Bioconjugate Chemistry

EDITORIAL: What's New for 1998

Professor Mitsuru Hashida of the University of Kyoto has joined the editorial staff of the journal as Associate Editor. Professor Hashida has an outstanding record of achievements in many areas of science and technology related to bioconjugate chemistry, and we are delighted to have his advice and help as the manuscript flow continues to increase.

There is good news for authors who use color illustrations: the ACS will now charge \$300 per color figure. The 1998 Instructions to Authors for *Bioconjugate Chemistry*, which may be downloaded from the worldwide web address <http://pubs.acs.org/journals/bcches/index.html>, informs authors about practical aspects of electronic manuscript submission and the preparation of illustrations.

Finally, we note the passing of Professor Edgar Haber, who made fundamental contributions to our field, and who will be remembered with friendship and admiration.

Thanks to Our Reviewers

It is a pleasure to acknowledge the contributions of the reviewers of manuscripts submitted in 1997 for publication in *Bioconjugate Chemistry*. Their unselfish service has been essential in the shaping of the eighth volume of the journal. The scientific community is fortunate that its members are willing to share their time and specialized knowledge in this way. The list of reviewers is on the following page.

Claude F. Meares

In Memoriam

Friends, colleagues, former fellows, and residents mourn the death of a preeminent scientist, cardiologist, immunologist, mentor, an ultimate renaissance gentleman and a friend: Edgar Haber, MD. Dr. Haber, the Elkan R. Blout professor of biological science at the Harvard School of Public Health and professor of medicine at the Harvard Medical School, died on October 13, 1997, at the age of 65. Dr. Haber is survived by his wife Carol Avery Haber, three sons, Justin, Graham, and Eben, and his mother and sister.

Edgar Huber was born in Berlin, Germany, in 1932 to Fred Siegfried and Dorothy Judith Haber. The family immigrated to America, and in 1944 Edgar Haber, became a naturalized U.S. citizen. He received his undergraduate degree in philosophy from Columbia College at New York in 1952 and an M.D. from Columbia College of Physicians and Surgeons in 1956. An illustrious career took a maiden flight at Massachusetts General Hospital in 1957. From 1957 to 1962, he served as a resident in internal medicine, with a 3-year sabbatical postdoctoral fellowship in the Laboratory of Cellular Physiology of Christian Anfinsen, at the National Institutes of Health. Dr. Haber's penchant for excellence in science was evident even then. While at the laboratory of Dr. Anfinsen, Ed Haber's work led to the demonstration that the amino acid sequence dictated the three-dimensional structure of ribonuclease. The importance of this finding was manifested by the awarding of the Nobel Prize for Chemistry to Dr. Anfinsen in 1972 for the establishment of the concept that the information necessary for the three-dimensional conformation of a protein is inherent in the linear sequence of the nucleotide bases of the gene. After an additional year of training in the Cardiac Department of St. George's Hospital in London, Dr. Haber was appointed the (young-

est ever) chief of the Cardiac Unit of the Massachusetts General Hospital in 1964, a full professor of Medicine at Harvard Medical School in 1971 and an endowed Higgins professor of medicine in 1982.

Unparalleled success in clinical cardiology and immunology was the hallmark of Dr. Haber's 24-year tenure as the chief of the cardiac unit at the Massachusetts General Hospital. In 1988, Dr. Haber became president of the Squibb Institute for Medical Research. After the merger of Bristol Myers and Squibb, Dr. Haber, as president of the BMS Pharmaceutical Research Institute, was instrumental in creating one of the largest pharmaceutical research organizations in the world. In 1991, Dr. Haber returned to Boston to head the Division of Biological Sciences and Center for the Prevention of Cardiovascular Disease, as Director at the Harvard School of Public Health. He was appointed Elkan R. Blout professor of biological sciences.

Dr. Haber was a fellow of the American Academy of Arts and Sciences, and a member of the Institute of Medicine of the National Academy of Sciences. He had also been showered with innumerable prestigious awards and honors. He published more than 550 manuscripts in cardiology, immunology, and molecular biology. He mentioned more than 100 postdoctoral fellows and graduate students. Ten are now department chairs, 35 division directors, and 48 full professors. "It was his pride and joy to follow the success of his charges", said Carol.

Those of us who benefited directly will deeply miss the gentle smile, inordinate patience and immense wisdom of a scientific giant and patriarch. We are indeed fortunate to be touched by the life of this illustrious mentor and friend.

5. Future Perspectives	15

1. INTRODUCTION

Gene therapy may be broadly defined as a genetic technology aimed at modifying cells for therapeutic gain. There have been many proposals to modify genetically, or to suppress gene expression in, tumor cells (1). An early suggestion was antisense oligonucleotide strategies that target specific mRNA sequences. Another approach is the "antigen oligonucleotide" approach, which aims to target DNA sequences. Other strategies involve antisense RNA (which interferes with transcription and translation, blocks RNA splicing, or induces double-stranded DNA cleavage) and antioncogene ribozymes (1, 2). Cytokine gene therapy has also been proposed in an attempt to elicit an immune response against tumor cells and thus enhance the patient's immune system to destroy the tumor. The introduction of tumor suppressor genes is also being investigated (1).

Other approaches include attempts to stabilize normal tissues, especially those that are rapidly dividing (e.g., bone marrow, duodenum) by expressing enzymes that regulate DNA repair in these tissues but not in the tumor cells. In this approach, it is hoped that the normal tissues which are most sensitive to chemotherapeutic agents can be modified to overcome drug toxicity and thus reduce the side effects of chemotherapy (3–6). Alternatively, cancer cells may be rendered more sensitive to chemotherapy or toxins, either by suppressing the expression of resistance genes [e.g., multidrug resistance (MDR)] or by introducing "suicide genes", which increase sensitivity to chemotherapeutics (1). Hence, it can be seen that it is possible to modify genetically either the malignant or nonmalignant cells for therapeutic gain. There are two suicide gene approaches. The first is a toxin gene therapy, whereby genes are introduced into malignant cells and the protein produced directs the killing of the tumor cells. The second is termed gene-directed enzyme prodrug therapy (GDEPT) (7, 8) or

Scheme 1. Cancer Gene Therapy

virally directed enzyme prodrug therapy (VDEPT) (9). This review will discuss the GDEPT system of making tumor cells more sensitive to chemotherapeutic agents. (See Scheme 1.)

In GDEPT (or VDEPT), foreign enzymes are expressed in target cells, where they can activate subsequently administered nontoxic prodrugs in to active drugs.

To achieve success in GDEPT, a number of factors must be accomplished. GDEPT requires (1) a gene expressing a nonendogenous enzyme or an endogenous enzyme that is poorly expressed in tumors, which is able to activate a prodrug; (2) a means of delivering the gene to the target cells; and (3) a prodrug.

The gene must be expressed exclusively or with a relatively high ratio in tumor cells compared to normal tissues and blood. The catalytic activity of the foreign or endogenous enzymes, which are only expressed at low concentrations, should be high enough to achieve therapeutic benefit, which may require a specific threshold to be reached. A wide range of enzyme/prodrug systems have been considered. (See section 3.)

The gene should be expressed exclusively or with relatively high ratio in tumor cells compared to normal tissues and blood and must occur in sufficient number

of cells that there be a clinical benefit (see section 4 for bystander effect). After gene delivery, prodrug administration must be delayed to permit protein expression and stable accumulation in the targeted cells, and the catalytic activity of the protein should be high enough to achieve a therapeutic benefit at these expression levels, which may require a specific threshold to be reached.

2. VECTORS USED IN GDEPT

A number of vector systems have been proposed for gene therapy. These include the RNA viruses: retroviruses (10); the DNA viruses: adenovirus, parvovirus (10, 11), and herpes simplex virus (12); cationic lipids (13, 14), peptides (15), and naked DNA (16). In addition, antibody-directed and ligand-directed (17) delivery of DNA have been proposed. There has also been a suggestion that the anaerobic bacterium *Clostridium* could be used for targeting to the hypoxic regions of tumors (18).

The majority of the proposals have been for viral vectors that have been modified to be deficient in replication functions, although the use of replication-competent viruses has also been considered (19). For applications such as *ex vivo* infections, direct administration of vectors to target tissues *in vivo* or for locoregional delivery, the ability to target malignant cells specifically may not be necessary. However, if systemic delivery is used, targeting to malignant cells is an absolute necessity. Some viruses have restricted tropisms that may be of value. For example, the minute virus of mice is oncotropic and can deliver DNA to transformed cells (20); similarly, the human parvovirus B19 targets primary hematopoietic progenitor cells. The B19 tropism can be transferred to adeno-associated virus by recombinant means (21). The two groups of viruses that have been most extensively studied, retroviruses and adenoviruses, have much less restricted tropisms, and efficient targeting in the clinic is, as yet, unaccomplished. The manipulation of these viruses to modify their tropism by altering their coat proteins is described below. Furthermore, the possibility of ensuring expression of therapeutic genes in particular subsets of cells, by modifying the regions that control gene expression and by adding promoter sequences that will only be active in malignant cells, is discussed.

The issue of transfer efficiency is of paramount importance in GDEPT. *Ex vivo* transfer efficiencies of ~100% have been achieved with viral carriers. However, *in vivo* transfer efficiencies are much lower, and conflicting data are reported.

Retroviruses mediate stable gene transfer with low potential immunogenicity. Difficulties in producing high-titer virus (maximum 10^7 cfu mL⁻¹), the fact that only dividing cells are infected, and the possibility of insertional mutations are nevertheless serious drawbacks. Direct injection of retrovirus in brain tumors resulted in low efficiency (1–3%) (22). However, 10–55% transfer efficiencies were reported in the case of direct implantation of retrovirus producer cells in such systems (22).

Adenoviruses as alternative vectors, have the advantage of producing higher titers (maximum 10^{11} – 10^{12} pfu mL⁻¹) capable of generating infections regardless of the proliferative status of the cells (23). Efficiency ≈50% (at virus titer, 10^{10} pfu mL⁻¹) was observed in mouse hepatocytes after an intravenous injection of adenovirus carrying the lac Z gene (24).

2.1. Retroviruses. Most of the retroviral vectors currently being examined for gene therapy have been derived from the Moloney murine leukaemia virus (MoMuLV). There are of two types, defined by their infection

spectrum: ecotropic, which infect murine cells only; or amphotropic, which can infect a wide range of mammalian cells, including human and murine cells. Neither ecotropic nor amphotropic viruses display tissue specificity, although different cell types within the host organism differ in their sensitivity to infection and some cells are very resistant (e.g., hepatocytes and early hematopoietic progenitor cells). Therefore, for targeting specific populations of cells *in vivo*, a means of altering retrovirus specificity would be of great value.

Mammalian type C retroviruses can infect human cells *in vitro*, but since they are inactivated by human serum, transmission of these viruses to humans is restricted. Inactivation correlates in part with the sensitivity of producer cells to lysis by human serum, so that, for example, retroviruses produced from murine or dog cells are all sensitive to human serum while viral particles from human cells are more resistant (25). Exposure of sensitive producer cells and sensitive retrovirus to human serum would presumably decrease gene transfer *in vivo*, a serious barrier for gene therapy. It had been thought that antibody-independent activation of the classical complement pathway was responsible, due to direct binding of human C1q (the first component of this pathway) to retroviral envelope proteins. However, recently, this view has been challenged, since anti- α -galactosyl antibodies in human serum inactivate retroviruses whose envelopes contain the Gal α 1–3Gal β 1–4GlcNAc-R carbohydrate epitope (26, 27). These experiments have implications for the production of retroviruses for gene therapy: soluble Gal α 1–3Gal can protect retrovirus from human serum and might be administered with the retrovirus. Alternatively, production of retrovirus from producer cell lines that do not express α -galactosyl modifications should permit production of retroviral particles with prolonged survival in human serum.

Another recent advance has been the discovery of a number of packaging cell lines that produce high-titer recombinant retroviruses, and these have been engineered to be resistant to human serum (28, 29). These cell lines will overcome the technical barriers that prevent production of the large number of viral particles required for systemic administration of retrovirus into patients. It should be remembered that, although human serum inactivates many retroviruses, both retroviruses and producer cells survive exposure to cerebrospinal fluid and fluid from the tumor bed in patients with malignant glioma (30, 31). Thus, gene transfer from nonmodified retroviruses to tissues within the central nervous system may be more successful than gene transfer to other tissues.

Retroviral host range is determined by the interaction of the retrovirus envelope (env) glycoprotein with host cell surface proteins (32). Glycoprotein env is synthesised as a precursor, which is proteolytically cleaved into two disulfide-linked proteins. In MoMuLV, one is the hydrophobic p15(E) transmembrane protein (TM) responsible for tethering env to the viral particle, and the other is the hydrophilic glycosylated surface gp70 protein that is responsible for interacting with host cell receptors.

These env host cell receptor interactions can be overcome by biochemical means to retarget virus particles. Bispecific antibody complexes have been prepared by using streptavidin to link biotinylated anti-major histocompatibility complexes (MHC) class I antibodies with biotinylated anti-ecotropic receptor antibodies and to link biotinylated anti-MHC class II antibodies with biotinylated anti-ecotropic receptor antibodies. These complexes

can act as bridges permitting infection of human cells (33). Similar bispecific complexes have permitted targeting via the epidermal growth factor receptor and the insulin receptor, but this system is not universal, since it does not work via the transferrin, high-density lipoprotein, or galactose receptors (34). However, chemical conjugation of lactose to ecotropic virus particles allows infection of human hepatic cells, presumably via the galactose receptor (35).

Some proteins, such as Thy-1 (36), CD4 (37), β 2-microglobulin, HLA DR, actin, and ubiquitin (38), can be incorporated naturally into retroviral particles and so have the potential to influence retroviral tropism. Many approaches have followed a more directed route, specifically altering env to attempt retroviral retargeting. Since structural variations of gp70 determine whether the virus has ecotropic or amphotropic host range, one approach to targeting might be to engineer the env gene to confer new tissue specificity to the env protein. Early attempts fused DNA encoding a single-chain Fv antibody fragment (scFv) specific for a hapten with DNA encoding the env glycoprotein of MoMuLV (39) and spleen necrosis virus (40). When coexpressed with a retrovirus expressing wild-type env, retrovirus particles that could bind haptens were recovered. The hapten specificity had been overlaid upon the normal cell tropism, but the presence of wild-type env meant that normal tropism was not ablated.

Similar approaches fused a scFv specific for the low-density lipoprotein receptor to MoMuLV env (41) and a scFv specific for a cell-surface antigen expressed on human colon carcinoma cells to spleen necrosis virus env (42). Other targeting motifs fused to env include a 16 amino acid peptide containing the integrin-binding motif RGD fused to avian leukosis virus env (43); erythropoietin fused to MoMuLV env (44); heregulin, a ligand for human epidermal growth factor receptors 2 and 4, fused to MoMuLV env (45); CD4, for targeting HIV-infected cells fused to MoMuLV env (46); epidermal growth factor (47); and the first 208 amino acids of amphotropic virus env fused to murine leukemia virus ecotropic env (47). In all cases, expression was in packaging cell lines that also expressed the appropriate wild-type env, resulting in viral particles with an overlaid specificity that permitting redirected cell binding, although not always productive infection (for example, the EGF-env fusion was blocked at a postbinding stage) (47).

A substantial reduction in postbinding block and up to a 100-fold increase in gene transfer efficiency were achieved by introducing spacer peptides separating the amphotropic and ecotropic moieties of an amphi/ecotropic fusion env (48). If this proves to be a general phenomenon, it might be of great value for gene therapy.

The requirement for wild-type env glycoprotein has led to the idea that it may act as a helper function (42), but it may depend upon the nature of the fused ligand. A scFv (anti-MHC class I)-ecotropic env fusion permitted retroviral binding to, and infection of, human cells, even when produced from cells that did not coexpress wild-type env (49). A strategy that may also target cells efficiently relies upon the fusion of the targeting ligand to env via a protease-sensitive linker (50). Here, cell-specific targeting was determined by the fused EGF ligand, but the ligand blocked the env-receptor interaction and gene delivery did not proceed until the linker was cleaved.

Despite the generally low efficiencies of gene transfer, the principle of retargeted retroviruses is now well established, although the criticism that the important

event may simply be to concentrate the modified retrovirus to a particular cell surface cannot be ignored (51).

2.2. Adenoviruses. The adenoviral capsid is icosahedral, each vertex terminating in a penton base structure that interacts with cellular integrins. A trimeric fiber that terminates in a trimeric knob is inserted into each penton base. The knob is the primary ligand for the cellular adenoviral receptor. Serotypes differ, in part, in the length of the fiber shaft. A chimeric fiber, with the shaft of adenovirus serotype 5 (Ad5) fused to the knob of Ad3, confers Ad3-type specificity (52). Thus it is possible to alter adenoviral specificity by manipulating the knob domain. A refinement was the introduction of a decapeptide encoding part of the gastrin releasing peptide (GRP) to the carboxy terminus (knob) of an adenoviral fiber (53). The resulting fiber could still trimerize, and the peptide was accessible to an anti-GRP antibody, raising hopes that incorporation of such a fiber into an adenovirus might permit targeting to cells expressing GRP receptors. Whether such manipulations ablate normal targeting is not clear, although it is known that there are considerable constraints in knob structure. While the shaft can tolerate large deletions, removal of just the two carboxy-terminal amino acids of the Ad2 knob results in monomeric fibers, as does addition of a 27-mer peptide (54). To date, none of these targeting strategies has been attempted for a GDEPT approach to cancer.

2.3. Transcriptional Targeting. Another area in which malignant cell targeting progress has been made is at the transcriptional level. If a tumor cell overexpresses a particular protein due to increased specific transcriptional activity of its promoter (rather than through gene duplication), this characteristic can be exploited for the GDEPT approach. Foreign genes can be cloned downstream of the promoter and introduced into appropriate tumor cells to allow specific high-level expression of the protein. Here, normal tissue that is also transduced would express much lower levels of the gene product and in an ideal system, none.

High-level expression of hepatoma-associated α -feto-protein (AFP) makes hepatocellular carcinoma (HCC) a prime target for this approach (55). Varicella zoster virus (VSV) thymidine kinase (TK) was cloned under the transcriptional control of specific promoters, the AFP tissue regulatory sequence (TRS) and the albumin (ALB) TRS, in replication defective retroviruses. Infection of Hep G2 hepatoma cells and HuH7 non-hepatoma cells, both of which express AFP and ALB, resulted in greatly increased sensitivity to the prodrug 6-methoxypurine arabinonucleoside (ara-M) (a good substrate for VZV-TK, see section 3.1). If these systems were used *in vivo*, further levels of selectivity might be expected, due to failure of retrovirus to infect nondividing hepatocytes and the lack of toxicity of ara-ATP to nondividing cells. A retrovirus expressing HSV-TK under AFP regulation control conferred ganciclovir (GCV) sensitivity to infected AFP-producing cells, but not to cells that did not express AFP (56). In addition, the presence of a glucocorticoid-responsive element in the AFP promoter permitted enhancement of acyclovir (ACV)-activated cytotoxicity by administration of dexamethasone, raising the possibility of pharmacological modulation of therapy.

Similarly, replication defective adenovirus expressing herpes simplex virus HSV-TK from AFP promoter/enhancer elements increased sensitivity of Hep G2 and HuH7 cells to GCV, but did not increase sensitivity of cells that did not express AFP (24). In murine tumor models, gene transfer by adenovirus delivery of HSV-TK

under AFP promoter/enhancer control and subsequent GCV administration led to inhibition of HCC growth (57). In nude mice, adenoviral transduction of HSV-TK expressed from a Rous sarcoma virus promoter led to nonspecific killing of human tumor cells upon subsequent administration of GCV, but using the AFP promoter restricted cell death to only those cells expressing AFP, leading to complete regression of HuH7 tumors (58). In transgenic mice, expression of HSV-TK was found to be predominantly in the liver when under the transcriptional control of an AFP/enhancer/ALB promoter fusion, demonstrating the high degree of tissue specificity of this promoter system (59). Adenovirus-associated virus delivery of this construct followed by GCV treatment was shown to kill cells expressing both AFP and ALB, but not cells expressing neither.

A range of tissue-specific promoters has been suggested for use in the GDEPT approach. Secretory leukoprotease inhibitor is expressed in a wide range of carcinomas, including lung, breast, ovarian, bladder, oropharyngeal, and colorectal, and its promoter has been used to express HSV-TK (60). Osteocalcin is a noncollagenous bone matrix protein expressed at high level in osteoblasts. Its promoter has also been used to express HSV-TK and, when delivered to cells in an adenovirus vector, results in TK activity in both murine and human osteoblast cell lines. There was no expression in a panel of murine and human nonosteoblast cell lines, and subsequent treatment with ACV led to cell death only in the targeted cells (61). Intratumoral (i.t.) injection of this adenovirus into murine osteosarcoma followed by intraperitoneal (ip) injection of ACV abolished tumor growth. For small-cell lung cancers that overexpress Myc, transcriptional control of HSV-TK by the Myc-Max response elements appears to be of value (62).

Carcinoembryonic antigen (CEA) is overexpressed by a number of carcinomas. Transfection of HSV-TK under the transcriptional control of a truncated (445 bp) CEA promoter into a CEA-producing human lung cancer cell line increased its sensitivity to GCV, while transfection into two CEA-nonproducing lines, a lung cancer cell line and HeLa cells, did not. In nude mice, significant regressions of CEA-producing lung cancer tumors expressing this CEA/HSV-TK construct were obtained after GCV treatment (63). Tumors were derived by subcutaneous (sc) implantation of CEA-expressing pancreatic carcinoma cells transduced with a retrovirus expressing HSV-TK downstream from a CEA promoter into severe combined immunodeficient (SCID) mice (64). After GCV treatment, reductions in tumor size were noted. An adenovirus expressing HSV-TK from the CEA promoter conferred GCV sensitivity to CEA-producing gastric carcinoma cell lines, but not to CEA-nonproducing cell lines or to HeLa cells (65). Optimization of expression by recombinant techniques has resulted in a small CEA promoter (important because of virus packaging limitations) that can direct high-level expression of cytosine deaminase (CD) in CEA-positive cells (66).

The c-erb B2 proto-oncogene is overexpressed in 25–30% of breast and pancreatic carcinomas, ~40% of non-small-cell lung cancers (NSCLC), 20–30% of ovarian carcinomas, and 20% of stomach and bladder carcinomas. In breast cancer, overexpression correlates with poor prognosis and resistance to chemotherapy, so a new treatment modality is very important. Overexpression of c-erb B2 occurs in part at the level of gene transcription, owing to elevated levels of a developmentally regulated transcription factor (67, 68). Expression of CD from a truncated c-erb B2 promoter has been proposed

for VDEPT in cells overexpressing c-erb B2 (69). After treatment of retrovirally transduced cells with 5-fluorocytosine (5-FC), significant cell death was noted in c-erb B2-positive cell lines but not in c-erb B2-negative cell lines. The enhancer sequence of the DF3/MUC1 gene that encodes a polymorphic high molecular weight glycoprotein can also regulate TK expression, limiting it to breast cancer cells (70). Similarly, the DF3 promoter has been used in adenovirus to confer selective expression of HSV-TK in DF3 positive breast carcinoma cell lines (71).

A problem frequently encountered using retroviral vectors containing tissue-specific promoters is interference with specificity from the viral enhancer in the 3' long terminal repeat (LTR). For example, the SV40 enhancer and the immunoglobulin heavy chain enhancer both promote gene expression in lymphoid cells. However, introduction of these promoter regions into retroviral vectors that express HSV-TK fails to enhance expression in a murine lymphoma cell line (72).

Melanin biosynthesis is restricted to melanocytes due to transcriptional regulation. The tyrosinase promoter has been used successfully for specific expression of genes in melanoma cells (73–75), as has the promoter for tyrosinase-related protein 1 (76). Recently, a truncated (769 bp) tyrosinase promoter/enhancer has been used to replace the enhancer in the 3' LTR of MoMuLV (10). The result was abolition of promoter interference, with very low expression levels of the downstream gene, interleukin 2, in nonmelanoma cell lines, but high-level expression in melanoma cell lines infected with the retrovirus. Increasing the length of the tyrosinase promoter/enhancer to 2.5 kb improved levels of gene expression further. If such an approach can be extended to other tissue-specific or cancer-specific promoters, then powerful tools for transcriptionally regulated gene transfer should become available.

3. ENZYMES/PRODRUG SYSTEMS USED IN GDEPT

Enzymes used in GDEPT should meet some specific requirements. Ideally they should be: able to catalyze scission reactions or other types of reactions (e.g., redox reactions); different from any circulating endogenous enzyme accessible to prodrug; expressed in sufficient amounts in the tumor target cells; and able to effect high catalytic activity. It may be possible to improve on the enzymes that are currently available. For example, mutants have been created in viral TK that improved the kinetics of the enzyme for the prodrugs GCV and ACV (see section 3.2) (77). Alternatively, the prodrug may be modified to make it a better substrate for the enzyme to overcome enzyme inadequacies.

The enzymes proposed for GDEPT are summarized in Table 1 and can be characterized into two classes: (a) One class consists of enzymes of nonhuman origin, e.g., viral TK, *Escherichia coli* CD, *Pseudomonas* sp. carboxypeptidase, *E. coli* purine nucleotide phosphorylase, *E. coli* xanthine-guanine phosphoribosyltransferase, and *E. coli* nitroreductase. They may elicit cell-mediated immune responses in humans, which may be an advantage, producing more extensive bystander cytotoxicity (see section 4). In experiments with cytosolically expressed herpes simplex virus thymidine kinase in mouse of malignant melanoma (78) and colon carcinoma (79), the bystander effect was greater in immunocompetent mice than in nude mice and was diminished after sublethal irradiation, implying a strong immune component. After treatment with GCV, tumor deposits had greater leukocyte infiltration than those of control animals (80) and

Table 1. Enzymes Used in GDEPT

no.	enzyme	code	source	reaction catalyzed by the enzyme	comments	refs
1	thymidine kinase	EC 2.7.1.21	herpes simplex virus	phosphorylation of GCV, ACV, and FIAU	exogenous, viral origin	82
2	thymidine kinase	EC 2.7.1.21	varicella zoster virus	phosphorylation of ara-M (6-methoxypurine); poor activity against GCV, ACV, and FIAU	exogenous, viral origin	52, 81
3	cytosine deaminase cytochrome P450	EC 3.5.4.1	<i>E. coli</i> rat	conversion of cytosine to uracil (or 5FC to 5FU) activation of oxazaphosphorines (CP, IF, etc.) by hydroxylation of the oxazaphosphorine cycle	exogenous, bacterial origin exogenous, CYP2B1, mammalian origin; its human counterpart, CYP2B6 is expressed in liver but not in tumor cells	106–108 116
4	purine nucleoside phosphorylase	EC 2.4.2.1	<i>E. coli</i>	reversible phosphorylation of purine nucleosides	exogenous; human counterpart expressed in erythrocytes but presents important differences in specificity	122
5	thymidine phosphorylase	EC 2.4.2.4	human	reversible phosphorolytic cleavage of thymidine, deoxyuridine, and their analogues	endogenous, low level in tumor cells	124
6	deoxycytidine kinase	EC 2.7.1.74	human	phosphorylation of deoxycytidine (but as well some purine deoxynucleosides)	endogenous, low level in tumor cells	125
7	carboxypeptidase G2	EC 3.4.22.12	<i>Pseudomonas</i> sp.	cleavage of the amidic bond between an aromatic nucleus and glutamic acid	exogenous, bacterial origin	127
8	xanthine-guanine phosphoribosyltransferase	EC 2.4.2.22	<i>E. coli</i>	catalyzes the conversion of hypoxanthine, xanthine, and guanine to IMP, XMP, and GMP	bacterial origin with human counterpart (HPRT)	135
9	nitroreductase		<i>E. coli</i>	reduction of aromatic nitro groups	exogenous, bacterial origin having a human counterpart with different substrate specificity	134

cytokine release from these was implicated in up-regulation of the costimulatory molecules B7 and ICAM and with enhanced host T-cell proliferative response.

(b) The other class of enzymes are of human origin and are not present or are expressed only at low concentrations in tumor cells, e.g., deoxycytidine kinase, thymidine phosphorylase, and cytochrome P450. Their main advantage resides in the reduction of the potential for inducing an immune response. However, their presence in normal tissues is likely to preclude specific activation of the prodrugs only in tumors.

The prodrug/drug system for GDEPT should also meet a number of requirements: the prodrug must be able to cross the tumor cell membrane for intracellular activation; the cytotoxicity differential between the prodrug and its corresponding drug should be as high as possible; the prodrug should be a good substrate for the expressed enzyme but not activated by endogenous enzymes in other tissues; and the active drug should be highly diffusible or be actively taken up by neighboring cells to achieve the bystander effect (see section 4). The differential between the prodrug and the active drug should be as large as possible.

The design of a prodrug with low cytotoxicity which can release highly toxic active drug requires effective knowledge of the structure–activity relationship (SAR) or preferably of the quantitative structure–activity relationship (QSAR) for the particular type of compound. For this reason, most of the prodrugs used in GDEPT to date have been compounds that have already been used clinically as anticancer agents. An additional advantage of this approach is that the pharmacological, pharmacokinetic, dosage, and safety parameters of these compounds are known.

To date there have been many different prodrugs/enzyme combinations that have been tested in various GDEPT systems. They are summarized in Table 2.

The rationale for their use and the results obtained with each of them are discussed below.

3.1. 6-Methoxypurine Arabinonucleoside (Ara-M)/Varicella Zoster Virus Thymidine Kinase (VZV-TK). The rationale for this prodrug choice was that ara-M is a good substrate for VZV-TK but a poor substrate for the three major mammalian nucleotide kinases (55, 81). The prodrug is activated by the viral enzyme to ara-M-monophosphate (ara-MMP), which is then further converted by the mammalian AMP-deaminase to inosine arabinonucleoside monophosphate (ara-IMP). This metabolite is further catalyzed by mammalian adenylosuccinate synthetase lyase into adenine arabinonucleoside monophosphate (ara-AMP), which is then phosphorylated by the AMP-kinase and subsequently by the cellular nucleoside diphosphate kinases to the anabolite adenine arabinonucleoside triphosphate (ara-ATP) (see Scheme 2). An alternate possible pathway is through hypoxanthine arabinonucleoside (ara-H), which involves the adenosine deaminase-catalyzed demethoxylation of ara-M. Ara-ATP exerts its cytotoxic effects on dividing cells, by inhibiting DNA synthesis.

In the absence of VZV-TK, traces of ara-ATP are formed presumably through the intermediate ara-H. Ara-M is converted to ara-H by adenosine deaminase and undergoes further catalysis to ara-IMP by cellular kinases.

Activation of ara-M was used to develop a therapeutic model for the treatment of HCC (55) (see also section 2.3). This model takes advantage of the transcriptional differences between normal and malignant cells, by cloning the VZV-TK gene under the transcriptional control of the

hepatoma-associated AFP, TRS, or the liver-associated (ALB) TRS. These chimeric tumor and liver specific genes were cloned into replication defective retroviral vectors and used to infect human hepatoma Hep G2 cells (expressing high levels of both ALB and AFP) and HuH7 nonhepatoma cells (expressing high levels of AFP and moderate levels of ALB). In control Hep G2 parental cells, the IC₅₀ ratio of prodrug to drug was >2000 (ara-M, IC₅₀ > 2000 μ M; araATP < 1 μ M). After infection, the IC₅₀ of araM was greatly decreased in Hep G2 cells (IC₅₀ = 3.1–6.5 μ M) as well as in HuH7 cells (IC₅₀ = 11–36 μ M). The cytotoxicity of ara-M in infected cells paralleled the level of TK activity, and metabolic studies demonstrated an increase in the levels of ara-A of 2000- and 7000-fold in the VZV-TK expressing cells (55).

3.2. Purine Nucleosides: ACV, GCV, and 1-(2'-Deoxy-2'-fluoro- β -D-arabinofuranosyl)-5-iodouracyl (FIAU)/Herpes Simplex Virus TK (HSV-TK). This system is based on the metabolic activation by the HSV-TK of certain purine nucleosides which have previously demonstrated clinical efficacy for the treatment of herpes in humans. HSV-TK catalyzes the phosphorylation of the purine nucleoside analogues ACV, GCV, and FIAU, which are poor substrates for VZV-TK (81). The conver-

sion is to the corresponding nucleoside monophosphates, which are catalyzed to nucleoside triphosphates by mammalian nucleoside monophosphate kinases. These latter nucleotides are able to inhibit DNA synthesis and thus kill dividing cells (82) (see Scheme 3). Evidence has been obtained for the inhibition of DNA polymerase by ACV-triphosphate, resulting in inhibition of the elongation of newly synthesized DNA. Incorporation of ACV-triphosphate into DNA is also a chain-terminating event, and GCV-triphosphate also acts as a chain terminator (82, 83).

Cells transfected with the HSV-TK gene and treated with GCV have been shown to die by apoptosis. This process is probably mediated by induction of DNA damage and occurs via a pathway that is independent of p53 (84).

The GCV/HSV-TK system is the most intensively studied and reported system despite some limitations. These include the fact that the bystander effect requires cell to cell contact and that deoxythymidine (dT) is a better substrate than GCV for HSV-TK. However, it represents the best example of the evolution of a GDEPT system from studies *in vitro* to the clinic.

This system is also interesting as a method to monitor therapy for the noninvasive imaging, using a gamma camera and single-photon emission tomography (SPET) with ¹³¹I-FIAU, of the HSV-TK enzyme (85). Furthermore, it may not be necessary to administer GCV systemically. In a mouse transgenic system for HSV-TK, regressions of breast tumours were obtained by direct i.t. administration of GCV (86).

The following steps, which are essential for all GDEPT systems, have been demonstrated for the HSV-TK sys-

tems: (1) demonstration *in vitro* of the stability of the transfected/infected tumor cells and their ability to express the encoded enzyme at concentrations high enough to activate the prodrug of choice; (2) demonstration *in vivo* of the viability of the transfected/infected cells, their propensity to generate tumors, and their sensitivity to the selected prodrug; (3) demonstration of a bystander effect; (4) feasibility of the delivery *in vivo* of the suicide gene.

The *in vivo* experimental studies have shown cures for GCV/HSV-TK and have led to at least 15 ongoing clinical trials involving this gene (87).

Early studies were undertaken with the GCV/HSV-TK system to substantiate the "tissue mosaicism" strategy, which represents a preventative approach (72, 88). This strategy assumes that genes which modify cellular sensitivity to various anticancer agents could be introduced prophylactically into a tissue so that some cells acquire a given gene while others do not. The result is a mosaic of cells that differ in sensitivity to the anticancer agent under consideration. If a tumor of clonal origin develops later from this tissue, therapy could be conducted at whatever sensitivity the tumor displays, while the host would be protected by those cells in the mosaic normal population that do not share this gene (88). This strategy was tested using BALB/c murine cancer cells bearing the HSV-TK gene. Treatment with GCV in clonogenic assays showed that the HSV-TK negative lines were resistant to doses 200- to >1000-fold higher than the HSV-TK positive lines. A bystander effect, called "metabolic cooperation", was shown. Treatment of TK⁺-tumor-bearing animals with GCV (150 mg/kg/injection, twice daily, for 5 days), after tumors became visible, induced complete regressions, and long-term survivors were obtained. In contrast, there were no survivors in the control animals with TK⁺ tumors that did not receive GCV or in TK⁻-tumor-bearing animals treated with GCV. Furthermore, animals treated with CP alone, in another chemotherapeutic control, also have no survivors (88). These studies were further extended using retrovirus delivery of the HSV-TK gene to murine sarcoma and lymphosarcoma cell lines. Tumors derived from these were sensitive to GCV treatment, and long-term regressions were obtained in 12 of 19 animals for sarcoma cell lines. Although regressions were seen for sarcoma cells, the tumors regrew and were found to have become TK-negative, a failure attributed to genomic instability (72).

More recent studies used a retroviral vector to transduce the HSV-TK gene into preneoplastic murine mammary epithelial cells, to yield a clonal subline sensitized to GCV. GCV treatment of tumors that arose from the transduced cells retarded tumor growth and induced durable regressions in 7 of 20 mice. GCV was ineffective in the controls (89). Unfortunately, the mosaicism strategy suffers from the drawback that the gene transfection cannot be confined to a single tissue and is therefore only justified for people with exceptionally high risks of malignancies (e.g., myelodysplastic syndrome) (72).

Further attempts focused on generating curative tumor models. Plasmid vectors have been engineered, with the TK gene under the transcriptional control of the mouse mammary tumor virus long terminal repeat (MTV-LTR). These were used to express TK in rat fibroblasts that subsequently became sensitive to ACV (60% cell death at 10 μ M and 98% at 100 μ M) or to FIAU (>60% cell death at 0.1 μ M and 98% at 3.0 μ M) (90). The cytotoxicity was proportional to the level of HSV-TK expression and dose dependent for ACV and FIAU.

The GCV/HSV-TK system was not as effective in inhibiting human pulmonary adenocarcinoma cells. No bystander effect was observed with TK-positive cells, but confluence was not achieved in these assays (91). A number of strategies involve tissue specific expression of HSV-TK, using promoter and enhancer sequences of a variety of genes (see also section 2.3).

The choice of prodrug for a given HSV-TK system is an important one. In murine and rat HCC retrovirally transduced with the HSV-TK gene, GCV treatment killed the cells at concentrations lower than the plasma level attainable in clinical trials. By contrast, ACV was less effective in GDEPT (92).

Recently, random sequence mutagenesis was used to create mutant genes of HSV-TK that render cells more sensitive to specific nucleotide analogues than cells expressing wild-type HSV-TK (77). Twenty-six HSV-TK mutants were obtained that made cells more sensitive to GCV, and 56 made cells more sensitive to ACV. Only 6 of the mutants gave increased sensitivity to both compounds. Using these genes, stable mammalian cell transfectants were obtained that were 43-fold more sensitive to GCV and 20-fold more sensitive to ACV than cells expressing wild-type HSV-TK (77).

The HSV-TK system has been tested in numerous tumor models to date. One of the earliest of these was in brain tumours, which are an interesting model for GDEPT for the following reasons: the brain represents an immunologically privileged site; the tumors are localized to the CNS; retroviral vectors integrate only into dividing cells, therefore the majority of the cells in the brain will not be infected; and GCV is able to cross the blood-brain barrier and tumor destruction is not immune-mediated (22).

In these *in vivo* studies, numerous long-term survivors have been described and tumor regressions have also been documented (93–102) (see Table 3).

HSV-TK has also been used successfully in animal model HCCs, using the AFP promoter to express HSV-TK (56–58); it has been employed for treatment of metastatic liver disease in conjunction with retroviral delivery, which does not infect normal hepatocytes (80), for the treatment of melanoma, where the tyrosinase promoter directed the expression of HSV-TK in the melanocytes (73, 74), and in a wide variety of other models (103–105).

GCV/HSV-TK is perceived to be safe for patient studies since retroviral producer cells are likely to be destroyed by the GCV treatment, and coupled with the success of the *in vitro* and animal studies, clinical studies are currently proceeding in brain tumors (nine studies), melanoma (one study), head and neck tumors (one study), and ovarian carcinomas (two studies) (87).

3.3. 5-Fluorocytosine (5-FC)/*E. coli* Cytosine Deaminase (CD). CD is an *E. coli* enzyme, which has homology to human cytidine deaminase but different substrate specificity. CD converts the nontoxic 5-FC to 5-fluorouracil (5-FU), which is then transformed by cellular enzymes to a potent pyrimidine antimetabolite. Its cytotoxicity depends upon cellular anabolism to 5-fluorodeoxyuridine-5'-monophosphate (5-FdUMP) and then to 5-fluorouridine-5'-monophosphate (5-FUMP) by endogenous enzymes (106, 107). 5-FdUMP is a powerful inhibitor of thymidylate synthase (TS) through the formation of the covalently linked ternary enzyme-inhibitor-cofactor complex, resulting in an irreversible inhibition of TS, a key enzyme for DNA biosynthesis and leading to cell death (see Scheme 4). 5-FUMP is phosphorylated to 5-fluorouridine-5'-triphosphate (5-FUTP),

resulting in the formation of “fraudulent” (5-FU)RNA. This affects RNA maturation and processing and may sometimes be an essential event for cytotoxicity. 5-FUMP is also converted into the corresponding triphosphate (5-FdUTP), by diphosphate kinase, which is incorporated into DNA, interfering with its biosynthesis.

The CD gene has an unusual protein synthesis initiation codon, GTG, and when this is mutated into an ATG, its expression in eukaryotic cells was considerably enhanced (108). Murine cells expressing CD with the altered initiation codon showed increased sensitivity to 5-FC, although in this study no bystander effect was seen. In human glioblastoma cells expressing CD, by contrast, a bystander effect was observed with 5-FC, and 5-FU could be detected in tissue culture medium of these cells. Uptake studies revealed a moderate and nonsaturable accumulation of 5-FC in tumor cells supporting its entry by passive diffusion, but a rapid efflux has also been demonstrated, suggesting a possible mechanism for the bystander effect and the reason for the accumulation of 5-FU in tissue culture medium (109).

Colorectal carcinoma models have been developed *in vivo* to test 5-FC/CD as a possible novel therapy for metastatic disease in the liver. This is suggested as an innovative alternative therapy since 5-FU is used as chemotherapeutic agent for colorectal carcinoma. Some of these models have recently been reviewed (9). In one such system both nonmetastatic colon carcinoma cells and fibrosarcoma cells expressing CD demonstrated dose-dependent sensitivity to 5-FC. In immune competent mice, these cell lines all produced tumors, but treatment with 5-FC was able to give significant tumor regressions. However, different rates of regression were observed (6–47%), depending on the parental tumor line used, indicating that tumor cells differ greatly in their sensitivity to the 5-FC/CD system. Intriguingly, the animals that

Scheme 5. Metabolism of Cyclophosphamide and Ifosfamide^a

survived the experiment were found to be resistant to subsequent rechallenge with the unmodified parental cell line used, indicating that long-term immune responses had been induced.

Another study with 5-FC/CD has indicated the efficacy of this treatment for colorectal carcinoma. Expression of CD increased the sensitivity of WiDr cells to 5-FC *in vitro*, by ~1000 fold (from $IC_{50} = 26$ mM to $27 \mu M$), while the expression of CD in these cells did not affect their sensitivity to 5-FU ($IC_{50} = 5 \mu M$) (110).

In mice bearing xenografts expressing CD, 5-FU concentration in the tumors, of $>400 \mu M$, could be generated following 5-FC administration and 5-FU could be detected in the environment surrounding the tumor (111). The liberated 5-FU may account for the bystander effect seen in this studies, where it was found that only 2% of tumor cells were needed to express CD to obtain significant regressions following 5-FC administration. These studies have also addressed dose scheduling and found that appropriate dosing could give cure rates of up to 75% in tumor-bearing mice.

Further studies were conducted in attempts to target CD expression to human models, using promoters [c-erb B2 and CEA (66, 69)], adenoviral vectors (112), and recently *Clostridium* bacteria, which grow specifically in hypoxic regions of tumors (18). Although these studies have met with encouraging success, they have also shown that whereas 5-FC/CD is effective against colorectal cancers (110) and lung adenocarcinoma (91), disappointing results were obtained with breast and pancreatic cancer models.

3.4. Oxazaphosphorines [Cyclophosphamide (CP), Ifosfamide (IF)]/Rat Liver Cytochrome P450 Isoenzyme (CYP2B1) or Human Isoenzyme (CYP2B6). CP and IF are good candidates for GDEPT since they are prodrugs and their biochemical and pharmacological properties are known. CP is activated in rat liver by microsomal CYP to 4-hydroxy-CP, which exists in equilibrium with its ring-opened tautomer aldophosphamide (113) as shown in Scheme 5.

This reaction requires NADH and O_2 , and its $K_M = 0.5$ – 1.5 mM (113). There is evidence that the significant

circulating and pharmacologically important metabolite is 4-hydroxy-CP/aldo-CP. The cytotoxic metabolite is the corresponding phosphoramidate mustard, which is generated together with acrolein from the decomposition of aldo-CP (see Scheme 5). The spontaneous β -elimination of acrolein from aldo-CP is a base-catalyzed process (involving hydroxide ions, carbonate anion, and organic or inorganic phosphate) (113). There are, however, data suggesting that 3',5'-exonucleases (and especially those related to DNA polymerase) catalyze the release of the phosphoramidate mustard, and this could be the basis of its relative specificity to the cancer cells (114). The activation of IF occurs in a similar way (115). These bifunctional alkylating agents kill both cycling and noncycling cells by cross-linking DNA.

CYP is a complex enzyme of which there are many isoenzymes with different substrate specificities. Not all of the isoenzymes are equally effective in activating CP or IF. Isoenzymes 2B1 (CYP2B1, phenobarbital inducible), 2C6 (CYP2C6), and 2C11 (CYP2C11) (the latter two are constitutively expressed) are the enzymes involved in activating oxazaphosphorines in rats. Isoenzymes 2B6 (CYP2B6) and 3A4 (CYP3A4, expression restricted to liver) are responsible for this process in humans (116). CYP2B6 and CYP3A4 are not found in tumor cells. Glioma cell lines expressing CYP2B1 were found to be sensitive to both CP ($IC_{50} = 70 \mu M$) and IF ($IC_{50} = 145 \mu M$), whereas the parental lines were resistant to millimolar concentrations of these prodrugs. The difference in the IC_{50} figures of CP and IF is in good agreement with the kinetic data, which showed that the CYP2B1 enzyme cleaves IF with an efficiency (V_{max}/K_M) 3–4-fold lower than that of CP. In xenograft models in rats tumors expressing CYP2B1 were found to be sensitive to subsequent CP administration. After 7–8 weeks, none of the rats bearing non-CYP2B1-expressing tumors had survived, whereas 19 of 20 of the animals carrying CYP2B1-expressing tumors were still alive. In these experiments a bystander effect was seen.

The CP/CYP2B1 system has also been shown to be effective in murine glioma models (117). In this system, an important observation was that the CP treatment was effective against the tumors, and there was no apparent host toxicity, despite significant levels of isoenzyme capable of activating CP present in normal liver. It should be noted, however, that since the activating enzyme in liver, CYP2C6, is distinct from CYP2B1 used in the therapy, potential problems of activation of CP by liver enzymes could be overcome by the use of CYP-isoform specific inhibitors such as 21,21-dichloroprogesterone or 3,5-dimethoxy-2,6-dimethyl-4-ethyl-1,4-dihydropyridine (118, 119).

Retroviral and adenoviral vectors have been used to transduce CYP2B1 into established intracerebral gliomas in rats resulting in significantly prolonged survival of the animals after treatment with prodrugs (120). When compared to GCV/TK, the CYP/CP system was found to be less efficient, possibly due to poor penetration of CP across the blood–brain barrier or low viral titers (120).

In addition to glioma models, expression of CYP2B1 in other tumor cell types (breast and prostate cancer lines) has been shown to increase the sensitivities of these cells to CP and IF, *in vitro* (121). These sensitivities to CP and IF can be reversed by metyrapone, a CYP2B1-selective enzyme inhibitor. Intratumoral CYP2B1 expression conferred a distinct therapeutic advantage in the treatment of MCF-7 (human breast) xenografts in nude mice. CYP2B1-expressing tumors were found to be 15–20-fold more sensitive to appropriate prodrugs than

Scheme 6. Metabolism of 6-MePdR^a

^a PNP, purine nucleotidophosphorylase.

the nonexpressing controls (121). Encouragingly, the therapeutic benefit was obtained without apparent increases in host toxicity.

3.5. 6-Methylpurine-2'-deoxyribonucleoside (6-MePdR)/*E. coli* Purine Nucleoside Phosphorylase (PNP). PNP (or purine nucleoside orthophosphate transferase) catalyzes the reversible phosphorolysis of purine ribonucleotides (122). These enzymes are found in bacteria and in eukaryotes, but there are important differences in substrate specificity between the bacterial and the human enzymes. For instance, adenine is a good substrate for bacterial PNP but not for the human enzyme. Purine arabinosides have at least 10-fold greater activity with *E. coli* PNP compared to the human enzyme. On the other hand, mammalian PNP is more efficient in the synthesis of nucleosides from 2-oxo-6-substituted purines and their analogues than is the bacterial PNP.

In GDEPT, the bacterial PNP was used to activate the relatively nontoxic 6-MePdR to the toxic 6-methylpurine (6-MeP) (see Scheme 6). In human colonic carcinoma cells, 6-MeP was ~100-fold more toxic than 6-MePdR (123). When these cells were engineered to express *E. coli* PNP, their sensitivity to 6-MePdR was found to increase 60-fold. Furthermore, a significant bystander effect has been shown, with <1% of cells expressing *E. coli* PNP resulting in the death of virtually all of the cells in the population following prolonged 6-MePdR treatment (123).

This system has been tested in human melanoma cell lines, using the tyrosinase promoter to direct melanocyte expression (75). Human colonic carcinoma cells were used as a control for the promoter. The melanoma cells were sensitized to 6-MePdR, whereas the control cells were not. Furthermore, using murine melanoma cell lines, *in vitro*, complete cell kill could be achieved with only 2% of cells expressing *E. coli* PNP under the control of the SV40 promoter, following long incubation with prodrug.

Other adenine nucleosides such as 2-fluoroadenine, 2-azaadenine, and 4-aminopyrazolo[3,4-*d*]pyrimidine are also potential prodrugs for bacterial PNP and, indeed, tumor cell sensitization to arabinofuranosyl-2-fluoroadenine has been demonstrated using this enzyme (75).

3.6. 5'-Deoxy-5-fluorouridine (5'-DFUR)/Thymidine Phosphorylase (TP). Human TP has been proposed for GDEPT in connection with the activation of 5'-DFUR (124). TP catalyzes the reversible phosphorolytic cleavage of deoxythymidine, deoxyuridine, and some of their analogues to the corresponding bases and deoxyribose-1-phosphate. (See Scheme 7.) Although TP is implicated in the activation of 5'-DFUR, there has been no clear demonstration that TP of human origin can cleave the glycosidic bond of 5'-DFUR to yield 5-FU.

Nevertheless, it was shown that overexpression of human TP in human breast cancer cells led to a ~90-fold increase in enzyme levels and a concomitant 165-

Scheme 7. Metabolism of 5'-DFUR^a

^a TP, thymidine phosphorylase.

fold increase in sensitivity to 5'-DFUR. The sensitivity of the cells to 5-FU and 5-FUdR remained unchanged (124).

3.7. Arabinosylcytosine [1-(β-D-Arabinofuranosyl)cytosine (Ara-C), 2-Chloro-2'-deoxyadenosine (CdA), 2-Fluoro-9-(β-D-arabinofuranosyl)cytosine (Fara-C), 2-Fluoro-9-(β-D-arabinofuranosyl)adenine (Fara-A), and 2',2'-Difluorodeoxycytidine (dFdC)/Deoxycytidine Kinase (dCK)]. Human dCK is an enzyme involved in the salvage pathway of deoxyribonucleotides biosynthesis. The phosphorylation reaction is the limiting step in this pathway (125). The prodrugs ara-C, CdA, Fara-C, Fara-A, and dFdC can all be activated by a phosphorylation reaction to the corresponding deoxynucleotide monophosphates which, after further phosphorylation to the corresponding triphosphates, are biosynthetically incorporated into RNA and DNA, leading to DNA fragmentation and consequent cell death. (See Scheme 8.)

There have been suggestions that tumor sensitivity to these drugs correlates with dCK activity, but since tumors have relatively low levels of dCK, it has been proposed that dCK-gene transfer will be useful for chemotherapy.

To investigate this proposition, human colon carcinoma and small-cell lung adenocarcinoma cell lines have been engineered to express the human dCK-protein. MCF-7 cells expressing dCK showed a 2.5-fold increased sensitivity to ara-C, whereas H1437 cells expressing dCK displayed 106-fold increase to ara-C. In these studies a linear correlation between IC₅₀ and dCK activity was suggested (125).

The ara-C/dCK system represents a good model for brain tumors, since ara-C can cross the blood-brain barrier and the activated drug is not toxic to postmitotic cells. Glioma cells expressing dCK were ~10-fold more sensitive to ara-C than parental cells, although this was observed following 4 days of continuous exposure (126). The bystander effect, which requires cell to cell contact, was disappointing, with only 50% cell kill occurring when 10% of the cells expressed dCK. In spite of these results, six of seven rats with intracerebral gliomas that expressed dCK were cured (survival >120 days, in comparison with control animals, which were dead after 19-

Scheme 8. Activation of Ara-C by dCK and Other Nucleosides That Could Be Activated by the Same Enzyme^a^a dCK, deoxycytidine kinase.**Scheme 9. Activation of CMDA by the CPG2 Enzyme^a**^a CPG2, carboxypeptidase G2.

29 days). Furthermore, the dCK gene was transduced into established intracerebral glioma tumors using adenoviral vectors which, following ara-C treatment, resulted in significantly longer survival than found for animals treated with the control adenoviral vector plus ara-C.

3.8. (2-Chloroethyl)(2-mesyloxyethyl)aminobenzoate-L-glutamic Acid (CMDA)/*Pseudomonas* Sp. Carboxypeptidase G2 (CPG2). CPG2 is a bacterial enzyme from a *Pseudomonas* species (127) for which there are no known human homologues, and it is therefore a good candidate for GDEPT. CPG2 catalyzes the scission of amidic, urethanic, and ureidic bonds between an aromatic nucleus and L-glutamic acid (see Scheme 9) (128–130). It can therefore be used to activate prodrugs such as CMDA to aromatic bifunctional alkylating agents.

CMDA, a benzoylglutamate mustard, is cleaved by CPG2 to a benzoyl mustard which can cross-link DNA. Since no endogenous enzymes are required for this activation, the chance of developing resistance is greatly reduced. The released drug is also active against cycling and noncycling cells and therefore has an advantage over antimetabolite toxins (e.g., GCV or 5-FC). CPG2 has been expressed stably in a variety of human tumor cell lines (breast, ovarian, and colon carcinomas) which rendered the cells sensitive to the prodrug CMDA. The cell lines expressing CPG2 were found to be 10–100

Scheme 10. Metabolism of CB 1954^a^a NR, nitroreductase; 1, acetyl-coenzyme A.

times more sensitive to CMDA than appropriate controls *in vitro*. Total cell kill could be achieved when 4–12% of the cells expressed CPG2, depending on the cell line tested (8).

3.9. 5-Aziridinyl-2,4-dinitrobenzamide (CB 1954)/*E. coli* Nitroreductase (NR). The prodrug CB 1954, a monofunctional alkylating agent, was found to be extremely potent against the Walker carcinosarcoma in rats but inactive against a panel of tumors used in screening anticancer agents (131). It has subsequently been shown that the sensitivity of the Walker cell line was due to DT-diaphorase present in these cells, which activates CB1954 into the bifunctional alkylator 5-aziridinyl-4-(hydroxylamino)-2-nitrobenzamide (132, 133). This is probably converted by acetyl-CoA or other endogenous enzymes to a more potent electrophile, for example, the corresponding acetate, which then reacts with DNA. The metabolism of CB 1954 is shown in Scheme 10. Since the active drug is an alkylating agent, it is able to kill both cycling and noncycling cells, an advantage compared to antimetabolite toxins. Human DT-diaphorase is much less able to activate CB 1954 than is the rat enzyme and therefore should not pose a problem for the use of CB1954 in patients.

Bacterial NR is also able to activate CB 1954, and NR is much more effective than human DT-diaphorase in activating the prodrug (134). A recent study found that expression of *E. coli* NR in NIH3T3 cells increased their sensitivity to NR. Some co-operative killing was observed when cells expressing both NR and TK were treated with a combination of CB 1954 and GCV, supporting their different mechanisms of action (7).

3.10. 6-Thioguanine (6-TG) and 6-Thioxanthine (6-TX)/*E. coli* Xanthine-Guanine Phosphoribosyl-transferase (XGPRT). Bacterial XGPRT and its human counterpart (HPRT) catalyze the conversion of hypoxanthine and guanine to inosine monophosphate (IMP) and guanosine monophosphate (GMP), respectively. XGPRT also efficiently converts xanthine to XMP, a reaction that is poorly catalyzed by the human enzyme (135). These nucleoside monophosphates serve as substrates for pathways involved in the biosynthesis of DNA and RNA. The bacterial enzyme is also able to transfer the ribose phosphate moiety to 6-TX and 6-TG. (See Scheme 11.)

XGPRT is encoded by the *E. coli* gpt gene (135, 136). XGPRT expression in mammalian cells can be used either as a positive or negative selection depending on the

Scheme 11. Activation of 6-TX and 6-TG by XGPRT^a

^a XGPRT, xanthine-guanine phosphoribosyltransferase.

prodrug used (e.g., hypoxanthine and xanthine positively select cells that express XGPRT, whereas 6-TX kills these cells) (136). 6-TG can also be used, despite the fact that it is not a XGPRT substrate, since 6-TG is metabolized to 6-TX by endogenous enzymes, which are subsequently activated by XGPRT.

Clonal glioma lines expressing XGPRT showed significantly increased sensitivity to 6-TX ($IC_{50} = 2.5 \mu\text{M/L}$; parental line $IC_{50} > 50 \mu\text{M/L}$). The XGPRT expressing cell line was also sensitive to 6-TG ($IC_{50} = 0.05 \mu\text{M/L}$, parental line $IC_{50} = 0.5 \mu\text{M/L}$). Cell to cell contact was shown to be required for bystander effects, and under these conditions, significant bystander effects were seen when $\sim 11\%$ of cells expressed XGPRT. Both 6-TG and 6-TX significantly inhibited the growth of tumors in nude mice formed from the sc or intracerebral (ic) transplantation of XGPRT expressing cells.

3.11. Design of Prodrugs for GDEPT. The design of prodrugs for GDEPT should address several issues related to clinical situations. These include the following: penetration of prodrugs into cancer cells for intracellular activation; low toxicity of prodrugs; effective activation of prodrug by the expressed enzyme with favorable activation kinetics; high cytotoxicity of the active drug; ideally, the released drugs should be effective in both cycling and noncycling cells; and the released drugs should induce a bystander effect.

Lipophilic prodrugs are required to penetrate across cell membranes, or prodrugs could be synthesized that are taken up by active transport. It appears that the prodrugs so far in use (nucleoside analogues, 5-FC, CP, CMDA, and CB 1954) penetrate cells by passive diffusion as opposed to active uptake. Low cytotoxicity for the prodrugs is essential since they will also be taken up by normal cells. Activation of the prodrugs is one of the critical steps in GDEPT. It is an advantage if prodrug activation proceeds directly by the expressed enzyme, without the requirement for further catalysis by endogenous enzymes. The involvement of host enzymes in prodrug activation may lead to resistance of tumor cells if the endogenous enzymes are deficient or defective. Furthermore, cells may differ in the levels of the endogenous enzymes they express and thus individual tumors may differ in their sensitivity to prodrugs, even if they express equivalent amounts of exogenous protein. With ara-M, GCV, and ACV the toxic metabolites are gener-

ated by mammalian adenosine monophosphate deaminase, AMP- and/or GMP-kinases following initial activation by TK (see Schemes 2 and 3). With 5-FC, which is converted to 5-FU by CD, the active metabolite is 5-FdUMP or 5-FUTP, which results from 5-FU conversion by a number of mammalian enzymes involving a complicated activation pattern (see Scheme 4). The complex activation pathway of these antimetabolites is partially responsible for their propensity to induce resistance (137).

The prodrugs CP, IF, and CB 1954 are dependent on fewer endogenous enzymes for activation than those cited above. CP, after the primary activation by CYP, requires a second step by 3',5'-exonuclease to generate the active metabolite. For CB 1954, the 5-aziridinyl-4-hydroxylamino-2-nitrobenzamide intermediate resulting from the prodrug reduction by NR needs a further enzymatic step to be converted to the electrophile which alkylates DNA. With the alkylating agent prodrug CMDA, catalysis by CPG2 leads directly from the prodrug to the activated drug (see Scheme 9). These prodrugs, theoretically, have less opportunity to generate resistance.

It is an advantage if the prodrugs are activated to drugs with high cytotoxicity and optimum half-lives to maximize the benefits for GDEPT. The half-lives should be short enough not to allow the drug to leak out from the tumor but long enough to induce a bystander effect. Good kinetic parameters (higher k_{cat}) seem favorable. This effect was noticed when the activity of CP (higher k_{cat} , lower IC_{50}) was compared with that of IF (lower k_{cat} , higher IC_{50}) (138). Also, as described above, improving the kinetic parameters of TK by mutagenesis has resulted in enzymes that make cells more sensitive to prodrugs than wild-type enzymes (77).

Ideally the released drug should be effective against both cycling and noncycling cells. Unfortunately, the majority of prodrugs used in GDEPT release active drugs that are antimetabolites, which require cycling cells (S phase) for cytotoxicity. It has been speculated that the resistance to GCV in GDEPT is not an acquired one but resulted from tumor cells being in G_0 during the time of GCV administration (139). This argument is supported by the fact that the tumors which grew out remained sensitive to GCV. The use of prodrugs that are activated to alkylating agents should have an advantage over purine nucleosides or 5-FC, since they are cytotoxic to both cycling and noncycling cells and this has been shown to be true for the alkylating agent CB 1954 (7). Alkylating agents also have the advantage that they are less prone than other anticancer compounds to induce resistance (140, 141).

4. BYSTANDER EFFECT AND ACQUIRED IMMUNITY

Since expression of the foreign enzymes will not occur in all cells of a targeted tumor *in vivo*, a bystander cytotoxic effect is required whereby the prodrug is cleaved to an active drug that kills not only tumor cells but also neighboring nonexpressing tumor cells (111). This means that expression in $<100\%$ of tumor cells can still give total tumor cell kill. It was demonstrated, *in vivo*, that when as few as 2% of the tumor cells expressed the foreign enzyme, subsequent treatment with suitable prodrug gave long-term animal survivors (111). Therefore, an expression efficiency of 10–20% should be enough to achieve 100% cell kill in tumors, and efficiencies of 1–5% are considered sufficient for a therapeutic benefit (111). Even with lower transfer efficiencies,

beneficial results were obtained if the transduced cell population was allowed to expand before prodrug administration.

The systems reported have exhibited a significant bystander effect *in vivo*. However, the mechanisms may be different for individual drugs. For instance, for the toxic nucleoside phosphates resulting from the activation of purine (GCV, ACV, etc.) or pyrimidine (ara-C, 5-FUDR, etc.) nucleosides, which do not diffuse across cell membranes, cell to cell contact is required to obtain the bystander effect (142). By contrast, for diffusible drugs such as 5-FU or aldophosphamide (or phosphoramidate mustard) no such requirement is necessary (see below) (111, 138).

The responses described in GDEPT would surely not be possible without the existence of the bystander effect. It is very difficult to compare bystander effects obtained in different experimental models due to the different conditions employed by the various investigators. However, we have summarized the data on the bystander effects in different systems in Table 4.

The bystander effects vary depending not only on which prodrug is combined with which enzyme but also on whether the effects are monitored with *in vitro* or *in vivo* systems. It is also clear that different tumor cell types give different results even within the same prodrug/enzyme system. For example, using CMDA with CPG2 *in vitro* in the colorectal carcinoma cell line WiDr, 12% transfected cells were required for total cell kill, whereas with the colorectal carcinoma cell line LS174T only 4% were needed to give 100% cytotoxicity (8). With the GCV-TK combination, 25% of Ov-Ca-1225 TK expressing cells were required for total cell kill *in vitro*. In a liver carcinoma cell line, 10–20% of cells expressing TK were needed for total regression of tumors (80).

The mechanisms responsible for the bystander effects are not completely understood. Several explanations are plausible, and there is the possibility that more than one mechanism is involved. It is also plausible that the mechanisms are different when different types of prodrugs are used. In addition, mechanisms *in vivo* are different from those *in vitro*.

Toxic metabolites are formed during prodrug activation. These are released by efflux from dead and dying genetically modified cells. This is postulated for 5-FU formed from 5-FC, for the metabolites of CP or IF, aldophosphamide, phosphoramidate mustards, or acrolein (7, 111, 138), and for 6-MeP, formed from the corresponding deoxynucleoside (123). This assumption is supported by the fact that no cell to cell contact is required to obtain a bystander effect in these systems. In WiDr cells, this effect was observed both *in vitro* and *in vivo*. *In vitro*, 30% of cells expressing CD were required to eradicate the whole cell population (111). However, *in vivo* the bystander effect was more dramatic and 2% WiDr-CD cells were enough to obtain 100% tumor regression in nude mice, while 4% of cells expressing CD resulted in cures in 66% of the animals (91, 111, 143). When similar experiments were performed in immunocompetent animals, the results were better, indicating that there is a significant immune component to GDEPT.

For purine or pyrimidine nucleosides, where the toxic metabolites, being phosphorylated, are not diffusible across cell membranes, direct cell to cell contact is required to achieve a bystander effect (142). When TK⁺ cells were separated by a 0.4 μ m filter membrane from TK[−] cells, the bystander effect was abrogated. A similar mechanism could also be postulated for other systems involving different purine or pyrimidine nucleotides as

active drugs, for instance ara-C/dCK (126), 6-TA, 6-TX/XGPRT (136), or 5'-DFUR/TPP (124). Since purine and pyrimidine nucleotides formed during activation cannot cross cell membranes, it was assumed that gap junctions are involved in the transfer of toxic metabolites from cell to cell (142, 144). Another suggestion is that the TK-enzyme itself is transported by apoptotic vesicles or through gap junctions (142, 145, 146). Using a flow cytometry assay, it has been shown (in a coculture of HSV-TK expressing murine fibroblasts with rat glioma cells or human hepatoma cells) that bystander tumor cytotoxicity during GCV treatment was highly correlated ($p < 0.001$) with the extent of gap junction mediated coupling, supporting their role in mediating the bystander effect (147).

Phagocytosis by the nonenzyme-expressing cells of materials other than the active drug or the activating enzyme from the dying cells (e.g., hydrolases or other lytic enzymes) has been suggested as a mediator of the bystander effect (142, 148). However, in contrast with this theory, during the period of apoptosis, in bystander cells cocultured with HSV-TK-expressing cells, no phagocytosis could be observed (149). Apoptosis has been shown in bystander cells and was found to be inhibited by bcl2 expression supporting a role for apoptosis in bystander events (149). Furthermore, it has also been suggested that killing of tumor cells by apoptosis could heighten the immune response to wild-type tumor cells (142).

There have been suggestions that the immune response is a favorable event in GDEPT. Although data are available which show that the bystander effect also occurs in immunoincompetent animals, more recent findings suggest that the bystander effect *in vivo* can be mediated through the release of cytokines (148, 150). Co-injection of mouse colon carcinoma cells with HSV-TK-expressing retroviral packaging cells followed by GCV treatment resulted in almost total tumor ablation in immunocompetent BALB/c mice but not in immunocompromised athymic BALB/c animals (79). In another study, HSV-TK-expressing 3T3, which were transformed by Ki-Ras V12G, were shown to be sensitive to GCV. Tumor growth with these cells was inhibited for up to 50 days following GCV treatment in immunocompromised nude mice, but this was not sufficient to eliminate all of the tumor cells in these animals (tumors regrew 40–50 days after cell implantation). By contrast, in immunocompetent BALB/c mice, this treatment led to the development of a long-lasting immunity (151). Similarly, in experimental metastasis of murine melanoma models, a greater reduction in the number of metastatic sites was seen in immunocompetent mice than in nude mice, indicating an immune component to the bystander effect (152).

The role of IL-2 in these systems has also been investigated. Syngeneic colon carcinoma cells grown in BALB/c mice were injected with an adenoviral vector containing the HSV-TK gene or the IL-2 gene, followed by treatment with GCV. While the tumors continued to grow in the animals injected with a control vector or the vector carrying the IL-2 gene, those treated with HSV-TK, with or without coadministration of IL-2, exhibited tumor necrosis and regressions. However, only animals treated with HSV-TK together with the IL-2 genes developed effective systemic antitumoral immunity against tumorigenic rechallenges. The antitumoral immunity was associated with the presence of tumor cell specific cytolytic CD8⁺ T-lymphocytes (153). To enhance and prolong the antitumoral immunity, a third vector con-

Table 4. Bystander Effect

8	xanthine-guanine phosphoribosyl-transferase/6-thioxanthine, 6-thioguanine	complete inhibition of growth at C6GPT:C6 glioma cells ratio of 1:1		cell to cell contact required	136

taining the mouse granulocyte macrophage colony stimulating factor (mGM-CSF) gene was also employed. The animals treated simultaneously with HSV-TK + IL-2 + mGM-CSF vectors, followed by administration of GCV, developed long-term antitumor immunity and survived for >4 months without recurrence (154).

The synergism between "suicide gene" and "cytokine gene" therapies has also been tested in head and neck squamous carcinoma in mice. Animals receiving both HSV-TK and IL-2 genes, followed by GCV treatment demonstrated a significantly greater regression in tumours compared to those treated with the components without the cytokine gene (155). Taken together, these studies suggest strongly that an intact immune system is important for long term tumour suppression *in vivo*.

5. FUTURE PERSPECTIVES

As described above there are a large number of prodrug/enzyme combinations that have shown efficiency *in vitro* and *in vivo*. There remain some hurdles to overcome before GDEPT will become a clinically efficient treatment of solid tumors. These include the development of better and more efficient delivery systems for the exogenous genes together with restricted expression in the tumour alone; the synthesis of prodrugs that are better substrates for the transfected genes, which are not substrates for endogenous enzymes and that exhibit good bystander effects; and the use of mutated genes that express enzymes with higher specificity for their substrates.

The following steps have already been achieved in GDEPT: transfection of tumor cells with the gene for an enzyme *in vitro* have been able to activate specific prodrugs, converting them to cytotoxic drugs; transfected tumor cells, when injected into animals, are able to grow and to generate tumors, which have subsequently undergone regressions or been cured by administration of appropriate prodrugs; the "bystander effect" has been measured *in vitro* and *in vivo* (in the presence of an immune system, this bystander effect may become long-term); gene transfection has been achieved *in vivo* using direct DNA injection (naked DNA) liposomes, cationic lipids, or gene transduction with adenoviral or retroviral vectors; and gene infection has been achieved *in vivo* using packaging cells that continuously produce the desired retroviral vector.

The demonstration of these steps in combination with the prodrugs described herein illustrates not only the feasibility of the current systems but also the future promise of GDEPT.

Immunoassay Reagents for Thyroid Testing. 3. Determination of the Solution Binding Affinities of a T₄ Monoclonal Antibody Fab Fragment for a Library of Thyroxine Analogs Using Surface Plasmon Resonance

Maciej Adamczyk,* Donald D. Johnson, Phillip G. Mattingly, Jeffrey A. Moore, and You Pan

Diagnostics Division Organic Chemistry (9-NM), Abbott Laboratories, Building AP 20, 100 Abbott Park Road, Abbott Park, Illinois 60064. Received July 23, 1997; Revised Manuscript Received October 1, 1997[®]

A library of thyroxine analogs and tracers was prepared, and their solution binding affinities for an anti-T₄ Fab fragment were determined using a single high-density L-T₄ biosensor surface in a BIAcore surface plasmon resonance instrument. The high-density L-T₄ analog biosensor was calibrated by determination of the initial binding rate was of known concentrations of free anti-T₄ Fab fragment in solution to the biosensor surface. A range of individual thyroxine analog and tracer concentrations was subsequently mixed with a fixed concentration of anti-T₄ Fab fragment. The concentration of free anti-T₄ Fab fragment in each solution at equilibrium was determined, and the equilibrium dissociation constant (K_D) for each case was derived. The K_D values determined in solution are compared to values determined by a direct kinetic analysis on the BIAcore instrument using individual biosensor surfaces.

INTRODUCTION

The need for well-characterized immunoreagents utilized in immunoassays is widely recognized (1–6). While haptens, tracers, and antibodies are routinely characterized chemically to determine their identity and purity, the kinetic and thermodynamic properties of their binding interactions are generally only inferred from their performance in a particular assay format. These binding interactions are critical to all stages of assay development from selection of antibody through determination of the structural features important for tracer design. Unfortunately, determination of these binding parameters traditionally has been a laborious endeavor (7). The recent development of automated BIAcore (BIAcore, Inc.) surface plasmon resonance technology (SPR) has greatly simplified this task.

We recently reported the utility of the automated BIAcore SPR technology in assessing the binding kinetics of an anti-T₄ mAb and its Fab fragment to a library of surface-bound thyroxine analogs (2). In that study, individual thyroxine analogs were conjugated to a solid-supported hydrophilic dextran matrix of an SPR chip to form a biosensor, mimicking a heterogeneous assay format. A solution of the mAb or Fab fragment was then introduced at a constant rate to the surface of each biosensor, and binding was monitored continuously, providing real-time kinetic information. Dissociation of

bound mAb or Fab fragment was subsequently monitored after the sample had traversed the biosensor surface. By using a range of binding protein concentrations, a series of sensorgrams was produced for each thyroxine analog biosensor. Nonlinear regression analysis of the data provided the association and dissociation rate constants (k_a and k_d) from which the equilibrium association constant (K_A) and the change in free energy (ΔG) of binding were calculated. These values helped to define the structural features of the thyroxine analogs that were required for the binding interaction, but necessitated production of a different biosensor for each analog studied. Additionally, this format neither allowed for the direct measurement of antibody interaction with a native analyte (underivatized T₄) or tracer nor served as a good model for homogeneous assay formats. These issues are addressed in this study.

The BIAcore instrument was used to study the binding interactions between an anti-T₄ Fab fragment and a library of thyroxine analogs and tracers in solution using a single thyroxine analog biosensor. Thus, anti-T₄ Fab fragment is known to bind to a biosensor surface of thyroxine immobilized through an aminoalkyl linker (2). With high-density T₄ biosensor surfaces, the binding observed is limited by the diffusion of the protein to the surface. Under such conditions, initial binding rates are proportional to the free anti-T₄ Fab fragment concentration in solution and independent of the interaction kinetics or analyte–ligand affinity (8, 9). High-density T₄ biosensor surfaces were prepared, and the initial binding rates were measured with known concentrations of anti-T₄ Fab fragment to construct a calibration curve. A range of individual thyroxine analog and tracer con-

[®] Abstract published in *Advance ACS Abstracts*, November 15, 1997.

centrations were subsequently mixed with a fixed concentration of antibody fragment in solution and allowed to reach equilibrium. The concentration of free anti-T₄ Fab fragment in each solution was subsequently determined, and the equilibrium dissociation constant (K_D) for each case was derived.

MATERIALS AND METHODS

Sodium L-thyroxine pentahydrate (**L-1**) and all other reagents were obtained from Aldrich Chemical Co. (Milwaukee, WI) unless otherwise noted. Sodium D-thyroxine pentahydrate (**D-1**), sodium L-3,3',5-triiodothyronine (**L-2**), and L-3,5-diiodothyronine (**3**) were obtained from Sigma Chemical Co. (St. Louis, MO). D-3,3',5-Triiodothyronine (**D-2**) was obtained from ICN Biochemicals (Cleveland, OH). Compounds **4–16** were prepared as reported earlier (2). 5-Carboxyfluorescein was obtained from Calbiochem (La Jolla, CA). Acridinium chemiluminescent label **39** was prepared following the general procedure of Mattingly *et al.* (10, 11). Synthesized compounds were purified by HPLC [Waters (Millford, MA) system consisting of a model 590 pump, a Lambda-Max 481 UV detector, a model 745B data module, and a 40 × 100 mm μ Bondapak C18 column; flow rate, 45 mL/min]. Analytical HPLC was performed on a Beckman Gold system with UV detection at 254 nm using a Waters 8 × 100 mm μ Bondapak C18 column eluting with aqueous acetonitrile (v:v, CH₃CN/H₂O) containing 0.05% trifluoroacetic acid at a flow rate of 2 mL/min. ¹H NMR spectra were recorded at 300 MHz on a Varian Gemini spectrometer (Palo Alto, CA). Chemical shifts are reported in parts per million (δ) using tetramethylsilane (TMS) as the internal reference; coupling constants (J) are in hertz. Electrospray ionization mass spectrometry (ESI/MS) was carried out on a Perkin-Elmer (Norwalk, CT) Sciex API 100 Benchtop system employing the Turbo IonSpray ion source. Surface plasmon resonance measurements were carried out on a BIAcore 2000 (BIAcore, Inc., Piscataway, NJ) automated system using CM-5 four-channel sensor chips. Reagents for the BIAcore instrument consisted of HBS buffer [10 mM Hepes (pH 7.4), 150 mM NaCl, 3.4 mM EDTA, and 0.05% surfactant P-20] and a coupling kit containing *N*-hydroxysuccinimide (NHS), *N*-ethyl-*N*-(3-(diethylamino)propyl)carbodiimide (EDAC), and 1 M ethanolamine hydrochloride (pH 8.5), all from BIAcore, Inc. Anti-thyroxine Fab fragment was prepared and purified as previously described (2).

General Procedure for Preparation of 5-Carboxyfluorescein Tracers. (A) *In Situ Activation of 5-Carboxyfluorescein.* A solution of 5-carboxyfluorescein (250 mg, 0.681 mmol), EDAC (196 mg, 1.02 mmol), and *N*-hydroxysuccinimide (117 mg, 1.02 mmol) in DMF (6.8 mL) was stirred overnight. The reaction solution (0.1 M) was used without further purification.

(B) *Coupling of Succinimidyl 5-Carboxyfluorescein to Thyroxine Analogs.* To a solution of the analog compound (**9–16**) (0.03 mmol) in DMF (3 mL) were added a 5-carboxyfluorescein-activated ester stock solution (0.34 mL, 0.1 M, 0.34 mmol) and *N,N*-diisopropylethylamine (100 μ L). After stirring for 4 h, the reaction mixture was acidified with TFA and purified by preparative HPLC.

Compound **L-17** was obtained from compound **L-9** (79%). HPLC (55:45): retention time, 5.8 min, 98%. ¹H NMR (methanol-*d*₄): 8.45 (1 H, s), 8.20 (1 H, d, J = 8), 7.89 (2 H, s), 7.33 (1 H, d, J = 8), 7.05 (2 H, s), 6.74 (2 H, s), 6.65 (2 H, d, J = 8), 6.60 (2 H, d, J = 8), 4.70 (1 H, m), 3.43 (2 H, m), 3.22 (1 H, m), 2.93 (1 H, m), 2.24 (2 H, m), 1.65 (4 H, m), 1.40 (2 H, m). ESI/MS m/z : 1247 ($M - H$)⁻.

Compound **D-17** was obtained from compound **D-9** (59%). HPLC (55:45): retention time, 5.8 min, 96%. ¹H NMR (methanol-*d*₄): 8.48 (1 H, s), 8.19 (1 H, d, J = 8), 7.80 (2 H, s), 7.34 (1 H, d, J = 9), 7.05 (2 H, s), 6.78 (2 H, s), 6.71 (2 H, d, J = 8), 6.65 (2 H, d, J = 8), 4.72 (1 H, m), 3.42 (2 H, m), 3.24 (1 H, m), 2.90 (1 H, m), 2.24 (2 H, m), 1.67 (4 H, m), 1.38 (2 H, m). ESI/MS m/z : 1247 ($M - H$)⁻.

Compound **L-18** was obtained from compound **L-10** (61%). HPLC (55:45): retention time, 4.4 min, 98%. ¹H NMR (methanol-*d*₄): 8.45 (1 H, s), 8.20 (1 H, d, J = 8), 7.79 (2 H, s), 7.33 (1 H, d, J = 8), 6.98 (1 H, d, J = 3), 6.74 (2 H, s), 6.71 (3 H, m), 6.65 (2 H, d, J = 8), 6.57 (1 H, dd, J = 8, 3), 4.71 (1 H, m), 3.42 (2 H, m), 3.25 (1 H, m), 2.91 (1 H, m), 2.24 (2 H, m), 1.66 (4 H, m), 1.41 (2 H, m). ESI/MS m/z : 1123 ($M + H$)⁺.

Compound **D-18** was obtained from compound **D-10** (42%). HPLC (55:45): retention time, 4.4 min, 99%. ¹H NMR (methanol-*d*₄): 8.48 (1 H, s), 8.19 (1 H, d, J = 8), 7.79 (2 H, s), 7.35 (1 H, d, J = 8), 6.98 (1 H, d, J = 3), 6.80 (2 H, s), 6.76 (3 H, m), 6.64 (2 H, d, J = 8), 6.56 (1 H, dd, J = 8, 3), 4.68 (1 H, m), 3.42 (2 H, m), 3.25 (1 H, m), 2.88 (1 H, m), 2.24 (2 H, m), 1.64 (4 H, m), 1.38 (2 H, m). ESI/MS m/z : 1123 ($M + H$)⁺.

Compound **19** was obtained from compound **11** (49%). HPLC (50:50): retention time, 4.6 min, >99%. ¹H NMR (methanol-*d*₄): 8.45 (1 H, s), 8.20 (1 H, d, J = 9), 7.77 (2 H, s), 7.32 (1 H, d, J = 9), 6.75 (2 H, s), 6.65 (4 H, m), 6.61 (2 H, d, J = 9), 6.49 (2 H, d, J = 9), 4.67 (1 H, m), 3.42 (2 H, m), 3.23 (1 H, m), 2.87 (1 H, m), 2.21 (2 H, m), 1.64 (4 H, m), 1.23 (2 H, m). ESI/MS m/z : 995 ($M - H$)⁻.

Compound **20** was obtained from compound **12** (59%). HPLC (55:45): retention time, 5.5 min, >99%. ¹H NMR (methanol-*d*₄): 8.46 (1 H, s), 8.21 (1 H, d, J = 8), 7.81 (2 H, s), 7.33 (1 H, d, J = 8), 7.03 (1 H, d, J = 3), 6.83 (1 H, d, J = 3), 6.76 (2 H, s), 6.68 (2 H, d, J = 9), 6.62 (2 H, d, J = 9), 4.72 (1 H, dd, J = 10, 4), 3.42 (2 H, m), 3.23 (1 H, m), 2.85 (1 H, m), 2.23 (2 H, m), 1.66 (4 H, m), 1.38 (2 H, m). ESI/MS m/z : 1201, 1203 ($M + H$)⁺.

Compound **21** was obtained from compound **13** (47%). HPLC (55:45): retention time, 4.1 min, >99%. ¹H NMR (methanol-*d*₄): 8.46 (1 H, s), 8.21 (1 H, d, J = 8), 7.79 (2 H, s), 7.34 (1 H, d, J = 8), 6.77 (4 H, m), 6.72 (2 H, d, J = 8), 6.63 (2 H, d, J = 9), 6.54 (1 H, m), 4.69 (1 H, m), 3.44 (2 H, m), 3.22 (1 H, m), 2.88 (1 H, m), 2.24 (2 H, m), 1.66 (4 H, m), 1.57 (2 H, m). ESI/MS m/z : 1075, 1077 ($M + H$)⁺.

Compound **22** was obtained from compound **14** (44%). HPLC (55:45): retention time, 5.1 min, 98%. ¹H NMR (methanol-*d*₄): 8.43 (1 H, s), 8.20 (1 H, d, J = 8), 7.81 (2 H, s), 7.31 (1 H, d, J = 8), 6.83 (2 H, s), 6.72 (2 H, s), 6.62 (2 H, d, J = 9), 6.57 (2 H, d, J = 9), 4.72 (1 H, m), 3.41 (2 H, m), 3.28 (1 H, m), 2.88 (1 H, m), 2.23 (2 H, m), 1.63 (4 H, m), 1.38 (2 H, m). ESI/MS m/z : 1151, 1153, 1155 ($M - H$)⁻.

Compound **23** was obtained from compound **15** (58%). HPLC (55:45): retention time, 7.6 min, 98%. ¹H NMR (methanol-*d*₄): 8.44 (1 H, s), 8.21 (1 H, d, J = 8), 7.83 (2 H, s), 7.37 (1 H, d, J = 8), 7.05 (2 H, s), 6.71 (2 H, s), 6.62 (2 H, d, J = 8), 6.58 (2 H, d, J = 8), 5.07 (1 H, m), 3.42 (2 H, m), 3.02 (3 H, s), 2.96 (1 H, m), 2.91 (3 H, s), 2.85 (1 H, m), 2.23 (2 H, m), 1.66 (4 H, m), 1.35 (2 H, m). ESI/MS m/z : 1276 ($M + H$)⁺.

Compound **24** was obtained from compound **16** (60%). HPLC (55:45): retention time, 5.3 min, >99%. ¹H NMR (methanol-*d*₄): 8.46 (1 H, s), 8.22 (1 H, d, J = 8), 7.81 (2 H, s), 7.31 (1 H, d, J = 8), 6.94 (1 H, d, J = 3), 6.72 (2 H, s), 6.61 (3 H, m), 6.58 (3 H, m), 5.07 (1 H, m), 3.42 (2 H, m), 3.03 (3 H, s), 2.98 (1 H, m), 2.92 (3 H, s), 2.85 (1 H,

m), 2.23 (2 H, m), 1.64 (4 H, m), 1.38 (2 H, m). ESI/MS m/z : 1150 ($M + H$)⁺.

Compound **29** was obtained from compound **D-1** (80%). HPLC (55:45): retention time, 6.9 min, >99%. ¹H NMR (DMSO-*d*₆): 9.39 (1 H, d, $J = 7$), 8.44 (1 H, s), 8.15 (1 H, d, $J = 8$), 7.89 (2 H, s), 7.36 (1 H, d, $J = 8$), 6.99 (2 H, s), 6.66 (2 H, d, $J = 2$), 6.54 (4 H, m), 4.67 (1 H, m), 3.03 (1 H, m), 2.95 (1 H, m). ESI/MS m/z : 1136 ($M + H$)⁺.

L-Thyroxine 6-carboxyfluorescein tracer (**25**) was prepared from compound **L-9** and 6-carboxyfluorescein according to the general procedure used for the 5-carboxyfluorescein tracers above (70%). HPLC (55:45): retention time, 5.4 min, >99%. ¹H NMR (methanol-*d*₄): 8.11 (2 H, d, $J = 3$), 7.77 (2 H, s), 7.67 (1 H, s), 7.03 (2 H, s), 6.72 (2 H, s), 6.65 (2 H, d, $J = 9$), 6.58 (2 H, d, $J = 9$), 4.66 (1 H, m), 3.21 (3 H, m), 2.85 (1 H, m), 2.16 (2 H, m), 1.54 (4 H, m), 1.27 (2 H, m). ESI/MS m/z : 1247 ($M - H$)⁻.

N-(Carboxymethyl)-L-thyroxine 4'-Aminomethylfluorescein Tracer (26). (A) *N*-(Carboxymethyl)-L-thyroxine *tert*-butyl ester (**4**) (38 mg, 0.04 mmol) and *N*-hydroxysuccinimide (5 mg, 0.04 mmol) were dissolved in DMF (500 μ L) and stirred with DCC for 14 h under nitrogen. The crude active ester solution was filtered and then added to a solution of 4'-aminomethylfluorescein hydrochloride (17 mg, 0.04 mmol) and triethylamine (3 drops) in DMF (500 μ L). The reaction mixture was stirred under nitrogen in the dark. After 14 h, the reaction solvent was removed *in vacuo*, and the residue was purified by preparative HPLC (78:22:0.4, CH₃OH/H₂O/HOAc). Product fractions were pooled and evaporated *in vacuo* to give the *tert*-butyl ester-protected tracer (30 mg, 57%) as an orange powder. Analytical HPLC (78:22:0.4, CH₃OH/H₂O/HOAc; 1 mL/min, 240 nm): retention time, 12.97 min, 99.7%. FAB/MS m/z : 1235 ($M + H$)⁺. (B) The *tert*-butyl ester-protected tracer (13 mg) was dissolved in 1:1 TFA/CH₂Cl₂ (1 mL). After the mixture was stirred for 4 h, the reaction solvent was removed *in vacuo*. The residue was dissolved in methanol (0.6 mL) and purified by preparative HPLC as above to give **26** (9 mg, 69%). Analytical HPLC (75:25:0.4, CH₃OH/H₂O/HOAc; 1 mL/min, 240 nm): retention time, 11.2 min, 99%. FAB/MS m/z : 1179 ($M + H$)⁺.

N-(Carboxymethyl)-L-thyroxine 5-aminomethylfluorescein tracer (**27**) was prepared from *N*-(carboxymethyl)-L-thyroxine *tert*-butyl ester (**4**) and 5-aminomethylfluorescein hydrobromide (**12**) according to the procedure used for compound **26** (61%). Analytical HPLC (80:20:0.4, CH₃OH/H₂O/HOAc; 1 mL/min, 240 nm): retention time, 6.1 min, 99%. FAB/MS m/z : 1179 ($M + H$)⁺.

L-Thyroxine 4'-N-glycylaminomethylfluorescein tracer (**28**) was prepared from *N-tert*-(butoxycarbonyl)-L-thyroxine (**2**) and 4'-N-glycylaminomethylfluorescein (Molecular Probes, Eugene, OR) according to the procedure outlined for compound **26** (61%). Analytical HPLC (75:25:0.4, CH₃OH/H₂O/HOAc; 1 mL/min, 240 nm): retention time, 10.3 min, 99%. ESI/MS m/z : 1178 ($M + H$)⁺.

General Procedure for Preparation of 10-(3-Sulfofpropyl)-*N*-tosyl-*N*-(3-carboxypropyl)acridinium-9-carboxamide Tracers. To a solution of the analog compound (**9-16**) (0.03 mmol) in DMF (3 mL) were added the acridinium active ester (**39**) (0.03 mmol) and *N,N*-diisopropylethylamine (100 μ L). After being stirred for 6 h, the reaction mixture was acidified with TFA and purified by preparative HPLC.

Compound **L-31** was obtained from compound **L-9** (52%). HPLC (50:50): retention time, 6.5 min, >99%. ¹H NMR (methanol-*d*₄): 8.92 (2 H, d, $J = 10$), 8.43 (2 H, m), 8.05 (2 H, d, $J = 10$), 7.85 (2 H, m), 7.77 (2 H, s), 7.17 (4 H, bs), 7.03 (2 H, s), 5.73 (2 H, b), 4.67 (1 H, m),

4.24 (2 H, m), 3.24 (5 H, m), 2.90 (1 H, m), 2.65 (2 H, m), 2.44 (2 H, m), 2.36 (3 H, s), 2.32 (2 H, m), 2.20 (2 H, m), 1.55 (4 H, m), 1.34 (2 H, m). ESI/MS m/z : 1457 ($M + H$)⁺.

Compound **D-31** was obtained from compound **D-9** (51%). HPLC (50:50): retention time, 6.5 min, >99%. ¹H NMR (DMSO-*d*₆/TFA-*d*): 9.01 (2 H, dd, $J = 12, 9$), 8.42 (2 H, bt), 8.16 (1 H, d, $J = 7$), 8.01 (2 H, m), 7.85 (2 H, m), 7.85 (1 H, t, $J = 8$), 7.80 (2 H, d, $J = 6$), 7.69 (1 H, d, $J = 9$), 7.63 (1 H, d, $J = 9$), 7.16 (1 H, d, $J = 8$), 7.11 (1 H, d, $J = 8$), 7.03 (2 H, d, $J = 2$), 5.66 (2 H, b), 4.44 (1 H, b), 4.20 (2 H, b), 3.42 (1 H, m), 3.08 (2 H, m), 2.92 (2 H, m), 2.81 (1 H, m), 2.47 (2 H, m), 2.37 (1 H, m), 2.30 (3 H, s), 2.27 (1 H, m), 2.06 (2 H, m), 1.65 (1 H, b), 1.43 (4 H, m), 1.23 (2 H, m). ESI/MS m/z : 1457 ($M + H$)⁺.

Compound **L-32** was obtained from compound **L-10** (63%). HPLC (50:50): retention time, 4.8 min, >99%. ¹H NMR (DMSO-*d*₆/TFA-*d*): 8.96 (2 H, dd, $J = 14, 9$), 8.40 (2 H, bt), 8.13 (1 H, d, $J = 9$), 7.97 (2 H, m), 7.82 (1 H, t, $J = 7$), 7.76 (2 H, d, $J = 6$), 7.68 (1 H, d, $J = 9$), 7.60 (1 H, d, $J = 9$), 7.16 (1 H, d, $J = 8$), 7.08 (1 H, d, $J = 8$), 6.94 (1 H, t, $J = 3$), 6.80 (1 H, dd, $J = 9, 3$), 6.53 (1 H, m), 5.65 (2 H, b), 4.46 (1 H, m), 4.18 (2 H, b), 3.42 (2 H, m), 3.06 (4 H, m), 2.73 (1 H, m), 2.43 (2 H, m), 2.30 (1 H, m), 2.27 (3 H, s), 2.14 (1 H, m), 2.05 (2 H, m), 1.64 (1 H, m), 1.40 (4 H, m), 1.22 (2 H, m). ESI/MS m/z : 1331 ($M + H$)⁺.

Compound **D-32** was obtained from compound **D-10** (55%). HPLC (50:50): retention time, 4.8 min, >99%. ¹H NMR (DMSO-*d*₆/TFA-*d*): 9.01 (2 H, dd, $J = 13, 10$), 8.41 (2 H, bt), 8.15 (1 H, d, $J = 8$), 7.98 (2 H, m), 7.85 (1 H, bt), 7.78 (2 H, d, $J = 5$), 7.66 (1 H, d, $J = 9$), 7.62 (1 H, d, $J = 9$), 7.16 (1 H, d, $J = 8$), 7.12 (1 H, d, $J = 8$), 6.95 (1 H, t, $J = 3$), 6.78 (1 H, dd, $J = 9, 3$), 5.66 (2 H, b), 4.45 (1 H, m), 4.20 (2 H, b), 3.45 (2 H, b), 3.07 (2 H, m), 2.94 (2 H, m), 2.86 (1 H, m), 2.47 (2 H, m), 2.31 (1 H, m), 2.29 (3 H, s), 2.15 (1 H, m), 2.03 (2 H, m), 1.65 (1 H, b), 1.42 (4 H, m), 1.27 (2 H, m). ESI/MS m/z : 1331 ($M + H$)⁺.

Compound **33** was obtained from compound **11** (67%). HPLC (45:55): retention time, 9.2 min, >99%. ¹H NMR (DMSO-*d*₆/TFA-*d*): 9.87 (2 H, dd, $J = 13, 10$), 8.42 (2 H, bt), 8.17 (1 H, d, $J = 8$), 8.01 (2 H, m), 7.86 (1 H, t, $J = 8$), 7.76 (2 H, d, $J = 5$), 7.67 (1 H, d, $J = 9$), 7.63 (1 H, d, $J = 9$), 7.18 (1 H, d, $J = 8$), 7.11 (1 H, d, $J = 8$), 6.64 (2 H, d, $J = 9$), 6.49 (2 H, d, $J = 9$), 5.65 (2 H, b), 4.43 (1 H, m), 4.20 (2 H, b), 3.44 (2 H, b), 3.06 (2 H, m), 2.95 (2 H, m), 2.85 (1 H, m), 2.48 (2 H, m), 2.31 (1 H, m), 2.29 (3 H, s), 2.14 (1 H, m), 2.06 (2 H, m), 1.65 (1 H, b), 1.43 (4 H, m), 1.23 (2 H, m). ESI/MS m/z : 1205 ($M + H$)⁺.

Compound **34** was obtained from compound **12** (57%). HPLC (50:50): retention time, 4.8 min, >99%. ¹H NMR (DMSO-*d*₆/TFA-*d*): 9.00 (2 H, dd, $J = 14, 10$), 8.42 (2 H, bt), 8.14 (1 H, d, $J = 7$), 7.97 (2 H, m), 7.83 (1 H, m), 7.78 (2 H, d, $J = 6$), 7.68 (1 H, d, $J = 9$), 7.62 (1 H, d, $J = 9$), 7.15 (1 H, d, $J = 9$), 7.10 (1 H, d, $J = 9$), 7.03 (1 H, t, $J = 3$), 6.85 (1 H, t, $J = 3$), 5.65 (2 H, m), 4.48 (1 H, dd, $J = 10, 4$), 4.19 (2 H, m), 3.44 (2 H, m), 3.05 (2 H, m), 2.93 (2 H, m), 2.81 (1 H, m), 2.46 (2 H, m), 2.30 (1 H, m), 2.28 (3 H, s), 2.15 (1 H, m), 2.01 (2 H, m), 1.64 (1 H, b), 1.38–1.23 (4 H, m). ESI/MS m/z : 1407, 1409 ($M - H$)⁻.

Compound **35** was obtained from compound **13** (35%). HPLC (50:50): retention time, 4.5 min, >99%. ¹H NMR (methanol-*d*₄): 8.93 (2 H, d, $J = 9$), 8.43 (2 H, dd, $J = 11, 9$), 8.05 (2 H, d, $J = 9$), 7.83 (2 H, m), 7.76 (2 H, s), 7.16 (4 H, s), 6.77 (2 H, m), 6.54 (1 H, m), 5.73 (2 H, b), 4.66 (1 H, m), 4.24 (2 H, b), 3.26 (5 H, m), 2.84 (1 H, m), 2.61 (2 H, m), 2.42 (2 H, m), 2.37 (3 H, s), 2.37 (2 H, m), 2.20 (2 H, m), 1.56 (4 H, m), 1.38 (2 H, m). ESI/MS m/z : 1283, 1285 ($M + H$)⁺.

Compound **36** was obtained from compound **14** (51%). HPLC (50:50): retention time, 5.7 min, 97%. ^1H NMR (methanol- d_4): 8.93 (2 H, d, $J = 9$), 8.44 (2 H, dd, $J = 11, 9$), 8.07 (2 H, d, $J = 9$), 7.87 (2 H, m), 7.81 (2 H, s), 7.17 (4 H, s), 6.83 (2 H, s), 5.76 (2 H, b), 4.67 (1 H, m), 4.25 (2 H, m), 3.22 (5 H, m), 2.87 (1 H, m), 2.61 (2 H, m), 2.44 (2 H, m), 2.37 (3 H, s), 2.29 (2 H, m), 2.18 (2 H, m), 1.60 (4 H, m), 1.32 (2 H, m). ESI/MS m/z : 1361, 1363, 1365 ($M + H$) $^+$.

Compound **37** was obtained from compound **15** (67%). HPLC (50:50): retention time, 8.6 min, 96%. ^1H NMR (DMSO- d_6 /TFA- d): 9.04 (2 H, dd, $J = 12, 9$), 8.41 (2 H, bt), 8.17 (1 H, d, $J = 7$), 7.84 (1 H, m), 7.80 (2 H, d, $J = 3$), 7.69 (1 H, d, $J = 9$), 7.66 (1 H, m), 7.15 (1 H, d, $J = 9$), 7.11 (1 H, d, $J = 9$), 7.04 (2 H, s), 5.66 (2 H, b), 4.87 (1 H, m), 4.20 (2 H, m), 3.44 (2 H, m), 3.05 (2 H, m), 2.94 (3 H, s), 2.85 (2 H, m), 2.80 (3 H, s), 2.72 (2 H, m), 2.41 (2 H, m), 2.30 (3 H, s), 2.14 (2 H, m), 2.05 (2 H, m), 1.66 (1 H, m), 1.43 (4 H, m), 1.22 (2 H, m). ESI/MS m/z : 1484 ($M + H$) $^+$.

Compound **38** was obtained from compound **16** (41%). HPLC (50:50): retention time, 5.9 min, >99%. ^1H NMR (DMSO- d_6 /TFA- d): 8.99 (2 H, dd, $J = 12, 9$), 8.41 (2 H, bt), 8.18 (1 H, d, $J = 9$), 8.01 (2 H, d, $J = 9$), 7.87 (1 H, bt), 7.80 (2 H, d, $J = 3$), 7.69 (1 H, d, $J = 8$), 7.66 (1 H, b), 7.18 (1 H, d, $J = 8$), 7.11 (1 H, d, $J = 8$), 6.91 (1 H, t, $J = 3$), 6.82 (1 H, dd, $J = 9, 4$), 6.56 (1 H, m), 5.65 (2 H, b), 4.88 (1 H, m), 4.20 (2 H, b), 3.44 (2 H, m), 3.06 (2 H, m), 2.94 (3 H, s), 2.89 (2 H, m), 2.80 (3 H, s), 2.71 (2 H, m), 2.46 (2 H, m), 2.29 (3 H, s), 2.15 (2 H, m), 2.04 (2 H, m), 1.65 (1 H, m), 1.42 (4 H, m), 1.22 (2 H, m). ESI/MS m/z : 1358 ($M + H$) $^+$.

Preparation of a Biosensor Surface. Immobilization of L-T₄ analog L-**9** through the free amine to the CM-5 sensor chip was performed by a modification of the method previously described (2). Briefly, a continuous flow of HBS buffer at 20 $\mu\text{L}/\text{min}$ was initiated over the biosensor surface. The carboxymethylated dextran matrix on the sensor surface was activated by a 6 min injection of a solution of 0.2 M EDAC and 0.05 M NHS. L-T₄ analog L-**9** (25 $\mu\text{g}/\text{mL}$ in 10% EtOH, 50 mM NaHCO₃, and 1 M NaCl at pH 8.5) was then immobilized (5 min injection), followed by a 6 min injection of 1 M ethanolamine hydrochloride to block remaining unreacted active ester groups. Typical immobilizations yielded 350–450 RU of L-**9** bound to the biosensor surface.

Solution Competition Analysis. (A) *Construction of a Standard Curve.* All BIAcore studies were carried out at 25 $^{\circ}\text{C}$ using the Fab fragment of an anti-T₄ mAb which eliminated the complexity associated with the bivalency of the monoclonal antibody. Seven concentrations (0, 5, 10, 15, 20, 25, and 30 nM) of anti-T₄ Fab fragment were serially diluted into HBS buffer and allowed to equilibrate for 1 h. Each sample was then injected over the L-T₄ biosensor surface at 5 $\mu\text{L}/\text{min}$ for 2 min. The biosensor surface was regenerated after each run with a 1 M formic acid wash for 1 min. Initial rates of binding of anti-T₄ Fab fragment to the biosensor surface were measured over a 15 s window beginning 15 s postinjection using homogeneous association model type 3 (13). A standard curve was obtained from the linear fit of a plot of initial binding rates versus concentration of added anti-T₄ Fab fragment.

(B) *Determination of Solution Affinities.* Ten concentrations of each soluble T₄ analog, determined from preliminary studies to completely define the competition curve, were serially diluted into HBS buffer and mixed with 20 nM anti-T₄ Fab fragment. Samples were allowed to equilibrate (≥ 2 h) and then injected over the calibrated

T₄ biosensor surface at 5 $\mu\text{L}/\text{min}$ for 2 min. The biosensor surface was regenerated after each run with a 1 M formic acid wash for 1 min. Sensorgrams for each solution were obtained in duplicate, and initial binding rates of free anti-T₄ Fab fragment to the biosensor surface were measured as described above. The resulting free anti-T₄ Fab fragment concentrations in solution, measured as initial binding rates to the biosensor surface, were plotted against the concentration of added soluble T₄ analog to generate competition curves. Equilibrium dissociation constants (K_D) were obtained by nonlinear regression analysis of the data using the solution affinity model built into BIAevaluation 2.1 software (BIAcore, Inc.) with the slope and intercept obtained from the standard curve.

RESULTS

Preparation of Soluble T₄ Analogs. Thyroxine analogs with and without aminoalkyl linkers (**1–16**) were obtained from commercial sources or synthesized as previously described (2). Analogs **9–16** bearing an aminoalkyl linker were coupled with the NHS active ester of 5-carboxyfluorescein to give tracers **17–24** in 42–79% yield after preparative HPLC (Scheme 1). Analog L-**9** was coupled in an identical manner to the NHS active ester of 6-carboxyfluorescein to yield compound **25** in 70% yield. The fluorescein tracers **26** and **27** were prepared from the NHS active ester of *N*-(carboxymethyl)-L-thyroxine *tert*-butyl ester and 4'-aminomethylfluorescein or 5-aminomethylfluorescein in 39 and 61% overall yields, respectively, after deprotection with TFA. *N-tert*-(Butoxycarbonyl)-L-thyroxine NHS active ester and 4'-*N*-glycylaminomethylfluorescein were reacted to give the carboxy-substituted thyroxine tracer **28** after deprotection with TFA in 61% overall yield. Fluoresceinated compound **29** was prepared by the direct conjugation of D-thyroxine and 5-carboxyfluorescein NHS ester in 80% yield. Analogs **9–16** were also coupled with the NHS active ester of 10-(3-sulfopropyl)-*N*-tosyl-*N*-(3-carboxypropyl)acridinium-9-carboxamide (**39**) to give chemiluminescent tracers **31–38** in 35–67% yield after preparative HPLC (Scheme 1).

Preparation of an L-T₄ Biosensor. L-T₄ containing an aminoalkyl linker (L-**9**, Figure 1) was immobilized on the activated carboxymethylated dextran surface of a CM-5 sensor chip through amine coupling and used for all experiments to determine the concentration of free anti-T₄ Fab fragment in solution. To ensure that initial rates of binding of anti-T₄ Fab fragment to the immobilized L-T₄ biosensor surface were mass transport limited, a relatively high-density surface was prepared via a modification of the method utilized for the preparation of low-density thyroxine analog biosensors previously described (2). Thus, high-density L-T₄ surfaces were obtained by increasing the flow rate across the biosensor surface from 5 to 20 $\mu\text{L}/\text{min}$ for the activation (NHS/EDAC), coupling (L-**9**), and blocking (ethanolamine) solutions. Additionally, the concentration of L-**9** in the coupling solution was increased from 5 to 25 $\mu\text{g}/\text{mL}$. Typical immobilizations yielded 350–450 RU due to L-**9** covalently bound to the biosensor surface. Initial binding rates obtained for a given concentration of anti-T₄ Fab fragment (≤ 30 nM, *vide infra*) to all biosensor surfaces generated during these studies were identical within experimental error, indicating that mass transport limiting binding conditions were met. Biosensors prepared in this manner were suitable for use in the solution affinity analyses described below.

Construction of a Standard Curve. Typical sensorgrams obtained for different concentrations of anti-

T₄ Fab fragment binding to a high-density L-T₄ biosensor surface under mass transport limiting conditions are shown in Figure 2. Both the initial binding rates and the total response units obtained during the binding phase of the sensorgrams increase proportionately with the increase in binding protein concentration within the range examined (0–30 nM). The initial binding rate for each anti-T₄ Fab fragment concentration was obtained

by averaging the binding rate observed over a 15 s window beginning 15 s postinjection. Data from the first 15 s of each sensorgram were omitted due to sample dispersion effects at the start of injections. A plot of initial binding rate versus concentration of anti-T₄ Fab fragment yields a standard curve which can be used to determine the concentration of free Fab fragment in equilibrium with various T₄ analogs from which K_D

Figure 2. Overlay plot of sensorgrams generated with 0, 5, 10, 15, 20, 25, and 30 nM anti- T_4 Fab fragment binding to the immobilized T_4 biosensor surface. Initial binding rates were obtained from the shaded portion of each sensorgram.

Figure 3. Average standard curve obtained for binding of anti- T_4 Fab fragment to the immobilized T_4 biosensor surface.

values in solution can be determined. Thirteen identical standard curves were generated during the course of these studies. The initial binding rates measured for each concentration of anti- T_4 Fab fragment were averaged and plotted against the Fab fragment concentration, providing an average standard curve depicted in Figure 3. The standard curve is linear ($r^2 = 0.998$) over the Fab fragment concentration range of 0–30 nM with measured binding rates from 0 to 6 RU s^{-1} . The slope and intercept for the average standard curve are $2.0 \times 10^8 \text{ RU M}^{-1} \text{ s}^{-1}$ and -0.099 RU s^{-1} , respectively.

Determination of Solution Affinities of Soluble T_4 Analogs for Anti- T_4 Fab Fragment. Ten concentrations of each T_4 analog tested were mixed with a fixed concentration of anti- T_4 Fab fragment (20 nM) in HBS buffer. After the solutions had reached equilibrium, the samples were individually injected over the calibrated high-density T_4 biosensor surface to generate a series of sensorgrams. A typical result is illustrated in Figure 4A for the solution affinity analysis of L- T_3 Br fluorescein tracer (**20**) with anti- T_4 Fab fragment. As the concentration of T_4 analog increases, the amount of free anti- T_4

Figure 4. Analysis of anti- T_4 Fab fragment binding to L- T_3 Br fluorescein tracer in solution. (A) Overlay plot of sensorgrams generated from solutions of 0.5, 1, 4, 7, 10, 13, 16, 19, 22, and 25 nM L- T_3 Br fluorescein tracer with 20 nM anti- T_4 Fab fragment. Initial binding rates were obtained from the shaded portion of each sensorgram. (B) Nonlinear regression plot of initial binding rate versus concentration of added L- T_3 Br fluorescein tracer.

Fab fragment in solution available for binding to the biosensor surface decreases. Since the concentration of free binding protein is proportional to the binding rate of anti- T_4 Fab fragment to the biosensor surface, the initial binding rate also decreases. A plot of initial binding rate, determined as above, versus total concentration of added L- T_3 Br fluorescein tracer (**20**) provides the competition curve depicted in Figure 4B. The data points represent the experimentally determined initial rates of binding of free Fab fragment to the biosensor surface at a given concentration of soluble T_4 analog in solution. The curve represents the best nonlinear fit of the data using eq 1 (solution affinity model in BIAevaluation 2.1 software)

$$r_0 = r_m - \frac{k \left(x + \frac{r_m - I}{k} + K_D \right)}{k \sqrt{\frac{1}{4} \left(x + \frac{r_m - I}{k} + K_D \right)^2 - x \left(\frac{r_m - I}{k} \right)}} \quad (1)$$

where r_0 is the initial binding rate, r_m is the maximum initial binding rate where $[T_4 \text{ analog}] = 0$, x is the total concentration of T_4 analog or tracer, and k and I are the slope and intercept, respectively, determined from the standard curve above. K_D is the equilibrium dissociation constant for the binding of the T_4 analog to anti- T_4 Fab fragment in solution. In the example depicted, values for K_D of $122 \pm 50 \text{ pM}$ and an r_m of 3.76 RU s^{-1} were obtained. Using the standard curve slope and intercept

Table 2. Effect of the Linker and Fluorescein Regioisomer on the Binding Properties of T₄ Fluorescein Tracers with Anti-T₄ Fab Fragment

Tracer	K _D	Tracer	K _D
 25	227 ± 47 pM	 28	2.5 ± 0.72 nM
 26	166 ± 60 pM	 29	≤ 100 pM
 27	≤ 100 pM		

determined above and the equation for a straight line ($y = mx + b$), an r_m value of 3.76 RU s⁻¹ corresponds to 19.3 nM free anti-T₄ Fab fragment without any L-T₃Br fluorescein tracer added which is very close to the predicted value of 20 nM. Solution affinity studies with all T₄ analogs were conducted in a similar manner.

Equilibrium dissociation constants obtained for several T₄ analogs and tracers with the anti-T₄ Fab fragment in solution are summarized in Table 1. For comparison, the table also contains K_D values obtained previously for the same T₄ analogs bound to the biosensor chip surface through aminoalkyl linkers (compounds 9–16) using the direct kinetic analysis protocol on the BIAcore instrument (2). In general, the K_D values obtained in solution were comparable to those determined by direct kinetic analysis. The largest differences are seen in the T₃ analog series (L- and D-T₃, L-T₂Br, and L-T₃NMe₂) with K_D values obtained in solution being higher. As seen previously, the T₄ analogs (L- and D-T₄, L-T₃Br, and L-T₄NMe₂ series) bind exceedingly tight with several K_D values being outside the range for which the BIAcore instrument can accurately provide values from solution competition studies (≤100 pM) (14). Conversely, the L-T₂ analogs

bind much weaker with K_D values in the micromolar range. There is no preference for the stereochemistry of the α-amino group. Significantly, incorporation of fluorescein or acridinium moieties into any of the T₄ analogs for generation of tracers had little effect on the observed K_D.

To determine the effect of the linker position and the fluorescein regioisomer utilized for a tracer on the K_D values, five additional fluorescein tracers were studied. The results are summarized in Table 2. 5-Carboxyfluorescein tracers (27 and 29) bind the anti-T₄ Fab fragment the tightest with K_D values being outside the range for which the BIAcore instrument can accurately provide values from solution affinity studies (≤100 pM). For the tracers linked through the 5-position of fluorescein studied here, there is no apparent preference for the stereochemistry of the α-amino group or the length of the linker arm. Similar K_D values were obtained for analogs containing aminoalkyl linkers attached to fluorescein through the 4'- and 6-positions (25 and 26). However, the tracer bearing a 4'-N-glycylaminomethylfluorescein moiety linked through the carboxyl group of L-T₄ (28)

showed a considerable decrease in affinity for the anti-T₄ Fab fragment.

DISCUSSION

Surface plasmon resonance technology allows for the direct real-time observation of molecular interactions between an analyte in solution and a binding partner immobilized on a biosensor surface. The SPR phenomenon measures small changes in the refractive index at the biosensor surface which is directly proportional to the mass of the bound analyte (8, 15). The larger the mass of the analyte used, the larger the instrumental response. Thus, the majority of studies which have utilized BIAcore SPR technology have involved binding interactions between two macromolecules. In such cases, the choice of which macromolecule to conjugate to the biosensor surface is largely arbitrary since binding of either macromolecule to the immobilized partner will result in an easily measurable instrument response. However, the observed kinetics of the interaction may be different for each approach because the process of immobilization of a macromolecule is generally nonspecific and can effect the conformation and reactivity of the species involved (16).

Relatively few studies have been reported in which one of the binding partners is a low-molecular weight ligand or analyte. In this case, the design of the experiment is critical to the reliability of the information obtained. Conjugation of the macromolecule member of the binding pair to the biosensor surface is again nonspecific, and a subsequent binding interaction with the low-molecular weight analyte would generate a minimal instrument response. The complementary experiment in which the low-molecular weight species is conjugated to the biosensor surface is more advantageous with regard to generation of an instrument response upon binding of the macromolecular analyte. However, there are limitations in the conjugation of low-molecular weight ligands to a biosensor surface. Small molecules generally have fewer functional groups available for coupling to a biosensor surface and in many cases require chemical modification for incorporation of a linker functionality (2, 14, 17). In fact, the acridinium and fluorescein tracers described here contain no functionalities which would allow them to be coupled to a biosensor surface. Low-molecular weight ligand immobilizations also cannot be followed directly, since the instrument response obtained for small molecules is too low. A subsequent binding experiment with saturating amounts of the macromolecular analyte is required to obtain a large and easily quantitated instrument response. Moreover, the amount of a low-molecular weight ligand immobilized on the biosensor surface is difficult to control and often represents an excessively high binding capacity for the macromolecular analyte.

The need to study binding interactions involving low-molecular weight ligands or analytes using SPR technology is still of considerable importance since many ligand–receptor interactions of biological significance involve at least one low-molecular weight interactant. Several approaches to the study of binding interactions involving a low-molecular weight ligand or analyte have been described. One approach involves the direct, simultaneous analysis of a low-molecular weight analyte binding to multiple sensing surfaces with varying amounts of an immobilized ligand (multispot sensing) (18). The methodology was shown to be applicable to analytes as small as 180 Da and particularly useful for low-affinity interac-

tions. Drawbacks to this approach include a requirement for the most sensitive BIAcore instrument, BIAcore 2000, and the need to use several sensor surfaces for a single binding study. Furthermore, the kinetic information obtained from this method is more qualitative than quantitative. A more quantitative analysis of binding interactions involving a low-molecular weight analyte can be obtained from a competitive study in which the low-molecular weight analyte competes with a larger macromolecule for the same immobilized ligand (surface competition) (8). The method provides both the rate and affinity constants in a one-step procedure that monitors binding directly. In a qualitative manner, the method allows for a rapid affinity ranking of different low-molecular weight analytes interacting with the same immobilized ligand. However, the mathematics used to characterize the surface competition experiment are much more complex than that required for a direct binding experiment. The instrument response for a given low-molecular weight/high-molecular weight analyte combination binding to an immobilized ligand is dependent upon the association and dissociation rate constants of both the low- and high-molecular weight analytes and their respective molecular weights. The approach also requires the additional preparation and characterization of the high-molecular weight analyte to be used in the competition studies. An alternative and simpler competitive experiment involves an immobilized ligand and a soluble ligand free in solution competing for binding sites on a single analyte (solution competition) (8, 19, 20). For the solution competition experiment, if high-density immobilized ligand surfaces are employed and the association rate between the analyte and immobilized ligand is $\geq 1 \times 10^5 \text{ M}^{-1} \text{ s}^{-1}$, the observed binding will be limited by mass transfer. Under such conditions, initial binding rates are directly proportional to the amount of free analyte (not bound to soluble ligand) in solution and independent of the interaction kinetics or analyte–ligand affinity. Measuring concentrations of free analyte in equilibrium solutions with different concentrations of soluble ligand allows one to determine equilibrium dissociation constants. This was the method utilized in these studies. The advantage to the solution competition experiment is that a single biosensor surface can be utilized for determination of binding affinities for a series of related analogs, making direct comparison of results more reliable. Unfortunately, the method is indirect and does not provide individual association and dissociation rate constants.

Solution competition experiments require the generation of a standard curve from which the concentration of free analyte in equilibrium solutions with a soluble ligand can be determined. Several high-density L-T₄ surfaces, ranging from 350 to 450 RU of immobilized L-9, were prepared during the course of these studies, and a standard curve was generated at the start of each experiment. As depicted in the average standard curve (Figure 3), the measured initial binding rate for a given concentration of anti-T₄ Fab fragment binding to the different immobilized L-T₄ surface densities was quite reproducible, indicating a mass transport limiting situation. The high reproducibility of initial binding rates also supports the accuracy of the slope and intercept obtained from the average standard curve which are critical to evaluation of solution competition data by the solution affinity model (cf. eq 1), particularly for high-affinity interactions. For low-affinity interactions (micromolar concentrations), K_D values obtained are largely independent of the slope and intercept values from the

standard curve (8). The standard curves and solution competition studies described here were all carried out with the Fab fragment of an anti-T₄ mAb. Anti-T₄ mAb contains two identical binding sites and under the conditions described for solution competition experiments can bind zero, one, or two T₄ antigens (immobilized and/or soluble). Under such conditions, the observed binding rate is no longer proportional to free antibody binding sites in solution. Equations accounting for mAb bivalency have been derived, but they do not necessarily correct the problem (8, 14). The Fab fragment contains a single binding site and eliminates the problems associated with mAb bivalency.

