block copolymer micelles that are pH-responsive. Although this approach appears to be a generalizable motif by which it is possible to imagine designing hydrogel nanoparticles that "sense" their surroundings, very little else has been done on creating hydrogel nanoparticles for real chemical-sensing applications. However, a few examples are beginning to emerge. For example, we have demonstrated that hydrogel microstructures can be rendered sensitive to protein binding, provided the interaction is multivalent and therefore results in an increase in the microgel cross-link density.[40] This approach has the potential to be extended to reversible biosensors based on antibody–antigen displacement or competitive binding. New methods for glucose sensing based on shell-restricted swelling in core–shell microgels are also currently under development.[174] It is clear that numerous opportunities exist for the design of new bioresponsive structures, and given the current focus on extending the complexity of hydrogel-nanoparticle architectures, more studies of this type can be expected in the near future.

In addition to these sensing applications, microgels have been used for the separation of proteins from complex media. Kawaguchi et al. reported that proteins could be separated using thermoresponsive microgels.[145] They used regular pNIPAm microgels and observed that at $T >$ VPTT larger amounts of protein bound to the particles than at $T <$ VPTT. The higher degree of protein adsorption at $T >$ VPTT was attributed to the hydrophobic interaction between the protein and dehydrated polymer. In an approach that utilized Coulombic interactions, Elaissari et al. used cationically charged pNIPAm microgels for the extraction of RNA. It was observed that the interaction between the cationic particles and negatively charged RNA decreased with an increase in pH value, ionic strength, or temperature, thereby indicating that adsorption was mainly governed by electrostatics.[175] In an immunoseparation study, Kondo et al. synthesized poly(styrene/NIPAm/glycidyl methacrylate) microgels. These particles were designed so that they flocculated at high temperature and at high ionic strength. Using the glycidyl methacrylate comonomer as a chemical handle for chemoligation, BSA was coupled to the particles, which were then used for the immunoseparation of anti-BSA from serum. After incubation with the serum, the particles were separated by flocculation.[176] Similarly, particles that contained magnetite were used for separation and purification, the particles could be collected by using a magnetic field.[177]

Stimuli-sensitive microgels can also be envisioned for applications in which the partition coefficient of a solute can be tuned over a wide range. For example, Kanzawa and coworkers have used the thermoresponsive properties of pNIPAm in chromatography for the separation of variety of compounds, such as steroids, peptides and proteins. Their construct uses silica particles, to which pNIPAm is grafted. These particles are an interesting stationary phase in chromatography, as the partition coefficient of a solute between the mobile and stationary phase should be strongly temperature dependent. Below the pNIPAm LCST, the particles are considered to behave as a normal, hydrophilic chromatography phase, while above the LCST, the particles should act as a hydrophobic reversed phase. The relative hydrophobicity of the polymer and the LCST can be further changed by incorporating other copolymers. Figure 20 shows chromato-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

grams for separation of steroids with respect to increasing the hydrophobic content of the stationary phase. Using these methods, it has been possible to increase the number of theoretical plates in separations of a wide range of analytes by running temperature gradients as opposed to the standard solvent-composition gradients that are the norm in most HPLC methods.[178–180] Doherty et al. have used nanogels in capillary electrophoresis (CE) based separation of DNA.[181,182] Currently CE is widely used for high-throughput DNA sequencing, in which polyacrylamide solutions are the most common sieving matrix. In the case of nanogel-based matrices, inverse emulsion polymerization was used to synthesize materials of the desired size and cross-linker concentration. These particles were synthesized from acrylamide and a small amount of BIS to obtain sparsely cross-linked networks. These nanogels were used for both conventional capillary electrophoresis and chip-based electrophoresis. In both cases they gave better selectivity and longer read lengths for single-stranded DNA than that obtained with conventional matrices.

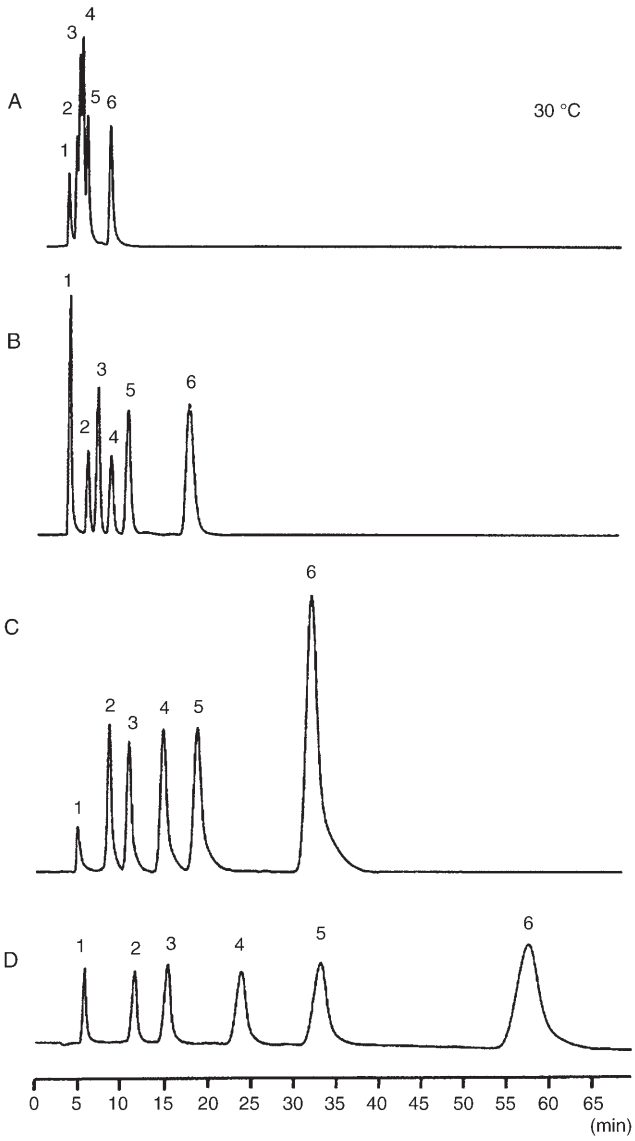

Figure 20. HPLC separations of steroid mixtures using a column packed with particles having thermally tunable hydrophobicities. The hydrogel hydrophobicity increases from A to D. The chromatograms indicate that a higher hydrophobicity results in a better separation under these mobile-phase conditions. Reprinted with permission from ref. [178].

Hydrogel nanoparticles have also been employed in a molecularly imprinted polymer (MIP) scheme. The principle behind MIP is based on both shape and molecular-recognition templating. When the polymerization is carried out in the presence of "template" molecules, it is envisioned that the polymer will rigidify around that template, forming a cavity that is optimized for binding that molecule. After the templates are removed, it is hoped that the cavity retains its shape and is able to bind and detect that particular molecule or similar molecules in a complex mixture. Ye et al. have synthesized hydrogel nanoparticles in the presence of theophylline and 17-β-estradiol. The sensing molecules were dissolved in the mixture of methacrylic acid and trimethylolpropane trimethacrylate ($[H_2C{=}C(CH_3)CO_2CH_2]_3CC_2H_5$) and then polymerized either thermally or by UV irradiation. In these studies radio ligand binding analysis was used to determine the sensitivity and selectivity of analyte binding.[183] Competition binding experiments showed high selectivity for the analyte.

In an attempt to couple simple optical interrogation of microgel behavior with responsive structures, we have developed a method to fabricate dynamically tunable microlenses that respond to light, temperature, pH value, and protein binding.[40,184–186] For this application, large (>1 micron) pNIPAm-*co*-acrylic acid particles were synthesized. These particles were then attached to a glass surface by electrostatic assembly. Since these microgels are soft, they deform upon attachment to the surface into planoconvex or hemispherical shapes. Because of the dual responsive nature of this simple polymer, the refractive index of the microgels can be controlled by temperature and pH value, where the more swollen form has a lower refractive index, with the index increasing as the gel becomes more condensed. Because of the specific shape of the microgels, the particles behave as planoconvex lenses, and the lens performance can be interrogated on a simple optical microscope (Figure 21).

In addition to these constructs we have also fabricated microlenses that respond to light.[184] In this experiment gold nanoparticles are assembled on the surface prior to attaching of the microgels. Gold nanoparticles can cause local heating when the surface plasmon modes are excited by a frequency-doubled Nd:YAG laser. We observed that only the region interrogated by the laser underwent phase transition (as a result of the local heating caused by the underlying gold-nanoparticle layer) and projected sharper images. The image quality was also controlled by the power of the laser, ambient temperature, and the pH value of the solution (Figure 22). Finally, microlenses with surface-localized ligands display dramatic changes in focal length upon protein binding, provided the protein–ligand interaction is a multivalent one.[40] This technique of fabricating microlens arrays is inexpensive, simple, and provides a method to interrogate

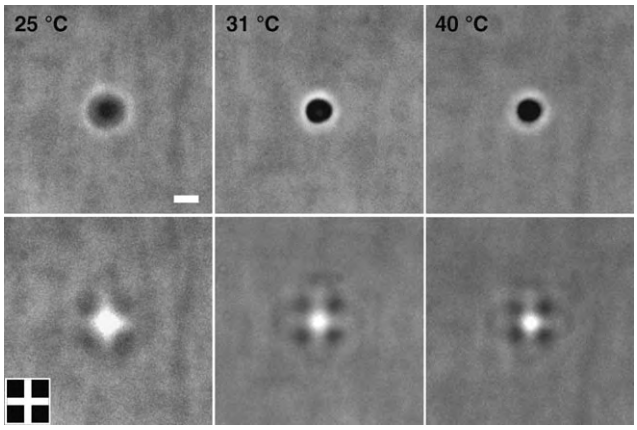

Figure 21. DIC microscopy images (top) of microgels on a glass substrate. The microgel acts as a microlens by projecting a cross pattern (bottom). The quality of the image improves with the increase in the temperature and concomitant gel deswelling. Reprinted with permission from ref. [186]

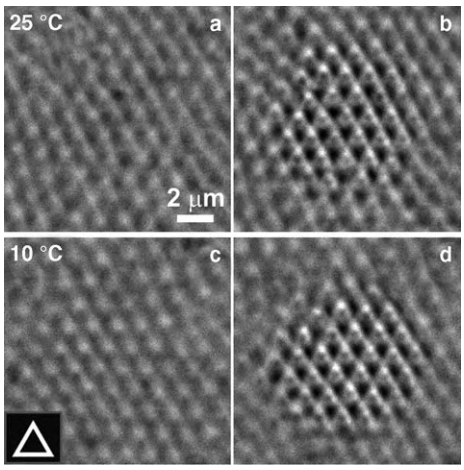

Figure 22. Photoswitching of a microlens array at 25 °C (a and b) and at 10 °C (c and d) as a function of laser power, where in the case of (b) and (d) the laser power is high enough to collapse the particles and thereby increase the microlens focusing power.[184]

single transducing elements, which makes it an attractive construct for various optical and sensing applications.

3.4. Biomaterials

Perhaps the broadest definition of biomaterials comes from the National Institutes of Health Consensus Development Conference: *"[a biomaterial is] any substance (other than a drug) or combination of substances, synthetic or natural in origin, which can be used for any period of time, as a whole or part of a system which treats, augments, or replaces any tissue, organ, or function of the body"*.[187] Research in the field of biomaterials is often linked to developing a more biocompatible system, such as making an implant or surgical device less damaging to the body. In case of hydrogels, much of the effort has been put in to coating the surface of the implants or devices with polymers or bulk gels. With the advent of responsive hydrogels, many researchers began working on making "smarter biomaterials", materials which can sense a change in the environment and respond in a programmed fashion to it. In this Section we describe a few of those examples pertaining specifically to hydrogel nanoparticles.

As mentioned previously, Kawaguchi and co-workers have studied the interaction of proteins with microgels extensively.[145,188,189] For example, the group has studied the effect of temperature on the nonspecific adsorption of proteins to thermoresponsive microgels. They have also investigated the activity of enzymes that are covalently bound to the microgels. In one example, trypsin peroxidase was attached to pNIPAm microgels and its activity was studied as a function of temperature.[190] The enzyme activity decreased with increasing temperature. This change was attributed to the decrease in the pore size which caused the decrease in the rate of diffusion of substrate to the enzyme. In a similar system with a small molecule (ubiquinone) attached to the particle, similar temperature-dependent results were obtained.

Duracher et al. have studied the adsorption of HIV-1 capsid protein p24 on polystyrene-core-pNIPAm-shell particles.[191] As predicted by numerous studies, at $T >$ VPTT of pNIPAm a higher adsorption was observed which was due to hydrophobic interactions. Similarly Urakami et al. studied the phagocytosis of polystyrene-*co*-polyacrylamide gel particles as a function of hydrophobicity. They observed that phagocytosis by granulocytes increased with the increase in polystyrene content of the particles, again presumably arising from an increase in hydrophobic association with the granulocyte.[192] In similar studies, Kimhi and Bianco-Peled used isothermal titration calorimetry (ITC) to study the adsorption of small molecules (aspartic acid and valine) to pNIPAm microgels as a function of temperature.[193] At 25 °C aspartic acid binds strongly to the polymer particles owing to the formation of hydrogen bonds, at 37 °C valine binds strongly because of the hydrophobic effect.

More advanced architectures can be prepared that take advantage of biocatalytic systems. For example, Ogawa et al. have synthesized pNIPAm microgels containing a pendant vinyl imidazole side-chain, which again allows for pH-tunable gel swelling.[38] The enzyme urease, which catalyses the hydrolysis of urea into ammonia, was then physically entrapped in the particles. As the enzyme produced ammonia, the pH value of the medium increased. Hence, in the presence of urea the particles shrank owing to the increase in pH value and subsequent deprotonation of the imidazole unit. When the substrate was removed, the particles swelled to their original size as the local pH value equilibrated with the pH value of the surrounding bath. To demonstrate the potential utility of such a biomechanical system, these particles were incorporated into a membrane. Upon introduction of urea to one of the solvent reservoirs, the permeability of the membrane increased as the particles shrank.

An important aspect of many implanted biomaterials relates to the ability of cells to adsorb and proliferate on the material surface. Even materials with low surface energies

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

and hence low degrees of non-specific protein adsorption can tend to foul over time in cell culture or after implantation. Hence, it is important to evaluate fouling of biomaterials as well as to arrive at new strategies for mediating cellular recruitment at synthetic surfaces. Thus, in addition to the aforementioned protein adsorption studies, Kawaguchi and co-workers have also studied the effect of cell binding to thermoresponsive particles on a solid surface.[145] pNIPAm microspheres were deposited on a plate to produce a 2D array upon which the cell culture medium was seeded. It was observed that the cells produced more reactive oxygen species at 37 °C than at 25 °C, indicating that the cells are under more mechanical stress at the higher temperature. This stress is presumably due to stronger attachment at $T > \mathrm{VPTT}$. It was also observed that the amount of reactive oxygen species produced when the system was heated from 25 °C to 37 °C was much higher than when just incubated at 37 °C. This result was attributed to the stimulus inflicted by the dynamic deswelling process. In addition to this system a ligand–receptor system was also used a to study the mechanical stress on the cells.[145]

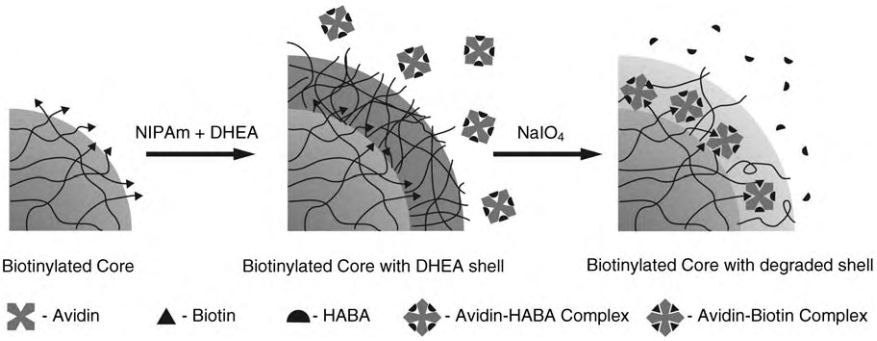

Figure 23. Permeation-selective core-shell microgels. The particles exhibit shell cross-linker-density dependent permeation of the protein.[195]

Our group has fabricated particles in which the adsorption of the proteins to the particles is reduced by using PEG grafting.[194] We used pNIPAm-core/pNIPAm-shell particles and attached PEG either to the core or to the shell by copolymerization of PEG-monomethacrylate. Reduced protein adsorption was observed for both the core- and shell-grafted PEG particles. NMR spectroscopy and protein adsorption measurements, showed that at high temperature the PEG chains phase separate to the particle surface, and because of the polymer's hydrophilicity reduce protein adsorption. For particles in which the PEG is attached to the core, the PEG chains are able to penetrate the shell and phase separate to the surface, thus reducing the surface energy of the deswollen particles.

In another example of core–shell particles that may have utility in biomaterials applications, we have prepared a system in which the shell acts a barrier between the protein in the solution and a core-localized ligand buried under the shell.[195] In this case we have synthesized a core to which biotin is attached, then added a shell containing a degradable cross-linker. Initially the cross-linker density is high enough that the pore sizes are smaller than the size of the protein avidin. As the cross-linker is degraded, the average pore size increases and allows permeation of avidin to the core, where it can bind to biotin (Figure 23). We have also observed protein-size-dependent permeation, that is, for larger proteins, more cross-links have to be degraded to allow for binding. These systems are interesting from the view of the topological complexity and also because they may be a model system for a particle that can "express" a particular functionality at the surface in response to a biological or chemical signal which disrupts shell-localized cross-links.

3.5. Colloidal Assemblies

Perhaps one of the most intriguing properties of monodispersed colloidal systems is their ability to form thermodynamically stable, ordered, periodic phases.[196] The most common of these phases is the cubic crystalline lattice observed in natural opal.[197,198] Synthetic colloidal crystals have potential applications in the field of diffractive optics, especially in the context of photonic band-gap structures.[199] Traditionally, hard sphere particles, such as silica or polystyrene beads, are used to form synthetic crystals. Recently, however a great deal of effort has been put into assembling crystals from soft colloidal precursors owing to their interesting phase behavior and the potential for creating dynamically tunable assemblies.[72–75,200–202]

Of particular interest is the potential for using microgel particles as colloidal model systems.[69,203–205] The Richtering group has extensively investigated the microgel phase diagram and has shown that deviations from hard-sphere behavior can be observed at high particle concentrations.[73,98,203,206,207] Furthermore, neutron-scattering studies have enabled the elucidation of the microgel network structure, and how that structure dictates the observed phase behavior.[207] Others have used computational methods to investigate how particle "softness" can change the effective interaction potential and the resultant phase diagram of both microgels[205,208,209] and star polymers.[210–214] Importantly, these calculations have revealed a potentially very rich phase behavior for soft colloids,[205,209,211,212] in contrast to the structures observed for hard spheres.[215]

Our group has worked intensively in the field of soft-sphere assembly, wherein we have developed methods for preparing colloidal crystals from thermoresponsive hydrogel particles. For an in-depth discussion of our work, see a recent review article on this subject.[200] One of the particular advantages of using thermoresponsive particles is that the volume phase transition allows assemblies to be annealed that have been formed by harsh methods, such as centrifugation.[72] In this fashion, it is possible to form crystals much more rapidly than those prepared by slow sedimentation of hard-sphere colloids. The thermoresponsivity of the particles has also been used to tune the Bragg peak of the crystals, both in a

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

dynamic sense, and also by controlling the temperature at which the particles are centrifuged.[216]

We have also studied the phase behavior of particles that display unusual, weak attractive interactions.[217] pNIPAm-*co*-acrylic acid particles were synthesized and assembled at various volume fractions. Owing to the soft nature of the particles it was possible to overpack the system so that the effective volume fraction was greater than 100%. It was also observed that, in comparison to the hard spheres, the crystals did not melt until very low volume fraction. This property arises from multibody attractive interactions that result from dipole–dipole and ion–dipole interactions. Images corresponding to such crystals at various stages of growth are shown in Figure 24.

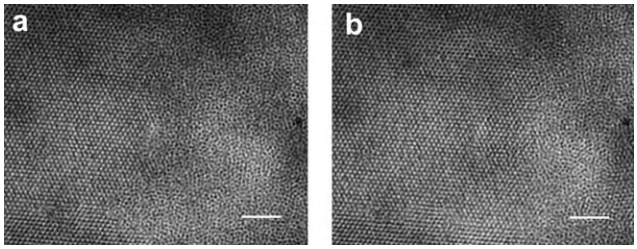

Figure 24. Growth process of weakly attractive hydrogel colloidal crystals as observed by differential interference contrast microscopy. Note that the effective particle volume fraction for this sample is approximately 40%. Panels (a) and (b) were acquired 5 minu apart; the progression of the crystal growth can be observed as the crystalline region extends further into the sample in panel (b). The scale bar is 20 μm. The unique phase behavior of these crystals is described in reference [217]. We thank Saet Byul Debord for supplying these images.

Composite colloidal crystals have also been made by incorporating gold nanoparticles, for photopatterning, into the system.[218] A frequency doubled Nd:YAG laser ($\lambda =$ 532 nm) was used to optically heat the system. In this fashion, it was possible to convert crystalline regions into glassy state (non-ordered state) and vice versa, by controlling the laser power and illumination times. Using this approach it was also possible to write patterns in the crystal assembly by a laser direct-writing approach.[219]

Asher and co-workers have fabricated polymerized colloidal crystal arrays from hydrogels for a number of applications. In one example they crystallized polystyrene beads and then polymerized the system using pNIPAm.[201] This system allows thermal tuning of Bragg diffraction, as the thermoresponsivity of the polymer chains is used to control the interparticle distance and hence the Bragg peak. These systems have also been used for detecting various analytes, where the polymer that connects the particles is responsive to the analyte and, in the presence of that analyte, causes a change in lattice spacing.[220] In one example boronic acid groups were incorporated into the crystalline array for glucose-sensing applications.[221]####Another example of polymerized colloidal crystal assembly was reported by Hu et al.[74] They synthesized two types of pNIPAm microgels, one had acrylic acid units and the other had 2-hydroxyethyl acrylate units. These nanoparticles were self-assembled to form crystals and then bonded together covalently using small linking molecules. For the acrylic acid particles epichlorohydrin was used for covalent bonding of the particles and for 2-hydroxyethyl acrylate particles divinylsulfone was used. These assemblies exhibited iridescent color patterns indicating that the particles assembled in a crystal phase. The covalent nature of the assembly provided stability to the crystal structure, which then enabled the color of the crystal to be tuned by temperature or an electric field.

4. Conclusions and Outlook

Towards the end of the last century, it was commonly thought that the term "nanotechnology" was coined exclusively for "hard materials" but this has changed as polymeric materials became more common ingredients in nanometric systems. Herein we have discussed various types of hydrogel nanoparticles and their applications in nanotechnology. As more and more research is carried out in this field, it becomes clearer that these materials hold great promise on their own, and as a bridge between more traditional nanostructures and biological systems. For example, gels that respond to a change in their environment are potentially useful in the context of truly bioresponsive structures that may enable natural systems to be manipulated in a rational fashion.

Although a great deal of research has been carried out in this field, we believe that most of the potential resources are untapped. There are opportunities for new efforts in advanced synthetic approaches to complex hydrogel nanomaterials, both in colloid synthesis (e.g. size and shape control) and in new chemoligation methods for controlled bioconjugate synthesis. The rational design of multifunctional architectures will be enabled by such efforts, thereby allowing the improvement of current applications, as well as the implementation of hydrogels in new arenas. In the case of core–shell particles reported by our group and others, the range of potential applications in which such materials can be used is just beginning to be uncovered. Early studies of the detailed structure–function relationships in hydrogel particles are now leading to the design of primitive applications-oriented nanomaterials. These proof-of-concept studies can then provide guidance for the synthesis of the second-generation of materials. In parallel, it will become increasingly important to perform detailed studies of cytotoxicity, immunogenicity, and pharamcokinetics, if these materials are to be employed in biotechnological applications. Finally, ground-level cooperation between chemists, biochemists, engineers, and clinicians is desired to enable the design, synthesis, and testing of structures that are truly applicable in clinical applications, such as drug-delivery devices, implantable biomaterials, biosensors/assays, and targeted chemotherapeutic formulations.

Transition-metal complexes are shown to act as ligands in the linking of Li_4O_4 cubane units. The organometallic complex $[(\eta^4\text{-quinone})Rh(cod)]^-$ is used to form a unique doubly bridged assembly, which incorporates a quinone oxygen atom at one corner of each cubane unit. For more information, see the Communication by D. A. Sweigart and co-workers on the following pages.

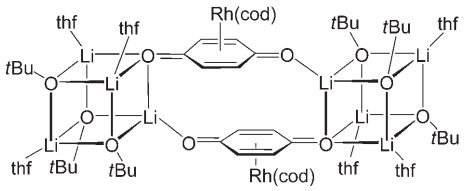
Lithium Alkoxide $\{Li_4O_4\}$ Cubanes Bridged by Rhodium–Quinonoid Organometalloligands**

*Seung Uk Son, Jeffrey A. Reingold, Sang Bok Kim, Gene B. Carpenter, and Dwight A. Sweigart**

Organolithium reagents with alkoxide and similar oxygen-donor ligands frequently aggregate in aprotic solvents into rectangular $\{Li_2O_2\}$ and cubic $\{Li_4O_4\}$ fragments.[1–3] Lithium $\{Li_4O_4\}$ cubane species are especially prevalent and have been extensively investigated because of the great importance of organolithium reagents in organic synthesis.[1–2] Herein, we report the synthesis and characterization of the novel lithium cubane aggregate **1**, which possesses two unprecedented features: 1) $\{Li_4O_4\}$ units that incorporate a quinone oxygen-donor atom at one of the corners and 2) $\{Li_4O_4\}$ units bridged by two rhodium $[(\eta^4\text{-benzoquinone})Rh(cod)]^-$ (cod = cyclooctadiene) organometalloligands.



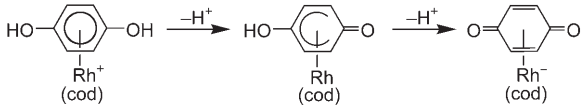
$[Li_4(OtBu)_3(thf)_3(\eta^4\text{-benzoquinone})Rh(cod)]_2$

1

It is known that Li_4O_4 cubanes can be linked or bridged by sharing a corner oxygen-donor atom. Bridged structures are also known in which the organic moiety attached to a cubane corner oxygen atom either covalently links to an oxygen atom in a second cubane or provides a donor atom that coordinates to a lithium corner in a second cubane. Examples of bridging units in these categories include carbonate and benzamide aza enolates.[4] Cubane fragments can also be linked together by "external" multifunctional donors that coordinate to two or more lithium corners.[4c,5] In these cases, the cubanes function as so-called secondary building units (SBUs) that self-assemble in the presence of multifunctional ligands or spacers to generate main-group metal-coordination networks. Spacers utilized in this manner include chloride, tetramethylethylenediamine (TMEDA), and *p*-dioxane.

Compound **1** reported herein is unique in that the bifunctional ligand that connects the cubane units is a transition-metal complex. As discussed below, it is likely that supramolecular structures analogous to **1** are accessible with a variety of transition-metal fragments.

The starting materials for the synthesis of **1** consisted of LiO*t*Bu in THF and the recently reported quinonoid complex $[(\eta^6\text{-hydroquinone})Rh(cod)]^+$ (**2**).[6] π-Coordination of a metal center to hydroquinone is known to greatly facilitate deprotonation, which is accompanied by electron transfer to the metal center and changes in the hapticity of the quinonoid ring.[6,7] In the case of **2**, neutral η^5-semiquinone and anionic η^4-quinone complexes **3** and **4**, respectively, are formed as shown in Scheme 1. π-Bonded quinone complexes analogous



Scheme 1. Deprotonation of a π-bonded rhodium–hydroquinone complex.

to **4** have already found significant applications in the catalysis of aldehyde arylation (rhodium as the metal) and in the formation of metal–organometallic coordination networks (manganese as the metal).[6,8] Herein, it is shown that the rhodium–quinone complex **4** reacts with LiO*t*Bu in THF to afford a novel structural motif in which a quinone oxygen atom functions as a pseudo butoxide ligand in a $\{Li_4O_4\}$ cubane unit, while the other quinone oxygen atom links to a lithium atom in a second companion cubane unit.

Deprotonation of **2** in THF at room temperature with a fivefold excess of LiO*t*Bu led to a homogeneous yellow solution that slowly deposited crystals of **1** when stored at −15 °C for a period of weeks. The X-ray structure of **1** is shown in Figure 1. Each of the two $\{Li_4O_4\}$ cubanes contains three butoxide oxygen atoms and one quinone oxygen atom. Three thf ligands and an "external" quinone oxygen atom complete the pseudo tetrahedral coordination at each cubane lithium center. The quinonoid ring in **1** adopts a boat conformation with the phenolic carbon atoms C1 and C4 bent out of the C2-C3-C5-C6 diene plane away from the rhodium center by 10 and 13°, respectively. As a consequence, the {Rh(cod)} fragment is only weakly bonded to C1 and C4, and the overall structure is perhaps best described as an η^4-quinone. The relatively short C1–O1 and C4–O2 bond lengths of 1.29 and 1.26 Å support this interpretation.

The Li–O bond lengths in **1** are all in the typical 1.8–2.0 Å range, except for Li1–O1 which is much larger at 2.36(2) Å.

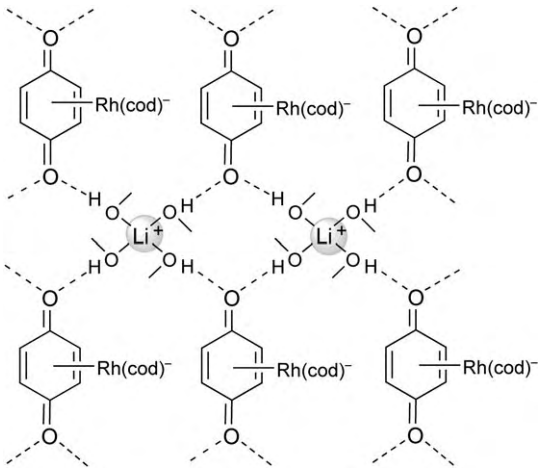

Figure 2. Hydrogen-bonding network in **5**.

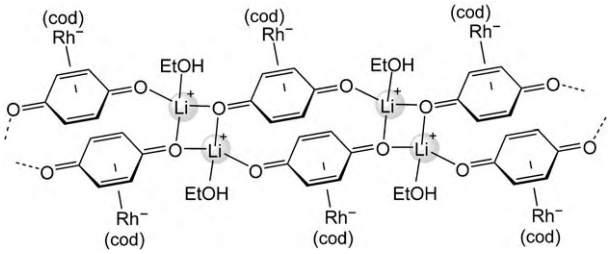

Figure 3. One-dimensional metal–organometallic coordination network **6**.

The consequence of the long Li1–O1 bond is that the O1 corner of the cubanes bends out of the O1-Li2-O50-Li3 face with a dihedral angle of 13°. The opposite face of the cubane, Li1-O30-Li4-O40, is planar to within 1°. The 13° bending of the cubane O1 corners effectively increases the separation of the two bridges from each other, which is probably the reason for the approximate 0.4-Å elongation of the Li1–O1 bond beyond that typically found in $\{Li_4O_4\}$ structures. The C1–O2 separation in **1** is just 3.1 Å, and the quinone rings partially eclipse, with a 3.2-Å ring-to-ring separation which indicates fairly strong π–π stacking interactions.[8,9] If the Li1–O1 bond length was similar to the others (ca. an average of 1.95 Å), the bridge-to-bridge separation would be greatly decreased, thus necessitating significantly different angles from those observed to avoid repulsive interactions between the bridges. In terms of the thermodynamic driving force, it is apparent that having a long Li1–O1 bond is the preferred compromise in the generation of the observed doubly bridged assembly.

To explore possible chemical processes relevant to the formation of **1**, a solution of complex **2** in THF with a fivefold excess of LiO*t*Bu was evaporated before any cubane dimer **1** had formed (one hour after mixing). The residue was washed with diethyl ether and THF. A portion of the residue dissolved in methanol afforded the salt $[Li(MeOH)_4][(\eta^4\text{-quinone})Rh(cod)]$ (**5**). The X-ray structure of **5** shows that it consists of the two-dimensional hydrogen-bonded network illustrated in Figure 2. The hydrogen bonds between the quinone oxygen atoms and the methanol ligands have average O···O distances of 2.63 Å.

The fundamentally different product **6** (Figure 3) was afforded by dissolution of the residue in ethanol instead of methanol. Complex **6** is a one-dimensional metal–organometallic coordination network (MOMN) containing rectangular $\{Li_2O_2\}$ units linked by anionic $[(\eta^4\text{-quinone})Rh(cod)]^-$ organometalloligand. Each lithium ion is bonded to three quinone oxygen atoms and one ethanol molecule. One quinone oxygen atom from each spacer molecule is bidentate and forms part of the $\{Li_2O_2\}$ ring, whereas the other oxygen atom is unidentate and propagates the network by coordinating "externally" to a lithium ion.

The X-ray structure of **6** shows that the $\{Li_2O_2\}$ rings are nearly square (internal angles: 84 and 96°) and the Li–O bond lengths average 1.94 Å, which is in the range found for most of the Li–O bonds in the cubane units in **1** (other than Li1–O1). The coordinated ethanol ligand in **6** is not hydrogen bonded. The addition of one equivalent of 1,1-bis(4-hydroxyphenyl)-methane to **6** in ethanol resulted in displacement of the quinone monodentate oxygen atom from the lithium ion and afforded the new two-dimensional network **7**, in which polymeric one-dimensional $\{Li_2O_2\}$ chains are linked through hydrogen-bonding interactions (Figure 4). The X-ray structures of **6** and **7** are given in the Supporting Information.

Having established the viability of $\{Li_4O_4\}$ and $\{Li_2O_2\}$ aggregates that incorporate a rhodium–η^4-quinone organometalloligand at a vertex, we next used NMR spectroscopy to probe any dynamic behavior that may occur. A solution of the slightly soluble cubane **1** in $[D_8]$THF gave no evidence for dynamic processes on the NMR timescale at room temperature. However, a solution of hydroquinone complex **2** in THF with ten equivalents of LiO*t*Bu, from which the **1** evolves over a period of days/weeks (see below), shows site exchange of the quinone hydrogen atoms in the deprotonated

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

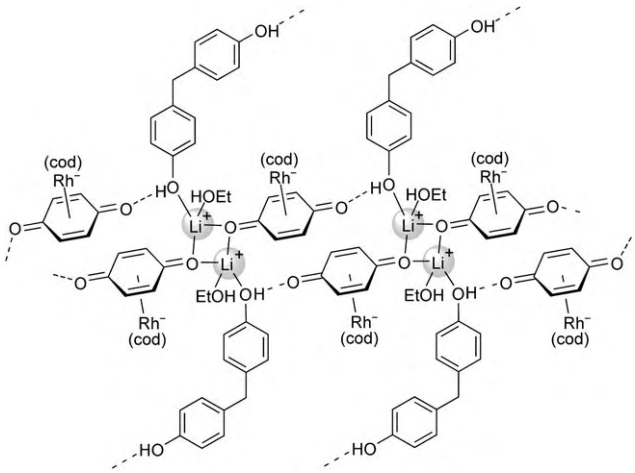

Figure 4. Two-dimensional metal–organometallic coordination network **7**.

complex $[(\eta^4\text{-benzoquinone})\text{Rh(cod)}]^-$, which is rapidly formed in situ according to Scheme 1. The NMR spectra of the quinone hydrogen atoms is illustrated in Figure 5 for the

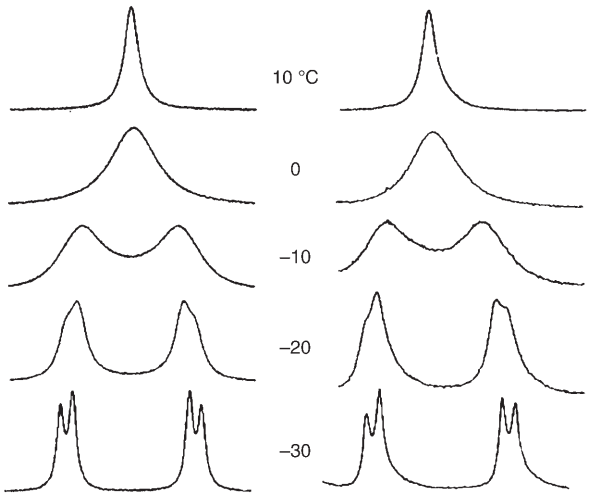

Figure 5. Simulated (left) and observed (right) ^{1}H NMR spectra of the quinone hydrogen atoms in a solution of $[(\eta^4\text{-benzoquinone})\text{Rh(cod)}]$ in $[D_8]$THF with excess LiO*t*Bu.

temperature range 10 to −30 °C. Simulations[10] of the observed two-site exchange process gave a very good fit to the Eyring equation, with the following activation parameters: $\Delta H^{\neq} = 84\ \text{kJ mol}^{-1}$ and $\Delta S^{\neq} = 110\ \text{J K}^{-1}\text{mol}^{-1}$. The process that occurs almost certainly involves differential lithium coordination to the quinone oxygen atoms, possibly as depicted in Figure 6. The ligands (L) likely include thf, although the butoxide groups may also be involved.

The actual exchange may be more complex than that illustrated, for example, species with a $\{Li_2O_2\}$ core may be present. The highly positive entropy of activation is suggestive of solvent loss in the transition state to give an activated complex such as that illustrated in Figure 6. Whatever the

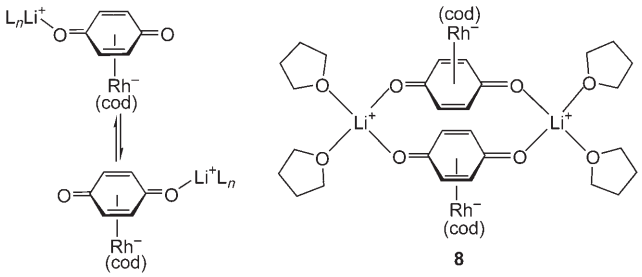

Figure 6. Dynamic coordination of the quinone oxygen atoms to lithium in a solution of THF, possibly via activated complex **8**.

specific details, the NMR behavior demonstrates that the quinone oxygen atoms can rapidly change their mode of coordination to the lithium centers in the species that exists prior to the formation of the cubane aggregate **1**.

In conclusion, it has been demonstrated that lithium alkoxide aggregates[11] can be synthesized that have two $\{Li_4O_4\}$ cubane units bridged by a quinone organometalloligand. The key to the construction of this discrete species, as well as related polymeric $\{Li_2O_2\}$ species, is the ability of the quinone oxygen atoms in $[(\eta^4\text{-quinone})\text{Rh(cod)}]^-$ to function as ligands, both as part of and external to the cubane aggregate itself. The methodology described herein should be readily extendable to anionic π-bonded quinone complexes of a variety of transition metals.

Experimental Section

All reactions were carried out under N_2 in flame-dried glassware. THF and diethyl ether solvents were HPLC grade. $[\{\text{RhCl(cod)}\}_2]$ was purchased from Strem Chemicals, Inc. The ^{1}H NMR spectra were recorded on a 300 MHz Bruker spectrometer. Elemental analyses were performed by Quantitative Technologies Inc. (New Jersey, USA).

$[\{Li_4(t\text{OBu})_3(\text{thf})_3(\eta^4\text{-benzoquinone})\text{Rh(cod)}\}_2]$ (**1**): $[(\eta^6\text{-hydroquinone})\text{Rh(cod)}]BF_4$ (**2**; 0.10 g, 0.25 mmol) in HPLC-grade THF (7 mL) was placed in a flame-dried 50-mL Schlenk flask and LiO*t*Bu (0.10 g, 1.25 mmol) was added with stirring at room temperature. A yellow precipitate of the neutral $[(\eta^5\text{-semiquinone})\text{Rh(cod)}]$ formed initially, but dissolved after addition of the base was complete. The homogeneous yellow solution was stirred for 1 h and placed in a refrigerator at −15 °C for several weeks, during which time yellow crystals of **1** formed in 68% yield of the isolated product (0.096 g, 0.085 mmol). ^{1}H NMR ($[D_8]$THF): $\delta = 5.64$ (d, $J = 7.0$ Hz, benzoquinone, 4H), 4.53 (d, $J = 6.9$ Hz, benzoquinone, 4H), 4.27 (br, cod, 8H), 2.25 (m, cod, 8H), 2.01 (m, cod, 8H), 1.15 ppm (s, *t*BuO, 54H). Washing **1** with THF and drying under vacuum produced **5**, which was characterized by NMR (see below) and elemental analysis ((%) calcd for $C_{14}O_2H_{16}Rh_1Li_1$: C 51.56, H 4.95; found: C 51.55, H 4.93).

Preliminaries for the synthesis of complexes **5**–**7**: **2** and LiO*t*Bu were combined as described above at room temperature, stirred for 1 h, and the solvent removed with a rotary evaporator. The residue was vacuum dried for 30 min, washed with diethyl ether, washed with THF, and dried again under vacuum. The residue, which contained an equivalent of $LiBF_4$, was obtained in 56% yield (0.057 g, 0.14 "mmol"). ^{1}H NMR ($[D_6]$DMSO): $\delta = 4.96$ (s, benzoquinone, 4H), 3.51 (br, cod, 4H), 2.20 (m, cod, 4H), 1.98 ppm (m, cod, 4H); elemental analysis (%) calcd for $C_{14}O_2H_{16}Rh_1Li_2B_1F_4$: C 40.05, H 3.84; found: C 40.04, H 4.17.

$[\text{Li(MeOH)}_4][\text{Rh}(\eta^4\text{-benzoquinone})(\text{cod})]$ (**5**): The residue described above (20 mg) was dissolved in methanol (1 mL), filtered

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

through a celite pad, and transferred to a 5-mL vial. THF (3 mL) was carefully added to this solution as a layer, and the solution placed in a refrigerator (−15 °C) for three weeks. The yellow crystals formed in a yield of 55 % (0.011 g). ^{1}H NMR (CD_3OD): $\delta = 5.61$ (s, benzoquinone ring, 4H), 3.94 (br, cod, 4H), 2.33 (m, cod, 4H), 2.08 ppm (m, cod, 4H); elemental analysis (%) after drying under vacuum calcd for $C_{14}O_2H_{16}Rh_1Li_1$: C 51.56, H 4.95; found: C 51.50, H 4.60.

[Li(EtOH)(η^4-benzoquinone)Rh(cod)] (**6**): The residue described above (25 mg) was dissolved in ethanol (2 mL), filtered through a celite pad, and transferred to a 5-mL vial. After standing for two weeks at room temperature, yellow crystals had formed and were collected in a yield of 90 % (0.023 g). ^{1}H NMR(CD_3OD): $\delta = 5.61$ (s, benzoquinone, 4H), 3.94 (br, cod, 4H), 3.59 (q, $J = 5.2$ Hz, EtOH, 2H), 2.33 (m, cod, 4H), 2.08 (m, cod, 4H), 1.16 ppm (t, $J = 5.2$ Hz, EtOH, 3H); elemental analysis (%) after drying under vacuum calcd for $C_{14}O_2H_{16}Rh_1Li_1$: C 51.56, H 4.95; found: C 51.45, H 5.15.

[Li(EtOH)(1,1-bis(4-hydroxyphenyl)methane)(η^4-benzoquinone)Rh(cod)] (**7**): The residue described above (25 mg) and 1,1-bis(4-hydroxyphenyl)methane (18 mg) were dissolved in ethanol (2 mL), filtered through a celite pad, and transferred to a 5-mL vial. After standing for two weeks at room temperature, yellow crystals had formed and were collected in a yield of 64 % of the isolated product (0.026 g). After drying under vacuum (loss of EtOH): ^{1}H NMR ([D_6]DMSO): $\delta = 9.10$ (s, 2H, phenolic OH, 2H), 6.95 (d, J = 8.1 Hz, aryl ring, 4H), 6.64 (d, J = 8.3 Hz, aryl ring, 4H), 4.95 (s, benzoquinone, 4H), 3.68 (s, CH_2, 2H), 3.50 (br, cod, 4H), 2.20 (m, cod, 4H), 1.99 ppm (m, cod, 4H); elemental analysis (%) calcd for $C_{27}O_4H_{28}Rh_1Li_1$: C 61.61, H 5.36; found: C 61.51, H 5.91.

Dynamic NMR study: **2** (5.0 mg, 0.012 mmol) was dissolved in [D_8]THF (1.5 mL) under N_2 in an NMR tube, and Li*O*t*Bu* (9.8 mg, 0.12 mmol) was added at room temperature. The NMR tube was shaken to generate a homogeneous yellow solution, which was then used to record NMR spectra over the temperature range −78–25 °C.

Crystallography: X-ray data collection was carried out using a Bruker single-crystal diffractometer equipped with an APEX CCD area detector and controlled by SMART version 5.0. Collection was done either at 100 K. Data reduction was performed by SAINT version 6.0 and absorption corrections were applied by SADABS version 2.0. The structures were typically determined by direct methods and refined on *F* squared by use of programs in SHELXTL version 5.0. Most hydrogen atoms appeared in a difference map, or they were generally inserted in ideal positions, riding on the atoms to which they are attached. CCDC-281279 (**1**), -281276 (**5**), -281277 (**6**), and -281278 (**7**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Crystal data for **1**: $C_{38}H_{67}Li_4O_8Rh$, $M_r = 782.59$, triclinic, $P\bar{1}$, $a = 10.116(3)$, $b = 14.625(4)$, $c = 16.304(4)$ Å, $\alpha = 101.790(5)$, $\beta = 105.855(5)$, $\gamma = 107.430(4)°$, $V = 2103.3(9)$ Å^3, $Z = 2$, $\rho_{calcd} = 1.236$ g cm^{-3}, $F_{000} = 832$, $\mu = 0.451$ mm^{-1}, $\theta = 1.54$–$21.04°$, reflections collected 13816, independent reflections 4499 ($R_{int} = 0.1682$), GOF = 1.008, $R_1 = 0.0752$, $wR_2 = 0.1633$, largest diffraction peak/hole 0.826/−0.879 Å^{-3}.

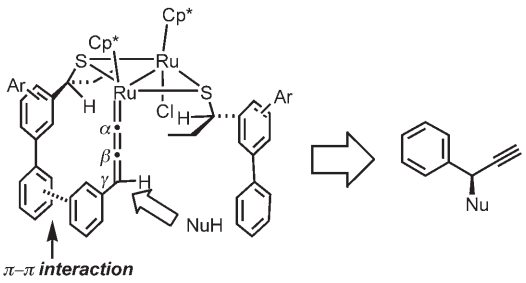
Ruthenium-Catalyzed Asymmetric Propargylic Substitution Reactions of Propargylic Alcohols with Acetone**

Youichi Inada, Yoshiaki Nishibayashi, and Sakae Uemura*

In sharp contrast to enantioselective allylic substitution reactions of allylic alcohol derivatives with nucleophiles catalyzed by transition metal complexes,[1] its propargylic version has not yet been developed. We recently disclosed that ruthenium-catalyzed propargylic substitution reactions of propargylic alcohols with a variety of heteroatom- and carbon-centered nucleophiles affords the corresponding functionalized propargylic compounds in high yields with complete regioselectivity.[2] The reactions were catalyzed only by thiolate-bridged diruthenium complexes[3] such as $[\{Cp^*RuCl(\mu_2\text{-}SR)\}_2]$ ($Cp^* = \eta^5\text{-}C_5Me_5$; R = Me, *n*Pr, *i*Pr) and $[Cp^*RuCl(\mu_2\text{-}SMe)_2RuCp^*(OH_2)]OTf$ (OTf = OSO_2CF_3), but not by various monoruthenium complexes,[2] and they proceeded via allenylidene complexes[4] as key intermediates under the synergistic effect of the two ruthenium atoms in the diruthenium complexes.[2]

More recently, we have prepared several diruthenium complexes bearing chiral thiolate bridging ligands and applied them as catalysts in the catalytic enantioselective propargylic alkylation of propargylic alcohols with acetone, which resulted in the formation of the propargylic alkylated compounds in good yields, but only with moderate enantioselectivity (up to 35% *ee*).[5] To achieve higher enantioselectivity, a different concept than steric repulsion between substrates and chiral ligands, which was considered in our previous system,[5] would be needed. Therefore, we envisaged a new type of chiral ligands with a phenyl ring that might interact with a phenyl ring of ruthenium–allenylidene complexes by π–π interaction.[6] In this system, nucleophilic attack of nucleophiles at the C_γ atom of the allenylidene ligand should occur from the side that is not blocked by the chiral ligand (Scheme 1). Indeed, high enantioselectivity was observed in catalytic propargylic alkylation with the second-generation catalyst (up to 82% *ee*). Preliminary results are described here.



Scheme 1. Nucleophilic attack of acetone on the C_γ atom of the allenylidene complex.

A new class of chiral disulfides was prepared from the corresponding aldehydes (Scheme 2).[7] Treatment of 1-phenyl-2-propyn-1-ol (**2a**) with acetone in the presence of a catalytic amount of chiral thiolate-bridged diruthenium com-

plexes, which were prepared in situ from the tetranuclear ruthenium(II) complex and the corresponding chiral disulfides in THF at room temperature for 12 h,[3,5] and NH_4BF_4 at reflux temperature for 6 h afforded the propargylic alkylated product 4-phenyl-5-hexyn-2-one (**3a**) in moderate yields with complete regioselectivity (Scheme 3). The enantiomeric excess of the product was determined by GLC on a chiral capillary column. Compared with our previous result,[5] the introduction of a phenyl group in the *meta* position of the phenyl ring of a chiral disulfide (**1a**) increased the enantioselectivity from 11 to 37% *ee*. Interestingly, introduction of a further phenyl group into the phenyl ring (**1f** and **1g**) greatly increased the enantioselectivity to 43 and 64% *ee*, respectively, but the enantioselectivity decreased when the positions of the phenyl rings were not appropriate (**1b**–**1e**). Finally, the use of a chiral disulfide (**1h**) bearing three phenyl groups on a phenyl ring achieved the highest enantioselectivity (74% *ee*).[7] Unfortunately, the introduction of a *p*-methylphenyl or *p*-*tert*-butylphenyl group on the phenyl ring of a chiral disulfide (**1i** and **1j**) did not improve the enantioselectivity. The use of **1h** as chiral ligand at lower reaction temperature did not influence the enantioselectivity. Other additives such as NH_4PF_6 did not affect the enantioselectivity. In the absence of additives such as NH_4BF_4 and NH_4PF_6, no reaction occurred. When other simple ketones such as 2-butanone and 3-methyl-2-butanone were used in place of acetone, the catalytic reactions did not proceed smoothly.

Next, the catalytic alkylation of propargylic alcohols **2** was investigated using **1h** as chiral ligand. Typical results for various alcohols **2** are shown in Table 1. The presence of substituents such as methyl, methoxy, and chloro in the benzene ring of the propargylic alcohols did not greatly affect the enantioselectivity for the products (Table 1, entries 2–4). Enantioselectivity at the same level was observed in the reactions of 1-naphthyl-2-propyn-1-ols (**2e** and **2f**) with acetone under the same reaction conditions (Table 1, entries 5 and 6). Although the reaction of propargylic alcohol bearing a phenyl group in the benzene ring (**2g**) with acetone gave the same enantioselectivity (Table 1, entry 7), the introduction of two phenyl groups at the *meta* positions of the benzene ring of the propargylic alcohols further increased the enantioselectivity to 82% *ee* (Table 1, entry 8).

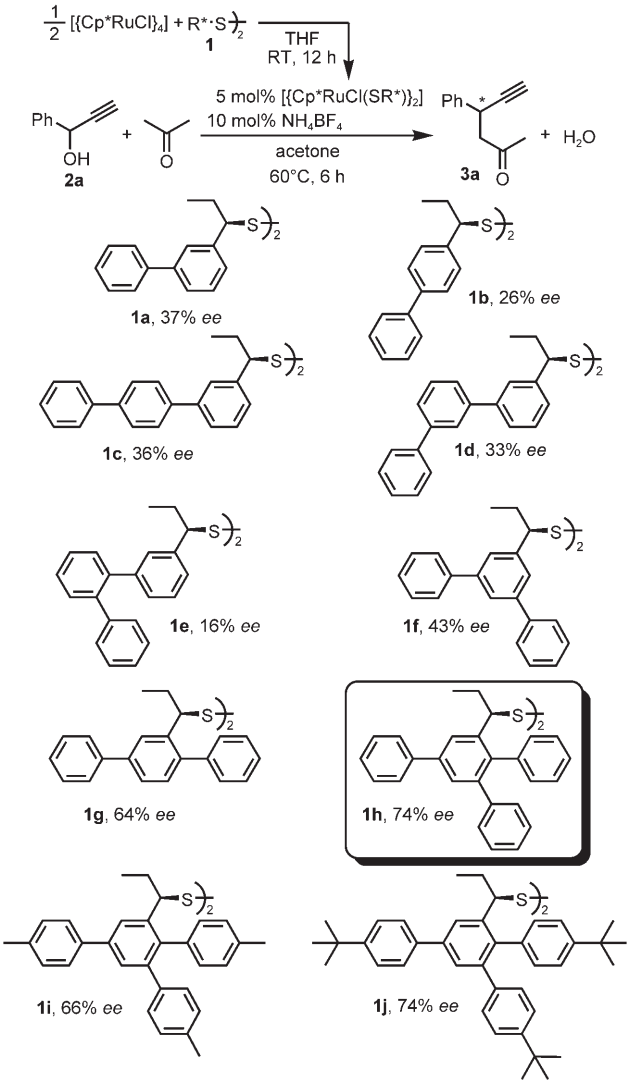
[a] All reactions of **2** (0.300 mmol) with acetone were carried out in the presence of ruthenium complex (0.015 mmol, generated in situ from $[\{Cp^*RuCl\}_4]$ and **1h**) and NH_4BF_4 (0.030 mmol) in acetone (4.5 mL) at 60°C for 6 h. [b] Yield of isolated product. [c] Determined by HPLC. [d] Determined by GLC.

To obtain more information on the propargylic alkylation, the stereochemistry of the alkylated product **3a** in the reaction with **1h** as a chiral ligand was determined. Hydrogenation of the alkylated product in the presence of a catalytic amount of Pd/C under 1 atm of H_2 at room temperature for 20 h gave (*S*)-4-phenyl-2-hexanone (**4a**)[7,8] quantitatively (Scheme 4), that is, the original alkylated product **3a** has an *R* absolute configuration. This result is consistent with our proposed reaction pathway (Scheme 1), and the π–π interaction[6] of phenyl rings between the ligand and allenylidene moieties might be considered to be one of the reasons for achievement of high enantioselectivity.



Scheme 3. Reactions of 1-phenyl-2-propyn-1-ol (**2a**) with acetone in the presence of chiral thiolate-bridged diruthenium complexes generated in situ from $[\{Cp^*RuCl\}_4]$ and chiral disulfides.

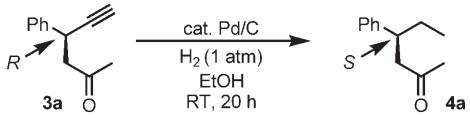

Scheme 4. Palladium-catalyzed hydrogenation of **3a**.

In summary, we have developed a diruthenium complex-catalyzed, highly enantioselective propargylic substitution reaction of propargylic alcohols with acetone to give the propargylic alkylated products with up to 82% *ee*. Here, π–π interaction of phenyl rings between the ligand and allenylidene moieties is considered to play a crucial role in achieving such a high selectivity. The method presented is in sharp contrast to the so-far-known highly diastereoselective and enantioselective propargylic substitution reactions, which use a stoichiometric amount of transition metal complexes.[9] Further work is currently in progress to improve the enantioselectivity and to broaden the scope of this enantioselective propargylic substitution reaction by using other nucleophiles.[10]

Experimental Section

Typical experimental procedure for the reaction of **2a** with acetone: $[\{Cp^*RuCl\}_4]$ (8.2 mg, 0.0075 mmol) and **1h** (11.4 mg, 0.015 mmol) were placed in a 20 mL round-bottomed flask under N_2. Anhydrous THF (1.0 mL) was added, and then the mixture was magnetically stirred for 12 h at room temperature. The solvent was evaporated in vacuo. NH_4BF_4 (3.1 mg, 0.030 mmol) and anhydrous acetone (4.5 mL) were added under N_2, and then the mixture was magnetically stirred at room temperature. After the addition of **2a** (39.7 mg, 0.30 mmol), the reaction flask was kept at 60°C for 6 h. The solvent was concentrated under reduced pressure by an aspirator, and then the residue was purified by column chromatography (SiO_2) with hexane and AcOEt to give **3a** as a pale yellow oil (30.3 mg, 0.18 mmol, 56% yield, 74% *ee*); ^{1}H NMR (270 MHz, $CDCl_3$): $\delta =$ 2.13 (s, 3H), 2.26 (s, 1H), 2.80 (dd, 1H, $J = 16$, 5.2 Hz), 3.00 (dd, 1H, $J = 16$, 8.4 Hz), 4.20 (br, 1H), 7.22–7.39 ppm (m, 5H); ^{13}C NMR (67.5 MHz, $CDCl_3$): $\delta = 30.4$, 32.4, 51.5, 71.0, 84.8, 127.1, 127.2, 128.6, 140.1, 205.4 ppm. The optical purity of **3a** was determined by HPLC analysis (column: Daicel, OD; eluent: hexane/2-propanol 97:3).

