## Iron-Catalyzed Reductive Radical Cyclization of Organic Halides in the Presence of NaBH<sub>4</sub>: Evidence of an Active Hydrido Iron(I) Catalyst\*\*

Audrey Ekomié, Guillaume Lefèvre, Louis Fensterbank,\* Emmanuel Lacôte, Max Malacria, Cyril Ollivier,\* and Anny Jutand\*

Radical chain reactions have become a very useful tool for organic synthesis.<sup>[1]</sup> Organotin hydrides stand out as the leading mediators for these processes. However, organotin hydrides generate toxic by-products that are extremely difficult to remove at trace level.<sup>[2]</sup> Currently, an actively pursued goal in radical chemistry is the discovery of alternatives to tin hydride mediators.<sup>[3–5]</sup> Hydrides of other main-group elements including silicon,<sup>[3a]</sup> boron,<sup>[3c,4e-h]</sup> gallium,<sup>[4b]</sup> and indium<sup>[4a-d]</sup> as well as hydrides of transition metals have been examined.<sup>[6]</sup>

In this context, we became interested in exploring the reactivity of iron hydrides. Iron is abundant, cheap, and has low toxicity. Although organoiron catalysis is a very active field,<sup>[7]</sup> iron hydride radical chemistry is still in its infancy.<sup>[8]</sup> Iron is known to accommodate low oxidation states,<sup>[9-12]</sup> and thus we decided to investigate iron(II) catalysts in the presence of NaBH<sub>4</sub> for the direct reduction and cyclization of organic halides. The mechanism of the reaction was investigated by means of electrochemistry (Scheme 1).

In a typical experiment, a solution of iodoalkene  ${\bf 1a}$  in acetonitrile (0.5 m) was treated with FeCl<sub>2</sub> (10 mol%) and NaBH<sub>4</sub> (1.5 equivalents) at 50 °C under argon for 16 hours; the bicyclic product  ${\bf 2a}$  was isolated in 73% yield (Scheme 2). Control experiments with  ${\bf 1a}$  confirmed that both the iron salt and NaBH<sub>4</sub> were required for the transformation.

Secondary iodides 1b and 1c were converted into the corresponding bicyclic compounds 2b and 2c in good and

**Scheme 1.** Iron(II)-mediated reductive cyclization of 3-iodo-2-(allyloxy)-tetrahydropyran in the presence of NaBH<sub>4</sub>.

**Scheme 2.** Optimization of reaction conditions for the  $FeCl_2$ -mediated cyclization of iodoalkene 1a in the presence of  $NaBH_4$ .

moderate yields, respectively (Table 1, entries 1 and 2). A small amount of unsaturated acetal 2c' was formed together with the expected product 2c.[13] Primary iodoalkene 1d gave the 5-exo product 2d (70%; Table 1, entry 3). The O-homoallyl derivative 1e gave the 6-exo product 2e (Table 1, entry 4), which was obtained in relatively low yield, together with the directly reduced compound 2e', thus showing, as expected, that the 6-exo-trig cyclization is less favored than the 5-exo-trig cyclization. [14] The iodoalkyne 1 f gave 2f through a 5-exo-dig cyclization (52%; Table 1, entry 5). The method was successfully extended to the reduction of tertiary iodide 1g (94%; Table 1, entry 6) and aryl iodides **1h** (96%; Table 1, entry 7). Similarly, the ethyl 4bromobutyrate 1i and 4-bromopiperidine derivative 1j gave the reduced ethyl butyrate 2i and piperidine 2j in 85% and 84% yield, respectively, (Table 1, entries 8 and 9).[15] The reaction of primary bromoalkene 1k and secondary bromoalkene 11 led to cyclopentane 2k (78%; Table 1, entry 10) and hexahydrofuropyranyl derivative 2a (70%; Table 1, entry 11), respectively.