In general, structural requirements important for the anti-T₄ Fab fragment-T₄ analog binding interaction in solution were the same as those identified from the direct analysis of Fab fragment interaction with individual T₄ analog biosensors (2). Specifically, the diphenyl ether ring system, including the degree and type of halogenation, was the major determinant in binding affinity. The binding interaction became less favorable with the loss of each halogen from the terminal aryl ring (K_D for a series, L,D-T₄ $\approx$ L-T₄NMe₂ < L-T₃Br < L-T₂Br₂ < L,D-T₃ $\approx$ L-T₃NMe₂ < L-T₂Br < L-T₂). Iodo-bromo exchanges in the terminal aryl ring system also resulted in slight decreases in binding affinity. These observations have been attributed to the acidity of the phenolic hydroxyl group and the effect the different halogenation patterns have on the pK_a of this moiety (2). As previously observed in the direct kinetic analysis, the binding interaction in solution is relatively insensitive to modifications to the amino acid portion of the T₄ analogs. Specifically, there is no preference for the stereochemistry of the α -amino chiral center (L-T₄ series $\approx$ D-T₄ series) or a requirement for an ionizable carboxyl group (L-T₄ series $\approx$ L-T₄NMe₂ series). Binding interactions were generally more favorable for the analogs bearing an aminoalkyl linker relative to those of the native analytes. This was not unexpected since the immunogen used to elicit the antibody was prepared by conjugating *N*-acetyl-L-T₄ to the carrier protein. With an immunogen thus prepared, the animal's immune system was presented a hapten in which both the α -amino and carboxylic acid groups had been converted into amides, unlike the native analyte. Incorporation of the acridinium or 5-carboxyfluorescein labels via an aminohexyl linker also had little effect on the observed binding affinity in solution (Table 1). However, the linker, linker position, and regioisomer of the label incorporated can effect the binding interaction as revealed by the particular combinations that were tested (Table 2).

In absolute terms, some significant differences were observed between K_D values determined by the solution competition method and those determined by direct kinetic analysis (solid phase) on the BIAcore instrument (Table 1), with the disparity being more pronounced for the weaker binding interactions. In these cases, the K_D value determined by the solution competition method was always higher than the K_D value determined by direct kinetic analysis. Previous literature reports applying BIAcore technology to the study of binding interactions have noted similar differences between solution competition studies and direct kinetic analysis studies (14, 21, 22). The disparity has been primarily attributed to the different experimental designs of the two methods. A direct kinetic analysis of binding interactions involves the determination of association and dissociation rate constants (k_a and k_d) for an analyte free in solution binding to individual immobilized ligands. Equilibrium

dissociation constants (K_D) can then be calculated from the measured rate constants. However, the density of the immobilized ligand can greatly effect the measured rate constants due to mass transport effects and rebinding of analyte to the immobilized ligand. Rebinding can become particularly problematic with rapid association rates which will favor reassociation of analyte to the immobilized ligand during the dissociation phase of the study. Rebinding of analyte to the immobilized ligand will artificially slow the observed dissociation rate constant. This phenomenon will become more pronounced as the true dissociation rate becomes faster and can result in an artificially low equilibrium dissociation constant ($K_D = k_d/k_a$) for weaker binding interactions. Association rates measured by direct kinetic analysis of the anti-T₄ Fab fragment-T₄ analog binding interaction were all rapid, ranging from 1 to $7 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$ (2). Dissociation rates measured by the direct kinetic analysis method were much more varied, ranging from 6 to $920 \times 10^{-5} \text{ s}^{-1}$. It would not be surprising if some of the anti-T₄ Fab fragment-T₄ analog binding affinities previously determined by direct kinetic analysis were artificially low. Thus, due to the solution-surface reaction format, the values can only be regarded as apparent rate and equilibrium constants. In contrast, the K_D values determined here by the solution competition method involve equilibrium mixtures in solution which are independent of the solution-surface interactions described above for the direct kinetic analysis method. Equilibrium dissociation constants measured in solution can be regarded as true affinity constants.

CONCLUSION

Direct kinetic analysis of binding interactions using BIAcore SPR technology provides individual association and dissociation rate constants from which equilibrium constants can be calculated. However, the biosensor optimization process for minimizing mass transport effects and analyte rebinding during the dissociation phase of the sensorgram can be time-consuming and subjective. Furthermore, direct comparison of binding affinities determined for a series of related analogs with a single binding protein is difficult since a different biosensor must be generated for each analog studied. In contrast, the solution competition format utilized in these studies provides only equilibrium constants but allows for a reliable, direct comparison of binding affinities using a single biosensor surface.

The binding affinities of an anti-T₄ Fab fragment for a series of T₄ analogs and tracers were determined using the solution competition format and compared to results obtained by the direct kinetic analysis method on the BIAcore instrument. Qualitatively, results obtained from solution competition studies of the anti-T₄ Fab fragment-T₄ analog binding interaction followed the same trend as that observed in the direct kinetic analysis. Primary T₄ analog structural features important for the binding interaction include the diphenyl ether ring system and the ionizable phenolic hydroxyl moiety. Incorporation of fluorescein or acridinium labels to generate tracers had little effect on the observed binding affinities. Quantitatively, some significant differences were observed between results determined by the solution competition method and those determined by direct kinetic analysis. We attribute the differences to the different experimental designs (solution-surface versus solution phase) and the considerations affecting these interactions.

The synthesis of oligodeoxynucleotides (ODNs) containing 5-[N-[2-[N,N-bis(2-aminoethyl)amino]ethyl]carbamoyl]-2'-deoxyuridine (**BAE**) and 5-[N-[3-[N,N-bis(3-aminopropyl)amino]propyl]carbamoyl]-2'-deoxyuridine (**BAP**) is described. The thermal stabilities of duplexes containing these ODNs and either the complementary DNA or RNA strand and of triplexes consisting of these ODNs and the target duplex were studied by thermal denaturation. ODNs containing **BAE** or **BAP** stabilize duplex formation with either the complementary DNA or RNA strands but destabilize triplex formation with the target duplex. Furthermore, the resistance of these ODNs to nuclease hydrolysis was studied by using snake venom phosphodiesterase (a 3'-exonuclease) and nuclease S1 (an endonuclease). It was found that ODNs containing either **BAE** or **BAP** were more resistant to nucleolytic hydrolysis by either of the nucleases than the unmodified ODN.

INTRODUCTION

Oligodeoxynucleotide (ODN)¹ analogues with a variety of functional groups (i.e. intercalating, alkylating, DNA-degrading, and fluorescent groups) have been synthesized and used for biological and biochemical studies, including antisense and antigen studies (1–6). To be able to apply these ODN analogues to antisense and antigen studies, the ODNs must form stable Watson–Crick hybrids with the complementary target RNAs and form stable triple-stranded DNA with target DNA duplexes (1–4).

It is well-known that naturally occurring polyamines, such as spermidine and spermine, bind strongly to DNA (7–9) and stabilize duplex (10, 11) and triplex formations (12–14), although the precise mode of binding is not clear. Their enhanced thermal stability is explained by the reduction of the anionic electrostatic repulsion between the phosphate moieties by the cationic polyamines. Therefore, ODN analogues carrying various polyamines have been synthesized to improve the thermal stability of duplexes and triplexes (15–24).

We recently developed a new and convenient postsynthetic modification method for the synthesis of ODNs containing various amino linkers using either 5-(methoxycarbonyl)-2'-deoxyuridine (**1**) or 5-(trifluoroethoxycarbonyl)-2'-deoxyuridine (**2**) as a convertible nucleoside

(25–30). If ODNs containing **1** or **2** at specific positions are treated with one of several diaminoalkanes, the desired ODNs containing 5-(N-aminoalkyl)carbamoyl-2'-deoxyuridines are readily obtained. Using this method, we found that ODNs containing 5-(N-aminoethyl)carbamoyl-2'-deoxyuridines (**Hs**) efficiently stabilize duplex formation with either the complementary DNA or RNA strands (25, 26, 30). The terminal amino groups of the amino linkers can be further modified by the addition of a variety of functional groups (27). By converting the amino linker to a mercapto linker, we successfully synthesized 5'-5'-linked ODNs with the potential for triplex formation (28) and succeeded in the chemical ligation of ODNs via a disulfide bond in the presence of a template (29).

The enhanced thermal stability of duplexes containing **Hs** has been explained in the following manner. Reduction of the electrostatic repulsion between the phosphate moieties by the ammonium ion of the aminoethylcarbamoyl linker and the enhanced hydrogen-donor ability at N3-H combine to give duplex stabilization, due to incorporation of an electron-withdrawing carbamoyl group at the 5-position of the uracil (26). Tris(2-aminoethyl)amine and tris(3-aminopropyl)amine have a greater positive net charge than diaminoalkanes such as diaminoethane and 1,6-diaminohexane. Therefore, we envisioned that ODNs containing either tris(2-aminoethyl)amine or tris(3-aminopropyl)amine would stabilize duplex formation with the complementary DNA or RNA strand more efficiently than the ODNs carrying the diaminoalkanes.

In this paper, we report the synthesis of ODNs containing 5-[N-[2-[N,N-bis(2-aminoethyl)amino]ethyl]carbamoyl]-2'-deoxyuridine (**BAE**) and 5-[N-[3-[N,N-bis(3-aminopropyl)amino]propyl]carbamoyl]-2'-deoxyuridine (**BAP**). The thermal stability of duplexes containing these ODNs and either the complementary DNA or RNA strand, the thermal stability of triplexes consisting of these ODNs and the target duplex, and the resistance of

the ODNs to nucleolytic hydrolysis by snake venom phosphodiesterase (a 3'-exonuclease) and nuclease S1 (an endonuclease) were also studied.

RESULTS AND DISCUSSION

Synthesis. The synthesis of ODNs containing **BAE** or **BAP** was accomplished in a DNA synthesizer by using a suitably protected 5-[*N*-[2-[*N,N*-bis(2-aminoethyl)amino]ethyl]carbamoyl]-2'-deoxyuridine (**5**) or 5-[*N*-[3-[*N,N*-bis(3-aminopropyl)amino]propyl]carbamoyl]-2'-deoxyuridine phosphoramidite (**8**). The synthesis of the 3'-phosphoramidite derivatives **5** and **8** is shown in Scheme 1. 5'-*O*-(Dimethoxytrityl)-5-(trifluoroethoxycarbonyl)-2'-deoxyuridine (**3**), prepared by a previously described method (27), reacted readily with either tris(2-aminoethyl)amine or tris(3-aminopropyl)amine. Without purifying the product, we protected the amino group with a trifluoroacetyl group to give **4** or **7**. The modified nucleoside (**4** or **7**) was converted to the protected nucleoside phosphoramidite, **5** or **8**, by the usual method of ODN synthesis (31). To incorporate **BAE** or **BAP** into the 3'-end of the ODNs, **4** or **7** was further modified to produce the corresponding 3'-succinate, **6** or **9**, which was then reacted with controlled pore glass (CPG) to give a solid support containing **4** (35.0 $\mu\text{mol/g}$) or **7** (34.7 $\mu\text{mol/g}$).

An unmodified DNA heptadecamer (control) and heptadecamers containing **BAEs** or **BAPs** were synthesized in a DNA synthesizer (31). The average coupling yields of **5** and **8** were 96 and 95%, respectively, using a 0.12 M solution of the amidite derivatives in CH_3CN and 360 s for the coupling time. The fully protected ODNs (each 1 μmol scale) linked to the solid supports were treated with concentrated NH_4OH at 55 $^\circ\text{C}$ for 16 h. This was followed by C-18 column chromatography. Detritylation gave

ODNs **11–20**. Each ODN in this preparation showed a single peak by reversed phase HPLC analysis. ODNs **13** and **17** were analyzed by matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF/MS), and the observed molecular weight supported its structure.

UV Melting Studies of Duplex and Triplex Formation. Duplex formations of the heptadecamers **10–20** with the complementary DNA, $d[TGG(AG)_9GT]-3'$ (**21**), was studied by thermal denaturation in a buffer of 0.01 M sodium cacodylate (pH 7) containing 0.01 M NaCl. One transition was observed in a melting profile of each duplex. Melting temperatures (T_m s) are listed in Table 1. All of the T_m values for the modified ODNs containing **BAEs** or **BAPs** were greater than that of the corresponding unmodified ODN **10**. Therefore, the modified nucleosides, **BAE** and **BAP**, were found to thermally stabilize duplex formation. The stability of the duplexes was dependent on the position and number of the modified nucleosides. Duplexes with ODN **17** or **18** containing one molecule of **BAP** at either the center or 5'-end ($T_m = 56.1$ and 56.2 $^\circ\text{C}$, respectively) were more stable than the duplex with ODN **16** containing **BAP** at its 3'-end ($T_m = 54.3$ $^\circ\text{C}$). On the other hand, the T_m values for the duplexes containing ODNs **11–13** which had one molecule of **BAE** at either the 3'-end, center, or 5'-end were almost same. The duplexes became more stable as the number of **BAEs** and **BAPs** increased. ODNs containing **BAPs** stabilized duplex formation more efficiently than ODNs containing **BAEs**. A 9.8 $^\circ\text{C}$ increase in T_m was observed for ODN **20**.

In a previous paper, we reported the thermal stability of duplexes constructed from ODNs containing **Es** or 5-(*N*-aminoethyl)carbamoyl-2'-deoxyuridines (**Es**) using

the same sequences and conditions described here (25, 26). The length of the amino linkers was found to affect the thermal stability of the duplexes. The ODNs containing **H** stabilized duplex formation with either the complementary DNA or RNA strands more efficiently than ODNs containing **Es** (25). If ODNs containing **Hs** and **Es** are considered, the order of ΔT_m values for ODN–DNA duplexes containing three molecules of the modified nucleosides in a buffer containing 0.01 M NaCl is as follows: ODN **20** containing **BAEs** ($\Delta T_m = 9.8$ °C) > ODN containing **Hs** ($\Delta T_m = 8.0$ °C) > ODN **15** containing **BAEs** ($\Delta T_m = 6.3$ °C) > ODN containing **Es** ($\Delta T_m = 6.0$ °C).

The enhanced thermal stability of duplexes containing **Hs** and **Es** is thought to be due to both a reduction of the electrostatic repulsion between phosphate moieties by the ammonium ion of the aminoalkylcarbamoyl linker and the enhanced hydrogen-donor ability at N3-H caused by incorporation of an electron-withdrawing carbamoyl group at the 5-position of the uracil (26). Therefore, to confirm the importance of the terminal ammonium ion of the *N,N*-bis(2-aminoethyl)aminoethyl and *N,N*-bis(3-aminopropyl)aminopropyl linkers in stabilizing duplexes, T_m s were measured under conditions with a higher ionic strength (0.1 M NaCl) and the ΔT_m values were compared with those measured under conditions with a low ionic strength (Table 1). The ΔT_m values with the high ionic strength for the duplexes containing **BAEs** were similar to that with the low ionic strength, whereas the ΔT_m values with the high ionic strength for the duplexes containing **BAP** became smaller than that with the low ionic strength as the number of **BAP** increased. These results indicate that the terminal ammonium ion of the *N,N*-bis(3-aminopropyl)aminopropyl linker more effectively neutralized the phosphate anions than that of the *N,N*-bis(2-aminoethyl)aminoethyl linker. The *N,N*-bis(3-aminopropyl)aminopropyl linker is longer than the *N,N*-bis(2-aminoethyl)aminoethyl linker and has a more positive net charge than either the aminoethyl or aminoethyl linkers. Therefore, ODNs containing **BAPs** should stabilize duplex formation with the complementary DNA more efficiently than ODNs containing **Hs**, **Es**, or **BAEs**.

Stable duplex formation with mRNA is one of the most important factors in antisense research. Therefore, duplex formation by heptadecamers with the complementary RNA strand, 5'-[UGG(AG)₉GU]-3' (**22**), was next studied by thermal denaturation in a buffer containing 0.1 M NaCl. As shown in Table 1, the trend shown by the T_m s of the modified ODNs containing **BAEs** or **BAPs** was similar to that of the corresponding ODN–DNA duplexes. However, the ΔT_m values were evidently different. The ΔT_m values for ODNs **11–13** and **16–18**,

containing one molecule of **BAE** or **BAP**, were slightly greater than those of the corresponding ODN–DNA duplexes. On the other hand, those for ODNs **14**, **15**, **19**, and **20**, containing either two or three molecules of **BAE** or **BAP**, were smaller than those of the ODN–DNA duplexes. The duplexes were more stable as the number of **BAE** and **BAP** molecules increased. A 7.0 °C increase in T_m was observed for ODN **20**. If ODNs containing **Hs** and **Es** are considered, the order of ΔT_m values for ODN–RNA duplexes containing three molecules of the modified nucleosides in a buffer containing 0.1 M NaCl is as follows: ODN **20** containing **BAEs** ($\Delta T_m = 7.0$ °C) > ODN **15** containing **BAEs** ($\Delta T_m = 3.4$ °C) > ODN containing **Hs** ($\Delta T_m = 3.0$ °C) > ODN containing **Es** ($\Delta T_m = 2.0$ °C).

When ODN analogues containing **BAEs** and **BAPs** form duplexes with the complementary DNA or RNA strand, the amino linkers should be accommodated in the major groove, since the 5-position of 2'-deoxyuridine is in the major groove. The major groove of a DNA–RNA duplex is narrower than that of a DNA–DNA duplex (32). So bulky functional groups may not fit into the narrower major groove of DNA–RNA duplexes as well as they do in DNA–DNA duplexes. The difference in ΔT_m values between DNA–RNA and DNA–DNA duplexes may reflect this conformational difference.

Triplex formation of heptadecamers with the target duplex, d[AG(TC)₉C(T)₅AG(GA)₉CT]-3' (**23**), was also studied by thermal denaturation in a buffer containing 0.5 M NaCl (pH 7.0). Two transitions were observed in the melting profile of each triplex; the transition with the higher T_m was due to melting of the target duplex **23** (88 °C), and the transition with the lower T_m corresponded to dissociation of the third strand from the triplex. The T_m s are also listed in Table 1.

While ODNs containing one molecule of **BAE** at either the 5'- or 3'-end have slightly destabilized triplex formation ($T_m = 39.8$ and 40.0 °C, respectively), the ODN with one molecule of **BAE** in its center showed markedly destabilized triplex formation ($T_m = 35.5$ °C). Furthermore, a 13.6 °C decrease in T_m was observed in ODN **14**, which contains two molecules of **BAE** in the middle of it. ODN **15**, containing three molecules of **BAE**, one in the middle and one at either end, had a T_m similar to that of ODN **13**. Furthermore, similar results were observed in the case of ODNs containing **BAPs**.

When the polypyrimidine ODNs form triplexes with target duplexes, the ODNs are accommodated in the major groove of the target duplexes and Hoogsteen-type base triplets (T·T and C⁺·GC) are formed (4). When ODN analogues containing **BAEs** and **BAPs** form triplexes with the target duplexes, the amino linkers should lie in the

major groove of the target duplexes, since the 5-position of the 2'-deoxyuridine residue of the third strand is located in the major groove of the target duplex in the triplex. The vicinity of the 5-position of the 2'-deoxyuridine residue of the third strand in the triplex is sterically crowded. Therefore, bulky amino linkers, such as the *N,N*-bis(3-aminopropyl)aminopropyl linker and the *N,N*-bis(2-aminoethyl)aminoethyl linker, may not fit into the major groove of target duplexes, especially when they are located in the middle of the third strands.

Partial Digestion of ODNs with Snake Venom Phosphodiesterase and Nuclease S1. Since resistance to nucleolytic hydrolysis by nucleases is an important factor in antisense and antigene studies, the stability of ODNs containing ^{BA_E} or ^{BA_P} to nucleolytic digestion was examined next (1-4). Two nucleases, snake venom phosphodiesterase (a 3'-exonuclease) and nuclease S1 (an endonuclease), were used in this study. ODNs **11**, **14**, **16**, and **19** were labeled at the 5'-end with ³²P and

Figure 3. Polyacrylamide gel electrophoresis of 5'-³²P-labeled ODNs hydrolyzed by snake venom phosphodiesterase: (a) **10**, (b) **11**, and (c) **16**. ODNs were incubated with snake venom phosphodiesterase for 0 min (lane 1), 10 min (lane 2), 30 min (lane 3), 60 min (lane 4), and 120 min (lane 5). Experimental conditions are described in Experimental Procedures.

Figure 4. Polyacrylamide gel electrophoresis of 5'-³²P-labeled ODNs hydrolyzed by nuclease S1: (a) **10**, (b) **14**, and (c) **19**. ODNs were incubated with nuclease S1 for 0 min (lane 1), 10 min (lane 2), 30 min (lane 3), 60 min (lane 4), and 120 min (lane 5). Experimental conditions are described in Experimental Procedures.

incubated separately with these nucleases. The reactions were then analyzed by denaturing polyacrylamide gel electrophoresis (31). While the control, ODN **10**, was randomly hydrolyzed by snake venom phosphodiesterase after 120 min of incubation (Figure 3a, lane 5), ODNs containing ^{BA_P} or ^{BA_E} at their 3'-ends were completely resistant to hydrolysis by this nuclease (Figure 3b,c, lane 5). ODNs **14** and **19**, which contained two molecules of the modified nucleoside ^{BA_E} and ^{BA_P} in their middles, were also more resistant to nuclease S1 than the control, ODN **10** (Figure 4). The half-lives of ODNs **10**, **14**, and **19** were 23, 39, and 54 min, respectively. Therefore, ODNs containing ^{BA_E} or ^{BA_P} were more resistant to nucleolytic hydrolysis by both snake venom phosphodiesterase and nuclease S1 than the unmodified ODN.

CONCLUSION

In this paper, we report the synthesis of ODNs containing 2'-deoxyuridine analogues carrying either an *N,N*-bis(2-aminoethyl)aminoethylcarbamoyl or *N,N*-bis(3-aminopropyl)aminopropylcarbamoyl linker. The thermal stabilities of duplexes containing these ODNs and either the complementary DNA or RNA strand and of

triplexes of these ODNs and the target duplex were studied by thermal denaturation. We found that ODNs containing ^{BAE} or ^{BAP} stabilize duplex formation with either the complementary DNA or RNA strand but destabilize triplex formation with the target duplex. Furthermore, resistance of these ODNs to nuclease hydrolysis was examined by using snake venom phosphodiesterase (a 3'-exonuclease) and nuclease S1 (an endonuclease). The ODNs containing ^{BAE} or ^{BAP} were more resistant to nucleolytic hydrolysis by either of these nucleases than the unmodified ODN.

EXPERIMENTAL PROCEDURES

General Remarks. Thin-layer chromatography was done on Merck 60F₂₅₄ coated plates. The silica gel or the neutralized silica gel used for column chromatography was Merck silica gel 5715 or ICN silica 60A, respectively. Melting points were measured on a Yanagimoto MP-3 micromelting point apparatus (Yanagimoto) and are uncorrected. Fast atom bombardment mass spectrometry (FAB-MS) was measured on a JEOL JMS-HX110 instrument (JEOL) at an ionizing voltage of 70 eV. The ¹H-NMR spectra were recorded with a JEOL EX-270 instrument with tetramethylsilane as an internal standard. Chemical shifts are reported in parts per million (δ), and signals are expressed as an s (singlet), d (doublet), t (triplet), q (quartet), m (multiplet), or br (broad). All exchangeable protons were detected by the addition of D₂O. UV absorption spectra were recorded with a Shimadzu UV-240 spectrophotometer (Shimadzu Co.).

5-[N-[2-[N,N-Bis[2-(trifluoroacetyl-amino)ethyl]-amino]ethyl]carbamo-yl]-5'-O-(dimethoxytrityl)-2'-deoxyuridine (4). Tris(2-aminoethyl)amine (900 μ L, 6.00 mmol) was added to a solution of **3** (**27**) (1.31 g, 2.00 mmol) in pyridine (20 mL), and the mixture was stirred at room temperature. After 1 h, pyridine (20 mL), triethylamine (5.60 mL, 40.0 mmol), and ethyl trifluoroacetate (4.80 mL, 40.0 mmol) were added to the solution, and the mixture was stirred at room temperature for 5 h. The solvent was concentrated, and then the residue was dissolved in CHCl₃. The whole was washed with aqueous saturated NaHCO₃, dried over Na₂SO₄, and concentrated. The residue was chromatographed over a silica gel column (3.2 $\times$ 10 cm) with 75–100% EtOAc in hexane to give **4** (1.41 g, 79% as a white foam): FAB-MS m/z 895 ($M^+ + 1$); ¹H-NMR (CDCl₃) δ 8.89 (t, 1H, CONH, $J = 5.3$ Hz), 8.70 (s, 1H, 3-NH), 8.64 (s, 1H, H-6), 7.52 (t, 2H, CF₃CONH, $J = 4.6$ Hz), 7.41–7.20 (m, 9H, DMTr-phenyl), 6.84–6.81 (m, 4H, DMTr-phenyl), 6.15 (t, 1H, H-1', $J_{1',2'} = 6.4$ Hz), 4.35–4.31 (m, 1H, H-3'), 3.99–3.94 (m, 1H, H-4'), 3.78 (s, 6H, DMTr-OMe), 3.52–3.34 (m, 8H, H-5'ab, CF₃CONHCH₂, CONHCH₂), 2.69–2.61 (m, 6H, NCH₂), 2.50 (ddd, 1H, H-2'a, $J_{2'a,3'} = 4.3$ Hz, $J_{2'a,1'} = 6.4$ Hz, $J_{2'b,2'a} = 14.0$ Hz), 2.20 (ddd, 1H, H-2'b, $J_{2'b,3'} = 6.4$ Hz, $J_{2'b,1'} = 6.7$ Hz, $J_{2'b,2'a} = 14.0$ Hz), 2.06 (d, 1H, 3'-OH, $J = 3.1$ Hz); FAB exact MS calcd for C₄₁H₄₅F₆N₆O₁₀ ($M^+ + 1$) 895.3099, found 895.3077.

5-[N-[2-[N,N-Bis[2-(trifluoroacetyl-amino)ethyl]-amino]ethyl]carbamo-yl]-5'-O-(dimethoxytrityl)-3'-O-[(2-cyanoethyl)(N,N-diisopropylamino)phosphinyl]-2'-deoxyuridine (5). After successive coevaporation with pyridine, **4** (537 mg, 600 μ mol) was dissolved in CH₂-Cl₂ (6 mL) containing N,N-diisopropylethylamine (310 μ L, 1.80 mmol). 2-Cyanoethyl N,N-diisopropylchlorophosphoramidite (270 μ L, 1.20 mmol) was added to the solution, and the reaction mixture was stirred for 20 min at room temperature. The mixture was diluted with

CHCl₃ and washed with aqueous saturated NaHCO₃ and brine. The separated organic phase was dried over Na₂SO₄ and concentrated. The residue was chromatographed over a neutral silica gel column (3.3 $\times$ 9 cm) with 50–80% EtOAc in hexane to give **5** (488 mg, 74% as a white foam): FAB-MS m/z 1095 ($M^+ + 1$); ³¹P-NMR (CDCl₃) δ 149.90, 149.64 (85% H₃PO₄ as an internal standard); FAB exact MS calcd for C₅₀H₆₂F₆N₆O₁₁P ($M^+ + 1$) 1095.418, found 1095.4240.

5-[N-[2-[N,N-Bis[2-(trifluoroacetyl-amino)ethyl]-amino]ethyl]carbamo-yl]-5'-O-(dimethoxytrityl)-3'-O-succinyl-2'-deoxyuridine (6). After successive coevaporation with pyridine, **4** (179 mg, 200 μ mol) was dissolved in pyridine (2 mL). Succinic anhydride (40 mg, 400 μ mol) and DMAP (12 mg, 100 μ mol) were added to the solution, and the mixture was stirred at room temperature for 3 days. The mixture was diluted with CHCl₃ and washed with H₂O, aqueous saturated NaHCO₃, and then brine. The separated organic phase was dried over Na₂SO₄ and evaporated. The residue was chromatographed on a silica gel column (3.0 $\times$ 9 cm) with 80–100% EtOAc in hexane and then 0–30% MeOH in EtOAc to give **6** (117 mg, 59% as a white foam): ¹H-NMR (CDCl₃) δ 8.73 (s, 1H, H-6), 7.61 (s, 2H, CF₃CONH), 7.41–7.11 (m, 9H, DMTr-phenyl), 6.88–6.78 (m, 4H, DMTr-phenyl), 6.02–5.95 (m, 1H, H-1', $J_{1',2'} = 6.4$ Hz), 5.12–5.10 (m, 1H, H-3'), 4.23–4.15 (m, 1H, H-4'), 3.73 (s, 6H, DMTr-OMe), 3.48–3.24 (m, 8H, H-5'ab, CF₃CONHCH₂, CONHCH₂), 2.65–2.44 (m, 12H, NCH₂, H-2'ab, OCOC-H₂CH₂COOH).

5-[N-[3-[N,N-Bis[3-(trifluoroacetyl-amino)propyl]-aminol]propyl]carbamo-yl]-5'-O-(dimethoxytrityl)-2'-deoxyuridine (7). Tris(3-aminopropyl)amine (90 μ L, 450 μ mol) was added to a solution of **3** (**27**) (98 mg, 150 μ mol) in pyridine (2 mL), and the mixture was stirred at room temperature. After 4 h, pyridine (2 mL), triethylamine (420 μ L, 3.00 mmol), and ethyl trifluoroacetate (360 μ L, 3.00 mmol) were added to the solution, and the mixture was stirred at room temperature for 5 h. The mixture was diluted with CHCl₃, which was washed with aqueous saturated NaHCO₃. The separated organic phase was dried over Na₂SO₄ and concentrated. The residue was chromatographed over a silica gel column (2.5 $\times$ 8 cm) with 0–20% MeOH in EtOAc to give **7** (105 mg, 75% as a white foam): FAB-MS m/z 937 ($M^+ + 1$); ¹H-NMR (CDCl₃) δ 8.66–8.59 (m, 3H, CONH, 3-NH, H-6), 7.76–7.74 (m, 2H, CF₃CONH), 7.50–7.16 (m, 9H, DMTr-phenyl), 6.87–6.80 (m, 4H, DMTr-phenyl), 6.15 (t, 1H, H-1', $J_{1',2'} = 6.5$ Hz), 4.31 (m, 1H, H-3'), 3.97 (m, 1H, H-4'), 3.78 (s, 6H, DMTr-OMe), 3.48–3.32 (m, 8H, H-5'ab, CF₃CONHCH₂, CONHCH₂), 2.51–2.42 (m, 7H, NCH₂, H-2'a), 2.23 (m, 1H, H-2'b), 1.77–1.66 (m, 6H, NCH₂CH₂CH₂-NH); FAB exact MS calcd for C₄₄H₅₁F₆N₆O₁₀ ($M^+ + 1$) 937.3568, found 937.3620.

5-[N-[3-[N,N-Bis[3-(trifluoroacetyl-amino)propyl]-aminol]propyl]carbamo-yl]-5'-O-(dimethoxytrityl)-3'-O-[(2-cyanoethyl)(N,N-diisopropylamino)phosphinyl]-2'-deoxyuridine (8). Compound **7** (562 mg, 600 μ mol) was phosphitylated as described in the preparation of **5** to give **8** (469 mg, 69% as a white foam): FAB-MS m/z 1137 ($M^+ + 1$); ³¹P-NMR (CDCl₃) δ 149.78, 149.57 (85% H₃PO₄ as an internal standard); FAB exact MS calcd for C₅₃H₆₈F₆N₈O₁₁P ($M^+ + 1$) 1137.464, found 1137.4710.

5-[N-[3-[N,N-Bis[3-(trifluoroacetyl-amino)propyl]-aminol]propyl]carbamo-yl]-5'-O-(dimethoxytrityl)-3'-O-succinyl-2'-deoxyuridine (9). Compound **7** (281 mg, 300 μ mol) was succinylated as described in the preparation of **6** to give **9** (145 mg, 47% as a white foam): ¹H-

NMR (CDCl₃) δ 8.85 (m, 2H, H-6, 3-NH), 8.14 (m, 2H, CF₃CONH), 7.40–7.14 (m, 9H, DMTr-phenyl), 6.83–6.80 (m, 4H, DMTr-phenyl), 6.02 (t, 1H, H-1', $J_{1',2'} = 6.2$ Hz), 4.99 (m, 1H, H-3'), 4.24 (m, 1H, H-4') 3.75 (s, 6H, DMTr-OMe), 3.55–3.14 (m, 8H, H-5'ab, CF₃CONHCH₂, CONHCH₂), 2.97–2.21 (m, 12H, NCH₂, H-2'ab, OCOCH₂CH₂-COOH), 1.86–1.59 (m, 6H, NCH₂CH₂CH₂NH).

Synthesis of the Controlled Pore Glass Support Containing **4 and **7**.** Aminopropyl controlled pore glass (323 mg, 29.0 μ mol, 89.8 μ mol/g, CPG Inc.) was added to a solution of **6** (115 mg, 0.116 mmol) and 1-ethyl-3-[3-(dimethylamino)propyl]carbodiimide hydrochloride (WSCl) (22 mg, 0.116 mmol) in anhydrous DMF (3 mL), and the mixture was kept for 4 days at room temperature. After the resin was washed with anhydrous pyridine, 3 mL of a capping solution (0.1 M DMAP in 9:1 pyridine/Ac₂O) was added, and the whole was kept for 1 days at room temperature. The resin was washed with EtOH and acetone and was dried under vacuum. The amount of nucleoside **4** loaded onto the solid support is 35.0 μ mol/g from the calculation of released dimethoxytrityl cation by a solution of 70% HClO₄/EtOH (3:2, v:v). In a similar manner, the solid support containing **7** was obtained in 34.7 μ mol/g of loading amounts.

Synthesis of ODNs. ODNs were synthesized on a DNA/RNA synthesizer (Applied Biosystem model 392) by the phosphoramidite method (29). Each ODN (1 μ mol) linked to the resin was treated with concentrated NH₄-OH (2 mL) for 16 h at 55 °C. After filtration of the resin, the filtrate was concentrated under reduced pressure. The residue obtained from the reaction with concentrated NH₄OH was purified by C-18 silica gel column chromatography (1 $\times$ 10 cm) with a linear gradient of CH₃CN in 0.1 M TEAA buffer (pH 7.0). Fractions were concentrated, and the residue was treated with 80% AcOH for 20 min at room temperature. The solution was concentrated, and the residue was coevaporated with H₂O. The residue was dissolved in H₂O, and the solution was washed with Et₂O; then, the H₂O layer was concentrated to give deprotected ODN **11** (14.4), **12** (11.1), **13** (27.7), **14** (18.0), **15** (19.7), **16** (16.8), **17** (24.2), **18** (17.5), **19** (10.6), and **20** (8.2). The yields are indicated in parentheses as OD units at 260 nm starting from a 1 μ mol scale.

Matrix-Assisted Laser Desorption/Ionization Time-of-Flight Mass Spectrometry. Spectra were obtained on a Voyager Elite reflection time-of-flight mass spectrometry system (PerSeptive Biosystems, Inc., Framingham, MA) equipped with a nitrogen laser (337 nm, 3 ns pulse) in the negative ion mode. 3-Hydroxypicolinic acid (HPA), dissolved in H₂O to give a saturated solution at room temperature, was used as the matrix. Time-to-mass conversion was achieved by calibration by using the peak representing the C⁺ cation of the charged derivative to be analyzed. The observed average molecular masses of **13** and **17** were 5258.33 and 5299.89, respectively, and fit the calculated molecular weights (theoretical average molecular masses) for these compounds, i.e. 5258.69 (for **13**, C₁₇₆H₂₄₄N₄₆O₁₁₀P₁₆) and 5300.77 (for **17**, C₁₇₉H₂₅₀N₄₆O₁₁₀P₁₆), within a commonly accepted error range of MALDI-TOF/MS.

Thermal Denaturation. Each solution contains each ODN (3 μ M) and the complementary DNA **21** (3 μ M), RNA **22** (3 μ M), or the target duplex **23** (3 μ M) in an appropriate buffer. The solution containing each ODN was heated at 90 °C for 10 min, then cooled gradually to an appropriate temperature, and used for the thermal denaturation studies. Thermal-induced transitions of each mixture were monitored at 260 nm on a Perkin-

Elmer Lambda2S instrument. The sample temperature was increased 0.5 °C/min.

Partial Hydrolysis of ODNs with Snake Venom Phosphodiesterase. Each ODN labeled with ³²P at the 5'-end (10 pmol) was incubated with snake venom phosphodiesterase (0.4 μ g) in the presence of Torula RNA (0.15 OD₂₆₀ unit) in a buffer containing 37.5 mM Tris-HCl (pH 8.0) and 7.5 mM MgCl₂ (total of 20 μ L) at 37 °C. At appropriate periods, aliquots of the reaction mixture were separated and added to a solution of EDTA (5 mM, 10 μ L), and then the mixtures were heated at 100 °C for 5 min. The solutions were analyzed by electrophoresis on a 20% polyacrylamide gel containing 8 M urea (31).

Partial Hydrolysis of ODNs with Nuclease S1. Each ODN labeled with ³²P at the 5'-end (10 pmol) was incubated with nuclease S1 (0.2 unit) in the presence of Torula RNA (0.54 OD₂₆₀ unit) in a buffer containing 30 mM sodium acetate (pH 4.6), 1 mM ZnSO₄, and 280 mM NaCl (total of 20 μ L) at 37 °C. At appropriate periods, aliquots of the reaction mixture were separated and added to a solution of EDTA (5 mM, 10 μ L), and then the solutions were heated for 5 min at 100 °C. The solutions were analyzed by gel electrophoresis as described above. Densities of radioactivity of the gel were visualized by a Bio-imaging Analyzer (Bas 2000, Fuji, Co. Ltd.).

ACKNOWLEDGMENT

This investigation was supported in part by a Grant-in-Aid for Encouragement of Young Scientists from the Ministry of Education, Science, Sports, and Culture of Japan and a Grant from the "Research for the Future" Program of the Japan Society for the Promotion of Science (JSPS-RFTF97I00301).

Poly(amino acid)-*b*-Poly(*N,N*-diethylacrylamide)-*b*-Poly(amino acid) Conjugates of Well-Defined Structure

Lev Bromberg^{*,†} and Gideon Levin

Department of Materials and Interfaces, The Weizmann Institute of Science, Rehovot 76100, Israel.
Received June 4, 1997; Revised Manuscript Received September 11, 1997[®]

Carboxy-terminated oligomers of *N,N*-diethylacrylamide (DEAAm) with low polydispersity were synthesized by group-transfer polymerization. The oligomers were conjugated with the N terminus of ϵ -*N*-CBZ-protected poly(lysine) and *s*-CBZ-protected poly(L-cysteine). The resulting conjugates precipitated in a narrow region of lower critical solution temperatures (LCST) around 29 °C. The LCST of poly(lysine)–polyDEAAm–poly(lysine) conjugates was pH-independent and independent of the lengths of poly(lysine) segments. Water-soluble nonstoichiometric conjugate–DNA complexes precipitated above the conjugate's LCST. Covalent complexes of human albumin and poly(cysteine)–polyDEAAm–poly(cysteine) conjugates showed temperature-sensitive behavior in aqueous solutions.

INTRODUCTION

Binding of biologically active compounds to polymers that possess a lower critical solution temperature (LCST) leads to conjugates with temperature-dependent solubility in aqueous solutions, a feature useful to control bioaffinity, enzyme separations, bioassays, and drug release (1–9). The field of temperature-sensitive polymers has been dominated by poly(*N*-isopropylacrylamide) (NIPA), because of its sharp, almost discontinuous volume phase transition corresponding to a LCST of about 32 °C (1–8, 10). Poly(*N*-isopropylacrylamides) are synthesized by free-radical polymerization (FRP) that usually results in high molecular weight polymers with a broad distribution of molecular weights and thus undefined molecular architecture. Okano and co-workers (6–8) used thiols as chain-transfer agents in FRP to produce NIPA oligomers with reactive end groups. The resulting oligomers had polydispersities of 1.2–2.0 and contained one carboxyl end group per molecule (6). Limitations of chain-transfer telomerization lie in complications associated with numerous side reactions and difficulties of finding a proper chain-transfer agent for a particular FRP system. Another means of controlling the molecular weight, end groups, pendent functionality, and chain configuration of a polymer is the group-transfer polymerization (GTP) involving transfer of trialkylsilyl groups (12). Since active hydrogen compounds interfere with GTP and stop chain growth, application of GTP to (unprotected) *N*-isopropylacrylamide presents a hurdle. *N,N*-Diethylacrylamide (DEAAm), a monomer that possesses a well-defined LCST in water of around 30 °C (13–15), can be used instead (16–18). DEAAm is devoid of active hydrogens and has been shown to be effectively polymerized by GTP, resulting in isotactic, highly uniform oligomers (16–18).

In this work, we have taken interest in the synthesis of carboxy-terminated polyDEAAm with the goal of

obtaining temperature-sensitive poly(amino acid)–poly-DEAAm triblock copolymers of well-defined architecture. Such conjugates can employ multiple amino acid functionality for bonding with specific drugs (19) via electrostatic interactions or can be used as a carrier molecule to bind and condense DNA into small particles (20, 21). PolyDEAAm was polymerized by GTP and end-capped by addition of methacrylic acid to the living macromonomer. Hydrolysis of the initiator, dimethylketene bis-(trimethylsilyl) acetal, produced a COOH group at the starting end of the polyDEAAm chain. The carboxy-terminated polyDEAAm was conjugated with several poly(amino acids) to result in conjugates with pH-independent LCSTs capable of complexing with DNA or proteins.

EXPERIMENTAL MATERIALS

Tetrahydrofuran (THF, >99%) was distilled under nitrogen from the purple sodium/benzophenone ketyl. Trimethylsilyl methacrylate (97%), chlorotrimethylsilane (>99%, redistilled), lithium diisopropylamide (97%), and isobutyric acid (>99%) were vacuum-distilled prior to use and found to be pure by GC. Tetrabutylammonium acetate (97%), *N*-hydroxysuccinimide (NHSI, 97%), 1,3-dicyclohexylcarbodiimide (DCCD, 99%), anhydrous ammonia (>99.99%), 2,2'-dipyridil disulfide (AldrichiolTM-2, 98%), dithiothreitol (DTT), and sodium spheres (2–5 mm) under nitrogen were used as received. Palladium black was freed from water by repeated washing with anhydrous ethanol. The monomer *N,N*-diethylacrylamide was stirred over CaH₂ for 24 h, vacuum-distilled, and found to be pure by GC. The monomer was kept at –20 °C in a septum-sealed flask prior to use. All above chemicals except for *N,N*-diethylacrylamide (Polysciences, Inc., Warrington, PA) were obtained from Aldrich Chemical Co. (Milwaukee, WI). 2,2'-Azobis(2-methylpropionitrile) (Eastman Kodak, Rochester, NY) was repeatedly crystallized from acetone. Poly(ϵ -CBZ-DL-lysine), poly(ϵ -CBZ-L-lysine), and poly(*s*-CBZ-L-cysteine) with average chain lengths of 90, 10, and 50 amino acid residues, respectively, as well as bacteriophage T7 DNA (lyophilized, from *Escherichia coli* B host, strain ATCC 11303, molecular weight of 25×10^6), human albumin

[®] Abstract published in *Advance ACS Abstracts*, December 1, 1997.

(99%, globulin-free) (HA), and 2,4,6-trinitrobenzenesulfonic acid were all obtained from Sigma Chemical Co. (St. Louis, MO) and used as received. 1-Benzotriazolyl-oxy-tris-pyrrolidinophosphonium hexafluorophosphate (Py-BOP) was obtained from Calbiochem-Novabiochem Co. (La Jolla, CA) and was dissolved in *N,N*-dimethylformamide (DMF) immediately prior to use.

All other chemicals, gases, and dry organic solvents used were obtained from commercial sources and were of highest purity available.

PROCEDURES

Glassware was heated at 300 °C until dry. Glassware, syringes, reagents, and solutions used in synthetic procedures involving group-transfer polymerization were stored in a glovebox under a moisture-free argon atmosphere.

Chromatography was carried out at 20 °C on a Hewlett-Packard series 1050 system, including a variable wavelength detector, 1050 pumping system, 3396 series II integrator, and 19395A headspace sampler, as well as a Waters 410 differential refractometer, Viscotek differential viscometer, and right angle laser light scattering detector (Viscotek, Houston, TX). Columns and run conditions are given throughout.

NMR spectra of 10 wt % solutions in D₂O or DMSO-*d*₆ were acquired on a Bruker AM300 or a Bruker AMX400 spectrometer. Tetramethylsilane and dioxane were used as external frequency locks for ¹H and ¹³C NMR, respectively. Infrared spectra of dry polymer samples dispersed in KBr at a concentration of 1 wt % were recorded in a water-free atmosphere on a Nicolet Magna-IR model 560 spectrometer. Resolution was 2 cm⁻¹, and 256 scans of each sample were collected.

Dynamic light scattering experiments were performed with a Brookhaven Instruments BI-200SM goniometer, a BI-9000 correlator, and a Spectra Physics He-Ne model 127 laser operating at a scattering angle θ of 90° and a wavelength of incident light of 633 nm at a power of 50 mW. A 10 μ L quartz scattering cell was thermostated using refractive index matching silicone oil, and the temperature was controlled to within 0.02 $^\circ$ C. The intensity autocorrelation function was fitted to a triple-exponential form as described elsewhere (22). Correlation lengths ξ were calculated from the characteristic decay times of various scatterers using the Stokes-Einstein equation (22).

Lower critical solution temperatures (LCSTs) of polymer suspensions were determined as an onset of the transmittance decrease with the increasing temperature (8). Transmittance at 500 nm was continuously monitored in a flow-through quartz cell (path length of 0.2 cm) under controlled temperature (± 0.1 °C) conditions. The rate of temperature increase was 0.05 °C/min. Electronic absorbance spectra were measured on a Shimadzu UV-1601 spectrophotometer.

Matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF-MS) was carried out on a Comstock model LTOF-160 spectrometer (Oak Ridge, TN). The 337.1 nm nitrogen laser parameters were as follows: pulse width, 3 ns; and pulse energy, 120 μ J. The matrix used was 2,5-dihydroxybenzoic acid, dissolved in 60:40 acetonitrile/0.1% TFA at a concentration of about 10 mg/mL (23). Insulin was used as an internal standard.

SYNTHESES

Dimethylketene Bis(trimethylsilyl) Acetal (1) (24).

A solution of isobutyric acid in THF (2 M, 25 mL) chilled

Scheme 1. Synthesis of Carboxy-Terminated Poly(*N,N*-diethylacrylamide) (2)

to 0 °C was added dropwise to 0.1 mol of lithium diisopropylamide. The mixture was stirred at 0 °C for 0.5 h, and 25 mL of chlorotrimethylsilane was added cautiously. After being stirred for 0.5 h at 20 °C, the mixture was filtered and concentrated using a rotary evaporator. The mixture was repeatedly washed with dry diethyl ether and refiltered. Ether was removed by evaporation, and the residue was distilled under vacuum (10 Torr). Calcd for $C_{10}H_{24}O_2Si_2$: C, 51.66%; H, 10.41%. Found: C, 51.49%; H, 10.59%. ^1H NMR (300 MHz, CCl_4): δ 1.48 (s, CH_3), 0.16 [s, $Si(CH_3)_3$].

Carboxy-Terminated Poly(*N,N*-diethylacrylamide)
(2) (Scheme 1). Dry THF (30 mL) was charged to a rigorously cleaned and dried one-necked round-bottom flask equipped with a magnetic stirrer and a rubber septum under a prepurified nitrogen atmosphere. A calculated amount of **1** was added *via* syringe to the reaction flask to yield a polymer with the desired molecular weight. Then calculated amount of *N,N*-diethylacrylamide was slowly added to produce the desired monomer-to-initiator molar ratio. The reaction mixture was cooled to 0 °C, and an aliquot of the 0.04 M solution of tertbutylammonium acetate catalyst (TBAC) solution in dry THF (250 μ L) was charged to the flask by rapid injection under stirring. An aliquot of trimethylsilyl methacrylate in THF was injected after 4 h, and the reaction was allowed to proceed for another 24 h at 0 °C under stirring. An amount of trimethylsilyl methacrylate was chosen which resulted in 1:1 molar ratio of trimethylsilyl methacrylate to **1**. The reaction was then stopped by excess methanol following addition of an aliquot of 1% HCl to remove the trimethylsilyl protecting groups. The solution was evaporated under vacuum (5 Torr), dissolved in dry THF, precipitated from hexane, and dried under vacuum (0.5 Torr) until a constant weight was reached. For comparison, random poly(*N,N*-diethylacrylamide-co-methacrylic acid) was synthesized by free-radical polymerization as follows. *N,N*-Diethylacrylamide (0.1 mol) and various amounts of methacrylic acid ranging from 1 μ mol to 10 mmol were dissolved in 200 mL of THF and deaerated by nitrogen flow overnight and following addition of 1 mmol of 2,2'-azobis(2-methylpropanitrile) in THF were kept at 50 °C for 48 h. The polymer was recovered as described above.

Table 1. Composition of Reaction Mixtures and Molecular Weights of Carboxy-Terminated Poly(*N,N*-diethylacrylamide)

no.	[DEAAM]/[initiator] (mol/mol)	M_n	M_w/M_n	n^a	COOH per molecule ^b
1	9	1060	1.17	7	2.01 ± 0.08
2	12	1570	1.19	11	2.04 ± 0.07
3	17	2100	1.12	15	1.98 ± 0.03
4	20	2800	1.21	20	1.93 ± 0.09
5	30	4000	1.09	30	2.09 ± 0.07
6	free-radical	390000	2.7	nd	nd

^a n is calculated from the measured number-average molecular weight from formula 2 in Scheme 1. ^b The number of carboxyl groups per molecule was obtained using M_n by titration of the corresponding polymer fractions. Three titrations of each fractions were averaged.

Polymer fractions dissolved in THF at 1 wt % were characterized by gel-permeation chromatography with PLgel analytical GPC columns (porosities, 50, 100, 500, 10^3 , 10^4 , and 10^6 Å; particle sizes, 5 or 10 µm; dimensions, 300 × 7.5 mm, Polymer Laboratories, Inc., Amherst, MA) using the refractive index and differential viscometer detectors. The flow rate, concentration, and injection volume were 1 mg/mL, 0.2%, and 30 µL, respectively. Initial DEAAM-to-initiator (1) mole ratios set in reaction mixtures and molecular weights of the resulting copolymers are collected in Table 1. Oligomer that resulted from run 1 was passed through a PLgel preparative mixed-bed column (10 µm, 300 × 7.5 mm) at a flow rate of 0.05 mL/min with THF as an eluent. The central part of the peak was collected, and the polymer was dried under vacuum until a constant weight was reached and subjected to MALDI-TOF-MS analysis.

Run 5 (Table 1). ¹³C NMR (D_2O , 100.6 MHz): δ 177.5 (O=CN), 173.2 (O=COH), 50.5, 45.1, 43.8 (CN, CO), 38.9, 37.4, 29.7 (secondary CN, CC), 16.2, 15.7, 15.2, 14.9, 11.0 (CC). ¹H NMR (DMSO- d_6 , 400.1 MHz, 343 K): δ 7.10 (COOH), 3.35, 3.20 [m, 4H, (CH₂)₂NCO], 2.50 (m, 1H, CH), 1.62 (m, 2H, CH₂), 1.07 (m, 6H, CH₃). The ratio of integrations of resonances corresponding to CH₂NCO, CH, CH₂, and CH₃ groups, respectively, was found to be 4.0:1.0:1.8:6.9; the calculated ratio was 4.0:1.0:2.0:6.0. FTIR (KBr): 2973, 2934 (asymmetrical and symmetrical CH₂CH₃ stretch), 1724 (COOH), 1634 (CON), 1451 (CH₂-CH₃ deform.), 1381, 1362 (CON), 1309 (COOH), 1276, 1218 (CH₂ wag., C₂H₅), 951 cm⁻¹.

Poly(lysine)-*b*-Poly(*N,N*-diethylacrylamide)-*b*-Poly(lysine) (3). Two methods of synthesis of this triblock copolymer were explored as follows.

Method 1 (Scheme 2). A calculated amount of NHSI was added to the 20 mg/mL solution of 2 in DMF at 4 °C while stirring. After 1 h, a calculated amount of DCCD in DMF was added, and the reaction was allowed to proceed for another 24 h at 4 °C under stirring. The molar ratio DCCD:NHSI:(COOH in polymer) was set at 10:10:1, and the total volume of the mixture was 100 mL. Formed dicyclohexylurea was removed by filtration, and the reaction mixture was reprecipitated into excess diethyl ether four times and dried under vacuum (10 Torr) until a constant weight was reached. Activated ester group was assayed as described in ref 25. Activated polymer in DMF was slowly added to a 100 mM solution of poly(ε-CBZ-DL-lysine) or poly(ε-CBZ-L-lysine) in 10 mM phosphate buffer (pH 8.0) [concentration of poly(CBZ-lysine)s is given on a monomer basis] at 4 °C while stirring. The molar ratio [activated ester group in poly-(DEAAM)]:[α-NH₂ groups in poly(CBZ-lysine)] was set at 1:1, and the total volume of the mixture was 30 mL. α-Amino groups in poly(CBZ-lysine)s were assayed using

Scheme 2. Synthesis of Poly(lysine)-polyDEAAM-Poly(lysine) Conjugate (3) by Method 1

2,4,6-trinitrobenzenesulfonic acid as described elsewhere (26). The coupling reaction was carried out for 24 h at 4 °C under stirring. The reaction mixture was then dialyzed against excess deionized water at 4 °C for 48 h using a Spectra/Por cellulose ester membrane (molecular weight cutoff of 500, Spectrum, Laguna Hills, CA) and passed through a PL-SCX semipreparative cation-exchange column (1000 Å, 8 µm, 100 × 10 mm, Polymer Laboratories, Inc., Amherst, MA) at flow rate of 0.5 mL/min with 10 mM phosphate buffer as an eluent. The fraction absorbance was monitored at 214 nm. The conjugate fractions were collected, dialyzed against deionized water, and lyophilized. Deprotection of ε-amino groups of lysine residues from benzyloxycarbonyl group was carried out by catalytic hydrogenolysis as follows (27). Anhydrous ammonia was passed over KOH pellets and placed in a three-necked round-bottom flask immersed in dry ice and fitted with dry ice reflux condenser and drying tube. Protected conjugate (1 mmol) was dissolved in 50 mL of liquid ammonia with magnetic stirring. Palladium black (0.6 g) wet with methanol was added under a nitrogen blanket. A stream of dried nitrogen was passed through the stirred refluxing solution for 8 h. The solution was then filtered and the solvent evaporated at room temperature under the stream of nitrogen. The conjugates were dissolved in degassed 0.1% TFA and purified on a PLRP-S 300 Å (250 × 4.6 mm) column (Polymer Laboratories, Inc.) which was eluted at 10 mL/min with 0.1% TFA and acetonitrile (5–20% over 0.5 h) while measuring absorbance at 214 nm. Fractionation of the conjugate samples was performed at 15 °C on a Hewlett-Packard 1050 HPLC system with the refractive index detector. A 1.0 mg/mL polymer solution in 0.05 M NaNO₃ was loaded onto a PLgel preparative three-column system (porosities, 50, 100, 500, 10^3 , and 10^4 Å; particle sizes, 10 µm; dimensions, 300 × 25 mm, Polymer Laboratories, Inc.). Frac-

Figure 1. Gel-permeation chromatograms illustrating the process of fractionation of poly(lysine)-poly(*N,N*-diethylacrylamide) conjugates (**3**): (1) a mixture of conjugates obtained after purification of the synthesis products (method 1), (2) conjugate Lys₉₀DEAAm₁₅Lys₉₀ (molecular weight of 29 000, lysine content of 90 wt %) obtained by fractionation of the mixture in chromatogram 1, and (3) conjugate Lys₉₀DEAAm₁₅ (molecular weight of 17 000, lysine content of 80 wt %) obtained by fractionation of the mixture in chromatogram 1.

tions around the peaks were collected and precipitated by heating at 37–45 °C. The precipitates were filtered off and redissolved in cold deionized water. The resulting polymer fractions were subjected to GPC. Fractions were collected and analyzed for lysine content by titration (28). Typical gel-permeation chromatograms illustrating the process of fractionation are shown in Figure 1. The yield of poly(lysine)-*b*-polyDEAAm-*b*-poly(lysine) conjugates obtained by method 1 per initial amount of carboxy-terminated polyDEAAm varied from 9.4 to 14.8%.

Lys₁₀DEAAm₂₀Lys₁₀. ¹³C NMR (D₂O, 100.6 MHz): δ 177.9 (O=CN), 176.5 (O=COH), 56.2 (α-CH of Lys), 50.5, 45.4, 43.7 (CN, CO of DEAAm), 42.0 (ε-CH₂ of Lys), 38.8, 33.5, 37.4 (CN, CC of DEAAm), 33.5 (β-CH₂ of Lys), 29.2 (δ-CH₂ of Lys), 25.0 (γ-CH₂ of Lys), 16.7, 15.7, 15.1, 15.1, 14.8, 11.0 (CC). ¹H NMR (DMSO-*d*₆, 400.1 MHz, 343 K): δ 7.9 (COOH), 4.21 (t, 2H, α-CH of Lys), 3.31, 3.20 (m, CH₂NCO), 3.06 (t, 4H, ε-CH₂ of Lys), 2.77 (m), 2.50 (m, 1H, CH), 1.90 (m, β-CH₂ of Lys), 1.65 (m, δ-CH₂ of Lys, CH₂ of DEAAm), 1.43 (m, γ-CH₂ of Lys), 1.07 (m, CH₃). The ratio of integrations of resonances corresponding to α-CH of Lys, ε-CH₂ of Lys, CH of DEAAm, and CH₃ of DEAAm, respectively, was found to be 2.0:4.2:1.9:14; the calculated ratio was 2.0:4.0:2.0:12. FTIR (KBr): 3671, 3425 (NH₂), 2971, 2935 (asymmetrical and symmetrical CH₂CH₃ stretch), 1639 (CON), 1543, 1455 (CH₂CH₃ deform.), 1381, 1362 (CON), 1309 (COOH), 1275, 1219 (CH₂, C₂H₅), 1136, 1098 (CH₂NH₂), 950 cm⁻¹.

Method 2 (Scheme 3). Solid phase peptide synthesis was conducted by the Fmoc continuous flow methodology in DMF on a PC-interfaced synthesizer (Advanced ChemTech, Lexington, KY) using *N*-α-Fmoc-protected lysine (Boc) attached to NovaSyn PA 500 resin [poly(styrene)-poly(*N,N*-dimethylacrylamide) composite, Novabiochem Co.]. First, a peptide containing five or seven lysine residues with Boc-protected side chains and an Fmoc-protected N terminus was synthesized at a resin concentration of 0.48 mmol/g. Fmoc deblocking was performed by flashing the column with 25% piperidine for 30 min while continuously monitoring the absorbance at 320 nm. A 3-fold molar excess of *N,N*-diethylacrylamide oligomer of the structure HOCC(CH₃)₂-DEAAm₇-CH₂CH(CH₃)COOH in DMF was activated *in situ* with 14 mL of 0.2 M PyBOP and 0.4 M diisopropylethylamine mixture in DMF for 30 min. The activated oligomer was then added at a 1:1 molar ratio of activated

carboxy groups to amino groups, and the coupling reaction was carried out for 8 h by recirculation through the column. At completion, the resin with the attached conjugate was washed with 1% acetic acid, dichloromethane, and diethyl ether and dried. Cleavage and removal of Boc protective groups were carried out with the TFA/ethanedithiol/water (95:2.5:2.5 v:v) solution for 30 min at room temperature. The resulting conjugate was washed with diethyl ether and lyophilized. The conjugates were dissolved in degassed 0.1% TFA and purified on a PLRP-S 300 Å (250 × 4.6 mm) column (Polymer Laboratories, Inc.) which was eluted at 10 mL/min with 0.1% TFA and acetonitrile (5 to 20% over 0.5 h) while measuring absorbance at 214 nm. Peptides were subjected to MALDI-TOF-MS analysis (Table 2). While mass spectra showed the presence of oligomers ranging from DEAAm₄ to DEAAm₁₁ (Figure 2A) and several peptide-containing species (Figure 2B), fractions corresponding to HOCC(CH₃)₂-DEAAm₇-CH₂CH(CH₃)-COOH and Lys₅OCC(CH₃)₂-DEAAm₇-CH₂CH(CH₃)-

COLys₅ (A and B in Figure 2, respectively) dominated the spectra. The molecular weights of the main fractions in MALDI spectra are listed in Table 2. The overall yield of poly(lysine)-*b*-polyDEAAm-*b*-poly(lysine) conjugates obtained by method 2 per initial amount of carboxy-terminated polyDEAAm was estimated to be 25–33%.

Poly(L-cysteine)-*b*-Poly(*N,N*-diethylacrylamide)-*b*-Poly(L-cysteine). NHSI (0.58 g) was added to the 5 mM solution of **2** (run 5 in Table 1) in 100 mL of DMF at 4 °C while stirring. After 1 h, 1.03 g of DCCD in DMF was added, and the reaction was allowed to proceed for another 24 h at 4 °C under stirring. Formed dicyclohexylurea was removed by filtration, and the reaction mixture was reprecipitated into excess diethyl ether four times and dried under vacuum until a constant weight was reached. Activated polymer in DMF was slowly added to a 10 mM solution of poly(s-CBZ-cysteine) in 10 mM phosphate buffer (pH 8.0) at 4 °C while stirring. The molar ratio [activated ester group in polyDEAAm]:[α-NH₂ groups in poly(s-CBZ-cysteine)] was set at 1:1, and the total volume of the mixture was 100 mL. The coupling reaction was carried out for 48 h at 4 °C under stirring. The reaction mixture was then dialyzed against excess deionized water at 4 °C for 48 h using a Spectra/Por cellulose ester membrane (molecular weight cutoff 1000) and passed through a MetaPore 10 μm C₈ column (250 × 4.6 mm) (MetaChem Technologies, Inc., Torrance, CA) at a flow rate of 0.5 mL/min. Buffer A was 0.1% TFA in water, and buffer B was acetonitrile/water/TFA (90:10:0.1 v:v). The elution profile was set at 5 min to 5% B and then to 100% B over 60 min. The fraction absorbance was monitored at 214 nm. The conjugate fractions were collected, dialyzed against deionized water, and lyophilized. Fractionation of the conjugate samples was performed at 15 °C on a Hewlett-Packard 1050 HPLC system with the refractive index detector. A 1.0 mg/mL polymer solution in 0.05 M NaNO₃ was loaded onto a PLgel preparative three-column system. Fractions around the peaks were collected and precipitated by heating at 37–45 °C. The precipitates were filtered off and redissolved in cold deionized water. The resulting polymer fractions were subjected to GPC. Fractions were collected and analyzed for S content by elemental analysis. Deprotection of thiol groups of cysteine residues from the benzyloxycarbonyl group was carried out by sodium in liquid ammonia as follows (19). Anhydrous ammonia was passed over KOH pellets and immersed in a three-necked round-bottom flask immersed in dry ice and fitted with a dry ice reflux condenser and a drying tube. To a 10 mg/mL solution of protected conjugate in anhydrous liquid ammonia were incrementally added sodium spheres with magnetic stirring which resulted in a 10 mg/mL effective sodium concentration. The suspension was stirred under reflux for 16 h, until a permanent blue color persisted (29). Then, the ammonia was allowed to evaporate, and the residue was dissolved in oxygen-free water. The solution was repeatedly washed with ether and acidified with concentrated HCl. The solution was then filtered on a sintered glass filter and the solvent evaporated over phosphorus pentoxide under the stream of nitrogen. The conjugates were dissolved in degassed 0.1% TFA and purified on a PLRP-S 300 Å (250 × 4.6 mm) column (Polymer Laboratories, Inc.) and eluted at 2 mL/min with 0.1% TFA and acetonitrile (5 to 20% over 1 h) while measuring absorbance at 214 and 280 nm. The solutions of the conjugate in water above pH 8 contained free sulfhydryl groups as detected upon addition of nitroprusside, which gave a faint violet color (30). The yield of poly(cysteine)-*b*-polyDEAAm-*b*-poly(cysteine) con-

Scheme 4. Activation of the Poly(cysteine)–PolyDEAAm–Poly(cysteine) Conjugate by the 2-Pyridyldisulfanyl Group Followed by Reaction with a Thiol-Containing Protein

jugates was 11% per weight of initial carboxy-terminated polyDEAAm.

Cys₅₀DEAAm₂₀Cys₅₀. ¹H NMR (DMSO-*d*₆, 400.1 MHz, 343 K): δ 8.1 (COOH), 3.74 (m, NCHCO), 3.35 (m), 2.94 (m, HCNCO), 2.35 (m, CH₂S), 1.64 (m, CH₂ of DEAAm), 1.1 (m, CH₃). The ratio of integrations corresponding to CH₂S of Cys to CH₂N of DEAAm was found to be 1.0:1.3; the calculated ratio was 1.0:1.2. FTIR (KBr): 2975, 2930 (asymmetrical and symmetrical CH₂CH₃ stretch), 2877 (CH₂S), 1621 (CON), 1553, 1463 (CH₂CH₃ deform.), 1384, 1362 (CON), 1308 (COOH), 1278, 1254 (CH₂S), 1217, 1114, 960 cm⁻¹.

Conjugate–DNA Condensates. Temperature-dependent interaction of DNA with poly(lysine)–polyDEAAm conjugates was assessed with the bacteriophage T7 DNA that has been used by Wilson and Bloomfield in their light scattering study of DNA condensation (31). A 20 μg/mL DNA solution was prepared in a 1.0 mM NaCl, 1.0 mM sodium cacodylate buffer (pH 7.2) as described in ref 31. The DNA solutions were centrifuged at 7000g for 0.5 h to eliminate dust. To prepare condensates, 100 μL of a DNA solution was mixed with 100 μL of a conjugate solution of a known concentration, and the mixture was vortexed for about 10 min and transferred to a scattering cell. The degree of binding of DNA to the conjugates was estimated by a method similar to the one used by Wadhwa et al. (20, 32). Namely, an aliquot of DNA solution was assayed spectrophotometrically (absorbance at 260 nm, Abs₂₆₀) at a given temperature below the conjugate's LCST. At a temperature above the LCST, the ensuing precipitates were removed by centrifugation at 7000g for 0.5 h which was carried out at the same temperature following measurement of Abs₂₆₀ in the resulting supernatant solution. The degree of DNA removal was expressed as $R(\%) = 100[1 - (\text{Abs}_{260} \text{ after precipitation})/(\text{Abs}_{260} \text{ before precipitation})]$.

Pyridine-2-disulfide-Derivatized Poly(cysteine)–PolyDEAAm–Poly(cysteine). The poly(cysteine)–polyDEAAm–poly(cysteine) conjugate was activated by derivatization of the free thiol groups with pyridine-2-disulfide by a procedure analogous to the one developed for activation of glutathione–agarose (33) (Scheme 4).

Namely, the conjugate was dissolved in excess 0.1 M Tris-HCl, 1 mM EDTA, and 30 mM DTT buffer (pH 8.0), and the solution was incubated at 4 °C overnight to reduce all available sulfhydryl residues. The conjugate was then precipitated from the solution at 60 °C, filtered off, and redissolved in excess 2 mM 2,2'-dipyridyl disulfide at room temperature, shaking gently. The activated

Figure 3. Typical molecular weight distribution of carboxy-terminated poly(*N,N*-diethylacrylamide) (polyDEAAm) polymers prepared by group-transfer polymerizations (GTPs) (1–3) and poly(*N,N*-diethylacrylamide-co-methacrylic acid) synthesized by free-radical polymerization (FRP) (4). In curve 4, the ratio DEAAm:methacrylic acid is 1000:1 on a monomer basis.

conjugate was precipitated at 60 °C, filtered off, and gently shaken at 60 °C in several portions of 10 mM Tris-HCl buffer (pH 8.0) until no further absorbance at 280 nm was detectable in the wash solutions. After washing, the activated conjugate was snap-frozen and lyophilized.

In conjugate–protein interaction studies, HA and activated conjugate solutions of known concentrations in a 10 mM Tris-HCl buffer (pH 8.0) prepared at 4 °C were incubated at a given temperature for 16 h and centrifuged at 16000*g* for 5 min. Precipitate (if any) and supernatant were separated, and the supernatant was evaporated under vacuum, redissolved in fresh 10 mM Tris-HCl buffer (1.0 mL), and assayed for protein content using bicinchoninic acid (34). The degree of albumin removal was expressed as $R_{HA}(\%) = 100[1 - (\text{HA concentration at a given temperature})/(\text{HA concentration at 4 °C})]$.

RESULTS AND DISCUSSION

Temperature Sensitivity of Conjugates. Application of the group-transfer polymerization technique yielded carboxy-terminated polyDEAAm with a narrow molecular weight distribution, when compared to the polymers which resulted from free-radical polymerization (see Table 1 and Figure 3). Average molecular weights calculated from GPC demonstrated good consistency with the initial molar [DEAAm]/[initiator] ratio, with somewhat smaller numbers at higher initiator concentrations. The possibility of minor spontaneous termination reaction in GTP synthesis of polyDEAAm has been shown by Freitag et al. (16–18).

The highly uniform structure of carboxy-terminated polyDEAAm allowed synthesis of well-defined sequences of triblock copolymers and oligomers of polyDEAAm and poly(lysine) (Table 2) as well as poly(cysteine).

Potentiometric titration of carboxy-terminated polyDEAAm and poly(lysine)– and poly(cysteine)–polyDEAAm conjugates yielded pK_a values for the terminal COOH group in the starting copolymer and the ϵ -NH₂ and SH groups in the corresponding poly(lysine) and poly(cysteine) segments of 4.41, 10.25, and 9.25, respectively (Figure 4). These values agree well with the reported pK_a values of methacrylic acid, lysyllysine, and cysteinylcysteine (35). Next, we examined whether ionization of carboxy-terminated polyDEAAm and its conjugates would impact their thermoprecipitation properties.

In contrast to the LCST of carboxy-terminated polyDEAAm synthesized by GTP which was pH-independent, ionization of poly(*N,N*-diethylacrylamide-co-methacrylic acid) prepared by free-radical polymerization (DEAAm:methacrylic acid ratio of 12:1 on a monomer basis) caused a dramatic shift of its LCST to higher

temperatures (Figure 5A). Interestingly, thermoprecipitation curves of poly(lysine)–polyDEAAm–poly(lysine) conjugates showed a slight shift of the LCST to lower temperatures with the increase of the length of the polyDEAAm segments (Figure 5B). Virtually no dependence of the LCST on pH (Figure 5C) or the length of the poly(lysine) chains at fixed lengths of the polyDEAAm segments (Figure 5D) was observed. Similarly, ionization of sulfhydryl groups of poly(cysteine) segments in the corresponding conjugates had no substantial effect on the conjugate thermoprecipitation (Figure 6).

The sharpness of (almost discontinuous) transition in the conjugate solutions can be explained by the low polydispersity of the polyDEAAm segments which resulted from GTP. Random copolymerization of the temperature-sensitive monomer (DEAAm) with the ionizable monomer (methacrylic acid) leads to a drastic shift of the volume transition of the resulting copolymer to higher temperatures, when the pH is higher than the pK_a of the ionizable component (Figure 5A). This is because of the solubility that the ionized component conveys to the incipient formation of insoluble, temperature-sensitive aggregates of polyDEAAm (36). It has been shown that in order to retain reversible temperature-induced volume phase transition of an ionizable copolymer over a broad range of pH the latter should contain long enough segments of a hydrophobic component. The hydrophobic segments will provide entropy-driven aggregation of the entire copolymer at temperatures not significantly different from those of the hydrophobic component itself, whereas ionizable segments will render the copolymer ion-sensitive. The block or graft copolymers where pH- and temperature-sensitive segments either alternate along the chain or are grafted onto each other are therefore the only type of copolymers where volume phase transitions can be due to either pH or temperature or both simultaneously (36, 37).

The observed insensitivity of the conjugates to ionization is an important feature that may allow for their application as switching agents in controlling bioactivity and affinity of the conjugate–DNA or conjugate–protein complexes by means of finely tuned temperature changes. Experiments that support this hypothesis are described below.

Poly(lysine)–PolyDEAAm–Poly(lysine) Conjugates as Temperature-Controlled DNA-Condensing Agents. To verify formation of DNA–conjugate condensates, total light scattering at 90° was measured (Figure 7). When increasing amounts of conjugate were added to T7 bacteriophage DNA, an abrupt increase in the relative intensity was observed at the nanomoles per microgram conjugate-to-DNA ratios of 7.0, 5.0, and 3.5 for Lys₅DEAAm₇Lys₅, Lys₇DEAAm₇Lys₇, and Lys₁₀DEAAm₁₅Lys₁₀, respectively. These ratios indicate, with a good consistency, that about 70 kmol of lysine residues is required for the condensation of 1 mol (about 35 kbp) of DNA under the conditions studied. This corresponds to a 1:1 stoichiometry on the DNA bases per mole of lysine basis. Thus, aggregates form when the DNA–conjugate complex is neutral overall. A further increase in the conjugate:DNA ratio leads to recharging of the complexes and therefore to their redissolution (Figure 7).

Similarly, Wadhwa et al. (20) observed maximum sedimentation of dipeptides such as Lys₈TrpCys-S-S-CysTrpLys₈, Lys₁₃TrpCys-S-S-CysTrpLys₁₃, and Lys₁₈TrpCys-S-S-CysTrpLys₁₈ complexed with a 5.6 kbp DNA at a 1:1 moles of peptide per DNA base ratio. At

stoichiometries larger than the charge neutral, the peptide-DNA complexes sedimented to a much lesser extent (20).

Temperature-induced aggregation of the DNA-conjugate complexes was studied by dynamic light scattering at the conjugate-to-DNA nanomoles per microgram ratio of 3.0 when neither conjugate-DNA solution demonstrated an increase of light scattering intensity at 15 °C compared to that of the DNA solution (Figure 7). The effect of temperature on correlation lengths (ξ) and relative intensity of the DNA-conjugate solutions is depicted in Figure 8. Below conjugates' LCST, the scattering intensity was that of the background, whereas above the LCST, the scattering intensity and correlation

lengths drastically increased, indicating formation of larger aggregates.

The ξ values exceeding 1000 nm that are 20-fold larger than the sizes of condensed bacteriophage T7 DNA particles reported by Wilson and Bloomfield (31) indicate formation of aggregates among the DNA-conjugate complexes due to hydrophobic interactions between polyDEAAm segments. The mechanism of such aggregation in poly(alkylacrylamide) solutions is reasonably well understood (9, 10).

To ascertain binding of the conjugates to the DNA throughout the temperature range, amounts of DNA remained in the conjugate-DNA solutions after the temperature-induced aggregate precipitation was mea-

Figure 6. Transmission vs temperature curves for 0.05% w/w aqueous solutions of Cys₅₀DEAAM₃₀Cys₅₀ conjugates as a function of pH.

Figure 7. Light scattering titration of DNA with poly(lysine)-polyDEAAM-poly(lysine) conjugates. Slow modes combined (scatterers with ξ values of >10 nm) were normalized to the total intensity without conjugate added, resulting in relative intensity units. Experiments were conducted in a 1.0 mM NaCl, 1.0 mM sodium cacodylate buffer (pH 7.2); $T = 15^\circ\text{C}$: (1) Lys₅-DEAAM₇-Lys₅, (2) Lys₇-DEAAM₇-Lys₇, and (3) Lys₁₀-DEAAM₁₅-Lys₁₀.

Figure 8. Correlation lengths (ξ) (open points) and relative intensity ($I_{T=20^\circ\text{C}} = 1$) (filled points) of DNA-conjugate solutions versus temperature. Squares- Lys₅DEAAM₇-Lys₅; circles- Lys₇-DEAAM₇-Lys₇; diamonds- Lys₁₀DEAAM₁₅-Lys₁₀. Open and lightly filled points represent ξ , whereas black filled points show relative intensity. Lightly filled points represent background (fast modes with $\xi < 10$ nm). Vertical line corresponds to the conjugates' LCST. Conjugate-to-DNA nmol per μg ratio was 3.0 throughout. For other conditions see the legend to Figure 7.

sured (Figure 9). To ensure the absence of precipitation when $T < \text{LCST}$, the conjugate:DNA nanomoles per microgram ratio was 3.0 throughout.

While the amount of DNA removed did not exceed 11%

Figure 9. Percent of DNA removal [$R_{\text{DNA}}(\%)$] from DNA-conjugate solutions following centrifugation as a function of temperature: (1) Lys₅DEAAM₇-Lys₅, (2) Lys₇DEAAM₇-Lys₇, and (3) Lys₁₀DEAAM₁₅-Lys₁₀. The conjugate-to-DNA molar ratio was 3.0 throughout. For other conditions, see the legend to Figure 7.

Scheme 5. DNA forms a Nonstoichiometric Complex with the Poly(lysine)-PolyDEAAM-Poly(lysine) Conjugate^a

^a The complex reversibly aggregates in response to changes in the solution temperature.

below the conjugate's LCST, almost complete DNA removal was observed above the LCST. This is a strong indication that the DNA remained complexed to the precipitated conjugates.

The phenomenon of formation and redissolution of interpolyelectrolyte complexes between nucleic acids and synthetic polyelectrolytes is well-known and has been applied to the delivery of genetic material into cells (20, 38, 39). It seems that we hereby introduced a novel, temperature-regulated mode of behavior of interpolyelectrolyte complexes of DNA with a polycation modified with a segment that has a LCST (Scheme 5).

The next step would be to test functioning of poly(lysine)-polyDEAAM-poly(lysine) conjugates in cell transfection.

Poly(cysteine)-PolyDEAAM-Poly(cysteine) Conjugates in Temperature-Controlled Protein Precipitation. A sorption-desorption process involving thiol-disulfide exchange has been utilized in "covalent chromatography", a type of affinity chromatography whereby disulfide-modified gel adsorbents are capable of removing thiol-containing proteins from their mixtures with non-thiol-containing proteins (33, 40, 41). Drawing an analogy with covalent chromatography, we hypothesized that the poly(cysteine)-containing conjugate would be a powerful binding agent toward a thiol-containing protein, due to its numerous thiol groups. Yet, the poly-DEAAM segment of the conjugate may impart thermoreversible solubility to the protein-conjugate complex. To test this concept, we have chosen human albumin, a thiol-containing protein prone to forming covalent attachments to polymer supports modified with reactive disulfide groups (40, 41). The thiol groups in the poly(cysteine)-polyDEAAM-poly(cysteine) conjugate were converted into 2-pyridyldisulfanyl groups (Scheme 4). The resulting

Figure 10. Removal of human albumin [R_{HA} (%)] by the 2-pyridyldisulfanyl-activated $Cys_{50}DEAAM_{30}Cys_{50}$ conjugate as a function of temperature. The initial solution contained 0.1% w/w HA in 10 mM Tris-HCl (pH 8.0). The conjugate was added which resulted in 0.05% w/w (1), 0.1% w/w (2 and 4), and 0.2% w/w (3). Curve 5 represents a control without conjugate added. In curve 4, the solution contained 10 mM dithiothreitol.

protein–conjugate complex precipitated at temperatures above the conjugate's LCST, causing HA removal from the solution (Figure 10). At the conjugate-to-protein weight ratio of 2:1, the protein was removed almost quantitatively at 37–45 °C (curve 3 in Figure 10). Addition of DTT that destroys disulfide bonds in the protein–conjugate complex lowered the HA removal at least 5-fold (compare curves 4 and 2 in Figure 10). These data indicate the possibility of reversible protein–conjugate complexation that, in turn, may provide a thermoreversible precipitation of a thiol-containing protein. We believe this may conceptually add another dimension to the area of protein separation by thermally induced precipitation utilizing polymer–protein conjugates (2–5, 42).

CONCLUSIONS

Carboxy-terminated oligomers of *N,N*-diethylacrylamide (DEAAM) with low polydispersity were synthesized by group-transfer polymerization. Carboxyl functionality allowed conjugation of the DEAAM oligomers with the N terminus of ϵ -*N*-CBZ-protected poly(lysine) in both batch and continuous solid phase synthesis modes, resulting in poly(lysine)–polyDEAAM–poly(lysine) triblock copolymers with well-defined structure. Similarly, *s*-CBZ-protected poly(L-cysteine) was conjugated with polyDEAAM, producing triblock copolymers. The LCST of the conjugates was observed in a narrow region of temperatures around 29 °C and was pH-independent. The LCST was shown to be independent of the lengths of poly(lysine) segments, given constant length of the polyDEAAM segments. A shift of about 2 °C to a lower LCST was observed with increasing lengths of the polyDEAAM segments. Stoichiometric poly(lysine)–polyDEAAM–poly(lysine) conjugates formed condensed complexes with bacteriophage T7 DNA. Nonstoichiometric conjugate–DNA complexes precipitated above the conjugate's LCST due to hydrophobic interactions between the polyDEAAM segments in the conjugates. Poly(cysteine)–polyDEAAM–poly(cysteine) conjugates complexed with human albumin via the thiol–disulfide exchange reaction imparted temperature sensitivity to the conjugate–protein complex. The newly obtained conjugates may appear to be a means of regulating cell transfection with DNA and affinity precipitation of enzymes by regulating the temperature of the aqueous environment.

Received March 28, 1997; Revised Manuscript Received October 7, 1997[®]

A lectin such as concanavalin A (Con A) was immobilized on the surfaces of poly(methacrylic acid) branches covered with polystyrene nanospheres with a diameter of 360 nm, which were obtained by the free radical copolymerization of styrene with the poly(*tert*-butylmethacrylate) macromonomer, followed by hydrolysis. Using Con A-immobilized (0.3 $\mu\text{g}/\text{cm}^2$) nanospheres, the interaction of the nanospheres with HIV-1 was determined by the reduction of the gp120 level and the viral infectivity of the HIV-1 suspensions after a 60 min incubation at room temperatures. Con A-immobilized nanospheres achieved a 95 and a 77% reduction of the gp120 level and the infectivity at a concentration of 0.5 mg/mL, respectively, indicating the effective capture of the gp120 and the virions.

INTRODUCTION

Human immunodeficiency virus-1 (HIV-1) is a spherical virus with a diameter of 100 nm and possesses an envelope with glycoprotein gp120 and gp41 (1). Gp120 is a mannose-rich glycoprotein, so it strongly interacts with some kinds of lectins (2, 3). In particular, concanavalin A (Con A) is reported to have a high affinity for gp120. Thus, there is a strong possibility that gp120 and HIV-1 virions will be effectively captured by lectins, if they are ideally immobilized to certain materials. Actually, purification of the HIV envelope glycoprotein by means of Con A–agarose affinity chromatography was reported (4).

Polymeric materials such as gels, films, beads, and particles are frequently used for the immobilization of biomolecules such as antibodies and enzymes in order to realize immuno assays (5, 6) and catalytic systems (7). Among these, polystyrene beads and particles are quite useful because of the ease of their preparation. Since there is no functional group on their surfaces, the immobilization of biomolecules by means of covalent bonds is inadequate. In addition, as the surfaces of the polystyrene beads and the particles are highly hydrophobic, nonspecific adsorption of other biomolecules seems to be unavoidable. To circumvent these problems, we recently developed technology for hydrophilic polymer chains with functional group-coated polystyrene nanospheres (8, 9), which is dispersed well in water and very useful for biomolecule immobilization. Consequently, these nanospheres are quite useful as immunolates, when antibodies, for example, are introduced into surface-

modified nanospheres. Moreover, the peptide drug calcitonin shows a pharmaceutical activity in oral administration when it has been physically immobilized onto polystyrene nanospheres coated with water-soluble polymer chains (10). In this paper, we will discuss the immobilization of lectins onto surface-modified polystyrene nanospheres and their capture of HIV-1 particles through affinity interaction between gp120 mannose and the immobilized lectins.

RESULTS AND DISCUSSION

First, poly(methacrylic acid)-covered polystyrene nanospheres were prepared by the copolymerization of styrene with the poly(*tert*-butyl methacrylate) macromonomer and the following acid hydrolysis, and analyzed according to the method described previously (8). Because methacrylic acid oligomers contain many active carboxyl groups that are inadequate for macromonomer synthesis, we prepared the poly(*tert*-butyl methacrylate) macromonomer by the reaction between poly(*tert*-butyl methacrylate) oligomers and *p*-vinylbenzyl chloride. The resulting nanospheres (mean diameter of 360 nm) were dispersed well in water and were completely collected by centrifugation or freeze-drying after dialysis. Electron spectroscopy for chemical analysis (ESCA) of the surface suggested that poly(methacrylic acid) chains were favorably located on the surfaces of the polystyrene particles. Scheme 1 illustrates the immobilization of Con A onto the surface of the polystyrene nanospheres. Lectins were immobilized on the surface of polystyrene particles by means of their amino group. Using water-soluble carbodiimide (WSC), the condensation between the carboxyl group of poly(methacrylic acid) on the polystyrene surface and the amino group of Con A gave Con A-immobilized polystyrene nanospheres in a 0.01 M HEPES buffer solution (pH 8.0) at 4 °C for 24 h. After reaction, the centrifuged nanospheres were repeatedly washed in order to correct the Con A-immobilized nanospheres. The surfaces of the obtained nanospheres were fully covered with Con A.

To investigate how Con A-immobilized polystyrene nanospheres can capture HIV-1, they were added to an

Scheme 1. Immobilization of Lectins onto the Surface of Polystyrene Nanospheres

Scheme 2. Capture of HIV-1 Virions by Lectin-Immobilized Polystyrene Nanospheres

HIV-1 medium, as shown in Scheme 2. The suspension (0.5 mL) of the Con A-immobilized nanospheres (final concentration of 0.5 mg/mL) was added to an equal volume of the medium that contained HIV-1 (III_B strain), and the mixed suspension was incubated at room temperature for 60 min. It was assumed that the Con A-immobilized nanospheres would be aggregated, if the HIV-1 virions or the gp120 could interact with the nanospheres. In fact, the Con A-immobilized nanospheres but not the control nanospheres apparently aggregated. Consequently, the Con A-immobilized nanospheres were easily precipitated by centrifugation (Scheme 2). The amount of captured HIV-1 was determined by the residual gp120 antigen level and the viral infectivity in the supernatants after centrifugation at 8200*g* for 10 min. The gp120 level was measured by using an HIV-1 gp120 antigen capture ELISA kit (Advanced Biotechnologies, Columbia, MD). Viral infectivity was assessed by microscopic observation for HIV-1-induced cytopathicity in MT-4 cells and expressed as a 50% cell culture infectious dose (CCID₅₀).

In these assay systems, Con A-immobilized nanospheres achieved a 95 and a 77% reduction of the gp120 level and the viral infectivity at a concentration of 0.5 mg/mL, respectively (Figure 1). In contrast, there was only a slight reduction of the gp120 level and the viral infectivity was identified for the nanospheres that were not immobilized with Con A (Figure 1). Since a small amount of free Con A was contaminated with the suspension of the Con A-immobilized nanospheres, we also examined the effects of the free Con A on the HIV-1 capture assays. The contamination-free Con A (0.79 µg/mL) did not significantly affect the gp120 level or the viral infectivity (data not shown). In order to know the capture activity using other lectins, the mannose-sepecific lectins such as lens culinaris agglutinin (LCA), galanthus nivalis lectin (GNL), and hippeastrum hybrid lectin (HHL) and also the galactose-specific ricinus communis agglutinin (RCA₁₂₀) were immobilized onto the nanospheres by the same procedure. The amounts of lectins immobilized onto the nanospheres and their capture

Figure 1. Effect of Con A-immobilized nanospheres on the (A) gp120 and (B) viral infectivity of HIV-1. The medium containing HIV-1 was mixed with an equal volume of (1) control medium, (2) control nanospheres (final concentration of 0.5 mg/mL), or (3) Con A-immobilized nanospheres (final concentration of 0.5 mg/mL). After a 60 min incubation at room temperature, the mixtures were centrifuged, and the supernatants were examined for their gp120 antigen level and viral infectivity. Data represent mean values in triplicate experiments.

^a The concentration of their nanospheres was 0.5 mg/mL.

^b Estimated by the ELISA technique.

Figure 2. Dose-dependent HIV-1 capture by Con A-immobilized nanospheres. The medium containing HIV-1 was mixed with an equal volume of (1) control medium or Con A-immobilized nanospheres at a final concentration of (2) 0.02, (3) 0.1, and (4) 0.5 mg/mL. After a 60 min incubation at room temperature, the mixtures were centrifuged, and the supernatants were examined for their gp120 antigen level and viral infectivity. Data represent mean values in triplicate experiments.

activities are listed in Table 1. The LCA-, GNL-, and HHL-immobilized nanospheres still performed effective capture activity, even though smaller amounts of their lectins compared to Con A were immobilized. The steric hindrance or direction of binding pockets as well binding specificity of each lectin will be significant for their activity. Also, the RCA₁₂₀-immobilized nanospheres showed little effect on the HIV-1 capturing as expected from its specificity. Figure 2 shows dose-dependent HIV-1 capture activity of Con A-immobilized nanospheres. Even at a concentration of 0.1 mg/mL, the Con A-immobilized nanospheres reduced the gp120 level by 50%. To determine the specificity of the Con A-immobilized nanospheres, we conducted an inhibition assay

Figure 3. Mannose inhibits HIV-1 capture by Con A-immobilized nanospheres. The medium containing HIV-1 was mixed with an equal volume of (1) control medium or Con A-immobilized nanospheres (final concentration of 0.5 mg/mL) containing mannose at a final concentration of (2) 0, (3) 10, (4) 100, and (5) 250 mg/mL. After a 60 min incubation at room temperature, the mixtures were centrifuged, and the supernatants were examined for their gp120 antigen level and viral infectivity. Data represent mean values in triplicate experiments.

for HIV-1 capture by the addition of mannose. When an excess amount of mannose was added to the Con A-immobilized nanospheres, their capture activity was weakened in a dose-dependent fashion (Figure 3), indicating that the Con A-immobilized nanospheres primarily recognize the mannose molecules in gp120. Furthermore, capture activity was not hampered by the addition of galactose (data not shown).

In this study, we have shown that HIV-1 particles and the gp120 antigen can be effectively captured by lectin-immobilized nanospheres. Thus, the lectin-immobilized nanospheres may be potential chemotherapeutic or prophylactic agents in HIV-1 infection. Apparently, several issues, including efficacy and toxicity *in vivo*, still need to be elucidated. The selection of immobilized lectins and the diameter of nanospheres are important determinants for their capture activity and selectivity. In fact, nanospheres that immobilized mannose-specific lectins other than Con A were found to be equally effective with a smaller amount of immobilization (data not shown). Further research is now in progress that will attempt to obtain more effective and selective nanospheres for the capture of HIV-1.

EXPERIMENTAL PROCEDURES

Materials. Styrene (Wako Pure Chemical Ind., Tokyo, Japan) and *tert*-butyl methacrylate (Wako Pure Chemical Ind.) were used after distillation under reduced pressure. 2-Mercaptoethanol (2-MEtOH) (Wako Pure Chemical Ind.), sodium hydride (NaH) (Nacalai Tesque, Kyoto, Japan), and tetrabutylphosphonium bromide (TBPB) (Wako Pure Chemical Ind.) were used without further purification. 2,2'-Azobis(isobutyronitrile) (AIBN) was recrystallized from methanol and dried under vacuum. Tetrahydrofuran (THF), *N,N*-dimethylformamide (DMF), ethanol, water, and other solvents were distilled by the ordinary ways. *p*-Chloromethylstyrene (CMSt) was a gift from Nippon Oil and Fats Co. (Tokyo, Japan) and used without further purification.

Preparation of *tert*-Butyl Methacrylate Oligomers. *tert*-Butyl methacrylate oligomers that were terminated with a hydroxyl group were prepared by the free radical polymerization of *tert*-butyl methacrylate with AIBN as an initiator in the presence of 2-mercaptoethanol as a chain transfer reagent (8). For instance, into a 200 mL three-necked round-bottomed flask equipped with a mechanical stirrer, a condenser, and a nitrogen

inlet tube were placed 176 mmol of *tert*-butyl methacrylate, 0.176 mmol of AIBN, and 2.18 mmol of 2-mercaptoethanol in 60 mL of THF. After dry nitrogen gas was bubbled into the reaction media at 0 °C for 30 min, it was kept at 60 °C for a further 6 h. The reaction mixture was poured into H₂O/methanol (1/1, v/v). The precipitated polymer was filtered off and dried under reduced pressure. The polymer was resolved again in 2-propanol, and then the solution was poured into H₂O/methanol (1/1, v/v). The purification procedure was repeated several times. The yield was 74%. The M_n and M_w/M_n were 3870 and 2.07, respectively.

Preparation of Poly(*tert*-butyl methacrylate) Macromonomers. The macromonomer was prepared by combination of CMSt with a hydroxyl group of the oligomer under an alkaline condition (8). The 0.78 mmol of the *tert*-butyl methacrylate oligomer was stirred with a 10-fold molar excess of NaH in 100 mL of DMF at 30 °C for 30 min. After that, the 10-fold molar excess (7.8 mmol) of CMSt was added into the flask and the mixture stirred for another 48 h in the presence of TBPB as a phase transfer catalyst. The reaction mixture was poured into H₂O/methanol (1/1, v/v). The precipitated polymer was filtered off and dried under reduced pressure. The polymer was resolved again in 2-propanol, and then the solution was poured into H₂O/methanol (1/1, v/v). The purification procedure was repeated several times. The yield was 84%. The M_n and M_w/M_n were 4100 and 1.97, respectively.

Preparation of Poly(*tert*-butyl methacrylate)-Covered Polystyrene Nanosphere. The poly(*tert*-butyl methacrylate)-covered polystyrene nanosphere was prepared by the free radical polymerization of the corresponding macromonomer and styrene in a polar solvent (8). The 0.115 mmol of the poly(*tert*-butyl methacrylate) macromonomer and the 40-fold molar excess (4.6 mmol) of styrene were weighted into a glass tube with 0.047 mmol of AIBN and 5 mL of ethanol, and then the mixture was degassed by freeze-thaw cycles on a vacuum apparatus, sealed off, and kept at 60 °C for 24 h. The reaction medium was dialyzed in methanol by using a cellulose dialyzer for 5–6 days. The nanosphere was obtained by lyophilization. The yield was 41%. The particle size and its standard deviation of the size were 199 and 34 nm, respectively.

Preparation of Poly(methacrylic acid)-Covered Polystyrene Nanosphere. The poly(methacrylic acid)-covered polystyrene nanosphere was prepared by hydrolysis of the poly(*tert*-butyl methacrylate) that was introduced on the poly(*tert*-butyl methacrylate)-covered polystyrene nanosphere under an acidic condition (8). An adequate amount of the poly(*tert*-butyl methacrylate)-covered polystyrene nanosphere was dispersed in a 12 N HCl water/ethanol (1/5, v/v) solution. The dispersion was heated at 70 °C for 24 h. The reaction mixture was dialyzed in water for several days. The particle size was 360 nm, which was larger than that of the poly(*tert*-butyl methacrylate)-covered polystyrene nanosphere. It seemed that electrostatic repulsion of anionic poly(methacrylic acid) on the nanosphere enlarged its size. The standard deviation was 120 nm, which means its size distribution became slightly larger with the acid hydrolysis of the poly(*tert*-butyl methacrylate).

Immobilization of Con A onto Poly(methacrylic acid)-Covered Polystyrene Nanosphere. A carboxyl group of polystyrene nanospheres (2.5 mg) was first activated by WSC (1.0 mg/mL in 0.05 M KH₂PO₄) for 30 min. The nanospheres that were obtained by centrifugation were mixed with 1.0 mg of lectin in 1.0 mL of 0.01

M HEPES buffer solution (pH 8.0), and the mixture was kept at 4 °C for 24 h. After reaction, the centrifuged nanospheres were repeatedly washed. The amount of immobilized lectin was evaluated by means of the ninhydrin method. The surfaces of the obtained nanospheres were covered with 0.3 μg of Con A/cm².

Characterization Method. The number-average molecular weights (M_n) of the oligomer and macromonomer were determined by GPC (Shimadzu LC-6A system with a Shodex AC-800P column), calibrated with polystyrene standards. The terminal vinylbenzyl group of the macromonomer was confirmed by ¹H-NMR spectra obtained with a JEOL FX-400 (400 MHz) instrument. Particle-size measurements were achieved by direct observation with a scanning electron microscope (SEM) (Hitachi H-7010A) and a submicron particle analyzer (Coulter model N4SD). Surface analysis by ESCA was carried out a Shimadzu ESCA 1000 apparatus.

Viruses. The III_B strain of HIV-1 was used in the experiments. The virus was propagated in MOLT-4 cells. The infected cells were cultured in RPMI-1640 medium supplemented with 10% heat-inactivated fetal calf serum and antibiotics (culture medium), and their culture supernatants were centrifuged at 3000 rpm for 10 min, filtered, and stored at -80 °C until they were used. The infectivity of viral stocks was determined in MT-4 cells, and their gp120 antigen level was measured by a gp120 antigen-capture ELISA kit (Advanced Biotechnologies).

Terminal Groups in Starburst Dendrimers: Activation and Reactions with Proteins[†]

Pratap Singh*

Dade Behring Inc., P.O. Box 520672, Miami, Florida 33152-0672. Received April 2, 1997;
Revised Manuscript Received August 21, 1997[®]

Starburst dendrimers are novel nanoscopic synthetic polymers of defined molecular mass and geometry. These macromolecules, available in commercial quantities, contain methyl carboxylate and primary amino-terminal groups. The presence of these groups on any macromolecule limits its usefulness especially in cases where, for specific modulation of the properties of biologically active molecules, covalent bond formation is desirable between the biologically active molecules and the macromolecule. This paper describes activation of the surface groups of Starburst dendrimers for incorporation of a number of reactive electrophilic and nucleophilic groups and utilization of these reactive groups in formation of covalent bonds between dendrimers and alkaline phosphatase. The protein–dendrimer complexes have been reacted further with the Fab' fragment of an anti-creatine kinase MB isoenzyme antibody to form multifunctional dendrimer reagents. The enzymatic and immunochemical properties of these protein–dendrimer reagents have been evaluated by an immunoassay system. Nucleophilic thiols and electrophilic phenyliodoacetamido, iodoacetamido, and epoxy groups have been incorporated into amino-terminal dendrimers by their reactions with appropriate heterobifunctional reagents. Two independent sets of reactions have been used to prepare the reactive *N*-hydroxysuccinimidyl esters from dendrimers containing the terminal carboxyl groups. Quantitation of the reactive groups has been carried out by direct titration of these activated dendrimers and the products obtained by reactions of these dendrimers with small molecules and proteins.

INTRODUCTION

In recent years, dendrimers (1–6) have attracted attention as structurally unique synthetic macromolecules with a very broad range of applications in physical, chemical, and biological processes (7–12). Dendrimers are synthesized by either a divergent or a convergent approach (1). The method of choice depends on the desired generation (4) of a specific structure, which in turn dictates the molecular mass, the terminal functional groups, and the physical dimensions of the molecule.

To modulate some specific properties of biologically active molecules, a number of these molecules that show specific activity such as drugs, enzymes, antibodies, and nucleotides have been covalently coupled to macromolecules [e.g. poly(ethylene glycol) or polysaccharides]. Very limited chemical manipulations are generally possible on many of the biologically active molecules, of either natural or synthetic origin, due to the labile nature or specific structural requirements for the maintenance of their biological activity.

Functional groups on the surface of dendrimers show remarkably higher chemical reactivity (13) in comparison to their activity when present in other macromolecules. This unusual reactivity is expected to allow coupling reactions to occur under mild reaction conditions. These characteristics make a dendrimer, with its controlled interior, the macromolecule of choice for covalent coupling

reactions. A biologically active molecule is likely to retain its maximum possible activity when present in a dendrimer–biologically active molecule complex prepared via the surface groups of dendrimers. The feasibility of such a concept has been demonstrated by preparation of dendrimer–peptide (14), dendrimer–antibody (11, 15), dendrimer–fullerene (16), and dendrimer–antibody–porphyrin (17) complexes. However, full exploitation of these molecules for a number of applications is limited due to the nature of the terminal functional groups available in the presently known dendrimer structures. A limited number of dendrimers are known (18) to contain reactive terminal groups. However, these reactive dendrimers have been synthesized by the convergent method, where it is often difficult to prepare large quantities of higher-generation macromolecules, thus limiting the choice of available molecules. Kilogram quantities of highly pure dendrimers, with broad molecular mass ranges, that have been synthesized by the divergent method are available (19, 20). One category

[®] Abstract published in *Advance ACS Abstracts*, December 15, 1997.

of dendrimers available in large quantities is the full and half-generations of Starburst dendrimers (1).

This paper describes methods for modifying the terminal amino and carboxyl groups of Starburst dendrimers (1) to prepare dendrimer derivatives containing a defined number of reactive nucleophilic and electrophilic groups. These reactive groups have been utilized to couple two proteins in sequence, namely calf intestine alkaline phosphatase (ALP)¹ and the Fab' fragment of an anti-creatine kinase MB isoenzyme (CKMB) antibody, to form ALP-dendrimer and ALP-dendrimer-Fab' complexes. The performance characteristics of these protein-dendrimer complexes have been studied on Stratus II, an automated enzyme immunoassay system.

MATERIALS AND METHODS

All reagents used were of analytical grade or better and were purchased from either Aldrich Chemical Co. (Milwaukee, WI), Sigma Chemical Co. (St. Louis, MO), or Fluka Chemical Corp. (Ronkonkoma, NY). The heterobifunctional reagents were purchased from BioAffinity Systems Inc. (Rosco, IL). Ultrogels AcA 44 and AcA 34 were obtained from BioSeptra (Marlborough, MA). BCA protein assay reagent was obtained from Pierce (Rockford, IL). Alkaline phosphatase was obtained from Boehringer Mannheim Corp. (Indianapolis, IN). Mass spectra were run by the Mass Spectrometry Laboratory of the University of California at Riverside. The performance of the protein-dendrimer complexes was evaluated on Stratus II, an automated fluorometric enzyme immunoassay system available from Dade International Inc. (Miami, FL). The ALP-Fab' conjugate, sold commercially in the CKMB assay kit for Stratus II, was used to compare the performance of the ALP-dendrimer-Fab' complexes.

Unless otherwise indicated, all reactions were carried out at room temperature. All full and half-generation poly(amidoamine) dendrimers, with ethylenediamine as the initiator core molecule (1), were obtained from Dendritech, Inc. (Midland, MI). The half-generation dendrimers were obtained as the sodium salts prepared by hydrolysis of the corresponding methyl esters with sodium hydroxide. Partially hydroxylated dendrimers were prepared at Dendritech, Inc., by using a mixture of ethylenediamine and ethanolamine in place of ethylenediamine at the final stage of synthesis. This modified synthetic procedure was used to prepare dendrimers containing a mixture of terminal hydroxyl (77%) and primary amino (23%) groups. Partially carboxymethylated dendrimer was prepared by treating a methanol solution of the dendrimer with 0.85 mol of bromoacetic acid at 37 °C for 4 h. The methanol solution was evaporated under reduced pressure, and the number of amino groups remaining in the treated dendrimer was determined by reaction with fluorescamine (21).

Derivatized dendrimers of generations 1–3 were purified by repeated precipitation of a methanol solution on addition of ethyl acetate, benzene, or dioxane. The 4.0-, 4.5-, and 5th generation dendrimers were purified by ultrafiltration in an Amicon cell using a YM 10 membrane (molecular mass cutoff of 10 kDa). The Amicon concentrate, containing the derivatized dendrimer solution, was either used immediately to react with a protein or evaporated under reduced pressure to isolate the derivative. The ALP-dendrimer complexes were separated from the low-molecular mass contaminants, including the derivatized dendrimers by ultrafiltration (Amicon cell with a YM 10 membrane) or by gel filtration. A

column of either Sephadex G-25 or Ultrogel AcA 44 (fractionation range of 10–130 kDa; exclusion limit of 200 kDa) equilibrated with a buffer containing 100 mM phosphate/1.0 mM magnesium chloride (phosphate buffer) at pH 7.0–7.4 was used for gel filtration.

Free thiols in the derivatized dendrimer and the protein-dendrimer-SH complex were determined by measuring the increase in absorption at 324 nm on addition of a solution of 4,4'-dithiodipyridine (22). Titration of electrophilic epoxy, phenyliodoacetamido, and iodoacetamido groups in the derivatized dendrimers and the dendrimer-X and protein-dendrimer-X complex (X = epoxy, phenyliodoacetamido, and iodoacetamido) was carried out by reaction with an excess of dithiothreitol followed by reaction of the remaining dithiothreitol with 4,4'-dithiodipyridine essentially as previously described (23). The *N*-hydroxysuccinimidyl esters were quantitated as described by Miron and Wilchek (24).

The periodate-oxidized ALP was prepared by a procedure similar to that described by Husain and Bieniarz (25). ALP-SH was prepared by the reaction of ALP with sulfosuccinimidyl 6-[3-(2-pyridyldithio)propionamido]hexanoate (sulfo NHS LC SPDP; 26) followed by reaction with dithiothreitol. Excess dithiothreitol was separated from the protein solution by passage over a Sephadex G-25 column equilibrated with the phosphate buffer at pH 7.0. The poly(amidoamine) dendrimers and many of the derivatives prepared in this study do not contribute to absorptions between 260 and 280 nm. Protein concentrations (mg/mL) of the solutions containing ALP and ALP-dendrimer complexes were therefore calculated from absorptions measured at 280 and 260 nm and using the formula $A_{280}/0.689 - A_{260}/1.351$. In this formula, 0.689 and 1.351 are the extinction coefficients (milliliters per milligram per centimeter) at 280 and 260 nm, respectively. BCA protein assay reagent was used to determine protein concentrations for the ALP-dendrimer complexes prepared from a dendrimer derivative containing an aromatic or another chromophoric group, e.g. sulfosuccinimidyl (4-iodoacetyl)aminobenzoate (sulfoS-IAB)-activated dendrimer.

Preparation and Reactions of Dendrimer Derivatives Containing Phenyliodoacetamido 1 and Iodoacetamido Groups 3. The carboxymethylated 5th generation dendrimer (16 mg, 0.5 μ mol) was dissolved in 1 mL of the phosphate buffer at pH 7.4. A 277 μ L solution of sulfoSIAB (10 mg/mL in water, 5.5 μ mol) was then added. After 1 h at 30 °C, the reaction mixture was diluted with 50 mL of the phosphate buffer at pH 7.6 and concentrated to about 2 mL in an Amicon ultrafiltration cell. This dilution-concentration process was repeated two more times. The dendrimer derivative 1 present in about 1 mL of concentrate was combined with a 1 mL solution of the periodate-oxidized ALP (8.1 mg, 58 nmol) in the phosphate buffer at pH 7.4 and the combined mixture concentrated to 1.2 mL. After 16 h at 4 °C, the reaction mixture was adjusted to pH 6.3 by a careful addition of 1 N HCl and then incubated for 1 h with a 200 μ L aqueous solution of sodium cyanoborohydride (30 mg/mL, 95 μ mol). The ALP-dendrimer complex 2 formed by this sequence of reactions was purified by passage over an Ultrogel AcA 44 column equilibrated and eluted with the phosphate buffer at pH 7.4.

A solution of *N*-hydroxysuccinimidyl iodoacetate (NIA, 60.4 mg, 213.4 μ mol) in 1 mL of tetrahydrofuran was added dropwise to a solution of the 1st generation aminoterminal dendrimer (32.7 mg, 20.4 μ mol) in 2 mL of 50% alcohol. After 1 h, excess solvents were removed under reduced pressure, and the residue was washed with

tetrahydrofuran. The tetrahydrofuran-insoluble semi-solid product, the iodoacetamido-dendrimer **3**, was dried. The solid residue dissolved in 1 mL of alcohol and 0.5 mL of the phosphate buffer at pH 7.0 was mixed with a solution of ALP-SH (11.9 mg, 85 nmol) in 12 mL of the phosphate buffer at pH 7.0. ALP-SH, used in these reactions, contained an average of 1.4 free thiols per mole of protein. After incubation for 16 h at 4 °C, the protein-dendrimer complex **4** was purified over a column of Ultrogel AcA 44 in the phosphate buffer at pH 7.0.

Preparation of Dendrimer Derivatives 6 Containing Epoxy Groups. A solution of the 5th generation dendrimer (165.8 mg, 5.7 μ mol), in 1 mL of 50% alcohol, was mixed with sodium carbonate (200 mg, 1.9 mmol) and epibromohydrin (0.96 g, 7.1 mmol). After stirring for 4 h, the reaction mixture was diluted with 10 mL of 50% alcohol. The solution was concentrated to about 1 mL in an Amicon ultrafiltration cell. The concentrate was diluted again to 10 mL with 50% alcohol. This concentration-dilution process was continued till the effluent was neutral (pH paper). The dendrimer derivative **6** present in the concentrate was stored at 4 °C until it was used for reaction with ALP.

A 0.4 mL alcohol solution of the 2nd generation dendrimer (41.5 mg, 13 μ mol) was mixed with epibromohydrin (0.5 g, 3.7 mmol) and triethylamine (36 mg, 0.36 mmol). After 4 h at 37 °C, the reaction mixture was evaporated under vacuum to a semisolid residue. The product **6** was purified by repeated precipitation (alcohol/benzene). A solution of this product in 0.2 mL of alcohol and 0.2 mL of the phosphate buffer at pH 7.2 was mixed with a 1.5 mL solution of ALP-SH (1.9 mg, 13.6 nmol) in the phosphate buffer at pH 7.2. The ALP-SH used for this reaction contained 2.6 free thiols per mole of the protein. After 16 h at 4 °C, the ALP-dendrimer complex **7**, formed in the reaction mixture, was then separated from other contaminants by passage over a Sephadex G-25 column in the phosphate buffer at pH 7.2.

The succinyl-dendrimer-epoxide was prepared by stirring a reaction mixture containing the 5th generation dendrimer (222 mg, 7.7 μ mol) and succinic anhydride (148 mg, 1.5 mmol) in 5 mL of 50% alcohol. After 2 h, epibromohydrin (2 mL, 23.5 mmol) was added and the mixture stirred for an additional 16 h. The derivatized dendrimer was purified by ultrafiltration in an Amicon cell (YM 10 membrane) using 50% alcohol as described above.

Reaction of Dendrimers To Incorporate Thiol Groups. A 3.0 mL methanolic solution of the 5th generation dendrimer (330 mg, 11.4 μ mol) was flushed with nitrogen. The dendrimer solution was then allowed to react for 1 h with a solution of sulfo NHS LC SPDP (50 mg, 95 μ mol) in 0.5 mL of water. This reaction produced the 6-[3-(2-pyridyldithio)propionamide]hexanoate derivative of dendrimer **8**, i.e. NH_2 -dendrimer- $\text{NHCO}(\text{CH}_2)_5\text{NHCO}(\text{CH}_2)_2\text{S-S-Py}$ (dendrimer-PDH). The methanol solution was evaporated under vacuum and the semisolid residue stored at -10 °C.

To block the residual amino groups in the dendrimer-PDH derivative prepared above, a 1.8 mL methanol solution of this derivative (148 mg, 5 μ mol) was mixed with succinic anhydride (550 mg, 5.5 mmol) and 2 mL of tetrahydrofuran. The trinitrobenzenesulfonic acid color test (27) was used to monitor reaction of the primary amino groups in the dendrimer-PDH derivative. After 24 h, the organic solvents were removed by evaporation under reduced pressure and the dendrimer derivative was separated from the side products by Amicon ultrafiltration of the mixture using water. The aqueous

solution of the succinyl-dendrimer-PDH, present in the Amicon concentrate, was evaporated under vacuum to provide 173 mg of the succinyl-dendrimer-PDH derivative as an oil.

The 2nd generation dendrimer (75 mg, 23.4 μ mol) dissolved in 4 mL of methanol was reacted for 1 h with a solution of sulfo NHS LC SPDP (55 mg, 104.4 μ mol) in 0.5 mL of water. The reaction mixture containing this dendrimer-PDH derivative **8** was concentrated to 1.0 mL by evaporation under reduced pressure and then mixed with a 9 mL solution of the periodate-oxidized ALP (18 mg, 128.6 nmol) in 50 mM sodium phosphate/50 mM sodium carbonate at pH 9.0. After 1 h, the reaction mixture was adjusted to pH 6.5 by a careful addition of 1 N HCl. An aqueous solution (0.7 mL) of sodium cyanoborohydride (27 mg, 0.44 mmol) was then added. After 30 min, the resulting ALP-dendrimer-PDH complex was buffer exchanged with the phosphate buffer at pH 7.0 in an Amicon ultrafiltration cell (YM 10). The dithiothreitol/4,4'-dithiodipyridine titration of this ALP-dendrimer-PDH complex showed the presence of 25 free thiols (as pyridyl disulfide linkage) per mole of the protein. The thiol content was calculated from the increase in absorption at 343 nm resulting from the formation of pyridine-4-thione.

The dendrimer derivative succinyl-dendrimer-PDH (43 mg, 1.5 μ mol) dissolved in 1.0 mL of 100 mM sodium phosphate/5 mM EDTA at pH 6.0 (phosphate/EDTA buffer) was mixed with a 0.2 mL solution of dithiothreitol (3.1 mg, 20 μ mol) in the phosphate/EDTA buffer. After 1 h at 30 °C, the reaction mixture was passed through a Sephadex G-25 column equilibrated and eluted with the phosphate/EDTA buffer. The column fractions, containing the dendrimer derivative with free thiols, were monitored by measuring the increased absorption at 324 nm on addition of a solution of 4,4'-dithiodipyridine (22) to aliquots of the individual fractions. The dendrimer derivatives dendrimer-PDH and ALP-dendrimer-PDH were similarly treated with dithiothreitol to provide the derivatives NH_2 -dendrimer-SH **9** and ALP-dendrimer-SH **10**, respectively. The derivative ALP-dendrimer-SH **10** was separated from excess dithiothreitol either by a Sephadex G-25 column or by an exchange with the phosphate/EDTA buffer in an Amicon ultrafiltration cell till the effluent showed a negative reaction on addition of a solution of 4,4'-dithiodipyridine. A titration of the NH_2 -dendrimer (D5)-SH **9** and succinyl-dendrimer (D5)-SH derivatives with 4,4'-dithiodipyridine (22) showed the presence of 3.8 and 3.7 thiols per mole of the dendrimer, respectively.

Synthesis of [6-(Bromoacetamido)hexyl]amine (BAHA). BAHA **14** was synthesized (Scheme 2) by a procedure similar to that described by Heindel et al. (28). In brief, 2 mL of a methanol solution of *N*-BOC-1,6-diaminohexane **11** (0.5 g, 2.3 mmol) was added to a solution of *N*-hydroxysuccinimidyl bromoacetate **12** (0.5 g, 2.1 mmol) in 5.0 mL of tetrahydrofuran. The ethyl acetate solution (20 mL) of the residue, obtained on evaporation of the organic solvents, was washed with 10 mM HCl (3 $\times$ 5 mL). The dichloromethane solution (5.0 mL) of the dry intermediate **13**, obtained after removal of ethyl acetate, was mixed with trifluoroacetic acid (5 mL, 65 mmol). The trifluoroacetate salt of BAHA **14** was obtained in 50% yield as a white hygroscopic solid on crystallization from 2-propanol/hexane: mp 114-115 °C (corrected). The purity of the material was determined to be >90% by quantitation of the bromoacetamido groups as described before (23). MS *m/z* (relative intensity): 236, 238 (M^+ , due to two isotopes of bromine of

atomic weights 79 and 81; 28%), 121, 123 (the bromoacetyl residue; 58%), and 116 [the protonated form of the residue $\text{NH}_2(\text{CH}_2)_6\text{NH}$; 100%].

Activation of the Half-Generation Carboxy-Terminal Dendrimers. The sodium salts of the half-generation dendrimers, dissolved in water, were converted to the acid form by acidification with 5 N hydrochloric acid to pH 3.0. The acidified solutions were evaporated to dryness under high vacuum. Activation reaction of the free acid form of these dendrimers was carried out with *N,N,N',N'*-tetramethyl-*O*-(*N*-succinimidyl)uronium tetrafluoroborate (TSTU) essentially as described by Bannwarth and Knorr (29). A solution containing the 2.5th generation dendrimer (30 mg, 7.2 μmol) in 0.2 mL of water and 0.8 mL of DMF was mixed with *N,N*-diisopropylethylamine (90 mg, 0.7 mmol) and TSTU (74 mg, 0.24 mmol). After 1 h, solvents were removed from a red reaction mixture under reduced pressure. The residue was washed with ethyl acetate (3×10 mL), and the red residue obtained on removal of all the solvents was dissolved in 0.4 mL of water. The aqueous solution of the dendrimer-active ester **15** (Scheme 3) was stored in an ice bath while the active ester concentration was being determined by titration (24). A 100 μL aliquot of the aqueous solution, containing 4.4 μmol of the active ester as determined by titration, was mixed with 1 mL of a refrigerated solution of ALP (3 mg, 21 nmol) in the phosphate buffer at pH 7.0. After

incubation for 30 min in an ice bath, the reaction mixture was combined with 0.4 mL of a 2-propanol solution of BAH (20 mg, 62.5 μmol) and stirred gently at 4 $^\circ\text{C}$ for 16 h. The ALP-dendrimer complex **17**, containing reactive bromoacetamido groups, was purified over an Ultrogel AcA 44 column in the phosphate buffer at pH 7.0. To incorporate other functional groups, the intermediate **16**, obtained after reaction of ALP with the activated dendrimer, was combined separately with either a 1 mL solution of 100 mM ethylenediamine or 2-aminoethanethiol in the phosphate buffer to react with a homo- or heterobifunctional nucleophile. These reactions produced the complexes ALP-dendrimer- NH_2 **18** and ALP-dendrimer-SH **19**, respectively.

A solution of the free acid form of the 1.5th generation carboxyl-terminal dendrimer (33.4 mg, 15.2 μmol) in 1 mL of 80% DMF was mixed with *N*-hydroxysuccinimide (115 mg, 1 mmol) and 1-ethyl-3-[3-(dimethylamino)propyl]carbodiimide hydrochloride (EDC, 200 mg, 1 mmol). The reaction mixture was stirred for 16 h followed by washing the reaction mixture with ethyl acetate (2×5 mL) and 2-propanol (2×5 mL). The active ester **15** obtained on removal of the combined organic solution was dissolved in 0.5 mL of water. The aqueous solution containing 32 μmol of the active ester was reacted with a 1.8 mL solution of ALP (6.2 mg, 44.3 nmol) after titration of its active ester content as described above.