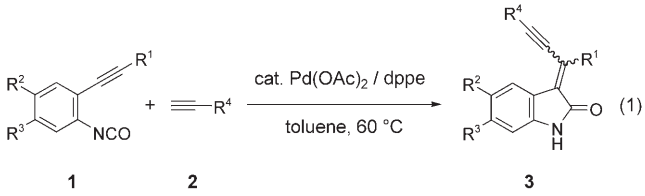
Oxindole Synthesis through Intramolecular Nucleophilic Addition of Vinylpalladiums to Aryl Isocyanates**

Shin Kamijo, Yuya Sasaki, Chikashi Kanazawa, Thomas Schüßeler, and Yoshinori Yamamoto**

One of the main targets in the field of synthetic organic chemistry these days is the development of reactions promoted by a catalyst. Not only metal catalysts but also organo-derived catalysts have been studied and applied in various kinds of transformation.[1] Among the transition metals applied in catalytic reactions so far, palladium complexes have found wide utility in various types of transfomation.[2] In most cases, organopalladium species containing a Pd–C bond generated during the course of the reaction act either as electrophiles or as neutral species, and it is rare for these species to behave as nucleophiles.[3] Several methods have been reported to transform the electrophilic reactivity to a nucleophilic one, although these methods are generally based on the transmetalation of a C–Pd bond to a nucleophilic C–M bond in situ.[4] Recently, direct nucleophilic reactions of organopalladiums to carbon–heteroatom unsaturated bonds were discovered by us and by other groups in the allylpalladation of imines and aldehydes,[5] vinylpalladation of ketones, aldehydes, imines, and cyanides,[6] and the arylpalladation of ketones and cyanides.[7] We report herein the first example of intramolecular nucleophilic vinylpalladation of isocyanates to produce oxindoles **3**[8] from 2-(alkynyl)phenylisocyanates **1** and terminal alkynes **2** [Eq. (1)].



1 2 3

During the course of our investigation into the dual-role catalysis of palladium and platinum in the reaction between 2-(alkynyl)phenylisocyanates and alcohols that leads to the formation of indoles,[9] we found that a coupling reaction between 2-(alkynyl)phenylisocyanates **1** and terminal alkynes **2** took place to afford oxindoles **3**. We chose 2-(1-pentynyl)-phenylisocyanate **1a** and 1-pentyne **2a** as a standard set of starting materials for the optimization of the reaction conditions to yield the corresponding oxindole **3a** (Table 1).

Table 1: Optimization of reaction conditions for the formation of the oxindole **3a** from **1a** and **2a** [cf. Eq. (1)].[a]

Entry	Pd catalyst (mol%)	Phosphine (mol%)	*t* [h]	Yield of **3a** [%][b]
1	$Pd(OAc)_2$ (5)	tdmpp (10)	2	45[c]
2	$Pd(OCOCF_3)_2$ (5)	tdmpp (10)	>20	23[c]
3	$[(\eta^3\text{-}C_3H_5)PdCl]_2$ (2.5)	tdmpp (10)	>20	0[d]
4	$Pd_2(dba)_3\cdot CHCl_3$ (2.5)	tdmpp (10)	>20	7[c,d]
5	$Pd(OAc)_2$ (5)	ttmpp (10)	2	51[c]
6	$Pd(OAc)_2$ (5)	PPh_3 (10)	2	17[c]
7	$Pd(OAc)_2$ (5)	dppe (5)	2	62[c]
8	$Pd(OAc)_2$ (5)	dppp (5)	2	50[c,e]
9	$Pd(OAc)_2$ (5)	dppb (5)	2	26[c,e]
10	$Pd(OAc)_2$ (3)	dppe (3)	2	80[c]
11	$Pd(OAc)_2$ (3)	dppe (3)	1	80[f]
12[g]	$Pd(OAc)_2$ (3)	dppe (3)	1.5	76[e,h]

[a] dba = *trans*,*trans*-dibenzylideneacetone, tdmpp = tris(2,6-dimethoxyphenyl)phosphine, ttmpp = tris(2,4,6-trimethoxyphenyl)phosphine, dppe = 1,2-bis(diphenylphosphanyl)ethane, dppp = 1,3-bis(diphenylphosphanyl)-propane, dppb = 1,4-bis(diphenylphosphanyl)butane. [b] Yield of isolated product unless otherwise noted. [c] *E* isomer, (*E*)-**3a**, was obtained almost exclusively. [d] Substrate **1a** was recovered. [e] Yield measured by NMR spectroscopy with CH_2Br_2 as an internal standard. [f] Combined yield of the *E* and *Z* isomers (*E*)-**3a** and (*Z*)-**3a**. *E*/*Z* = 85:15. [g] The reaction was conducted at 40 °C. [h] (*E*)-**3a**/(*Z*)-**3a** = 33:67.

The reaction under a catalytic amount of $Pd(OAc)_2$ and TDMPP produced **3a** in 45% yield in 2 h (entry 1). The *E* isomer of the oxindole, (*E*)-**3a**, was obtained almost exclusively (cf. Eq. (2) for structures of (*E*)- and (*Z*)-**3a**). The combination of $Pd(OCOCF_3)$ and TDMPP catalyzed the formation of **3a** in 23% yield, but the $[(\eta^3\text{-}C_3H_5)PdCl]_2$/TDMPP catalyst did not give the corresponding oxindole **3a** at all (entries 2 and 3). The desired oxindole **3a** was also obtained from the reaction with $[Pd_2(dba)_3\cdot CHCl_3]$ and TDMPP, although the yield was rather low (entry 4). We then investigated the effects of phosphine ligands combined with $Pd(OAc)_2$. The reactivity of ttmpp was comparable to

that of TDMPP, whereas the reactivity of PPh_3 was inferior (entries 5 and 6). The bidentate phosphine ligands in dppe, dppp, and dppb also produced the corresponding oxindole **3a** (entries 7–9). Among these catalysts, the combination of $Pd(OAc)_2$ and dppe showed the highest catalytic activity: **3a** was formed in 62% yield. When the amounts of the catalysts were reduced to 3 mol% each for $Pd(OAc)_2$ and dppe, the yield of the oxindole **3a** was increased to 80% yield with almost exclusive formation of the *E* isomer, (*E*)-**3a** (entry 10). When the reaction was quenched right after the consumption of the starting isocyanate **1a** (1 h), a mixture of the *E* and *Z* isomers of the oxindole, (*E*)-**3a** and (*Z*)-**3a**, was obtained in 80% combined yield with a ratio of 85:15 (entry 11). The reaction could proceed even at 40°C to give the oxindole in 76% combined yield with a 33:67 ratio of the *E* and *Z* isomers (entry 12).

With the optimized reaction conditions in hand, we examined the scope and limitations of the present palladium-catalyzed oxindole-forming reaction (Table 2). As mentioned above, treatment of **1a** with **2a** in the presence of a catalytic amount of $Pd(OAc)_2$ (3 mol%) and dppe (3 mol%) in toluene (0.5 M) at 60°C for 2 h afforded the *E* isomer of **3a** almost exclusively in 80% yield after isolation (entry 1). The isocyanate **1b** bearing a cyclohexyl group at the end of the acetylenic group gave the corresponding oxindole **3b** in 58% yield as the *E* isomer (entry 2). In the case of the isocyanate **1c** with a bulky *tert*-butyl substituent, the reaction did not reach completion even after 24 h, and the desired product **3c** was obtained in only 26% yield (entry 3). The phenyl-substituted isocyanate **1d** gave a complex mixture of unidentified products (entry 4). The substrates **1e** and **1f**, having electron-donating methoxy and methylthio groups, respectively, *para* to the isocyanato group, produced the corresponding oxindoles **3e** and **3f** in moderate to good yields (entries 5 and 6). The isocyanate **1g** with an electron-withdrawing chloride substituent on the benzene ring gave the desired product **3g** in 44% yield (entry 7). The reactions of isocyanates **1h** and **1i**, each bearing a substituent *para* to the alkynyl group, furnished the corresponding oxindoles **3h** and **3i**, respectively, in moderate yields (entries 8 and 9). A mixture of *E* and *Z* isomers of the corresponding oxindole, (*E*)-**3h** and (*Z*)-**3h**, was obtained in the case of **1h**, which bears an electron-donating group *para* to the alkynyl group.

Table 2: Reaction between various isocyanates **1** and **2a**.[a]

Entry	R^1	R^2	R^3	**1**	*t* [h]	**3**	Yield [%][b] (*E*/*Z*)
1	Pr	H	H	**1a**	2	**3a**	80 (>99:1)
2	cyclohexyl	H	H	**1b**	4	**3b**	58 (>99:1)
3	*t*Bu	H	H	**1c**	24	**3c**	26 (>99:1)[c]
4	Ph	H	H	**1d**	24	**3d**	–[d]
5	Pr	OMe	H	**1e**	1	**3e**	73 (>99:1)

8	Pr	H	OMe	**1h**	2	**3h**	48 (33:67)
9	Pr	H	CF_3	**1i**	24	**3i**	33 (>99:1)[e]

[a] The reaction of **1** and **2a** (2 equiv) was conducted in the presence of $Pd(OAc)_2$ (3 mol%) and dppe (3 mol%) in toluene (0.5 M) at 60°C for the time shown in the table. [b] Yield of isolated product unless otherwise noted. [c] Substrate **1c** was recovered. [d] Complex mixture. [e] Substrate **1i** was recovered.

We next investigated the reactions between the isocyanate **1a** and a variety of terminal alkynes **2** (Table 3). With increases in the bulkiness of the terminal alkynes **2a–c**, the yields of the desired products **3a**, **3j**, and **3k** decreased (entries 1–3). It is worth mentioning that the *Z* isomer of **3k** was obtained almost exclusively when bulky *tert*-butylacetylene **2c** was used as the starting material. Phenylacetylene **2d** and (trimethylsilyl)acetylene **2e** reacted to produce the corresponding oxindoles **3l** and **3m**, respectively, in moderate yields as a mixture of the *E* and *Z* isomers (entries 4 and 5). The structures of oxindoles were determined by detailed analyses of the spectroscopic data. Furthermore, the structure of the oxindoles (*E*)-**3l** and (*Z*)-**3l** were unambiguously confirmed by X-ray crystallographic analyses (Figure 1).

Table 3: Reaction between **1a** and various terminal alkynes **2**.[a]

[a] The reaction of **1a** and **2** (2 equiv) was conducted in the presence of $Pd(OAc)_2$ (3 mol%) and dppe (3 mol%) in toluene (0.5 M) at 60°C for the time shown in the table. [b] Yield of isolated product. [c] TMS = trimethylsilyl.

The following mechanism is proposed for the unprecedented intramolecular vinylpalladation of isocyanates to form

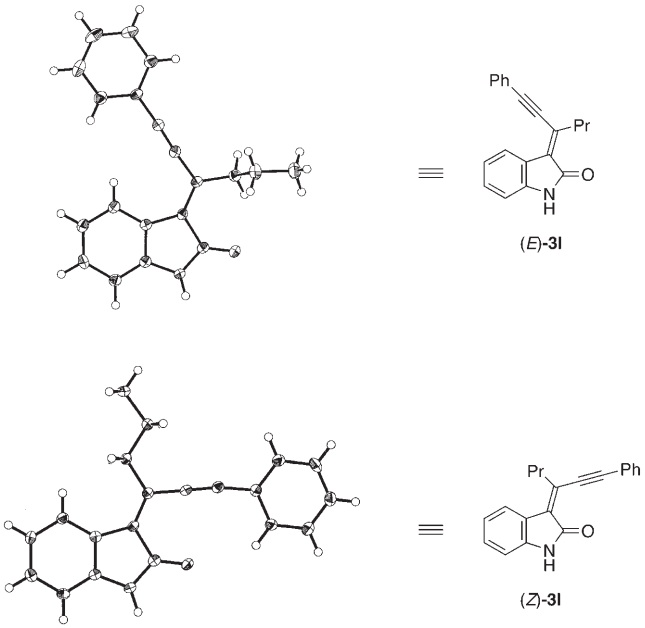

Figure 1. X-ray crystal structures of (*E*)-**3l** and (*Z*)-**3l**.

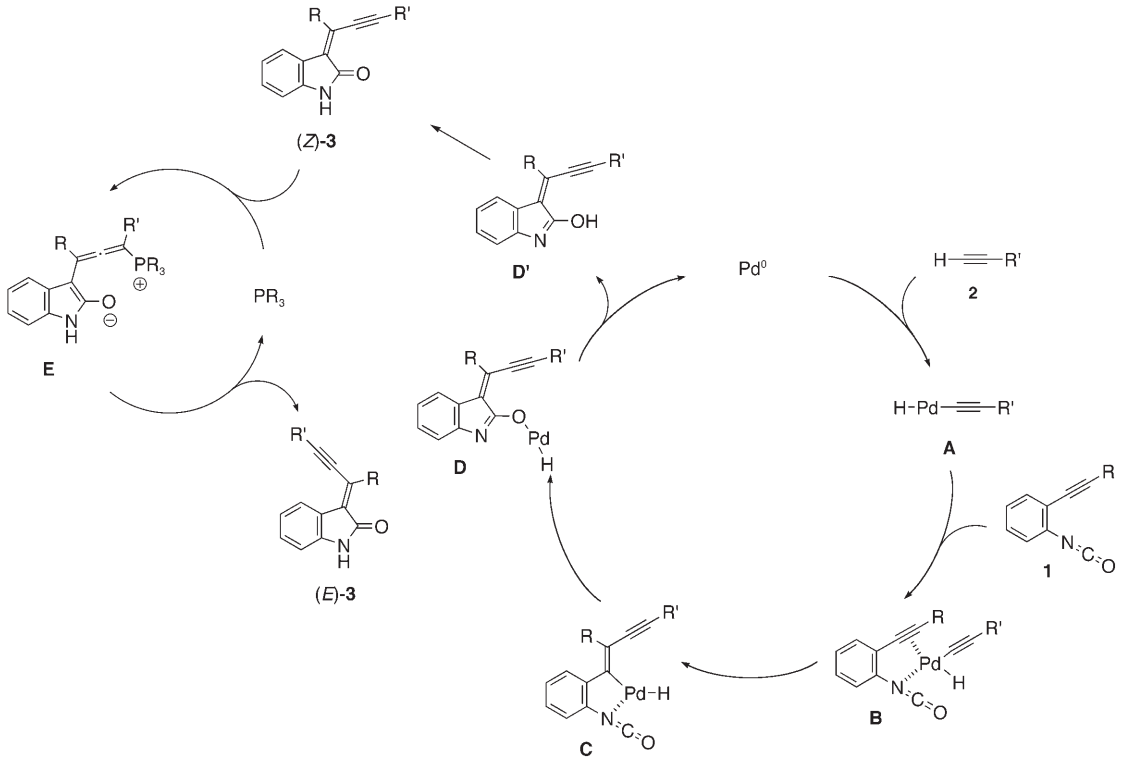
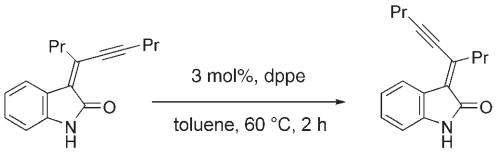


Scheme 1. Proposed mechanism for the formation of oxindoles through intramolecular vinylpalladation of isocyanates.

oxindoles (Scheme 1). A Pd^0 species is generated in situ[10] and oxidatively adds to the C–H bond of terminal alkyne **2** to give intermediate **A**. The derived species **A** would coordinate to both the alkynyl and the isocyanato moieties in **1** to form intermediate **B**, in which the palladium metal behaves as a dual-role catalyst.[9,11] Carbopalladation of the C–C triple bond in **1** yields the vinylpalladium intermediate **C**.[12] Intramolecular nucleophilic attack of the vinylpalladium species on the isocyanato group would produce the cyclized oxypalladium intermediate **D**, which would be transformed into **D′** after reductive elimination of the Pd^0. The intermediate **D′** would isomerize to the corresponding oxindole (*Z*)-**3**.

Conversion of the *Z* isomer of oxindole **3** into its *E* isomer, (*E*)-**3**, is catalyzed by the phosphine, dppe, existing in the reaction mixture. Nucleophilic addition of the phosphine to the electrophilic carbon center in the alkynyl moiety of (*Z*)-**3** would produce the zwitterionic intermediate **E**.[13] Rotation of the newly formed σ bond between the indole core and the allenyl moiety and subsequent elimination of the phosphine furnishes the corresponding *E* oxindole (*E*)-**3**. This explains well that the exclusive or predominant formations of *Z* oxindoles were observed when the reaction was conducted with the methoxy-substituted isocyanate **1h** and the bulky terminal alkynes **2c–e** as substrates. The electron flow from the properly substituted methoxy group to the enyne moiety in (*Z*)-**3i** or the steric congestion around the enyne moiety in (*Z*)-**3k–m** would hinder the nucleophilic approach of the phosphine toward the electrophilic carbon center in the alkynyl moiety in the corresponding *Z* oxindoles (entry 8 in Table 2 and entries 3–5 in Table 3). Indeed, the reaction of (*Z*)-**3a** in the presence of a catalytic amount of dppe resulted in a clean formation of (*E*)-**3a** in 2 h [Eq. (2)].



94% NMR yield (2)

We have achieved the synthesis of oxindoles **3** from aryl isocyanates **1** and terminal alkynes **2** in the presence of a catalytic amount of $Pd(OAc)_2$ and dppe. This oxindole-forming reaction most probably proceeds through the intramolecular nucleophilic attack of a vinylpalladium species on the isocyanato group. Further studies on synthetic applications and a mechanistic investigation are in progress in our laboratory.

Experimental Section

1-Pentyne (60 μL, 0.6 mmol) was added to a toluene solution (0.6 mL) of **1a** (55.6 mg, 0.3 mmol), $Pd(OAc)_2$ (2.0 mg, 0.009 mmol), and dppe (3.6 mg, 0.009 mmol) under an argon atmosphere. The solution was stirred at 60 °C for 2 h. The reaction mixture was cooled to RT, filtered through a short Florisil pad with AcOEt as

Tetraphenylborate as a Novel Bridging Ligand in a Zwitterionic Nickel(I) Dimer**

*Yaofeng Chen, Christine Sui-Seng, and Davit Zargarian**

Heterolytic abstraction of anionic ligands such as halides or alkyl substituents can convert coordinatively saturated organometallic complexes into highly electrophilic, usually transient, cationic species that can serve as efficient initiators in various catalytic reactions. This strategy has been used in the development of many catalytic processes based on (quasi) square-planar d^8 metal precursors, including the recently reported systems for olefin polymerization reactions.[1]

In this context, we have shown that abstraction of Cl^- from the complexes [(R-ind)Ni(PPh_3)Cl] (R-ind = indenyl and its substituted derivatives)[2] leads to the generation of a transient species (presumed to be $[(R\text{-ind})Ni(PPh_3)]^+$) that reacts with excess substrate to promote the oligomerization or polymerization of various olefins,[3] PhC≡CH,[4] and $PhSiH_3$,[5] or catalyzes the hydrosilylation of olefins and ketones[6]

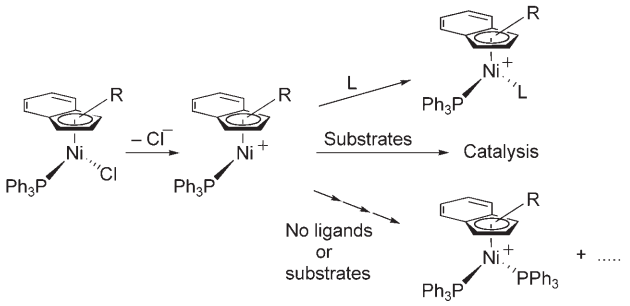
(Scheme 1). We have also shown that abstraction of Cl^- in the presence of suitable ligands L gives $[(R\text{-ind})Ni(PPh_3)L]^+$ (L = PR'_3; R″CN, *t*BuNC).[3a,4c,5d] If, on the other hand, Cl^- is



Scheme 1. Reaction pathways following abstraction of Cl^- from the complexes $[(R\text{-ind})Ni(PPh_3)Cl]$.

abstracted in the absence of sufficiently strong coordinating ligands or substrates, we obtain $[(R\text{-ind})Ni(PPh_3)_2]^+$ in low yields.[3a] Varying amounts of the latter species also form during the above-noted catalytic reactions, thus resulting in lower catalytic activities.

In the search for a strategy to circumvent this built-in deactivation pathway, we set out to determine whether placing sterically bulky substituents on the ind ligands might prevent the formation of $[(R\text{-ind})Ni(PPh_3)_2]^+$ during catalysis. An initial study showed that the catalytic activities of $[(R\text{-ind})Ni(PPh_3)Cl]$ for the hydrosilylation of styrene do increase with more bulky ind ligands (1-Me-ind < 1-$SiMe_3$-ind < 1,3-$(SiMe_3)_2$-ind).[7] To answer this question more directly, we have studied the abstraction of Cl^- from $[(1\text{-}SiMe_3\text{-}3\text{-}R\text{-ind})Ni(PPh_3)Cl]$ (R = H, **1**; $SiMe_3$, **2**) and report our findings herein.

Treatment of **1** with $NaBPh_4$ gave an initial product whose NMR spectra are consistent with the formation of $[(1\text{-}SiMe_3\text{-ind})Ni(PPh_3)_2][BPh_4]$,[8] although the ready decomposition of this new species prevented its isolation and full characterization. It appears, therefore, that the presence of one $SiMe_3$ substituent on ind destabilizes the bis(phosphane) complex but does not block its formation. In contrast, treatment of **2** with $NaBPh_4$ gave a product that was stable and isolable, but whose spectral features were not those of a bis(phosphane) cation. For instance, the $^{31}P\{^1H\}$ NMR spectrum of this product displays an A_2X system with a doublet at around $\delta = 22$ ppm and a triplet at around $\delta = 126$ ppm ($J_{P,P} = 35$ Hz), while the ^1H and ^{13}C NMR spectra contain many signals in regions typical of phenyl groups (^1H: $\delta = 6.5$–7.3 ppm; ^{13}C: $\delta = 122$–138 ppm) in addition to a few peaks farther upfield (^1H: $\delta = 5.5$–5.9 ppm; ^{13}C: $\delta = 86$–102 ppm). Significantly, the signals expected for the $(SiMe_3)_2$-ind moiety were absent from the latter spectra. In a search for clues regarding the fate of this moiety, we analyzed the reaction mixture by GC-MS and ^1H NMR spectroscopy, which enabled the detection of 3-phenyl-1,1-bis(trimethylsilyl)indene.

These spectral analyses did not, however, allow an unambiguous characterization of the main product, but X-ray diffraction analysis of single crystals obtained from repeated recrystallizations allowed us to identify it as **3**, which is a dinuclear zwitterion composed of two $(PPh_3)Ni^I$ cations bridged by the anions μ-$[PPh_2]^-$ and *syn*,μ-$[(\eta^2{:}\eta^2\text{-Ph})BPh_3]^-$ (Figure 1). The main features of this crystal structure are consistent with the solution spectra: the A_2X signals observed in the ^{31}P NMR spectrum of **3** can be assigned to a μ-PPh_2 and two PPh_3 moieties,[9] while the upfield signals in the ^1H and ^{13}C NMR spectra can be assigned to the $(\eta^2{:}\eta^2\text{-Ph})BPh_3$ moiety.

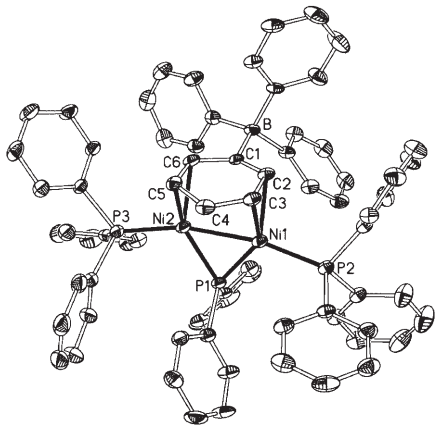


Figure 1. ORTEP view of **3**. Thermal ellipsoids are shown at the 30% probability level. Selected distances [Å] and angles [°]: Ni1-Ni2 2.4471(11), Ni1-P1 2.1397(16), Ni2-P1 2.1395(13), Ni1-P2 2.2055(15), Ni2-P3 2.1841(16), Ni1-C1 2.670(4), Ni1-C2 2.120(4), Ni1-C3 2.094(4), Ni1-C4 2.617(4), Ni2-C1 2.666(5), Ni2-C4 2.522(5), Ni2-C5 2.075(5), Ni2-C6 2.125(5), C1-C2 1.421(6), C2-C3 1.415(6), C3-C4 1.396(6), C4-C5 1.392(6), C5-C6 1.415(6), C6-C1 1.414(6); P1-Ni1-P2 116.27(6), P1-Ni2-P3 110.98(6), P2-Ni1-Ni2 168.82(5), P3-Ni2-Ni1 165.66(5), Ni2-P1-Ni1 69.76(5), P1-Ni1-Ni2 55.12(4), P1-Ni2-Ni1 55.12(4).

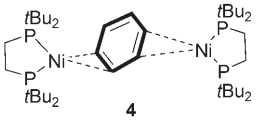
The most notable structural feature of **3** is the novel bonding mode of the borate moiety: although there are many precedents for complexes featuring $[(\eta^{2-6}\text{-Ph})_nBPh_{4-n}]^-$,[10,11] the formation of a complex in which one of the Ph groups bridges two metals is without precedent.[12] Interestingly, the synfacially coordinated μ-$PhBPh_3$ moiety interacts with the two NiL_2 moieties through two nonadjacent double bonds from opposite edges of the μ-arene ring, i.e., C2–C3 and C5–C6. We propose that this unusual bonding mode[13] minimizes the steric interactions between the Ph groups on the PPh_3 ligands and the borate moiety in **3**.[14]

A more complete picture of the bonding in the Ni_2-$[\mu,\eta^2,\eta^2\text{-PhBPh}_3]$ moiety emerges from a careful inspection of the individual Ni–C distances, which show that the μ-Ph ring straddles the Ni–Ni axis and is somewhat tilted, giving the following unsymmetrical Ni–C interactions: Ni1–C2 > Ni1–C3; Ni2–C6 > Ni2–C5; Ni(1/2)–C1 > Ni(1/2)–C4. Interestingly, these interactions result in only minor and more or less uniform lengthening of the C–C bond lengths within the μ-Ph ring (1.39–1.42 Å), although the dihedral angle of about 15° between the planes (C1,C2,C3,C4) and (C1,C6,C5,C4) signals a relatively significant butterfly distortion of the ring.[15,16]

It is instructive to compare the unusual Ni–arene interactions found in **3** to those in complex **4**[17], which is a rare

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

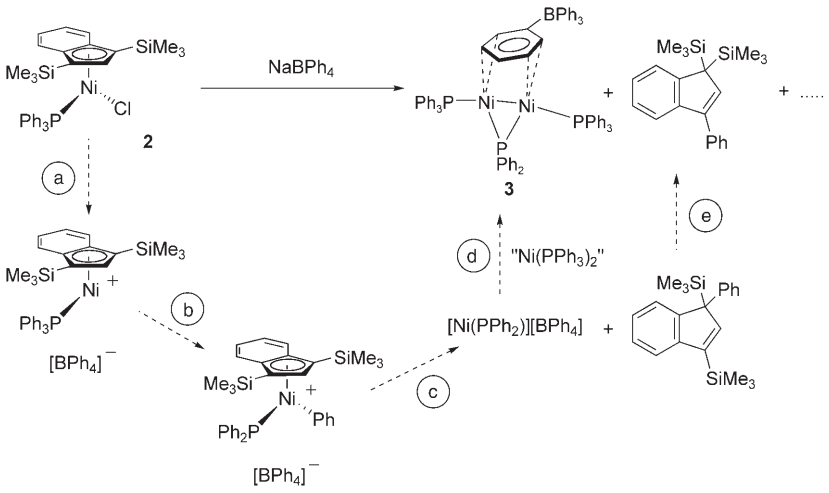


4

$Ni_2(\mu$-arene) species.[18] In contrast to **3**, the $Ni_2(\mu\text{-}C_6H_6)$ interactions in **4** are antifacial and involve two adjacent double bonds, i.e., a 1,3-diene moiety. Furthermore, the Ni–C distances are significantly shorter in **4** (ca. 2.00–2.02 vs. 2.10 Å in **3**), which is presumably due to greater backbonding possible in the Ni^0 complex. It should be noted, however, that the interactions of the Ni centers in **3** with (μ-$PhBPh_3$) are reinforced by the electrostatic attractions within this zwitterionic compound. Accordingly, the arene moiety in **3** cannot be displaced by aromatic solvents, even when heated for extended periods.

The structural parameters discussed above are consistent with a simple bonding picture involving the contribution of two pairs of electrons from $[(\mu,\eta^2,\eta^2\text{-Ph})BPh_3]^-$; when the Ni–Ni bond is taken into consideration,[19] each Ni center ends up with a total of 16 valence electrons. This is in agreement with the conclusions of a theoretical analysis[20] showing that the analogous fragment $[\{(PH_3)Pd\}_2(\mu\text{-Br})]^+$ has only two low-lying vacant orbitals of appropriate symmetry to interact with the two HOMO orbitals of a (μ-C_6H_6) ligand.

The unexpected formation of **3** from **2** raises the question of how this transformation might take place. Although definitive conclusions regarding the reaction mechanism must await further experimental evidence, the sequence of steps shown in Scheme 2 serves to rationalize the conversion



Scheme 2. Suggested pathway for the conversion of **2** into **3**.

of **2** into **3**. The proposed addition of a P–Ph bond (step b) is well known;[21] indeed, a particularly relevant example of such P–C bond activation has been observed during the formation of $[Pd_2(t\text{Bu}_2\text{PH})_2(\mu\text{-}t\text{Bu}_2\text{P})(\mu\text{-}C_6H_5O)]$, which is a closely related, isoelectronic analogue of **3**.[22] The reductive elimination from a Ni^{IV} intermediate (step c) is also quite reasonable, as is the rearrangement of the initially formed 1-phenyl-1,3-bis(trimethysilyl)indene to the observed 3-phenyl-1,3-bis(trimethysilyl)indene isomer by a silyl migration (step e).[23] Finally, comproportionation of Ni^{II} and Ni^0 species to give Ni^I dimers (step d) has been reported,[24] although the origin of the putative "$Ni^0(PPh_3)_2$" fragment is not known at this point.

We conclude that the greater steric bulk in [{($SiMe_3$)$_n$-ind}Ni(PPh_3)Cl] indeed hinders the generation of the cationic bis(phosphane) side-products that form with less bulky analogues, and this might contribute to the observed increase in the catalytic reactivity of these complexes.[7] On the other hand, the presence of $SiMe_3$ substituents on ind also opens a new decomposition pathway that, in the case of the 1,3-($SiMe_3$)$_2$-ind derivative **2**, results in the formation of the Ni^I dimer **3**. The observation of a $[(\mu,\eta^2,\eta^2\text{-Ph})BPh_3]^-$ ligand in **3** expands the range of coordination modes that should be taken into account when contemplating the use of BPh_4^- and its various analogues as weakly coordinating counterions. Preliminary experiments have shown that **3** does not react with $PhSiH_3$ or styrene, thus implying that this compound is not involved in the hydrosilylation catalysis promoted by its precursor. In view of the interesting catalytic reactivities exhibited by some Pd^I–Pd^I dimers,[25] however, future studies are planned to probe the reactivities of **3** towards other substrates.

Experimental Section

A slurry of [{1,3-($SiMe_3$)$_2$-ind}Ni(PPh_3)Cl] (191 mg, 310 μmol) and Na[BPh_4] (113 mg, 330 μmol) was stirred in Et_2O (20 mL) at room temperature for two days. The reaction mixture was then filtered and the solid residues extracted with CH_2Cl_2 (total volume ca. 15 mL). (Analysis of the filtrate is described below.) Concentration of the extracts to about 2 mL and layering with hexane (ca. 5 mL) resulted in the formation of dark-brown crystals overnight, which were isolated, washed quickly with acetone, and dried under vacuum to give **3** (30 mg, 25% yield). ^{1}H NMR (400 MHz, $CDCl_3$, 25 °C): $\delta = 7.33$–6.50 (m, 55H; Ph-H), 5.92 (brs, 2H; benzene-$H^{2,6/3,5}$), 5,79 (brs, 1H; benzene-H^4), 5.52 ppm (brs, 2H; benzene-$H^{2,6/3,5}$); ^{13}C{^{1}H} NMR (100.56 MHz, $CDCl_3$, 25 °C): $\delta = 138.5$, 136.1, 135.6, 134.8, 133.3, 132.1, 129.5, 127.1, 125.8, 122.3, 102.6, 97.1, 86.2 ppm; ^{31}P{^{1}H} NMR (161.92 MHz, $CDCl_3$, 25 °C): $\delta = 126.5$ (t, $^2J_{PP} = 35$ Hz), 22.3 ppm (d, $^2J_{PP} = 35$ Hz); elemental analysis calcd (%) for $C_{72}H_{60}BP_3Ni_2$: C 75.44, H 5.28; found: C 74.70, H 5.25.

Crystal data for **3**: monoclinic ($P2_1/n$); $a = 18.6631(6)$, $b = 13.5095(5)$, $c = 25.0944(9)$ Å; $\beta = 110.350(2)°$; $V = 5932.1(4)$ Å^3; $Z = 4$; $\rho_{calcd} = 1.283$ g cm^{-1}; Bruker AXS diffractometer; $\mu = 1.869$ mm^{-1}, $\lambda = 1.54178$ Å ($Cu_{K\alpha}$); ω scan, $\theta_{max} = 60.13°$; temperature: 223(2) K; h,k,l range: $-20 \le h \le 20$; $-14 \le k \le 15$; $-28 \le l \le 27$; 5072 reflections used ($I > 2\sigma(I)$); absorption correction multiscan SADABS; $R(F^2 > (2\sigma F^2))$, $wR(F^2)$: 0.0591, 0.1336; GOF: 0.929. CCDC-279748 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

[8] For example, the $^{31}P\{^1H\}$ NMR spectrum shows two very broad peaks at around $\delta = 30$ and 33 ppm (width at half-height approximately 400 Hz), which are assigned to the two inequivalent PPh_3 groups that are in a dissociation/re-association equilibrium. The observation in the ^{1}H NMR spectrum of a significantly downfield-shifted signal for H3 (from $\delta = 3.5$ ppm in **1** to about $\delta = 5$ ppm in the product) is also consistent with the greater ind→Ni donation in such cationic species (ref. [2]). This spectrum also shows the anticipated signals for H2 and the aromatic protons at about $\delta = 6.5$–7.5 ppm, as well as an upfield singlet for the Si-CH_3 protons at around $\delta = -0.12$ ppm.

[9] For comparison, the ^{31}P NMR signals of the μ-PPh_2 moieties in $[(CNR)_2Ni_2(\mu\text{-}PPh_2)_2(\mu\text{-}Ph_2PNHPPh_2)_2]$ (E. Simón-Manso, C. P. Kubiak, *Inorg. Chem. Commun.* **2003**, *6*, 1096) and $[Fe_2(CO)_6(\mu\text{-}PPh_2)_2]$ (E. P. Kyba, R. E. Davis, C. N. Clubb, S.-T. Liu, H. O. A. Palacios, J. S. McKennis, *Organometallics* **1986**, *5*, 869) are found at around $\delta = 190$ and 143 ppm, respectively. On the other hand, the general range for the ^{31}P NMR signal of a PPh_3 coordinated to Ni is $\delta = 25$–50 ppm.

[10] The main coordination modes of BPh_4^- and its derivatives have been reviewed: a) S. H. Strauss, *Chem. Rev.* **1993**, *93*, 927; b) M. Bochmann, *Angew. Chem.* **1992**, *104*, 1206; *Angew. Chem. Int. Ed. Engl.* **1992**, *31*, 1181.

[12] Multiple searches of the CCSD (up to August 6, 2005) did not lead to any complex in which one of the Ph rings of BPh_4^- is coordinated to two or more metal centers. These searches also indicated that complex **3** is the first instance of a Ni complex bearing a coordinated $[PhBPh_3]^-$.

[13] The following complexes featuring $\mu(\eta^2{:}\eta^2)$-arene ligands coordinated through nonadjacent C=C bonds have been reported: a) $[\{(t\text{Bu}_3\text{SiO})_3\text{Ta}\}_2(\mu,\eta^2{:}\eta^2\text{-}C_6H_6)]$ (D. R. Neithamer, L. Párkányi, J. F. Mitchell, P. T. Wolczanski, *J. Am. Chem. Soc.* **1988**, *110*, 4421); b) $\{AgN(SO_2F)_2(C_6H_6)\}_n$ (M. J. Begley, D. B. Sowerby, R. D. Verma, A. Vig, *J. Organomet. Chem.* **1994**, *481*, 243); c) $[\{Fe(CO)_3\}_2\{\mu,\eta^2{:}\eta^2\text{-}1,4\text{-}(CH_2NPh)_2\text{-}3,6\text{-}\eta^1,\eta^1\text{-}\{Fe(CO)_3\}_2\text{-}C_6H_2\}]$ (W. Imhof, A. Göbel, *J. Organomet. Chem.* **2000**, *610*, 102); d) $[Pd_2(GaBr_4)_2\{\mu(\eta^2{:}\eta^2\text{-arene})\}_2]$ (M. Gorlov, A. Fischer, L. Kloo, *J. Organomet. Chem.* **2004**, *689*, 489).

[14] Structural simulations have shown that rotating the borate anion in such a way as to orient a 1,3-diene moiety of the μ-$PhBPh_3$ ligand towards the Ni atoms results in significant steric interactions between the Ph groups of the PPh_3 ligand and the borate anion. The authors are grateful to Prof. F. Schaper for carrying out these simulations.

[15] For comparison, values of about 20° and 43° have been reported for the corresponding fold angles in the complexes $[Cp_2V_2(\mu\text{-}H)_2(\mu\text{-}Ph)]$ (K. Jonas, V. Wiskamp, Y.-H. Tsay, C. Krüger, *J. Am. Chem. Soc.* **1983**, *105*, 5480) and $[Cp_2Fe_2(\mu\text{-}C_6R_6)]$ (K. Jonas, G. Koepe, L. Schieferstein, R. Mynott, C. Krüger, Y.-H. Tsay, *Angew. Chem.* **1983**, *95*, 637; *Angew. Chem. Int. Ed. Engl.* **1983**, *22*, 620).

Thiooligosaccharide Conjugate Vaccines Evoke Antibodies Specific for Native Antigens**

David R. Bundle, Jamie R. Rich, Sandra Jacques, Henry N. Yu, Mark Nitz, and Chang-Chun Ling*

Conjugate vaccines composed of polysaccharides or oligosaccharides covalently linked to immunogenic proteins successfully overcome the limitations of pure polysaccharide antigens, which are classical T-cell-independent antigens.[1] To date, the use of oligosaccharides to provide the recognition element of such conjugate vaccines has largely been limited to experimental, proof of concept investigations, whereas polysaccharide conjugates are successfully employed in efficacious vaccination strategies against life-threatening bacterial infections.[1–3] Intensive efforts are directed toward the synthesis and evaluation of glycopeptide and glycolipid vaccines that present tumour-associated carbohydrate antigens,[4–6] the epitopes of which may contain glycosidic linkages that are potentially susceptible to endogenous glycosyl hydrolases, for example, ganglioside-specific plasma-membrane sialidase.[7–9] Such structural features include, but are not limited to, terminal sialyl residues, the loss of which would destroy crucial recognition elements. A method for the formation of glycosidic linkages that are resistant to enzymatic or acid hydrolysis in vivo has been proposed; C-glycosides are one class of compound that has received attention.[10–12] Herein we present data for four distinct antigen systems that show, for the first time, conjugate vaccines constructed from oligosaccharides that contain a thioglycosidic linkage function as well as antigens that induce antibodies specific for O-linked oligosaccharides.

The choice of sulfur (over atoms such as carbon) to replace oxygen at the glycosidic center was based on three considerations: the ease of synthesis,[13] the existence of well-documented examples with a similar conformational preference about the thioglycosidic and aglyconic bonds both when in solution and when complexed with a protein,[14–17] and significantly lower susceptibility to enzymatic and acid hydrolysis.[18,19] Although the sulfur–carbon bond is longer than the carbon–oxygen single bond, the C–S–C bond angle is significantly smaller than the C–O–C angle, which often results in relatively small differences between the position of the carbon atoms of the glycosidic linkage.[20] However, the longer bonds and weaker stereoelectronic effect that result when oxygen is replaced with sulfur allow substantially greater flexibility.

This flexibility creates a potential obstacle to the use of thioglycoside immunogens. S-Glycosidic bonds are less constrained than the corresponding O-glycosides and can access the higher energy anti conformation in the unbound and bound state more readily. In the search for effective protective carbohydrate epitopes, it remains an open question as to whether such conformational flexibility would preclude the effective use of antigenic determinants that contain metabolically stable S-linkages. Although the structural similarity of O- and S-linked oligosaccharides is critical to this concept, their differences may also identify S-glycosides as non-self antigens and thus further enhance their immunogenicity.

To investigate the immunochemistry of S-linked oligosaccharides, we initially considered two microbial antigens and subsequently two tumour-associated ganglioside antigens (Scheme 1), in which the existence of a potentially labile sialoside linkage might account for the poor immune response toward synthetic conjugate vaccines. Amine-terminated saccharides were coupled to bovine serum albumin (BSA) or tetanus toxoid (TT) by using either of the squarate or adipate homobifunctional linkers shown in Scheme 2.[21,22] Protein

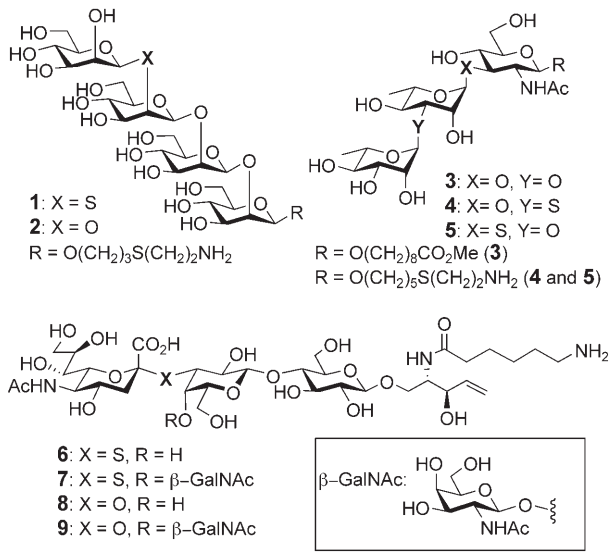
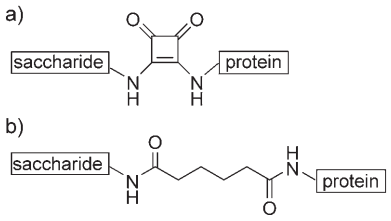


Scheme 1. S- and O-linked synthetic carbohydrate antigens described herein.



Scheme 2. Linkers used in the preparation of glycoconjugates: a) squarate linker and b) adipate homobifunctional linker.

conjugates of the O-glycosides, and for the first time S-glycosides, were evaluated for their ability to induce an antibody response. The antisera from each immunogen was then screened for binding to the immunizing and heteroatom-substituted oligosaccharides that were coupled to a heterologous protein carrier. In general, the S-glycosides induced high titer sera containing carbohydrate-specific immunoglobulin (Ig) and produced a class switch to the IgG isotype, which is associated with the development of immunological memory. Typically, the sera derived from either class of oligosaccharide displayed a similar affinity for the heterologous and homologous oligosaccharides.

Monoclonal antibodies specific for the β-1,2-mannan component of phospomannan and phospholipomannan homopolymers present in the cell wall of *Candida albicans*, protect mice against disseminated and vaginal candidiasis.[23–25] The minimal protective epitope appears to be a β-1,2-linked mannose trisaccharide.[26] Trisaccharide–TT conjugates are highly immunogenic in rabbits and bind to phospomannan when it is part of the cell wall.

Conjugation of oligosaccharides **1** and **2** to TT and BSA provided glycoconjugates for use as immunogens and ligands for ELISA screening (Table 1).[27] The results for the titrations of sera from rabbits, immunized with **10** or **12**, against a crude *C. albicans* cell-wall extract were comparable. The sera of

rabbits immunized with **12** had a titre that was approximately tenfold higher than the sera from rabbits immunized with the corresponding S-linked antigen **10**, when screened against the *C. albicans* cell wall extract. Sera raised against **10** exhibited titer volumes that exceeded 1:100 000 demonstrating clearly that carbohydrate-specific antibodies to the thioglycoside cross-react with O-glycosides (Figure 1). Polyclonal sera

raised against the thiotetrasaccharide–TT conjugate **10** and the O-linked congener **12** were titrated against the corresponding BSA conjugates **11** and **13**. These data obtained with chemically defined antigens not only show production of high titer sera, but also confirm that the S-linked antigen **11** is recognized by antibodies that are produced in response to the corresponding O-linked immunogen **12**. Furthermore, the O-linked antigen **13** is bound tightly by antibodies induced by the S-linked immunogen **10** (Figure 2).

saccharide has a linear tetrasaccharide repeat [→2)α-L-Rha*p*(1→2)-α-L-Rha*p*(1→3)-α-L-Rha*p*(1→3)-β-D-GlcNAc*p*(1→]. Binding studies with a monoclonal antibody SYA/J6 has identified the trisaccharide α-L-Rha*p*(1→3)-α-L-Rha*p*(1→3)-β-D-GlcNAc*p* as the minimal recognition epitope. This trisaccharide was synthesized as the O-linked structure **3** and as two monothiooligosaccharide analogues, **4** and **5**.[28–30] BSA conjugates of the three trisaccharides were prepared, and murine sera derived from immunization with each trisaccharide–BSA conjugate **14**–**16** (Table 1) were titrated against purified LPS that had been extracted from the parent *S. flexneri* bacteria (Figure 3). Recognition of LPS

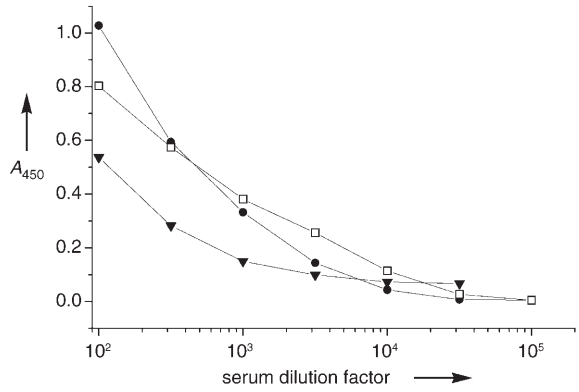

Figure 3. Binding of antibodies from polyclonal sera, derived by immunization with conjugates **14** (▼), **15** (□), and **16** (●), to immobilized *S. flexneri* LPS. Data are averaged for groups of five mice.

by immune sera derived from S-linked oligosaccharides is (represented by specific IgG) to S-glycosides appears equivalent, if not superior, to the response to O-glycosides as judged by the antibody recognition of native LPS. Consistent with these observations, antibodies to the conjugates **15** and **16** were also shown to bind the trisaccharides **4** and **5** and the tetrasaccharide α-L-Rha*p*(1→3)-α-L-Rha*p*(1→3)-β-D-GlcNAc*p*(1→2)-α-L-Rha*p* when they were immobilized on microtiter plates by noncovalent adsorption (data not shown).

Aberrant expression of gangliosides on malignant cells has highlighted the potential of these glycolipids to serve as antigens in cancer immunotherapy.[4,6] Both the trisaccharide GM_3 (α-Neu5Ac-(2→3)-β-Gal-(1→4)-β-Glc-(1→1)-ceramide) and the tetrasaccharide GM_2 (α-Neu5Ac-(2→3)-[β-GalNAc-(1→4)]-β-Gal-(1→4)-β-Glc-(1→1)-ceramide) are considered promising vaccine targets, yet their status as self-molecules and their correspondingly poor immunogenicity have hampered progress toward the development of a successful conjugate vaccine. Although endogenous enzyme hydrolysis of GM_2 is not a concern, at least in serum, extracellular enzymatic degradation of GM_3 is known.[7] We have modified the common terminal glycosidic linkage of GM_3 and GM_2 by replacement of the interresidue oxygen atom with sulfur to give the ganglioside analogues for use as antigens with potentially enhanced immunogenicity. The thiogangliosides **6** and **7**[31] and their O-linked counterparts **8** and **9**[32] bear a truncated ceramide aglycon for coupling to proteins.

The in vivo immunogenicity of ganglioside glycoconjugates (Table 1) was evaluated by ELISA. Immunization of BALB/C mice with TT conjugates (**17** and **21**) of the S- and O-linked GM_3 analogues **6** and **8** yielded a carbohydrate-specific IgG response in three out of five mice. Sera derived from either immunogen were found to cross-react with the homo- and heterosubstituted counterparts **18** and **22** (Figure 4). The

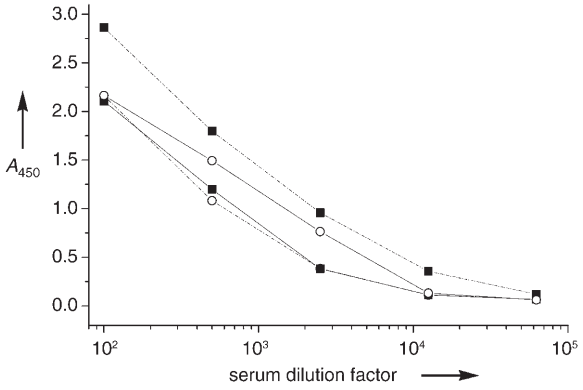

Figure 4. Binding to immobilized **22** (○) and **18** (■) by murine IgG generated from immunization of mice with **21** (——) or **17** (-----). Data are averaged for three mice from each group.

S-linked conjugate **17** was the more immunogenic of the two GM_3 analogues when screened against the immunizing carbohydrate. Cross-reactivity of these antisera with the O-glycoside was further supported by its unambiguous recognition of a α-Neu5Ac-(2→3)-β-Gal-BSA–disaccharide conjugate (see Supporting Information). Furthermore, binding of the same sera to glycoconjugate **22** could be inhibited by the addition of synthetic O-linked oligosaccharides **25** and **26** (Figure 5).[31]

Immunization with the S-GM_2–TT conjugate **19** also generated a strong carbohydrate-specific IgG response, although recognition of the immobilized glycoconjugates was restricted to the S-linked GM_2 analogue **20**. In contrast, sera to the related O-GM_2–TT conjugate **23** bound both O-

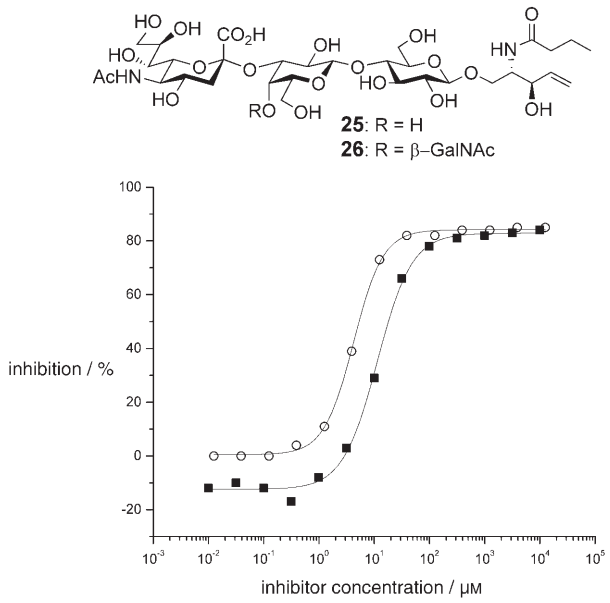

Figure 5. Synthetic oligosaccharides **25** (○) and **26** (■) inhibit the binding of polyclonal sera (IgG) against conjugate **17** to immobilized **22**. IC_{50} values were determined to be 4.2 μM (**25**) and 11.3 μM (**26**).

and S-glycosides and demonstrated equivalent or superior binding of the heterologous oligosaccharide (see Supporting Information). The apparent incongruity in the response to thioimmunogens **17** and **21**, evident in the inability of antibodies to S-GM_2 to recognize the O-glycoside, can be rationalized in terms of the flexibility of the thioglycosidic linkage in **7**. Although the *exo* anomeric effect would be expected to hold the O-linked GalNAc residue in its preferred family of low-energy conformations, the S-linked Neu5Ac should be less constrained and any steric demands imposed by vicinal substitution could be relieved by adoption of conformations that might not be populated as readily by O-linked GM_2.

S-linked immunogens, as components of conjugate vaccines, clearly generate an antigen-specific immune response that approaches (**10** and **19**) or exceeds (**15**, **16**, and **17**) the response to the native oligosaccharide. With the exception of antigens that have terminal, vicinal-branching residues (**19**), antibodies against S-glycosides demonstrate a clear cross-reactivity with the O-glycosides, which suggests a certain degree of conformational similarity. In the systems studied, superior or equivalent recognition of a heterologous oligosaccharide was demonstrated for either the O- or S-linked immunogens or both. The recognition of S-glycosides by sera derived from the native antigens may be explained by the flexibility of the thioglycosidic linkage, which may allow for an induced fit.

We have shown for the first time that carbohydrate epitopes of conjugate vaccines may be modified to contain S-linked residues and that immune responses to such vaccines are of comparable magnitude in terms of antibody titer. Furthermore, the specificity of these antibodies exhibits only a modest loss of fidelity with respect to recognition of the native O-linked epitope. We anticipate that antigens bearing critical residues attached through hydrolysis-resistant linkages will find application either in active immunotherapy or as ligands for immunoabsorption of pathological antiganglioside antibodies present in the sera of patients with certain autoimmune neuropathies.[33]

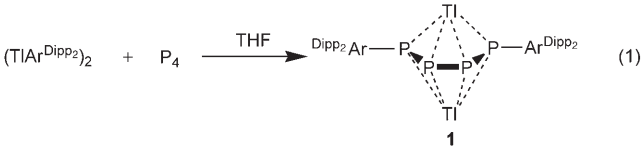
$Tl_2[Aryl_2P_4]$: A Thallium Complexed Diaryltetraphosphabutadienediide and its Two-Electron Oxidation to a Diaryltetraphosphabicyclobutane, $Aryl_2P_4$**

*Alexander R. Fox, Robert J. Wright, Eric Rivard, and Philip P. Power**

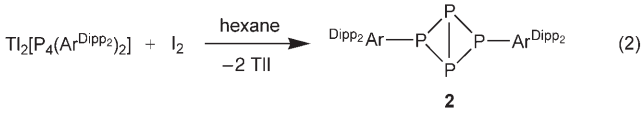
The synthesis and characterization of multiply bonded heavier main group element compounds is a major area of interest in organometallic chemistry.[1] A primary focus of this work has been the stabilization of homonuclear multiply bonded dimeric species of the heavier group 13, 14, and 15 elements and the study of their reactivity.[2] More recently this has led to the stabilization of multinuclear conjugated heavier element arrays containing more than two multiply bonded heavier elements.[3] For example, Weidenbruch and co-workers have prepared silicon[3a] and germanium[3b] analogues of 1,3-butadiene with the use of bulky triisopropylphenyl substituents and have been shown by spectroscopy that they display conjugation. However, the corresponding tetraphosphabutadienes (P_4R_2) and heavier group 15 congeners have not been isolated.[4] Calculations on three parent P_4H_2 isomers (**A**–**C**, Scheme 1) revealed that the tetraphosphabutadiene (**A**) is ca. 20 kcal mol^{-1} less stable than the tetraphosphacyclobutane isomer **B**, while the tetraphosphacyclobutene isomer **C** is 10.7 kcal mol^{-1} less stable than **B**.[5]

The prediction that **A** is the least stable isomer suggests that the preparation of substituted analogues of **A** is a formidable challenge. We were led to consider the existence of stable species with structural frameworks related to **A** during the investigations of reactions of the recently reported "dithallene"[2a] $(TlAr^{Dipp_2})_2$ ($Ar^{Dipp_2} = C_6H_3$-2,6-(C_6H_2-2,6-iPr$_2$)$_2$) with white phosphorus.[6] We now report that the reaction of the weakly dimerized "dithallene" $(TlAr^{Dipp_2})_2$ with P_4 results in aryl group transfer to phosphorus to afford $Tl_2[P_4(Ar^{Dipp_2})_2]$ (**1**), a thallium salt of the diaryltetraphosphabutadienediide, which is a doubly reduced analogue of **A** [Eq. (1)]. Furthermore, we describe the facile two-electron oxidation of **1** by I_2 to yield the neutral diaryltetraphosphabicyclobutane, $P_4(Ar^{Dipp_2})_2$ (**2**), a substituted analogue of **B** [Eq. (2)].