The generation of bicycle 2a (R'H) from 1a (RI) probably proceeds through a mechanism involving the generation of a radical 3 (R') by reduction of 1a (Scheme 3), followed by a 5-exo-trig intramolecular attack of the radical onto the C=C bond; the resulting radical 4 (R'') is then converted into the reduction product R'H.

When NaBD<sub>4</sub> was used as the stoichiometric reductant, [D]-2a was isolated with greater than 95% incorporation of

[a] The major diastereoisomer (as depicted) was assigned by analogy with literature data. [b] The diastereomeric ratio was determined by <sup>1</sup>H NMR analysis. [c] A 36:64 mixture of the product derived from the direct reduction of 1c and a product derived from isomerization of 2c' (8% yield overall) was also isolated. [d] Yield based on <sup>1</sup>H NMR analysis with sulfolene as an internal standard.

Scheme 3. Radical pathway in the reductive cyclization of 1a.

Scheme 4. Deuterium-labelling experiment.

deuterium at one of primary C-H bonds (Scheme 4). In contrast, no deuterated product was detected when the reaction was carried out with NaBH<sub>4</sub> in CD<sub>3</sub>CN. This rules out any hydrogen atom transfer from the solvent and suggests that the hydrogen atom in  $\bf 2a$  might come from  $\bf BH_4^-$  directly, from an in situ formed derivative of BH<sub>4</sub>-, or from an iron hydride generated by hydride transfer from BH<sub>4</sub><sup>-</sup> (see below).

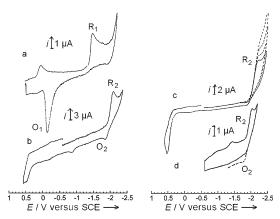

The iron species that was responsible for the reaction was unknown. It could be either the Fe<sup>II</sup> species that is added to the reaction or a reduced derivative that is generated in the presence of NaBH<sub>4</sub>. Fe<sup>I</sup>, [9,10] Fe<sup>0</sup>, [10,11] and Fe<sup>-II</sup>[12] species have been reported. Electrochemical techniques appeared well suited for obtaining insight into the mechanism of the reaction.<sup>[10,16]</sup> Indeed, iron complexes can be characterized by their reduction/oxidation potential. Moreover, their concentration in solution can be quantified by their oxidation/ reduction current.[16]

The cyclic voltammetry (CV) of FeCl<sub>2</sub> in acetonitrile did not give a clean voltammogram because of the lack of stabilizing ligands.  $[FeCl_2(dppe)_2]$  (dppe = 1,2-bisdiphenylphosphinoethane)<sup>[17]</sup> was thus tested. The reaction of **1a** (1 mmol) with [FeCl<sub>2</sub>(dppe)<sub>2</sub>] (10 mol%) and NaBH<sub>4</sub> (1.5 equivalent) in acetonitrile was allowed to proceed for 4 hours at 50°C and led to the expected product 2a in 77% yield (Scheme 5). This result suggests that [FeCl<sub>2</sub>(dppe)<sub>2</sub>] is a valid model catalyst for mechanistic investigation.

Scheme 5. [FeCl<sub>2</sub>(dppe)<sub>2</sub>]-mediated reductive cyclization of iodoalkene 1a in the presence of NaBH<sub>4</sub>.

The CV of [FeCl<sub>2</sub>(dppe)<sub>2</sub>] in acetonitrile (4 mm) exhibited an irreversible reduction peak at  $E^{P}_{R1} = -1.47 \text{ V}$  versus the standard calomel electrode (SCE; Figure 1a). A broad oxidation peak characteristic of an iron(0) species that is adsorbed at the electrode surface was observed at O<sub>1</sub> on the reverse scan (Figure 1a). The reduction peak of [FeCl<sub>2</sub>- $(dppe)_2$ ]  $(E^p_{R1} = -1.47 \text{ V})$  disappeared upon addition of NaBH<sub>4</sub> (1 equivalent) and a new reduction peak was observed at  $E^{P}_{R2} = -1.99 \text{ V}$ . The new peak was assigned to the reduction peak of the 18 electron complex [HFeCl-(dppe)<sub>2</sub>] by comparison to an authentic sample (Figure 1 b).<sup>[17]</sup> The latter was irreversible at the scan rate of 0.5 V s<sup>-1</sup> but became partly reversible at a higher scan rate (5 V s<sup>-1</sup>, see O<sub>2</sub> at  $E^{p}_{O2} = -1.90 \text{ V}$  in Figure 1b). Therefore, [HFeCl(dppe)<sub>2</sub>] undergoes a one-electron reduction to the anionic 19 electron

