Received October 5, 1989

SUMMARY: In Drosophila melanogaster (Dm), polypeptidic domains have been found in different morphogenetic genes. Two types of them are characterized by the repetition of nucleotidic triplets: the M repeat (CAX), and the paired repeat (CAXCCX), In this paper we described a third type of repeat isolated from the genome of a Polychaete annelid: Owenia fusiformis. This repeat is characterized by the repetition of the triplet CCPurine. Phylogenetic studies showed the presence of this repeat in all the invertebrate genomes tested (eight copies in Dm genome) while we failed to detect it in vertebrate genomes.

• 1990 Academic Press, Inc.

Recent studies on gene structure have clearly demonstrated that a great number of genes can be subdivided into functional domains that are subjected to recombination and independent assortment (1,2). Thus any multifunctional gene might share sequences with several gene sets (3). A typical example is provided by the association of different domains in homeotic genes (4,5,6). Several domains have already been described, among which the first one was the "homeobox" (4,7). Then, other domains constituted by highly repeated sequences were evidenced, mainly in the *Drosophila melanogaster* genome:

The M repeat or OPA repeat formed by the repetition of CAX (4,8) was present in a great number of copies.

The "paired" repeat, present in ten genomic regions, was characterized by the repetition of CAXCCG. This one was detected in two segmentation genes, "paired" and "gooseberry" (9). Finally, a GCX and GAX repeats were described in "engrailed" (10).

Previously, Lewis (11) observed in his genetic study of Drosophila melanogaster's bithorax complex, that such complex genes had probably evolved from a few ancestral genes. According earlier statements, morphogenetic genes might evolved by different recombination of a few ancestral domains. it interesting to follow the phylogenetic is distribution of these domains as previously done homeobox (4).

To look for sequences similarity between morphogenetic genes of *Drosophila melanogaster* and genomic regions of more primitive animals, we decided to screen a genomic library of *Owenia fusiformis*. This one is a marine Polychaete annelid and one

among most primitive metamerized animal living nowadays. We used as probes two distinct sequences from the Antennapedia complex: "Antennapedia" (Antp) and "Fushi-Tarazu" (Ftz) (12).

While Antp did not give any hybridization signal, allowed us to clone a new type of repeat characterized by the repetition of the triplet CCPu and its association to a putative double α helix protein structure. Phylogenetic distribution of this sequence was studied.

MATERIALS AND METHODS

Owenia fusiformis were obtained from Station Marine

Owenia fusiformis were obtained from Station Marine de Roscoff (France).

Probes were: i) a 650 bp Bam HI-Pvu II fragment from p903G clone (13) which contained a part of complementary DNA to an Antennapedia gene transcript (further refered as Antp). ii) a 1.1 Kb Pvu II fragment from pFS2, a genomic clone from the Fushi-Tarazu gene (6) (further refered as Ftz).

The genomic library was constructed by one of us (M.F.) in Dr. V. Pirotta's laboratory at the E.M.B.L. (Heidelberg, F.R.G.). This was performed by inserting partial Sau3A digestion fragments of Owenia fusiformis genome into bacteriophage L47 (14). This library was screened with [32P]labelled, nick translated probes, under classic conditions. Nitrocellulose filters were washed in 2xSSC buffer, at 42°C. DNA of hybridizing clones was prepared and subcloned into pUC 18 and 19, as well as into M13 mp18 and mp19, according to standard methods (15). Sequencing was performed according to Sanger's method (16) and genomic DNA preparation according to Mc Ginnis' (17).