(1)

1



(2)

2

Reaction of $(TlAr^{Dipp_2})_2$ with P_4 in THF and subsequent recrystallization from hexane yielded **1** as burgundy crystals in 40 % yield. Complex **1** was characterized by ^{1}H, ^{13}C, ^{31}P, and $^{203/205}$Tl NMR spectroscopy, UV/Vis spectroscopy, and single-crystal X-ray crystallography. The structure[7a] of **1** (Figure 1) revealed a planar C(1)-P(1)-P(2)-P(2A)-P(1A)-C(1A) dianionic core with a *cis* conformation which is complexed to Tl(1) and Tl(1A) ions disposed equidistant above and below the P_4C_2 array (Tl–P distances 3.032(3)–3.168(3) Å). The Tl^I centers also interact with the flanking Dipp substituents of Ar^{Dipp_2} (Tl–centroid distances are 3.290(3) and 3.204(3) Å).

The Tl–centroid distances in **1** are greater than those in $[(Mes)_6Tl_4(GaBr_4)_4]$[8a] (2.94–3.03 Å), $TlN(Me)Ar^{Mes_2}$[8b] (3.03 Å), and $[Tl\{N[C(C_3F_7)N(Ar)]_2\}]$[8c] (ca. 3.0 Å; Ar = Mes or Dipp) and are substantially greater than the Tl–centroid distances (2.49 Å) observed in the dimer $[C_5(CH_2Ph)_5Tl]_2$.[2b] Calculated Tl–arene interaction energies vary from very weak (ca. 3 kcal mol^{-1})[8b] to relatively strong (ca. 20 kcal mol^{-1})[8c] depending on the model.[9] The Tl–arene interaction energies in **1** are probably weak, however, they may be responsible for the *cis* conformation. The P–P distances in **1** are almost identical (P(1)–P(2) 2.136(4); P(2)–P(2A) 2.143(6) Å) and lie between those observed in doubly-bonded diphosphenes[10] (1.98–2.05 Å) and typical P–P single bonds[11] (ca. 2.21 Å).

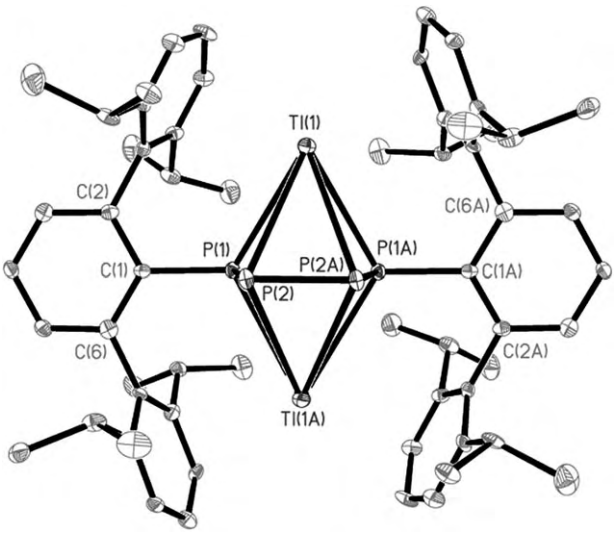

Figure 1. Thermal ellipsoid (30%) plot of **1**. H atoms are not shown for clarity. Selected bond lengths [Å] and angles [deg]: P(1)–C(1) 1.868(11), P(1)–P(2) 2.136(4), P(2)–P(2A) 2.143(6), Tl(1)–P(1) 3.066(3), Tl(1)–P(1A) 3.032(3), Tl(1)–P(2) 3.168(3), Tl(1)–P(2A) 3.144(3); C(1)-P(1)-P(2) 100.7(3), P(1)-P(2)-P(2A) 101.75(10), C(1)-P(1)-Tl(1) 120.9(3), C(1)-P(1)-Tl(1A) 117.8(3).

The ^{205}Tl NMR spectrum of **1** consisted of a broad signal (1750 Hz at half height) at ca. 2730 ppm, which is within the range observed for Tl^{I} compounds.[12] There is a pair of satellite signals ($^{2}J_{^{205}Tl,^{203}Tl} \approx 12000$ Hz) arising from coupling to the ^{203}Tl isotope (Figure 2). A pseudo-quintet pattern is superimposed on the three broad signals, which presumably results from the similar $^{1}J_{^{205}Tl,P(1)}$ and $^{1}J_{^{205}Tl,P(2)}$ coupling constants of ca. 500 Hz. The ^{203}Tl NMR spectrum consists of the same pseudo-quintet pattern, with a pair of ^{205}Tl satellite signals ($^{2}J_{^{203}Tl,^{205}Tl} \approx 12000$ Hz). However, because of the greater abundance of the ^{205}Tl isotope (^{203}Tl 29.5%, ^{205}Tl 70.5%), the ^{205}Tl satellite signals are larger. The large size of the $^{2}J_{^{205}Tl,^{203}Tl}$ coupling constant (ca. 12000 Hz) in both spectra is noteworthy.[13] The pseudo quintet displayed in the Tl NMR spectra indicates that the association of the thallium ions and the P_4 array is preserved in solution.

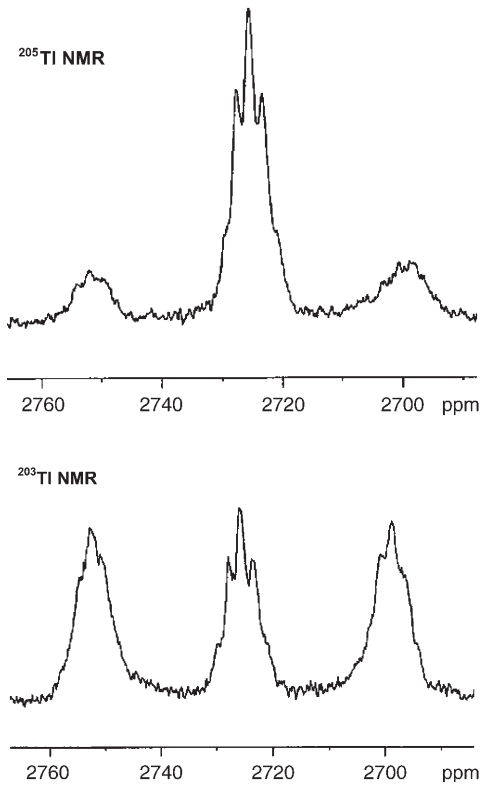

Figure 2. ^{205}Tl and ^{203}Tl NMR spectra of **1**.

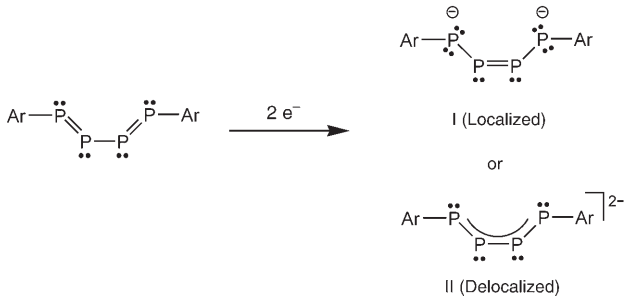
The ^{31}P NMR spectrum revealed two broad multiplets (width at half height ca. 850 Hz) at 280 and 185 ppm, likely due to $^{1}J_{P,P}$, $^{1}J_{^{205}Tl,P}$, and $^{1}J_{^{203}Tl,P}$ coupling. Variable-temperature spectroscopy in the range −90 to 60 °C did not allow for extraction of specific coupling constants. The UV/Vis spectrum displayed three intense absorptions at 322, 432, and 546 nm ($\varepsilon = 1000$–$13000\ mol^{-1}\,L\,cm^{-1}$), where the longer-wavelength absorptions are probably due to the orbitally allowed $\pi \rightarrow \pi^*$ and $n \rightarrow \pi^*$ transitions.

Compound **1** is a thallium complexed diaryltetraphosphabutadienediide and can formally be derived from the two-electron reduction of the neutral diaryltetraphosphabutadiene. This affords a 6π system where two bonding forms are possible: the negative charge can be localized on the terminal phosphorus atoms (**I**) or the negative charge can be delocalized over the entire P_4 unit (**II**) (Scheme 2).



Scheme 2.

The isolated dianions of substituted 1,3-butadiene[14] and 1,2-bis(diphosphinyl)ethenes,[15] which are isoelectronic to **1**, display a localized bonding pattern analogous to structure **I**, where minimization of the Coulombic repulsion between the two negative charges is achieved. However, the P–P distances in **1** are nearly identical suggesting that a more delocalized bonding scheme (structure **II**) is present, which gives a formal P–P bond order of 1.33.[16] The Tl–P interactions may be responsible for decreasing intrachain electronic repulsion in **1**.

The synthesis of a neutral diaryltetraphosphabutadiene derivative analogous to **A** was attempted by oxidation of **1**. However, reaction of **1** with I_2 gave $P_4(Ar^{Dipp_2})_2$ as the diaryltetraphosphabicyclobutane isomer.[7c,17] It seems likely that a species with a structure analogous to **A** is generated initially but that this isomerizes to **2**.[18] The isomerization is reminiscent to that of 1,3-butadiene to bicyclobutane which

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

has been well explored in the classic work of Woodward and Hoffmann.[19]

The ^{31}P NMR spectrum of **2** gave two triplet resonances centered at $\delta = -331.8$ (bridgehead P atoms) and $\delta = -163.0$ ppm ($^{1}J_{P,P} = 189$ Hz), consistent with either a rigid *trans*,*trans*-diaryltetraphosphabicyclobutane, or a fluxional structure with C_{2v} symmetry. Previously reported disubstituted tetraphosphabicyclobutanes, R_2P_4 (R = 2,4,6-*t*Bu$_3$C$_6$H$_2$ (**3**),[17a] (Me$_3$Si)$_2$N (**4**),[17b] [(Me$_3$Si)$_2$N]$_2$P (**5**),[17c]) crystallized in the *trans*,*trans* configuration. However, unlike **2**, the ^{31}P NMR spectra of **4** and **5** showed evidence for both the C_s-symmetric *cis*,*trans* conformer and *trans*,*trans* conformer in solution. In contrast, the ^{31}P NMR spectrum of the Mes* substituted **3** afforded only two resonances ($\delta = -272$ and -130 ppm) with chemical shift values similar to **2**.

The crystal structure (**2a**; from benzene)[7b] revealed a *trans*,*trans* structure (Figure 3), which is similar to a range of previously structurally characterized tetraphosphabicyclobutanes and is consistent with the ^{31}P NMR spectrum of **2** in solution ([D$_8$]THF, −90 to 60 °C). However, crystals of **2** grown from hexane[7c] displayed a *cis*,*trans* structure (**2b**), an isomeric form that has not been observed in the solid state. The P–P distances, including the bridgehead P–P bonds, of **2a** (2.203(1)–2.207(2) Å) and **2b** (2.205(2)–2.243(2) Å) are similar and consistent with P–P single bonding. The bridgehead P–P bonds (**2a**, 2.203(2); **2b**, 2.219(2) Å) are ca. 0.10 Å longer than in **4** and ca. 0.05 Å longer than in **3** and **5**. The P_4 fold angle of **2a** is 92.9° and falls only slightly outside of the known range (95.2–95.6°) for **3**–**5**. However, the P_4 fold angle of 71.9° in **2b** is accompanied by a widening of the P(1)-P(2)-P(4) (89.33(7)°) and P(1)-P(3)-P(4) (88.66(7)°) angles resulting from alleviation of the steric interactions between the two Ar^{Dipp_2} substituents. Calculations regarding the relative stability of the *trans*,*trans* and *cis*,*trans* conformations of P_4H_2 indicate that the *trans*,*trans* isomer is more stable, but only by 1.2 kcal mol^{-1}.[20] Since both isomers are obtainable in the solid state, crystal packing effects probably dictate the solid state conformation.

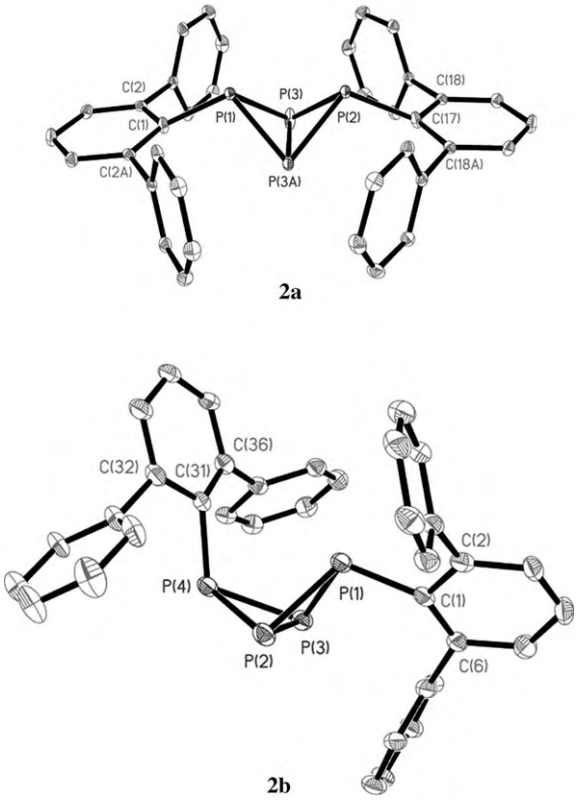


Figure 3. Thermal ellipsoid (30%) plots of **2a** and **2b**. H atoms and isopropyl groups on Ar^{Dipp_2} are not shown for clarity. Selected bond lengths [Å] and angles [deg]: **2a**: P(1)–C(1) 1.866(3), P(2)–C(17) 1.887(3), P(1)–P(3) 2.207(1), P(2)–P(3) 2.201(1), P(3)–P(3A) 2.203(2); P(1)-P(3)-P(2) 77.81(4); the P_4 fold angle, defined as the dihedral angle between the P(1)-P(3)-P(3A) and P(2)-P(3)-P(3A) planes, is 92.9. **2b**: P(1)–C(1) 1.874(6), P(1)–P(2) 2.205(2), P(1)–P(3) 2.243(2), P(2)–P(4) 2.216(2), P(2)–P(3) 2.219(2), P(3)–P(4) 2.205(2), P(4)–C(31) 1.821(6); P(1)-P(2)-P(4) 89.33(7), P(1)-P(3)-P(4) 88.66(7); the P_4 fold angle, defined as the dihedral angle between the P(1)-P(2)-P(4) and P(4)-P(3)-P(2) planes, is 71.9°.

In conclusion, the thallium complexed diaryltetraphosphabutadienediide (**1**) has been synthesized from the reaction of (Ar^{Dipp_2}Tl)$_2$ and white phosphorus. The negative charge is delocalized over the P_4 array, as suggested by the essentially equal P–P distances and planar P_4C_2 core, to afford an average P–P bond order of approximately 1.33. Reaction of **1** with I_2 afforded the diaryltetraphosphabicyclobutane **2** which depending on the solvent of crystallization can be obtained as either the *trans*,*trans* (**2a**) or the *cis*,*trans* isomer (**2b**). Future work will focus on evaluating the ability of **1** as a $[P_4Aryl_2]^{2-}$ transfer agent, and exploring the reduction chemistry of **2**.

Experimental Section

All manipulations were carried out under anhydrous and anaerobic conditions.

1: An aluminum foil-wrapped 100-mL Schlenk flask was charged with equimolar portions of (Ar^{Dipp_2}Tl)$_2$ (0.916 g, 0.761 mmol) and freshly distilled white P_4 (0.094 g, 0.76 mmol). This mixture was placed in a water–ice bath and, with vigorous magnetic stirring, THF (ca. 60 mL) that had been pre-cooled to 0 °C was added. The resulting deep red solution was stirred for 12 h, whereupon it was filtered from some precipitate (presumably Tl metal) using a glass-fiber tipped cannula. The solvent was removed under a dynamic vacuum and the residue was washed with ca. 15 mL of cold hexane. The product was obtained as a burgundy microcrystalline solid that is sparingly soluble in hydrocarbon solvents and does not display any detectable light sensitivity. Redissolving with warm hexane (ca. 35 mL) followed by overnight cooling to ca. −15 °C afforded X-ray quality crystals of **1**. Yield: 0.205 g, 40%; Mp: darkens at 130 °C, 226 °C (dec.) ^{1}H NMR (300.1 MHz, [D$_8$]THF, 25 °C): $\delta = 0.96$ (d, 24 H, CH(C*H*$_3$)$_2$, $^{3}J_{H,H} = 6.9$ Hz), 1.33 (d, 24 H, CH(C*H*$_3$)$_2$, $^{3}J_{H,H} = 6.9$ Hz), 2.70 (sept, 8 H, C*H*(CH$_3$)$_2$, $^{3}J_{H,H} = 6.9$ Hz), 6.88 (d, 4 H, *m*-C$_6$H$_3$, $^{3}J_{H,H} = 7.5$ Hz), 6.99 (t, 4 H, *p*-dipp, $^{3}J_{H,H} = 7.7$ Hz), 7.11–7.16 (t, partially buried, *p*-C$_6$H$_3$), 7.11 ppm (d, 8 H, *m*-dipp, $^{3}J_{H,H} = 8.1$ Hz); ^{13}C{^{1}H} NMR: (75.5 MHz, [D$_8$]THF, 25 °C): $\delta = 24.1$ (*o*-CH(*C*H$_3$)$_2$), 26.0 (*o*-CH(*C*H$_3$)$_2$), 31.8 (*o*-CH(*C*H$_3$)$_2$), 124.4 (*p*-C$_6$H$_3$), 126.5 (*p*-dipp), 129.4 (*i*-C$_6$H$_3$), 130.8 (*m*-C$_6$H$_3$), 142.6 (*o*-C$_6$H$_3$), 144.5 (*i*-dipp), 147.5 (*o*-dipp), 148.1 ppm (*m*-dipp); ^{31}P{^{1}H} NMR (121.5 MHz, [D$_8$]THF, 50 °C, referenced externally to 85% H$_3$PO$_4$): $\delta = 185$ (m), 280 ppm (m); ^{205}Tl NMR (230.71 MHz, [D$_8$]THF, 25 °C, referenced externally to TlNO$_3$(aq)): $\delta = 2730$ ppm (m, $^{2}J_{^{205}Tl,^{203}Tl} \approx 12000$ Hz); ^{203}Tl NMR (228.47 MHz, [D$_8$]THF, 25 °C, referenced externally to TlNO$_3$(aq)): $\delta = 2730$ ppm (m, $^{2}J_{^{205}Tl,^{203}Tl} = 12000$ Hz); UV/Vis (hexanes) λ_{max} [nm] (ε in mol^{-1} L cm^{-1}): 222 (45000), 322 (13000), 432 (990), 546 (2400).

2: I_2 (0.068 g, 0.270 mmol) was dissolved in hexane (80 mL). This solution was added dropwise to **1** (0.355 g, 0.267 mmol) dissolved in hexane (20 mL). Upon complete addition the color of the solution had changed from deep red to colorless. The slurry was stirred for 2 h and the precipitate (TlI) was removed by filtration through a Celite-padded frit. The solution was concentrated to ca. 10 mL and storage at ca. −20 °C overnight afforded colorless X-ray quality crystals of **2b**. Yield: 0.130 g, 53 %; Mp > 320 °C. ^{1}H NMR (300.1 MHz, [D$_8$]THF, 25 °C): $\delta = 0.93$ (d, 24 H, CH(CH_3)$_2$, $^3J_{H,H} = 6.6$ Hz), 1.13 (d, 24 H, CH(CH_3)$_2$, $^3J_{H,H} = 6.9$ Hz), 2.31 (sept, 8 H, CH(CH$_3$)$_2$, $^3J_{H,H} = 6.6$ Hz), 6.94 (d, 4 H, *m*-C$_6$H$_3$, $J_{HH} = 7.5$ Hz), 7.14 (d, 8 H, *m*-dipp, $J_{H,H} = 7.8$ Hz), 7.20 (t, 4 H, *p*-C$_6$H$_3$, $J_{H,H} = 7.8$ Hz), 7.37 ppm (t, 4 H, *p*-dipp, $J_{H,H} = 7.8$ Hz); ^{13}C{^{1}H} NMR (75.5 MHz, [D$_8$]THF, 25 °C): $\delta = 22.9$ (CH(*C*H$_3$)$_2$), 25.2 (CH(*C*H$_3$)$_2$), 30.8 (CH(CH$_3$)$_2$), 123.1 (*m*-dipp), 127.0 (*p*-C$_6$H$_3$), 129.0 (*m*-C$_6$H$_3$), 129.3 (*p*-dipp), 135.5 (m, *i*-C$_6$H$_3$), 138.7 (*o*-C$_6$H$_3$), 145.4 (m, *i*-dipp), 146.5 ppm (*o*-dipp); ^{31}P NMR (121.5 MHz, [D$_8$]THF, 25 °C): $\delta = -331.8$ (t, 2 P, bridgehead, $^1J_{P,P} = 189.2$ Hz), −163.0 ppm (t, 2 P, terminal, $^1J_{P,P} = 189.2$ Hz). X-ray quality crystals of **2a** were obtained by dissolving **2b** in C$_6$D$_6$ followed by slow cooling to 7 °C. The spectroscopic properties of **2a** (in [D$_8$]THF) were identical to those of **2b** (in [D$_8$]THF).

$Ba_8CoNb_6O_{24}$: A d^0 Dielectric Oxide Host Containing Ordered d^7 Cation Layers 1.88 nm Apart**

*Phillip M. Mallinson, Mathieu M. B. Allix, John B. Claridge, Richard M. Ibberson, David M. Iddles, Tim Price, and Matthew J. Rosseinsky**

The search for multiproperty materials,[1] in which one cooperative phenomenon can control another through modulation of the local structure and bonding, is complicated by the need to separate the chemical units responsible for these different properties. Thus, rules are required for the synthesis of materials that assemble with spatial segregation of the elements conferring distinct properties. These rules should be sufficiently strict to operate at the high synthesis temperatures required for processing many inorganic materials.

This challenging synthetic task can be addressed by exploiting the diversity of site chemistries[2] available in a complex perovskite structure and harnessing the combination of the specific bonding requirements of the d^0 cations and the site symmetries in the structure to drive the cation ordering. Here we present the functional material $Ba_8CoNb_6O_{24}$ comprising isolated single layers of Co^{2+} d^7 cations separated by intervening d^0 cation layers and 1.88 nm away from the next Co^{2+} layer. Most remarkable is that this long-range ordering is driven despite the low concentration of Co^{2+} cations in the structure. These site-ordered solids are then processed to permit their evaluation as microwave dielectric resonators.

In the chemistry of transition-metal oxides, elements in the d^0 oxidation state (particularly Ta^V, Ti^{IV}, and Nb^V), with their characteristic directional M–O multiple bonding, are the basic components of ferroelectric, relaxor, and high-permittivity materials.[3] Transition-metal centers that bear d electrons (d^n centers) confer magnetic, optical, and electronic properties on materials. The development of extended metal oxide networks in which d^n centers can be separated by long distances with precise site order within a d^0 matrix offers great potential in materials design. The ordering of cations of different sizes and charges is possible on the octahedral B site of the ABO_3 perovskite structure[4]—hexagonal stacking of the AO_3 close-packed layers produces face-sharing octahedral sites in addition to the corner-sharing sites characteristic of a cubic stacking sequence. The face-sharing sites thus introduced are favorable locations for cation vacancies, with mixed hexagonal and cubic stacking sequences resulting in the family of "hexagonal perovskites".[5]

Complex tantalum oxides are widely employed as microwave resonators in mobile telecommunications, but the cost of raw materials makes niobium-based alternatives desirable. The eight-layer hexagonal perovskite $Ba_8ZnTa_6O_{24}$ adopts a $(chcc)_2$ sequence (an AO_3 layer (B) is described as h if its two neighboring layers are the same (ABA) or c if they are different (ABC)) and has interesting dielectric properties with a moderately high Q of 20800 at 3.28 GHz ($Q = (\tan\delta)^{-1}$).[6] Our initial investigations on the Nb analogue $Ba_8ZnNb_6O_{24}$ consistently lead to the synthesis of polyphasic material with several competing stacking sequences of hexagonal and cubic layers.

Investigation of the cobalt-substituted niobate $Ba_8CoNb_6O_{24}$ revealed that this composition afforded single-phase material with an eight-layer ($c \approx 18$ Å , BaO_3 layer thickness ≈ 2.3 Å) repeat in contrast to the mixed phases in the Ba-Zn-Nb-O field at this composition. Surprisingly, although $Ba_8CoTa_6O_{24}$ is isostructural with $Ba_8ZnTa_6O_{24}$ and tolerance factor effects associated with stacking sequence changes[5] are absent, the new Nb phase adopts a different eight-layer stacking sequence in which two hexagonal ABA AO_3 layer units are adjacent to each other in an ccchhccc motif (Figure 1).[7] High-resolution electron microscopy images directly demonstrate that this sequence is adopted without stacking faults (Figure 2a). The $P\bar{3}m1$ space-group symmetry is confirmed by electron diffraction (Figure 2b,c) and the cation composition and homogeneity by energy dispersive spectroscopy (EDS) in the electron microscope. Although all the occupied octahedra in such a sequence are corner sharing, and the triple layer of face-sharing octahedral sites in the hh region of the structure

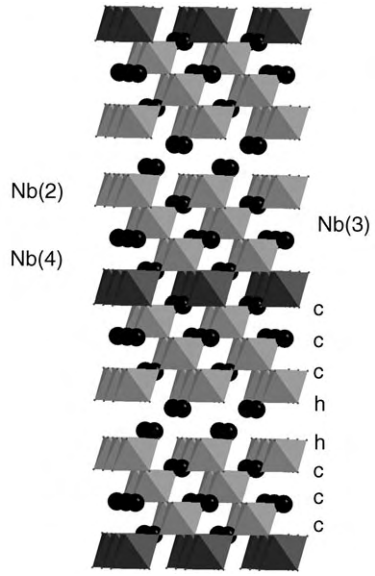

Figure 1. The cchhccc stacking sequence of $Ba_8CoNb_6O_{24}$ shows strict ordering of the Co^{2+} cations (comprising only 12.5% of the total octahedral-site cations) on the central layer of octahedral sites within the seven-block unit of corner-sharing octahedra. Cobalt- and niobium-centered octahedra are shown in dark gray and light gray, respectively, and barium cations are represented as black spheres. The layer of vacant octahedral sites in the hh region of the stacking sequence produces a structure consisting solely of corner-sharing octahedra.

results in a central layer of vacant sites (Figure 1), $Ba_8CoNb_6O_{24}$ displays essentially complete ordering of the Co^{2+} and Nb^{5+} cations. Refinement of high-resolution time-of-flight neutron powder diffraction data reveal the superiority of fully ordered ($\chi^2 = 2.92$) over fully disordered ($\chi^2 = 3.15$) models; permitting antisite disorder between the single Co (*1a*) and three crystallographically distinct Nb sites results in 95(3)% Co occupancy of the *1a* site and pure Nb(2) and Nb(3) sites within 1σ; improvements in agreement indices when site disorder was permitted were insignificant. (The atomic displacement parameters in the partially ordered model are unphysical, with several atoms refining to negative values, and the convergence was not robust). The fully site-ordered model was thus adopted (Table 1 and Table 2) The bond valence sums for Co^{2+} and Nb^{5+} on the *1a* site are 1.95 (3% deviation from expected) and 3.51 (30% deviation), respectively, while the maximum deviation from the ideal bond valence of 5 for Nb^{5+} cations on the other three sites in the structure is 8%. As the Nb^{5+} bond valence in fully site-ordered $Ba_3MgNb_2O_9$ is 4.66,[8] both the site occupancies and bond-valence considerations indicate that the cation site order is complete in $Ba_8CoNb_6O_{24}$.

The *1a* sites solely occupied by Co^{2+} are at the centers of the seven-layer blocks of corner-sharing octahedra. This is surprising as a statistical distribution of cobalt cations over the four available sites might have been expected given their low concentration (only 12.5% of the octahedral sites are occupied by Co^{2+}) and the existence of only corner-sharing sites in the structure. The *1a* site is the most regular environment amongst the four symmetry-inequivalent octahedral sites, as it is located necessarily at a center of symmetry

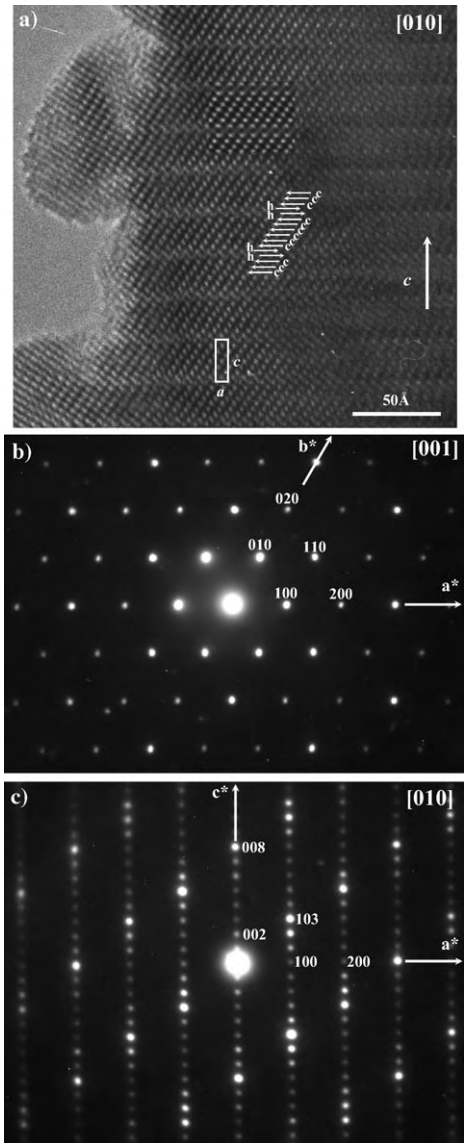

Figure 2. a) HREM image of $Ba_8CoNb_6O_{24}$ recorded along the [010] direction. The simulated image is embedded. Experimental [001] (b) and [010] (c) electron diffraction patterns.

as a result of the odd number of occupied layers in the stacking sequence. The symmetry-imposed requirement that all the bond lengths between oxygen and the central atom on this site are equal is inconsistent with the multiple-bonding preference of Nb^{5+}, which is often displaced from the center of an octahedral environment to form multiple bonds to oxygen (Figure 3a). This in turn favors all the Co^{2+} cations, which are more commonly found in centrosymmetric oxide octahedra (Figure 3b), occupying the site to avoid forcing Nb^{5+} into an unfavorable environment. The availability of the distinctly bonded *1a* site together with the cation charge difference (which is more pronounced here than between the cations with charges of +3, +4, and +5 of site-disordered $Ba_8In_{0.5}Ti_2Nb_{4.5}O_{24}$)[7] drives the strict site ordering and resulting extreme long-range separation of the cobalt cation layers. This strict site ordering results in the separation of Co^{2+} layers by 1.88 nm along *c*. Ordering over this distance

Table 1: Refined coordinates of $Ba_8CoNb_6O_{24}$. Space group $P\bar{3}m1$; $a = 5.789813(10)$, $c = 18.89355(6)$ Å; $\chi^2 = 2.9$ $R(F^2) = 5.88\,\%$ $R(F) = 4.34\,\%$. The global instability index,[14] which measures the mean deviation of the bond valence sum of all ions in the structure from their formal valence, is 0.21, which is consistent with that observed in high-permittivity niobates based on site-ordered cubic perovskites.[8] The weighted average deviation from the ideal bond valence sums is 0.058, which is consistent with those observed in cubic perovskite niobates. The valence sums at Ba of over 2 indicate compression around these sites, as is commonly observed in perovskite niobates.[8]

over purely six coordinate sites is unusual (Mn^{2+} and W^{6+} are ordered within a three-layer block in $Ba_2La_2MnW_2O_{10}$, where the concentration of the centrosymmetric cation is considerably higher than the present case[9]), although discrete Fe^{3+} tetrahedral layers are observed separated by mixed iron/titanium octahedral layers in complex barium iron titanium oxides.[10]

The Nb(2) site adjacent to the layer of vacant octahedral sites has the most pronounced off-center displacement of Nb^{5+} towards a triangular face of the octahedral oxide environment along the threefold axis due to the absence of other cations competing for bonding with the O2 oxide anions. The other two Nb sites, which share all their coordinating oxide anions with neighboring B site cations, have off-center displacements similar to those observed in fully site-ordered $Ba_3MgNb_2O_9$,[8] in accord with the proposed structural model for $Ba_8CoNb_6O_{24}$. It is interesting to note that the separation of the BaO_3 layers neighboring the vacant site is at 1.65 Å consistent with that of $Ba_5Nb_4O_{15}$ but distinctly shorter than found in the Q blocks of ferrites,[11] where the corresponding distance is 2.15 Å.

Magnetization data for $Ba_8CoNb_6O_{24}$ obeyed the Curie–Weiss law between 2 and 300 K with an effective moment of 4.06 μ_B per Co (the spin-only value is 3.87 μ_B) and −4.26(6) K antiferromagnetic Weiss constant) and no irreversibility between field and zero-field cooled runs (Figure 4). This is consistent with the structural model of Co^{2+} cations with near-neighbor Co–Co distances within the layer of 5.786 Å without direct Co-O-Co superexchange pathways. Deviations from the spin-only prediction are commonly observed for

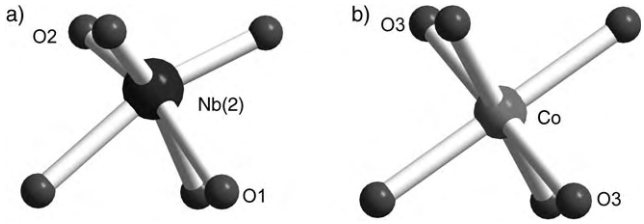

Figure 3. a) The asymmetric multiple bonding to oxide by Nb^{5+} produces displacement of Nb(2) from the center of the octahedron towards the face of three O2 oxide anions bordering the layer of vacant face-sharing octahedral sites, whereas in b) the Co^{2+} cation is located in a centrosymmetric environment that does not permit ordered displacements of the type required to optimize the bonding at Nb. The *c* axis (layer stacking direction) is vertical in both structures.

octahedral Co^{2+}—the slight enhancement of the magnetic moment over the spin-only value results from incomplete quenching of the orbital contribution from the $^4T_{1g}$ state of high-spin Co^{2+} by the trigonal ligand field, and agrees with the value of 4.1 μ_B observed for Co^{2+} in anatase.[12]

For oxides containing metals with variable oxidation states, hopping conduction offers a mechanism for dielectric loss. However, the Co^{2+} oxidation state seems robust in $Ba_8CoNb_6O_{24}$, as indicated both by the magnetic data and the invariance of the cell parameters to processing conditions. The phase can be processed into resonators with a density of 89.6 % of the crystallographic density with a relative permittivity of 31: Q values are sensitive to processing, but resonators with the most dense microstructure (scanning electron micrographic images of sectioned high-Q material shown in Figure S2 and S3 reveal lath- and platelike grains $\geqq 10$ μm thick and of similar aspect to but with larger dimensions than those for $Ba_8ZnTa_6O_{24}$[13]) have Q of 16700 at 3.2 GHz ($Qf = 53200$ GHz). The temperature coefficient of the resonant frequency, τ_f, is 16 ppm K^{-1}. EDS analysis of the grains (Figure S2) at both interior and exterior surfaces of the

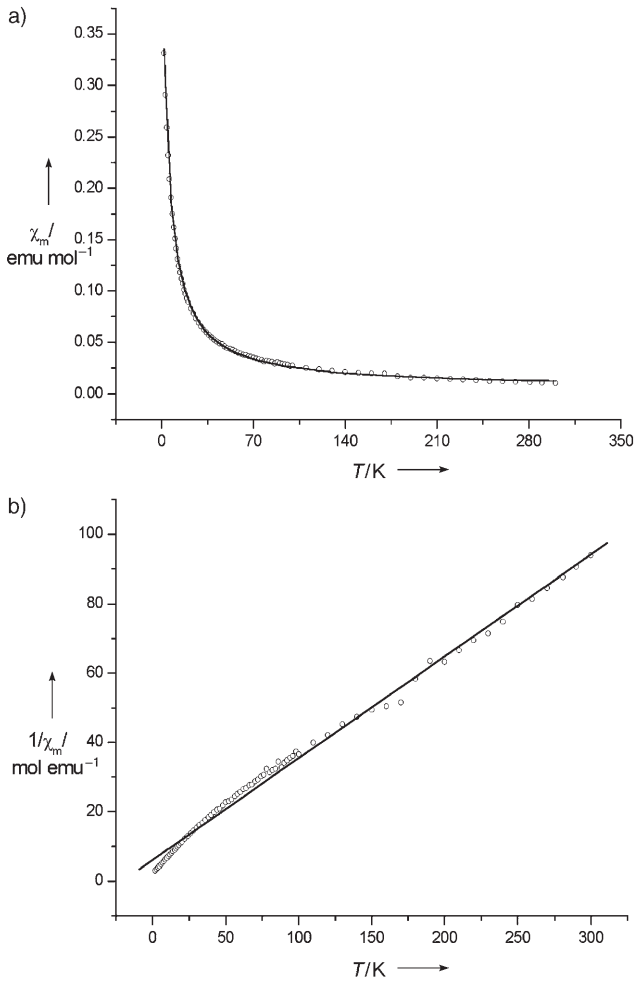

Figure 4. a) Fit of the magnetic susceptibility of $Ba_8CoNb_6O_{24}$ to the Curie–Weiss law. A single-ion Kotani fit gives an unphysical value for the spin-orbit coupling constant and thus the assignment of the observed value of θ to exchange coupling between the cobalt cations is preferred. b) Plot of the inverse susceptibility versus temperature.

resonator ceramics confirms the homogeneity of the Co distribution and the absence of $Ba_3CoNb_2O_9$ perovskite.

The structure of $Ba_8CoNb_6O_{24}$ shows that subtle differences in bonding are sufficient to produce long-range order over nanometer-distance scales even in high-temperature reactions producing complex structures containing solely six coordinate corner-sharing sites. The extension of this motif to compositionally more complex arrays in which three or more metal centers can be manipulated spatially in this manner is now a significant challenge.

relatively weak forces, have high compressibilities; organometallics, in addition, have soft metal-centered bonds. Thus, at HP it should be possible to observe significant changes in both inter- and intramolecular distances.

We have recently discussed the nature of M–M bonds of metal carbonyl clusters using experimental and theoretical charge densities;[2] here we report the first attempt to "directly" observe the behavior of a M–M bonded system under pressure. As suggested by HP spectroscopy, $[Mn_2(CO)_{10}]$, $[Re_2(CO)_{10}]$, and $[MnRe(CO)_{10}]$ undergo a staggered to eclipsed conformational rearrangement of the equatorial carbonyl ligands,[3] which seems to be associated with a reconstructive phase transition (PT) and extensive crystal fragmentation.

To obtain "indirect" proof of this process we considered a related species, $[Co_2(CO)_6(PPh_3)_2]$ (**1**), which at room temperature and pressure (RT and RP) has an unsupported M–M bond and a staggered arrangement of equatorial CO ligands. In the solid state, **1** is isomorphous to $[Co_2(CO)_6(AsPh_3)_2]$ (**2**), which is known to undergo a reversible "crystal to crystal" PT (at $T \approx 200$ K) characterized by an incipient staggered to eclipsed rearrangement.[4] Thus, according to the well-known relationship between low-temperature (LT) and HP changes, **1** (as well as **2**) should be the ideal candidate for a single-crystal HP diffraction study of this process. Here we report the detailed crystallographic analysis of the structural behavior of **1** on lowering T (down to 28 K) and on raising P (up to 46 kbar).[5]

At RT and RP, **1** crystallizes in the trigonal space group $R\bar{3}$ and lies about a $\bar{3}$ symmetry element (*b* in Wickoff notation). The molecule (Figure 1) consists of two trigonal-bipyramidal cobalt atoms linked by an unsupported Co–Co bond along the axial direction. The remaining axial site of each metal center is occupied by a PPh_3 group and three CO ligands are bound in the equatorial positions. Given the observed crystallographic symmetry the CO ligands are constrained to be exactly staggered, and the same occurs for the phenyl groups of the triphenylphosphane ligands. In the crystal, molecules of **1** stack on top of each other in columns (parallel to *c*, Figure 2a), the projections of which define a hexagonal motif in the *ab* plane (Figure 2b). The packing along the columns is dominated by the presence of "sextuple embraces" between opposite PPh_3 groups.[6] The six neighboring columns are shifted along the *c* axis by $\pm 1/3$ (three upwards, three downwards) to allow the optimization of "lateral" interactions (π stacking of phenyl groups and CH···O contacts).

On lowering the temperature below 120 K or on increasing the pressure above 13 kbar, we observed a reversible solid–solid PT,[7] in which doubling of the *c* axis reduces the molecular symmetry from $\bar{3}$ to 3 without losing the crystal symmetry class ($\bar{3}$). After the PT, the perfect staggering of the ligands no longer holds and different structural changes are observed, the most striking of which is the rapid progress toward eclipsing of the two sets of CO ligands.

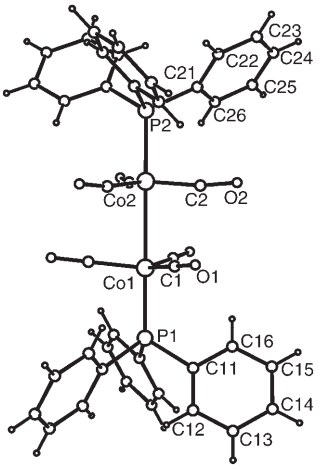

Figure 1. $[Co_2(CO)_6(PPh_3)_2]$ (**1**); independent atoms of the HP/LT phases are labeled. Before the transition the presence of an intramolecular inversion center halves the asymmetric unit and limits the significant degrees of freedom to a few angles (C11-P1-Co1-O1, C16-C11-P1-Co1, and Co2-Co1-C1) and bond lengths (Co1-Co2 and Co1-P1). After the transition the inversion center is lost, the CO-Co-Co-CO and Ph-P-P-Ph torsions are freed, and the above-mentioned parameters doubled.

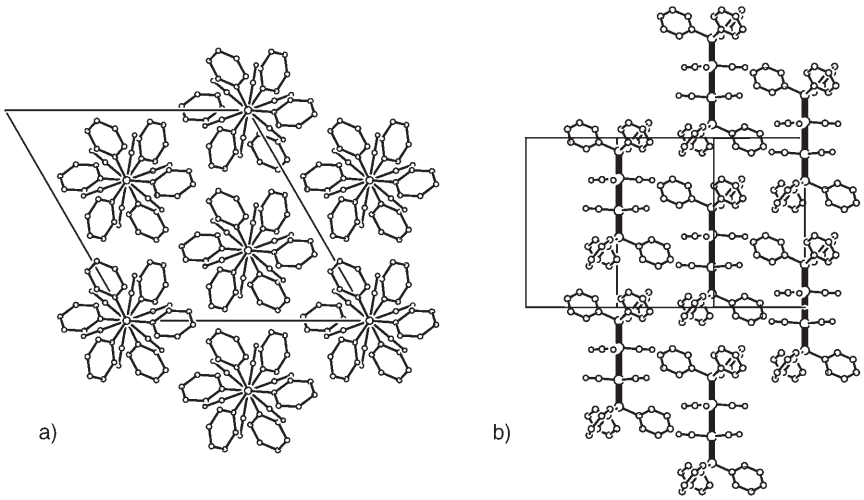

Figure 2. Crystal packing of **1** under ambient conditions. a) View normal to (001). b) View normal to (100).

Temperature-induced structural modifications are mainly due to reduced atomic motion and span a limited region of the molecular potential energy surface (at 28 K the OC-Co-Co-CO angle is ca. 56°), but larger effects are expected and found on increasing the pressure (at 46 kbar the OC-Co-Co-CO angle is as small as ca. 20°).

To estimate the energies associated with the observed molecular deformations, we performed a series of constrained DFT gas-phase optimizations of $[Co_2(CO)_6(PH_3)_2]$ (mimicking **1**, see Table 1), which showed a correlation between CO eclipsing and Co–Co elongation (the eclipsed conformer is ca. 0.2 Å longer and 10 kcal mol^{-1} less stable than the staggered one).[8] Further insight is offered by normal-mode analysis of the staggered conformer: H-P-P-H (33 cm^{-1}), OC-Co-Co-CO

(47 cm^{-1}); Co-Co-CO (96 cm^{-1}); and Co–Co (156 cm^{-1}), Co–P (320 cm^{-1}) are the softer torsional, bending, and stretching modes, respectively.

These computations, although neglecting effects of crystal packing, clearly highlight the most accessible deformation modes of the molecule. However, before the PT, Ph-P-P-Ph and OC-Co-Co-CO torsions are locked in by the crystal symmetry; thus, other deformation modes must occur, even if associated with higher energies. Indeed, at 8 kbar we observed significant compression of the Co–Co and Co–P bonds.

After the PT, other intramolecular degrees of freedom become available (see legend to Figure 1) and the response of the molecule to the "external field" can be different. For example, the Co–Co bond elongates, that is, its stretching energy is released and redistributed over the softer deformation modes now available. However, using as reference the values calculated for the isolated molecule (at different OC-Co-Co-CO torsion angles) we were able to identify, above the PT, a continuous (relative) compression of the Co–Co bond, in spite of its actual (absolute) elongation (see Table 1 and Supporting Information).

As the pressure increases, the *ab* plane shrinks (see Supporting Information) and a series of concatenated deformations occurs. We suggest the following order of (major) events (see Figure 3): P2-bound phenyl groups come into contact with the neighboring Co1-bound CO ligands, which rotate about the threefold axis and bend toward the Co2-bound ones, which in turn are pushed away. At the same time, a translation along the *c* axis of the whole molecule generates an alternation of closely (P2···P2) and loosely (P1···P1) packed sextuple embraces (like a Peierls distortion), and thus the P2-bound phenyl groups are forced to become less parallel to the molecular axis, and the opposite behavior is exhibited by their P1-bound counterparts).

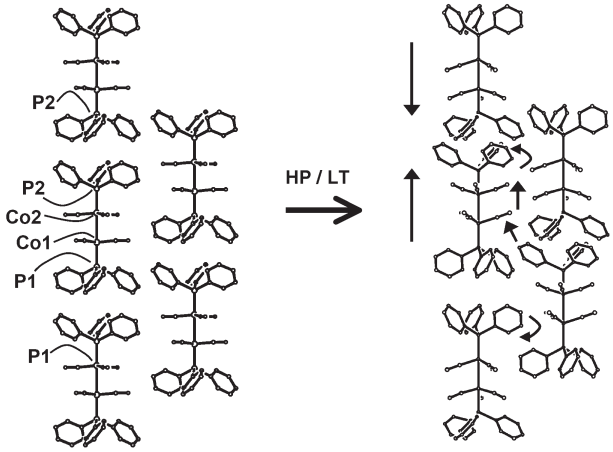

Figure 3. Schematic representation of the pressure-induced concatenated effects: bending of Co ligands, shifting of molecules, torsion of phenyl groups, and shortening of Co–P bonds.

Noteworthily, the shortening of the P2···P2 distance within the sextuple embrace is paralleled by shrinking of the related Co2–P2 bond. This is quite extraordinary as this deformation is associated with a rather deep energy well.

The interesting outcome of our experiments is that *T* and *P* induce not only modifications in the intermolecular packing but also a continuous variation of the molecular stereochemistry.

High-pressure (more than LT) crystallography is a very powerful tool for exploring the molecular potential energy surface quite far from the stationary points. Here, for

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

example, we could observe the previously undetected eclipsing of a staggered carbonyl metal dimer and the consequent "molecular response" (mainly Co–Co elongation), together with crystal effects leading to the compression of the more energetic Co–P bond.

As **2** undergoes the same transition as **1**, but at higher *T*, very likely it will also undergo a lower pressure PT. Presently we are performing HP experiments on **2**, to possibly take a wider picture of the molecular rearrangements.

Experimental Section

HP experiments were conducted on one side of a Merrill Basset diamond anvil cell equipped with 600 μm culet diamonds. The sample, a hexagonal single crystal of dimensions $0.18 \times 0.18 \times 0.1$ mm was loaded in a W gasket with a 300 μm hole pre-indented to 200 μm. Diffraction data at HP were collected on a Smart-APEX CCD Bruker diffractometer following literature methods.[9] Pressure was measured by the ruby fluorescence method, using a JASCO TRS-300 spectrometer equipped with a Kr laser source.

Details of the DFT calculations and crystallography can be found in the Supporting Information.

The Effects of Triplet Sensitizers' Energies on the Photoreactivity of β,γ-Unsaturated Methyl Ketones**

Diego Armesto, Maria J. Ortiz,**
Antonia R. Agarrabeitia, and Noureddin El-Boulifi

The photochemistry of β,γ-unsaturated ketones has been a topic of great interest to organic photochemists for many years.[1] The results of studies in this area show that these substances undergo a 1,3-acyl migration on direct irradiation and an oxa-di-π-methane (ODPM) rearrangement in the presence of triplet sensitizers. Both processes usually occur with high chemical and quantum efficiencies and high degrees of stereoselectivity.[1] As a result, the photochemical 1,3-acyl migration and ODPM rearrangement reactions have found important synthetic applications.[1] Despite the fact that a large majority of β,γ-unsaturated ketones undergo triplet-state ODPM reactions, some acyclic compounds in this series, even those having substitution patterns that are known to favor this reaction, are unreactive.[1a] For example, it has been reported that the β,γ-unsaturated ketones **1a**,[2] **1b**[3] **1c**,[4] and **1d**[2] do not undergo the ODPM rearrangement in the presence of acetophenone or 3-methoxyacetophenone. Instead, under these conditions **1a** and **1b** undergo alkene *E*/*Z* isomerization.

To gain a better understanding of this unusual behavior, we have carried out a more detailed study in which we have probed the photochemistry of enones **1a–e** by using a variety of other triplet sensitizers. The results arising from this effort reveal that these acyclic β,γ-unsaturated ketones do indeed undergo the ODPM process when the triplet energies of the sensitizers used to promote the reaction are close to those of the triplet states of the alkene moieties, and that the ODPM reactivity of these substrates is intimately related to the features of the triplet formed in the energy-transfer processes.

In this study, solutions of β,γ-unsaturated ketones **1a–e** containing sensitizers of varying triplet energies[5] (acetophenone: $E_T = 74$ kcal mol^{-1}; 3-methoxyacetophenone: $E_T = 71$ kcal mol^{-1}, depending on the absorption properties of the enone; thioxanthone: $E_T = 63$ kcal mol^{-1}; 4-phenylbenzophe-

none: $E_T = 61$ kcal mol^{-1}; chrysene: $E_T = 57$ kcal mol^{-1}) were irradiated in an immersion apparatus through Pyrex using a 400-W medium-pressure mercury arc lamp. The results of an earlier study showed that irradiation of the β,γ-unsaturated ketone **1a**[2] (the E_T of the styrene chromophore is about 62 kcal mol^{-1})[5] with acetophenone triplet sensitization (E_T = 74 kcal mol^{-1}) for 5 h led to 91% recovery of the enone as a 1:1 mixture of *E* and *Z* isomers. In contrast, irradiation of **1a** (1:2 mixture of *E* and *Z* isomers) in CH_2Cl_2 with thioxanthone ($E_T = 63$ kcal mol^{-1}) as the sensitizer for 8.5 h resulted in formation of the ODPM product (*E*)-**2a** (50%) and recovered starting material **1a** (20%), as a 2:3 mixture of *E*- and *Z*-isomers (Scheme 1). Likewise, irradiation of **1a** (1:2, *E*/*Z*)

	2a	3a	1a
Acetophenone	—	—	91%
Thioxanthone	50%	—	20%
4-Phenylbenzophenone	10%	28%	35%
Chrysene	—	6%	56%

Scheme 1. Photoreactivity of enone **1a** using different triplet sensitizers. Sens.=sensitizer.

with 4-phenylbenzophenone ($E_T = 61$ kcal mol^{-1}) as sensitizer for 8.5 h promoted formation of the ODPM product (*E*)-**2a** (10%), the 1,3-acyl migration product **3a** (28%), and recovered starting material **1a** (35%), as a 2:5 mixture of *E* and *Z* isomers (Scheme 1). In this case, three different types of photochemical reactions, namely *E*/*Z* isomerization, ODPM rearrangement, and 1,3-acyl migration, take place from the triplet excited state of **1a**, a phenomenon rarely observed in photochemistry.[6] Finally, when the photoreaction of **1a** was carried out with chrysene ($E_T = 57$ kcal mol^{-1}) as the triplet sensitizer, **3a** (6%) and recovered starting material **1a** (56%, 1:6 mixture of *E* and *Z* isomers) were isolated (Scheme 1).

To the best of our knowledge, these unusual observations, which suggest that the excited-state reaction pathways followed by enone **1a** depends on the triplet energy of the sensitizer, are unprecedented. In order to determine if this behavior is observed with other β,γ-unsaturated ketones, the photochemistry of ketones **1b–e** was also explored. We found that (*E*)-**1b** behaves in a similar manner to **1a** in photoreactions promoted by the triplet sensitizers listed above. The only difference observed in this case is that the ODPM photoproduct **2b** is also formed in low yield, along with **3b** as the major product, when chrysene is used as triplet sensitizer (Scheme 2 and Table 1). The diphenylvinyl chromophore in **1c** has a triplet energy of about 53–62 kcal mol^{-1},[7] and irradiation of **1c** with 3-methoxyacetophenone ($E_T = 71$ kcal mol^{-1}) as the sensitizer leads to recovered starting material

(80%) exclusively.[4] When thioxanthone is used as sensitizer, **1c** reacts to form the ODPM photoproduct **2c** (39%) exclusively, and both **2c** (20%) and **3c** (10%) are obtained when the process is sensitized by 4-phenylbenzophenone. Finally, the chrysene-sensitized photoreaction of **1c** gives only **3c** (23%) (Scheme 2 and Table 1).

The photochemical behavior of dicyano-substituted enone **1d**, which has a triplet energy of about 60 kcal mol^{-1},[7] also follows the general pattern described above. Thus, the acetophenone-sensitized reaction of this substrate leads to recovered starting material (60%) only.[2] With thioxanthone, the photoreaction of **1d** gives the ODPM product **2d** (39%) exclusively, and with 4-phenylbenzophenone **2d** (16%) and **3d** (6%) are obtained. Finally, chrysene sensitization also transforms **1d** into **2d** (10%) and **3d** (8%) (Scheme 2 and Table 1).

The photochemistry of β,γ-unsaturated ketone **1e**, which contains a piperylene group ($E_T = 59$ kcal mol^{-1}),[5] was studied to test the generality of this novel reactivity profile. Irradiation of **1e** (1:6 mixture of *E* and *Z* isomers) with 3-methoxyacetophenone as the sensitizer gives rise to *E*/*Z* isomerization (3:2, *E*/*Z*) only. However, with thioxanthone the ODPM product **2e** (20%) is formed in addition to recovered starting material **1e** (3:2 mixture of *E*- and *Z*-isomers). With 4-phenylbenzophenone as the triplet sensitizer, **2e** (53%) and **3e** (7%) are generated along with recovered **1e** (1:1, *E*/*Z*). Chrysene sensitization ($\Delta E_{D-A} \approx -2$ kcal mol^{-1}) also affords **2e** (23%), **3e** (30%), and **1e** (3:1, *E*/*Z*) (Scheme 2 and Table 1).