Scheme 3. Activation and Reactions of Dendrimers Containing Terminal Carboxyl Groups^a

^a (a) TSTU or EDC/NHS; (b) ALP-NH₂; (c) BAHA; (d) ethylenediamine; (e) 2-aminoethanethiol; (f) Fab'.

The nonspecific binding of the ALP-dendrimer complexes was measured by using a solution of the complex in place of the ALP-Fab' conjugate on Stratus II. The complex was diluted to 500 ng of protein/mL of solution in a buffer containing 100 mM Tris/1% BSA/1% Triton X-100/2 mM magnesium chloride/0.1 mM zinc sulfate at pH 7.2.

Coupling of Fab' with the ALP-Dendrimer Complex. The mouse monoclonal IgG₁ was converted to its fragments F(ab')₂ and Fab' as described by Ishikawa et al. (pages 29–30 of ref 23). The number of free thiols per mole of Fab' was found to be 2.5 ± 0.2 .

A typical procedure for the coupling of Fab' and the ALP-dendrimer complex, **4** or **17**, involved mixing of a 5.5 mL solution of Fab' (5.5 mg, 119.6 nmol) in the phosphate/EDTA buffer with 5.4 mL of a solution of the ALP-dendrimer complex (2.9 mg of protein, 20.7 nmol) in the phosphate buffer at pH 7.0. For this specific example, the ALP-dendrimer complex was prepared by a reaction of the NIA-activated 3rd generation dendrimer and ALP-SH. The mixture of Fab' and the ALP-dendrimer complex was concentrated to about 2 mL in an Amicon ultrafiltration cell (YM 10) and then buffer exchanged with the phosphate buffer at pH 7.6 till concentration of EDTA in the concentrate was $\leq 5 \mu\text{M}$ and the pH of the effluent was 7.6. The reaction mixture, 1.6 mL, was incubated at 4 °C for 16 h and then mixed with 32 μL of a 20 mg/mL solution of *N*-ethylmaleimide (0.64 mg, 5.1 μmol) in *N,N*-dimethylformamide. After 2 h, the reaction mixture containing free unconjugated Fab' and the ALP-dendrimer-Fab' complex, **5** or **20**, was applied to an Ultrogel Aca 34 column (fractionation range of 20–350 kDa; exclusion limit of 750 kDa) equilibrated with 10 mM Tris/100 mM NaCl/0.1 mM magnesium chloride/0.01 mM zinc sulfate/0.1% azide at pH 7.0 (Tris buffer). The performance of the fractions was evaluated on Stratus II. The fractions containing the ALP-dendrimer-Fab' complex, eluting as the first peak from the Aca 34 column, were pooled on the basis of their performance being similar to that shown by the ALP-Fab' conjugate. The protein concentration of the ALP-dendrimer-Fab' conjugate was determined using the BCA protein assay with alkaline phosphatase as an internal standard. The column was calibrated with protein standards from Pharmacia Biotech using blue dextran (2000 kDa), thyroglobulin (669 kDa), catalase (232 kDa), aldolase (158 kDa), bovine serum albumin (67

kDa), and ovalbumin (43 kDa). The linear regression analysis of this calibration curve (fraction number vs molecular mass) was used to calculate the apparent molecular mass of the ALP-dendrimer-Fab' complex present in the specific column fraction.

RESULTS

The biochemical and immunochemical evaluations of the protein-dendrimer complexes, ALP-dendrimer and ALP-dendrimer-Fab', were carried out on Stratus II. This heterogeneous immunoassay system utilizes a sandwich format to analyze samples containing an analyte, e.g. CKMB. Glass fiber filter paper, a negatively charged surface, is used in this system to immobilize an anti-CKMB antibody called the capture antibody. The capture antibody provides one component necessary to form the sandwich. The second component of the sandwich is provided by a solution of the conjugate ALP-Fab'. These two sandwich components that utilize antibodies have distinctly different requirements for the solid phase in any heterogeneous immunoassay system. For optimum performance, the capture antibody must be able to bind strongly to the solid phase whereas the antibody-enzyme conjugate should have the least affinity for the solid support. An affinity of the antibody-enzyme conjugate for the solid support would increase nonspecific binding and thus compromise the sensitivity of the system.

During the initial phase of these studies, it was clear that to minimize the solid support (glass fiber) affinity for a protein-dendrimer complex it would be necessary to block all the terminal primary amino groups of the full generation dendrimer used to prepare the complex. Two strategies were applied for this purpose. The first approach involved selection of the activation conditions in such a way so as to functionalize all the terminal groups of the full generation dendrimer. Alternatively, the amino groups that remained free during the activation procedure were blocked by reaction with a reagent so as to introduce terminal carboxyls or neutral hydroxyl groups, the groups that are expected to have the least affinity for a negatively charged solid support such as glass fiber. The reactions used to activate the terminal groups of the full and half-generation dendrimers are shown in Schemes 1 and 3, respectively.

The electrophilic iodoacetamido groups are generally introduced under mild reaction conditions by treatment

of molecules containing primary amines, such as a full generation poly(amidoamine) dendrimer, with a heterobifunctional reagent (e.g. the commercially available sulfoSIAB and NIA). By activation with a 10–20-fold molar excess of sulfoSIAB, it is possible to incorporate 3–5 phenyl iodoacetamido groups in the 5th generation dendrimer containing a total of 128 surface amino groups to produce **1** (NH₂–dendrimer–NHCOPhNHCOCH₂I). Irrespective of the generation of dendrimer used, all efforts to incorporate the maximum possible number of the reactive phenyliodoacetamido groups by reaction of all the surface amino groups with an excess of the activating reagent produced a white nonreactive precipitate. This precipitate was found to be insoluble in buffers of pH 2.0–12.0 and all common solvents such as alcohol, *N,N*-dimethylformamide, and dimethyl sulfoxide.

A clear solution was obtained when a solution of the full generation dendrimer, in 50% alcohol, was treated with an excess of NIA dissolved in tetrahydrofuran. By this method, it was possible to activate different generations of dendrimers, including partially functionalized dendrimers such as the partially hydroxylated and carboxymethylated dendrimers. Fluorescamine titration of these NIA-activated dendrimers **3** showed the absence of any surface amino groups present originally before the activation reaction. However, the reactive iodoacetamido groups that can be titrated with dithiothreitol in these derivatized dendrimers ranged from 13 to 26% of the values expected (Table 1). To calculate these values, it is assumed that all the terminal amino groups present originally in the dendrimer would react with the activating reagent. The first two generations of dendrimers contained the highest percentage of the incorporated reactive groups. All of these dendrimer derivatives were stable to storage in 50% alcohol or pH 5.0 buffer for at least 3 days at –10 °C.

The dendrimers derivatized by reaction with sulfoSIAB or NIA were reacted with ALP to form the complex ALP–dendrimer–COCH₂I in two different sets of reactions (Scheme 1). A Schiff base was formed between the periodate-oxidized ALP and amino groups of the dendrimer activated with sulfoSIAB to form the intermediate

ALP–CH=N–dendrimer–NHCOPhNHCOCH₂I. This intermediate was reduced with sodium cyanoborohydride to form the stable secondary amine derivative **2**. Alternatively, ALP–SH (containing 1–3 free SHs per mole of the protein) was reacted with an excess of the NIA-activated dendrimer derivative to form the complex **4** (ALP–SCH₂CONH–dendrimer–NHCOCH₂I). The reactive iodoacetamido groups present in the complexes prepared by the two methods were quantitated by titration with dithiothreitol (Table 1).

The product formed on reaction of the 1st generation amino-terminal dendrimer with NIA was analyzed with an electrospray ionization mass spectrum. This analysis was carried out on a methanol/water solution of the product under the positive ion mode. The three most intense peaks present in this spectrum show *m/z* (relative intensity) of 903.3 (100%), 780.1 (85%), and 678.1 (50%) corresponding to +3, +2, and +4 charged states of the molecules, respectively. These three peaks represent the molecular species of *m/z* 2708.7, 1558.2, and 2708.4, respectively. The highest peak observed in this spectrum shows *m/z* of 1361.6 (10% relative intensity) corresponding to a +2 charged state. This peak represents a molecular species of *m/z* 2721.2. The 1st generation dendrimer derivative containing eight iodoacetamido groups introduced by reaction of all eight terminal amino groups would be expected to have a molecular mass of 2780 Da.

A reaction of terminal amino groups of the full generation dendrimers with an excess of epibromohydrin resulted in the formation of epoxy–dendrimers **6**. A number of dendrimers were functionalized with the epoxy groups. Fluorescamine titration of the derivatized dendrimers showed that 96–99% of the terminal amino groups had been reacted during this activation procedure. Similar to the NIA activation above, all the epoxy–dendrimers prepared by reaction with epibromohydrin showed complete solubility in 50% aqueous alcohol and these solutions could be stored for several days at –20 °C without loss of the reactive groups. The complex ALP–S–dendrimer–epoxide **7** was prepared by reaction of an excess of the epoxy–dendrimer (prepared from the 2nd generation dendrimer) with ALP–SH containing 2.6 free SHs per mole of protein (Scheme 1). Titration of the electrophilic groups in this complex and epoxy–dendrimer was carried out with dithiothreitol (22), and results are shown in Table 2. The reactive epoxide groups in the dendrimer–epoxide **6**, available for titration, were found to be 1.6–8.5% of the total terminal amino groups present in the specific generation of the dendrimer.

Dendrimers containing the nucleophilic sulfhydryls (dendrimer-SH) **9** have been prepared by a reaction of the terminal amino groups in the full generation dendrimers with a 4–10-fold molar excess of sulfo NHS LC SPDP (26) to form the intermediate NH₂-dendrimer-S-S-Py (dendrimer-PDH) **8**, followed by reaction of this intermediate with a reagent such as dithiothreitol. By utilizing a limited amount of the activation reagent, it has been possible to prepare a dendrimer derivative **9** containing two surface nucleophiles with distinctly different reactivity, i.e. NH₂ and SH (Scheme 1). In addition, succinic anhydride/dithiothreitol treatment of the intermediate dendrimer-PDH, containing the surface amino groups that were not involved during reaction with sulfo NHS LC SPDP, resulted in the formation of COOH-dendrimer-SH. This derivative contains the nucleophilic sulfhydryls in addition to the free carboxyl groups which show a low reactivity. A solution of the succinylated dendrimer derivative with free sulfhydryl groups was found to form an insoluble precipitate when stored at –20 °C for 48 h.

Quantitative conversion of the terminal amino groups in the intermediate dendrimer-PDH, during reaction with succinic anhydride, was confirmed by titration with fluorescamine. However, under identical reaction conditions, ≤90% of the amino groups were involved in reaction with reagents such as gluconolactone, butyrolactone, or acetoxyacetyl chloride.

An excess of the intermediate dendrimer-PDH, prepared from the 2nd generation amino-terminal dendrimer, was reacted with the periodate-oxidized ALP. A cyanoborohydride/dithiothreitol treatment of the intermediate Schiff base resulted in the formation of the complex ALP-dendrimer-SH **10** (Scheme 1).

BAHA, a heterobifunctional reagent, was synthesized in three steps by a procedure similar to that described by Heindel et al. (28). The synthetic scheme is shown in Scheme 2.

The electrophilic *N*-hydroxysuccinimidyl esters **15** (Scheme 3) were prepared by activation of the terminal carboxyl groups in the half-generation dendrimers. This activation was carried out by two different methods. An 80% dimethylformamide solution of the free acid form of the dendrimer was treated either with TSTU (29) or with EDC in the presence of NHS. A titration of the active esters incorporated in different generations of the carboxyl dendrimers was found to be 4.4–7.5% of the total carboxyl groups present in the specific generation of the dendrimer (Table 3). The purified active esters **15** were reacted with ALP followed by reaction of the intermediate

Figure 1. Gel filtration elution profiles of the ALP-dendrimer complexes. The NIA-activated dendrimers were reacted with ALP-SH, and the reaction mixture was applied to an Ultrogel AcA 44 column (1.6 × 70 cm) equilibrated and eluted with the phosphate buffer at pH 7.0. The figure shows the elution profiles of products obtained on reaction of the 1st, 2nd, 4th, and 5th generations of dendrimers (D1, D2, D4, and D5, respectively). The inset shows the elution profile of ALP-PDH obtained by reaction of ALP with sulfo NHS LC SPDP.

ALP-dendrimer-active ester **16** with either BAHA, ethylenediamine, or 2-aminoethanethiol to prepare complexes **17–19**, respectively. Additional amino, sulfhydryl, and bromoacetamido groups present in the complex ALP-dendrimer-X (X = NH₂, SH, and NHCOCH₂Br) were quantitated by titration with fluorescamine, 4,4'-dithiodipyridine, and dithiothreitol/4,4'-dithiodipyridine, respectively (Table 3).

A number of the ALP-dendrimer complexes were purified on a gel filtration column (Ultrogel AcA 44; fractionation range of 10–130 kDa). The elution profiles of a few of these complexes along with that of ALP-6-[3-(2-pyridyldithio)propionamide]hexanoate (ALP-PDH), prepared by activation of ALP with sulfo NHS LC SPDP, are shown in Figure 1. The peak fractions (showing maximum absorption at 280 nm) in these profiles were eluted from this column in the same position, i.e. the fraction number 23 ± 1. Activation of proteins with sulfo NHS LC SPDP does not lead to polymerizations, and since the elution profiles of the ALP-dendrimer complexes are similar to that of ALP-PDH, the predominant component in all these ALP derivatives is the monomeric form of the protein. The polymeric forms of ALP, especially a dimer when present as an impurity in the monomeric form of the protein, elute in front of the main peak containing the monomeric form of the protein when chromatographed on a column prepared with this gel. A small amount of this dimeric form of ALP is evident as a small shoulder (Figure 1) in a few of the ALP-dendrimer complexes as well as in ALP-PDH.

The specific enzyme activity of all of the ALP-dendrimer complexes described above has been found to be very similar to that of ALP used for the coupling reactions. The enzyme activity was determined spectrophotometrically from the rate of hydrolysis of *p*-nitrophenyl phosphate in 1 M Tris buffer at pH 8.0. For example, ALP-dendrimer-COCH₂I, prepared from the 2nd and the hydroxylated 5th generation dendrimers, shows specific activities of 450 and 399 units/mg, respectively. Under identical conditions, ALP, used for these reactions, shows an activity of 500 units/mg.

Kinetic parameters of the ALP–dendrimer complexes were found to be comparable to those of ALP. For example, the ALP–CH₂NH–dendrimer complexes prepared from the 3rd and the 5th generation dendrimers show K_m values of 0.19 and 0.11 mM, respectively, as compared to 0.17 mM for that of ALP. The K_{cat}/K_m ratios for these dendrimer complexes were found to be 8.6×10^6 and $1.20 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$, respectively. This ratio was found to be $9.8 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$ for ALP under identical reaction conditions.

Prior to conjugation of Fab' to an ALP–dendrimer complex, the nonspecific binding of these ALP–dendrimer complexes was evaluated on Stratus II. Nonspecific binding is the response generated, at 0 ng/mL of the analyte, by the ALP–dendrimer complex when applied to the glass fiber solid support used in Stratus II. The complexes **4** prepared by a reaction of ALP–SH with the NIA-activated dendrimers showed (15) nonspecific binding of 146–2571 mV/min at a protein concentration of 500 ng/mL. This interaction was found to increase with the generation of the dendrimers containing terminal amino groups. The reagents prepared with the half-generation dendrimers show very low nonspecific binding (35–83 mV/min) regardless of the generation of dendrimer used. The nonspecific binding of complexes prepared by dendrimers activated with the other methods was found to be extremely high. For example, the complexes ALP–dendrimer (D2)–epoxide **7**, ALP–CH₂NH–dendrimer (hydroxylated D5)–NHCOPhNHCOCH₂I **2**, and ALP–CH₂NH–dendrimer (D5)–SH **10** showed responses of 10 668 (20 ng/mL), 2544 (0.94 ng/mL), and 2973 mV/min (100 ng/mL), respectively, as compared to a response of 108 mV/min for the ALP–Fab' conjugate.

The ALP–dendrimer complexes **4** and **17** containing terminal iodoacetamido and bromoacetamido groups were reacted separately with the Fab' fragment of an anti-CKMB antibody to form the multifunctional dendrimer reagents ALP–dendrimer–Fab'. The reaction mixtures containing the ALP–dendrimer–Fab' complexes (**5** and **20**) were purified on an Aca 34 column (fractionation range of 20–350 kDa; exclusion limit of 750 kDa). The column fractions were tested on Stratus II. This testing evaluates both the enzyme activity of ALP and the antigen binding activity of the antibody in the ALP–dendrimer–Fab' complex. The first peak that elutes from the column represents the ALP–dendrimer–Fab' complex followed by elution of the two unreacted components ALP–dendrimer and Fab'. The elution profiles of a few of these representative complexes are shown in Figure 2.

The presence of fractions appearing as a shoulder and representing higher-molecular mass complexes in front of the main ALP–dendrimer–Fab' complex peak is dependent on the generation of the dendrimer used to prepare the ALP–dendrimer complex. For example, in the complex prepared from the 1st generation dendrimer, this front shoulder is almost nonexistent, whereas this set of fractions becomes the major component when the 5th generation dendrimer was used for the coupling reactions. The presence of this shoulder (Figure 2) is quite obvious in cases where the 3rd and the 4.5th generation dendrimers were used for the reactions. The apparent molecular mass of the peak fractions (showing highest absorption at 280 nm) in these ALP–dendrimer–Fab' complexes prepared from the 3rd and the 5th generation dendrimers was calculated to be 194 and 517 kDa, respectively. All complexes, except for the one prepared from the 5th generation dendrimer, showed performances (15) similar to that of the ALP–Fab'

Figure 2. Gel filtration elution profiles for the purification of ALP–dendrimer–Fab' complexes. The reaction mixture obtained after reaction of the ALP–dendrimer complex with an excess of Fab' was applied to an Ultrogel Aca 34 column (1.6 × 100 cm) equilibrated and eluted with the Tris buffer. The figure shows the profiles of products obtained from the 1st, 3rd, 5th, and 4.5th generation dendrimers (D1, D3, D5, and D4.5, respectively).

conjugate. The ALP–dendrimer–Fab' complex, prepared from the 5th generation dendrimer, could not match the performance of the commercial conjugate even at a very high protein concentration of 9.26 µg/mL as compared to other complexes which showed comparable performances at 0.434–0.740 µg/mL protein (15).

DISCUSSION

Reaction conditions normally used to activate functional groups may adversely affect the structural integrity or specific activity of a biologically active molecule. However, a number of reaction conditions affecting the surface groups of Starburst dendrimers do not impact their structural integrity (3, 30, 31). For coupling of biologically active molecules to a natural or a synthetic macromolecule, such as a dendrimer, it is therefore desirable to activate the surface groups of these macromolecules.

For optimum performance, the complex prepared by reacting biologically active material with a dendrimer, e.g. antibody–dendrimer (11) and antibody–dendrimer–enzyme (15), may require either partial or essentially complete reaction of the terminal functional groups present originally in a dendrimer. The results presented here make it possible to achieve these goals by activation of a dendrimer with a specific reagent in defined molar ratios. A number of full and half-generation dendrimers have been used for these derivatizations. Respective reactions with sulfoSIAB and NIA (Scheme 1 and Table 1) allow partial or complete reaction of terminal amino groups of a full generation dendrimer to incorporate the electrophilic iodoacetamido groups **1** and **3**. Similarly, incorporation of the electrophilic epoxy **6** and *N*-hydroxy-succinimidyl groups **15** (Tables 2 and 3) has been achieved by reaction with an excess of the appropriate reagents. By a similar choice of reactions, it has been possible to derivatize dendrimers containing either two nucleophilic groups **9** (i.e. SH and NH₂; Scheme 1) with selective reactivity patterns or a nucleophilic sulfhydryl and a nonreactive carboxyl or hydroxyl. These derivatized dendrimers have been reacted with a limited amount of a model protein (ALP) to form the complex

ALP–dendrimer–active group. This complex can be reacted further with a homo- or heterobifunctional reagent to achieve specific chemical or ionic characteristics. Alternatively, active groups in the intermediate are available for further reaction with other similar or dissimilar biologically active materials for formation of dendrimer-based multifunctional reagents.

The feasibility of preparation of multifunctional reagents has been demonstrated by reaction of the ALP–dendrimer complexes with the Fab' fragment of an anti-CKMB antibody. The resulting bifunctional reagents have been prepared using both full and half-generations of the poly(amidoamine) dendrimers. The performance characteristics of these ALP–dendrimer–Fab' complexes are influenced by the dendrimer generation (15), the nature of the terminal functional groups present, and the method of activation used to prepare the derivatized dendrimer.

The bifunctional reagent ALP–dendrimer–Fab' prepared from the 5th generation dendrimer did not show optimum performance on Stratus II probably due to the very large size of the complex formed. However, it may rather be beneficial to prepare a large sized complex for other applications such as that utilized for a slow and sustained release of a biologically active molecule targeted either at a specific site of action or in circulation. The results presented here clearly show that by an appropriate selection of the dendrimer it is possible to control the size (Figure 2) and thus the performance of these dendrimer-based multifunctional reagents.

The number of reactive functional groups introduced in the derivation reactions described here is lower than that expected on the basis of the number of terminal groups present originally in the specific generation of the Starburst dendrimer. The reasons for this effect are not very clear. Although a standard method for titration of the electrophilic groups when present in proteins, dithiothreitol/4,4'-dithiodipyridine reaction (23) may not be optimum for quantitation of such groups in dendrimers. Furthermore, the terminal functional groups in a dendrimer have been shown (13) to possess enhanced chemical reactivity as compared to their activity when present in other molecules. This higher than usual activity may be responsible for inter- and intramolecular reactions of the incorporated groups and thereby decreasing the number of such groups actually available during titrations and for coupling with biologically active molecules. The gel filtration column profiles of ALP–dendrimer complexes (Figure 1) have shown that the molecular mass of the protein eluted was not dramatically different as compared to that of ALP; i.e. formation of dimers and other polymers of ALP was not evident. This interpretation is supported further by the calculated molecular mass (194 kDa) of the peak fraction (with maximum absorbance at 280 nm) in the complex ALP–D3–Fab'. This number is very close to what would be expected (193.7 kDa) for such a complex containing ALP–D3–Fab' in a 1:1:1 ratio.

The mass spectrum of a product formed from the activation reaction of the 1st generation amino-terminal dendrimer shows the presence of species with a molecular mass of <3 kDa. This observation would rule out the possibility of the multimeric derivatives of the dendrimer being the predominant component of this reaction product. The unusual reactivity of a terminal group in a dendrimer, the reactivity of the introduced iodoacetamido groups, an absence of primary amino terminal groups (fluorescamine), and a small number of the available iodoacetamido groups (dithiothreitol titration) suggest an

intramolecular coupling of the activated derivative. Work is in progress to further characterize the nature of the major component present in this reaction mixture. The intermolecular coupling of appropriately activated dendrimers has been used (2) to prepare multimeric forms of dendrimers but may not be the major reaction path under the conditions utilized in this study.

In conclusion, dendrimer derivatives of different generations have been prepared that contain nucleophilic, electrophilic, and nonreactive groups by an appropriate selection of the specifically defined reaction conditions. The methods described here allow for the preparation of reagents with desirable characteristics such as controlled molecular mass and a defined number of reactive groups. These reactions show that Starburst dendrimers can be subjected to a series of defined chemical reactions. Due to the controlled architecture and geometry of dendrimers and the use of a defined sequence of chemical reactions, the methods developed here allow for reproducible preparation of reagents that have the potential for very broad applications.

Epoch Pharmaceuticals, Inc., 1725 220th Street, S.E., #104, Bothell, Washington 98021. Received July 23, 1997; Revised Manuscript Received October 6, 1997[®]

A versatile method is described for preparing aryl nitrogen mustard–oligodeoxyribonucleotide (mustard–ODN) conjugates under anhydrous conditions. The chemistry uses DMSO soluble triethylammonium or tributylammonium salts of the ODNs. A G/A motif triplex forming ODN was chosen for study since it had been shown earlier to bind with high affinity and specificity to a duplex DNA target. A 5'-hexylamine derivative of this ODN was reacted with three different 2,3,5,6-tetrafluorophenyl ester derivatives of aryl nitrogen mustards which were designed to have different alkylation rates. An HPLC assay was used to determine reaction rates of these mustard–ODNs under various conditions. The reactivity of the mustard groups depended on chloride concentration and the presence of nucleophiles. Conjugation of mustards to G/A-containing ODNs decreased their aqueous stability. Hydrolysis and alkylation rates of these agents were consistent with reaction via an aziridinium intermediate. Rates of sequence specific alkylation within a triplex were determined by denaturing gel electrophoresis and shown to depend on inherent reactivity of the mustard group. The improved synthesis and chemical characterization of mustard–ODNs should facilitate their use as sequence specific alkylating agents and as probes for nucleic acid structure.

INTRODUCTION

Aryl nitrogen mustards are one of the oldest and most studied classes of cancer chemotherapy agents (1). Their cytotoxic effects are attributed to random alkylation of vital macromolecular targets, especially the nucleophilic N7 position of the purine bases in genomic DNA (ref 2 and references therein). Formation of interstrand cross-links in DNA by these bifunctional alkylating agents is believed to be especially lethal, but monoalkylation, depurination, and strand scission may also contribute to cytotoxic and mutagenic effects (3). Our goal is to deliver these (and other) alkylating agents to specific genetic targets as triplex-forming oligodeoxynucleotide (ODN) conjugates in order to induce sequence specific mutations or gene knockouts. We have recently shown (4) sequence specific targeting and covalent modification of human genomic DNA by aryl nitrogen mustard–ODN conjugates (mustard–ODNs). Mustard–ODNs are also valuable probes for nucleic acid structure. For example, the mechanisms of RecA-mediated synaptic joint formation (5) and RNA polymerase-catalyzed transcription (6) have recently been explored using mustard–ODNs. As shown in Figure 1, the alkylation mechanism of the aryl nitrogen mustards is believed to occur mainly via spontaneous formation of an electrophilic aziridinium cation intermediate (7). Although aromatic aziridinium cations have not been directly detected, the first-order reactions observed for this class of mustards are in accord with the proposed mechanism. Mustards have been attached to ODNs with appropriate length linkers that position the short-lived aziridinium cation in the proximity of a

Figure 1. Mechanism for reaction of aryl nitrogen mustard–ODN conjugates. The major pathway is via the aziridinium cation intermediate. Alkylation of N7 in dG is shown, but other nucleophilic centers in DNA can also be alkylated. The second (2-chloroethyl)amine group reacts in a similar manner.

dG residue after hybridization to a single-stranded (ss) or double-stranded (ds) DNA target (ref 8 and references therein). Targeted alkylation of a single DNA strand in dsDNA by a triplex-forming mustard–ODN can occur in high yield (4), and efficient interstrand cross-linking has been accomplished by conjugating a mustard group to each end of the ODN (9). Nonetheless, there are competing side reactions such as hydrolysis and nonsequence specific alkylation that can decrease alkylation efficiency in some triplex systems. To understand effects of sequence-directed DNA alkylation in more complex biological systems, we have explored the aqueous stability and reactivity of mustard–ODNs.

Mustard–ODNs have been used for many years, but

[®] Abstract published in *Advance ACS Abstracts*, December 15, 1997.

synthesis and characterization of these reactive ODNs remains a challenging problem (10). ODNs have poor solubility in organic solvents, and the (2-chloroethyl)-amino functionality of biologically relevant nitrogen mustards is rapidly hydrolyzed. In addition, self-reaction of mustard groups with the ODN carrier is possible. In the course of our studies, we have developed a general method for preparation of reactive ODN conjugates in anhydrous organic solvents. In this paper, we describe synthesis of three aryl nitrogen mustard-activated esters and conjugation to a G/A motif triplex-forming ODN. These mustard groups were designed to have different inherent reaction rates. The ability to vary the reactivity of the mustard–ODNs is especially important for biological applications where uptake and degradation rates of the ODN carrier are a concern. Rates of reaction of mustard–ODNs under various conditions were analyzed by reverse phase HPLC, and alkylation of duplex DNA targets was determined by gel electrophoresis.

EXPERIMENTAL PROCEDURES

Nitrogen mustards are potent alkylating agents and were handled with great care. DMSO solutions are especially hazardous, and disposable nitrile gloves were used for these operations. Excess reagents were decomposed in water.

^1H and ^{13}C NMR spectra were recorded on a Varian Gemini 300 MHz spectrometer. Infrared spectra were obtained with a Perkin-Elmer 783 spectrophotometer. Elemental analyses were performed by Quantitative Technologies Inc. (Boundbrook, NJ). Melting points were determined on a Mel-Temp melting point apparatus in open capillary tubes and are uncorrected. All air and water sensitive reactions were carried out under a slight positive pressure of argon. Flash chromatography was performed on 230–400 mesh silica gel. Analytical thin-layer chromatography was carried out on EM Science F_{254} aluminum-backed, fluorescent indicator plates. 4-[Bis(2-chloroethyl)amino]benzenebutanoic acid (chlorambucil) was purchased from Fluka Chemical Co. 4-[Bis(2-chloroethyl)amino]phenylacetic acid and 3-[bis(2-chloroethyl)amino]benzoic acid were made by variations of the literature method (11). 2,3,5,6-Tetrafluorophenyl trifluoroacetate (TFP-TFA) was prepared as described earlier (12). Triethylammonium bicarbonate (TEAB, 0.1 M) and tributylammonium bicarbonate (TBAB, 0.1 M) were prepared by sparging a heterogeneous mixture of the appropriate amine with CO_2 until the organic layer disappeared.

2,3,5,6-Tetrafluorophenyl 4'-[Bis(2-chloroethyl)-amino]benzenebutanoate (1). To a solution of 0.25 g (0.82 mmol) of chlorambucil and 0.3 g (1.1 mmol) of TFP-TFA in 5 mL of dry dichloromethane was added 0.2 mL of dry triethylamine. The mixture was stirred under argon at room temperature for 0.5 h and evaporated. The residual oil was purified by column chromatography on silica gel with hexane/chloroform (2:1) as the eluting solvent to give 0.28 g (75% yield) of **1** as a colorless oil: TLC (CHCl_3) $R_f = 0.6$; IR (CHCl_3) 3010, 1780, 1613, 1521, 1485 cm^{-1} ; ^1H NMR (CDCl_3) δ 7.11 (d, $J = 8.8$ Hz, 2H), 7.06–6.94 (m, 1H), 6.65 (d, $J = 8.8$ Hz, 2H), 3.8–3.6 (m, 8H), 2.7–2.6 (m, 4H), 2.1–2.0 (m, 2H); ^{13}C NMR (CDCl_3) δ 147.69, 144.54 (dt), 144.30 (dt), 142.30 (dd), 138.5 (dd), 129.88, 112.22, 103.17 (t), 53.61, 40.52, 33.63, 32.64, 30.99, 26.64. Anal. ($\text{C}_{20}\text{H}_{19}\text{Cl}_2\text{F}_4\text{NO}_2$) C, H, N, F.

2,3,5,6-Tetrafluorophenyl 4'-[Bis(2-chloroethyl)-aminol]phenylacetate (2). 4-[Bis(2-chloroethyl)amino]phenylacetic acid was converted to TFP ester **2** using a

procedure similar to that described for synthesis of **1** to give 0.45 g (74% yield) of **2** as a white crystalline solid: mp 99–100 $^\circ\text{C}$ (from hexanes/ethyl acetate); TLC (2:1 hexanes/ethyl acetate) $R_f = 0.68$; ^1H NMR (CDCl_3) δ 7.26 (d, $J = 8.8$ Hz, 2H), 6.99 (m, 1H, TFP), 6.71 (d, $J = 8.8$ Hz, 2H), 3.89 (s, 2H), 3.75 (m, 4H), 3.65 (m, 4H); ^{13}C NMR (CDCl_3) δ 167.97, 147.69 (m), 144.40 (m), 142.35 (m), 139.11 (m), 145.61, 130.64, 121.00, 112.17, 103.24 (t), 53.53, 52.06, 40.45, 40.07. Anal. ($\text{C}_{18}\text{H}_{15}\text{NO}_2\text{Cl}_2\text{F}_4$) C, H, N.

2,3,5,6-Tetrafluorophenyl 3'-[Bis(2-chloroethyl)-amino]benzoate (3). To a suspension of 2.62 g (10 mmol) of 3-[bis(2-chloroethyl)amino]benzoic acid in 20 mL of dry dichloromethane was added 3.37 g (13 mmol) of TFP-TFA followed by 2 mL (14.4 mmol) of dry triethylamine. A mild exothermic reaction was observed, and the mixture formed a clear solution within 5 min. The mixture was stirred under argon for an additional 15 min and evaporated. The residual oil was purified by column chromatography on silica gel using dichloromethane as the eluting solvent. The solid was recrystallized from 15 mL of hexanes to give 3.04 g (74% yield) of **3** as a white solid: mp 56–59 $^\circ\text{C}$; TLC (CHCl_3) $R_f = 0.7$; ^1H NMR (CDCl_3) δ 7.65–7.6 (m, 1H), 7.5–7.4 (m, 2H), 7.1–7.0 (m, 2H), 3.9–3.96 (m, 4H); ^{13}C NMR (CDCl_3) δ 147.75 (dt), 146.57, 144.47 (dt), 142.50 (dd), 139.23 (dd), 130.26, 128.50, 119.73, 117.91, 113.41, 103.32 (t), 53.41, 40.30. Anal. ($\text{C}_{17}\text{H}_{13}\text{Cl}_2\text{F}_4\text{NO}_2$) C, H, N, F.

(R/S)-3-[4'-[[Bis(2-chloroethyl)amino]phenyl]-acetamido]-1,2-propanediol (4). To a solution of 241 mg (2.65 mmol) of 3-amino-1,2-propanediol in 5 mL of dry DMF was added 226 mg (0.53 mmol) of TFP ester **2**. After 1 h, the reaction mixture was evaporated and applied onto a silica gel column (2 $\times$ 28 cm). Elution with methylene chloride/methanol (95:5) followed by concentration of the proper fractions gave 174 mg (94% yield) of **4** as a white solid: mp 76–78 $^\circ\text{C}$; TLC (9:1 dichloromethane/methanol) $R_f = 0.42$; ^1H NMR (CDCl_3) δ 7.12 (d, $J = 6.6$ Hz, 2H), 6.66 (d, $J = 6.6$ Hz, 2H), 5.88 (m, 1H), 3.8–3.3 (m, 9H), 1.7 (br s, 2H). Anal. ($\text{C}_{15}\text{H}_{22}\text{N}_2\text{O}_3\text{Cl}_2$) C, H, N.

Synthesis and Purification of Oligodeoxynucleotides. ODNs were prepared on an Applied Biosystems model 394 synthesizer using the 1 μmol protocols supplied by the manufacturer. Protected β -cyanoethyl phosphoramidites, CPG supports, deblocking solutions, cap reagents, oxidizing solutions, and tetrazole solutions were purchased from Glen Research (Sterling, VA). The sequences of the 65-mer dsDNA target and the triplex-forming ODN (ODN-NH₂) are shown in Figure 2. A 3'-hexanol modification was introduced into ODN-NH₂ using 2 μmol of hexanol-modified CPG support (12), and a 5'-aminohexyl linker was introduced using an *N*-MMT-hexanolamine phosphoramidite (Glen Research). Preparative HPLC purification, detritylation, and butanol precipitation of the synthetic ODNs were carried out as previously described (13). Aliquots (0.2 mg) of the 65-mer ODNs were further purified by preparative gel electrophoresis for triplex cross-linking experiments.

Characterization of ODNs. The concentrations of all ODNs were determined from the UV absorbance at 260 nm in phosphate-buffered saline (pH 7.2). An extinction coefficient for each ODN was estimated using a nearest neighbor model (14). For the triplex-forming ODN used in these studies, a value of 29.1 $\mu\text{g/mL}$ per A_{260} unit was used. All modified ODNs were analyzed by reverse phase HPLC (C_{18} HPLC) using a 250 $\times$ 4.6 mm C_{18} column equipped with a guard column (Rainin Dynamax, 10 μm particle size, 300 $\text{\AA}$ pore size). A

gradient of 5 to 65% solvent B over 30 min was used (flow rate = 1 mL/min), where solvent A was 0.1 M triethylammonium acetate (TEAA, pH 7.5) and solvent B was acetonitrile; detection was by UV absorbance at 260 nm. Unless otherwise noted, all modified ODNs were greater than 95% pure by C_{18} HPLC.

Typical Synthesis of Mustard-ODN Conjugates (ODN I). Dried, detritylated ODN-NH₂ from a 2 μ mol scale synthesis was dissolved in 0.5 mL of water and injected onto a Hamilton PRP-1 column (Reno, NV) that was equilibrated with 0.1 M TEAB (pH 7.2). The TEA salt of the ODN was eluted from the column using a gradient of 0 to 60% acetonitrile over 30 min, with a flow rate of 2 mL/min. The desired peak (~15 min) was collected and dried in vacuo on a centrifugal evaporator. The residue was dissolved in 0.5 mL of water, and the concentration was determined to be 2.36 mg/mL. C_{18} HPLC analysis showed one major peak (90% purity). A 1 mg aliquot (424 μ L, 71 nmol) was redried in a 1.7 mL Eppendorf tube, and the residue was dissolved in 0.2 mL of DMSO with 5 μ L of ethyldiisopropylamine. A 20 mg/mL solution of TFP ester **1** in DMSO was prepared, and 31.5 μ L (0.63 mg, 1.4 μ mol) was added to the ODN. The mixture was shaken for 3 h at room temperature, and then the ODN was precipitated by adding 10 mL of 2% NaClO₄/acetone in a 14 mL polypropylene tube. The mixture was centrifuged at 3000 rpm for 5 min, and the pellet was sonicated with 2 mL of acetone and recentrifuged. The pellet was dried in vacuo for 15 min, and the crude product was stored at -20 °C. The crude reaction mixture was analyzed by C_{18} HPLC. Purification by C_{18} HPLC used the same gradient and column specified above. The peak eluting at 19 min was collected in ~1 mL of TEAA/acetonitrile and immediately precipitated by adding 100 μ L of 3 M sodium acetate and 4 mL of ice cold absolute ethanol. The mixture was centrifuged at 3000 rpm for 5 min, and the pellet was sonicated with 2 mL of ethanol and recentrifuged. The pellet was dried in vacuo for 15 min, and the purified product was dissolved in 0.25 mL of water. A 5 μ L aliquot was removed for C_{18} HPLC analysis, and another 5 μ L aliquot was removed for concentration determination. The bulk solution of ODN **I** was immediately frozen and stored at -20 °C for future use. HPLC analysis showed 98% purity. The concentration was 1.76 mg/mL (0.44 mg, 44% yield).

ODN **I** was prepared in similar yield and purity using TBAB for the initial salt exchange. The more lipophilic TBA salt was eluted from the PRP-1 column using a gradient of 0 to 100% acetonitrile over 30 min, with a flow rate of 2 mL/min. The desired peak (~23 min) was collected and dried in vacuo on a centrifugal evaporator as usual. ODN **II** and ODN **III** were prepared in similar yields and purities from the TBA salts.

HPLC Assay for Kinetics Studies. Reverse phase HPLC analysis of mustard-ODNs was carried out using a Rainin Gradient HPLC system (Emeryville, CA) equipped with 10 mL pump heads and a Rainin Dynamax PDA-1 photodiode array detector. For kinetics studies, 10 μ L of each sample was injected onto a 4.6 $\times$ 150 mm Rainin Microsorb C_{18} column and eluted using a gradient of 5 to 65% acetonitrile in 0.1 M triethylammonium acetate (pH 7.5) over 20 min (flow rate of 1 mL/min). ODN products were detected by UV absorbance at 260 nm, and data were integrated and analyzed using Rainin Dynamax software.

Aqueous Stability of Mustard Conjugates. One hundred microliters of a 0.1 mM solution of the conjugate of interest was prepared in 20 mM HEPES buffer (pH

7.2) with 140 mM KCl and 10 mM MgCl₂. For the chloride-free experiments, 20 mM HEPES buffer (pH 7.2) was used with no additional salts. The 0.1 mM stock solution was immediately aliquoted to six Eppendorf tubes that were submerged in a 37 °C bath. For ODN **I**, ODN **II**, and the aminopropanediol conjugate **4**, aliquots were removed at 30, 45, 60, 90, 120, and 240 min. For ODN **III**, aliquots were removed at 2, 4, 6, 8, and 12 h. The aliquots were immediately frozen (-20 °C) and thawed just prior to HPLC analysis. Intact mustard-ODNs eluted at ~10 min, and a mixture of degradation products eluted at 5–8 min. Intact compound **4** eluted at ~14 min. After integration, the percent of intact conjugate was plotted vs time and the half-life for disappearance of starting material was determined from the line of best fit using an equation for exponential decay.

Reaction of Mustard Conjugates with a Model Nucleophile. One hundred microliters of a 0.1 mM solution of ODN **I**, **II**, or **III** was prepared in 20 mM HEPES buffer (pH 7.2) with 140 mM KCl and 10 mM MgCl₂. Sodium thiosulfate (10 mM, 100 equiv) was added to the mixtures. The half-life for disappearance of the starting conjugate was determined as described for the stability studies.

Determination of DNA Alkylation Rates for Triplex-Forming Mustard-ODNs. The duplex used in these studies was 65 bp long and contained a 33 bp homopurine-homopyrimidine run. The purine-rich strand of the duplex was 5'-end labeled by treatment with T4 polynucleotide kinase and [γ -³²P]ATP under standard conditions (15). Labeled ODN was purified using a Nensorb column (NEN Research Products) and had a specific activity of ~6000 cpm/fmol. Duplexes were formed by annealing 20 nM purine-rich strand with 40 nM complementary pyrimidine-rich strand in 20 mM HEPES (pH 7.2) with 140 mM KCl, 10 mM MgCl₂, and 1 mM spermine using an incubation profile of 1 min at 95 °C and 30 min at 37 °C. After annealing, coralyne chloride (Sigma) was added to give a final concentration of 10 μ M. The concentration of the labeled duplex was kept constant (20 nM), while the concentration of TFO was varied (0.2–2 μ M). Triplexes were formed in capped and siliconized polypropylene microcentrifuge tubes (0.65 mL) at 37 °C in a final volume of 25 μ L. The labeled duplex (22.5 μ L) was combined with 2.5 μ L of ODN **I** or ODN **II** (2 or 20 μ M), and the solutions were incubated at 37 °C. Aliquots (2.5 μ L) were removed at 0, 30, 60, 120, 240, 360, and 1320 min and stored frozen in 4 μ L of loading buffer (80% formamide, 0.01% xylene cyanol, and bromphenol blue). The aliquots were thawed, and alkylated products were electrophoretically resolved in a denaturing 8% polyacrylamide gel. The labeled bands were visualized by autoradiography and quantified using a BioRad GS-250 Phosphorimager. The percent of monoalkylated labeled strand was plotted vs time, and the half-life for alkylation was determined from the line of best fit using an equation for exponential growth.

RESULTS AND DISCUSSION

Triplex-Forming Mustard-ODN Model System. The specific ODN chosen for this study (ODN-NH₂) is a 21-mer G/A motif triplex-forming ODN, designed to hybridize to a homopurine run in the human DQB1*0302 allele (16). Inheritance of this allele predisposes individuals to insulin-dependent diabetes mellitus. This endogenous genetic target provides an ideal system for comparison of different triplex-forming motifs. In a

Figure 2. Design of triplex-forming ODN (ODN-NH₂) and the dsDNA target. ODN-NH₂ was reacted with the aryl nitrogen mustard TFP esters **1–3** to give ODN conjugates **I–III** as shown in Scheme 2. The position of the alkylated dG residue in the purine-rich strand is indicated by an arrow.

separate study (17), triplex formation in this model system was examined using a gel retardation assay. In a physiologically relevant buffer (pH 7.2 HEPES, 140 mM KCl, 10 mM MgCl₂, and 1 mM spermine), we found that the G/A motif triplex-forming ODN binds with the highest association constant. This buffer was designed to model salt concentrations expected to be found in the nucleus of cells (18). Although some self-association was observed with this G-rich ODN, it did not appear to affect triplex formation, especially in the presence of the triplex specific intercalating agent coralyne (19). ODN-NH₂ was prepared with a 5'-hexylamine linker in order to provide a site for attachment of the mustards. The linker length was not optimized for this target system but provides a long enough tether to allow each of the mustards studied herein to find a suitable conformation for alkylation of the targeted guanine in the homopurine-containing strand. The sequence of ODN-NH₂, the site of triplex formation, and the position of the targeted dG in the purine-rich strand are shown in Figure 2. Since cell culture experiments were planned, a 3'-hexanol modification was incorporated into the ODN in order to block the 3'-end of the ODN from nuclease degradation (12).

Conjugation Chemistry. Many simple conjugate groups such as amine-containing linkers can be conveniently added to the growing ODN chain during automated synthesis (20). However, the harsh deprotection conditions require postsynthetic addition of more sensitive conjugate groups. This generally involves treatment of an aqueous solution of an ODN containing a nucleophilic linker group with an electrophilic form of the conjugate group. For example, amine-modified ODNs react with "activated esters" to give amide bonds. We have found that 2,3,5,6-tetrafluorophenyl (TFP) esters are particularly convenient to make and use for ODN conjugation reactions. These compounds can be purified by flash chromatography with little decomposition, and they hydrolyze slowly in relation to some other activated esters. In addition, the chemical shift of the H4 proton ($\delta = 7.0$ ppm) can be monitored by ¹H NMR to give an indication of the purity of these compounds. Three different aryl nitrogen mustard TFP esters were prepared as shown in Scheme 1. In our earlier work (9), we used TFP ester **1** prepared from the clinically used anticancer compound chlorambucil. The reactivity of the aniline mustards can be "tuned" by judicious selection of the substituents on the aromatic ring. Increasing the electron density of the aryl group increases the nucleophilicity of the aniline nitrogen, thus increasing the rate of cyclization to the aziridinium cation. Phenyl acetate mustard (**2**) and benzoate mustard (**3**) were prepared as described for **1** and investigated as slower-reacting analogues of **1**. Early work had shown the relative rates of hydrolysis of the carboxylic acid precursors to **1**, **2**, and **3** to be 27, 17, and 4 when measured in 50% acetone (11). Synthesis of mustard-ODNs is problematic due to the rapid hydrolysis of the (chloroethyl)amino functional groups in neutral or basic aqueous conditions. Thus, anhydrous conditions were developed for synthesis of

Scheme 1. Synthesis of Aryl Nitrogen Mustard TFP Esters **1–3**^a

^a TFP is 2,3,5,6-tetrafluorophenyl.

Scheme 2. Synthesis of Mustard-ODN Conjugates^a

^a The structure of ODN-NH₂ is shown in Figure 2. Three different mustard-ODNs (ODNs **I–III**) were prepared using TFP esters **1–3**, respectively. Structures of the different aryl nitrogen mustard groups (R) are shown in Scheme 1.

mustard-ODNs as illustrated in Scheme 2. Others have used organic soluble cetyltrimethylammonium salts of the ODNs (21), but this method can be troublesome since the nonvolatile cetyltrimethylammonium chloride is not easily removed from the reaction mixtures. We recently found that triethylammonium (TEA) or tributylammonium (TBA) salts of ODNs are soluble in polar aprotic solvents such as DMSO. As the first step in mustard-ODN synthesis (Scheme 2, step 1), alkylammonium salts were prepared by loading the sodium form of the ODN onto a reverse phase HPLC column (equilibrated with TEA or TBA bicarbonate) and eluting with a gradient of acetonitrile. The excess volatile TEAB or TBAB is removed in vacuo to give the organic salt form of the

Figure 3. Reaction of ODN-NH₂ with TFP ester **1**. The progress of the reaction was followed by C₁₈ HPLC as described in Experimental Procedures. Unreacted starting ODN was removed by HPLC to give purified ODN **I**.

ODN. Most ODNs are soluble in DMSO as the TEA salts (~5 mg of ODN per milliliter of DMSO), but some modified ODNs require the extra lipophilicity provided by the TBA salts. We used TEA and TBA salts interchangeably for preparation of ODNs **I–III**. Preparation of the mustard-ODNs (Scheme 1, step 2) involved treatment of the DMSO solution of ODN-NH₂ (TEA salt) with 20 equiv of activated ester (**1**, **2**, or **3**) and excess ethyldiisopropylamine. Progress of the reaction from ODN-NH₂ to the more lipophilic mustard-ODN conjugate (**I**, **II**, or **III**) was easily monitored by reverse phase (C₁₈) HPLC as shown in Figure 3. Isolation and purification of the mustard-ODN (Scheme 2, step 3) was accomplished by first precipitating the crude product from DMSO solution by adding sodium perchlorate in acetone. The resulting pellet was dissolved in TEAA buffer and immediately purified by reverse phase HPLC and precipitation from the desired fraction. Although some yield was lost during the final HPLC and precipitation steps, ODNs **I–III** were routinely prepared with >95% purity.

Aqueous Stability of Mustard-ODNs. Reverse phase HPLC was used to study the aqueous reactivity of ODNs **I–III**. Mustard-ODNs were prepared at 100 μ M in an aqueous buffer (pH 7.2) that contained a physiological concentration of chloride ion. Typical chromatograms that illustrate the kinetics for degradation of ODN **II** are shown in Figure 4A. A complex mixture of less lipophilic ODN degradation products was observed. Hydrolyses of ODN **I** and ODN **III** showed similar mixtures of degradation products.

The large separation in retention times between degradation products and starting mustard-ODN allowed disappearance of ODNs **I–III** to be determined as shown in Figure 4B. As expected, the concentration of mustard-ODNs decayed exponentially, consistent with first-order reaction via a reactive aziridinium cation intermediate. Apparent residual ODN **I** at 240 min is due to baseline noise in the HPLC assay. Half-lives for hydrolysis of ODNs **I–III** were approximately 27, 57, and 216 min, respectively.

Aqueous decomposition of mustard-ODNs indicated other degradation products in addition to simple hydrolysis products (Figure 1, Nu⁻ = OH⁻). Observed products for these G-rich ODNs most likely result from intramolecular or intermolecular self-alkylation. G/A-containing ODNs have been shown to self-associate in solution, presumably as parallel strands held together through G–G and A–A hydrogen bonds (22). Analysis of degra-

Figure 4. Aqueous stability of ODN **II**. (A) Decomposition of **II** in chloride-containing buffer (pH 7.2) at 37 °C was followed by C₁₈ HPLC at 0, 30, 60, 120, and 240 min. A mixture of ODN degradation products resulted. (B) Plot of the percentage of unreacted ODN vs time for each of the mustard-ODNs. The percentage of intact ODN was calculated from integration of chromatograms.

dation products in a related mustard-ODN by gel electrophoresis provided further evidence of self-alkylation (23).

Reactivity of Mustard-ODNs with a Model Nucleophile. To further characterize the reactivity of mustard ODNs, we used the same HPLC assay and followed reaction of ODNs **I–III** with 100 equiv (10 mM) of sodium thiosulfate. As shown in Figure 5A, only two major reaction products were observed for reaction of ODN **II** with this strong nucleophile. Stepwise formation and disappearance of the 7.8 min peak is indicative of a mono-thiosulfate adduct, and steady appearance of the final reaction product at 6.6 min is indicative of a bis-thiosulfate adduct. The same product profile was observed for ODN **I** and **III**. As shown in Figure 5B, relative rates for reaction of ODNs **I–III** with excess thiosulfate depend on the inherent reactivity of the nitrogen mustard conjugate group. Half-lives for reaction of ODNs **I–III** with thiosulfate were approximately 18, 52, and 192 min, respectively.

Effects of Buffer Composition on Reaction Rate. It appeared from our preliminary studies that adding thiosulfate to the buffer mixture shortened half-lives of mustard-ODNs. To determine the significance of this effect (and accuracy of our HPLC assay), we performed more careful kinetic measurements on ODN **II**. We also examined the reactivity of ODN **II** in a chloride-free buffer. Log[ODN **II**] vs time was plotted, and linear regression analysis gave first-order rate constants as shown in Figure 6. Adding a strong nucleophile (thiosulfate) slightly increased the reaction rate, presumably by trapping the aziridinium intermediate. An increase

Figure 5. Reaction of ODN II with a model nucleophile. (A) Reaction of II with 100 equiv of sodium thiosulfate at 37 °C was followed by C₁₈ HPLC at 0, 30, 60, 120, and 240 min. Stepwise conversion to mono- and bis-thiosulfate adducts resulted. (B) Plot of the percentage of unreacted ODN vs time for each of the mustard–ODNs. The percentage of intact ODN was calculated from integration of chromatograms.

in the mustard–ODN half-life in the presence of chloride ion was observed, consistent with earlier studies on the reactivity of chlorambucil (24). Chloride ion can react with the aziridinium ion intermediate to regenerate the starting (2-chloroethyl)amine functional group. It should be noted that ionic strength was not held constant in our studies, and Debye–Huckel or specific salt effects may also be affecting reaction rate.

Effects of ODN on Reaction Rate. As described above, mixtures of self-alkylation products result from decomposition of G-rich mustard–ODNs in the absence of a competing nucleophile. The reactive aziridinium cation can be trapped by appropriately positioned nucleophilic DNA residues in a complex. To further explore the effects of the ODN carrier on reactivity of the phenyl acetate mustard, a small molecule analogue (**4**) was prepared by reacting TFP ester **2** with 1-amino-2,3-propanediol. The aqueous stability of **4** was measured using the HPLC assay described above. As expected, two major decomposition products were observed for **4**, consistent with simple hydrolysis of the (chloroethyl)-amine groups. The $t_{1/2}$ for hydrolysis of this derivative was 92 min as compared to 57 min for ODN II in the same buffer. Aminodiol analogue **4** reacted with thiosulfate in the same stepwise fashion with a $t_{1/2}$ of 48 min as compared to 52 min for ODN II in the same buffer. These results show that the ODN carrier can significantly affect the aqueous stability of the mustard conjugate group. The effects may be sequence-dependent, thus making the stability of mustard–ODNs difficult to predict accurately. Relative half-lives of ODNs I–III under various conditions are summarized in Table 1.

Figure 6. Kinetics plots for reaction of ODN II at 37 °C in different buffers. Buffers are described in Table 1. The HPLC assay described in Figures 5 and 6 was repeated in triplicate for each buffer. Linear regression analysis of log(percentage of intact ODN) vs time gave the rate constants (k) as indicated from the slope.

Table 1. Half-Life (Minutes) for Reaction of Nitrogen Mustard Conjugates^a

buffer ^c	ODN I	ODN II	ODN III	4 ^b
KCl	27	57	216	92
thiosulfate	18	52	192	48
no chloride	—	44	162	—

^a Structures of nitrogen mustards are shown in Scheme 1. $t_{1/2}$ for the disappearance of the starting compound was determined by HPLC assay. ^b Compound **4** is an aminopropanediol derivative of TFP ester **2**. In the reactions, 0.1 mM solutions of the indicated compound were used at 37 °C. ^c Reactions of nitrogen mustards were in pH 7.2 HEPES buffer (20 mM). KCl contains 140 mM KCl and 10 mM MgCl₂. Thiosulfate indicates addition of 10 mM Na₂S₂O₃ to the KCl buffer. No chloride used only HEPES buffer. Except for ODN II, results are from a single representative experiment.

DNA Alkylation Rates for Triplex-Forming Mustard–ODNs. Rates of DNA alkylation by ODNs I and II within a triplex were measured by denaturing gel electrophoresis using a synthetic 65-mer dsDNA target as shown in Figure 7. Alkylation of the labeled purine-rich strand in the duplex by ODN I or II gave a species with two linked strands that was observed as a slower-running band in the gel. This slow-running band is a result of monoalkylation of the dsDNA target. In separate sequencing experiments, the alkylated base was determined to be the dG directly 3' of the triplex region as shown in Figure 2. Trace amounts (<2%) of a very slow-moving band was observed where the mustard–ODN alkylates both strands of the dsDNA target. This level of interstrand cross-linking is low despite the presence of a preferred GNC site in the dsDNA target (25, 26). Hybridization buffers were identical with those used for the aqueous stability studies described in Figure 4 except for the presence of spermine and coralyne in the triplex assays. Initial experiments used duplexes with

Figure 7. Alkylation of the 65-mer dsDNA target by triplex-forming ODNs **I** and **II**. Hybridization conditions are described in Experimental Procedures. (A) Denaturing gel analysis at an ODN:dsDNA ratio of 100:1. Upper bands correspond to alkylated purine-rich DNA strands. Lower bands are unmodified purine-rich DNA strands: lanes 1–6, ODN **I** at 30, 60, 120, 240, and 360 min; lanes 7–12, ODN **II** at the same time points; and lane 13, no mustard-ODN. (B) Plot of the percentage of DNA alkylation vs time for ODNs **I** and **II** at ODN:dsDNA ratios of 100:1 and 10:1.

either the purine- or pyrimidine-rich strand 5'-labeled with ^{32}P . Since alkylation of the pyrimidine-rich strand was negligible (<2%), we conducted quantitative kinetic studies using duplexes prepared from the 5'- ^{32}P -labeled strand containing the homopurine run.

The extent of alkylation measured at 22 h depended on the ratio of triplex-forming ODN to dsDNA target. At 100:1 ODN:dsDNA ($2\ \mu\text{M}$ ODN), alkylation plateaued at 48% for both ODN **I** and **II**, whereas at 10:1 ODN:dsDNA ($0.2\ \mu\text{M}$ ODN), the extent of alkylation was 27%. We were initially concerned that excess spermine in the buffer would compete for reactive aziridinium ion, but separate experiments showed that DNA alkylation in fact increased (from 42 to 48% for ODN **II**). In the absence of coralyne, alkylation was ~25% lower. Alkylation kinetics were not studied for ODN **III**, but the extent of DNA alkylation after 24 h was approximately the same as that for **I** and **II**.

As expected, the rate of DNA alkylation for ODN **I** was faster than that for ODN **II**. It is also clear that the absolute rate of alkylation depended on the ratio of triplex-forming ODN to dsDNA target. For 100:1 ODN **I**:dsDNA, ~46 min was required for half of the alkylation products to form, whereas at 10:1, ~81 min was required.

Likewise, for 100:1 ODN **II**:dsDNA, ~108 min was required for half of the alkylation products to form, whereas at 10:1, ~160 min was required. DNA alkylation rates for mustard-ODNs in the triplex assay are slower than inherent rates of formation of the aziridinium cation in solution. This may reflect both inherent inefficiency of DNA alkylation and the presence of degraded mustard-ODN that can compete for hybridization to target dsDNA. As expected, the percent of DNA alkylation increases until nitrogen mustard conjugate groups are completely degraded. Since there are two (2-chloroethyl)amine groups, the half-life for complete degradation of mustard-ODN should be 2 times the half-life for reaction of a single alkylating group (Table 1).

CONCLUSION

Versatile methods have been developed for preparation and analysis of mustard-ODNs. The anhydrous conditions are useful for addition of other aqueous sensitive or lipophilic conjugate groups to oligonucleotides. The three aryl nitrogen mustard-ODN conjugates studied herein had different inherent rates of reaction as designed. Although other factors had some effect on reaction rates, kinetic studies support the concept of a reactive aziridinium intermediate which either alkylates neighboring nucleophiles or is hydrolyzed. Electrophoresis studies showed that a large excess of triplex-forming mustard-ODN over dsDNA improved DNA alkylation efficiency and increased alkylation rates. Since genomic DNA targets are present in very low concentrations, large excesses of triplex ODN over DNA are easily achieved. For example, we have used ODN **I** to target a specific sequence in genomic DNA with 90% efficiency at a concentration of $0.5\ \mu\text{M}$ (4). The synthetic and analytical procedures described here will facilitate the use of mustard-ODNs as genetic probes, and allow design of other types of alkylating ODNs for applications in gene therapy.

Maleimidocysteineamido-DOTA Derivatives: New Reagents for Radiometal Chelate Conjugation to Antibody Sulfhydryl Groups Undergo pH-Dependent Cleavage Reactions

Michael R. Lewis[†] and John E. Shively^{*,‡}

City of Hope Graduate Program in Biological Sciences, Duarte, California 91010, and Division of Immunology, Beckman Research Institute of the City of Hope, Duarte, California 91010. Received July 18, 1997; Revised Manuscript Received October 15, 1997[®]

We have synthesized two bifunctional derivatives of the macrocyclic chelating agent 1,4,7,10-tetraazacyclododecane-*N,N',N'',N'''*-tetraacetic acid (DOTA) equipped with maleimide groups for conjugation to reduced disulfide bonds of monoclonal antibodies. Using water-soluble carbodiimide chemistry, DOTA was coupled to L-cysteine to incorporate both a "pendant-type" carboxyl group for metal coordination and an orthogonal thiol group for protein attachment. The homobifunctional reagent 1,6-bis(maleimido)hexane was then used to introduce the maleimide functionality via a sulfide linkage to the macrocycle, and alternatively, the sulfide group was converted to a sulfone side chain. Both maleimide derivatives were conjugated to the anticarcinoembryonic antigen chimeric monoclonal antibody cT84.66 after light reduction of the mAb with dithiothreitol. In this manner, antibody conjugates were prepared which afforded near-quantitative labeling with the radiometals ¹¹¹In(III) and ⁹⁰Y(III) as well as quantitative immunoreactivity. Radioimmunoconjugates prepared with the sulfide and sulfone compounds exhibited relatively rapid linker-dependent radiometal loss when incubated in human serum and aqueous solutions at physiological temperature and pH. The unconjugated maleimidocysteineamido-DOTA derivatives and their Y(III) complexes were incubated in aqueous solution at 37 °C, and the resulting decomposition products were analyzed by HPLC and mass spectrometry. These studies revealed that the two bifunctional chelating agents underwent linker-specific cleavage reactions which were considerably faster at pH 7.4 than at pH 5.4. The chemically labile linker systems are expected to release chelated radiometal from mAb conjugates in a pH-dependent manner. This property may impart favorable tumor uptake and normal tissue clearance on radioimmunoconjugates prepared with these reagents, on the basis of the observation that many solid tumors are significantly more acidic than normal tissues.

INTRODUCTION

Bifunctional chelating agents (BCAs¹) have been used widely to derivatize tumor-specific monoclonal antibodies (mAbs) with radiometal ions for cancer imaging and

therapy (1–3). Since most radionuclides are metals, the conjugation of antibodies to radiometal complexes represents one of the most versatile strategies for selective delivery of diagnostic or therapeutic radiation to primary tumors or metastatic disease. This versatility stems not only from the variety of metallic radionuclides available, encompassing a range of coordination chemistries, half-lives, and radioemissions suitable for imaging and therapy, but also from the variety of chemical methods for attachment of radiometal complexes to mAbs. In addition, the versatility of chelate conjugation chemistry introduces the potential of optimizing several important properties in the resulting mAb conjugates, including radiolabeling efficiency, specific activity, immunoreactivity, and physiological stability. Considerable progress has been made in this field, beginning with EDTA derivatives (4) and leading to progressively more stable mAb–radiometal conjugates modified with derivatives of DTPA (5–11) and polyazamacrocyclic chelating agents (12–29).

Each generation of improvements has produced bifunctional radiometal chelates with greater thermodynamic, kinetic, and physiological stability, as well as more versatile chemistry for attachment to antibodies. The costs of these improvements, however, have been progressively elaborate synthetic schemes for generating BCAs and increased difficulty in labeling the resulting mAb conjugates with radiometals. The macrocyclic chelating agents possess relatively rigid, preorganized

¹ Abbreviations: BCA, bifunctional chelating agent; DOTA, 1,4,7,10-tetraazacyclododecane-*N,N',N'',N'''*-tetraacetic acid; MC-DOTA, maleimidocysteineamido-DOTA; MSC-DOTA, maleimidosulfonylcysteineamido-DOTA; DOTA-OSSu, *N*-hydroxysulfosuccinimide ester of DOTA; sulfo-NHS, *N*-hydroxysulfosuccinimide; EDC, 1-ethyl-3-[3-(dimethylamino)propyl]carbodiimide; BMH, 1,6-bis(maleimido)hexane; DTPA, diethylenetriaminepentaacetic acid; EDTA, ethylenediaminetetraacetic acid; TFA, trifluoroacetic acid; PBS, phosphate-buffered saline; DTT, dithiothreitol; SDS, sodium dodecyl sulfate; HSA, human serum albumin; CEA, carcinoembryonic antigen; cT84.66, human/murine chimeric anti-CEA mAb; cT84.66–MC-DOTA, cT84.66 conjugated with MC-DOTA; cT84.66–MSC-DOTA, cT84.66 conjugated with MSC-DOTA; cT84.66–DOTA, cT84.66 conjugated with DOTA-OSSu; ESI MS, electrospray ionization mass spectrometry; FAB MS, fast atom bombardment mass spectrometry.

cavities which enable them to bind a wide variety of metal ions with extremely high stability constants (30–35), but the adverse consequences of this structural property are the slow rate of incorporation of the metal ion into the chelate complex (36) and effective competition for the ligand by trace metals (33). It has been shown that the chelation of metals by the macrocyclic ligand DOTA is often a two-step process in which a reversibly formed initial adduct (a type I complex) slowly transforms to the final chelate (a type II complex) (37, 38).

Given this mechanism, our hypothesis is that low radiochemical yields observed for labeling antibody–macrocycle conjugates, compared to free ligand, may be a result of competition between nonspecific metal-binding sites on the protein surface and formation of the type I complex. Macrocyclic BCAs bearing “pendant-type” carboxyl groups have been synthesized by Takenouchi et al. (39, 40), and the addition of a side chain carboxylate was shown to accelerate the formation of Y(III) complexes. These authors reasoned that the Y(III) ion was captured quickly but loosely by the pendant donor group, forming a more stable type I complex and raising the local metal concentration in the vicinity of the macrocyclic backbone, thus increasing the ultimate rate of complexation. The serum stabilities of the pendant-type bifunctional chelates were found to be identical with those of the corresponding nonpendant-type chelates, indicating that the pendant donor has no effect on type II complex stability. However, the Y(III)-binding properties of only the free chelating agents were investigated, and it was not determined whether the same effects would be borne out at the antibody conjugate level. We believe that structural modifications leading to better kinetics of type I complex formation will lead to improved radiometal labeling efficiency for antibody–macrocycle conjugates, and we set out to test this concept by synthesizing and conjugating to antibody a series of DOTA derivatives containing similarly positioned pendant-type carboxyl groups.

Takenouchi and co-workers employed six- and eight-step synthetic routes to introduce pendant-type carboxyl groups to the side chains of two *C*-substituted DOTA derivatives. They observed a rate enhancement for Y(III) complexation when the carboxylate oxygen of the pendant donor was spaced six, but not seven, chemical bonds from the amino nitrogen of the macrocyclic ring. We have developed a simplified synthetic strategy for introducing a similar pendant-type carboxylate donor, spaced six chemical bonds from the macrocyclic ring nitrogen, via peptide bond formation between one carboxyl group of DOTA and the α -amino group of an amino acid. Previously, we demonstrated that amide bond formation between DOTA and endogenous antibody amino groups allowed for the formation of extremely stable $^{111}\text{In(III)}$ and $^{90}\text{Y(III)}$ chelates on the mAb conjugates (29); that is, the conversion of one carboxyl group of DOTA to an amide did not affect type II complex stability to an appreciable degree. Therefore, we synthesized a monocysteineamide derivative of DOTA to introduce not only the pendant carboxylate donor group but also an orthogonal functionality for attachment to mAbs. The DOTA monocysteineamide compound was subsequently derivatized for antibody conjugation by reaction with 1,6-bis-(maleimido)hexane. Maleimidocysteineamido-DOTA derivatives containing both sulfide and sulfone linkers were prepared and conjugated to cysteine residues of cT84.66 (41), a human/murine chimeric mAb which displays high specificity and high affinity for carcinoembryonic antigen (42). Under the conditions used, it is believed that the

conjugation occurs specifically at the interchain disulfide bonds in the hinge region of the antibody (43–45).

We report here that the cT84.66 conjugate prepared with maleimidocysteineamido-DOTA (MC-DOTA, **2**) exhibits significantly improved rates of radiometal complexation under carrier-free conditions, leading to substantial increases in radiolabeling yields with ^{111}In and ^{90}Y . Furthermore, we have studied the radiometal-labeled antibody conjugates and free chelate complexes of the sulfide compound MC-DOTA and its sulfone derivative (MSC-DOTA, **3**) *in vitro* and found that these molecules undergo pH-dependent cleavage reactions in aqueous media. Our results indicate that both of these BCAs are chemically labile at physiological temperature and pH but significantly more stable under moderately acidic conditions. This attachment of kinetically stable radiometal chelates to monoclonal antibodies using pH-dependent chemically labile linkers offers the possibility of creating radioimmunoconjugates with favorable biodistribution properties.

EXPERIMENTAL PROCEDURES

General. DOTA trisodium salt was purchased from Parish Chemical Co. (Orem, UT). Sulfo-NHS, EDC, and BMH were obtained from Pierce (Rockford, IL). Human serum albumin (99%, fatty acid- and globulin-free) and L-cysteine were purchased from Sigma (St. Louis, MO). DTPA was obtained from Fluka (Milwaukee, WI). EDTA, yttrium chloride hexahydrate (99.999%), cobalt powder (99.995%), and Oxone (potassium hydrogen persulfate) were purchased from Aldrich (Milwaukee, WI). Chelex 100 (Biotechnology Grade, 100–200 mesh, sodium form) was obtained from Bio-Rad (Hercules, CA), and buffers used for radiolabeling reactions were passed over a Chelex 100 column (1 $\times$ 15 cm). Ultrapure water (18 M Ω -cm) was used for all procedures, and all other reagents were of the highest purity available. All laboratory glassware was washed with a mixed acid solution (46) and thoroughly rinsed with ultrapure water. $^{57}\text{CoCl}_2$ and Na^{131}I were obtained from ICN (Costa Mesa, CA). $^{111}\text{InCl}_3$ was obtained from Amersham (Arlington Heights, IL), and $^{90}\text{YCl}_3$ was obtained from Nordion (Kanata, ON) and Hanford (Richland, WA). The mAb cT84.66 was prepared as described previously (41).

HPLC and TLC were performed as described previously (29). Mass spectra were recorded on a Finnigan LCQ ion trap mass spectrometer equipped with a custom nanospray interface built at City of Hope. The mass spectrometer was operated under manual control with the automatic gain control active. In a few cases, manual control of the ion injection time was utilized to improve the quality of weaker product ion spectra. NMR spectra were recorded at pH 2.6 (not corrected for the deuterium isotope effect) on a Varian Unity spectrometer, operating at 300 MHz for ^1H and 75 MHz for ^{13}C , or a Varian Unity Plus spectrometer, operating at 500 MHz for ^1H and 125 MHz for ^{13}C . ^1H chemical shifts are reported relative to HOD (4.80 ppm), and ^{13}C chemical shifts are reported relative to 1,4-dioxane (66.66 ppm) as an internal reference. Concentrations of antibody were determined by absorbance measurements at 280 nm (A_{280} at 1 mg/mL = 1.42, within 5% of the concentration determined by amino acid analysis). UV spectrophotometry was performed on a Pharmacia LKB Ultrospec III instrument, using a 1 cm sample cell. Melting points were recorded on a Thomas Hoover uni-melt capillary melting point apparatus and are uncorrected.

Cysteineamido-DOTA (1). To a solution of 100 mg (213 μmol) of trisodium DOTA and 92.3 mg (425 μmol)

of sulfo-NHS in 1 mL of H₂O was added dropwise with continuous stirring a solution of 81.5 mg (425 μ mol) of EDC in 151 μ L of H₂O. The reaction mixture was stirred at room temperature for 1 h, after which a solution of 51.5 mg (425 μ mol) of L-cysteine in 326 μ L of H₂O was added dropwise with continuous stirring. The pH was adjusted to 7.0 with 50% NaOH, and the reaction mixture was stirred at room temperature for 22 h. The reaction mixture was then cooled to 4 °C, made 1 M in HCl with the addition of 155 μ L of concentrated HCl, and stirred at 4 °C for 17 h. The acidified mixture was applied to a Dowex AG50W-X8 column (H⁺ form, 1 $\times$ 6.5 cm), which was washed with 50 mL of H₂O and then eluted with a 40 mL step gradient from 0.5 to 4 M NH₄OH. A mixture of the desired product, disubstituted cysteine adducts of DOTA, and unreacted DOTA eluted in 2 M NH₄OH and was lyophilized to a pale yellow gum. The crude product was dissolved in 1 mL of H₂O and applied to a Dowex AG1-X4 column (HCO₂⁻ form, 1 $\times$ 11 cm), which was washed with 50 mL of H₂O and eluted with a 60 mL step gradient from 0.05 to 2 M HCO₂H. Unreacted DOTA eluted in 0.2 M HCO₂H, and the desired product eluted in 0.5 M HCO₂H. These fractions were lyophilized to give white powders, which were dissolved in 1 mL of H₂O and concentrated to dryness by lyophilization. This process was repeated four times to remove residual HCO₂H. This procedure afforded 25.2 mg (29.3%) of DOTA, which was recrystallized from H₂O/CH₃OH (1:9) and used for other syntheses, and 23.3 mg (21.6%) of **1** as a white powder: mp 177–178 °C (dec); ¹H NMR (D₂O) δ 2.93–3.06 (m, 2H, CH₂SH), 3.16–3.24 (m, 8H, CH₂NCH₂), 3.42 (m, 8H, CH₂NCH₂), 3.56–3.71 (m, 2H, CH₂CONH), 3.84 (s, 6H, CH₂CO₂H), 4.56 (dd, 1H, CHCH₂SH); ¹³C NMR (D₂O) δ 25.42, 48.61, 50.97, 53.53, 54.41, 55.42, 56.16, 170.50, 173.71, 174.63; FAB MS *m/z* calcd for C₁₉H₃₄N₅O₉S (M + H)⁺ 508.2077, found 508.2098.

Maleimidocysteineamido-DOTA (2). To a solution of 29.2 mg (106 μ mol) of 1,6-bis(maleimido)hexane in 1.0 mL of degassed *N,N*-dimethylformamide, under an argon atmosphere, was added dropwise with continuous stirring a solution of 5.4 mg (10.6 μ mol) of **1** in 1.9 mL of degassed 50 mM K₂HPO₄ at pH 7.5. The reaction mixture was stirred at room temperature for 2 h, after which it was extracted with 3 $\times$ 15 mL of ethyl acetate. The pH of the aqueous layer was adjusted to 1.5 with trifluoroacetic acid, and the desired product was purified by reversed phase HPLC using a 10 $\times$ 250 mm column (Vydac Protein & Peptide C₁₈, 5 μ m, 300 Å), a flow rate of 4.0 mL/min, and a linear gradient from 0 to 60% solvent B (solvent A, 0.1% TFA; solvent B, 0.1% TFA/90% CH₃CN) over 60 min. The major peaks, eluting at retention times of 26.8 and 27.2 min, were collected, pooled, and lyophilized to give 2.0 mg (24.5%) of **2** as a white powder: mp 120–122 °C; ¹H NMR (D₂O) δ 1.25 (m, 4H, CH₂CH₂CH₂N(CO)₂), 1.53 (m, 4H, CH₂CH₂N(CO)₂), 2.69 (dt, 1H, CH₂S), 3.01–3.49 (m, 24H, CH₂S + CH₂NCH₂ + CH₂CHS + CHS + CH₂N(CO)₂), 3.66 (br s, 2H, CH₂CONH), 3.81 (br s, 6H, CH₂CO₂H), 4.08 (m, 1H, CHCH₂S), 6.81 (s, 2H, C=CH); ¹³C NMR (D₂O) δ 25.47, 26.58, 27.55, 30.00, 35.83, 36.27, 37.55, 39.09, 39.87, 48.27, 48.66, 50.77, 51.56, 52.58, 134.34, 173.50, 174.23, 178.69, 179.82, 180.88; FAB MS *m/z* calcd for C₃₃H₅₀N₇O₁₃S (M + H)⁺ 784.3187, found 784.3205. A 5 μ g aliquot of the product was reinjected onto the HPLC instrument, using a 4.6 $\times$ 250 mm column (Vydac Protein & Peptide C₁₈, 5 μ m, 300 Å), a flow rate of 1.0 mL/min, and a linear gradient from 0 to 60% solvent B (solvent A, 0.1% TFA; solvent B, 0.1% TFA/90% CH₃CN) over 60 min. Two peaks were observed at retention times of 26.5 min (peak area of 49.5%) and 26.8

min (peak area of 50.5%). The two peaks gave identical mass spectra and presumably represent diastereomers of the product.

Maleimidosulfonylcysteineamido-DOTA (3). A solution of 2.0 mg (2.6 μ mol) of **2** in 0.4 mL of H₂O was cooled to 0 °C, and 10.2 μ L (2.4 mg, 3.8 μ mol) of a 23% (w/w) solution of Oxone in H₂O was added with continuous stirring. The reaction mixture was then stirred at room temperature for 4 h, after which 1.0 mg (5.1 μ mol) of sodium metabisulfite in 15.2 μ L of H₂O was added. The reaction mixture was stirred for 30 min at room temperature, and the desired product was purified by reversed phase HPLC using a 10 $\times$ 250 mm column (Vydac Protein & Peptide C₁₈, 5 μ m, 300 Å), a flow rate of 4.0 mL/min, and a linear gradient from 0 to 60% solvent B (solvent A, 0.1% TFA; solvent B, 0.1% TFA/90% CH₃CN) over 60 min. The major peak, eluting at a retention time of 25.8 min, was collected and lyophilized to afford 1.0 mg (48.1%) of **3** as a white powder: mp 151–154 °C; ¹H NMR (D₂O) δ 1.26 (m, 4H, CH₂CH₂CH₂N(CO)₂), 1.55 (m, 4H, CH₂CH₂N(CO)₂), 3.12–3.84 (m, 26H, CH₂-CH(SO₂) + CH₂NCH₂ + CH₂CONH + CH₂CO₂H), 3.27 (m, 2H, CH₂(SO₂)), 3.49 (dd, 2H, CH₂N(CO)CH(SO₂)), 3.55 (t, 2H, CH₂N(CO)C=), 4.07–4.11 (m, 1H, CHCH₂(SO₂)), 4.24–4.30 (m, 1H, CH(SO₂)), 6.82 (s, 2H, C=CH); ¹³C NMR (D₂O) δ 25.33, 26.40, 27.58, 30.34, 35.69, 36.54, 37.56, 38.78, 39.43, 47.88, 48.65, 51.52, 52.38, 53.09, 134.35, 170.15, 171.02, 172.47, 173.48, 176.51; FAB MS *m/z* calcd for C₃₃H₅₀N₇O₁₅S (M + H)⁺ 816.3086, found 816.3051. A 5 μ g aliquot of the product was reinjected onto the HPLC instrument, using a 4.6 $\times$ 250 mm column (Vydac Protein & Peptide C₁₈, 5 μ m, 300 Å), a flow rate of 1.0 mL/min, and a linear gradient from 0 to 60% solvent B (solvent A, 0.1% TFA; solvent B, 0.1% TFA/90% CH₃CN) over 60 min. A single peak was observed at a retention time of 25.7 min.

Preparation of cT84.66–MC-DOTA and cT84.66–MSC-DOTA Conjugates. An aliquot of 21.5 mg of cT84.66 in 2 mL of PBS (pH 7.4) was dialyzed against 1 L of PBS/20 mM DTPA (pH 7.4) for 24 h at 4 °C and then against 1 L of PBS (pH 7.4), over Chelex 100, for 43.5 h at 4 °C, with one buffer change. To 17.2 mg (115 nmol) of cT84.66 in 2.05 mL of PBS (pH 7.4) was added 230 μ L (2.30 μ mol) of freshly prepared 10 mM DTT in degassed H₂O. The reaction mixture was incubated at 37 °C for 3 h under an argon atmosphere, after which it was applied in equal volumes to four 1 mL Sephadex G-25–50 spin columns. The mAb was eluted from the spin columns by centrifugation (4) at 1200 rpm for 2 min under argon. The eluents were pooled, and the volume, concentration, and sulfhydryl titer of the reduced mAb solution were measured. Then, to 4.68 mg (31.2 nmol) of reduced cT84.66 was added 245 μ g (312 nmol) of **2** in 49.0 μ L of degassed H₂O, and to 4.38 mg (29.2 nmol) of reduced cT84.66 was added 240 μ g (294 nmol) of **3** in 48.0 μ L of degassed H₂O. The reaction mixtures were incubated on a tube rotator under an argon atmosphere for 1.5 h at room temperature, after which they were dialyzed against 1 L of 0.25 M ammonium acetate/20 mM DTPA (pH 7.0) for 24 h at 4 °C. The conjugates were then dialyzed against 1 L of 0.25 M ammonium acetate, over Chelex 100, for 138 h at 4 °C, with five buffer changes. Typical mAb recoveries ranged from 72 to 79% for the conjugation procedure.

Alternatively, preparations of cT84.66–MC-DOTA and cT84.66–MSC-DOTA were alkylated at unreacted cysteine residues with iodoacetic acid. After reaction with **2** or **3**, 100 μ L (10 μ mol) of freshly prepared 100 mM iodoacetic acid in degassed 0.2 M ammonium bicarbon-

ate/1 mM EDTA (pH 8.4) was added. The reaction mixtures were incubated on a tube rotator in the dark under an argon atmosphere for 1 h at room temperature, and the carboxymethylated conjugates were then dialyzed as described above.

Radiolabeling of cT84.66–MC-DOTA and cT84.66–MSC-DOTA. The cT84.66–MC-DOTA conjugate was labeled with the radiometals $^{111}\text{In}(\text{III})$ and $^{90}\text{Y}(\text{III})$, and the cT84.66–MSC-DOTA conjugate was labeled with $^{111}\text{In}(\text{III})$ only. In a typical $^{111}\text{In}(\text{III})$ labeling reaction, 1.00 mCi of $^{111}\text{InCl}_3$ in 68 μL of 0.04 N HCl was added to 110 μL of 0.25 M ammonium acetate (pH 5.7), followed by an aliquot of 0.2 mg of the mAb conjugate in 44 μL of 0.25 M ammonium acetate (pH 7.0). The reaction mixture was incubated at 43 °C for 45 min, after which the solution was made 1 mM in EDTA with the addition of 24 μL of 10 mM EDTA (pH 6.5). The reaction mixture was incubated at 37 °C for 15 min, and then the ^{111}In -labeled antibody was purified by size exclusion HPLC using a TosoHaas TSKgel G2000 SW column (10 μm , 7.5 $\times$ 300 mm) and an isocratic mobile phase of normal saline at a flow rate of 0.5 mL/min. The mAb peak, eluting at a retention time of 8.3 min, was collected in 0.5 mL fractions containing 1 drop of 25% (w/v) HSA each.

In a typical ^{90}Y labeling reaction, 1.90 mCi of $^{90}\text{YCl}_3$ in 24 μL of 0.05 N HCl was added to 48 μL of 0.25 M ammonium acetate (pH 5.7). Then 0.2 mg of cT84.66–MC-DOTA in 44 μL of 0.25 M ammonium acetate (pH 7.0) was added, and the reaction mixture was incubated at 43 °C for 1 h. The solution was made 1 mM in DTPA with the addition of 13 μL of 10 mM DTPA (pH 6.0) and incubated at 37 °C for 15 min. The ^{90}Y -labeled conjugate was purified by size exclusion HPLC in the same manner as the ^{111}In -labeled antibody.

The cT84.66–MC-DOTA conjugate was labeled with ^{131}I using the Iodogen method (47). An aliquot of 0.4 mg of cT84.66–MC-DOTA in 100 μL of 0.25 M ammonium acetate (pH 7.0) was placed in a polypropylene tube that had been coated with 100 μg of Iodogen. Then, 0.4 mCi of Na^{131}I in 7.3 μL of PBS (pH 7.4) was added, and the reaction mixture was incubated at room temperature for 2 min. The ^{131}I -labeled conjugate was purified by gel filtration HPLC on two Pharmacia Superose 12 HR 10/30 columns (1 $\times$ 30 cm) in series, using an isocratic mobile phase of normal saline and a flow rate of 0.5 mL/min. The mAb peak, eluting at a retention time of 42 min, was collected in 0.5 mL fractions containing 1 drop of 25% (w/v) HSA each.

Immunoreactivity Determination. A dilution of the purified ^{111}In - or ^{90}Y -labeled cT84.66–MC-DOTA conjugate, containing approximately 200 000 cpm of radioactivity, was mixed with a 20-fold molar excess of purified CEA (48, 49) in 150 μL of 1% HSA/PBS (pH 7.4). A control sample was prepared in an identical manner, except that CEA was not added. The reaction mixtures were incubated at 37 °C for 15 min with continuous end-over-end mixing, after which aliquots of 100 μL were analyzed by gel filtration HPLC, using two Pharmacia Superose 6 HR 10/30 columns (1 $\times$ 30 cm) in series and an isocratic mobile phase of 0.05 M Na_2SO_4 /0.02 M NaH_2PO_4 /0.05% NaN_3 (pH 6.8) at a flow rate of 0.5 mL/min. Immunoreactivity was calculated as the percentage of the total radioactivity shifted to complexes with apparent molecular masses higher than that of the mAb.

Serum Stability Studies. An aliquot of radiolabeled cT84.66–MC-DOTA or carboxymethylated cT84.66–MSC-DOTA containing approximately 1.6×10^7 cpm of ^{111}In radioactivity or 4.0×10^7 cpm of ^{90}Y radioactivity was added to 1.1 mL of fresh human serum containing

10 μL of 10% NaN_3 . The mixture was incubated at 37 °C throughout the study, during which 100 μL samples were analyzed by gel filtration HPLC on two Pharmacia Superose 12 HR 10/30 columns (1 $\times$ 30 cm) in series, using an isocratic mobile phase of 0.05 M Na_2SO_4 /0.02 M NaH_2PO_4 /0.05% NaN_3 (pH 6.8) and a flow rate of 0.5 mL/min. Serum samples were analyzed at intervals ranging from 6 to 72 h for 7–8 days to determine conjugate stability.

Stability Studies in Aqueous Solutions. The carboxymethylated cT84.66–MC-DOTA conjugate was labeled with ^{111}In and purified by size exclusion HPLC as described above, except that the mAb peak was collected in 0.5 mL fractions without HSA. Aliquots of ^{111}In -labeled carboxymethylated cT84.66–MC-DOTA containing 1.6×10^7 cpm of radioactivity were added to 1.1 mL of PBS/0.1% NaN_3 (pH 7.4), 1.1 mL of 1 mM DTPA/PBS/0.1% NaN_3 (pH 7.2), and 1.1 mL of 1 mM DTT/PBS/0.1% NaN_3 (pH 7.4). The three mixtures were incubated at 37 °C over the course of the study, during which 100 μL samples were analyzed by gel filtration HPLC as described for the serum stability studies. Samples of the aqueous solutions were analyzed at intervals ranging from 12 to 48 h for 7 days to determine conjugate stability.

Bifunctional Chelate Stability Studies. To 100 μg (128 nmol) of **2** in 20.0 μL of H_2O was added 388 μg (1.28 μmol) of freshly prepared $\text{YCl}_3 \cdot 6\text{H}_2\text{O}$ in 77.6 μL of 0.25 M ammonium acetate (pH 5.7). The reaction mixture was incubated at 43 °C for 1 h, after which the Y(III) complex of **2** was purified by reversed phase HPLC, using a 4.6 $\times$ 250 mm column (Vydac Protein & Peptide C₁₈, 5 μm , 300 Å), a flow rate of 1.0 mL/min, and a linear gradient from 0 to 60% solvent B (solvent A, 0.1% TFA; solvent B, 0.1% TFA/90% CH_3CN) over 60 min. The major peak, eluting at a retention time of 24.7 min, was collected, and the correct structure of the Y(III) chelate of **2** was confirmed by ESI MS and MS². This fraction was lyophilized to a white powder and redissolved in 20.0 μL of H_2O , and two 10.0 μL aliquots of the resulting solution were added to 0.5 mL of PBS at pH 7.4 and 0.5 mL of PBS at pH 5.4, respectively. Two control reactions were set up in which **2** was dissolved in PBS at pH 7.4 and PBS at pH 5.4, respectively. The four reaction mixtures were incubated at 37 °C throughout the study, during which 50 μL samples were analyzed by reversed phase HPLC, using a 2 $\times$ 250 mm column (Column Engineering Reliasil C₁₈, 5 μm , 300 Å), a flow rate of 0.2 mL/min, and a linear gradient from 0 to 60% solvent B (solvent A, 0.1% TFA; solvent B, 0.1% TFA/90% CH_3CN) over 60 min. Samples were analyzed at intervals ranging from 3 to 287 h over a period of 23 days to determine the stability of the bifunctional chelate. The peaks corresponding to the major decomposition products were collected and stored at –80 °C prior to analysis by ESI MS, MS², and MS³.

To 100 μg (123 nmol) of **3** in 20.0 μL of H_2O was added 373 μg (1.23 μmol) of freshly prepared $\text{YCl}_3 \cdot 6\text{H}_2\text{O}$ in 74.6 μL of 0.25 M ammonium acetate (pH 5.7). The reaction mixture was incubated at 43 °C for 1 h, after which the Y(III) complex of **3** was purified by reversed phase HPLC in the same manner as the Y(III) complex of **2**. The major peak, eluting at a retention time of 24.3 min, was collected, and the correct structure of the Y(III) chelate of **3** was confirmed by ESI MS and MS². This fraction was lyophilized, redissolved in H_2O , and added to PBS at pH 7.4 and PBS at pH 5.4 in the same manner as the Y(III) complex of **2**. Two control reactions were also set up in which **3** was dissolved in PBS at pH 7.4 and in

Scheme 1

PBS at pH 5.4. The four reaction mixtures were incubated at 37 °C throughout the study, and for 5 days, samples were analyzed by reversed phase HPLC at intervals ranging from 3 to 72 h, using the method employed for **2** and its Y(III) chelate. The peaks corresponding to the major decomposition products were collected and stored at -80 °C prior to analysis by ESI MS, MS², and MS³.

RESULTS

Synthesis. The synthesis of MC-DOTA (**2**) and MSC-DOTA (**3**) is shown in Scheme 1. DOTA *N*-hydroxysulfosuccinimide ester was prepared by a modification of the procedure employed for direct conjugation to proteins (29). Reaction of the active ester with L-cysteine at pH 7.0 results in the formation of an intermediate thioester, which in aqueous solution rearranges spontaneously to the more stable amide derivative (50). After purification by sequential cation- and anion-exchange chromatography, the DOTA cysteineamide adduct **1** was reacted with an excess of the sulfhydryl-specific homobifunctional reagent 1,6-bis(maleimido)hexane. The major product, **2**, could be purified easily by reversed phase HPLC by virtue of its long, hydrophobic side chain. Two byproducts from the preparation of **2** were also collected and identified by mass spectrometry. The side product eluting at a retention time of 22.1 min was determined to be the adduct of BMH and two molecules of DOTA cysteineamide, and the compound eluting at 24.2 min was identified as a product resulting from the addition of one molecule of water to **2**. Compound **3** was prepared by Oxone oxidation of **2**, a reaction which is highly chemoselective for conversion of sulfides to sulfones (51). During the purification of **3** by reversed phase HPLC, a trace byproduct eluting at a retention time of 24.4 min was collected and identified by mass spectrometry as the sulfoxide.

Antibody Conjugation. MC-DOTA and MSC-DOTA were conjugated to the human/murine chimeric anti-CEA

Table 1. Conjugation and ⁹⁰Y Radiolabeling Yields for cT84.66–MC-DOTA Conjugates^a

MC-DOTA:mAb	chelates/mAb	labeling efficiency (%)	specific activity (mCi/mg)
1:1	0.542	0.982	0.0982
2:1	0.655	3.64	0.364
4:1	1.32	25.8	2.58
10:1	3.80	81.2	8.12
20:1	6.28	95.8	9.58
40:1	6.34	97.1	9.71

^a Radiolabeling was performed for 1 h at 43 °C, using 2.00 mCi of ⁹⁰Y and 0.200 mg of mAb conjugate. Immunoreactivity of all ⁹⁰Y-labeled conjugates was 100%.

mAb cT84.66, isotype IgG₁, κ, using a modification of the method of Willner et al. (52). Antibody reduction was monitored using Ellman's reagent (53, 54). Treatment of cT84.66 with 20 molar equiv of DTT (1 mM) resulted in the generation of 10.3 ± 0.7 reactive sulfhydryl groups per antibody molecule, and further addition of DTT did not increase the SH titer (data not shown). In our experience, cT84.66 was fully reduced in a reproducible manner under these conditions, allowing the extent of conjugation to be controlled by the amount of maleimide reagent added.

As shown in Table 1, conjugation of lightly reduced cT84.66 with MC-DOTA at six BCA:mAb molar ratios, ranging from 1:1 to 40:1, resulted in average incorporations of 0.5–6.3 chelates per antibody molecule, as determined by a modification of a ⁵⁷Co(II) binding assay (4, 29). The reduced antibody was maximally modified with 6.3 chelates/mAb after reaction with 20 molar equiv of MC-DOTA. SDS–polyacrylamide gel electrophoresis of the six cT84.66–MC-DOTA conjugates under nonreducing conditions [Figure 1 (top)] showed that the conjugation reaction is relatively specific for reduced interchain disulfide residues. The addition of increasing amounts of MC-DOTA to reduced cT84.66 resulted in progressive conversion of the intact mAb to species which, in the presence of SDS, dissociated into various combina-

Figure 1. (Top) Nonreducing SDS-polyacrylamide gel electrophoresis of unconjugated cT84.66 and cT84.66-MC-DOTA conjugates prepared with 1–40 molar equiv of MC-DOTA. The MC-DOTA:mAb conjugation ratio is shown above each lane. Molecular mass markers are shown to the left. Aliquots of 8–12 μ g of the conjugates were loaded onto a 10% polyacrylamide gel (8×8 cm) with a 3% stacking layer (2×8 cm). (Bottom) Gel filtration chromatography of unconjugated cT84.66 and cT84.66-MC-DOTA conjugates prepared with 1–40 molar equiv of MC-DOTA. The MC-DOTA:mAb conjugation ratio is shown above each chromatogram. Aliquots of 8–120 μ g of the conjugates were injected onto two Pharmacia Superose 12 HR 10/30 columns (1×30 cm) in series and eluted with an isocratic mobile phase of 0.05 M Na_2SO_4 /0.02 M NaH_2PO_4 /0.05% NaN_3 (pH 6.8) at a flow rate of 0.5 mL/min. Absorbance was monitored at 280 nm. The peak eluting at a retention time of 45 min corresponds to an apparent molecular mass of 150 kDa.

tions of the heavy and light polypeptide chains: H₂L, H₂, HL, and modified and unmodified H and L chains. The same six preparations were also analyzed by gel filtration chromatography [Figure 1 (bottom)], which revealed that, under nondenaturing conditions, all of the conjugates exist as species with an apparent molecular mass of 150 kDa.

Antibody Radiolabeling. Also shown in Table 1 are radiochemical yields and radioimmunoconjugate specific

Table 2. Radiolabeling Yields for cT84.66–DOTA-OSSu and –MC-DOTA Conjugates^a

radiometal	T (°C)	time (min)	cT84.66–DOTA labeling efficiency (%)	cT84.66–MC-DOTA labeling efficiency (%)
¹¹¹ In	43	45	73.5 $\pm$ 12.2	96.6 $\pm$ 2.5
⁹⁰ Y	43	60	56.4 $\pm$ 3.4	78.6 $\pm$ 3.7

^a The average number of chelates per mAb was 3.8 for both conjugates. Immunoreactivity of all radiolabeled conjugates was 100%. Radiochemical yields represent the average of three experiments.

activities for ⁹⁰Y labeling of the six cT84.66–MC-DOTA conjugates. The conjugate prepared at an MC-DOTA:mAb molar ratio of 10:1, modified with an average of 3.8 chelates per antibody molecule, was the least modified product to give high-specific activity labeling with ⁹⁰Y. Using our standard labeling conditions at 43 °C, the average yield for ⁹⁰Y incorporation into this cT84.66–MC-DOTA conjugate was 78.6% after 60 min, and the average ¹¹¹In incorporation was 96.6% after 45 min (Table 2). In contrast, average labeling yields for a cT84.66 conjugate prepared with DOTA *N*-hydroxysulfosuccinimide ester (29), also modified with 3.8 chelates per mAb, were 56.4% for ⁹⁰Y and 73.5% for ¹¹¹In. The efficiency of ¹¹¹In incorporation into the cT84.66–MSC-DOTA conjugate was 72.9% for a single experiment, affording a radioimmunoconjugate with a specific activity of 3.65 mCi/mg.

Immunoreactivity of Radiolabeled cT84.66–MC-DOTA. The immunoreactivity of ¹¹¹In- and ⁹⁰Y-labeled cT84.66–MC-DOTA was determined by a solution phase assay using purified CEA. Gel filtration chromatography on tandem Superose 6 columns routinely allowed separation of the 2:1 CEA–mAb complex, the 1:1 CEA–mAb complex, and free antibody. The binding percentages for a 1:190 dilution of the ¹¹¹In-labeled and a 1:50 dilution of the ⁹⁰Y-labeled mAb were both 100% after a 15 min incubation with 20 molar equiv of CEA at 37 °C. In each case, only the 2:1 CEA–mAb complex was observed by gel filtration chromatography, indicating that both antigen-combining sites remained fully immunoreactive.

Serum Stability of cT84.66–MC-DOTA and cT84.66–MSC-DOTA. The kinetic stabilities of ¹¹¹In- and ⁹⁰Y-labeled cT84.66–MC-DOTA and ¹¹¹In-labeled cT84.66–MSC-DOTA were studied in fresh human serum at 37 °C. The serum samples were analyzed by gel filtration chromatography with radioactivity detection, and the area of each radioactive peak was divided by the total area of all radioactive peaks in the chromatogram to determine the percentage of radiometal associated with that fraction.

The serum stability results for ¹¹¹In-labeled cT84.66–MC-DOTA are shown in Figure 2. Fifty percent of the radiolabel was lost from the antibody fraction of the mixture after approximately 27 h, resulting in the transfer of ¹¹¹In to a fraction with an apparent molecular mass of 70 kDa and to a low-molecular mass fraction (<1350 Da). After 7 days, 24.7% of the ¹¹¹In label remained bound to the mAb, 61.3% was associated with the 70 kDa fraction, and 14.0% of the activity was obtained as a low-molecular mass species. Addition of CEA to the serum and reanalysis by gel filtration chromatography revealed that only the 150 kDa fraction was immunoreactive. Similar results were obtained for ⁹⁰Y-labeled cT84.66–MC-DOTA (data not shown). Carboxymethylation of unconjugated cysteine residues in cT84.66–MC-DOTA with iodoacetic acid resulted in a moderate improvement in serum stability. In that case,

Figure 2. Percentage of ^{111}In associated with cT84.66-MC-DOTA (●), serum albumin (■), and low-molecular mass (▲) fractions as a function of time of incubation in human serum at 37 °C, determined by gel filtration HPLC.

Figure 3. Percentage of ^{111}In associated with cT84.66-MSC-DOTA (●), serum albumin (■), and low-molecular mass (▲) fractions as a function of time of incubation in human serum at 37 °C, determined by gel filtration HPLC.

50% of the ^{111}In label was lost from the mAb in about 47 h, but after 8 days, 21.1% of the ^{111}In activity was bound to the mAb fraction, 59.3% eluted in the 70 kDa fraction, and 19.6% eluted as a low-molecular mass species (data not shown). In contrast, the ^{131}I -labeled cT84.66-MC-DOTA conjugate was completely stable in human serum for a period of 7 days; 100% of the ^{131}I activity remained associated with the mAb fraction (data not shown).

The 70 kDa ^{111}In species was found to coelute with purified, ^{131}I -labeled human serum albumin by gel filtration chromatography. Also, the ^{90}Y activity associated with the 70 kDa peak was collected, analyzed by reducing and nonreducing SDS-polyacrylamide gel electrophoresis with autoradiography detection, and found to migrate with an apparent molecular mass of 66.4 kDa (data not shown). No evidence that either radiometal associated with transferrin was obtained by gel filtration chromatography or gel electrophoresis. When the radiolabeled mAb was incubated with purified HSA at physiological temperature and pH, alkylation of Cys-34 of HSA with iodoacetic acid had no effect on the rate of transfer of ^{111}In to HSA.

The serum stability results for ^{111}In -labeled carboxymethylated cT84.66-MSC-DOTA are shown in Figure 3. After 6 h at 37 °C, only 14.1% of the radiometal label remained with the mAb. However, unlike the cT84.66-MC-DOTA conjugate, most of the ^{111}In activity remained

Figure 4. Reversed phase chromatograms of MC-DOTA[Y(III)] before incubation (A) and after incubation in PBS at 37 °C for 555 h at pH 7.4 (B) or for 555 h at pH 5.4 (C). Aliquots of 5 μg were injected onto a C_{18} column (2 $\times$ 250 mm, 5 μm , 300 Å) and eluted with a linear gradient from 0 to 60% solvent B (solvent A, 0.1% TFA; solvent B, 0.1% TFA/90% CH_3CN) over 60 min at a flow rate of 0.2 mL/min. Absorbance was monitored at 214 nm.

in the low-molecular mass fraction (83.1% at 6 h), with very little transfer to HSA (2.90% at 6 h). After 7 days, the amounts of the ^{111}In associated with cT84.66-MSC-DOTA, HSA, and the low-molecular mass species were 1.65, 21.3, and 77.1%, respectively.

Stability of cT84.66-MC-DOTA in Aqueous Solutions. In the absence of other proteins, the kinetic stability of ^{111}In -labeled carboxymethylated cT84.66-MC-DOTA was studied in aqueous media at physiological temperature and pH. At 37 °C in 1 mM DTPA (pH 7.2), 1 mM DTT (pH 7.4), and PBS (pH 7.4), the ^{111}In label was lost from the mAb component and converted to a low-molecular mass species. Formation of the ^{111}In -labeled low-molecular mass fraction was observed to follow slow, pseudo-first-order kinetics in all three mixtures. Therefore, the rates of formation of this species could be expressed in linear plots, where $\exp(-k_i t) \approx 1 - k_i t$ when $k_i t \ll 1$ (28). The observed rate constants for formation of the ^{111}In -labeled low-molecular mass species were $0.336\text{--}0.361\text{ h}^{-1}$ ($r^2 = 0.985\text{--}0.990$) in 1 mM DTPA, 1 mM DTT, and PBS.

Stability of MC-DOTA[Y(III)] and MSC-DOTA[Y(III)] in Aqueous Solution. The kinetic stabilities of the purified yttrium chelates of MC-DOTA and MSC-DOTA were studied in PBS at 37 °C and pH 7.4 or 5.4. Figure 4 shows the reversed phase chromatograms of MC-DOTA[Y(III)] (4) before heating to 37 °C (A) and after incubation at 37 °C for 555 h at pH 7.4 (B) or at pH 5.4 (C). In the absence of chelated yttrium, MC-DOTA exhibited nearly identical reaction rates and produced identical proportions of the analogous decomposition products at the two pH values. Figure 5 shows the rates of formation of decomposition products from MC-DOTA[Y(III)] at pH 7.4 and 5.4. The kinetic profile at pH 7.4 [Figure 5 (top)] indicated that 4 was converted to

Figure 5. Peak areas, expressed as percentages of the total peak area, of MC-DOTA[Y(III)] (○) and decomposition products **5** (□), **6** (◇), **7** (△), **8** (▽), and **9** (+) as a function of time of incubation in PBS at 37 °C at pH 7.4 (top) or pH 5.4 (bottom). compound **9** within 24 h, followed by the conversion of **9** to compounds **5–8**. In addition, a second decomposition pathway produced compounds **10** and **11** in minor amounts (<15%, data not shown). At pH 5.4 [Figure 5 (bottom)], the reaction was considerably slower, and **4** was converted to compounds **9** and **5**, with small quantities of **11** produced (<2%, data not shown) and negligible formation of products **6–8**. The formation of compound **10** could not be confirmed at pH 5.4, because the comparatively large quantity of unreacted MC-DOTA[Y(III)] eluted at a nearly identical retention time.

Shown in Figure 6 are the reversed phase chromatograms of purified MSC-DOTA[Y(III)] (**12**) before heating to 37 °C (A), after incubation at 37 °C for 6 h at pH 7.4 (B), and after incubation at 37 °C for 50 h at pH 5.4 (C). Figure 7 shows the rates of formation of decomposition products from MSC-DOTA[Y(III)] at pH 7.4 and 5.4. The plot for the decomposition at pH 7.4 [Figure 7 (top)] indicated that **12** was rapidly converted to compounds **13** and **15**, after which **15** was converted to compound **11**, which in turn gave rise to product **10**. The same decomposition products were obtained from MSC-DOTA[Y(III)] at pH 5.4, but at significantly slower rates [Figure 7 (bottom)]. Decomposition of MSC-DOTA produced identical proportions of the analogous decomposition products at both pH values. However, the presence of chelated yttrium resulted in an approximately 3-fold acceleration in the decomposition at pH 7.4 and an approximately 2-fold increase in the reaction rate at pH 5.4.

Mass Spectrometry Analysis of Decomposition Products from MC-DOTA[Y(III)] and MSC-DOTA-

Figure 6. Reversed phase chromatograms of MSC-DOTA[Y(III)] before incubation (A) and after incubation in PBS at 37 °C for 6 h at pH 7.4 (B) or for 50 h at pH 5.4 (C). Aliquots of 5 μ g were injected onto a C₁₈ column (2 $\times$ 250 mm, 5 μ m, 300 Å) and eluted with a linear gradient from 0 to 60% solvent B (solvent A, 0.1% TFA; solvent B, 0.1% TFA/90% CH₃CN) over 60 min at a flow rate of 0.2 mL/min. Absorbance was monitored at 214 nm.

[Y(III)]. After separation by reversed phase HPLC, fractions corresponding to MC-DOTA[Y(III)] (**4**) and its decomposition products **5–11** were collected and analyzed by ESI MS with collision-induced dissociation. Fractions were collected and analyzed from reaction mixtures incubated at pH 7.4 and 5.4, in the presence and absence of chelated yttrium, to determine the identities of products generated at both pH values and of the analogous products generated in the absence of yttrium. Table 3 summarizes the mass spectrometry results obtained for **4** and its decomposition products. Taken together, the results of mass spectrometry and kinetic analysis allowed a mechanism for the decomposition of MC-DOTA[Y(III)], which is depicted in Figure 8, to be proposed.

The mass spectrum of fraction **4** gave a singly charged molecular ion at $m/z = 870.54$, consistent with that expected for MC-DOTA[Y(III)] (calcd for C₃₃H₄₇N₇O₁₃SY, 870.20). MS² of the parent ion produced complete fragmentation of **4** to yield a number of characteristic product ions. The product ions at $m/z = 826.2$, 782.3, 738.3, and 694.5 corresponded to the loss of 1–4 molecules of CO₂, respectively, from the chelate carboxylate groups. The product ion at $m/z = 594.2$ corresponded to the yttrium chelate of DOTA cysteineamide, and the product ions at $m/z = 560.2$ and 516.1 were consistent with progressive loss of H₂S and CO₂ from DOTA-cysteineamide[Y(III)]. The product ion at $m/z = 491.2$ was the smallest fragment obtained and corresponded to the yttrium chelate of DOTA monoamide.

Compound **9** afforded a singly charged molecular ion at $m/z = 888.04$, 18 mass units higher than **4** and consistent with the addition of H₂O to MC-DOTA[Y(III)]. MS² of the $m/z = 888.04$ ion yielded a major product ion at $m/z = 790.2$, which corresponded to the loss of maleic

Figure 7. Peak areas, expressed as percentages of the total peak area, of MSC-DOTA[Y(III)] ($\diamond$) and decomposition products **10** ($\circ$), **11** ($+$), **13** (Δ), **14** (∇), and **15** ($\square$) as a function of time of incubation in PBS at 37 °C at pH 7.4 (top) or pH 5.4 (bottom).

anhydride. MS^3 of the ion at $m/z = 790.2$ produced secondary product ions at $m/z = 594.1$, 560.1, 516.0, and 491.1. Compared to **4**, decomposition product **9** appeared to arise from addition of H_2O , contain a maleic acid moiety, and otherwise possess fragmentation patterns similar to those of the starting material. Thus, the structure of **9** was assigned to a hydrolysis product of **4** in which the maleimide ring had been opened.

Fractions **6–8** all gave singly charged molecular ions at a nominal m/z value of 906, an increase of 36 mass units compared to MC-DOTA[Y(III)], and major product ions at $m/z = 808$, corresponding to loss of maleic anhydride. In addition, all three of these decomposition products showed secondary product ions characteristic of the DOTA-cysteineamide[Y(III)] moiety, at $m/z = 594$, 560, 516, and 491. The parent ion was consistent with the addition of 2 equiv of H_2O to **4**, and the only reasonable structure consistent with the mass spectral data was that of a hydrolysis product in which both the maleimide and succinimide rings of MC-DOTA[Y(III)] had been opened. This process would generate two regioisomeric products, each of which would exist as a pair of diastereomers. Compounds **6** and **7** gave nearly identical MS^3 spectra, with the major secondary product ions at $m/z = 790.1$ and 763.0. In contrast, compound **8** yielded major secondary product ions at $m/z = 710.1$ and 692.1. The fact that two HPLC peaks, **6** and **7**, gave identical mass spectra suggested that they represent one pair of diastereomers which are chromatographed with different retention times on the reversed phase column. In the case of compound **8**, only one HPLC peak was

^a Relative intensities are given in parentheses. ^b nd = not done.

obtained, which may represent the coelution of the other diastereomeric pair. We were not able to determine conclusively which regioisomers correspond to fractions **6/7** and **8** on the basis of the MS data. However, opening of the succinimide ring should be favored at the site distal to the sulfide group for steric reasons. Since the peak area for fraction **8** was always greater than the combined peak areas for fractions **6** and **7**, we have tentatively assigned their structures as shown in Figure 8.

Compound **5** yielded a singly charged molecular ion at $m/z = 790.43$, consistent with the mass of a decomposition product arising from hydrolytic loss of maleic acid from **4**. MS^2 of **5** afforded product ions at $m/z = 594.1$, 560.2, 561.1, and 491.1, indicative of the DOTA-cysteineamide[Y(III)] moiety. Hydrolytic loss of maleic acid from MC-DOTA[Y(III)] generated the primary amine derivative of the bifunctional chelate, the only cleavage product we observed in this experiment. The split peak obtained for fraction **5** suggested that this pair of diastereomers was chromatographed with slightly different retention times. When collected separately, the two peaks from fraction **5** gave identical mass spectra.

The peak marked with an asterisk (*) in the chromatograms shown in Figure 4 was also analyzed by ESI MS. This fraction gave a singly charged molecular ion at $m/z = 130.04$. MS^2 of this parent ion generated product ions at $m/z = 74.1$ and 57.1. MS^3 of the product ion at $m/z =$

Figure 8. Proposed mechanism for the decomposition of MC-DOTA[Y(III)] in aqueous solution.

Figure 9. Proposed mechanism for the decomposition of MSC-DOTA[Y(III)] in aqueous solution.

74.1 yielded the ion at $m/z = 57.2$ as the secondary product. Because these studies were performed in an ion trap instrument, the data were consistent with the structure of any isomer of dibutylamine. Dibutylamines are commonly used as stabilizers and vulcanization accelerants in the manufacture of rubber products.² The decomposition reactions were performed in screw-cap polypropylene vials containing rubber O-rings. It is likely that solvent evaporation and condensation was responsible for extraction of dibutylamine from the O-rings and introduction of this contaminant into the reaction mixtures. The observation that considerably more dibutylamine was obtained at pH 5.4 than at pH 7.4 supports this conclusion.

After separation by reversed phase HPLC, MSC-DOTA[Y(III)] (**12**) and its decomposition products, **10**, **11**, and **13–15**, were collected and subjected to the same ESI

MS analysis. Again, fractions were collected from reaction mixtures incubated at pH 7.4 and 5.4, with and without chelated yttrium, to verify that the same products were obtained at both pH values and that the analogous products were obtained in the absence of yttrium. Table 4 summarizes the ESI MS data for compounds **10–15**, and the proposed reaction mechanism derived from the mass spectrometry and kinetic analysis is shown in Figure 9.

MSC-DOTA[Y(III)] (**12**) gave a singly charged molecular ion at $m/z = 902.23$ (calcd for $\text{C}_{33}\text{H}_{47}\text{N}_7\text{O}_{15}\text{SY}$, 902.19). MS² of this parent ion produced complete fragmentation of **12** to afford characteristic product ions at $m/z = 858.2$ and 814.3 , corresponding to loss of 1 and 2 CO_2 molecules, respectively, as well as at $m/z = 626.1$, consistent with the structure of the yttrium chelate of DOTA-cysteinesulfenic acid. The product ions at $m/z = 560.2$ and 516.1 resulted from loss of H_2SO_2 and CO_2 from DOTA-cysteinesulfenic acid[Y(III)]. The product ion cor-

responding to DOTA-monoamide[Y(III)] was also prominent at $m/z = 491.2$.

The initial products formed from the decomposition of MSC-DOTA[Y(III)] were compounds **13** and **15**. Fraction **13** exhibited a singly charged molecular ion at $m/z = 626.12$, one product ion at $m/z = 608.2$, and secondary product ions at $m/z = 560.2$, 516.2 , and 491.2 . These data were consistent with the structure of the yttrium chelate of DOTA-cysteinesulfenic acid. Fraction **15** generated a singly charged molecular ion at $m/z = 277.09$. MS² of **15** gave a product ion at $m/z = 180.1$, corresponding to loss of maleimide, and MS³ afforded a major secondary product ion at $m/z = 83.1$, again consistent with loss of maleimide. These product ions, along with the loss of several 14 mass unit fragments in the MS³ spectrum, led us to assign the structure of **15** as that of 1,6-bis-(maleimido)hexane. Thus, as depicted in Figure 9, the first step in the decomposition mechanism of MSC-DOTA[Y(III)] appeared to be a β -elimination reaction involving the sulfone and succinimide groups, generating **13** and **15** as cleavage products.

Compounds **10** and **11** gave mass spectra which were consistent with the structures of hydrolysis products derived from 1,6-bis-(maleimido)hexane. Fraction **11** had a singly charged molecular ion at $m/z = 295.01$, 18 mass units higher than that of **15**. MS² of **11** yielded a peak at $m/z = 277.1$, corresponding to loss of H₂O in the gas phase to generate BMH as a product ion, and MS³ produced a fragmentation pattern similar to that observed for **15**. The structure of compound **11** was assigned as the BMH hydrolysis product in which one of the maleimide rings had been opened. Fraction **10** gave a singly charged molecular ion at $m/z = 312.99$, 36 mass units higher than that of **15**, and upon MS² analysis

afforded product ions at $m/z = 295.0$, representing loss of H₂O, and $m/z = 215.1$, representing loss of maleic anhydride. MS³ of the ion at $m/z = 215.1$ produced loss of a second molecule of maleic anhydride to give a secondary product ion at $m/z = 117.1$, corresponding to the ion expected for 1,6-hexanediamine. Thus, the structure of **10** was assigned as a BMH hydrolysis product in which both maleimide rings had been opened.

MS of fraction **14**, like that of **15**, showed a singly charged molecular ion at $m/z = 277.08$. However, the MS² fragmentation pattern of **14** was dramatically different from that obtained for compound **15** and was not consistent with any reasonable structure we could derive for a possible MSC-DOTA[Y(III)] decomposition product. At this point, we are not able to assign an unequivocal structure to compound **14**.

DISCUSSION

The macrocyclic chelating agent DOTA is an attractive candidate for labeling monoclonal antibodies with radiometals because it has been shown to bind a large number of main group and transition metal ions with extremely high stability constants (30–35). Unfortunately, for many metals of interest, the rates of incorporation into the DOTA chelate complex are relatively slow (36), especially in the context of an antibody conjugate. Thus, yields for radiometal labeling of these conjugates under ambient conditions can be low or variable. Chelation of a wide variety of metal ions by free DOTA has been shown to be a two-step process, involving the reversible formation of the loosely associated type I complex and a slow transformation to the fully coordinated and kinetically stable type II complex (37, 38).

We hypothesized that for antibody-conjugated DOTA derivatives, especially at carrier-free radiometal concentrations, competition from nonspecific metal-binding sites on the protein surface may cause formation of the type I complex to become the rate-limiting step for radiolabeling. On the basis of the model compounds synthesized by Takenouchi and co-workers (39, 40), we synthesized similar bifunctional DOTA derivatives bearing “pendant-type” carboxylates, to determine whether the presence of such additional metal coordinating groups would have an effect on mAb radiolabeling yields.

The maleimidocysteineamido-DOTA derivatives **2** and **3** were prepared by a simple, straightforward synthetic route, taking advantage of water-soluble chemistry to circumvent the need for lengthy sequences of protection and deprotection reactions. These compounds can be synthesized and purified in a relatively short period of time, on the order of 2 weeks. The key intermediate, the monocysteineamide derivative of DOTA (**1**), was prepared by a reaction that was once commonly employed in peptide synthesis (50) and more recently used to synthesize entire proteins by native chemical ligation (55). The mechanism of coupling active esters to cysteine involves nucleophilic attack of the ionized thiolate to form an intermediate thioester, which in aqueous solution rearranges via a pentacyclic transition state to the more stable amide (50). The thiol group of **1** was then exploited as an orthogonal functionality for antibody conjugation, using the homobifunctional linker 1,6-bis-(maleimido)-hexane. The resulting product, MC-DOTA (**2**), was oxidized with potassium hydrogen persulfate (Oxone), a reagent which is highly chemoselective for conversion of sulfides to sulfones (51), to give MSC-DOTA (**3**).

