S Supporting Information

ABSTRACT: β -Barrel proteins are folded and inserted into the outer membranes of *Escherichia coli* by the Bam complex. The Bam complex has been purified and functionally reconstituted in vitro. We report conditions for reconstitution that increase the folding yield 10-fold and allow us to monitor the time course of folding directly. We use these conditions to analyze the effect of a mutation in the Bam complex and to demonstrate the ability of the reconstituted complex to catalyze more than one round of substrate assembly.

Integral membrane proteins in the outer membranes (OMs) of Gram-negative bacteria have β -barrel structures and perform a variety of functions, including creating pores in an otherwise impermeable membrane. These outer membrane proteins (OMPs) are synthesized in the cytoplasm, translocated across the inner membrane, and transported across the aqueous periplasmic space in an unfolded state.^{1,2} They are folded and inserted into the OM by the Bam complex, which, in *E. coli*, consists of five proteins, BamA–E.^{3–6} BamA is an integral β -barrel protein that also contains an N-terminal periplasmic region composed of five polypeptide transport-associated (POTRA) domains. The other four Bam proteins are lipoproteins and associate with the POTRA domains of BamA.⁷ Genetic deletions of BamB, -C, and -E can be generated, but BamA and BamD are essential. Orthologs of BamA are found in the OMs of all Gram-negative bacteria and in the mitochondria and chloroplasts of eukaryotes.^{8–11} These orthologs are also responsible for assembling β -barrels, and the mechanism by which they function is believed to be conserved.

Crystal and NMR structures have indicated that the POTRA domains of BamA can bind peptides with β -structure and may thereby template folding of substrates.^{7,12–14} Structures of the lipoprotein components of the Bam complex have led to several hypotheses about how these proteins interact with one another and with substrate OMPs.^{15–22} It has been suggested that BamB may template β -strand formation, affect the conformation of the POTRA domains to bind substrates or chaperones optimally, or channel substrates toward BamA.^{15–17} A pocket in BamD may bind the C-terminal sequence of substrate OMPs, which has been suggested to act as a targeting sequence for the Bam complex.^{18,21,23,24} To better understand the mechanism of OMP assembly, these hypotheses need to be evaluated in a functional system.

We have demonstrated that proteoliposomes containing purified Bam complex can fold and insert an OMP.²⁵ We used OmpT as the substrate OMP because it has protease activity when it is folded, we monitored cleavage of a fluorogenic peptide as a reporter of its folded state. The enzymatic, proteolytic reaction amplified the signal of folded OmpT in real time, and the folding kinetics were evaluated indirectly by using the derivative of the fluorescent signal. The activity of the Bam complex was also demonstrated in a gel-based assay using radiolabeled substrate protein, but the low (5–7%) yields of the folded product precluded direct observation of the kinetics of folding. The substrate concentrations used were also subsaturating, which made it impossible to study turnover of the Bam complex. Therefore, we have investigated how the conditions of the assay affect folding to increase the yield.

The protease activity of OmpT is dependent upon lipopolysaccharide (LPS),²⁶ but LPS is not required for the folding of OmpT. When it is omitted from the assay buffer, we observe a large increase in the folding yield as determined by comparing the amounts of folded and unfolded radiolabeled OmpT. We observe that approximately 60% of the OmpT substrate is folded in the presence of the wild-type, five-protein Bam complex after 30 min (Figure 1). No folding is observed in the absence of Bam complex, and as we previously reported, a subcomplex lacking BamB is much less efficient. We can now directly monitor the accumulation of folded OmpT over time. The kinetics of OmpT folding agree with those determined using the real-time fluorescence assay; folding occurs rapidly during the first 2 min of the experiment and is virtually complete after 10 min. Although the gel-based assay is discontinuous, it directly reports on the folding reaction and does not require that the substrate possess enzymatic activity.