In summary, we have explored triplet-sensitized reactions of the acyclic β,γ-unsaturated methyl ketones **1a–e** by using sensitizers with different triplet energies. It has been reported that **1a–d**[2–4] do not undergo an ODPM rearrangement when acetophenone and 3-methoxyacetophenone are used as triplet sensitizers: under these conditions, **1a** and **1b** instead undergo alkene *E*/*Z* isomerization. Enone **1e** behaves similarly in that it undergoes *E*/*Z* isomerization exclusively when irradiated in the presence of 3-methoxyacetophenone as triplet sensitizer. Both of the sensitizers used in these processes have triplet energies that are about 12 kcal mol^{-1} higher than those of the alkene moieties present in the β,γ-unsaturated enones. In contrast, photoreactions of enones **1a–e** with triplet sensitizers having triplet energies that are about 5 and 1 kcal mol^{-1} higher than those of the alkene triplets follow ODPM rearrangement pathways to afford cyclopropyl ketones **2a–e** (Scheme 2). An ODPM rearrangement still takes place (albeit inefficiently) even when the triplet energies of the sensitizer are slightly lower (ca. −1 to −5 kcal mol^{-1}) than those of the alkene groups in **1a–e**, and a new process involving 1,3-acyl migration to form enones **3a–e** (Scheme 2) becomes competitive.

These results clearly show that the energy of the triplet sensitizer plays an important role in determining the outcome of triplet-sensitized reactions of β,γ-unsaturated ketones **1a–e**. The reactivity patterns suggest that, regardless of their triplet energies, all sensitizers promote photo-*E*/*Z* isomerization of the alkene moiety. However, the "hot" triplet excited states, with a large excess of vibrational energy, that are formed when sensitizers with a high triplet energy are used deactivate by *E*/*Z* isomerization exclusively. "Warm" triplet excited states of the alkene chromophores in the β,γ-unsaturated ketones are formed upon lowering the triplet energy of the sensitizer, and these undergo ODPM rearrangements in addition to the *E*/*Z* isomerization, and sensitizers that have a triplet energy close to that of the alkene groups give "cold" triplet excited states that undergo *E*/*Z* isomerization, 1,3-acyl migration, and ODPM rearrangement. Finally, when the energy of the sensitizer is slightly lower than that of the alkene, the efficiency of the ODPM rearrangement reaction path falls or is totally suppressed and *E*/*Z* isomerization and 1,3-acyl migration become the main routes followed.

It is interesting to view the conclusions presented above in the context of basic photochemical principles. Triplet sensitization is a standard method to promote triplet reactivity in molecules that do not undergo spontaneous intersystem crossing from their singlet excited states. This topic is discussed in great detail in all standard photochemical textbooks and monographs.[8] However, no reports exist, to the best of our knowledge, in the massive amount of literature on this topic that show that triplet excited states generated by intermolecular energy transfer can undergo different reactions depending on the energy of the triplet sensitizer used. Consequently, the generality of these novel findings and the accuracy of our mechanistic postulates will be tested in further studies we plan to carry out in this area.

Molecular Wheels

DOI: 10.1002/anie.200502699

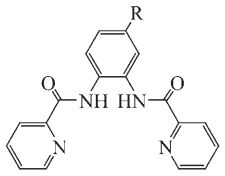
$[Mn^{III}(salen)]_6[Fe^{III}(bpmb)(CN)_2]_6 \cdot 7H_2O$: A Cyanide-Bridged Nanosized Molecular Wheel**

Zhong-Hai Ni, Hui-Zhong Kou, Li-Fang Zhang, Chunhua Ge, Ai-Li Cui, Ru-Ji Wang, Yadong Li, and Osamu Sato**

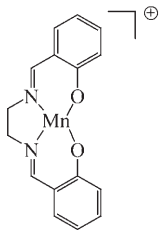
In the past decade, the design and synthesis of metallamacrocycles has attracted extensive interest in several research fields, including materials chemistry,[1] magnetochemistry,[2] supramolecular chemistry,[3] and molecular nanotechnology.[4] Many structurally appealing metallamacrocycles[1–8] have been synthesized and some unique physical properties have been observed to date. However, most of them are homometallic $[M–O]_n$,[2,3,5] $[M–N–O]_n$,[1,6] or $[M–N–N]_n$[7] cyclic clusters, which are easier to construct than heterometallic cycles. More significantly, as far as magnetic properties are concerned, homometallic compounds are usually antiferromagnetic and therefore in a low-spin ground state, which is unfavorable for single-molecule magnets (SMMs) because the observation of such phenomena requires a high-spin ground state and significant uniaxial magnetic anisotropy.[2,5,7]

As one of the more well-known linkers, the CN^- group has been used extensively to assemble heterometallic compounds because the topological structures and the nature of the magnetic interactions between different metal ions can be readily controlled and anticipated. Therefore, we have endeavored to synthesize large, cyanide-bridged, heterometallic cycles that might exhibit high-spin ground states and even single-molecule magnet behavior. Cyanide-bridged metallamacrocycles are still scarce, and only a few tetranuclear cyclic squares[9] have been synthesized by rational design.

Recently, we have shown that the use of the rigid building block *trans*-$[Fe^{III}(bpb)(CN)_2]^-$ (H_2bpb = 1,2-bis(pyridine-2-carboxamido)benzene) is a suitable strategy for the construction of low-dimensional heterometallic species.[10] In this study, we prepared a new cyanide-containing analog $[Fe^{III}(bpmb)(CN)_2]^-$ (H_2bpmb = 1,2-bis(pyridine-2-carboxamido)-4-methylbenzene).[11] We inferred that the reaction of $[Fe(bpb)(CN)_2]^-$ or $[Fe(bpmb)(CN)_2]^-$ with $[Mn(salen)]^+$ ($salen^{2-}$ = *N*,*N*′-ethylenebis(salicylideneaminato) dianion) might lead to a one-dimensional, polynuclear or metallacyclic compound. Indeed, we have successfully obtained a unique cyanide-bridged, dodecanuclear, nanosized molecular wheel $[\{Mn(salen)\}_6\{Fe(bpmb)(CN)_2\}_6]\cdot 7H_2O$ (**1**) with a repeating [-Fe-CN-Mn-NC-]$_6$ unit. Herein we report the synthesis of this novel metallamacrocycle together with the new one-dimensional chain complex $[\{Mn^{III}(salen)\}\{Fe^{III}(bpb)(CN)_2\}]_\infty$ (**2**). To the best of our knowledge, complex **1** is the largest cyanide-bridged heterometallic metallamacrocycle to date.



R = CH_3, H_2bpmb
R = H, H_2bpb



$[Mn(salen)]^+$

Compounds **1** and **2** were synthesized by the slow evaporation of a solution of equimolar amounts of $[Mn(salen)]ClO_4$ and $K[Fe(bpmb)(CN)_2]$ or $K[Fe(bpb)(CN)_2]$ in MeOH/MeCN/H_2O (6:3:1) at room temperature. An X-ray single-crystal structural analysis[12] showed that complex **1** is comprised of six Mn^{III} and six Fe^{III} ions alternately bridged by cyanide ligands to give a centrosymmetrical, elliptical, dodecanuclear molecular wheel (Figure 1), while complex **2** has a neutral infinite chain structure in which alternating $[Fe(bpb)(CN)_2]^-$ and $[Mn(salen)]^+$ fragments are linked by the cyanide ligands in $[Fe(bpb)(CN)_2]^-$ (Figure 2).

All bond distances and bond angles in complexes **1** and **2** are in the normal range. The Fe–C bond lengths (1.941(6)–1.984(6) Å for **1** and 1.956(4)–1.990(4) Å for **2**) are in good agreement with those observed previously in related compounds.[10,11] The Mn–$N_{cyanide}$ bonds range from 2.258(5) to 2.354(4) Å for **1** and from 2.301(3) to 2.439(3) Å for **2**. The Fe–C≡N bond angles in the two complexes are approximately linear (173.5(4)–178.2(5)°), except for N2≡C2–Fe1 in complex **1** (168.5(5)°). However, the Mn–N≡C bond angles (140.8(4)–163.3(5)° for **1** and 151.8(3)–158.6(3)° for **2**) deviate significantly from strict linearity. The shortest intermolecular metal–metal separations are 6.808 and 5.387 Å for **1** and **2**, respectively. In addition, the cell packing diagram (Figure 3) of complex **1** along the *a* axis shows a highly ordered pattern.

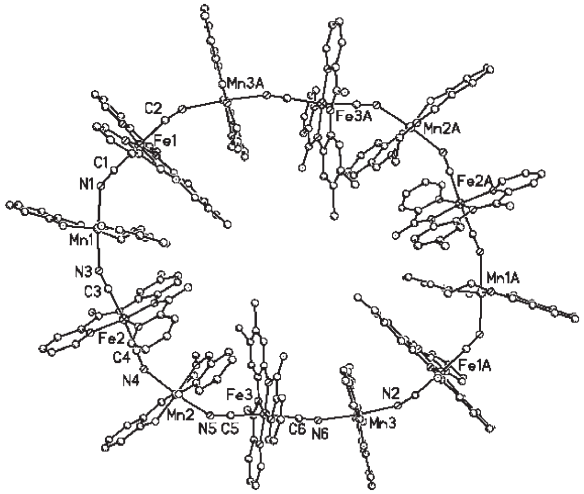

Figure 1. Structure of $[\{Mn(salen)\}_6\{Fe(bpmb)(CN)_2\}_6]\cdot 7H_2O$ (**1**). All solvent molecules and hydrogen atoms have been omitted for clarity. Selected bond lengths [Å] and angles [°]: Mn1–N1 2.354(4), Mn1–N3 2.322(4), Mn2–N4 2.290(5), Mn2–N5 2.258(5), Mn3–N2 2.327(5), Mn3–N6 2.309(5); Mn1–N1–C1 140.8(4), Mn1–N3–C3 151.7(4), Mn2–N4–C4 147.6(4), Mn2–N5–C5 147.8(4), Mn3–N6–C6 163.3(5), Mn3–N2–C2 158.0(4). Separations between opposite metal atoms [Å]: Fe1···Fe1a 21.152, Fe2···Fe2a 19.804, Fe3···Fe3a 17.728, Mn1···Mn1a 21.778, Mn2···Mn2a 19.776, Mn3···Mn3a 19.349.

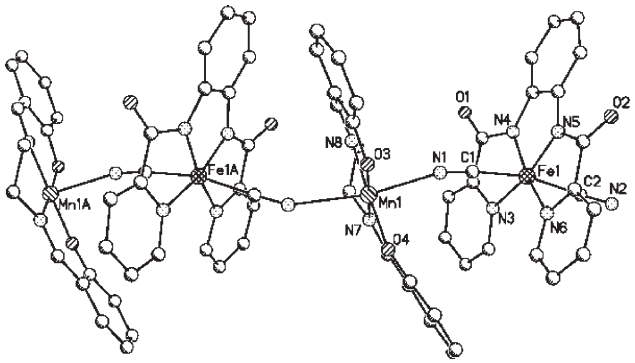

Figure 2. Structural unit of $[\{Mn(salen)\}\{Fe(bpb)(CN)_2\}]_\infty$ (**2**). Hydrogen atoms have been omitted for clarity. Selected bond lengths [Å] and angles [°]: Mn1–N1 2.301(3), Mn1–N2 2.439(3); Mn1–N1–C1 158.6(3), Mn1–N2–C2 151.8(3). The neighboring Fe···Mn distance is 5.280 Å.

It is worth noting that the largest intramolecular metal–metal distance is 2.178 nm, which corresponds to the major axis of the ellipse; the minor axis of the ellipse corresponds to a metal–metal separation of 1.773 nm, which indicates that complex **1** is a nanosized molecular wheel.

Similar to the wheel compounds previously reported,[1–8] the mechanism for the formation of wheel or chain structures is very subtle, and we have not yet been able to isolate the wheel compound containing $[Fe(bpb)(CN)_2]^-$ or the 1D compound with $[Fe(bpmb)(CN)_2]^-$. This indicates that only these two compounds are formed under the present synthetic conditions, as further proven by the powder XRD patterns (see Supporting Information). Steric effects are likely to be responsible for formation of the molecular wheel structure,

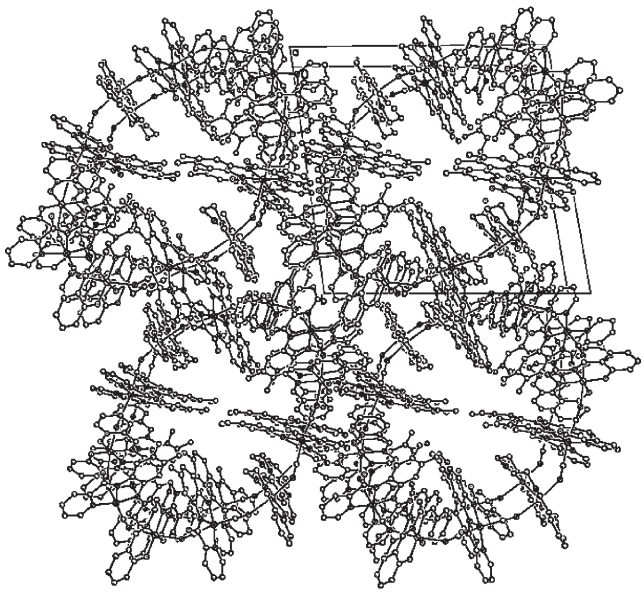

Figure 3. Cell packing diagram of complex **1** along the *a* axis showing the ordered architectural pattern.

although other factors (e.g. solvents) probably contribute. In this context, the study of the wheel-formation process and mechanism is worthwhile.

The magnetic susceptibilities of complexes **1** and **2** were measured in the range 5–300 K in an external magnetic field of 1000 Oe. As shown in Figure 4, the room temperature $\chi_m T$

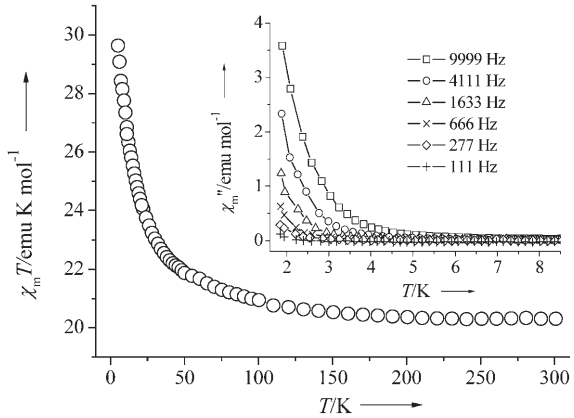

Figure 4. Temperature dependence of $\chi_m T$ for **1** at a field of 1000 Oe. Inset: the out-of-phase (χ_m'') signals in the ac susceptibility for **1**.

value for **1** is 20.3 emu K mol^{-1}, which is close to the spin-only value of 20.25 emu K mol^{-1} for six high-spin Mn^{III} ($S = 2$) and six low-spin Fe^{III} ($S = 1/2$) ions assuming that $g = 2.00$. When the temperature is decreased, the $\chi_m T$ value of complex **1** gradually increases and reaches 29.64 emu K mol^{-1} at 5 K. The reciprocal magnetic susceptibilities in the 5–300 K range obey the Curie–Weiss law, with a Curie constant, C, of 20.06 emu K mol^{-1} and a Weiss constant, θ, of $+3.5$ K. The behavior of $\chi_m T$ and the positive Weiss constant confirm the presence of overall ferromagnetic interactions in complex **1**.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The field dependence of the magnetization for **1** at 2 K shows that the experimental values below 8 kOe are higher than the Brillouin curve corresponding to six noninteracting S_{Mn} and six S_{Fe} spins, thus confirming the overall ferromagnetic Mn^{III}–Fe^{III} coupling (see Supporting Information). The high-field magnetization values are lower than calculated, which may be due to the zero-field splitting effect of Mn^{III}.

For complex **2**, the room temperature $\chi_m T$ value is 3.45 emu K mol^{-1}, which is close to the spin-only value of 3.375 emu K mol^{-1} for one Mn^{III} ($S=2$) and one Fe^{III} ($S=1/2$) ion. As the temperature decreases, $\chi_m T$ remains nearly constant until about 50 K, and then decreases rapidly to 1.50 emu K mol^{-1} at 5 K (Figure 5). The Curie–Weiss law gives

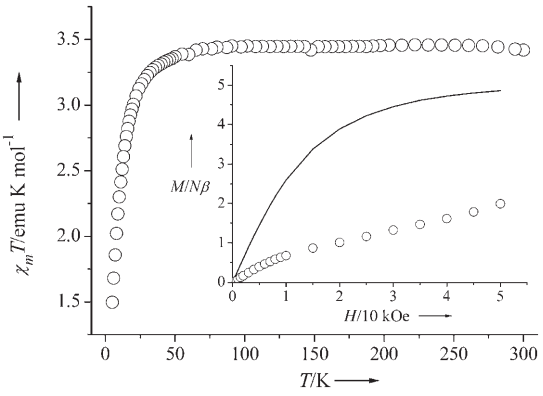

Figure 5. Temperature dependence of $\chi_m T$ for **2** at a field of 1000 Oe. Inset is the field dependence of the magnetization at 2.0 K. The line represents the Brillouin function that corresponds to noninteracting $S = S_{Mn} + S_{Fe}$ with $g = 2.0$.

a Curie constant of 3.52 emu K mol^{-1} and a Weiss constant of −3.2 K. The field dependence of the magnetization for **2** shows that the experimental values are significantly lower than the Brillouin curve corresponding to one noninteracting S_{Mn} and one S_{Fe} spin, as displayed in the inset of Figure 5. This suggests an overall antiferromagnetic Mn^{III}–Fe^{III} interaction in **2**. Similar to other cyanide-bridged high-spin Mn^{III} (d^4, $(t_{2g})^3(e_g)^1$) and low-spin Fe^{III} (d^5, $(t_{2g})^5$) systems, both ferromagnetic and antiferromagnetic contributions coexist. The overall magnetic interaction is determined by the coordination environment and configurations of the Mn^{III} and Fe^{III} ions to some extent. Therefore, the inversion of the magnetic coupling for **1** and **2** may be attributed to the different average Mn−N≡C angles of 151.4(5)° for **1** and 155.2(3)° for **2**, and the different linking of the $[Mn(salen)]^+$ unit to the $[Fe(bpmb)(CN)_2]^-$ or $[Fe(bpb)(CN)_2]^-$ building blocks, which can alter the overlap between the magnetic orbitals.[13]

As the largest cyanide-bridged, heterometallic, macrocyclic complex with ferromagnetic exchange between anisotropic Mn^{III} ions and low-spin Fe^{III} ions, **1** might represent a new type of SMM. One of the most important characteristics of an SMM is the observation of a frequency-dependent, out-of-phase (χ_m'') ac susceptibility signal. Thus, ac magnetic susceptibility measurements were performed in a 3 Oe ac field oscillating at 111–9999 Hz with a zero dc field (inset of Figure 4). Indeed, there is an obvious frequency-dependent χ_m'' signal below 4 K, along with a clear frequency-dependent decrease in the $\chi_m' T$ signals (see Supporting Information). These results are very similar to those observed for the recently published complexes $[\{Mn^{II}(tmphen)\}_3\{Mn^{III}(CN)_6\}_2]$[14a] (tmphen = 3,4,7,8-tetramethyl-1,10-phenanthroline), $[(Tp)_8(H_2O)_6Cu^{II}_6Fe^{III}_8(CN)_{24}]^{4+}$ (Tp^- = hydrotris(pyrazolyl)borate),[14b] $[Mn^{II}_4Mn^{III}_{22}(pdol)_{12}(\mu_3\text{-}CH_3O)_{12}(\mu_3\text{-}O)_{10}(\mu_4\text{-}O)_6(N_3)_6]$ ($pdol^{2-}$ = dipridylketonediolate ion),[14c] and $[Dy_6Mn_6(H_2shi)_4(Hshi)_2(shi)_{10}(CH_3OH)_{10}(H_2O)_2]\cdot 9CH_3OH\cdot 8H_2O$[14d] ($H_3shi$ = salicylhydroxamic acid), all of which have been considered as SMMs. Unfortunately, there is no maximum for the χ_m'' signals down to 2 K, and the observation of hysteretic behavior at 2 K was not possible. Thus, measurements are underway at lower temperatures to check hysteresis and to confirm whether the frequency dependence is in accord with Arrhenius-type behavior.

In summary, we have successfully synthesized a unique nanosized, dodecanuclear, molecular wheel that is the largest cyanide-bridged, heterometallic, supramolecular macrocycle known to date. Magnetic measurements indicate that **1** exhibits an interesting frequency-dependent ac magnetic susceptibility. The present study demonstrates that this synthetic route may be a promising approach to cyanide-bridged heterometallic macrocycles that may potentially exhibit SMM behavior. We are currently investigating other Mn^{III}–Schiff base building blocks and various pyridine carboxamine ligands similar to H_2bpb and H_2bpmb. Moreover, we will try to introduce other metal ions such as anistropic Ru^{III} and Mn^{III} into the system in place of the low-spin Fe^{III} ion, which may improve the magnetic properties.

Experimental Section

Complexes **1** and **2** were synthesized by the reaction of $[Mn(salen)]ClO_4$ (42.0 mg, 0.1 mmol) and $K[Fe(bpmb)(CN)_2]$[11] (48.0 mg, 0.1 mmol) or $K[Fe(bpb)(CN)_2]$[11] (46.5 mg, 0.1 mmol) in MeOH/MeCN/H_2O (10 mL, volume ratio 6:3:1) at room temperature. Uniform, well-shaped, red-brown single crystals were collected after about three days. Both **1** and **2** were isolated in high yield (ca. 60%). $C_{220}H_{176}Fe_6Mn_6N_{48}O_{31}$ (**1**) calcd: C 56.79, H 3.81, N 14.45; found: C 56.38, H 3.60, N 14.25. IR: $\tilde{\nu}$ = 2122 (m, C≡N), 1622 cm^{-1} (vs, C=O). $C_{36}H_{26}FeMnN_8O_4$ (**2**) calcd: C 58.01, H 3.52, N 15.03; found: C 57.65, H 3.57, N 15.07. IR: $\tilde{\nu}$ = 2134(m, C≡N), 2109 (m, C≡N), 1619 cm^{-1} (vs, C=O).

Characterization of a Complex Comprising a $\{Cu_2(S_2)_2\}^{2+}$ Core: Bis(μ-S_2^{2-})dicopper(III) or Bis(μ-$S_2^{\cdot-}$)dicopper(II)?**

*John T. York, Eric C. Brown, and William B. Tolman**

Copper–sulfur interactions play a critical role in the function of several classes of biological molecules, with the soft, polarizable nature of sulfur being uniquely suited for modulating the electronic structure and reactivity of copper-protein active sites. For example, copper–thiolate bonds with significant covalent character in type 1 monocopper and

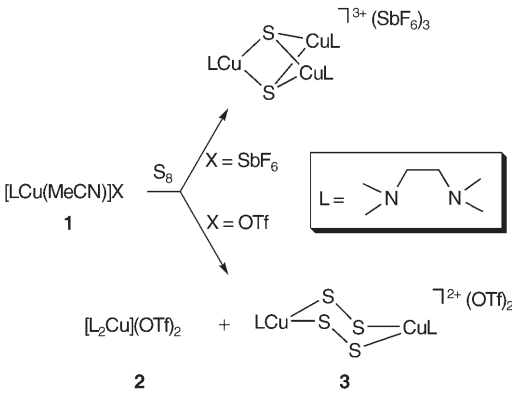
mixed-valent dicopper "Cu_A" centers mediate electronic delocalization, which facilitates electron-transfer reactions.[1] The inorganic sulfur recently identified in the "Cu_Z" site of nitrous oxide reductase, which features four copper ions linked by a μ_4-sulfido ligand and attached to the protein through multiple histidine imidazolyl ligands, has also been postulated to play a role in electronic delocalization.[2,3] To gain insight into the properties of the unique "Cu_Z" catalytic cluster through the study of synthetic model complexes, the chemistry of copper–sulfur complexes containing N-donor ligands needs to be developed. In efforts towards this aim, complexes with (μ-η^2:η^2-disulfido(2-))dicopper(II)[4a,b] or (*trans*-μ-1,2-disulfido(2-))dicopper(II)[4c,d] cores have been isolated by using sterically bulky multidentate N-donor coligands. We recently discovered that reactions of the copper(I) complexes [Cu(tmeda)(MeCN)]SbF_6 (**1a**) and [Cu(tmchd)(MeCN)]PF_6 with S_8 yield clusters with fully delocalized mixed-valent $\{Cu_3(\mu\text{-}S)_2\}^{3+}$ cores (Scheme 1).[5,6] Herein, we report that the reaction of [Cu(tmeda)(MeCN)]OTf (**1b**)[5] with S_8 instead yields a complex with a heterocyclic $\{Cu_2(\mu\text{-}1,2\text{-}S_2)_2\}^{2+}$ core,[7] for which an unexpected electronic structure is proposed on the basis of structural and spectroscopic data.



Scheme 1.

The addition of excess elemental sulfur (4 equiv) to a colorless solution of **1b** in THF or CH_2Cl_2 at room temperature resulted in the gradual development of a deep-blue color. Two products were isolated from the reaction mixture by removal of solvent, filtration, and fractional crystallization/precipitation, and were structurally characterized by X-ray diffraction (Scheme 1).[8] The blue–green complex [Cu(tmeda)$_2$](OTf)$_2$ (**2**, see Supporting Information) is a minor product (13% yield) that apparently derives from partial disproportionation of **1b**, as small amounts of metallic copper were also observed. The dark-blue complex $[Cu_2(tmeda)_2(\mu\text{-}1,2\text{-}S_2)_2](OTf)_2$ (**3**, Figure 1) was isolated in 63% yield, and features two square-pyramidal copper centers, each with two S and two N donors occupying equatorial positions and a weakly coordinated axial triflate anion.

In assessing the structural parameters for **3**, two extreme resonance formulations may be considered for its $\{Cu_2(\mu\text{-}1,2\text{-}S_2)_2\}^{2+}$ core: two Cu^{III} ions bridged by disulfide(2-) ions (S_2^{2-}), or two Cu^{II} ions bridged by disulfide($\cdot$1−) ions ($S_2^{\cdot-}$).[9] Similar resonance forms have been invoked in ruthenium and iron complexes.[7d,10] The Cu–N bond lengths in **3** of 2.032(3) and 2.058(3) Å are significantly longer than those in Cu^{III} complexes with similar diamine ligands (Cu–N $\approx$1.93 Å),[11] and are more consistent with those in Cu^{II}–N(amine) complexes (Cu–N 2.06–2.17 Å in **2**). The S–S bond length in **3** is 1.950(1) Å, which falls between that of free S_2 (S=S 1.892 Å) and H_2S_2 (S–S 2.055 Å).[12] As a comparison, the S–S bonds in transition-metal μ-1,2-disulfido(2-) complexes typically range from 2.01 to 2.06 Å;[7,10a,b,d,13,14] the only structurally characterized (*trans*-μ-1,2 disulfido(2-))dicopper(II) complex has a S–S bond length of 2.044 Å.[4c] In summary, the X-ray structural data are most consistent with a bis(μ-disulfido($\cdot$1−))dicopper(II) formulation for **3**.

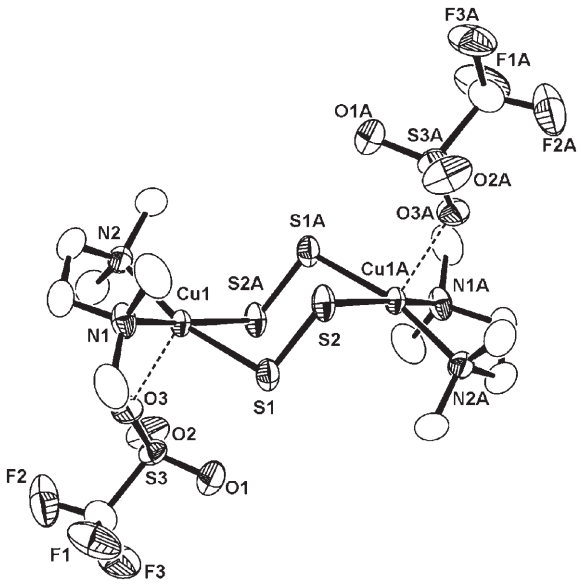


Figure 1. Molecular structure of **3** (50% ellipsoids, H atoms excluded, only heteroatoms labeled). Selected interatomic distances [Å]: S1-S2, 1.9500(13); Cu1-S1, 2.2696(11); Cu1-S, 2.2729(12); Cu1-N1, 2.032(3); Cu1-N2, 2.058(3); Cu1-O3, 2.304(2).

Further insight is provided by spectroscopic data. Complex **3** is EPR silent (X-band, 20 K) and exhibits a sharp, well-resolved ^{1}H NMR spectrum, indicative of a diamagnetic ground state; this is consistent with either resonance formulation if one invokes strong antiferromagnetic coupling in the case of the bis(μ-disulfido($\cdot$1−))dicopper(II) species. The UV/Vis spectrum of **3** in THF at 25 °C has intense absorption features at 251 ($\varepsilon = 11\,000\,M^{-1}cm^{-1}$), 394 ($\varepsilon = 9000\,M^{-1}cm^{-1}$), and 575 nm ($\varepsilon = 6400\,M^{-1}cm^{-1}$), which bleach upon exposure to air (Figure 2a). Unlike many *trans*-disulfido(2-)-bridged complexes,[4c,9c,13e,13f,15] **3** exhibits no absorption features generally attributable to the 4-center–6-electron $\{M_2S_2\}$ chromophore in the near-IR region of the spectrum. Resonance Raman spectra (Figure 2b) of a frozen solution of **3** in THF obtained by using 514.5-nm laser excitation wavelength reveal strong S-isotope sensitive bands at 613 and 336 cm^{-1} that are consistent with ν(S–S) and ν(Cu–S) vibrations, respectively ($\Delta^{34}S_{exptl} = 19$ and $9\,cm^{-1}$; $\Delta^{34}S_{calcd} = 18$ and $7\,cm^{-1}$). The ν(S–S) vibration at 613 cm^{-1} is at a much higher wavenumber

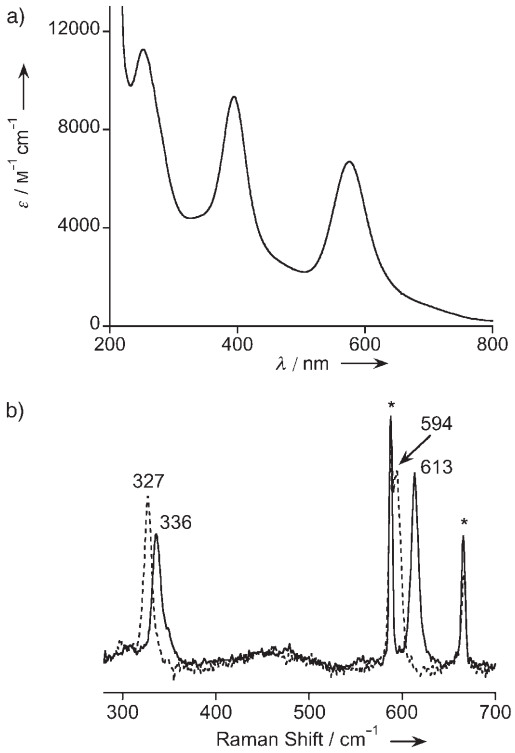

Figure 2. a) UV/Vis spectrum of **3** in THF at 25 °C. b) Resonance Raman spectrum of **3** in THF at −196 °C, $\lambda_{ex} = 514.5$ nm (^{32}S, solid line; ^{34}S, dashed line; asterisks indicate peaks arising from the solvent).

than that normally observed in μ-disulfido(2-) complexes,[9b,g,14c,16] including dicopper examples, which have ν(S–S) vibrations in the range from around 450 to 500 cm^{-1}.[4] Indeed, comparison with published ν(S–S) values for Na_2S_2 (446 cm^{-1}),[17] $S_2^{\bullet-}$ (601 cm^{-1}),[18] and doubly bonded S_2 (718 cm^{-1})[19] clearly supports a $S_2^{\bullet-}$ formulation for the bridging ligands in **3**.

In summary, the combined structural and spectroscopic data indicate that **3** is best described as a bis(μ-disulfido-(·1−))dicopper(II) complex,[9] which represents a new motif in copper–sulfur chemistry. The lack of further reduction of the sulfur ligands to yield a bis(μ-disulfido(2-))dicopper(III) species can be rationalized on the basis of the relatively low electronegativity of sulfur (relative to that of oxygen). A further intriguing aspect is the fact that **3** is the major product of the reaction of S_8 with **1b**, but under identical conditions, the reaction with **1a** yields the mixed-valent cluster $[Cu_3S_2(tmeda)_3](SbF_6)_3$.[5] The better coordinating ability of OTf^- relative to that of SbF_6^- may be in part responsible for the divergent reactivity, but the nature of the N-donor ligand also is important, as both the PF_6^- and OTf^- salts of [Cu(tmchd)(MeCN)]$^+$ yield the bis(μ-sulfido)tricopper cluster.[20] Future studies will address this effect of counterion, as well as aspects of the reactivity of **3**.

Experimental Section

All solvents and reagents were obtained from commercial sources and used as received unless noted otherwise. The solvents tetrahydrofuran (THF), pentane, diethyl ether, and dichloromethane were passed through solvent purification columns (Glass Contour, Laguna, CA) prior to use. All metal complexes were prepared and stored in a Vacuum Atmospheres inert-atmosphere glove box under a dry nitrogen atmosphere or were manipulated by using standard Schlenk line techniques. Labeled elemental sulfur (^{34}S, 99 % enrichment) was purchased from Cambridge Isotope Laboratories, Inc. NMR spectra were recorded on a Varian VI-300 or VXR-300 spectrometer. Chemical shifts (δ) for ^1H or ^{13}C NMR spectra were referenced to residual protons in the deuterated solvent. UV/Vis spectra were recorded on a HP8453 (190–1100 nm) diode-array spectrophotometer. X-band EPR spectra were recorded on a Bruker E-500 spectrometer with an Oxford Instruments EPR-10 liquid-helium cryostat. Resonance Raman spectra were recorded on an Acton 506 spectrometer by using a Princeton Instruments LN/CCD-11100-PB/UVAR detector and ST-1385 controller interfaced with Winspec software. The spectra were obtained at −196 °C by using a backscattering geometry. Samples were frozen in an NMR tube by submersion in a dewar flask containing liquid nitrogen. Raman shifts were externally referenced to liquid indene. ESI mass spectra were obtained on a Bruker BioTOF II spectrometer. The ligand tmeda was purchased from Aldrich Chemical Co. and used as received. The complex [Cu(MeCN)$_4$]OTf was prepared according to a published procedure.[21] Crystallographic information on **2** are listed in the Supporting Information.

[Cu(tmeda)(MeCN)]OTf (**1b**): A solution of tmeda (0.055 g, 0.47 mmol) in CH_2Cl_2 (2 mL) was added to a solution of [Cu(MeCN)$_4$]OTf (0.160 g, 0.43 mmol) in CH_2Cl_2 (4 mL). The reaction was stirred for 30 minutes, filtered through celite, and the filtrate concentrated under reduced pressure to approximately 2 mL. Addition of pentane (10 mL) resulted in the precipitation of a white solid, which was collected, washed with diethyl ether (3 × 5 mL), and dried under vacuum. Yield: 148 mg (93 %); ^1H NMR (CD_2Cl_2, 300 MHz): $\delta = 2.56$ (s, 4H), 2.52 (s, 12H), 2.23 ppm (s, 3H); ^{13}C NMR (CD_2Cl_2, 75 MHz): $\delta = 120.7$ ($J_{C,F} = 320$ Hz), 115.9, 57.9, 48.1, 2.1 ppm; ESIMS: calcd for [Cu(tmeda)(MeCN)]$^+$: m/z 220.0870; found: 220.0853.

$[Cu_2(S_2)_2(tmeda)_2](OTf)_2$ (**3**): Elemental sulfur (0.117 g, 0.46 mmol) was added to a solution of **1b** (0.170 g, 0.46 mmol) in THF (15 mL). The solution was stirred for 18 h at room temperature, during which time it turned deep blue. The solvent was removed by vacuum and the resulting residue was extracted with THF (10 mL) and filtered through celite. The filtrate was placed in a freezer at −20 °C overnight. Two different forms of crystals of **2** were formed, along with excess sulfur, which were collected by filtration and separated mechanically (0.035 g, 13 % yield). Elemental analysis (%) calcd for $C_{14}H_{32}N_4CuS_2O_6F_6$ (**2**): C 28.30, H 5.43, N 9.43; found: C 27.70, H 5.14, N 9.13. The solvent was removed from the filtrate in vacuo to give **3** as a dark blue powder. The solid was washed with diethyl ether (2 × 5 mL) and dried under vacuum. Purple crystals of **3** were grown from a solution in THF by slow diffusion of pentane at −20 °C. Yield: 115 mg (63 %); ^1H NMR (CD_2Cl_2, 300 MHz): $\delta = 2.49$ (s, 8H), 2.37 ppm (s, 24H); UV/Vis (THF): λ_{max} (ε, $M^{-1}cm^{-1}$) = 251 (11 000), 394 (9000), 575 nm (6400); elemental analysis (%) calcd for $C_{14}H_{32}N_4Cu_2S_6O_6F_6$ (**3**): C 21.40, H 4.10, N 7.13; found: C 21.84, H 4.05, N 6.94.

[8] X-ray structural analysis of **3**: An X-ray quality crystal was mounted on a Siemens SMART Platform CCD diffractometer for data collection. A randomly oriented region of reciprocal space was surveyed to the extent of one sphere and to a resolution of 0.84 Å. The intensity data were corrected for absorption and decay by using SADABS (R. Blessing, *Acta Crystallogr. Sect. A* **1995**, *51*, 33). Final cell constants were calculated from the *xyz* centroids of strong reflections from the actual data collection after integration with SAINT (SAINT version 6.2, Bruker Analytical X-ray Systems, Madison, WI, **2001**). The structure was solved by direct methods with SHELXL97 software (SHELXTL version 6.10, Bruker Analytical X-Ray Systems, Madison, WI, **2000**). Full-matrix least-squares/difference Fourier cycles were performed by using SHELXL97 software, which located the remaining non-hydrogen atoms. All non-hydrogen atoms were refined with anisotropic displacement parameters. All hydrogen atoms were placed in ideal positions and refined as riding atoms with relative isotropic displacement parameters. $C_{14}H_{32}N_4F_6O_6S_6Cu_2$, $M_r = 785.88$, monoclinic, space group $P2(1)/n$, $a = 8.697(5)$, $b = 13.269(5)$, $c = 13.029(5)$ Å, $\beta = 92.481(5)°$, $V = 1502.1(12)$ Å^3, $Z = 2$, $\rho_{calcd} = 1.737$ g cm^{-3}, $\lambda(Mo_{K\alpha}) = 0.71069$ Å, $T = 173(2)$ K, crystal dimensions $0.25 \times 0.25 \times 0.20$ mm^3, $\mu(Mo_{K\alpha}) = 1.906$ mm^{-1}, θ range from 2.19 to 25.06°, 7497 measured reflections, 2651 independent reflections ($R_{int} = 0.0243$), R_1 ($I > 2\sigma(I) = 0.0314$), wR_2 ($I > 2\sigma(I)) = 0.0710$, GOF = 1.027, 172 parameters, final difference map within 0.569 and −0.230 e Å^{-3}. The crystallographic data for the two forms of **2** are given in the Supporting Information. CCDC-282801–282803 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Structural Transition and Tuning of *tert*-Butylamine Hydrate**

*Do-Youn Kim, Jong-won Lee, Yu-Taek Seo, John A. Ripmeester, and Huen Lee**

Gas hydrates, or more generally clathrate hydrates, are a type of inclusion compound and take the form of nonstoichiometic solid crystalline materials formed from water and small guest molecules.[1] Under sufficient pressure of the guest material and at specific temperatures, 3D hydrate structures are formed by the stacking of polyhedral cages of hydrogen-bonded water molecules. Suitably sized guest molecules are enclathrated in cages and their presence stabilizes the compounds formed. Although the guest molecules are physically enclosed within the cages, there are no direct chemical bonds between host water molecules and guest molecules.

In general gas hydrates form three distinct structural families known as structure I (sI), structure II (sII), and structure H (sH), which differ in the combination of cage types required to build a 3D structure.[2] In addition, there are a variety of more complex clathrate hydrate structures, labeled as types III–VII[2] and structure T (sT).[3] It is clear that many of the physical attributes of gas hydrates remain unknown and thus need to be examined in more detail. The gas hydrates are of particular interest in the fields of energy research and environmental science because of the possible applications for the storage of natural gas,[4] sequestration of CO_2 in the deep ocean,[5] and separation of greenhouse gases from flue gas.[6] It is noteworthy that for lowering the pressure of hydrate formation without significant reduction of the capacity to store CH_4, the use of sH hydrate was suggested.[7] Many experimental and theoretical works to understand macroscopic phase behavior and microscopic structural characteristics of the pure and mixed hydrates have been reported.[8–12] Most recently, we proposed a tuning mechanism to increase the storage capacity of hydrogen in double hydrogen hydrate.[13]

Herein, we report a structural transition of the simple amine hydrate to produce a novel double (CH_4 + tBuNH$_2$) hydrate as confirmed by using microscopic analytical methods. Powder X-ray diffraction (PXRD) was adopted as the primary method to identify the structure of the gas hydrates and to provide lattice parameters. More importantly, the distribution of guest molecules over the hydrate cages was investigated by NMR spectroscopy, as it is imperative to establish a mutual consistency between the structures from PXRD and the structure-specific chemical-shift signatures from NMR spectroscopy to obtain a more complete description of the hydrates. In addition, the corresponding hydrate compositions were determined from a quantitative analysis of the NMR spectroscopic results. We note that during sample preparation in a high-pressure vessel, the composition of the aqueous phase continuously changes. However, for this work we have focused only on the final equilibrium compositions that are spontaneously determined by the pressure of CH_4 gas, system temperature, and initial concentration of tBuNH$_2$.

The tBuNH$_2$ clathrate hydrate, $16\,(CH_3)_3CNH_2{\cdot}156\,H_2O$, which Jeffrey designated as a type VI structure,[2] is a true clathrate as there is no evidence of hydrogen bonding between host water and guest amine molecules. tBuNH$_2$ molecules occupy large complex cages with 17 sides ($4^3 5^9 6^2 7^3$) while the small cages ($4^4 5^4$) remain empty.[14] Figure 1 represents the PXRD patterns of both pure tBuNH$_2$ and double (CH_4 + tBuNH$_2$) hydrate at 113.15 K. According to a previous report,[14] the structure of pure tBuNH$_2$ hydrate is cubic (space group $I\bar{4}3d$) with a unit cell dimension of 18.81 ± 0.02 Å. The PXRD patterns of pure tBuNH$_2$ hydrate samples are consistent with the reported single-crystal structure;[14] the slightly smaller unit cell dimension of 18.7117 ± 0.0019 Å arises from the different temperatures at which the parameter was measured. In Figure 1a, all of the observed reflections for pure tBuNH$_2$ hydrate were attributed to type VI structure,[2] as indexed by the Checkcell program.[15] However, it should be noted that there are clear structural differences when we compare the PXRD patterns for pure tBuNH$_2$ hydrate with those of the double (CH_4 + tBuNH$_2$) hydrate. The introduction of CH_4 molecules as guests changes the structure of the pure tBuNH$_2$ hydrate. Preliminary X-ray results suggested that the transformed structure is a cubic sII hydrate, $16S{\cdot}8L{\cdot}136\,H_2O$, with space group $Fd3m$. Because the ideal mole ratio of liquid guest (tBuNH$_2$) is 5.6 when it completely fills the large cages of the host (water), we chose to prepare a double (CH_4 + 5.6 mol % tBuNH$_2$) hydrate to verify the structural transition. The collected PXRD patterns were indexed by using the Checkcell program,[15] and the unit cell dimension was determined to be 17.3060 ± 0.0033 Å (see Supporting Information). The resulting refined pattern (Figure 1b) agrees with the reported value for a face-centered-cubic sII hydrate with $a = 17.31 \pm 0.01$ Å.[16]

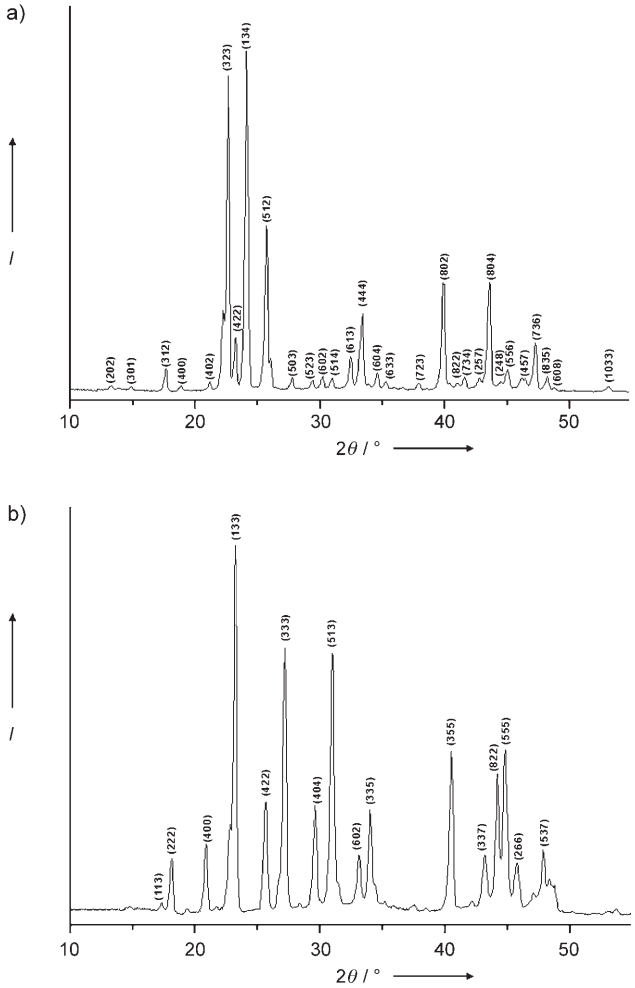

Figure 1. Powder X-ray diffraction patterns: a) pure tBuNH$_2$ hydrate, $a = 18.7117 \pm 0.0019$ Å; b) double (CH_4 + tBuNH$_2$) hydrate, $a = 17.3060 \pm 0.0033$ Å.

One of the objectives of this work was to determine the guest distribution of the two types of guest molecules and to use this information to find the equilibrium composition of the double hydrate. Although the 5^{12} cages are common to many hydrate structures, the symmetry and size of these small cages in the structures are somewhat different and their interactions with guest molecules are also different.[17] Accordingly, encaged guest molecules show different chemical shifts in the NMR spectrum which were used for structural assignments and the identification of guest distribution in cages of pure tBuNH$_2$ hydrate and double (CH_4 + tBuNH$_2$) hydrate that range from a concentration of tBuNH$_2$ from 9.3 to 1.0 mol%. Figure 2 shows ^{13}C magic-angle spinning (MAS) NMR spectra of pure tBuNH$_2$ hydrate and double (CH_4 + tBuNH$_2$) hydrate, which were used to assign the chemical shifts of tBuNH$_2$ molecules as well as those of CH_4 molecules in the hydrate cages. The spectrum of pure tBuNH$_2$ hydrate (Figure 2a) is consistent with the tBuNH$_2$ molecules occupying the large cages of this hydrate, as attested by signals at $\delta = 47.3$ (-C(CH$_3$)$_3$) and 31.6 ppm (-C(CH$_3$)$_3$); the signal intensities reflect the molecular formula. Figures 2b and c show the ^{13}C NMR spectra of double (CH_4 + tBuNH$_2$) hydrate (tBuNH$_2$ concentrations of 9.3 and 7.0 mol%, respectively), which both have CH_4 and tBuNH$_2$ as guest molecules. The CH_4 molecules occupy only the small cages of the double hydrate, as indicated by a single signal at about $\delta = -4.7$ ppm. At the same time, tBuNH$_2$ molecules are present in the large cages, which can be identified by two resonances ($\delta = 46.5$ and 33.1 ppm). However, at these concentrations of tBuNH$_2$, the pure tBuNH$_2$ hydrate and the double (CH_4 + tBuNH$_2$) hydrate are found to coexist as the NMR signals characteristic of both hydrates appear downfield of the NMR spectrum. As the concentration of tBuNH$_2$ decreases further, the relative amount of double hydrate increases so that the number of encaged CH_4 molecules in the small cages also increases. When the concentrations of tBuNH$_2$ were 5.6 or 4.5 mol% (Figures 2d and e), only the double hydrate was found, as just three peaks were obtained for the double (CH_4 + tBuNH$_2$) hydrate. In contrast, pure sI CH_4 hydrate also formed in addition to the double hydrate (sII) when the concentration of tBuNH$_2$ was lowered to 3.0 mol% and 1.0 mol% (Figures 2f and g).

The distribution of CH_4 molecules throughout the cages in the pure CH_4 hydrate and in the double hydrate was investigated for concentrations of tBuNH$_2$ from 3.0 to 1.0 mol%; expanded NMR spectra are presented in Figure 3. In the ^{13}C NMR spectra of the sII double hydrate, two CH_4 resonances at $\delta = -4.7$ (small cage) and -8.3 ppm (large cage) are present, and the resonance of CH_4 molecules in a large cage is clearly seen below 3.0 mol% of tBuNH$_2$. Moreover, the number of encaged CH_4 molecules in the large cages of the double hydrate continues to increase as the concentration of tBuNH$_2$ decreases down to 1.0 mol%. In this region, when the aqueous tBuNH$_2$ solution was cooled below the phase boundary of pure CH_4 hydrate, it was found that pure CH_4 hydrate also formed as indicated by two resonances at $\delta = -4.3$ and -6.7 ppm, which are characteristic of CH_4 molecules trapped in small and large cages of sI hydrate, respectively. As the concentration of tBuNH$_2$ decreases, the amount of pure CH_4 hydrate formed becomes larger because the amount of water participating in the formation of the double hydrate decreases. In the case of 1.0 mol% of tBuNH$_2$, four NMR signals indicate the presence of CH_4 molecules enclathrated in each of the four hydrate cages of pure (sI) and double hydrate (sII). Therefore, Figure 3e precisely indicates the coexistence and guest distribution of CH_4 molecules in pure sI CH_4 hydrate and the sII double hydrate. In our experiments, the relative amount of sI and sII hydrate observed at low concentrations of tBuNH$_2$ is a variable that depends on the amount of excess water present and the reaction time. For practical purposes, it is desirable to work at a pressure that is just below the point at which sI hydrate appears. Therefore, the appearance of the spectra is not necessarily characteristic of the equilibrium distribution of the various hydrates. Note that the signal intensity in Figure 2 and Figure 3 does not directly represent the absolute amount of formed hydrates.

For several concentrations of tBuNH$_2$, the ratio of signal areas for CH_4 molecules in large cages to that of small cages of the double hydrates is plotted in Figure 4. As described above, the CH_4 molecules can occupy only the small cages of

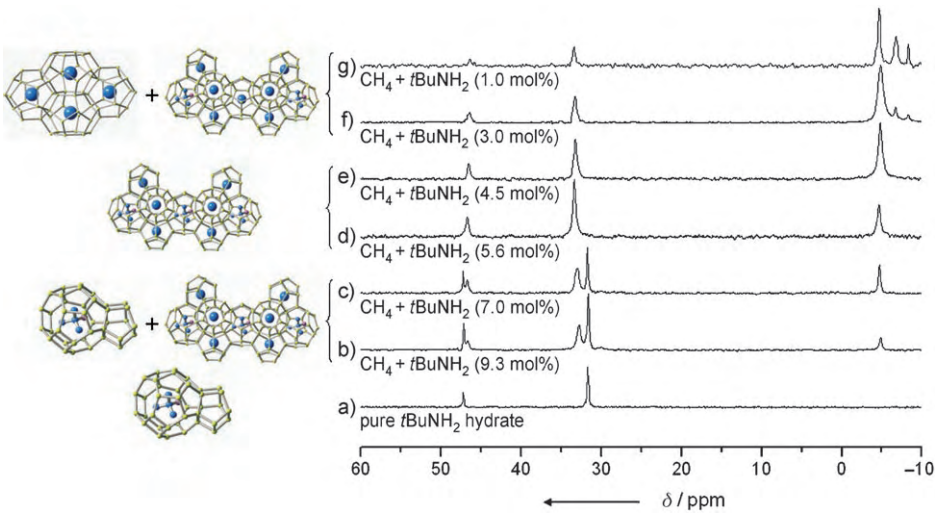

Figure 2. ^{13}C MAS NMR spectra and structural diagrams of the pure and double hydrates: a) pure tBuNH$_2$ hydrate; b) and c) both pure tBuNH$_2$ hydrate and sII double hydrate coexisted (9.3 and 7.0 mol% tBuNH$_2$, respectively); d) and e) only the sII double hydrate formed (5.6 and 4.5 mol% tBuNH$_2$, respectively); f) and g) both pure sI CH_4 hydrate and sII double hydrate coexisted (3.0 and 1.0 mol% tBuNH$_2$, respectively). All samples, except for the pure tBuNH$_2$ hydrate, were prepared for NMR analysis by using the same experimental procedure (see text, Experimental Section, and Supporting Information for details). Hydrogen atoms were omitted in the structural diagrams.

resulting values are shown in Figure 4. A value of 1.46, the lowest mole ratio of CH_4 to tBuNH$_2$ found, indicates that about 75% of the small cages are occupied by CH_4 molecules in the double hydrate; if all small and large cages encapsulate the CH_4 and tBuNH$_2$ molecules in the double hydrate, respectively, the mole ratio of CH_4 to tBuNH$_2$ becomes 2.0. As the concentration of tBuNH$_2$ decreases, the number of CH_4 molecules captured in cages increases. Based on the assumption that the occupancy of the small cage by CH_4 molecules is 0.75 (according to the result obtained for 5.6 mol% of tBuNH$_2$), the remaining CH_4 molecules should be confined in large cages of the double hydrate, which is about 31% of the large cages at 1.0 mol% of tBuNH$_2$.[18]

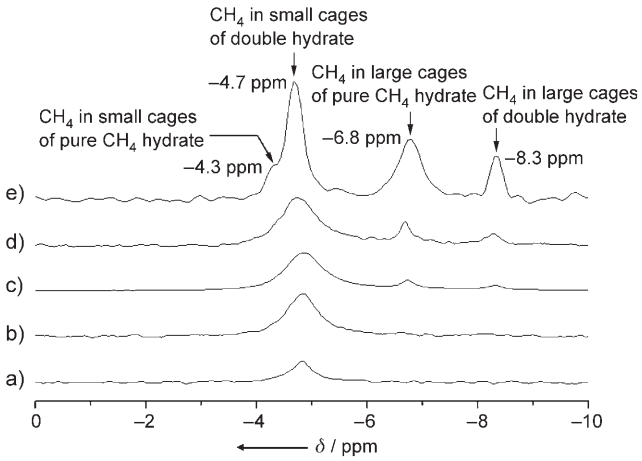

Figure 3. Expanded ^{13}C MAS NMR spectra of double (CH_4 + tBuNH$_2$) hydrates. Concentrations of tBuNH$_2$: a) 5.6; b) 4.0; c) 3.0; d) 2.0; e) 1.0 mol%.