Compounds **2** and **3** were conjugated to the lightly reduced anticarcinoma embryonic antigen mAb cT84.66,

using a modification of the procedure of Willner et al. (52). According to Ellman's test, treatment of cT84.66 with 20 molar equiv of DTT generated approximately 10 reactive thiol groups per antibody molecule, a titer slightly higher than that anticipated for a human IgG₁ mAb, which contains four interchain disulfide bonds. However, these results are similar to those obtained by Willner et al., who generated a titer of 9.6 sulfhydryl groups per molecule of the isotype-matched mAb BR64 at a DTT:mAb molar ratio of 20:1. Addition of up to 40 molar equiv of maleimide-derivatized bifunctional chelating agent resulted in modification with a maximum of six chelates per antibody molecule. The conjugation results suggested that at least two of the cysteine residues of cT84.66 remained unreactive to modification. Since SDS-polyacrylamide gel electrophoresis of the maximally modified conjugate [Figure 1 (top)] clearly showed 100% modification of the light chain, the heavy chain likely contained the unreactive cysteine residues. Steric hindrance may have played a role in preventing all of the heavy chain cysteines from being modified.

The cT84.66-MC-DOTA conjugate containing an average of 3.8 chelates per antibody molecule was the minimally modified product that gave high specific activity radiolabeling with ¹¹¹In and ⁹⁰Y. Fortunately, the minimally modified cT84.66 conjugate prepared with the *N*-hydroxysulfosuccinimide ester of DOTA (29) which exhibited high-specific activity radiometal labeling was also modified with an average of 3.8 chelates per mAb. Conjugates prepared with both reagents and coupled to an average of 1–2 chelates per antibody displayed an approximate 4-fold reduction in radiometal labeling yield. The "threshold" modification value of 3–4 chelates per mAb, required for the conjugate to carry high radiometal activity, was in good agreement with the findings of other groups (56, 57). However, a direct comparison of the cT84.66 conjugates prepared with MC-DOTA and DOTA-OSSu showed that the MC-DOTA conjugate afforded an average 22–23% increase in radiolabeling yields for both ¹¹¹In and ⁹⁰Y. At present, we cannot conclude unequivocally whether this improvement in radiometal labeling can be attributed to the pendant-type carboxyl group of MC-DOTA, the change in conjugation site to reduced disulfides in the mAb, or the addition of a longer linker to the macrocycle. Using modifications of the water-soluble route for the synthesis of MC-DOTA, we can now test each of these parameters independently for their respective contributions to radiolabeling yields.

Kinetic stability studies of cT84.66-MC-DOTA and cT84.66-MSD-DOTA were performed in human serum and in aqueous solutions containing DTPA, DTT, and buffer alone at physiological temperature and pH. In serum, both conjugates exhibited relatively rapid loss of radiometal, and this process was approximately 10 times faster for the conjugate prepared with the sulfone compound. A dramatic difference in the fate of the radiometal was observed, depending on which type of chelate-antibody linker was used. Radiometal lost from the MC-DOTA conjugate was predominantly associated with serum albumin, while the vast majority of metal lost from the MSD-DOTA conjugate remained as a low-molecular mass species. In these experiments, no ¹¹¹In was associated with transferrin, the usual acceptor protein for this metal. Furthermore, in the absence of serum and other proteins, large quantities of exogenous chelating agent or reducing agent had no effect on the observed rate of radiometal loss. These results were inconsistent with those expected for radiometal ion dissociation or a disulfide exchange reaction, suggesting that a solvent-

mediated or intramolecular cleavage reaction involving the linker portion of the bifunctional chelates might be responsible for radiometal release. The cT84.66-MC-DOTA conjugate, however, has afforded highly reproducible radiolabeling yields over a period of more than 6 months of storage under metal-free conditions at 4 °C and pH 7.0, indicating that the stability of the antibody conjugate is temperature-dependent.

The properties of the unconjugated Y(III) chelates of MC-DOTA and MSD-DOTA at physiological temperature were studied in order to elucidate the mechanisms of their decomposition reactions. When MC-DOTA[Y(III)] (4) and MSD-DOTA[Y(III)] (12) were incubated in PBS at 37 °C, pH-dependent cleavage of the linker moiety occurred in both compounds. HPLC and ESI MS analysis of the reaction products revealed that MC-DOTA (2) and its yttrium chelate underwent imide bond hydrolysis, while MSD-DOTA (3) and its yttrium chelate decomposed by a β -elimination reaction involving the sulfone group. The decomposition of 2–4 and 12 occurred much faster at pH 7.4 than at pH 5.4, and neither yttrium compound showed any evidence of metal ion dissociation during the course of these reactions. Interestingly, MC-DOTA-[Y(III)] showed a much slower rate of decomposition at pH 7.4 than the corresponding radiolabeled antibody conjugate, indicating that the protein also played a role in the decomposition reaction. Further evidence of the mAb's role in the decomposition of the MC-DOTA conjugate was provided by the modest, but significant, improvement in radiolabel stability upon alkylation of the unconjugated cysteines with iodoacetic acid.

In the case of MSD-DOTA and its Y(III) chelate, the same reaction products were generated in the same proportions at both pH values. The presence of chelated yttrium accelerated the elimination reaction 2–3-fold, indicating that the sulfone group is activated by the bound metal ion. In contrast, imide bond hydrolysis of MC-DOTA was not significantly enhanced by chelated yttrium, but the profile of decomposition products depended on the pH of the reaction mixture. At pH 5.4, no products resulting from succinimide ring opening of MC-DOTA or its yttrium chelate were generated, although the cleavage product resulting from maleimide ring hydrolysis (5) was obtained in much greater yield than at pH 7.4. It could be argued that the maleimide ring of MC-DOTA is less stable to hydrolysis than the succinimide ring, causing it to open first to yield intermediate 9, which hydrolyzes further to generate compound 5 as the only observed cleavage product in this system. However, when MC-DOTA is conjugated to an antibody, the maleimide group is converted to a succinimide group. If the hydrolysis mechanism holds for the mAb conjugate, then loss of the radiolabel might occur by cleavage at one of the succinimide rings to release the radiometal chelate. On the basis of the HPLC results, this process would not be expected to occur to an appreciable degree at pH 5.4 but might occur at physiological pH. Maleimide ring opening (58) and succinimide ring opening on protein conjugates (59–64) have been observed or postulated to occur at pH >7.5 in many other systems, but to our knowledge, this is the first case in which succinimide ring cleavage may be responsible for release of a conjugated molecule from a protein.

Conjugation of kinetically stable radiometal chelates to monoclonal antibodies by means of a linker system that is chemically labile at physiological pH offers the possibility of imparting favorable biodistribution properties to the resulting radioimmunoconjugates. The serum studies of cT84.66-MSD-DOTA suggested that this

conjugate would probably exhibit an insufficient *in vivo* stability to be useful for tumor targeting with intact IgG. On the other hand, the *in vitro* serum half-life of cT84.66-MC-DOTA was comparable to the biological half-life of radiolabeled IgGs in animal models and human subjects. Controlled hydrolysis of the linker between chelate and antibody might be expected to improve the clearance of radioactivity from normal organs and tissues, since the radiometal should be released in chelated form, and free chelates have been shown to clear by rapid urinary excretion (65–68).

In contrast, the increase in stability of the MC-DOTA linker and lack of succinimide hydrolysis at moderately acidic pH may have an important effect on the stability of the radiometal-labeled antibody at the tumor site. The interstitial pH of solid tumors in both rodents and humans has been shown to be significantly lower than that of normal tissues (69–77); for reviews, see refs 78 and 79. The extracellular pH of malignant tissue has been measured in the range of 5.8–7.7, while normal tissues fall in the range of 7.0–8.1 (78). In general, tumors with a higher percentage of epithelial tissue are more acidic (72), and adenocarcinomas in particular fall in the lower ranges of extracellular pH, from 5.7 to 7.8 (75). Since the mAb cT84.66 recognizes the adenocarcinoma-associated antigen CEA and is not internalized upon binding, the increased stability of the MC-DOTA linker at moderately acidic pH may allow tumor uptake of the radiometal-labeled mAb to remain high. In the accompanying article (80), we show that ^{111}In - and ^{90}Y -labeled cT84.66-MC-DOTA exhibited high tumor uptake, with improved blood clearance and low uptake in normal organs, in a nude mouse model of human colorectal adenocarcinoma.

The maleimidocysteineamido-DOTA derivatives described here allowed conjugation of macrocyclic radiometal chelates to reduced disulfide bonds of antibodies. Compared to the conjugate prepared with an active ester of DOTA, cT84.66-MC-DOTA showed increases in radiolabeling yields of 22–23% for ^{111}In and ^{90}Y . Using MC-DOTA, we have achieved our goal of near-quantitative antibody labeling with both radiometals. Immunoconjugates prepared with the two maleimidocysteineamido-DOTA derivatives exhibited linker-dependent loss of radiometal at physiological temperature and pH. We attributed this phenomenon to imide bond hydrolysis for the sulfide compound MC-DOTA and to a β -elimination reaction in the case of the sulfone MSC-DOTA. We found that the cleavage reactions were dramatically slower at moderately acidic pH. The use of such pH-dependent chemically labile linkers may be an important determinant of the *in vivo* distribution properties of antibody-radiometal chelate conjugates, on the basis of the observed differences between the extracellular pH of solid tumors and that of normal tissues.

ACKNOWLEDGMENT

The authors thank Jim Kao, Randall Woo, and Mike Davis for excellent technical assistance, Jim Primus and Karen Rickard-Dickson for providing the mAb cT84.66, and Terry Lee and Andrew Raubitschek for helpful discussions. Biodistributions of two radiometal chelate conjugates of the human/murine chimeric anticarcinoembryonic antigen monoclonal antibody cT84.66 were obtained in nude mice bearing LS174T human colorectal carcinoma xenografts. Derivatives of the macrocyclic chelating agent 1,4,7,10-tetraazacyclododecane-*N,N',N'',N'''*-tetraacetic acid (DOTA) were covalently attached to the antibody by a stable amide linkage and by a maleimidocysteineamido side chain (MC-DOTA) that has been shown to be chemically labile at physiological temperature and pH. Biodistributions of both ^{111}In and ^{90}Y labels were obtained in these studies. At common biodistribution time points, it was found that the ^{111}In label had greater uptake in the liver than ^{90}Y for both conjugates. No significant differences were found with respect to bone uptake of ^{90}Y using either chelate. Blood curves were generally lower at comparable time points for MC-DOTA, indicative of faster clearance as compared to DOTA. Tumor uptake was high for both conjugates (57–68% ID/g at 48 h), with a longer tumor residence time in the case of the DOTA conjugate, probably a result of its longer blood circulation times. We conclude that bone uptake of ^{90}Y would be minimal if either DOTA or MC-DOTA were used as the bifunctional chelator. This would imply preference for these macrocyclic ligands if radiation doses to the bone marrow would be considered to be dominated by skeletal uptakes. Alternatively, if bone marrow radiation dose is dominated by circulating antibody, the chemically labile linker system employed by the MC-DOTA conjugate offers the advantage of enhanced blood clearance.

INTRODUCTION

Radiolabeled monoclonal antibodies (mAbs) have applications for both imaging and therapy of malignant tumors (1). A large number of radionuclides, including radioiodines but primarily radiometals, are available for these applications. Generally, pure photon emitters and particulate emitters are favored for imaging and therapy, respectively. In the case of clinical radioimmunotherapy (RIT¹), however, an imageable photon must be emitted along with the particulate radiation so the absorbed dose

can be estimated. If one utilizes only one radiolabel, such as a radioiodine, the associated photon yield may be of the wrong energy and/or too intense for effective quantitation. Human therapies require total injected activities approaching or exceeding 100 mCi (2). An example is the application of ^{131}I -labeled anti-CD20 in the treatment of B-cell lymphomas (3), where injected activities have exceeded 500 mCi. Such levels lead to γ camera count rate limitations at early time points postinjection. This may limit the accuracy of patient iodine uptake measurements and consequently the estimation of the absorbed dose.

Because of this ineffective or hazardous photon production, in many situations two radiolabels are used in RIT. One label must be suitable for the imaging or therapy planning situation, and the second, essentially of a particulate type, provided for the subsequent treatment(s). If the particulate emitter has no associated

¹ Abbreviations: RIT, radioimmunotherapy; BCA, bifunctional chelating agent; DOTA, 1,4,7,10-tetraazacyclododecane-*N,N',N'',N'''*-tetraacetic acid; MC-DOTA, maleimidocysteineamido-DOTA; DTPA, diethylenetriaminepentaacetic acid; CEA, carcinoembryonic antigen; cT84.66, human/murine chimeric anti-CEA mAb; cT84.66-DOTA, cT84.66 conjugated with the *N*-hydroxysulfosuccinimide ester of DOTA; cT84.66-MC-DOTA, cT84.66 conjugated with MC-DOTA.

photon suitable for imaging, the provision of an imaging label becomes a necessity. From the earliest discussions of therapeutic efficacy, $^{90}\text{Y}(\text{III})$ has been described as a possible RIT radionuclide (4). Its pure, high-energy β^- (range, 1.1 cm) leads to the clinical advantage of cross-fire capability in treating tumor cells distant from those to which the radioimmunoconjugate has localized. The corresponding γ emitter $^{111}\text{In}(\text{III})$ generally has been used for imaging and dosimetry applications in ^{90}Y therapy. Both trivalent metals can be attached to mAbs using the same bifunctional chelating agent (BCA). ^{111}In emits two γ photons at 171 and 247 keV, energies that are efficiently detected with commercial Anger cameras.

Given that two labels must be used for ^{90}Y -based RIT, it is incumbent upon the investigator to demonstrate that variation of the radiometal has minimal and predictable impact upon biodistributions. If this is so, then an imaging sequence can be used to plan and document patient RIT treatments. Biodistributions in an animal model of human cancer can be used to show the variation of organ uptake with a change in the radiometal or bifunctional chelate coupled to the mAb.

An important consideration for the selection of the BCA is the formation of a physiologically stable radiometal complex, to minimize uptake in and radiation toxicity to normal tissues (5). In the case of ^{90}Y , uptake in mice approaching 20% of the injected dose per gram (% ID/g) of bone has been seen for the ionic form (6). Since bone marrow is an organ at risk in cancer radiotherapy, the dissociation of ^{90}Y in the bloodstream and other tissues as a function of time postinjection of the radiolabeled mAb must be evaluated. The stability of the conjugated radiometal complex will depend upon the type of BCA used.

Macrocyclic ligands have been suggested as one possible methodology for reducing ^{90}Y loss *in vivo* (7–10). Meares and co-workers (7–9) have demonstrated bone uptakes on the order of 2% ID/g in nude mice receiving 1,4,7,10-tetraazacyclododecane-*N,N',N'',N'''*-tetraacetic acid (DOTA) derivatives labeled with ^{90}Y and conjugated to Lym-1 (7) and chimeric L6 (9) antibodies. In these studies, the radiometal was incorporated into the BCA prior to mAb conjugation. Similar bone uptake values have been demonstrated by Harrison et al. (10) using the anti-colon cancer antibody B72.3, which had been covalently linked to DOTA before radiolabeling. In these earlier works, however, little numerical comparison was made between ^{111}In and ^{90}Y biodistributions in animals. Deshpande et al. (7) utilized Lym-1 mAb, which targets to B lymphocytes within the bone and confounds analyses. Harrison and co-workers utilized only ^{90}Y in their B72.3 studies (10). One recent report (9) included both radiometals, but did not analyze their differences statistically *in vivo*. The need to compare ^{111}In - and ^{90}Y -labeled antibody biodistributions for DOTA-based BCAs led to the studies described herein.

The human/murine chimeric anticarcinoembryonic antigen (anti-CEA) mAb cT84.66 (11) has shown minimal cross-reactivity with normal human or murine tissues, and biodistributions of ^{111}In - and ^{90}Y -labeled cT84.66 were evaluated earlier using a bifunctional DTPA derivative (12). Athymic nude mice implanted with CEA-expressing LS174T human colorectal tumor xenografts were used in that study. In this work, we obtained the ^{111}In and ^{90}Y biodistributions of cT84.66 conjugated to two new DOTA derivatives in the LS174T-bearing nude mouse model. When endogenous primary amino groups of the mAb were reacted with the *N*-hydroxysulfosuccinimide ester of DOTA, the radiometal-labeled conjugate

displayed extremely high kinetic stability *in vitro* (13). In contrast, radiometals conjugated to reduced disulfide bonds in the mAb with maleimidocysteineamido-DOTA (MC-DOTA) were chemically labile at physiological temperature and pH. This BCA exhibited pH-dependent linker hydrolysis *in vitro*, which resulted in release of $\text{Y}(\text{III})$ in the chelated form (14).

For both macrocycle–antibody conjugates, we compared the biodistributions obtained with ^{111}In versus those obtained with ^{90}Y . The likelihood of bone uptake of ^{90}Y was evaluated with either macrocycle. In addition, blood clearance curves were analyzed for all four combinations of label and BCA. The latter two studies provided information that can be used to select an optimal BCA for reducing bone marrow absorbed dose during clinical trials.

EXPERIMENTAL PROCEDURES

Conjugation of mAb and Radiolabeling. The preparation, ^{111}In and ^{90}Y labeling, and *in vitro* characterization of cT84.66–DOTA have been described previously (13). Reagents, synthesis of MC-DOTA, antibody conjugation, radiometal labeling, and *in vitro* evaluation of cT84.66–MC-DOTA were detailed in the preceding paper by Lewis and Shively (14). Briefly, the mAb conjugates were labeled with ^{111}In by incubating the conjugate with $^{111}\text{InCl}_3$ in 0.25 M ammonium acetate for 45 min at 43 °C. Then EDTA was added to a final concentration of 1 mM, and the mixture was incubated at 37 °C for 15 min. Labeling with ^{90}Y was performed using a 1 h incubation at 43 °C, after which DTPA was added to a final concentration of 1 mM, and the mixture was incubated for an additional 15 min at 37 °C. The radiometal-labeled mAb conjugates were purified by size exclusion HPLC, using a TosoHaas TSKgel G2000 SW column (10 μm , 7.5 $\times$ 300 mm) and an isocratic mobile phase of normal saline at a flow rate of 0.5 mL/min. In each case, the radiolabeled mAb peak was collected in 0.5 mL fractions containing 1 drop of 25% (w/v) human serum albumin, and the fraction containing the highest activity of radiolabeled mAb was used to prepare biodistribution doses. The cT84.66–MC-DOTA conjugate used for the biodistribution experiments was not treated with iodoacetic acid, a procedure which was shown to afford a moderate improvement in serum stability (14).

cT84.66–DOTA Biodistributions. In the case of cT84.66–DOTA, separate animal experiments were conducted with either the ^{111}In or ^{90}Y label. Female nu/nu BALB/c mice were injected subcutaneously with approximately 10^6 LS174T tumor cells in the hind flank, and tumors were allowed to grow for 10–14 days. Radiolabeled immunoconjugate (8 μCi of ^{111}In per 3.79 μg of mAb or 30 μCi of ^{90}Y per 3.49 μg of mAb) was injected into the tail vein of the animals when single tumors were palpable. Biodistributions were obtained at 0, 4, 18, 48, 72, and 96 h postinjection of the ^{111}In -labeled antibody. Corresponding values for the ^{90}Y label were 0.75, 6, 24, 48, 72, and 96 h. At these times, animals were euthanized and tissues (drained of blood) were taken, weighed, and counted in a well counter. Tissues included blood, liver, spleen, kidney, lung, bowel, bone, tumor, and carcass for the ^{111}In label. ^{90}Y biodistributions included blood, liver, spleen, kidney, bone, tumor, and carcass sampling. For the ^{111}In label, γ radiation was counted directly. ^{90}Y samples were quantitated using a β^- counter detecting Cerenkov radiation produced in a fixed volume (tissue plus saline) of 10 mL. Prior to Cerenkov counting, blood samples were clarified

by treatment with 10% sodium dodecyl sulfate at room temperature, bleach at 56 °C, and 30% hydrogen peroxide at room temperature. Other tissue samples were dissolved in perchloric acid at 56 °C, followed by treatment with 30% hydrogen peroxide at 56 °C and with bleach at room temperature, to make the emitting volume transparent to Cerenkov radiation. By comparison with a standard equal in activity to the injected dose per animal, the decay of either radiolabel was corrected so that normal organ and tumor uptake were calculated as the percent injected dose per gram of tissue.

cT84.66–MC-DOTA Biodistributions. When the cT84.66–MC-DOTA biodistributions were evaluated, we had become aware that tumor sizes could be different in separate groups of animals used for different radiolabels. Thus, in the case of cT84.66–MC-DOTA, the two radiolabeled preparations were mixed (8 μ Ci of ^{111}In per 10 μ Ci of ^{90}Y per 2.22 μ g of mAb) and co-injected into the same animal group. Biodistributions were performed at 0, 4, 12, 18, 48, 96, and 120 h postinjection. ^{111}In and ^{90}Y counting were performed as described above, and count crossover was taken into account in these analyses.

Because of the logistical difficulty of processing a large number of tissues simultaneously for both γ and Cerenkov counting, only blood, liver, bone, and tumor were evaluated for ^{90}Y activity per gram. In addition to those tissues, ^{111}In counts from spleen, lung, kidney, bowel, and carcass were also measured.

Statistical Methods. To compare differences between ^{111}In and ^{90}Y for the DOTA chelate at comparable time points (48, 72, and 96 h) and for each organ separately, the independent two-sample *t*-test was used (15). Similarly, the *t*-test was used to compare differences between the cT84.66–DOTA and cT84.66–MC-DOTA conjugates for a given label at comparable time points (4, 18, 48, and 96 h) and for each organ separately. For the cT84.66–MC-DOTA biodistribution studies, the agent was labeled with both ^{111}In and ^{90}Y . Therefore, to evaluate the agreement between the organ biodistributions for the two labels, Lin's concordance correlation coefficient (16) was estimated for each time point separately and all time points combined (referred to as pooled concordance coefficients). The concordance correlation coefficient evaluates the degree to which the pairs of data fall on the line of identity. All statistical testing was done at the *p* = 0.05 level using the SAS/STAT software package (17).

Blood Clearance. The rapidity of blood clearance was evaluated for all four combinations of BCA and radiometal. In these analyses, first and second biological half-lives were obtained by using the ADAPT II program of D'Argenio and Schumitzky (18). A biexponential function of time (*t*) having the form

$$U_B(t) = A_1 \exp(-k_1 t) + A_2 \exp(-k_2 t) \quad (1)$$

was fit to the blood data that had been corrected for radiodecay. In the equation, $U_B(t)$ represents the blood activity in percent injected dose per gram. Inverting the first and second rate constants allowed us to determine the two corresponding biological half-lives. These were intracompared among the radioimmunoconjugates studied here and also to the values of the antibody–chelate conjugates in the literature (9). It should be kept in mind that a double-exponential function may not be the best description of blood clearance. It is, however, a standard form that has been used in earlier analyses and can be applied, to the lowest order, in these data sets.

Figure 1. (Top) Percent injected dose per gram (% ID/g) of blood (●), liver (■), bone (○), and tumor (△) for ^{111}In -labeled cT84.66–DOTA in LS174T tumor-bearing nude mice. (Bottom) Percent injected dose per gram (% ID/g) of spleen (▲), kidney (□), lung (◆), and bowel (▽) for ^{111}In -labeled cT84.66–DOTA in LS174T tumor-bearing nude mice. Standard errors of the mean (SE) are indicated; all data were corrected for radiodecay.

Figure 2. Percent injected dose per gram (% ID/g) of blood (●), liver (■), bone (○), tumor (△), spleen (▲), and kidney (□) for ^{90}Y -labeled cT84.66–DOTA in LS174T tumor-bearing nude mice. Standard errors of the mean (SE) are indicated; all data were corrected for radiodecay.

RESULTS

cT84.66–DOTA Biodistributions. The results of separate biodistribution studies for ^{111}In - and ^{90}Y -labeled cT84.66–DOTA are given in Figures 1 and 2, respectively. For both radiometals, blood was the dominant normal tissue out to 48 h. High uptakes were seen in

Figure 3. (Top) Percent injected dose per gram (% ID/g) of blood (●), liver (■), bone (○), and tumor (Δ) for ^{111}In -labeled cT84.66-MC-DOTA in LS174T tumor-bearing nude mice. (Bottom) Percent injected dose per gram (% ID/g) of spleen (▲), kidney (□), lung (◆), and bowel (▽) for ^{111}In -labeled cT84.66-MC-DOTA in LS174T tumor-bearing nude mice. Standard errors of the mean (SE) are indicated; all data were corrected for radiodecay.

the lung (18% ID/g) initially and in the liver as time exceeded 18 h. With the ^{111}In label, hepatic accumulation (11–14% ID/g) eventually exceeded that of ^{90}Y (4–7% ID/g). The highest accumulation, however, was ultimately obtained in the tumor, where values approached 60% ID/g at time points as early as 18–24 h. This level of tumor uptake remained relatively constant out to 96 h for both radiometals.

cT84.66-MC-DOTA Biodistributions. Organ and tissue uptakes for the simultaneous biodistribution of ^{111}In - and ^{90}Y -labeled cT84.66-MC-DOTA are shown in Figures 3 and 4, respectively. As in the case of the DOTA conjugate, blood was the dominant normal tissue out to 48 h. At early time points, lung accumulation was the second highest value with the ^{111}In label (9–17% ID/g). No lung data were obtained with ^{90}Y . Hepatic uptakes for both labels approached 10% ID/g by the end of the experimental period. Tumor accumulation exceeded 60% ID/g for both radiometals at 48 h but began to decrease slowly at later time points.

Comparison of Radiometals. Comparison of the ^{111}In and ^{90}Y uptakes resulting from the cT84.66-DOTA agent revealed that only the liver showed consistently different values at the three common time points (48, 72, and 96 h). At these intervals, hepatic uptake of ^{111}In was consistently higher ($p < 0.05$) than that of ^{90}Y . None of the other six tissues showed more than one point at which the uptakes differed significantly ($p > 0.05$).

Figure 4. Percent injected dose per gram (% ID/g) of blood (●), liver (■), bone (○), and tumor (Δ) for ^{90}Y -labeled cT84.66-MC-DOTA in LS174T tumor-bearing nude mice. Standard errors of the mean (SE) are indicated; all data were corrected for radiodecay.

Figure 5. Concordance correlation analysis of blood data for cT84.66-MC-DOTA. Uptakes are plotted along both axes, with the ^{111}In -labeled cT84.66-MC-DOTA along the horizontal and the ^{90}Y -labeled cT84.66-MC-DOTA along the vertical axis. All time points are considered. The reference line shown is the line of identity.

^{111}In and ^{90}Y uptakes from the cT84.66-MC-DOTA biodistributions were evaluated using the Lin concordance coefficient (16). For blood, bone, tumor, and liver, pooled concordance coefficients were 0.9942, 0.8698, 0.9042, and 0.6460, respectively. Graphical representations of the blood and liver data are shown in Figures 5 and 6. It was noteworthy that the reduced concordance of hepatic samples was a result of greater accumulation of ^{111}In from the MC-DOTA conjugate in liver tissues. Reference lines shown on each of the two graphs are the lines of identity.

Bifunctional Chelate Effects. The biodistribution properties of the cT84.66-DOTA and cT84.66-MC-DOTA conjugates were compared for the ^{111}In label. Five time points were common to the two experiments: 0, 4, 18, 48, and 96 h. Blood values of ^{111}In were generally higher for cT84.66-DOTA than for cT84.66-MC-DOTA throughout, but statistically significant differences were found only at 18 and 48 h. The cT84.66-MC-DOTA conjugate showed significantly greater ^{111}In uptake in the kidneys at two of five times (48 and 96 h).

Corresponding tissue uptakes of ^{90}Y from cT84.66-DOTA and cT84.66-MC-DOTA were also compared. Four tissues were available at two common time points.

Figure 6. Concordance correlation analysis of liver uptake for cT84.66-MC-DOTA. The ^{111}In -labeled cT84.66-MC-DOTA is plotted along the horizontal and the ^{90}Y -labeled cT84.66-MC-DOTA along the vertical axis. All time points are considered. The reference line shown is the line of identity.

At both times, significantly lower ^{90}Y blood levels were obtained with cT84.66-MC-DOTA. No significant differences were observed for hepatic or bone uptakes.

^{90}Y Loss from Macrocyclic and Bone Uptake. Bone uptake of ^{90}Y was compared for the two macrocyclic BCAs using the *t*-statistic. Using data from Figures 2 and 4, no significant differences were seen in bone uptake at the 5% level of confidence. Initial values ($t = 0$) were on the order of 2% ID/g and decreased to 1.07% ID/g by the end of the experiment ($t = 96$ h) for ^{90}Y -labeled cT84.66-DOTA. In the case of cT84.66-MC-DOTA, the experiments were carried out to 120 h, at which time the bone uptake had been further reduced to 0.95% ID/g.

Blood Curve Analyses. Results from the blood curve analyses are given in Table 1. Half-lives were determined from the rate constants by the relationship $T_{1/2} = \ln(2)/k$. The first exponential (k_1) could be estimated, but its error or that of its associated half-life was indeterminate for either macrocycle-antibody conjugate. The primary reason for this difficulty appeared to be a slight inflection in the blood curves for cT84.66-DOTA and cT84.66-MC-DOTA, making eq 1 a more approximate representation for the early time points (18). For both radiometals, it was found that characteristic blood half-times were comparable for cT84.66-DOTA and cT84.66-MC-DOTA. Initial biological half-times were generally on the order of 0.2–0.4 h, while the second biological half-time was much larger, on the order of 40 h or longer. Figure 7 shows the ^{90}Y blood clearance curves for cT84.66-DOTA and cT84.66-MC-DOTA. The curve for the MC-DOTA conjugate was below that of the corresponding DOTA conjugate throughout the time range; significant differences were observed at both common time points (48 and 96 h). It should be noted that ^{111}In -labeled cT84.66-MC-DOTA exhibited faster blood clearance throughout the experimental period, but this difference was only significant at two time points, as described above.

DISCUSSION

Figures 1–4 show that both the amide-linked cT84.66-DOTA conjugate and the cT84.66-MC-DOTA conjugate, with its cleavable imide linker, demonstrate high tumor targeting in the LS174T nude mouse model. These results were consistent for both radiometals. At the 48 h time point, tumor uptake of the DOTA conjugate was

between 3- and 5-fold greater than that of the normal tissue having the next highest accumulation (typically blood or liver). The MC-DOTA conjugate exhibited an approximate 7-fold difference between tumor and the highest normal tissue uptake at 48 h. The absolute magnitude of tumor uptake was between 50 and 70% ID/g for both conjugates. These values were comparable to those observed previously in the LS174T nude mouse model by our group (12) for cT84.66 conjugated with a benzylisothiocyanate derivative of DTPA. Other xenograft data using the Lym-1 (7) and chimeric L6 (9) antibodies conjugated to DOTA derivatives have indicated maximum uptakes approaching only 17 and 18% ID/g, respectively. These lower values may be a result of differences in antibody-antigen affinity constants and/or xenograft models. Tumor masses were not specified in those earlier analyses; our xenograft sizes ranged from approximately 0.1 to 0.2 g at the 48 h time point.

Table 2 contains a summary of our biodistribution comparisons. It was seen that hepatic accumulation of ^{111}In was significantly greater than that of ^{90}Y when either BCA was coupled to cT84.66. Transchelation of ^{111}In by transferrin is one possible mechanism for transport to the hepatocytes, but we found no evidence of this mechanism with either conjugate *in vitro* or *in vivo*. Kinetic stability studies of radiolabeled cT84.66-DOTA in human serum (13) showed that <1% of ^{111}In or ^{90}Y was converted to a low-molecular mass species, possibly a result of hydrolytic (7, 19) or proteolytic cleavage of the chelate from the mAb. Even though MC-DOTA underwent a linker-dependent cleavage reaction under physiological conditions, both released radiometal chelates were found to associate with serum albumin and not with transferrin upon incubation in human serum at 37 °C (14).

Blood samples drawn from animals in this study were also analyzed by gel filtration HPLC. Radiolabeled mAb was the only radioactive species detected in the circulation of mice injected with cT84.66-DOTA (data not shown). Blood of animals receiving cT84.66-MC-DOTA contained radiolabeled antibody and serum albumin, but the label associated with albumin cleared faster than the mAb (data not shown). It is possible that clearance of serum albumin plays a role in hepatic uptake of radiometal from the MC-DOTA conjugate. However, the differences between ^{111}In and ^{90}Y were not dramatic and amounted to a $\leq 5\%$ ID/g increase with ^{111}In . Figure 6 shows this clearly in the concordance analyses of cT84.66-MC-DOTA. The difference between radiometal uptake in hepatic tissues would have to be considered when estimating the patient-absorbed dose resulting from radioimmunotherapy. In that case, the ^{111}In biodistribution is used to predict the ^{90}Y -induced absorbed dose. No other organ system studied showed such consistent disparity between uptake of the two radiolabels. A similar difference has been observed previously using DTPA benzylisothiocyanate as the BCA for ^{111}In and ^{90}Y (12).

For a given radiolabel, several differences were seen in our analyses with variation of the BCA. With ^{111}In , cT84.66-MC-DOTA demonstrated less uptake in the blood at two of the five common time points. Renal accumulation, however, was found to be greater for the MC-DOTA conjugate in two of five time points. In the case of the ^{90}Y (Figure 7), blood clearance was increased by using the chemically labile MC-DOTA, a result similar to that found with ^{111}In . No significant differences of hepatic uptake were observed comparing ^{90}Y -labeled cT84.66-DOTA and cT84.66-MC-DOTA.

Table 1. Results of Two-Exponential Fits of Blood Curves for cT84.66–DOTA and cT84.66–MC-DOTA^a

BCA-label	A ₁ (% ID/g)	A ₂ (% ID/g)	k ₁ (h ⁻¹)	k ₂ (10 ⁻² h ⁻¹)	T _{1/2,1} (h)	T _{1/2,2} (h)
DOTA- ¹¹¹ In	6.47 (6.1)	27.8 (5.3)	3.26 (–)	1.48 (0.44)	0.212 (–)	46.8 (14.0)
MC-DOTA- ¹¹¹ In	11.4 (7.9)	23.5 (6.1)	3.31 (–)	1.60 (0.82)	0.209 (–)	43.3 (22.1)
DOTA- ⁹⁰ Y	42.4 (–)	29.7 (5.0)	1.69 (–)	1.02 (0.33)	0.410 (–)	68.0 (21.8)
MC-DOTA- ⁹⁰ Y	11.2 (6.3)	23.5 (4.9)	3.49 (–)	1.72 (0.70)	0.199 (–)	40.3 (16.3)

^a Standard deviations are shown in parentheses. The symbol (–) denotes that an error could not be estimated with the two-exponential fit of eq 1.

Table 2. Summary of Biodistribution Comparisons

BCA or radiometal	no. of common time points	organ with significant difference (points/total) ^a	times at which difference was significant with <i>t</i> -test	uptake result
DOTA	3	liver (3/3)	48, 72, 96 h	¹¹¹ In > ⁹⁰ Y
MC-DOTA	7	liver (N/A) ^b	N/A ^b	¹¹¹ In > ⁹⁰ Y
¹¹¹ In	5	blood (2/5)	18, 48 h	MC-DOTA < DOTA
		kidney (2/5)	48, 96 h	DOTA < MC-DOTA
⁹⁰ Y	2	blood (2/2)	48, 96 h	MC-DOTA < DOTA

^a Significant when *p* < 0.05. ^b Significant difference was determined by concordance analysis.

Figure 7. Blood clearance curves (% ID/g) for ⁹⁰Y-labeled cT84.66–DOTA (●) and cT84.66–MC-DOTA (○). All data have been corrected for radiodecay. Measured standard errors of the mean (SE) are indicated.

Blood clearance kinetic analyses were consistent (Table 1) with biphasic curves for all combinations of radiometal and BCA. The difference between the two half-times was almost 2 orders of magnitude, with the larger value being between 40 and 70 h. This *T*_{1/2,2} was somewhat smaller than the comparable quantity observed by DeNardo et al. (9). This difference may not be significant, as no errors were quoted for their *T*_{1/2,2} values. By comparing ⁹⁰Y data for our DOTA and MC-DOTA conjugates, we have been able to show that the latter BCA results in a generally lower blood clearance curve (Figure 7). This difference may have important consequences in the bone marrow-absorbed dose in a clinical situation.

The dominant source organ for the bone marrow-absorbed dose in patients cannot be predicted at this time. If we assume that murine data correspond to the human case, it can be anticipated that blood and bone will be contributors. Both BCAs studied here exhibited substantially reduced bone uptake compared to the benzylisothiocyanato-DTPA chelate studied earlier by our group (12). Thus, the use of a macrocycle can be generally justified for minimization of the marrow dose arising from bone as a source organ. As noted above, skeletal uptake of ⁹⁰Y was comparable for both BCAs.

If the bone marrow radiation dose in human subjects proves to be dominated by circulating ⁹⁰Y-labeled antibody, selection of an optimal agent for RIT applications may be accomplished using a direct numerical compari-

son of blood clearance data. Since β^- -induced tissue radiation doses are proportional to the area under that tissue's curve (AUC), it is appropriate to compare the ratios of such areas for the two BCAs studied here. For blood-associated radioactivity, the relevant ratio is AUC-(tumor)/AUC(blood). In the case of cT84.66–MC-DOTA, this value was 4.06, while the comparable magnitude for cT84.66–DOTA was only 3.22. Thus, assuming that the blood activity curve was of primary toxicity significance as a result of the blood-induced marrow dose, the cT84.66–MC-DOTA conjugate appeared to be superior. This result could provide a reason for selecting this conjugate for use in clinical RIT trials.

Polymeric Conjugates of Gd^{3+} –Diethylenetriaminepentaacetic Acid and Dextran. 2. Influence of Spacer Arm Length and Conjugate Molecular Mass on the Paramagnetic Properties and Some Biological Parameters

Richard Rebizak,[†] Michel Schaefer,[‡] and Édith Dellacherie^{*,†}

Laboratoire de Chimie-Physique Macromoléculaire, URA CNRS 494, ENSIC-INPL, BP 451, 54001 Nancy Cedex, France, and Guerbet-GCA, BP 15, 93601 Aulnay-sous-Bois, France. Received August 8, 1997;

Revised Manuscript Received October 5, 1997[©]

Macromolecular conjugates of dextran 40 ($\overline{M}_n = 38$ kg/mol, $\overline{M}_w = 43$ kg/mol) and diethylenetriaminepentaacetic acid (DTPA), capable of complexing Gd^{3+} , were synthesized in order to obtain contrast agents for nuclear magnetic resonance imaging, with long intravascular persistence. As already reported, relaxivity of these macromolecular complexes was greater than that of molecular complexes (2–2.5 times). On the other hand, as relaxivity of paramagnetic agents partially depends on their rotation speed, the influence of the length of the spacer arm inserted between DTPA and dextran was investigated. Various conjugates with spacer arms comprised of methylenic chains $-(\text{CH}_2)_n-$ with varying lengths ($2 \leq n \leq 6$) were prepared. The result was that, whatever the distance between DTPA and dextran, all of the Gd^{3+} -complexed polymeric conjugates with similar DTPA content (0.6–0.8 mmol/g) exhibited, at 20 MHz, about the same relaxivity values. On the other hand, in the same way, no significant effect of the molecular masses ($\overline{M}_n$ between 166 and 224 kg/mol and $\overline{M}_w$ between 332 and 865 kg/mol) of the polymeric conjugates on relaxivity were observed. Toxicity studies carried out on mice, showed very similar LD_{50} values whatever the spacer arm and molecular mass of the macromolecular conjugates. Finally the urinary excretion studied on rats (after 4 h) and on rabbits (after 24 h) was relatively low (15–20% of the administered dose), and, as expected, the lower values were obtained with the higher molecular mass conjugates.

INTRODUCTION

The usefulness of paramagnetic metals to decrease the proton spin relaxation times (T_1 and T_2) of water molecules was discovered in 1948 by Bloch (1). Then, Solomon (2) and Bloembergen et al. (3) contributed to establishing the theoretical relations between the nature of paramagnetic elements (metallic ion or molecular complex) and T_1/T_2 . The most commonly used paramagnetic metals are Mn^{2+} , Fe^{3+} , and Gd^{3+} because of the great number of unpaired electrons on the last electronic orbital, which results in strong dipolar interactions between the electronic and protonic spins.

Because of their high toxicity, these elements have to be used under the form of very stable complexes. In fact, the LD_{50} values of these ions, intravenously injected in rats, are very low, respectively 0.22, 1.6, and 0.5 mmol kg^{-1} for MnCl_2 , FeCl_3 , and GdCl_3 (4). At present, the gadolinium complexes used in NMR imaging in humans are based on two types of structures: gadolinium–diethylenetriaminepentaacetic acid (GdDTPA^{2-}) and gadolinium–tetraazacyclododecanetetraacetic acid (GdDOTA^-). Their thermodynamic stability constants are, respectively, $10^{22.5}$ (5) and 10^{28} L mol^{-1} (6). Studies carried out on healthy volunteers and patients showed

that, when injected, these complexes were well tolerated and that risks of anaphylactic shocks were very low (7). However cation complexation by DTPA or DOTA leads to a decrease in the amount of water molecules in the first hydration shell of the ion and consequently to a decrease in the transversal (r_2) and longitudinal (r_1) relaxivity values. Thus, Gd^{3+} that binds 9 and 1 water molecules in its first hydration shell, when it is respectively free in solution and complexed by DTPA, is characterized by r_1 values of respectively 9.1 and 4.1 $\text{mM}^{-1} \text{s}^{-1}$ at 20 MHz (4).

Besides a relatively low relaxivity, these molecular complexes present another disadvantage that is their rapid removal from the blood vessels through the vascular interstitium, which makes it necessary, in a prolonged clinical examination, to inject several doses. For example, in humans, 50% of GdDTPA^{2-} has been excreted 90 min after the injection, and its blood concentration is only about 30% of the initial administered dose after 5 min (8). To increase the complex *in vivo* half life, many authors have focused their attention on the synthesis of macromolecular paramagnetic compounds, generally obtained by coupling GdDTPA^{2-} or GdDOTA^- to different types of macromolecules or polymers such as polypeptides (9, 10), proteins (8, 11–16) and polysaccharides (17–21).

Besides the expected increase in the intravascular persistence, the use of macromolecules as contrast agent carriers leads to another benefit. In fact, increasing the molecular size of the paramagnetic element improves the transversal and longitudinal relaxivities by reducing the rotation speed of the gadolinium complex (4). Moreover,

the choice of a particular macromolecule as complex carrier, for example a labeled monoclonal antibody specific to a particular tumor line, can contribute to target the paramagnetic agent (16).

This paper describes the properties of macromolecular conjugates with various molecular masses obtained by coupling DTPA to a polysaccharide dextran with a M_w of about 40 kg/mol, well known for its biocompatibility and its biodegradability. Indeed, it is often used as a plasma expander to prevent blood platelet aggregation (22). DTPA was bound to dextran 40 via spacer arms of various lengths. This paper reports on the influence of the spacer arm length and of the conjugate molecular mass and size on the r_1 and r_2 relaxivity values of the macromolecular Gd^{3+} -complexes. Some results of *in vivo* toxicity and urinary excretion experiments are also commented on with respect to the effect of these parameters.

EXPERIMENTAL PROCEDURES

Syntheses. The polymer synthesis previously described in details (23) was achieved in three steps (Figure 1). The first consisted in the synthesis of carboxymethyl dextran (CMD) by reacting chloroacetic acid with dextran hydroxyl groups in aqueous medium. In the second step, the carboxylate groups of CMD were allowed to react with a linear diamine $\text{NH}_2(\text{CH}_2)_n\text{NH}_2$, with $2 \leq n \leq 6$ by means of a peptide coupling agent, 2-ethoxy-1-(ethoxycarbonyl)-1,2-dihydroquinoline (EEDQ), to give CMDA_n . Finally, three different experimental procedures were used to bind DTPA to CMDA_n in order to obtain CMDA_n -DTPA (23). In the two first ones, DTPA bisanhydride (DTPAba) was used, and in the third, DTPA was activated in the form of succinimidic ester (DTPA-ONSu) by means of dicyclohexylcarbodiimide (DCC) and *N*-hydroxy-succinimide (HONSu). In the first method using DTPAba that is previously prepared according to a method deriving from that of Eckelman and Karesh (24), 1 g of CMDA_n (1.7 mmol of NH_2/g) was dissolved in 30 mL of water. Then DTPAba (11 g, 30.8 mmol) was progressively added to the solution while maintaining the pH between 8 and 10. In the second procedure, 1 g of CMDA_n (1.7 mmol of NH_2/g) was dissolved in 10 mL of water. Then, 1/20 of the CMDA_n solution and 1/20 of the total DTPAba amount (11 g) were successively added to 20 mL of water. During this step, the pH was kept constant at 10 by means of 6 N NaOH. When the pH was stabilized, the operation was repeated until total

consumption of all of the reagents. The third method used DTPA-ONSu: DTPA (8 g, 20.3 mmol) was dissolved in 10 mL of acetonitrile in the presence of triethylamine (11.3 mL, 81.3 mmol). Then, 2.87 g (14.4 mmol) of DCC and 1.66 g (14.4 mmol) of HONSu were added. After 90 min of reaction, the solution was filtered to get rid of the precipitated urea, and the filtrate was dropped into a solution of 1 g of CMDA_n (1.7 mmol of NH_2/g) in 10 mL of distilled water while maintaining a constant pH at 10. The solution was stirred for 24 h, and then acetonitrile was removed by rotative evaporation. All of the final polymeric derivatives were purified by dialysis against water and recovered by freeze-drying (23). Finally, CMDA_n - GdDTPA^- was prepared as already described (23) from CMDA_n -DTPA and $\text{GdCl}_3 \cdot 6\text{H}_2\text{O}$, at pH 6.5 using a $\text{Gd}^{3+}/\text{DTPA}$ molar ratio of 1.

Physicochemical Methods. The DTPA contents of the various conjugates were determined by a reverse complexometric method using EDTA as described elsewhere (23). M_n and M_w were determined by size exclusion chromatography coupled to low angle laser light scattering (SEC-LALLS). The LALLS detector was a Chromatix KMX6 (Milton Roy, Riviera Beach, FL) and the refractometric detector, a Waters R 410 model (Milford, MA). The two SEC columns were a TSK PW G 4 000 and a TSK PW G 6 000 (Touzart et Matignon, Courtaboeuf, France; 7.8 mm $\times$ 30 cm) and were connected in series. The eluent was a 0.15 M NaNO_3 water solution.

The polymer hydrodynamic size distribution profiles were determined by high performance size exclusion chromatography (HP-SEC). The experiments were carried out with a system equipped with a refractometric detector (Waters R 410) and with a Lichrosorb Diol Si 300 column (Merck-Clévenot, Chelles, France; 1 cm $\times$ 30 cm). The eluent was 0.05 M phosphate buffer, pH 7.2.

The values of longitudinal (r_1) and transversal (r_2) relaxivity were measured at 20 MHz and 37 °C with a Minispec PC 20 (Bruker, Karlsruhe, Germany). The NMRD (nuclear magnetic relaxation dispersion) profiles that represent the dependence of longitudinal relaxivity on magnetic field were recorded at 37 °C, between 0.1 and 50 MHz with an IBM Research field cycling relaxometer using an inversion recovery pulse sequence (Mons University, Belgium).

Evaluation of the *in Vivo* Toxicity and of the Urinary Excretion. LD_{50} experiments were carried out on mice (SWISS OF1, Iffa Credo). A water solution of each paramagnetic conjugate was intravenously injected in animals at a rate of 2 mL/min. All of the administered solutions had the same gadolinium concentration (0.1 M). The LD_{50} values were determined by increasing the administered solution volume according a geometric progression and keeping the value smaller than 50 mL/kg. The final value of LD_{50} was calculated by the method of Reed and Muench (25) from the results obtained for five animals per injected dose.

Urinary excretion was determined on anesthetized Wistar rats and New Zealand rabbits after the injection of a 0.1 M gadolinium solution (0.05 mmol Gd/kg). The urine was regularly removed by bladder catheterization, and the gadolinium content of the total volume collected after 24 h and 4 h, respectively, on rats and rabbits, was determined.

RESULTS AND DISCUSSION

Polymer Chemical Structure. The synthesized CMD sample contained 0.6 mol of COONa/mol of glucose

Figure 2. NMRD profiles of water proton molecules for GdDTPA²⁻ (◆), GdDOTA⁻ (○), and CMDA₂-GdDTPA⁻ with 0.60 mmol of GdDTPA/g of CMDA₂-DTPA (■). Profiles obtained with a field cycling relaxometer at 37 °C.

unit. Different CMDA_n derivatives with linear diamines having between 2 and 6 carbons (NH₂(CH₂)_nNH₂, 2 ≤ *n* ≤ 6) were prepared and whatever the *n* value, the different polymers had similar amine and residual carboxylate contents, that is 0.3 mol of NH₂/mol of glucose unit and 0.3 mol of unsubstituted COONa/mol of glucose unit.

The various CMDA_n-DTPA conjugates prepared from DTPAba by the first method (see Experimental Part) had about the same DTPA content, between 0.5 and 0.6 mmol of DTPA/g, whatever the length of the spacer arm. The DTPA content of CMDA_n-DTPA synthesized by the second method using DTPAba was about 0.7 mmol DTPA/g, i.e. slightly higher than those of the derivatives prepared by the first method. The method using DCC and HONSu led to the highly substituted CMDA_n-DTPA sample with about 0.8 mmol DTPA/g. As already noted (23) these values of DTPA contents correspond only to the dextran-monoamidified DTPA molecules since they were determined by a EDTA back titration procedure.

Effect of Polymer on Relaxivity: Comparison between the NMRD Profiles of Molecular and Macromolecular Complexes. Figure 2 shows the NMRD profiles (*r*₁), between 0.1 and 50 MHz, of two molecular complexes GdDTPA²⁻ and GdDOTA⁻ and of one macromolecular complex, CMDA₂-GdDTPA⁻ (0.60 mmol of DTPA/g of CMDA₂-DTPA). For the whole range of frequencies, it is observed that CMDA₂-GdDTPA⁻ *r*₁ relaxivity is greater than that of GdDTPA²⁻. Moreover, while between 1 and 50 MHz, relaxivity of GdDTPA²⁻ regularly decreases from 6.3 to 3.5 mM⁻¹ s⁻¹, that of the polymer decreases from 9.8 to 8.5 mM⁻¹ s⁻¹ between 1 and 6 MHz and then increases up to a maximum of 10.2 mM⁻¹ s⁻¹ for a frequency of 40 MHz. Thus at 20 MHz, an usual frequency of imaging, CMDA₂-GdDTPA⁻ relaxivity is 2.5 times as great as that of GdDTPA²⁻, when at low frequency, below 2 MHz, polymer relaxivity is only 1.5 times as great as that of GdDTPA²⁻. The increase in relaxivity of paramagnetic agents (proton relaxation enhancement, PRE) upon fixation to macromolecular species has already been reported and explained in other works (4, 10, 11) and mainly results from the increase in the rotational correlation time of the paramagnetic metal chelate when bound to a slowly tumbling macromolecule.

Table 1. Relaxivity Values of Various CMDA_n-GdDTPA⁻ Conjugates as a Function of the Spacer Arm Length -(CH₂)_n-

<i>n</i>	DTPA content, mmol/g of CMDA _n -DTPA	<i>r</i> ₁ , ^b mM ⁻¹ s ⁻¹	<i>r</i> ₂ , ^b mM ⁻¹ s ⁻¹

6	0.62	8.9	10.8

^a The CMDA_n-DTPA samples were synthesized according to the first DTPAba method (see Experimental Part). ^b Longitudinal (*r*₁) and transversal (*r*₂) relaxivity values were measured at 20 MHz, 37 °C.

Table 2. Longitudinal (*r*₁) and Transversal (*r*₂) Relaxivity Values of CMDA_n-GdDTPA⁻ Samples of Various Molecular Masses

sample ^a number	DTPA content, mmol/g of CMDA _n -DTPA	<i>M</i> _n , ^b kg/mol	<i>M</i> _w , ^b kg/mol	<i>r</i> ₁ , ^c mM ⁻¹ s ⁻¹	<i>r</i> ₂ , ^c mM ⁻¹ s ⁻¹
1	0.60	224	865	10.4	12.0
2	0.76	166	332	10.1	10.7
3	0.62	183	706	9.3	11.2
4	0.66	154	348	9.9	12.0

^a Samples 1–4 were synthesized as described in the text. Samples 1 and 2 have a spacer arm with *n* = 2 and samples 3 and 4 a spacer arm with *n* = 6. ^b *M*_n and *M*_w were measured by SEC-LALLS. ^c Relaxivity values were measured at 20 MHz, 37 °C.

On the other hand, it is known (26) that between 0.1 and 1 MHz, relaxivity decreases with the paramagnetic element symmetry. *r*₁ relaxivity of GdDOTA⁻ is thus higher than that of GdDTPA²⁻ in this frequency range (Figure 2). As symmetry of GdDTPA²⁻ decreases when it is bound to dextran, relaxivity of CMDA_n-GdDTPA⁻ below 1 MHz should be lower than that of free paramagnetic metal chelate. However, an opposite result is seen in Figure 2. Such a result was also obtained at low frequencies (≤0.4 MHz) by Aime (27) who observed a greater relaxivity for a complex of Gd³⁺ with monoamidified DOTA than for GdDOTA⁻. The conclusion was that the increase in the ligand molecular mass, resulting from the amidification of one of the four carboxylic functions, compensated for the lost of symmetry provoked by DOTA amidification.

Effect of the Spacer Arm Length on Relaxivity. As already mentioned (11), the PRE observed when paramagnetic species are bound to macromolecules depends on how rigidly the chelate is attached to the macromolecule. Thus, as increasing the length of the spacer arm (-HN(CH₂)_nNH-) leads to an increase in the motional freedom of the paramagnetic element, an effect of this increase on *r*₁ and *r*₂ relaxivity values was expected. However, whatever the length of the spacer arm, the various CMDA_n-GdDTPA⁻ samples were characterized by similar *r*₁ and *r*₂ values (Table 1) which means that the motional freedom of the paramagnetic species resulting in the spacer arm motions is not a dominating factor in the relaxation phenomena. As already proposed by Meyer et al. (29), it can thus be concluded that, since it is known that in dextran paramagnetic derivatives the rapid rotation of the glucose units within the polymer plays a significant role in the relaxation phenomena, the chemical modification of the dextran backbone results in a greater effect on relaxivity than the lengthening of the spacer arm.

Influence of the CMDA_n-GdDTPA⁻ Molecular Masses and Sizes on Relaxivity. Table 2 shows the *M*_n and *M*_w molecular masses of several CMDA_n-DTPA

Table 3. Values of LD₅₀ and of Urinary Excretion for Two CMDA_n-GdDTPA⁻ Samples^a

<i>n</i> value	DTPA content mmol/g of CMDA _n -DTPA	$\overline{M}_n$, kg/mol	LD ₅₀ , mmol of Gd/kg	urinary excretion after 4 h (rats), %	urinary excretion after 24 h (rabbits), %
2	0.74	132	2.2	22.7 ± 3.0	20.3 ± 5.4
6	0.68	154	2.4	15.0 ± 1.4	18.6 ± 0.4

^a LD₅₀ experiments were carried out with mice and urinary excretion, with rats and rabbits, under conditions described in the Experimental Part. LD₅₀ of free GdDTPA²⁻ under the same conditions was 5.8 mmol of Gd/kg. The results given for urinary excretion are relative to the total administered dose.

Figure 3. HP-SEC elution profiles of CMDA_n-DTPA samples 1–4 (see Table 2). (a) Samples 1 (—) and 2 (---). (b) Samples 3 (—) and 4 (---) on a Si 300 diol column. Eluent: 0.05 M phosphate buffer, pH 7.2. Refractometric detection. Flow rate: 0.7 mL/min.

conjugates prepared with diaminoethane ($n = 2$, samples 1 and 2) and with diaminoethane ($n = 6$, samples 3 and 4). Sample 2 was synthesized by means of DCC and HONSu, and the three other ones were obtained by using DTPAba. Samples 1 and 3 were prepared following method 1 and sample 4 following method 2 (see Experimental Part). As it is seen in Table 2, sample 1 has $\overline{M}_n$ and $\overline{M}_w$ values greater than sample 2 does, and the $\overline{M}_n$ and $\overline{M}_w$ values of sample 3 are greater than those of sample 4. These results are corroborated by those obtained from the HP-SEC analyses (Figure 3) where it can be seen that the proportions of the elution peaks in the void volume are less large for samples 2 and 4 than for samples 1 and 3. Consequently, samples 2 and 4 have, in average, hydrodynamic sizes smaller than those of samples 1 and 3. The CMDA_n-DTPA molecular sizes and masses ($\overline{M}_n$, $\overline{M}_w$) are too great to only result from

the coupling of DTPA to CMDA_n. In fact, whatever the CMDA_n-DTPA conjugate and the spacer arm length, $\overline{M}_n$ and $\overline{M}_w$ are respectively higher than the theoretical ones which can be calculated for CMDA_n-DTPA polymers with the same chemical composition. These theoretical $\overline{M}_n$ and $\overline{M}_w$ are, respectively, 95 and 142 kg/mol. The difference between the experimental and calculated values thus results from some cross-linking reactions which can occur during CMDA_n-DTPA synthesis to a more or less large extent according to the procedure employed. The cross-linking mechanism results from the reaction between one DTPAba molecule or one DTPA molecule polyactivated by DCC and HONSu, with at least two amine functions carried by different CMDA chains. According to the molecular masses and HP-SEC profiles, the fraction of dextran-diamidified DTPA is smaller for CMDA_n-DTPA samples 2 and 4 than for samples 1 and 3, and taking into account the absolute values of $\overline{M}_n$ and $\overline{M}_w$ for the last ones, it is clear that those samples contain cross-linked fractions, i.e. large molecular size fractions. However, relaxivity of these conjugates is quite similar to that of the smaller molecular size samples (2 and 4) which means that relaxivity of GdDTPA linked to high molecular mass chains must be of the same order as that of GdDTPA bound to smaller molecular size chains.

For molecular complexes with molecular masses between 400 and 900 g/mol, it was shown (28) that longitudinal relaxivity at 20 MHz regularly increased with molecular mass. On the other hand when a paramagnetic element is bound to a macromolecule, its relaxivity is also increased. In all of the cases, the improvement of relaxivity is partially assigned to the slowing down of the paramagnetic agent rotation motion because of the increase in the size of the whole molecule. Nevertheless, a stability of the relaxivity values was observed for the CMDA_n-DTPA samples while their molecular masses increased. Similar observations were done by Spanoghe et al. (10) on polylysines labeled with GdDTPA with molecular masses between 7.7 and 288 kg/mol. The conclusion was that, while binding the molecular paramagnetic agent to a slow tumbling macromolecule results in an increase of its rotational correlation time and consequently of relaxivity, there is no interest in further lengthening the polymer chain because the electron spin relaxation time and the exchange relaxation time are sufficiently short to preclude any additional increase in correlation time (17).

In Vivo Toxicity and Urinary Excretion of Macromolecular Paramagnetic Conjugates. The LD₅₀ values of two conjugates differing by the spacer arm length ($n = 2$ and $n = 6$) are shown in Table 3. These values are very close to each other (2.2–2.4 mmol of Gd/kg) and smaller than that of the molecular complex (5.8 mmol of Gd/kg under the same conditions). On the other hand another CMDA₆-GdDTPA⁻ conjugate with 0.3 mmol of DTPA/g of polymer, prepared from dextran 20

(M_w about 20 kg/mol) instead of dextran 40, exhibited a LD_{50} of 2.9 mmol/kg (29) which means that in this type of conjugate, neither the molecular mass nor the spacer arm length have an effect on the conjugate toxicity. Furthermore, the LD_{50} values shown in Table 3, are higher than those found for other dextran-GdDTPA⁻ samples described by Meyer et al. (29). These samples were prepared by procedures involving dextran periodate oxidation or dextran epichlorohydrin activation, and these methods do not introduce carboxylate functions on the dextran backbone. The difference in toxicity between the conjugates described in this paper and those of Meyer et al. (29) can thus be ascribed to the difference in the chemical structure of the polymeric backbones and probably to the presence of an excess of free carboxylate functions on the conjugates of this paper.

Finally, as shown in Table 3, the urinary excretion of the two conjugates ($n = 2$ and $n = 6$) is relatively low, respectively, 22.7 and 15% of the administered dose for rats after 4 h and 20.3 and 18.6% for rabbits after 24 h. These results have to be compared to those obtained by Bligh et al. [19] who found that 2 h after a GdDTPA²⁻ injection in rats, the urinary excretion was about 90% of the injected dose. This comparison shows that binding GdDTPA²⁻ to dextran leads to a significant decrease in the urinary excretion of gadolinium as a consequence of the increase in the paramagnetic complex size and as expected the lower values were obtained with the higher molecular mass conjugates.

In conclusion, it was shown that dextran-linked DTPA could be complexed with Gd³⁺ and that the r_1 and r_2 relaxivity values of resulting complexes, between 0.1 and 50 MHz, was not influenced by the length of the spacer arm (between two and six methylene groups) inserted between DTPA and the polysaccharidic backbone. On the other hand, it was also shown that coupling GdDTPA²⁻ to a polymer such as dextran 40 had a great influence on relaxivity as for the macromolecular complexes, r_1 and r_2 at 20 MHz were 2.5 times as great as those of free GdDTPA²⁻. However, in the range of the studied high molecular masses (M_n between 166 and 224 kg/mol) no increase in relaxivity was observed when increasing the conjugate molecular mass. Anyway, even these polymeric conjugates carrying some diamidified DTPA ligands (resulting from cross-linking reactions) that, according to Sherry's work (13), have less affinity for Gd³⁺ than monoamidified DTPA, exhibit interesting paramagnetic properties. As the urinary excretion is greatly decreased compared to that of free GdDTPA²⁻, which must lead to a longer intravascular persistence, these conjugates can be regarded as potential contrast agents which could be used in a low dose in magnetic resonance imaging.

ACKNOWLEDGMENT

This work was supported by a CIFRE grant (Société Guerbet-GCA, Aulnay-sous-Bois, France, and ANRT, France). We thank Mrs. T. Geoffroy for her helpful technical assistance in LALLS analyses. We also thank Prof. R. N. Muller (Mons University, Belgium) for his insight concerning the relaxivity values.

Streptavidin in Antibody Pretargeting. Comparison of a Recombinant Streptavidin with Two Streptavidin Mutant Proteins and Two Commercially Available Streptavidin Proteins

D. Scott Wilbur,^{*,†} Patrick S. Stayton,[‡] Richard To,[‡] Kent R. Buhler,[§] Lisa A. Klumb,[‡] Donald K. Hamlin,[†] James E. Stray,[§] and Robert L. Vessella[§]

Departments of Radiation Oncology, Urology, and Bioengineering, University of Washington, Seattle, Washington 98195. Received August 11, 1997; Revised Manuscript Received October 10, 1997[®]

In this investigation, a comparison of wild type recombinant streptavidin (r-SAv) with two genetically engineered mutant r-SAv proteins was undertaken. The investigation also included a comparison of the r-SAv with two streptavidin (SAv) proteins from commercial sources. In vitro characterization of the SAv proteins was conducted by HPLC, SDS–PAGE, IEF, and electrospray mass spectral analyses. All SAv proteins studied appeared to be a single species by size exclusion chromatography (HPLC) and SDS–PAGE analyses, but multiple species were noted in the IEF and MS analyses. In vivo comparisons of the SAv proteins were accomplished with dual isotope-labeled SAv in athymic mice. In an initial experiment, tissue localization of r-[¹³¹I]SAv directly radiolabeled using chloramine-T was compared with r-SAv radiolabeled with the *N*-hydroxysuccinimidyl *p*-iodobenzoate conjugate ([¹²⁵I]-PIB), a radioiodination reagent that has been shown to result in iodine-labeled proteins which are stable to in vivo deiodination. The data obtained indicated that there is little difference in the distribution (except kidney localization) when r-SAv labeled by the two methods. Data obtained from comparison of r-[¹³¹I]SAv with a disulfide-stabilized r-SAv mutant (r-SAv-H127C), a C-terminal cysteine-containing r-SAv mutant (r-[¹²⁵I]SAv-S139C), and two ¹²⁵I-labeled SAv proteins obtained from commercial sources indicated that their distributions were quite similar, except the kidney concentrations were generally lower than that of r-[¹³¹I]SAv. On the basis of the similar distributions of the SAv proteins studied, it appears that the r-SAv mutants may be interchanged for the (wild type) r-SAv in pretargeting studies. Further, the similarity of distributions with two commercially available SAv proteins suggests that the results obtained in our studies and those of other groups may be directly compared (with consideration of animal model, sacrifice time, etc.).

INTRODUCTION

A monoclonal antibody-based method of delivering radionuclides to cancer tissue for diagnosis and/or therapy termed tumor "pretargeting" is under investigation by a number of research groups (1–14). In tumor pretargeting, an antibody conjugate is injected into a patient and allowed to localize at the tumor, and then a radiolabeled molecule which binds avidly with the antibody conjugate is administered in a "two-step" or "three-step" procedure (3). Due to the very high affinity of biotin for the proteins streptavidin (SAv¹) and avidin (i.e. 10^{13} – 10^{15} M⁻¹) (15, 16), combinations of these molecules with monoclonal antibodies have formed the basis for a large number of

the investigations conducted in pretargeting research. In addition to the high affinity of biotin for SAv and avidin, the biotin/(strept)avidin system is particularly attractive for application to cancer therapy as SAv and avidin are tetrameric proteins which have the capacity to bind four molecules of biotin (16). This multi-biotin binding nature of SAv and avidin is of particular interest as it provides the potential for increasing the quantity of radioactivity localized on cancer cells. Thus, a major focus of our research effort is directed at developing a method for using the multi-biotin binding capacity of SAv to maximize the amount of radioactivity delivered to cancer cells in vivo. In the approach under investigation, the first step is to pretarget a biotinylated antibody [or antibody–(strept)avidin conjugate] to a tumor, and then alternate administrations of SAv and a radiolabeled cross-linking biotin molecule are given to increase the amount of radioactivity localized at the tumors (14).

A key component of our investigations of antibody-based tumor pretargeting is the biotin binding protein SAv. Although SAv is similar in structure to avidin (16), it has a longer half-life in blood than avidin (17). The longer blood half-life is primarily due to the fact that SAv is not glycosylated (17–19). Interaction of glycosylation sites on proteins with asialoglycoprotein receptors on liver cells results in rapid clearance from blood (20). Importantly, it has been demonstrated that the longer blood half-life of SAv results in higher concentrations in tumor xenografts implanted in athymic mice (14, 18).

[®] Abstract published in *Advance ACS Abstracts*, December 15, 1997.

¹ Abbreviations: PIB, *p*-iodobenzoate; ChT, chloramine-T; cpm, counts per minute; DTT, dithiothreitol; EDTA, ethylenediaminetetraacetic acid; ESMS, electrospray mass spectrometry; NEM, *N*-ethylmaleimide; % ID/g, percent injected dose per gram; PMSF, phenylmethanesulfonyl fluoride; r-SAv(s), recombinant streptavidin(s); rt, room temperature; SAv(s), streptavidin(s); T/B, tissue-to-blood.

Deglycosylation of avidin produces a tetrameric biotin binding protein which is similar to SAV in its in vivo clearance (19); however, we chose to use a recombinant SAV (r-SAV) in our studies. The r-SAV employed is obtained from bacterial (*Escherichia coli*) expression and is primarily a single protein with a discrete molecular size (21). SAV obtained through recombinant molecular biology methods was chosen over SAV obtained from commercial sources for use in our studies as production by this method permits specific alterations in the SAV molecule by site-directed mutagenesis (21). In fact, site-directed mutagenesis of r-SAV has allowed for the production of unique r-SAV mutants which may have broad application in biotin/(strept)avidin technology (22–24), as well as in tumor pretargeting. For example, one of the r-SAV mutants produced, r-SAV-H127C,² has two intersubunit disulfide bonds that were designed to provide stabilization of the tetramer from dissociation in vivo. Another r-SAV mutant of interest in our pretargeting studies, r-SAV-S139C,² was obtained by substitution of a cysteine residue for the serine residue at the C-terminal end of the polypeptide subunit. The r-SAV-S139C mutant was designed to allow site-specific conjugations at a location in the molecule that is not adjacent to the biotin binding pockets.

Many other investigators have reported the use of SAV in tumor pretargeting (4, 7, 8, 11–13, 25–28). In reviewing the literature, we were surprised to note the large variation in the biodistribution data of radiolabeled SAV which had been previously reported, with the most striking differences being in kidney localization. Indeed, reported kidney concentrations have ranged from 1% injected dose per gram (% ID/g) to over 100% ID/g. The reported wide variation in the in vivo characteristics, particularly kidney localization of SAV used in tumor pretargeting studies, prompted us to compare the in vitro and in vivo characteristics of two SAV mutants, r-SAV-H127C and r-SAV-S139C, with those of the r-SAV presently used in our pretargeting studies. Since previously reported studies were conducted with SAV obtained from several different commercial sources, we chose to include two commercially available SAV proteins³ in the comparison studies. In vitro comparison of the SAV proteins was obtained by conducting HPLC, SDS–PAGE, IEF, and mass spectrometric analyses. In vivo comparison of radiolabeled SAV was obtained in dual isotope experiments. Direct comparison of sets of biodistribution data was obtained by co-injection of r-[¹³¹I]SAV with each of the other radiolabeled ([¹²⁵I]) SAV proteins in athymic mice.⁴ The results of our comparison of SAV proteins are described herein.

EXPERIMENTAL PROCEDURES

General. All chemicals from commercial sources were analytical grade or better and were used without further

purification. Chloramine-T (ChT) was obtained from Sigma Chemical Co. (St. Louis, MO). SAV proteins were obtained from Boehringer Mannheim (CS1,³ lot 133816721, Indianapolis, IN) and from CALBIOCHEM (CS2,³ lot B12651, La Jolla, CA). Reconstitution of the commercial SAV proteins in water was carried out as recommended by the package inserts.

The radioisotopes, Na¹²⁵I and Na¹³¹I, were purchased from NEN/Dupont (Billerica, MA) as high-concentration/high-specific activity radioiodide in 0.1 N NaOH. Measurement of ¹²⁵I and ¹³¹I was accomplished on a Capintec CRC-15R or a Capintec CRC-6A Radioisotope Calibrator. Dual isotope counting of tissue samples was accomplished in a LKB 1282 γ counter with the following window settings: channels 35–102 (20–90 keV) and channels 165–185 (300–450 keV) when ¹²⁵I and ¹³¹I were counted together. When dual isotope counting was conducted, all cpm measurements of ¹²⁵I were corrected for spillover (13.5%) from the ¹³¹I emissions.

Recombinant Protein Gene Design, Expression, and Purification. The design of the recombinant core SAV gene and the construction of the r-SAV-H127C mutant have been described previously (29). The r-SAV-S139C mutant was created by cassette mutagenesis. The cassette for the r-SAV-S139C gene was constructed from oligonucleotides spanning the 5' *Mlu*I restriction enzyme site and the 3' *Hind*III site. The sequence for the last serine residue, S139, was changed from TCC to TGC, thus encoding a cysteine residue. The S139C cassette was annealed and ligated into a pUC18 construct containing the truncated r-SAV at the *Mlu*I/*Hind*III sites. Colonies containing the *Mlu*I/*Hind*III insert were selected and sequenced to confirm the production of the S139C coding sequence. The mutant r-SAV-S139C sequence was excised from the pUC18 vector by *Nde*I and *Hind*III digestion and ligated into the pET21a T7 expression vector (Novagen, Inc., Madison, WI).

The r-SAV proteins were expressed and purified as previously described (29). Briefly, r-SAV was initially isolated as insoluble inclusion bodies and dissolved in 6 M guanidine·HCl. The guanidine·HCl also contained 10 mM dithiothreitol (DTT) when the cysteine mutants were dissolved. r-SAV was subsequently refolded in 0.05 M Tris·HCl (pH 7.6), 0.1 M NaCl, 0.005 M EDTA, and 0.1 mM phenylmethanesulfonyl fluoride (PMSF). r-SAV-S139C was refolded in the presence of 1 mM DTT to prevent disulfide bond formation. Refolded streptavidin (100 mg or less) was exchanged into binding buffer (pH 11, 50 mM Na₂CO₃ and 500 mM NaCl) and concentrated to a volume of about 30 mL using an ultrafiltration cell (Amicon, Beverly, MA). The concentrated protein solution was applied to a 20–25 mL iminobiotin–agarose column (Pierce, Rockford, IL) that had been pre-equilibrated with at least 125 mL of binding buffer. After washing with an additional 100–150 mL of binding buffer, the protein was eluted with a low-pH aqueous solution (pH 3, 100 mM HOAc). The flow-through was collected in 10 mL fractions, and the streptavidin content was checked by UV. Those fractions containing protein (50–60 mL) were pooled, immediately exchanged into a phosphate buffer (pH 7, 50 mM sodium phosphate and 100 mM NaCl), and concentrated via ultrafiltration. Recovery yields of 70–90% of the initial amount of refolded protein were obtained.

Protein Characterization. Protein concentrations in aqueous solution were estimated using the Beer's law equation, wherein the measured absorbance in water at

² The notations for site-directed streptavidin mutants studied, r-SAV-H127C and r-SAV-S139C, include the amino acid number (127 or 139; based on native streptavidin numbering) and the identity of the amino acid substitution [i.e. cysteine (C) for histidine (H) or serine (S)].

³ To limit the extent of the investigation, two commercial sources were chosen to be representative of commercially available streptavidin. Commercial source 1 (CS1) was Boehringer Mannheim (Indianapolis, IN), and commercial source 2 (CS2) was CALBIOCHEM (La Jolla, CA).

⁴ Athymic mice were used to allow correlation of data from this investigation with data obtained in previous and planned studies employing athymic mice bearing human tumor xenografts.

280 nm was divided by 2.56 L/g.⁵ Characterization of all SAV proteins included IEF, SDS-PAGE, HPLC, and protein electrospray mass spectrometry (ESMS) analyses. IEF and SDS-PAGE analyses were conducted using a PhastSystem electrophoresis apparatus (Pharmacia Biotech, Uppsala, Sweden). Conditions used to conduct the IEF are described in the legend of Figure 1. Reducing denatured and nondenatured SDS-PAGE analyses were conducted on 12.5% homogeneous gels (see Supporting Information). SDS-PAGE analyses were also carried out using precast MiniProtein 10 to 20% gradient gels (BioRad Inc., Hercules, CA) with a discontinuous buffer system. Native PAGE was performed by omitting SDS during the heat denaturation, and in the sample application buffer and the gel running buffer. Mass spectral analyses were obtained for all SAV proteins, except the r-SAV-S139C. ESMS of protein samples was performed on an API-III electrospray mass spectrometer (PE Sciex, Thornhill, ON) or a VG Quattro II tandem quadrupole mass spectrometer (VG BioTech, Cheshire, U.K.). Protein concentrations were 20–60 μ M (subunit) after extensive dialysis against distilled water (dialysis membrane MWCO of 10 000), with 0.1% formic acid added just prior to the ESMS. Mass spectra for r-SAV, SAV-CS1, and SAV-CS2 are provided in the Supporting Information. Mass spectral data have been previously published for r-SAV-H127C (29).

HPLC separations of nonlabeled SAV proteins were conducted on a system consisting of a Hewlett-Packard 1050 Multiple Wavelength Detector (280 nm), an isocratic pump, and a TSK-GEL G3000SW size exclusion column (7.5 mm $\times$ 600 mm, 10 μ m; TosoHaas, Montgomeryville, PA). The mobile phase was an aqueous solution containing 50 mM potassium phosphate (pH 6.8), 300 mM NaCl, 1 mM EDTA, and 1 mM NaN₃. A flow rate of 0.75 mL/min was used. The retention times for SAV proteins were approximately 30 min.

HPLC separations of radioiodinated SAV proteins were conducted on a system consisting of two model 306 Gilson pumps with 10SC titanium pump heads, a Gilson model 118 UV-Visible detector (280 nm), a Beckman model 170 radioisotope detector, a Gilson System Interface Module, and an IBM 486 computer with Gilson Unipoint HPLC Controller software. The proteins were separated by size exclusion chromatography on a 300 SW Protein Pak column (8 mm $\times$ 300 mm glass column; 10 μ m silica particle size), eluting with a solvent mixture of 25 mM Tris-HCl, 75 mM NaCl, and 1 mM EDTA at pH 7.2 with a flow rate of 0.70 mL/min. The retention time for the radiolabeled SAV proteins was approximately 15 min using this system. Chromatograms of the SAV variants are provided in the Supporting Information.

Preparation of r-SAV-S139C-NEM. To 100 μ L of r-SAV-S139C (13 mg/mL) was added 6 μ L of a 1 M aqueous DTT solution. After 1 h at rt, the mixture was passed over a Sephadex G-25 (PD-10) column and eluted with 20 mM sodium phosphate at pH 6.8. To a 2 mL aliquot of DTT-treated r-SAV-S139C (0.25 mg/mL) solution was added 100 μ L (50 equiv, 0.64 mg/mL) of a solution containing *N*-ethylmaleimide (NEM) in 20 mM sodium phosphate at pH 6.8. The reaction was allowed to proceed at rt for 30 min before the mixture was divided

into two equal volume fractions and the fractions were placed in separate Centricon-10 microconcentrators (Amicon) that were prewashed with 1 mL of 20 mM sodium phosphate at pH 6.8. The solutions were centrifuged at 3200 rpm for 15 min to concentrate the solutions to a 100 μ L volume. Each Centricon retentate was rinsed four times with 500 μ L of the phosphate buffer, reducing the volume to 100 μ L by centrifugation during each rinse.

General Procedure for Radioiodination of r-SAV Using ChT. A 500–650 μ g quantity of SAV in 40–100 μ L of a 50 mM Tris/50 mM NaCl solution (pH 8.0) was added to a mixture of 25 μ L of 0.5 M sodium phosphate (pH 7.4) and 1 μ L (0.5–0.7 mCi) of Na^{125/131}I in 0.1 N NaOH. To that solution was added 10–20 μ L of a 1 mg/mL solution of ChT in H₂O (final concentration of 0.15 μ g/mL). After 5 min at rt, 1–2 μ L of a 10 mg/mL solution of sodium metabisulfite in H₂O was added to quench the reaction. The radioiodinated SAV was eluted on a NAP-10 column (Sephadex G-25; Pharmacia Biotech) with 0.9% saline to give a 48–93% radiochemical yield of the radiolabeled SAV. The radiochemical purity of the isolated SAV proteins was >98% (by HPLC) in all reactions conducted.

Radioiodination of r-SAV Using [¹²⁵I]PIB-NHS. Synthesis of *N*-hydroxysuccinimidyl 4-(tri-*n*-butylstannyl)benzoate (PSnB-NHS) was accomplished as previously reported (30). The radioiodination was conducted as follows. A 1.0 mCi quantity of Na¹²⁵I in 3 μ L of 0.1 N NaOH was added to a mixture of 50 μ g of PSnB-NHS in 50 μ L of a 1% HOAc solution in MeOH. To that solution was added 10 μ L of a 1 mg/mL solution of NCS in MeOH. After 5 min at rt, 1 μ L of a 10 mg/mL solution of sodium metabisulfite was added to quench the reaction. The solvent was removed under a stream of argon (through a charcoal filter), and the crude residue containing [¹²⁵I]PIB-NHS was used directly in the radiolabeling reaction.

To the vial containing [¹²⁵I]PIB-NHS (1.04 mCi) was added a mixture containing 35 μ L of a 15 mg/mL solution of r-SAV in PBS and 100 μ L of a 0.5 M sodium borate buffer at pH 9.3. After a 5 min reaction time, the mixture was placed on a NAP-10 column and eluted with 0.9% saline. A total of 496 μ Ci (48%) of PIB-labeled SAV was obtained, with a specific activity of 1.23 μ Ci/ μ g, which had a radiochemical purity of >98% by HPLC analysis.

Biodistribution Studies. All animal use and procedures were approved by the University of Washington's Animal Care Committee. Animal care and use was conducted in accordance with the NIH guidelines.⁶ Male athymic mice (BALB/c *nu/nu*), 4–5 weeks of age, were obtained from Simonsen Laboratories (Gilroy, CA). All mice were housed for 1 week in the animal facility prior to beginning the study.

In the biodistribution studies, mixtures of r-[¹³¹I]SAV and ¹²⁵I-labeled r-SAV mutants, or ¹²⁵I-labeled SAV from commercial sources,³ were administered to mice in a total volume of approximately 100 μ L via the lateral tail vein. The actual amount of injectate administered to each animal was determined by weighing the administering syringe pre- and postinjection. Groups of five mice were sacrificed at 4, 24, and 48 h postinjection to obtain tissue distributions. The tissues excised were muscle, lung, kidney, spleen, liver, intestine, neck (including thyroid), and stomach. Blood samples were obtained by cardiac

⁵ The 2.56 L/g value was obtained by dividing the molar absorptivity of SAV (i.e. 136 000 mol L⁻¹ cm⁻¹) by the quantity per mole of SAV (i.e. 53 084 g/mol). The molar absorptivity was obtained by multiplying the SAV molar absorptivity (ϵ_{280}) of 34 000 mol L⁻¹ cm⁻¹ for one subunit (16) by 4 (subunits). The path length of the cell used in the measurements was 1 cm.

⁶ NIH guidelines are described in NIH Publication 86-23, Guide for the Care and Use of Laboratory Animals.

⁷ Studies with r-[¹²⁵I]SAV-S139C have shown that reduction is needed before conjugations will take place.

Table 1. Distribution of Radioactivity at 4, 24, and 48 h Post-Coadministration of [¹²⁵I]PIB-Labeled r-SAv and ChT-Labeled r-[¹²⁵I]SAv in Athymic Mice^a

puncture. Urine samples were obtained by syringe bladder tap at the time the tissues were excised. Excised tissues were blotted free of blood, weighed, and counted. Calculations of the percent injected dose (% ID) and percent injected dose per gram (% ID/g) in the tissues were based on internal standards (quadruplicate) containing 1 μL of the injected dose. The total blood volume was estimated to be 8% of body weight for the calculations (31). A spreadsheet program in Excel (Microsoft Corp., Redmond, WA) was used to perform the calculations, including ratios of isotopes in tissue/fluids for the radiolabeled SAv proteins. Statistical analyses were conducted on each tissue in the set of five mice using Excel's *t* test function for two samples assuming equal variances. The biodistribution data obtained are provided in Tables 1 and 2 in this paper and Tables A–D in the Supporting Information. Information on the number of animals per time point, the specific activity of each preparation, and quantities administered are provided in the footnotes of the tables. The complete biodistribution data obtained, and additional information on average animal weight and pairs of data in which the differences were highly significant (i.e. *P* < 0.005), are provided in Tables A–D in the Supporting Information.

RESULTS

In Vitro Comparison of SAv Proteins. To evaluate the differences in size, charge, and homogeneity of mass of the SAv proteins, each protein studied was evaluated by HPLC, SDS–PAGE, IEF, and electrospray mass spectral analyses. Size exclusion HPLC analyses of the SAv proteins had only one peak present at the expected

molecular mass range (by comparison with MW standards) for the tetrameric protein, indicating that they were not contaminated with higher- or lower-molecular mass proteins. It was interesting to note that the retention times of r-SAv proteins (*t_R* = 29.5 min) were found to be approximately 0.6 min shorter than that of the truncated commercial preparations (*t_R* = 30.1 min).

SDS–PAGE analysis of denatured r-SAv proteins demonstrated the correct molecular mass for the monomer, with the cysteine mutants being indistinguishable from r-SAv under reducing conditions. r-SAv-S139C and r-SAv-H127C also showed the presence of a dimeric species in the absence of reductant due to the formation of disulfide bonds. This dimeric species was not present under reducing conditions (6% β-mercaptoethanol in sample loading buffer). Nondenatured samples demonstrated the expected molecular mass of the tetramer for all r-SAvs.

An IEF gel comparing the five SAv proteins is shown in Figure 1. Although there appears to be one primary protein band for each SAv, all proteins studied had a minimum of three species present (percentages of each species not quantified). The *pI* value of the species present for the r-SAv (wild type) is very nearly the same as that of the site-directed mutant r-SAv-S139C (i.e. pH 6.6–7.4), but the *pI* values of the other mutant, r-SAv-H127C are lower (i.e. pH 5.2–6.6). The SAv protein obtained from one commercial source, SAv-CS2, has a *pI* profile quite similar to that of the r-SAv (wild type), except that it appears that the major species has a slightly higher *pI* (i.e. estimated to be 7.3 vs 7.0). The SAv protein obtained from the other commercial source,

Figure 1. Digitized image of an IEF gel showing SA v protein *pI* values. The gel (PhastGel IEF 3–9) was run on a PhastSystem electrophoresis apparatus using the optimized method for IEF described in “Separation Technique File #100”. The protein staining was done by the silver stain method described in “Development Technique File #210”: lane A, IEF standards (Isoelectric Focusing Calibration Kit, broad *pI*; 3–10) run in the direction of application (bottom to top); lane B, IEF standards run from top to bottom; lane C, r-SA v-S139C (NEM-capped); lane D, r-SA v-H127C; lane E, SA v-CS1 (Boehringer Mannheim); lane F, r-SA v (wild type); lane G, SA v-CS2 (CALBIOCHEM); and lane H, IEF standards run from bottom to top.

SA v-CS1, has a *pI* profile somewhat different from those of the other SA v proteins as the *pI* range for the species present is quite small (i.e. pH 7.0–7.4).

In contrast to r-SA v, electrospray mass spectrometry (ESMS) of the commercially available SA v proteins indicated that they were heterogeneous in nature. Native streptavidin consists of amino acid residues 1–159; however, the recombinant streptavidin used is composed of residues 13–139 (based on native SA v numbering system), and core or “truncated” SA v proteins purchased from commercial sources generally are composed of 125–127 amino acid fragments containing residues beginning as low as amino acid 13 and ending with amino acids 133–139. The major component of the SA v proteins which were analyzed had molecular masses within 1 Da of the expected (calculated) subunit masses. The r-SA v mass spectrum had one major mass peak at the expected mass (13 271 Da). The mass spectrum for the SA v protein from commercial source 1 (Boehringer Mannheim) is a mixture which appears to have the 14–136 residues (12 971 Da) as its major component and the 13–135 residues (12 954 Da) as a minor component. The mass spectrum for the SA v protein from commercial source 2 (CALBIOCHEM) had several species present. It also had the 14–136 residues as the predominant species, but had a significant quantity of a second species with a mass of 13 042 Da, corresponding to either fragment 14–137 or fragment 13–136, and may be a mixture of the two.

Radioiodination of SA v Proteins by the ChT Method. Recombinant “core” (16, 32) SA v has 6 tyrosine residues per subunit (24 per tetramer) and is readily radioiodinated by the ChT method. It should be noted that there is a very important tyrosine residue in both avidin (Tyr-33) and SA v (Tyr-43) which participates in binding with the biotin ureido group (33–35). In avidin, nitration of that tyrosine, which is the only one present in the protein (36), has been shown to decrease biotin binding (37). For this reason, the specific activity of the radioiodinated SA v proteins in this study was kept below

2 $\mu\text{Ci}/\mu\text{g}$ to assure iodination on the more accessible (non-biotin binding) tyrosines in SA v. The SA v proteins were radioiodinated with either ^{125}I or ^{131}I by reaction with chloramine-T at pH 7.4. Generally, the SA v radioiodination yields ranged from 74 to 98%, but radioiodination of SA v from one commercial source (CS2)³ resulted in 48–50% radiochemical yields. It is not known why this protein gave consistently lower labeling yields.

Assessment of Radioiodination Method. As an initial part of the SA v biodistribution study, we were interested in determining if the radioiodine distribution was reflective of the distribution of the ChT-labeled r-SA v. To determine this, r-SA v was radiolabeled directly with $\text{Na}^{131}\text{I}/\text{ChT}$ and separately radiolabeled with *N*-succinimidyl *p*-[^{125}I]iodobenzoate ([^{125}I]PIB). PIB labeling of proteins (e.g. antibodies) has been shown to be resistant to in vivo deiodination (30). After r-SA v was labeled by the two methods, equal quantities of [^{125}I]PIB-r-SA v and r-[^{131}I]SA v were combined and injected into athymic mice. The distribution of radioactivity at 4, 24, and 48 h postinjection is provided in Table 1. The two methods of radiolabeling r-SA v gave similar distributions at all time points, except the amine-conjugated [^{125}I]PIB-labeled r-SA v had slightly reduced kidney concentrations. The data clearly showed that in vivo deiodination of SA v labeled directly with ChT was not a problem. Indeed, very little difference was observed in the neck and stomach concentrations of radioiodine nuclides. If significant deiodination had occurred, large differences between the PIB-labeled protein and the ChT-labeled protein would have been observed. These data indicated that the ChT labeling method was appropriate for labeling the SA v proteins in the comparative investigation.

Comparative Biodistribution of SA v Proteins. The biodistributions of two r-SA v mutant proteins and two SA v proteins available from commercial sources were compared with that of the (wild type) r-SA v. In the comparisons, one of the r-SA v mutants, r-[^{125}I]SA v-H127C or r-[^{125}I]SA v-S139C, or one of the SA v proteins obtained from commercial sources, SA v-CS1 or SA v-CS2, was mixed and co-injected with an equal quantity (i.e. 15 μg) of r-[^{131}I]SA v. By co-injection of the dual isotope-labeled SA v proteins into each animal, a direct comparison of the SA v variants was obtained. With the exception of the blood and kidney concentrations (Table 2), the concentrations in tissues were not appreciably different for the r-SA v mutants or commercially available SA v proteins from those for the r-SA v (wild type) used in our studies. The complete distribution data for the comparisons of SA v variants is provided in the Supporting Information as Tables A–D.

DISCUSSION

Recombinant streptavidin has been used extensively in our pretargeting studies because it is composed of a single protein species and can be prepared readily in large quantities from *E. coli* (21). Another factor in the choice of r-SA v was the fact that, through site-directed mutagenesis of the recombinant gene, it is possible to prepare r-SA v mutants that have unique properties. It is our belief that r-SA v mutants can be prepared which have properties that will improve in vivo characteristics and/or allow the preparation of improved reagents for pretargeting. This study was initiated to compare the in vivo characteristics of two r-SA v mutants, r-SA v-H127C and r-SA v-S139C, with those of the r-SA v being used in our studies (14). In addition to the r-SA v mutants, two commercially available SA v proteins were evaluated for the reasons described below.

In order to determine if the r-SAv mutants constituted "improved" reagents, we needed to understand the *in vivo* characteristics of SAv proteins other than the r-SAv used. As with our studies of r-SAv, inspection of the *in vivo* data previously reported in the literature indicated that SAv does not accumulate to any extent in tissues except kidney. Although localization of SAv in the kidney was consistently reported, the quantity localized varied widely (i.e. from 1 to >100% ID/g) (8, 12, 13, 18, 38–41). Our assumption was that the large reported differences could be caused by heterogeneity in the SAv proteins supplied by commercial sources. In 1990, it was reported that *some* commercial preparations contained unprocessed SAv (16). More recently, it has been reported that many commercially available SAv proteins are treated with proteases to provide the core SAv and maximize the homogeneity of the terminal structure (32).

SAv has 159 amino acid residues in its native state (16); however, native SAv is highly susceptible to enzymatic degradation, and both the C- and N-terminal amino acid sequences are truncated after secretion (16, 42–45). Importantly, truncation occurs which yields a "natural core SAv" which is resistant to further proteolysis. Truncation of SAv does not appear to significantly alter biotin binding properties, but removal of terminal amino acids appears to improve binding with biotinylated macromolecules (32). Further, truncation also improves the aqueous solubility of SAv and decreases the formation of aggregates. Unfortunately, the truncation process can result in heterogeneity within monomer and tetramer (44). The wide variation in the literature reports with regard to the kidney localization of commercially available SAv proteins and the potential for having nonhomogeneous mixtures of SAv proteins from commercial sources prompted us to include two representative SAv proteins from commercial sources in our biodistribution studies.

Before the *in vivo* studies were conducted, the proteins were characterized with regard to their purity, homogeneity, and *pI*. This was done as part of the characterization of r-SAv mutants, and to provide data on the physical differences between SAv variants. Analyses of the SAv variants by HPLC and SDS–PAGE provided data that indicated the proteins were pure. The wild type r-SAv is homogeneous in molecular mass, having 127 amino acid residues and a mass of 13 271 Da per subunit protein (21). The r-SAv mutants were also homogeneous in molecular mass, having subunit masses consistent with the desired amino acid substitution of wild type r-SAv. Contrary to this, the commercial SAv proteins were heterogeneous in molecular mass as judged by ESMS. IEF analyses indicated that multiple charged species exist for all of the SAv and r-SAv preparations. Although the origins of these charged species are not known, the IEF heterogeneity data obtained are consistent with previously reported data from SAv that has been truncated by proteolytic degradation (46) and for commercially available recombinant SAv (Sigma) (47). Indeed, microheterogeneity of proteins observed in IEF analyses, in general, is considered common (48). It is particularly interesting to note the much lower *pI* values found for the r-SAv-H127C mutant. As this protein is different from the r-SAv in only one amino acid (per subunit), the large shift in *pI* was unexpected. The explanation for the change in *pI* is not readily apparent, but the change in *pI* observed could be brought about by a number of factors, such as formation of alternate stable conformations of the subunits and/or various combinations of the subunits in forming the tetramer (48).

The primary goal of this investigation was to compare the *in vivo* characteristics of two r-SAv mutants with those of r-SAv. In one of the r-SAv mutants studied, r-SAv-H127C, the amino acid sequence of r-SAv has been altered by replacing the histidine residue at amino acid 127 with a cysteine. This substitution resulted in formation of two disulfide links between subunits in the r-SAv molecule which can readily be observed when evaluated by nonreducing SDS–PAGE analysis. Formation of disulfide cross-linked subunits in this mutant has been shown to increase the stability of r-SAv (49). This higher stability for subunit dissociation of r-SAv-H127C made it of interest for *in vivo* application as we thought it might alter its degradation and tissue distribution. Unfortunately, little difference in the biodistributions of the r-SAv-H127C and (wild type) r-SAv was noted. The one difference noted was that the kidney localization decreased relative to r-SAv. The relative amount of the decrease in kidney at the three time points is similar (Table 2) to that seen in the PIB-labeled r-SAv (Table 1). The reason for this decrease is not known, but we are investigating whether it might be related to a decrease in the *pI* of the proteins.

In the other site-directed r-SAv mutant studied, r-SAv-S139C, the C-terminal serine was replaced by a cysteine in the subunit polypeptide chain. This mutant is of particular interest as its use should allow conjugations to be carried out at locations which would not be expected to interfere with biotin binding. Although r-SAv which has more than one terminal cysteine has been reported (50), for our studies, it was desirable to have only one terminal cysteine for modification. The sulfhydryl group in the refolded r-SAv-S139C is present as disulfide linked subunits. As our primary interest in this SAv protein is the capacity for site-specific conjugations, prior to the *in vivo* evaluation, the disulfide bridges were reduced with DTT and the free sulfhydryl groups were conjugated with *N*-ethylmaleimide. The biodistribution of the r-SAv-S139C conjugate is quite similar to that of r-SAv. While they may not be applicable for all conjugates, these data suggest that sulfhydryl conjugations (of small molecules) will not affect the *in vivo* distribution appreciably. Additional conjugate studies are planned with r-SAv-S139C.

Aside from the kidney localization, there were only small differences in the tissue distributions of SAv variants studied. A comparison of blood and kidney concentrations of all the SAv variants vs r-SAv is provided in Table 2. It is interesting to note that blood concentrations of commercially available SAv proteins decreased more rapidly than that of the slightly larger r-SAv variants. Importantly, the mass heterogeneity of the commercially available SAv proteins did not appear to alter the kidney localization appreciably. Because all of the SAv variants were heterogeneous with regard to their *pI*, it is not possible to determine with certainty whether such heterogeneity contributes to the kidney localization. Our results indicate that a range of 15–29% ID/g (or 3–6% ID) is accumulated in the kidneys of athymic (BALB/c *nu/nu*) mice. In a three-step pretargeting protocol, and in our proposed method of increasing tumor radioactivity (14), the biotin derivative is the only species which carries radioactivity. Therefore, in these situations, the concentration of SAv in the kidneys may not be important if it is not available to bind with the radiolabeled biotin.

We plan to investigate the localization of r-SAv to kidneys further. If there is a specific receptor uptake, it may be possible to block uptake. Of course, the most

relevant question for our studies is whether the r-SAv localized in kidneys is available for binding with radiolabeled biotin derivatives. Due to concerns about misinterpretation of results, studies of kidney localization of radioiodinated biotin derivatives could not be conducted until a biotinidase-stabilized radioiodinated biotin derivative was obtained. Now that we have synthesized and tested a biotinidase-stabilized biotin derivative (51), its co-localization to SAv localized at kidney will be examined.

Summary. New r-SAv proteins are of interest for development of antibody pretargeting methods. As part of that development, two mutant r-SAv proteins have been compared with the (wild type) r-SAv. In an initial biodistribution study, it was demonstrated that radioiodination of r-SAv with ChT resulted in a (relatively) stable label, permitting the use of that labeling method in the subsequent comparison studies. Data obtained when r-SAv was compared with a disulfide-stabilized r-SAv mutant, r-SAv-H127C, indicated that the distribution was similar to that of r-SAv, except the kidney concentration was lower for the mutant than for r-SAv. Similarly, comparison of the r-SAv with C-terminal cysteine residues, r-SAv-S139C, demonstrated that their distributions were similar. Comparison of r-SAv with two commercially available SAv proteins in mice also indicated that there were only minor differences in their in vivo distributions. The results obtained indicate that truncated or recombinant SAv proteins might be used interchangeably for in vivo applications because they have similar distribution properties.

ACKNOWLEDGMENT

We are grateful for the financial support provided by the Department of Energy, Medical Applications and Biophysical Research Division, Office of Health and Environmental Research, under Grant DE-FG06-95ER62029. The animal studies were also supported in part by funding from the Richard M. Lucas Foundation.

Supporting Information Available: HPLC chromatograms and SDS-PAGE gels (denatured and nondenatured) of SAv proteins studied; mass spectra of r-SAv, SAv-CS1, and SAv-CS2 proteins; and Tables A–D containing biodistribution data for the r-SAv mutants, H127C and S139C, and the two commercially available SAv proteins (9 pages). BC970152S

Size exclusion HPLC chromatograms of the streptavidin proteins evaluated. HPLC equipment and conditions were as described for non-labeled proteins in manuscript. All protein evaluations were conducted on the same day under identical HPLC conditions to obtain relative retention times (t_R). Differences in t_R observed for r-SAv proteins and commercial SAv proteins appear to be real as co-injection of r-SAv (wild type) with SAv-CSI had a clearly discernible shoulder at about 30 min on a major peak at 29.5 min.

r-Streptavidin (wild type; $t_R = 29.5$ min)

r-SAv-H127C ($t_R = 29.4$ min)

r-SAv-S139C (NEM capped; $t_R = 29.5$ min)

SAv-CSI (Boehringer Mannheim; $t_R = 30.2$ min)

SAv-CS2 (CALBIOCHEM; $t_R = 30.1$ min)

Digitized images of denatured and non-denatured (reducing, β -mercaptoethanol) SDS-PAGE gels of SA_v proteins conducted on a PhastSystem™ electrophoresis apparatus (using PhastGel®, Homogeneous 12.5%). Lanes 1, 4, and 8; molecular weight standards (MW STDS; LMW Electrophoresis Calibration kit (Pharmacia)). Lane 2; r-SA_v-S139C. Lane 3; r-SA_v-H127C. Lane 5; SA_v-CS1 (Boehringer Mannheim). Lane 6; r-SA_v (wild type). Lane 7; SA_v-CS2 (CALBIOCHEM). Gels were run by optimized method for Homogeneous 12.5% gel using "Separation Technique File #111. The protein band was developed by the silver staining method from "Development Technique File #210.

Electrospray Mass Spectrum (ESMS) of the wild type recombinant streptavidin (r-SAv) used in studies. Note that the minor peaks are thought to be Ca ion adducts or other background noise and are not considered to be impurities in the protein.

Electrospray Mass Spectrum (ESMS) of the streptavidin obtained from Boehringer Mannheim (SAv-CS1; lot number 133816721). Three proteins of different masses are readily apparent (with masses marked). Note that the minor peaks are thought to be Ca ion adducts or other background noise and are not considered to be impurities in the protein.

Electrospray Mass Spectrum (ESMS) of the streptavidin obtained from CALBIOCHEM (SAv-CS2; lot number B12651). Two proteins of different masses are readily apparent, with several other peaks likely to be attributed to different SAv proteins. Note that the smallest peaks are thought to be Ca ion adducts or other background noise and are not considered to be impurities in the protein.

Simplified Preformed Chelate Protein Radiolabeling with Technetium-99m Mercaptoacetamidoadipoylglycylglycine (N₃S-Adipate)

Sudhakar Kasina,* James A. Sanderson, Jeffrey N. Fitzner, Ananthachari Srinivasan, Tripuraneni N. Rao, Lori J. Hobson, John M. Reno, Donald B. Axworthy, Paul L. Beaumier, and Alan R. Fritzberg

NeoRx Corporation, 410 West Harrison Street, Seattle, Washington 98119. Received April 1, 1997; Revised Manuscript Received October 7, 1997[©]

A simplified kit has been developed for ^{99m}Tc protein radiolabeling using an N₃S triamide mercaptide bifunctional chelating agent and the preformed chelate approach. The process combined N₃S chelating agent, gluconate intermediate transfer agent, stannous reducing agent, and gentisic acid stabilizer into a lyophilized formulation. With sulfur donor atom hemithioacetal protection of the ligand, δ -2,3,5,6-tetrafluorothiophenyl α -S-(1-ethoxyethyl)mercaptoacetamido-L-adipoylglycylglycine, optimum ^{99m}Tc chelation was achieved in a single step. Subsequent reaction with NR-LU-10 antibody Fab fragment followed by purification via QAE Sephadex anion exchange resin filter afforded ^{99m}Tc-N₃S-NR-LU-10 Fab conjugate with retained immunoreactivity and effective tumor targeting properties.

INTRODUCTION

Earlier investigations have shown that amide thiolate (N₂S₂, N₃S)¹ chelating agents form well-defined ^{99m}Tc complexes of high stability (1, 2). Application of N₂S₂ chelating agents for the bifunctional attachment of ^{99m}Tc to proteins such as antibodies was established with 4,5-dimercaptoacetamidopentanoate via chelation, *in situ* esterification, and protein coupling (3). The chelating agent was subsequently modified to a tetrafluorophenyl active ester and incorporated into a kit (4) that has been used clinically with various antibody fragments, including NR-ML-05 Fab fragment for melanoma (5) and NR-LU-10 Fab fragment for small cell lung carcinoma and other solid tumor cancers (6–8). Additionally it has been used with annexin V, a 36 kD human placental anticoagulant protein for thrombus imaging (9).

Although the pentanoate-based N₂S₂ chelating kit served successfully to stably attach ^{99m}Tc without negatively impacting tumor targeting ability of the Fab fragments and annexin V protein, some drawbacks were

experienced. Catabolism of the radiolabeled protein following kidney and liver uptake yielded a lysine adduct of the ^{99m}Tc-chelate that was excreted via the hepatobiliary system (10). This excretion interfered in the detection of disease in the lower abdomen. Furthermore, the kit was cumbersome, involving manipulation of several components prior to the ^{99m}Tc chelation step. Thus, the opportunity existed for further simplification of the radiolabeling process to yield a product of improved biodistribution and ease of use.

Previously (11), we have shown that the addition of a carboxyl group to the N₂S₂ ligand core decreased hepatobiliary excretion of the radioactivity. Additional carboxyl groups added to the ligand further decreased hepatobiliary excretion. We have now extended these results to the N₃S ligand system and herein describe the bifunctional chelate, 2,3,5,6-tetrafluorothiophenyl-S-(1-ethoxyethyl)mercaptoacetamidoadipoylglycylglycine (N₃S-adipate-STFP), and its incorporation into a kit for protein radiolabeling for clinical application. This kit combined N₃S-adipate-STFP, gluconate intermediate transfer agent, and stannous reducing agent into a lyophilized formulation that reduced the number of steps and time required for protein radiolabeling. Comparative mice biodistribution studies of this ^{99m}Tc-N₃S Fab conjugate, noncarboxylate ^{99m}Tc-N₂S₂ Fab conjugate (4), and ¹²⁵I-PIP Fab conjugate (2) are herein described. Comparative rat biodistribution and hepatobiliary excretion studies for the series of carboxylate-substituted amide thiolate bifunctional chelating agents will be described in a separate report.

MATERIALS AND METHODS

Reagents. All reagents were obtained from Aldrich Chemical Co. (Milwaukee, WI) except BSA, transferrin, cysteine, and sodium phosphate, all obtained from Sigma Chemical Co. (St. Louis, MO), and QAE Sephadex obtained from Pharmacia Biotech, Inc. (Piscataway, NJ). All solvents were reagent or HPLC grade. Two intermediate precursor compounds, S-(1-ethoxyethyl)mercap-

¹ Abbreviations: Ab-NH₂, antibody fragment with lysine ϵ -amino group; BSA, bovine serum albumin; BuOH, butanol; CBZ, carbobenzyloxy; DCC, 1,3-dicyclohexylcarbodiimide; DMF, dimethylformamide; DMSO, dimethyl sulfoxide; DTPA, diethylenetriaminepentaacetic acid; EtOAc, ethyl acetate; HOAc, acetic acid; HPLC, high pressure liquid chromatography; IPA, 2-propanol; ITLC, instant thin layer chromatography; NR-LU-10 Fab, pancarcinoma papain fragmented murine antibody fragment; N₂S₂, diamide disulfur; N₃S-adipate-STFP, δ -2,3,5,6-tetrafluorothiophenyl- α -S-(1-ethoxyethyl)mercaptoacetamido-L-adipoylglycylglycine; N₃S-adipate-OTFP, δ -2,3,5,6-tetrafluorophenyl α -S-(1-ethoxyethyl)mercaptoacetamido-L-adipoylglycylglycine; PBS, phosphate-buffered saline; PIP, P-iodophenylate; QAE, quaternary aminoethyl; TCA, trichloroacetic acid; TLC, thin layer chromatography.

toacetic acid **11** and *N*-hydroxysuccinimidyl *S*-(1-ethoxyethyl)mercaptoacetate **12**, were prepared as described earlier (4). NR-LU-10 Fab antibody fragment was prepared in-house from standard papain digestion of whole antibody isolated from the supernatant of cultured murine hybridoma cells (12, 13). The ^{99m}Tc - N_3S -NR-LU-10 Fab purification column was manufactured to NeoRx specifications by BioProbe, Inc. (Tustin, CA) and Sepratech, Inc. (American Canyon, CA). Lyophilization vials were obtained from Miles, Pharmaceutical Div. (Spokane, WA), and stoppers were purchased from The West Co. (Lionville, PA).

General Instrumentations. Proton NMR spectra were obtained on a Varian Gemini-200 spectrometer with tetramethylsilane as an internal standard. IR data were obtained on a Perkin-Elmer 1310 infrared spectrophotometer. Mass spectral data (both low and high resolution) were obtained on a Micromass 70 SEQ tandem hybrid mass spectrometer (Micromass Ltd., Manchester, U.K.) with associated DEC PDP 11-250J Data System. Mass spectral data were obtained by fast atom bombardment (FAB^+) by electron impact (EI) ionization on the sample introduced by the direct insertion probe (DIP). Melting points were obtained on a Thomas-Hoover apparatus and are uncorrected. Elemental analyses were performed by Desert Microanalytical Laboratories, Tucson, AZ. Moisture analyses were performed on a Photo Volt Moisture Analyzer.

Chromatography. High performance liquid chromatography (HPLC) of small molecule forms of the organic syntheses and radiolabeling of bifunctional chelates was carried out on Beckman-Altex systems using 5 μm ODS (Beckman Ultrasphere) C-18 columns. Beckman Models 153 and 331 spectrophotometers with fixed wavelength or 155–400 variable wavelength were used for optical detection, while a Beckman Model 170 radiometric detection in series with the former was used in identifying the radiolabeled products.

^{99m}Tc - N_3S -adipate-STFP analyses was performed isocratically using a mobile phase of acetonitrile in 0.01 M sodium phosphate (pH 6.8) at a ratio of 24:76 at 1.5 mL/min on a reverse phase column. Additionally the separation was performed on a gradient system going from an acetonitrile:water:glacial acetic acid ratio of 5:94:1 (pump A) to 60:39:1 (pump B) at 1.0 mL/min. The program for the gradient elution involved a 10 min pumping of 100% A followed by a 35 min pumping of 100% B.

Antibody protein conjugate radiochemical purity was assessed by size-exclusion chromatography using Zorbax (DuPont de Nemours) HPLC with 0.2 M phosphate, pH 7.2 as mobile phase. Detection was performed as noted above. Separation of free and protein-bound ^{99m}Tc was also performed using silica gel impregnated glass fiber instant thin layer chromatography (ITLC) supplied by Gelman Sciences, Inc., Ann Arbor, MI, as ITLC SG. The silica gel strips were precut to 2 $\times$ 10 cm, activated at 100 $^\circ\text{C}$ for at least 2 h and stored according to the manufacturer's instructions. The ITLC strips were developed with freshly prepared 12% w/v trichloroacetic acid (TCA). In this system, the ^{99m}Tc -labeled Fab fragment remained at the origin and non-protein bound ^{99m}Tc -labeled species migrated with the solvent front. The TLC strips were cut into two halves and separately counted for final purity on a Packard MINAXI 500 series γ counter.

Syntheses of N_3S -Adipate-STFP (17) and N_3S -Adipate-OTFP (15). Scheme 1 outlines the syntheses of thio and oxo 2,3,5,6-tetrafluorophenyl *S*-(1-ethoxyethyl)mercaptoacetamido-*L*-adipoylglycylglycine bifunctional

chelating moieties, N_3S -adipate-STFP and N_3S -adipate-OTFP. The final compounds were purified by preparative reverse phase HPLC. The detailed procedures were performed as follows.

L- α -*N*-(Carbobenzyloxy)amino adipic Acid (**2**). 4.47 g (27.7 mmol) of *L*-amino adipic acid (**1**) was dissolved in 14 mL of 4 N sodium hydroxide and cooled to 0 $^\circ\text{C}$. To the magnetically stirred solution was added a solution of 4.35 mL (30.5 mmol) of carbobenzyloxy chloride (CBZ-Cl) in 14 mL of dioxane dropwise over a period of 30 min. The pH of the solution was periodically monitored during the addition, maintaining a basic pH by adding portions of 8.2 mL of 4.0 N sodium hydroxide during the addition. After 2 h and 15 min, the progress of the reaction was monitored by TLC in *n*-BuOH:HOAc:H₂O = 3:2:1. Due to the presence of trace amounts of starting amino adipic acid, an additional 1.0 mL (0.25 equiv) of CBZ-Cl in 3.0 mL dioxane was added. Immediately following this addition, 2.0 mL of 4.0 N sodium hydroxide was added to the reaction mixture to maintain basic pH. After incubation at 0 $^\circ\text{C}$ for an additional 3 h, the reaction mixture was allowed to warm up to room temperature. The pH of the reaction mixture was checked, and, as necessary, the pH was adjusted to ~ 10.0 with 4.0 N NaOH during the workup. The reaction mixture was washed two times with ether to remove excess CBZ-Cl, and the ether washes were discarded. The aqueous layer was then acidified with 6.0 N hydrochloric acid to $\sim \text{pH}$ 1.0. The aqueous acidified solution was then extracted with three portions of ethyl acetate. The combined ethyl acetate extracts were then dried over anhydrous sodium sulfate and filtered. The solvent from filtrate was removed under vacuum to concentrate the product to an oil that solidified upon drying. The crude product was recrystallized from hot ethyl acetate:hexane to yield 7.4 g (90.3%) of white crystalline solid, mp 134–135 $^\circ\text{C}$. ^1H NMR (DMSO-*d*₆): δ 1.40–1.80 (m, 4H), 2.10–2.30 (t, 2H), 3.85–4.05 (m, 1H), 5.05 (s, 2H), 7.37 (s, 5H, C₆H₅), 7.64 (d, 1H, NH), 12.36 (s, COOH). IR (KBr, cm^{-1}): 3300, 3000, 2920, 1690, 1520, 1420, 1270, 1240, 1200, 1170, 1050, 900, 750, 700, 670. HRMS: mass calcd for $\text{C}_{14}\text{H}_{17}\text{NO}_6$ ($\text{M} + \text{H}$)⁺, 296.1134; found, 296.1126.

Dibenzyl L- α -*N*-(Carbobenzyloxy)amino adipate (**3**). 6.50 g (22.0 mmol) of *N*-(carbobenzyloxy)amino adipic acid was suspended in 180 mL of benzene containing 4.76 g (44.0 mmol) of benzyl alcohol. To the reaction mixture was added 0.2 g of *p*-toluenesulfonic acid. The reaction mixture was heated overnight under reflux with a Dean-Stark condenser. After 20 h, the reaction mixture turned colorless and homogeneous with about 1.6 mL of water collected. Completion of the reaction was monitored by TLC in 1:1 ethyl acetate/hexane as well as in 96:4 EtOAc/HOAc with spots stained in potassium permanganate. Benzene from the reaction mixture was removed under vacuum. The mixture was taken up into ethyl acetate and washed twice with dilute aqueous sodium bicarbonate followed by brine solution. The organic layer was dried over anhydrous sodium sulfate and filtered. Solvent from the filtrate was removed under reduced pressure to concentrate the product. The crude product was purified by flash chromatography on a silica gel 60 column using 30% ethyl acetate in hexane as an eluting solvent. The fractions containing the product were pooled, and the solvent was removed to yield 9.09 g (87%) desired product as a viscous colorless oil: ^1H NMR (DMSO-*d*₆): δ 1.40–1.90 (m, 4H), 2.30–2.45 (t, 2H), 4.0–4.20 (m, 1H), 5.05 (s, 2H), 5.09 (s, 2H), 5.14 (s, 2H), 7.36 (s, 15H, C₆H₅), 7.84 (d, 1H, NH). IR (NaCl cells, cm^{-1}): 3380, 3060, 3040, 2980, 1740, 1730, 1520, 1470, 1390,

1000, 980, 910, 860, 815, 760, 700, 650. HRMS: mass calcd for $\text{C}_{25}\text{H}_{26}\text{N}_2\text{O}_8$ ($\text{M} + \text{H}$) $^+$, 483.17673; found 483.1767412.

2,2,2-Trichloroethyl N-(Carbobenzyloxy)glycylglycinate (7). 1.0 g (3.76 mmol) of N-(carbobenzyloxy)glycylglycine (**6**) was dissolved in 6.0 mL of anhydrous DMF. To this solution under magnetic stirring was added 0.56 g (3.76 mmol) of 2,2,2-trichloroethanol, followed by 0.91 mL (11.26 mmol) of gold label grade pyridine. To the stirred reaction mixture was added 0.77 g (3.76 mmol) of DCC, followed by 4.0 mL of anhydrous DMF to rinse the DCC vial. The reaction mixture was stirred at room temperature for two days. Precipitated dicyclohexylurea was removed by filtration. Solvent from the filtrate was removed under vacuum leaving a crude brown oil after five days. The crude product was purified by flash chromatography on a silica gel column using 1:1 ethyl acetate:hexane as an elution solvent. Fractions containing the product were combined. Solvent was removed under vacuum to yield 0.86 g (58%) of pure white compound **7**. ^1H NMR ($\text{DMSO}-d_6$): δ 3.71 (d, 2H), 4.05 (d, 2H), 4.95 (s, 2H), 5.07 (s, 2H), 7.39 (s, 5H, C_6H_5), 7.56 (t, 1H, NH), 8.47 (t, 1H, NH).

2,2,2-Trichloroethyl Glycylglycinate (8). 0.2 g (0.503 mmol) of 2,2,2-trichloroethyl N-CBZ-glycylglycinate (**7**) was dissolved in 1.5 mL of glacial acetic acid. This reaction solution was added to a flask containing 2.0 mL of HBr in acetic acid (9.35 mmol, ~30–32 wt % HBr). The reaction mixture was allowed to stand at room temperature for 30 min. The reaction solution darkened without any evidence of carbon dioxide evolution. Following addition of 40 mL of diethyl ether, the reaction mixture was cooled in the freezer for 1 h. The white precipitate that formed was collected by filtration and dried to yield 0.148 g (86%) of pure compound **8**, mp 208 °C dec. ^1H NMR ($\text{DMSO}-d_6$): δ 3.67 (s, 2H), 4.17 (d, 2H), 4.97 (s, 2H), 8.06 (bs, 3H, $^+\text{NH}_3$), 8.93 (t, 1H, NH). IR (KBr, cm^{-1}): 3280, 3200, 3000, 1740, 1660, 1530, 1410, 1370, 1250, 1160, 1100, 1070, 1040, 980, 900, 860, 800, 720, 680, 620. HRMS: mass calcd for $\text{C}_6\text{H}_9\text{N}_2\text{O}_3\text{Cl}_3$ ($\text{M} + \text{H}$) $^+$, 262.97568; found, 262.9757005.

2,2,2-Trichloroethyl δ -Benzyl L- α -N-(carbobenzyloxy)-aminoadipoylglycylglycinate (9). 0.59 g (1.18 mmol) of compound **5** was dissolved in 4.0 mL of dry DMF. To the solution was added 0.406 g (1.18 mmol) of compound **8** followed by 2.0 mL of dry DMF. The reaction solution turned slightly yellow and became homogeneous. With stirring 164 μL of neat triethylamine was added dropwise over a 5 min time period. The reaction mixture was stirred at room temperature for two days. The DMF from the reaction mixture was removed under vacuum. The crude product was purified by flash chromatography on a silica gel column using 75% ethyl acetate–hexane as an eluting solvent. The fractions containing the desired product were pooled, and the solvent was removed under reduced pressure and dried to yield 0.55 g (75%) of product. ^1H NMR ($\text{DMSO}-d_6$): δ 1.45–1.80 (m, 4H), 2.37 (t, 2H), 3.78 (d, 2H), 4.04 (d, 3H), 4.93 (s, 2H), 5.04 (s, 2H), 5.09 (s, 2H), 7.37 (s, 5H, C_6H_5), 7.52 (d, 1H, NH), 8.27 (t, 1H, NH), 8.38 (t, 1H, NH).