RESULTS AND DISCUSSION

We screened a genomic library of Owenia fusiformis with Ftz and Antp as probes. Spreading more than three genomes, we could isolate six recombinant clones, named $\lambda 1$ to $\lambda 6$. We found by restriction mapping and hybridization analysis that $\lambda 1$ and $\lambda 6$, as well as $\lambda 2$ and $\lambda 5$ were identical. Each of the four remaining clones exhibited two Hind III fragments able to be recognized by Ftz probe, under our stringency conditions (0.5 x SSC, 50°C). Both fragments hybridized each other. Moreover, from one clone to another, these fragments could cross-hybridize. Thus, focused our work on one of them, namely $\lambda 1$. Its restriction map in pUC 18 is presented on Fig. 1. We subcloned hybridizing fragments, the 1.8 Kb Pst I-Hind III one and the 1.8 Hind III-Hind III one. These subclones were respectively named 18 and H 18. The major part of the PH 18 sequence is presented on Fig. 2. We noted the presence of 49 triplets CCPu. This repeat was surrounded by AT-rich regions. Sequence of H 18 displayed a similar CCPu, although shorter (25 triplets)(Fig. 3); This second repeat was also surrounded by AT-rich regions. Comparison of these repeats showed a high similarity percentage between them: among 68 nucleotides, only 5, all located at the In the Drosophila melanogaster Pu position, were differing. previously described repeats (M repeat = CAX, "paired" repeat = CAXCCG) exhibit some analogous features. They are GC-rich and the third variable base of the triplet is a Purine base. Concerning Ftz that we used as probe, this gene displays a CCX region (extending from nucleotide 1167 to nucleotide 1244) (6) which does not constitute a monotonous repetition. Nevertheless we compared this region from Ftz with

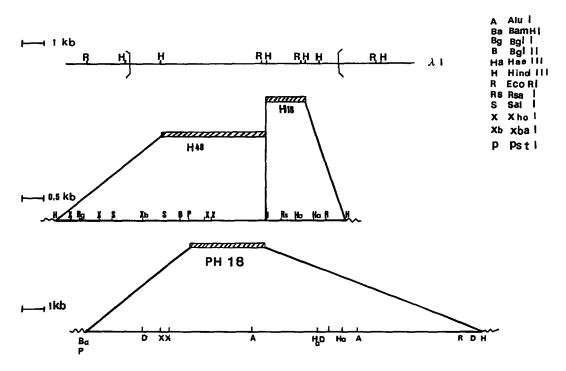

FIGURE 1: RESTRICTION MAP OF λI AND SUBCLONES. The restriction map was established with the following enzymes: Alu I (A), BamH I (Ba), Bgl II (Bg), Dra I (D), Hae III (Ha), Hind III (H), EcoR I (E) Rsa I (R), Sal I (S), Xho I (X), Xba I (Xb) and Pst I (P). The position of the different fragments subcloned into Puc vectors (H18, PH18 and H48) is indicated below the restriction map by dashed boxes. These boxes indicated the regions of homology between the λI fragments and Ftz. Brackets indicate the limits of the insert.

the CCPu sequence, (Fig. 4). We found two regions of high similarity. The richness in GC content of these similar regions was likely to account for the stability of the hybridization that we observed between Ftz and PH 18. Furthermore it might indicate the presence in the Ftz gene of an ancestral CCPu repeat which could have diverged during evolution.

In a further step, we looked for putative coding sequences, and found in pH18 two open reading frames (ORF). The first ORF (ORF1) included the CCPu repeat and encoded for a polypeptidic chain partly formed by the repetition of amino-acid Proline. The second ORF (ORF2) encoded for a highly basic polypeptidic chain. If these two ORFs are present on the same transcript, then the CCPu repeat should be read as a polyproline peptide. assumption comes from the observation that, these two ORFs are separated by two intron consensus (18)(Fig. 5a). The putative secondary structure of the polypeptide possibly encoded by ORF2 by Garnier's method (19). According to examined separated by a short β-turn potential existence of two α-helix was evidenced. (Fig. 5b). Such a structure has previously been described in several DNA binding proteins (for instance Mat lpha 1and $\alpha 2$, λ cro and rep, homeobox containing genes, ... \rangle (6,20). To go further in the interpretation of this data, it would be

interesting to determine the existence of this polypeptide *in yivo* and look for its putative DNA binding function.