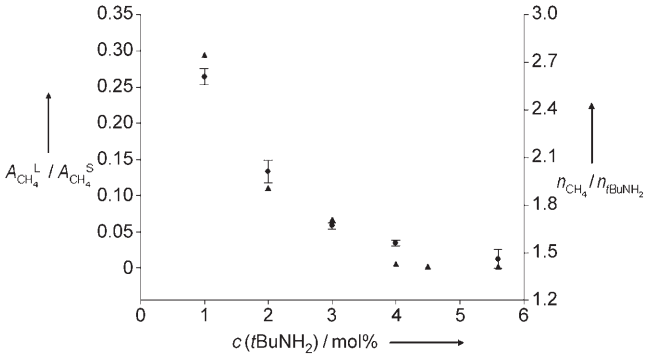

Figure 4. The area ratio (▲) of ^{13}C MAS NMR signals for CH_4 molecules occluded in large and small cages and the CH_4/tBuNH$_2$ mole ratio (●) in the double hydrate.

the double hydrate up to 4.5 mol% but occupy both small and large cages of the double hydrate below concentrations of 4.0 mol% of tBuNH$_2$. The ratio of the integrated intensities for the two signals was 0.04 at 4.0 mol% but jumped to 0.294 at 1.0 mol% of tBuNH$_2$. To check the actual amount of CH_4 molecules stored in the hydrate phase, we measured the volume of CH_4 gas released from the double hydrate samples. The samples were prepared at 70 bar and 283.65 K to eliminate the possible formation of pure CH_4 hydrates that may result from a reaction between residual water and CH_4 gas in the low concentration region of tBuNH$_2$. The measured volume of CH_4 gas was converted into moles by considering the compressibility factor of the CH_4 molecule, and the Thus, the amount of CH_4 in the sII double hydrate can be tuned by decreasing the concentration of tBuNH$_2$.

The results reported in this study show for the first time that a structural transition occurs in tBuNH$_2$ hydrate according to the initial concentration of tBuNH$_2$ when small molecules such as CH_4 are introduced. The structural transition was confirmed by PXRD and analysis of the solid-state NMR spectrum. At sufficiently low concentrations of tBuNH$_2$, pure CH_4 hydrate (sI) and double (CH_4 + tBuNH$_2$) hydrate (sII) coexist when crossing the corresponding phase boundary so that there is a complex mixture of solid phases. Moreover, it is shown that the storage capacity of CH_4 gas in the hydrate phase increases drastically as the initial concentration of tBuNH$_2$ decreases. These results confirm that the gaseous distribution of guest molecules and the hydrate composition can be altered by adjusting the concen-

tration of the liquid guest. This "tuning mechanism" plays an important role in understanding the dynamics of hydrate cages and should be one of the strategies used to enhance the gas-storage capacity of double-hydrate systems, including a water-soluble liquid hydrate promoter for application to gas storage and transportation areas.

Experimental Section

The PXRD patterns were recorded at 113.15 K on a Rigaku Geigerflex diffractometer (D/Max-RB) by using graphite-monochromatized $Cu_{K\alpha 1}$ radiation ($\lambda = 1.5406$ Å) in the $\theta/2\theta$ scan mode. The XRD experiments were carried out in step mode with a fixed time of 10 s and a step size of 0.05° for $2\theta = 10$–60°, thus rendering a total acquisition time of approximately 2 h for each hydrate sample.

To identify hydrate structure and guest distribution, a Bruker DSX 400 MHz solid-state NMR spectrometer was used. The powdered samples were placed in a zirconia rotor with an outer diameter of 4 mm, which was loaded into a variable temperature probe. The initial temperature (T) and pressure (P) were 293.15 K and 70 bar, respectively, and then T was gradually reduced to 270.15 K. The pure tBuNH$_2$ hydrate was made by freezing an aqueous solution of tBuNH$_2$ (9.3 mol%, the ideal stoichiometric concentration of tBuNH$_2$ hydrate) at 243.15 K. All ^{13}C NMR spectra were recorded at a Larmor frequency of 100.6 MHz with MAS at about 3 kHz. A pulse length of 2 μs and pulse repetition delay of 40 s under proton decoupling were employed with a radio frequency field strength of 50 kHz, which corresponded to 5-μs 90° pulses. The downfield carbon resonance signal of adamantane, which was assigned a chemical shift of $\delta = 38.3$ ppm at 300 K, was used as an external chemical shift reference. For the mixed hydrate samples, $^{13}CH_4$ gas was used to obtain higher-intensity CH_4 signals.

[18] In this case, by assuming that $\theta^{S}_{CH_4} = 0.75$ and $\theta^{L} = \theta^{L}_{CH_4} + \theta^{L}_{t\mathrm{BuNH_2}} = 1$ due to stability of sII hydrate, we could determine the number of moles of guest molecules, CH_4 and tBuNH$_2$, in small and large cages of double hydrate, which was in agreement with $n_{CH_4}/n_{t\mathrm{BuNH_2}} = 2.61$. From the resulting values, it appears that the final composition of double hydrate is $(12\,CH_4)_S\left(\frac{2.46\,CH_4}{5.54\,t\mathrm{BuNH_2}}\right)_L \cdot 136\,H_2O$.

assembly processes or molecular recognition of complimentary functional moieties.[1–5] For example, numerous assemblies of trimesic acid,[6] 1,2,4,5-benzenetetracarboxylic acid,[7] cyanuric acid,[8] trithiocyanuric acid,[9] and related compounds demonstrate the spectrum of versatile assemblies available in the literature.

In fact, the molecular recognition of complimentary nucleobases (adenine (A) and thymine (T); guanine (G), and cytosine (C)) through the formation of A-T and G-C base pairs leads to the complex structure of DNA.[10] However, it is rather surprising that utilization of the native nucleobases in molecular recognition studies for the creation of adducts or assemblies is rare, except for a few studies reported by Sasada and co-workers conducted as part of a study on the interactions of nucleic acids and amino acids.[11] An analysis of the Cambridge Structural Database (CSD),[12] with conquest version 1.7, reveals that only a handful of structures of molecular adducts of nucleobases are known.

Considering the present developments in the areas of nucleic acid/protein interactions, and in particular, the interaction of nucleobases with bioactive molecules, we believe that evaluation of a large cluster of molecular adducts of nucleobases is essential as it would enable the formulation of ideal basis sets for accurate predictions in biomolecular modeling experiments.

In this context, the potential ability of the nucleobases having both acceptor and donor functionalities (Scheme 1) led us to initiate the synthesis of numerous molecular adducts of nucleobases with the complimentary carboxylic acid derivatives shown in Scheme 1. However, we noted that only A and C formed complexes readily while G, T, and uracil (U) did not yield any complexes: XRD analysis of the resulting precipitates revealed a mixture of reactants.[13] Thus, herein we report the molecular adducts of A with benzoic acid (BA); C with BA, phthalic acid (PA) and isophthalic acid (IA) as single crystals; we also report the adducts of A with the dicarboxylic acids in the crystalline powder form. These adducts can serve as representative examples in future studies of supramolecular assemblies involving nucleobases as well as for better evaluation of biological studies.

Cocrystallization of A and BA from a CH_3OH solution gave good quality single crystals and structure determination by XRD methods revealed that the adduct of A and BA formed in a 1:2 ratio.[14] In the crystal lattice, molecules of A and BA interact with each other through the formation of a cyclic arrangement of hydrogen bonds involving COOH, NH_2, and hetero N atoms (N^1 and N^7)[15] similar to Watson–Crick and Hoogsteen base pairs. The 2D recognition pattern and molecular arrangement is shown in Figure 1. Thus, BA interacts with A through both the pyrimidine and imidazole rings with the formation of O–H···N (H···N, 1.83 and 1.86 Å)

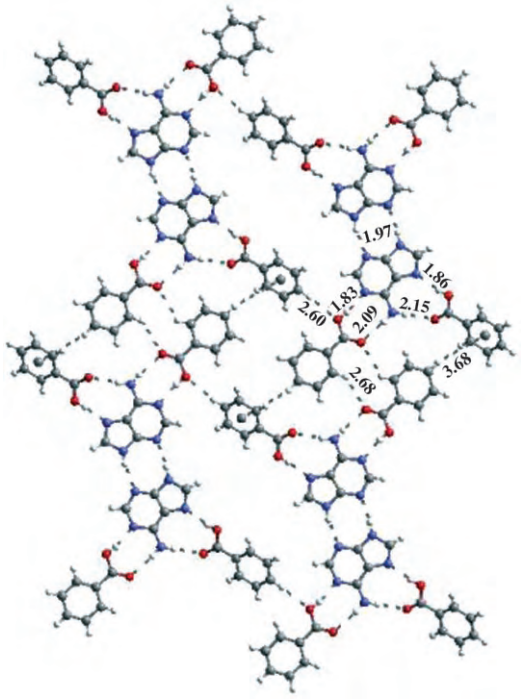

Figure 1. Arrangement of adenine (A) and benzoic acid (BA) in the molecular adduct. Hydrogen bonds are shown as dashed lines. Lines between hydrogen atoms and the center of the phenyl moiety of BA molecules represent C–H···π interactions.

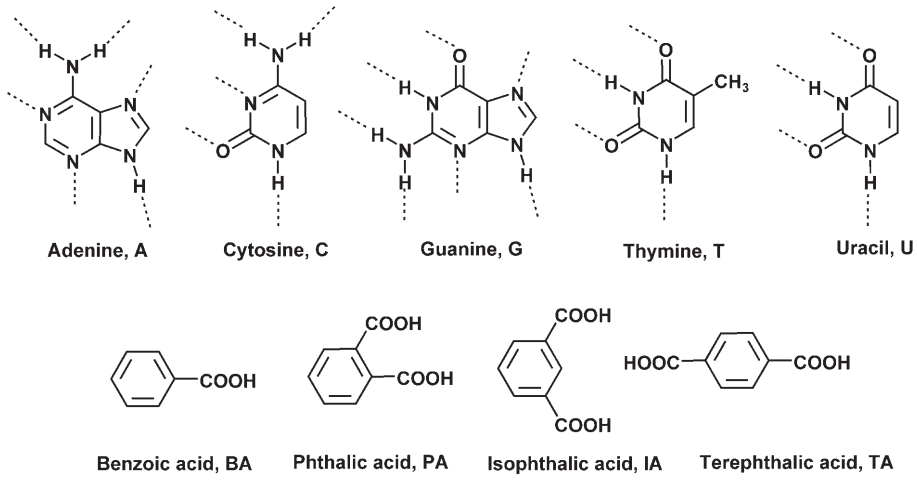

Scheme 1.

and N–H···O (H···O, 2.09 and 2.15 Å) hydrogen bonds. Furthermore, the 1:2 units are held together by centrosymmetric N–H···N hydrogen bonds between the pyrimidine N^3 atom and imidazole NH at the 9-position. The H···N distance is 1.97 Å. Such aggregates form 1D networks through a cyclic arrangement of C–H···O hydrogen bonds (H···O, 2.68 Å) formed between BA molecules to yield infinite molecular tapes. The adjacent tapes are held together by further single C–H···O hydrogen bonds (H···O, 2.60 Å) as well as C–H···π interactions (3.68 Å; Figure 1).

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

We also anticipated similar interactions with dicarboxylic acids but unfortunately, to date, we have not been successful in obtaining single crystals for the evaluation of intermolecular interactions.[16] However, evidence for the formation of adducts has been obtained by XRD analysis of the residues isolated from cocrystallization experiments.[13] Nevertheless, we were able to isolate single crystals for the adducts of cytosine, except with terephthalic acid, and the analyses disclose intriguing features.

In the 1:1 molecular adduct of C and BA, however, two molecules of each C and BA, are present in the asymmetric unit.[14] While one pair of C and BA exists in a neutral form, in the other pair proton transfer from the COOH group to the pyrimidine N^3 atom occurs. Furthermore, the interaction between C and BA is established through N^1, such that each deprotonated acid interact with both the symmetry-independent molecules of C, while the adjacent molecules of C exist as dimers connected together by a triple hydrogen bond involving N^3H, carbonyl, and the NH_2 groups, thus resembling a pseudo Watson–Crick pattern. A pictorial representation of the interactions between the cytosine and BA molecules is shown in Figure 2. The hydrogen bond lengths (H···O and H···N) in the cytosine duplex are 1.65, 1.84, and 1.94 Å (Figure 2a). Furthermore, the adjacent cytosine dimers are held together by two N–H···O hydrogen bonds with H···O distances of 2.13 and 2.15 Å, formed by NH_2 and carbonyl groups (Figure 2b). An intriguing ladderlike structure is formed in the 3D arrangement of these species (Figure 2c).

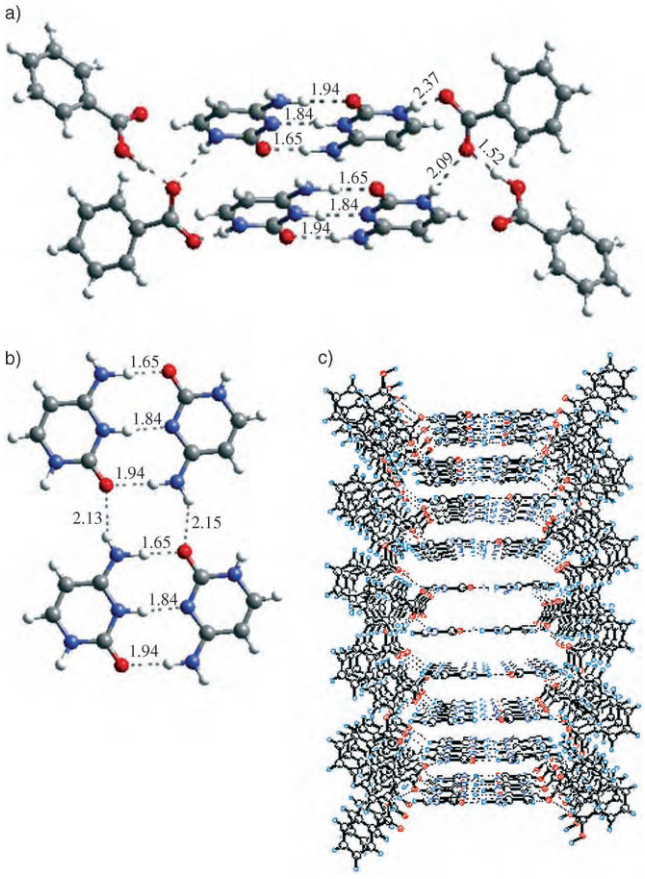

Figure 2. a) Recognition pattern between cytosine (C) and benzoic acid (BA) in the molecular adduct. b) Duplexes of cytosine residues connected together by N–H···O hydrogen bonds. c) 3D packing of C and BA in the molecular adduct forming a supramolecular ladder.

The interaction of C with PA and IA is much more interesting, with the formation of novel supramolecular structures. In both the adducts the cytosine dimers were observed as found in the complex with BA. The molecular packing in a typical 2D arrangement of the adduct between C and PA is shown in Figure 3. The adduct of C with PA is a 2:1

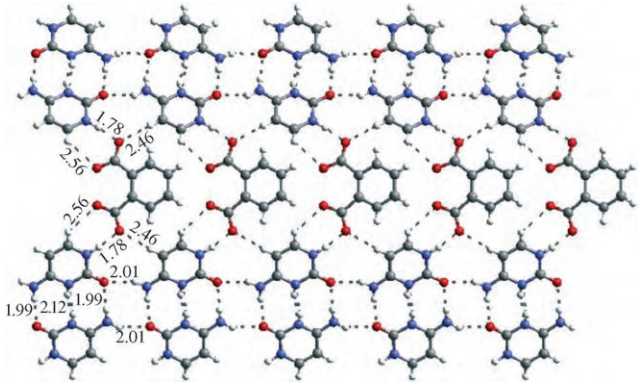

Figure 3. Arrangement of molecules of cytosine (C) and phthalic acid (PA) in the adduct forming a pillarlike structure.

complex,[14] with C and PA interacting through the deprotonated carboxyl groups of PA and C to form cyclic hydrogen-bonding patterns consisting of N–H···O (H···O, 1.78 Å) and C–H···O (H···O, 2.56 Å). Such adjacent units further interact with each other through molecules of C to yield dimers of C connected by triple hydrogen bonds, as observed in the complex of C and BA, but with different hydrogen bond lengths (H···O, 1.99 and H···N, 2.12 Å). As a result, crinkled chains are formed in the 2D arrangement (Figure 3) which are further held together by N–H···O hydrogen bonds (H···O, 2.01 Å) between molecules of C, and by C–H···O hydrogen bonds (H···O, 2.46 Å) between C and PA molecules. Thus, in each sheet the PA molecules appear as though they are inserted between tapes of C molecules.

Although 3D packing into a stacked sheets arrangement prevails in the adduct of C with IA,[14] as observed in the adduct with PA, the molecular packing is quite different within the 2D arrangement (Figure 4). Molecules of IA and C appear to exist as homomeric chains formed by strong hydrogen bonds such that while the adjacent IA molecules are held together by catemeric type O–H···O hydrogen bonds (H···O, 1.80 Å) through COOH and COO^-, molecules of C are held together by two different hydrogen bonding networks. Further, the adjacent chains are held together by a centrosymmetric cyclic arrangement of C–H···O hydrogen bonds (H···O, 2.69 Å) as shown in Figure 4b, which leads to the formation of a quartet of IA molecules (Figure 4c). In the two patterns of C, one of them is identical to that observed in

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

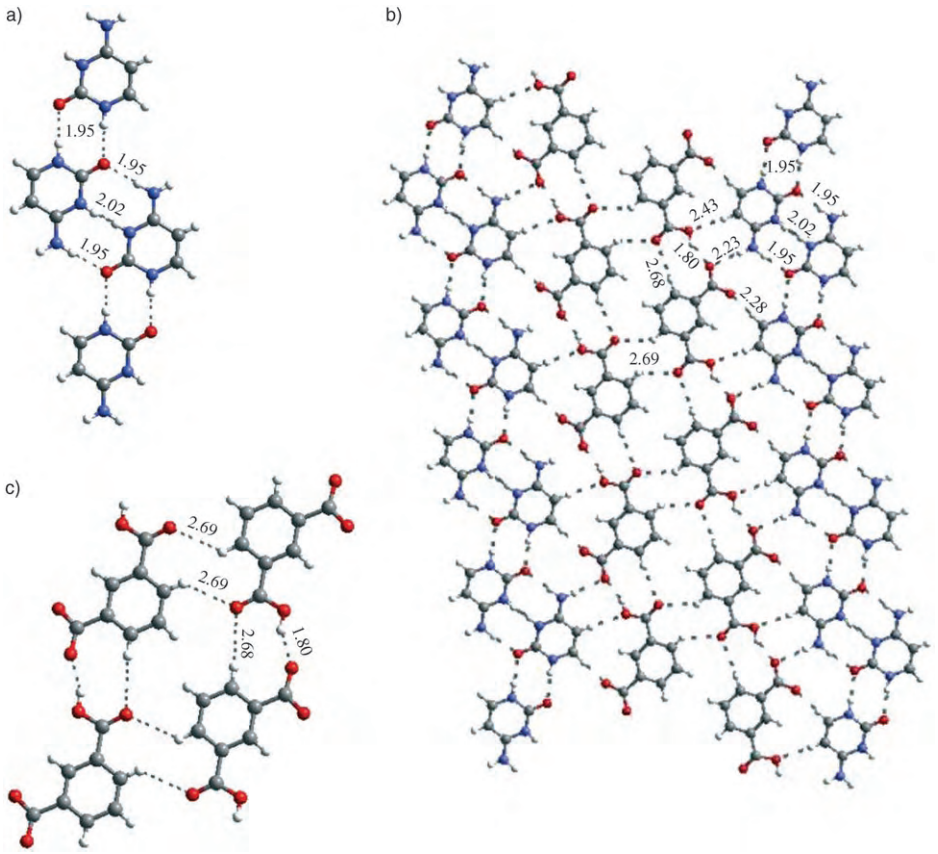

Figure 4. a) Interaction of the adjacent triple hydrogen-bonded duplexes of cytosine (C) through a dimeric hydrogen-bonding pattern. b) 2D arrangement of C and isophthalic acid (IA) in the crystal lattices of their adduct. c) Quartet arrangement of IA molecules.

the complex formed between C and PA with a triple hydrogen-bonding pattern. In contrast to the patterns observed in the complexes with BA and PA, the triplet dimers are further held together by dimeric hydrogen-bonding patterns in the adduct with **IA** through N–H···O hydrogen bonds (H···O, 1.95 Å) formed between pyridyl NH rather than NH_2 groups (Figure 4a).

Comparisons of the three adducts of C discussed above show that in all cases C exists as dimers connected together by triple hydrogen bonds and yields molecular tapes. These molecular tapes are arranged in the crystal lattice as rungs in a ladderlike structure with BA, but are sandwiched in the 2D arrangement in the adducts of PA and IA. A schematic representation of systematic variations in the arrangement of molecules in the different adducts is shown in Figure 5.

In conclusion, we have reported the formation of 3D assemblies of molecular adducts of cytosine with benzoic, phthalic, and isopthalic acids, as well as the adduct of adenine with benzoic acid. It was noted that cytosine and adenine both show the tendency to form duplexes, irrespective of the nature of the other species involved in the recognition process. Furthermore, by correlating the patterns obtained in this study with the patterns observed in other structures available in the literature, it appears that cytosine duplexes with triple hydrogen-bonding patterns are predominant in the vicinity of COOH functional groups. The cocrystallization studies with molecules containing COOH functional groups also shows that adenine binds with the other molecules through the N^1 and N^7 sites, in a similar manner to binding generally observed with thymine in the DNA structure. However, cytosine participated in molecular recognition preferentially through the N^1-position, which is generally connected to the sugar moiety in DNA, but mimics the hydrogen-bonding pattern that it forms with guanine in a G-C base pair by a homomeric process. Although these results are quite intriguing, a large number of synthetic studies of molecular adducts of nucleobases and their systematic analysis need to be made to address several problems in biological studies. We are engaged in the synthesis of cocrystals of nucleobases with different functional moieties, aimed in particular to identify groups that could interact with guanine and thymine.

charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.
[15] Labeling of N atoms have been adopted from IUPAC labeling of atoms in the nucleobases.
[16] In the literature, a 3:1 adduct of phthalic acid and adenine is known as an hexahydrate,[11b] in which the phthalic acid was produced in situ as an hydrolyzed product of *N*,*N*-phthaloyl-DL-glutamic acid. A comparison of the simulated powder patterns of it with the one we obtained show drastic differences,[13] thus suggesting the possibility of a new solid-state structure of phthalic acid and adenine in our adduct.

Porous Capsules Allow Pore Opening and Closing That Results in Cation Uptake**

Achim Müller, Liviu Toma, Hartmut Bögge, Christian Schäffer, and Anja Stammler*

Dedicated to Prof. Herbert W. Roesky on the occasion of his 70th birthday

Structurally well-defined spherical porous molybdenum oxide based nanocapsules of the type $\{Pentagon\}_{12}\{Linker\}_{30}$[1,2] can be described as artificial cells as they allow the modeling—in solution studies—of passive biological ion transport[3a,b] as well as cell response to stimuli[3c] (see also ref. [4]); for biochemically related literature, see ref. [5a]. Specifically we refer herein to spherical, nanoscale, porous capsules/artificial cells of the type $[\{(Mo)Mo_5O_{21}(H_2O)_6\}_{12}\{Mo_2O_4(ligand)\}_{30}]^{n-}$,[1,2] the overall charges and internal surfaces of which can be fine-tuned by changing the ligands, thus allowing the type and structure of encapsulates to be influenced.[4] Most important, the 20 $\{Mo_9O_9\}$-type pores have crown-ether-like function and can be opened and closed with noncovalently bonded guests in a supramolecular fashion.[6a] Herein we will refer to the special situation of (protonated) urea molecules as guest species,[6b] which are found in all 20 of the capsule pores. Interestingly, after exposition of a solution of this type of capsule to Ca^{2+} ions the Ca^{2+} ions are incorporated, however, in the final precipitated product all 20 pores are again closed with the urea-type guests. This situation is not only of some interest regarding modeling of cell environment interactions but fundamentally shows in an example that supramolecular chemistry is, according to J.-M. Lehn,[5b] a "dynamic chemistry/science": the interaction between the parts, that is, the capsule pores and the "corks"/guests, is based on lability, which allows an easy exchange corresponding to the reversibility of noncovalent interactions. Furthermore, we should note that "*calcium probably fulfills a greater variety of biological functions than any other cation*";[6c] this includes for instance the special role of Ca^{2+} ions in information mediation in connection with the ubiquitous presence of Ca^{2+} channels in excitable cells.[5a] In the present case, the up-taken Ca^{2+} ions influence/direct the structure of the capsule encapsulates, that is, of the water-molecule-based assembly.

Exposition of an aqueous solution of **1**[6d]—where the 20 pores are closed with protonated urea molecules—to Ca^{2+} ions leads finally to the precipitation of **2** which was characterized by elemental analysis, thermogravimetry (to determine the number of crystal water molecules), redox titration (to determine the number of Mo^V centers), bond valence sum (BVS) calculations,[7] spectroscopic methods (IR, Raman), and single-crystal X-ray structure analysis.[8,9]

$$(H^+ \cdot OC(NH_2)_2)_{23}(NH_4)_{29-n}[\{(H^+ \cdot OC(NH_2)_2)_{20} + (H_2O)_{81-n} + (NH_4)_n\} \subset \{(Mo^{VI})Mo^{VI}{}_5O_{21}(H_2O)_6\}_{12}\{Mo^V{}_2O_4(SO_4)\}_{30}] \cdot \approx 100\,H_2O \equiv (H^+ \cdot OC(NH_2)_2)_{23}(NH_4)_{29-n}\mathbf{1a} \cdot \approx 100\,H_2O \quad \mathbf{1}^{[10]}$$

$$(H^+ \cdot OC(NH_2)_2)_{15}(NH_4)_{21-n}[\{(H^+ \cdot OC(NH_2)_2)_{20} + Ca_8 + (H_2O)_{60} + (NH_4)_n\} \subset \{(Mo^{VI})\,Mo^{VI}{}_5O_{21}(H_2O)_6\}_{12}\{Mo^V{}_2O_4(SO_4)\}_{30}] \cdot \approx 150\,H_2O \equiv (H^+ \cdot OC(NH_2)_2)_{15}(NH_4)_{21-n}\mathbf{2a} \cdot \approx 150\,H_2O \quad \mathbf{2}$$

According to the X-ray crystallographic results, the capsule **2a** (Figure 1) shows the characteristic basic polyoxomolybdate skeleton[1,2]—the artificial cell's "inorganic membrane"[4b]—that is present in **1a**,[10] and which also occurs in other spherical capsules.[1,2,4] However, in **2a** there are additionally 20 protonated urea guests closing the 20 $\{Mo_9O_9\}$ pores/rings through noncovalent (that is, hydrogen-bond) interactions[6ab], and, encapsulated Ca^{2+} ions; furthermore, the structure of the encapsulated water-molecule assembly is different in **2a** from that of **1a**. (The presence of Ca^{2+} can also be demonstrated by IR spectroscopy by the shift of a specific sulfate band from 1036 in **1** to 1057 cm^{-1} in **2**; see ref. [3a].) The eight calcium cations found in **2a** are disordered over 20 equivalent positions below the $\{Mo_9O_9\}$ pore openings at the end of the channels (Figure 1), that is, on the C_3 axes, and exhibit the expected octahedral coordination environment which is formed by three oxygen atoms of three sulfate ligands and three oxygen atoms belonging to the encapsulated water shell/assembly (see below and ref. [4]). Whereas **1a** shows the known structure of the NH_4^+/H_2O assembly within a capsule containing SO_4^{2-} ligands,[4a] in **2a** a

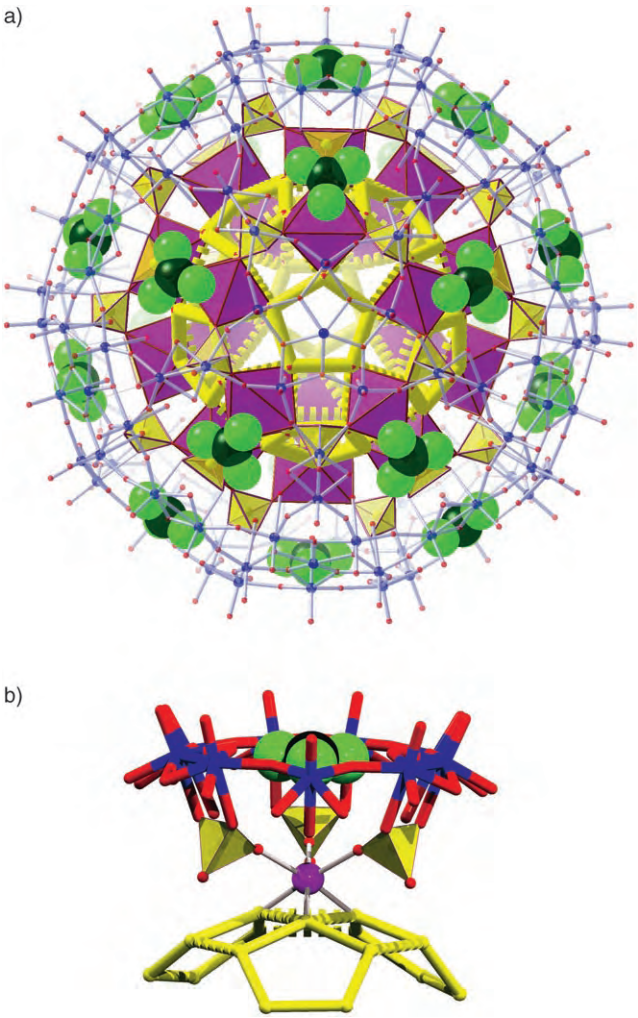

Figure 1. a) Structure of the capsule **2a** with the skeleton in ball-and-stick representation (Mo blue, O red), sulfate ligands (yellow tetrahedra), Ca^{2+} ions in the octahedral coordination of oxygen atoms (pink octahedra), the rhombicosidodecahedral $(H_2O)_{60}$ water assembly inside the capsule (yellow wire-frame representation, solid and dotted lines), and the protonated urea corks (space-filling representation, C dark green, N/O (urea) green). b) For clarity one segment of **2a** is shown separately (same color code as in (a)).

pure, well-defined water assembly/shell $\{H_2O\}_{60} \approx 12\{H_2O\}_5$ (radius 6.81–7.12 Å; occupation factor 1 for the O atoms) acting as ligand to the Ca^{2+} ions is observed,[11a] the formation and positioning of which is directed by the abundance of the fixed Ca^{2+} ions. (Though the exact NH_4^+ and H_2O positions in **1a** cannot be distinguished by X-ray crystallography because of a related disorder, there is clear evidence that NH_4^+ ions are involved in the formation of the central $\{X_{20}\}$ dodecahedron.[11a]) The $(H_2O)_{60}$ shell of **2a** corresponds to a distorted rhombicosidodecahedron which might be regarded as an unprecedented polydentate/macrocyclic ligand for the calcium ions or other cations.

Recall that we start with a capsule **1a** closed by the protonated urea "corks" and detect Ca^{2+} ions afterwards in the capsule **2a**, the pores of which are again closed by the same corks. The inorganic membrane pores are definitely not permanently closed, and in solution only a fraction of the pores is always (statistically) open (Figure 2). This problem related to the "behavior" of the corks in solution cannot of course be solved by an X-ray crystallography study. On the other hand, preliminary ^1H NMR spectra of solutions of **2** in DMF at room temperature clearly indicate the abundance of oxygen-protonated urea species in the pores.[11b] (Oxygen protonation would agree with earlier results for the protonation sites of urea determined by IR and ^{17}O NMR spectroscopy.[6b]) In this case, the peak-intensity analysis reveals that approximately a third of the capsule pores are occupied.[11c] Interesting, in this context, is the possibility of stabilizing the OH-type protonated urea species by integration into the pores. Furthermore, a well-defined temperature-dependent equilibrium can—in the case of guest cations exhibiting a much higher affinity[6a] for the pores than protonated urea—be easily studied by NMR spectroscopy in different solvents.[11d] With such guests the remarkable situation arises in which all the 20 pores are completely closed at lower temperatures and can be (reversibly) opened on heating with the consequence that uptake of different types of cations only occurs at higher temperatures (temperature gating). This process can be demonstrated nicely by ^1H- and metal-NMR spectroscopy studies including EXSY data.[11d]

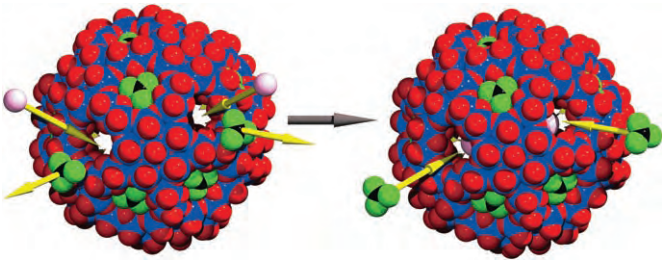

Figure 2. Space-filling representation demonstrating a simplified view of the Ca^{2+} ion uptake based on the capsule **1a**. In the anions of **1** the pores are closed. Treating a solution of **1** with Ca^{2+} ions leads to cation uptake (left) while in the final product **2** the pores again are closed (right; Mo blue, O red, C black, N/O(urea) green, Ca^{2+} pink, yellow arrows indicate direction of motion).

Under the conditions employed the Ca^{2+} ions cannot pass through the pores with their hydrate coat: for an effective trafficking the comparably large Ca^{2+} complexes must release their water ligands and some of these ligands are "taken up" again inside the artificial cell. (Note: the inorganic membrane pores are semipermeable allowing uptake and release of water but not of organic solvents such as DMF or DMSO.[3b,11d]) A condition for the uptake is therefore that the affinity of Ca^{2+} ions for the H_2O ligands is not too strong. This condition is met in this case as the water ligand "mean residence time" is of the order around 10^{-8} s at room temperature,[12] which is comparable to the published water exchange rate constant of $6–9 \cdot 10^8\ s^{-1}$.[13ab,14] As $[Ca(H_2O)_6]^{2+}$ shows a much greater lability compared to the related Be^{2+} and Mg^{2+} hydrate complexes, Be^{2+} and Mg^{2+} should therefore both show a different behavior with respect to their inter-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

actions with the capsule(s).[14] In this context there is another attractive aspect which is related to the possibility of trapping complete hydrate complexes above the capsules' pores based on hydrogen-bond interactions between the O atoms of the $\{Mo_9O_9\}$ pores/rings and the H_2O ligands. But this type of trapping only occurs for the present type of hydrate complex, which has a low stability-constant value, with less negatively charged capsules, for example, those with linkers containing less negatively charged ligands, such as acetates (instead of sulfates), where the capsule–cation interaction is weaker.[15] Interesting in this context is that the coordination environment of calcium ions in water is not very well defined, and correspondingly different coordination numbers for Ca^{2+} ions are reported in the literature.[13a] This gives, in principle, the option to trap different hydrate complexes in this or in related metal complexes at the capsule surface sites under different conditions,[13c] including different capsule charges (so called "Sphere Surface Chemistry").

An aspect of more general interest in this context is the chance to carry out systematic studies on the interaction between the capsules/artificial cells—the pores of which are partially or temporarily closed with different kinds of complementary guests—and a series of different hydrated cations present in solution; this would allow information to be obtained on the properties and behavior of hydrate complexes. The entrance of appropriate cations can nicely be studied in solution with NMR spectroscopy.[3a,b] Importantly, most of the biological ion pores/channels are not continuously open (note: the K^+ ion leak channels are) they are gated, that is, they can open and then close again.[5a] The opening is due to a response to specific stimuli, for example, corresponding to a change in the voltage across the membrane (leading to the channel protein conformational changes), a mechanical stress, or binding of a ligand.[5a] Referring to the present situation, the abundance of a large number of added cations, such as Ca^{2+}, in the vicinity or at the surface of the highly charged capsule decreases the capsule's charge, that is, diminishes the formal electrochemical gradient.[5a] This can 1) facilitate the release of guests such as protonated (even comparably strongly bonded) organic bases complementary to the $\{Mo_9O_9\}$ pores, and 2) allow subsequent entering of the cations (voltage gating of channels[5a]). In the case of more strongly bonded guests (see above and ref. [6]), this leads to complete pore closing at lower temperatures and cation uptake is observed only at higher temperatures (temperature gating (see above)). Once the cations are encapsulated the charge distribution changes, which might again influence the gating of the pores.

In the present system cation entrance is interesting because of the following facts: Voltage-gated calcium channels—ubiquitous in excitable cells in which Ca^{2+} functions as the ubiquitous intracellular messenger—play a key role in various physiological processes, such as muscle contraction, hormone and neurotransmitter secretion, and neuronal excitability. Several extracellular signals can induce an increase in the cytosolic Ca^{2+} ion concentration by 10–20-fold, which triggers the response.[5a,16,17] An interesting result of the present study is also that the uptake of Ca^{2+} ions leads to a "response in the cavity" in the form of a change in the structure of the encapsulates, that is, of the water/electrolyte based assembly.

Experimental Section

Synthesis of **1** (see also ref. [10]): A mixture of $(NH_4)_{42}[\{(Mo)Mo_5O_{21}(H_2O)_6\}_{12}\{Mo_2O_4(CH_3COO)\}_{30}]\cdot\approx[10\,CH_3COONH_4+300\,H_2O]$ (1.0 g, 0.04 mmol),[2d] ammonium sulfate (4.0 g, 30 mmol), urea (3.0 g, 50 mmol), and water (100 mL) was acidified with 16% HCl (8 mL) in a 250-mL conical flask (covered with a watch-glass) and stirred for 45 min at room temperature. The solution was kept in an open 250-mL beaker at around 23 °C for 10 days. Then the precipitated brown rhombohedral crystals of **1** were collected by filtration and dried in air. Yield: 0.35 g (35% based on Mo); elemental analyses (%) calcd N 5.69, H 2.62, C 1.82; found: N 5.6, H 2.7, C 1.8.

Characteristic IR bands: (KBr pellet, some characteristic bands for the range 1700–500 cm^{-1}): $\tilde{\nu}=1703$ [w, $\delta(ureaH^+)$], 1622 [s, $\delta(H_2O)$], 1555 [w, $\delta(ureaH^+)$], 1402 [m, $\delta(NH_4)$], 1196 (w), 1140 (m), 1036 (w) [all $\nu_{as}(SO_4)$], 972 [s, ν(Mo=O)], 852 (m), 795 (s), 723 (s), 630 (w), 569 cm^{-1} (s). (The $ureaH^+$ bands are influenced by the hydrogen bonds in the pores and are rather different from those of urea itself.)

Characteristic Raman bands: (solid state, KBr dilution, $\lambda_e\approx1064$ nm): $\tilde{\nu}=950$ [m, ν(Mo=O)], 880 [ν_s ($O_{bridging}$ breathing/A_{1g})], 372 (m), 303 cm^{-1} (w).

2: A mixture of **1** (2.0 g, 0.07 mmol), $CaCl_2\cdot2H_2O$ (0.5 g, 3.40 mmol), and water (50 mL; pH < 2) was stirred for 2 h at room temperature. The solution was then kept in an open 250-mL beaker at about 23 °C and after one week the precipitated brown rhombohedral crystals were collected by filtration through a glass frit (D2) and dried in air. Yield: 0.6 g (30% based on Mo); elemental analyses (%) calcd N 4.47, C 1.47, H 2.55, Ca 1.12; found: N 4.5, C 1.5, H 2.4, Ca 1.1.

Characteristic IR bands: (KBr pellet, some characteristic bands for the range 1700–500 cm^{-1}): $\tilde{\nu}=1703$ [w, $\delta(ureaH^+)$], 1624 [s, $\delta(H_2O)$], 1555 [w, $\delta(ureaH^+)$], 1402 [s, $\delta(NH_4)$], ≈1200 (sh), 1143 (m-s), 1057 (w) [all $\nu_{as}(SO_4)$], 976 (s), 947 (w) [both ν(Mo=O)], 854 (m), 796 (s), 725 (s), 632 (w), 573 cm^{-1} (s).

Characteristic Raman bands: (solid state, KBr dilution, $\lambda_e\approx1064$ nm): $\tilde{\nu}=950$ [m, ν(Mo=O)], 879 [ν_s ($O_{bridging}$ breathing/A_{1g})], 372 (m), 302 cm^{-1} (w).

The chemical formulae of **1** and **2** refer to the maximum possible number of crystal water molecules which correspond to the related volume calculated from the cell volume and the sum of volumes of all cell ingredients excluding those of the crystal water molecules. The given calculated values for C, N, Ca are related to a formula with 50 crystal water molecules less than given (note: **1** and **2** as all similar compounds show slow weathering, that is, loss of crystal water).

[6] a) The first published example referred to the integration of $20[C(NH_2)_3]^+$ ions into the $20\{Mo_9O_9\}$ pores/rings in the same way as into a crown ether host, that is, the O···H–N bonding is comparable to that in crown ether hosts; for details see ref. [3c]. The pore(host)–guest interactions with other protonated bases such as $H^+{\cdot}OC(NH_2)_2$ (see below) and $HC(NH_2)_2^+$ (unpublished results; see also comments in the text) are as expected weaker, while with the increasing basicity of the corresponding unprotonated base—which is lowest in case of urea—the stability of the protonated species increases (H. R. Christen, F. Vögtle, *Organische Chemie, Vol. 1*, Salle and Sauerländer, Frankfurt am Main, **1992**, p. 452); b) Urea is, apart from its biological (e.g., protein denaturation) and industrial importance (see, for example, J. W. Steed, J. L. Atwood, *Supramolecular Chemistry*, Wiley, New York, **2000**, p. 273), especially interesting structurally and chemically: firstly because of the abundance of the (complementary) hydrogen-bonding sites giving rise to the remarkable cage/inclusion structures (see, for example, G. A. Jeffrey, *An Introduction to Hydrogen Bonding*, Oxford University Press, New York, **1997**, p. 175), and secondly to the (in principle) different sites for protonation, that is, at the N and O atoms. The OH type species is stabilized by the contribution of the mesomeric border structure exhibiting the $C{=}NH_2^+$ fragment (K. P. C. Vollhardt, N. E. Schore, *Organische Chemie*, Wiley-VCH, 3. Aufl, Weinheim, **2000**, p. 956; see also: H. Beyer, W. Walter, *Lehrbuch der Organischen Chemie*, Hirzel, Stuttgart, 21. Aufl., **1988**, p. 356). Important in this case is that O protonation allows hydrogen-bond interactions in the pores in three directions. The problem of protonated sites was controversial for a long time starting from Alfred Werner's opinion: From vibrational spectra of normal urea salts, for example, with the $PtCl_6^{2-}$ ion, it was concluded for the first time that the preferable site of protonation is the O atom (W. Kutzelnigg, R. Mecke, *Chem. Ber.* **1961**, *94*, 1706 – 1716). Also from ^{17}O NMR spectroscopy studies over a wide pH range, from aqueous solution to fluoro sulfonic acid, it was concluded that (the first) protonation takes place at the O atom; in a magic acid even double protonation was observed (B. Valentine, T. E. St. Amour, D. Fiat, *Org. Magn. Reson.* **1984**, *22*, 697–700); c) W. Kaim, B. Schwederski, *Bioinorganic Chemistry: Inorganic Elements in the Chemistry of Life*, Wiley, Chichester, **1994**, p. 293; d) Note: this type of capsules is stable in solution at pH values between 1.5 and 4 and under exclusion of oxygen.

[11] a) The shell system in the cavity of **1a** spanned by $n\,NH_4^+/m\,H_2O = X$ centers with $m \gg n$ is X_{60} (distorted rhombicosidodecahedron) + X_{20} (dodecahedron) + X (in the center) and is also found, for example, in an ammonium/sulfate-based capsule with open pores;[4a] the X_{60} shell is geometrically similar to the known pure water assembly $\{H_2O\}_{60}$ shell such as that in **2a** (see also ref. [4b,c]). There is clear evidence that the NH_4^+ ions in **1a** are rather strongly fixed in the cavity, as shown by combined thermogravimetry, mass spectroscopy, and temperature-dependent elemental analyses studies up to 450 °C; remarkably, the release of the "last" NH_3 molecules out of the capsules upon heating occurs at rather high temperatures (A. Malecki, A. Bielanski, E. Diemann, A. Müller, unpublished results). On the other hand it is evident that a change of the positions of the NH_4^+ ions during the conversion of **1a** into **2a** occurs while a Ca^{2+}–NH_4^+ counter transport takes place which leads to very small values of n in **2** and is currently being investigated in detail by ^{15}N HSQC NMR spectroscopy (E. T. K. Haupt, A. Müller, unpublished results); b) A. Mix, H. Bögge, T. Mitra, D. Rehder, A. Müller, unpublished results; c) In an aqueous solution of **1** the ratio of open to closed pores is unknown. The complete pore closing observed in solid **2** is to some extent influenced by the fact that it lowers the capsule charge and leads to a lower solubility of **2**; d) A. Mix, H. Bögge, D. Rehder, T. Mitra, M. Schmidtmann, A. Müller, unpublished results.

Enantiospecific Chemisorption of Small Molecules on Intrinsically Chiral Cu Surfaces**

*Bhawna Bhatia and David S. Sholl**

Solid surfaces that define chiral interfaces are of great interest for potential applications in chiral processing.[1–4] The observation that highly stepped metal surfaces are intrinsically chiral has created interest in the use of these surfaces for enantiospecific separations and catalysis.[5–9] An enantiospecific separation based on the reversible adsorption of molecules on a chiral Cu surface has recently been demonstrated.[10] Chemisorption of enantiopure amino acids on low-index Cu surfaces has been shown to lead to the spontaneous formation of homochiral surface facets.[11] A number of common mineral surfaces are also intrinsically chiral.[12] Enantiospecific adsorption on chiral surfaces is controlled by the preferred locations and orientations of adsorbed molecules, but assessment of these properties experimentally is extremely challenging. Below, we present predictions of the preferred binding configurations of two small species on a chiral Cu surface, Cu(874), made by using density functional theory (DFT) calculations.

Previous theoretical studies of molecular adsorption on chiral metal surfaces have focused on physisorbed molecules, which can be described using empirical potentials.[6,8,9,13] DFT has been used to study the chemisorption of $HSCH_2CHNH_2CH_2P(CH_3)_2$ on a chiral Au surface,[14] thus predicting a binding-energy difference between the two molecular enantiomers of 0.09 eV. Unfortunately, neither this molecule nor the Au surface used in these calculations have been characterized experimentally. Herein, we consider a chiral Cu surface of the type that has been used in a number of experiments[15–18] and examine two molecular adsorbates, one of which, propylene oxide, has been used in several experimental studies of surface chirality.[1,16,19] We recently used DFT methods very similar to those used below to determine the structure of chiral adlayers of amino acids on low-index Cu surfaces and found very good agreement between the calculated structures and those observed experimentally.[20,21]

Our calculations examined the adsorption of the amino(fluoro)methoxy (FAM) species and propylene oxide on a Cu(874) surface. A schematic view of these moieties as they bind on Cu surfaces is shown in Figure 1. Cu(874) is intrinsically chiral because of the kinked steps that separate its (111)-oriented terraces (Figure 2).[5–9] Using the standard notation for defining the chirality of these surfaces,[5–9] the surface shown in Figure 2 and used in our calculations is denoted Cu(874)^S. Real chiral Cu surfaces exhibit a distribution of step and kink lengths because of the thermal motion of step-edge atoms.[22,23] Detailed models of these step distributions suggest that the structures that define Cu(874) are representative of a large number of surface orientations with (111)-oriented terraces.[13,24] Cu(643), which has been used in most experiments of intrinsically chiral metal surfaces, also has (111)-oriented terraces.[10] The unit cell of Cu(874) is somewhat larger than Cu(643), thus making it more suitable for calculations in which the effect of adsorbate–adsorbate interactions is minimal.

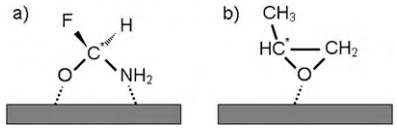

Figure 1. Schematic representations of a) FAM and b) PO binding on a metal surface. In each species, the chiral center is denoted by an asterisk and bonds with the surface are shown with dashed lines.

A challenging aspect of examining molecular adsorption on stepped metal surfaces computationally is that large numbers of adsorption configurations must be examined.[14,18] This task can be simplified if some information is available on

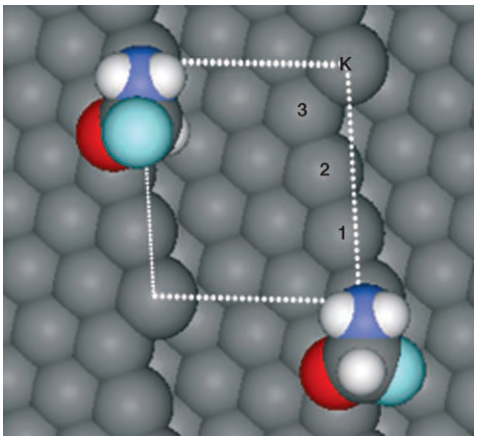

Figure 2. The most favorable binding geometries of *R*-FAM (top left) and *S*-FAM (bottom right) on Cu(874)^S as computed by using DFT. Dashed lines indicate a single surface unit cell. The surface-kink atom (K) and step-edge atoms (1–3) are labeled.

the types of binding sites preferred by the moieties of interest. We first examined the adsorption of methoxy (OCH_3), chlorofluoromethoxy (OCHClF), methylamine (H_3CNH_2), and chlorofluoromethylamine ($HClFCNH_2$) species on Cu(111) (see the Supporting Information). We previously used DFT to examine the adsorption of fluoroethoxy species on Cu(111) and found excellent agreement between the calculated and experimental adsorption geometries and energies.[25] Both methoxy (amine) species were found to favor threefold fcc (top) sites, with each forming a single bond with the surface. We then examined the adsorption of chlorofluoromethoxy and chlorofluoromethylamine species on Cu(874) for multiple positions of these species near the step edge; both favor adsorption on the upper edge of the surface step. Binding energies on the stepped surface were 0.33–0.40 eV more stable than on Cu(111). Based on this observation, we only consider configurations with molecules bound to step edges in the calculations described below. The difference between the binding energy of terrace and step sites is larger for the amine than the methoxy species. The preferred binding site for the amine is on top of the kink atom shown in Figure 2.

Based on our preliminary calculations, we investigated the adsorption of *R*- and *S*-FAM on Cu(874)^S in detail. For *S*-FAM, we considered configurations with the amino group on top of atoms K, 1, 2, and 3 in Figure 2. For each configuration, six distinct rotations of the N–O direction about the surface normal were considered. For each of these configurations, two distinct orientations that differ in the angle formed by C–H and C–F with respect to the surface normal were examined. This procedure yields 48 distinct configurations for *S*-FAM/Cu(874)^S. An equivalent set of 48 configurations for *R*-FAM was also examined. From these 96 configurations, we excluded 64 states in which the O atom was located in what could be considered a pure terrace site. The remaining 32 states were geometrically optimized by using $3\times3\times1$ *k* points. The 21 states with the most favored energies from these calculations were further optimized with $7\times7\times1$ *k* points and dipole corrections.

Two views of the most favored adsorption configurations for *S*- and *R*-FAM on Cu(874)^S are shown in Figures 2 and 3. There is a significant energy difference between the two

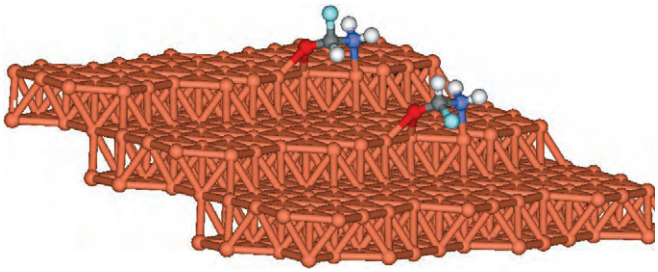

Figure 3. Side view of *R*- (left) and *S*-FAM (right) on Cu(874)^S.

enantiomers, as the *R*-FAM binding to the surface is 0.13 eV stronger than the *S*-FAM binding. This difference is the largest enantiospecific adsorption-energy difference that has been predicted or observed to date for molecular adsorption on a chiral metal surface. The origin of this enantiospecific binding can be understood as follows: Both enantiomers bind to the same surface atoms (see Figure 3). These bonds, as characterized by the Cu–O and Cu–N distances (see the Supporting Information), are essentially the same for the two adsorbed enantiomers. These surface bonds constrain the C–F bond to point towards (away from) the surface for *S*-FAM (*R*-FAM) and vice versa for the C–H bond. The energy difference between the adsorbed enantiomers arises from the different local environments of the F atom; the more stable *R* enantiomer has the F atom far from the surface. The energetic preference for F atoms to not lie close to a Cu surface has been observed before with DFT calculations and experiments for 2-fluoroethoxy/Cu(111).[25] Interactions between the F atom and step edge in *S*-FAM induce slight distortions in the molecule; the O-C-F bond angle is 114° for adsorbed *S*-FAM but 109° for *R*-FAM.

Many local minima exist for *R*- and *S*-FAM on Cu(874)^S. For *R*-FAM, the next four most favorable states had energies of 0.12, 0.18, 0.20, and 0.22 eV relative to the most stable state. For *S*-FAM, the next four locally stable states had energies of 0.16, 0.19, 0.21, and 0.23 eV relative to the favored configuration of *R*-FAM. The distribution of energy minima accessible to each adsorbed enantiomer is shown in Figure 4.

The species treated above exhibits strongly enantiospecific binding on Cu(874)^S but suffers from the serious drawback that it is not readily available for experiments. To address this point, we performed similar calculations for propylene oxide (PO) on Cu(874)^S. PO has previously been used experimentally as a probe for enantiospecific binding on both intrinsically chiral metal surfaces[16] and chirally templated surfaces.[1,19] We first examined the adsorption of PO on Cu(111) and found that the molecule favors a configuration in which the terminal methyl group is oriented away from the surface. Test calculations with PO on Cu(874)^S showed that PO binds much more strongly to step-edge sites than to terrace sites, so only adsorption configurations with the molecule above the step edge were considered

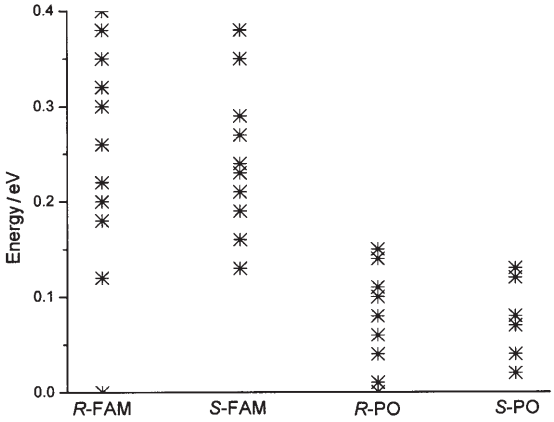

Figure 4. Energies of the distinct local minima observed for FAM and PO adsorbed on Cu(874)^S measured relative to the energy of the most favorably bound configuration of either enantiomer of the species of interest. These results are from calculations using $3\times3\times1$ *k* points. Calculations using $7\times7\times1$ *k* points were performed for 21 states of FAM and 15 states of PO; the figure does not change appreciably if these energies are plotted.

further. A set of configurations sampling the placement and orientation of *S*- and *R*-PO were examined by using methods analogous to our calculations for FAM. In all, 23 configurations were examined. The most stable orientations for each enantiomer on the surface are shown in Figures 5 and 6. Both

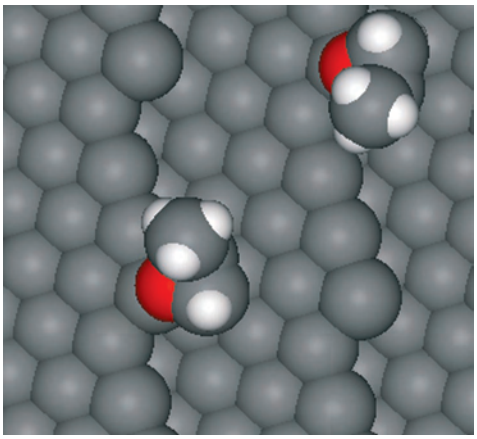

Figure 5. The most favorable binding geometries of *R*- (bottom left) and *S*-PO (top right) on Cu(874)^S, as computed by using DFT.

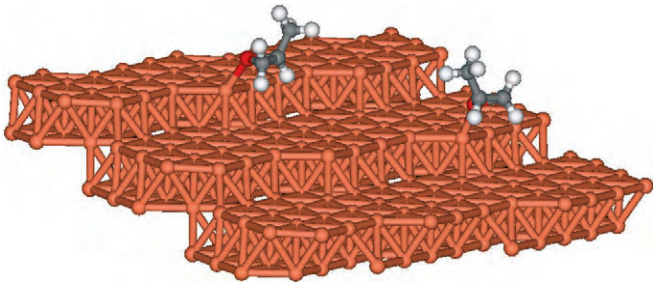

Figure 6. Side view of *R*- (left) and *S*-PO (right) on Cu(874)^S.

enantiomers favor geometries with the O atom above the surface-kink atom and the terminal methyl group oriented away from the surface. The calculated energy difference between the two adsorbed enantiomers is much smaller than the energy difference for FAM; for PO, the energy difference is 0.02 eV with the *R* enantiomer being favored. Energy differences of this magnitude lie close to the limit of those that can be reliably distinguished with DFT, but the distinct orientations of the adsorbed molecules in Figure 5 and the other less favored adsorption configurations described below make it clear that the adsorption of PO on Cu(874)^S is enantiospecific. The energy differences between adsorbed enantiomers of PO are considerably smaller than those described above for FAM. This difference can be understood by noting that the enantiomers differ by which atom, F or H, interacts with the step edge for FAM in its favored configurations. For PO, the same atoms, both H, interact with the step edge for both adsorbed enantiomers, which strongly limits the size of the energy difference between the adsorbed enantiomers.