2,2,2-Trichloroethyl L- α -Amino- α -adipoylglycylglycinate (10). 0.515 g (0.816 mmol) of compound **9** was dissolved in 2.0 mL of glacial acetic acid. The solution was then transferred to a Parr hydrogenation bottle containing ~100 mg of 5% palladium on activated carbon. The reaction mixture was shaken with hydrogen at 60 psi for 24 h and then filtered through a Celite pad using additional acetic acid to rinse the flask and the Celite pad. Solvent from the filtrate was removed under

reduced pressure yielding a thick residue. The residue was rotary evaporated from heptane three times and then triturated with ether and dried in vacuo to yield 0.39 g (100%) of hygroscopic white solid. ^1H NMR ($\text{DMSO}-d_6$): δ 1.45–1.65 (m, 2H), 1.65–1.80 (m, 2H), 2.25 (t, 2H), 3.70–3.90 (m, 4H), 4.0–4.10 (m, 2H), 4.93 (s, 2H), 8.64 (t, 1H, NH), 8.80–8.95 (m, 2H, NH).

2,2,2-Trichloroethyl L- α -S-(1-Ethoxyethyl)mercaptoacetamido- α -adipoylglycylglycinate (13). 0.34 g (0.729 mmol) of compound **10** was dissolved in 4.0 mL of anhydrous DMF. To the solution was added 0.2 g (0.766 mmol) of compound **12** and the mixture stirred at room temperature until dissolved. Additionally 2.0 mL of anhydrous DMF was added to rinse down the sides of the flask. To the reaction mixture was added 305 μL (2.19 mmol) of triethylamine dropwise over a period of 2 min. The reaction mixture was then stirred at room temperature overnight. The DMF was removed in vacuo. Ethyl acetate was added to the residue and the precipitated solid filtered off. The filtrate was repeatedly washed with 0.1 N HCl until no NHS remained in the organic phase as indicated by TLC in a solvent mixture of $\text{Et}_2\text{O}:\text{CH}_3\text{OH}:\text{HOAc}$ (92:4:4). The organic layer was then washed with brine and dried over anhydrous sodium sulfate. The solution was filtered and concentrated under vacuum to a solid. The solid was triturated with ether, collected by filtration, and dried under vacuum to yield 0.182 g (45%) of product. ^1H NMR ($\text{DMSO}-d_6$): δ 1.097 (t, 3H), 1.414 (2d, 3H), 2.200 (t, 2H), 3.225 (d, 2H), 3.25–3.50 (m, 4H), 3.55–3.70 (d, 1H), 3.70–3.80 (d, 2H), 4.0–4.05 (d, 2H), 4.20–4.35 (m, 1H), 4.70–4.85 (p, 1H), 4.924 (s, 2H), 8.10–8.225 (d, 1H), 8.25–8.45 (m, 2H). IR (KBr, cm^{-1}): 3300, 3280, 2980, 2920, 1760, 1720, 1640, 1540, 1520, 1450, 1400, 1380, 1220, 1180, 1110, 1060, 1030, 940, 900, 850, 820, 790, 730, 660, 630. HRMS: mass calcd for $\text{C}_{18}\text{H}_{28}\text{Cl}_3\text{N}_3\text{O}_8\text{S}$ ($\text{M} + \text{H}$) $^+$, 552.07409; found, 552.0724.

2,2,2-Trichloroethyl α -S-(1-Ethoxyethyl)mercaptoacetamido(L- δ -2,3,5,6-tetrafluorophenyl)adipoylglycylglycinate (14). 0.145 g (0.262 mmol) of compound **13** was dissolved in 4.0 mL methylene chloride. To the solution was added 65 mg (0.393 mmol) of tetrafluorophenol with stirring. 65 mg (0.315 mmol) of dicyclohexylcarbodiimide was added followed by 1.0 mL of methylene chloride to rinse DCC from the vial. The reaction mixture was stirred at room temperature overnight. The dicyclohexyl urea precipitate was removed by filtration, and the solvent from the filtrate was removed under vacuum to concentrate the residue. The crude product was purified by flash chromatography on a silica gel column using $\text{EtOAc}:\text{hexane}:\text{acetic acid}$ at a ratio of 71:25:4 as an eluting solvent. Fractions containing the product were pooled. The solvent from the combined fractions was removed under reduced pressure to yield 114 mg (62%) of desired compound **14**. ^1H NMR ($\text{DMSO}-d_6$): δ 1.111 (t, 3H), 1.447 (t, 3H), 1.50–1.90 (m, 3H), 2.822 (t, 2H), 3.255 (d, 2H), 3.342 (s, 2H), 3.55–3.75 (m, 1H), 3.80–3.90 (d, 2H), 4.0–4.10 (d, 2H), 4.30–4.45 (m, 1H), 4.75–4.90 (p, 1H), 4.934 (s, 2H), 7.85–8.1 (m, 1H), 8.20–8.30 (d, 1H, NH), 8.30–8.50 (m, 2H, NH).

L- δ -2,3,5,6-Tetrafluorophenyl α -S-(1-Ethoxyethyl)mercaptoacetamidoadipoylglycylglycinate (15). 0.107 g (0.15 mmol) of compound **14** was dissolved in 1.0 mL of THF. To the solution was added 203 μL of 1.0 M potassium dihydrogen phosphate, pH 4.26. Then 100 mg of zinc dust was added with stirring at room temperature. The progress of the reaction was monitored by TLC in a solvent mixture of ethyl acetate:acetic acid (96:4). After 30 min, an additional 203 μL of buffer and 100 mg of

zinc dust were added. Stirring was continued for 90 min. The reaction mixture was then filtered through a Celite plug using THF to rinse material from the Celite. Solvent from the filtrate was then removed under reduced pressure and the crude product purified by flash chromatography on a silica gel column using the mixture CH_2Cl_2 :IPA:HOAc at a ratio of 75:20:5 as eluting solvent. Fractions containing the product were pooled, and the solvent was removed. The resulting purified residue was rotatory evaporated three times from heptane to remove the residual acetic acid and dried in vacuo overnight. The dried residue was then triturated with diethyl ether and allowed to stand for a few minutes, yielding a fine white precipitate. The supernatant ether layer was carefully decanted and residual solvent was removed under reduced pressure. This dried residue was then triturated with fresh ether. The resulting combined white solid was dried in vacuo to yield 63 mg (72%) of pure product. ^1H NMR ($\text{DMSO}-d_6$): δ 1.090 (2t, 3H), 1.43 (2d, 3H), 1.50–1.90 (m, 4H), 2.81 (t, 2H), 3.24–3.26 (d, 2H), 3.50–3.70 (2Q, 2H), 3.69 (s, 2H), 3.76 (s, 2H), 4.25–4.45 (m, 1H), 4.70–4.85 (Q, 1H), 7.85–8.05 (m, 1H, aromatic), 8.09 (t, 1H, NH), 8.23 (d, 1H, NH), 8.34 (t, 1H, NH). MS (CI): 570 ($M + 1$). Anal. Calcd for $\text{C}_{22}\text{H}_{27}\text{N}_3\text{O}_8\text{SF}_4$: C, 46.40, H, 4.78, N, 7.38, S, 5.63. Found: C, 46.29, H, 4.73, N, 7.15, S, 5.38.

2,2,2-Trichloroethyl *L*- δ -2,3,5,6-Tetrafluorothiophenyl α -S-(1-Ethoxyethyl)mercaptoacetamidopoylglycylglycinate (**16**). ^1H NMR ($\text{DMSO}-d_6$): δ 1.118 (t, 3H), 1.426 (t, 3H), 1.45–1.80 (m, 3H), 2.895 (t, 2H), 3.224–3.238 (d, 2H), 3.324 (d, 2H), 3.55–3.75 (m, 1H), 3.70–3.80 (d, 2H), 4.0–4.10 (d, 2H), 4.25–4.40 (m, 1H), 4.70–4.85 (p, 1H), 4.914 (s, 2H), 8.05–8.25 (m, 2H, NH), 8.30–8.50 (m, 2H, NH).

L- δ -2,3,5,6-Tetrafluorothiophenyl α -S-(1-Ethoxyethyl)mercaptoacetamidopoylglycylglycine (**17**). The synthesis of compound **17** is similar to compounds **14** and **15** except for using tetrafluorothiophenol in place of tetrafluorophenol to activate the carboxylic acid as described in **14**. ^1H NMR ($\text{DMSO}-d_6$): δ 1.10 (2t, 3H), 1.45 (2d, 3H), 1.50–1.85 (m, 4H), 2.85–3.0 (t, 2H), 3.20–3.25 (d, 2H), 3.25–3.50 (m, 2H), 3.50–3.80 (2Q, 4H), 4.20–4.45 (m, 1H), 4.70–4.90 (P, 1H), 8.05–8.25 (m, 1H, aromatic), 8.15–8.25 (2d, 2H, NH), 8.25–8.40 (t, 1H, NH). Anal. Calcd for $\text{C}_{22}\text{H}_{27}\text{N}_3\text{O}_7\text{S}_2\text{F}_4$: C, 45.12, H, 4.65, N, 7.18, S, 10.95. Found: C, 45.16, H, 4.54, N, 6.97, S, 11.0.

Formulation of N_3S -Adipate-STFP Reagent. The N_3S -adipate-STFP prelyophilized reagent was formulated as a 1 mL aqueous solution containing 100 μg of N_3S -adipate-STFP, 2.5 mg of sodium gluconate, 0.1 mg of stannous chloride, 0.1 mg of gentisic acid, 40 mg of lactose filler, and 26% v/v *tert*-butyl alcohol. During preparation, N_3S -adipate-STFP was dissolved at 350 $\mu\text{g}/\text{mL}$ in an $\text{H}_2\text{O}/\text{tert}$ -butyl alcohol solution (1:9) and added to an aqueous concentrate (1.4 $\times$) of the remaining ingredients adjusted to pH 1.8 with sulfuric acid. The solution was vialled in grade A borosilicate 10 mL vials fitted with 25 mm diameter gray butyl rubber lyophilization stoppers and frozen at -40°C within 30 min of preparation. Lyophilization proceeded at 50–100 m torr vacuum with maintenance of product below a collapse temperature of -25°C for 23 h for primary drying. Secondary drying proceeded upon $0.3^\circ\text{C}/\text{min}$ ramping to -12°C , holding for 16 h, followed by ramping in like manner to 25°C and holding for 20 h. Afterwards, the vials were back-filled with nitrogen to 6 in. of Hg and stoppered. Final moisture content was $<0.4\%$ as assessed by Karl Fischer assay.

Formulation of NR-LU-10 Fab Lyophilizate. NR-LU-10 Fab fragment was prepared at 20 mg/mL in 20 mM sodium citrate buffer, pH 6.2, containing 1% sorbitol as cryogenic stabilizer. Following aseptic filtration through a 0.2 μm Sartorius filter, the solution was vialled in grade A borosilicate 2 mL vials. The vials were then fitted with 13 mm diameter gray butyl rubber lyophilization stoppers and quick frozen in liquid nitrogen prior to placement on lyophilization chamber shelves cooled to -40°C . A vacuum of 50–100 m torr was applied to achieve primary sublimation over the next 17 h. Secondary drying proceeded upon ramping the temperature at $0.5^\circ\text{C}/\text{min}$ to 25°C and holding at this temperature for the next 16 h. Afterward, the vials were back-filled with nitrogen to 6 in. of Hg and stoppered. Moisture content as assessed by Karl Fischer assay was $<1\%$.

$^{99\text{m}}\text{Tc}-\text{N}_3\text{S}$ NR-LU-10 Fab Purification Column Design. Purification of the final radiolabeled protein reaction mixture utilized a custom designed plastic cartridge packed with 5 mL of QAE Sephadex anion exchange resin conditioned in 37 mM sodium phosphate, pH 6.8, at time of packing. The cartridge included a top leir lock to accommodate leir syringe loading of the radioactive reaction mixture and a bottom leir locked 25 mm diameter Sartorius filter of 0.2 μm pore size. The cartridge contained an internal channeling spoke for uniform distribution of applied reaction mixture to the resin bed. The entire assembly was sterilized by autoclaving in a Chex-all sterilizing pouch.

Preparation of $^{99\text{m}}\text{Tc}-\text{N}_3\text{S}$ -NR-LU-10 Fab Conjugate. Radiolabeling of $^{99\text{m}}\text{Tc}$ antibody Fab conjugate by the kit procedure (Scheme 2) involved the preparation of $^{99\text{m}}\text{Tc}-\text{N}_3\text{S}$ -adipate-STFP and then conjugation to the protein followed by purification using a small QAE-Sephadex column.

To prepare $^{99\text{m}}\text{Tc}$ N_3S -adipate-STFP, 1.0 mL of [$^{99\text{m}}\text{Tc}$] pertechnetate in saline (100 mCi) was added to the lyophilized N_3S -adipate-STFP reagent. The vial was shaken to dissolve contents and then vented to the air. Following addition of 0.4 mL of 2-propanol, the reaction vial was mixed, heated to 100°C for 10 min, and then cooled on ice.

While the radiolabeled active ester cooled, 10 mg of lyophilized protein was reconstituted in 2.0 mL of 0.25 M carbonate buffer, pH 9.3. The protein solution was then added to the $^{99\text{m}}\text{Tc}-\text{N}_3\text{S}$ -adipate-STFP reaction vial and incubated for 20 min at room temperature. The $^{99\text{m}}\text{Tc}-\text{N}_3\text{S}$ -NR-LU-10 Fab conjugate was purified by loading onto the QAE-Sephadex cartridge and subsequently eluting with 5 mL of normal saline (150 mM NaCl) solution.

Challenge Studies of $^{99\text{m}}\text{Tc}-\text{N}_3\text{S}$ -NR-LU-10 Fab Conjugate. The stability of $^{99\text{m}}\text{Tc}-\text{N}_3\text{S}$ -NR-LU-10 Fab was tested by incubation at 37°C for 2 h in the presence of various challenging agents. They included human serum (diluted to 50%), 100 mM DTPA, 250 mM carbonate, 10 mM cysteine, BSA, human transferrin, and 8 M urea. Samples were removed after 2 h and analyzed for radiochemical purity by either ITLC or by size exclusion chromatography.

Radiolabeled Cell Binding Assay. The immunoreactivity of $^{99\text{m}}\text{Tc}-\text{N}_3\text{S}$ -NR-LU-10 Fab was assessed in an antigen-excess cell binding assay and compared to NR-LU-10 Fab radiolabeled with ^{125}I -PIP reagent (**14**) as previously described (**15**).

Biodistribution Studies of $^{99\text{m}}\text{Tc}$ -labeled NR-LU-10 Fab. Time course biodistribution studies at 4 and 20 h postinjection were conducted separately with ^{125}I and $^{99\text{m}}\text{Tc}$ labeled NR-LU-10 Fab in nude mice bearing

Scheme 2. ^{99m}Tc Labeling and Ab Conjugation with N_3S -adipate-STFP

LS-180 colon carcinoma xenografts (16). Three to four mice per timepoint were injected intravenously via lateral tail vein with $10\ \mu\text{g}$ of protein in a $100\ \mu\text{L}$ volume. The volume of injectate was determined by weighing the syringe before and after injection. At the designated times post-injection, mice were weighed, bled via the retro-orbital plexus, and sacrificed by cervical dislocation. Thirteen organs and tissues were collected: blood (BL), tail (TA), tumor (TU), skin (SK), muscle (MU), bone (BO), lung (LU), liver (LI), spleen (SP), stomach (ST), neck (NE), kidneys (KI), and intestine (IN). Tissues were blotted when appropriate, weighed, and counted in a γ scintillation counter with the counting window set from 80 to 200 keV.

RESULTS

As seen in the synthesis of N_3S -adipate-TFP active ester ligands shown in Scheme 1, several steps involved novel or nonroutine peptide synthesis precursor derivatives to incorporate an adipate active ester moiety in the N_3S amide thiolate ligand. Selective protection of the δ -carboxylate group of adipic acid was achieved via differential hydrolysis of the dibenzyl ester. This allowed subsequent preparation of an NHS active ester at the α -carboxylate group. Trichloroethyl ester protected diglycine was then coupled to the NHS adipate derivative. Afterwards, N-CBZ and benzyl ester groups were re-

Figure 1. HPLC reverse phase isocratic (A) and gradient (B) chromatograms of ^{99m}Tc - N_3S -adipate-STFP reaction mixture. A: Retention peak at 2.45 min is a mixture of ^{99m}Tc -gluconate and ^{99m}Tc - N_3S -adipate acids while retention peaks of 5.02 and 7.30 min are ^{99m}Tc - N_3S -adipate active esters in syn/anti-epimers resulting from adipate with reference to the ^{99m}Tc oxo group (19). B: Retention peak at 2.71 min is ^{99m}Tc -gluconate; retention peaks at 20.36 and 20.91 min are syn/anti-epimers of the free acids, and retention peaks at 26.75 and 27.75 min are the syn/anti-epimers of the active esters.

moved in one step by catalytic hydrogenation. The resulting primary amine was then coupled in good yield to the S-ethoxyethyl-protected mercaptoacetate via its NHS-active ester. Final modifications to the ligand were formation of the desired TFP active ester followed by selective removal of the trichloroethyl ester protecting group using zinc dust in 1.0 M potassium hydrogen phosphate buffered solution at pH 4.26.

The ^{99m}Tc radiolabeling of the N_3S -adipate-TFP active ester requires reduction of the starting ^{99m}Tc pertechnetate, formation of an exchange ^{99m}Tc gluconate complex, transchelation of ^{99m}Tc to the N_3S -adipate-TFP active ester, conjugation of the active ester metal complex to the protein, and finally purification of the resultant product (Scheme 2). Various parameters were studied in order to optimize yields as well as minimize steps and time required for the radiolabeling process.

Stannous gluconate was used for the initial steps of pertechnetate reduction and formation of exchange gluconate chelate. Upon addition of the N_3S -adipate-TFP ligand and heating, the S-ethoxyethyl group was cleaved concomitant with ^{99m}Tc transfer into the N_3S -adipate active ester. Yields of the ^{99m}Tc chelate active ester were monitored by HPLC using isocratic and gradient systems. Elution profiles are shown in Figure 1. As the ligand contains a carboxylic acid group, it was expected that its polarity would increase water solubility, negating the need for an organic solvent such as isopropyl alcohol (IPA) (4). However, it was found that yields increased from 58% at no added IPA to 90% at 28% IPA. Low pH facilitated the loss of the ethoxyethyl hemithioacetal sulfur protecting group during chelation of the amide thiolate donor atom set. Little change in yield was noted over the pH range of 1.70–2.30. Sulfuric acid was chosen

to adjust the pH of the prelyophilized solution of stannous gluconate and N_3S -adipate-TFP ligand since strong acid maintained pH control during the subsequent lyophilization process. Stannous ion in the prelyophilized solution was quite unstable to air (Figure 2). To stabilize this reagent during the manufacturing process, gentisic acid was incorporated at 100 μg per mL of prelyophilized solution. The time required for chelation at 100 °C was also studied. Yields increased over the first 5 min, plateaued from 6 to 10 min, and then decreased upon further heating due to ester hydrolysis. Finally, the amount of ligand needed for good ester yields was determined using 100 mCi of pertechnetate from normal $^{99}Mo/^{99m}Tc$ generator elution as well as activity spiked with $^{99}TcO_4^-$ at 10^{-5} and 10^{-6} M (Table 1). At the no carrier added and 10^{-6} M levels, little dependency was seen down to a level of 25 μg N_3S -adipate-STFP ligand. As would be expected with the 10^{-5} M level of added carrier ^{99}Tc , yields increased in a stoichiometric fashion between 25 μg to 220 μg of N_3S -adipate-STFP ligand. A level of 100 μg ligand was sufficient to chelate 5.6 nmol of $^{99}TcO_4^-$, well above that found in normal generator use. For the above parameters, no significant differences in yields of purity were seen for the OTFP and STFP active esters.

Protein Labeling with ^{99m}Tc - N_3S -Adipate-TFP Active Esters. The parameters of pH, amount of protein added, and time were evaluated. In the earlier work on the pentanoate N_2S_2 kit (4), optimal yields of protein conjugate with the oxo active ester (OTFP) were obtained at pH 10. While this high pH appears to be tolerated by antibodies and their fragments, for other applications it is desirable to carry out this step at a lower pH. Consequently the thio ester of N_3S -adipate (N_3S -adipate-STFP) was synthesized and evaluated. The dependency

Figure 3. Conjugation of ^{99m}Tc - N_3S -adipate-STFP with NR-LU-10 Fab fragment as a function of pH.

Figure 4. Radiochromatogram of ^{99m}Tc - N_3S -adipate-NR-LU-10 Fab on Zorbax HPLC following anion exchange purification. Elution conditions: 0.2 M sodium phosphate (pH 7.0) at 1.0 mL/min.

of antibody conjugation yields on pH show a rise from 40% at pH 7.5 to greater than 70% at pH 9.2. Beyond this pH, yields fell off due to competing hydrolysis (Figure 3). In comparison, the optimal yield for the N_3S oxo ester (OTFP) was at pH 10. Conjugation yields increased with increasing Fab amount, rising from 40% at 2 mg to above 70% at 10 mg. Using 10 mg of Fab fragment, conjugation required 20 min incubation at room temperature for optimal yields.

Purification of the ^{99m}Tc conjugate was carried out using a closed system anion exchange QAE Sephadex cartridge column as described (4). The ^{99m}Tc forms including gluconate, pertechnetate, and N_3S carboxylates were retained on the column while the protein conjugate was eluted at neutral pH. The radiochemical purity by ITLC was 90–96% and protein recovery was $\geq 85\%$.

In Vitro Analysis. The ^{99m}Tc - N_3S -NR-LU-10 Fab conjugates were analyzed by various techniques. A size exclusion HPLC radiochromatogram (Figure 4) shows that greater than 90% of the ^{99m}Tc is attached to protein, eluting at a 45 kD molecular size. Of the later eluting non-protein bound radioactive species, 90% was ^{99m}Tc - N_3S -carboxylate and 10% was ^{99m}Tc -gluconate. Immunoreactivity assessment of the conjugate, using the Lindmo cell binding assay at antigen excess (15) showed 70% compared to 75% for the ^{125}I -PIP labeled conjugate standard.

The *in vitro* stability was evaluated by incubation of radiolabeled protein with various challenge conditions (Table 2). Insignificant loss of radioactivity after 2 h at 37 °C was seen with buffer (pH 9), DTPA, serum, and 8

**Figure 5.** Biodistribution of ^{99m}Tc -N₃S NR-LU-10 Fab and ^{125}I -PIP NR-LU-10 Fab in tumored nude mice. Panels A and B depict 4 h and 20 h timepoints, respectively.

M urea. A loss of 14% versus control was seen from challenge at a relatively high concentration of 10 mM cysteine.

In Vivo Evaluation. The tissue biodistribution and tumor targeting ability of the ^{99m}Tc -N₃S-adipate NR-LU-10 Fab was compared with ^{125}I -PIP labeled NR-LU-10 Fab in mice bearing LS-180 xenograft colon carcinoma tumors at 4 (panel A) and 20 (panel B) h postinjection (Figure 5). In normal tissues, 20 h levels are much lower, reflecting blood disappearance of radioactivity. As the kidney is the major organ processing the Fab fragment,

**Figure 6.** Biodistribution of ^{99m}Tc -N₃S NR-LU-10 Fab and ^{99m}Tc -N₂S₂ NR-LU-10 Fab in tumored nude mice. Panels A and B depict 4 h and 20 h timepoints, respectively.

the levels are relatively high in this organ for both preparations at the 4 h timepoint, but are reduced by the 20 h timepoint. In contrast, tumor uptake is about 18% ID/g at 4 h and still nearly 14% at 20 h resulting in ~40:1 tumor to blood and other organ ratios. Although, the radioiodinated Fab control was somewhat lower in tumor at 20 h post-injection, the difference is not meaningful with the number of animals at that time point.

A comparison was also made between ^{99m}Tc N₃S Fab and N₂S₂ Fab (Figure 6) at 4 (panel A) and 20 (panel B) h post-injection. Activity levels are similar in normal tissues at all timepoints. The tumor radioactivity levels are higher for the ^{99m}Tc -N₃S-adipate labeled Fab at 20 h but due to interstudy tumor uptake differences, the observed difference is not considered meaningful.

DISCUSSION

The N₃S-adipate ligand described in this study for the attachment of ^{99m}Tc to proteins represents changes in both donor atoms and an added carboxylate group over the first generation adaptation of N₂S₂ amide thiolate ligands as bifunctional chelating agents (3, 4). These changes are in the direction of added hydrophilic character of the chelating agent as well as the ^{99m}Tc chelate and ^{99m}Tc protein catabolites. It was expected that such changes would result in an all aqueous system for preformed chelate ^{99m}Tc labeling resulting in deletion of the IPA organic solvent component of the earlier N₂S₂ kit (4). Further, it was expected that reduced intestinal radioactivity would result following catabolism of the antibody Fab fragment.

Kit simplification was achieved by combining stannous reducing agent, exchange chelate gluconate, and N_3S -adipate TFP active ester chelating agent in a single vial at acid pH. The "cosolvent" isopropyl alcohol, however, was found to be essential in maintaining high yields of the intermediate chelate active ester. Thus, the process for production of the $^{99\text{m}}\text{Tc}$ chelate active ester required only the addition of pertechnetate, IPA, and heating. This contrasts with the earlier N_2S_2 kit that involved six separate components and five transfers (4).

The conjugation of the N_3S -adipate-TFP active ester chelate was improved by using a more reactive thio TFP ester rather than the oxo analog. This change allowed the conjugation to be done at a lower pH range of 8.5 to 9.5. This pH is a milder condition for base labile proteins. It also reduced both the amount of buffer needed to raise the pH for conjugation and final pH adjustment needed for radiolabeled protein purification via the anion exchange column cartridge.

The *in vitro* evaluation indicated that a $^{99\text{m}}\text{Tc}$ protein conjugate of high purity can be obtained. The resulting $^{99\text{m}}\text{Tc}$ radiolabeled protein was stable to a variety of challenge conditions except for 10 mM cysteine which caused a partial loss of radioactivity from the protein after 2 h at 37 °C. Under these conditions, no loss was seen with N_2S_2 bifunctional chelate. It should be noted that normal cysteine concentrations in serum are 0.1–0.2 mM, 50 to 100 times lower than the 10 mM concentration used here. Thus, the cysteine challenge may be seen as an indicator of relative stability.

Although the N_3S ligand appears to result in somewhat less stable attachment of $^{99\text{m}}\text{Tc}$ to protein, the *in vivo* evaluation studies in a mouse colon carcinoma xenograft model showed the $^{99\text{m}}\text{Tc}$ – N_3S antibody conjugates to have excellent tumor uptake and retention without significant accumulation in normal organs, being slightly lower than the N_2S_2 conjugate in liver, spleen, and intestine. In rat studies in which blood time course levels were compared to radioiodinated standards, the $^{99\text{m}}\text{Tc}$ – N_3S conjugates showed similar pharmacokinetics, indicating that the N_3S amide thiolate chelating group has sufficient stability for *in vivo* conditions (11).

More detailed studies of a series of related N_3S ligands (11) indicated that in the rat model, hepatobiliary excretion was decreased by about 30% due to the additional carboxylate group and thus afforded improved imaging capability in the lower abdomen. However, the added charge resulted in increased levels of radioactivity in the kidneys which would be a concern for application of these charged ligands for ^{186}Re or ^{188}Re radioimmunotherapy (17).

Limited unpublished clinical studies with the N_3S Fab conjugate show decreased lower abdominal radioactivity compared to the N_2S_2 Fab conjugate (7, 8).

CONCLUSION

The $^{99\text{m}}\text{Tc}$ labeling of proteins such as antibody Fab fragments can be done efficiently with carboxylate-substituted N_3S ligands. A formulation was developed which combines the stannous reductant, gluconate exchange chelating agent, and ligand into one vial for simpler preparation of the $^{99\text{m}}\text{Tc}$ chelate active ester. The performance of this ligand shows promise in animal and human tumor imaging studies as well as when used for the $^{99\text{m}}\text{Tc}$ radiolabeling of IL2 for autoimmune disease evaluation (18).

Effect of Biodegradable Polyrotaxanes on Platelet Activation

Nobuhiko Yui,* Tooru Ooya, and Takashi Kumeno

School of Materials Science, Japan Advanced Institute of Science and Technology, 1-1 Asahidai, Tatsunokuchi, Ishikawa 923-12, Japan. Received March 10, 1997; Revised Manuscript Received October 27, 1997[®]

Cellular response to our designed biodegradable polyrotaxanes was evaluated in terms of physicochemical interaction with plasma membrane and intracellular metabolism of platelets. The polyrotaxanes, in which many hydroxypropylated (HP-) α -cyclodextrins are threaded onto a poly(ethylene glycol) chain capped with a L-phenylalanine moiety via a peptide linkage, were synthesized and characterized. The polyrotaxanes inhibited cytoplasmic calcium increase in platelets, increased plasma membrane fluidity of red blood cell ghosts, and elevated cytoplasmic cyclic-3',5'-AMP levels in platelets. Such cellular response to the polyrotaxanes was observed, which was more than that to constituent molecules. These results suggest that the supramolecular structure of the polyrotaxanes contributes to acceleration of the physicochemical interaction with plasma membrane and intracellular metabolism of platelets. Thus, biodegradable polyrotaxanes can be useful as new biomaterials for fabricating blood-contacting devices.

INTRODUCTION

Current studies in supramolecular sciences have explored fascinating fields by constructing nanoscale devices as biomimetic systems (1, 2). A polyrotaxane has been recently demonstrated to be a molecular necklace in which many α -cyclodextrins (α -CDs) are threaded onto a poly(ethylene glycol) (PEG) chain capped with bulky end groups (3, 4). From the viewpoint of a polymeric drug carrier aiming for therapeutic application, we previously synthesized a series of biodegradable polyrotaxanes in which hydroxypropylated (HP) α -CDs are threaded onto a PEG chain capped with L-phenylalanine (L-Phe) moieties via peptide linkages (5–7). It was found that the release of HP- α -CDs was achieved only when the terminal peptide moiety was degraded by a hydrolytic enzyme (7). The cellular response to synthetic polymers is of fundamental importance to their possible therapeutic application as pharmacologically active polymers and polymeric carriers for biologically active agents (8). In our previous study, we examined interaction of the polyrotaxanes with hairless rat stratum corneum to demonstrate the feasibility of them being a transdermal penetration enhancer (9, 10). The polyrotaxanes were found to interact with lipid components in the stratum corneum (9) and to enhance the permeation of indomethacin through a full-thickness rat skin (10). Considering these results, such polymers may interact with cellular systems in a certain period until the polymers disappear due to hydrolysis.

Thrombogenesis has been shown to be initiated via both activation pathways of coagulation factors and platelets. Platelet response to synthetic polymers forms an important investigative basis for the design of blood compatible polymers (11, 12). It is well-known that platelet activation by extracellular stimuli such as thrombin is mediated by an elevation of cytoplasmic free

calcium concentration ($[Ca^{2+}]_i$) in relation to decreased membrane fluidity (13). Our systemic studies concerning blood-contacting properties of synthetic polymer surfaces have demonstrated that the prevention of contact-induced activation of platelets is a dominant factor for designing nonthrombogenic surfaces (14–16). Through these studies, it has been clarified that nonthrombogenic polymer surfaces showed no increase in $[Ca^{2+}]_i$ but enhanced membrane fluidity of platelets (11, 12). Thus, it is suggested that the regulation of intracellular calcium levels in platelets is enhanced by contacting the nonthrombogenic surfaces. In this paper, we report on cellular response to our designed polyrotaxanes by inhibiting thrombin-induced platelet activation. It was found that the polyrotaxanes inhibit thrombin-induced cytoplasmic calcium increase in platelets, increase plasma membrane fluidity of red blood cell ghosts, and, to a certain extent, elevate cytoplasmic cyclic-3',5'-AMP levels in platelets. This finding has many applications in polymeric supramolecular assemblies for constructing blood-contacting devices.

EXPERIMENTAL PROCEDURES

Chemicals. α -Cyclodextrin (α -CD), (benzyloxy-carbonyl)(Z)-L-phenylalanine (L-Phe), and propylene oxide were purchased from Wako Pure Chemical Co. Ltd. (Osaka, Japan) and used as received. *N*-Hydroxysuccinimide (HOSu) was purchased from Peptide Institute, Inc. (Osaka, Japan) and used as received. α -[(2-Amino-2-methylethyl)-x-oxypropyl]- ω -(amino-y-oxypropyl)polyoxyethylene ($x + y = 2.5$) with a number-average molecular weight (M_n) of 2000 (PEG-BA2000) was kindly supplied from Suntechno Chemical Co. (Tokyo, Japan) as JEF-FAMINE ED-2001. α -(3-Aminopropyl)- ω -(3-aminopropyl)polyoxyethylene with an M_n of 4000 (PEG-BA4000) was kindly supplied by Sanyo Chemical Co. Ltd. (Kyoto, Japan) as IONET YB-400. Fura 2-AM [1-[2-(5'-carboxyoxazol-2'-yl)-6-aminobenzofuran-5-oxy]-2-(2'-amino-5'-methylphenoxy)ethane-*N,N,N',N'*-tetraacetic acid pentaacetoxymethyl ester] was purchased from Dojin Chemical Co. (Kumamoto, Japan). Thrombin from bovine plasma (5000 units/bottle) was purchased from

[®] Abstract published in *Advance ACS Abstracts*, December 15, 1997.

Scheme 1. Synthesis of Biodegradable Polyrotaxanes in Which the $\bar{M}_n$ of PEG Is 4000 (HP- α /E4-PHE) and 2000 (HP- α /E2-PHE)^a

^a A $\approx$ 6 and B $\approx$ 2 will be assumed when the degree of HP substitution is ca. 8.

Sankyo Co. Ltd. (Tokyo, Japan). 1,6-Diphenyl-1,3,5-hexatriene (DPH) was purchased from Wako Pure Chemical Co. Ltd. Bicinchoninic acid (BCA) protein assay reagents were purchased from Pierce (Rockford, IL). Unless otherwise noted, all chemicals were purchased from Wako Pure Chemical Co. Ltd.

Synthesis of the Polyrotaxanes. Two types of biodegradable polyrotaxanes, in which the $\bar{M}_n$ of PEGs was 2000 and 4000 (Scheme 1), were synthesized according to our previous method (5–7). The synthesis of the polyrotaxanes was as follows. The inclusion complex of α -CD and PEG-BA2000 or PEG-BA4000 was prepared as reported previously (3, 4). Z-L-Phe succinimide (Z-L-Phe-OSu), which was prepared as reported previously (17), was dissolved in dry DMSO, followed by the addition

of the inclusion complex. Then, DMSO was added to the suspension until homogeneous conditions were reached and the mixture stirred at room temperature for 48 h. After washing with acetone and water to remove unreacted Z-L-Phe-OSu and the inclusion complex, the obtained polyrotaxanes (α /E2-PHE-Z or α /E4-PHE-Z) were allowed to react with propylene oxide in a 1 N NaOH solution at room temperature for 24 h. After neutralizing with HCl solution, the solution was dialyzed against water and lyophilized. Finally, the Z group in α /E2-PHE-Zs was deprotected under a H_2 atmosphere with palladium-carbon to obtain hydroxypropylated polyrotaxanes (HP- α /E2-PHE and HP- α /E4-PHE) (yield, 40%).

As reference samples, HP- α -CD and L-Phe-terminated PEGs (E2-PHE and E4-PHE) were prepared as follows.

Figure 1. ^1H -NMR spectrum of HP- α /E4-PHE (in D_2O).

α -CD was hydroxypropylated by the same manner used in the case of the polyrotaxanes. E2-PHE and E4-PHE were synthesized using Z-L-Phe-OSu and PEG-BA2000 or PEG-BA4000 in DMF. The reaction mixture was poured into excess dry ether and then washed with ether to obtain pure E2-PHE or E4-PHE. The purity was checked by ^1H -NMR and GPC (yield of HP- α -CD, 64%; yield of E2-PHE, 82%; and yield of E4-PHE, 88%).

Characterization of the Polyrotaxanes. The polyrotaxanes were characterized by ^1H -NMR and high-performance size exclusion chromatography (SEC) (5–7). From ^1H -NMR spectra of both HP- α /E2-PHE and HP- α /E4-PHE, the peaks of α -CDs, PEG, L-Phe, and hydroxypropyl groups were observed. A representative ^1H -NMR spectrum of HP- α /E4-PHE is shown in Figure 1. ^1H -NMR (D_2O): δ 7.50–7.20 (m, 5H, phenyl of L-Phe), 5.22, 5.07 (s, 6H $\times$ 23, C-1 H of α -CD), 4.20–3.35 (m, 18H $\times$ 23, C-3 H, C-6 H, C-5 H of α -CD, 3H $\times$ 184, CH₂ of hydroxypropyl groups), 3.72 (s, 4H $\times$ 90, CH₂ of PEG), 1.18 (d, 3H $\times$ 184, CH₃ of hydroxypropyl groups). The average number of α -CDs threaded onto a PEG chain was determined to be ca. 11 for HP- α /E2-PHE and ca. 23 for HP- α /E4-PHE from the ^1H -NMR, comparing the integration of the signals at δ 5.22 and 5.07 (C-1 H of α -CD) with those at δ 3.72 (CH₂ of PEG). With comparison of the integration of the signals at δ 5.22 and 5.07 (C-1 H of α -CD) with those at δ 1.18 (CH₃ of hydroxypropyl groups), the average ratio of hydroxypropylation per α -CD molecule was determined to be ca. 8 in HP- α /E2-PHE, HP- α /E4-PHE, and HP- α -CD.

SEC was performed on a column of G3000SW (30 $\times$ 2.5 cm, Tosoh, Tokyo, Japan). A HPLC system (two-line DG-980–51 degasser, Intelligent HPLC PU-980 pump, Column CO-965 oven, and Chiral OR-990 detector, Jasco, Tokyo, Japan) was used at a flow rate of 1.0 mL/min at 40 $^\circ\text{C}$. The eluent was 0.05 mol/L phosphate buffer (PBS, pH 7.0) containing 0.3 mol/L NaCl. The sample solution was prepared by dissolving HP- α /E2-PHE or HP- α /E4-PHE (4 mg) in the eluent (1 mL) and passing the solution through a filter (0.45 μm). $\bar{M}_n$ and the weight-averaged molecular weight ($\bar{M}_w$) of HP- α /E2-PHE and HP- α /E4-

PHE were determined from the SEC spectra using the PEG standard.

In order to confirm the supramolecular structure (the threading of HP- α -CDs onto a PEG chain) of the polyrotaxanes, the *in vitro* degradation experiment of the polyrotaxanes by papain was carried out as follows. HP- α /E2-PHE or HP- α /E4-PHE (3.3×10^{-3} mmol) was dissolved in 10 mL of a citrate buffer (5 mmol/L citric acid, 58 mmol/L Na_2HPO_4 , 2 mmol/L ethylenediamine-tetraacetic acid (EDTA), and 10 mmol/L mercaptoethanol at pH 7.1), followed by the addition of papain (9.5 mg, 200 units per 10 mL), and stirred at 37 $^\circ\text{C}$. The reaction mixture (0.1 mL) was sampled at an appropriate time and diluted with water (0.1 mL), followed by heating to precipitate papain. The hydrolysis of the terminal L-Phe moiety and the release of HP- α -CDs were calculated by the result of HPLC analysis [SEC columns, G2500PW_{XL} (Tosoh) for monitoring the hydrolysis of the terminal L-Phe moiety and G3000SW (Tosoh) for monitoring the release of HP- α -CD measurements] (7). As to the reference experiment, the similar *in vitro* degradation of the polyrotaxanes without papain was carried out.

Measurement of Cytoplasmic Calcium Change in Platelets. A change in the cytoplasmic free calcium concentration ($[\text{Ca}^{2+}]_i$) in platelets in contact with the polyrotaxanes was examined using a Fura 2-AM-loaded platelet suspension (11, 12). A platelet suspension in Ca^{2+} - and Mg^{2+} -free Hanks' balanced salt solution (HBSS) (platelet concentration, $3 \times 10^8/\text{mL}$) was prepared from citrated blood of male Japanese white rabbits, weighing 2.5–3.0 kg. Fura 2-AM was loaded into platelets by incubating the platelet suspension with a Fura 2-AM solution at 37 $^\circ\text{C}$ for 60 min at a Fura 2-AM concentration of 5 mM. The platelets were washed with HBSS and were finally resuspended in HBSS so that the final platelet concentration was $3 \times 10^8/\text{mL}$. The platelet suspension was recalcified with CaCl_2 so that the external calcium concentration was 1 mM just prior to use in the $[\text{Ca}^{2+}]_i$ measurements.

A $[\text{Ca}^{2+}]_i$ in platelets was measured according to the method of Tsien et al. (18). HP- α /E2-PHE or HP- α /E4-

PHE in HBSS (10 wt %, 100 μ L) was mixed with a Fura 2-AM-loaded platelet suspension (400 μ L) in a fluorescence cuvette in a fluorimeter (Japan Spectroscopic Co., Tokyo, Japan, CAF-110) at 37 °C with magnetic stirring. The mixture was excited at both 340 and 380 nm, and emission was measured at 500 nm. Fluorescence intensities at each of the two wavelengths were used to determine the fluorescence dichroic ratio 340/380 (R). $[Ca^{2+}]_i$ was calculated on the basis of the R value using the following equation (18):

$$[Ca^{2+}]_i = K_d[(R - R_{min})/(R_{max} - R)]S_{f2}/S_{b2}$$

where K_d is the dissociation constant for Ca^{2+} binding to the fluorescent dye, R_{min} and R_{max} are ratios of fluorescence emission intensities at the selected excitation wavelengths (340 and 380 nm, respectively, with very low and very high calcium concentrations, and S_{f2} and S_{b2} are proportionality coefficients for free dye and Ca^{2+} -bound dye measured at the longer excitation wavelength (380 nm), respectively. The K_d for the Ca^{2+} -Fura 2 interaction is assumed to be 224 nM in the cytoplasmic environment. R_{min} , R_{max} , and S_{f2}/S_{b2} were measured under the same conditions by adding 10 μ L of a 1% Triton-X aqueous solution and then 10 μ L of a 3 M ethylene glycol bis(β -aminoethyl ether)- N,N,N',N' -tetraacetic acid (EGTA) aqueous solution. As a control, 100–200 nM $[Ca^{2+}]_i$ in unused platelets is checked prior to the mixing with the solution.

Thrombin was used as an agonist of platelets in order to evaluate the effect of the polyrotaxanes on the platelet activation. Thrombin in HBSS (4 units/mL, 10 μ L) was added to the platelet suspension 1 min after mixing with the polyrotaxane solution (final thrombin concentration, 0.1 unit/mL). The magnitude of the increase in $[Ca^{2+}]_i$ in platelets, $\Delta[Ca^{2+}]_i$, was determined by the following equation:

$$\Delta[Ca^{2+}]_i = ([Ca^{2+}]_i)_{thr} - ([Ca^{2+}]_i)_0$$

where $([Ca^{2+}]_i)_{thr}$ is the $[Ca^{2+}]_i$ in platelets after adding thrombin in HBSS and $([Ca^{2+}]_i)_0$ is the $[Ca^{2+}]_i$ in platelets before adding thrombin in HBSS. In order to minimize time-dependent effects on platelet functions or leakage of Fura 2-AM, these experiments were completed within 1 h of Fura 2-AM loading. In the same manner, $[Ca^{2+}]_i$ was calculated for constituent molecules of the polyrotaxanes and their mixture.

Fluorescence Polarization Measurement of DPH-Loaded Red Blood Cell (RBC) Ghosts. Hemoglobin-free RBC ghosts were prepared according to Dodge et al. (19). Citrated blood of male Japanese white rabbits weighing 2.5–2.8 kg was collected and centrifuged at 1000 rpm for 15 min to obtain RBCs. RBCs were washed with a 0.155 M NaCl solution at pH 7.4 and centrifuged at 1000 rpm for 10 min two times. The suspension was washed with 15–20 volumes of 0.01 M PBS at pH 7.4 several times. After centrifugation (18 000 rpm for 30 min at 4 °C), the RBC ghost suspension was adjusted at 0.1 mg of protein/mL with a 0.155 M NaCl solution at pH 7.4 by a micro BCA method (20). DPH solution in tetrahydrofuran (2 mM) was diluted into the RBC ghost suspension to 2 μ M and incubated with gentle agitation at 37 °C for 60 min in the dark (21).

Fluorescence anisotropy of DPH in RBC ghosts was measured in order to assess the membrane fluidity (22). Fluorescence emission spectra (360–500 nm) of DPH-loaded RBC ghosts were checked at an excitation wavelength of 360 nm. The polyrotaxane solution in 0.155 M

NaCl at pH 7.4 (10 wt %, 100 μ L) was mixed with 400 μ L of the DPH-loaded RBC ghost suspension in a fluorescence cuvette in a spectrofluorimeter (Japan Spectroscopic Co., FP-777) equipped with a fluorescence polarization accessory (Japan Spectroscopic Co., ADP-300) at 37 °C with magnetic stirring. DPH was excited at 360 nm, and the fluorescence was detected at 430 nm. The slit widths for both excitation and emission were 10 nm. Fluorescence intensities were measured with polarizers inserted into the excitation and emission light paths. Fluorescence anisotropy, $\langle r \rangle$, was calculated with the following equation (22):

$$\langle r \rangle = (I_H - I_{Hb}) - G(I_V - I_{Vb}) / (I_H - I_{Hb}) + 2G(I_V - I_{Vb}), \quad G = I_V'/I_H'$$

where I_H and I_V are emission intensities observed with the analyzing polarizer horizontal and vertical with respect to the polarized excitation beam. I_{Hb} and I_{Vb} are fluorescence intensities for a blank solution (0.155 M NaCl) at the same position of the polarizer as I_H and I_V . G is a correction factor, equal to I_V'/I_H' , the primes indicating excitation polarized in a horizontal direction.

In the same manner, $\langle r \rangle$ was measured for constituent molecules of the polyrotaxanes and their mixture.

Platelet Cyclic-3',5'-AMP Assay. Cytoplasmic cyclic-3',5'-AMP (cyclic AMP) levels ($[cyclic AMP]_i$) in platelets were measured by means of a ^3H -labeled cyclic AMP assay according to the method reported by Beretz et al. (23). HP- α /E2-PHE or HP- α /E4-PHE solution (0.1 g/mL, 200 μ L) in HBSS was mixed with the platelet suspension (3×10^8 /mL, 800 μ L) in HBSS at 37 °C for 1 or 2 min. Cold trichloroacetic acid (50%, 100 μ L) was added to the suspension 1 or 2 min after the polyrotaxane addition to stop the cellular metabolism. The suspension was then centrifuged at 12 000 rpm for 1 min. The supernatant was decanted and trichloroacetic acid extracted by five washings with 3 volumes of water-saturated ether. Cyclic AMP was then measured in the supernatant by the protein binding method of Gilman (24) using a commercial kit containing [^3H]cyclic AMP (Yamasa Co., Chiba, Japan).

RESULTS AND DISCUSSION

Synthesis and Characterization of the Polyrotaxanes. The hydroxypropylation of α -CDs improved the solubility of the polyrotaxanes in PBS at pH 7.4. For example, the solubility of HP- α /E4-PHE was 85 wt %, whereas that of HP- α /E2-PHE was 28 wt % in spite of similar degree of HP substitution (eight per α -CD) (7). On SEC curves of HP- α /E2-PHE and HP- α /E4-PHE, a single peak which was detected by both optical rotation (detection of α -CD) and absorbance at 280 nm (detection of the terminal L-Phe moiety) was obtained (Figure 2). Taking the obtained ^1H -NMR spectra of the polyrotaxanes into account, the observed single peak may indicate that α -CDs are threaded onto a PEG chain with the L-Phe moiety at both terminals. $\bar{M}_n$, $\bar{M}_w$, and $\bar{M}_w/\bar{M}_n$ of the polyrotaxanes were summarized in Table 1. $\bar{M}_n$ values of HP- α /E2-PHE and HP- α /E4-PHE were determined to be 1.29×10^4 and 1.06×10^4 , respectively. These values were smaller than the calculated $\bar{M}_n$ values (1.81×10^4 for HP- α /E2-PHE and 3.75×10^4 for HP- α /E4-PHE). Since these $\bar{M}_n$ and $\bar{M}_w$ values were calculated by both $\bar{M}_n$ and $\bar{M}_w$ values of PEG maintaining the random coil structure, the $\bar{M}_n$ value of the polyrotaxanes may not be accurately estimated by SEC. Furthermore, the $\bar{M}_w$ value of HP- α /E2-PHE was larger than that of HP- α /E4-

Figure 2. SEC curves of polyrotaxanes (a) HP- α /E2-PHE and (b) HP- α /E4-PHE. Column, Tosoh G3000SW 4.4 $\times$ 30 cm; eluent, 0.05 M PBS (pH 7.0) containing 0.3 M NaCl; flow rate, 1 mL/min.

Table 1. Molecular Weight of the Polyrotaxanes^a

polyrotaxane	$\bar{M}_n (\times 10^4)$	$\bar{M}_w (\times 10^4)$	$\bar{M}_w/\bar{M}_n$
HP- α /E2-PHE ^b	1.29	3.42	2.65
HP- α /E4-PHE ^b	1.06	1.23	1.16

^a Molecular weights of the polyrotaxanes were determined by SEC as described in Experimental Procedures. A calibration curve was prepared with the PEG standard. ^b The number of α -CD in HP- α /E2-PHE and HP- α /E4-PHE was determined by ¹H-NMR to be ca. 11 and 23, respectively.

Figure 3. HP- α -CD release from HP- α /E4-PHE with (○) and without (●) 20 units/mL papain. HP- α -CD was determined by HPLC analysis (flow rate, 1 mL/min; detect, optical rotation).

PHE (Table 1). Recently, the $\bar{M}_w$ value of the polyrotaxanes was determined by static light scattering (SLS) measurements, and the $\bar{M}_w$ value of HP- α /E2-PHE was found to be larger than that of HP- α /E4-PHE (25). From these results, it is suggested that the larger $\bar{M}_w$ value of HP- α /E2-PHE was caused by the association of HP- α /E2-PHE molecules under a physiological condition (25).

Figure 3 shows HP- α -CD release from HP- α /E4-PHE by the hydrolysis of the terminal L-Phe moiety with or without papain *in vitro*. It was found that HP- α -CD was released only in the presence of papain. A similar phenomenon was observed in the case of HP- α /E2-PHE. In our previous study, it has been clarified that the HP- α -CD release was dominated by the hydrolysis of the

Figure 4. Relationship between the polyrotaxane concentration and thrombin-induced cytoplasmic calcium increase in platelets ($n = 4$, $\pm$ SEM): HP- α /E2-PHE (○) and HP- α /E4-PHE (Δ).

Figure 5. Inhibition of thrombin-induced cytoplasmic calcium increase in platelets by the polyrotaxanes ($n = 5$, $\pm$ SEM). The concentration of constituent molecules (HP- α -CD + E-PHEs, E-PHEs, HP- α -CD, and E2-OH) is equal to the mole percentage in the polyrotaxanes. Entries marked with *, **, and *** were significantly different at $P < 0.1$, $P < 0.05$, and $P < 0.001$, respectively, calculated using the *t*-test.

terminal L-Phe moiety (7). Therefore, the HP- α -CD release by the enzymatic hydrolysis indicates the threading of HP- α -CDs onto the PEG chain; i.e. the polyrotaxanes form a supramolecular structure.

Effect of the Polyrotaxanes on Cytoplasmic Calcium Change in Platelets. With the viewpoint of fabricating blood-contacting devices with these supramolecular-structured surfaces, platelet response to the polyrotaxanes will be the most important basis for preventing thrombus formation. Figure 4 shows a dose-response relationship between polyrotaxane concentration and thrombin-induced increase in $[Ca^{2+}]_i$. From this result, the most effective concentration of the polyrotaxanes (2 wt %) was selected to compare with the constituent molecules of the polyrotaxanes. With this concentration, an increase in $[Ca^{2+}]_i$ was not observed without thrombin, indicating no cytotoxicity and cellular activation (25). The thrombin-induced increase in $[Ca^{2+}]_i$ was significantly decreased by the addition of HP- α /E2-PHE or HP- α /E4-PHE solution, as shown in Figure 5. As to reference samples, a mixture of HP- α -CD and L-Phe-terminated PEG (HP- α -CD + E2-PHE or HP- α -CD + E4-PHE), E2-PHE, and E4-PHE showed a lower inhibitory effect on $[Ca^{2+}]_i$ increase, although HP- α -CD and PEG (E2-OH) showed no inhibitory effect (Figure 5). These results indicate that the polyrotaxanes significantly inhibited thrombin-induced platelet activation. Further, in order to confirm the inhibitory effect of the polyrotaxanes on thrombin-induced activation process, a similar experiment was carried out using sodium azide (NaN_3)-treated platelets. Here, NaN_3 was added to the recalcified platelet suspension to 40 mM, followed by incubation at 37 $^{\circ}C$ for 5 min prior to the addition of the polyrotax-

Figure 6. Effect of sodium azide on thrombin-induced cytoplasmic calcium increase in platelets by the polyrotaxanes ($n = 3$, $\pm$ SEM). Entries marked with *, **, and *** were significantly different at $P < 0.05$, $P < 0.01$, and $P < 0.001$, respectively, calculated using the t -test.

ane solution or the constituent molecules. The polyrotaxanes showed a significant effect on $[Ca^{2+}]_i$ increase in NaN_3 -treated platelets compared with the constituents (Figure 6). It is recognized that NaN_3 inhibits the platelet metabolism via regulation of ATP production in cytoplasmic mitochondria (26). As far as platelet metabolism is inhibited, the interaction of the polyrotaxanes with plasma membranes may induce the increase in $[Ca^{2+}]_i$. Thus, it is suggested that regulation of $[Ca^{2+}]_i$ in platelets is enhanced by physicochemical interaction of the polyrotaxanes, the mechanism of which is metabolically directed.

Quite recently, static light scattering of the polyrotaxane solutions under a physiological condition was measured (25, 27). Rod-like structure and/or associated natures of these polyrotaxanes were observed, and the association was found to depend upon the hydrophilic-hydrophobic balance of threaded HP- α -CDs and terminal L-Phe moieties. It was found that HP- α /E2-PHE showed a loosely packed association nature under a physiological condition, although HP- α /E4-PHE showed a little association. E2-PHE and E4-PHE showed a much more closely packed association nature in the physiological condition, and HP- α -CD and E2-OH showed no association (25). From these characteristics, it is considered that supramolecular structure (rod-like structure) of HP- α /E4-PHE contributes to regulating platelet functions. In addition, supramolecular association of HP- α /E2-PHE may also contribute to physicochemical interaction with cell membrane. Our previous studies have demonstrated that poly(acrylamide-co-methacrylic acid) (PAAMMAC) microparticles exhibit a similar effect on platelet activation (11, 12). Molecular assemblies seen in the polyrotaxanes as well as PAAMMAC particles may induce local interaction with plasma membrane and/or membrane proteins.

Changes in Membrane Fluidity of RBC Ghosts Caused by the Polyrotaxanes. It has been well reported that any physicochemical changes in plasma membrane such as membrane fluidity change are related to platelet activation (13). The effect of the polyrotaxanes on the plasma membrane fluidity was examined using a DPH-loaded rabbit RBC ghost suspension. A significant decrease in $\langle r \rangle$ was observed when the HP- α /E2-PHE solution was mixed with the RBC ghost suspension (Figure 7). Here, the $\langle r \rangle$ decrease indicates an increase in membrane fluidity. It was found that the addition of HP- α -CD + E2-PHE, E2-PHE, HP- α -CD, and E2-OH showed a much smaller decrease in $\langle r \rangle$ than HP- α /E2-

Figure 7. Changes in anisotropy of DPH fluorescent polarization in red blood cell (RBC) ghosts by the polyrotaxanes ($n = 3$, $\pm$ SEM). The concentration of constituent molecules (HP- α -CD + E-PHEs, E-PHEs, HP- α -CD, and E2-OH) is equal to the mole percentage in HP- α /E-PHEs. Entries marked with *, **, and *** were significantly different at $P < 0.05$, $P < 0.01$, and $P < 0.005$, respectively, calculated using the t -test.

Figure 8. Increase in cytoplasmic cyclic AMP levels in platelets by the polyrotaxanes for 1 min (shaded) and 2 min (solid) ($n = 4$, $\pm$ SEM). Entries marked with * and ** were significantly different from HP- α /E4-PHE at $P < 0.002$ and $P < 0.001$, respectively, calculated using the t -test.

PHE, as shown in Figure 7. Similar phenomena were observed in the case of samples using PEG with an $\bar{M}_n$ of 4000. Since the increase in membrane fluidity was enhanced more by HP- α /E2-PHE than by HP- α /E4-PHE, the supramolecular association of HP- α /E2-PHE may lead to a much more enhanced membrane fluidity increase than that of HP- α /E4-PHE (25). This membrane fluidity change was observed within a few seconds after the polyrotaxane addition (data not shown). Taking the rapid increase in membrane fluidity and the results of the $[Ca^{2+}]_i$ change in platelets into account, the polyrotaxanes are considered to perturb membrane structure triggering membrane-dependent signaling pathways to regulate intracellular metabolism.

Effect of the Polyrotaxanes on Cyclic AMP Levels in Platelets. As mentioned above, it is suggested that the $[Ca^{2+}]_i$ increase in platelets by the polyrotaxanes is regulated by the metabolically directed mechanism in relation to the increase in membrane fluidity. One possible way will be used to explain the inhibition as follows. The polyrotaxane can accelerate the biochemical mechanism regulating $[Ca^{2+}]_i$ in platelets. A well-known mechanism for regulating $[Ca^{2+}]_i$ in platelets is calcium inhibition by cyclic-3',5'-AMP (cyclic AMP)-dependent protein kinase via the activation of adenylate cyclase or the inhibition of cyclic AMP phosphodiesterase (28). The polyrotaxane induced an increase in $[cyclic\ AMP]_i$ in platelets, although the other references showed almost the same $[cyclic\ AMP]_i$ as the control, as shown in Figure 8. This finding was statistically significant; however, the

extent of $[\text{cyclic AMP}]_i$ increase was ca. 20%. This result suggests that the polyrotaxanes inhibit the $[\text{Ca}^{2+}]_i$ increase in platelets, the mechanism of which may involve the contribution of the $[\text{cyclic AMP}]_i$ increase. Previously, it was reported that an increase in membrane fluidity of rat reticulocytes allows adenylate cyclase to be activated by enhancing the coupling with β -adrenergic receptor (29). Taking the above report into account, it is likely that the polyrotaxanes could enhance the membrane fluidity of platelets to elevate $[\text{cyclic AMP}]_i$.

CONCLUSION

Cellular response to our designed biodegradable polyrotaxanes was examined in terms of the intracellular metabolism of platelets and physicochemical interaction with plasma membrane. The polyrotaxanes were characterized by $^1\text{H-NMR}$, SEC, and an *in vitro* degradation experiment. The inhibition of thrombin-induced cytoplasmic calcium levels in platelets was observed with the addition of our designed polyrotaxanes. Further, the polyrotaxanes were found to enhance membrane fluidity in RBC ghosts. These effects of the polyrotaxanes were statistically more significant than those of their constituent molecules such as a mixture of HP- α -CDs and L-Phe-terminated PEGs. The 20% increase in cyclic AMP levels in platelets by the polyrotaxanes suggests that the polyrotaxanes inhibit the $[\text{Ca}^{2+}]_i$ increase in platelets, the mechanism of which may involve the contribution of the $[\text{cyclic AMP}]_i$ increase. Although the relation with the supramolecular structure and association is currently under investigation, these findings could contribute to new fields of polyrotaxanes in medical and therapeutic application. These biodegradable polyrotaxanes will degrade into noninteractive components (HP- α -CD, PEG, and L-Phe) within a period of time, and will be naturally removed from the body. It is believed that biodegradable polyrotaxanes can be used to fabricate blood-contacting devices which ultimately can be absorbed in the body.

ACKNOWLEDGMENT

We thank Yamasa Co. for the cyclic AMP assay. This study was partially supported by a Proposal-Based Advanced Industrial Technology R&D Program, New Energy and Industrial Technology Development Organization (NEDO), Japan.

TECHNICAL NOTES

A New Method for the Synthesis of Neoglycopeptides[†]

Paul R. Hansen,* Carl E. Olsen, and Arne Holm

Revised Manuscript Received September 30, 1997[®]

A new method for conjugation of small carbohydrates to peptides based on maleimido–thiol chemistry is described. The reducing carbohydrate is reacted with *S*-trityl-2-mercaptoethylamine in methanol. The resulting Schiff base is then stabilized by acetylation with acetic anhydride to give an *S*-trityl-protected glycosylamide. Activation of the carbohydrate is effected by brief treatment with trifluoroacetic acid/triisopropylsilane, followed by precipitation in ether. The thiol-functionalized carbohydrate is then reacted with a maleimido-modified peptide to give a neoglycopeptide. The potential of this method was investigated using maltose as the model compound. Furthermore, we prepared five maleimido-modified model peptides. In contrast to some literature reports, we found that the maleimido group is stable to treatment trifluoroacetic acid/triisopropylsilane which was used to cleave the modified peptides from the resin.

INTRODUCTION

Glycopeptides containing an unnatural type of linkage between the saccharide moiety and peptide (e.g. a spacer) are termed neoglycopeptides. For a review of the area, see Magnusson (2) and references cited therein. Neoglycopeptides have been used for various purposes, including the determination of the influence of carbohydrate molecules on biological activity, conformation, and stability of the parent peptides (3). Neoglycopeptides have been prepared by reacting an amino group in the carbohydrate with a carboxyl group in the peptide (C-terminal, Asp,¹ Glu) (3, 4) or by reacting 3-mercaptopropionic acid spacer glycosides with the N terminus of a peptide (5). Furthermore, reductive amination (6), use of a protected valine Amadori compound in peptide synthesis (7), and

Scheme 1

periodate oxidation followed by reductive amination (8) have been described.

Boas et al. (9) reported the coupling of an unprotected sugar to the N terminus of a protected resin-bound peptide, following the method described by Blomberg et al. (10) for immobilization of reducing sugars to matrices. The formed glycosylamine was stabilized by N-acetylation and the product cleaved from the resin. However, the yield was low, and many byproducts were observed.

Schneller and Geiger (11) described a method in which a sulfhydryl group is introduced into the carbohydrate by reductive amination with cysteamine. The resulting product is then coupled to a SPDP-modified protein to form a disulfide bridge.

In this paper, we describe a new strategy for conjugation of small carbohydrates to peptides based on maleimido–thiol chemistry. Maleimido moieties react fast, selectively, and irreversibly with sulfhydryl groups to form a thioether as shown in Scheme 1.

This approach has been used for a variety of applications, including conjugation of enzymes to insulin (12), peptides to proteins (13), phosphorothioate nucleotides to proteins (14), and lipids to peptides (15), radioiodolabeling of hormones (16), and immunoassays (17). However, to the best of our knowledge, this chemistry has not been utilized for synthesis of neoglycopeptides.

RESULTS AND DISCUSSION

The principle of our approach is shown in Scheme 2 using maltose and a 6-maleimidocaproic acid-modified peptide as an example.

[†] This work was presented in part at the 24th European Peptide Symposium, Edinburgh, Scotland, September 8–13, 1996, and will be published in the proceedings (1).

¹ Abbreviations used for amino acids are according to the IUPAC-IUB Commission on Biochemical Nomenclature [(1985) *J. Biol. Chem.* **260**, 14–42]. Additional abbreviations: BME, β -mercaptoethanol; CCK, cholecystokinin; DCM, dichloromethane; DIC, *N,N'*-diisopropylcarbodiimide; DIEA, *N,N*-diethylisopropylamine; DMF, dimethylformamide; FAB-MS, fast atom bombardment mass spectrometry; Fmoc, 9-fluorenylmethyloxycarbonyl; HOBt, 1-hydroxybenzotriazole; MALDI-TOF-MS, matrix-assisted laser desorption/ionization time-of-flight mass spectrometry; Mca, 6-maleimidocaproyl; RP-HPLC, reversed-phase high-performance liquid chromatography; SPDP, *N*-succinimidyl-3-(2-pyridyldithio)propionate; SPPS, solid-phase peptide synthesis; TFA, trifluoroacetic acid; TIS, triisopropylsilane; TLC, thin-layer chromatography; Trt, triphenylmethyl.

Scheme 2

First, the protected thiol spacer *S*-trityl-2-mercaptoethylamine **1** is reacted with the reducing carbohydrate **2** in methanol. The resulting imine **3**, which is in equilibrium with the glycosylamine **4**, is then stabilized by *N*-acetylation with acetic anhydride. This principle was first described by Blomberg et al. (10) for immobilization of sugars to matrices. *N*-Acetyl-*S*-trityl-2-mercaptoethylamine **5** is generated as a coproduct in the reaction. When using a small carbohydrate such as **2**, the resulting spacer saccharide **6** may be purified by preparative RP-HPLC. Alternatively, the byproduct **5** may be removed from the crude reaction mixture by extraction. The *S*-trityl group, which is a commonly used protecting group for cysteine in Fmoc solid-phase peptide synthesis (18), is cleaved by brief treatment with trifluoroacetic acid/triisopropylsilane. Most glycosidic linkages and carbohydrate moieties are stable to treatment with TFA for 2 h, even with unprotected hydroxyl groups (19). Triisopropylsilane (20) was chosen as the scavenger for the trityl group, since water or thiol scavengers cannot be present during deprotection. Following precipitation in ether, the thiol-functionalized carbohydrate is then reacted with a maleimido-modified peptide² or protein to

²For obvious reasons, a cysteine residue with an unprotected thiol group cannot be present in the maleimido-modified peptide.

Figure 1. Analytical HPLC of **6** following purification by preparative HPLC.

give a neoglycopeptide or neoglycoprotein. When small carbohydrates are conjugated to peptides, the neoglycopeptide may be purified by preparative RP-HPLC. When small carbohydrates are conjugated to proteins, workup may be done by gel filtration.

Synthesis of a Spacer-Modified Carbohydrate Model Compound. Using the above-described procedure with maltose, we prepared the model spacer saccharide *N*-acetyl-[2-[*S*-(triphenylmethyl)mercapto]ethyl]-[α -D-glucopyranosyl(1 $\rightarrow$ 4)]- β -D-glucopyranosylamine (**6**). The course of the reaction was easily monitored by RP-HPLC. After overnight reaction, two peaks were observed. The imine **3** and starting material **1** eluted approximately after 30 and 40 min, respectively. After acetylation with a large excess of acetic anhydride and overnight reaction, the aforementioned peaks had disappeared; two new peaks appeared at approximately 37 min (**6**) and 47 min (**5**). HPLC analysis of the crude reaction mixture before workup always revealed some accompanying *O*-acetylated carbohydrate, with a t_R of $\sim$ 39 min, usually less than 5%. Attempts to recover unreacted maltose by collecting the elute from the first 10 min only resulted in minute amounts of sugar. Compound **6** was obtained in 62% yield following preparative RP-HPLC (Figure 1).

An alternative purification procedure for **6** involved washing the crude reaction mixture extensively with DCM. Using this approach, **6** could be obtained in 43.5% yield. The crude product may be used without further purification since unreacted maltose will not interfere with the subsequent conjugation reaction. When using 5 equiv of *S*-trityl-2-mercaptoethylamine, the reaction

product was completely soluble in DCM. In this case, crude **6** was obtained by washing the lyophilized mixture extensively with water.

As described by Blomberg et al. (10), we observed two methyl signals in the ^1H NMR spectrum of **6** (at 1.82 and 2.10 ppm), indicating the presence of two rotamers in the ratio 1:3.4. The $J_{1,2}$ values for the two rotamers (9.4 Hz, 5.24 ppm, H-1a; and 8.9 Hz, 4.65 ppm, H-1b) show that the glycosylamide **6** has the β -configuration. For α -linked *N*-glycopeptides, the $J_{1,2}$ value is typically 5–6 Hz (21).

The ^{13}C NMR spectrum of **6** revealed 22 signals stemming from the major rotamer. All the expected peaks were identified. As with the ^1H NMR spectrum, minor peaks indicated the presence of the other rotamer.

Synthesis of a Maleimido-Modified Model Peptide. Keller and Rudinger (22), Marburg et al. (23), and Wünsch et al. (24) have reported that the maleimido group is sufficiently stable toward TFA to allow its incorporation into a peptide chain. However, Papini et al. (25) reacted several histidine-containing porcine CCK-related peptides with *N*-hydroxy succinimido maleoyl- β -alaninate in DMF. They found that during workup under neutral conditions the *N*^{im}-imino function of the side chain of histidine reacts nearly quantitatively with the maleimido function. Furthermore, Papini and co-workers found this intramolecular cyclization reaction to proceed at remarkably higher rates than the bimolecular alkylation of histidine derivatives with *N*-ethylmaleimide.

Jensen and Jakobsen (26) reported the direct solid-phase peptide synthesis of *N*-maleoyl- β -alanyl-Leu-Ala-Gly-Val-OH using Fmoc chemistry. The product was cleaved from the resin with neat TFA, TFA/H₂O, or TFA/triethylsilane and isolated in good purity after gel filtration. Contrary to the above, Rusiecki et al. (27) claim that the maleimido group is degraded in TFA/CH₂Cl₂.

In order to investigate the stability of the maleimido group to cleavage conditions of Fmoc SPPS, the model peptide Mca-WHRQDGKL-OH was synthesized. The peptide was designed so that it would contain the most commonly used side chain protecting groups (Boc, *t*Bu, trityl, and Pmc) in Fmoc SPPS. Furthermore, we chose 6-maleimidocaproic acid (Mca) as the spacer, since this compound would be less prone to intramolecular cyclization compared to *N*-hydroxy succinimido maleoyl- β -alaninate.

After each coupling step, starting with Asp⁵, 50 mg of resin was removed and derivatized with 6-maleimidocaproic acid. The product was then cleaved from the resin with TFA/TIS (95:5) and subjected to analytical HPLC. In each case, the desired maleimido-modified peptide was obtained in >80% purity and showed the correct mass by FAB-MS. Analytical HPLC of crude Mca-WHRQDGKL-OH is shown in Figure 2. In order to establish that the maleimido function was available for conjugation, we reacted both Mca-HRQDGKL-OH and Mca-WHRQDGKL-OH with β -mercaptoethanol (BME) in 0.1 M NaOAc buffer at pH 4. After 18 h, the mixture was analyzed by HPLC and FAB-MS. In both cases, FAB-MS showed that BME had reacted with the maleimido group. Furthermore, the analytical HPLC showed no sign of starting material, but one new peak eluting 0.5 min earlier than the maleimido-modified peptide.

Conjugation of a Spacer-Modified Carbohydrate to Maleimido-Modified Peptides. Encouraged by these results, we then synthesized two maltose-containing model neoglycopeptides, α -D-Glcp(1 $\rightarrow$ 4)- β -D-Glcp-1-*N*-(Ac-(CH₂)₂-S-Mca-DRVYIHPF (**9a**) and α -D-Glcp(1 $\rightarrow$ 4)- β -D-Glcp-1-*N*-(Ac-(CH₂)₂-S-Mca-YETPTRMLVAGIAA (**9b**)

Figure 2. Analytical HPLC of crude WHRQDGKL-OH modified with 6-maleimidocaproic acid.

in a small scale using the approach outlined in Scheme 2. The crude maleimido-modified peptides Mca-DRVYIHPF and Mca-YETPTRMLVAGIAA were obtained in greater than 80% purity and used without further purification. The conjugation reaction was carried out in 0.1 M NaOAc at pH 4. The progress of the reaction was followed by analytical RP-HPLC and found to be complete after 18 h. Following purification by RP-HPLC, the neoglycopeptides were isolated in 71.2 and 55.4% yield, based on **6**. Both **9a** (Figure 3) and **9b** (Figure 4) were isolated in high purity. The products were analyzed by MALDI-TOF-MS, and in both cases, the expected mass was obtained.

In conclusion, we have investigated a new strategy for conjugation of reducing carbohydrates to peptides based on maleimido–thiol chemistry. We were able to show that this method works on a small scale for short carbohydrates by conjugating the maltose spacer saccharide *N*-acetyl-*N*-[2-[*S*-(triphenylmethyl)mercapto]ethyl]-[α -D-glucopyranosyl(1 $\rightarrow$ 4)]- β -D-glucopyranosylamine (**6**) to some maleimido-modified peptides. In both cases, very pure products were obtained, upon purification by RP-HPLC.

EXPERIMENTAL PROCEDURES

General. Analytical HPLC was performed using a Waters C₁₈ reversed-phase column (Delta-Pak, 100 Å, 15 μm , Millipore) on a Waters 600E system equipped with Millennium software. Samples were chromatographed at a flow rate of 1.5 mL/min starting with 0.1% aqueous TFA (buffer A) for 10 min and increasing over 45 min to 0.1% TFA in CH₃CN/H₂O (9:1) (buffer B), with detection at 220 nm. For preparative HPLC, a Waters C₁₈ reversed-phase column (RCM-module, Millipore) was used.

Figure 3. Analytical HPLC of **9a** following purification by preparative HPLC.

NMR spectra were recorded on a Bruker AC 250P instrument. Amino acid analyses were performed on a Waters Pico-Tag analyzer after samples were hydrolyzed with 6 N aqueous HCl/0.1% phenol at 110 °C for 18 h. MALDI-TOF-MS was carried out on a Fisons ToFSpec E instrument in the linear mode. FAB-MS was carried out on a JEOL JMS AX505W instrument. TLC was carried out on Kiesel Gel 60 F₂₅₄ Plates (Merck, Germany). Spots were visualized by UV or spraying with a dilute solution of sulfuric acid followed by heating. Melting points were determined on a Gallenkamp melting point apparatus.

Chemicals. Protected amino acids and Pepsyn KA resin were purchased from Milligen (Bedford, MA). Triisopropylsilane, DIC, MBS, and HOBt were obtained from Aldrich. 6-Maleimidocaproic acid was obtained from Fluka. DMF and DCM were from Riedel de Haën (Seelze, Germany).

Peptide Synthesis. Peptide synthesis was accomplished manually in a syringe equipped with a filter by a stepwise solid-phase peptide synthesis procedure starting with a Pepsyn K resin (0.200 g, 0.1 mequiv/g) using the Fmoc/tBu protection scheme (18). The following side chain-protected amino acid derivatives were used: Arg-(Pmc), Asp(tBu), His(Boc), Tyr(tBu), Lys(Boc), Thr(tBu), and Trp(Boc).

The amino acids were coupled in 3-fold excess using DIC (3 equiv) and HOBt (1.5 equiv) in DMF for 2 h. Fmoc removal was accomplished by treatment for 2 × 10 min with 20% piperidine in DMF.

Following peptide synthesis, 6-maleimidocaproic acid (10 equiv) was coupled overnight to the peptidyl resin using DIC (10 equiv) and HOBt (1.5 equiv) in DMF. The product was cleaved from the support with TFA/TIS (90: 5, v:v) (2 mL) for 2 h and the resin washed with TFA.

Figure 4. Analytical HPLC of **9b** following purification by preparative HPLC.

The combined TFA washes (3 × 5 mL) were evaporated *in vacuo*, and the product was precipitated in dry ether (5 mL). After centrifugation, the product was washed three times with ether (3 × 5 mL) and dried. In order to investigate the stability of the 6-maleimidocaproic acid (Mca) moiety to cleavage conditions of Fmoc SPPS, a 6-maleimidocaproic acid-modified model peptide, Mca-WHRQDGKL-OH, was synthesized. After each coupling step, starting with Asp⁵, 50 mg of resin was removed and derivatized with 6-maleimidocaproic acid as described above and subjected to analytical HPLC.

Mca-DGKL-OH HPLC purity: >95%. FAB-MS: calcd for [M + H⁺] (C₂₈H₄₄N₆O₁₀) 624, found 625. Mca-QDGKL-OH HPLC purity: >95%. Mca-RQDGKL-OH HPLC purity: >95%. Mca-HRQDGKL-OH HPLC purity: >80%. FAB-MS: calcd for [M + H⁺] (C₄₅H₇₁N₁₅O₁₄) 1046, found 1068 [M + Na]⁺. Amino acid analysis (found/theory): Asp (1.0/1), Glu (1.0/1), Gly (1.1/1), His (0.9/1), Arg (1.0/1), Leu (1.1/1), Lys (1.1/1). Mca-WHRQDGKL-OH HPLC purity: >80%. MALDI-TOF-MS: calcd for [M + H⁺] (C₅₆H₈₂N₁₇O₁₅) 1233, found 1233.

In order to establish that the maleimido function was available for conjugation, Mca-HRQDGKL-OH (1 mg, 1.0 × 10⁻³ mmol) was dissolved in 0.1 M NaOAc buffer at pH 4 (1 mL), to which was added BME (10 μL, 1.2 × 10⁻¹ mmol). After 18 h, the reaction mixture was analyzed by HPLC which showed no sign of starting material, but one new peak eluting 0.5 min earlier as compared to the maleimido-modified peptide. FAB-MS: calcd for [M + H⁺] (C₄₇H₇₆N₁₅O₁₅S) 1123, found 1124.

A similar experiment was carried out with Mca-WHRQDGKL-OH. MALDI-TOF-MS: calcd for [M + H⁺] (C₅₈H₈₇N₁₇O₁₆S) 1310, found 1308. Mca-DRVYIHPF amino acid analysis (found/theory): Asp (0.9/1), His (1.0/

1), Arg (0.8/1), Pro (0.8/1), Tyr (0.9/1), Val (1.0/1), Ile (0.9/1), Phe (1.0/1). MALDI-TOF-MS: calcd for $[M + H^+]$ ($C_{60}H_{83}N_{14}O_{15}$) 1240, found 1241. HPLC showed one major peak with a t_R of 34 min ($>85\%$ purity). Mca-YEVPTRMLVAGIAA amino acid analysis (found/theory): Glu (0.8/1), Gly (1.0/1), Arg (0.8/1), Ala (3.0/3), Thr (1.5/2), Pro (0.9/1), Tyr (0.8/1), Val (1.7/2), Met (1.0/1), Ile (0.9/1), Leu (1.0/1). MALDI-TOF-MS: calcd for $[M + H^+]$ ($C_{81}H_{130}N_{19}O_{24}S$) 1786, found 1786. HPLC showed one major peak with a t_R of min 37 ($>80\%$ purity).

Synthesis of S-Trityl-2-mercaptoethylamine (1). The title compound was prepared as described by Herman et al. (28).

Synthesis of N-Acetyl-N-[2-[S-(triphenylmethyl)mercapto]ethyl][α -D-glucopyranose(1 $\rightarrow$ 4)]- β -D-glucopyranosylamine (6). Method A. Maltose monohydrate (18 mg, 0.05 mmol) and S-trityl-2-mercaptoethylamine (32 mg, 0.1 mmol) in MeOH were refluxed for 18 h. Next, Ac_2O (500 μ L, 5.0 mmol) was added at 0 $^{\circ}C$, and the mixture was left stirring for 18 h. The solvent was then removed by evaporation and the residue dissolved in H_2O/CH_3CN (4:1) and lyophilized. The resulting white powder was dissolved in methanol (2 mL) and purified by preparative HPLC to give 21.2 mg (61.8%) of the title compound. FAB-MS: calcd for $[M + H^+]$ ($C_{35}H_{44}O_{11}NS$) 686, found 686.

Selected ^1H NMR data (a = minor rotamer, b = major rotamer; 250 MHz, CH_3OD): δ 7.3 (m, 15H, aromatic H), 5.24 ($J_{1,2} = 9.39$ Hz, β -D-Glcp, H-1a), 5.18 ($J_{1,2} = 3.9$ Hz, α -D-Glcp, H-1), 4.65 ($J_{1,2} = 8.9$ Hz, β -D-Glcp, H-1b), 3.10 (t, 2.2H, CH_2N), 2.5 (m, 2H, CH_2S), 2.10, (s, 2.3H, methyl), 1.82 (s, 0.7H, methyl). ^{13}C NMR (62 MHz, CH_3OD): δ 174.7 (CON), 146.5 (C-1 aromatic ring), 130.9, 129.1, 129.0, 128.1, 128.0 (aromatic ring C), 103.0 (C-1, α -D-Glcp), 88.6 (C-1, β -D-Glcp), 81.1 (C-4, β -D-Glcp), 79.2, 78.8 (C-5, α -D-Glcp and β -D-Glcp), 75.1, 74.9 (C-3, α -D-Glcp and β -D-Glcp), 74.2 (C-4, α -D-Glcp), 71.5, 71.3 (C-2, α -D-Glcp and β -D-Glcp), 68.0 [$SC(Ph)_3$], 62.7 (C-6, α -D-Glcp and β -D-Glcp), 45.3 (CH_2N , a), 42.1 (CH_2N , b), 32.7 (CH_2S , a), 31.5 (CH_2S , b), 22.0 (CH_3). The carbohydrate carbon atoms were assigned on the basis of literature values (29).

Anal. Calcd for $C_{35}H_{43}O_{11}NS$: C, 61.3; H, 6.32; N, 2.04; S, 4.67. Found C, 59.9; H, 5.8; N, 1.9; S, 4.2.

Method B. Maltose monohydrate (36 mg, 0.1 mmol) and S-trityl-2-mercaptoethylamine (64 mg, 0.2 mmol) were reacted in MeOH as described above. Following lyophilization, the reaction mixture was washed with DCM (10 $\times$ 2 mL) to remove excess **1** and byproduct **5**. The product was then lyophilized to give 29.8 mg of crude **6** (43.5%).

Method C. Maltose monohydrate (36 mg, 0.1 mmol) and S-trityl-2-mercaptoethylamine (160 mg, 0.5 mmol) were reacted in MeOH as described above, except that 2 mL of acetic anhydride was used. Following lyophilization, the product was extracted by washing with H_2O (250 mL) to give 32.1 mg of product (46.9% crude yield).

Synthesis of α -D-Glcp-(1 $\rightarrow$ 4)- β -D-Glcp-1-N-Ac-(CH_2)₂-S-Mca-DRVYIHPF (9a). **6** (1 mg, 1.5×10^{-3} mmol) was deprotected by treatment with TFA/TIS (95:5, 1 mL) for 5 min. The solution turned yellow upon adding the deprotection mixture. However, the color disappeared after a few seconds, indicating a very fast reaction. Following evaporation, the product was precipitated in ether and dried. In a separate experiment, HPLC analysis of the product showed no trace of the starting material **6**. The thiol-functionalized carbohydrate was then dissolved in 500 μ L of 0.1 M NaOAc buffer at pH 4, transferred to a test tube containing conjugate Mca-

DRVYIHPF (3.5 mg, 2.8×10^{-3} mmol), and diluted with buffer to a final volume of 1 mL. The reaction mixture was left on a rocking table overnight, lyophilized, and purified by preparative HPLC. The yield was 1.8 mg (71.2% based on **6**). Analytical HPLC is shown in Figure 3. MALDI-TOF-MS: calcd for $[M + H^+]$ ($C_{76}H_{113}N_{15}O_{25}S$) 1684.9, found 1685.0.

Synthesis of α -D-Glcp-(1 $\rightarrow$ 4)- β -D-Glcp-1-N-Ac-(CH_2)₂-S-Mca-YETPTRMLVAGIAA (9b). **6** (1.5 mg, 2.2×10^{-3} mmol) was conjugated to Mca-YETPTRMLVAGIAA (5 mg, 2.8×10^{-3} mmol) as described above. The product was purified using preparative HPLC (Figure 4). The yield was 2.7 mg. (55.4% based on **6**). MALDI-TOF-MS: calcd for $[M + H^+]$ ($C_{97}H_{160}N_{20}O_{35}S_2$) 2230.6, found 2229.3.

Synthesis of Carbon-3-Substituted 1,5,9-Triazacyclododecanes, RNA Cleavage Agents Suitable for Oligonucleotide Tethering

Jari Hovinen*,†

Department of Chemistry, University of Turku, FIN-20014 Turku, Finland. Received June 2, 1997;
Revised Manuscript Received September 30, 1997*

Two derivatives of 1,5,9-triazacyclododecane bearing an alkylamino tether group at carbon-3 (**7** and **13**) were synthesized. The first of them, **7**, was prepared starting from diethyl 2-(2-cyanoethyl)malonate and the second one, **13**, from glycerol. In both cases, the cyclization reaction was performed by allowing the corresponding ditosylates (**5** and **12**) to react with TBD. The guanidinium salts formed were reduced *in situ* to the orthoamides (**6** and **12**), acid-catalyzed hydrolysis of which yielded the title compounds. The suitability of the azacrowns prepared for oligonucleotide tethering is also demonstrated.

INTRODUCTION

The use of oligonucleotides in the treatment of certain viral diseases and types of cancer is based on inhibition of the unwanted protein translation by hybridization of the target mRNA molecule with a complementary oligonucleotide (*1*). When unmodified oligodeoxyribonucleotides or oligonucleotide monothioates are employed, the RNA/DNA duplex formed serves as a substrate for cellular RNase H that cleaves the mRNA strand. Direct degradation of the target RNA fragment can be achieved by oligonucleotides tethered to catalytically active groups. The oligonucleotide moiety recognizes a complementary base sequence in the target nucleic acid, and the catalytic group cleaves the chain over a narrow range of nucleotide units. Up to now, several such catalytically active oligonucleotide conjugates that hydrolyze the target RNA chain have been synthesized (2–9). However, many of them have some drawbacks; they either exhibit only moderate RNA cleaving activity or use “unnatural” metals, such as europium.

It has been shown that certain azacrowns, such as 1,5,9-triazacyclododecane, promote hydrolysis of RNA fragments in the presence of Zn²⁺ ions (10–12). The greatest rate enhancement observed was a reaction 10⁷–10⁸-fold faster compared to the uncatalyzed reaction. Thus, by linking these metal ion complexes covalently to oligodeoxyribonucleotides, we could obtain an efficient site specific hydrolysis of the complementary RNA sequence, upon hybridization.

We have recently developed a versatile strategy for oligonucleotide tethering. A thioester function is attached to the oligonucleotide during chain assembly, and upon completion of the synthesis, the desired functional group is introduced by treating the oligomer, when still anchored to the solid support, with an appropriate primary amine (9, 13). To exploit our tethering strategy

in the preparation of oligonucleotide conjugates, synthesis of azacrowns bearing an alkylamino spacer in their structure is needed. The only method reported in the literature that can be applied to our tethering strategy involves a multistep synthesis of 2-(4-aminobutyl)-1,4,7-triazacyclononane starting from L-alanine methyl ester (14). Here is presented a simple synthesis of two carbon-3-substituted 1,5,9-triazacyclododecanes (**7** and **13**). Their suitability for oligonucleotide tethering is also demonstrated.

EXPERIMENTAL PROCEDURES

Adsorption column chromatography was performed on columns packed with Kieselgel 60 (Merck). Analytical TLC was conducted on silica gel 60 F₂₅₄ plates (Merck) using the following solvent systems: (A) 9:1 CH₂Cl₂/MeOH (v:v); and (B) 99:1 CH₂Cl₂/MeOH (v:v). Compounds containing Boc-protected primary amino functions were detected using the following procedure. After normal elution with the appropriate solvent system, the TLC plate was kept on a hot plate for a few seconds. This removes the Boc group, and the spots containing primary amino groups were visualized on spraying with ninhydrin.

NMR spectra were recorded on a JEOL LA-400 spectrometer operating at 399.8 and 100.5 MHz for ¹H and ¹³C, respectively. If not otherwise stated, TMS was used as an internal reference (0.00 ppm). Coupling constants are given in hertz. Identification of NMR signals is based on ¹H, ¹H and ¹H, ¹³C COSY experiments. Mass spectra were recorded either on a VG Analytical MM 7070E (electron impact) or on a VG ZabSpec-ao TOF (fast-atom bombardment) spectrometer. IR spectra were recorded on a Mattson Instruments 6030 Galaxy Series spectrophotometer, and elemental analyses were performed on a Perkin-Elmer 2400 Series II instrument. Melting points were measured on a Büchi 510 apparatus and are uncorrected.

Oligonucleotides were assembled on an Applied Biosystems 392 DNA synthesizer using phosphoramidite chemistry and recommended protocols (DMTr-Off synthesis). Oligonucleotides were purified by HPLC techniques as described previously in detail (15). MALDI-TOF spectrometric measurements of oligonucleotides were performed on a Finnigan LaserMat mass spectrometer using protocols described by Piele et al. (16).

tert-Butyl-N-[4-(hydroxymethyl)-5-hydroxypentyl]-carbamate (3) and tert-Butyl-N-[4-(ethoxymethyl)-5-hydroxypentyl]carbamate (4). Diethyl 2-(2-cyanoethyl)malonate (23.4 mmol, 5.0 g) was dissolved in dry THF (20 mL). The borane–methyl sulfide complex (15 mL, 10 M) was added dropwise under a flow of nitrogen. The mixture was heated at reflux with distilling off the methyl sulfide liberated. When the distillation had ceased, the reaction mixture was cooled on an ice bath, and aqueous HCl (6 M, 30 mL) was added dropwise (Caution! Vigorous liberation of H₂). The mixture was refluxed for 30 min, and the clear solution obtained was concentrated *in vacuo*. The residue was suspended in water and filtered. The filtrate was basified with solid NaOH; di-*tert*-butyl dicarbonate (5.46 g, 25 mmol) in THF (100 mL) was added, and the mixture was stirred overnight at ambient temperature. The mixture was concentrated *in vacuo*. The residue was suspended in dichloromethane and washed with water. The organic layer was separated, dried (Na₂SO₄), and concentrated. The oil obtained was dissolved in the mixture of dichloromethane and methanol (9:1, v:v) and purified on a silica gel column using the same solvent system as the eluent. Two products were separated.

Compound 4: 3.60 g (59%); *R_f* (A) 0.65; ¹H NMR (DMSO-*d*₆) δ 6.72 (1H, br t, NH), 4.32 (1H, t, *J* = 5.1, OH), 3.39–3.20 (6H, q, *J* = 7.1, OCH₂CH₃ and m, 2 × CH₂OH), 2.86 (2H, m, CH₂NH), 1.59 (1H, m, CH), 1.19 (12H, s and m, *t*-Bu and CH₂CH), 1.20 (2H, m, CH₂CH₂-CH₂), 1.08 (3H, t, *J* = 7.1, CH₂CH₃); ¹³C NMR (DMSO-*d*₆) δ 155.6, 77.2, 70.7, 65.5, 61.3, 40.8, 40.3, 28.3, 27.1, 25.3, 15.2.

Compound 3: 1.9 g (34%); *R_f* (A) 0.45; ¹H NMR (DMSO-*d*₆) δ 6.76 (1H, br t, *J* = 5.4, NH), 4.30 (2H, t, *J* = 5.1, 2 × OH), 3.40 (4H, m, overlapping with the signal of H₂O, 2 × CH₂OH), 2.87 (2H, m, CH₂NH), 1.43–1.38 (3H, m, CH and CH₂CH), 1.37 (9H, s, *t*-Bu), 1.19 (2H, p, CH₂CH₂-CH₂); ¹³C NMR (DMSO-*d*₆) δ 155.6, 77.3, 61.5, 42.9, 40.4, 28.3, 27.2, 24.9. Anal. (C₁₁H₂₃NO₄): C, H, N.

cis-2-(Cyanoethyl)-1,3-benzylidene Glycerol (9). *cis*-1,3-Benzylidene glycerol **8** (17) (20 g, 0.11 mol) and acrylonitrile (15 mL, 0.2 mol) were dissolved in dry THF (200 mL), and the mixture was cooled on an ice bath. NaH (0.1 g) was added, and the mixture was allowed to stir for 30 min, after which water (50 mL) was added. THF was evaporated *in vacuo*. Water (100 mL) was again added, and the resulting suspension was extracted with diethyl ether (2 × 100 mL). The etheral layer was dried (Na₂SO₄) and concentrated to an oil, which was crystallized from ether to give **9** (15 g, 58%); mp 54 °C; IR (KBr, cm⁻¹) 2251 (CN); ¹H NMR (CDCl₃) δ 7.45 (2H, m), 7.36 (3H, m), 5.56 (1H, s), 4.37 (2H, dd, *J* = 1.5 and 13.0), 4.10 (2H, dd, *J* = 1.7 and 13.0), 3.85 (2H, t, *J* = 6.3), 3.42 (1H, m), 2.69 (2H, t, *J* = 6.3); ¹³C NMR (CDCl₃) δ 137.8, 129.0, 128.3, 126.0, 117.8, 101.3, 71.5, 68.8, 63.6, 19.2. Anal. (C₁₃H₁₅NO₃): C, H, N.

2-[3-[N-(tert-Butoxycarbamoyl)aminolpropyl]glycerol (10). Compound **9** (14.68 g, 63.1 mmol) was dissolved in methanol (300 mL). Cobalt(II) chloride hexahydrate (30 g) was added, and the mixture was cooled on an ice bath. Sodium borohydride (24 g) was added portionwise (Caution! Exothermic reaction and vigorous foaming), and the mixture was allowed to stir for 2 h, after which concentrated aqueous ammonia (150 mL) was added. The black precipitate was filtered off cautiously (paper filter and no vacuum). Methanol was removed *in vacuo*, and the residue was extracted with dichloromethane. The organic phase was concentrated and dissolved in the mixture of 1 M HCl and THF (200

mL, 1:1, v:v) and kept overnight at ambient temperature. All volatile material was removed *in vacuo*. The residue was dissolved in water and basified with solid NaOH. Di-*tert*-butyl dicarbonate (13 g, 65 mmol) in THF (20 mL) was added, and the mixture was allowed to stir overnight at ambient temperature. The mixture was concentrated to ca. 20 mL and extracted with dichloromethane until TLC analysis showed that all the product was transferred into dichloromethane. The combined organic phases were dried (Na₂SO₄), concentrated, and purified on silica gel (eluent, 9:1 CH₂Cl₂/MeOH, v:v). Pure fractions were pooled and concentrated to give **10** as an oil (5.9 g, 38%); ¹H NMR (CDCl₃) δ 4.96 (1H, br), 3.76 (2H, dd, *J* = 4.1 and 12.0), 3.69 (2H, dd, *J* = 5.1 and 12.0), 3.62 (2H, t, *J* = 5.6), 3.44 (1H, m), 3.30 (2H, br t, *J* = 6.1), 2.60 (2H, br), 1.74 (2H, p), 1.44 (9H, s); ¹³C NMR (CDCl₃) δ 156.7, 80.3, 79.6, 66.7, 62.1, 30.6, 28.4. Anal. (C₁₁H₂₃NO₅): C, H, N.

(2-Methyl-*p*-tolylsulfonyl)-5-(N-tert-butoxycarbamoyl)pentane Tosylate (5). Compound **3** (1.0 g, 4.3 mmol) was dried by coevaporations with dry pyridine and dissolved into the same solvent (15 mL). Tosyl chloride (2.4 g, 12.9 mmol) and a catalytic amount of DMAP were added, and the mixture was stirred overnight at ambient temperature. All volatile materials were evaporated off *in vacuo*, and the residue was dissolved in dichloromethane, washed with aqueous NaHCO₃, and dried (Na₂SO₄). After concentration, the residue was redissolved in CH₂Cl₂ and applied onto a silica gel column. The column was eluted initially with CH₂Cl₂ to remove the excess tosyl chloride and then with the mixture of CH₂Cl₂ and methanol (99:1, v:v) to elute the product. The yield was 1.86 g (80%); *R_f* (B) 0.38; ¹H NMR (CDCl₃) δ 7.74 (4H, d, *J* = 8.3), 7.36 (4H, d, *J* = 8.3), 4.57 (1H, br t), 3.95 (4H, m), 3.00 (2H, m), 2.50 (6H, s), 2.00 (1H, m), 1.43 (9H, s), 1.40 (2H, m), 1.32 (2H, m); ¹³C NMR (CDCl₃) δ 155.9, 145.3, 132.5, 130.0, 127.9, 79.2, 68.6, 40.1, 37.7, 28.4, 26.9, 24.2, 21.7. Anal. (C₂₅H₃₅NO₈S₂): C, H, N, S.

2-[3-(N-tert-Butoxycarbamoyl)propoxy]propane 1,3-Ditosylate (11). Compound **10** (5.0 g, 20 mmol) was tosylated and purified as described above for **5**. The yield was 9.4 g (84%); *R_f* (B) 0.39; ¹H NMR (CDCl₃) δ 7.76 (4H, d, *J* = 8.1), 7.35 (4H, d, *J* = 8.1), 4.06 (4H, m), 3.68 (1H, p, *J* = 5.1), 3.35 (2H, t, *J* = 5.9), 3.07 (2H, br q), 2.43 (6H, s), 1.60 (2H, p, *J* = 6.1), 1.43 (9H, s); ¹³C NMR (CDCl₃) δ 155.7, 144.9, 132.0, 129.7, 127.5, 78.5, 74.4, 68.0, 67.3, 37.1, 29.5, 28.0, 21.2. Anal. (C₂₅H₃₅NO₈S₂): C, H, N, S.

Synthesis of the Orthoamides (6 and 12). A mixture of compound **5** or **11** (3.9 mmol) and TBD (0.82 g, 7.8 mmol) in DME (20 mL) was stirred for 2 days at ambient temperature. NaBH₄ (0.74 g, 20 mmol) was added, and the mixture was allowed to stir for an additional day. Methanol was then added, and the mixture was allowed to stir for 30 min, after which volatile materials were removed *in vacuo*. The residue was suspended in aqueous NaHCO₃ with stirring. When the liberation of gas had ceased, the mixture was extracted twice with dichloromethane. The organic phase was dried (Na₂SO₄) and concentrated. The residue was dissolved in a mixture of CH₂Cl₂ and MeOH (9:1, v:v) and applied on a silica gel column. The column was eluted with the same solvent system. Fractions containing pure products were pooled and concentrated to give **16** and **17** as oils that solidified on standing.

Compound **6** (0.41 g, 31%); *R_f* (A) 0.29; ¹H NMR (CDCl₃) δ 4.71 (1H, br), 3.08 (2H, br q), 2.83 (3H, m), 2.29 (1H, s), 2.23 (4H, m), 2.00 (2H, m), 1.78 (2H, t, *J* = 11.8), 1.45 (13H, s and m), 1.12 (4H, m); ¹³C NMR (CDCl₃)

Compound **12** (0.72 g, 52%): ¹H NMR (CDCl₃) δ 4.87 (1H, br), 3.68 (1H, m), 3.55 (2H, t, *J* = 5.9), 3.20 (2H, br q), 3.07 (2H, dd, *J* = 4.4 and 10.5), 2.84 (4H, m), 2.37 (1H, s), 2.23–1.99 (6H, m), 1.75 (2H, p), 1.47 (11H, s and m); ¹³C NMR (CDCl₃) δ 156.0 (C=O), 98.9 (C-13), 79.0 (CMe₃), 70.5 (C-3), 67.1 (CH₂O), 58.1 (C-2 and C-4), 53.8–53.7 (C-6, C-8, C-10, and C-12), 38.4 (NHCH₂), 30.0 (CH₂CH₂CH₂), 28.4 (*t*-Bu), 24.0 (C-7 and C-11); EI (relative intensity) *m/z* 354 (20%), 353 (100%), 297 (46%); HRMS (EI) 353.2554 (*M*⁺ - H), calcd for C₁₈H₃₂N₄O₃⁺ 353.2552.

3-(3-Aminopropyl)-1,5,9-triazacyclododecane (7) and 3-(3-Aminopropoxy)-1,5,9-triazacyclododecane (13). Compound **6** or **12** (1.0 mmol) was dissolved in

hydrochloric acid (6 M, 50 mL), and the mixture was heated for 48 h at reflux. All volatile materials were removed *in vacuo*, and the residue was coevaporated twice with water. Precipitation from ethanol yielded the title compounds as tetrahydrochlorides.

Compound **9**: ¹H NMR (D₂O, external reference of DSS at 0.00 ppm) δ 3.45 (12H, m, H-2a/b, H-4a/b, H-6a/b, H-8a/b, H-10a/b, and H-12a/b), 3.24 (2H, t, *J* = 5.8, NH₂CH₂), 2.34 (1H, m, H-3), 2.27 (4H, H-7a/b and H-11a/b), 1.84 (2H, m, NH₂CH₂CH₂), 1.65 (2H, m, NH₂CH₂CH₂); ¹³C NMR (D₂O, external reference of DSS at 0.00 ppm) δ 46.3, 43.6, 41.2, 40.3, 32.7, 27.9, 24.9, 19.6; HRMS (EI) 228.2313 (*M*⁺), calcd for C₁₂H₂₈N₄⁺ 228.2325.

Compound **15**: ¹H NMR (D₂O, external reference of DSS at 0.00 ppm) δ 4.03 (1H, m, H-3), 3.59 (2H, t, *J* = 5.8, CH₂O), 3.34 (2H, dd, *J* = 6.6 and 14.0, H-2a/H-4a), 3.20 (10H, H-2b, H-4b, H-6a/b, H-8a/b, H-10a/b, and H-12a/b), 2.91 (2H, t, *J* = 7.3, NH₂CH₂), 2.01 (4H, p, H-7a/b and H-11a/b), 1.78 (2H, p, *J* = 6.8, NH₂CH₂CH₂-CH₂O); ¹³C NMR (D₂O, external reference of DSS at 0.00 ppm) δ 70.9 (C-3), 68.6 (CH₂O), 45.2 (C-2/C-4), 44.0 (C-6/C-12), 40.6 (C-8/C-10), 38.3 (NH₂CH₂), 27.9 (C-7/C-11), 19.0 (NHCH₂CH₂CH₂O); HRMS (FAB) 245.2341 (*M*⁺ + H), calcd for C₁₂H₂₉N₄O⁺ 245.2344.

The azacrowns **7** and **13** were converted to the free bases by passing them through a Dowex-1 resin (200 mesh, hydroxide ion form) using water as the eluent. The basic fractions were collected and concentrated to give the title compounds as oils.

Synthesis of the Oligonucleotide Conjugate (16).

The oligonucleotide d(T₆XT₇) was assembled on an ABI DNA synthesizer using standard protocols in a 0.2 mmol scale. The phosphoramidite **14** was used in the seventh coupling step (13). Upon completion of the oligonucle-

otide chain assembly, the protected oligonucleotide, **15**, was treated with **7** (free base; 0.5 M solution in water) for 6 h followed by ammoniolysis (13). The oligonucleotide, **16**, was purified on HPLC as described previously (15) and characterized with MALDI-TOF mass spectrometry.

RESULTS AND DISCUSSION

Synthesis of the Azacrowns. Synthesis of 3-(3-aminopropyl)-1,5,9-triazacyclododecane (**7**) is outlined in Scheme 1. Diethyl 2-(2-cyanoethyl)malonate was initially reduced into 2-(hydroxymethyl)-5-aminopentan-1-ol, **1**, by using the method of Brown (18). To simplify

the purification procedure, the primary amino group of **1** was protected as a carbamate without isolation. Surprisingly, TLC analysis of the reaction mixture showed the presence of two major products. They were separated and characterized as the desired diol, **3**, and the ether **4**, produced from **2**. The formation of **2** is quite surprising since conversion of esters into ethers has been reported only with trichlorosilane and UV light or by catalytic reduction (19). Furthermore, BMS reduction of diethyl succinate is known to produce butane-1,4-diol in good yield (18). Thus, the formation of ether seems to be a unique characteristic of malonates. Fortunately, **4** was easily separated on silica gel column chromatography, and the desired product, **3**, could be isolated in 34% overall yield. Tosylation of **3** with tosyl chloride in dry pyridine gave the key intermediate, **5**, in good yield.

From the several methods described for the preparation of azacrowns (20), the method of Alder *et al.* (21), later modified by Haseltine *et al.* (22), was chosen. In this approach, an alkane ditosylate is initially allowed to react with 1,5,7-triazabicyclo[4.4.0]dec-5-ene (TBD) to form a guanidinium salt which is reduced *in situ* to an orthoamide. Acid-catalyzed hydrolysis of the orthoamide function gives the azacrown. Accordingly, **5** was treated with a 2-fold excess of TBD in DME for 2 days at ambient temperature followed by borohydride reduction. Although the yield of **6** was considerably lower than that reported (22) for the corresponding 3-unsubstituted analogue (32% vs quantitative), the product was easily separated from the reaction mixture on silica gel. Acid-catalyzed hydrolysis of the orthoamide function and concomitant removal of the amino protecting group yielded **7** as the final product. It was converted, prior to oligonucleotide tethering, to the corresponding free base by passing it through a strong anion exchange resin.

The second azacrown, **13**, was synthesized from *cis*-1,3-benzylidene glycerol, **8**, according to Scheme 2. Michael addition of acrylonitrile to **8** in the presence of a catalytic amount of sodium hydride gave **9** in moderate yield. It is worth noting that alkylations which require stoichiometric amounts of base were not successful, in all likelihood due to epoxidation of **8**. The cyano group of **9** was reduced to the amino function with cobalt(II) chloride in the presence of sodium borohydride (23, 24). To simplify the purification procedure, the product was converted without isolation into **10** by removal of the diol protection followed by protection of the amino group. Tosylation as described above gave rise to **11**. It was then converted to the orthoamide, **12**, as above in 52% isolated yield. Acid-catalyzed hydrolysis gave rise to **13** as the final product.

Preparation of the Oligonucleotide Conjugate.

To demonstrate the suitability of the azacrowns prepared for oligonucleotide tethering, a model sequence dT₆XT₇ (X = abasic site) was synthesized (Scheme 3). The phosphoramidite **14** was used in the seventh coupling step in the conventional manner (13). When the oligonucleotide chain assembly was completed, the solid support-bound material, **15**, was treated with 0.5 M aqueous **7** for 6 h at room temperature. This introduces the tether group and removes the phosphate protections. The deprotection procedure was completed by conventional ammonolysis to release all of the oligonucleotide from the solid support. The oligonucleotide, **16**, was isolated on ion exchange HPLC, further purified on an RP column, and desalted by gel filtration (15). Its ion exchange HPLC profile (unpurified reaction mixture) is shown in Figure 1A. The identity of the oligonucleotide conjugate was confirmed on MALDI-TOF mass spectrom-

etry (Figure 1B). The observed molecular weight was in agreement with the calculated value. Studies on the ability of oligodeoxyribonucleotides tethered to azacrowns to promote sequence specific RNA hydrolysis are in progress in our laboratory.

Methods for the Characterization of Phosphatase-Stabilized 2–5A-Antisense Chimeras

Mark R. Player, Wei Xiao, Hagen Cramer, and Paul F. Torrence*

Section on Biomedical Chemistry, Laboratory of Medicinal Chemistry, National Institute of Diabetes and Digestive and Kidney Diseases, National Institutes of Health, Bethesda, Maryland 20892-0805.

Received August 21, 1997; Revised Manuscript Received November 3, 1997[®]

We have developed chromatographic and spectrophotometric assays for determining the degree of thiolation in phosphatase-resistant 5'-monothiophosphate-capped 2–5A-antisense chimeras. Concomitantly, we have explored the reactivity of this 5'-monophosphorothioate moiety with reporter reagents such as 5-iodoacetamidofluorescein and 5,5'-dithiobis(2-nitrobenzoic acid). On the basis of these reactions, analyses for 5'-monothiophosphate-functionalized 2–5A-antisense chimeras were made possible. Kinetic experiments demonstrated that oligonucleotide backbone negative charge could retard mixed disulfide formation in the reaction of 5,5'-dithiobis(2-nitrobenzoic acid) with 5'-monothiophosphorylated 2–5A-antisense chimeras.

INTRODUCTION

Selective inhibition of gene expression with antisense oligodeoxynucleotides is possible through several pathways. Hybridization arrest by the antisense oligonucleotide and RNase H-mediated cleavage of the duplex formed between that oligonucleotide and its mRNA target have been presented as two predominant mechanisms (1). Recently, a third mechanism has been realized through a novel structural class of oligonucleotides. Conjugation of a 5'-phosphorylated 2',5'-oligoadenylate tetramer (2–5A)¹ to a 3',5'-deoxyribonucleotide complementary to a targeted sequence in an RNA provides a novel reagent which effects the selective and specific cleavage of that RNA through intervention of RNase L (EC 3.1.26.) (2–6).

The general structure of these 2–5A-antisense chimeras is pA2'p(5'A2'p)₂5'ApBupBup5'dN3'[p5'dN3']_np5'dN, where Bu is 1,4-butanediol, *n* is any integer, and dN is any common deoxyribonucleoside. The presence of a 5'-monophosphate group is necessary for this principle, as the chimera with no 5'-monophosphate (or core chimera) has been demonstrated to bind only poorly and not to activate RNase L.

As phosphatases are ubiquitous in the biological systems in which 2–5A-antisense chimeras are used, stabilization against this activity became necessary.

Although 3'-exonuclease stabilization of antisense oligonucleotides has been vigorously pursued, phosphatase stabilization is pertinent only to the 2–5A mechanism. Nucleoside 5'-monothiophosphates show dramatically increased resistance toward phosphatase compared to 5'-nucleoside monophosphates (7). We have demonstrated that an oxygen to sulfur substitution in the 5'-monophosphate to afford a 5'-monothiophosphate 2–5A trimer (ps5'A2'p5'A2'p5'A) yields several distinct benefits, including (1) dramatically increased resistance of ps5'A2'p5'A2'p5'A toward degradation by bacterial alkaline phosphatase and calf intestinal alkaline phosphatase compared to p5'A2'p5'A2'p5'A and (2) the fact that ps5'A2'p5'A2'p5'A is as efficient in binding to and activating RNase L as p5'A2'p5'A2'p5'A (8). A 2–5A-antisense chimera targeting the protein kinase PKR, ps5'A2'p(5'A2'p)₃BupBupd(GTACTACTCCCTGCTTCTG), was equipotent with its 5'-monophosphate-containing analogue (4). Finally, a 2–5A-antisense chimera, stabilized by such a 5'-thiophosphate substitution, has been found to be a potent inhibitor of respiratory syncytial virus replication (6). The vital role played by the 5'-monothiophosphate in the cellular biological activity of 2–5A-antisense chimeras, coupled with the relative paucity of data on functionalization of this moiety, led us to develop facile approaches for quantitative analysis of the 5'-monothiophosphate group in these oligonucleotides.

EXPERIMENTAL PROCEDURES

Instrumental Techniques. For HPLC analysis, a HP1050 instrument with Chemstation software and data analysis was used throughout. Four different columns and methods were used for analytical and preparative evaluations. The ion-pair method (method A) utilized a Hamilton polystyrene reverse-phase (PRP-1) 300 × 7 mm column with a flow rate of 1.5 mL/min running a convex gradient of 5 to 90% mobile phase B in A over 60 min, where A was 10 mM tetrabutylammonium phosphate (TBAP) solution (pH 7.5) and B was 10 mM TBAP (pH 7.5) in an acetonitrile/water (8:2, v:v) solution. The enzyme method (method B) used a Beckman Ultrasphere ODS (4.6 × 250 mm) column with a flow rate of 0.5 mL/min running 2% B isocratically for 20 min and then a

linear gradient of 2 to 45% B in A over 15 min, followed by isocratic conditions for another 10 min where A was 100 mM ammonium phosphate (pH 5.5) and B was methanol/water (1:1, v:v). The reverse-phase method (method C) employed a Beckman Ultrasphere ODS (10 × 250 mm) reverse-phase C₁₈ column with a flow rate of 1 mL/min running a linear gradient of 0 to 50% solvent B in A over 30 min, where A was 50 mM ammonium acetate and B was acetonitrile/water (1:1, v:v). The ion-exchange method (method D) made use of a Dionex PA-100 (4 × 250 mm) ion-exchange column with a flow rate of 1.0 mL/min running a linear gradient of 10 to 90% solvent B in A over 25 min, followed by isocratic conditions for another 25 min where A was 25 mM Tris-HCl (pH 7.0) in MeCN/H₂O (1:200, v:v) and B was 25 mM Tris-HCl and 1 M ammonium chloride (pH 7.0) in MeCN/H₂O (1:200, v:v).

Capillary gel electrophoretic (CGE) analyses and snake venom phosphodiesterase (SVPDE) digestion were performed as previously described (9). 5'-Monothiophosphate-modified 2-5A-antisense chimera syntheses were also performed as described (9) with modifications in the sulfurization step as described below. The following compounds were synthesized: **1**, p5'A2'p(5'A2'p)₃BupBupd(GTACTACTCCCTGCTTCTG); **2**, ps5'A2'p(5'A2'p)₃BupBupd(GTACTACTCCCTGCTTCTG); and **3**, A2'p(5'A2'p)₃BupBupd(GTACTACTCCCTGCTTCTG).

The 2-5A-antisense chimeras were synthesized automatically on an ABI 392 DNA/RNA synthesizer using multiple cycles and phosphoramidite chemistry. The four different domains present within 2-5A-antisense oligonucleotides, each of which requires different coupling wait times, were antisense DNA, a 1,4-butanediol linker, 2',5'-oligoadenylate, and 5'-monophosphate. The corresponding coupling wait times were 15, 300, 600, and 60 s, respectively.

Compound **2** was prepared using two different sulfurization reactions. The first used TETD with a 6 s delivery time and a 900 s wait time and generated preparation **I**; the second employed 3H-1,2-benzodithiol-3-one 1,1-dioxide (Beaucage reagent) (10) with a 30 s delivery time and a 10 s wait time which yielded preparation **II**. Preparations **I** and **II** were obtained after initial purification using method A.

Conjugation Reactions with pA, psA, I, and II. 5-Iodoacetamidofluorescein Conjugation. 5-Iodoacetamidofluorescein (30 μL of a 100 mM DMF solution) (Pierce, Rockford, IL) was added to 20 μL of either (i) a 100 mM solution of pA or psA, (ii) a 10 mM solution of **1**, or (iii) a 10 mM solution of preparation **II**, all in 100 mM Tris (pH 8) buffer. After they were vortexed, the reaction preparation was incubated at 55 °C for 18 h, fully immersed in a water bath. For workup of reaction preparations containing **1** or preparation **II**, the resultant solution was applied to a Chromaspin column (Clontech, Palo Alto, CA) and centrifuged at 700g for 5 min. The eluant from the spin column was purified using method D with the following modification. Buffer A contained 25 mM Tris-HCl (pH 7.0) in MeCN/H₂O (1:9, v:v), and buffer B contained 25 mM Tris-HCl and 1 M lithium chloride (pH 7.0) in MeCN/H₂O (1:9, v:v). The reaction

mixtures containing pA or psA were purified directly by HPLC using method C.

Manipulation of reaction conditions did not provide an increase in the percentage of conversion of compound **2** to **4**. Therefore, a correction factor of 1.25 was applied to the product peak on the basis of empirically derived reaction product yields. The A₂₆₀ of the fluoresceinated product peak was also corrected for the absorbance of fluorescein at 260 nm (Promega Technical Bulletin 213). This was determined experimentally by measurement of A₂₆₀/A₄₉₅ under the buffer conditions used during elution. Therefore, the formula used to estimate the percentage of **2** from the HPLC results was 100 - 100[AUC of all nonproduct peaks/AUC of all nonproduct peaks + 1.25-AUC of product peak - (AUC of product peak × 0.45)]].

5,5'-Dithiobis(2-nitrobenzoic acid) Conjugation. A 10 mM 5,5'-dithiobis(2-nitrobenzoic acid) (DTNB) (Pierce) solution was prepared in 100 mM NaH₂PO₄ (pH 8.0) buffer. The buffer was first deaerated with Ar and extensive sonication in order to prevent reoxidation of the mixed disulfide generated during the reaction. A 45 μM psA solution was prepared in 1 mL of ddH₂O. The DTNB solution (50 μL) was added to an appropriate amount of the 45 μM stock psA solution to give five final psA concentrations ranging between 2 and 35 μM. Triplicate psA standards were prepared. The spectrophotometer was zeroed with DTNB solution (50 μL) diluted to 1 mL. Triplicate concentrations were measured at 420 nm, averaged, and plotted with the biased standard deviation serving as the error bar. With a standard curve thus constructed, the corresponding A₄₂₀ of a similarly treated 12.1 μM solution of preparation **I** was determined.

Preparation **I** was diluted to 12.1 μM, lyophilized, and rediluted in sodium phosphate buffer to 1 mL, and again with 50 μL of a DTNB solution. Measurement of the spectrum showed an A₄₂₀ of 0.0967. This corresponded to a concentration of 8.4 μM as determined by the psA concentration calibration curve.

Kinetic experiments with preparation **I** and psA were performed as follows. psA or preparation **I** was prepared as a 10 μM solution and reacted with 50 μL of the DTNB solution prepared as described above, in 1 mL of phosphate buffer (pH 8). The extent of the reaction was monitored at 420 nm.

Mass Spectrometric Analysis. Advances in matrix-assisted laser desorption ionization mass spectroscopy (MALDIMS) using 6-aza-2-thiothymine (ATT) cocrystallized with ammonium citrate as a matrix (11) were used to obtain a mass spectrum of **1**, **2**, and **5** (Table 1, Scheme 1). The matrix solution was prepared with ATT (10 mg/mL) in acetonitrile/20 mM ammonium citrate (1:1, v:v). This solution (3 μL) and 10 pmol of **1**, **2**, and **5** (total volume, 4 μL) were lyophilized and then analyzed on a Kompact MALDI III instrument using a 337 nm N₂ laser. With the instrument in the linear mode, the desorption took place with a static electric potential of approximately 22 keV. High-resolution fast-atom bombardment mass spectroscopy (HRFABMS) of **4** was performed with a JEOL JMS-SX102 instrument in the negative ion mode using a glycerol matrix (Table 1).

Scheme 2

Identification of Higher-Molecular Weight Contaminants in Preparations I and II. Before or after purification of preparation **I** or **II** (or any 5'-ps chimera) using method A or D, a contaminant with a higher R_t can be observed. To determine if this material was the disulfide, product with approximately 70% of higher- R_t material was applied to a prewashed Sep-Pak cartridge, and the column was washed with 20 mL of ddH₂O and eluted with methanol/ddH₂O (1:1). After evaporation of the methanol, dialysis with a 3500 MWCO membrane was performed to remove any remaining low-molecular weight impurities. After lyophilization, the oligonucleotide was dissolved in 10 mM Tris (pH 7.5) at 3.5 μM for 12 h at 4 °C with 2-mercaptoethanol concentrations of either 0, 3.5, or 35 μM .

Dionex Separation of 5'-ps and 5'-po Chimeras. Preparations **I** and **II**, which had initially been purified by method A, were analyzed for homogeneity by method D. The main product peak for preparation **I** was observed at 15.36 min (Figure 1a) and for preparation **II** at 15.37 min (Figure 1b). The primary side product for both preparations eluted with a shorter retention time and was observed at 14.86 min for preparation **I** and at 14.88 min for preparation **II**.