The improved assay conditions allow study of Bam subcomplexes that have lower activities. We have evaluated one mutation (denoted *bamA6*) that is a duplication of Q217 and K218 in a long loop in the third POTRA domain of BamA.²⁷ This two-amino acid insertion results in the assembly of approximately 10% less of the abundant OMPs, OmpA and LamB, in the OM; a *bamB* null mutation, by comparison, more severely decreases the levels of OmpA and LamB.²⁷ The

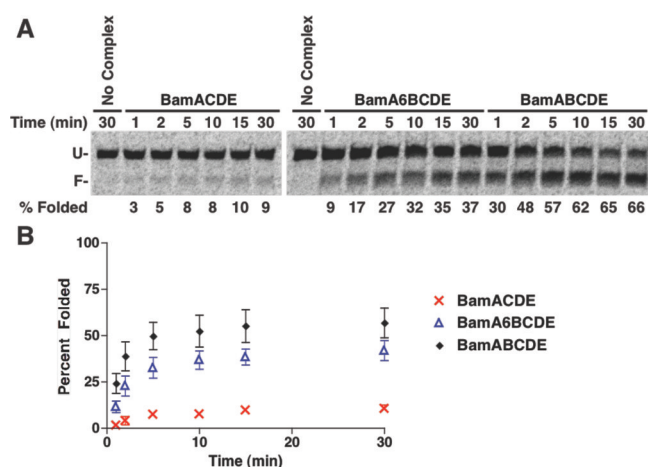

Figure 1. Folding of ^{35}S -labeled OmpT by wild-type and deficient Bam complexes can be monitored directly. (A) Autoradiogram of the time course of OmpT folding reactions in proteoliposomes containing BamACDE, BamA6BCDE, or BamABCDE. Folding reactions were stopped at the indicated time points and run on SDS-PAGE without prior boiling. The folded OmpT product migrates as the band with the lower apparent molecular weight (U for unfolded OmpT, F for folded OmpT). The percent yield in each lane was determined by comparing the densities of the folded and unfolded bands. (B) Average yield of folded OmpT produced over time in three separate experiments.

BamA6BCDE complex in proteoliposomes assembles significantly less OmpT than the wild-type complex but more than the BamACDE subcomplex (Figure 1 and Figure S1 of the Supporting Information). The proteoliposomes are identical in their composition and preparation, but they demonstrate different activities consistent with the *in vivo* behavior of their respective complexes. *In vivo*, the lower OMP levels cannot be directly attributed to a difference in Bam complex activity because the mutations induce the envelope stress response, which reduces the synthesis of OMPs. *In vitro*, however, the same amount of OmpT should be folding-competent in each of the reactions. Therefore, the BamA6BCDE and BamACDE complexes must be less functional than the wild-type complex. The *bamA6* and *bamB* null mutations directly affect the activity of the Bam complex; BamB and the long loop in the third POTRA domain of BamA play a role in binding and/or folding the substrate.

OMP substrates are delivered to the Bam complex by SurA, a periplasmic chaperone, and we previously reported that preincubating urea-denatured OmpT with SurA increases the yield of the folded product upon dilution into the proteoliposome solutions.^{25,28,29} Although the concentration of this chaperone is important in generating a folding-competent substrate, a relatively high concentration of urea also improves the folding yield. When denatured OmpT was preincubated with an excess of SurA in the presence of increasing concentrations of urea from 0.5 to 2 M, the yield of folded OmpT increased with urea concentration (Figures 2A and S2). Accordingly, when the SurA-OmpT substrate is diluted, it begins to lose folding competence. We observe that if the SurA-OmpT substrate is diluted prior to addition of the BamABCDE proteoliposomes, the folding yield decreases (Figures 2B and S3). If the interaction with SurA is dynamic, higher concentrations of urea may be necessary to maintain the substrate in a foldable state while SurA dissociates and reassociates.