**Figure 1.** Cyclic voltammetry performed at a gold disk electrode (d=1 mm) at 22 °C in acetonitrile containing  $nBu_4NBF_4$  (0.3 M) as the supporting electrolyte. a) Reduction of [FeCl<sub>2</sub>(dppe)<sub>2</sub>] (4 mM) at a scan rate of 0.5 Vs<sup>-1</sup>. b) Reduction of [HFeCl(dppe)<sub>2</sub>] (4 mM) at a scan rate of 5 Vs<sup>-1</sup>. c) Reduction of [HFeCl(dppe)<sub>2</sub>] (4 mM) at a scan rate of 5 Vs<sup>-1</sup> in the presence of increasing amounts of **1a** (1 equiv, solid line; 2, 3, and 4 equiv, dashed lines). d) Reduction of [HFeCl(dppe)<sub>2</sub>] (4 mM), (solid line); reduction of [HFeCl(dppe)<sub>2</sub>] (4 mM) in the presence of NaBH<sub>4</sub> (2 mM) at a scan rate of 0.5 V.s<sup>-1</sup> (dashed line).

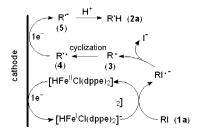

complex  $[HFe^{I}Cl(dppe)_{2}]^{-}$ , which is oxidized at the voltage corresponding to the  $O_{2}$  peak and is moderately stable within the time scale of the CV.

Iodoalkene 1a, analyzed as a solution in acetonitrile, was not reduced up until -2.5 V. The addition of 1a to [HFeCl-(dppe)<sub>2</sub>] resulted in a lack of reversibility in reduction/ oxidation events at a scan rate of 5 Vs<sup>-1</sup> (Figure 1c). The oxidation peak O<sub>2</sub> of [HFe<sup>I</sup>Cl(dppe)<sub>2</sub>]<sup>-</sup> disappeared whereas the reduction peak current of [HFeCl(dppe)<sub>2</sub>] at R<sub>2</sub> increased with increasing amounts of 1a (from one to four equivalents; Figure 1c). From these experiments, one deduces that the one-electron reduction of [HFeCl(dppe)<sub>2</sub>] gives the anionic hydrido Fe<sup>I</sup> complex [HFe<sup>I</sup>Cl(dppe)<sub>2</sub>] which transfers one electron to 1a to generate the radical anion 1a- and [HFeCl(dppe)<sub>2</sub>]. [HFeCl(dppe)<sub>2</sub>] again undergoes reduction in the diffusion layer at the electrode, thus giving rise to a catalytic-reduction current, which is observed at R<sub>2</sub> (Figure 1c). A preparative-scale electrolysis of a solution of **1a** (0.4 mmol) in the presence of [HFeCl(dppe)<sub>2</sub>] (10 mol %) in acetonitrile (12 mL) was performed at the controlled reduction potential of  $[HFeCl(dppe)_2]$  (-2 V, Scheme 6). After the passage of 85 Cb (2.2 F), the electrolysis gave the expected product 2a in 50% yield.