To demonstrate that method D was resolving **1** and **2**, a co-injection experiment was performed with **1** and preparation **II**. First, the faster-eluting peak ($R_t = 14.88$ min) and the main product peak ($R_t = 15.37$ min) of preparation **II** were purified using method D, and then collected, desalted, and quantified. The homogeneity of the method D-purified main product peak of preparation **II** and **1** was demonstrated by injection with method D. Compound **1** had a retention time of 14.35 min, and the isolated main product peak of preparation **II** had a retention time of 14.99 min. This difference of 0.64 min was approximately the same as that seen between the main product peak and the faster-eluting peak ($R_t = 14.88$ min), when preparations **I** and **II** were analyzed

Figure 1. (a) Ion-exchange HPLC chromatogram of preparation **I** (method D), (b) ion-exchange HPLC chromatogram of preparation **II** (method D), and (c) ion-exchange HPLC chromatogram of a co-injection of **1** and preparation **I** (method D).

by method D. Next, **1** and the main product peak of method D-purified preparation **II** were mixed in an equimolar ratio and co-injected. A doublet with individual peaks at 14.38 and 14.99 min was observed (Figure 1c), again in good agreement with the retention times obtained with each compound separately.

The major and minor product peaks observed during method D purification of preparation **I** were collected as

they separated. The peak that eluted first at 14.86 min (**1**) and the main product peak which eluted later at 15.36 min (**2**) were each desalted with a Sep-Pak cartridge (Waters), lyophilized, and subjected to MALDIMS (11) (Table 1) which confirmed the identity of the peaks as monophosphate (**1**) and thiophosphate (**2**). This permitted a precise determination, in this instance, of the percentage of **2** in the compounds prepared by alternate sulfurization protocols. The percentage of **2** in preparation **I** was 67% and in preparation **II** 83%.

RESULTS AND DISCUSSION

2–5A-Antisense chimeric nucleic acids are relatively complex structures when compared with antisense nucleic acids in general since they contain several structural domains that are vital for the biological activity of these reagents. Proceeding from the 5'-terminus to the 3'-terminus, these domains are: (1) a 5'-monophosphate or 5'-monothiophosphate moiety that is required for the activation of RNase L, (2) a 2',5'-phosphodiester-linked oligoadenylate tetranucleotide (2–5A) which also is necessary for activation of RNase L, (3) a linker domain made up of two 1,4-butanediol monophosphates in tandem, and (4) an antisense domain consisting of, for instance, a 3',5'-deoxyribonucleotide that may or may not be stabilized to degradation. Thus, four distinct chemical entities must be structurally intact in order to act in harmony as biologically active 2–5A-antisense agents. The ability to adequately characterize synthetic 2–5A-antisense products is absolutely a prerequisite for their effective use in biological systems and as potential therapeutic agents.

As described previously, a combination of chromatographic analysis, MALDIMS, Maxim–Gilbert sequencing, and SVPDE digestion can be employed to characterize completely such 2–5A-antisense composite nucleic acids. Of these analytical approaches, the most informative is the latter SVPDE digestion since it dissects the purified synthetic product into nucleotidic products that reflect the structural integrity of the 2–5A-antisense molecule as described above. Specifically, the following are produced: 3 mol of 5'-AMP from the intact 5'-phosphorylated 2',5'-oligoadenylate tetramer, 1 mol of 5'-AMP still linked to the two butanediol phosphate linkers, and the various dNMPs from the antisense component. In the event that a key determinant of biological activity, the 5'-phosphate, is missing, or that 5'-phosphorylation is incomplete, then A itself is produced in the SVPDE digestion.

A second generation of 2–5A-antisense chimeras possess a 5'-monothiophosphate (e.g. **2**) that is resistant to the action of phosphatases and thereby extends the biological half-life of 2–5A-antisense chimeras. Analysis of such 5'-monothiophosphorylated 2–5A-antisense chimeras by ion-exchange HPLC using Dionex PA-100 columns frequently revealed what appears at first to be the presence of an unusually large percentage of the $n - 1$ failure sequence.² For instance, when preparation **I**, from sulfurization using TETD, was analyzed using HPLC method D, a major product peak was observed at 15.36 min (Figure 1a) with a minor product at 14.86 min. A similar chromatographic picture emerged when preparation **II** was analyzed (Figure 1b).

The major and minor peaks observed during the above HPLC method D analysis of preparation **I** were collected separately. After the homogeneity of each collected peak was checked by HPLC method D, fractions containing each peak (R_t s of 14.86 and 15.36 min, respectively) were

desalted with a Sep-Pak cartridge, lyophilized to dryness, and subjected to MALDIMS. The peak with the faster retention time possessed an observed weight consistent with structure **1**, whereas the peak with the slower R_t (15.36 min) gave an observed weight consistent with oligonucleotide **2** (Table 1). Co-injection experiments showed that the two observed peaks of both preparation **I** and **II** were identical, corresponding to oligonucleotide **1** with the faster R_t and **2** with the slower R_t .

The above Dionex ion-exchange HPLC proved to be neither a definitive nor practical methodology for routine analysis since the core chimera (**3**) also elutes earlier than the desired product peak **2**. Discrimination among free 5'-OH (**3**), 5'-monophosphate (**1**), and 5'-monothiophosphate (**2**) derivatives of the chimeric oligonucleotide would thus require independent syntheses of reference 5'-monophosphate and 5'-OH core derivatives for each 2–5A-antisense sequence prepared, an impractical requirement.

The direct application of the powerful SVPDE digestion analysis to 5'-thiophosphorylated chimeric oligonucleotide **2** was problematic. Digestion with SVPDE itself, as for the analysis of chimeric oligonucleotides such as **1**, was not successful because reliable separation of psA and pA could not be achieved using the routine HPLC method B or any variation thereof that would still allow appropriate separation of the other digestion products. In one variation of the analysis, the percentage of **2**, as compared to the percentages of **3** and **1**, might be addressed by digestion of the oligonucleotide sample with a combination of SVPDE and calf intestinal phosphatase. Since the thiophosphate, psA, was resistant to phosphatase, it would remain intact and could be directly determined. However, this approach would not permit direct estimation of the percentages of **1** and **3** in a sample since all pA, produced by SVPDE cleavage, would be converted to A itself.

Another possible strategy for analysis of the psA content of a sample of oligonucleotide **2** would be selective covalent modification of psA in the oligonucleotide so that, after SVPDE digestion, the modified psA could be readily detected and analyzed. Relevant requirements for such an acceptable reporter group would include the absence of reactivity toward pA and the other components of a 2–5A-antisense chimera and fast and complete reaction with psA.

When 5-iodoacetamidofluorescein (5-IAF), which has been shown to react with sulfhydryls (17) as well as with phosphorothioate diesters (18), was reacted with pA or oligonucleotide **1**, no detectable reaction occurred. In contrast, when 5-IAF was reacted with psA, a product was obtained which was easily distinguished by its high

²Occasionally, an additional product has been observed in some preparations of 5'-monothiophosphorylated 2–5A-antisense chimeras. It migrates in Dionex HPLC or CGE with a markedly increased retention time, indicating that it possesses a much higher molecular weight. HPLC analysis (method D) revealed that the addition of 2-mercaptoethanol effected a quantitative conversion of this high- R_t component to oligonucleotide **2**, in support of the hypothesis that this additional product corresponded to a P1,P2-bis(adenosine 5'-monophosphoryl)oligonucleotide disulfide. In further support of this, the 5'-thiophosphates of adenosine, thymidine, uridine, and inosine have all been reported to dimerize after oxidation with I_2 or $K_3Fe(CN)_6$ or when passed through a short column of activated charcoal (12–14). 5'-Thiophosphoryl and 5'-dithiophosphoryl oligodeoxyribonucleotides also have been reported to undergo dimerization in the presence of dilute $K_3Fe(CN)_6$ solution (15, 16).

Figure 2. Reverse-phase HPLC chromatogram of the reaction mixture of psA and 5-IAF demonstrating the formation of **4**. Solid lines represent A_{260} . Dashed lines represent A_{495} .

Figure 3. Reverse-phase HPLC chromatogram of the reaction mixture of preparation **I** and 5-IAF demonstrating the formation of **5**. Solid lines represent A_{260} . Dashed lines represent A_{495} .

A_{260}/A_{495} ratio (0.91) (Figure 2). HRFABMS showed that the structure of the product was consistent with **4**.

Reaction of 5-IAF with preparation **II** under the identical conditions gave a new product, consistent with structure **5**, according to MALDIMS (Table 1). SVPDE digestion of oligonucleotide adduct **5** gave, in addition to the usual nucleotidic products of digestion, a new product peak (**4**) which, however, eluted very late under method C conditions due to its hydrophobic nature.

A variation of this approach for analysis of oligonucleotide **2**-containing samples involved determination of the extent of reaction of oligonucleotide with 5-IAF. Since oligonucleotide **1** did not react with 5-IAF, the extent of reaction would provide a direct measure of the percentage of **2** in the mixture. In trial reactions of **2** with 5-IAF, the maximum conversion to **5** that could be obtained ranged from 77 to 83% as determined by HPLC method D so that a correction factor of 1.25 was applied for determination of the percentage of **2** in a product mixture. Preparation **II** analyzed for 80 and 82% **2** in two separate determinations, in good agreement with the 83% value determined by Dionex HPLC method D (Figure 3).

5, 5'-Dithiobis(2-nitrobenzoic acid) (DTNB) reacts with compounds containing a sulfhydryl moiety to generate a

Figure 4. Standard curve of psA concentration versus A_{420} resulting from thiolate anion formation.

mixed disulfide and a thiolate dianion, the latter of which has a $\lambda_{\max}$ of 420 nm and an ϵ of about 14 000 (19). Although there are several reagents which can label sulfhydryls to produce a visible product, DTNB is the most likely to be useful for 5'-monothiophosphates due to its high reactivity at neutral pH, high ϵ , and high water solubility, the latter allowing the reaction to be performed with no cosolvent (20). The reaction with peptide and cysteine standards has been reported to follow Beer's law down to $0.41 \mu\text{M}$ (21).

When DTNB was reacted with psA, there resulted a linear ($r^2 = 0.9988$) dependence of A_{420} on the concentration of psA in the range of $2\text{--}34 \mu\text{M}$ (Figure 4). Nonlinearity at concentrations of less than $2 \mu\text{M}$ was due to an unfavorable signal:noise ratio, whereas nonlinearity above $34 \mu\text{M}$ was possibly due to an ionic strength dependence of the reaction as has been demonstrated in the case of cysteine (22). When preparation **I** was analyzed using this approach, a percentage of **2** value of 69% was obtained, in good agreement with the 67% value determined with HPLC method D.

During the above experiments, we observed that oligonucleotide **2** in preparation **I** took much longer to react with DTNB than did the psA mononucleotide standard. Specifically, the reaction with psA was 50% complete in 10 s and 100% complete in 50 s, whereas the reaction with oligonucleotide **2** was 50% complete at 200 s and 100% complete at 850 s. These results may be related to the increased negative charge on the oligonucleotide **2** substrate. Glutathione, which carries a negative charge under DTNB reaction conditions, has been observed to react more slowly with DTNB than with cysteine (21). In contrast, neighboring group positive charge greatly accelerates the rate of reaction of DTNB with protein sulfhydryls through Coulombic and inductive effects (22).

CONCLUSIONS

We have explored the ability of several methodologies to provide a convenient, facile, and reliable determination of the extent of 5'-thiolation in 2-5A-antisense chimeras. Of the various chromatographic, enzymatic, and chemical approaches examined, we found the most suitable to be

the reaction of the 2–5A-antisense chimera with 5-IAF, resulting in the conjugation of the 5'-terminal adenosine 5'-monothiophosphate residue with fluorescein. The conjugated product could be quantitated after HPLC separation. This method was superior to an alternate chemical approach involving DTNB as time was required to carry out the requisite steps of standard steps of standard curve generation and the reaction itself.

During the course of these experiments, we identified the disulfide as an occasional significant contaminant on preparation of **2**. We further provided conditions under which formation of the disulfide could be eliminated.

Preparation and Photoactivation of Caged Fluorophores and Caged Proteins Using a New Class of Heterobifunctional, Photocleavable Cross-Linking Reagents

Johannes Ottl, Daniela Gabriel, and Gerard Marriott*

Biomolecular and Cellular Dynamics Research Group, Max Planck Institute for Biochemistry, 82152 Martinsried, Germany. Received August 13, 1997; Revised Manuscript Received October 13, 1997*

The design, synthesis, and spectroscopic and chemical properties of four members of a new class of heterobifunctional photocleavable (caged) cross-linking reagents were described. One of the two reactive groups of the cross-linker reacted with amino groups to form the corresponding photolabile carbamates. Amino group containing compounds or proteins caged with these reagents can be coupled through the thiol reactive oxirane group of the cross-linker to a different biomolecule or to a thiol-derivatized surface. The 3,4-dimethoxy-6-nitrophenyl photoisomerization group of the reagent was physically and chemically isolated from the cross-linking functionality, and the high extinction coefficient and red-shifted action spectrum of this chromophore make it suitable for photoactivation applications of caged compounds on surfaces or in living cells. The bifunctional, photocleavable cross-linking reagents were used to prepare a thiol reactive caged rhodamine 110. The new reagents and conjugation procedures described may be used as part of a general procedure to cage the activity of proteins by physically masking binding sites.

INTRODUCTION

Light-directed activation of caged compounds has emerged as a powerful technique for generating concentration jumps of biomolecules in complex molecular environments (1) and has provided important information on the reaction mechanism of protein activity in muscle and in living cells (1, 2). Functional groups of molecules that have been protected with caged compounds include the primary amine (3), primary and secondary alcohol (4), phosphate (5), ketone (6), thiol (7, 13), and carboxylic

acid (8). Irradiation of functional groups protected with the 2-nitrophenyl-based caged reagents with near-ultraviolet light leads to a photoisomerization reaction that cleaves the bond linking the protected functionality of interest to the caged group. Caged reagents have been used to prepare inactive yet photoactivatable enzyme substrates (5), receptor ligands (9, 10), and fluorescent probes (11, 12). In addition, caged reagents capable of labeling amino and thiol groups have been used to inhibit the activity of proteins (caged proteins) by modifying one or more essential amino acid residues (7, 13–15, 26). These caged groups can be efficiently removed from the caged protein with concomitant recovery of its activity following irradiation of the conjugate with near-ultraviolet light.

® Abstract published in *Advance ACS Abstracts*, December 15, 1997.

In addition to these monofunctional caged reagents, heterobifunctional photocleavable reagents have been described to protect amino or thiol groups of small molecules (25) and proteins (7, 15) as their corresponding photolabile carbamates or thioethers, respectively (7, 15, 25). The second reactive group of the cross-linking reagent may be used to attach the caged compound to a different biomolecule; for example, an antibody molecule for targeting the caged compound to a specific site (15), or a derivatized surface, or a fluorescent dye for imaging or for probing protein–protein interactions (7, 25).

The few photocleavable cross-linking reagents described in the literature all harbor this second reactive group at the 4-position of the 2-nitrophenyl ring (7, 15, 25). In this study, we designed a new class of reagents in which the second reactive group was introduced off the benzylic carbon atom. The photocleavable cross-linking reagents were designed with the following operational considerations in mind. (1) Caged reagents should react with the functional group of interest in aqueous solution and at a slightly alkaline pH. The second reactive group, an epoxide, is stable in the absence of free thiols and can then be reacted in a second step with thiol functions. (2) The photoactivation reaction should exhibit a reasonable quantum yield and an action spectrum in the near-ultraviolet wavelength region (340–400 nm) to avoid interference with other biomolecules. (3) The caged group should exhibit a high molar absorptivity for photoactivation reactions performed on optically thin samples. (4) The photoproducts of the photoactivation reaction should not be toxic or reactive with other functional groups. The new reagents described in this report fulfill most of the requirements listed above. Suitable examples are provided to demonstrate the functional group selectivity of the two reactive groups. Members of this new class of cross-linking reagents were used for the preparation and photoactivation of caged fluorophores and caged proteins.

MATERIALS AND METHODS

3,4-Dimethoxy-6-nitrobenzaldehyde, di-*N*-succinimidylcarbonate (DSC), vinyl magnesium bromide, *m*-chloroperoxybenzoic acid (MCPBA), 4-(dimethylamino)pyridine (DMAP), and 4,6-diphenylthieno[3,4-*d*][1,3]dioxol-2-on-5,5-dioxide (TDO) were purchased from Aldrich. Bovine serum albumin (BSA), polylysine (average molecular weight of 40 000 kDa), and 2-iminothiolane were purchased from Sigma. Tetramethylrhodamine iodoacetamide (IATMR) was a gift from J. Corrie (NIMR, Mill Hill, London). Acrylodan and aminodextran were purchased from Molecular Probes (Eugene, OR). Rhodamine 110 was purchased from Lambda Physik (Göttingen, Germany). All other reagents were of the highest quality available and obtained from Sigma or Aldrich unless stated otherwise. G-Actin was prepared according to Marriott (14).

The NMR spectra were measured on a 500 MHz Bruker instrument; mass spectrophotometry was carried out on a Finnigan MAT 900 or Finnigan HSQ 30 instrument. Infrared spectra were recorded on a Perkin-Elmer 1760 X FT-IR spectrophotometer. Absorption spectra were recorded on a Hewlett-Packard 82152 diode array spectrophotometer. Fluorescence spectroscopy was performed on an SLM-AB2 fluorometer (Sopra, Buttelborn, Germany). Light-directed photoactivation of caged compounds was performed essentially as described by Marriott (14).

Syntheses. All syntheses were conducted in a darkened room or protected from room light with aluminum foil.

Preparation of 1-Hydroxy-1-(3,4-dimethoxy-6-nitrophenyl)-2-propene (I). 3,4-Dimethoxy-6-nitrobenzaldehyde (1.88 g, 8.95 mmol) freshly recrystallized out of toluene, was dissolved in 50 mL of dry THF under an argon atmosphere. The yellow solution was cooled to -70°C and 10.7 mL of a 1 M solution of vinylmagnesium bromide in THF added dropwise. The deep red solution was stirred for 3 h and slowly warmed to 20°C and then 40 mL of a saturated NH_4Cl solution added dropwise. The red solution was extracted three times with ethyl acetate and the organic phase washed five times with saturated NaCl and dried over MgSO_4 and the solvent removed. The red oily residue (2.44 g) was taken up in a little ethyl acetate and eluted through a silica gel column developed in 3:1 hexane/ethyl acetate. The solvent was removed from the product fractions producing an orange-red powder. Yield: 1.53 g (6.33 mmol, 72%). MW: 239.23 ($\text{C}_{11}\text{H}_{13}\text{NO}_5$). Mp: $101\text{--}102^{\circ}\text{C}$. $^1\text{H-NMR}$ (CDCl_3 , in ppm): 2.63 (s, broad, 1H), 3.94 (s, 3H), 3.96 (s, 3H), 5.24 (dd, $J = 11$ Hz, 2 Hz, 1H), 5.42 (dd, $J = 18$ Hz, 2 Hz, 1H), 5.92 (d, $J = 6$ Hz, 1H), 6.07 (ddd, $J = 18$ Hz, 11 Hz, 6 Hz, 1H), 7.20 (s, 1H), 7.57 (s, 1H). MS (70 eV) m/z (%): 239 (42) M^+ , 162 (100) $\text{C}_9\text{H}_8\text{NO}_2^+$.

Preparation of 1-(3,4-Dimethoxy-6-nitrophenyl)-2,3-epoxypropyl Hydroxide (II). *m*-Chloroperoxybenzoic acid (MCPBA, technical grade, about 80% pure) was washed three times with phosphate buffer at pH 7.5 and dried. Purified MCPBA (1.311 g, 7.60 mmol) was dissolved in 20 mL of CH_2Cl_2 and slowly dropped into a precooled solution of 1.80 g (7.52 mmol) of I in 15 mL of CH_2Cl_2 . The bright yellow solution was stirred for 48 h at room temperature. The white precipitate was filtered and washed with CH_2Cl_2 and then 70 mL of a saturated solution of NaHCO_3 added to the solution which was stirred for 30 min. The organic phase was washed seven times with a saturated solution of NaHCO_3 , then three times with a saturated solution of NaCl. The organic phase was dried over MgSO_4 and the solvent removed. The yellow, oily residue (1.90 g) was recrystallized out of ethyl acetate/hexane. Yield: 1.55 g (6.10 mmol, 81%, orange needles). MW: 255.23 ($\text{C}_{11}\text{H}_{13}\text{NO}_6$). Mp: $118\text{--}121^{\circ}\text{C}$. $^1\text{H-NMR}$ (CDCl_3 , in ppm): isomer a, 2.62 (s, 1H), 2.71 (dd, $J = 5$ Hz, 2 Hz, 1H), 2.90 (dd, $J = 5$ Hz, 2 Hz, 1H), 3.32 (ddd, $J = 5$ Hz, 5 Hz, 2 Hz, 1H), 3.96 (s, 3H), 3.98 (s, 3H), 5.57 (dd, $J = 5$ Hz, 2 Hz, 1H), 7.23 (s, 1H), 7.66 (s, 1H); isomer b, 2.63 (s, 1H), 2.82 (dd, $J = 5$ Hz, 2 Hz, 1H), 3.02 (dd, $J = 5$ Hz, 2 Hz, 1H), 3.62 (ddd, $J = 5$ Hz, 5 Hz, 2 Hz, 1H), 3.96 (s, 3H), 4.02 (s, 3H), 5.76 (dd, $J = 5$ Hz, 2 Hz, 1H), 7.28 (s, 1H), 7.67 (s, 1H). MS (70 eV) m/z (%): 255 (35) M^+ , 164 (100) $\text{C}_9\text{H}_{10}\text{NO}_2^+$. FAB-MS m/z : 256.1 MH^+MS .

Photolytic Isomerization of II. A 100 μM solution of II dissolved in methanol was irradiated in a quartz cuvette with ultraviolet light (350 and 420 nm) according to Marriott (14). The absorption spectrum of the sample was recorded at different irradiation times.

Preparation of 1-(3,4-dimethoxy-6-nitrophenyl)-2,3-epoxypropyl chloroformate (III). In a well-ventilated hood, 566 mg of II (2.22 mmol) dissolved in 10 mL of water free dioxane in a dried 50 mL flask was treated with 0.18 mL of water free pyridine (2.25 mmol) together with 0.26 mL of diphosgene (2.20 mmol) which was slowly dropped into the yellow solution. The reaction mixture was stirred for 2 h at room temperature, the precipitate filtered off, the solvent removed, and the flask left for 1 h under a high vacuum to remove excess diphosgene. The

oily orange-brown residue was taken up in a little ethyl acetate and eluted through a silica gel column developed in 3:1 hexane/ethyl acetate. The solvent was removed from the product fractions yielding a yellow powder. Yield: 620 mg (1.95 mmol, 88%). MW: 317.68 ($C_{12}H_{12}NO_7Cl$). Mp: 178–181 °C. ^1H -NMR ($CDCl_3$, in ppm): isomer a, 3.57 (dd, $J = 12$ Hz, 4 Hz, 1H), 3.76 (dd, $J = 12$ Hz, 4 Hz, 1H), 3.94 (s, 3H), 3.97 (s, 3H), 5.52–5.56 (m, 1H), 6.32 (d, $J = 8$ Hz, 1H), 7.20 (s, 1H), 7.71 (s, 1H); isomer b, 3.92 (s, 3H), 3.96 (s, 3H), 4.00 (dd, $J = 12$ Hz, 2 Hz, 1H), 4.19 (dd, $J = 12$ Hz, 3 Hz, 1H), 4.66–4.68 (m, 1H), 6.13 (d, 3 Hz, 1H), 7.00 (s, 1H), 7.73 (s, 1H). MS (70 eV) m/z (%): 317 (82) M^+ , 136 (100) $C_8H_8O_2^+$.

Preparation of 4-[1-(3,4-Dimethoxy-6-nitrophenyl)-2,3-epoxypropyl-1-oxycarbonyloxy]-3-oxo-2,5-diphenyl-2,3-dihydrothiophen-1,1-dioxide (IV). **II** (500 mg, 1.959 mmol) dissolved in 4 mL of water free THF was treated with 672 mg of freshly recrystallized, 4,6-diphenylthienof[3,4-*d*][1,3]dioxol-2-on-5,5-dioxide (2.062 mmol). The orange solution was refluxed for 4 h in the absence of base and the solvent evaporated to give an orange residue that was recrystallized out of dry toluene. Yield: 186.7 mg (0.321 mmol, 82%). MW: 581.56 ($C_{28}H_{23}NO_{11}$). Mp: 176–180 °C. ^1H -NMR (in $CDCl_3$, in ppm): isomer a, 2.35 (dd, $J = 4$ Hz, 3 Hz, 1H), 3.06 (dd, $J = 4$ Hz, 3 Hz, 1H), 3.53 (ddd, $J = 4$ Hz, 4 Hz, 2 Hz, 1H), 3.90 (s, 3H), 3.95 (s, 3H), 5.14 (s, 1H), 6.62 (d, $J = 4$ Hz, 1H), 7.01 (s, 1H), 7.27–7.32 (m, 4H), 7.43–7.48 (m, 4H), 7.60 (s, 1H), 7.92–7.97 (m, 2H); isomer b, 2.39 (dd, $J = 4$ Hz, 3 Hz, 1H), 3.08 (dd, $J = 4$ Hz, 3 Hz, 1H), 3.64 (ddd, $J = 4$ Hz, 4 Hz, 2 Hz, 3H), 3.92 (s, 3H), 3.97 (s, 3H), 5.15 (s, 1H), 6.67 (d, $J = 4$ Hz, 1H), 7.07 (s, 1H), 7.27–7.32 (m, 4H), 7.43–7.48 (m, 4H), 7.63 (s, 1H), 7.92–7.97 (m, 2H); isomer c, 2.83 (ddd, $J = 4$ Hz, 4 Hz, 2 Hz, 1H), 3.48 (ddd, $J = 4$ Hz, 4 Hz, 2 Hz, 1H), 3.64 (ddd, $J = 4$ Hz, 4 Hz, 2 Hz, 3H), 3.96 (s, 3H), 3.98 (s, 3H), 5.16 (s, 1H), 6.78 (d, $J = 3$ Hz, 1H), 7.08 (s, 1H), 7.43–7.48 (m, 4H), 7.52–7.57 (m, 8H), 7.65 (s, 1H), 7.92–7.97 (m, 2H); isomer d, 2.92 (ddd, $J = 4$ Hz, 4 Hz, 2 Hz, 1H), 3.48 (ddd, $J = 4$ Hz, 4 Hz, 2 Hz, 1H), 3.64 (ddd, $J = 4$ Hz, 4 Hz, 2 Hz, 3H), 3.96 (s, 3H), 3.99 (s, 3H), 5.18 (s, 1H), 6.81 (d, $J = 3$ Hz, 1H), 7.14 (s, 1H), 7.43–7.48 (m, 4H), 7.52–7.57 (m, 8H), 7.67 (s, 1H), 7.92–7.97 (m, 2H). FAB-MS m/z : 582.4 MH^+ .

Preparation of 1-(3,4-Dimethoxy-6-nitrophenyl)-2,3-epoxypropyl Carbonate (V). **IV** (150 mg, 0.258 mmol) dissolved in 0.5 mL of water free THF was treated with 65.8 mg of **II** (0.258 mmol) and 30 μ L of *N*-ethyl-diisopropylamine (0.258 mmol). The flask was subjected to bath sonification for 2 min, and the orange solid, which precipitated out of solution, was left for 1 h at room temperature. This precipitate was filtered off and the solvent evaporated to give an orange residue that was crystallized out of toluene/hexane as an orange powder. Yield: 106 mg (0.198 mmol, 77%). MW: 536.2 ($C_{23}H_{24}N_2O_7$). Mp: 115–120 °C. ^1H -NMR ($CDCl_3$, in ppm): isomer a, 2.38 (dd, $J = 6$ Hz, 3 Hz, 1H), 2.77 (ddd, $J = 6$ Hz, 6 Hz, 3 Hz, 1H), 2.98 (dd, $J = 6$ Hz, 3 Hz, 1H), 3.92 (s, 3H), 6.61 (d, $J = 3$ Hz, 1H), 7.00 (s, 1H), 7.58 (s, 1H); isomer b, 2.38 (dd, $J = 6$ Hz, 3 Hz, 1H), 2.80 (ddd, $J = 6$ Hz, 6 Hz, 3 Hz, 1H), 2.98 (dd, $J = 6$ Hz, 3 Hz, 1H), 3.93 (s, 3H), 6.64 (d, $J = 3$ Hz, 1H), 7.02 (s, 1H), 7.62 (s, 1H); isomer c, 2.41 (dd, $J = 6$ Hz, 3 Hz, 1H), 2.87 (ddd, $J = 6$ Hz, 6 Hz, 3 Hz, 1H), 3.55 (dd, $J = 6$ Hz, 3 Hz, 1H), 3.95 (s, 3H), 6.67 (d, $J = 3$ Hz, 1H), 7.05 (s, 1H), 7.63 (s, 1H); isomer d, 2.41 (dd, $J = 6$ Hz, 3 Hz, 1H), 3.48 (ddd, $J = 6$ Hz, 6 Hz, 3 Hz, 1H), 3.55 (dd, $J = 6$ Hz, 3 Hz, 1H), 3.95 (s, 3H), 6.72 (d, $J = 3$ Hz, 1H), 7.11 (s, 1H), 7.72 (s, 1H). MS (70 eV) m/z (%): 536 (20) M^+ , 238 (100) $C_{11}H_{12}NO_5^+$.

Preparation of *N*-1-[(3,4-Dimethoxy-6-nitrophenyl)-2,3-

epoxypropyloxycarbonyl]-4-(*N,N*-dimethylamino)pyridinium 3-Oxo-2,5-diphenyl-2,3-dihydrothiophen-1,1-dioxide-4-hydroxide (VIa). **IV** (150 mg, 0.258 mmol) dissolved in 0.4 mL of dry THF was treated with a solution of 35 mg of DMAP (0.285 mmol) in 0.1 mL of dry THF. After a 2 min sonification treatment, an orange precipitate formed that was left to stand for 1 h at room temperature and centrifuged, and the orange residue was washed with THF. Yield: 166 mg (0.237 mmol, 92%). MW: 704.7 (cation, 404.4; cation, $C_{19}H_{22}N_3O_7$). Mp: 85 °C (dec). ^1H -NMR ($CDCl_3$, in ppm): isomer a, 2.84 (dd, $J = 5$ Hz, 2 Hz, 1H), 3.02 (dd, $J = 5$ Hz, 2 Hz, 1H), 3.25 (s, 6H), 3.58 (ddd, $J = 5$ Hz, 5 Hz, 2 Hz, 1H), 3.93 (s, 3H), 4.04 (s, 3H), 6.63 (d, $J = 4$ Hz, 1H), 6.70 (d, $J = 7$ Hz, 2H), 7.05 (s, 1H), 7.64 (s, 1H), 8.12 (d, $J = 7$ Hz, 2H); isomer b, 2.89 (dd, $J = 5$ Hz, 2 Hz, 1H), 3.11 (dd, $J = 5$ Hz, 2 Hz, 1H), 3.25 (s, 6H), 3.63 (ddd, $J = 5$ Hz, 5 Hz, 2 Hz, 1H), 3.96 (s, 3H), 4.06 (s, 3H), 6.72 (d, $J = 7$ Hz, 2H), 6.75 (d, $J = 3$ Hz, 1H), 7.09 (s, 1H), 7.66 (s, 1H), 8.14 (d, $J = 7$ Hz, 2H); counterion, 4.91 (s, 1H), 7.10–7.40 (m, 8H), 7.95–8.30 (m, 2H). FAB-MS m/z : 404.5 M^+ (cation).

Preparation of *N*-1-[(3,4-Dimethoxy-6-nitrophenyl)-2,3-epoxypropyloxycarbonyl]-4-(*N,N*-dimethylamino)pyridinium Succinimide-*N*-hydroxide (VIb). **VII** (150 mg, 0.378 mmol) dissolved in 0.4 mL of dry THF was treated with a solution of 51 mg of DMAP (0.42 mmol) in 0.1 mL of dry THF. After a 2 min sonification treatment, an orange precipitate formed that was left to stand for 1 h at room temperature and centrifuged, and the orange residue was washed with THF. Yield: 180 mg (0.34 mmol, 90%). MW: 704.7 (cation, 404.4; cation, $C_{19}H_{22}N_3O_7$). Mp: 88 °C (dec). ^1H -NMR ($CDCl_3$, in ppm): isomer a, 2.84 (dd, $J = 5$ Hz, 2 Hz, 1H), 3.02 (dd, $J = 5$ Hz, 2 Hz, 1H), 3.25 (s, 6H), 3.58 (ddd, $J = 5$ Hz, 5 Hz, 2 Hz, 1H), 3.93 (s, 3H), 4.04 (s, 3H), 6.63 (d, $J = 4$ Hz, 1H), 6.70 (d, $J = 7$ Hz, 2H), 7.05 (s, 1H), 7.64 (s, 1H), 8.12 (d, $J = 7$ Hz, 2H); isomer b, 2.89 (dd, $J = 5$ Hz, 2 Hz, 1H), 3.11 (dd, $J = 5$ Hz, 2 Hz, 1H), 3.25 (s, 6H), 3.63 (ddd, $J = 5$ Hz, 5 Hz, 2 Hz, 1H), 3.96 (s, 3H), 4.06 (s, 3H), 6.72 (d, $J = 7$ Hz, 2H), 6.75 (d, $J = 3$ Hz, 1H), 7.09 (s, 1H), 7.66 (s, 1H), 8.14 (d, $J = 7$ Hz, 2H); counterion, 2.79 (s, 8H). FAB-MS m/z : 404.5 M^+ (cation).

Preparation of 1-(3,4-Dimethoxy-6-nitrophenyl)-2,3-epoxypropylsuccinimidyl Carbonate (VII). **II** (100 mg, 0.392 mmol) dissolved in 2 mL of acetonitrile was treated with 110 mg (0.431 mmol) of di-*N*-succinimidyl carbonate. *N*-Ethyl-diisopropylamine (70 μ L, 0.431 mmol) was added and the reaction mixture stirred for 5 h at room temperature. After evaporation of the solvent, the residue was dissolved in ethyl acetate and washed three times with 20% citric acid, sodium bicarbonate solution, and saturated sodium chloride. The organic phase was dried over magnesium sulfate, the solvent evaporated, and the yellow residue recrystallized out of chloroform/hexane producing yellow-orange crystals. Yield: 138 mg (0.348 mmol, 89%). MW: 396.32 ($C_{16}H_{16}N_2O_{10}$). ^1H -NMR ($CDCl_3$, in ppm): isomer a, 2.79 (s, 4H), 2.82 (dd, $J = 5$ Hz, 2 Hz, 1H), 3.02 (dd, $J = 5$ Hz, 2 Hz, 1H), 3.56 (ddd, $J = 5$ Hz, 5 Hz, 2 Hz, 1H), 3.95 (s, 3H), 4.04 (s, 3H), 6.66 (d, $J = 4$ Hz, 1H), 7.05 (s, 1H), 7.64 (s, 1H); isomer b, 2.79 (s, 4H), 2.90 (dd, $J = 5$ Hz, 2 Hz, 1H), 3.10 (dd, $J = 5$ Hz, 2 Hz, 1H), 3.63 (ddd, $J = 5$ Hz, 5 Hz, 2 Hz, 1H), 3.96 (s, 3H), 4.06 (s, 3H), 6.77 (d, $J = 3$ Hz, 1H), 7.09 (s, 1H), 7.67 (s, 1H). MS (70 eV) m/z (%): 396 (51) M^+ , 238 (100) $C_{11}H_{12}NO_5^+$. FAB-MS m/z : 397.4 MH^+ .

Preparation of Bis[1-(3,4-dimethoxy-6-nitrophenyl)-2,3-epoxypropyl]-*N,N'*-rhodamine Carbonate (VIII). **IV** (100 mg, 0.180 mmol) dissolved in 0.5 mL of water free THF was treated with 40 μ L of *N*-ethyl-diisopropylamine (0.350

mmol) and 32 mg of rhodamine 110 hydrochloride (0.086 mmol). An orange precipitate developed over a 2 min sonification treatment. The reaction mixture was left to stand for 4 h at room temperature and centrifuged, and the solvent was evaporated and the orange residue taken up in 5 mL of ethyl acetate. Successive washing of this organic solution with saturated NaHCO_3 , 20% citric acid, and saturated NaCl was used to remove the sulfonate. The organic phase was then dried over MgSO_4 , the solvent removed, and the product recrystallized from the residue out of toluene. Yield: 58 mg (0.065 mmol, 75%). MW: 892.5 ($\text{C}_{44}\text{H}_{36}\text{N}_4\text{O}_{17}$). Mp: 188–193 °C. $^1\text{H-NMR}$ (CDCl_3 , in ppm): isomer a, 2.35 (dd, $J = 4$ Hz, 3 Hz, 1H), 3.06 (dd, $J = 4$ Hz, 3 Hz, 1H), 3.53 (ddd, $J = 4$ Hz, 4 Hz, 2 Hz, 1H), 3.90 (s, 3H), 3.95 (s, 3H), 6.62 (d, $J = 4$ Hz, 1H), 7.01 (s, 1H), 6.68 (d, 8 Hz, 1H), 7.10 (s, 1H), 7.15 (d, 8 Hz, 1H), 7.17 (d, 7 Hz, 1H), 7.19 (dd, $J = 7$ Hz, 7 Hz, 1H), 7.30 (dd, $J = 7$ Hz, 7 Hz, 1H), 7.60 (s, 1H), 8.10 (d, $J = 7$ Hz, 1H); isomer b, 2.39 (dd, $J = 4$ Hz, 3 Hz, 1H), 3.08 (dd, $J = 4$ Hz, 3 Hz, 1H), 3.64 (ddd, $J = 4$ Hz, 4 Hz, 2 Hz, 3H), 3.92 (s, 3H), 3.97 (s, 3H), 6.65 (d, $J = 4$ Hz, 1H), 6.68 (d, $J = 8$ Hz, 1H), 7.07 (s, 1H), 7.10 (s, 1H), 7.15 (d, $J = 8$ Hz, 1H), 7.17 (d, $J = 7$ Hz, 1H), 7.19 (dd, $J = 7$ Hz, 7 Hz, 1H), 7.30 (dd, $J = 7$ Hz, 7 Hz, 1H), 7.63 (s, 1H), 8.10 (d, $J = 7$ Hz, 1H); isomer c, 2.83 (ddd, $J = 4$ Hz, 4 Hz, 2 Hz, 1H), 3.48 (ddd, $J = 4$ Hz, 4 Hz, 2 Hz, 3H), 3.64 (ddd, $J = 4$ Hz, 4 Hz, 2 Hz, 3H), 3.96 (s, 3H), 3.98 (s, 3H), 6.68 (d, $J = 8$ Hz, 1H), 6.78 (d, $J = 3$ Hz, 1H), 7.08 (s, 1H), 7.10 (s, 1H), 7.15 (d, $J = 8$ Hz, 1H), 7.17 (d, $J = 7$ Hz, 1H), 7.19 (dd, $J = 7$ Hz, 7 Hz, 1H), 7.30 (dd, $J = 7$ Hz, 7 Hz, 1H), 7.65 (s, 1H), 8.10 (d, $J = 7$ Hz, 1H); isomer d, 2.92 (ddd, $J = 4$ Hz, 4 Hz, 2 Hz, 1H), 3.48 (ddd, $J = 4$ Hz, 4 Hz, 2 Hz, 1H), 3.64 (ddd, $J = 4$ Hz, 4 Hz, 2 Hz, 3H), 3.96 (s, 3H), 3.99 (s, 3H), 6.81 (d, $J = 3$ Hz, 1H), 6.68 (d, $J = 8$ Hz, 1H), 7.10 (s, 1H), 7.14 (s, 1H), 7.15 (d, $J = 8$ Hz, 1H), 7.17 (d, $J = 7$ Hz, 1H), 7.19 (dd, $J = 7$ Hz, 7 Hz, 1H), 7.30 (dd, $J = 7$ Hz, 7 Hz, 1H), 7.67 (s, 1H), 8.10 (d, $J = 7$ Hz, 1H). Reaction of 2-Iminothiolane with BSA and Aminodextran. BSA (4 mg) dissolved in 1 mL of 50 mM borate buffer at pH 8.5 was treated with 40 μL of a freshly prepared solution of 3.5 mg of 2-iminothiolane in 250 μL of distilled water. The solution was left at room temperature for 1 h and then centrifuged for 10 min at 10 000 rpm. The protein conjugate was dialyzed overnight against two changes of phosphate buffer at pH 7.5, previously degassed and saturated with nitrogen gas to prevent oxidation of the thiol groups. After dialysis, the thiolated BSA conjugate was centrifuged at 14 000 rpm at 4 °C. A similar labeling procedure was used to prepare the thiolated dextran from aminodextran.

Determination of the Free Thiol Content of BSA. A 10 mM stock solution of Acrylodan (15 μL) (the thiol reactive form of the fluorescent dye Prodan) dissolved in DMF was added to 300 μL of a 60 μM solution of iminothiolane-BSA at pH 8.0. The reaction mixture was left for 2 h at room temperature, and the solution was centrifuged for 10 min at 10 000 rpm and dialyzed for 2 days against phosphate buffer at pH 7.5 and 4 °C with three changes of buffer. The protein conjugate was centrifuged for 20 min at 14 000 rpm at 4 °C before recording its absorption spectrum. The concentration of Prodan in the conjugate was calculated from the absorption value at 385 nm using an extinction coefficient of 18 500 $\text{M}^{-1} \text{cm}^{-1}$ (24).

Reaction of II with Thiolated BSA. A 60 μM solution of thiolated BSA (500 μL) in borate buffer at pH 9.0 was treated with 20 μL of a 20 mM stock solution of compound II dissolved in acetonitrile. The solution

turned yellow and was left to stand for 2 h. The BSA conjugate was centrifuged for 10 min at 10 000 rpm at 4 °C and the solution dialyzed for 2 days against phosphate buffer at pH 7.5 and 4 °C with three changes of buffer. The conjugate was then centrifuged for 20 min at 14 000 rpm at 4 °C and the absorption spectrum recorded. The labeling ratio of II:BSA was determined using an extinction coefficient for II of 5000 $\text{M}^{-1} \text{cm}^{-1}$ at 350 nm, no losses in BSA were assumed to occur during the workup of the conjugate.

Coupling of G-Actin with Tetramethylrhodamine-Iodoacetamide. Rabbit muscle G-actin, purified according to Marriott (14), in G-buffer (2 mM Tris, 0.2 mM CaCl_2 , and 0.2 mM ATP at pH 8.0) containing 0.5 mM DTT was treated with 13 μL of a 10 mM stock solution of IATMR dissolved in DMF and the reaction mixture left for 2 h at room temperature. The protein was centrifuged for 30 min at 100 000g at 4 °C and dialyzed overnight against two changes of G-buffer without DTT at 4 °C. After a clear spin at 100 000g for 1 h, the polymerization was initiated by addition of 2 mM MgCl_2 and 0.1 M KCl to the supernatant and the mixture left for 2 h at room temperature. Ultracentrifugation at 100 000g for 1 h and resuspension of the F-actin pellet in G-buffer was followed by overnight dialysis against G-buffer without DTT. The labeled G-actin solution was clarified by centrifugation (100 000g for 1 h) and absorption spectrometry used to calculate a labeling ratio of 0.4 fluorophore per actin monomer using an extinction coefficient for TMR of 96 500 $\text{M}^{-1} \text{cm}^{-1}$ at 550 nm (26).

Labeling of TMR-G-Actin with VI. A 30 μM solution of TMR-labeled G-actin (800 μL) in G-buffer without DTT was mixed with 20 μL of a freshly prepared 20 mM stock solution of VI in acetonitrile. After a 45 min reaction at room temperature in the dark, the protein was centrifuged for 20 min at 14 000 rpm at 4 °C and dialyzed for 16 h at 4 °C against nitrogen-purged G-buffer without DTT with two buffer changes. The protein was clarified by ultracentrifugation at 100 000g for 1 h and the absorption spectrum recorded. The protein labeling ratio was calculated using an extinction coefficient for VI of 5000 $\text{M}^{-1} \text{cm}^{-1}$ at 350 nm and 3400 $\text{M}^{-1} \text{cm}^{-1}$ at 290 nm (14).

Reaction of the TMR-G-Actin Conjugate of VI with Thiolated Dextran. Aminodextran labeled with 2-iminothiolane as described earlier was added to a 20 μM solution of TMR-labeled G-actin in a borate-based G-buffer at pH 9.5. After a 1 h reaction, the complex was centrifuged for 20 min at 14 000 rpm at 4 °C and dialyzed overnight against two changes of Tris-based G-buffer with 1 mM DTT. The fluorescent actin-dextran complex was clarified by centrifugation for 20 min at 14 000 rpm at 4 °C.

Reaction of VIII with G-Actin. Two milliliters of 25 μM F-actin was depolymerized during dialysis over 2 days at 4 °C against nitrogen-purged G-buffer without DTT. The G-actin solution was clarified by centrifugation for 1 h at 100 000g at 4 °C. A 20 mM stock solution of VIII (20 μL) was added to 500 μL of the G-actin solution after adjusting its pH to 9.0. After a 1 h reaction at room temperature, the actin conjugate was clarified by centrifugation for 30 min at 10 000 rpm and dialyzed for 2 days against G-buffer (pH 8.0) containing 1 mM DTT. After a clear spin for 1 h at 100 000g at 4 °C, the labeling ratio of VIII:G-actin was determined by absorption spectroscopy using an extinction coefficient for VIII of 5000 $\text{M}^{-1} \text{cm}^{-1}$ at 350 nm and 3400 $\text{M}^{-1} \text{cm}^{-1}$ at 290 nm (14).

Scheme 1

RESULTS AND DISCUSSION

The Grignard reaction of vinylmagnesium bromide on 3,4-dimethoxy-6-nitrobenzaldehyde created a hydroxyl and vinyl group off the benzylic carbon which provided the starting point for the synthesis of the two different reactive groups of the cross-linking reagent (Scheme 1). The first group, an activated carbamate or carbonate, was used to react with and cage an amino group of the compound of interest to its corresponding photolabile carbamate, while the second group, an oxirane, was used to alkylate thiol groups and served to cross-link the caged amino compound to a different thiol-containing bio-molecule. This synthetic approach also allowed the physical and chemical separation of the two nucleophilic reactive groups from the photoisomerization functionality. This design feature permitted the use of the 3,4-dimethoxy-6-nitrophenyl group, which has a high molar absorptivity and a red-shifted action spectrum in the 340–420 nm wavelength region. These spectroscopic properties are important for applications of caged compounds in living cells or on surface monolayer (27). Since the photocleavable cross-linking reagents introduced by Senter et al. (15), Marriott et al. (7), and Olejnik et al. (25) incorporate the second reactive group at the 4-position of the nitrophenyl group, no other substitutions of the nitrophenyl ring are possible, and correspondingly, these reagents exhibit a low molar absorptivity and blue-shifted action spectra.

Reactivity of the Oxirane Group with Thiols.

Treatment of compound **I** with MCPBA generated the epoxy alcohol, compound **II**, in excellent yield (Scheme 1). Although the benzylic proton was resolved for each isomer of compound **II** using NMR spectroscopy, it was not possible to physically isolate the diastereomers. To show that the oxirane group of compound **II** reacted specifically with thiol groups, a qualitative analysis of the reactions of compound **II** with 2-mercaptoethanol was performed under various conditions of pH and solvent composition. In summary, these results showed alkylation of mercaptoethanol with compound **II** occurred in aqueous solutions at a pH value of 8.0–9.5 or in organic solvents under slightly acidic or neutral conditions. Compound **II** did not react with primary amines under these conditions (data not shown). Investigations were also made on the reactions of the oxirane group of compound **II** with reduced thiol groups of native BSA, containing a single reduced thiol group, and a 2-iminothiolane conjugate of BSA containing several reactive thiol groups. Dialysis of these reaction mixtures removed excess compound **II**, and allowed an absorption spectro-photometric analysis-based calculation of the labeling ratio of **II**:BSA for each conjugate. Native BSA was found to harbor a single molecule of **II** per BSA molecule, while the iminothiolane–BSA was labeled with six molecules of **II** per BSA (Figure 1). An independent determination of the number of reactive thiol groups in the iminothiolane–BSA conjugate using the thiol labeling reagent Acrylodan (24) also showed there were six free thiol groups (data not shown). Evidently at this slightly basic

Figure 1. Absorption spectra of (a) native BSA labeled (59 μ M) with compound **II** and (b) iminothiolane-labeled BSA (59 μ M) labeled with compound **II**.

Figure 2. (A) Absorption spectra of **II** in ethanol (a) before irradiation with 365 nm light and (b) after irradiation for 30 s, (c) 90 s, and (d) 900 s. (B) Infrared spectra of **II** before (dashed line) and after a 90 s irradiation with near-ultraviolet light (solid line).

pH, the oxirane group was able to react selectively with reduced thiol groups of proteins.

Spectral Properties of II. The absorption spectrum of a defined concentration of an ethanolic solution of compound **II** (Figure 2A) showed that the chromophore had a broad $n-\pi^*$ transition centered at 350 nm and an extinction coefficient at this wavelength of $5000 \text{ M}^{-1} \text{ cm}^{-1}$. Excitation of this ethanolic solution with near-ultraviolet light (340–420 nm) led to a dose-dependent loss of the 350 nm band, while two new absorption

Scheme 2

transitions evolved with maxima at 268 and 378 nm (Figure 2A). These absorption bands most probably belong to the 3,4-dimethoxy-6-nitrosoacetophenone photoproduct. Evidence that this reaction occurred via a photoisomerization reaction of the nitrophenyl group was provided by an analysis of the infrared spectra of a film of **II** recorded before and after near-ultraviolet irradiation (Figure 2B) which showed a loss of the hydroxyl absorption band at 3450 cm^{-1} of compound **II** and a gain of a ketone absorption band at 1705 cm^{-1} . These results are consistent with the reaction pathway presented in Scheme 1.

Preparation of Photocleavable, Cross-Linking Reagents Based on Compound II. Compound **II** proved to be a key intermediate in the synthesis of the four cross-linking reagents described in this report (Scheme 2). On the basis of earlier, successful studies in which NVOC-Cl was used to cage amino groups (14, 15, 20), we decided to prepare compound **III**, the corresponding chloroformate of **II**, by activation of its benzylic hydroxyl group using diphosgene. Analysis of the reaction showed the presence of two major products which, after purification over silica gel and NMR analysis, proved to be two isomers at the benzylic carbon. Isomer **IIIa** was crystallized out of 2:1 hexane/ethyl acetate. The isomers exhibited identical absorption and infrared spectra, and they could not be distinguished by mass spectrophotometry. The photoisomerization rates of **IIIa** and **IIIb** were found to be similar as judged by a qualitative TLC analysis of the amount of product that formed upon irradiation of each isomer with 365 nm light (data not shown). Compound **III** reacted poorly with the amino groups of polylysine or G-actin in bicarbonate buffer at pH 8.5. Furthermore, although the unsubstituted chloroformate, NVOC-Cl, has been shown to react with amino groups in both organic and aqueous solvents (3, 14), this was not the case with compound **III**, and presumably, the substituent on the benzylic carbon atom deactivated the chloroformate group. These findings prompted the syntheses of more activated carbonates and

carbamates of compound **II** that could be used to protect amino groups in aqueous or organic solvents.

Steglich's reagent (TDO) (17) was chosen to make a more activated carbonate of compound **II**. This reaction proceeded smoothly in THF under reflux to produce compound **IV** in high yield. The two isomers of compound **IV** were not resolved using the purification scheme described in Materials and Methods. However, the photoisomerization rates of the isomers of compound **IV** should not differ to any significant extent given the similarity of the photoisomerization rates found for the isomers of compound **III**.

An interesting, competing side reaction was discovered in the synthesis of compound **IV**. This involved the reaction of compound **IV** with compound **II**, accelerated by the addition of catalytic amounts of base, which yielded the symmetrical carbonate **V**, a further, thiol reactive, homobifunctional, photocleavable cross-linking reagent (Scheme 2).

Photocleavable, Cross-Linking Reagents and the Preparation of a Thiol Reactive Caged Rhodamine 110. Compound **IV** was shown to react efficiently with amino groups (e.g. rhodamine 110, glycine and polylysine, data not shown) in organic solvent and in aqueous solution at pH 8.5 to produce the corresponding carbamate. Amidation of the two aromatic amino groups of the highly fluorescent rhodamine 110 fluorophore has been shown to form the nonfluorescent, lactone form of the dye which lacks a visible absorption band and fluorescence emission (18). Similarly, compound **IV** was shown to react with rhodamine 110 to produce a nonfluorescent, bis-substituted carbamate (**VIII**, Scheme 3). Irradiation of the nonfluorescent (caged) rhodamine 110 with near-ultraviolet light cleaved the two carbamate bonds and liberated free rhodamine 110 with concomitant recovery of its visible absorption band and intense fluorescence emission centered at 523 nm (Figure 3A,B). This reaction was quite rapid since the photoactivation of a $500\text{ }\mu\text{L}$

Scheme 3

sample of 50 μ M solution of caged rhodamine 110 in the presence of 5 mM DTT was complete within 240 s (Figure 3A,B).

One of the oxirane groups of compound **VII** was used to label a thiol group on a cysteine residue of G-actin in a reaction conducted in aqueous buffer at pH 8.5. A labeling ratio of 1:1 for compound **VIII**:G-actin was calculated using absorption spectroscopy, suggesting the caged fluorophore was covalently attached to cysteine-374 (24). This caged fluorescent G-actin conjugate was able to polymerize under physiological conditions as seen by a comparison of the absorption spectra of the supernatant and pellet fractions of a high-speed centrifugation run, which showed the pellet fraction contained the majority of the photoactivated actin (Figure 4). Irradiation of the nonfluorescent G-actin conjugate with near-ultraviolet light cleaved the carbamate bond that linked the caged groups to rhodamine 110 and liberated the highly fluorescent rhodamine 110, and a polymerization competent G-actin that harbored the 3,4-dimethoxy-6-nitrosophenylketone-based photoproduct (Figure 4).

Photocleavable, Cross-Linking Reagents with Improved Water Solubility and Amino Group Reactivity. To improve upon the water solubility of heterobifunctional photocleavable cross-linking reagents, and to increase their reactivity toward the ϵ -amino group of lysine residues of proteins, compound **VI**, the DMAP salt of compound **IV** was prepared via two synthetic routes outlined in Scheme 2. In the first approach, the succinimide carbonate of **II** was prepared in a reaction of **II** with di-*N*-succinimidyl carbonate in acetonitrile which produced the crystalline product **VII** in high yield. Treatment of compound **VII** in THF with DMAP led to the precipitation of the DMAP salt of compound **VI**. In the second synthetic approach, compound **VI** was prepared in a single-step reaction of compound **IV** with DMAP as described in Materials and Methods. Compound **VI**, a highly activated, water soluble carbamate reacted rapidly with amino groups of proteins at a pH between 8 and 9 (Scheme 4). Compound **VI** was found to hydrolyze in water, and consequently, its reactions with proteins should be performed using the reactants at a relatively high concentration. Compound **VI** can be added to protein labeling reactions as a solid to reduce any risk of organic solvent-based protein denaturation.

Figure 3. (A) Absorption spectra of a 50 μ M solution of caged rhodamine 110 in EtOH/H₂O (10:1) containing 2 mM DTT before irradiation (a) and after near-ultraviolet irradiation (340–400 nm) for the following times: (b) 5 s, (c) 10 s, (d) 180 s, and (e) 240 s. (B) Fluorescence emission spectra of caged rhodamine 110 with excitation at 488 nm of a 15 μ M solution of caged rhodamine 110 in EtOH/H₂O (10:1) before irradiation (a) and after near-ultraviolet irradiation (340–400 nm) for the following times: (b) 5 s, (c) 20 s, (d) 60 s, and (e) 240 s.

Figure 4. (a) Absorption spectrum of G-actin-labeled caged rhodamine 110 before irradiation with near-ultraviolet light in G-buffer containing 2 mM DTT. The G-actin was treated with MgCl₂ and KCl to 2 and 100 mM, respectively, and after 2 h, the protein was centrifuged at 100000*g* for 60 min. (b) Absorption spectrum of the pellet fraction of this centrifugation run after resuspension in an equal volume of F-buffer. (c) Absorption spectrum of the supernatant fraction of this centrifugation run. (d) Absorption spectrum of the resuspended pellet fraction (from part b) after irradiation with near-ultraviolet light for 10 min in the presence of 5 mM DTT.

It should be noted however that in organic solvents and in the presence of nucleophiles DMAP-activated salts such as **VI** undergo esterification or even reaction to

Scheme 4

Figure 5. (a) Absorption spectra of the IATMR-labeled G-actin-dextran complex in G-buffer containing 2 mM DTT. After addition of MgCl_2 and KCl to 2 and 100 mM, respectively, and 2 h at room temperature, the sample was centrifuged at $100000g$ for 60 min. (b) Absorption spectrum of the supernatant fraction. No pellet fraction was found after the centrifugation; i.e. the actin was caged. The supernatant fraction was then irradiated with near-ultraviolet light for 10 minutes, and after 2 h at room temperature, the sample was centrifuged at $100000g$ for 60 min. (c) Absorption spectrum of the pellet fraction resuspended in an equal volume of F-buffer.

isocyanates (21), and therefore, stock solutions of **VI** made in acetonitrile should be prepared just before the protein labeling reaction.

Application of Photocleavable, Cross-Linking Reagents for the Preparation of Caged G-Actin.

Compound **VI** was used as part of a new labeling procedure to prepare caged G-actin, i.e. a G-actin conjugate that does not polymerize under physiological conditions (14). An average of 3.5 lysine residues of TMR-labeled G-actin were protected as their corresponding photolabile carbamates with compound **VI**. One or more of the oxirane groups of this fluorescent G-actin conjugate of compound **IV** were then cross-linked to a thiolated dextran. Sixty minutes after addition of physiological salt to this caged G-actin cross-linked complex, the sample was subjected to high-speed centrifugation and the absorption spectra of the supernatant and resuspended pellet fractions were recorded (Figure 5). These data showed the majority of the fluorescently labeled G-actin conjugate was contained in the supernatant fraction and was, consequently, polymerization incompetent (Figure 5). A $500\ \mu\text{L}$ sample of this caged G-actin complex in F-buffer was exposed to near-ultraviolet light for 10 min in the presence of 5 mM DTT to photocleave the cross-link between G-actin and the dextran, and then left for 60 min at room temperature to allow for polymerization. After high-speed centrifugation of the sample, absorption spectroscopic analysis now showed the majority of the actin was in the resuspended pellet fraction; i.e. the photoactivated actin had polymerized into F-actin filaments (Figure 5). The inability of the G-actin cross-linked dextran complex to polymerize in physiological salt probably arose from a physical masking of the actin binding site on the caged G-actin by the flexible, cross-linked dextran molecule. This mode of inhibition was

evidently relieved after the light-directed dissociation of the carbohydrate polymer. Importantly, the photocleavage reaction released native, fully functional G-actin, while the photoproduct remained covalently attached to the thiolated dextran. This new approach to caging the activity of G-actin required the modification of fewer lysine residues compared to the NVOC-Cl method (14).

An interesting parallel to the caged G-actin complex described above has been reported by Mann and Vannan (26). These authors demonstrated that, although a succinimidyl D-biotin conjugate of calmodulin could still activate the enzyme phosphodiesterase, this activity was completely blocked when the calmodulin conjugate was pretreated with avidin. Presumably, avidin, like the dextran in G-actin, physically masked the PDE binding site of calmodulin. Given the importance of specific interactions in protein function, targeted disruption of protein binding sites using the photocleavable reagents and the dextran conjugation methods described herein could be used as part of a general approach to caging the activity of a wide range of proteins. Native, active proteins would then be liberated from these caged dextran cross-linked complexes upon illumination with near-ultraviolet light.

SUMMARY

In this study, we designed, synthesized, and characterized four members of a new class of heterobifunctional photocleavable cross-linking reagents. Biomolecules or fluorophores caged with these reagents can be covalently cross-linked to a second thiol-containing protein, ligand, or derivatized surface through the oxirane moiety. The cross-linking reaction may be used for the following applications: (1) to prepare a caged protein by masking an active site with a thiolated dextran, (2) to target the caged compound to a specific site using a thiolated antibody (15), (3) to attach the caged compound to a thiol-derivatized surface, and (4) to render the caged compound fluorescent in order to image or to quantify the yield of the photoactivation reaction.

The activated carbonate and carbamate groups of two of the reagents described in this report can be used to protect almost any amino group as a photolabile carbamate in either water or organic solvent. The order of reactivity toward amino groups of the different activated groups in water was found to be $\text{R-DMAP}^+ > \text{R-TDO} > \text{R-OSu} > \text{R-Cl}$. Compound **IV**, the TDO carbonate of compound **II**, was used to protect amino groups in organic solvents, while compound **VI**, the DMAP salt of compound **IV**, was the most water soluble and reactive toward amino groups. The physical and chemical separation of the cross-linking functionality from the photoisomerization functionality in these reagents allowed the introduction of one or more methoxy groups into the nitrobenzyl ring which increased its absorption cross section and shifted its action spectrum to a lower energy.

One of the new bifunctional, photocleavable cross-linking reagents, compound **IV**, was used to prepare a thiol reactive, nonfluorescent (caged) rhodamine 110. Irradiation of this caged fluorescent actin conjugate with near-ultraviolet light generated free, highly fluorescent rhodamine 110 and a polymerization competent G-actin conjugate. Compound **V**, a water soluble photocleavable cross-linking reagent, was used as part of a new approach to caging the activity of G-actin by exploiting the ability of a dextran molecule cross-linked to G-actin to physically mask its actin binding site. Photocleavage of the G-actin-dextran cross-linked complex in F-buffer with near-ultraviolet light liberated native G-actin which polymerized into filaments and released the dextran conjugate of the 3,4-dimethoxy-6-nitrosoketone-based photoproduct. The new photocleavable, cross-linking reagents and conjugation methods described in this article can form the basis of a new, general approach to caging the activity of proteins.

Received April 23, 1997; Revised Manuscript Received November 3, 1997

This work deals with the synthesis and lectinic recognition ability of galactosylated telomers. To investigate if telomeric carriers could exhibit cellular recognition properties, we have synthesized mono- and polygalactosylated tris(hydroxymethyl)acrylamidomethane (THAM) telomers. The affinity of such macromolecular drug carriers toward a receptor, the yeast Kb CWL1 lectin, was defined, and the influence of mono- or polygalactosylation of THAM units on the recognition phenomenon was assessed. The lectinic affinity of the compounds was estimated by measuring the inhibition of yeast aggregation. The average degree of polymerization as well as the hydrophilic–lipophilic balance of such galactosylated telomers affects their recognition ability for the lectin.

INTRODUCTION

The cell–cell recognition mechanisms as well as the potentialities offered by natural or synthetic macromolecular delivery systems have been widely investigated in recent years (Duncan and Kopecek, 1984; Ouchi and Ohya, 1995).

Binding bioactive molecules to polymers is expected to modulate several disposition parameters, including solubility, absorption and desorption rates, ability to cross membranes, and also cell targeting.

In the course of our project dealing with the study of new drug carriers, we have developed the synthesis and assessments of a new class of low macromolecular carriers or telomers. These compounds were obtained by radical polymerization of an acryloyl or vinylic monomer in the presence of an alkane/perfluoroalkane thiol as the transfer reagent. The physicochemical parameters of prepared multifunctional molecules can be adjusted through both the starting material and the experimental conditions (Pucci et al., 1988). In previous reports (Pucci et al., 1990), we described the synthesis of new amphiphilic telomers derived from tris(hydroxymethyl)acrylamidomethane (THAM)¹ and showed that such compounds were able to cross physiological membranes to diffuse in all biological tissues and could be used for an in vivo drug-delayed delivery (Maurizis et al., 1994). Indeed, no toxicity was observed and, after iv (intravenous) or po (oral) administration to rat, these compounds were slowly released, i.e., within 100 h. Moreover, glycosylation of THAM hydroxyl functions affects the hydrophilic–lipophilic balance (HLB) of these macromolecules and could ensure selective cell targeting via

a specific recognition of pendent carbohydrates by membrane lectins.

The goal of this work is to demonstrate and to specify the recognition ability toward specific lectins of such glycosylated telomers.

It is known that glycosidic compounds are recognized by yeast lectins. These carbohydrate binding proteins are specific and can selectively bind galactose (Al-Mahmood et al., 1991), mannose (Straver et al., 1994), or other glucidic structures (Johnson et al., 1988). In several yeasts, lectins are anchored at the periphery of the cell membrane. The yeast *Kluyveromyces fragilis* bears on its surface a galactose specific Kb CWL1 lectin which has been isolated by Al-Mahmood et al. (1991). This lectin is involved in flocculation or aggregation of this yeast which is a specific cell–cell recognition phenomenon. We observed (Attoui et al., 1994) that the galactose-substituted cyclodextrins were able to inhibit the flocculation of these yeast cells and to change their growth properties. In these phenomena, the linkage of the galactose-substituted cyclodextrins to the cells via a lectinic mechanism seemed to be the initial but important event.

Similar results were obtained with other lectins by Lee (1978) using bis- and mono- β -D-galactopyranoside analogues of the Tris derivative suitable for attachment to proteins on solid matrixes. Kitano et al. (1995) prepared and used amphiphilic compounds bearing several galactose residues in their hydrophilic head groups. These compounds were obtained by telomerization of a galactose containing vinyl monomers using a lipophilic radical as the initiator. Plank et al. (1992) showed that in artificial ligands galactose residues were very important for their

recognition by lectin-like proteins located on the surface of parenchymal hepatocytes.

To investigate if the telomeric carriers could ensure cellular recognition properties, first, we report herein the telomer synthesis from mono- or polygalactosylated THAM and from galactosylated *N*-(acryloyl)ethanolamine. Second, we determine their cellular recognition ability of ligand using as the receptor the galactose specific Kb CWL1 lectin and as target cells the yeast *K. bulgaricus*. Like mammalian cells, yeasts are eukaryotic cells bearing at their surface lectins and ligands. As they are surrounded by a cell wall that protects them against osmotic shocks, they can easily be used in various assays without alterations of their cellular morphology to evaluate recognition properties of galactose derivatives.

EXPERIMENTAL PROCEDURES

Chemistry and Synthesis. The progress of the reaction and the homogeneity of the compounds were monitored by thin-layer chromatography (TLC, Merck F₂₅₄). Detection was achieved by either iodine absorption, exposure of plates to UV light (254 nm), or charring with a methanol/sulfuric acid (1:1) solution. Chromatographic separations were carried out on silica gel 60 (70–230 mesh, Merck), and gel permeation was carried out on Sephadex LH 60 (Pharmacia LKB). Melting points were measured on a electrothermal 9100 type apparatus and are reported uncorrected. The ¹H, ¹³C, and ¹⁹F nuclear magnetic resonance (NMR) spectra were recorded at 250 MHz (or 67.3 MHz for ¹³C) on a Bruker AC 250 apparatus in CDCl₃ or DMSO-*d*₆, and the chemical shifts are expressed in parts per million relative to tetramethylsilane as an internal reference for the ¹H and ¹³C spectra. Elemental analyses were performed by the "Service Central de Microanalyses" of the CNRS of Montpellier (France).

Reactions were performed under anhydrous conditions under dry nitrogen. All the solvents were distilled and dried according to standard procedures. For the telomerization, the solutions were previously carefully deoxygenated by nitrogen bubbling. AIBN (2,2'-azobisisobutyronitril) was purified by recrystallization from absolute ethanol (twice).

Synthesis of mono-, di-, and trigalactosylated monomers **3**, **5**, and **8** and fluorocarbonated monoadducts **15**–**17** have been previously reported (Polidori et al., 1994).

Telomerization of *N*-Tris[[[(2,3,4,6-tetra-*O*-acetyl-β-*D*-galactopyranosyl)oxy]methyl]methyl]acrylamide (3**) in the Presence of 1*H*,1*H*,2*H*,2*H*-Perfluorodecanethiol (**20**).** To a solution of trigalactosylated monomer **3** (3 g, 2.57 mmol) in anhydrous methanol (100 mL) warmed to 40–50 °C under a nitrogen atmosphere were added 1*H*,1*H*,2*H*,2*H*-perfluorodecanethiol (0.246 g, 0.514 mmol, *R*_o = [thiol]/[monomer] = 0.2) in methanol (10 mL) and freshly recrystallized AIBN (0.010 g, 6.43 × 10^{−2} mmol). The mixture was refluxed under stirring; the progress of the reaction was monitored by thin-layer chromatography (7:3 ethyl acetate/hexane). After refluxing for 12 h, the monomer **3** was entirely consumed. Solvent was evaporated, and the resulting oil was subjected to column chromatography on Sephadex LH 60 (1:1 dichloromethane/methanol) to afford the peracetylated telomer **20'** as a white powder (2.1 g, 65%). The average degree of polymerization (DP_n) (4.8) was estimated by ¹H NMR by comparing the area of the signal attributed to methylene α to the sulfur in the fluoroalkyl chain (*d* = 2.75 ppm) with the area of those ascribed to H₄ protons (*d* = 5.4 ppm) of the galactopyranosyl residues. It was con-

firmed by elemental analysis using the nitrogen-to-fluorine ratios %N/%F (=14 DP_n/(17 × 19)). Anal. Found: C, 48.02; H, 5.63; N, 1.20; F, 5.1. Anal. For a DP_n of 5.4, calcd: C, 48.60; H, 5.40; O, 39.45; N, 1.12; S, 0.49; F, 4.94 and an average degree of polymerization of approximately 5 for peracetylated telomer **20**.

Deacetylation was performed at room temperature in methanol containing a catalytic amount of sodium methoxide. After treatment with a H⁺ type resin (Amberlite IRC 50), filtration, and evaporation of the solvent, deacetylated derivative **20** was isolated in quantitative yield.

The same procedure used for the preparation of telomer **20** was applied to the synthesis of telomers **18** and **19**.

Synthesis of telomers bearing a hydrocarbon tail such as **21** was previously described (Polidori et al., 1994). The DP_n values were determined by ¹H NMR spectroscopy (CDCl₃) on telomers before deacetylation by comparing the area of the signal ascribed to the terminal methyl group (*d* = 0.85 ppm) with that of H₄ proton(s) of the galactopyranose moiety (*d* = 5.4 ppm).

Telomerization of *N*-(Acryloyl)ethanolamine **9.** Sixteen milliliters of acryloyl chloride (197 mmol) was added at 0 °C dropwise to 7.9 mL of ethanolamine (130 mmol) solubilized in 150 mL of methanol. A solution of KOH (1 N) was simultaneously added in order to maintain the pH of the methanolic solution at 8–9. The mixture was stirred for 4 h at room temperature. After filtration of the KCl salt, the solvent was evaporated under reduced pressure and the crude oil was purified by column chromatography on silica gel (eluent, 10:90 ethanol/AcOEt, v/v). Pure *N*-(acryloyl)ethanolamine **9** was isolated as an oil (10 g, 67% yield, *R*_f 0.4 with 10:90 EtOH/AcOEt). ¹H NMR (DMSO-*d*₆): δ 3.2 (2H, q, CH₂OH), 3.5 (2H, t, CH₂NH), 3.55 (1H, m, OH), 5.6 (1H, dd, CH₂=C), 6.05 (1H, dd, CH₂=C), 6.25 (1H, dd, C=CH), 8.15 (1H, m, NH). ¹³C NMR (DMSO-*d*₆): δ 164.9 (CONH), 131.81 (CH=), 125.04 (CH₂=), 59.7 (CH₂OH), 41.57 (CH₂NH).

Telomerization of *N*-[[[(2,3,4,6-Tetra-*O*-acetyl-β-*D*-galactopyranosyl)oxy]ethyl]acrylamide **10.** *N*-(Acryloyl)ethanolamine **9** (5.4 g, 43.5 mmol) and mercuric cyanide (15.4 g, 56.5 mmol) were solubilized in freshly distilled acetonitrile. After the mixture was stirred for 15 min in the presence of Drierite, acetobromogalactose (25.05 g, 56.5 mmol) was added and the mixture was sonicated under a nitrogen atmosphere for 25 min at room temperature. Then, the precipitate was filtered off and the solvent evaporated. The crude oil was solubilized in ethyl acetate and successively washed with sodium hydrogen carbonate (200 mL), 10% sodium iodide (200 mL), saturated sodium thiosulfate (200 mL), and water. The organic layer was dried over sodium sulfate and then concentrated. Monomer **10** was isolated as a white powder after chromatography on the silica gel column (13.1 g, 67.6% yield, *R*_f = 0.3 with 80:20 AcOEt/hexane, this compound is very hygroscopic). ¹H NMR (CDCl₃): δ 2.1 (12H, 3s, CH₃CO), 3.5 (2H, m, CH₂NH), 3.7 (2H, m, CH₂O), 3.9 (1H, m, H₅), 4.15 (2H, d, H₆), 4.5 (1H, d, H₁), 5.0 (1H, dd, H₃), 5.2 (1H, dd, H₂), 5.4 (1H, d, H₄), 5.65 (1H, dd, CH₂=), 6.1 (1H, dd, CH₂=), 6.25 (2H, m, CH₂=, NH). ¹³C NMR (CDCl₃): δ 170.4, 170.2, 170.1, 169.8 (CH₃CO), 165.5 (CONH), 130.7 (CH₂=), 126.7 (CH=), 101.5 (C₁, β-anomer), 70.9 (C₅ or C₃), 70.7 (C₅ or C₃), 69.1 (CH₂O or C₂), 68.9 (CH₂O or C₂), 67 (C₄), 61.4 (C₆), 39.2 (CNH), 20.5 (CH₃CO), 20.6, 20.55, 20.3.

Synthesis of *N*-[[[(2,3,4,6-Tetra-*O*-acetyl-β-*D*-galactopyranosyl)oxy]ethyl]-4-thiadodecanamide **22.** To a solution of compound **10** (0.9 g, 2.62 mmol) in anhydrous methanol (40 mL) warmed to 40–50 °C under a nitrogen

atmosphere were added 1.05 mL of octanethiol (6.066 mmol) in methanol (10 mL) and freshly recrystallized AIBN (0.010 g, 6.43×10^{-2} mmol). The mixture was refluxed under stirring and the progress of the reaction was monitored by thin-layer chromatography (7:3 ethyl acetate/hexane). After refluxing for 12 h, the monomer **10** was entirely consumed. Solvent was evaporated, and the resulting oil was subjected to column chromatography on silica gel to afford the pure peracetylated monoadduct **22'** as a white powder (0.595 g, 46.6%, hygroscopic). ^1H NMR (CDCl_3): δ 1.0 (3H, t, CH_3), 1.4 (10H, m, $(\text{CH}_2)_5$), 1.7 (H, m, $\text{CH}_2\text{CH}_2\text{S}$), 2.2 (12H, 4s, CH_3CO), 2.6 (4H, m, CH_2SCH_2), 2.85 (2H, t, CH_2CO), 3.6 (2H, m, CH_2NH), 3.9 (H, m, CH_2O), 4 (1H, m, H_5), 4.2 (2H, d, H_6), 4.6 (1H, d, H_1), 5.2 (1H, dd, H_2), 5.4 (1H, d, H_4), 6.2 (1H, t, NH). ^{13}C NMR (CDCl_3): δ 171.3, 170.4, 170.2, 170, 169.8 (CO), 101.4 ($\text{C}_1 \beta$), 70.9 (C_5 or C_3), 70.7 (C_3 or C_5), 69 (C_2 or CH_2O), 68.8 (CH_2O or C_2), 67.0 (C_4), 61.3 (C_6), 39.3 (CNH), 36.7 (CH_2CO), 22.6 to 32.4 ($(\text{CH}_2)_n$), 20.8, 20.7, 20.6, 20.5 (CH_3CO), 14.1 (CH_3).

Deacetylation was realized as above (compound **20**).

Telomerization of Monomer 10 in the Presence of Octanethiol. The procedure was similar to that described above for telomer **20**. For example, starting from monomer **10** (0.92 g, 2.68 mmol), octanethiol (0.06 g, 0.41 mmol, $\text{Ro} = [\text{thiol}]/[\text{monomer}] = 0.153$), and AIBN (0.02 g, 0.12 mmol), acetylated telomer **22'** (0.81 g, 82% yield) was isolated after purification by column chromatography on Sephadex LH₆₀. The D_pn (6.2) was obtained by comparing the area of the terminal methyl signal ($d = 0.85$ ppm) with the signal integration of the H_4 of the galactopyranosyl residues ($d = 5.4$ ppm). For acetyl hydrolysis, the same procedure as for compound **20** was applied to telomer **22'**.

Microorganisms and Culture Conditions. The flocculent yeast *K. bulgaricus* (ATCC 96631) was grown aerobically (air flow of 40 L/h) at 25 °C over 24 h in 1.5 L of a liquid medium [4% glucose, 0.4% bactopeptone (Difco), 0.1% KH_2PO_4 , 0.02% $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$, and 0.02% CaCl_2 (Prolabo, Paris, France)] contained in a 2 L capacity fermentor (LSL Biolafitte S.A., Saint Germain en Laye, France). The flocculent yeast *Saccharomyces cerevisiae* obtained from "Laboratoire de Microbiologie et Génétique ENSAM" at Montpellier (France) was grown under the same aerobic conditions but in a Sabouraud liquid medium [2% glucose and 1% bactopeptone (Difco)].

Growth Assays. The monogalactosylated and digalactosylated monomers or telomers were tested on the growth of *K. bulgaricus* and *S. cerevisiae*. The inoculum (10^7 cells/mL) was obtained from an overnight culture of the yeast in liquid medium. The cultures were grown aerobically at 25 °C in 100 mL Erlenmeyer flasks containing 20 mL of their respective liquid culture medium supplemented with compounds to test. The culture flasks were stirred on a rotary shaker for 48 h. The growth of the yeasts was followed by measuring the absorption at 620 nm with a Perkin-Elmer spectrophotometer. The growth rate calculated according the method of Libudzisz (1986) corresponds to the number of cell divisions per unit of time. All the compounds were solubilized in sterile distilled water before addition in the culture medium at appropriate concentrations.

Extraction of a Galactose Specific Lectin from the Yeast Cells. The Kb CWL1 lectin, involved in the flocculation phenomenon of *K. bulgaricus* (Al-Mahmood et al., 1991), was isolated from whole yeast cells. After growth in a 2 L fermentor under aerobic conditions *K. bulgaricus* cells were harvested by centrifugation at

3000g for 10 min at 4 °C, washed with Helm's buffer (150 mM CH_3COONa , 3.75 mM CaCl_2 , and 3 mM NaN_3 at pH 4.5), treated with a 0.2 M D-galactose solution, and extensively washed with a 0.01 M phosphate buffer (pH 7). Then, cells were suspended at a concentration of 4% (w/v) in PBS supplemented with 5 mM EDTA and incubated at 37 °C for 90 min with weak stirring. After centrifugation at 3000g for 10 min, the supernatant was collected, dialyzed at 4 °C for at least 48 h against distilled water, and then freeze-dried.

The residual flocculating activity of the yeast cells was assessed in Helm's acetate buffer.

Flocculation and Flocculation Inhibition Tests. Nonflocculating yeast cells obtained after lectin extraction were washed first with distilled water, then with a 1% EDTA aqueous solution, and then twice with distilled water. Washed cells (about 2.5×10^6 cells/mL) were suspended in 10 mL of Helm's acetate buffer.

The lectin titer determination was assayed in glass tubes by mixing together 50 μL of 2-fold serial dilutions of lectin solution in the Helm's buffer at pH 4.5 and 50 μL of yeast suspension (2.5×10^6 cells/mL) in the same buffer.

A positive reaction resulted in formation of aggregate (flocs), and the lectin titer corresponded to the reciprocal of the highest dilution of the lectin solution giving detectable aggregation of deflocculated yeasts.

Flocculation (or reflocculation) of the yeast cells was achieved in glass tubes by mixing 50 μL of lectin solution titer 4 with 50 μL of deflocculated yeast cells.

Inhibition of flocculation was assayed in glass tubes by mixing 50 μL of a 2-fold serial dilution of galactosylated substrate solutions in Helm's acetate buffer with 50 μL of lectin solution titer 4. Flocculation inhibition was controlled with galactose, methylgalactose, and *p*-nitrophenylgalactose derivatives. After incubation for 60 min at room temperature, 50 μL of the deflocculated yeast suspension was added. Yeast flocculation was estimated by visual reading or optical microscope observation after 1 h of incubation at room temperature. The inhibitory concentration of the flocculation (ICF) corresponded to the tube which shows a visible aggregation phenomenon. These assays allow us to specify the affinity of the compounds for the lectin. When the amount of compound inhibiting the reflocculation increases, its affinity for the lectin decreases.

RESULTS AND DISCUSSION

Chemistry. The synthesis of A type surfactants requires the selective glycosylation of hydroxyl groups of THAM. For the sake of convenience, we decided to achieve glycosylation on the THAM molecule and to telomerize them subsequently.

Syntheses of mono-, di-, and trigalactosylated monomers derived from THAM have been already reported (Polidori et al., 1994) and are summarized in Scheme 1.

Surfactants were prepared as previously reported (Pucci et al., 1988, 1990; Polidori et al., 1994) by radical telomerization (Scheme 2). Basically, this reaction follows the same rule as a classic radical polymerization. Both methods involve self-condensation of an unsaturated polymerizable monomer in the presence of a radical initiator. Both exhibit the conventional initiation, propagation, and termination steps. The major difference between both processes arises from the fact that telomerization involves the participation of a further chemical species, a chain transfer reagent (or telogen), in this case an alkanethiol.

Scheme 1. Synthesis of Galactosylated THAM Monomers^a

^a (a) Acetobromogalactose, $\text{Hg}(\text{CN})_2$, CH_3CN , ultrasounds, 67–90%; (b) benzaldehyde, *p*-toluenesulfonic acid, CH_3CN , 70%; (c) acetic anhydride, pyridin, 90%; (d) 7/3 $\text{CH}_3\text{COOH}/\text{H}_2\text{O}$, 50 °C, 50–90%; (e) MeONa , MeOH , 95%; (f) acryloyl chloride, MeOH , KOH , 90%.

Scheme 2. Radical Telomerization of Surfactants

The reaction was carried out in boiling methanol under a nitrogen atmosphere in the presence of 2,2'-azobisisobutyronitrile (AIBN) as the radical initiator. Telomerizations were monitored by thin-layer chromatography, and the reaction was pursued until the complete disappearance of monomer **3**, **5**, or **8** (12–24 h).

Two thiols were used as the telogen: octanethiol and the 1*H*,1*H*,2*H*,2*H*-perfluorodecanethiol leading to various monoadducts and/or telomeric surfactants of the **A** or **B** type.

Monoadducts were isolated in pure form after column chromatography on silica gel ($\text{AcOEt}/\text{hexane}$). Telomeric

Figure 1. Growth of *K. bulgaricus* in the presence of mono- and digalactosylated monomers and telomers and galactose: (a) (□) control, (◆) monogalactosylated monomer (**11**), and (■) monogalactosylated telomer (**18**); (b) (□) control, (◆) digalactosylated monomer (**12**), and (■) digalactosylated telomer (**19**); and (c) (□) control and (◆) galactose. The monomers and telomers were tested at a concentration of 1.25 mM, and galactose was tested at a concentration of 2 mM. Each curve corresponds to the average curve of three assays, and the bar corresponds to the standard deviation.

surfactants were purified by gel filtration on Sephadex LH 60.

When the telomer bore a hydrocarbon tail, the $\overline{\text{DPn}}$ was determined by ^1H NMR spectroscopy (CDCl_3) by comparing the area of the signal ascribed to the terminal methyl group ($\delta = 0.85$ ppm) with the H_4 proton(s) signal area of the galactopyranose moiety ($\delta = 5.4$ ppm). In the case of fluorocarbon compounds, the elemental analysis allowed us to calculate %N/%F. The $\overline{\text{DPn}}$ was determined with the equation

$$\%N/\%F = 14n/(17 \times 19) \text{ where } \overline{\text{DPn}} = n$$

All compounds were isolated as white amorphous solids which were very difficult to crystallize. Acetyl deprotection with the monogalactosylated compounds (monomers or telomers), cleavage of the dioxane ring, used as hydroxyl protecting groups, was achieved in an 8:2 acetic acid/water mixture at 60°C for 1 h. Acetyl groups were entirely removed with a catalytic amount of sodium methoxide in anhydrous methanol.

Effects of Mono- and Digalactosylated Monomers and Telomers on *K. bulgaricus* Growth and Flocculation. When *K. bulgaricus* was cultivated in control medium, the exponential growth phase started after 5 h of incubation with a growth rate of 0.15 h^{-1} . Flocculation was observed 10 h after the inoculation.

The presence in the medium of monogalactosylated monomer **11** and telomer **18** (Figure 1a) or digalactosylated monomer **12** and telomer **19** (Figure 1b) at a concentration of 1.25 mM showed no toxic effect on the yeast cells. However, a slight stimulating effect on growth occurred at the beginning of the culture with growth rates of 0.11 and 0.10 h^{-1} for monogalactosylated and digalactosylated derivatives, respectively. No flocculation was observed. When the stationary phase is reached, the biomasses were identical for control and cultures realized in the presence of galactosylated monomers or telomers. This stimulation effect could be due to the inhibition of flocculation at the beginning of growth, or the lack of aggregation increasing the cell degree of freedom and thus facilitating their multiplication. A similar effect was observed when the medium was supplemented with 2 mM galactose (Figure 1c) instead of the galactosylated monomers or telomers. The growth rate in culture in the presence of galactose was 0.13 h^{-1} . Indeed, *K. bulgaricus* cells bear at their

periphery galactose specific Kb CWL1 lectin (Al-Mahmood et al., 1991) which is involved in yeast flocculation. Galactose molecules or galactosylated monomers and telomers inhibit this cell-cell aggregation phenomenon.

The same galactosylated monomers or telomers were tested on the yeast *S. cerevisiae*. In this case, we observed a flocculation phenomenon; furthermore, these compounds did not modify the cell growth. Indeed, this yeast species bears mannose specific lectins on its outer surface (Stratford et al., 1992).

Inhibition of Yeast Reflocculation by Monosaccharides and Derivatives. Several studies have already been carried out to determine the main structural parameters involved in the recognition phenomenon (Kornfeld and Kornfeld, 1976). In lectinic recognition mechanisms, monosaccharides characterize the specificity of the different lectins, but it is well-known that oligosaccharides could exhibit a higher lectin affinity than the free specific monosaccharides (Kawaguchi et al., 1980). In this report, the reflocculation of *K. bulgaricus* cells induced by the galactose specific Kb CWL1 lectin was used to determine the recognition affinity of different galactosylated derivatives. Their ability to inhibit the yeast cell reflocculation process is directly correlated to their lectin affinity. Results reported in Table 1 show that the functionalization of the glycoside anomeric carbon induces an increase of the affinity. Indeed, methyl- β -D-galactose, lactose, and *p*-nitrophenyl- β -D-galactose have a higher inhibitory activity of the lectin than free galactose. These results underline the fact that a hydrophobic structure grafted to the galactose anomeric

position enhances the inhibitory activity, i.e., increases the affinity of these derivatives for the Kb CWL1 lectin.

Inhibitory Activity on the Reflocculation of Mono- and Polygalactosylated Tris Monomers. As reported in Table 2, all the galactosylated monomers derived from THAM showed a higher affinity for the Kb CWL1 lectin than galactose (3.12 mM) used as a control. This affinity improvement can be related to the results obtained with the α and β *p*-nitrophenyl-D-galactose and the melibiose.

The di- or trigalactosylated THAM monomers (compounds **12** and **13**) exhibited an affinity for the lectin 4 times higher than that observed with the monogalactosylated monomer (compound **11**). However, this affinity enhancement is not proportional to the number of galactose moieties. Thus, if the activity of monomer **12** bearing two galactose units is slightly higher than that observed for the monogalactosylated monomer **11**, the presence of three galactose residues did not enhance further the affinity of monomer **13**. The grafting of several sugars on the Tris central carbon involves a steric hindrance which appears to be detrimental to the recognition. Each sugar must be accessible and recognized as a guest. The presence of a hydrophobic structure near the sugar improves the affinity for the lectin; this assumption is checked with the benzylidene derivative (compound **14**). The presence of the hydrophobic character close to the sugar increases 5-fold the affinity of the ligand for the lectin.

Inhibitory Activity on the Reflocculation of Perfluoroalkylated and/or Polygalactosylated Monoadducts and Telomers. Results listed in Table 3 demonstrate that when a hydrophobic perfluoroalkylated chain is linked to the mono- or polygalactosylated monoadducts (compounds **15–17**) the affinity of such ligands for the lectin increased from 2.5- to 10-fold compared to the values for monomer derivatives (compounds **11–13**, Table 2). Taking into account the effect of this perfluoroalkyl chain on the compound's affinity, it seemed interesting to specify how the number of galactosylated structures grafted on the telomer affected this affinity. As reported in Table 4, we can observe that the inhibitory

^a ICF, concentration of galactosylated THAM monomers necessary to inhibit the yeast flocculation. Results are the average of three independent experiments.

activity of the telomers increases from the mono- to the trigalactosylated derivatives. However, it is noteworthy that, compared to that of the corresponding monoadducts (compounds **15–17**), telomerization decreases the affinity for the lectin. These results could be attributed to an alteration of the molecule hydrophilic–lipophilic balance (HLB) due to telomerization. Enhancement of THAM units or polygalactosylated moieties gives to the macromolecule a higher hydrophilic character which induces a loss of affinity. The clustering effect brought on by increasing galactose moieties does not compensate for the HLB alteration.

Effect of the Polymerization Degree on the Monogalactosylated Telomer Recognition Ability. Previous assays have shown that polygalactosylation of

Figure 2. Relation between the degree of polymerization of the monogalactosylated telomers and their recognition ability and comparison of Tris and ethanolamine derivatives.

THAM enhanced the affinity of the derivatives for the Kb CWL1 lectin. The affinity of the molecule for this lectin is also increased in the presence of a hydrophobic moiety.

In this assay, we tried to obtain a clustering effect by polymerizing the monogalactosylated adduct. In this case, the sugar is linked to the backbone chain by either a hydrophilic Tris structure (compound **21**) or an ethanolamine moiety (compound **22**). The latter acts as a spacer and a hydrophobic structure.

Results in Figure 2 show that for both polymers, the affinity of the telomers increases with the degree of polymerization to reach an optimum value. It can be supposed that telomerization induces a clustering effect for the lectin recognition as already reported (Lee, 1978; Kornfeld and Kornfeld, 1976). However, if an equal optimum affinity was obtained with both telomers, the way to reach this optimum depends on the structure bearing the galactose unit. The ethanolamine derivatives (compound **22**) reach this optimum with a $\overline{DPn}$ of 12, while Tris derivatives reach this value when $\overline{DPn}$ is 35. These results demonstrate that clustering and hydrophobicity may have synergetic effects on affinity. Several parameters must be considered to give to a macromolecular carrier an optimum recognition efficiency for a given lectin and thus a good cell targeting. Among them, the molecular mass value, the number and kind of carbohydrate moieties, the accessibility to the sugars, and the HLB of the whole macromolecule must be carefully adjusted.

CONCLUSION

Mammalian, vegetal, and microbial lectins are able to recognize as ligands not only free mono- and disaccharides or isolated oligosaccharides but also various natural or synthetic carbohydrate-containing complex compounds. In each case, the lectins can recognize structural differences in the carbohydrate-containing target site. Moreover, the hydrophobic or hydrophilic character of the recognized epitope of the ligands seems to affect their affinity for the lectins.

Such a heterophilic recognition mechanism has been involved in specific drug targeting on cells bearing lectins on their outer surface. Glycoconjugate derivatives containing galactose residues at their nonreducing end are recognized by the lectin of hepatic parenchymatic cells.

Thus, such compounds are considered efficient antimalarial agents and antiviral nucleotide carriers. In a same way, mannose-conjugated derivatives are recognized by a macrophage peripheral lectin. They are efficient carriers of nucleotides against viruses (*Herpes*) or parasites (*Leishmania*).

Taking into account the in vivo biodistribution of THAM telomers (Zarif et al., 1993) and the present results, especially the efficient recognition of glycosylated telomers by lectin, one can consider that these compounds are valuable tools for ensuring in vivo cell targeting and drug delivery. Current studies involving antimetabolic agents such as arabinofuranosylcytosine or 5-fluorouracil substantiate the validity of this approach (Contino et al., 1996).

However, the carrier must take an appropriate structure to produce the best affinity. First, the specific sugars recognized by the cell lectins have to be accessible, and second, a balance between the clustering effect and the whole carrier HLB has to be maintained.

A Homobifunctional Rhodamine for Labeling Proteins with Defined Orientations of a Fluorophore

John E. T. Corrie,* James S. Craik, and V. Ranjit N. Munasinghe

National Institute for Medical Research, The Ridgeway, Mill Hill, London NW7 1AA, U.K. Received September 22, 1997; Revised Manuscript Received December 15, 1997

The synthesis and characterization of a bifunctional rhodamine dye bearing 2-(iodoacetamido)ethyl substituents on the 3'- and 6'-nitrogen atoms is described. Aspects of the conversion of chloroacetamides to iodoacetamides are discussed, including a remarkably mild dehalogenation of an aromatic haloacetamide in the presence of NaI and camphorsulfonic acid. The bifunctional rhodamine has been designed for two-site, 1:1 labeling of proteins that contain two suitably disposed cysteine residues and is intended to constrain the orientation of the rhodamine absorption and emission dipoles in a predictable relationship to the protein structure.

INTRODUCTION

We have previously described (1) the synthesis and characterization of the 5- and 6-isomers of iodoacetamidotetramethylrhodamine **1** and **2**, and these compounds

have been used to label Cys 707 (SH-1) on the myosin heavy chain of rabbit skeletal muscle and Cys 108 on the regulatory light chain of chicken gizzard myosin. Fluorescence polarization measurements with sub-millisecond time resolution on these labeled proteins in skeletal muscle fibers have provided strong evidence that the regulatory domain of myosin changes orientation during the power stroke of muscle contraction (2a) while the catalytic domain does not (2b). The probe on Cys 707 of the catalytic domain gave evidence for coupling between

the actin–myosin and the myosin–nucleotide interaction sites (2b). Despite the success of these biophysical studies, there have been residual uncertainties of interpretation because the orientation of the reporter fluorophore relative to the protein might change during the contractile cycle (3). More importantly, we envisaged that new information would become available if the rhodamine fluorophore could be linked to muscle proteins, particularly to the 20 kDa myosin regulatory light chain (RLC), by two bonds which would constrain the dye to particular orientations fixed by the termini of the two links to the protein. With the probe dipole fixed in the coordinate frame of the RLC, which is itself contained in the ordered filament lattice of muscle cells, it should be possible to measure molecular coordinates in real time in a working muscle cell and thus to bridge the gap between static crystal structures and cellular function.

Other workers have used homo- and heterobifunctional reagents as immobilized or oriented probes, with particular activity in the synthesis and use of EPR probes. Gaffney et al. (4) described a series of spin-labeled α,ω -alkanedioic acids and studied their interaction with lipid bilayers. A membrane-spanning orientation was found only when the total chain length matched the bilayer thickness. A similar strategy has been used to locate a photolabile diazirene moiety deep in a lipid bilayer, thereby providing a reagent with which to identify transmembrane domains of membrane-spanning proteins (5). In a series of papers, Beth and co-workers have used bis(*N*-sulfosuccinimidyl) esters of spin-labeled pimelic and azelaic acids to link near-neighbor lysine groups on the extracellular domains of membrane proteins (6). Two-site linkage was demonstrated, and tight immobilization of the probe relative to the protein was found for both reagents. Heterobifunctional spin-labeled reagents have been described (7) which react first with a thiol group on the protein to provide a single attachment site and are then linked nonspecifically to a second site by photolysis of an aryl azide. Rigidification of the label following formation of the second link was explicitly demonstrated.

Examples of bifunctional fluorescent probes include crabescien, a fluorescein derivative which has been used specifically to label a reduced disulfide bond in immu-

noglobulin G (8), and bifunctional cyanine dyes (9) which label ϵ -amino groups of lysine residues. The attachment site of crabscein can be predicted with some accuracy when, as in immunoglobulin G, the site of the most readily reduced disulfide is known, but for the lysine-directed cyanines, there is little opportunity to control the site of labeling. Nevertheless, results with each of these probes confirmed a reduction in independent probe mobility resulting from the two-site attachment (8, 10).

The studies reviewed above indicate that two-site attachment of spectroscopic probes can provide significant information gain. It is particularly important that 1:1 probe-protein stoichiometry can be demonstrated and achieved with reasonable yields. These factors should not be taken for granted, since formation of a very large macrocycle is an implicit feature of the concept. The protein scaffold, which holds the two attachment sites on the protein in a restricted spatial distribution, evidently makes a major contribution to the experiments described above (8, 10).

A key part of our strategy was the possibility that the dye should react with its target protein at chosen sites. We anticipated this would most readily be achieved with a reagent which would alkylate two cysteine residues on the protein, and for our particular application we planned to use the known three-dimensional structures of myosin proteins (11) to select suitable sites at which to introduce these cysteine residues by site-directed mutagenesis. Thus, we hoped to create a set of labeled regulatory light chains which could carry the fluorophore with differing three-dimensional orientations into the ordered actomyosin filament lattice of muscle fibers. The emission dipole of xanthene dyes is coincident with the long axis of the xanthene (12), and we anticipated that fluorescence polarization measurements on these labeled fibers would be able to map the orientations of the dye and hence of their carrier protein in both static and dynamic experimental protocols.

This paper deals with the synthesis of the bis-iodoacetamide **3**, which was chosen with the expectation that the linker arms would substantially constrain the movement of the fluorophore. These linker arms are as short as is practical, consistent with chemical stability and maintaining the rhodamine chromophore. In accordance with our previous convention (1), all rhodamine compounds are drawn and named as their nonfluorescent tautomeric lactone form.

MATERIALS AND METHODS

Microanalyses were carried out by the Chemical Analysis Centre (University of Kent, Canterbury, U.K.) or MEDAC Ltd. (Brunel University, Uxbridge, U.K.). Low-resolution electrospray mass spectra were determined on a VG Platform instrument, and high-resolution FAB spectra were determined on a VG ZAB-SE instrument. ^1H NMR spectra were determined in deuteriochloroform on JEOL FX90Q, Bruker WM400, and Varian Unity 500Plus spectrometers with tetramethylsilane as the internal standard unless otherwise stated. J values are given in hertz. The concentration-dependent UV-vis spectra of rhodamine derivatives were recorded on a Cary 3E spectrophotometer.

Buffer solutions were prepared from boric acid or potassium dihydrogen phosphate at the molarities specified and adjusted to the required pH value by addition of solid KOH, followed by 4 M aqueous KOH for final adjustment. Merck 9385 silica gel was used for flash chromatography. Trimethylsilyl polyphosphate was from

Fluka (Gillingham, Dorset, U.K.). Other reagents were from Aldrich (Gillingham, Dorset, U.K.). Petroleum ether was the fraction boiling at 40–60 °C. Procedures involving rhodamines were performed under subdued light. Organic extracts were dried over anhydrous sodium sulfate and evaporated under reduced pressure.

3',6'-Bis(1-pyrrolidiny)spiro[isobenzofuran-1(3H),9'-[9H]xanthen]-3-one (5). A suspension of 3',6'-dichlorospiro[isobenzofuran-1(3H),9'-[9H]xanthen]-3-one **4** (13) (0.074 g, 0.2 mmol), anhydrous ZnCl_2 (0.136 g, 1 mmol), and pyrrolidine (0.142 g, 2 mmol) in dry chlorobenzene (1 mL) was heated at reflux under nitrogen for 4 h and then cooled to room temperature. The reaction mixture was diluted with chloroform (50 mL), and the solution was washed with 2 M aqueous KOH (50 mL) and dried. Silica gel (0.5 g) was added, and the solvent was removed under reduced pressure. The silica gel containing the adsorbed reaction products was added to the top of a flash chromatography column containing silica gel (40 mL), and the column was successively eluted with chloroform (50 mL), methanol-chloroform (1:9 v/v, 100 mL), methanol-chloroform (1:4, 100 mL), and methanol-chloroform (1:3, 200 mL) to afford the rhodamine **5** as a purple glass (0.067 g, 76%): low-resolution electrospray mass spectroscopy (ES-MS) m/e ($M + H$) calcd 439, found 439; ^1H NMR (90 MHz) δ 1.86–2.06 (m, 8H, NCH_2CH_2), 3.17–3.34 (m, 8H, NCH_2CH_2), 6.23 (dd, 2H, $J = 9$ and 2.5, 2',7'-H), 6.34 (d, 2H, $J = 2.5$, 4',5'-H), 6.60 (d, 2H, $J = 9$, 1',8'-H), 7.07–7.20 (m, 1H, 7-H), 7.40–7.63 (m, 2H, 5,6-H), 7.86–8.03 (m, 1H, 4-H). This compound has previously been reported as its hydrochloride salt (**14a**) and characterized by its visible absorption spectrum and elemental analysis.

Ethyl *N*-[(2-Methylamino)ethyl]carbamate (7). Aqueous methylamine (40%, 100 mL) was added to a solution of ethyl *N*-(2-bromoethyl)carbamate **6** (25) (3.9

g, 20 mmol) in methanol (20 mL), and the mixture was stirred for 2 h at room temperature. The solvents were removed under reduced pressure, and the residue was partitioned between 5% aqueous NaHCO_3 (50 mL) and dichloromethane (50 mL). The organic extract was dried and concentrated under reduced pressure to afford the carbamate **7** as a clear liquid (1.9 g, 65%) which was used without further purification as it decomposed on distillation: ^1H NMR (90 MHz) δ 1.23 (t, 3H, $J = 7$, CH_3), 2.40 (s, 3H, NCH_3), 2.69 (t, 2H, $J = 6$, MeNHCH_2), 3.23 (q, 2H, $J = 6$, CONHCH_2), 4.08 (q, 2H, $J = 7$, OCH_2), 5.31 (br s, 2H, $2 \times \text{NH}$). The derived ethyl *N*-[(2-[*N'*-(3,5-dinitrobenzoyl)-*N'*-methylamino]ethyl)carbamate had a melting point of 125–126 °C (EtOAc–petroleum ether). Anal. ($\text{C}_{13}\text{H}_{16}\text{N}_4\text{O}_7$) C, H, N.

3-Methoxy-*N*-methylaniline (10). The preparation of the starting amine was modified from the procedure of Amery and Corbett (16) to give a convenient method with minimal manipulation. Benzenesulfonyl chloride (86 g, 487 mmol) was added over the course of 0.5 h to a mechanically stirred mixture of freshly distilled *m*-anisidine (50 g, 406 mmol) and 2 M aqueous KOH (1100 mL). The mixture was stirred for 1.25 h at room temperature and then heated on a steam bath for 1 h.

The hot solution was filtered, and the filtrate was cooled in an ice bath. Dimethyl sulfate (42.5 mL, 447 mmol; **Caution: potent alkylator**) was added, and the mixture was allowed to warm to room temperature and stirred for 1.5 h, and then kept overnight. Concentrated aqueous ammonia (50 mL) was added, and the mixture was stirred for 0.5 h and then extracted with ether (4 × 150 mL). The ether solution was washed with 2 M aqueous HCl (2 × 100 mL), dried, and evaporated under reduced pressure to give the crude *N*-methylsulfonamide (54 g). This material was refluxed with 6 M aqueous HCl (350 mL) for 7 h, then cooled to room temperature, neutralized by addition of solid KOH, and extracted with ether. The ether extract was dried and evaporated, and the residue was distilled to give the title compound as a pale yellow oil (20.55 g, 37% overall): bp 98 °C at 1.6 mmHg [lit. (17) 131 °C at 17 mmHg]; ¹H NMR (400 MHz) δ 2.76 (s, 3H, NCH₃), 3.74 (s, 3H, OCH₃), 6.13 (t, 1H, *J* = 2.2, 2-H), 6.18–6.27 (m, 2H, 4,6-H), 7.06 (t, 1H, *J* = 8, 5-H). The *N*-acetyl derivative was crystallized from petroleum ether, with a melting point of 64–65 °C [lit. (17) 64 °C].

Ethyl *N*-(3-Methoxyphenyl)-*N*-methylglycinate (11). A solution of the amine **10** (17.0 g, 124 mmol) and ethyl bromoacetate (16.5 mL, 149 mmol) in acetonitrile (175 mL) together with NaHCO₃ (10.9 g, 130 mmol) was stirred and refluxed under nitrogen for 4 h and allowed to cool. Triethylamine (9.8 mL) was added, and the mixture was stirred for 16 h at room temperature and then filtered and evaporated. The residue was dissolved in ether (250 mL), washed with water (3 × 150 mL), dried, evaporated, and distilled to give the ester **11** as a clear liquid (24.0 g, 86%): bp 130–132 °C at 0.6 mmHg; low-resolution ES-MS *m/e* (*M* + *H*) calcd 224, found 224; IR (film) 1745 cm⁻¹; ¹H NMR (400 MHz) δ 1.23 (t, 3H, *J* = 7.15, CH₂CH₃), 3.04 (s, 3H, NCH₃), 3.76 (s, 3H, OCH₃), 4.02 (s, 2H, NCH₂), 4.16 (q, 2H, *J* = 7.15, CH₂CH₃), 6.23 (br s, 1H, 2-H), 6.28–6.32 (m, 2H, 4,6-H), 7.12 (t, 1H, *J* = 8.2, 5-H).

2-[*N*-(3-Methoxyphenyl)-*N*-methylamino]ethanol (12). A suspension of sodium borohydride (7.1 g, 187 mmol) and lithium bromide (16.3 g, 187 mmol) in dry THF (188 mL) was refluxed under nitrogen for 1 h. A solution of the ester **11** (22.0 g, 98.7 mmol) in dry THF was added over the course of 10 min, and the mixture was refluxed for a further 5 h. The solvent was evaporated, and the residue was treated slowly with 1 M aqueous KH₂PO₄ (500 mL) and stirred until hydrogen evolution ceased (ca. 1 h), and then extracted with dichloromethane (5 × 100 mL). The organic extracts were washed with saturated aqueous NaHCO₃ (150 mL), dried, and evaporated. The residue was distilled to give the alcohol **12** as a colorless viscous oil (15.1 g, 84%): bp 127–128 °C at 0.7 mmHg; low-resolution ES-MS *m/e* (*M* + *H*) calcd 182, found 182; IR (film) 3350 cm⁻¹; ¹H NMR (90 MHz) δ 2.40 (br s, 1H, OH), 2.86 (s, 3H, NCH₃), 3.37 (t, 2H, *J* = 5, OCH₂CH₂N), 3.71 (s, 3H, OCH₃) superimposed on 3.70 (t, 2H, *J* = 5, OCH₂CH₂N), 6.17–6.45 (m, 3H, Ar-H), 7.06 (t, 1H, *J* = 8, 5-H). The derived 2-[*N*-(3-methoxyphenyl)-*N*-methylamino]ethyl 3,5-dinitrobenzoate was crystallized from EtOAc–petroleum ether as red needles, with a melting point of 152–153 °C. Anal. (C₁₇H₁₇N₃O₇) C, H, N.

***N*-(2-[*N'*-(3-Methoxyphenyl)-*N'*-methylamino]ethyl)phthalimide (13).** A mixture of the alcohol **12** (7.88 g, 43.5 mmol), triphenylphosphine (12.3 g, 47 mmol), 4 Å molecular sieves (4.0 g), and phthalimide (6.8 g, 46.3 mmol) in dry THF (230 mL) and dry acetonitrile (38 mL) was stirred at –78 °C under nitrogen. Diethyl

azodicarboxylate (8.1 g, 46.6 mmol) was added dropwise over a period of 5 min, and the solution was stirred for 3 h at –78 °C and then allowed to warm to room temperature and stirred overnight. The solvent was evaporated under reduced pressure, and the residue was dissolved in 1 M aqueous sulfuric acid (100 mL) and washed with ether (200 mL). The organic layer was back-extracted with 1 M aqueous sulfuric acid (5 × 50 mL), and the combined aqueous solution was stirred vigorously and basified to pH 8.5 by slow addition of 2 M aqueous KOH and solid NaHCO₃. The resulting suspension was extracted with ether (4 × 100 mL), dried, and evaporated. The residue was filtered through a short column of silica gel (flash chromatography grade) in EtOAc–petroleum ether (1:4), and the eluate was evaporated and triturated with diisopropyl ether to give the phthalimide **13** (8.37 g, 62%) as yellow needles: mp 81 °C from diisopropyl ether; IR (Nujol) 1770, 1705 cm⁻¹; ¹H NMR (400 MHz) δ 2.98 (s, 3H, NCH₃), 3.60 (t, 2H, *J* = 7, CH₂N), 3.76 (s, 3H, OCH₃), 3.88 (t, 2H, *J* = 7, CH₂N), 6.15 [dd, 1H, *J* = 8 and 1.9, 4(6)-H], 6.33 (t, 1H, *J* = 1.9, 2-H), 6.37 [dd, 1H, *J* = 8 and 1.9, 6(4)-H], 7.03 (t, 1H, *J* = 8, 5-H), 7.64–7.69 (m, 2H, phthaloyl 4- and 5-H), 7.76–7.80 (m, 2H, phthaloyl 3- and 6-H). Anal. (C₁₈H₁₈N₂O₃) C, H, N.

***N*-(2-[*N'*-(3-Acetoxyphenyl)-*N'*-methylamino]ethyl)-acetamide (14).** A solution of the phthalimide **13** (11.2 g, 36.1 mmol) in concentrated aqueous hydrobromic acid (325 mL) was refluxed under nitrogen for 2 h and allowed to cool. The solution was evaporated to dryness in vacuo (dry ice condenser), and the crude amine hydrobromide was dissolved in 2 M aqueous potassium borate (pH 9.3, 360 mL) under nitrogen and cooled in an ice bath. A solution of acetic anhydride (27 mL, 286 mmol) in dichloromethane (180 mL) was added over the course of 20 min with vigorous stirring. The aqueous phase was maintained at pH 9.0–9.5 by addition of KOH pellets as required, and after 15 min, a further portion of acetic anhydride (9 mL) in dichloromethane (18 mL) was added. The solution was stirred for 2 h with ice cooling, while the pH was maintained as described above, and then allowed to warm to room temperature and treated with a final portion of acetic anhydride (4 mL) in dichloromethane (10 mL). After a further period of 0.5 h at pH 9–9.5, the organic phase was separated and the aqueous phase was extracted with dichloromethane (3 × 100 mL). The combined organic extracts were washed with saturated aqueous sodium hydrogen carbonate (2 × 100 mL), dried, and concentrated to give a pale gum which solidified upon trituration with ether and was recrystallized from EtOAc–petroleum ether to afford the acetamide **14** (6.65 g, 74%) as clear slabs: mp 87 °C; UV (EtOH) nm (ε in M⁻¹cm⁻¹) 256 (17 700), 310 (3100); IR (Nujol) 3270, 1740, 1630 cm⁻¹; ¹H NMR (400 MHz) δ 1.91 (s, 3H, NCOCH₃), 2.29 (s, 3H, OCOCH₃), 2.93 (s, 3H, NCH₃), 3.42–3.47 (m, 4H, CH₂CH₂), 5.74 (br s, 1H, NH), 6.41–6.43 (m, 2H, Ar-H), 6.60 (1H, dd, *J* = 8.5 and 2, Ar-H), 7.23 (t, 1H, *J* = 8.5, 5-H). Anal. (C₁₃H₁₈N₂O₃) C, H, N.

2-[4'-[*N*-(2-Acetamidoethyl)-*N*-methylamino]-2'-hydroxybenzoyl]benzoic Acid (15). The acetamide **14** (1.00 g, 4 mmol) was dissolved in methanol (10 mL) containing KOH (0.5 g) and stirred at room temperature under nitrogen for 25 min. The solvent was removed under reduced pressure, and the residue was mixed with 2 M aqueous potassium phosphate (pH 8.5, 50 mL) and extracted with dichloromethane (4 × 35 mL). The combined organic extracts were dried and evaporated, and the residual gum was azeotroped with dry toluene (3 × 5 mL) to remove traces of water to leave the crude

phenol **9** (0.83 g), which was dissolved in dry dichloromethane (5 mL) and transferred to a glass tube (150 × 16 mm). The solvent was removed under a current of nitrogen and finally by evacuation (~1 mmHg). Freshly sublimed phthalic anhydride (0.65 g, 4.4 mmol) was added, and the tube was flushed with nitrogen, sealed, and then heated at 135 °C for 4 h. During the first 1 h of heating, the tube was inverted each 15 min to ensure mixing of its contents. After cooling to room temperature, the contents of the tube were dissolved in a mixture of hot ethanol (200 mL) and ethylenediamine (2 mL) to quench excess phthalic anhydride. The solution was concentrated to ~5 mL, diluted with EtOAc (200 mL), and washed with 2 M hydrochloric acid (2 × 70 mL). The aqueous washings were back-extracted with EtOAc (2 × 50 mL), and the combined organic layers were extracted with 10% aqueous NaHCO₃ (5 × 50 mL). The combined aqueous extracts were acidified (pH < 2) with 6 M hydrochloric acid, saturated with NaCl, and extracted with EtOAc (4 × 100 mL). The organic extract was washed with saturated brine (30 mL), dried, and evaporated to leave the benzoylbenzoic acid **15** as a gum which solidified on trituration with ether. The pale orange solid (0.74 g) resisted crystallization and was used without further purification: high-resolution FAB mass spectroscopy (FAB-MS) *m/e* (M + H) calcd 357.1440, found 357.1450; IR (CH₃CN) 1725, 1670, 1625 cm⁻¹; ¹H NMR (400 MHz, [²H₆]DMSO, TMS as reference) δ 1.76 (s, 3H, COCH₃), 2.98 (s, 3H, NCH₃), 3.19 (q, 2H, *J* = 6, CH₂-NH), 3.39 [t, 2H, *J* = 6, ArN(Me)CH₂], 6.16 (d, 1H, *J* = 2.2, 3'-H), 6.25 (dd, 1H, *J* = 8.8 and 2.2, 5'-H), 6.80 (d, 1H, *J* = 8.8, 6'-H), 7.36 (d, 1H, *J* = 7.4, 3-H), 7.60 [t, 1H, *J* = 7.4, 4(5)-H], 7.67 [t, 1H, *J* = 7.4, 5(4)-H], 7.94–7.97 (m, 2H, 6-H and NH), 12.55 (br s, 1H, ArOH).

3',6'-Bis[*N*-(2-acetamidoethyl)-*N*-methylamino]spiro[isobenzofuran-1(3*H*),9'-[9*H*]xanthen]-3-one (16**).** The acetamide **14** (1.25 g, 5.1 mmol) was hydrolyzed as described above (compound **15**), and the crude phenol **9** was mixed with the acid **15** (0.63 g) and a solution of trimethylsilyl polyphosphate (1.54 g) in dry dimethylformamide (31 mL). The mixture was heated at 130 °C under nitrogen for 4 h, cooled, and evaporated (~1 mmHg) to ~1 mL; 1 M aqueous NaOH (50 mL) was added, and the mixture was stirred at room temperature under nitrogen for 16 h. The aqueous solution was saturated with NaCl and extracted with chloroform (5 × 70 mL). The organic extract was dried and evaporated, and the residue dissolved in CHCl₃-MeOH (9:1, 2 mL) was applied to a column of silica gel (flash chromatography grade, 50 mL). The column was successively eluted with CHCl₃-MeOH (9:1, 250 mL), CHCl₃-MeOH (3:1, 300 mL), and CHCl₃-MeOH (1:1, 600 mL) to give the bis-acetamide **16** as a dark purple glass (0.56 g, 60%): low-resolution ES-MS *m/e* (M + H) calcd 529, found 529; ¹H NMR (500 MHz) δ 1.92 (s, 6H, COCH₃), 2.95 (s, 6H, NCH₃), 3.37–3.47 (m, 8H, CH₂CH₂), 6.28 (t, 2H, *J* = 7, NH), 6.40 (dd, 2H, *J* = 9.0 and 2.6, 2',7'-H), 6.52 (d, 2H, *J* = 2.6, 4',5'-H), 6.59 (d, 2H, *J* = 9.0, 1',8'-H), 7.15 (d, 1H, *J* = 7.5, 7-H), 7.58 (t, 1H, *J* = 7.5, 5-H), 7.63 (t, 1H, *J* = 7.5, 6-H), 8.00 (d, 1H, *J* = 7.5, 4-H).

3',6'-Bis[*N*-(2-chloroacetamido)ethyl]-*N*-methylamino]spiro[isobenzofuran-1(3*H*),9'-[9*H*]xanthen]-3-one (17**).** The bis-acetamide **16** (0.264 g, 0.5 mmol) was refluxed for 8 h with 1.5 M hydrochloric acid (18 mL) and then evaporated to dryness (~1 mmHg) and azeotroped with toluene (3 × 5 mL). The residual solid was cooled in an ice bath and mixed under nitrogen with chloroacetyl chloride (0.16 mL, 2 mmol) and diisopropylethylamine (0.7 mL, 4 mmol) in dry dichloromethane (17

mL), and the solution was stirred in the ice bath for 2 h and then at room temperature for 1 h. A mixture of chloroform and methanol (9:1, 400 mL) was added, and the solution was washed with 0.5 M hydrochloric acid (15 mL). The aqueous layer was back-extracted with CHCl₃-MeOH (9:1, 2 × 10 mL), and the combined organic layers were washed with 10% aqueous NaHCO₃ and brine, dried, and evaporated. The residue was dissolved in CHCl₃-MeOH (9:1, 2 mL) and applied to a flash chromatography column (50 mL silica gel), which was successively eluted with CHCl₃-MeOH (9:1, 200 mL), CHCl₃-MeOH (4:1, 200 mL), and CHCl₃-MeOH (65:35, 600 mL) to afford the bis-chloroacetamide **17** as a purple glass (0.149 g, 50%): low-resolution ES-MS *m/e* (M + H) calcd 597, found 597; ¹H NMR (400 MHz, 9:1 CDCl₃-CD₃OD) δ 3.06 (s, 6H, NCH₃), 3.49 (t, 4H, *J* = 6, CH₂), 3.58 (t, 4H, *J* = 6, CH₂), 3.96 (s, 4H, CH₂Cl), 6.56 (dd, 2H, *J* = 9 and 2.5, 2',7'-H), 6.62 (d, 2H, *J* = 2.5, 4',5'-H), 6.77 (d, 2H, *J* = 9, 1',8'-H), 7.15–7.17 (m, 1H, 7-H), 7.60–7.66 (m, 2H, 5,6-H), 8.03–8.05 (m, 1H, 4-H).