To determine the occurrence of the CCPu repeat in owenia genome, genomic Southern blots were undertaken, by using DNA from a single individu. As seen in Fig. 6, ten bands hybridized under high stringency conditions with A4 (Fig. 1) as probe. Assuming two repeats by regions (as demonstrated by the hybridization pattern of all clones we isolated), we may conclude that CCPu repeat is located in 4 to 5 distinct regions

of the Owenia fusiformis genome. Therefore we can conclude that the CCPu repeat is closer in its genomic distribution to the "paired" repeat than to OPA repeat.

In order to determine the phylogenic distribution of the CCPu repeat, DNA from several species was prepared and submitted

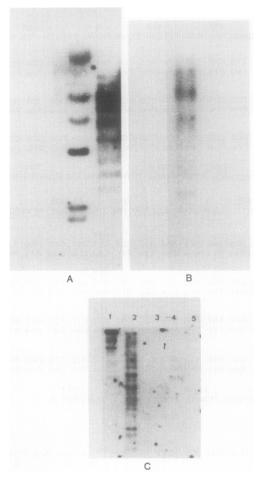

FIGURE 6: DETECTION OF CCPU REPEAT RELATED SEQUENCES IN THE GENOME OF VARIOUS ANIMALS.

Blots of Eco RI-digested DNA from Owenia fusiformis (A), Drosophila melanogaster (B), Ciona intestinalis, a tunicate (C, lane 1), Amphoxius (C, lane 2), Xenope (C, lane 3), Mouse (C, lane 4) and Man (C, lane 5) were hybridized with the Alu I fragment of PH18 (see Fig. 2) as probe. This CCPu repeat-containing fragment had been [32]P-labelled by oligopriming. Blots were washed by 0.1xSSC, at 68°C and exposed for 12 hours. Hind III digested \(\text{\text{D}}\) DNA was used as a size marker. 0.5 to 1 \(\mu\)g of Owenia DNA, 2 \(\mu\)g of Drosophila, Ciona and Amphoxius DNA and 10 \(\mu\)g of Xenope, mouse and man DNA, have been deposed. All DNAs were extracted from a single animal.

to hybridization with A4 as probe. Results are shown on Fig. 6. All tested invertebrate genomes displayed a comparable number of The greater number of bands exhibited by bands (about 10). Amphoxius pattern is likely to be due to the triplication of the genome between Urochordates and Cephalochordates, as proposed by Atkin and Ohno (21). Concerning the hybridization pattern Drosophila melanogaster, observed our washing we under conditions (0.1 X SSC, 68°C) 7 to 8 bands. Nevertheless, none of them corresponded to Fushi-Tarazu. Therefore we have to assume that A4 displayed with some drosophila genomic regions a closer similarity that it did with Fushi-Tarazu gene. Surprisingly it should be noted that no vertebrate genome displayed bands, even after a longer exposure of the film (10 fold). As a control, an was successfully hybridized, probe under the stringency conditions (data not shown). This result cannot allow us to know whether the CCPu repeat has either diverged or is absent in vertebrate genomes.

In conclusion, we cloned, from the genome of an annelid, regions formed by the repetition of CCPu triplet. Like the "paired" repeat, this new repeat is only present in a few copies the annelid genome, as well as in other invertebrates genomes. This sequence is absent or divergent in vertebrates. The biological role of this repeat might be enlighted by the isolation in the Drosophila melanogaster genome, of one gene which contained it. Moreover, because of it structural analogies with the "paired" repeat, our sequence should be checked for its involvement in traumatic regeneration of this annelid. biological system provides an alternative model for the study of morphogenetic events (22).

Acknowledgments: We are indebted to Doctors M. Akam and S. Kerridge with probes for providing us and for helpful discussion. We are thankful to Dr. V. Pirrotta for giving us the opportunity to construct the Owenia's library in his lab.