Figure 2. SurA-OmpT substrate becomes less folding-competent upon urea dilution. In all three experiments, urea-denatured OmpT was preincubated with a 25-fold excess of SurA and then diluted into solutions containing BamABCDE proteoliposomes. Reactions in panels A and B were stopped at 30 min. (A) Autoradiogram of OmpT folding following preincubation with SurA and increasing amounts of urea. The folding yield increases with urea concentration until the final concentration in the reaction exceeds ~ 1 M. (B) The SurA-OmpT substrate loses folding competence over time following dilution. The preincubated SurA-OmpT substrate was diluted into buffer, and proteoliposomes containing the Bam complex were then added at the indicated time points. Less OmpT folds the longer it is allowed to incubate under dilute conditions. (C) Folding stops after ~ 10 min, but the Bam complex is still active. One aliquot of the SurA-OmpT substrate was added at time zero, and a second aliquot was added at 15 min.

Urea is required for generating a folding-competent substrate *in vitro*, but it has detrimental effects on the activity of the Bam complex. The Bam complex remains active in the presence of relatively low concentrations of urea; when a second aliquot of substrate is added 15 min into the folding reaction, it is folded as efficiently as the first aliquot (Figure 2C). However, at final urea concentrations of > 1 M, we observe a decrease in the rate of OmpT folding and in the final yield of folded product (Figures 2A and S4). Urea may cause some unfolding or dissociation of components of the Bam complex or interfere with the interaction of the substrate with the Bam complex. If the substrate is bound by formation of hydrogen bonds (perhaps by β -strand augmentation), urea could alter the affinity of that interaction.⁷ The requirement for an intermediate urea concentration is an artifact of the *in vitro* system, but it must be addressed to study turnover of the Bam complex.

We attempted to determine whether the reconstituted Bam complex can turn over by adding higher concentrations of the SurA-OmpT substrate to the Bam complex while keeping the final urea concentrations under 1 M (Figures 3, S5, and S6). The yield of folded protein increased linearly with substrate under these conditions, and at the highest concentrations, the amount of folded OmpT produced was greater than the amount of BamABCDE in the reaction mixture. Therefore, the Bam complex is capable of folding multiple OmpT molecules *in vitro*. If all of the reconstituted Bam complexes are active, these results represent ~ 1.6 turnovers of the Bam machine. However, it is possible that not all of the complexes are active and that a smaller percentage of them are responsible for the observed folding and thus are performing a larger number of turnovers. For example, in initial reconstitutions of the preprotein translocase, only $\sim 15\%$ of the reconstituted machines were active, but they were capable of catalyzing ~ 22 rounds of

Figure 3. Reconstituted BamABCDE can fold multiple OmpT molecules. (A) Autoradiogram of folding reactions of increasing amounts of SurA-OmpT substrate. OmpT was preincubated with a 10-fold excess of SurA and then diluted into solutions containing ~ 2.5 μ M BamABCDE in proteoliposomes. Reactions were stopped after 30 min. (B) The yield of folded OmpT produced in the experiment described in A. At the highest substrate concentrations, the amount of folded OmpT produced exceeds the amount of BamABCDE in the reaction mixture.

translocation.³⁰ Regardless of exactly how many turnovers the reconstituted Bam complex is performing, it is clear that no additional cellular components, including ATP, are required to complete the assembly cycle.

The efficiency and essentiality of OMP assembly make it challenging to study this process in vivo. Mutations in or deletions of the proteins in the assembly pathway often produce pleiotropic phenotypes because of gross changes in the composition of the OM; thus, the roles of the individual components of the pathway have been difficult to deconvolute. An in vitro assay allows analysis of the effects of individual proteins in isolation. The correlation between the effects of mutations or deletions in the Bam complex in vitro and in vivo indicates that the reconstituted system reasonably reproduces several aspects of the in vivo process.

We have reconstituted the folding of only one OMP substrate. We have learned that the way in which the OMP substrate is prepared significantly affects the efficiency of folding in vitro; therefore, it may be necessary to alter the preincubation conditions to study the folding and insertion of other OMP substrates. However, the reconstitution conditions recapitulate the in vivo environment of the Bam complex sufficiently well that we can distinguish the effects of mutations in its component proteins and begin to study its mechanism.