Reaction of Ethyl 4-[*N*-(Chloroacetyl)amino]benzoate (18**) with NaI-Acetone.** (a) The chloroacetamide **18** (**18**) (0.12 g, 0.5 mmol) was dissolved in a solution of

NaI (4.1 g) in acetone (27.5 mL) under nitrogen, and the solution was kept overnight in the dark at room temperature and then diluted with EtOAc (50 mL) and washed with 5% aqueous sodium ascorbate (20 mL) and water. The organic phase was dried and evaporated to give the iodoacetamide **19** (0.22 g, 65%): mp 158 °C; δ_H 1.36 (t, 3H, *J* = 7, CH₂CH₃), 3.84 (s, 2H, CH₂I), 4.35 (q, 2H, *J* = 7, CH₂CH₃), 7.48–7.74 (m, 2H, ArH), 7.90–8.12 (m, 2H, ArH), 8.22 (br s, 1H, NH). Anal. (C₁₁H₁₂INO₃) C, H, N.

(b) The reaction was performed as in part (a) above, but with camphorsulfonic acid (0.125 g, 0.5 mmol) added to the solution at the start of the reaction. Workup as described above gave the acetamide **20** (0.058 g, 57%): mp 103 °C (benzene-cyclohexane) [lit. (19) 104 °C]. No other product was detected in the crude reaction product by ¹H NMR or TLC analysis.

3',6'-Bis[*N*-(2-(iodoacetamido)ethyl)-*N*-methylamino]spiro[isobenzofuran-1(3*H*),9'-[9*H*]xanthen]-3-one (3**).** Sodium iodide (6.6 g, 44 mmol) was dissolved in a mixture of dry acetone, methanol, and chloroform (65:25:10 v/v, 44 mL), and a stream of nitrogen was passed through the solution for 10 min. This solution was added to the bis-chloroacetamide (0.12 g, 0.20 mmol), and the flask was flushed with nitrogen and kept in the dark at room temperature for 3 days. The reaction mixture was diluted with chloroform (400 mL), washed with 5% aqueous sodium ascorbate (150 mL), and water (3 × 30 mL), and dried. The yield of recovered rhodamine

chromophore was 57%, determined by quantitative visible spectroscopy (10% aqueous EtOH) based on an ϵ_{547} of $89\,250\text{ M}^{-1}\text{ cm}^{-1}$ (see Results and Discussion). The chloroform solution was evaporated to give the bis-iodoacetamide **3** as a purple glass: high-resolution FAB-MS m/e ($M + H$) calcd 781.0384, found 781.0360; $^1\text{H NMR}$ (400 MHz, 9:1 $\text{CDCl}_3\text{--CD}_3\text{OD}$) δ 3.10 (s, 6H, NCH_3), 3.39 (t, 4H, $J = 6.5$, CH_2), 3.54 (t, 4H, $J = 6.5$, CH_2), 3.59 (s, 4H, ICH_2), 6.68–6.71 (m, 4H, 2',4',5',7'-H), 6.98 (d, 2H, $J = 9.7$, 1',8'-H), 7.12 (dd, 1H, $J = 7.2$ and 1.4, 7-H), 7.56–7.64 (m, 2H, 5,6-H) and 8.12 (dd, 1H, $J = 7.1$ and 1.4, 4-H). The product was dissolved in dry DMF and stored in aliquots (10–20 mM) at -70°C .

Concentration Dependence of Rhodamine Spectra. An aliquot (0.02 mL) of a solution of the bis-iodoacetamidorhodamine **3** (ca. 20 mM in DMF) was mixed with 200 mM aqueous sodium 2-mercaptoethanesulfonate (0.08 mL) and 200 mM potassium phosphate (pH 7.2, 0.35 mL) and allowed to stand at room temperature for 24 h. Aliquots of this solution were diluted with 25 mM potassium phosphate (pH 7.2) which contained 150 mM NaCl to give solutions of differing concentrations over the range of 5–500 μM . The UV–vis spectra were recorded using quartz cells with path lengths of 10, 1, or 0.105 mm as appropriate to the concentrations. Spectra were corrected for path length and dilution factors and plotted on the basis of an assumed extinction coefficient at the isosbestic point as outlined in Results and Discussion.

RESULTS AND DISCUSSION

Our initial plan for synthesis of the target compound was to perform a 2-fold displacement on the dichlorofluoran **4** with an unsymmetrical derivative of ethylenediamine. Many such displacements on dichlorofluoran or the related sulfofluoran have been described for simple amines (14). In a brief study with pyrrolidine as a model amine, chlorobenzene was found to be a particularly effective solvent, and the rhodamine **5** was readily obtained. To obtain an amine reagent appropriate to our purpose, we examined displacements on a range of *N*-acyl derivatives of 2-bromoethylamine, which were often complicated by cyclization to oxazolines. We eventually found that the *N*-ethoxycarbonyl compound **6** could be efficiently converted to the secondary amine **7** by treatment with methylamine in aqueous methanol. However, treatment of dichlorofluoran **4** with amine **7** under a variety of conditions gave a poor yield of rhodamine, probably because the amine cyclized rapidly to the imidazolidinone **8**. Rather than pursue this approach, we turned instead to a conventional rhodamine synthesis, i.e., condensation of a suitable *N*-substituted *m*-aminophenol **9** with phthalic anhydride. The synthesis of compound **10** (Scheme 1) began from *N*-methyl-*m*-anisidine **10**, preparation of which was initially approached from *m*-anisidine by treatment with triethyl orthoformate under reflux to give the formimidate, followed by reduction with $\text{NaBH}_4\text{--THF}$ (20). However, the product was consistently contaminated by ~15% of the starting *m*-anisidine, and we fell back upon the less convenient methylation of *N*-(3-methoxyphenyl)benzenesulfonamide (16), which gave the required product **10** without contamination. This material was cleanly alkylated by ethyl bromoacetate to give the ester **11**, which was smoothly reduced to the alcohol **12** with $\text{NaBH}_4\text{--LiBr}$ in tetrahydrofuran (21). Treatment of the alcohol **12** with phthalimide under Mitsunobu conditions (22) gave a satisfactory yield of the substituted phthalimide **13** as bright yellow crystals. Stacking between a phthalimide and an

adjacent electron-rich aromatic system leading to a presumed charge-transfer complex has been reported previously (23). The methoxy and phthaloyl protecting groups were simultaneously removed from **13** with concentrated hydrobromic acid under reflux, and acetylation of the crude product gave the *O,N*-diacetyl derivative **14**. Although acetylation of the phenolic hydroxyl added an additional step to the synthesis, it was beneficial since it allowed isolation and storage of a stable, crystalline precursor from which the air-sensitive aminophenol **9** could be prepared as required by brief alkaline hydrolysis. An alternative sequence for synthesis of **14** in which a methoxymethyl group was used to protect the phenolic oxygen was also explored. However, the sensitivity of this group to cleavage under acidic conditions meant that the route was less satisfactory than the one described above, and it is not discussed further.

With the phenol **9** available, we turned to assembly of the rhodamine system via the two-stage process shown (Scheme 2) and were surprised to find that reaction of **9** with phthalic anhydride to give the benzoylbenzoic acid **15** was capricious. Although simple *m*-dialkylaminophenols react readily with phthalic anhydrides in toluene under reflux (1, 24), phenol **9** was poorly soluble under these conditions and failed to react. In more polar

solvents (e.g., chlorobenzene or anisole) in which simple *m*-dialkylaminophenols still reacted readily with phthalic anhydride and in which phenol **9** was soluble, the latter compound was nevertheless still unreactive. Dimethylformamide as solvent, with or without added trimethylsilyl polyphosphate (**1**), completely prevented the reaction of phthalic anhydride with all *m*-dialkylaminophenols tested. However, when **9** was heated with phthalic anhydride in the absence of solvent, the required acid **15** was obtained in reasonable yield. The origin of this poor reactivity remains obscure.

Despite the difficulties encountered above, condensation of the benzoylbenzoic acid **15** with a second molecule of aminophenol **9** proceeded smoothly in a DMF solution with trimethylsilyl polyphosphate catalysis (**1**) to give the bis-acetamidorhodamine **16**. In our previous work on monofunctional rhodamines (**1**), the rhodamine was isolated in rather poor yield after brief treatment of the reaction mixture with aqueous sodium hydroxide, which broke down a complex of the dye with the polyphosphate. We have now found that much longer exposure to alkali (see Materials and Methods) is necessary to maximize the product recovery. Acidic hydrolysis of the acetamido groups of **16**, followed by treatment of the crude product with chloroacetyl chloride–diisopropylethylamine, gave the bis-chloroacetamide **17**. Completion of the synthesis of compound **3** required only exchange of the chloro groups on **17** for iodides. The fact that the exchange was complete was thought to be important since the half-exchanged (i.e., mono-chloro and mono-iodo) intermediate would be expected to cause difficulties during the eventual use of the reagent to effect 1:1 labeling of a bis-thiol protein. This simple transformation had been easily achieved in synthesis of the isomeric iodoacetamides **1** and **2**, and we were therefore surprised to encounter considerable difficulties. Treatment of **17** with NaI–acetone gave the expected Cl → I exchange (assessed by an upfield shift of the halomethyl proton signal in the ¹H NMR spectrum), but the product was contaminated with material which appeared to be oligomeric from a number of broadened peaks in the ¹H NMR spectrum. In addition, intense singlet resonances at δ 1.18 (6H), 2.17 (3H), and 2.64 (2H) were consistent with the presence of diacetone alcohol. The latter product was not formed when a solution of NaI alone in acetone was kept for a comparable period of time, and we assume that the displaced chloride ion, acting as a base, is responsible for formation of the aldol product. This reasoning led us to believe that the chloride ion might also be responsible for formation of the apparent rhodamine oligomer(s), and we performed a series of experiments which aimed to combat the basicity of chloride ion under the aprotic conditions of the reaction. We initially used the chloroacetamide **18** as a model compound and showed that treatment with NaI–acetone at room temperature cleanly gave the expected iodoacetamide **19**, although again with contaminating diacetone alcohol. When the reaction was repeated with 1:1 chloroacetamide–camphorsulfonic acid (CSA) to neutralize the released chloride, the dehalogenated acetamide **20** was the sole product, uncontaminated by diacetone alcohol. We are not aware of previous reports of similar dehalogenation of haloacetamides, but α-haloketones are known to undergo clean reductive dehalogenation with NaI in the presence of dilute sulfuric acid (25). When the amount of CSA was progressively reduced, the proportion of the reduction product **20** decreased but remained detectable at 0.005 equiv of CSA, which was still sufficient to suppress formation of diacetone alcohol. When acetic

Figure 1. Partial ¹H NMR spectrum (400 MHz) of the bis-iodoacetamidorhodamine **3**. The peak marked * is from residual CHCl₃.

acid was used in place of CSA, dehalogenation was much diminished but still detectable and no diacetone alcohol was formed. These conditions were also investigated using *N*-benzylchloroacetamide, where the aliphatic amino group is more similar to those in the rhodamine **17**. With either CSA (0.1 equiv) or acetic acid, only a very low degree of dehalogenation was detectable. Nevertheless, it was undesirable to risk any dehalogenation in the rhodamine product **3**, and we abandoned these experiments. A protocol for the Cl → I exchange which minimized the formation of the apparent oligomeric material was established empirically and used a mixture of chloroform–acetone–methanol that ensured complete solubility of the rhodamine together with full exchange. The aromatic region of the ¹H NMR spectrum of typical material so obtained is shown in Figure 1 to illustrate the extent to which impurities contaminate the final product **3**. The reasons underlying the difficulties encountered in this reaction remain unclear.

Use of the bifunctional rhodamine **3** as a labeling reagent requires some information about its visible absorption spectrum for aiding quantification of labeled proteins. Rhodamine dyes are known to undergo a noncovalent concentration-dependent dimerization (26), and this property, together with the noncrystalline nature of **3**, meant that determination of an extinction coefficient was not straightforward. In our previous work (**1**) on monofunctional rhodamines, we used a radiolabeled derivative with a known specific activity to determine the extinction coefficient and, in conjunction with spectra of the products formed from each dye by displacement of the iodo group with 2-mercaptoethanesulfonate, showed that the spectra had an isosbestic point at 528 nm, where the extinction coefficient was 52 000 M⁻¹ cm⁻¹. Corresponding spectra from the aqueous solution of the species **21** formed by reaction of **3** with excess 2-mercaptoethanesulfonate were markedly less concentration-dependent than those for the derivatives of the monofunctional tetramethylrhodamines, with the extinction coefficient (547 nm) measured at 500 μM being only 6% lower than the value measured at 5 μM. As for the monofunctional rhodamines, the spectra show an isosbestic point at 528 nm, and we made the assumption that the extinction coefficient at this point was the same as that for the tetramethylrhodamines. On the basis of this assumption, the monomer spectrum of **21** has an extinction coefficient of 89 250 M⁻¹ cm⁻¹ at its maximum of 547 nm. This maximum is blue-shifted by only 2 nm from

that of the tetramethylrhodamines, while the extinction coefficient at the maximum is 92% of the value found for the tetramethylrhodamine monomers. In view of these rather small perturbations and the very similar overall appearance of the monomer spectrum for the different rhodamines, the assumptions made seem reasonable, and hence, the extinction coefficient data appear to be reliable estimates. The diminished tendency of the derivative **21** to dimerize probably reflects the presence of the extended, flexible side chains, which could be expected to interfere with face-to-face stacking of the xanthene rings.

In conclusion, we have synthesized a new rhodamine derivative suitable for two-site linkage to proteins. Data now at hand indicate that the desired 1:1 labeling of mutant myosin regulatory light chain proteins containing two cysteine residues at various positions can be achieved with acceptable yields. These results and the consequent fluorescence polarization studies have been presented as conference proceedings (27) and will be described in detail elsewhere.

ACKNOWLEDGMENT

We are grateful to the MRC Biomedical NMR Centre for access to facilities and to Dr. M. J. Gradwell for assistance with NMR spectroscopy. We thank Drs. S. Howell and K. J. Welham for mass spectroscopic determinations at low and high resolution, respectively, and Drs. Y. E. Goldman, M. Irving, and D. R. Trentham for helpful discussions.

Hybridization Characteristics of Biomolecular Adaptors, Covalent DNA–Streptavidin Conjugates

Christof M. Niemeyer,^{*,†} Wolfgang Bürger,[†] and Rein M. J. Hoedemakers[‡]

Department of Biotechnology and Molecular Genetics, University of Bremen, FB 2-UFT, Leobener Strasse, D-28359 Bremen, Germany, and Centre for Biomedical Technology, University of Groningen, Hanzeplein 1, 9713 HZ Groningen, The Netherlands. Received September 19, 1997;
Revised Manuscript Received December 12, 1997

Semisynthetic, covalent streptavidin–DNA adducts are versatile molecular connectors for the fabrication of both nano- and microstructured protein arrays by use of DNA hybridization. In this study, the hybridization characteristics of six adduct species, each containing a different DNA sequence of 21 or 24 bases, have been compared. First, the adducts were conjugated to biotinylated alkaline phosphatase, and their binding to immobilized oligomer complements of similar lengths was quantified in a microplate assay. The binding efficiency observed varied to a great extent with the specific sequence of the oligonucleotide attached, and could not be predicted from affiliated thermodynamic data of duplex stability. To further elucidate the hybridization properties, the hybridization rate constants of association and dissociation (k_{assn} and k_{dissn}) have been determined for both unconjugated oligonucleotides and protein adducts, using a surface plasmon resonance biosensor. The k_{assn} values observed for the oligonucleotides are in the range of 9×10^3 to $2 \times 10^5 \text{ M}^{-1} \text{ s}^{-1}$ and correlate with structural properties of the probe strands. Up to 3-fold decreased k_{assn} values were obtained for the corresponding protein adducts. Likewise, values were observed for k_{dissn} ranging from 1.4×10^{-4} to $1.9 \times 10^{-5} \text{ s}^{-1}$ for the oligonucleotides. The dissociation of the analogous protein conjugates was reduced by up to 5-fold. The extent of this decrease correlates with the formation of homodimeric or intramolecular aggregation of probe strands. A mechanistic model for explaining these data is based on attractive intramolecular interaction between the nucleic acid and protein moiety.

INTRODUCTION

The generation of new biomaterials for analytical, industrial, or pharmaceutical applications is a central goal of biotechnology. Owing to its unique recognition capabilities, physicochemical stability, and mechanical rigidity, DNA is a promising candidate for the construction of nanometer-sized frameworks (1, 2) which are potentially useful for the selective positioning of molecular devices such as conducting polymers (3), proteins (4), or nanocrystal metal clusters (5, 6). Recently, hybrid molecules of short single-stranded DNA and streptavidin (STV) have been applied in the supramolecular assembly of novel bioconjugates (4). The covalent attachment of an oligonucleotide moiety to STV provides a specific recognition domain for a complementary nucleic acid sequence in addition to the four native biotin-binding sites. These bispecific binding capabilities allow the adducts to serve as versatile connectors in a variety of applications, such as the fabrication of nano- and microstructured protein arrays. While the nanostructures can be accessed by positioning several DNA–protein adducts along a single-stranded RNA or DNA carrier molecule containing a set of complementary sequences, the microstructures can be obtained from given surface-immobilized DNA arrays, such as microchip-based oligonucleotide arrangements currently under active investigation for integrated nucleic acid analysis (7–9). For example,

the “self-sorting translation” of a model DNA array into polyfunctional immunoglobulin G (IgG) arrays was attained by hybridization of a mixture of specific sequence-containing DNA–STV adducts, each previously conjugated to a particular biotinylated IgG (4).

Due to the sensitivity of most biomolecular devices, such as antibodies and enzymes, the effective employment of nucleic acid hybridization-based assembly strategies requires mild reaction conditions such as moderate temperatures and salt concentrations. Thus, binding efficiency of oligonucleotide-tagged compounds is controlled by hybridization rate constants for association, k_{assn} , and dissociation, k_{diss} , rather than thermodynamic duplex stability. Kinetic data of DNA hybridization are scarce (10–17), and it is difficult a priori to design sequences of single-stranded oligonucleotides that are optimized for fast and efficient binding to their complementary target strands. As an experimental approach for selecting appropriate sequences, the hybridization characteristics of six covalent DNA–protein adducts have been analyzed in this study. Each of these hybrids (HA through HF; for sequences of A24 through F24, see Table 1) contains a different oligonucleotide sequence of 21 or 24 bases, chosen from the antisense strand of the multiple cloning site of the bacteriophage M13mp18. As a relevant test of near-surface hybridization properties, a binding assay of the DNA–STV adducts was carried out in microplates (Figure 1). The adducts were pre-conjugated to biotinylated alkaline phosphatase (AP), and their binding to immobilized single-stranded oligonucleotide targets was quantified by colorimetric detection of enzymatic activity. The hybridization efficiency observed varied to a great extent with the specific sequence of the

^a Melting temperatures (T_m) and free energies of duplex stability (ΔG) have been calculated for underivatized oligonucleotides at 25 °C and 150 mM NaCl using Primer Select version 3.01a (DNA-Star Inc.), following a model based on adjacent dinucleotides (19, 20).

Figure 1. Schematic drawing of the enzyme-linked oligonucleotide sorbent assay (ELOSA) for the determination of hybridization efficiency of covalent DNA-STV adducts. The latter were coupled with a signal-generating enzyme by mixing with biotinylated alkaline phosphatase (AP) to form preconjugates (e.g., HA24-AP). Biotinylated capture oligonucleotides were immobilized on STV-coated microplates, and remaining biotin-binding sites of the surface-bound STV were blocked with free D-biotin, represented by shaded spheres. The preconjugates were then allowed to bind to their complement by formation of specific Watson-Crick base pairs. Subsequently, the amount of hybridized material was determined by AP-dependent color reaction using pNPP as a substrate.

oligonucleotide domain, thus, enabling a classification of strong or weak binders. To further elucidate the results observed for the enzyme conjugates, real-time biospecific interaction analysis (BIA) technology was used to quantify the hybridization kinetics of both the STV-DNA hybrid and their analogous, unconjugated oligonucleotides, TA through TF. BIA, a method based on surface plasmon resonance (SPR), has previously been used to study DNA hybridization (10, 13, 14, 18). The kinetic rate constants for association (k_{assn}) and dissociation (k_{diss}), measured here for the six sequences under investigation, confirm the hybridization characteristics previously observed in the microplate assay, and correlate with structural features of the probe strands rather than thermodynamic duplex stability (19, 20). Owing to their elevated information contents, the BIA data also reveal influences of the protein moiety on the process of nucleic acid hybridization. Both annealing and dissociation rate constants are reduced relative to those of the analogous oligonucleotides. This effect may be due to intramolecular surface interaction between the nucleic acid and, for

example, positively charged side chain groups of the protein moiety.

MATERIALS AND METHODS

Oligonucleotides. The 5'-thiol-modified oligonucleotides (TA24 through TF24; for sequences, see Table 1) were purchased from MWG-Biotech (Germany) or NAPS (Göttingen, Germany). The oligonucleotides were synthesized by standard methods using C6 Thiolmodifier reagent (Glen Research) and were purified by HPLC. The purity of the samples was determined from anion-exchange chromatography analysis on a Mono Q column (Pharmacia). The concentrations were determined by UV absorbance measurement. Biotinylated oligomer complements were also purchased from MWG-Biotech or NAPS (for sequences, see Table 1).

Synthesis of DNA-Streptavidin Adducts and ELOSA. Synthesis and purification of covalent DNA-STV adducts were carried out from thiolated oligonucleotides, TA24 through TF24, and recombinant streptavidin (Boehringer Mannheim), as previously described (4). In brief, STV (10 nmol) was derivatized with maleimido groups using a heterobispecific cross-linker (sulfo-SMPB, Pierce), reacted with a 5'-thiolated oligonucleotide (10 nmol) and subsequently purified by anion-exchange chromatography. A 1:1 molar ratio of nucleic acid and protein moiety of the hybrids was verified by gel electrophoretic and photometric analysis, and concentrations of the preparations were determined by absorbance measurements (4). Conjugates of the DNA-STV hybrids and AP were prepared by mixing 0.1 μM stock solutions of the hybrids (HA24 through HF24; for sequences, see Table 1) and a 4-fold molar excess (3.8 μM stock solution) of biotinylated AP (Sigma) in TETBS buffer [20 mM Tris-HCl buffer (pH 7.3), 150 mM NaCl, 5 mM EDTA, and 0.01% (w/v) Tween-20] containing 0.1 mg/mL bovine serum albumin. After incubation for 60 min at room temperature, the mixtures were diluted to a final concentration of 10–1 nM for the conjugates with TETBS containing 0.1 mg/mL bovine serum albumin and 10 mM D-biotin (Fluka), and the dilutions were incubated for an additional 30 min. STV-coated microplates were prepared as previously described (21), and 50 μL of a 600 nM solution of the biotinylated oligomer complements (capture oligomers) in TETBS was allowed to bind for 60 min. After the plate was washed with TETBS containing 10 mM D-biotin, 50 μL of the AP conjugate solution described above was allowed to hybridize for 60 min at room temperature. Negative controls were run

in parallel by applying preconjugates to wells, coated with noncomplementary oligonucleotides. After incubation, the plate was washed four times with TETBS and twice with TBS [Tris-buffered saline, 20 mM Tris-HCl buffer (pH 7.3) and 150 mM NaCl]. AP-dependent color reactions were carried out with 200 μ L of 1 M diethanolamine (pH 9.8) and 0.5 mM MgCl_2 containing 10 mM *p*-nitrophenyl phosphate (pNPP). The absorbance at 405 nm was determined with a Victor Multilabel-Counter (Wallac) after incubation for 10 min at 37 $^\circ\text{C}$. Relative intensities (signal to noise, *S/N* values) were calculated from the observed absolute signal intensities divided by the corresponding background signal obtained for binding to noncomplementary capture oligomers, and typically fell in the range of 2–25, depending upon the preconjugate concentration. Standard deviations were calculated from the signal intensities of interest. Typically, duplicate determination of a particular sample revealed a percent error of 15%.

BIA Measurements. Biospecific interaction analysis was performed using a BIAcore-1000 instrument from Pharmacia Biosensor AB (Uppsala, Sweden).

Immobilization of Capture Oligomers. A continuous flow of hybridization buffer [150 mM NaCl, 30 mM sodium phosphate, 3 mM EDTA, and 0.25% Triton X-100 (pH 7.4)] at 10 $\mu\text{L}/\text{min}$ and 25 $^\circ\text{C}$ was maintained throughout the entire analysis. Biotinylated capture oligomer (10 μM in hybridization buffer) was injected for 4 min over STV-coated sensorchips (SA-Chips, Pharmacia Biosensor AB). Loosely attached material was removed by three cycles of 10 μL of 50 mM NaOH. An amount of 500–2000 RU of the biotinylated oligomer complements was immobilized for kinetic analysis.

Kinetic Analysis. Oligonucleotides or DNA–STV adducts at various concentrations in hybridization buffer, typically in the range of 400–25 nM, were injected over the DNA-specific surface at 10 $\mu\text{L}/\text{min}$ for 4 min. The interaction was monitored continuously as the change in SPR signal. Dissociation was effected by injecting hybridization buffer only and was followed for 15 min. The surface was regenerated by injection of 10 μL of 50 mM NaOH. The entire process was automated. Binding and dissociation curves were recorded automatically, and analytical cycles were preprogrammed. The data analysis was carried out using BIAcore Evaluation 2.1 software (Pharmacia). The pseudo-first-order kinetic model was used, and parts of the binding curves where mass transport was evident were excluded from the calculations. A series of controls was carried out (data not shown). Injection of probes across surfaces, modified with noncomplementary oligonucleotides, revealed no significant increase in RU response, suggesting that the binding observed in the kinetic experiments is due exclusively to specific single-stranded DNA hybridization. Lowering the amount of coupling density of the biotinylated oligomer did not result in differences in kinetic constants, suggesting that any influence of rebinding (22) is negligible in these experiments.

RESULTS AND DISCUSSION

Semisynthetic hybrids of DNA and STV were synthesized from various 5'-thiolated oligonucleotides (Table 1) by means of chemical cross-linking as previously described (4). In brief, STV was derivatized with maleimido groups using a heterobispecific cross-linker, and subsequently reacted with a thiolated oligonucleotide. The chief products, hybrids containing a single oligonucleotide moiety per STV, were purified by anion-exchange chromatography.

ELOSA Analysis of Conjugate Hybridization. As a relevant test for quantifying the hybridization characteristics of the DNA–streptavidin biomolecular adaptors, a microplate assay in the form of an enzyme-linked oligonucleotide sorbent assay (ELOSA) (23) was used (Figure 1). For this purpose, DNA–STV covalent adducts were conjugated to biotinylated AP. Initially, to determine the optimal conjugation stoichiometry, a fixed amount of the hybrid HA24 was mixed with varying quantities of the biotinylated enzyme. After incubation, the reaction was quenched by addition of free D-biotin. The resulting preconjugates (HA24–AP) were then allowed to bind to their corresponding oligomer complement (bcA24), previously immobilized on a STV-coated microplate (21), by using the STV–biotin interaction (see Materials and Methods for details). After hybridization, the amount of material immobilized was estimated from the enzymatic activity of AP, using colorimetric pNPP as a substrate. Negative controls were carried out by incubation of a similar preconjugate containing a noncomplementary oligonucleotide sequence, HC21-AP (prepared from 2.5 equiv of AP), as well as by incubation of biotinylated AP or buffer only. As shown in Figure 2, the low background signal obtained for the controls confirmed that binding occurred exclusively via specific single-stranded DNA hybridization. Relative intensities (signal-to-noise, *S/N*) of about 20 were obtained for a 1:0.25 molar ratio of the biotin binding sites of STV and the biotinylated enzyme. An increase of the amount of biotinylated AP did not lead to significantly stronger signals (Figure 2). These findings indicate that an approximately equimolar conjugation stoichiometry of the two protein components occurred despite the tetravalent binding capabilities of STV, and is likely due to steric hindrance of the voluminous AP. Furthermore, variations of the concentration of the biotinylated capture oligomer during immobilization on the microplate showed that saturation of the binding capacity of single microplate wells occurred at oligonucleotide concentrations of about 60 nM (Figure 2), which corresponds to an estimated biotin-binding capacity of about 1–2 pmol/well (24).

Further experiments were carried out using DNA–STV adducts containing the various oligonucleotide sequences of A24, B21, C21, D21, E21, and F24 as indicated in Table 1. The adducts were conjugated with biotinylated AP and allowed to bind to their immobilized complement at analyte concentrations ranging from 10 to 1 nM. Negative controls were carried out for all experiments by incubation of the 10 nM preconjugate solutions in microplate wells containing noncomplementary capture oligonucleotides. The *S/N* values observed were concentration-dependent and typically in the range of 25–2. Investigation of a large number of independently synthesized preconjugates gave percent errors of about 25%, thus satisfying the requirements for the reproducibility of chemical hybrid synthesis and AP conjugation as well as the microplate binding assay protocol. Time course experiments, carried out over varying periods of hybridization, revealed that maximum signal intensities are reached within 30 min (not shown). Therefore, the signal intensities obtained after 1 h of binding reflect equilibrium binding and, thus, the stability of a DNA duplex under the given reaction conditions. As indicated in Figure 3, the amount of hybridization varied to a great extent with the oligonucleotide sequence of the conjugates. The relative fraction of binding observed for particular sequences was linearly dependent on reagent concentration in the range of 10–1 nM. A

Figure 2. Optimization of the preconjugation stoichiometry for ELOSA. Fixed amounts of DNA-STV adduct HA24 were mixed with varying amounts of biotinylated AP. The molar ratio of biotin-binding sites of the adduct to biotinylated AP was in the range of 1:2.5 to 1:0.025. Negative controls (NCs) were carried out with a comparable HC21-AP preconjugate, containing a noncomplementary oligonucleotide sequence (NC1), bAP only (NC2), and buffer only (NC3). The low signal intensities observed for controls indicate that binding is exclusively due to specific DNA base pairing.

Figure 3. Quantification of the sequence-dependent hybridization efficiency, as determined from ELOSA microplate analysis. The binding of several DNA-STV AP conjugates, containing oligonucleotide sequences A through F (see Table 1), was quantified in an ELOSA assay at analyte concentrations of 10, 5, and 1 nM, respectively. The relative amounts of preconjugate immobilized were calculated from enzyme-generated signals observed and normalized as a percentage fraction of the signal intensity obtained for 10 nM HA24-AP.

comparison of the hybridization efficiency, calculated from the average slope of concentration-dependent signal increase, allows a classification of the sequences studied. The 24-mer species HA24-AP exhibited the strongest binding (relative slope of 1.00). The preconjugates HF24-AP and HB21-AP bind less efficiently (0.53 and 0.56, respectively). Species HC21-AP and HD21-AP exhibited low hybridization efficiencies (0.19 and 0.20, respectively), and the binding of HE21-AP (0.04) was barely detectable. These results could not be predicted

from thermodynamic data of the particular oligomer sequences (19, 20), such as the calculated melting temperatures and free energies of duplex formation (T_M and ΔG , see Table 1).

Analysis of DNA Hybridization by SPR Measurements. To elucidate further the binding characteristics, the rate constants of association (k_{assn}) and dissociation (k_{diss}) of single-stranded DNA interactions have been determined by biomolecular interaction analysis (BIA) using a biosensor based on surface plasmon resonance (SPR). With this technique, the refractive index within a gold sensor chip-immobilized dextran matrix is continuously monitored, plotted against time, and presented in a sensorgram. The change of SPR response, measured in resonance units (RU), allows a quantification of interaction between chip-immobilized and liquid phase-diluted binding partners. Here, the biotinylated oligomer complements, bcA through bcF (see Table 1), were immobilized on streptavidin-coated sensor chips, and real-time kinetic measurements at several analyte concentrations were carried out with the various oligonucleotides and the analogous DNA-STV hybrids. A series of controls was carried out by injecting oligonucleotides or DNA-STV adducts over sensor chips modified with noncomplementary capture oligomers (not shown). No significant change in SPR response indicated that the binding observed was due exclusively to specific single-stranded DNA hybridization, a result similar to that obtained from ELOSA. Although the data obtained from BIA for triplicate determinations of a particular sample were generally very reproducible (errors of 10%), deviations increased upon measuring identical samples after a certain period of storage and/or on a different sensor chip (percent error of up to 50%). As no degradation products of the probes could be detected by gel electrophoretic analysis, these alterations may reflect quality differences of the sensor surfaces or changes in, i.e., the salt concentration of the buffers that were used (10, 25). Implementation of a large number of measurements, including various ($n \geq 5$) independently synthesized analyte samples and statistical analysis of the data obtained, allowed elucidation of the trends discussed below.

To confirm the applicability of BIA, a kinetic study of the hybridization of three oligonucleotides was carried

Table 2. Kinetic Constants of Single-Stranded DNA Hybridization Obtained from BIA Measurements of the Binding of Thiolated Oligonucleotides TA16, TA21, and TA24 to the Immobilized Biotinylated Oligomer Complement bcA24^a

probe	$10^3 k_{\text{assn}} (\text{M}^{-1} \text{s}^{-1})$	$10^{-7} k_{\text{dissn}} (\text{s}^{-1})$	$10^7 K_A (\text{M}^{-1})$
TA16	148 ± 29	527 ± 41	2.8
TA21	211 ± 13	446 ± 47	4.7
TA24	216 ± 35	253 ± 63	8.6

^a For sequences, see Table 1.**Figure 4.** Representative sensorgrams obtained from BIA. (A) Binding of covalent the STV-DNA adduct HA24 to sensor-immobilized oligomer complement, bcA24, carried out at several analyte concentrations. Computational analysis of binding and dissociation phases yields their reaction rate constants, k_{assn} and k_{dissn} , respectively. (B) Overlay of sensorgrams obtained for the binding of covalent STV adduct HA24 and oligonucleotide TA24 at a concentration of 0.4 μM to sensor-immobilized bcA24 (for sequences, see Table 1). The decrease in hybridization rate constants is detectable from eye inspection of the sensorgrams. The binding of HA24 proceeds over a period of more than 200 s, while the TA24 association curve has reached saturation after this period of time. The decreased k_{dissn} of HA24 is clearly visible in a normalized overlay of sensorgrams, obtained for the dissociation phase (boxed inset).

out. The affinity constants ($K_A = k_{\text{assn}}/k_{\text{dissn}}$) of the probes investigated were expected to increase in the order TA16 < TA21 < TA24, as they contain identical sequence stretches of increasing lengths and TA21 contains a single G $\rightarrow$ A mismatch (Table 1). The kinetic rate constants observed (Table 2) were 1.5×10^5 , 2.1×10^5 , and $2.2 \times 10^5 \text{ M}^{-1} \text{s}^{-1}$ for association (k_{assn}) and 5.3×10^{-5} , 4.5×10^{-5} , and $2.5 \times 10^{-5} \text{ s}^{-1}$ for dissociation (k_{dissn}) of TA16, TA21, and TA24, respectively. Although derived from near-surface hybridization, these values are in a range comparable to the range of those obtained in

homogeneous reactions. For example, in a recent study, diffusional fluorescence correlation analysis was used to measure the hybridization of a set of six oligodeoxyribonucleotides to a complementary 101-mer target RNA (17). Different probes, designed for equal thermodynamic stability, revealed association constants between 3×10^4 and $1.5 \times 10^6 \text{ M}^{-1} \text{s}^{-1}$. The similar association rates of TA24, TA21, and TA16 presented in Table 2 are consistent with the general principle of nucleic acid hybridization. The low activation barrier of duplex formation is associated with rate-limiting nucleation of a small number of base pairs, which is then followed by rapid hybridization of the remaining base pairs (26–28). As a consequence, oligonucleotides containing identical sequence stretches may reveal similar association rates. The decrease in stability, observed in the order TA24 > TA21 > TA16, is also affected by variations in dissociation, particularly in the case of TA24 versus TA21. This result is in agreement with a recent study of homogeneous nucleic acid hybridization carried out by Kool and co-workers (15).

Sequence-Specific Hybridization Characteristics. Binding efficiency and kinetic rate constants have been determined for the hybridization of oligonucleotides and the analogous covalent STV adducts, respectively (Figure 4). The results obtained are summarized in Table 3. The amount of analyte bound to the sensor chip increased linearly with the amount of immobilized capture probe. Therefore, relative RU values (RU_{rel}; see column 2 of Table 3) can be calculated for each experiment by dividing the RU obtained from analyte by the RU obtained from capture probe binding. Owing to the higher molecular mass, the RU_{rel} values observed for the hybrids are generally greater than those of the corresponding oligonucleotide (Figure 4B). Normalization of the RU_{rel} of the particular sequences as a percentage of the binding efficiency of sequence A24 allowed a comparison of the amount of hybridization measured by ELOSA or BIA. As shown in Figure 5, the similarity of the resulting patterns of sequence-dependent binding indicates good agreement between both methods. Furthermore, attachment of a protein moiety evidently results in only minor changes of sequence-specific hybridization efficiencies.

Upon comparison of the kinetic data determined for the oligonucleotides of sequences A through F, differences

Figure 5. Comparison of the sequence-dependent hybridization efficiency obtained from ELOSA (left group of bars) and bio-specific interaction analysis (BIA) of oligonucleotides (right group) or covalent DNA-STV adducts (middle group). The signal intensities observed were normalized as a percentage fraction of the signal intensities obtained from species containing the A24 sequence. The amount of material immobilized in BIA was calculated from relative RU values (see Table 3 and the text for details).

of up to 2 orders of magnitude could be observed for both k_{assn} and k_{dissn} with no obvious correlation with thermodynamic values T_m and ΔG (see Table 1). A distinct dependency of k_{assn} and the formation of secondary structure via intramolecular hydrogen bonds competing with intermolecular hybridization has previously been reported (17, 29). The k_{assn} values of the binding of oligonucleotides to target RNA correlated with secondary structures of probes and target sites. The lowest rate constants were observed for probes exhibiting tight stem-loop structures. Within this context, the structural characteristics of the DNA sequences studied here have

been examined by software analysis, and the free energies (ΔG) for intramolecular loop formation and intermolecular self-association were calculated, following a model based on adjacent dinucleotides (19, 20). As indicated in Figure 6, sequences A24, B21, and F24 form less stable intermolecular aggregates, while the G/C-rich sequences of C21, D21, and E21 produce more stable hairpin loops and dimeric duplexes. Although no aggregates could be detected by photometric, gel electrophoretic, or chromatographic analysis (not shown), dimerization or intramolecular folding of the probes will be present in equilibrium and bias the kinetics of DNA hybridization. However, a simplistic correlation with energies of homodimeric duplex or loop formation is evidently not sufficient to explain subtle differences, such as those observed in the hybridization characteristics of, e.g., B21 and F24 or C21 and E21. More complex models, combined with computational methods (8), may assist in predicting hybridization characteristics from mere sequence information.

Influences of the STV Moiety on Hybridization Kinetics. A comparison of oligonucleotides and the analogous STV adducts (Table 3) exhibits some clearly perceptible differences. The latter exhibited reduced rate constants of hybridization which could already be detected from eye inspection of the sensorgrams (Figure 4B). The amount of decrease in the dissociation rate constant correlated with structural features of the oligonucleotide. The k_{dissn} of linear sequences, as in HA24, HB21, and HF24, decreased approximately 2–5-fold, while those of dimer-forming sequences, as in HC21, HD21, and HE21, were only affected 1–2-fold. A similar trend was evident from the comparison of k_{assn} values. The decrease was 2–3-fold for linear sequences, as in HA24, HB21, and HF24, while the annealing of HD21 was almost unaffected. The rates of structurally rich sequences, HC21 and HE21, were even slightly acceler-

Figure 6. Secondary structures of the oligonucleotides used in this study. Oligonucleotide duplexes and hairpin loops of the sequences have been calculated with Primer Select version 3.01a (DNA-Star Inc.). The numbers indicate the free energy of structure formation at 25 °C.

Figure 7. Schematic model of covalent DNA-STV adducts. The putative attractive interaction between surfaces of the protein and nucleic acid moiety is decreased by secondary structures of the DNA strand, e.g., in HE21. For linear sequences (e.g., in HA24), a closer contact of the surfaces influences the process of intermolecular hybridization to a greater extent.

ated by the protein attached. These phenomena were further investigated by melting temperature analysis of the duplex structures formed by DNA-STV conjugates or the analogous oligonucleotides with their oligomer complements (data not shown). T_m values in agreement with the predicted thermodynamic parameters were obtained for sequences A through F. However, a slight decrease in T_m of approximately 1–2 °C was observed for the protein conjugates, indicating a weak, duplex-destabilizing effect of the STV moiety under conditions in which the influences of DNA native structure as well as intramolecular DNA-protein interactions are reduced.

A possible model mechanism for explaining these data is based on intramolecular attractive interactions between the protein and nucleic acid moiety of the hybrid (Figure 7). An attraction of the surfaces may be mediated by positively charged lysine or arginine residues of STV and the negatively charged phosphate backbone of the DNA. This would restrict the degrees of freedom of the nucleic acid, and thus reduce the number of potential nucleation sites along the DNA strand. As a consequence, both association and dissociation velocities would be reduced. Additional steric hindrance of the protein may also affect the hybridization process. The fact that the influence of the STV molecule is lower on dimer- or loop-forming sequences is in agreement with this model; linear strands of nucleic acids might be affected to a greater extent, due to a more intimate interaction of their surface with the STV moiety (see HA24 in Figure 7). The slight increase observed for association of HC21 and HE21 suggests influences of an additional mechanism, recently suggested by Corey and co-workers, for explaining an accelerated hybridization of oligonucleotides that are conjugated with positively charged peptides or a basic protein, staphylococcal nuclease, to double-stranded DNA targets (30–32). As a result of Coulomb attraction of the protein moiety, the DNA domain of the probe is held in close proximity to the DNA template, thereby increas-

ing its effective concentration near its target site. This mechanism, however, appears to be of minor importance in the case of rapid single-stranded DNA hybridization but may be significant for slow, single-stranded DNA hybridization reactions.

We have investigated the sequence-specific near-surface hybridization of both covalent DNA-protein conjugates and their analogous oligonucleotides at nondenaturing temperatures. The hybridization efficiencies, determined for binding to surface-immobilized complements, varied to a great extent with the base composition of the nucleic acid and correlated with DNA native structure rather than standard thermodynamic parameters. As demonstrated in a microplate assay, covalent DNA-STV adducts are convenient reagents for the quantification of sequence-dependent binding efficiency. The kinetic rate constants of the covalent adducts and the analogous unmodified oligonucleotides have been determined by SPR measurements. A comparison of the data suggests intramolecular interactions between the protein and nucleic acid moiety within the adducts. This study emphasizes the importance of structural influences on hybridization reactions proceeding with kinetic control, such as the supramolecular assembly of delicate DNA-tagged molecular devices. It is difficult to draw systematic conclusions at this stage since much remains to be learned about hybridization of nucleic acids near surfaces or tagged with macromolecules. Nevertheless, binding will profit from sequences specially optimized for fast and efficient hybridization.

ACKNOWLEDGMENT

We thank D. Blohm for generous support and valuable discussion, S. Rohlfing, S. Behrens, and M. Adler for experimental help with the microplate assay, and T. Ferdelman for critical reading of the manuscript. Financial support for this work was obtained from Deutsche Forschungsgemeinschaft, Fonds der Chemischen Industrie, and Tönjes-Vagt Stiftung Bremen.

Extending Insulin Action in Vivo by Conjugation to Carboxymethyl Dextran

Miroslav Baudyš,[†] Didier Letourneur,[‡] Feng Liu,[†] Don Mix,[†] Jacqueline Jozefonvicz,[‡] and Sung Wan Kim^{*†}

Department of Pharmaceutics and Pharmaceutical Chemistry/Center for Controlled Chemical Delivery, Biomedical Polymers Research Building, Room 205, University of Utah, Salt Lake City, Utah 84112, and Laboratoire de Recherches sur les Macromolécules, CNRS URA 502, Université Paris Nord, Avenue J. B. Clement, 93430 Villetaneuse, France. Received October 15, 1997; Revised Manuscript Received December 18, 1997

The biochemical and pharmacological properties of bioactive peptides and proteins can be altered by conjugation with polymers. This report describes site-specific attachment of insulin to activated carboxyl groups of carboxymethyl dextran (CMD, MW = 51 000) through the GlyA1 insulin amino group. On average, three or four insulin molecules were grafted to a CMD linear chain. Coupled insulin molecules were properly folded, and the bioactivity of conjugated insulin in the blood glucose depression assay was 9.6 IU/mg, which was only 2.6 times less than that for native insulin. The cell growth study indicated that the CMD–insulin conjugate was as mitogenic as insulin on vascular smooth muscle cells, whereas the starting CMD polymer was not. The insulin receptor binding constant of the conjugate ($3.6 \times 10^9 \text{ M}^{-1}$) compared well with that of native insulin ($7.6 \times 10^9 \text{ M}^{-1}$), indicating that the CMD chain does not present any major constraints to binding. Plasma clearance of CMD–insulin obeyed a two-compartment pharmacokinetic (PK) model with a CMD–insulin conjugate plasma elimination half-life of 114.1 min, which was significantly longer than that of soluble Zn–insulin (12.4 min). In contrast, pharmacodynamic (PD) profiles (blood glucose lowering effects) after intravenous (iv) administration of the conjugate or insulin in rats were not different. Subcutaneous (sc) administration of the conjugate resulted in a significantly prolonged plasma profile with a noncompartmental PK parameter mean residence time (MRT) of 103.5 min which was significantly longer than that of soluble Zn–insulin (40.5 min). This was reflected in the protracted PD effect of sc administered conjugate with time needed to reach minimum glucose concentration T_{nadir} of 95.7 min, which was significantly longer than that of insulin (62 min). We conclude that the conjugation of insulin to CMD leads to a bioactive conjugate with a delayed sc PD profile showing prolonged response, resembling intermediate acting insulin preparations.

INTRODUCTION

Since the 1980s, many proteins with great therapeutic potential have become available due to enormous progress in recombinant DNA techniques. Their clinical efficiency, however, is often limited (compromised) due to a short half-life in vivo, instability, or immunogenicity. One general approach for overcoming these shortcomings is conjugation of a protein drug to soluble polymeric carriers such as poly(vinyl alcohol) (1), poly(ethylene glycol) (2), or dextran (3), which usually results in a significantly longer circulatory half-life, increased stability, and attenuated immunogenicity.

Originally, unmodified dextran activated with cyanogen bromide or periodate was used for protein coupling (4). Functionalized dextran derivatives as protein carriers, such as carboxymethyl dextran (CMD)¹ or diethyl-aminoethyl dextran, were introduced and studied later (5). For instance, the superoxide dismutase–carboxymethyl dextran conjugate has been shown to have a long plasma half-life compared to that of the free enzyme because of impaired glomerular filtration and tissue

interaction (6). In this case, the enzyme was coupled by periodate oxidation. Others took advantage of functional carboxyl groups on CMD to prepare stable enzyme conjugates by using water-soluble carbodiimide as the activating agent (7–9). The use of carbodiimide activation is, however, problematic because of the well-recognized tendency of the activated intermediate to undergo an O- to N-acyl shift to form more stable nonreactive N-acyl urea derivatives (10).

Insulin, a polypeptide hormone discovered more than 70 years ago (11), is the only drug used to control type I diabetes. As for any polypeptide hormone in general, its half-life in circulation is short, ranging from about 10 min for rats to about 40 min for humans (12, 13). As a consequence, soluble insulin action after intravenous (iv) or subcutaneous (sc) administration is relatively short-

¹ Abbreviations: CMD, carboxymethyl dextran; IBCF, isobutylchloroformate; TBA, tributylamine; MWCO, molecular weight cutoff; DMSO, dimethyl sulfoxide; FPLC, fast protein liquid chromatography; RI, refractivity index; SEC, size exclusion chromatography; PBS, phosphate-buffered saline; IR, insulin receptor; MEM, minimum essential medium; FCS, fetal calf serum; SMC, smooth muscle cell; PK, pharmacokinetic(s); PD, pharmacodynamic(s); EDTA, ethylenediaminetetraacetic acid; BGL, blood glucose level; AUC, area under the curve; AUMC, area under the first moment curve; MRT, mean residence time; MAT, mean absorption time.

lived. This makes it necessary to prolong action of exogenously given insulin in diabetic patients. The basic principle of prolonging insulin action used in current pharmaceutical formulations is to delay the absorption after sc injection by altering the solubility of insulin at physiological pH (14). In practical terms, insulin is administered as a suspension which dissolves slowly.

We decided to investigate whether the coupling of short-lived insulin to carboxymethyl dextran used as a polymeric carrier would substantially increase the insulin half-life. Early experiments with insulin conjugated to unmodified dextran activated with cyanogen bromide or periodate yielded conflicting bioactivity data (15, 16). The effect of the size of the dextran carrier was also ambiguous and contradictory (17–19). These incompatibilities, from today's point of view, can likely be explained by a rather broad molecular weight distribution of commercial dextran fractions used, chain fragmentation by aggressive activation methods, and inadequate purification and physicochemical characterization of conjugates.

By using well-defined CMD for insulin conjugation, we hoped to substantially increase insulin half-life since it has been shown that polyanionic CMD is retained in circulation for a long period of time (20). We employed a mixed anhydride method to selectively activate CMD carboxyl groups under defined conditions so that we could control the site of attachment of CMD to the insulin molecule (21). We characterized the conjugate physicochemically and studied its insulin receptor binding features as well as its effect on *in vitro* smooth muscle cell proliferation and the hypoglycemic effect *in vivo*. Finally, we evaluated the pharmacokinetic properties of the CMD–insulin conjugate in rats and found that its elimination rate is significantly smaller than that of insulin and, consequently, the sc pharmacodynamic profile shows a delayed, prolonged response, resembling the intermediate acting insulin preparations (14).

EXPERIMENTAL PROCEDURES

Materials. All chemicals were commercially available and used without further purification. Bovine Zn–insulin was obtained from Sigma Chemical Co. (St. Louis, MO) and GlyA1–glucosyl insulin (bovine) was synthesized according to ref 21. Ethylenediaminetetraacetic acid, dansyl chloride, ammonium bicarbonate, and Trizma base were also purchased from Sigma. Acetic and iodoacetic acids, isobutylchloroformate (IBCF), tributylamine (TBA), urea, and all other reagents as well as all organic solvents used were at least ACS grade and were purchased from Aldrich Chemical Co. (Milwaukee, WI). Carboxymethyl dextran was prepared from dextran T-40 (Pharmacia AB, Uppsala, Sweden) using monochloroacetic acid under alkaline treatment as described previously (22). Spectra/Por dialysis tubing (MW cutoff of 3500) was purchased from Spectrum Medical Industries (Houston, TX). Insulin radioimmunoassay kits from ICN Pharmaceuticals (Costa Mesa, CA) were used. Trypsin–ethylenediaminetetraacetic acid (EDTA), fetal calf serum (FCS), and Eagle's minimal essential medium (MEM) were from Gibco BRL (Cergy-Pontoise, France). Twenty-four-well tissue cultures dishes from Costar (Cambridge, MA) were used. 6-[³H]Thymidine (20 Ci/mmol) was from Amersham (Les Ulis, France).

Synthesis and Purification of the CMD–Insulin Conjugate. One hundred milligrams of freeze-dried CMD [degree of substitution, 0.61 mol of carboxymethyl group/mol of glucose (dextran unit), COOH form], subsequently dried under high vacuum over P₂O₅, was

Figure 1. Purification of the CMD–insulin conjugate on a preparative 16/60 Superdex 75 column (Pharmacia AB). The pooled fraction containing the conjugate is marked by a horizontal bar. See Experimental Procedures for details.

dissolved in 2 mL of dry DMSO (three parallel experiments); 25, 50, or 75 μ mol of TBA and 25, 50, or 75 μ mol of IBCF were added at room temperature, and the mixture was stirred for 15 min under N₂. Simultaneously, three fixed amounts of insulin (145 mg, 25 μ mol) were dissolved in 3 mL of dry DMSO and mixed with the activated CMD solutions, irrespective of the IBCF amount used for activation. Additional TBA (25, 50, or 75 μ mol) was added, and the resulting solutions were stirred overnight at room temperature under N₂. The mixtures were then diluted with 3 volumes of ice cold water, dialyzed exhaustively against 0.02% NH₄HCO₃, and then freeze-dried. Separation of the conjugate and uncoupled insulin was achieved using FPLC on a HiLoad 16/60 Superdex 75 column (Pharmacia AB) in 0.05 M Tris-HCl buffer (pH 8.0) containing 0.5 M NaCl at a flow rate 1 mL/min. Fifty milligrams of the mixture in 2 mL of the buffer was injected, and the refractive index (RI) and A₂₈₀ of the eluent were continually monitored. The first major peak eluted giving both A₂₈₀ and RI response (Figure 1) was pooled, dialyzed against 0.02% NH₄HCO₃, and lyophilized. To remove traces of physically bound insulin, rechromatography under identical conditions was necessary.

CMD–Insulin Conjugate Chemical Characterization. The relative distribution of insulin covalently attached to polydisperse CMD in the purified conjugate fraction was examined by size exclusion chromatography on an analytical Superose 12 column (10 mm $\times$ 30 cm) (Pharmacia AB) using FPLC. The column was eluted with 0.05 M Tris-HCl buffer (pH 8.0) at a flow rate 0.4 mL/min at 22 $^{\circ}$ C. A 0.2 mL sample ($\sim$ 1 mg of CMD–insulin/mL) was injected, and the RI and A₂₈₀ of the eluent were continuously monitored.

UV absorption spectra were obtained on a Perkin-Elmer UV/Vis Lambda 19 spectrophotometer. CD absorption spectra for CMD–insulin conjugates were measured on a JASCO J-720 spectropolarimeter. In this case, samples (1 mg/mL or lower) were dissolved in phosphate-buffered saline (PBS) (0.01 M phosphate and 0.15 M NaCl at pH 7.4) containing 0.01% azide, and the ellipticity of the solution was measured in a cylindrical quartz cell (0.1 cm optical path length).

Free N-terminal amino acids in insulin conjugated to CMD were determined by the N-terminal dansylation technique. Released dansyl amino acids were identified after acid hydrolysis (6 N HCl, 105 $^{\circ}$ C, 8 h) by two-dimensional thin layer chromatography (23).

The insulin content in the conjugates was determined by two independent methods. First, A_{276} of the CMD–insulin conjugate of known concentration was measured and the insulin content calculated assuming that A_{276} of the 0.1% insulin solution is 1.00 (24). Alternatively, the insulin amount attached to CMD was determined by amino acid analysis.

In Vitro Cell Growth Studies. Thoracic aorta smooth muscle cells (SMCs) from Sprague-Dawley rats were isolated as previously described (25, 26). SMCs grown from aorta explants were cultured in MEM supplemented with 10% FCS and 2 mM L-glutamine at 37 °C in a humidified atmosphere containing 5% CO₂. Cultures of third and fourth passage were used throughout the study. The nature of SMCs was confirmed by the aspect of confluent cultures (hills and valleys pattern) and by positive immunofluorescence for α -smooth muscle actin (27).

SMCs (10^4) were plated into 16 mm multiwell plates in MEM containing 10% FCS. After 48 h, cell growth was arrested (G_0) by placing them in medium with 0.4% FCS for 72 h. Cell growth was initiated by changing the medium to MEM with 2% FCS and adding insulin, CMD, or the CMD–insulin conjugate (26). The control cells were exposed to medium with 2% FCS and positive control cells to 10% FCS. After 3 days, cells in quadruplicate wells were harvested after dislodging them with 0.05% trypsin/0.5 mM EDTA treatment and then counted using a Coulter Counter ZM (Coultronics, Beds, U.K.). The net growth of SMC in cultures was obtained by subtracting the cell number at the end of the experiment from the starting cell number (at the time the cells were released from G_0), and results were expressed as the net growth above the control.

The effect on cell proliferation was also assessed with the tritiated thymidine uptake method as previously described (26). Confluent SMCs were placed in MEM and 0.4% FCS for 48 h. Then, the cells were incubated with or without (control) the tested compounds for 24 or 48 h. Cells were pulsed with 1 μ Ci per well of [³H]-thymidine for the last 3 h. At the end of the assay, the plates were washed, DNA was precipitated with 10% trichloroacetic acid and solubilized, and radioactivity was determined by β -liquid scintillation counting (LKB-Pharmacia, Uppsala, Sweden).

Insulin Receptor Binding Studies. A rat insulinoma cell line (RINm5F) was used for CMD–insulin conjugate insulin receptor (IR) binding studies. The cells were grown in 75 mL flasks in MEM supplemented with 10% heat-inactivated FCS, 2 mM L-glutamine, 50 units/mL penicillin, and 50 μ g/mL streptomycin. The cells were harvested at the exponential growth phase, 4 days after seeding, using a calcium- and magnesium-free medium at 4 °C. The harvested cells were washed and resuspended in the binding buffer (15 mM Tris, 120 mM NaCl, 1.2 mM MgSO₄, 5 mM KCl, 10 mM glucose, 15 mM sodium acetate, 1% bovine serum albumin, 20 μ g/mL bacitracin, and 50 μ g/mL merthiolate) at a final concentration of 1.5×10^7 cells/mL. The cell suspension (200 μ L) was mixed with 200 μ L of insulin solution, insulin concentration varying from 10^{-11} to 4×10^{-10} M. The insulin solution consisted either of pure [¹²⁵I]insulin having an activity of ~ 300 μ Ci/ μ g (CIS Biointernational, Saclay, France) or a mixture of [¹²⁵I]insulin and a particular insulin derivative, specifically unlabeled insulin, GlyA1-glucosyl insulin (28), or the CMD–insulin conjugate. The molar ratios of 2:1, 1:1, and 1:2 between unlabeled insulin or the insulin conjugate and [¹²⁵I]-insulin were usually used. The incubation was per-

formed at 4 °C for 1 h. The fractions of bound and free insulin were separated by centrifugation. The cell pellet was resuspended in 400 μ L of binding buffer and the whole procedure repeated five times to remove insulin nonspecifically adsorbed. The bound radioactivity was measured in a γ -counter (LKB-Pharmacia). First, the adsorption isotherm for pure [¹²⁵I]insulin was measured, and the results were replotted according to Scatchard (29) to determine its affinity constant for IR. In the next step, the binding isotherm for a mixture of [¹²⁵I]insulin and the insulin derivative, with their molar ratio fixed at 2:1, 1:1, or 1:2, was acquired, and the affinity constant for a particular insulin derivative was then calculated.

Blood Glucose Depression Assay. The biological activity of CMD–insulin conjugates was tested in a rat model (male Sprague-Dawley rats, 300 ± 25 g) by measuring blood glucose depression levels. All procedures in handling animals adhered to the *Principles of Laboratory Animal Care* (NIH Publication 85-23, revised in 1985). The animals fasted overnight (16 h) prior to the experiment. Water was allowed *ad libitum*. In the morning, the rats ($n = 6-9$) were anesthetized with sodium pentobarbital intraperitoneally (21). Each animal received an intravenous (iv) injection (tail vein) of insulin (3.4 nmol/mL NS/kg) or the CMD–insulin conjugate (equimolar amount attached insulin dose/mL NS/kg). Blood samples were taken through a catheter introduced into the jugular vein 15 and 5 min before injection and 15, 30, 60, 90, 120, 180, and 240 min after injection. Blood glucose levels (BGLs) were measured with an Accucheck III blood glucose monitor (Boehringer Mannheim, Indianapolis, IN). Bioactivity of CMD–insulin conjugates was calculated from AUC (area under the curve) values and the AUC value for the same dose of unmodified insulin.

Pharmacokinetic and Pharmacodynamic Studies. Male Sprague-Dawley rats weighting 250–350 g were used throughout the studies. At least six animals were used in individual experiments. The basic animal protocol was the same as that described above (see the bioactivity determination).

For the iv route of administration and pharmacokinetic (PK) and pharmacodynamic (PD) analysis of the CMD–insulin conjugate, blood samples were taken at 0, 3, 7, 15, 30, 60, 90, 120, 180, 240, and 300 min. EDTA/plasma samples were prepared and stored at -20 °C until analysis. Blood sample volumes were replaced with the same volume of saline (37 °C). Three different CMD–insulin doses of 0.125, 0.25, and 0.5 mg/mL/kg dissolved in 0.01 M PBS (pH 7.4) were administered through a tail vein of rats that fasted overnight. Insulin reference for PK analysis (0.5 IU/mL) was injected at a dose 0.5 IU/kg, and blood samples were collected at 0, 1, 3, 5, 7, 10, 15, 20, 30, and 45 min; for PD analysis, blood samples were taken at 0, 15, 30, 60, 90, 120, 180, 240, and 300 min.

For the subcutaneous (sc) route of administration and PK analysis, blood samples were taken at 0, 10, 20, 30, 45, 60, 90, 120, 180, and 240 min, while for PD analysis, blood samples were obtained at 0, 30, 60, 90, 120, 180, 240, 300, and 360 min. Three different CMD–insulin doses of 0.125, 0.25, and 0.5 mg/mL/kg in PBS were administered sc into the nape of the neck. Insulin reference was injected at a dose 0.5 and 1.0 IU/mL/kg.

Usually, both BGLs and plasma insulin concentrations (EDTA/plasma) were determined. BGLs were immediately measured using Chemstrip bG reagent strips with an Accucheck III blood glucose monitor. Plasma insulin and CMD–insulin concentrations were determined with

a commercial insulin radioimmunoassay kit (ICN Pharmaceuticals). The CMD–insulin standard curve was used for radioimmunoassay of plasma CMD–insulin.

Statistical Analysis. Both iv administered insulin and CMD–insulin appear to follow a two-compartment PK model. Thus, the data were fitted by a nonlinear least-squares fit into biexponential eq 1, where preexponential and exponential terms have the units $\mu\text{units/mL}$ and min^{-1} , respectively.

$$C = Ae^{-\alpha t} + Be^{-\beta t} \quad (1)$$

Data were analyzed using the PKAnalyst software package (MicroMath, Salt Lake City, UT) that provided basic PK parameters, including biological plasma half-life and area under the curve (AUC). Basal insulin levels were considered to be $20 \mu\text{units/mL}$, and the area below this threshold was subtracted from AUC.

To process PK data of the sc as well as iv administered CMD–insulin conjugate and reference insulin, statistical moment-derived noncompartmental analysis was applied (30). The AUCs for insulin and CMD–insulin plasma concentration–time curves above controls were calculated by the linear trapezoidal method. If the insulin levels were still higher than those of control experiments ($20 \mu\text{units/mL}$), the last two points were extrapolated to a time point where the plasma insulin concentration reached $20 \mu\text{units/mL}$ and this region was also included. The areas under the first momentum curve (AUMC) were also calculated and used to calculate the mean residence time (MRT) of CMD–insulin and insulin after iv as well as sc administration. Finally, mean absorption times (MAT) for sc administered CMD–insulin and insulin were calculated, using eq 2.

$$\text{MAT} = \text{MRT}_{\text{sc}} - \text{MRT}_{\text{iv}} \quad (2)$$

The time needed to reach the maximum plasma insulin and CMD–insulin concentration (T_{max}) after sc administration was also used as an independent PK parameter.

For PD analysis, two parameters reflecting the time dependency of BGL after CMD–insulin or insulin administration and prolongation of the blood glucose lowering effect were selected. The most important PD parameter measured was the time to reach minimum BGL (T_{nadir}). The duration over which BGL remained below 70% of the initial value ($T_{70\% \text{ BGL}}$) was taken as the second PD parameter.

For the assessment of the statistical significance of the difference, the Student's *t* test, with one- and two-way analysis of variance, was used. Results were termed significant when $P < 0.02$. To pool data for different insulin or CMD–insulin conjugate doses (see Results and Discussion), *P* had to be > 0.3 .

RESULTS AND DISCUSSION

CMD–Insulin Conjugate Synthesis, Purification, and Characterization. Previously, we have shown that the GlyA1 insulin amino group is a preferential site of reaction and attachment of any structural moiety containing a carboxylic group activated by a mixed anhydride method (21). We decided to use this activation method after having established that the free acid (COOH) form of CMD is easily soluble in dry DMSO. Exclusion of water enabled us to activate only a small molar fraction of CMD carboxylic groups. In the first experiment, only 8 mol % of available carboxyl groups in the polymer, which corresponded to about 12 groups per CMD molecule, was activated with IBCF and reacted

with an equimolar insulin amount to minimize cross-linking. No insoluble material was formed, indicating no cross-linking occurred. Separation of the conjugate from uncoupled insulin was accomplished by size exclusion chromatography on a Superdex 75 column (Figure 1). The refractive index RI (CMD) and A_{280} (insulin) of the eluent were monitored. The first peak eluted, containing the conjugate, was collected, dialyzed, freeze-dried, and rechromatographed under identical conditions to remove residual, physically bound insulin since insulin is well-known for its tendency to form physical dimers and hexamers (24). The conjugate emerged from the Superdex 75 column, however, in the void volume peak, so there was a possibility that a soluble, high-molecular-weight, insulin-cross-linked material was present in the same fraction (see below). Using analytical Superose 6 and 12 columns that have high-molecular-weight exclusion limits, for both proteins and dextrans, we established that purified conjugate is chromatographically homogeneous (single peak) and that the RI to A_{280} signal ratio was practically constant, which indicates that the insulin moiety was evenly distributed (attached) with regard to the polydispersity of CMD. This means that a constant insulin amount was attached per arbitrary unit length of linear CMD chain. We excluded the possibility that the insulin molecule behaved like a cross-linking agent bridging two or more CMD molecules, because no significant difference between the retention volume of free CMD and the CMD–insulin conjugate was found. To have definite proof that no physically bound insulin was present in the conjugate fraction, the conjugate was again examined on Superose 6 and 12 columns with the elution buffer containing 8 M urea. Under such conditions, the insulin molecule unfolds and can no longer form dimers and/or hexamers. No peak corresponding to the unfolded insulin monomer was detected. Thus, the structure of the conjugate corresponds to the linear CMD chain with grafted insulin molecules. For future preparative production, repetitive size exclusion chromatography is not an ideal method for the conjugate purification because of its limited capacity. An obvious simple and efficient alternative method is pH-dependent isoelectric precipitation of free insulin (pH range 5.0–6.0), because the solubility of the CMD–insulin conjugate is not significantly affected (as compared to the solubility at pH 8.0). By using this procedure, at least one inconvenient chromatographic step can be avoided.

The UV spectrum of the CMD–insulin conjugate was identical to the UV spectrum of insulin, so no chemical modification of aromatic amino acids occurred. The far-UV CD spectrum was indistinguishable from that of Zn-free insulin or GlyA1-glucosyl insulin (21), indicating that the attached insulin molecule is properly folded (data not shown). We have also studied the site of the insulin molecule attachment to CMD carboxyl groups with the N-terminal dansylation technique. Insulin is a two-chain molecule with two N-terminal amino acids, GlyA1 and PheB1. The third insulin amino group comes from LysB29 (24). Since only DNS-Phe and DNS- ϵ -Lys were detected by two-dimensional TLC (23), we concluded that insulin molecules were attached to the CMD chain by an amide bond through the GlyA1 amino group. Insulin molar content in the CMD–insulin conjugate was determined by UV absorption spectrometry and amino acid analysis. As an average, 3.26 mol of insulin was found per mole of CMD. Thus, only 25% of activated COOH groups reacted with insulin, even though equimolar amounts of insulin and activated COOH groups were used. To shed more light on the limiting step, we

Figure 2. SMC growth stimulation by insulin and the CMD-insulin conjugate. Rat aorta SMCs were plated in 2% serum containing insulin (□), the CMD-insulin conjugate (■), or the starting CMD polymer (○). After 3 days, the cell numbers were counted. The net growth was then determined and normalized by the control values in the presence of 2% serum. Results are mean $\pm$ SD of two experiments performed in quadruplicate.

increased the amount of activated COOH groups to 16 mol % (equivalent to 24 mol % of available carboxyl groups in the polymer), keeping the insulin amount constant (equivalent to 8 mol % of available COOH groups). Surprisingly, the insulin content in the conjugates increased only marginally to 3.5–3.9 mol of insulin/mol of CMD in two separate experiments. In both cases, no cross-linking was detected. Apparently, a maximum of three or four insulin molecules can be conjugated per CMD chain, and then the remaining activated carboxylic groups become unavailable for coupling.

CMD-Insulin Conjugate Studies in Vitro. The in vitro effects of the CMD-insulin conjugate containing 3.5 mol of insulin/mol were studied with the mitogenic activity on vascular cells and the binding to the insulin receptor. The in vitro cell growth effects of the CMD-insulin conjugate were investigated by the assessment of cell counting and [^{3} H]thymidine uptake using rat aorta smooth muscle cells. The results shown in Figure 2 indicated that the CMD-insulin conjugate as well as native insulin, but not the starting CMD polymer, increased SMC growth. [^{3} H]Thymidine incorporation was used as an alternative method to measure the mitogenic effect, and also indicated after 24 and 48 h (data not shown) that the CMD-insulin conjugate enhanced cell proliferation in a concentration-dependent manner (from 0.1 to 50 μ g/mL, i.e., about 20 nM to 10 μ M). These results indicated that insulin grafted to CMD kept its mitogenic activity on cells in culture.

The characteristics of CMD-insulin binding to insulin receptor (IR) were then measured in vitro in a competitive binding assay with [^{125} I]insulin. First, the binding isotherm for [^{125} I]insulin was obtained, and the binding constant was determined from a Scatchard plot (Table 1). Its magnitude is well within the range of those published by others (32, 33). As a next step, the binding constant for native insulin was determined to show that radiolabeling of insulin did not have a substantial negative effect on IR binding. Since the effect was negligible, we proceeded with GlyA1-glucosyl insulin and, finally, with CMD-insulin binding studies (Table 1). The modification of the GlyA1 insulin amino group with succinamidophenyl glucopyranoside (GlyA1-glucosyl insulin)

Table 1. Binding Constants (Mean $\pm$ SD) for the CMD-Insulin Conjugate and GlyA1-Glucosyl Insulin and the Insulin Receptor Using the RINm5F Cell Line

insulin derivative	binding constant (M^{-1})
native insulin	$(7.64 \pm 0.17) \times 10^9$
[^{125} I]insulin	$(6.37 \pm 0.14) \times 10^9$
GlyA1-Glc-insulin	$(2.46 \pm 0.06) \times 10^9$
CMD-insulin conjugate ^a	$(1.19 \pm 0.08) \times 10^{10}$
CMD-insulin conjugate ^b	$(3.61 \pm 0.11) \times 10^9$

decreased the binding constant 3-fold (25). This is in agreement with previous studies aimed at modification of this particular amino group with low-molecular-weight compounds (31), which established that GlyA1 is not directly involved in, but is very close to, the IR binding region of the insulin molecule. The binding constant for the CMD-insulin conjugate can be expressed in terms of either the conjugate concentration or the insulin concentration (Table 1). The two apparent affinity constants can be viewed as a reflection of two different CMD-insulin conjugate binding modes and consequently two different models of binding. The first binding constant, expressed in terms of conjugate concentration, shows that the affinity of the conjugate for IR is 4.8 times higher than that of GlyA1-glucosyl insulin and even 1.5 times higher than that of native insulin. This can be physically interpreted in such a way that only one insulin molecule in the conjugate binds IR and that a positive cooperative binding of the CMD chain increased the affinity for IR. In the second alternative, the CMD-insulin binding constant, expressed in terms of conjugated insulin concentration, is much closer to the GlyA1-glucosyl insulin binding constant (only 1.5 times higher) and likely better reflects the physical reality. Here, one can view individual conjugated insulin molecules as being statistically distributed along CMD chain and, thus, more or less independent. The insulin modification on GlyA1 in the CMD-insulin conjugate, as in the case of GlyA1-glucosyl insulin, leads to decreased affinity. However, this decrease is smaller than that for GlyA1-glucosyl insulin (Table 1), because after the binding of the first insulin molecule the remaining insulin molecules attached to the CMD chain have a higher probability of interaction with cell surface IR (entropic factor). In other words, the binding of one insulin molecule in the conjugate facilitates the binding of other insulin molecules in the conjugate to proximal IRs on the cell surface. The bioactivity data (see below), on the other hand, suggest that the first model better describes the interaction with IR on the cell surface.

Blood Glucose Depression Assay. The in vivo activity of CMD-insulin conjugates was first tested by blood glucose depression test in rats after an iv injection of 20 μ g of conjugated insulin/kg/mL. Its bioactivity was found to be 9.6 ± 2.1 IU/mg of conjugated insulin or 2.5 ± 0.5 IU if expressed per milligram of the conjugate. Consequently, conjugated insulin is 2.6 times less active than native insulin (~ 25 IU/mg) in this bioassay. The earlier studies with dextran-insulin conjugates found either a very low insulin bioactivity of about 1.0 IU/mg of conjugated insulin (15, 18) or a high insulin bioactivity (16, 17, 19) which was comparable to that of native insulin. Thus, the bioactivity value of insulin coupled to CMD is between these two extremes. For comparison, the bioactivity of structurally related GlyA1-glucosyl insulin is 22.2 ± 4.2 IU/mg (21), which is very close to that of native insulin. Apparently, the presence of the

Figure 3. Fit of the observed plasma insulin concentrations and plasma CMD–insulin conjugate concentrations following intravenous administration of insulin (0.5 IU/kg) or the CMD–insulin conjugate (0.125 mg/kg) in rats ($n = 8$) to the equation for a two-compartment pharmacokinetic model: $A = 3743 \mu\text{units/mL}$, $B = 60 \mu\text{units/mL}$, $\alpha = 0.702 \text{ min}^{-1}$, and $\beta = 0.056 \text{ min}^{-1}$; and $A' = 2056 \mu\text{units/mL}$, $B' = 316 \mu\text{units/mL}$, $\alpha' = 0.124 \text{ min}^{-1}$, and $\beta' = 0.0089 \text{ min}^{-1}$.

CMD polymeric chain carrier interferes with insulin activity in vivo or a fraction of attached insulin molecules cannot exert its action. Thus, we investigated in detail the pharmacokinetic (PK) and pharmacodynamic (PD) properties of one CMD–insulin conjugate in rats using iv and sc administration routes.

Intravenous Administration of the CMD–Insulin Conjugate. Intravenous administration of soluble Zn–insulin (0.5 IU/kg) resulted in plasma concentration–time profiles characteristic of an apparent two-compartment PK model, best described by biexponential eq 1 (Figure 3). The distribution half-life was only $1.03 \pm 0.22 \text{ min}$, while the overall elimination half-life was found to be $12.4 \pm 3.4 \text{ min}$, which are consistent with results reported by others (12, 34). In contrast, iv administration of 0.125 mg/kg of the CMD–insulin conjugate (3.47 mol of insulin/mol) resulted in a significantly prolonged plasma profile (Figure 3). Another CMD–insulin dose, 0.25 mg/kg, was also tested. Since both CMD–insulin doses provided very similar constants (dose-independent) with statistically insignificant differences, the data were pooled giving a distribution half-life of $4.94 \pm 1.06 \text{ min}$ and an elimination half-life of $114.1 \pm 28.6 \text{ min}$. Thus, the main goal of the study, i.e., the substantial increase of insulin elimination half-life, was achieved. To our knowledge, this study is the first to report this effect, since all previous studies with insulin–dextran conjugates failed to investigate this important parameter (15–19). Interestingly, iv PD profiles of the CMD–insulin conjugate and insulin were not different (Figure 4), even though the CMD–insulin mean residence time (MRT) for iv administration was 57.7 min (average for 0.125 and 0.25 mg/kg doses), which was very significantly increased as compared to the native insulin MRT of 3.16 min (Table 2). Our findings differ from those of Torchilin et al. (35), who reported that the hypoglycemic effect of periodate activated dextran-bound insulin was much longer than that of native insulin after iv administration in dogs. In addition to the differences in the conjugation chemistry (chloroformate activation of carboxyl groups versus periodate activation of hydroxyl groups), another plausible explanation may be the difference in the basal metabolic

Figure 4. Blood glucose levels (mean $\pm$ SD) after intravenous administration of insulin (0.5 IU/kg, $n = 7$) and the CMD–insulin conjugate (0.25 mg/kg, $n = 8$) into the tail vein of rats that had fasted.

rate between the two animals (36). Rats, with a faster metabolism, also react faster to a blood glucose level drop with feedback mechanisms to bring the blood glucose concentration back to physiological levels. Consequently, blood glucose lowering effects of the conjugate in the later phase of PD response are suppressed, even though high plasma levels of the conjugate prevail.

Subcutaneous Administration of the CMD–Insulin Conjugate. Insulin administration into the back of the neck of rats (0.5 and 1.0 IU/kg) resulted in plasma insulin concentration–time profiles characteristic of a PK curve controlled by the absorption phase being a rate-limiting step (Figure 5). The insulin MRT for sc administration was 40.8 min (Table 2, pooled data for 0.5 and 1.0 IU/kg doses) and was not significantly different from that of the insulin mean absorption time (MAT), equal to 37.7 min (Table 2, average pooled data). Administration of the CMD–insulin conjugate by the sc route (0.125 mg/kg) resulted in a significantly prolonged plasma profile (Figure 5) in accord with iv data. Another CMD–conjugate dose, 0.25 mg/kg, was tested. As for the iv route, both doses provided parameters with statistically insignificant differences. All data were pooled, regardless of dose, for final PK evaluation using the statistical moment-derived noncompartmental approach. The MRT of insulin conjugate for sc administration (103.5 min) is significantly longer than that of insulin. Since MATs of insulin and CMD–insulin are not significantly different (Table 2), both free insulin and conjugated insulin are absorbed from sc depot at comparable rates, but are eliminated at different rates, similar to those found for the iv route of administration. In agreement with these results, the times T_{max} (Table 2) to reach the maximum plasma level for insulin and the conjugate differ substantially. The average T_{max} was more than 3 times longer for CMD–insulin than for free insulin. PD profiles of sc administered intravenously equipotent doses of insulin (0.5 IU/kg) and CMD–insulin (0.25 mg/kg) reflect the differences in sc PK profiles (Figure 6). The CMD–insulin conjugate showed a protracted PD profile. This differs from the iv administrative route, where no significant differences in PD profiles were observed. This finding can be explained by much lower initial phase exogenous insulin plasma concentrations, as compared with those of iv administered samples, controlled by the

Table 2. Pharmacokinetic and Pharmacodynamic Parameters (Mean $\pm$ SD) for the CMD–Insulin Conjugate and Insulin Administered by either the Intravenous (iv) or Subcutaneous (sc) Route

insulin derivative	administration route	dose	MRT ^a (min)	MAT ^b (min)	T _{max} ^c (min)	T _{nadir} ^d (min)	T _{70% BGL} ^e (min)

**Figure 5.** Plasma levels (mean $\pm$ SD) of insulin (0.5 IU/kg, $n = 7$) and the CMD–insulin conjugate (0.125 mg/kg, $n = 8$) after subcutaneous administration of the derivatives into the back of the neck of rats that had fasted.**Figure 6.** Blood glucose response (mean $\pm$ SD) following subcutaneous administration of insulin (0.5 IU/kg, $n = 8$) and the CMD–insulin conjugate (0.25 mg/kg, $n = 9$) into the back of the neck of rats that had fasted.

insulin or CMD–insulin absorption rate. The first quantitative PD parameter, T_{nadir} , the time needed to reach minimum BGL, was again dose-independent, for both insulin and the insulin conjugate (Table 2). How-

ever, T_{nadir} for the CMD–insulin conjugate was significantly longer than that for Zn–insulin, resembling intermediate-acting insulin preparations (14). The second quantitative PD parameter, $T_{70\% BGL}$, the time period over which BGL remained below 70% of the initial value, was, on the other hand, dose-dependent for both insulin preparations studied. This is quite obvious since, as the dose is decreased, the blood glucose lowering effect diminishes. Thus, Table 2 shows $T_{70\% BGL}$ for three equipotent doses of insulin (0.25, 0.5, or 1.0 IU/kg) and the CMD–insulin conjugate (0.125, 0.25, or 0.5 mg/kg). In all cases, $T_{70\% BGL}$ for the CMD–insulin conjugate was about twice as long as $T_{70\% BGL}$ for the corresponding insulin dose, again demonstrating the protracted blood glucose lowering effect of the CMD–insulin conjugate. The achieved protraction of insulin action still seems to be rather short for practical application. However, as discussed previously, the rat animal model is far from ideal, and a large animal model, such as dogs or pigs, should be used. Currently, we are planning PK and PD experiments in dogs. If the protraction of the insulin effect in dogs is still insufficient, obviously, the next step is to increase the length of the CMD chain. This should result in increased MRTs and possibly also MATs, both of which should lead to a further extended and prolonged action profile similar to that of insulin basal formulations. Similarly, the extension of the time action of insulin by chemical modification has been recently achieved through acylation of human insulin with fatty acids (37). In this case, however, the binding of acylated insulin to serum albumin in the interstitial liquid at the injection side was suggested (increase in MATs) to be mainly responsible for protracted action (38).

CONCLUSION

A bioactive CMD–insulin conjugate containing three or four insulin molecules was synthesized, purified, and characterized. By coupling the insulin molecule to the CMD chain with an amide bond, we achieved a significant increase in insulin half-life and protraction of the PD effect for the sc route, while the mean absorption time of the CMD–insulin conjugate was not significantly different from that of soluble insulin. Thus, prolongation of insulin action was realized with chemical modification, not by classical physical means through the manipulation of insulin solubility and consequently absorption at the sc injection site. Further studies will focus on optimization of the synthetic procedure to prepare a 1:1 conjugate on the molar basis. The effect of CMD molecular weight (chain length) will also be studied. Finally, PK and PD

properties of the optimized conjugate will be evaluated using a large animal model.

Antibody-Mediated versus Nontargeted Delivery in a Human Small Cell Lung Carcinoma Model

Edgardo Marecos, Ralph Weissleder, and Alexei Bogdanov, Jr.*

Center for Molecular Imaging Research, Department of Radiology, Massachusetts General Hospital, Building 149, 13 Street, Boston, Massachusetts 02129. Received August 1, 1997;
Revised Manuscript Received December 5, 1997

The uptake of macromolecular agents in tumor cells (LX-1, human small cell lung carcinoma) and in corresponding tumor xenografts was compared in a parallel study utilizing a long-circulating biocompatible graft copolymer, MPEGs-PL-DTPA [Bogdanov, A., Jr., et al. (1995) *Adv. Drug Delivery Rev.* 16, 335–348; Bogdanov, A., Jr., et al. (1996) *Bioconjugate Chem.* 7, 144–149] and a tumor-specific chimeric monoclonal antibody, BR96 [Hellstrom, I., et al. (1990) *Cancer Res.* 50, 2183–2190; Garrigues, J., et al. (1993) *Am. J. Pathol.* 142, 607–622]. Covalent grafted conjugates of methoxy-(polyethylene glycol)succinate and polylysine and BR96 were modified with DTPA, biotinyl, or rhodamine-X-residues. Using radionuclide and fluorescent labeled derivatives of the copolymer and the antibody, we established that (1) the copolymer does not associate with the plasma membrane in *N*-ethylmaleimide-treated cells and is slowly internalized by live cells at 37 °C; (2) the antibody binds rapidly to the surface of LX-1 cells and shows active internalization in vesicles with a subsequent slow decrease in the cell-associated antibody concentration; (3) LX-1 cells bear more than 1 million BR96 binding sites/cell (with an apparent K_d of 4.5×10^{-7} M); and (4) intravesicular fluorescence intensity in LX-1 cells was linearly dependent on copolymer concentration, suggesting fluid phase endocytosis. Tumor localization by nuclear imaging, biodistribution, microdistribution by histology, and determination of tumor cell fraction uptake was performed in LX-1 tumor xenografts. In vivo study showed that MPEGs-PL-DTPA progressively accumulates in the tumor, yielding from $2.8 \pm 1.5\%$ injected dose per gram of tissue (ID/g) at 24 h to $5.2 \pm 1.7\%$ ID/g of tissue at 48 h. The antibody accumulation peaked at 24 h ($6.0 \pm 3.2\%$ ID/g) and decreased thereafter. We determined that at 24 h $43.9 \pm 11.29\%$ of the polymer accumulated in the tumor was associated with tumor cell fraction with the remainder of the accumulated dose localized in the interstitium. Accumulation of the biotinylated graft copolymer and the antibody in LX-1 xenografts and their uptake in cells were confirmed by histology using avidin–peroxidase staining. Our study demonstrates that, although BR96 is highly specific in vitro, tumoral drug delivery in vivo can be equally high with long-circulating graft copolymers because of slow extravasation at the tumor site.

INTRODUCTION

A variety of tumor targets have been tested experimentally to deliver therapeutic or diagnostic payloads to solid tumors (5, 6). The most widely investigated approach of tumor targeting includes the conjugation of a tumor-specific antibody or antibody fragments to a given drug carrier so that the resultant conjugate specifically associates with tumor cells in vivo. Successful tumor antibody-mediated delivery to several classes of tumor-associated antigens has been achieved: (1) oncogene-encoded proteins [e.g., c-erb proto-oncogene product, an EGF-receptor like protein kinase (7–9)], (2) tissue-associated differentiation antigens, onco-fetoproteins [e.g., carcinoembryonic antigen (10–13)], (3) tumor-associated mucins (14) or glycoproteins [TAG-72 (11, 15)], (4) receptor subtypes [e.g., the folate receptor in adenocarcinomas (16–18)], or (5) antibodies against histones (TNT-1) to detect nuclei in the regions of massive cell necrosis in tumors (19, 20). Several difficulties are

associated with this targeting strategy because of three major obstacles: (1) rare occurrence of tumor-specific antigens (expression of antigen in normal tissues), (2) antigen expression heterogeneity of tumors, and (3) generation of anti-ideotype antibodies to the targeting ligand requiring the use of chimeric antibodies or small antibody fragments.

Most of the alternative approaches utilize the intravascular delivery to shuttle a given drug to the tumor and exploit elevated permeability of tumor vessels to achieve drug accumulation within the tumor. It has been demonstrated that macromolecular agents, such as linear polymer–drug conjugates (21, 22), accumulate in experimental tumors, presumably at sites of increased capillary permeability (23, 24). The permeability itself can be pharmacologically modulated, thus leading to more efficient intratumoral delivery (reviewed in ref 25). We have previously presented the evidence that MPEG-grafted long-circulating polymers and their conjugates with cisplatin efficiently accumulate in experimental mammary adenocarcinomas (2, 26). The property of tumor accumulation is shared also by other long-circulating drug carriers, such as liposomes bearing MPEG-conjugated lipids (27–32). Furthermore, it has been suggested that long-circulating polymeric agents are

taken up by tumor cells by fluid phase endocytosis (pinocytosis) (26, 33, 34), a process which is typically upregulated in rapidly proliferating cells and is cell cycle-dependent (35, 36).

In this study, we intended to compare directly the "specific" targeting of tumor-specific antibody and the "non-specific" accumulation of a long-circulating polymer in a model of human cancer *in vitro* and *in vivo*, i.e., to address the issue of "active" versus "passive" delivery of macromolecules into tumors.

MATERIALS AND METHODS

Graft Copolymer. Synthesis of a protected graft copolymer [*O*-methyl-poly(ethylene glycol)-*O'*-succinyl-*N*-*O'*-poly(L-lysine) (MPEGs-PL)¹] and its analogue modified with DTPA has been accomplished as described in refs 2 and 37. The product was purified by passing the copolymer through Sephadex A-25 and subsequent ultrafiltration (YM 50 membrane, Amicon, Beverly, MA). The duration of ultrafiltration was determined by subjecting an aliquot of purified copolymer to size-exclusion HPLC analysis (Hydropore-5-SEC column, 4.5 mm inside diameter $\times$ 25 cm long, Rainin Instrument Co., Woburn, MA) eluted with 50 mM sodium phosphate (pH 6.8) at 0.5 mL/min. The composition of the copolymer was confirmed by elemental analysis (Galbraith Labs, Knoxville, TN). The molecular mass of MPEG-PL was calculated as 410 kDa.

To label MPEGs-PL with rhodamineX-isothiocyanate (X-RITC, Molecular Probes, Eugene, OR), a solution of 20 μ M MPEGs-PL in 10 mM sodium bicarbonate and 0.15 M NaCl (pH 8.7) was treated with a 5-fold molar excess of X-RITC over MPEGs-PL. The rest of the free amino groups in MPEGs-PL were blocked with DTPA cyclic anhydride. Three or four X-RITC groups/mol of MPEGs-PL were incorporated, assuming $\epsilon = 92\,000$ at 572 nm for X-RITC.

Biotinylation of MPEGs-PL was performed by reacting 100 mg of *O*-biotinyl-poly(ethylene glycol) 3500 succinyl *N*-hydroxysuccinimide (Shearwater Polymers Inc., Birmingham, AL) with 200 mg of poly(L-lysine) [MW of 35 500, at 25 mM lysine monomer in 0.05 M sodium bicarbonate (pH 8.7)] for 3 h with subsequent modification of 30% of *N*- ϵ -amino groups of poly(L-lysine) with MPEG 5000 succinate as described previously (2, 37). The biotinylated polymer was purified using ultrafiltration as described before.

Indium (¹¹¹In) labeling of MPEGs-PL-DTPA was performed by incubating MPEGs-PL-DTPA in the presence of ¹¹¹InCl₃ (specific activity of 1.7×10^7 Ci/mol) at a ratio of 50 mCi/mg of copolymer (1 mol of In/600 mol of MPEGs-PL-DTPA) dissolved in 10 mM sodium citrate and 0.15 M NaCl at pH 6.0 (CBS), for 30 min. The yield of isotope chelation to DTPA was 85% from added ¹¹¹In. The labeled product was purified by gel filtration on Sephadex G-25m spin columns equilibrated with CBS. The properties of the labeled agent have been described in more detail previously (26).

Antibody Conjugates. Chimeric monoclonal antibody [Chi BR96 (38)] was kindly provided by P. Senter (Bristol-Myers Squibb Pharmaceutical Research Institute, Seattle, WA). Antibody was dialyzed overnight against 10 mM borate and 0.15 M NaCl (pH 8.7) and

centrifuged at 15000g for 15 min. BR96 modified with DTPA was obtained by reacting a 6-fold molar excess of DTPA cyclic anhydride per mole of antibody (9.4 mg of BR96/mL, final concentration) for 4 h with subsequent overnight dialysis against 10 mM sodium citrate and 0.15 M NaCl (pH 6) and Sephadex G-25m chromatography. Labeling of the BR96-DTPA with ¹¹¹In has been performed as described above. According to TNBS titration, three DTPA residues were conjugated with mAb on the average. Labeling with X-RITC has been performed using a ratio of 6 mol of X-RITC/mol of mAb at pH 8.7. Fluorescent antibody was purified from aggregates by centrifugation at 15000g for 30 min and passed through a column of Sephadex G-25m. The resultant preparation contained 1.2 mol of X-RITC/mol of antibody. The biotinylation of BR96 was performed with a 3-fold molar excess of biotinylation reagent per mole of antibody by reacting 65 μ M *N*-hydroxysulfosuccinimidyl[6-(biotinyl-amido)]hexanoate (Pierce Chemical Co.) with BR96 in 50 mM sodium bicarbonate and 0.1 M NaCl (pH 8). The biotinylated antibody was then purified by Sephadex G-25m column chromatography.

Nonspecific human IgG (Sigma Chemical Co. catalog no. I-4506) was purified from the aggregates and modified under conditions identical to those described above. The purity of modified antibodies was verified by SDS-PAGE using 7.5 and 10% gels and autoradiography.

Cell Culture Experiments. Human small cell lung carcinoma LX-1 (kindly provided by E. Neuwelt, University of Oregon, Portland, OR) was propagated in RPMI and 10% FBS. Cells were detached from the plastic by aspiration, sedimented, and resuspended in fresh medium at 2×10^5 cells/mL. Indium-labeled MPEGs-PL-DTPA and BR96-DTPA were added to 1 mL of cell suspension at the concentration of 0.1–70 μ g/mL and incubated with agitation at 37 °C. Cells were washed three times by centrifugation through a cushion of 30% Histopaque-1077 in HBSS (Sigma Chemical Co.) at 800g, for 10 min, and counted. The associated radioactivity was determined by γ -counting. Fluorescent microscopy was performed at 37 °C using live cells attached to the glass coverslips (39). Images were collected using a SenSys (Photometrics) CCD camera attached to a Zeiss Axiovert 100TV fluorescent microscope equipped with an XF22 filter set (Omega Optical Inc.). For intravesicular fluorescence measurements, images of 50–100 cells were digitized and segmented using a histogram method provided by IP LabSpectrum software (Signal Analytics Co., Vienna, VA). Fluorescence intensity of segments (intracellular vesicles, $n = 100$ –200 per data point) was measured. Segment areas were limited to a median of 10–20 arbitrarily chosen vesicles to exclude nonvesicular structures and cell fragments from consideration. The linearity of the CCD response was checked using standard X-RITC solutions. The response of the device was linear in the range of 50–3000 nM X-RITC.

Animal Model of Human Lung Carcinoma. Female nude mice ($n = 36$; 25–30 g; Edwin L. Steele Laboratory, MGH, Boston, MA) bearing 0.5–0.9 cm LX-1 human small cell lung carcinomas were used as a tumor model for all comparative experiments. In each animal, 1×10^6 LX-1 human lung small cell carcinoma cells were implanted subcutaneously in the left abdominal flank. Mice were used for biodistribution studies 15–17 days after implantation. Twelve were used for imaging studies. Six were used to process tumors for avidin-peroxidase histology. Six were used for the cell uptake experiment.

¹ Abbreviations: MPEGs-PL-DTPA, *O*-methyl poly(ethylene glycol)-*O'*-(succinyl)-*N*- ϵ -poly(L-lysyl)diethylenetriaminepentaacetamide; NEM, *N*-ethylmaleimide; ID, injected dose; hIgG, human immunoglobulin; PBS, 10 mM sodium phosphate and 0.15 M NaCl (pH 7.4).

Figure 1. Binding of BR96-[^{111}In]DTPA and MPEGs-PL-[^{111}In]DTPA to LX-1 cells (1 h, 37 °C) treated in the presence of 100 μM *N*-ethylmaleimide: (1) BR96-DTPA and (2) MPEGs-PL-DTPA. (Inset) Scatchard analysis of curve 1. Results are presented as mean $\pm$ SD ($n = 3$).

Animal Experiments. Biodistribution studies in 36 mice were performed after intravenous (iv) injection of the agents via the tail vein. Animals were divided into two experimental groups of 18. Animals were injected in the tail vein with 200 μg of BR96-[^{111}In]DTPA (60 nmol of mAb/kg, 30 μCi /animal) dissolved in 100 μL of sterile HBSS or with an equimolar amount of MPEGs-PL-[^{111}In]DTPA (ca. 60 μg of polymer/animal, 25 μCi /animal). In each group, sets of three animals were sacrificed at 6, 12, 48, and 72 h time points, and a set of six was sacrificed at the 24 h time point. Samples of blood, major normal tissues, and tumors were collected, and the tissues were blotted dry and weighed. Radioactivity of the samples was measured using a well-type γ -counter (LKB model 1282, Wallac, Turku, Finland). To correct for radioactive decay and to permit the calculation of activity in each organ as a fraction of the administered dose, aliquots of standard stock solutions were counted simultaneously. Biodistribution results were expressed as a percentage of the injected dose per gram of tissue (% ID/g).

Tumor Fractionation Experiment. To determine the intracellular and extracellular fractions of the graft copolymer and monoclonal antibody within tumors, the tumor tissue obtained from six animals was processed (three for each group, 24 h postadministration). The tumor (200–300 mg of tissue) was excised, minced to small fragments on ice, suspended in 20 mL of PBS supplemented with 1 mM PMSF, 5 mM NaN_3 , and 1 mM *N*-ethylmaleimide (pH 7), and passed three times through #4 wire mesh (Sigma Chemical Co.) at 4 °C. Samples were centrifuged at 18000g for 15 min. The integrity of cells released from the tissue was verified with the trypan blue exclusion method. The radioactivity of the pellet was determined in a γ -counter and was assumed to be associated with intracellular compartment, and radioactivity of the supernatant was assumed to be contained within the extracellular fluid (40).

Scintigraphy. Mice ($n = 12$, 6 in each group) were used for imaging 6, 12, and 24 h postinjection (2 of the animals in each group were imaged at all time points). Mice were anesthetized subcutaneously (sc) using a mixture of 90 mg/mL ketamine (Ketalar, Parke Davis, Morris Plains, NJ) and 9 mg/mL xylazine (Rompun, Miles, Shawnee Mission, KA). Images were acquired by using 20% windows over a 247 keV photopeak of ^{111}In (10 min at 6 h and 20 min at 12 and 24 h). All scintigrams were obtained by using a small-field of view

Figure 2. Time course of the uptake of BR96-[^{111}In]DTPA (open symbols) and MPEGs-PL-[^{111}In]DTPA (closed symbols) in LX-1 cells. Cells were incubated for the time indicated in the presence of equimolar concentrations (0.4 μM) of BR96 (60 μg /mL) and the copolymer (165 μg /mL) at 37 °C. Results are presented as mean $\pm$ SD ($n = 3$).

γ -camera equipped with a pinhole collimator (Sigma 410, Ohio Nuclear, Solon, OH) and analyzed using NucLear Mac 2.9 software (Scientific Imaging Inc.).

Histology. Mice (nu/nu, $n = 6$) were divided into two groups. The first group of animals received iv ca. 100 μg of BR96-biotin/animal. The animals of the second group were injected with 100–200 μg of MPEGs-PL-biotin. Animals were sacrificed at 24 h postinjection. Tumors were excised, and tumor tissue was quickly frozen and cryosectioned into 10–20 μm sections. Sections were fixed for 1 h in a mixture of ethyl acetate/acetone/acetic acid (6/3/1), washed with PBS, blocked in solution of 10% goat serum in PBS, and incubated with the avidin–peroxidase complex (ABC kit, Vector Laboratories, Burlingame, CA) as described by the manufacturer. Sections were stained using diaminobenzidine/hydrogen peroxide and counterstained with hematoxylin/eosin.

RESULTS

Interaction of the Copolymer and BR96 with LX-1 Cells. These experiments were conducted to determine whether the binding to plasma membrane may mediate the uptake of both MPEGs-PL-DTPA and BR96 in LX-1 cells. To abolish internalization, cells were preincubated in the presence of 100 mM NEM, an inhibitor of endocytosis (41). Indium-labeled BR96-DTPA showed a typical binding to *N*-ethylmaleimide-treated cells (Figure 1). Using Scatchard analysis, we established that LX-1 cells bear ca. 1 million BR96-DTPA binding sites/cell, with an apparent K_d of 4.51×10^{-7} M. The copolymer, MPEGs-PL-[^{111}In]DTPA, incubated with cells under identical conditions showed no detectable binding to the cell surface (Figure 1).

Kinetics of the labeled compound uptake by LX-1 cells was studied in live cells at equimolar concentrations (Figure 2). Labeled antibody was rapidly associated with LX-1 cells (16 pmol of antibody was taken up by 1 million cells during the first hour of incubation). The radioactivity associated with mAb-labeled cells slowly diminished with time. Graft copolymer was gradually taken up by cells, with the relatively fast initial phase (6 ng/h per 1 million cells) and slower later accumulation (Figure 2).

Figure 3. Fluorescent microscopy of live LX-1 cells incubated in the presence of BR96-X-RITC (1 and 3) or MPEGs-PL-X-RITC (2 and 4) for 15 min (1 and 2) or 3 h (3 and 4) at 37 °C. Equal concentrations of fluorophore were used (500 nM).

Approximately 150 ng (ca. 0.1% of added copolymer) was associated with 2×10^5 cells after incubation for 15 h at 37 °C, whereas a total of 2500 ng of BR96 (16.7 pmol, 4.1% of the added antibody) was associated with the same number of cells.

Using fluorescence microscopy and rhodamine-labeled BR96 antibody, we observed a characteristic fluorescent "halo" indicating association of antibodies with the cell surface at 15 min (Figure 3, panel 1). The majority of cells exhibited typical extracellular fluorescence with concomitant uptake in vesicles. At 3 h, most of the cell-associated fluorescence appeared to be distributed inside the vesicles (Figure 3, panel 3). For MPEGs-PL-DTPA, virtually no association of the polymer with plasma membrane was seen at the initial stage of incubation (Figure 3, panel 2). At 3 h, however, the morphology of intracellular distribution of fluorescence was almost identical to that of BR96 cells (Figure 3, panel 4). The main difference detected was in the number of fluorescent vesicles per cell which was lower in the case of the copolymer. To obtain a semiquantitative measure of the uptake of both fluorescently labeled BR96 and MPEG-PL, we digitized fluorescent images of intracellular vesicles. This made it feasible to study the concentration dependence of the uptake only and allowed the exclusion of the fraction of plasma membrane-bound antibody or copolymer that was not internalized. Normalized vesicular fluorescence intensity of the cells incubated in the presence of MPEGs-PL-X-RITC showed a nearly linear increase with the concentration of fluorophore (Figure 4, closed symbols). Vesicular fluorescence intensity of BR96-treated LX-1 cells was very similar to that of cells treated with the copolymer in the broad range of rhodamine concentrations (Figure 4). In the higher concentration range of BR96 ($>20 \mu\text{g/mL}$, $>1500 \text{ nM}$ rhodamine-X), LX-1 cells showed signs of cytotoxicity which were manifested by the presence of fragmented cells. The cytotoxicity resulted in a dramatic increase of fluorescence (Figure 4, open symbols).

Biodistribution. Biodistribution experiments were performed to compare kinetics of ^{111}In -labeled BR96-DTPA and MPEGs-PL-DTPA accumulation in LX-1 tumor xenografts (Table 1). At the dose used for intra-

Figure 4. Concentration dependence of vesicular fluorescence intensity measured by a CCD device in LX-1 cells: BR96-X-RITC (1, open symbols) and MPEGs-PL-X-RITC (2, closed symbols). Cells were incubated with labeled compounds for 3 h at 37 °C and subjected to microfluorimetry as described in Materials and Methods.

venous injections (60 nmol/kg), both ^{111}In -labeled copolymer and antibody showed very long blood residence times in nude mice, with a $T_{1/2}$ of 26.6 h for mAb (monoexponential fitting, $r^2 = 0.925$). The blood half-life of the copolymer could be approximated as 60 h. Indium-labeled BR96-DTPA accumulated in the tumor rapidly and exhibited the highest accumulation 6–12 h after the injection at 7.1–7.9% of the injected dose per gram of tissue. Graft copolymer showed a slower uptake in the tumor with the maximum accumulation reached at 48 h (Table 1). Corresponding γ -camera images reveal a clear tumor mass which could be detected by the antibody at 6 h postadministration (Figure 5), whereas the copolymer accumulation was evident at 12 h postinjection. Over time, BR96-DTPA showed good retention within the tumor with high tumor/muscle localization ratios at 48–72 h post-IV administration. The copolymer was taken up by the tumor ca. 5-fold more efficiently than in the muscle at the peak of tumor accumulation (at 48 h). At this time point, we did not observe any statistically significant differences between tumor/muscle ratios calculated for BR96 (range of 6.75–7.25) and MPEG-PL-DTPA (range of 2.7–7.7) (Table 1). Both ratios were higher than the tumor/muscle ratio of nonspecific hIgG (1.3–2.6).

Compartmental Distribution of Labeled Agents in the Tumor. Tumor compartmental distribution of labeled BR96-DTPA and MPEGs-PL-DTPA was determined by separating the cellular fraction from the extracellular fluid. Twenty-four hours after injection,

Figure 5. Nuclear imaging of mice bearing LX-1 xenografts. Animals were injected iv with MPEGs-PL-[^{111}In]DTPA (images 1–3) or BR96-[^{111}In]DTPA (images 4–6). Images collected at 6 (images 1 and 4), 12 (images 2 and 5), and 24 (images 3 and 6) h postinjection as described in Materials and Methods. Arrows indicate localization of the tumor.

$43.9 \pm 11.3\%$ of the total amount of ^{111}In -labeled copolymer located in tumor was associated with the cellular fraction. The remainder of the dose localized in the tumor was found in the extracellular compartment. The cell-associated fraction of the injected dose was $60.4 \pm 3.9\%$ of mAb, and $39.6 \pm 3.6\%$ of the antibody was located in the extracellular compartment. Histological examination of the tumor obtained from the animal injected with MPEGs-PL-biotin (Figure 6A) and biotinylated antibody (Figure 6B) showed the presence of extravasation of both antibody and the polymer in perivascular stroma and certain accumulation in cells located in the perivascular area.

DISCUSSION

This study was undertaken with the goal of comparing, in a set of parallel experiments, the ability of a cancer cell-specific monoclonal antibody (BR96) and a nonspecific long-circulating polymer to localize within cancer cells (LX-1) *in vitro* and *in vivo*. The tumor-specific monoclonal antibody used in this study binds to a variant of a Le^y antigen abundantly expressed (>200000 molecules per cell) at the plasma membrane of human colon, lung, breast, and ovary carcinomas (3, 42). This antibody rapidly internalizes in human carcinoma cells and is cytotoxic *in vitro* (3, 4). Intravenous administration of BR96 results in antitumor activity against tumor xenografts in mice (38).

The copolymer, MPEGs-PL-DTPA, was used because of its controllable size, relatively narrow molecular mass distribution, and long circulation time (1, 43). Furthermore, the copolymer is relatively inert in nature and is not immunogenic (37). Additionally, the copolymer does not induce local changes in capillary permeability and accumulates within tumors in experimental cancer (2, 26). The latter property was explained by the extravasation from vessels with abnormally elevated permeability (44, 45).

It has been shown before that intravenous administration of tumor-specific antibodies may result in a very high

Figure 6. Extravasation and uptake of biotinylated BR96 (A) and biotin-MPEGs-PL-DTPA (B) in LX-1 xenografts by histology. Staining of tumor slices was performed with the avidin–peroxidase complex with hematoxylin/eosin counterstaining. Arrows indicate extravasation sites. Asterisks indicate vascular lumens. (Insets) Magnified image of cells positively stained by avidin–peroxidase.

percentage of dose accumulated in tumor tissue, and that this effect is not accompanied by efficient binding to tumor cells. Tumor-specific antibodies accumulate *in vivo* in tumoral perivascular stroma (40, 46), and the majority of the dose (76–80%) is not bound to cells, but rather is associated with tumor-shed antigens (40). The discovery of interstitial fluid pressure gradients in tumors has also been used to explain the low efficiency of cellular uptake of tumor-specific antibodies (47–49). These findings prompted us to compare delivery to tumors and cellular uptake of a tumor-specific antibody and a copolymer which can associate with tumor cells only as a result of endocytosis. For “inert” particulates and macromolecules which do not bind to cell surfaces, constitutive fluid phase endocytosis is the predominant pathway of uptake (33, 34, 50–52). Therefore, we hypothesized that MPEG-PL-DTPA may accumulate in tumor cells as a result of fluid phase uptake.

The results of *in vitro* experiments clearly indicate that MPEGs-PL-DTPA does not bind to the LX-1 cell plasma membrane, whereas BR96, labeled with either DTPA or rhodamine-X (Figures 1 and 3), binds to the plasma membrane at a very high density (1 million sites/cell were detected) and rapidly internalizes in live cells. After NEM treatment which blocks fluid phase uptake (41), the cells avidly bound the antibody while no binding of polymer was observed (Figure 1). Fluorescence microscopy suggested that nearly all association of MPEGs-PL with LX-1 cells is a result of fluid phase uptake; the copolymer appears within the cells at a much later stage than surface-bound antibody and associates almost ex-

clusively with intracellular vesicles (Figure 3). In addition, semiquantitative intravesicular fluorescence measurements revealed a linear dependence of fluorescence intensity on fluorophore concentration. This observation is consistent with the fluid phase uptake (Figure 4). Vesicular fluorescence of BR96-treated cells showed certain level of saturation within the range of 250–750 nM rhodamine-X, presumably because of the saturation of antibody binding sites and the predominance of membrane-bound antibodies in the vesicles. With the further increase in antibody concentration, fluorescence intensity of vesicles increased as a result of cell permeabilization by the cytotoxic antibody. It should be noted that an internalized molecule encounters a vesicular environment different from that of an extracellular medium in pH, microviscosity, and high protein concentrations. These factors can affect the quantum yield of the fluorescence of the given probe. It is also possible that the antibody and the polymer can be taken up and sorted into different vesicular compartments with different degrees of "maturation" and compaction (53). This may lead to different levels of fluorescence quenching. However, the results of measurements performed using radioactive BR96 and copolymer (Figure 2) were consistent with fluorescent microscopy data, revealing rapid association of the antibody with the cells and slow uptake of MPEGs-PL-DTPA.

The results of the *in vivo* biodistribution study performed using an LX-1 xenograft model and the antibody–copolymer pair were remarkably similar to *in vitro* data. For example, tumor accumulation kinetics and corresponding tumor/muscle ratios were consistent with rapid accumulation of BR96 in cells (Figure 5). MPEGs-PL-DTPA, lacking the ability to bind to tumor cells, showed a delayed accumulation in the tumor. At the 48 h time point, which corresponds to the peak of accumulation of MPEGs-PL-DTPA (Table 1), we observed only an insignificant difference between the antibody and copolymer accumulation (5.8 ± 0.4 vs $5.2 \pm 1.7\%$ ID/g, $P > 0.05$). These values were only marginally higher than that of hIgG (Table 1) but resulted in substantially higher localization (tumor/muscle ratios). Both BR96 and the copolymer were present in tumor interstitium and in tumor cells in animals injected with biotinylated mAb and MPEGs-PL-DTPA (Figure 6). Strongly positive cells (Figure 6, insets) were detected in both cases, suggesting the internalization of biotinylated copolymer and BR96 *in vivo*. As expected, higher amounts of the antibody were found to be associated with LX-1 cells in xenografts (more than 60% of tumor-associated antibody) than the copolymer (44% of the tumor-accumulated dose) at 24 h. This may be explained by rapid initial uptake of mAb in the tumor. We believe that the high tumor cell-associated activity cannot be explained by the uptake of plasma components labeled as a result of transchelation of ^{111}In from the copolymer to plasma proteins since ^{111}In -labeled MPEGs-PL-DTPA is stable in plasma as well as in the presence of apotransferrin for at least 48 h (26).

Our data indicate that nonspecific fluid phase uptake in tumor cells is the major pathway of tumor-directed delivery of nontargeted macromolecular agents exemplified in our study by the MPEGs-PL graft copolymer. There are obvious differences in the kinetics of tumor accumulation of BR96 and MPEGs-PL graft copolymer resulting in rapid tumor-specific accumulation of the tumor-specific antibody. However, we showed that one can achieve a progressive increase of tumor delivery with increasing blood half-lives of the drug carriers with no

specificity against tumor cells. Approximately 100 molecules of diagnostic label (e.g., DTPA) or an antitumor drug can be conjugated to a nonimmunogenic MPEGs-PL copolymer. Thus, the nontargeted approach can potentially yield a high accumulation of the drug in the tumor and concomitant uptake by proliferating cancer cells, irrespective of the tumor antigenic status.

Identification of the Soluble *in Vivo* Metabolites of Indium-111-Diethylenetriaminepentaacetic Acid-D-Phe¹-Octreotide

Laura A. Bass,[†] Margaret V. Lanahan,[†] James R. Duncan,[†] Jack L. Erion,[‡] Ananth Srinivasan,[‡] Michelle A. Schmidt,[‡] and Carolyn J. Anderson^{*,†}

Division of Radiological Sciences, Washington University School of Medicine, St. Louis, Missouri 63110, and Mallinckrodt Inc., St. Louis, Missouri 63134. Received August 13, 1997; Revised Manuscript Received December 23, 1997

Indium-111-diethylenetriaminepentaacetic Acid-D-phenylalanine¹-octreotide (¹¹¹In-DTPA-octreotide) is a cyclic eight amino acid somatostatin analogue which is approved for gamma scintigraphy of neuroendocrine tumors. To address the factors that contribute to liver and kidney retention of this radiopharmaceutical, its metabolism was evaluated in normal and tumor-bearing rats. The soluble fractions from nontarget (liver and kidney) and target (tumor, pancreas, adrenals) organ homogenates were analyzed out to 21 h postinjection, and urine was analyzed out to 12 h postinjection. The blood was analyzed at shorter time intervals due to the rapid clearance of ¹¹¹In-DTPA-octreotide. Radio-TLC and HPLC were used to analyze organ homogenates, blood, and urine. By TLC, intact ¹¹¹In-DTPA-octreotide was resolved from the soluble metabolites, and a similar apparent rate of metabolism was observed in the liver, kidney, tumor, and pancreas with ~30% intact ¹¹¹In-DTPA-octreotide at 4 h postinjection. In the adrenals, metabolism occurred more slowly with ~60% intact ¹¹¹In-DTPA-octreotide at 4 h postinjection. At 4 h postinjection, the activity excreted in the urine consisted of 85% intact ¹¹¹In-DTPA-octreotide. HPLC provided resolution of the individual extractable metabolites. In an attempt to identify these metabolites, two DTPA-amino acid sequences were synthesized: DTPA-D-Phe-Cys and DTPA-D-Phe. Under the conditions used for metabolite analysis, ¹¹¹In-DTPA-D-Phe-Cys-OH eluted at 14.6 min and ¹¹¹In-DTPA-D-Phe-OH eluted at 7.0 min. Each of these standard sequences was combined with the soluble portion of the organ homogenate and was shown by HPLC to coelute with the metabolites. These data suggest that ¹¹¹In-DTPA-octreotide was initially degraded to ¹¹¹In-DTPA-D-Phe-Cys-OH and ¹¹¹In-DTPA-D-Phe-OH. The ¹¹¹In-DTPA-D-Phe-Cys-OH was further degraded to ¹¹¹In-DTPA-D-Phe-OH, which appeared to be the final metabolite that was extracted from the organs. From these results, it can be concluded that at longer time points (>2 h postinjection) a significant amount of ¹¹¹In was retained in nontarget organs as ¹¹¹In-DTPA-D-Phe-OH and ¹¹¹In-DTPA-D-Phe-Cys-OH and not as intact ¹¹¹In-DTPA-octreotide.

INTRODUCTION

Somatostatin is a naturally occurring peptide hormone consisting of 14 or 28 amino acids. It is present in the hypothalamus, the cerebral cortex, the brain stem, the gastrointestinal tract, and the pancreas and exerts an inhibitory effect on several cell functions such as secretion of peptide hormones and growth factors (1–4). Neuroendocrine tumors have been found to have an increased number of somatostatin receptors. Other common types of tumors also contain somatostatin receptors, such as those of the CNS, breast, and lung (5–10). The clinical value of somatostatin is limited due to its very short half-life *in vivo* ($t_{1/2} < 3$ min) (11). Octreotide, an eight amino acid peptide, is an analogue of somatostatin that is highly resistant to degradation by enzyme attack and more effective than the native hormone in the suppression of growth hormone secretion (12).

Somatostatin analogues, including octreotide have been labeled with a variety of radiometals such as ¹¹¹In (13, 14), ⁶⁴Cu (15), ^{67/68}Ga (16, 17), ⁹⁰Y (18), and ¹⁸⁸Re (19) for targeted radiotherapy or for imaging of somatostatin receptor positive tumors by SPECT or PET. Radiometals are linked to octreotide via a bifunctional chelate. The bifunctional chelate contains a functional group through which it is conjugated to octreotide. The chelate is chosen such that it binds the metal strongly to prevent release of the metal *in vivo*. The biodistribution of a variety of octreotide conjugates has been investigated in tumor-bearing rodents, and although receptor-mediated tumor uptake was observed, many of these agents exhibited high nontarget uptake in the kidney and liver. To alleviate nontarget accumulation, research efforts have focused on altering the stability of the metal–chelate complex or the chemistry of the chelate–octreotide bond.

Understanding the mechanism of uptake, degradation and retention of octreotide conjugates is key to designing optimal somatostatin analogues. Since ¹¹¹In-DTPA-octreotide¹ (Figure 1) is clinically used for the scintigraphic imaging of neuroendocrine tumors (20–23) and, more recently, has been studied for its therapeutic efficacy (11,

Figure 1. Structure of ^{111}In -DTPA-octreotide.

24), we studied its metabolism *in vivo* in normal and tumor-bearing rats.

There have been few studies on the metabolism of radiolabeled octreotide analogues, although many reports have been published on the *in vivo* fate of various ^{111}In -labeled polypeptides and glycoproteins (25–30). It has been demonstrated that radiolabeled antibodies bound to cell surface antigens are internalized and delivered to the lysosome for degradation (31–34). Recent studies with liver-targeted ^{111}In -DTPA-glycoproteins have shown delivery of these molecules to lysosomes with subsequent degradation of the polypeptide backbone to a low molecular weight species. Chromatographic methods were used to identify ^{111}In -DTPA-lysine as this low molecular weight metabolite (25, 26, 35). ^{111}In -DTPA-lysine was also identified as the metabolic product of ^{111}In -DTPA-MAb conjugates in the liver and kidney (30). These results indicate that the DTPA–amino acid linkage (amide or thiourea bond) is stable *in vivo* and ^{111}In is not significantly dissociated from DTPA. It was therefore proposed that retention of radioactivity in the nontarget organs was due to the inability of In-DTPA-lysine to be released from the cell using the carrier-mediated transport systems designed for the intact polypeptide/antibody.

The internalization of ^{111}In -DTPA-octreotide has been evaluated by several research groups (11, 36, 37). Bree-man et al. injected ^{111}In -DTPA-octreotide into rats and at various times postinjection challenged receptor uptake with cold octreotide (36). He concluded that ^{111}In -DTPA-octreotide was rapidly internalized (<20 min) in somatostatin receptor positive tissues and normal organs. Recently, Duncan et al. confirmed that ^{111}In -DTPA-octreotide was rapidly internalized and, using subcellular fractionation techniques, identified lysosomes as the site of delivery in pancreatic, tumor, kidney, and liver cells (37). Andersson et al. studied the internalization and release of ^{111}In -DTPA-octreotide in human glucagonoma and carcinoid cells (11). Electron microscope autoradiography was used to determine the subcellular distribution of ^{111}In in the midgut carcinoid and activity was reported to be primarily in the cytoplasm, with about 30% found in the nucleus.