Similar to FAM, multiple local minima exist for PO on Cu(874)^S, as shown in Figure 4. Because of the relatively small energy differences between these minima, a distribution of states would be observed in any experiment that probes these species. This observation is consistent with the experimental observation that thermal desorption spectra from the most strongly bound surface states of *R*- and *S*-PO on Cu(643) yield broad features that cannot be readily analyzed in terms of adsorption enantiospecificity.[16] Desorption from other surface sites associated with higher surface coverages of PO has been seen experimentally to be enantiospecific.[16] We have not attempted to characterize these states computationally, as it would require the examination of large numbers of coadsorption configurations.

Our DFT calculations have provided two examples of the enantiospecific adsorption of small molecules on a chiral Cu surface, Cu(874)^S. Calculations of this type will be a great assistance to complement experimental studies of molecular adsorption on chiral surfaces.[10–12] By examining the adsorption of a variety of functional groups on stepped metal surfaces, DFT calculations can be used to understand what aspects of molecular architecture can lead to highly enantiospecific interactions with chiral metal surfaces. Similarly, performing analogous calculations on a range of chiral surfaces will provide insight into the role of surface structure on enantiospecific adsorption.[10]

Experimental Section

Our plane-wave DFT calculations were performed with the Vienna ab initio Simulation Package with the ultrasoft pseudopotentials available in this package.[26,27] The results reported above used the generalized gradient approximation (GGA) with the PW91 functional. A small number of configurations were also examined with the rPBE functional within the PAW formalism. The energy differences between configurations with the rPBE-PAW calculations were found to coincide with those of the GGA-PW91 calculations. All GGA calculations used a plane-wave expansion with a cutoff of 425 eV and Fermi-level smearing with a width of 0.2 eV. Geometries were relaxed until the forces on all unconstrained atoms were less than 0.03 eV Å^{-1}.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Final results were computed using a $7 \times 7 \times 1$ *k*-point mesh and dipole corrections. Prior to these calculations, the most favorable configurations were determined using $3 \times 3 \times 1$ *k* points as described above.

In our calculations, the DFT-optimized lattice parameter for Cu was used to define the periodicity of the material in the plane of the surface. The computational supercell contained a single surface unit cell of $Cu(874)^S$ with a vacuum spacing greater than 10 Å in the direction of the surface normal. The surface unit cell is shown in Figure 2. This computational supercell contains 32 metal atoms. Our calculations were performed using slabs equivalent in thickness to three (111)-oriented layers. Molecules were adsorbed on only one side of the slab, and all degrees of freedom of all the metal atoms and the molecule were allowed to relax in all energy minimization calculations. A limited number of calculations, in which all the metal atoms were constrained in their bulk positions, indicated that surface relaxation is not a dominant effect in the relative adsorption energies of the most stable molecular configurations we examined.

Tailoring the Active Site of Chemzymes by Using a Chemogenetic-Optimization Procedure: Towards Substrate-Specific Artificial Hydrogenases Based on the Biotin–Avidin Technology**

*Gérard Klein, Nicolas Humbert, Julieta Gradinaru, Anita Ivanova, François Gilardoni, Untung E Rusbandi, and Thomas R. Ward**

Dedicated to Professor George M. Whitesides

Catalysis offers efficient means to produce enantiopure products. Traditionally, enzymatic and homogeneous catalysis have evolved independently to afford mild, robust, active, and highly selective catalysts.[1,2] Both systems are often considered complementary in terms of substrate and reaction scope, operating conditions, enantioselectivity mechanism, reaction medium, etc. For the optimization of activity and selectivity, directed-evolution methodologies (combined with an efficient selection or screening tool) outperform combinatorial ligand libraries.[3–13] With the hope of alleviating some of the inherent limitations of both enzymatic and organometallic catalysis, two approaches have recently witnessed a revival: 1) organocatalysis[14–19] and 2) artificial metalloenzymes based on either covalent[20,21] or supramolecular anchoring[22] of a catalytic moiety in a macromolecular host.[23–30]

Inspired by the early works of Whitesides and Wilson,[22] we recently reported artificial metalloenzymes based on the biotin–avidin technology.[31–35] Herein, we report our efforts to produce substrate-specific and *S*-selective artificial metalloenzymes based on the biotin–avidin technology for the hydrogenation of α-acetamidodehydroamino acids.

The starting point for the chemogenetic-optimization procedure presented herein is the identification of [Rh(cod)-(biot–**1**)]$^+$⊂S112G Sav (cod = 1,5-cyclooctadiene, biot =

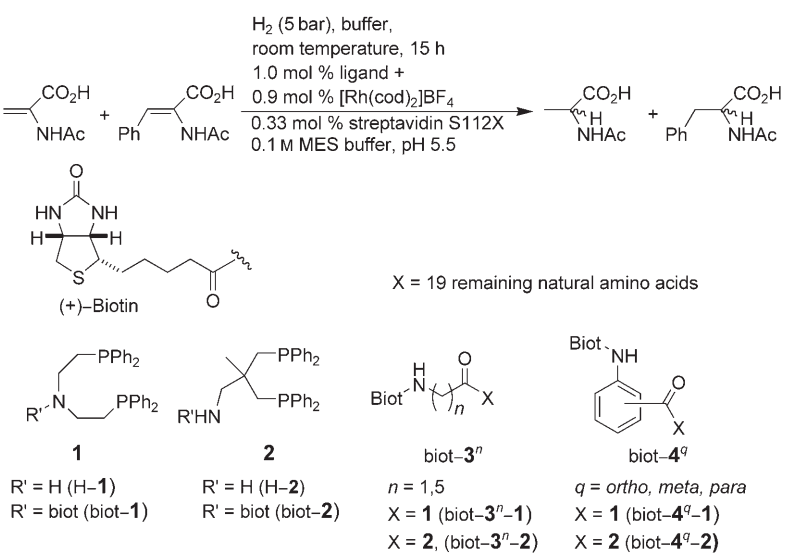
biotin, Sav = streptavidin, Scheme 1) as the best ligand–protein combination for the enantioselective reduction of α-acetamidoacrylic acid (up to 96 % *ee* in favor of (*R*)-acetamidoalanine (*N*-AcAla)).[32,33] These observations prompted us to perform saturation mutagenesis at position 112 of WT-Sav. The resultant 20 proteins were combined with the biotinylated catalyst precursors [Rh(biot-spacer-P_2)cod]BF_4 (P = diphenylphosphine donor; Scheme 1) to afford 360 artificial metalloenzymes. To gain broader insight into the substrate specificity, the catalytic runs were performed on both α-acetamidoacrylic acid and α-acetamidocinnamic acid simultaneously (both 50 equiv, Scheme 1). Control experiments established that the selectivity and conversion are identical to those obtained with a single substrate (i.e. no autoinduction).[6,36] The detailed experimental procedure is provided in the Supporting Information.



Scheme 1. Operating conditions used for the chemogenetic optimization of artificial hydrogenases in the reduction of α-acetamidoacrylic acid and α-acetamidocinnamic acid (50 equiv of each with respect to the ligand). MES buffer solution is composed of 4-morpholineethanesulfonic acid that is pH adjusted with sodium hydroxide.

The results of the chemogenetic-screening experiments with both substrates are summarized in Figure 1 by using a fingerprint display for each substrate–protein–ligand combination.[37] The selectivity is color coded: pink for *S*-selective and green for *R*-selective ligand–protein combinations. The intensity of the color reflects the percentage of conversion.[38] Both substrates are displayed as two hypotenuse-sharing triangles (HyShaTri) for each ligand–protein matrix element. This convenient display allows rapid identification of interesting ligand–protein combinations. Selected results are collated in Table 1 and a summary, including all catalytic runs (as well as multiple reproduction of selected experiments), is provided in the Supporting Information.

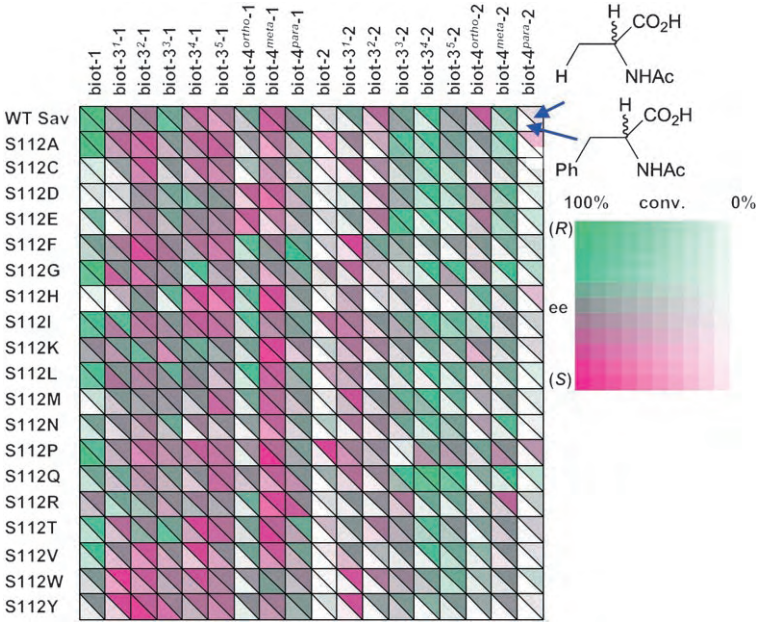


Figure 1. Fingerprint display of the results for the chemogenetic optimization for the reduction of α-acetamidoacrylic acid (top triangle) and α-acetamidocinnamic acid (bottom triangle) in the presence of 18 biotinylated ligands and 20 streptavidin isoforms obtained by saturation mutagenesis at position 112.

Analysis of the results that are displayed graphically in Figure 1 reveals several noteworthy general features:

1) Most ligand–protein combinations yield distinctively different results for both substrates. This trend is reflected by the differences in color (selectivity) and/or intensity (activity) for two HyShaTri (Figure 1). In general, enantioselectivity for *N*-AcPhe was higher than for *N*-AcAla; however, the reverse trend was observed for conversion as the smaller substrates systematically display higher yields.
2) The chemical optimization brings more diversity than the genetic counterpart. This is best illustrated through the comparison of line vectors (i.e. chemical optimization) with column vectors (i.e. genetic optimization). The line vector S112P yields reduction products with both *R* and *S* configurations in respectable *ee* values for *N*-AcPhe (Table 1, entries 5 and 8).
3) Overall, the ligand scaffold **1** outperformed the ligand scaffold **2** both in terms of enantioselectivity and conversion. The best spacer–ligand combinations are biot–**1** (which yields *R* products, Table 1, entries 1–5) and biot–**4**^{meta}–**1**, in combination with cationic amino acid residues in position 112 (which yields *S* products, Table 1, entries 6–9). We speculated that the cationic side chains interact through ionic hydrogen bonds with the carboxylate functionality of the substrate, thus favoring coordination of one of the prochiral faces of the substrate.
4) The most pronounced differences in substrate selectivity (in terms of conversion) are observed with biot–**3**^{1}–**2** in combination with aromatic residues in position 112 (Table 1, entries 10–12).
5) For the biot-**1** vector, the lowest conversions were obtained with mutants that had a potentially coordinating amino acid side chain in position 112 and included S112C (Table 1, entry 3), S112D, S112H, and S112M (to a lesser extent S112E and S112Y as well, Figure 1). We speculated

13	biot–**3**^{4}–**2**	S112Q	92(*R*)	87(*R*)	77	quant.[3]

[1] *N*-AcPhe = α-acetamidophenylalanine; [2] *N*-AcAla = α-acetamidoalanine; [3] quant. = quantitative conversion. Reproducibility: *ee* ± 1.5% (when *ee* > 60%; up to *ee* ± 5% with low *ee* values) and conversion ± 10%. All listed experiments were performed at least in duplicate.

that these Lewis basic side chains coordinate to the rhodium center, thus interfering with the catalytic cycle.

6) Introduction of a glutamine in position 112 yields *R*-selective artificial metalloenzymes when combined with biot-**3**^{4}-**2** (92% *ee* (*R*), Table 1, entry 13).

This study thus demonstrates the potential of saturation mutagenesis at position 112 coupled with chemical optimization to yield both *R* and *S* reduction products as well as substrate-specific artificial metalloenzymes. Although general trends in enantioselectivity are mostly dictated by the biot–spacer–ligand scaffold (chemical optimization), saturation mutagenesis (genetic optimization) provides the critical second-coordination-sphere interactions between the host protein and the prochiral substrate. It is precisely such crucial weak interactions between a catalyst and its substrate that distinguish enzymatic from homogeneous systems.[41]

[38] To generate the RGB codes for a catalytic experiment yielding one of the products in *x*% yield, *y*%(*R*), and *z*%(*S*) (100% − *y*% = *z*% (*S*)), the following formulas were imple-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

mented in an Excel macro: RGB1 = [100−(*y***x*)/100]*2.55; RGB2 = [100−(*z***x*)/100]*2.55; RGB3 = 0.5*(RGB1+RGB2).

[39] To solubilize both substrates, MES buffer solution (0.1M, pH 5.5) was used. Compared with the buffer solution traditionally used for α-acetamidoacrylic acid (0.1M acetate, pH 4.0), slightly lower conversions (up to −5%) and lower enantioselectivities (up to −3%) were occasionally encountered. For the sake of coherence, all results presented herein are based on the dual substrate screening which must be performed in 0.1M MES (pH 5.5). This is because of the low solubility of α-acetamidocinnamic acid in 0.1M acetate buffer at pH 4.0. The results reported previously for *N*-AcAla (96% *ee* (R) with the biot–**1**–S112G) can be attained only with an 0.1M acetate buffer (pH 4.0).[32,33]

Decoration of Microspheres with Gold Nanodots—Giving Colloidal Spheres Valences**

Gang Zhang, Dayang Wang, and Helmuth Möhwald*

To obtain a large variety of structures from colloids, one has to lend colloidal spheres a multiplicity of directed interactions that are analogous to those of atoms. This directionality is achieved in the work presented herein by combining the building of colloidal crystals with Au evaporation and plasma etching. The resulting colloidal spheres exhibit two, three, four, or five nanosized Au dots that are analogous to sp-hybridized atomic orbitals.

Colloidal spheres have been extensively investigated due to their broad spectrum of industrial and fundamental applications, especially their use in photonic crystals.[1–4] Various colloidal spheres, organic and inorganic, can be produced that are exceedingly monodisperse in terms of size and shape. Nevertheless, their surfaces still remain chemically homogeneous or heterogeneous in an undefined way despite there being well-established methods to modify surfaces. This surface chemistry renders the coupling of spheres spatially isotropic, so it is difficult to spatially direct the organization of the spheres. They self-assemble only into simple and energy-favorable structures such as face-centered-cubic (fcc) or hexagonal-close-packing (hcp) arrays. In this respect, colloidal spheres have changed little in at least a century.

The ability to spatially direct the integration of spheres or selectively link other nano-objects on spheres necessitates the spatially selective attachment of functional sites on colloidal spheres, thus creating analogues of valency of atoms and breaking the spatially isotropic coupling into anisotropic coupling. Up to date, however, little effort has been shown to address this challenge. Nelson theoretically testified the possibility of creating valences on microspheres by coating them with anisotropic objects such as nanorods.[5] Fitzmaurice and co-workers immobilized linear aggregates of Au nanoparticles on silica microspheres by fixing nanoporous membranes on microspheres to template the self-assembly of nanoparticles.[6] The controlled deposition of Au vapor allows capping of microspheres with half an Au shell.[7–9] Using the upper single layers of colloidal crystals as masks during Au vapor deposition, we recently demonstrated a simple and versatile way of fabricating various Au patterns on the upper halves of the lower spheres, whose dimension and feature are predominantly manipulated by the orientation of the template crystals.[10] Our methodology is demonstrably independent of the size and surface chemistry of the spheres. As the size of the Au patterns is comparable to that of the spheres, they may not be ideal as valences to direct the coupling of the spheres. Herein we have used the upper bilayers of polystyrene (PS) colloidal crystals that have been etched by O_2 plasma as masks for Au deposition on the spheres of the lower layers. This process allows decoration of microspheres with two, three, four, and five Au nanodots, whose arrangements are linear, trigonal, tetrahedral, or right-pyramidal in space, respectively. In terms of configuration, these Au nanodots might be considered as nanoscale analogues of the sp-hybridized chemical valences in, for example, carbon and silicon atoms.

Our previous study reported the formation of one Au nanodot on the upper half of a shell of microspheres by using the upper bilayers of their colloidal crystals.[10] However, the smaller interstices in the upper bilayers cause a non-uniform diffusion of Au vapor, so the dimension and features of the Au dots obtained in our previous study were not uniform or clear-cut as compared with those of patterns derived from a single-layer template.[10] To circumvent this non-uniform diffusion of Au vapor, in the present work we etched slightly PS colloidal crystals with O_2 plasma prior to Au vapor deposition. Yang and co-workers suggested that the shadow of the upper layers in the colloidal crystals renders the plasma etching anisotropic, which not only increases the interstice sizes between spheres but also allows the creation of new interstitial shapes.[11]

Figure 1 schematically represents our procedure for the fabrication of Au nanodots on microspheres by using the upper bilayers of O_2-plasma-etched colloidal crystals as masks for Au vapor deposition. In this work, we organized 270 or 920 nm PS spheres through a dip-coating process. After optimizing the withdrawing speed and the concentration of

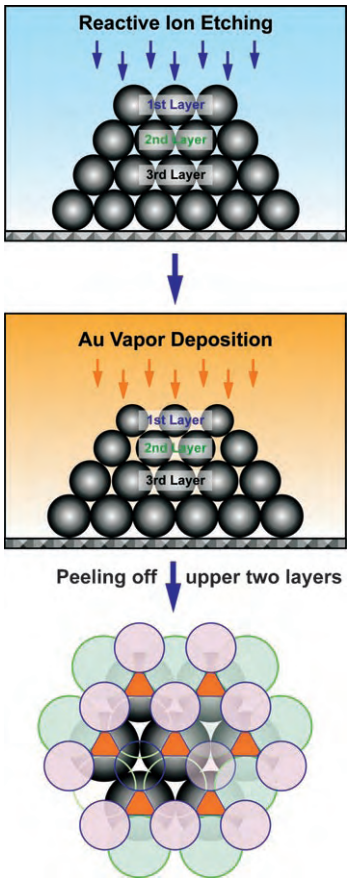

Figure 1. Construction of Au nanodots on microspheres by combining Au vapor deposition and the use of the upper bilayers of O_2-plasma-etched colloidal crystals with (111) facets parallel to the substrates as masks. The orange areas represent Au domains that remained on spheres after removal of the upper two layers.

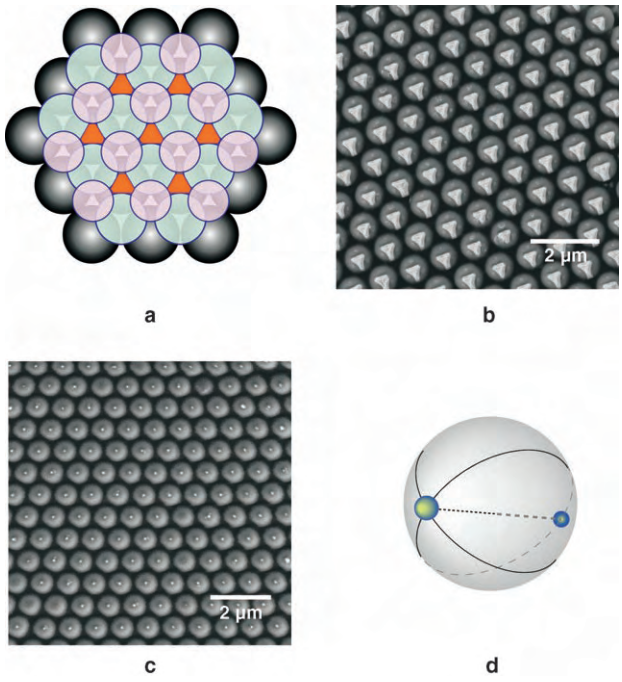

Figure 2. a) Au patterns obtained atop spheres in the third layer in O_2-plasma-etched colloidal crystals with an fcc structure by using the upper bilayers as a mask during Au vapor deposition. The stacking symmetry of the crystals is ABCABC and their (111) facets are parallel to the substrates. The spheres in the first, second, and third layers are highlighted by pink, light green, and black, respectively; the Au patterns on the third layer spheres are orange. The incidence angle between Au vapor flow and the normal direction of the crystals films is set as 0°. b) SEM image of the resulting Au patterns deposited on the upper halves of 925 nm PS spheres in the third layer obtained by templating their fcc colloidal crystals that had been etched by O_2 plasma for 10 min and coated with a 100 nm thick Au layer. The size of the resulting Au dots is in the range of 350–400 nm. c) SEM image of the Au patterns obtained on the lower halves of these spheres; the size of the resulting dots is around 80 nm. d) Schematic illustration of the spatial configuration of two Au nanodots constructed on microspheres.

PS suspensions, we constructed colloidal crystals with four or five layers of PS spheres on silicon wafers, in which single-crystal domains of a pure fcc structure extended over 50 μm and the preferential orientation parallel to the substrate was (111). In this packing structure, the spheres in the third layer are located just underneath the interstices in the upper bilayers, thus allowing Au vapor to reach them. After O_2-plasma etching, the PS spheres in the top layers are reduced in size due to direct exposure to O_2-plasma flow (see Figure 2a and Supporting Information), thus increasing the interstitial sizes between PS spheres. In this work, however, we found that prolonged plasma etching usually caused fusion of the spheres in colloidal crystals, which made it difficult to remove the upper layers. Hence the plasma-etching period was fixed at 3 min for 270 nm PS spheres and 10 min for 920 nm PS spheres. After Au vapor deposition and removal of the upper two layers with adhesive tape, a triangular Au dot was found exclusively atop the spheres. This can be seen by scanning electron microscopy (SEM, Figure 2b). The structural profiles of the resulting triangular dots were analyzed by atomic force microscopy (AFM; see Supporting Information), which indicated that the thicknesses of the triangular dots increase with an increase in the period of Au deposition.

After these third-layer PS spheres with a triangular Au nanodot on their upper halves were peeled off from the crystals, we observed a round Au nanodot on the apex of their lower halves (Figure 2c). According to the AFM analysis (see Supporting Information), the size and thickness of the resulting round Au nanodots increases with an increase in the Au vapor-deposition time. Thus, from a combination of the results shown in Figures 2b and c, we conclude that the PS spheres in the third layer are decorated with two Au nandots. These two dots are arranged opposite each other in the great circle of the sphere, as illustrated schematically in Figure 2d. In this scenario, the configuration of these two Au nanodots on a microsphere resembles that of the sp-hybridized atomic orbital of carbon atoms.

When the colloidal crystals with four layers of spheres were used, we found that round Au nanodots were visible on the lower halves not only of the third-layer spheres but also of the second-layer spheres and of the first-layer spheres, but not of the fourth-layer spheres that are attached directly to the substrate. The formation of these round Au dots is not

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

entirely explained so far. We speculate that when the Au vapor diffuses from the top layers into the lower layers in colloidal crystals through the interstitial voids between the spheres, it might be scattered or reflected back by the surface of the spheres or the substrate. The scattered or reflected vapor should condense on the lower halves of the spheres, opposite to the flow of the Au vapor, which should lead to the formation of the round Au dots. An investigation into the origin of this round Au nanodot is underway.

The features of Au patterns constructed on the spheres in the third layers in colloidal crystals are expected to be strongly dependent on the stacking structure of the colloidal crystals, ABCABC (fcc) or ABAB (hcp). However, so far we have had difficulty in controlling the stacking structures of colloidal crystals due to the exceedingly narrow energy difference between these two stacking structures.[12] The crystals, constructed by the existing methods, usually are a mixture of ABCABC (fcc) or ABAB (hcp) stacking structures. In the dip-coating process, we found that the rapid withdrawing speed led to the formation of more ABAB stacking structures. In an hcp array, the spheres in the third layer are positioned just under the spheres of the first layer, thus leaving air channels behind that allow Au vapor to penetrate freely through the whole crystal with little deposition on the lower-layer spheres. After plasma etching, the spheres in the first layer were smaller than those in the third layer, which may allow Au deposition on the edges of the latter (Figure 3a). After Au vapor deposition and removal of the upper two layers, three small triangular Au nanodots were observed on the edge of the upper halves of the spheres, which were arranged in a trigonal array (Figure 3c). In the current work, we learned that the number of Au dots atop the spheres is dependent on the incidence angle of the Au evaporation, the angle between the vapor flow and the normal direction of the sample surfaces.[13,14] If the incidence angle is increased from 0° to 10° (Figure 3b), the number of Au dots is reduced from three to two. Figure 3d reveals that the edges of the upper halves of the spheres are decorated with one large and one small triangular nanodots. In this case, one round Au nanodot was also found on the lower halves of the spheres in third layer in a way similar to that shown in Figure 2c. As shown in Figures 3e and f, the arrangement of Au nanodots on spheres can be expected to be tetrahedral (four dots) and trigonal (three dots), thus resembling nanoscale analogues of sp^3- and sp^2-hybridized molecular orbitals.

Thanks to enormous efforts in the past decade, it is possible to grow colloidal crystals with defined crystal orientation parallel to substrates. By use of substrates with V-shaped grooves, one can construct fcc colloidal crystals with a preferential plane of (100) parallel to the substrates.[15,16] In this square close-packing structure (ABAB stacking), the spheres in the third layers are located exclusively underneath those of the top layers. Therefore, no Au vapor may reach the third layer.[10] After plasma etching, four air gaps were opened up in the upper bilayers to allow the penetration of Au vapor (Figure 4a and Supporting Information). After Au vapor deposition and removal of the upper two layers, we constructed four rectangular Au nanodots on the edges of the upper halves of the PS spheres on the third layer (Figure 4b).

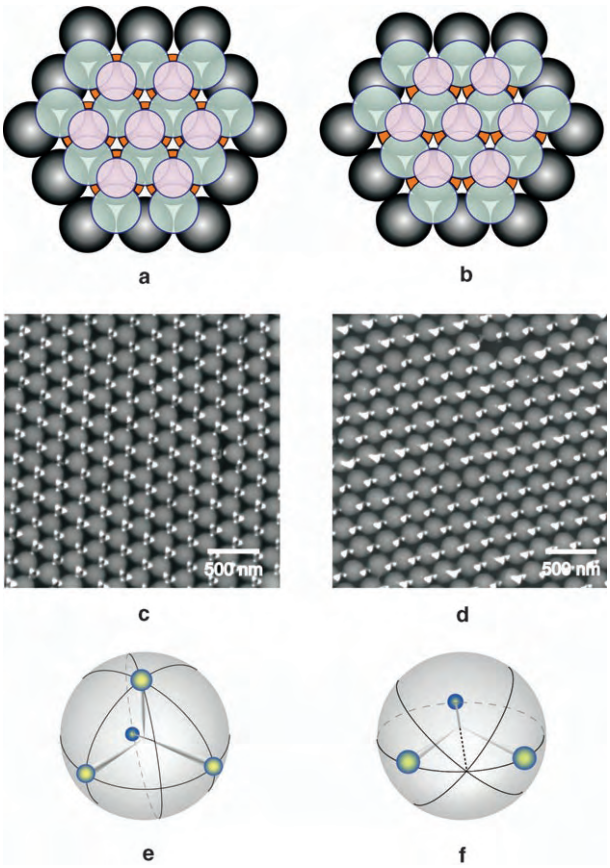

Figure 3. a, b) Au patterns atop the spheres in the third layer obtained by using the upper bilayers as a mask during Au vapor deposition in O_2-plasma-etched colloidal crystals with an ABAB stacking symmetry. The incidence angle between Au vapor flow and the normal direction of the crystal films is set as 0° (a) and 10° (b). c, d) SEM images of the Au patterns on the upper halves of 270 nm PS spheres in their hcp colloidal crystals, constructed at an incidence angle of 0° (c) and 10° (d). The crystals were etched by O_2 plasma for 3 min and coated by an Au layer 30 nm thick. c) Three Au dots of 20–45 nm in size on the edge of the PS spheres. d) One 90 nm and one 25 nm dot on the sphere edge. e, f) Spatial configurations of the resulting four (e) and three Au nanodots (f) on microspheres.

One round Au dot also formed on the center of the lower half of the spheres (see Supporting Information). As depicted in Figure 4c, five Au nanodots with a right-pyramidal configuration are therefore linked on one PS sphere. When the incidence angle of the Au vapor flow was set as 10°, only three rectangular Au nanodots—one big and two small—were obtained (Figure 4d). The spatial configuration of these three dots is expected to be similar to that shown in Figure 3e.

It is worth noting that the decoration of Au nanodots on microspheres is independent of the diameter of the spheres and is extendable to other polymer spheres. Nevertheless, the mechanical stability of the Au nanodots deposited on PS microspheres is currently poor. Redispersion of the PS spheres coated with Au dots into water resulted in the detachment of the Au dots, thus limiting their usage for directing self-assembly of spheres. To circumvent this drawback, we are currently extending our procedure to silica spheres with the aid of highly reactive ion etching. Further-

more, the selective fabrication of colloidal crystals with either fcc or hcp structures is also a promising extension of this work.

In summary, we have demonstrated the feasibility of the decoration of PS microspheres with two, three, four, or five Au nanodots by using their colloidal crystals, etched by O_2 plasma, as masks for Au vapor deposition. The number of dots per sphere can be manipulated by use of different crystal structures and by altering the conditions of Au vapor deposition. The Au nanodots deposited on the spheres are arranged in a linear, trigonal, tetrahedral, or right-pyramidal fashion, which provides the nanoscale analogues of sp-hybridized atomic orbitals of carbon. The Au nanodots obtained on microspheres can be used as the bonding site to dictate the integration of the spheres, thus paving a new way to colloidal self-assembly—colloidal valent chemistry of spheres[5]—to create hierarchical and complex "supraparticles".[17]

Experimental Section

Aqueous suspensions (10 wt %) of polystyrene of 270 and 925 nm in diameter were purchased from Microparticles GmbH, Germany. The crystallization of these spheres on silicon wafers was conducted by a dip-coating process. The withdrawing speeds were optimized in the range of 0.5–5 $\mu m\,s^{-1}$ and the concentration of these spheres in the range of 1.0–2.0 wt % for 270 nm spheres and 3.0–5.0 wt % for 925 nm spheres to produce crystals with four or five layers of spheres. By using a plasma cleaner (PDC-32G, Germany), O_2-plasma etching was performed at a pressure of 0.2 mbar and a power density of 100 W. The optimal etching period was adjusted to 3 min for 270 nm PS colloidal crystals and 10 min for those of 925 nm. Au vapor deposition was conducted in a high-vacuum coater (Edwards Auto 306, UK) at a pressure of 10^{-7} mbar and a deposition speed of $0.02\,nm\,s^{-1}$. By varying the deposition time, Au layers of 30, 50, 100, and 200 nm thick were deposited within the plasma-etched colloidal crystals. Note that prior to Au deposition, the crystals were coated with chromium layers 5 nm thick. The incidence angles between the Au vapor flow and the normal direction of the samples were adjusted by tilting the samples on the sample holding blocks within the thermal deposition chamber.

After Au deposition, we placed double-sided adhesive tapes on the Au-coated surfaces of colloidal crystals and subsequently covered glass slides atop the adhesive tapes.[10] The glass slides were pressed at a pressure of $0.2\,kg\,cm^{-2}$ for 5 min, then the upper two layers were stripped off to leave an Au pattern on the spheres in the third layers. A similar process allowed the spheres in the third layers to be removed from the crystals. Both sides of the third-layer spheres were visualized by SEM. SEM images were recorded with a Gemini LEO 1550 instrument operated at 3 kV. To directly reveal the Au patterns on colloidal spheres, the samples were not sputtered by thin Au films before SEM measurements. AFM imaging was performed by using the Nanoscope Dimension 3100 system operating in tapping mode.

Finely Tuning Metallic Nanogap Size with Electrodeposition by Utilizing High-Frequency Impedance in Feedback**

*Quan Qing, Fang Chen, Peigang Li, Weihua Tang, Zhongyun Wu, and Zhongfan Liu**

Nanomaterials and molecules have shown quite remarkable features for nanoscale devices when they are organized in fine structures either by top-down techniques or bottom-up approaches.[1–3] Making metallic pairs with gap sizes commensurate with the objects of interest so that such system can interact with the outside is one of the key issues that remains a challenge. The desired distance between electrodes ranges from less than 1 nm up to more than 100 nm for different systems involving small molecules,[4] nanoparticles,[5] nanotubes,[1a] and biomolecules such as DNA chains.[2d]

Conventional top-down techniques such as electron-beam lithography still suffers from a disadvantage in terms of yield when the feature size approaches 10 nm or below. However, recent reports have shown very promising results on the shrinkage of the gap size of a predefined pattern by electrodeposition with an active feedback loop. Compared with other techniques, such as break junction, which mechanically tears a narrow metallic wire,[6] and electromigration, which splits a very thin metallic layer by current-induced migration,[7] the electrochemical method is arguably more versatile with a controllable gap range.[8]

The feedback signal of such electrochemical systems normally utilizes a dc voltage or ac voltage of very low frequency (< 10 Hz)[9,10] to detect the occurrence of electron tunneling through the gap during metal deposition, or uses one of the electrodes as the reference to sense the sharp potential drop when the electrodes grow within the electrical double layer.[8] The electrochemical process is stopped when the feedback signal shows significant change, which results in a gap size normally around 1 nm in the tunneling region in the first case, or below 10 nm for the latter. These systems show the controllability of such a feedback design, but they also pose several problems, such as a very narrow range of available gap size or an asymmetric deposition behavior. These limitations can be mainly attributed to the low frequency of the feedback signal, electrodes playing different roles during deposition, or the features that are needed to arbitrarily separate the ac signal from the dc deposition current.

In the present study we used a very different system design, which showed very interesting frequency dependency on the final gap size in a previous study.[11] Herein we investigate this behavior in detail with improved electrode geometry[12] and demonstrate that a gap size larger than 10 nm can be obtained reproducibly by using a high-frequency feedback signal. We will discuss the mechanism of the prominent impedance change over a complete deposition process by reference to the amplitude and phase-shift data, and show that the gap size can be further tuned down to around 1 nm simply by controlling the subsequent deposition time. This method is unique in that it indicates the distinctive behavior of the high-frequency impedance in such a nanoscale electrochemical system, and it provides a very flexible and common way to fabricate nanogaps for various applications.

We first prepared an initial metallic electrode pair which was over 200 nm apart. The gap was then narrowed by controlled electrodeposition. A sharp tip-against-tip geometry of the initial electrodes was found to be more favorable than a flat-top configuration for a reproducible feedback signal and a good final shape.[10,12,13] This geometry was achieved in two steps: First, a metal bar of length 50 μm and width 5 μm was fabricated by using a conventional photolithography technique, which was followed by metal evaporation (15 nm Ti covered by 85 nm Au) and lift-off. The bar was then carved in the middle by a focused ion beam to form two sharp tips with a distance ranging from 200 to 500 nm (Figure 1a). A small amount of SiO_2 under the metal in this area was also etched away to make sure that the tips were isolated. The sample was then immersed in concentrated HNO_3 for 30 minutes and washed with sufficient Milli-Q water to remove the residue Ga^{3+} ions that became doped during the course of the ion bombardment.

A schematic diagram of the feedback system is shown in Figure 1b.[11] Briefly, both electrodes of the gap were used as cathodes to symmetrically deposit metal, Au in our experiments. The unique symmetric design ensures that the ac signal travels only in the symmetric circuit loop, while the faradic current can be recorded independently on the electrochemical workstation. The ac voltage (V_s) at one of the electrodes was analyzed by a two-phase lock-in amplifier and its amplitude (V_m) was used as the feedback signal. This ac voltage has a very simple relationship to the impedance of the gap,[11] and shows a prominent decay when the gap distance is close enough.

Figure 1c gives the typical V_m–t curves for a complete deposition process using different ac frequencies. The curves are composed of three stages: 1) the sudden decay in the first few seconds of the Au deposition, which is attributed to the charging process of the double layer; 2) a plateau before the

gap distance enters the critical region; and 3) a prominent decrease as the electrodes grow close enough and finally down to zero when a metallic contact is established.

A computer program was used to record the V_m signal and to detect the beginning of stage 3.[11] In other words, when the program detected an accelerated decrease in the value of V_m after the plateau (stage 2), it would take action—either stopping the deposition or doing so after a programmed period of time. We define the interval of time between the actual inflexion of the curve and the point at which the program reacted as Δt. The algorithm for such detection means we normally get a minimum Δt value of around seven seconds.

Three samples prepared at 3 KHz are presented in Figure 2. These samples showed consistent Δt values of around seven seconds (Figure 2a), which is a measure of the stability of the program algorithm and is consistent with a gap distance of around 30 nm (Figure 2b). It should be noted that the different initial gap distances of these samples did not show any critical effect on the final gap size. These results demonstrate persuasively the reproducibility of the system.[14]

Current mechanisms for the change in the feedback signal involve electron tunneling and the electrical double layer. The tunneling region in a vacuum is known to be only a few angstroms, while in solution it may be slightly larger because of the screening effect of ions.[15,16] Furthermore, the thickness of the electrical double layer is very sensitive to the ion strength in solution, but can be considered to be less than 1 nm in the buffer solution used in our experiments.[17] So our results here reach far beyond these regions, and imply quite a different story.

The first evidence of the mechanism lies in the different patterns of the third stages of the V_m–t curves shown in Figure 1c. At low frequencies, such as 70 and 300 Hz, the curves showed clear discrete behavior, which, when converted into conductance between the electrodes, gave steps at multiples of quantum conductance.[14] As for the 3 KHz case, the value of V_m decreased smoothly down to zero. The quantum conductance behavior clearly proved that the decrease in the feedback signal at low ac frequency reflected primarily the tunneling event and the quantum contact between the two electrodes. This is in good agreement with other reported results.[9] However, the capacitive reactance was actively involved at high ac frequency.

We can easily calculate the resistance and capacitive reactance from the amplitude and phase-shift data that were recorded simultaneously. Figure 3a and c give the raw data at a frequency of 300 Hz and 3 KHz, respectively. Similar to the amplitude signal, the phase-shift signal also showed a steady state followed by a remarkable increase.[18] Figure 3b gives the calculated resistance and capacitive reactance at 300 Hz on using an equivalent circuit of a resistor and a capacitor in parallel. Figure 3d shows the calculated resistance and capacitive reactance for 3 KHz obtained using an equivalent circuit of a resistor in series with a capacitor.

It can be seen from Figure 3b that the change of resistance and capacitive reactance was composed of two parts. In Part I only the resistance was decreasing while the capacitive reactance remained almost constant, while in Part II the capacitive reactance showed a radical increase, which is because the equivalent circuit was no longer valid in this region, since a quantum contact was formed. This effect was evidenced by the steps in the enlarged R–t curves of this region of the graph (inset of Figure 3b). The controlling program always stopped the deposition in Part I, where the change of resistance dominated. In sharp contrast, the resistance and capacitive reactance at 3 KHz decreased together to zero, as shown in Figure 3d.

The surface area of the electrodes and the frequency can be considered as constant within this region, so the media

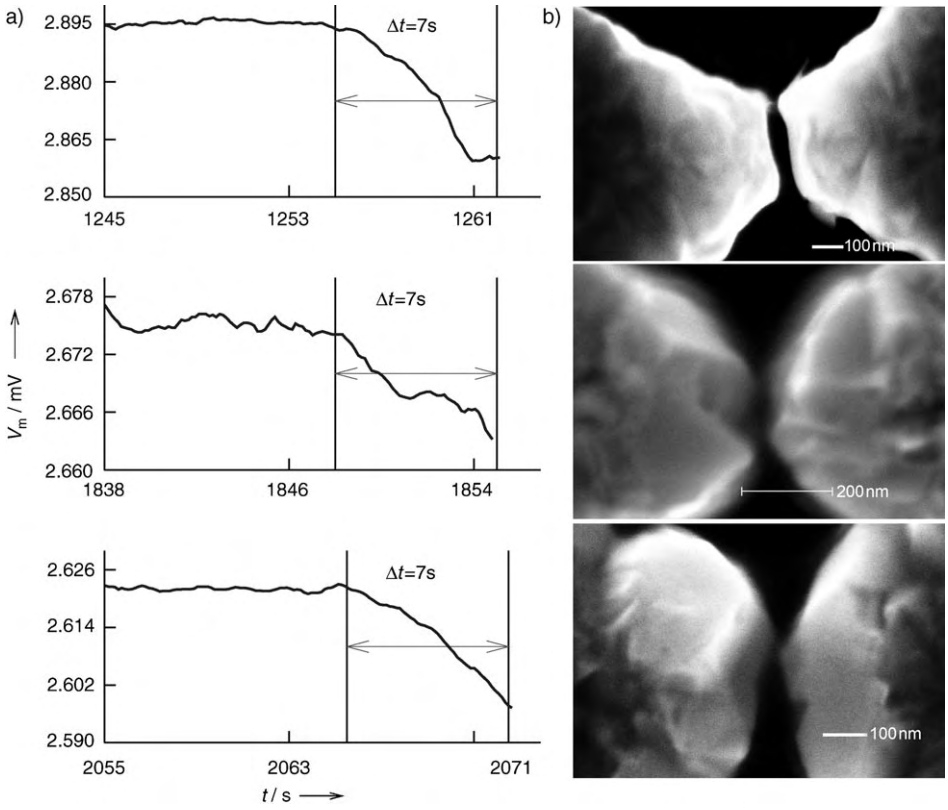

Figure 2. a) The V_m–t curves of three samples prepared at 3 KHz, only the last part is shown. The controlling program stopped the deposition at the last point. Δt is defined as the interval between the inflexion of the curve and the last point. b) The SEM images of the resulting gap in the three samples prepared as in (a), with a gap distance of 27, 35, and 25 nm, respectively.

between the electrodes could be the real cause of the behavior at 3 KHz. Considering the fact that there was an electric field of $10^5\,V\,m^{-1}$ between the electrodes (established by the feedback ac signal), the distribution of ions could be seriously perturbed, that is, the ions could be pushed and pulled according to the ac frequency between the electrodes. The solvent molecules could also be highly polarized, which will affect the dielectric constant.

In short, there will be a detectable change in the impedance for a frequency at which the capacitive reactance plays a dominant role, namely, when the nanogap shrinks to the extent that makes the electric field strong enough. This change is mainly affected by the field strength and the media between the electrodes, and thus is relatively stable. The frequency of the ac feedback signal can tune the ratio of the capacitive reactance, and the amplitude controls the strength of the electric field. The gap distance can be easily controlled by carefully tuning these two parameters.

Since the break point of the high-frequency feedback signal at which the gap distance was still relatively large can be detected very reproducibly, and the electrodeposition in the constant current mode evolved slowly and steadily, the gap size can be further developed by simply controlling the subsequent deposition time. For a frequency of 3 KHz, the deposition was stopped at $\Delta t = 9$, 25, 42, and 62 s on four samples, and the gap size was found to decrease from 26 nm to 16 nm, to 7 nm, and finally to around 1 nm, respectively (Figure 4). A simple analysis of these data showed a very good linear relationship between the final distance and the time, from which a deposition rate of $0.5\,nm\,s^{-1}$ can be calculated. In comparison, for a frequency of 300 Hz, gap sizes remained around or below 1 nm for $\Delta t = 7$ s and $\Delta t = 15$ s, which could not be measured directly by SEM (Figure 5). This result also indicated that only a very small portion of the deposited metal atoms helped to decrease the distance when the gap was less than 1 nm. This set of data is very clear proof of the important role that the high-frequency impedance plays in controlling the gap distance over a wider range.

The feedback signal at low frequencies could also establish an electric field strong enough to affect the movement of the ions between the electrodes. However, because the capacitive reactance was insignificant in the total impedance, it could not be observed. Furthermore, at a sufficiently high frequency, the electric field would change its direction before the ions could finish their movement across the short distance within a half cycle, which would cause them to oscillate between the electrodes.[19] This dynamic behavior could not be observed in our system because the surface area of the electrodes was large, and the impedance at such high frequencies was practically zero. The frequency range of the system could be expanded, and more information could be revealed by using a mask to minimize the surface area.

In summary, we have demonstrated that the high-frequency impedance of a pair of nanoscale electrodes can be greatly affected by a strong electric field between them. Utilization of this impedance change in the feedback loop enables nanogaps of 30 nm to be formed very reproducibly at a frequency of 3 KHz by an electrodeposition system. This distance is affected by the frequency and the amplitude of the ac signal, and the gap can be further finely tuned to around 1 nm by simply controlling the subsequent deposition time. This feedback system is stable and flexible, as well as providing a new strategy to prepare wide ranges of nanogaps for various applications. Furthermore, this method can also be used to study the impedance of a confined, nanoscale electrochemical system that is either in equilibrium or dynamic, for example, with a redox reaction proceeding on the surface. The dynamic behavior of molecules of special interest, such as DNA chains, proteins, or molecules with binding groups, could also be revealed with this system.

Experimental Section

The dc deposition was achieved with a commercial electrochemical station (CHI660B), and the current density was constant at 0.3 mA cm^{-2}. The electrolyte solution consisted of 0.1 M $KAu(CN)_2$ and 0.1 M potassium citrate buffer (pH 5.45). All solutions were prepared with analytic grade reagents and Milli-Q water (resistance: 18 MΩ). The electrochemical cell was elaborately designed to keep a constant electrode area exposed in the solution; in this study, the surface area was 0.30 ± 0.05 mm^2, as measured by an optical microscope.

Both electrodes of the gap were used as cathodes. A symmetric ac circuit composed of two 1 KΩ resistors and two ac sources with a phase difference of 180° was connected to them. The frequency could be adjusted from 30 Hz to 30 KHz, which resulted in different gap sizes ranging from less than 1 nm to 70 nm. The amplitude of the sources was normally set to 4 mV. The ac signals were monitored with a two-phase lock-in amplifier (Model 5206, EG&G Princeton Applied Research). In cases when we needed to record both amplitude and phase-shift data, a Keithley 4200 semiconductor characterization system was programmed for multichannel measurements. Otherwise a Keithley 6517a electrometer was used to collect real-time data. The electrodes with a nanogap separation after electrodeposition were imaged by scanning electron microscopy (SEM, XL30S-FEG, 15 kV).

[12] The large initial distance and flat geometry of the electrodes results in final electrodes which have a very high number of randomly distributed protuberances. This introduces extra diffusion limitation and shielding of electric fields, etc. The effect of frequency in this more complex system is thus less dominant and may show rather different behavior.

[18] When the amplitude of the input signal becomes very small, the phase-shift output of the lock-in amplifier used stays at a relatively constant value of around 10°. Thus, when the amplitude has approached zero the last portion of the phase-shift data should be considered as inaccurate and invalid for calculation of the impedance.
[19] Consider, for example, the SO_4^{2-} ion with a mobility of 8.27×10^{-8} m^2 s^{-1} V^{-1} in a electric field of 10^5 V m^{-1}. It will take 3.6×10^{-6} s for the ion to get through a 30 nm gap, which corresponds to a frequency of 551 KHz. In real systems, this frequency could be significantly lower because of the absorption of ions as well as the changes of the solution viscosity under the high electric field.

Side-Chain Orientation and Hydrogen-Bonding Imprint Supra-τ_c Motion on the Protein Backbone of Ubiquitin**

Nils A. Lakomek, Christophe Farès, Stefan Becker, Teresa Carlomagno, Jens Meiler, and Christian Griesinger**

Knowledge about protein dynamics is crucial for the understanding of protein function.[1] NMR spectroscopy can characterize the amplitudes and rates of motions that are either faster than the rotational correlation time τ_c (sub-τ_c motion) with heteronuclear relaxation experiments or between approximately 50 μs and 10 ms (μs/ms motion) with relaxation dispersion.[2,3] The extent of motions occurring in folded proteins on the time scale between the rotational correlation time τ_c and the μs/ms range (supra-τ_c motion) has been a matter of debate.[4] However, the functional relevance of such motions has recently been shown for the aggregation rate of natively unfolded proteins involved in neurodegenerative diseases.[5] Very recently, motions on this supra-τ_c time scale have been observed in a 0.2 μs molecular dynamics simulation of ubiquitin.[6]

Residual dipolar couplings (rdcs) were recognized early on as an ideal tool to widen the time window of dynamics that can be characterized by NMR spectroscopy, since they are sensitive to motional averaging occurring over the sub- *and* supra-τ_c time scales (ps to ms).[4] We recently analyzed NH rdcs of ubiquitin measured in 31 different alignment conditions and derived the order parameters $S^2_{rdc} = \frac{4\pi}{5} \sum_{M=-2}^{2} \langle Y_{2,M}(\theta',\phi') \rangle|^{ms}_0 \langle Y^*_{2,M}(\theta',\phi') \rangle|^{ms}_0$.[4c,7] To differentiate between the sub- and supra-τ_c time scale, these order parameters were compared to Lipari–Szabo order parameters S^2_{LS} that are derived from conventional relaxation time measurements and that are only sensitive to the sub-τ_c time scale.[8,9]

Interestingly, a periodic variation of the S^2_{rdc} value can be observed with a periodicity of two residues in the β strands of ubiquitin (amino acids 2–6, 12–16, 41–45, 66–71), while it is largely absent from the S^2_{LS} and exchange-rate data. Most prominently, the S^2_{rdc} values are larger for residues Gln 41, Leu 43, and Phe 45, and smaller for residues Arg 42 and Ile 44 in the β strand 41–45 (Figure 1). Correspondingly, the side chains of residues Gln 41, Leu 43, and Phe 45 point towards the hydrophobic core (core residues), whereas the side chains of Arg 42 and Ile 44 are exposed to solvent (exposed residues). Thus, the alternating pattern of the S^2_{rdc} values seems to correlate with the orientation of the side chains towards the solvent or away from it (Figure 2).

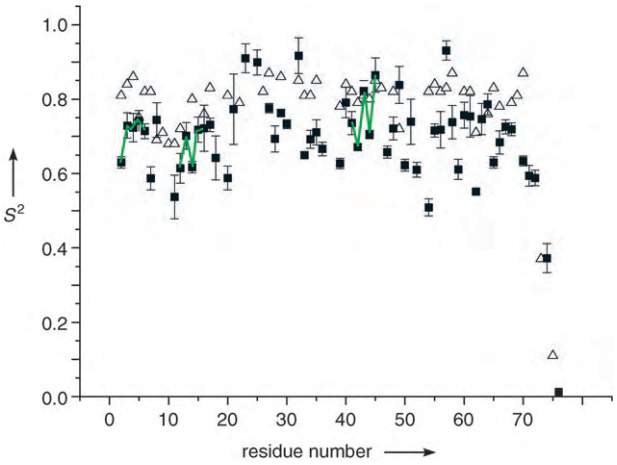

Figure 1. Comparison of the Lipari–Szabo order parameter S^2_{LS} (△) and the rdc derived order parameter S^2_{rdc} (■) as a function of residue number. The marked periodic variations of the S^2_{rdc} values are indicated by lines connecting sequential residues.

The observation that solvent-exposed residues exhibit reduced S^2_{rdc} values relative to core residues holds not only for the β strands but also for the rest of the protein. The amino acids of ubiquitin (1d3z) are color coded in Figure 3 according to the S^2_{rdc} value of the backbone amide groups. Residues with less-mobile NH vectors (blue and green) have side chains predominantly pointing towards the hydrophobic core (Figure 3a), while for those with more-mobile NH vectors (yellow, orange, and red), the side chains are solvent-exposed (Figure 3b).

To investigate this effect quantitatively, an order parameter for only the supra-τ_c time scale is derived: $S^2_{rdc}/S^2_{LS} = \frac{4\pi}{5} \sum_{M=-2}^{2} \langle Y_{2,M}(\theta',\phi') \rangle|^{ms}_{\tau_c} \langle Y^*_{2,M}(\theta',\phi') \rangle|^{ms}_{\tau_c}$. For residues with supra-τ_c motions, we expect a value for S^2_{rdc}/S^2_{LS} smaller than 1, while it should be 1 in the absence of such motions (see the Supporting Information).

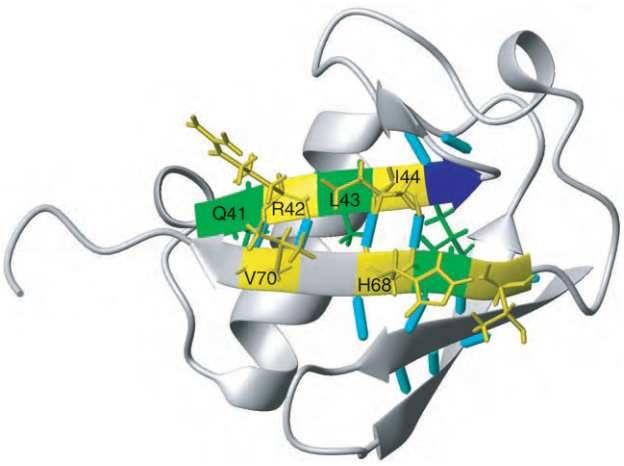

Figure 2. The residues 41–45 and 66–71 of the ubiquitin β strands (1d3z) are color-coded according to the rdc-based order parameters S^2_{rdc} (yellow $0.63 \le S^2_{rdc} < 0.73$, green $0.73 \le S^2_{rdc} < 0.83$, blue $S^2_{rdc} \ge 0.83$, gray unknown). Hydrogen bridges are displayed as cyan rods. The alternating pattern of S^2_{rdc} order parameters in residues 41–45 of the β strand is clearly correlated with the side-chain orientation.

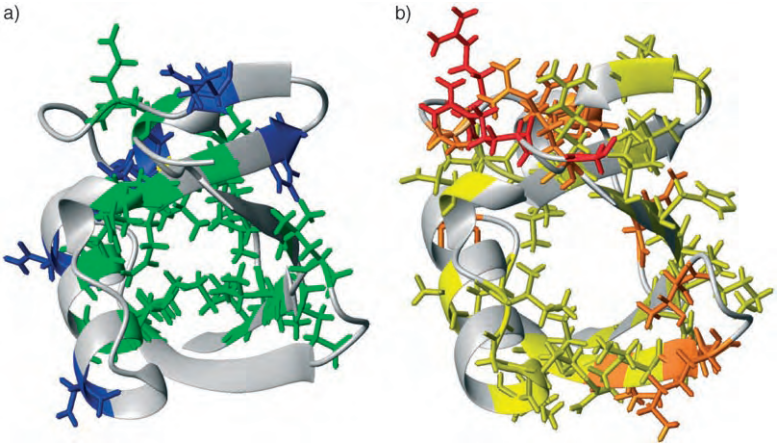

Figure 3. Residues of ubiquitin (1d3z) are color-coded with respect to the rdc-based order parameters S^2_{rdc} (red $S^2_{rdc} < 0.53$, orange $S^2_{rdc} < 0.63$, yellow $S^2_{rdc} < 0.73$, green $S^2_{rdc} < 0.83$, blue $S^2_{rdc} \ge 0.83$, gray unknown) and are distinguished between large (a) and small (b) S^2_{rdc} values. Interestingly, most of the residues with larger backbone amide S^2_{rdc} values have side chains pointing to the core (a), whereas residues with solvent-exposed side chains show smaller order parameters (b).

Core residues show an average S^2_{rdc}/S^2_{LS} value of 0.91 ± 0.02 as compared to 0.86 ± 0.02 for solvent-exposed residues (Table 1), while the exposure of the previous side chain does not have a significant influence (0.86 ± 0.02 versus 0.87 ± 0.02). Furthermore, 90% of the core residues have a S^2_{rdc}/S^2_{LS} value greater than 0.85. In contrast, this is true for only 55% of the solvent-exposed residues (Figure 4a). Thus, the supra-τ_c time order parameter of the NH vector is on average 0.05 ± 0.03 larger if the side chain is buried in the protein core.