**Scheme 6.** [HFeCl(dppe) $_2$ ]-mediated electroreductive cyclization of 1a.

These results suggest that [HFeCl(dppe)<sub>2</sub>] is a precatalyst, the reduction of which at the very beginning of the electrolysis to  $[HFe^{I}Cl(dppe)_{2}]^{-}$  allows the activation of **1a** by electron

transfer. A catalytic cycle is proposed for the cyclization of 1a (Scheme 7). The passage of two electrons per mole of substrate indicates that the cyclized radical R' (4) is reduced at the cathode to generate the anion R' (5), which is then protonated to give 2a. This mechanism is reminiscent of the radical cyclization of unsaturated  $\alpha$ -bromoesters by electrochemically generated nickel(I) complexes. [18,19]

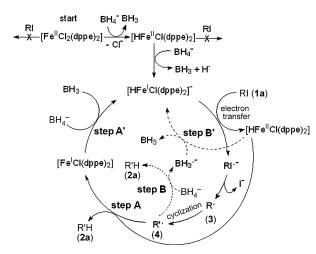

**Scheme 7.** Mechanism of the electroreductive cyclization of 1a catalyzed by electrogenerated [HFe<sup>I</sup>Cl(dppe)<sub>2</sub>]<sup>-</sup> in CH<sub>3</sub>CN.

The mechanism of the catalytic reductive cyclization performed in the presence of the chemical reductant NaBH<sub>4</sub> was then investigated (Scheme 5). In the presence of a stoichiometric amount of [FeCl<sub>2</sub>(dppe)<sub>2</sub>] and in the absence of NaBH<sub>4</sub>, **1a** did not undergo cyclization to give **2a**. In contrast, the cyclization did occur in the presence of a catalytic amount of [FeCl<sub>2</sub>(dppe)<sub>2</sub>] (10 mol %) and NaBH<sub>4</sub> (1.5 equivalents; Scheme 5). Thus, [FeCl<sub>2</sub>(dppe)<sub>2</sub>] is not the active catalyst. Similarly, no reaction was observed between [HFeCl(dppe)<sub>2</sub>], present in a stoichiometric amount, and **1a**, thus also ruling out [HFeCl(dppe)<sub>2</sub>] as being the active catalyst. As expected, **1a** underwent cyclization in the presence of a catalytic amount of [HFeCl(dppe)<sub>2</sub>] (10 mol %) and NaBH<sub>4</sub> (1.5 equivalents), thus delivering **2a** in 63 % yield (Scheme 8).

Scheme 8. [HFeCl(dppe)<sub>2</sub>]-mediated cyclization of iodoalkene 1a in the presence of NaBH<sub>4</sub>.

These experiments show that  $[HFeCl(dppe)_2]$  only becomes active upon its reduction by  $NaBH_4$ . The addition of  $NaBH_4$  (0.5 equivalents) to a solution of  $[HFeCl(dppe)_2]$  in acetonitrile (4 mm) resulted in an increase of the oxidation peak of  $[HFe^ICl(dppe)_2]^-$  at  $O_2$  (Figure 1 d), thus establishing that  $NaBH_4$  transfers one electron to  $[HFeCl(dppe)_2]$  to generate the active species  $[HFe^ICl(dppe)_2]^-$ . This active species then activates  $\bf 1a$  by single electron transfer (SET) to give  $\bf 1a^{--}$  (Scheme 9), which eventually gives  $\bf 2a$ .

The formation of [D]-2a in the presence of NaBD<sub>4</sub> (Scheme 4) suggests that the radical R'· (4), which is formed through intramolecular cyclization, abstracts a hydrogen atom from [HFe<sup>II</sup>Cl(dppe)<sub>2</sub>] (Scheme 9, step A) to generate 2a and [Fe<sup>I</sup>Cl(dppe)<sub>2</sub>], which then presumably reacts with

**Scheme 9.** Mechanism of the [HFe<sup>I</sup>Cl(dppe)<sub>2</sub>]<sup>-</sup>-catalyzed reductive cyclization of 1a (RI) to 2a (R'H) in the presence of NaBH<sub>4</sub> in CH<sub>3</sub>CN.