We also investigated the influence of backbone hydrogen bonds on the supra-τ_c order parameter S^2_{rdc}/S^2_{LS}. For this, each NH group was classified according to the number of backbone hydrogen bonds on the corresponding peptide plane, including the amino acids NH_i and the preceding carbonyl group CO_{i-1} (see the Supporting Information).

The average S^2_{rdc}/S^2_{LS} values (Table 1) reveal a dependence on the number of hydrogen bonds, and increases from 0.82 ± 0.05 to 0.86 ± 0.02 to 0.90 ± 0.02 as the number of hydrogen bonds increases from zero, to one, to two. Although 83% of residues with two backbone hydrogen bonds have S^2_{rdc}/S^2_{LS} values greater than 0.85, this is true for only 61% of the residues that are involved in only one hydrogen bond (Figure 4b).

In conclusion, side-chain orientation and hydrogen bonds influence supra-τ_c motions of the backbone amide groups to the same extent. The hydrogen-bridge dependency correlates with the secondary structure of the protein whereas solvent exposure is a property of the tertiary structure. It is interesting that the side-chain mobility is apparently transmitted only along the ϕ angle and not along the ψ angle (see the Supporting Information). The investigation of this effect is beyond the scope of this paper. One possibility for this finding could be that the side-chain motion is coupled with pyramidalization of the neighboring NH group in a dissipative manner; this NH group is closer than the NH group of the following amino acid. However, the reason could also be the different rotation barriers around the ϕ and the ψ angles arising from the constitutional difference of these two moieties. The finding that the side-chain orientation influences the supra-τ_c motions of the backbone has been independently observed by Blackledge and co-workers.[10] Alignment tensor fluctuations that have been proposed[13] as an alternative to supra-tc-motion would affect parallel NH vectors identically. However, as NH vectors are parallel in β-sheets, such fluctuations do not affect our conclusions.

Table 1: Average order parameters for core and exposed residues and for residues involved in 0,1, or 2 hydrogen bonds.[a]

	Exposure				Hydrogen bridges		
	solvent(i)	core(i)	solvent($i-1$)	core($i-1$)	0	1	2
S^2_{LS}	0.80 ± 0.01	0.82 ± 0.01	0.80 ± 0.01	0.81 ± 0.01	0.74 ± 0.02	0.81 ± 0.01	0.83 ± 0.01
S^2_{rdc}	0.69 ± 0.02	0.75 ± 0.02	0.71 ± 0.01	0.70 ± 0.02	0.65 ± 0.03	0.70 ± 0.02	0.77 ± 0.02
S^2_{rdc}/S^2_{LS}	0.86 ± 0.02	0.91 ± 0.02	0.87 ± 0.02	0.86 ± 0.02	0.82 ± 0.05	0.86 ± 0.02	0.90 ± 0.02

[a] The NH_i order parameter was correlated with the side-chain orientation of the same residue (i) and the orientation of the previous residue ($i-1$). Whereas a strong dependence on the side chain orientation is obtained for the first case, no correlation is observed for the second case, thus indicating that mobility is transferred only along the φ and not the ψ angle.

Experimental Section

A model free analysis on backbone NH rdcs has been performed on ubiquitin by Lakomek et al.[7]

The analysis of order parameters has been performed with Origin 6.1 and hydrogen bonds have been reported in the literature (see Supporting Information).[11,12] Figures 2 and 3 have been

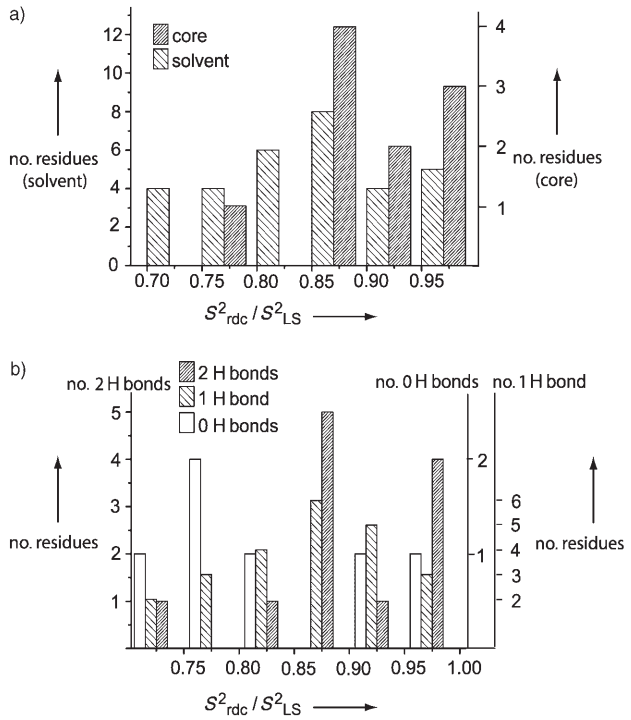

Figure 4. Histogram plot of the distribution of S^2_{rdc}/S^2_{LS} values. The residues are classified as core or solvent-exposed residues (a) or with respect to the number of backbone hydrogen bonds (b). The average S^2_{rdc}/S^2_{LS} order parameter is 0.91 ± 0.02 for core and 0.86 ± 0.02 for solvent-exposed residues. The values are 0.90 ± 0.02 for residues involved in two backbone hydrogen bonds, 0.86 ± 0.02 for one hydrogen bond, and 0.82 ± 0.05 for residues that are not involved in backbone hydrogen bonds. a) Core residues have a strong tendency for higher S^2_{rdc}/S^2_{LS} order parameters: 9 out of 10 core residues have a S^2_{rdc}/S^2_{LS} value greater than 0.85. b) Residues involved in two hydrogen bonds have higher S^2_{rdc}/S^2_{LS} values than those without any.

factors relies on short α helices that bind in the major groove. Isolated α-helical peptides could therefore be used to interfere selectively with protein–DNA interactions. However, isolated peptides do not normally adopt well-defined secondary structures, and the recognition helices in DNA binding proteins often rely on interactions with other proteins for stability with the potential for selectivity modulation.[1–7] For instance, the activity of the muscle-specific transcription factor MyoD is regulated through interaction with coactivators from the myocyte enhancer factor-2 (MEF-2) family.[8] MyoD belongs to a family of transcription factors that rely on a basic helix-loop-helix (bHLH) domain for DNA binding. MyoD dimerizes through the HLH domain and contacts the major groove of the DNA target sequences through its N-terminal recognition α helix. The production of MyoD in a wide variety of cell types, including fibroblasts and myoblasts, activates a cascade of genes that eventually results in cellular differentiation and the production of muscle cells.[9] The physiological activity of MyoD depends on the presence of DNA sequences that contain the symmetrical core motif CANNTG (E-box) that is found in the promoters and enhancers of many muscle specific genes, such as the creatine kinase enhancer.[10] In stark contrast to its high physiological specificity, MyoD displays only limited DNA-binding specificity in vitro.[11] The specificity of transcriptional activation that is needed to explain the physiological specificity of MyoD is therefore most likely achieved through cooperative interactions with other components of the transcriptional machinery such as MEF-2C.[8]

The identification of mechanisms to control the DNA-binding properties of transcription factors such as MyoD would permit the regulation of their activity. Previously, we have shown that stabilization of the DNA-recognition helix of MyoD, through two disulfide bonds from an N-terminally fused apamin extension, led to a tenfold increase in the DNA-binding specificity.[12] However, due to the lability of disulfide bonds in cells, the application of such apamin-stabilized recognition helices is limited. Furthermore, it would be desirable to control the properties of DNA-binding proteins in response to external signals such as light.

Previous work had shown significant stabilization of the α-helical conformation of peptides linked through cysteine residues in an i, $i+7$ spacing, to azobenzene-derived cross-linkers in their *cis* configuration (Figure 1a).[13] Met 116 and Ser 123, which are located on the water-exposed face of the recognition helix of MyoD, were therefore replaced with cysteine residues (Figure 1b). MyoD-bHLH-M116C-S123C was alkylated with 3,3′-bis(sulfo)-4,4′-bis(chloroacetamido)-azobenzene to generate photoMyoD (Figure 1c).[14] The i, $i+7$ spacing avoided unfavourable steric interactions between residues in the helix and the cross-linker. Furthermore, this spacing maximized the conformational differences in the *cis* and *trans* configurations of the cross-linker of the residues that make specific contacts to the nucleobases, namely Arg 111, Thr 115, and Glu 118.[15]

UV/Vis spectroscopy was used to follow the isomerization of photoMyoD. When the cross-linker was in its thermally stable *trans* configuration, the spectrum showed the strong maximum at 363 nm typical for amide-substituted azobenzene π–π* transitions (Figure 2).[16] However, irradiation with light at a wavelength of 360 nm led to the loss of that absorption maximum. The percentage of isomerization was determined by HPLC separation of the irradiated material and through monitoring the elution profile at the isosbestic point of 315 nm. Of the irradiated material, 61 % was found to be in the *cis* configuration, which is a value typically achieved by photoisomerization of *trans* azobenzenes.[13,17] The thermal reversion of irradiated photoMyoD to the *trans* configuration occurred with a half life of 193 min at 15 °C.

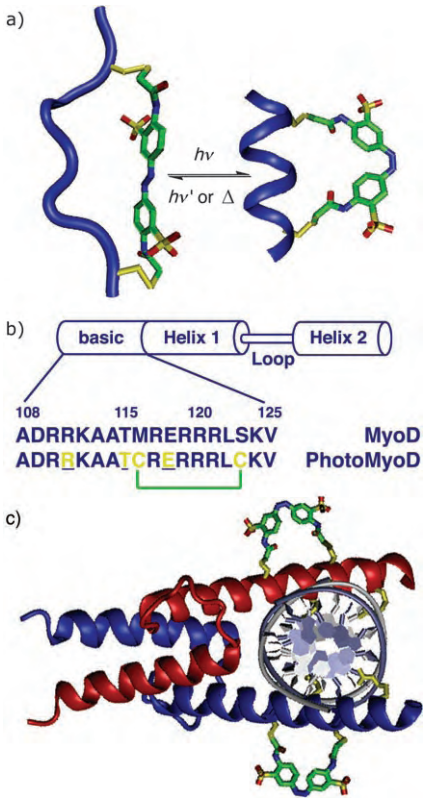

Figure 1. a) Sketch of the proposed structures of the basic regions of *trans* and *cis* photoMyoD indicating the conformational switch induced by the isomerization of the azobenzene cross-linker. b) Primary amino acid sequence of the basic region of MyoD and of photoMyoD. The residues that make specific contacts to the nucleobases in the X-ray crystal structure of the DNA complex of MyoD-bHLH[15] are underlined. c) Model of the DNA complex of photoMyoD with the cross-linker in its *cis* configuration. The DNA is complexed by the recognition helices of the two bHLH subunits of the dimeric protein. The cross-linker is located on the water-exposed face of the helices. The coordinates were from the crystal structure of MyoD-bHLH and DNA.[15]

CD spectroscopy revealed that the unalkylated MyoD-bHLH-M116C-S123C displayed only approximately 10 % helicity as judged from the mean residue ellipticity at 222 nm ($[\Theta]_{r,222} = -3658 \pm 232$ deg cm^2 dmol^{-1}) (Figure 3). The unalkylated form therefore existed predominantly in a random coil conformation like the parent MyoD-bHLH domain, which adopts an α-helical conformation only upon DNA binding.[11] The mean residue ellipticity of dark-adapted photoMyoD, in which the cross-linker is in its *trans* configuration, was similar to that of the non-cross-linked protein ($[\Theta]_{r,222} = -3328 \pm 345$ deg cm^2 dmol^{-1}). However, upon irra-

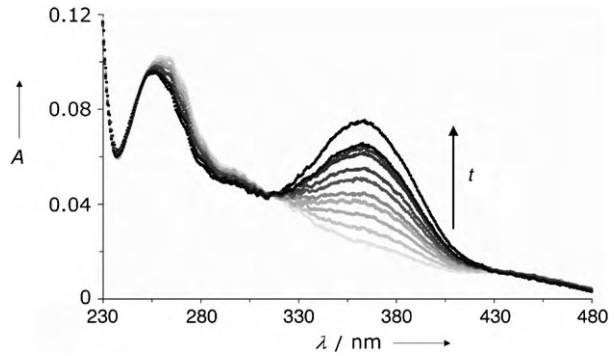

Figure 2. UV/Vis absorption spectra showing the photoisomerization of dark-adapted photoMyoD to the light-induced state. Black line (top) is the spectrum of dark-adapted photoMyoD (2 μM in 5 mM potassium phosphate buffer, pH 8.0, 15 °C). Light gray line (bottom) is the spectrum obtained immediately after exposure to 360 nm light. The intermediate curves show the spectra at varying times after photoisomerization (30, 60, 100, 135, 200, 260, 370, 430, 490 min). The sample was kept in the dark at 15 °C throughout the experiment.

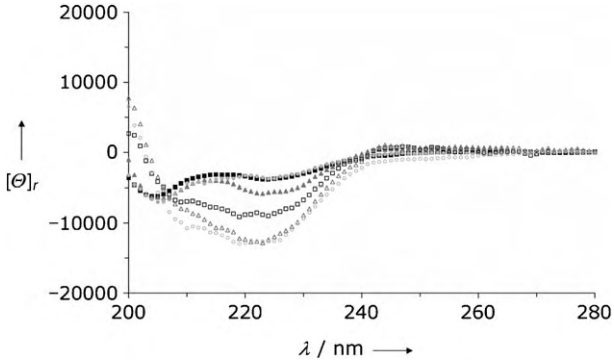

Figure 3. CD spectra showing DNA binding of MyoD-bHLH-M116C-S123C and photoMyoD. The protein concentrations were 2 μM in potassium phosphate (5 mM, pH 8.0) at 5 °C. ■ dark-adapted photoMyoD, ● non-cross-linked MyoD-bHLH-M116C-S123C, ▲ irradiated photoMyoD, ○ non-cross-linked MyoD-bHLH-M116C-S123C plus MCK-S (1 equiv, 1 μM), □ dark-adapted photoMyoD plus MCK-S (1 equiv, 1 μM); △ irradiated photoMyoD plus MCK-S (1 equiv, 1 μM). Mean residue ellipticity, [Θ]r, is in units of deg cm^2 dmol^{-1}.

diation with light of wavelength 360 nm, the mean residue ellipticity was reduced to -5597 ± 346 deg cm^2 dmol^{-1}. Given that this irradiated state of photoMyoD contained 39 % of the *trans* conformer, the mean residue ellipticity of pure *cis* photoMyoD could be calculated as -7060 ± 611 deg cm^2 dmol^{-1}. This corresponded to 19 % helicity or approximately 11 amino acids of the bHLH domain. It was not surprising that little helix induction was seen outside the eight residues spanned by the cross-linker as even at high concentrations where bHLH domains are folded dimers, the basic domain remains unstructured in the absence of DNA most likely owing to the electrostatic interactions of its many positively charged residues.[18]

The DNA-binding reactions of dark-adapted and irradiated photoMyoD, as well as that of the non-cross-linked parent protein, were studied with CD spectroscopy by using an oligonucleotide (MCK-S) comprised of 17 base pairs of the IgH enhancer-like element of the muscle-specific creatine kinase enhancer with the central E-box sequence, CAGGTG. Like MyoD-bHLH,[11] the non-cross-linked protein underwent a transition from a mostly disordered conformation to a mainly α-helical structure upon the addition of MCK-S (Figure 3). The observed value for the mean residue ellipticity at 222 nm, $[\Theta]_{r,222} = -13030 \pm 228$ deg cm^2 dmol^{-1}, indicated that the introduction of the two cysteine residues did not alter the DNA-binding properties of MyoD. The CD spectrum of the MCK-S complex of dark-adapted photoMyoD was characterized by $[\Theta]_{r,222} = -8913 \pm 182$ deg cm^2 dmol^{-1}, which indicates a significant loss of α-helical character. The CD spectrum of the DNA complex of irradiated photoMyoD was of a similar shape and intensity as that of the DNA complex of the non-alkylated protein. The value for $[\Theta]_{r,222}$ was reduced to -12130 ± 205 deg cm^2 dmol^{-1}. When the solution of the MCK-S complex of dark-adapted photoMyoD was irradiated with 360-nm light, the resultant CD spectrum was virtually identical to that of a solution of irradiated photoMyoD and DNA (Figure 3). This therefore indicated that the presence of DNA did not prevent the isomerization process.

The apparent dissociation constants of the DNA complexes of dark-adapted and irradiated photoMyoD were determined by using measurements of the fluorescence anisotropy.[12,19–22] The addition of protein to a solution of fluorescently labeled, double-stranded oligonucleotides resulted in a saturable increase in the fluorescence anisotropy, indicating that the protein had bound to the DNA in solution (Figure 4). The titration curves were fit to the Langmuir isotherm $\Phi_{Fit} = 1/(1 + K_D^n/[P]^n)$. For complexes with MCK-S, the best results were obtained for a model of cooperative two-state binding of two protein monomers to one DNA duplex as is commonly observed for bHLH proteins.[11,18,23] These fits yielded the apparent dissociation constant (K_D) from which the concentration of the protein, at which half-maximal DNA binding occurs ($[P]_{1/2}$) was calculated (see Supporting Information).

The K_D value for the MCK-S complex of dark-adapted photoMyoD ($1.5 \pm 0.38 \times 10^{-14}$ M^2) was similar to that of non-alkylated MyoD-bHLH-M116C-S123C ($8.8 \pm 2.2 \times 10^{-15}$ M^2). The stability of the MCK-S complex of irradiated photoMyoD, however, was increased significantly, and its apparent dissociation constant was reduced by more than three orders of magnitude to $4.4 \pm 0.16 \times 10^{-18}$ M^2. To the best of our knowledge, this almost 60-fold decrease in $[P]_{1/2}$ is the biggest change in DNA affinity caused by covalent helix stabilization reported to date.

The DNA-binding specificities of dark-adapted and irradiated photoMyoD were measured by comparison of the apparent dissociation constants of their complexes with MCK-S and with the oligonucleotide NoE-box (same base composition as MCK-S but with a scrambled sequence and without an E-box).[12] The bHLH proteins MASH-1 and MyoD have been shown previously not to distinguish efficiently between MCK-S and NoE-box.[11,23–25] Similarly, the K_D values for binding of non-alkylated MyoD-bHLH-M116C-S123C to MCK-S and NoE-box ($5.9 \pm 1.0 \times 10^{-15}$ M^2) were identical (Figure 4 and Supporting Information) and in

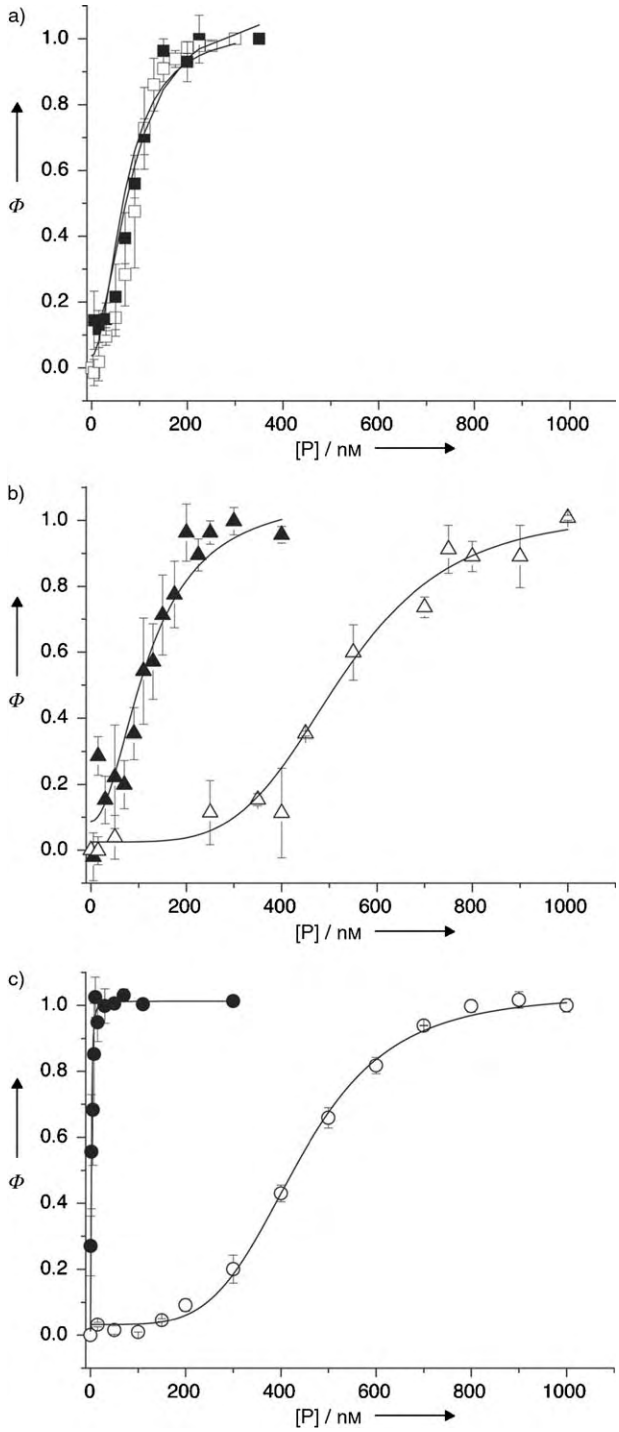

Figure 4. Characterization of DNA binding of non-cross-linked MyoD-bHLH-M116C-S123C and dark-adapted and irradiated photoMyoD measured by fluorescence anisotropy. Fraction (Φ) of bound MCK-S (solid symbols) and NoE-box (open symbols) in the complexes of a) MyoD-bHLH-M116C-S123C, b) dark-adapted and c) irradiated photoMyoD is plotted against the concentration of the free protein (P).

agreement with a previous study of MyoD-bHLH.[12] The association of MyoD-bHLH-M116C-S123C and NoE-box also displayed cooperative binding of two protein monomers per duplex DNA as had been observed for the MCK-S complex (Figure 4).

Dark-adapted photoMyoD showed only a slight increase in DNA-binding specificity. Although it bound MCK-S with comparable affinity to the non-alkylated parent protein MyoD-bHLH-M116C-S123C, the stability of its complex with NoE-box was reduced ($2.7 \pm 0.05 \times 10^{-13}$ M^2). In strong contrast, a reduction in affinity of irradiated photoMyoD for NoE-box ($1.9 \pm 0.06 \times 10^{-13}$ M^2) was accompanied by a dramatic increase in its affinity for MCK-S. The K_D value of the MCK-S complex of the irradiated protein ($4.4 \pm 0.16 \times 10^{-18}$ M^2) was reduced approximately 3400-fold relative to that of the dark-adapted state, whereas the K_D values of the NoE-box complexes of irradiated and dark-adapted photoMyoD ($2.7 \pm 0.05 \times 10^{-13}$ M^2) were similar.

At the high concentrations of irradiated and dark-adapted photoMyoD required to bind to the NoE-box duplex, the mechanism of DNA binding appeared to be altered when compared to the high-affinity binding reaction observed for binding to specific DNA. The best fit to the Langmuir isotherm for binding to noncognate DNA was obtained for binding orders of approximately 4.5 (Figure 4). This may be a consequence of interactions between the alkylated proteins at these elevated concentrations possibly through their aromatic cross-linkers.

The introduction of an azobenzene-derived photo-cross-linker into the DNA-recognition helix of the transcriptional activator MyoD produced a DNA-binding protein, the activity of which could be controlled by light pulses. In its irradiated state, in which the cross-linker was predominantly in the *cis* configuration, significant stabilization of the recognition helix and of the specific DNA complex was observed relative to the dark-adapted state. Because the affinity for heterologous DNA sequences was comparable for the dark-adapted and the irradiated proteins, photoactivation generated increases in the DNA-binding specificity of more than two orders of magnitude. Such photocontrolled DNA-binding proteins could serve as building blocks for the generation of reagents to control developmental processes and therapeutics. The activity of transcriptional activators is typically regulated through interaction with other protein domains, and these interfaces have proven difficult to target with small molecules. Reinforcing the native structure of DNA-recognition elements may be an alternative strategy to target these interactions and interfere with biological processes in a specific and controlled fashion.

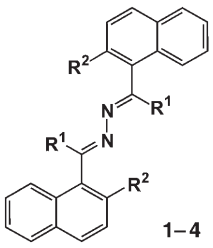
Solid-State Fluorescence

DOI: 10.1002/anie.200501781

Molecular Mechanism of the Solid-State Fluorescence Behavior of the Organic Pigment Yellow 101 and Its Derivatives**

Andreas Dreuw, Jürgen Plötner, Lisa Lorenz, Josef Wachtveitl, Juste E. Djanhan, Jürgen Brüning, Thomas Metz, Michael Bolte, and Martin U. Schmidt**

Many organic colorants that fluoresce in solution (e.g. fluoresceine) lose this property when they are crystallized. Pigment Yellow 101 (P.Y.101, **2**; $R^1 = H$, $R^2 = OH$) is the only commercial organic yellow pigment[1,2] that exhibits fluorescence also in the crystalline state. P.Y.101 has been known since 1899 and has been produced industrially for decades. It is used, for example, as a pigment for viscose, for printing inks, and for artists' applications. Analysis of the fluorescence properties of the derivatives **1** ($R^1 = R^2 = H$) **3** ($R^1 = H$, $R^2 = OCH_3$), and **4** ($R^1 = CH_3$, $R^2 = OH$) reveals an unexpected behavior: Pigments **1** and **3** do not fluoresce, neither in solution nor in the solid state. However, pigment **4** does exhibit fluorescence like **2** both in solution and in the solid state (Table 1).



1–4

This is remarkable for two reasons: 1) Compounds **2** and **4** are fluorescent in contradiction to an empirical rule that states that pigments with OH groups usually do not fluoresce. Here, only the pigments with OH groups exhibit fluorescence. 2) The fluorescent pigments remain fluorescent upon crystallization, although compound **4** displays short intermolecular distances in the crystal, which should lead to fluorescence quenching.[3] To understand the influence of the OH groups on the fluorescence of the pigments we performed extensive quantum-chemical calculations employing methods based on time-dependent density functional theory (TDDFT). In the following presentation of our theoretical study, we focus on the pigments **1** and **2**, but analogous results have been found for **3** and **4**.

The calculated geometrical parameters of the ground states of the individual molecules **1** and **2** agree very well with the X-ray crystal structure (see the Supporting Information). For all the molecules, excitation into the lowest-lying optically allowed state leads to bond-length equilibration of the N–N, C=N, and C–C bonds of the bisazomethine substructure, in other words, to a transition of the C=N–N=C to a C=N=N=C fragment (see the Supporting Information). The absorption and fluorescence spectra of the individual molecules have been calculated and compared with experimental spectra as shown in Figure 1 for **2**. The calculated excited states are shifted about 77 nm to smaller wavelengths (higher energy) to match the 0→0 transition of the strongly allowed and thus experimentally observed absorption band. The good agreement between theory and experiment in this case is striking. The experimentally observed absorption band at 413 nm (λ_{max}) exhibits a pronounced vibrational fine structure that points to a mode with a frequency of about 1400 cm^{-1} (Figure 1), which is excited upon optical transition from the ground state. This frequency corresponds to a typical value for symmetric stretching vibrations ν_s involving the bisazomethine subunit. This is also in agreement with the change of the equilibrium geometries from the ground state to the optically allowed excited state S_1 in the case of **2** (see the Supporting Information).

To answer the question why pigments **2** and **4** fluoresce while **1** and **3** do not, their excited states were calculated (Table 2). The relevant states and the corresponding orbitals are displayed in Figure 2. In the case of **1** and **3**, the energetically lowest excited state S_1 corresponds to a for-

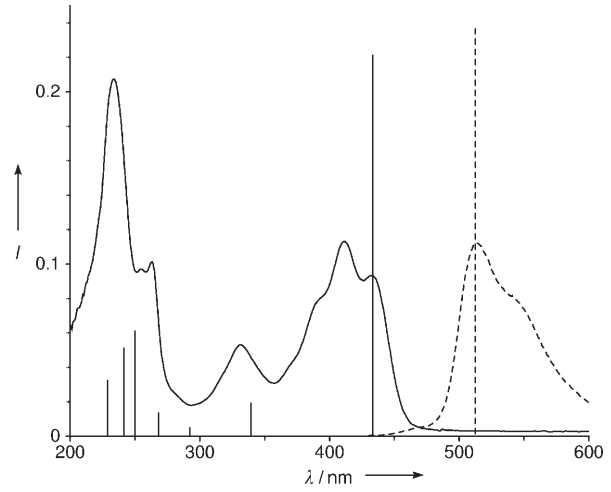

Figure 1. Comparison of the measured absorption (solid line) and fluorescence (dashed line) spectra with the corresponding calculated transitions (vertical lines) of **2**. The calculated wavelengths are all shifted by 77 nm to smaller wavelengths (see text).

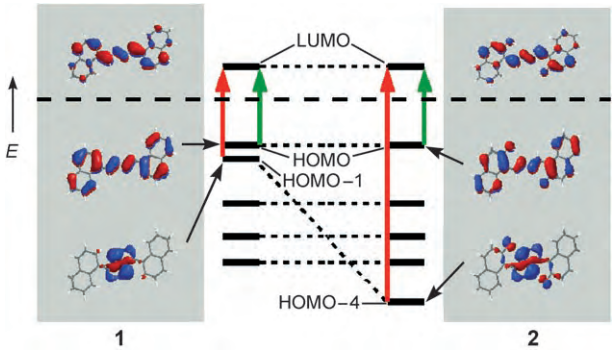

Figure 2. Energy diagrams of the molecular orbitals involved in the allowed π→π* transitions (green) and forbidden n→π* transitions (red) of pigments **1** and **2**. In **2** the n orbitals corresponding to the lone pairs are strongly stabilized by hydrogen bonds. Thus, the corresponding nπ* state becomes much higher in energy than the ππ* state. Note that the lengths of the arrows are not related to the transition energies of the corresponding states (see text).

bidden nπ* state, which is represented mostly by a HOMO-1→LUMO transition (red arrow). The second lowest state S_2 corresponds to an optically allowed ππ* state and can considered to arise almost exclusively a HOMO→LUMO transition (green arrow). Astonishingly, the HOMO−1→LUMO transition is lower in energy than the HOMO→LUMO transition, but this results from additional admixtures of other transitions into the wavefunction of the dark nπ* state which lower its energy substantially. In **2** and **4**, the allowed HOMO→LUMO transition leads to the energetically lowest-lying state S_1, and the forbidden n→π* transition leads to the fifth lowest-lying state S_5, owing to a strong stabilization of the nitrogen lone-pair orbital by the hydrogen bonds of the OH groups. The hydrogen bonds in **2** and **4** lower the energy of the n orbital, thus increasing the excitation energy for the n→π* transition. Hence the order of the excited states of the pigments **1**–**4** already explains the molecular fluorescence behavior of the pigments in solution.

To allow for fluorescence quenching in pigments **1** and **3**, a suitable reaction pathway on the potential energy surface of the excited state should exist that leads from the allowed S_2 (ππ*) state to the optically forbidden S_1 (nπ*) state. Most likely this pathway corresponds to a vibrational mode of the system. Several different modes have been considered, but only CNN bending proved to be relevant. The calculated potential energy curves of the three lowest excited states of **1** along the CNN angle are shown in Figure 3. The structure of the S_2 state has been reoptimized along this coordinate. For decreasing CNN angles, the dark S_1 state is strongly destabilized; its energy increases and crosses that of the S_2 state at a CNN angle of 108°. Even if one assumes a low vibrational frequency of only 300 cm^{-1}, already the second vibrational level of the S_2 state lies energetically above the state crossing as indicated in Figure 3. Consequently, every mode that

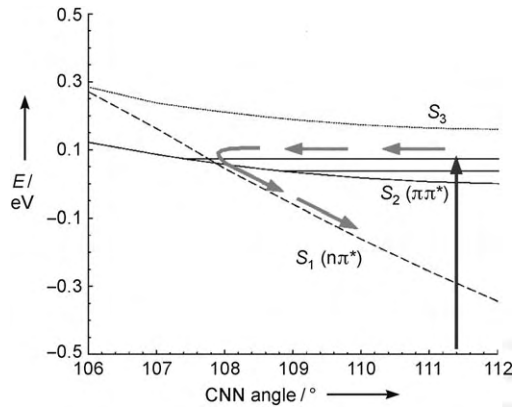

Figure 3. Calculated potential energy curves of pigment **1** along the CNN-bending vibration. Since a curve crossing between the state S_2 (optically allowed ππ* state) and the state S_1 (forbidden nπ* state) occurs, this vibrational motion is an efficient pathway for fluorescence quenching in pigment **1** (gray arrows).

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

contains a CNN-bending contribution will lead to state crossings. Based on simple geometric arguments, it can be expected that CNN bending is strongly coupled to the Franck–Condon-active symmetric stretching mode, thus allowing very efficient fluorescence quenching in **1** and **3**.

To understand why the molecular fluorescence properties of **1**–**4** are retained when the compounds are crystallized, we determined the structures of all compounds by single-crystal X-ray diffraction.[4] Structural details and different conformers of the pigments are discussed in the Supporting Information. Compounds **1**–**3** form isostructural arrangements in which the distances between the centers of the molecules are 6 to 7 Å (Table 1). The crystal structure of the simplest derivative **1** is displayed in Figure 4. Lattice-energy calculations demonstrate that CNN bending is also possible in the crystals. If, in a crystal of compound **1** or **3** consisting of molecules with the ground-state geometry only, a single molecule adopts the geometry of the excited state (CNN angle 108°, near the crossing between the S_1 and S_2 states), the lattice energy drops by 0.2 kJ mol^{-1}. Consequently, the vibration responsible for fluorescence quenching is not hampered by the crystal lattice, but is on the contrary even slightly facilitated. Thus nonfluorescent pigments **1** and **3** remain nonfluorescent in the crystal.

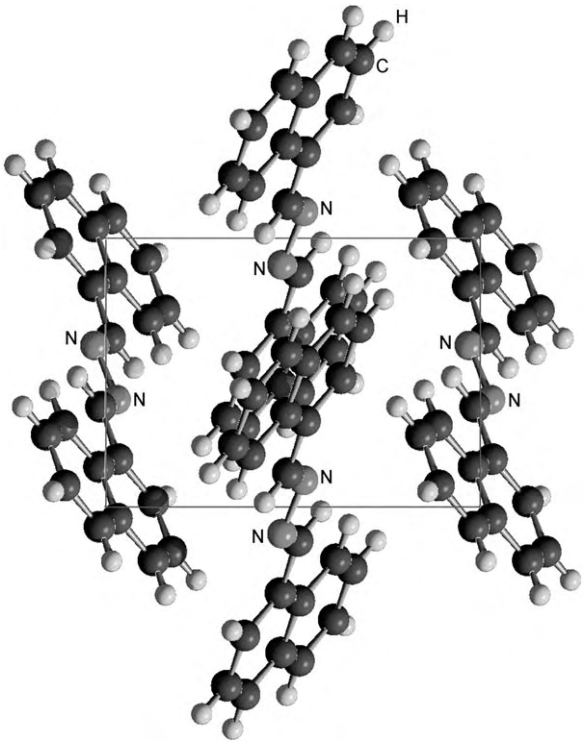

Figure 4. Crystal structure of the unsubstituted compound **1**. SCHAKAL plot,[11] view along [001], *a* axis horizontal, *b* axis vertical.

The crystal structure of **4** is different from the structures of pigments **1**–**3**. In crystals of **4** the molecules are stacked almost on top of each other, leading to short intermolecular distances of only 3.86 Å (Figure 5). According to a rule formulated by Langhals et al.,[3] solid-state fluorescence strongly depends on the intermolecular distance and is usually quenched when the distance between the chromophores is less than 5–6 Å as a result of enhanced exciton–phonon coupling. This typically results in electron-transfer (ET) quenching. Here, the observed solid-state fluorescence contradicts this rule: pigment **4** exhibits strong solid-state fluorescence, despite the short intermolecular distance of only 3.86 Å.

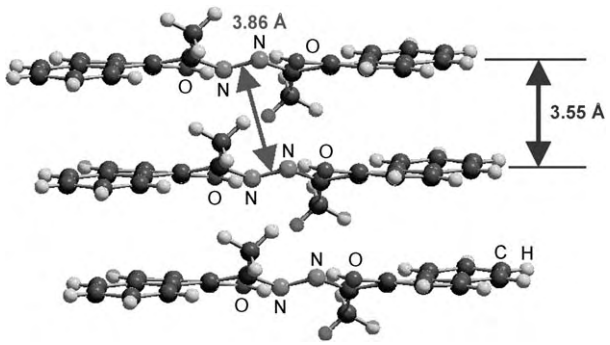

Figure 5. Molecular packing in the crystal structure of the strongly fluorescent pigment **4**. The small intermolecular distance of only 3.86 Å and the pronounced stacking of the planar pigment molecules in the crystal are apparent.

However, ET quenching can most likely be excluded. Calculations of the excited states of pigment dimers in the relative orientation taken from the crystal structures using a recently suggested hybrid approach[5] revealed that the required charge-transfer (CT) excited states are energetically not accessible. The lowest CT excited state of the dimer of **4** exhibits an excitation energy of about 3.0 eV (413 nm) and is thus higher in energy than the optically allowed state. Based on these findings, the solid-state fluorescence of Pigment Yellow 101 (**2**) and its derivative **4** can be interpreted as a molecular property retained in the crystal.

In this work we have demonstrated that the pigments **1**–**4** do not obey empirical rules for solid-state fluorescence. It has been shown that the optically allowed excited states of **2** and **4** can decay only by fluorescence, while the excited states of **1** and **3** can efficiently decay to a low-lying dark nπ* state through CNN bending of the bisazomethine substructure. This is also possible in the crystal lattice. Crystal-packing-controlled electron-transfer quenching has been ruled out as a possible quenching pathway. The fluorescence behavior of Pigment Yellow 101 and its derivatives is explained as a molecular property that is retained in the solid state. Moreover, the O–H···N bond has been proven to be essential for fluorescence. This insight may stimulate syntheses of new pigments based on substituted 2-hydroxynaphthalenes. Indeed, all compounds synthesized so far exhibit solid-state fluorescence.

Experimental Section

Syntheses and crystallization: The pigments **1**–**4** were synthesized by condensation of hydrazine with the corresponding formyl- and acetylnaphthalene derivatives.[6] Crystals of **1** were grown by slowly

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

cooling a heated dilute solution of **1** in CH_3OH/C_2H_5OH (1:1); for **2**, DMF was used, for **3** and **4** xylene/mesitylene (1:1) was used.

UV/Vis spectra were recorded with a Specord S100 spectrophotometer from Analytik Jena. Concentration of **2** in dichloromethane (LiChrosolv, Merck) was 3 μM in order to obtain an optical density of 0.1 (at 411 nm). The spectrum was recorded versus pure dichloromethane with an integration time of 38 ms and 100 accumulations. Fluorescence spectra were measured with a Cary Eclipse fluorescence spectrophotometer from Varian. For **2** the excitation wavelength was 410 nm, and the spectrum was recorded at high PMT voltage (800 V) with a scan rate of 120 nm min^{-1}.

The calculations were performed using the TURBOMOLE package of programs.[7] The ground-state and excited-state properties were calculated using DFT and TDDFT,[8,9] respectively, employing the BP86 exchange-correlation (xc) functional in combination with the double-zeta polarization (DZP) basis set.[10] An extensive study of various xc-functional/basis set combinations has been performed, the details of which shall be published elsewhere. Lattice-energy minimizations: DREIDING force field, with especially developed force-field parameters for the C=N and N–N bond streching, C–C=N and C=N–N angle bending, and C–C=N–N and C=C–C=N torsions in order to exactly reproduce the crystal structure of **2** with ground-state molecules.

$(Pr_4N)_4[Ag_3Fe_2(ECN)_{12}]$—Anionic Network Structures with Mutual Interpenetration**

*Stefan Gerber, Henriette Gröger, Jürgen Ensling, Philipp Gütlich, and Harald Krautscheid**

Dedicated to Professor Dieter Fenske

The synthesis and characterization of compounds with extended network structures has become a fast growing field of research.[1] In some cases these compounds show porous structures with large cavities, in others the formation of the cavities is prevented by interpenetration of the networks. 1998 Batten and Robson reviewed[2] network structures with mutual interpenetration, mostly formed by self-aggregation. Following this concept, it is possible, for example, to synthesize heteronuclear polymeric complexes, if SCN^- ions are coordinating to metal ions with different Lewis acidities.[3] In keeping with Pearson's HSAB principle,[4] the SCN^- ion acts as an ambidentate ligand; it coordinates to hard Lewis acids mainly through the N atom and to soft Lewis acids through the S atom. The central Fe^{II} and Fe^{III} atoms in the homoleptic complexes $(Et_4N)_4[Fe(NCS)_6]$[5] and $(Me_4N)_3[Fe(NCS)_6]$,[6] respectively, are coordinated octahedrally by six thiocyanato-N ligands, whereas in $K[Ag(SCN)_2]$, $K_4[Ag_2(SCN)_6]$, $K_3[Ag(SCN)_4]$, and $Rb_2[Ag(SCN)_3]$[7] terminal or bridging thiocyanato ligands are bound tetrahedrally through S atoms. If SCN^- ions are offered Fe^{2+}, Fe^{3+}, and Ag^+ ions at the same time, the two coordination motives are combined in such a way that $Fe(NCS)_6$ octahedra and $Ag(SCN)_4$ tetrahedra are linked, as the structures of $(Et_4N)_2[Ag_2Fe(SCN)_6]$, $(Bu_4N)_4[Ag_2Fe_2(SCN)_{12}]$,[5] and $(Me_3NPh)_6[Ag_6Fe_3(SCN)_{18}]$[8] show.

Scheer (Forschungszentrum Karlsruhe) for the thermochemical measurements. H.K. thanks Prof. D. Fenske (Universität Karlsruhe) for his invaluable support. E = S, Se.

Supporting information for this article is available on the WWW under http://www.angewandte.org or from the author.

Here we report on the heteronuclear, mixed-valent coordination compounds **1** and **2**, which contain Fe^{2+}, Fe^{3+}, and Ag^+ ions and are formed according to Equation (1) in nitromethane and crystallized by addition of diethyl ether. The partial reduction of the Fe^{3+} ions is due to the reducing effect of thiocyanate, which is oxidized to $(SCN)_2$ and subsequent products.[9]

$$2\,(Pr_4N)_3[Fe(NCE)_6] + 3\,AgECN \xrightarrow{MeNO_2} (Pr_4N)_4[Ag_3Fe_2(ECN)_{12}] + 2\,(Pr_4N)SCN + {}^1/_2\,(SCN)_2 \quad (1)$$

1: E = S

2: E = Se

The X-ray structure analyses show that **1** and **2** are isostructural and crystallize in the space group $I\bar{4}2d$.[10] As expected, Ag^+ ions are coordinated tetrahedrally to SCN^- and $SeCN^-$ ions through S and Se atoms, respectively, and Fe^{2+} and Fe^{3+} ions are coordinated octahedrally through the N atoms of SCN^- and $SeCN^-$ (Figure 1a). Two 1,3-μ_2 bridging ligands link single Fe and Ag atoms in such a way that each Fe atom is surrounded by three Ag atoms in a trigonal-planar arrangement with Ag···Fe distances of 560.5 and 560.8 pm in **1** and 568.3 and 570.6 pm in **2**. Each Ag atom is connected to two Fe atoms by two ECN^- ligands each (Fe···Ag···Fe > 174°). As shown in Figure 1b (Ag···Fe drawn as dotted lines), this connectivity results in a three-dimensional Fe_2Ag_3 network, whose topology corresponds to the *(10,3)-b* network of $\alpha ThSi_2$ (Figure 1c) and shows the highest possible tetragonal symmetry for this type of network.[2,11]

In this way channels are formed with a width of 1.2 nm × 2.7 nm in direction of the crystallographic *a* and *b* axes. These cavities are partially occupied according to the interpenetration of three of these *(10,3)-b* $[Ag_3Fe_2(ECN)_{12}]^{4-}$ nets, as shown in Figure 2. The Pr_4N^+ ions are located in the remaining cavities. After crystallization **1** is hardly soluble in nitromethane. The Pr_4N^+ ions could not be exchanged for Me_4N^+ ions. Similar three-dimensional networks with mutual interpenetration are found in $[Ag(H_2NC_{12}H_{24}NH_2)_2]^+$ and $[Ag_2(pz)_3]^{2+}$ ions (pz = pyrazine).[12]

Complexometric titrations show that **1** is a mixed-valent compound, whereas all Fe atoms occupy equivalent positions according to the X-ray structure analysis. Therefore Fe^{II} and Fe^{III} centers are undistinguishable by crystallographic means. The Fe–N bond lengths (210.1–212.2(2) pm in **1** and 209.9–211.1(4) pm in **2**) are between those observed in $(Me_4N)_3[Fe^{III}(NCS)_6]$[6] (204.8 pm) and $(Et_4N)_4[Fe^{II}(NCS)_6]$[5] (217.6 pm). The thermal ellipsoids of the N atoms are almost spherical and do not indicate differing Fe–ligand distances (Figure 1a). Differential thermal analysis/thermogravimetric analysis of **1** shows a phase transition at 161 °C (endothermic) and a thermal stability up to 250 °C under N_2.[13] Single crystals of **1** show no significant electric conductivity. Numerous complexes of SCN^- are known with Fe^{II} and also with Fe^{III} central atoms. In contrast, only a few iron complexes of $SeCN^-$ have been characterized by X-ray structure analysis, in many of which, however, also other ligands are present.[14] Only one mixed-valent iron complex with SCN^- and $SeCN^-$ ligands has been reported, but its crystal structure was not described.[15]

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

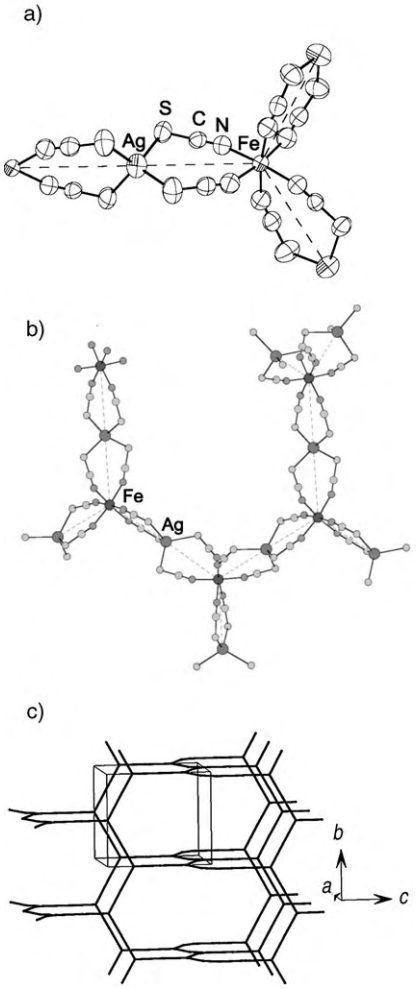

Figure 1. a), b) Fragments of the structure of the three-dimensional polymeric $[Ag_3Fe_2(SCN)_{12}]^{4-}$ ion in **1** (thermal ellipsoids with 70% probability). For clarity, Ag···Fe distances are marked with dashed lines. Distances [pm] and angles [°] in **1** [**2**]: Fe–N 210.1–212.2(2) [209.9–211.1(4)]; Ag–S 260.99–262.08(8) [Ag–Se 270.52–271.22(6)], C–N 115.5–116.3(3) [116.3–116.9(5)], C–S 163.3–163.7(3) [C–Se 178.0–178.3(4)]; N-Fe-N 83.14–93.74(8), 171.4–175.5(1) [83.3–94.3, 171.4–176.5(2)], S-Ag-S 91.18–119.39(4) [Se-Ag-Se 88.65–121.38(2)], S-C-N 177.7–178.6(3) [Se-C-N 178.1–179.5(4)]. c) *(10,3)-b* Network of α-$ThSi_2$ and of the Ag and Fe atoms in **1** and **2**, respectively; the Fe atoms occupy the positions of the Si atoms (linking position), between them are the Ag atoms. A section of the $[Ag_3Fe_2(SCN)_{12}]^{4-}$ network including the tetragonal unit cell is shown (view approximately along the *a* axis).

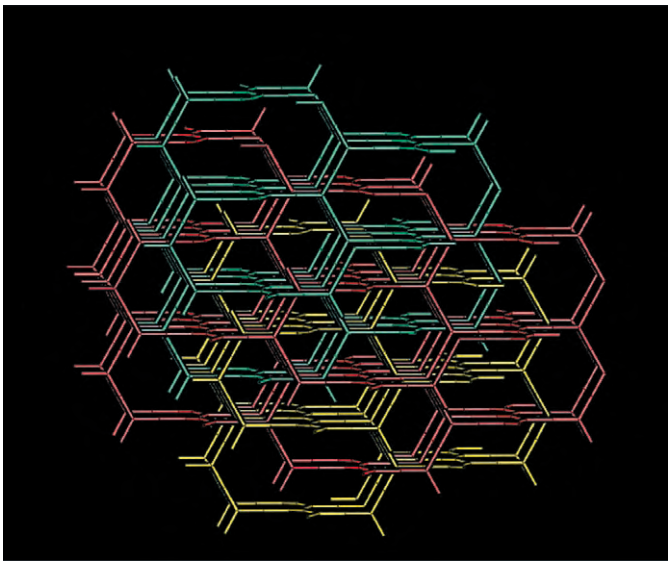

Figure 2. Interpenetration of three *(10,3)-b* nets in the structures of the anions of **1** and **2**; only the Ag···Fe lines are shown.

The IR spectrum of **1** shows intense vibrational resonances at 2112 (s) and 2069 (vs) cm^{-1}, which can be attributed to the stretching vibrations ν_{CN} of the SCN^- ligands. Because of the 1,3-μ bridging mode of the SCN^- ligands, these absorptions are slightly shifted compared to those of the mononuclear complexes with terminal N-bonded SCN^- ligands.[16] For comparison, the ν_{CN} frequencies are 2069 cm^{-1} in $(Pr_4N)_3[Fe(NCS)_6]$, 2085 cm^{-1} in $(Et_4N)_4[Fe(NCS)_6]$ and 2125, 2076, and 2042 cm^{-1} in $(Bu_4N)_4[Ag_2Fe_2(SCN)_{12}]$.[5]

The almost-black crystals of **1**, which appear red in thin layers, show a very strong absorption at 525 nm in the UV/Vis spectrum, which is interpreted as a ligand-to-metal charge-transfer (LMCT) transition.[17] The peak is broadened compared to that of the starting compound $(Pr_4N)_3[Fe(NCS)_6]$ ($\lambda_{max} = 480$ nm), and like the absorption of $(Bu_4N)_4[Ag_2Fe_3(SCN)_{12}]$ ($\lambda_{max} = 530$ nm) it is shifted to lower energy as a result of the coordination of the ligand S atoms to Ag^+.[5] The high intensity of the LMCT absorption prevents the identification of an intervalence charge-transfer (IVCT) absorption.

At room temperature the magnetic moment of **1** is $\chi = 2.88 \times 10^{-2}$ emu mol^{-1} (after subtraction of the diamagnetic increments).[18,19] Between 100 K and 300 K the magnetic susceptibility follows approximately Curie's law with a Curie constant of $C = 8.35$. If one assumes $\mu_{eff}(Fe^{3+}) = 5.92\,\mu_B$ as the spin-only value for the high-spin Fe^{3+} ions, the Fe^{2+} ions contribute $\mu_{eff}(Fe^{2+}) = 5.64\,\mu_B$. The magnetic moment for high-spin Fe^{2+} complexes in octahedral ligand fields is typically between 5.1 and $5.7\,\mu_B$.[19] Below 100 K the χT function drops off slightly. Apparently at these temperatures there are no significant exchange interactions between the Fe ions, which have separations of 1121 pm within and 1104 pm between two networks. According to the structure analysis, the Fe^{2+} and Fe^{3+} ions occupy equivalent positions, whereas the Mössbauer spectra can be interpreted as the superposition of signals of Fe^{2+} and Fe^{3+} (Figure 3). At room temperature, 130 K, and 4.2 K the spectra show quadrupole doublets with temperature-dependent splittings ranging from 0.38 mm s^{-1} at room temperature to 0.65 mm s^{-1} at 4.2 K. This signal with an isomeric shift of 1.15 to 1.27 mm s^{-1} can be assigned to high-spin Fe^{2+}. The comparatively small quadrupole splitting is a result of the almost equal contributions of the valence electrons and the lattice to the electric field gradient with opposite signs. The contribution of the valence electrons is responsible for the temperature dependence of the quadrupole splitting. The strongly broadened signal with an isomeric shift of about 0.5 mm s^{-1} indicates Fe^{3+} in a high-spin state. At room temperature both portions of the peak area are almost equal, but shift with decreasing temperature in favor of the

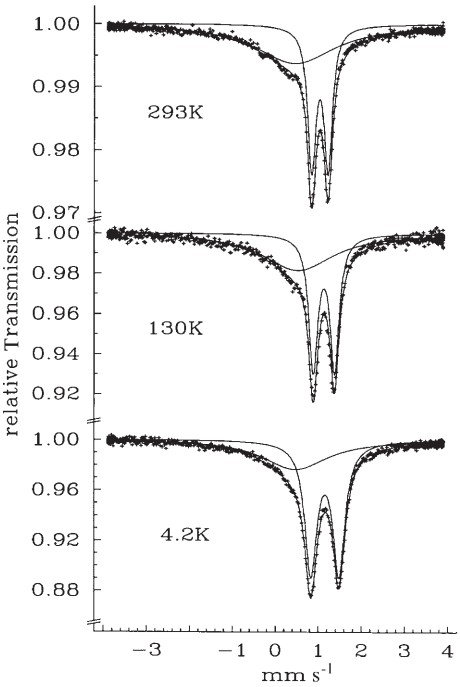

Figure 3. Mössbauer spectra of **1** at 293, 130, and 4.2 K. IS = isomeric shift, QS = quadrupole splitting, hs = high spin.

Fe^{2+} high-spin component. Probably spin relaxation leads to the strong broadening of the Fe^{3+} signal, since the relaxation times are comparable with the typical time window for the ^{57}Fe Mössbauer experiment.

The broad intervalence bands of $[(CN)_5Fe\text{-}ECN\text{-}Fe(CN)_5]^{6-}$ (E = S, Se) at $\lambda = 1300$ nm with half widths of 3550 and 3090 cm^{-1} show that exchange interactions through bridging SCN^- and $SeCN^-$ ligands, respectively, are possible.[15] These complexes can be assigned to class II in the sense of the Robin Day classification[20] with localized oxidation states, since the ν_{CN} frequencies for the $Fe^{II}(CN)_5$ and $Fe^{III}(CN)_5$ fragments are distinguishable. The Fe ions in $[(CN)_5Fe(\mu\text{-tz})Fe(CN)_5]^{5-}$ (μ-tz = 1,2,4,5-tetrazine), however, cannot be distinguished by either IR or Mössbauer spectroscopy, and can therefore be assigned to class III, which is also supported by a minor solvent dependence of the significantly sharper intervalence charge-transfer band at 2495 cm^{-1}.[21] Because in **1** the Fe^{2+} and the Fe^{3+} ions have similar chemical environments, the magnetic features correspond to those of the isolated complexes, and these ions also give rise to distinct signals in the Mössbauer spectra, **1** should be considered a Robin Day class II mixed-valent compound.

Experimental Section

1: Equimolar quantities of $(Pr_4N)_3[Fe(NCS)_6]$ (550 mg, 0.57 mmol) (prepared according to reference [22] and recrystallized from CH_2Cl_2/hexane), $AgNO_3$ (96 mg), and $(Pr_4N)SCN$ (139 mg) were stirred in nitromethane (5 mL) at room temperature. After 10 h the red–black solution was filtered and 15 mL of diethyl ether was condensed into the solution. After one week, black crystals of **1**, which in thin layers appear red, were isolated, washed with nitromethane and diethyl ether, and dried in vacuum. Yield: 50 mg (0.027 mmol, 14%); elemental analysis calcd (%) for $C_{60}H_{112}N_{16}Ag_3Fe_2S_{12}$: C 38.4, H 6.7, N 11.9, Fe 5.9; found: C 38.3, H 6.3, N 12.0, Fe 5.9.

Coordination compound **2** was obtained as dark blue crystals in small yield by reaction of AgSeCN with $Fe(ClO_4)_3$ and $(Pr_4N)SeCN$.

The amount of Fe^{2+} and Fe^{3+} in **1** was determined by complexometric titration under N_2 with 0.01M EDTA solution with 5-sulfosalicylic acid as indicator: Compound **1** (85 mg, 0.0453 mmol) was stirred with an excess of $AgNO_3$ in water acidified with HNO_3. Insoluble AgSCN was filtered off, and the resulting solution was titrated with EDTA solution to determine the Fe^{3+} content. The point of equivalence was reached after addition of EDTA solution (4.55 mL). After oxidation of the Fe^{2+} ions with added H_2O_2, the titration was continued until the second point of equivalence is reached after the addition of EDTA solution (4.40 mL).

A Triazadiphosphole**

Sebastian Herler, Peter Mayer,

Alexander Villinger, and Jan J. Weigand

In memory of Erhard Kurras

Phosphorus–nitrogen compounds with low-coordinated phosphorus(III) atoms are a well-established group of compounds.[1–3] However, covalent azide analogues such as R-PNN and R-NNP (R = organic group) are not yet known. As part of our research directed toward the synthesis of (TMS)PNN and (TMS)NNP species, we have recently investigated the elimination of trimethylsilylchloride (TMSCl) in the thermal decomposition of *N*,*N*′,*N*′-[tris(trimethylsilyl)hydrazino]dichlorophosphane (**1**).[4] This experimental and theoretical study revealed rather large activation barriers (38–45 kcal mol^{-1}) for the successive intrinsic elimination of TMSCl in **1** and led to the conclusion that Lewis acids should be used to eliminate TMSCl at ambient temperature. In this context, we have studied the reactions of **1** with gallium trichloride as a Lewis acid.[5]

Compound **1** is stable in dichloromethane at ambient temperature for several days as shown by ^{31}P NMR studies ($\delta(^{31}P) = 166.6$ ppm).[4] However, the ^{31}P NMR spectra for reaction mixtures of **1** (2 equiv) and $GaCl_3$ (1 equiv) in CH_2Cl_2 at ambient temperature show rapid, quantitative formation of the new phosphorus species **2** within 2 h (Scheme 1).[6] Two new different phosphorus resonances belonging to only one species are observed in the range typical for dicoordinated phosphorus(III) compounds (doublets at $\delta(^{31}P) = 317.2$ (P1) and 292.1 ppm (P2),[7a] $^2J_{P,P} = 22.1$ Hz; cf. 265.1 ppm, $^2J_{P,P} = 22.7$ Hz for a 1,2,3,5-diazadiphosphole (RN_2P_2C, R = Me)[8]). Removal of the solvent resulted in a yellow polycrystalline powder. ^{31}P MAS NMR studies proved the existence of the same species in the solid state as that observed in the solvent ^{31}P NMR experiment. Because there are two independent molecules in the unit cell, four resonances at $\delta(^{31}P) = 318/312$ (P1 or P3) and 296/285 ppm (P2 or P4) were found in the ^{31}P MAS NMR spectrum (Figures 1 and 2). Interestingly, we were able to

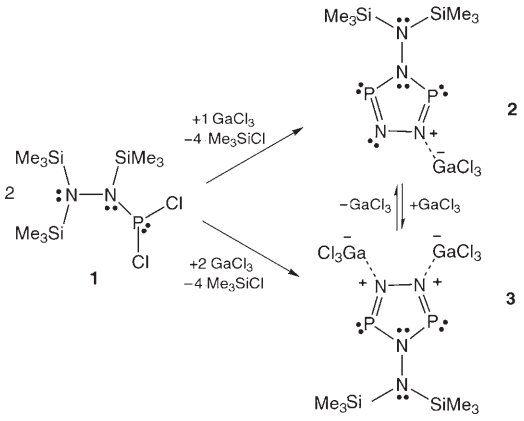

Scheme 1. Synthesis of $GaCl_3$ adducts **2** and **3** of 4-bis(trimethylsilyl)-amino-1,2,4,3,5-triazadiphosphole.

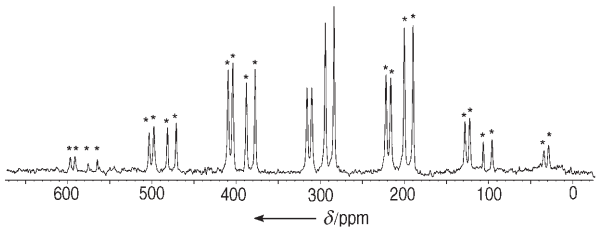

Figure 1. ^{31}P MAS spectrum of **3**. The four resonances arise from two independent molecules in the unit cell (spinning side bands are marked with asterisks).

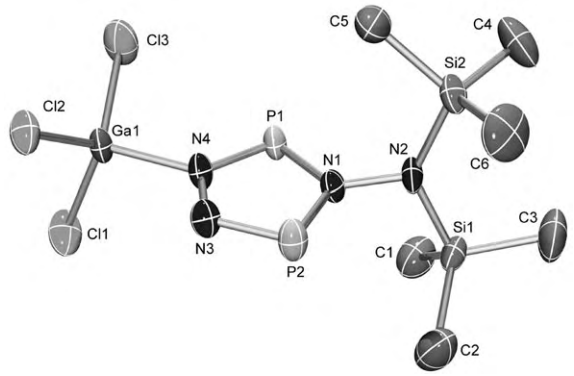

Figure 2. ORTEP drawing of the molecular structure of one independent molecule of **2** in the crystal.[9] Thermal ellipsoids with 50% probability at 200 K (hydrogen atoms omitted for clarity). Selected bond lengths [Å] and angles [°]: Ga1—N4 1.978(3), P1—N1 1.670(4), P1—N4 1.633(4), P2—N1 1.694(4), P2—N3 1.603(4), N1—N2 1.451(5), N3—N4 1.380(5); N1-P1-N4 93.2(2), N1-P2-N3 96.1(2), P1-N1-P2 116.4(2), P1-N4-N3 119.6(3), P2-N3-N4 114.8(3), P1-N1-N2 120.5(3), P2-N1-N2 122.9(3).[7b]

assign these two groups of resonances on the basis of the excellent agreement between theoretically and experimentally obtained values of the ^{31}P chemical shift tensor (δ_{iso}, δ_{aniso}, see the Supporting Information).[7a–b,9]

Crystals suitable for X-ray diffraction were obtained from a yellow hexane/CH_2Cl_2 solution of **2** after stepwise removal of solvent at −10 °C. Single-crystal X-ray studies revealed a surprising $GaCl_3$ adduct **2** of the hitherto unknown 4-bis(trimethylsilyl)amino-1,2,4,3,5-triazadiphosphole (Figure 2).[7b]

The $GaCl_3$-induced elimination of TMSCl (Scheme 1) from species **1** at ambient temperature leads to **2** quickly and in high yields (reaction time 2 h, yield > 95%). A solution of **2** in CH_2Cl_2 is stable for at least four weeks (according to ^{31}P NMR experiments). Adding yet another equivalent of $GaCl_3$ to a solution of **2** results immediately in the formation of a new species: the $GaCl_3$ diadduct **3** of 4-bis(trimethylsilyl)amino-1,2,4,3,5-triazadiphosphole (Scheme 1) as shown by ^{31}P NMR studies (CH_2Cl_2 solution: 304.6 ppm, solid (MAS): 298 ppm). The same product is formed from the reaction of **1** (1 equiv) and $GaCl_3$ (1 equiv). Removal of the solvent again results in a yellow polycrystalline powder (**3**, yield > 95%). X-ray quality crystals were obtained from a saturated solution of **3** in CH_2Cl_2 (Figure 3).[7b]

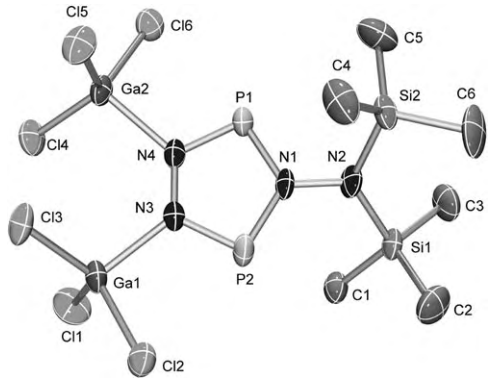

Figure 3. ORTEP drawing of the molecular structure of **3** in the crystal. Thermal ellipsoids with 50% probability at 200 K (hydrogen atoms omitted for clarity). Selected bond lengths [Å] and angles [°]: Ga1—N3 2.036(4), Ga2—N4 2.035(4), P1—N1 1.682(3), P1—N4 1.630(4), P2—N1 1.675(3), P2—N3 1.637(4), N1—N2 1.414(5), N3—N4 1.379(5); N1-P1-N4 94.4(2), N1-P2-N3 94.4(2), P1-N1-P2 117.1(2), P1-N4-N3 117.1(3), P2-N3-N4 116.9(3), P1-N1-N2 121.5(3), P2-N1-N2 121.4(3).[7b]

Both species **2** and **3** are air and moisture sensitive but stable under argon atmosphere over a long period as solids and in common organic solvents (e.g. benzene, CH_2Cl_2, ether). The yellow color of **2** and **3** vanishes rapidly when traces of H_2O are present. Compounds **2** and **3** are easily prepared in bulk and are infinitely stable when stored in a sealed tube and kept cool at 4 °C in the dark. This together with the very good solubility in almost all common organic solvents makes both compounds good precursors for further synthesis.[7a–d] Compound **2** is thermally stable up to over 130 °C, while **3** can be heated only up to 96 °C. At these temperatures decomposition starts, accompanied by a slow elimination of TMSCl (MS experiments).

Compound **2** crystallizes in the triclinic space group $P\bar{1}$ with two independent molecules in the unit cell consistent with the ^{31}P MAS NMR data (Figure 1).[7b,9] In agreement with our DFT calculations,[7c] the molecule adopts a staggered configuration with the planar five-membered P_2N_3 ring

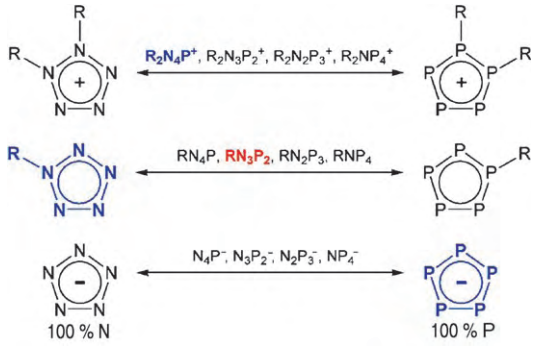
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

almost perpendicular to the Si1-N2-Si2 plane (P1-N1-N2-Si2 92.3(3), P2-N1-N2-Si1 84.7(3)°). Upon formation of the $GaCl_3$ adduct, the C_{2v} symmetry of the P_2N_3 ring is slightly distorted, with two shorter P–N bonds (P1–N4 1.633(4), P2–N3 1.603(4) Å) and two longer P–N bonds (P1–N1 1.670(4), P2–N1 1.694(4) Å). These P–N distances between 1.63 and 1.70 Å are substantially shorter than the sum of the covalent radii (d_{cov}: N–P 1.8, N=P 1.6 Å),[10,11] which indicates partial double-bond character for the P–N bonds. A similar situation is found for the N3–N4 bond (1.380(5) Å) of the P_2N_3 ring, which also lies in the range between a single and a double bond (d_{cov}: N–N 1.4, N=N 1.2 Å). The N1–N2 bond is a typical single bond, with a length of 1.451(5) Å. The Ga–N bond length of 1.978(3) Å (Ga1–N4) is slightly shorter than those found for the adducts $Cl_3Ga{\cdot}NMe_2SiMe_2NMe_2$ (2.003(5) Å),[12] $MeCl_2Ga{\cdot}H_2N{-}NHtBu$ (2.023(7) Å),[13] and the dimeric gallium amide $[\{Me_2Ga{-}N(Ph)SiMe_3\}_2]$ (2.071(2) Å).[14] The P-N-N angles (114–123°) are rather large compared to the N-P-N angles (93–96°), and the Cl-Ga-Cl angles decrease upon adduct formation (110–115°).

The structural features of **3** are very similar to those of **2** (Figure 3).[7b] The P–N, N–N, and Si–N bond lengths and all angles within the $\{P_2N_3\text{-}N(TMS)_2\}$ fragment do not change much upon addition of a second $GaCl_3$ molecule. However, as expected, the two Ga–N distances in **3** (Ga1–N3 2.036(3) and Ga2–N4 2.034(4) Å) are slightly longer than those in **2** (cf. Ga1–N4 1.978(3), Ga2–N8 1.968(3) Å)[7b,9] due to steric repulsion and a weaker donor–acceptor bond (smaller charge transfer, see below). It is interesting to note that for both adducts **2** and **3** noticeable $H_{TMS}\cdots Cl_{GaCl_3}$ contacts are found (**2**: 2.855(1); **3**: 2.840(1) Å), which are shorter than the sum of the van der Waals radii (d_{vdW}: H···Cl 2.95 Å).[7b,15] This intermolecular interaction links the molecules as a chainlike structure in the solid.

Adducts such as **2** and **3** are typical charge-transfer complexes, and the bond between the $GaCl_3$ and the RP_2N_3 fragments can be considered a donor–acceptor bond.[16] The calculated gas-phase Gibbs energy[7c] for the formation of the monoadduct, $P_2N_3\text{-}N(TMS)_2 + GaCl_3 \rightarrow$ **2** ($\Delta G_{298} = -7.8$ kcal mol^{-1}), is in agreement with the experiment since no equilibrium between **2** and the dissociated fragments could be observed in ^{31}P NMR studies. The diadduct formation, **2** + $GaCl_3 \rightarrow$ **3**, is a true equilibrium reaction at the B3LYP level of theory[7c] ($\Delta G_{298} = 0.6$ kcal mol^{-1}, Scheme 1). However, this was not evident in the ^{31}P NMR experiments since only species **3** was detected.[16] According to NBO analysis (NBO = natural bond orbital),[17] the charge transfer is about 0.16 *e* in **2** and 0.11 *e* per $GaCl_3$ fragment in **3**.[7e] The P–N σ and π bonds are highly polarized, while the adjacent N1–N2 and N3–N4 in **2** and **3** are almost ideally covalent (Figure 2 and Figure 3).[7e] The nitrogen atoms N1 and N2 have almost planar surroundings (e.g. **2**: Si2-N2-N1-Si3 174.9, Si1-N1-P1-N2 174.7°; all N-N-X (X = P, Si) angles are between 113 and 123°). Hence, as indicated by NBO analysis, the lone pair (LP) on each nitrogen atom in **2** and **3** is localized in a pure p-type atomic orbital (p-AO). The two lone pairs are also perpendicular to each other. As a consequence the p-AO lone pair of N2 atom lies in the ring plane and does not contribute to the π-electron system of the P_2N_3 ring whereas, the p-AO lone pair of N1 is part of the 6π-electron system of the P_2N_3 ring, as indicated by an investigation of the noncovalent effects.[17] There are no significant intramolecular interactions (noncovalent effects) between the bis(trimethylsilyl)amino group and the ring. Hence, neither the lone pair of the amino group nor the TMS groups stabilize the P_2N_3 ring significantly.

Over the past 50 years only a very small number of planar five-membered-ring molecules and ions containing only the elements phosphorus(III) and/or nitrogen have been isolated and fully characterized (Scheme 2). Only three are known:



Scheme 2. Binary P-N five-membered rings with P^{III} atoms. Species in blue are known and fully characterized, the triazadiphosphole is in red. (R = organic or inorganic group).

The neutral pentazole derivatives, RN_5,[18] the pentaphosphacyclopentadienide anion, P_5^-,[19] and the 1-alkyl-4-aryltetraazaphospholium cations, $R_2N_4P^+$ (as tetrachloroaluminate).[20] Additionally, the pentazolate anion, *cyclo*-N_5^-, has been detected recently.[21] Since the electronic structures of these three classes of planar ring systems and the novel triazadiphosphole all have $(4n+2)$ π electrons and therefore formally obey the Hückel rule, these compounds are related to aromatic hydrocarbons.[22]

Formally, the formation of the P_2N_3 ring in **2** and **3** might be regarded as a [3+2] cycloaddition of NNP^- and $(TMS)_2NNP^+$ ions or as a dimerization of an azide analogue of (TMS)NNP, which has been stabilized by cycloaddition followed by a 1,4-shift of one TMS group. We assume that in the first step a 1,2-elimination of TMSCl in **1** occurs assisted by $GaCl_3$. All together two TMSCl molecules are eliminated from **1**, and two condensation steps followed by adduct formation are needed. The exclusive formation of **2** and **3** demonstrates the thermodynamic preference for the five-membered framework over the six-membered alternatives and is consistent with the prominence of the known binary five-membered-ring PN cations, and polyphosphorus anions.[19,20]

In conclusion, we present here an easy, high-yielding (> 95 %) synthetic procedure and full characterization (see the Supporting Information) of the first triazadiphosphole stabilized as a $GaCl_3$ mono- and diadduct.[7a–d] Moreover, **2** and **3** are rare examples of structurally characterized Lewis acid–base adducts involving a ring atom within a PN ring.[23] Because of the astonishing stability of **2** and **3** in solution as

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

well as in solid, both compounds may have great synthetic potential, for example, as sources for binary PN or ternary PNGa species.

[16] It is known that for adducts in the solid state and gas phase, structural data and donor–acceptor energies can be quite different. Leopold et al. have indicated that the donor–acceptor bond is much shorter in the solid state than in the gas phase, and this change has been associated with the substantial dipole moment of the adduct. Intramolecular Hydroamination of Functionalized Alkenes and Alkynes with a Homogenous Zinc Catalyst**

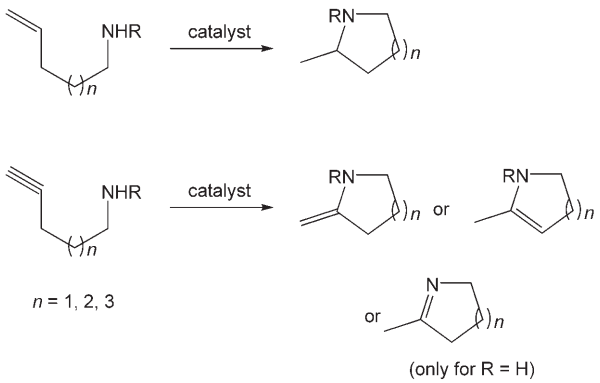
Agustino Zulys, Maximilian Dochnahl, Dirk Hollmann, Karolin Löhnwitz, Jost-Steffen Herrmann, Peter W. Roesky, and Siegfried Blechert**

Dedicated to Professor Dr. Herbert W. Roesky on the occasion of his 70th birthday

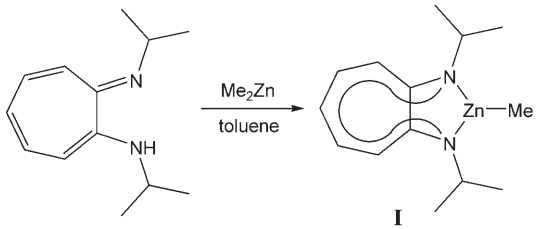


Scheme 1. Intramolecular hydroamination of alkenes and alkynes.

The catalytic addition of an organic amine N–H bond to alkenes or alkynes (hydroamination) to give nitrogen-containing molecules is of great interest to both academic and industrial researchers.[1] At present, most amines are made in multistep syntheses, and as such hydroamination offers an attractive alternative to give nitrogen-containing molecules that are important for fine chemicals, pharmaceuticals, and as useful chiral building blocks. Hydroamination can be catalyzed by d- and f-block transition metals, alkali metals,[2] as well as by calcium compounds, as shown very recently.[3] Early transition metals (Group 4[1d] and especially the lanthanides[1b]) are highly efficient catalysts for the hydroamination reaction of various C–C multiple bonds (Scheme 1), but the high sensitivity of these catalysts towards moisture and air limits their application. Furthermore, they show a very limited tolerance to polar functional groups. On the other hand, late-transition-metal catalysts offer the advantage of greater polar-functional-group compatibility; however, most of these catalysts are based on relatively expensive platinum[4] or on nickel,[5] which has only limited use in the synthesis of pharmaceuticals. Moreover, most of the late-transition-metal catalysts show limited scope, modest selectivity, and sluggish rates in their reactions with non-activated substrates. The scope of catalytic hydroamination was reviewed recently.[1]

Herein we report a new zinc-based catalyst, [*N*-isopropyl-2-(isopropylamino)troponiminato]methylzinc [{(iPr)$_2$ATI}-ZnMe] (**I**), for the hydroamination of non-activated double and triple bonds. Catalyst **I** is compatible with various polar functional groups such as ethers, amides and hydroxylamines. Furthermore, the complex is relatively robust in air and shows excellent catalytic activity. To the best of our knowledge, the only previously investigated molecular zinc compound used in catalytic hydroamination is zinc triflate, which in the presence of amines is only sparingly soluble in toluene.[6,7] Moreover, the intermolecular hydroamination of activated acetylenes by zinc-exchanged montmorillonite clay was reported recently.[8] Compared to other late-transition-metal catalysts, zinc compounds are relatively cheap and nontoxic. Furthermore Zn^{II} is stable against deactivation as it cannot be reduced to the metal under the reaction conditions.[6b]

Compound **I**, which is easily available from {(iPr)$_2$ATI}H and $ZnMe_2$ (Scheme 2), was reported previously by us as an intermediate in the synthesis of aminotroponiminate zinc



Scheme 2. Synthesis of [{(iPr)$_2$ATI}ZnMe] (**I**).

alkoxides.[9] Besides the catalytic properties, we now report the solid-state structure of **I**, which was established by single-crystal X-ray diffraction.[10] Compound **I** is a monomer in the solid state, and therefore the zinc atom has a trigonal-planar coordination sphere (Figure 1). The bond lengths and angles around the zinc center are in the expected range. In contrast to early-transition-metal–alkyl complexes, compound **I** is relatively robust towards moisture and air and thus no special experimental techniques are required for its use. This

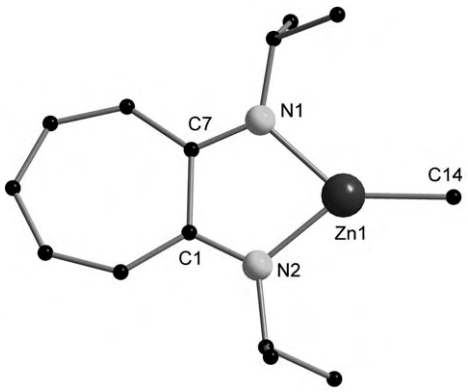

Figure 1. Solid-state structure of **I**. Hydrogen atoms have been omitted. Selected distances [pm] and angles [°]: Zn1–C14 194.1(5), Zn1–N1 198.0(4), Zn1–N2 195.5(4); C14-Zn1-N1 138.5(2), C14-Zn1-N2 139.6(2), N1-Zn1-N2 81.94(14).

behavior is very different to that of the starting material $ZnMe_2$, which is pyrophoric (see Supporting Information). The stability of compounds of the general formula [LZnMe] (L = ligand) has been described before.[11]

The goal of the current study was to explore the scope, selectivity, and functional-group tolerance of the intramolecular hydroamination reaction catalyzed by **I**. For this reason, several substrates bearing different functional groups and leading to different ring sizes were synthesized. The results are given in Table 1 and demonstrate that **I** exhibited good activity in this reaction. The best conditions were found to be when the reaction was carried out in benzene as the solvent at a temperature of 120 °C; under these conditions, total conversion occurred within reasonable reaction times in most cases. In the majority of cases it was possible to lower the catalyst loading from 10 to 1 mol %, and it was also found that the reaction rate could be accelerated by the addition of an equimolar amount (based on **I**) of $[PhNMe_2H][B(C_6F_5)_4]$ as a cocatalyst.

Interestingly, cyclization of propargyl ethers that bear a secondary amine moiety opened a new route to the corresponding 1,4-oxazines, as the double bond migrates to give the thermodynamically more stable vinyl ether. [12] A comparison of the reaction times of the α-branched amino ether **2a** and the corresponding primary amine **3a** demonstrates the greater propensity of secondary amines to react: even though the catalyst loading for substrate **3a** was 20 times higher, the reaction time was nearly double that for substrate **2a**. On the other hand, bulkier substituents, such as an isopropyl group α to the amine moiety, caused a significant decrease in the reaction rate. Nevertheless, valine derivative **4a** could be completely converted into the oxazine **4b** by the addition of 10 mol % of the catalyst/activator system.

To our surprise, the incorporation of large substituents in the β position had no beneficial effect on the cyclization. Therefore, amino benzyl ether **5a** was cyclized within the same time as substrate **3a**. Cyclic secondary amines, such as proline derivative **6a**, exhibited very high reactivity under these reaction conditions (Table 1, entry 6). Substituted amides underwent cyclization to the corresponding lactams (Table 1, entries 7 and 8). Depending on the reaction conditions, two different products were observed. When the reaction was performed in the absence of the cocatalyst, the cyclized product **7b** with an exocyclic double bond was detected. On the other hand, a 6:1 mixture of the isomerized dihydropyridone **8b** and δ-valerolactam **7b** was observed when an equal amount of the cocatalyst was added.

We were also able to cyclize methionine derivative **9a** to the dihydropyrazinone **9b**. This substrate is of particular interest as it contains both an amide functionality and a thioether group. To the best of our knowledge, this constitutes the first hydroamination of a compound bearing a thioether moiety, which is most likely incompatible with most well-known catalysts for hydroamination. The cyclization of phenylalanine propargylamide (**10a**) revealed an influence of the catalyst concentration on the structure of the product (Table 1, entries 10 and 11): When 10 mol % of the catalyst was used complete conversion into the resulting dihydropyrazinone **11b** was observed. In contrast, when only 5 mol % of the catalyst was added, only the methylene piperazinone **10b** was formed. Moreover we were able to apply our catalytic system to alkynes that bear an hydroxylamine functionality to afford cyclic nitrones (Entry 12).[13] Carbonic acid hydrazide **13a** was also cyclized to the resulting *N*-aminopiperidinone **13b**. Interestingly, the more-electron-poor nitrogen atom added preferentially to the triple bond, thus indicating that ring size has a larger influence than electronic effects on the outcome of the reaction. We were pleased to find that our system catalyzes the formation of seven-membered rings (Table 1, entry 14). It can be concluded that the rate of cyclization for aminoalkynes follows the order five-membered > six-membered ≫ seven-membered ring, consistent with classical, stereoelectronically controlled, cyclization processes.[1b]

With these results in hands, we also investigated the intramolecular hydroamination of non-activated alkenes (Table 2). However, it is well known that the hydroamination of alkenes is significantly slower than that of alkynes.[1g,3,4] Substrates that bear bulky geminal substituents β to the amino group (Thorpe–Ingold effect)[14] could be cyclized with reasonable catalyst/activator loadings of 5 mol % with moderate reaction times (Table 2, entries 1–3). Substrate **16a** was the most reactive and gave the corresponding pyrrolidine within 5 h. Compound **18a**, which is known to be a difficult substrate for this reaction, was converted into 2,5-dimethylpyrrolidine (**18b**) in modest yield.

In conclusion, compound **I** has proved to be an efficient catalyst for homogenous intramolecular hydroamination reactions and has a number of practical advantages, such as particularly high functional-group tolerance, good activity in the catalytic conversion of non-activated C–C multiple bonds, and a relatively high stability towards moisture and air. The reaction conditions allowed the manipulation of a multitude of polar functional groups, including ethers, thioethers, and amides. It is also notable that seven-membered heterocycles can be accessed. These advantages lead us to hope that **I**, which is an easily accessible reagent, will find further application as a hydroamination catalyst.

[a] Reaction conditions: amine (430 μmol), catalyst **I**, benzene (0.5 mL), 120°C. [b] Activator: $[PhNMe_2H][B(C_6F_5)_4]$. [c] Determined by ^1H NMR spectroscopy. [d] Yield of isolated product; the reaction was carried out at 100°C in toluene.

Experimental Section

I: A solution of $ZnMe_2$ (2.0 M in toluene; 0.64 mL, 1.28 mmol, 1.05 equiv) was diluted in toluene (25 mL) and cooled to −78°C. A solution of {(*i*Pr)$_2$ATI}H (250 mg, 1.22 mmol) in toluene (25 mL) was added. The reaction mixture was slowly warmed up to room temperature, and gas was evolved for about 3 h. The solution was then filtered off, the solvent was evaporated under reduced pressure. The resulting yellow solid was washed with *n*-pentane (3 × 10 mL) and dried under vacuum. Yield: 287 mg (83%). ^1H NMR (C_6D_6, 400 MHz, 25°C): $\delta = 0.00$ (s, 3H; $ZnCH_3$), 1.14 (d, $J = 6.1$ Hz, 12H; $NCH(CH_3)_2$), 3.76 (sept, $J = 6.2$ Hz, 2H; $NCH(CH_3)_2$), 6.35 (d, $J =$ 9.4 Hz, 1H; H_{Ar}), 6.57 (d, $J = 10.2$ Hz, 2H; H_{Ar}), 6.95 ppm (dd, $J =$ 9.4 Hz, 10.2 Hz, 2H; H_{Ar}); $^{13}C\{^1H\}$ NMR (C_6D_6, 100.4 MHz, 25°C): $\delta = -9.9$ ($ZnCH_3$), 24.5 ($NCH(CH_3)_2$), 48.3 ($NCH(CH_3)_2$), 111.6 (C_{Ar}), 117.7 (C_{Ar}), 134.5 (C_{Ar}), 160.2 ppm (C_{Ar}); MS (EI): *m*/*z* (%): 282 (33) $[M]^+$, 267 (51) $[M-CH_3]^+$, 204 (24) $[M-ZnCH_3]^+$.

NMR-tube-scale intramolecular hydroamination: All NMR-tube-scale reactions were prepared in an N_2-filled glovebox. The aminoalkynes (430 μmol) were dissolved in [D_6]benzene (0.5 mL) and then added to the catalyst (e.g. 4.30 μmol for 1 mol%). The mixture was injected into an NMR tube, which was removed from the glovebox and flame-sealed under vacuum. The reaction mixture was then heated to the appropriate temperature for the stated duration of time. All products were analyzed by ^1H, ^{13}C, ^{13}C DEPT, COSY, and HMQC NMR spectroscopy and by IR, MS, and HRMS when possible. The ratio between the reactant and the product was calculated by comparison of the integrations of the corresponding signals in the ^1H NMR spectra. The concentration of the catalyst was controlled by comparing the integration of a well-resolved signal for the heterocyclic product with that for a signal for a catalyst ligand.

Coordination Modes

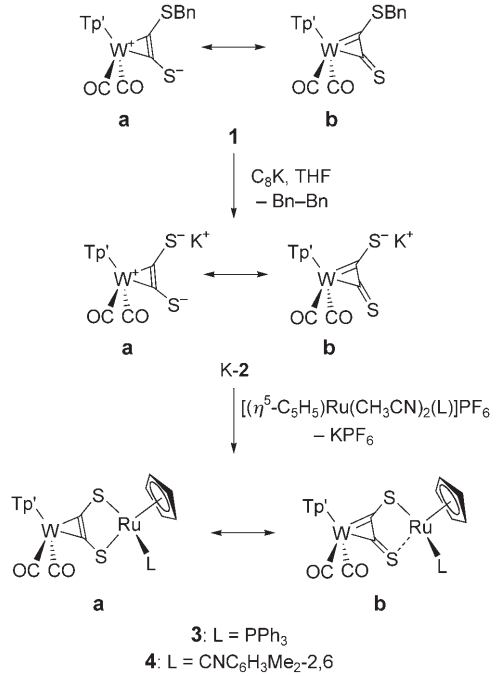
DOI: 10.1002/anie.200502489

Can Acetylenedithiolate Act as a Tetradentate Bridging Ligand?**

Wolfram W. Seidel, Markus Schaffrath, and Tania Pape*

Acetylenedithiolate is a small, intriguing bridging ligand. The four-atom dianion is potentially tetradentate and ambidentate at the same time, but its coordination chemistry has yet not been investigated. This gap is astonishing since η^2 binding at the triple bond and coordination of metal ions at the sulfur donors would allow the straightforward linkage of Werner-type complex ions with organometallic moieties. Separately, both binding options have already been demonstrated with alkynethiolates[1] and acetylenedisulfides.[2] However, the combination of the two binding modes in a bimetallic complex with acetylenedithiolate raises the question of whether the bend-back of the sulfur substituents upon coordination of the triple bond would be flexible enough to allow for chelate coordination of both thiolate donors at a second metal ion. Herein we report μ-η^2-*C*,*C*′-η^2-*S*,*S*′-binding of acetylenedithiolate.

Our approach to the controlled introduction of acetylenedithiolate in metal complexes comprises the synthesis of stable alkyne complexes with bis(benzylthio)acetylene and subsequent reductive removal of the benzyl groups in the complex. Recently we reported on the cleavage of one benzyl group from the cationic complex $[Tp'W(CO)_2\{\eta^2\text{-}(BnS)CC(SBn)\}]^+$ (Tp′ = hydrotris(3,5-dimethylpyrazolyl)borate, Bn = benzyl) leading to the neutral thioalkyne complex $[Tp'W(CO)_2\{\eta^2\text{-}(BnS)CC(S)\}]$ (**1**).[3] We found now that the second benzyl group can be cleaved similarly by the one-electron reduction of **1** with retention of the complex topology (Scheme 1). Reaction of **1** with one equivalent of C_8K in THF at −78 °C resulted in an intensively purple solution. Upon warming to ambient temperature the solution turned brown, and $K[Tp'W(CO)_2\{\eta^2\text{-}(S)CC(S)]$ (K-**2**) was isolated by precipitation.



Scheme 1. Synthesis of K-**2**, **3**, and **4**.

The identity of K-**2** was proven by IR, ESI-MS, and particularly ^{13}C NMR spectroscopy. The CO valence frequencies of K-**2** are shifted to lower energy with respect to **1** by 34 and 25 cm^{-1}, respectively. The C_s symmetry of K-**2** is reflected in the ^{13}C NMR spectrum, in which two alkyne resonances are observed only at −60 °C because of rotation of the alkyne ligand at the metal center.[4] However, the large shift difference (291 vs. 252 ppm) and the very low-field shift of one of the alkyne resonances with respect to reference values of tungsten(II) four-electron-donor alkyne complexes (cf. 180–240 ppm[4]) point to the contribution of resonance structure K-**2b** displaying a thioketo function.

To address the essential question whether $\mathbf{2}^-$ acts primarily as a mono- or a bidentate sulfur ligand, we reacted K-**2** with both $[(\eta^5\text{-}C_5H_5)RuCl(PPh_3)_2]$ and $[(\eta^5\text{-}C_5H_5)Ru(PPh_3)(CH_3CN)_2]PF_6$. Surprisingly both reactions yielded the same blue, neutral product **3**, which is characterized by a singlet at 55 ppm in the ^{31}P NMR spectrum and by slightly increased CO stretching frequencies compared to those of K-**2**. The structure determination of **3** disclosed that both sulfur donors of an individual acetylenedithiolate in $[\{Tp'W(CO)_2\}(C_2S_2)\{(\eta^5\text{-}C_5H_5)Ru(PPh_3)\}]$ (**3**) are coordinated to ruthenium in a chelate-like fashion, while the alkyne unit is stabilized by η^2 coordination with the tungsten center (Figure 1).[5]

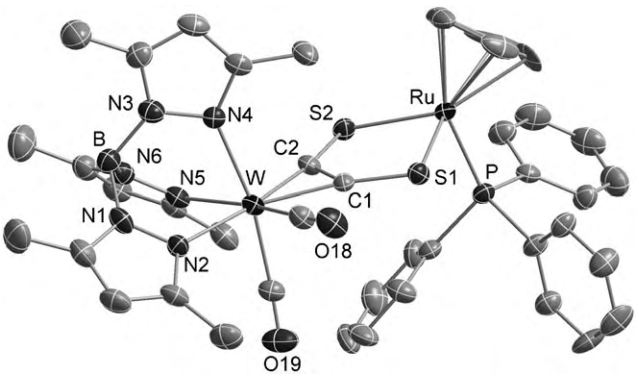

Figure 1. Solid-state structure of **3**. Selected bond lengths [Å] and angles [°]: W–C1 2.066(7), W–C2 2.049(6), C1–C2 1.391(9), C1–S1 1.665(7), C2–S2 1.677(7), Ru–S1 2.396(2), Ru–S2 2.369(2); C1-C2-S2 119.5(5), C2-C1-S1 127.5(5), S1-Ru-S2 85.5(1), Ru-S1-C1 101.3(2), Ru-S2-C2 105.2(2).

The C1–C2 alkyne bond determined to 1.391(9) Å is markedly elongated. The bond angles C1-C2-S2 and C2-C1-S1 amount to 119.5° and 127.5°, respectively, and hence they are close to the ideal value of 120° for sp^2 carbon atoms. This remarkable bend of the sulfur substituents on the coordinated alkyne is a consequence of a strong chelate effect, because the bond angles found in complexes of alkynes with free substituents are distinctively larger. Thus the corresponding C-C-S angles in **1** amount to 144.9° and 132.5°, respectively.[3] The planarity of the five-membered chelate ring is reflected in the angle sum of 539° with an acute S1-Ru-S2 angle (85.5°). The strong tendency to form the Ru-S-C-C-S chelate ring is supported by the fact that even the phosphine is substituted in $[(\eta^5\text{-}C_5H_5)Ru(PPh_3)_2Cl]$. The W–C1/W–C2 and the C1–S1/C2–S2 distances are equal within the margin of error, which is reflected in resonance structure **3a**. However, the strikingly larger C2-C1-S1 angle (compared with C1-C2-S2), which is in accordance with the longer Ru–S1 bond (2.396(2) Å) (compared to Ru–S2, 2.369(2) Å), indicates the contribution of resonance structure **3b**.

The observation of two ^{13}C NMR resonances for the CO ligands and for the alkyne carbon atoms in solution at −60 °C can be explained by the alignment of one CO ligand with the C1–C2 vector as found in the solid state. However, variable-temperature ^1H and ^{13}C NMR investigations revealed a roughly 90° oscillation process of the $\{Tp'W(CO)_2\}$ unit at the alkyne, rendering the CO ligands and the alkyne carbon atoms indistinguishable. The activation barrier was determined to be $\Delta G^*_{298} = 48.8\ kJ\,mol^{-1}$ by line-shape analysis. The similarity of the spectroscopic data of K-**2** and **3** provide evidence that the chelation of both sulfur donors to ruthenium and the resulting angle distortion at the alkyne does little to interfere with the η^2-*C*,*C*′ binding of the alkyne at the tungsten center.

The structure of the five-membered chelate ring in **3** is reminiscent of dithiolene complexes, where the backbone is stabilized by carbon-based substituents instead of a π-bound metal complex moiety. Stability in more than one oxidation state is a typical feature of dithiolene complexes.[6] Indeed, voltammetric studies with **3** show a reversible redox process at −250 mV versus Fc/Fc^+. The stoichiometric oxidation of **3** with $[(\eta^5\text{-}C_5H_5)_2Fe]PF_6$ yielding the corresponding complex **3**-PF_6 causes a distinct increase of the stretching frequencies of the tungsten-bound CO ligands ($\Delta\tilde{\nu} = 55$ and $59\ cm^{-1}$). However, the EPR spectrum of **3**-PF_6 in a frozen CH_2Cl_2/THF solution (Figure 2) displays a strong hyperfine coupling to phosphorus (43 to 70 G). This observation points to a SOMO, which is predominantly localized at ruthenium.[7]

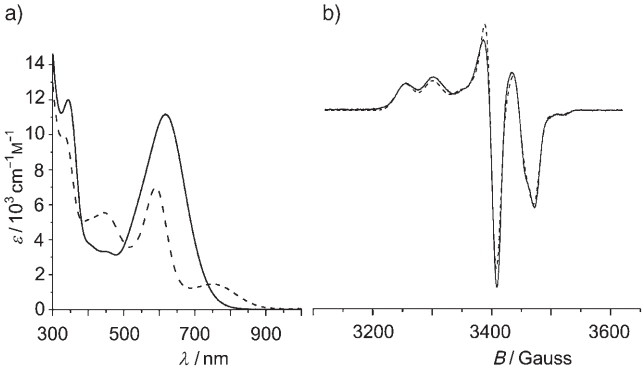

Figure 2. a) UV/Vis spectra of **3** (——) and **3**-PF_6 (-----) in CH_2Cl_2; b) X-band EPR spectrum of **3**-PF_6 in a frozen CH_2Cl_2/THF solution (experimental ——, calculated -----).

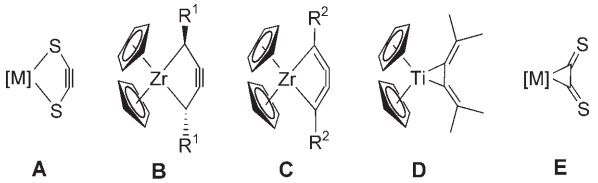
In order to compare the effect of the oxidation on both metal atoms the ruthenium center was furnished with an IR probe. For this purpose complex **4** was synthesized, in which the phosphine in **3** is replaced by 2,6-dimethylphenylisocyanide. Remarkably, the oxidation of **4** to $\mathbf{4}^+$ not only leads to a frequency increase for the tungsten-bound CO ligands, but also for the ruthenium-coordinated isocyanide ($\Delta\tilde{\nu} = 88\ cm^{-1}$). Accordingly, one-electron oxidation affects both metal centers to a comparable extent, which indicates a highly delocalized HOMO for **3** and **4**. The comparison of the electronic spectra of **3** and $\mathbf{3}^+$ (Figure 2) confirms the expected hypsochromic shift of the individual charge-transfer bands owing to the oxidation. The alteration of the ratio of the extinction coefficients points to changes in the electronic structure. The additional low-energy absorption at 758 nm in the UV/Vis spectrum of $\mathbf{3}^+$ can be interpreated as an intervalence transfer into the SOMO at ruthenium.[8]

The affirmative answer to the question in the title raises another challenging problem. Can acetylenedithiolate also act as a dithiolate chelate ligand without coordination at the triple bond? Alkyne complexes of acetylenedithiolate are related to complexes of ethenedithione according to **E** (Scheme 2) by a two-electron transfer. The smooth transition between the formulation of thiolates and thiones is obvious in



Scheme 2. Coordination modes of C_2X_2 ligands (X = S, CR_nH_{2-n}, CR).

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the complexes described herein. The rather paradoxical idea of having an acetylenedithiolate chelate ligand without coordination at the triple bond is realized in structure **A**. This type of linkage isomerism **A**/**E** has actually been established in corresponding carbon-based ligand systems by isolation of unusual zirconacyclopent-3-ynes **B**,[9] zirconacyclocumulenes **C**,[10] and the titana[3]radialene **D**.[11]

In conclusion, we present here a facile access to η^2-*C*,*C*′-acetylenedithiolate complexes and a full characterization of the first heterobimetallic complex containing acetylenedithiolate as an η^2-*C*,*C*′-η^2-*S*,*S*′-bridging ligand. Further investigations are necessary to verify the general applicability of alkyne complexes with acetylenedithiolate as dithiolate chelate ligands.

Experimental Section

K-**2**: At −78 °C C_8K (68 mg, 0.5 mmol) was added to a solution of **1** (300 mg, 0.42 mmol) in THF (10 mL) leading to an intensively purple solution. After 12 h of stirring at room temperature the now-brown solution was filtered through a pad of celite and layered with 60 mL of *n*-hexane. The brown precipitate K-**2** (42 %) formed overnight was sufficiently pure for further experiments.

3: $[(\eta^5\text{-}C_5H_5)RuCl(PPh_3)_2]$ (218 mg, 0.3 mmol) was added to a solution of K-**2** (200 mg, 0.3 mmol) in THF (30 mL). The solution turned green at ambient temperature and finally blue in the course of 12 h at reflux. Complex **3** (80 mg, 25 %) was isolated by chromatographic purification at SiO_2 using toluene as eluent. Crystallization was achieved by gas-phase diffusion of *n*-hexane into a THF solution of **3**. C,H,N analysis (%) calcd for $C_{42}H_{42}BN_6O_2PRuS_2W$: C 47.88, H 4.02, N 7.98; found: C 47.85, H 4.19, N 7.85. Complex **3** was also obtained after 12 h at room temperature using $[(\eta^5\text{-}C_5H_5)Ru(PPh_3)(CH_3CN)_2]PF_6$.

Complex **4** was obtained analogously from $[(\eta^5\text{-}C_5H_5)Ru(CNC_6H_3Me_2\text{-}2,6)(CH_3CN)_2]PF_6$ after reaction for 12 h at room temperature. C,H,N analysis (%) calcd for $C_{33}H_{36}BN_7O_2RuS_2W$ **4**: C 42.96, H 3.93, N 10.63; found: C 43.07, H 4.05, N 10.53.

3-PF_6: A solution of **3** (42 mg, 0.04 mmol) in CH_2Cl_2 (10 mL) was treated with $[(\eta^5\text{-}C_5H_5)_2Fe]PF_6$ (13 mg, 0.04 mmol). After 30 min the solvent was evaporated in vacuo, and the product was washed with Et_2O in order to remove ferrocene. Complex **3**-PF_6 was obtained as purple needles by gas-phase diffusion of Et_2O into a CH_2Cl_2 solution. Complex **4**-PF_6 was obtained analogously from **4** (37 mg, 0.04 mmol).

Spectroscopic data of K-**2**, **3**, **4**, **3**-PF_6, and **4**-PF_6 are included in the Supporting Information.

inhibitors.[1,2] Owing to the conjugated double bonds present in these isomers, they were called CLAs (conjugated linoleic acids). Food that is modified by the addition of CLAs (so-called functional foods) offers specific benefits and advantages for human health.[3] Although functional food has been at the center of traditional Chinese medicine for over 2000 years, the amount of research has only increased since the physiological benefits CLAs were proved. Most of this research has been in the field of food chemistry and is particularly anchored in a framework program of the European Union.[4,5] These studies have shown that CLAs exhibit a variety of positive qualities. Besides their anticarcinogenic and antioxidative qualities, they also influence the fat and muscle content in the body and display antiarteriosclerotic qualities. The latest theories attribute these qualities to the 9-*cis*,11-*trans* and the 10-*trans*,12-*cis* isomer.[6–10] The influence of the other CLA isomers on these qualities are largely unknown.

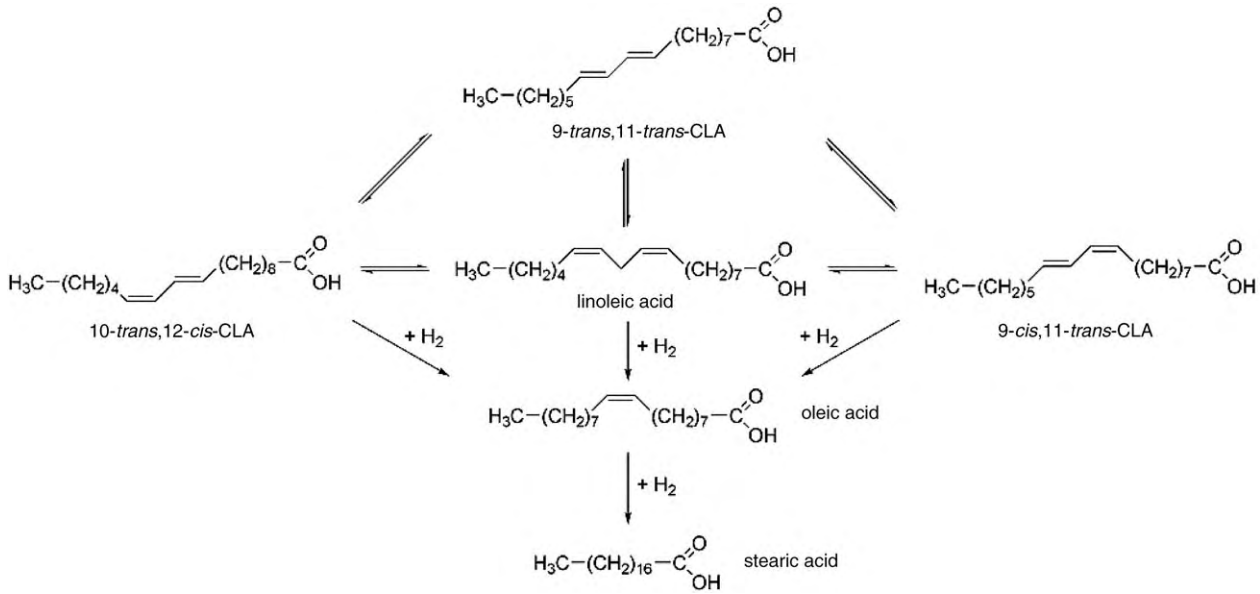
The established and industrial approach to the production of CLA is isomerization under alkaline conditions, which converts linoleic acids and their alkyl esters with alkali bases or potassium alkoxides into CLAs.[11] Subsequent neutralization with acid—typically phosphoric acid—is necessary. The alkali bases, solvents (e.g. DMSO and propylene glycol), and phosphoric acid are disadvantageous from an ecological and economic point of view. The enzyme-catalyzed production of CLA is known from biochemistry;[12] in nature, this process occurs in the rumen of cattle by means of *Butyrivibrio fibrisolvens*.[13,14] Homogeneous catalysts such as [{RhCl-$(C_8H_{14})_2$}$_2$] and [RhCl$(PPh_3)_3$] have also been applied in the isomerization of soybean oil.[15]

Very little work has been carried out on the production of CLA under heterogeneous catalysis, in which the problem of catalyst separation is avoided. This is due to the fact that the CLA have only received attention in the last few years as a result of investigations in the pharmaceutical field. On the other hand, direct CLA production is a very complex and difficult process. It is easy to find a catalyst that hydrogenates linoleic acid directly to stearic acid. In contrast, the search for a heterogeneous catalyst that favors selective isomerization to the physiologically important 9-*cis*,11-*trans* and 10-*trans*,12-*cis*-CLAs has proved to be much more challenging (Scheme 1).

In experiments described in the literature with heterogeneous ruthenium catalysts supported on Al_2O_3 and carbon, the catalyst was first covered with hydrogen, and linoleic acid was subsequently converted into CLA under nitrogen.[16] In order to produce CLA at all, this two-step reaction is necessary owing to the catalyst properties and the subsequent reactions competing with the desired isomerization. On the one hand, the excellent hydrogenation qualities of ruthenium catalysts results in the complete and rapid conversion of linoleic acid under hydrogen to give to stearic acid via oleic acid. On the other hand, it is clear that only a small quantity of hydrogen is required for the isomerization of linoleic acid into CLAs. It is therefore a fine line between the high activity of the catalyst, but under formation of unwanted hydrogenation products (oleic acid, stearic acid), and an increased selectivity towards CLAs controlled by the surface concentration of hydrogen over the catalyst.

Although we first achieved good results with ruthenium catalysts (Ru/C, Ru/Al_2O_3) in agreement with literature reports,[16] the two-step reaction (chemisorptive preadsorption of hydrogen onto the Ru catalyst followed by deactivation and chemical reaction in the semi-batch-mode under N_2) was a constant point of criticism in our considerations. The use of typical hydrogenation metal catalysts (e.g. Ni) promised no improvement, as was already discussed amply in the literature.[16c]

We describe herein a completely new and highly selective method for the synthesis of CLAs over heterogeneous silver catalysts and in the constant presence of hydrogen. According



Scheme 1. Reaction network for the hydrogenation/isomerization of linoleic acid.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

to the literature, silver is the metal with the lowest hydrogen-binding energy; experimental results and DFT calculations, although for Ag single crystals, showed weakly bound hydrogen on Ag.[17,18] Moreover, our work in the field of selective hydrogenation of polyunsaturated organic substances shows a much lower C=C hydrogenation activity over silver.[19] This reactivity is the exact prerequisite of the reaction network, which calls for a suppression of the parallel and/or consecutive hydrogenations to oleic acid and stearic acid. During isomerization experiments with silver catalysts carried out in the same way as those with ruthenium catalysts (i.e. under nitrogen after preactivation of the catalyst with hydrogen), we did not observe any conversions, as expected. As the success of the reaction depends on the surface coverage by hydrogen, as mentioned above, it seemed reasonable in the case of a metal such as silver to change the reaction procedure and to convert linoleic acid in the semi-batch-mode under hydrogen. At first, the catalyst was preactivated with hydrogen as in the case of the Ru catalysts.

We achieved surprisingly good results with respect to the direct synthesis of CLA (Table 1). Despite the simple reaction procedure under hydrogen, linoleic acid underwent 90% conversion on average after 90 min over Ag/SiO_2 using different grain fractions. The selectivity towards CLAs reached values between 60 and 67%. This shows at the same time that the particle size does not exhibit a noticeable influence on the catalytic properties. Therefore, there is no evidence of mass transport limitation in the examined area of ≤ 500 μm. The formation of the 9-*trans*,11-*trans* isomer was preferred at high conversions. The linoleic acid conversion increased with the reaction temperature, thus the physiologically important 9-*cis*,11-*trans*- and 10-*trans*,12-*cis* isomers were always the main components of the products. Furthermore, it was observed that the selectivity towards the hydrogenation products oleic acid and stearic acid decreased with decreasing substrate/catalyst mass ratio. Consequently, a desirable practical result is the increase in isomerization/hydrogenation ratio. From the selectivity–conversion data, CLA yields of up to 60% can be calculated, depending on the reaction conditions applied. Furthermore, the conversion of linoleic acid was carried out without previous contact of the Ag catalyst with hydrogen; this occurred primarily at the beginning of the reaction by switching from nitrogen to H_2. These experiments delivered the same degrees of conversion and selectivity as those with preactivation.

To understand the different effects of hydrogen on the Ru catalyst (hydrogenation to stearic and oleic acid) and the Ag catalyst (isomerization to 9-*cis*,11-*trans*- and 10-*trans*,12-*cis*-CLA), calorimetric experiments of H_2 adsorption were carried out with these catalysts. As seen in Figure 1a, at first an irreversible hydrogen adsorption occurs at the ruthenium catalyst. A reversible adsorption can be recognized only beyond the appearance of a saturation point (after the sixth pulse). The adsorption heat of the hydrogen determined from the calorimetric experiments has been estimated to about 90 kJ mol^{-1} from which a Ru–H bond strength of approximately 260 kJ mol^{-1} can be calculated.[20] On the silver catalyst (Figure 1B) only reversible hydrogen adsorption appears; an irreversible chemisorption could not be verified.[21] Therefore, we can distinguish between strongly adsorbed hydrogen on ruthenium and weakly adsorbed hydrogen in the case of the silver catalyst.[22] These findings suggest that the differences in the reactivity/selectivity patterns (hydrogenation activity on Ru versus isomerization activity on Ag) are based on differences in the hydrogen adsorption behavior of the active metal catalyst. It is clear that the weakly bound hydrogen plays a key role in the selective isomerization of conjugated double bonds (to CLA). A very similar situation is present in the case of the control of the intramolecular selectivity with respect to the hydrogenation of conjugated C=C–C=O double bonds.[19] With weakly chemisorbed hydrogen, a discrimination of the hydrogenation of the C=O- in contrast to the C=C-bond is possible; the latter is hardly hydrogenated by the weakly bonded hydrogen.[19,23] For the conversion of linoleic acid in the presence of H_2, an addition–elimination mechanism according to Horiuti–Polanyi[16g,20] is assumed, which is typical for the isomerization of C=C-double bonds in alkenes and alkadienes (Scheme 2). According to this mechanism, the selectivity of the reaction is decided by the type of reaction of the half-hydrogenated

Table 1: Catalytic properties of Ag/SiO_2 in the conversion of linoleic acid.[a]

Conditions	X_{LS} [%]	$S_{9\text{-}cis,11\text{-}trans}$ [%]	$S_{10\text{-}trans,12\text{-}cis}$ [%]	$S_{9\text{-}trans,11\text{-}trans}$ [%]	$S_{hydr.}$[e] [%]	S_{NP}[f] [%]	Σ_{CLA}[g] [%]	CLA/Hydr.
Variation of catalyst particle size:[b]								
< 63 μm	90	15	13	32	19	21	60	3.2
63–200 μm	91	20	14	33	17	16	67	3.9
200–500 μm	86	20	14	33	20	13	67	3.4
Variation of the temperature:[c]								
383 K	35	25	19	15	31	10	59	1.9
398 K	44	29	19	13	33	6	61	1.8