 $BH_4^-$  to regenerate  $[HFe^ICl(dppe)_2]^-$  (Scheme 9, step A'). However, a direct hydrogen-atom transfer from BH<sub>4</sub><sup>-</sup> to the radical 4 cannot be excluded (Scheme 9, step B). [6a,20]

Overall, the results suggest that NaBH4 is involved in a number of steps in the catalytic cycle, namely it can i) donate hydride to [FeCl<sub>2</sub>(dppe)<sub>2</sub>] in the very first step of the catalytic reaction, ii) donate hydride to [Fe<sup>I</sup>Cl(dppe)<sub>2</sub>] in a catalystturnover step of the catalytic cycle (step A') if step A takes place, iii) transfer one electron<sup>[21]</sup> to [HFe<sup>II</sup>Cl(dppe)<sub>2</sub>] to generate the key complex [HFe<sup>I</sup>Cl(dppe)<sub>2</sub>]<sup>-</sup>, or iv) transfer a hydrogen atom to substrate-derived radical 4 (step B; Scheme 9).

In conclusion, we have shown that unsaturated organic halides undergo a radical-based cyclization in the presence of an iron catalyst and NaBH<sub>4</sub> as the stoichiometric reductant. Data from electrochemical investigations suggest that the reaction proceeds though activation of the halide substrate by electron transfer. This electron transfer is mediated by an anionic hydrido iron(I) species, which is generated by reduction of the iron(II) precatalyst by NaBH<sub>4</sub>. Future work will focus on the use of other radical precursors and the incorporation of this inexpensive and environmentally friendly reaction into cascade and asymmetric reactions.

- [13] The formation of the unsaturated compound 2c' may result from a competitive radical-radical disproportionation of the intermediate radical if its lifetime is sufficiently long; the lifetime of tertiary radicals is relatively long because they are more stable than primary and secondary radicals. Inspired by the work of Oshima (see Ref [8a]) we can also suggest an alternative recombination mechanism involving the tertiary radical R and the iron(I) complex [Fe<sup>I</sup>Cl(dppe)] for the generation of the intermediate [RFe<sup>II</sup>Cl(dppe)], which could undergo a β-elimination reaction to form [HFeIICl(dppe)]. - [19] The fact that the reduction peak R<sub>2</sub> of [HFe<sup>II</sup>Cl(dppe)<sub>2</sub>] increases upon the addition of increasing amounts of RI establishes that [HFe<sup>II</sup>Cl(dppe)<sub>2</sub>] is generated at each catalytic cycle. This rules out an alternative mechanism involving an oxidative addition of RI to the 15-electron complex [HFe<sup>I</sup>Cl(dppe)]<sup>-</sup>, which can be formed upon dissociation of one dppe ligand from the 19electron complex [HFe<sup>I</sup>Cl(dppe)<sub>2</sub>]<sup>-</sup>. This oxidative addition would generate [HFe<sup>III</sup>R(I)(Cl)(dppe)]-, which would be in equilibrium with  $[HFe^{III}R(Cl)(dppe)]$ . An intramolecular carboferration reaction of the latter involving the C=C bond would generate, after C-H reductive elimination, the product R'H and [Fe<sup>I</sup>Cl(dppe)]; the latter species could then be transformed into  $[HFe^{I}Cl(dppe)_{n}]^{-}$  (n=1 or 2) after reaction with NaBH<sub>4</sub>; [Fe<sup>I</sup>Cl(dppe)] would not be transformed into [HFe<sup>II</sup>Cl(dppe)<sub>2</sub>] because of the reducing conditions. This sequence of chemical steps involving  $Fe^{I}$ ,  $Fe^{III}$ , and  $Fe^{I}$  species would not be consistent with the observed behavior of the reduction peak R2 of  $[HFe^{II}Cl(dppe)_2].$