In the present study, the metabolism of ^{111}In -DTPA-octreotide was evaluated *in vivo* in target (somatostatin receptor containing) and nontarget organs of normal and tumor-bearing rats. The aims of this investigation were (1) to analyze and compare metabolism patterns in target and nontarget tissues; (2) to identify the retained radiolabeled species; and (3) to gain an understanding of the factors that contribute to nontarget retention of octreotide radiopharmaceuticals.

MATERIALS AND METHODS

Materials. DTPA-octreotide and $^{111}\text{InCl}_3$ (4.2×10^5 Ci/g) were provided by Mallinckrodt Inc. (St. Louis, MO). DTPA was purchased from Sigma Chemical Co. (St. Louis, MO). Trifluoroacetic acid (TFA) was purchased

from J. T. Baker (Chicago, IL). C-18 Sep-Pak cartridges were from Waters/Millipore (Burlington, MA). Biospin-6 chromatography columns were from Bio-Rad Laboratories (Hercules, CA). Organs were prepared using a Tekmar tissue homogenizer (Cincinnati, OH), a Branson Sonifier 185 cell disrupter, and a Sorvall RC2-B centrifuge. Ultrafree-MC 0.22 μm filter units were from Millipore (Bedford, MA). Centricon-10 and -30 ultrafiltration units were from Amicon (Beverly, MA). Reversed-phase HPLC was performed on a Waters 600 system with a Waters 991 photodiode array detector (200–300 nm) and an Ortec (EG&G Instruments) radioactive detector. Reversed-phase columns used were either Vydac 218TP54 (C18, 4.6×250 mm, analytical) or Vydac 218TP1010 (C18, 10×250 mm, semi-prep). Unless otherwise indicated, a gradient elution was employed with 5% A to 70% A in 30 min (solvent A = 95% ACN:5% H_2O and solvent B = 95% H_2O :5% ACN, both solvents contained 0.1% TFA). Millenium software (Waters Corporation) was used to quantify chromatograms by integration. Reversed-phase silica gel (KC18F, 60 Å, 200 μm) TLC plates were from Whatman and the radioactive compounds were analyzed on a Bioscan System 200 imaging scanner after development in 70% MeOH:30% (5% $\text{NH}_4\text{-OAc}$). Radioactivity was quantified using a Beckman Gamma 8000 automated well-type gamma counter. Adult, female, Sprague–Dawley rats were purchased from Sasco (Omaha, NE), and female Lewis rats were purchased from Charles River Laboratories (Boston, MA). The rat pancreatic tumor CA20948 was obtained from the Tumor Bank at Biomeasure, Inc. (Hopkinton, MA). All animal experiments were performed in compliance with guidelines specified by the Washington University Animal Studies Committee.

Synthesis of DTPA-D-Phe-OH and DTPA-D-Phe-Cys-OH. Preparation of tri-*tert*-butyl-DTPA and a general method for the incorporation of DTPA by solid phase were previously described (38).

DTPA-D-Phe-OH (Figure 2A). To a solution of tri-*tert*-butyl-DTPA (42 mg, 75 μ mol) in 1 mL of anhydrous dimethylformamide 15.5 mg of dicyclohexylcarbodiimide in 500 mL was added and shaken for 30 min. A solution of 8 mg (50 μ mol) of D-phenylalanine in 1 mL of dimethylformamide containing 10 mg (12 mL, 100 μ mol) of triethylamine was added and the solution was shaken for 3–4 h at room temperature. Dimethylformamide was removed *in vacuo*, and the residue was treated with 95% trifluoroacetic acid:5% water to remove the *tert*-butyl groups. The solvents were removed *in vacuo* and DTPA-D-Phe-OH was isolated by preparative reversed-phase liquid chromatography [mobile phase, solvent A (water: 0.1% TFA) and solvent B (90% H₂O:10% acetonitrile:0.1% TFA); gradient, 95% A:5% B to 30% A:70% B in 40 min, linear gradient, detection mode UV at wavelength 214 nm] followed by lyophilization. DTPA-D-Phe-OH eluted at 6.1 min. MS, *m/z* 541.2 (M + 1).

DTPA-D-Phe-Cys-OH (Figure 2B). Solid-phase peptide synthesis (SPPS) was carried out using an Applied Biosystems Model 432 A "Synergy" Peptide synthesizer using Fmoc (9-fluorenylmethoxycarbonyl) strategy (39). The instrument protocol required 25 μmol of preloaded Fmoc amino acid to the resin and 75 μmol of subsequent Fmoc-protected amino acids. Activation was accomplished by a combination of hydroxylbenzotriazole (HOBt) and 2-(1-H-benzotriazol-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HBTU). Tri-*tert*-butyl DTPA (75 μmol) was placed at the appropriate location in the synthesizer and activated similar to the other amino acids for coupling. Fmoc-Cys(S-Trt)-Wang resin (50 mg,

¹ Abbreviations: DTPA, diethylenetriaminepentaacetic acid; SPECT, single-photon emission computerized tomography; PET, positron emission tomography; CNS, central nervous system.

Figure 2. Synthesis of metabolite standards. (A) Synthesis of Tri-*tert*-butyl-DTPAn and DTPA-D-Phe-OH; (B) synthesis of DTPA-D-Phe-Cys-OH.

0.5 mmol/g) was used. After successive coupling of Fmoc-D-Phe and tri-*tert*-butyl-DTPA, the peptide was cleaved and deprotected from the resin with trifluoroacetic acid: thianisole:phenol:water (85:5:5:5) for 8–10 h. The peptide was precipitated by the addition of 10 mL of *tert*-butylmethyl ether. Peptide-resin mixture was washed with 4×10 mL of *tert*-butylmethyl ether. Acetonitrile:water (2:3) was added to dissolve the peptide and the solution was filtered to remove the resin. The solution containing the crude peptide was lyophilized prior to purification by liquid chromatography. Final purification was accomplished by C-18 reversed phase chromatography [mobile phase, solvent A (water:0.1% TFA) and solvent B (90% H₂O:10% acetonitrile:0.1% TFA), gradient, 90% A:10%B to 30% A:70% B in 40 min, linear gradient, detection mode UV at wavelength 214 nm] followed by lyophilization. DTPA-D-Phe-Cys-OH eluted at 9.3 min. MS, m/z 644.2 ($M + 1$).

Radiolabeling. ¹¹¹In-DTPA-octreotide was prepared as previously described by Anderson et al. and was analyzed by radio-TLC and HPLC (15). DTPA, DTPA-D-Phe, and DTPA-D-Phe-Cys (1–3 μ g) were dissolved in NH₄OAc, pH = 5.5, 0.1 M, and incubated with ¹¹¹Indium-acetate (1–3 mCi) at room temperature for 1 h. The compounds were analyzed by radio-TLC and HPLC without purification. Transferrin was also labeled by its incubation with ¹¹¹Indium-acetate. It was purified from uncomplexed ¹¹¹In by passage through a Biospin-6 column and was analyzed by radio-TLC.

In Vivo Metabolism of ¹¹¹In-DTPA-Octreotide. Mature, female, Sprague–Dawley rats and female Lewis tumor-bearing rats ($n = 2$ –4) were injected with 200–2000 μ Ci of ¹¹¹In-DTPA-octreotide (specific activity, 1000–4000 μ Ci/ μ g) via the tail vein. Prior to injection, the dose

was diluted with 0.1% BSA in buffer or saline. At 1, 2, 4, 6, 8, 14, and 21 h postinjection the urine was collected and the liver, kidney, adrenals, pancreas, tumor, and blood removed. In the experiments, only a section of the liver was used (~1 g). All organs were rinsed with water and blotted dry. Samples were kept in an ice bath at all times.

To the organs and blood, 2.0 mL of 20% HEPES (1.0 M, pH = 7) in EtOH was added and the samples were homogenized (1–3 min), sonicated (30 s), and centrifuged (23000g for 10 min, 10 °C) to precipitate protein. This extraction was repeated with 1 mL of 20% HEPES in EtOH and the supernatants combined. Both supernatant and pellet were counted to determine extraction efficiency. Supernatants were passed through a 0.22 μ m Ultra-MC spin filter and analyzed by HPLC and/or TLC. Organ blanks, where the ¹¹¹In-DTPA-octreotide injectate was added directly to tissues prior to workup, were performed as controls.

In separate experiments, four female Sprague–Dawley rats were injected with 2 mCi ¹¹¹In-DTPA-octreotide. At 4 h postinjection, the rats were sacrificed and their livers and kidneys excised. A portion of the livers and one kidney were homogenized and extracted twice with 20% HEPES in EtOH as described above. The pellets then underwent digestion with 1.0 mg/mL collagenase at room temperature for 6 h, followed by digestion with pronase-E (0.5 mg/mL) for 6 h and trypsin (0.5 mg/mL) for 6 h as described by Paik et al. (28). Another portion of the livers and the second kidney underwent a similar procedure, except they were digested with each enzyme for 24 h at room temperature (40).

Metabolite Analysis by Radio-TLC. All samples were immediately analyzed by radio-TLC. The distribution of

Table 1. TLC and HPLC Retentions of Standard Compounds^a

standard compound	R _f	R _t (min)	radiochemical purity
¹¹¹ In-DTPA-octreotide	0.50	20.60	100%
¹¹¹ In-DTPA-D-Phe-OH	0.85	7.05	>98%
¹¹¹ In-DTPA-D-Phe-Cys-OH	0.85	14.70	>95%
¹¹¹ In-acetate	0.00	4.00 (void) ^b	ND ^c
¹¹¹ In-DTPA	1.00	4.00 (void)	ND
¹¹¹ In-transferrin	0.00	ND	ND

^a Radiochemical purity was determined by HPLC integration.

^b Void indicates that the activity was eluted in the void volume.

^c ND signifies that no data was collected.

activity was determined by integration of the chromatograms. The kidney supernatants were cospotted with the standards ¹¹¹In-DTPA-D-Phe-Cys-OH and ¹¹¹In-DTPA-D-Phe-OH and also with ¹¹¹In-DTPA and ¹¹¹Indium-transferrin for comparison. To further evaluate the metabolites by TLC, centricon filters were used to determine if organ extracts contained protein bound activity. Organ supernatants were passed through a centricon filter with a molecular mass cutoff of 30 000 Da, and the top and bottom fractions were analyzed.

Metabolite Identification by HPLC. In separate experiments, liver, kidney, tumor, and adrenal supernatants were analyzed by HPLC at 2, 6, or 8 and 24 h postinjection, and the pancreas supernatant was analyzed at 24 h. Supernatants with low amounts of radioactivity per milliliter were concentrated using a stream of nitrogen. To ensure reproducibility of retention, samples were diluted to less than 5% EtOH and the maximum volume injected was 300 μL. To verify the integrity of the standards under our extraction conditions, ¹¹¹In-DTPA-D-Phe-Cys-OH and ¹¹¹In-DTPA-D-Phe-OH were each added to a kidney, one 2 mL extraction was performed and the supernatant was analyzed by HPLC. To ensure that all activity was accounted for, fractions were collected from the 2 and 6 h analysis of the kidney, counted, and the activity compared to the amount injected. Greater than 90% of the activity was recovered from the column. To demonstrate comigration of the metabolites with each standard, the 6 h kidney supernatant was combined with ¹¹¹In-DTPA-D-Phe-Cys-OH and ¹¹¹In-DTPA-D-Phe-OH separately and then analyzed by HPLC.

RESULTS

Analysis of Standards. The standards DTPA-D-Phe and DTPA-D-Phe-Cys were analyzed by electron spray mass spectrometry and the expected mass peaks were observed at 541 and 644, respectively. The radiochemical purities of ¹¹¹In-DTPA-octreotide, ¹¹¹In-DTPA-D-Phe-Cys-OH, and ¹¹¹In-DTPA-D-Phe-OH were assessed using reversed-phase HPLC and radio-TLC. Radiochemical purities and chromatographic retentions of the ¹¹¹In labeled agents used are listed in Table 1.

Extraction of ¹¹¹In-DTPA-octreotide and Metabolites from Tissues. Organ blanks were done for every experiment in order to establish the inherent extraction efficiency of ¹¹¹In-DTPA-octreotide from the organ matter. This extraction efficiency was then used as a correction factor in determining the percent authentic intact (see Table 3).

Extraction efficiencies for each organ over the time course of an experiment are listed in Table 2. We found that, for the liver and kidney, the extraction efficiencies decreased over time, whereas for the tumor and pancreas, extraction efficiencies were initially lower than the other organs and remained fairly constant. Adrenals exhibited

Table 2. Extraction Efficiencies Are Listed for Each Organ at the Time Points Studied Postinjection^a

time (h)	liver	kidney	tumor	adrenal	pancreas

^a Normal organs are from Sprague–Dawley rats, whereas the tumor was excised from lewis rats (*n* = 3 or 4 unless noted). The data is expressed as: % extraction = cpm in supernatant/(cpm in pellet + cpm in supernatant). ^b *n* = 2 for these data. ^c ND, no data was collected at this time postinjection.

high extraction efficiencies throughout the experiment, probably due to the small size of the organ and the larger ratio of extraction solvent to tissue used in the extraction procedure.

A digestion procedure was evaluated to maximize the amount of ¹¹¹In-labeled intact DTPA-octreotide and metabolites from liver homogenates. Paik et al. determined that this digestion procedure increased their extraction of ¹¹¹In-labeled mAb metabolites from 75 to ~95% (28). With ¹¹¹In-DTPA-octreotide, it was determined that this procedure did not appreciably increase extraction efficiency, and in all samples, the additional ¹¹¹In-labeled agents extracted increased by less than 5%. No further samples were evaluated using this procedure.

Metabolite Analysis by Radio-TLC. Following extraction, the organ supernatants were immediately analyzed by radio-TLC. The formation of metabolites with time in the kidney is shown in Figure 3. In all organs, a broad metabolite peak at an *R_f* of 0.86 was observed. By TLC, these metabolites were separated from intact ¹¹¹In-DTPA-octreotide, which eluted at an *R_f* of 0.50. A species was intermittently observed at the origin in small amounts relative to the intact compound. This species did not pass through a centricon filter membrane with a 30 000 MW cutoff, suggesting that ¹¹¹In was protein bound.

Table 3 shows the percent authentic intact compound present in the organ extracts. These data were calculated from the integration of the radio-thin-layer chromatograms and took into account the unidentified activity left in the pellet, the extraction efficiency of the ¹¹¹In-DTPA-octreotide injectate determined from the organ blank experiments and the purity of the injectate. The tumor and pancreas exhibited a similar rate of metabolism with approximately 60% of the extracted activity in the form of intact ¹¹¹In-DTPA-octreotide at 1 h postinjection and only 22% at 4 h. In the adrenals, ¹¹¹In-DTPA-octreotide appeared to metabolize much more slowly with 99% intact ¹¹¹In-DTPA-octreotide at 1 h and 60% intact at 4 h. The liver and kidney exhibited an almost identical rate of metabolism with approximately 80–90% of the activity as intact ¹¹¹In-DTPA-octreotide at 1 h and 20% at 4 h. As indicated in Table 3, radioactivity in the blood could only be detected out to 1 h and was present as mostly intact ¹¹¹In-DTPA-octreotide. ¹¹¹In-DTPA-octreotide was initially excreted mostly intact with 85% of the excreted activity in the form of intact ¹¹¹In-DTPA-octreotide at 4 h postinjection. At 12 h postinjection only 23% of the excreted activity was intact compound.

Metabolite Identification by HPLC. In separate experiments, HPLC was used to resolve the individual

^a The % authentic intact (%AI) ^{111}In -DTPA-octreotide determined from the integration of the radio-TLCs and calculated as follows: %AI = %P × %I/[1 + (%Pellet/%Super)]%E. %P = purity of injectate determined by TLC; %I = intact ^{111}In -DTPA-octreotide determined by integration of the TLC; %Pellet/%Super = the ratio of the radioactivity in the pellet and supernatant of the organ blank; %E = the extraction efficiency of the harvested organ after injection of ^{111}In -DTPA-octreotide. ^b ND signifies that no data was collected at this time postinjection. ^c $n = 2$.

Figure 3. Radio-TLC time course of metabolite formation in the kidney shown out to 6 h postinjection. ^{111}In -DTPA-octreotide migrated with an R_f of 0.50 whereas the metabolites comigrated with an R_f of 0.85.

metabolites which, when analyzed by radio-TLC, coeluted at $R_f = 0.86$. In all organs studied two major metabolites were observed eluting at 7.0 and 14.6 min. To elucidate the identity of these metabolites the 6 h kidney supernatant was co-injected with ^{111}In -DTPA-D-Phe-Cys-OH and ^{111}In -DTPA-D-Phe-OH separately as shown in Figure 4. The species eluting at 7.0 min increased in integration area upon co-injection with ^{111}In -DTPA-D-Phe-OH and the species eluting at 14.6 min increased in area upon co-injection with ^{111}In -DTPA-D-Phe-Cys-OH. These data strongly suggest that the metabolites of ^{111}In -DTPA-octreotide were ^{111}In -DTPA-D-Phe-Cys-OH and ^{111}In -DTPA-D-Phe-OH.

The HPLC time course for formation of metabolites in the kidney is shown in Figure 5. At 24 h postinjection, no intact ^{111}In -DTPA-octreotide was observed, 85% of the activity coeluted with ^{111}In -DTPA-D-Phe-OH, and 7% coeluted with ^{111}In -DTPA-D-Phe-Cys-OH. In the adrenals at 24 h, 12% of the activity eluted as ^{111}In -DTPA-octreotide, 28% as ^{111}In -DTPA-D-Phe-Cys-OH and 60% as ^{111}In -DTPA-D-Phe-OH. These kidney and adrenal samples were analyzed immediately after organ preparation; however, other samples were stored up to 24 h at

−20 °C prior to analysis. After storage of the supernatants we observed further conversion of ^{111}In -DTPA-D-Phe-Cys-OH to ^{111}In -DTPA-D-Phe-OH (as indicated by the differing 6 h kidney chromatograms in Figure 4 versus Figure 5).

DISCUSSION

To design octreotide radiopharmaceuticals with optimal targeting (high target-to-nontarget ratios of radio-label), the mechanisms by which these agents are internalized, degraded, and released must be understood. In this study, we set out to determine if ^{111}In -DTPA-octreotide was metabolized in normal and target tissues, to compare the rates of degradation in these organs and to elucidate the identity of the metabolites.

The models used in these studies were normal and tumor-bearing rats. To obtain reproducible results, the methods for performing these *in vivo* studies had to be refined. This first involved maximizing the extraction efficiencies of ^{111}In -DTPA-octreotide and its metabolites from the selected tissues. In Table 2, the extraction efficiencies are listed for each organ over the time course studied. The same extraction procedure was used each time yet a decrease in extraction efficiencies was observed in the liver and kidney over time postinjection. The extraction efficiencies of the pancreas and tumor were initially lower than the other organs and did not vary much with time. At all times, greater than 75% of the activity was extracted from the adrenals.

The decrease in extraction efficiency with respect to time postinjection could represent the inability to extract an unidentified metabolite from the pellet, the binding of ^{111}In to intracellular proteins or the inefficient release of internalized metabolites during the extraction procedure. Paik et al. exhaustively extracted ^{111}In -DTPA-containing metabolites from the liver after injection of a ^{111}In -DTPA-labeled antibody and obtained a maximum of 75% extraction efficiency (28), whereupon with enzyme digestion of the liver homogenate they obtained greater than 90% extraction efficiency. In our experiments, exhaustive extractions did somewhat increase the activity extracted, but after the first two extractions, we did not observe appreciable increases in amounts of activity. Interestingly, radio-TLC and HPLC showed the same metabolite profile for each individual extraction, indicating that there were no new metabolites extracted in the later extractions. We observed an increase in extraction efficiency upon sonication of the organ samples, indicating the importance of bursting the intracellular vesicles; however, the digestion procedure similar to that described by Paik et al. (28) did not significantly increase the extraction efficiency in our hands.

Figure 4. HPLC co-injection of the kidney supernatant with the standards ^{111}In -DTPA-D-Phe-Cys-OH and ^{111}In -DTPA-D-Phe-OH. (a) In an aliquot of the 6 h kidney supernatant the integrated area of the peak eluting at 7.0 min was 7×10^6 mV·s and that of peak eluting at 14.6 min was 9×10^5 mV·s. (b) To the same volume aliquot of the 6 h kidney supernatant ^{111}In -DTPA-D-Phe-OH was added. The integrated area of the peak eluting at 7.0 min increased to 11×10^6 mV·s whereas the area of the peak eluting at 14.6 min remained constant at 9×10^5 mV·s. (c) ^{111}In -DTPA-D-Phe-Cys-OH was added to the same volume aliquot of the 6 h kidney. The integrated area of the peak eluting at 7.0 min was equal to that in panel a (7×10^6 mV·s) whereas the area of the peak eluting at 14.6 min increased to 36×10^6 mV·s.

A low extraction efficiency may indicate that it is more difficult to extract the metabolites than to extract the intact compound, or it may reflect the possibility that ^{111}In was bound to insoluble tissue proteins and was therefore not extracted. It is unlikely that the activity in the pellet is intact ^{111}In -DTPA-octreotide; however, because the identity of this activity is unknown, the percent authentic intact data presented in Table 3 has a degree of error associated with it. It is unlikely that the pellet contains polar or nonpolar smaller molecular weight metabolites, since several different combinations of polar and nonpolar solvents were used in order to increase extraction efficiency. Different combinations of isopropyl alcohol, deionized water, ethanol, acetonitrile, and a variety of buffers (including TEA, HEPES) and detergents (Icon-x, Triton-x) were attempted, and it was determined from these studies that no additional metabolites were extracted. Maximum extraction efficiency was obtained in 20% HEPES in ethanol.

Organ supernatants were analyzed by radio-TLC, and integration of these chromatograms allowed us to compare the rates of metabolism of ^{111}In -DTPA-octreotide in the various organs studied. As Table 3 indicates, similar rates of metabolism were observed for the tumor, pancreas, liver, and kidney. HPLC analysis provided resolution of the individual metabolites and revealed that in all organs studied the chromatographic retentions of the

two major soluble metabolites were the same. To identify these metabolites two DTPA-amino acid standards were synthesized. ^{111}In -DTPA-D-Phe-OH was chosen as a standard based on the lysosomal metabolism patterns of other ^{111}In -DTPA-polypeptides (25, 26, 30, 35). We also analyzed ^{111}In -DTPA-D-Phe-Cys-OH as a metabolite standard because of the potentially higher stability of the D-Phe-Cys bond (since Phe is a D-amino acid as opposed to the naturally occurring L-amino acids). The chromatographic elutions of the observed metabolites corresponded to those for ^{111}In -DTPA-D-Phe-Cys-OH and ^{111}In -DTPA-D-Phe-OH. As shown in Figure 4, co-injection of these standards with the 6 h kidney supernatant confirmed coelution. Identity of the metabolites is not, however, proven by coelution. Future characterization studies involving LC-MS (liquid chromatography-mass spectrometry) of the organ homogenates are planned to confirm the identity of the metabolites of ^{111}In -DTPA-octreotide.

Although HPLC provided better resolution, one caveat to its use for the study of metabolism is the length of time it takes for each analysis. Due to the time required for sample preparation and analysis, certain samples had to be stored at -20°C for up to 24 h before analysis. We observed further conversion of ^{111}In -DTPA-D-Phe-Cys-OH to ^{111}In -DTPA-D-Phe-OH after 24 h of storage at -20°C with subsequent thawing at room temperature. This was

Figure 5. HPLC time course of metabolite formation in the kidney shown out to 24 h postinjection. ^{111}In -DTPA-octreotide eluted at 20.5 min, ^{111}In -DTPA-D-Phe-Cys-OH eluted at 14.6 min and ^{111}In -DTPA-D-Phe-OH eluted at 7.0 min.

apparent in the 6 h kidney supernatant which initially had 54% of the activity eluting as ^{111}In -DTPA-D-Phe-Cys-OH and 46% as ^{111}In -DTPA-D-Phe-OH (Figure 5), yet after 24 h of storage it had only 11% of the activity eluting as ^{111}In -DTPA-Phe-Cys and 84% of the activity as ^{111}In -DTPA-D-Phe-OH (Figure 4). We were therefore unable to use HPLC as a means for accurately quantifying the distribution of metabolites in the samples.

The results obtained in this study will enable a better understanding of the factors that govern uptake and retention of peptides. We observed less than 25% of the activity in the form of ^{111}In -DTPA-octreotide in the tumor, pancreas, liver, and kidney at 4 h postinjection. We showed that, out to 21 h postinjection, approximately 50% of the activity in the organs was extractable and contained the metabolites ^{111}In -DTPA-D-Phe-Cys-OH and ^{111}In -DTPA-D-Phe-OH. Therefore, it is interesting to note that, in scintigraphic-imaging experiments, which are often carried out at 24 h postinjection, the images most likely represent metabolites remaining in the tissues and not intact ^{111}In -DTPA-octreotide.

To design octreotide radiopharmaceuticals that will result in enhanced target to nontarget ratios, it is important that the identity of the retained radiolabel is known and the transport mechanisms available to the various organs are taken into account. Breeman et al. demonstrated that ^{111}In -DTPA-octreotide was taken up in the target organs in less than 20 min postinjection (36). Duncan et al. showed that ^{111}In -DTPA-octreotide was internalized into the cell and delivered to the lysosomes

within 1 h postinjection (37). A preliminary experiment was carried out to analyze by TLC the kidney lysosomal fraction at 1 h postinjection of ^{111}In -DTPA-octreotide (Duncan et al., unpublished results). The majority of the activity was in the form of intact ^{111}In -DTPA-octreotide. These results were in agreement with our studies presented here and indicate that ^{111}In -DTPA-octreotide was delivered intact to the lysosomes and then degraded.

In biodistribution studies previously carried out by our group, retention of radioactivity was observed in the kidney, liver, and target organs (Figure 6) (15). Duncan et al. showed that at 20 h ^{111}In was retained in the lysosomes in the kidney, liver, tumor, and pancreas (37). Our data presented here show that, in these organs at 20 h postinjection, ^{111}In -DTPA-octreotide was almost completely metabolized to ^{111}In -DTPA-D-Phe-OH and ^{111}In -DTPA-D-Phe-Cys-OH and other insoluble metabolites. This retention must therefore be dependent on the cellular mechanisms available for transport of these metabolites out of the lysosomes. Although the clearance of activity from the various organs differed, as verified by the biodistribution results, we found the rates of metabolism to be very similar. This implies that the mechanisms by which the degradation products of radiometal-peptide complexes are transported from the cells varies with organ type. Recently, it has been shown that these degradation products are poor substrates for the carrier-mediated transport systems found in lysosomes (26, 30, 37). Although other routes are available, they are slow, and thus, radiometal metabolites ac-

Figure 6. Biodistribution of ¹¹¹In-DTPA-octreotide in CA20948 tumor-bearing Lewis rats. The data are presented as % injected dose/gram of tissue $\pm$ standard deviation; $n = 4$.

cumulate in the lysosomes of certain organs. Understanding the chemistry of the metabolites may allow us to take advantage of the specialized transmembrane transporters found in the hepatocyte and renal tubular cells that are not present in the target organs, therefore enhancing target to nontarget ratios of radiolabel.

This study along with studies done on the metabolism of other ¹¹¹In-DTPA-polypeptides stress the importance of the terminal amino acid (or amino acid to which conjugation occurs) on the fate of the radiolabel. Therefore, one approach to exploiting the different transport mechanisms may involve altering the terminal amino acid (as long as receptor binding is not compromised). Wu et al. observed the formation of two metabolites from an antibody fragment (41). These metabolites were identified as ⁶⁷Ga-2-(p-SCN-Bz)-NOTA-Met and ⁶⁷Ga-2-(p-SCN-Bz)NOTA-Lys and it was found that the Met containing metabolite had a significantly shorter residence time in the kidney than did the Lys containing metabolite. We are currently exploring the export mechanisms available to the liver and kidney in hopes of understanding the substrates they transport.

In conclusion, we have shown that ¹¹¹In-DTPA-octreotide is metabolized in the blood, liver, kidney, adrenals, pancreas, and tumor and have compared the rate at which metabolism occurs in these tissues. There are no significant differences in the rate of metabolism between target and nontarget tissues, with the exception of slower metabolism in the adrenal glands. The HPLC data indicate that ¹¹¹In-DTPA-D-Phe-Cys-OH and ¹¹¹In-DTPA-D-Phe-OH are the major extractable metabolites in both the target and nontarget organs; however, there are unknown insoluble metabolites that were not extracted from the tissues. Upon correlation of biodistribution results with the metabolism studies, we conclude that retention of ¹¹¹In in the organs studied is likely due to these metabolites. Evaluating other bifunctional chelates or peptides with different N-terminal amino acids may aid in increasing the clearance of these metabolites from tissues. In the design of radiometal-chelate-peptide conjugates that clear normal tissues but are retained in target tissues, we are currently investigating bifunctional

chelates that have specificity for transport systems found in nontarget organs such as liver and kidney, but are absent from target tissues such as tumors.

ACKNOWLEDGMENT

The authors thank Michael E. Cristel, Lynne A. Jones, and Elizabeth L.C. Sherman for their excellent technical assistance. Funding for this project was provided by NIH CA64475 and CA68699 (C.J.A. and L.A.B.) and Mallinckrodt Medical, Inc. (C.J.A.).

Interleukin 7 (IL-7) Receptor-Specific Cell Killing by DAB₃₈₉ IL-7: A Novel Agent for the Elimination of IL-7 Receptor Positive Cells

E. B. Sweeney,[†] F. M. Foss,[‡] J. R. Murphy,^{*,‡} and J. C. vanderSpek[§]

Evans Department of Clinical Research and Department of Medicine, Boston Medical Center, Boston, Massachusetts 02118. Received September 26, 1997; Revised Manuscript Received December 1, 1997

Interleukin 7 (IL-7) induces the proliferation of B cell progenitors in long-term bone marrow cultures, promotes the growth of resting fetal and adult thymocytes, and costimulates mature human T cell proliferation. IL-7 also induces cell growth in hematologic malignancies such as acute lymphoblastic leukemia, chronic lymphocytic leukemia, acute myelogenous leukemia, and Sezary syndrome. We have constructed a recombinant fusion protein, DAB₃₈₉ IL-7, composed of the catalytic and transmembrane domains of diphtheria toxin (DT), fused to IL-7. We demonstrate that DAB₃₈₉ IL-7 is selectively cytotoxic for only those cells bearing the IL-7 receptor and that entry into target cells is mediated through the receptor. The nontoxic mutant, DA(E149S)B₃₈₉ IL-7, was constructed and used to demonstrate that the catalytic domain of DT is responsible for the ADP ribosylation of elongation factor 2 that results in cytotoxicity. Finally, we demonstrate that DA(E149S)B₃₈₉ IL-7 induces the growth of IL-7-dependent cells, verifying the bioactivity of the IL-7 binding domain of DAB₃₈₉ IL-7. We propose that DAB₃₈₉ IL-7 may be an important reagent in studying the IL-7–IL-7 receptor complex and may possess potential as a therapeutic agent against IL-7 receptor-bearing hematologic malignancies.

INTRODUCTION

The techniques of protein engineering have allowed the generation of cell receptor-specific, diphtheria toxin (DT)-based, fusion protein toxins (Murphy and vanderSpek, 1995). DT-based fusion toxins are composed of the catalytic and transmembrane domains of DT, genetically fused to different targeting ligands. Some of the cell surface receptor targeting ligands used to replace the native receptor binding domain of DT include α -melanocyte stimulating hormone, interleukins 2, 4, and 6, epidermal growth factor, and CD4 (Murphy et al., 1986; Williams et al., 1987; Lakkis et al., 1991; Jean et al., 1992; Shaw et al., 1991; Aullo et al., 1992). Since the targeting ligand and toxophore are joined by a peptide bond, the site of linkage between the two is precisely defined. The cytotoxic action of these fusion protein toxins has been shown to be directed to only those cells that express the cognate receptor for a given targeting ligand. The sequence of events that led to cell death are as follows: (i) binding of the targeting ligand to its specific receptor, (ii) internalization by receptor-mediated endocytosis of the ligand–receptor complex, (iii) acidification of the endocytic vesicle and facilitated delivery of the catalytic domain to the cell cytosol, and (iv) ADP ribosylation of elongation factor 2 by the catalytic domain

which results in the inhibition of protein synthesis, and cell death. One molecule of catalytic domain delivered to the cytosol will result in cell death (Pappenheimer, 1977; Yamaizumi et al., 1978; Bacha et al., 1988; Waters, et al., 1990).

Phase I clinical studies on the first-generation form of the interleukin 2 (IL-2) receptor-targeted fusion toxin, DAB₄₈₆ IL-2, were conducted on patients with refractory, hematologic malignancies. Adverse effects were shown to be mild and transient and included nausea–vomiting, fever–malaise, hypersensitivity, chills, and elevations in serum hepatic transaminases. There were no changes in lymphocyte functions or subsets, and no increased rate of opportunistic infection occurred. Pharmacokinetics did not change following multiple courses of administration. Serum levels of soluble IL-2 receptors increased in many of the patients but did not effect serum clearance of DAB₄₈₆ IL-2. The presence of anti-DT or anti-IL-2 antibodies did not interfere with the *in vivo* effects of DAB₄₈₆ IL-2 (LeMaistre et al., 1991, 1992, 1993; Schwartz et al., 1992; Hesketh et al., 1993). The second-generation form of the fusion toxin, DAB₃₈₉ IL-2, has been evaluated in a phase II study on patients with advanced refractory cutaneous T-cell lymphoma (CTCL). As a result, phase III trials for DAB₃₈₉ IL-2 have been initiated for CTCL. Preliminary studies using DAB₃₈₉ IL-2 for treatment of severe rheumatoid arthritis, recent onset insulin-dependent diabetes mellitus, and severe methotrexate resistant psoriasis have also been very promising (Woodworth, 1993; Gottlieb et al., 1995).

Interleukin 7 (IL-7) is a 25 kDa glycoprotein originally identified for its ability to sustain the growth of pre-B cells in long-term bone marrow cultures (Namen et al., 1988). In studies on human hematopoietic malignancies, IL-7 has been shown to stimulate the growth of both B and T acute lymphoblastic leukemia (ALL) cells *in vitro* (Tuow et al., 1990). Other studies have demonstrated

that IL-7 is also able to stimulate the proliferation of malignant cells derived from patients with chronic lymphocytic leukemia (CLL) and the cutaneous T cell lymphoma, Sezary syndrome (Digel et al., 1991; Merle-Beral et al., 1993). As anticipated from studies with normal myeloid cells in vitro, IL-7 has been shown to induce an increase in DNA synthesis in acute myelogenous leukemia (AML) cells (Digel et al., 1991).

The widespread incidence of IL-7-responsive malignant cells led us to construct an IL-7 receptor targeted fusion protein toxin, DAB₃₈₉ IL-7. We describe here the genetic construction and properties of DAB₃₈₉ IL-7 and demonstrate that this fusion protein toxin selectively inhibits protein synthesis in IL-7 receptor-positive cells. We also show that the cytotoxic activity of DAB₃₈₉ IL-7 is mediated through the IL-7 receptor binding domain portion of the fusion protein. Using an ADP ribosyltransferase defective mutant, DA(E149S)B₃₈₉ IL-7, we demonstrate that the inhibition of protein synthesis in intoxicated cells is due to the ADP ribosylation of elongation factor 2 in target cells. Finally, since DA(E149S)B₃₈₉ IL-7 stimulates the proliferation of 2E8 cells, an IL-7-dependent cell line, we conclude that the initial events following binding of these fusion proteins to the IL-7 receptor result in signal transduction and stimulation of protein synthesis.

EXPERIMENTAL PROCEDURES

Cell Lines and Culture Conditions. Since human IL-7 interacts with the murine IL-7 receptor the murine, IL-7-dependent, immature B lymphocyte cell line 2E8 was used to test the cytotoxicity of the IL-7 receptor-directed fusion toxin, DAB₃₈₉ IL-7. The cells were seeded in 75 cm² flasks at a density of 5×10^5 cells/mL. The cells were maintained in Isocove's modified Dulbecco's medium, supplemented with 0.05 mM 2-mercaptoethanol, 2 mM glutamine, 50 IU/mL penicillin, 50 µg/mL streptomycin, 5 ng/mL IL-7, and 5% fetal bovine serum (Pietrangeli et al., 1988). The 2E8 cells grew in grape-like clusters and were harvested and plated at 5×10^5 cells/mL every 2–3 days. The human T cell leukemia HUT 102/6TG cells, which do not express IL-7 receptors, were tested as a control cell line and were maintained in RPMI 1640 medium supplemented with 2 mM glutamine, 50 IU/mL penicillin, 50 µg/mL streptomycin, and 10% fetal bovine serum.

Bacterial Strains. The JM101 strain (BRL) of *Escherichia coli* was used for plasmid propagation. The HMS174(DE3)pLysS strain of *E. coli* was the host used for expression of chimeric *tox* gene products. The structural genes encoding the fusion protein toxins were cloned downstream of the T7 promoter in derivatives of the expression plasmid pET11d.

Plasmids and Fusion Toxin Products. The plasmids and the fusion protein toxins they encode are listed in Table 1. The parental plasmid encoding DAB₃₈₉ IL-2 was pJV127 (vanderSpek et al., 1993). The gene encod-

ing human IL-7 was excised from pES5 (Cosenza et al., 1997) with the restriction endonucleases *Sph*I and *Hin*dIII and vectorially cloned into the *Sph*I and *Hin*dIII sites of pJV127 to construct plasmid pESDT-IL-7(E149S). The gene encoding DAB₃₈₉ IL-7 was then recloned into *Nco*I and *Hin*dIII sites of pET11d vector construct pETDT-IL-7.

The plasmid encoding DA(E149S)B₃₈₉ IL-7 was created by an *Nco*I to *Nsi*I exchange of the gene encoding the defective C domain from pDA(E149S)B₃₈₉ IL-2 into pESDT-IL-7 to construct pDA(E149S)B₃₈₉ IL-7. The gene encoding DA(E149S)B₃₈₉ IL-7 was then recloned into the pET11d vector to form pETDT-IL-7 E149S for high-level expression.

Expression and Purification of DAB₃₈₉ IL-7 and DA(E149S)B₃₈₉ IL-7. To express the fusion toxin DAB₃₈₉ IL-7, plasmid pETDT-IL-7 was transformed into the *E. coli* host HMS174(DE3)pLysS. This bacterial host carries the pLysS plasmid which encodes the T7 polymerase gene which is under the control of LacI, and therefore can be induced with isopropyl-thiogalactoside (IPTG). A 6 mL volume of LB/Amp/Cm [LB medium containing 100 µg/mL ampicillin (Amp) and 25 µg/mL chloramphenicol (Cm)] was inoculated with a single colony of HMS174-(DE3)pLysS carrying the desired plasmid and incubated overnight with shaking at 37 °C. The following day, 5 mL of the overnight culture was used to inoculate 1 L of LB/Amp/Cm. The culture was incubated at 37 °C, with shaking, until the A₆₀₀ was 0.7, and fusion protein toxin expression was then induced by the addition of IPTG to a final concentration of 0.4 mM. Two hours after induction, another 1.5 mL aliquot was taken and the bacteria were harvested by centrifugation. The bacterial pellet was frozen at –20 °C overnight. Fusion proteins expressed in this system accumulated as inclusion bodies in recombinant *E. coli*. The pellet from the 1 L expression was resuspended in 20 mL of STET buffer [50 mM Tris-HCl (pH 8.0), 8% glucose, 10 mM EDTA, and 5% Triton X-100]. The bacteria were lysed by pulsed sonication for 4 min on ice (Branson Cell Disruptor, dial 6, 40% duty cycle). The lysate was pelleted by centrifugation at 10500g for 30 min at 4° C. The inclusion body pellet was resuspended in 10 mL of STET buffer, sonicated, and washed twice in STET buffer as described. The final inclusion body pellet was resuspended in 5 mL of denaturation buffer [50 mM Tris-HCl (pH 8.0), 5 M guanidine hydrochloride, and 5 mM EDTA], and dithiothreitol (DTT) was added to a final concentration of 6 mM. The suspension was then sonicated and placed on ice for 1 h. The denatured protein was dialyzed against 2 L of refolding buffer [0.05 M glycine, 0.03 M NaOH (pH 10), and 1 mM DTT] and the mixture stirred gently at room temperature overnight to renature the proteins. The fusion protein preparation was then exhaustively dialyzed against 2 L of PBS [10 mM phosphate buffer, 2.7 mM KCl, and 137 mM NaCl (pH 7.4)] and centrifuged at 2000g for 10 min to remove any precipitate. The protein concentration in the supernatant fluid was determined by a Bradford assay, and the fusion protein toxins were stored in aliquots at –20 °C.

SDS-PAGE and Immunoblot Analyses. SDS-PAGE was performed according to the method of Laemmli (1970) using 12% polyacrylamide and 0.1% SDS. Following electrophoresis, gels were fixed in 12.5% trichloroacetic acid (TCA) for 5 min and stained with Coomassie brilliant blue.

Immunoblot analysis was carried out essentially as described by Towbin et al. (1979). Following electrophoresis, proteins were transferred to poly(vinylidene

difluoride) (PVDF) membrane and incubated in blocking buffer B [10 mM Tris-HCl (pH 7.5), 150 mM NaCl, and 0.1% Brij 58] for 1 h at room temperature. The membrane was then incubated with primary antibody: either polyclonal anti-DT antibody (1:500 dilution) or monoclonal anti-IL-7 antibody (1:1,000 dilution) for 30 min at room temperature in TNB buffer [10 mM Tris, 500 mM NaCl, and 0.1% Brij 58 (pH 7.4)]. Following incubation with the primary antibody, the appropriate secondary horseradish peroxidase-labeled (hrp) antibody was applied for another 30 min at room temperature in TNB buffer. The immunoblots were then rinsed with TNB buffer and developed by the addition of 0.5 mg/mL 3',3'-diaminobenzidine tetrahydrochloride in PBS and 5 mL of 33% H₂O₂.

Cytotoxicity Assays and Neutralization Experiments. Since the DT-based fusion proteins inhibit protein synthesis by the ADP ribosylation of elongation factor 2 (EF2), inhibition of [¹⁴C]leucine uptake was used to measure cytotoxicity. For cytotoxicity assays, 1×10^5 2E8 cells in 100 μ L of complete medium were seeded in 96-well plates. The fusion protein toxins were diluted so that the addition of 100 μ L volumes resulted in final concentrations of fusion toxin ranging from 10^{-8} to 10^{-12} M. For the neutralization experiments, 2E8 cells were also incubated with concentrations of fusion toxins ranging from 10^{-8} to 10^{-12} M and 1000 ng/mL monoclonal anti-IL-7 antibody was also added to each well. After an 18 h incubation at 37 °C in a 5% CO₂ atmosphere, the plates were centrifuged at 170g for 5 min. The medium was carefully aspirated and replaced with 200 μ L of leucine-free minimal essential medium containing 1 μ Ci/mL [¹⁴C]leucine (specific activity of >280 mCi/mmol), 2 mM L-glutamine, 50 μ g/mL streptomycin, and 50 IU/mL penicillin. The cell cultures were incubated at 37 °C for 2 h and then centrifuged at 170g for 5 min. The medium was carefully removed, and the cells were lysed by the addition of 0.4 M KOH (60 μ L/well) and incubated at room temperature for 10 min. Total protein was then precipitated by the addition of 160 μ L/well TCA. The insoluble material was collected on glass fiber filters using a cell harvester, and radioactivity was determined according to standard methods. Medium alone served as the control, and all assays were performed in quadruplicate.

Elongation Factor 2 (EF-2) ADP Ribosylation Assay. To demonstrate that the inhibition of protein synthesis, due to ADP ribosylation of EF-2, resulted from C domain activity, the levels of NAD incorporation were determined on cell-free EF-2 extracts. An EF-2-containing extract was prepared from wheat germ and stored in aliquots at -70 °C (Seal et al., 1972; Marcus et al., 1974). An assay cocktail was freshly prepared containing 5 μ Ci/mL [³²P]NAD (specific activity of 800 mCi/mmol), 2 μ M cold NAD, 40 mM DTT, and a 1:5 dilution of the EF-2 extract in TE buffer. Dilutions of the samples to be assayed were made in TE and added in 10 mL aliquots to a 96-well plate. Fifty microliters of the assay cocktail was added to each well. After gentle agitation, the plate was incubated at room temperature for 15 min, after which time the reaction was stopped by the addition of 200 μ L of 10% TCA. The precipitates were transferred to glass fiber disks. The disks were washed three times in 10% TCA and counted by liquid scintillation counting. Results were reported as the -fold increase in [³²P]NAD incorporation over the control. Assays were performed in triplicate.

To study the effects of DA(E149S)B₃₈₉ IL-7 stimulation on the level of EF-2 available for ADP ribosylation

following toxin exposure, the level of EF-2 was determined essentially as described by Moynihan and Pappenheimer (1981). The 2E8 cell line was seeded in 24-well plates at a concentration of 5×10^5 cells/well in 1 mL of medium. Wild-type DAB₃₈₉ IL-7 or the mutant DA(E149S)B₃₈₉ IL-7 toxin was added to the wells in 100 μ L of medium to yield final concentrations ranging from 10^{-8} to 10^{-13} M. After a 24 h incubation period, the cell suspension was transferred to microcentrifuge tubes and centrifuged for 4 min. The cell pellets were lysed in 20 μ L of assay buffer [10 mM Tris-HCl, 10 mM NaCl, 3 mM MgCl₂, 10 mM thymidine, 1 mM EGTA, and 1% Triton X-100 (pH 8.0)] and assayed for the level of EF-2 available for ADP ribosylation by the addition of purified CRM45 to 2 μ g/mL and [³²P]NAD (800 mCi/mmol) to 15 μ Ci/mL. After 10 min at 40 °C, the ADP-ribosyltransferase reaction was stopped by the addition of 5% TCA. The precipitated protein was then collected on glass fiber disks and treated as outlined above. The levels of EF-2 available for ADP ribosylation in toxin-treated cells are presented as the percentage of radiolabel incorporated when compared to that incorporated by untreated controls.

RESULTS

The cloning strategy used in the construction of DAB₃₈₉ IL-7 is shown in Figure 1A. A scheme representing the gene encoding DAB₃₈₉ IL-7 is shown in Figure 1B. The structural gene encoding the ADP-ribosyltransferase defective fusion protein DA(E149S)B₃₈₉ IL-7 was constructed by an *Nco*I-*Sph*I DNA fragment exchange from pDA(E149S)B₃₈₉ IL-2 into pESDT-IL-7 to form pDA(E149S)B₃₈₉ IL-7. The allele encoding the C domain in this mutant contains a Glu to Ser substitution at position 149 of the fusion toxin that inactivates the ADP-ribosyltransferase activity of the C domain (Killeen et al., 1992).

DAB₃₈₉ IL-7 was expressed in *E. coli*, HMS174(DE3)-plysS(pETDT-IL-7) as outlined in Experimental Procedures. Crude cell extracts containing DAB₃₈₉ IL-7 were analyzed on Coomassie blue-stained 12% SDS-polyacrylamide gels prior to and 2 h after IPTG induction (Figure 2A, lanes 2 and 3). It is evident that 2 h after induction there was expression of a recombinant protein with an *M_r* of approximately 60 kDa. This value is in excellent agreement with the molecular weight of 58 428 deduced from the nucleotide base sequence of the structural gene encoding DAB₃₈₉ IL-7. The cells were then lysed, and the inclusion bodies were pelleted by centrifugation, washed with STET buffer, and then solubilized and denatured in 5 M guanidine buffer (Figure 2A, lanes 4-6). Following refolding, the recombinant protein-purified inclusion body preparation is the major protein species (Figure 2, lane 7). To demonstrate that the *M_r* 60 kDa protein was the recombinant DAB₃₈₉ IL-7, proteins were analyzed by immunoblot using anti-DT and anti-IL-7 antibodies. As shown in Figure 2B, the *M_r* 60 kDa fusion protein was found to retain immunological determinants intrinsic to the DT-related component. The protein was also immunoreactive with anti-IL-7 antibodies (data not shown). Following the expression and purification of DA(E149S)B₃₈₉ IL-7, immunoblot analysis demonstrated that this recombinant protein was also immunoreactive with both anti-DT and anti-IL-7 antibodies (data not shown). In both instances, immunoblot analyses also revealed the presence of a 120 kDa dimeric species of the fusion protein as well as proteolytic degradation. The Coomassie-stained gel is more indica-

Figure 1. Cloning strategy employed to generate a DAB₃₈₉ IL-7 expression plasmid. (A) The structural gene encoding IL-7 was excised from pES5 by *Sph*I and *Hind*III digestion and cloned into pJV127, replacing the IL-2 structural gene. (B) Scheme representing the gene encoding DAB₃₈₉ IL-7. The restriction sites used for cloning are shown, and the arrow indicates the position of the Glu to Ser mutation in the C domain that is present in the nontoxic form of the fusion toxin, DA(E149S)-B₃₈₉ IL-7.

tive of the amounts of each species present however and indicates that the 60 kDa, full-length protein is the major product.

Figure 3 shows the dose-response analysis of DAB₃₈₉ IL-7 on the IL-7 receptor positive 2E8 cell line. DAB₃₈₉ IL-7 was found to have an IC₅₀ of 1×10^{-10} M on these cells. In marked contrast, DAB₃₈₉ IL-7 was not cytotoxic to the IL-7 receptor negative cell line, HUT 102/6TG. To demonstrate that the cytotoxic action of DAB₃₈₉ IL-7 on 2E8 cells was not due to receptor blockade, we constructed, expressed, purified, and tested the ADP-ribosyltransferase defective mutant DA(E149S)B₃₈₉ IL-7 on these cells. As shown, DA(E149S)B₃₈₉ IL-7 was not cytotoxic to 2E8 cells at concentrations of up to 1×10^{-9} M. Since at this concentration DAB(E149S)B₃₈₉ IL-7 stimulated protein synthesis in 2E8 cells by 2-fold compared to the control, we conclude that these fusion proteins bind to the IL-7 receptor and effect signal transduction (Figure 3).

To show that the cytotoxic effect of DAB₃₈₉ IL-7 was mediated through its IL-7 receptor binding domain, 2E8 cells were incubated with 10^{-8} – 10^{-12} M DAB₃₈₉ IL-7, in the presence and absence of 1000 ng/mL polyclonal anti-IL-7 antibody. Approximately 90% of the cytotoxic activity, at the highest concentration of DAB₃₈₉ IL-7 tested (10^{-8} M), was neutralized upon the addition of the anti-

IL-7 antibody. The presence of excess IL-7 was also found to block the cytotoxic effect of DAB₃₈₉ IL-7 in vitro (Figure 3).

We next demonstrated that the inhibition of protein synthesis in IL-7 receptor-bearing 2E8 cells treated with DAB₃₈₉ IL-7 was the result of the delivery of the C domain to the target cell cytosol. The levels of NAD incorporation on cell-free EF-2 extracts by DAB₃₈₉ IL-7 and DA(E149S)-B₃₈₉ IL-7 were determined as described in Experimental Procedures. DAB₃₈₉ IL-7 catalyzed [³²P]NAD incorporation 14-fold greater than did the control. In marked contrast, DA(E149S)B₃₈₉ IL-7 only catalyzed incorporation by 2-fold (Table 2).

To demonstrate the stimulatory effect of DA(E149S)-B₃₈₉ IL-2, 2E8 cells were incubated without fusion toxin, in the presence of 10^{-8} M DAB₃₈₉ IL-7 or in the presence of 10^{-8} M DA(E149S)B₃₈₉ IL-7 for 24 h. Cells were then lysed, and their respective levels of EF-2 available for ADP ribosylation were determined. Following incubation with DAB₃₈₉ IL-7, the level of EF-2 available for ADP ribosylation was 16% of the control, whereas following a 24 h incubation in the presence of DA(E149S)B₃₈₉ IL-7, the level of EF-2 was 135% of the control (Table 3). This observation further demonstrates that binding of the fusion protein toxins to the IL-7 receptor on 2E8 cells results in signal transduction and the stimulation of cell growth.

DISCUSSION

This work describes the genetic construction, expression, purification, and biological activities of two IL-7 diphtheria toxin-related fusion proteins: DAB₃₈₉ IL-7, a chimeric protein composed of the catalytic and transmembrane domains of DT fused to interleukin 7, and DA(E149S)B₃₈₉ IL-7, a nontoxic ADP-ribosylase-defective mutant of DAB₃₈₉ IL-7.

Following IPTG-induced expression and inclusion body purification of DAB₃₈₉ IL-7, SDS-PAGE analysis identified a major protein with an approximate molecular mass of 60 kDa which is in excellent agreement with the calculated molecular weight of 58 428 of the fusion protein toxin. Both DAB₃₈₉ IL-7 and DA(E149S)B₃₈₉ IL-7 were immunoreactive with anti-DT and anti-IL-7 antibodies.

The cytotoxic potency of DAB₃₈₉ IL-7 was determined using the IL-7-dependent murine pre-B cell line, 2E8, and the IL-7 receptor negative, human T-leukemic cell line, HUT102/6TG. As anticipated, this fusion protein toxin was selectively active against the 2E8 cells, which express the cell surface target receptor, but not the HUT102/6TG cells. Moreover, since the addition of either recombinant IL-7 or polyclonal anti-IL-7 antibody to the 2E8 cell assay mixture blocked the action of DAB₃₈₉ IL-7, we conclude that cytotoxicity is mediated through the IL-7 receptor.

The ADP-ribosyltransferase defective mutant DA(E149S)B₃₈₉ IL-2 was constructed to investigate the role of the C domain of the fusion toxin in the intoxication process. While this mutant fusion protein toxin did not inhibit protein synthesis in 2E8 cells, we found that, at a concentration of 10^{-9} M, the fusion protein induced a 2-fold increase in protein synthesis. These results indicate that the IL-7 receptor binding domain of the fusion protein is folded in a biologically active conformation and, upon binding to the IL-7 receptor, effects signal transduction and stimulates cell proliferation. This finding is analogous to that observed by vanderSpek et al. (1995), who reported that exposure to DA(E149S)B₃₈₉ IL-15

Figure 2. SDS-PAGE and Western blot analyses of DAB₃₈₉ IL-7 expression and inclusion body purification. Protein samples were separated by electrophoresis on 12% SDS-PAGE gels under denaturing conditions and analyzed by Coomassie staining (A) and DT Western blot analyses (B): lane 1, molecular weight standards; lane 2, *E. coli* cell extract before induction; lane 3, *E. coli* cell extract 2 h after induction; lane 4, cell lysate suspension; lane 5, inclusion body preparation wash; lane 6, inclusion body preparation; and lane 7, inclusion body preparation after dialysis and refolding. Apparent molecular weights are given as $10^{-3}M_r$.

Figure 3. Dose-response analysis of IL-7 receptor positive and negative cell lines following exposure to DAB₃₈₉ IL-7. The inhibition of protein synthesis by DAB₃₈₉ IL-7 was measured by the incorporation of [¹⁴C]leucine. Data are plotted as the percentage of [¹⁴C]leucine incorporation compared to control cells treated with medium alone. The effect of DAB₃₈₉ IL-7 on IL-7 receptor positive 2E8 cells (●) and on IL-7 receptor negative HUT 102/6TG cells (○). The effect of DA(E149S)B₃₈₉ IL-7 on 2E8 cells (please notice the change in scale, ◇) and the effect of DAB₃₈₉ IL-7 on 2E8 cells in the presence of 1000 ng/mL polyclonal anti-IL-7 antibody (▲).

Table 2. ADP Ribosylation of EF-2 Extract by DAB₃₈₉ IL-7 and DA(E149S)B₃₈₉ IL-7

fusion protein	[³² P]NAD incorporation (cpm)
none	2242
DAB ₃₈₉ IL-7 (10^{-8} M)	31044
DA(E149S)B ₃₈₉ IL-7 (10^{-8} M)	4200

resulted in the induction of proliferation and activation of IL-15 receptor positive CTLL-2 cells in vitro. These results demonstrate that DAB₃₈₉ IL-7 exerts its lethal effect by virtue of the delivery of its C domain to the cytosol of target cells and, second, that the IL-7 receptor

Table 3. Murine 2E8 EF-2 Available for ADP Ribosylation Following a 24 h Exposure to DAB₃₈₉ IL-7 or DA(E149S)B₃₈₉ IL-7

fusion protein	EF-2 available for ADP ribosylation (percentage of control)
none	100
DAB ₃₈₉ IL-7 (10^{-8} M)	16
DA(E149S)B ₃₈₉ IL-7	135

binding domain of the fusion toxin is capable of binding and inducing the proliferation in the 2E8 cells.

The C domain of DAB₃₈₉ IL-7 was further proven to be catalytically active by the ADP ribosylation of EF-2. The level of [³²P]NAD incorporation in the ribosylation assay was 14-fold greater than that of the control. The DA(E149S)B₃₈₉ IL-7 C domain mutant was only 2-fold above that of the control. On the basis of the fact that DA(E149S)B₃₈₉ IL-7 did not inhibit protein synthesis, was not catalytically active in the ADP ribosylation assay, but caused the IL-7-dependent 2E8 cell line to proliferate, the amount of EF-2 available for ADP ribosylation after pretreatment with DAB₃₈₉ IL-7 and DA(E149S)B₃₈₉ IL-7 was evaluated. In DAB₃₈₉ IL-7-treated cells, only 16% of control levels of EF-2 was available for ADP ribosylation following a 24 h exposure. As anticipated, due to cell proliferation and stimulation of protein synthesis induced by exposure of 2E8 cells to DA(E149S)₃₈₉ IL-7, increased levels of EF-2 were available for ADP ribosylation in 2E8 cells treated with the mutant fusion protein.

While there has been considerable investigation of the biologic effects of IL-7, the mechanisms by which the IL-7 receptor transduces growth signals remain poorly understood. Goodwin et al. (1990) cloned cDNA encoding both a membrane-bound and a soluble form of the IL-7 receptor. Noguchi et al. (1993) later demonstrated that association of the interleukin 2 γ -chain with the IL-7 receptor resulted in better binding affinity and increased efficiency of IL-7 internalization. Binding of IL-7 to its receptor induces tyrosine kinase activity, activates phosphatidylinositol 3-kinase, and induces production of inositol 1,4,5-triphosphate (Roifman et al., 1992; Dibirdik et al., 1991; Uckun et al., 1991a,b; Dadi and Roifman, 1993; Dadi et al., 1993). IL-7 also induces activation of some Janus nonreceptor tyrosine kinases and *src* family kinases (Seckinger and Fougereau, 1994; Foxwell et al., 1995; Musso et al., 1995).

Due to the frequent expression of the IL-7 receptor on a variety of human leukemias and lymphomas (e.g., ALL, CLL, Sezary syndrome), DAB₃₈₉ IL-7 may serve as an experimental therapeutic agent for patients with IL-7 receptor-bearing hematopoietic neoplasms. Further studies on the cytotoxic activity of this fusion toxin against tumor cell lines and freshly isolated leukemic cells from such patients are needed to further define its role as a cancer therapeutic.

ACKNOWLEDGMENT

We thank Sabina Sweeney for help with preparation of the manuscript. This study was supported in part by Public Health Service Grant CA-48626 from the NCI, National Institutes of Health (to J.R.M.).

High-Affinity No-Carrier-Added ^{99m}Tc -Labeled Chemotactic Peptides for Studies of Inflammation in Vivo

Kwamena E. Baidoo,* Ursula Scheffel, Marigo Stathis, Paige Finley, Susan Z. Lever, Yougen Zhan, and Henry N. Wagner, Jr.

Division of Radiation Health Sciences, Department of Environmental Health Sciences, The Johns Hopkins University, 615 North Wolfe Street, Baltimore, Maryland 21205. Received November 13, 1997; Revised Manuscript Received January 15, 1998

N^{α} -for-Nle-Leu-Phe-Nle-Tyr-Lys, a chemotactic peptide that binds with high affinity to the chemoattractant receptor on granulocytes and monocytes, was labeled with ^{99m}Tc using the diaminedithiol (DADT) chelating system to coordinate the Tc. ^{99m}Tc labeling of the DADT-coupled peptide was accomplished in 84% overall yield (room temperature for 10 min) using [^{99m}Tc]glucoheptonate as the donor of prereduced Tc. HPLC analysis showed two major ^{99m}Tc -labeled peptide peaks, ^{99m}Tc -DADT-Pep-I and ^{99m}Tc -DADT-Pep-II, were obtained in a ratio of 1:0.85. Using an iodoacetamide-derivatized gel to remove unlabeled peptide from the ^{99m}Tc labeling mixtures, essentially no-carrier-added (nca) high-specific activity ^{99m}Tc -labeled chemotactic peptides were obtained. The ^{99m}Tc analogues of the peptides were synthesized (72% yield) in a similar fashion and correlated with ^{99m}Tc complexes I and II by HPLC. In vitro competitive receptor binding assays of the isolated ^{99m}Tc analogues were performed against the tritiated chemotactic peptide [^3H]N-for-Met-Leu-Phe ([^3H]fMLF) using isolated granulocytes. The ^{99m}Tc -derivatized peptides showed similar binding affinities to the chemoattractant receptor as the unlabeled N^{α} -for-Nle-Leu-Phe-Nle-Tyr-Lys. The nca ^{99m}Tc -labeled peptides gave high contrast images of experimental inflammation in rabbits without causing neutropenia. Thus, it is feasible to attach the Tc-DADT chelate to low-molecular weight receptor binding chemotactic peptides and retain substantial binding to the receptor. Chemotactic peptides labeled with ^{99m}Tc via the DADT ligand system have the potential for imaging focal sites of inflammation without toxic effects, an important consideration in the successful utilization of chemotactic peptide agonists.

INTRODUCTION

Over the past two decades, a number of radiotracers have been proposed or used for the detection of focal sites of inflammation or infection in vivo by scintigraphy. These include ^{67}Ga citrate (1), leukocytes labeled with ^{111}In (^{111}In -WBC) (2, 3) or ^{99m}Tc (^{99m}Tc -WBC) (4), ^{99m}Tc - or ^{123}I -labeled antibodies against granulocytes (5, 6), nonspecific IgG and its Fc fragment labeled with ^{99m}Tc or ^{111}In (7, 8), and ^{99m}Tc -nanocolloid (9). Among these agents, the gold standard for imaging inflammation or infection in vivo has been autologous leukocytes labeled in vitro with ^{111}In (^{111}In -WBC). Inadequacies of the various techniques especially with respect to applicability in emergency situations and ease of preparation have spurred a search for the ideal radiopharmaceutical for imaging inflammation.

The labeling of leukocytes in vitro is cumbersome and requires very mild conditions and experienced personnel to avoid inactivating the cells. Radiopharmaceuticals that are systemically injected directly into patients for imaging focal sites of infection without the need for in vitro labeling of autologous leukocytes are more advantageous as has been demonstrated in humans using the labeled antibodies against granulocytes (5, 6). Chemotactic peptides (10) are another class of compounds that

have the potential to generate radiopharmaceuticals that could be used in a similar fashion by systemic injection. These are small oligopeptides that bind with high affinity to high-density chemoattractant receptor sites on granulocytes and monocytes (11, 12). The pharmacokinetics of small peptides would allow labeled chemotactic peptides to be used even in acute cases where the answer to the clinical question is needed under 1 h, a time frame in which current clinically available scintigraphic agents are not very effective. For these reasons, a great deal of attention has recently been focused on labeled chemotactic peptides (13–17).

The use of these important peptides for imaging applications has been tempered by their highly potent neutropenic nature (18). Successful utilization of labeled chemotactic peptides, therefore, necessitates the availability of very high-specific activity formulations. To achieve high specific activity, the radionuclide used must have a relatively short half-life and must be available with little or no carrier. Of desirable radionuclides utilized for scintigraphy in vivo, ^{99m}Tc , with its 6.02 h half-life and availability in no-carrier-added (nca) form from the $^{99}\text{Mo}/^{99m}\text{Tc}$ generator, offers the potential to generate ^{99m}Tc -labeled chemotactic peptides having the required specific activity for use in imaging without accompanying neutropenia. Previous efforts to generate high-specific activity ^{99m}Tc -labeled chemotactic peptides have involved a combination of utilizing low concentrations of peptide for synthesis, elution of the generator at the time of highest specific activity, and/or the use of HPLC to separate labeled from unlabeled ligand (14).

Scheme 1. Synthesis of the ^{99m}Tc-Labeled Chemotactic Peptides

These methods suffer from low labeling yields and cumbersome methodology that limits the availability of the radiopharmaceuticals for general use.

Previously, we reported the synthesis of a bifunctional chelate **1** (Scheme 1), derived from the diaminedithiol ligand system, capable of forming highly stable complexes with Tc (19). In this paper, we have utilized this bifunctional chelate in the preparation of ^{99m}Tc-labeled chemotactic peptides derived from *N*^α-for-Nle-Leu-Phe-Nle-Tyr-Lys, a potent chemotactic peptide that binds with high affinity to granulocytes (20). We have explored the chemical differences between the diaminedithiol ligand and its ^{99m}Tc complex to develop a highly efficient solid-phase separation procedure for the preparation of high-affinity and high-specific activity technetium derivatives of this chemotactic peptide devoid of contaminating unlabeled peptide, the usual culprit of low-specific activity ^{99m}Tc preparations. The results of our initial evaluation of this solid-phase technology were recently reported (21).

MATERIALS AND METHODS

Solvents and chemicals were reagent grade and used as received from the Aldrich Chemical Co. (Milwaukee, WI) unless specified. [^{99m}Tc]NH₄TcO₄ and [³H]-for-Met-Leu-Phe were purchased from NEN Life Science Products

(Boston, MA). [^{99m}Tc]Pertechnetate was purchased as a physiologic saline solution from Syncor (Timonium, MD). The Glucoscan kit was purchased from the Du Pont Radiopharmaceutical Division (Billerica, MA). Ultralink iodoacetamide gel was purchased from Pierce (Rockford, IL). Histopaque 1077, Histopaque 1119, *N*^α-for-Nle-Leu-Phe-Nle-Tyr-Lys, and *N*^α-for-Met-Leu-Phe were purchased from the Sigma Chemical Co. (St. Louis, MO). Male CD-1 mice and female New Zealand white rabbits were purchased from the Charles River Laboratories (Charles River, MA). Animal studies were performed according to a protocol approved by our institutional Animal Care and Use Committee.

HPLC was performed on either a Perkin-Elmer Series 2 instrument equipped with an LC-75 UV/visible detector or a Waters Chromatography Division system with two model 510EF pumps and an automated gradient controller model 680 equipped with a model 490 UV absorbance detector, an EG&G NaI scintillation detector, and a Hewlett-Packard HP 3392A or Shimadzu CR3A integrating recorder. [^{99m}Tc]Glucoheptonate and the diaminedithiol bifunctional chelating agent (BCA), **1**, were synthesized according to published procedures (19, 22). Infrared spectroscopic determinations of neat liquids or KBr pellets were performed on a Perkin-Elmer 399B or Nicolet 205 FTIR system. ¹H NMR spectra were recorded

in deuteriochloroform solution using a Bruker WM 300 MHz spectrometer. Elemental analyses were performed by Atlantic Microlabs (Norcross, GA). High-resolution MALDI mass spectral analyses were performed at the University of Minnesota Mass Spectrometry Laboratory (Minneapolis, MN) or Quality Controlled Biochemicals (Hopkington, MA). Amino acid analyses were performed at Quality Controlled Biochemicals or the Johns Hopkins School of Medicine Peptide Synthesis Laboratory (Baltimore, MD). Filtrations of in vitro binding assay mixtures were performed on a BRANDEL, 48M Harvester. Liquid scintillation counting was performed on an LKB Wallac instrument model 1219 Rackbeta using Ecolume (ICN Pharmaceuticals, Inc., Costa Mesa, CA) as a cocktail. The ^3H channel was corrected for $^{99\text{m}}\text{Tc}$ spillover. Leukocytes were counted with a hemacytometer from the American Optical Co. (Buffalo, NY). $^{99\text{m}}\text{Tc}$ activity was measured in a Capintec CRC-7 Dose Calibrator or an automated γ -counter (Pharmacia-Wallac model 1282). Planar scintigraphic imaging was performed with a Technicare Omega 500 single-headed SPECT system interfaced with a GE Starcam II computer.

EXPERIMENTAL PROCEDURES

Synthesis of N^α -for-Nle-Leu-Phe-Nle-Tyr-Lys(N^ϵ -DADT) (DADT-Pep). Coupling of the diaminedithiol ligand to N^α -for-Nle-Leu-Phe-Nle-Tyr-Lys was performed according to Scheme 1. A solution of N^α -for-Nle-Leu-Phe-Nle-Tyr-Lys (24 mg, 29 μmol) in THF/ H_2O (2:1 v/v, 3 mL) was adjusted to pH 9 with NaOH(aq) (70 μL , 1 M) followed by the addition of a solution of the thiolactone bifunctional chelate **1** (19) (44 mg, 145 μmol) in THF (0.5 mL). The solution was stirred at room temperature for 3 h. Solvents were removed by distillation under reduced pressure, and the solid residue was triturated with ether (4×20 mL). The crude product was purified by reversed-phase HPLC [C-18 Novapak column, 25×100 mm, 6 μm , Waters Chromatography Division; with a linear gradient from 10% solvent A (0.1% TFA in acetonitrile)/90% solvent B (0.1% TFA in water) to 90% solvent A/10% solvent B over the course of 40 min; flow rate of 6 mL/min, monitored on-line by UV at 220 nm]. The product eluting with a 31 min retention time was collected and lyophilized. High-resolution MALDI MS: calcd MW of 1127.65, found $[\text{M} + \text{H}]^+$ 1128.63. Amino acid analysis: found (expected) Nle, 2.02 (2); Leu, 0.96 (1); Phe, 1.04 (1); Tyr, 0.95 (1); Lys, 0.96 (1).

$^{99\text{m}}\text{Tc}$ Labeling of N^α -for-Nle-Leu-Phe-Nle-Tyr-Lys(N^ϵ -DADT). N^α -for-Nle-Leu-Phe-Nle-Tyr-Lys(N^ϵ -DADT) was labeled with $^{99\text{m}}\text{Tc}$ using [$^{99\text{m}}\text{Tc}$]glucoheptonate as the donor of prereduced $^{99\text{m}}\text{Tc}$ according to Scheme 1. Water (1.0 mL) was used to dissolve the contents of a glucoheptonate kit (Glucoscan). An aliquot of this solution (200 μL) was added to a [$^{99\text{m}}\text{Tc}$]pertechnetate solution (300 μL , 20 mCi) and vortexed for 1 min. The resulting [$^{99\text{m}}\text{Tc}$]glucoheptonate solution was added to a solution of N^α -for-Nle-Leu-Phe-Nle-Tyr-Lys(N^ϵ -DADT) (1.2 mg, 1.1 μmol) in THF/ H_2O (5:1 v/v, 0.6 mL), vortexed for 1 min, and then incubated at room temperature for 10 min. The reactions were followed by reversed-phase HPLC [C-18 Novapak column (8×100 mm, 4 μm , Waters Chromatography Division); 48% solvent A/52% solvent B for 20 min followed by a linear gradient to 70% solvent A/30% solvent B over the course of 15 min; flow rate of 4 mL/min, monitored on-line by UV at 220 nm and scintillation for radioactivity]. As shown in Figure 1A, two major $^{99\text{m}}\text{Tc}$ -labeled peptide peaks ($^{99\text{m}}\text{Tc}$ -DADT-Pep-I and $^{99\text{m}}\text{Tc}$ -DADT-Pep-II) were obtained in a ratio (I:II)

Figure 1. HPLC traces of the crude $^{99\text{m}}\text{Tc}$ labeling reaction mixture of BCA **1** coupled chemotactic peptide after incubation for 10 min (A) and after iodoacetamide gel treatment (B).

of 1:0.85. The total radiochemical yield of $^{99\text{m}}\text{Tc}$ -labeled peptide peaks I and II was 84%.

Unlabeled adduct was removed from the $^{99\text{m}}\text{Tc}$ labeling mixture according to Scheme 2. Two milliliters of iodoacetamide-derivatized gel (Ultralink iodoacetamide) was equilibrated in Tris buffer (50 mM, pH 8.5) containing 5 mM EDTA. Acetonitrile (1 mL) was added to the equilibrated gel followed by the crude labeling mixture (1 mL) containing N^α -for-Nle-Leu-Phe-Nle-Tyr-Lys(N^ϵ -DADT) (1 μmol) and the $^{99\text{m}}\text{Tc}$ -labeled peptides and the mixture incubated at room temperature for 30 min. The mixture was filtered. The gel was washed with an acetonitrile/saline mixture (3 $\times$ 2 mL, 20:80). The filtrate was concentrated into 0.4 mL of ethanol by solid-phase extraction using a Waters C-18 Sep-Pak cartridge (Waters Chromatography Division). The presence of thiol-containing compounds in the filtrate, crude reaction mixture before gel treatment, and HPLC-purified products were assayed by Ellman's method (23) using 2,2,4,9,9-pentamethyl-4,7-diaza-1,10-decanedithiol (**24**) as a standard to quantitate the thiols.

Synthesis of N^α -for-Nle-Leu-Phe-Nle-Tyr-Lys(N^ϵ - $^{99\text{m}}\text{Tc}$ -DADT). A solution of [$^{99\text{m}}\text{Tc}$]glucoheptonate (**22**) in water (1 mL, 10 μmol) was added to the purified N^α -for-Nle-Leu-Phe-Nle-Tyr-Lys(N^ϵ -DADT) (11.3 mg, 10 μmol) dissolved in THF/ H_2O (2:1 v/v, 1 mL). The mixture was stirred at room temperature for 30 min. The two major components formed, $^{99\text{m}}\text{Tc}$ -DADT-Pep-I and $^{99\text{m}}\text{Tc}$ -DADT-Pep-II, were purified by HPLC [C-18 Novapak column

Scheme 2. Solid-Phase Purification of ^{99m}Tc -Diaminedithiolate Complexes

(8 × 100 mm, 4 μm); 48% solvent A/52% solvent B for 20 min followed by a linear gradient to 70% solvent A/30% solvent B over the course of 15 min; flow rate of 4 mL/min, monitored on-line by UV at 220 nm].

High-resolution MALDI MS: calcd MW for ^{99m}Tc -DADT-Pep-I 1239.62, found $[\text{M} + \text{Na}]^+$ 1262.52. Amino acid analysis: found (expected) Nle, 1.96 (2); Leu, 0.98 (1); Phe, 1.05 (1); Tyr, 0.97 (1); Lys, 0.92 (1).

High-resolution MALDI MS: calcd MW for ^{99m}Tc -DADT-Pep-II 1239.62, found $[\text{M} + \text{Na}]^+$ 1262.51. Amino acid analysis: found (expected) Nle, 1.89 (2); Leu, 0.97 (1); Phe, 0.98 (1); Tyr, 0.94 (1); Lys, 0.97 (1).

^{99m}Tc Labeling of the Hydrolyzed Bifunctional Chelate (^{99m}Tc -DADT). NaOH (0.5 M, 250 μL) was added to a solution of **1** (5 mg, 16 μmol) in acetonitrile (250 μL) and the mixture incubated for 5 min at room temperature. The pH of the mixture was adjusted to 6 with HCl(aq) (100 μL , 1.0 M) followed by a solution of [^{99m}Tc]glucoheptonate (7 mCi, 1.5 mL). The resulting mixture was incubated at room temperature for 10 min. The reaction was monitored by reversed-phase HPLC [C-18 Novapak column (8 × 100 mm, 4 μm); linear gradient from 0% solvent A/100% solvent B to 60% solvent A/40% solvent B over the course of 30 min; flow rate of 2 mL/min, monitored on-line by UV at 254 nm and scintillation for radioactivity]. As shown in Figure 3, two main products with retention times of 22.1 and 26.2 min were obtained in a ratio of 1:3.1 and a total yield of 91%. For the *in vivo* studies, the two ^{99m}Tc -labeled peaks (^{99m}Tc -DADT) collected from HPLC purification were combined. The products were extracted from the HPLC eluate by solid-phase extraction procedures into ethanol, and the ethanol solution was diluted to 2% ethanol with saline for injection.

In Vitro Binding Assay. The binding assay was conducted according to an adaptation of the methods of Williams et al. (11) and Nidel et al. (20). Aliquots of human blood (15 mL) were gently layered over Histopaque 1077 (15 mL) underlayered with Histopaque 1119

Figure 2. Analytical chromatograph of the HPLC-purified ^{99m}Tc -labeled peptides.

Figure 3. HPLC chromatograph of the crude ^{99m}Tc labeling reaction mixture of the hydrolyzed BCA **1** (^{99m}Tc -DADT) after incubation for 10 min.

(15 mL). The mixture was then centrifuged at 700g for 30 min. Granulocyte cells at the Histopaque 1077–1119 interface were collected and washed twice in the incubation buffer [10 mM phosphate (pH 7.2) containing 117 mM NaCl, 0.15 mM CaCl₂, and 0.5 mM MgCl₂] by centrifugation at 200g for 10 min. The final pellet was suspended in incubation buffer at a concentration of 2×10^7 cells/mL. The incubation mixture consisted of 6 nM [^3H]N $^{\alpha}$ -for-Met-Leu-Phe, 1.5×10^5 cells, in the presence or absence of 0.01–600 nM N $^{\alpha}$ -for-Nle-Leu-Phe-Nle-Tyr-Lys, ^{99m}Tc -DADT-Pep-I, or ^{99m}Tc -DADT-Pep-II in a total volume of 150 μL . The mixture was incubated at 37 $^{\circ}\text{C}$ for 15 min. Nonspecific binding was ascertained using 10 μM unlabeled N $^{\alpha}$ -for-Met-Leu-Phe. After incubation, the mixture was filtered through GF/B filters presoaked with assay buffer using a BRANDEL manifold. The cells

were washed with ice cold buffer (3×5 mL) and the filters counted with a liquid scintillation counter. The results of the assay were analyzed with the EBDA/LIGAND computer programs (25).

Biodistribution of the ^{99m}Tc -Labeled Peptides in Normal Mice. For in vivo studies, the two major products from ^{99m}Tc labeling were separated by HPLC after gel treatment. Fractions containing ^{99m}Tc -DADT-Pep-I and ^{99m}Tc -DADT-Pep-II were collected. The labeled peptides were isolated into ethanol by solid-phase extraction procedures using a C-18 Sep-Pak cartridge. The ethanol solutions were reconstituted with saline. The final injectate contained 2% ethanol.

Male CD-1 mice (average weight, 22 g) were each injected via the tail vein with ^{99m}Tc -DADT-Pep-I or ^{99m}Tc -DADT-Pep-II ($2 \mu\text{Ci}$, 0.2 mL). At 5, 30, 60, and 120 min postinjection, five mice at each time point per tracer were euthanized by cervical dislocation and 0.1 mL of blood was collected. Major organs were dissected, weighed, and counted in an automated scintillation counter along with the blood collected, and aliquots of the injectate as standards.

Imaging of Experimental Inflammation in Rabbits. Twelve female New Zealand white rabbits (2.7–3.1 kg) were each injected in the right hind leg with 0.2 mL of turpentine. Forty-eight hours after the injection of the turpentine, the rabbits were sedated with a mixture of Ketaset (100 mg, 1.0 mL) and AceProm (5 mg, 0.5 mL). The rabbits were divided into four groups of three each. Each group was injected via the left ear vein with 1 mCi (1.5 mL) no-carrier-added ^{99m}Tc -DADT-Pep-I, ^{99m}Tc -DADT-Pep-II, $^{99m}\text{TcO}_4^-$, or ^{99m}Tc -DADT. At various time intervals up to 2 h postinjection, 0.5 mL of blood was drawn from the right ear vein. Aliquots (0.1 mL) of the blood were counted in the automated γ -scintillation counter and compared with aliquots of the injectate counted at the same time.

We obtained images of the rabbits carrying the experimental inflammation on a γ -scintillation camera. Planar lateral images of 500K counts were acquired 5, 30, 60, 180, and 360 min postinjection. The images were converted into the Image Program in Macintosh format for processing and analysis. Region of interest analyses were performed over the inflamed area compared to the contralateral thigh. The average counts per pixel per millicurie injected activity were calculated and corrected for decay with respect to the time of imaging after injection of tracer. The presence of inflammation was confirmed by euthanizing the rabbits and visually confirming the presence of pus in the inflamed area at the end of the studies.

Effect of the No-Carrier-Added ^{99m}Tc -DADT-Pep-I, ^{99m}Tc -DADT-Pep-II, and fMLF on the Leukocyte Count in Rabbits. Five minutes before the injection of ^{99m}Tc -DADT-Pep-I and ^{99m}Tc -DADT-Pep-II in the imaging studies above, 0.5 mL of blood was withdrawn via the right ear vein of the rabbits. Then at 5, 10, 15, 30, and 60 min postinjection, 0.5 mL of blood was withdrawn via the right ear vein. Another group of three rabbits were treated in a similar fashion except that they were injected via the left ear vein with 2 nmol of fMLF in 1.5 mL of saline containing 2% ethanol instead of the ^{99m}Tc -labeled tracers. Aliquots (0.1 mL) of the blood samples were diluted 5-fold with saline. A 0.1 mL aliquot of the saline-diluted blood sample was mixed with an equal volume of a 2% acetic acid solution, and the number of leukocytes per milliliter was determined by counting with a hemacytometer.

RESULTS AND DISCUSSION

Peptides are capable of coordinating technetium directly through side chain functional groups and the amide nitrogen atom. For small peptides, coordination of Tc this way especially at the binding site would inactivate the peptide. To prepare the Tc-derivatized peptides, the bifunctional chelate approach in which a strong chelating agent is used to carry the metal was used (26). Of chelating agents used in the bifunctional chelate approach for coordinating Tc, the diaminedithiol chelate (DADT) system offers an excellent combination of characteristics for application to peptides. The ligand forms one of the most stable complexes of the metal (27–30). The Tc complex cores are small, compact, well-defined, and characterized. The ligand system has been used for the stable and specific incorporation of ^{99m}Tc into proteins without utilizing the peptide bonds or other side chain coordinating groups of the protein (31).

Structure–activity studies of chemotactic peptides indicate that the active site is represented by the N^α -for-tripeptide sequence at the N terminus (11, 20, 32). We chose the chemotactic hexapeptide N^α -for-Nle-Leu-Phe-Nle-Tyr-Lys which binds with high affinity to granulocytes (20) for evaluation because this hexapeptide contains a terminal lysine residue at the carboxyl-terminal portion of the molecule not required for binding to the chemoattractant receptor that can be utilized for BCA coupling. During the course of this work, this peptide was also successfully labeled with ^{18}F (17), ^{111}In , and ^{99m}Tc using a diethylenetriaminepentaacetic acid dianhydride (13) and a hydrazinonicotinamide (14) as BCAs.

BCA **1** was synthesized as previously reported (19). Coupling of BCA **1** to the hexapeptide was accomplished at room temperature and pH 9 using a BCA:peptide mole ratio of 5 (Scheme 1). The reaction was followed by reversed-phase HPLC monitored by UV at 220 nm and was practically complete after incubation for 1 h. The crude product was purified by semipreparative HPLC to >95% purity in 53% isolated yield. The product was characterized by mass spectroscopy and amino acid analysis.

Figure 1A shows the chromatographic profile after incubation for 10 min from the labeling of the purified BCA **1** coupled peptide, N^α -for-Nle-Leu-Phe-Nle-Tyr-Lys(N^ϵ -DADT), with ^{99m}Tc using [^{99m}Tc]glucoheptonate as the donor of prereduced ^{99m}Tc . The HPLC chromatogram showed two major ^{99m}Tc -labeled peptide peaks (^{99m}Tc -DADT-Pep-I and ^{99m}Tc -DADT-Pep-II) in a ratio (I:II) of 1:0.85. The total yield of the ^{99m}Tc -labeled peptide peaks I and II was 84%. The formation of the two products is in agreement with the geometric isomerism (syn and anti forms) that can result from the complexation of technetium to nitrogen-substituted as well as carbon-substituted diaminedithiol ligands (33–35). It is also possible that the products are the result of differences in the way the peptide wraps around the chelate core.

The cause of the apparent low specific activity in labeled chemotactic peptides is the presence of unlabeled material in the labeling mixture which can also bind to the receptor. Current methods of achieving high specific activity for ^{99m}Tc -labeled chemotactic peptides include the use of low concentrations of unlabeled ligand coupled with the use of $^{99m}\text{TcO}_4^-$ eluted from the generator at the time of maximum specific activity and/or the application of HPLC to separate labeled from unlabeled conjugate (14, 36). The use of low concentrations of unlabeled ligand leads to low labeling yields as well as long reaction

Table 1. Results of the Ellman's Assay for the Determination of Thiol Groups

sample	peptide concentration (mM)
reaction mixture (before gel)	1.0
after gel treatment	not detectable ^a
HPLC purification	not detectable ^a

^a Minimum detection limit = 0.25 nmol.

times (the result of bimolecular reaction kinetics) and still does not produce formulations of high enough specific activity. While HPLC can potentially produce no-carrier-added formulations, the methodology is not available at the community hospital radiopharmacy level and therefore limits widespread utility. Furthermore, when high concentrations of ligand are used in order to boost labeling yield and shorten reaction time, unlabeled ligand can sometimes contaminate the labeled product peak due to insufficient separation, overloading, or tailing of the ligand peak.

Use of the DADT ligand for coordinating Tc presents a unique opportunity for chemical removal of the unlabeled conjugate. When DADT ligands form complexes with Tc, the two thiol groups participate in bond formation with the metal (Scheme 2). This allows the chemical removal of the unlabeled ligand from solution by use of an appropriately functionalized solid support (such as an iodoacetamide-derivatized gel) that reacts specifically and efficiently with free thiol groups, followed by filtration (21, 37). This simple but highly efficient procedure permits the preparation of the high-specific activity ^{99m}Tc formulations required for successful utilization of labeled chemotactic peptide agonists for imaging. Figure 1B shows the HPLC chromatogram of the gel-treated filtrate using the same HPLC conditions as depicted in Figure 1A. Compared to that in Figure 1A, the UV peak with a 10 min retention time associated with unlabeled DADT-peptide is not detectable, indicating complete removal of the unlabeled material from the gel. Table 1 shows the results of the Ellman's assay of thiol-containing compounds. There was no detectable thiol-containing peptide after gel treatment or HPLC purification, whereas the crude product showed a peptide concentration of 1 mM. These results show the powerful potential of this method to develop ^{99m}Tc -labeled chemotactic peptides in extremely high specific activity. Indeed, our initial evaluation of this procedure using model DADT compounds showed that >99.9% of the unlabeled ligand is removed after gel treatment (21). This takes into consideration a minimum detectable level of the DADT ligand by Ellman's assay of 0.25 nmol. The procedure is amenable to kit formulation since it requires no complex chromatographic procedure such as HPLC to obtain formulations of the requisite specific activity. Thus, the tracers can actually be prepared on demand from kits at community hospital radiopharmacies for use even in emergencies. We are currently developing a Sep-Pak procedure for removing the hydrophilic nonpeptide-associated UV active peaks that appear at the void volume in the chromatograph (Figure 1B) after gel treatment. The Sep-Pak procedure is fast and can be completed within 10 min. We are also investigating shorter incubation times for the iodoacetamide gel with the aim of completing the synthesis and separation procedures in <1 h.

In a recent report, Wu and co-workers (38) also reported the use of a *p*-chloromercuribenzoate gel to remove $\geq 98.3\%$ of the excess *N*¹-(2-mercapto-2-methylpropyl)-*N*²-(2-propargylthio-2-methylpropyl)-1,2-benzene-diamine (T691) after ^{99m}Tc labeling. These results sup-

**Figure 4.** Competitive binding of the ^{99m}Tc -labeled peptides versus [^3H]N-for-Met-Leu-Phe ([^3H]fMLF).

port the powerful potential of these solid-phase technologies for generating high-specific activity ^{99m}Tc radiopharmaceuticals.

To assess the receptor binding properties of the technetium-labeled peptides and to characterize the complexes conventionally, we synthesized the ^{99m}Tc analogues of the peptides (72% yield) by exchange from [^{99m}Tc]glucoheptonate. The products were characterized by amino acid analysis and high-resolution mass spectroscopy. To our knowledge, these are the first Tc derivatives of chemotactic peptides to be conventionally characterized. The ability to isolate and characterize these complexes is an advantage in toxicological studies in the FDA approval process. Previously reported Tc-derivatized chemotactic peptides did not report characterization of the Tc species (13–16). We performed in vitro competitive receptor binding assays using the isolated ^{99m}Tc analogues against the tritiated authentic chemotactic peptide [^3H]N-for-Met-Leu-Phe (fMLF) using human granulocytes according to published procedures (11, 20). Figure 4 shows that increasing concentrations of the technetium-labeled analogues efficiently inhibit the binding of the potent, authentic chemotactic peptide [^3H]fMLF, indicating competition for the same receptor. The results of the binding assays were analyzed by the EBDA/LIGAND computer program (25). As shown in Table 1, the inhibition constants, K_i , of the analogues were 13.7 ± 1.1 and 35.7 ± 9.3 nM for ^{99m}Tc -DADT-Pep-I and ^{99m}Tc -DADT-Pep-II, respectively. The unmodified peptide N^α-for-Nle-Leu-Phe-Nle-Tyr-Lys has a K_i of 21.3 ± 2.5 nM in the assay system. The ^{99m}Tc -labeled peptides therefore show comparable binding affinity to the potent chemotactic peptide N^α-for-Nle-Leu-Phe-Nle-Tyr-Lys from which they were derived. These binding experiments show that it is feasible to attach the Tc-DADT chelate to the low-molecular weight receptor binding chemotactic peptide and retain substantial binding to the receptor. The Tc chelate in these labeled peptides is sufficiently distant from the binding site so that it does not interfere with the interaction of the peptides with the receptor.

For the in vivo biological evaluation that follows, we separated the ^{99m}Tc -DADT-Pep-I and ^{99m}Tc -DADT-Pep-II by HPLC after gel treatment in order to study each product individually. ^{99m}Tc -DADT-Pep-I and ^{99m}Tc -DADT-Pep-II were each isolated to >95% radiochemical purity by HPLC. Figure 2 shows the analytical chromatograms of the HPLC-separated ^{99m}Tc -labeled peptides. There was no UV peak associated with the purified

Figure 5. Blood clearance of ^{99m}Tc -DADT-Pep-I and ^{99m}Tc -DADT-Pep-II, compared to those of ^{99m}Tc -DADT and [^{99m}Tc]-pertechnetate ($^{99m}\text{TcO}_4$) in rabbits.

Scheme 3. Synthesis of the ^{99m}Tc Complex of Hydrolyzed BCA 1 (^{99m}Tc -DADT)

radioactivity peaks even at the highest sensitivity of the UV detector (0.2 nmol detection limit), indicating extremely high specific activity of the labeled peptides. As is the case for nca ^{99m}Tc preparations, it is not possible to measure the mass amount of labeled material by conventional means due to the small amount of material involved. We estimated, on the basis of the history of the ^{99m}Tc generator used, that the specific activity of the labeled peptide was at least 100 000 mCi/ μmol .

When ^{99m}Tc -DADT-Pep-I and ^{99m}Tc -DADT-Pep-II are used in vivo, one point of possible metabolic cleavage is the amide bond between the Lys residue and the DADT ligand. If this occurred, the resultant ^{99m}Tc complex would be the same as the complex derived from hydrolyzed BCA 1 (^{99m}Tc -DADT, Scheme 3). Therefore, we prepared ^{99m}Tc -DADT as depicted in Scheme 3 for comparison to the labeled peptides during in vivo imaging. Figure 3 shows the HPLC chromatogram of the labeling mixture after incubation for 10 min. Two main products were obtained in a major:minor ratio of 3.1:1. Both products were combined for in vivo imaging studies.

Figure 5 shows the blood clearance of the saline-reconstituted, no-carrier-added ^{99m}Tc -labeled peptides compared with the clearance of $^{99m}\text{TcO}_4^-$ and the ^{99m}Tc complex of the hydrolyzed BCA 1 (^{99m}Tc -DADT) injected separately in different rabbits carrying turpentine-induced sterile inflammation. $^{99m}\text{TcO}_4^-$ and ^{99m}Tc -DADT served as controls. The ^{99m}Tc -labeled peptides as well as the ^{99m}Tc -DADT complex without peptide clear rapidly from the blood with less than 3% of the injected dose remaining in blood 20 min postinjection. The fast

Figure 6. Images of experimental inflammation in rabbits using ^{99m}Tc -DADT-Pep-I, the ^{99m}Tc -DADT chelate, and [^{99m}Tc]pertechnetate ($^{99m}\text{TcO}_4$) at 30 min, 1 h, and 3 h postinjection.

clearance of the activity from blood is a desired property of the labeled peptides that would permit imaging at shorter times postinjection. As is usual for $^{99m}\text{TcO}_4^-$, the activity of this tracer in the blood is much higher in these studies. Of the blood activity for the labeled peptides, $26.2 \pm 6.2\%$ was cell associated 60 min postinjection.

We obtained images of the rabbits carrying the experimental inflammation on a γ -scintillation camera. We compared images from the ^{99m}Tc -DADT-Pep-I and -II with those obtained from $^{99m}\text{TcO}_4^-$ and ^{99m}Tc -DADT. The $^{99m}\text{TcO}_4^-$ and ^{99m}Tc -DADT give an indication of the leakiness of blood vessels and blood flow to the inflammation site. Figure 6 shows representative results obtained using ^{99m}Tc -DADT-Pep-I, $^{99m}\text{TcO}_4^-$, and ^{99m}Tc -DADT. The results for ^{99m}Tc -DADT-Pep-I are similar to those obtained for ^{99m}Tc -DADT-Pep-II. It is clear that as early as 30 min postinjection the site of inflammation (arrow) could be seen and persists throughout the 3 h study period shown for the ^{99m}Tc -labeled peptides. It is more difficult to identify the inflammation site on the $^{99m}\text{TcO}_4^-$ and ^{99m}Tc -DADT images 30 min postinjection. This is an indication that accumulation of the ^{99m}Tc -labeled peptides at the inflammation site is not due to leakiness of blood vessels or blood flow alone.

Analyses of the images are shown in Figures 7 and 8. Figure 7 shows that the target (inflammation site): nontarget (contralateral region) ratio for the ^{99m}Tc -labeled peptides continues to increase from 2 to 9 over the 6 h study period. This is further confirmation that the accumulation of the peptide tracers at the inflammation site is not dependent on blood flow or leakiness of blood vessels alone. For $^{99m}\text{TcO}_4^-$ and the ^{99m}Tc -DADT chelate whose accumulation at the site of inflammation is dependent on blood flow or leakiness of blood vessels, the ratio remains practically constant at about 2 over the entire study period. The behavior of ^{99m}Tc -DADT suggests that the results obtained with the ^{99m}Tc -labeled peptides are not an artifact of the Tc chelate by itself.

Panels A and B of Figure 8 show the average counts per pixel (corrected for decay) at the inflamed site (target) and the contralateral region (nontarget) as a function of

Figure 7. Target:nontarget ratios as a function of time for ^{99m}Tc -DADT-Pep-I and ^{99m}Tc -DADT-Pep-II, compared to those of ^{99m}Tc -DADT and [^{99m}Tc]pertechnetate ($^{99m}\text{TcO}_4$) in rabbits carrying experimental inflammation.

Figure 8. Activity of ^{99m}Tc -DADT-Pep-I and ^{99m}Tc -DADT-Pep-II (A) and the ^{99m}Tc -DADT chelate alone and [^{99m}Tc]pertechnetate ($^{99m}\text{TcO}_4$) (B) in target and nontarget areas as a function of time postinjection.

time postinjection for ^{99m}Tc -DADT-Pep-I and -II (Figure 8A) as well as $^{99m}\text{TcO}_4^-$ and ^{99m}Tc -DADT (Figure 8B). Figure 8A shows that for the labeled peptides, activity continues to increase with time at the inflammation site,

Figure 9. Effect of no-carrier-added ^{99m}Tc -labeled peptides on leukocytes in vivo compared to the effect of 2 nmol of N^α -for-Met-Leu-Phe (fMLF).

whereas the activity in nontarget areas decreases with time. This explains why the target:nontarget ratios for the ^{99m}Tc -labeled peptides increase as a function of time postinjection. On the other hand, as shown in Figure 8B, the activity in both the target and nontarget areas decreases in a parallel fashion for $^{99m}\text{TcO}_4^-$ and ^{99m}Tc -DADT as a function of time. Therefore, the target:nontarget ratios for $^{99m}\text{TcO}_4^-$ and ^{99m}Tc -DADT do not increase with time but remain relatively constant. Thus, the pharmacokinetics of the labeled peptides differ from those of either $^{99m}\text{TcO}_4^-$ or ^{99m}Tc -DADT.

Agonists of the chemoattractant receptor cause acute neutropenia (18). This could be a very unwelcome side effect in patients undergoing studies with labeled chemotactic peptide agonists. That is why the requirement of high-specific activity radiopharmaceuticals is extremely important in this system. A major hypothesis of this work is that the amount of ^{99m}Tc (picomoles) at nca levels will be too small to cause a depression of the white blood cell count. Therefore, we investigated the effect of the nca ^{99m}Tc -labeled peptides on the level of white blood cells in the rabbits carrying the experimental inflammation. We compared the total white blood cell count of blood drawn 5 min before the injection of the tracers to the cell count in blood drawn 5, 10, 15, 30, and 60 min after injection of the tracers. The effects of the tracers were compared with the injection of 2 nmol of N^α -for-Met-Leu-Phe (fMLF). Figure 9 shows that, up to the 1 h study period, there was no significant difference in the white blood cell count before and after the injection of the ^{99m}Tc -labeled peptides, indicating that the tracers are devoid of neutropenic effects. On the other hand, 2 nmol of fMLF drastically reduced the leukocyte count immediately after injection.

These results demonstrate the feasibility of utilizing the diaminedithiol ligand system for the development of chemotactic peptide analogues for use in inflammation imaging without accompanying neutropenia. The advantage of using the DADT ligand in this system is that it is feasible to prepare the nonpharmacologically active formulations needed in a simple and highly efficient manner. Second, the structure of Tc-diaminedithiolate complexes are very well-defined, making it possible to isolate the Tc species formed for conventional characterization as done in these studies.

The general biodistribution studies in mice, however, show high liver and intestinal activity of the labeled peptides, indicating that the major route of excretion for

the labeled peptides presented in this study was the hepatobiliary system (Table 3). The DADT ligand and chemotactic peptide pair used in this study, therefore, may not be clinically useful for imaging applications in the abdominal area because of the high nonspecific abdominal activity. The hepatobiliary clearance is the result of the high lipophilicity of the neutral Tc-DADT chelate used. We are currently investigating more hydrophilic Tc-DADT chelates and chemotactic peptide combinations to obtain an optimum radiopharmaceutical that would be clinically useful for all areas of the body.

Design, Synthesis, and Initial Evaluation of High-Affinity Technetium Bombesin Analogues

Kwamena E. Baidoo,* Kuo-Shyan Lin, Yougen Zhan, Paige Finley, Ursula Scheffel, and Henry N. Wagner, Jr.

Division of Radiation Health Sciences, Department of Environmental Health Sciences, The Johns Hopkins University, 615 North Wolfe Street, Baltimore, Maryland 21205. Received November 13, 1997; Revised Manuscript Received January 15, 1998

Potent antagonists of bombesin-like peptides have shown great potential for applications in cancer therapy. A ^{99m}Tc -labeled agent capable of identifying patients who could benefit from these emerging therapies would have a great impact on patient management. This study involves the synthesis and initial evaluation of technetium diaminedithiolate analogues derived from the potent bombesin analogue Pyr-Gln-Lys-Leu-Gly-Asn-Gln-Trp-Ala-Val-Gly-His-Leu-Met-NH₂ (Lys³-bombesin). We coupled two diaminedithiol (DADT) bifunctional chelating agents (BCAs **1** and **2**) to the Lys³ residue at the N-terminal region that is not required for binding to the receptor. ^{99m}Tc labeling was performed by ligand exchange on addition of [^{99m}Tc]glucoheptonate to a solution of the adduct at room temperature. Two products were obtained from each adduct on analysis by HPLC. The major to minor product ratios of the ^{99m}Tc -labeled analogues were 3:1 for products from BCA **1** and 9:1 for the products from BCA **2**. Macroscopic amounts of the ^{99m}Tc analogues were similarly prepared using [^{99m}Tc]glucoheptonate. In this case, the major to minor ratios were 2:1 for the products from both BCAs. For initial evaluation of the binding of the Tc-labeled peptides to bombesin receptors, the ^{99m}Tc analogues were used in vitro in competitive binding assays in rat brain cortex membranes against [^{125}I -Tyr⁴]bombesin. Results of the in vitro assays showed that the inhibition constants (K_i) of the major and minor products were 3.5 ± 0.7 and 3.9 ± 1.5 nM, respectively, for the products from BCA **1**; and 7.4 ± 2.0 and 5.2 ± 1.5 nM for the products derived from BCA **2**, respectively. The high affinity exhibited by these technetium analogues is an indication of their potential for use in non-invasive in vivo biochemical characterization of cancers that possess receptors for bombesin.

INTRODUCTION

Bombesin is a 14-amino acid peptide initially isolated from frog skin (1). The main mammalian members of the bombesin family of peptides are gastrin-releasing peptide (GRP), a 27-amino acid peptide isolated from porcine stomach (2), and neuromedin B, a 10-amino acid peptide isolated from porcine spinal cord (3). Receptors for bombesin/GRP are expressed in the central nervous system as well as in peripheral tissues such as the intestines and pancreas. Many tumors are also known to express bombesin/GRP receptors. These include glioblastoma, small cell lung cancer, prostate, breast, gastric, colon, and pancreatic cancer (4–17). In many of these cancers, bombesin/GRP analogues function as autocrine growth factors. Activation of bombesin/GRP receptors on cancer cells causes a number of biochemical events such as phosphatidylinositol turnover, activation of protein kinase C, and elevation of cytosolic calcium leading to the expression of early oncogenes such as c-fos and c-jun and ultimately results in stimulated growth and proliferation of the cells (5, 18, 19). It is conceivable that disruption of the biochemical pathways of bombesin action on cancer cells would result in the inhibition of growth. This has been the basis of recent efforts to

develop therapeutic regimens in several cancers. For example, an antibody to the receptor binding C terminus of bombesin and GRP was reported to effect clinical remission of small cell lung cancer in a patient and partial remission in others (20). In another approach, several antagonists to the receptor have also been developed. The early antagonists were substance P analogues and were generally of low affinity (21, 22). The second-generation analogues, such as isobutyryl-His-Trp-Ala-Val-D-Ala-His-Leu-NH-CH₃ (23), D-Tpi⁶,Leu¹³Ψ(CH₂-NH)-Leu¹⁴-bombesin^{6–14} (RC-3095) (24), and 3-phenylpropanoyl-His²⁰,D-Ala²⁴,Leu²⁶Ψ(CH₂NH)-Phe²⁷-GRP^{20–27} (BW2258U89) (25), are highly potent. Among these, D-Tpi⁶,Leu¹³Ψ(CH₂NH)-Leu¹⁴-bombesin^{6–14} (RC-3095) has been shown to inhibit the growth of many cancers (9–14, 16, 17, 26, 27), and 3-phenylpropanoyl-His²⁰,D-Ala²⁴,Leu²⁶Ψ(CH₂NH)-Phe²⁷-GRP^{20–27} (BW2258U89) has been shown to inhibit the growth of small cell lung cancer cells (28). Furthermore, labeling bombesin analogues with therapeutic radionuclides would result in derivatives that could be used directly in cancer therapy as has been demonstrated using a ^{105}Rh -labeled bombesin analogue (29). A radiolabeled agent capable of identifying the patients that could benefit from these emerging therapies would have a great impact on patient management.

This study involves the synthesis and initial evaluation of receptor binding of technetium analogues derived from the bombesin analogue Pyr-Gln-Lys-Leu-Gly-Asn-Gln-Trp-Ala-Val-Gly-His-Leu-Met-NH₂ (Lys³-bombesin) and

the diaminedithiol (DADT) bifunctional chelating agents (BCA) **1** and **2** (Figure 1) (30, 31), which are capable of forming highly stable complexes with technetium.

MATERIALS AND METHODS

Solvents and chemicals were reagent grade and used as received unless specified. [^{99}Tc] NH_4TcO_4 and [^{125}I -Tyr ^{4}]bombesin were purchased from NEN Life Science Products (Boston, MA). [$^{99\text{m}}\text{Tc}$] NaTcO_4 was purchased as a solution in physiologic saline from Syncor (Timonium, MD). The Glucoscan kit was purchased from the Du Pont Radiopharmaceutical Division (Billerica, MA). Bombesin, Lys ^{3} -bombesin, and somatostatin were purchased from Advanced ChemTech (Louisville, KY). Male CD-1 mice and Sprague-Dawley rats were purchased from the Charles River Laboratories (Charles River, MA).

The DADT bifunctional chelating agents **1** and **2** were synthesized according to our previously published procedures (30, 31). Infrared spectroscopic determinations of neat liquids or KBr pellets were performed on a Nicolet 205 FTIR system. ^1H NMR spectra were recorded in a deuteriochloroform or deuteriomethylene chloride solution using a Bruker WM 300 MHz spectrometer. Elemental analyses were performed by Atlantic Microlabs (Norcross, GA). MALDI mass spectral analyses were performed by the University of Minnesota Mass Spectrometry Service Laboratory (Minneapolis, MN).

HPLC was performed with a Waters Chromatography Division HPLC System equipped with two model 510EF pumps, a model 680 automated gradient controller, a model 490 UV absorbance detector, an EG&G NaI scintillation detector, and a Hewlett-Packard HP 3392A or Shimadzu CR3A integrating recorder. HPLC solvents consisted of acetonitrile containing 0.1% trifluoroacetic acid (solvent A) and water containing 0.1% trifluoroacetic acid (solvent B). Liquid scintillation counting for quantification of ^{99}Tc activity was performed on an LKB Wallac instrument model 1219 Rackbeta using Ecolume (ICN Pharmaceuticals, Inc., Costa Mesa, CA) as a cocktail. Filtration of in vitro binding assay mixtures was performed on a BRANDEL, 48M Harvester. ^{125}I activity on filters from in vitro assays and $^{99\text{m}}\text{Tc}$ activity of tissues from biodistribution studies were counted in an automated γ -counter (Pharmacia-Wallac model 1282). Analyses of in vitro binding assay results were performed using the EBDA/LIGAND programs from Biosoft (Milltown, NJ). $^{99\text{m}}\text{Tc}$ activity for synthetic reactions was measured in a Capintec CRC-7 Dose Calibrator.

Coupling of the Diaminedithiol Bifunctional Chelating Agents 1 and 2 to Pyr-Gln-Lys-Leu-Gly-Asn-Gln-Trp-Ala-Val-Gly-His-Leu-Met-NH $_2$ (Lys ^{3} -Bombesin). BCAs **1** and **2** were coupled to Lys ^{3} -bombesin according to Scheme 1. For coupling reactions using BCA **1** (30), **1**·2HCl (19.4 mg, 53.4 μmol) and Pyr-Gln-Lys-Leu-Gly-Asn-Gln-Trp-Ala-Val-Gly-His-Leu-Met-NH $_2$ (9.0 mg, 5.3 μmol) were dissolved in borate buffer (0.8 mL, 0.1 M, pH 9) and acetonitrile (0.9 mL) and the pH was readjusted to 9 with triethylamine. The mixture

was incubated at room temperature for 4.5 h and then extracted with ether (3×2 mL). The aqueous fraction was chromatographed by semipreparative reversed phase HPLC [linear gradient from solvent B (100%) to solvent A (80%)/solvent B (20%) over the course of 40 min at a flow rate of 6 mL/min using a C-18 Novapak cartridge (25×100 mm, 6 μm , Waters Chromatography Division, Milford, MA) monitored on-line for UV absorption at 220 nm]. The product with a retention time of 25.6 min was isolated from the HPLC eluate by solid phase extraction using a C-18 Sep-Pak cartridge (Waters Chromatography Division), followed by lyophilization. The isolated yield of the adduct named Pyr-Gln-Lys(Pm-DADT)-Leu-Gly-Asn-Gln-Trp-Ala-Val-Gly-His-Leu-Met-NH $_2$ [Lys ^{3} (Pm-DADT)-bombesin] was 5.2 mg (57%). High-resolution MALDI MS: calcd MW for Lys ^{3} (Pm-DADT)-bombesin 1880.96, found $[\text{M} + \text{Na}]^+$ 1904.05.

Preparation of the BCA **2** (31) adduct was similarly performed by incubating a mixture of **2** (20.0 mg, 66 μmol) and Pyr-Gln-Lys-Leu-Gly-Asn-Gln-Trp-Ala-Val-Gly-His-Leu-Met-NH $_2$ (10.0 mg, 6.3 μmol) in a borate buffer (0.7 mL, 0.1 M, pH 9) containing acetonitrile (0.9 mL) for 2.5 h at room temperature. Using the same isolation procedure as above gave the product Pyr-Gln-Lys(Hx-DADT)-Leu-Gly-Asn-Gln-Trp-Ala-Val-Gly-His-Leu-Met-NH $_2$ [Lys ^{3} (Hx-DADT)-bombesin] with a 26.7 min retention time and a 52% (6.2 mg) isolated yield. High-resolution MALDI MS: calcd MW for Lys ^{3} (Hx-DADT)-bombesin 1894.97, found $[\text{M} + \text{Na}]^+$ 1917.95.

$^{99\text{m}}\text{Tc}$ Labeling of the Lys ^{3} (DADT)-Bombesin Adducts. $^{99\text{m}}\text{Tc}$ labeling of Lys ^{3} (Pm-DADT)-bombesin and Lys ^{3} (Hx-DADT)-bombesin was performed as depicted in Scheme 1. A glucoheptonate kit (Glucoscan) was reconstituted with water (1.0 mL). From this solution, [$^{99\text{m}}\text{Tc}$]glucoheptonate was prepared by addition of an aliquot (200 μL) to a [$^{99\text{m}}\text{Tc}$]pertechnetate solution (400 μL , 8 mCi) from the generator and vortexed for 1 min. The [$^{99\text{m}}\text{Tc}$]glucoheptonate solution (300 μL) was then added to a solution of the Lys ^{3} (DADT)-bombesin (0.5 μmol) in water (500 μL) and the mixture vortexed for 1 min and then incubated at room temperature for 10 min. The reactions were followed by reversed phase HPLC. Two products were obtained from either adduct. The total yield of products in either case was >90%.

The HPLC conditions for the isolation of the products from Lys ^{3} (Pm-DADT)-bombesin were a linear gradient from solvent A (15%)/solvent B (85%) to solvent A (50%)/solvent B (50%) over the course of 70 min at a flow rate of 4 mL/min using a C-18 Novapak cartridge (8×100 mm, 4 μm , Waters Chromatography Division) monitored on-line for UV absorption at 220 nm and scintillation for radioactivity. These products were designated Lys ^{3} ($^{99\text{m}}\text{Tc}$ -Pm-DADT)-bombesin-1 and Lys ^{3} ($^{99\text{m}}\text{Tc}$ -Pm-DADT)-bombesin-2 with retention times of 41.3 and 44.5 min, respectively, and a ratio of Lys ^{3} ($^{99\text{m}}\text{Tc}$ -Pm-DADT)-bombesin-1:Lys ^{3} ($^{99\text{m}}\text{Tc}$ -Pm-DADT)-bombesin-2 of 3:1.

To isolate the products obtained from Lys ^{3} (Hx-DADT)-bombesin, the HPLC conditions were solvent A (34%)/solvent B (66%) using the same column as above at a flow rate of 4 mL/min. The products were designated Lys ^{3} ($^{99\text{m}}\text{Tc}$ -Hx-DADT)-bombesin-1 and Lys ^{3} ($^{99\text{m}}\text{Tc}$ -Hx-DADT)-bombesin-2 with retention times of 11.3 and 13.5 min, respectively, and a ratio of Lys ^{3} ($^{99\text{m}}\text{Tc}$ -Hx-DADT)-bombesin-1:Lys ^{3} ($^{99\text{m}}\text{Tc}$ -Hx-DADT)-bombesin-2 of 1:9.

Preparation of the ^{99}Tc Analogues of the Lys ^{3} (DADT)-Bombesin Adducts. The general method for the preparation of the ^{99}Tc analogues was as follows. To a solution of Lys ^{3} (Pm-DADT)-bombesin or Lys ^{3} (Hx-

Scheme 1. Synthesis of Technetium Diaminedithiolate Analogues of Bombesin

1, R = H, R' = CH₃; **2**, R = CH₃, R' = H

DADT)-bombesin (0.9 μ mol) in methanol (850 μ L) and water (200 μ L) was added a solution of [⁹⁹Tc]glucoheptonate (32) in water (45 μ L, 20 mM), and the mixture was stirred at room temperature for 1.0 h. Similar products were obtained as described above for the ^{99m}Tc analogues. The overall yield of products was 48–69%. The products were isolated by reversed phase HPLC

using the same conditions above for the separation of the ^{99m}Tc analogues. The product ratios were as follows: 2.2:1 Lys³(^{99m}Tc-Pm-DADT)-bombesin-1:Lys³(⁹⁹Tc-Pm-DADT)-bombesin-2 and 1:2.3 Lys³(⁹⁹Tc-Hx-DADT)-bombesin-1:Lys³(⁹⁹Tc-Hx-DADT)-bombesin-2. High-resolution MALDI MS: calcd MW for Lys³(⁹⁹Tc-Pm-DADT)-bombesin-1 1993.94, found [M]⁺ 1993.86; calcd

MW for Lys³(⁹⁹Tc-Pm-DADT)-bombesin-2 1993.94, found [M]⁺ 1993.82; calcd MW for Lys³(⁹⁹Tc-Hx-DADT)-bombesin-1 2006.94, found [M + Na]⁺ 2029.85; calcd MW for Lys³(⁹⁹Tc-Hx-DADT)-bombesin-2 2006.94, found [M + Na]⁺ 2029.85.

In Vitro Binding Assay of the Bombesin Analogues. In vitro binding assays were performed using an adaptation of the method of Moody et al. (33). Briefly, adult male Sprague-Dawley rats were decapitated, the brains dissected on ice, and the medulla/pons removed. The rest of the brain was weighed and homogenized in 50 volumes of Tris-HCl buffer (50 mM, pH 7.4) at 4 °C with a Brinkmann Polytron instrument (setting 5, 15 s). The homogenate was centrifuged at 30000g for 15 min and the resulting pellet resuspended in 10 volumes of Tris-HCl buffer (50 mM, pH 7.4, 4 °C) containing NaCl (100 mM) and incubated at 4 °C for 60 min. The homogenate was centrifuged again at 30000g for 15 min. The resulting pellet was resuspended in 10 volumes of the Tris-HCl buffer (50 mM, pH 7.4). The protein concentration of the membrane suspension was determined using the Pierce (Rockford, IL) BCA Protein Reagent Kit and aliquoted for storage at -70 °C at a concentration of 5 mg protein/mL.

For the receptor binding assay, 400 µg of the membrane protein was incubated for 25 min with 0.25 nM [¹²⁵I-Tyr⁴]bombesin at 4 °C in a total volume of 125 µL of assay buffer in the presence or absence of 0.01–1000 nM bombesin, Lys³-bombesin, Lys³(Pm-DADT)-bombesin, Lys³(Hx-DADT)-bombesin, or the ⁹⁹Tc-labeled bombesin analogues or 1–10⁶ nM somatostatin. The assay buffer (50 mM Tris-HCl at pH 7.4) contained 1 mg/mL BSA and 2 µg/mL bacitracin. The incubation was terminated by addition of 5 mL of ice cold Tris-HCl (50 mM, pH 7.4) containing 1 mg/mL BSA followed by rapid filtration through Whatman GF/B glass fiber filters presoaked for 20 min in Tris-HCl buffer (50 mM, pH 7.4) at 4 °C. The filters were washed twice more with 5 mL aliquots of Tris-HCl buffer (50 mM, pH 7.4) at 4 °C and then counted in an automated scintillation γ-counter. Nonspecific binding was determined in the presence of 1 µM bombesin. The inhibition constants (K_i) were calculated using the EBDA/LIGAND computer programs (35).

Biodistribution of the Lys³(⁹⁹mTc-DADT)-Bombesin Analogues in Normal Mice. The HPLC-purified Lys³(⁹⁹mTc-DADT)-bombesin analogues were isolated from the respective HPLC eluates by solid phase extraction using a C-18 Sep-Pak cartridge. The Sep-Pak cartridge was first washed with ethanol (5 mL) followed by a solution of ammonium acetate (0.05 M, 5 mL). The HPLC eluate containing the Lys³(⁹⁹mTc-DADT)-bombesin analogue was diluted five times with ammonium acetate (0.05 M) and then passed through the Sep-Pak cartridge. The Sep-Pak cartridge was then washed with an ammonium acetate solution (0.05 M, 5 mL). The Lys³(⁹⁹mTc-DADT)-bombesin analogues were then eluted with ethanol. The ethanol solution was diluted with physiologic saline. The final injectate contained 2.5% ethanol. CD-1 mice were injected via the tail vein with the HPLC-purified Lys³(⁹⁹mTc-DADT)-bombesin analogues (2 µCi, 0.2 mL per mouse). At 15 min and 3 h postinjection, four mice for each time point per tracer were euthanized by cervical dislocation. Major organs were dissected, weighed, and counted in an automated scintillation γ-counter with aliquots of the injectate (as standards) counted at the same time.

RESULTS AND DISCUSSION

The development of biomarkers for detection of cancer is important in patient management. Because they are

rapidly metabolized in blood, autocrine growth peptides such as bombesin are not suitable as biomarkers for detection. The receptors, on the other hand, could be used as biomarkers for detection if suitable tracers could be developed for identifying them in vivo. Toward this end, bombesin/GRP receptors on cancer cells may be important for early diagnosis of certain cancers. For example, in a study by Preston et al. (36), only 1 of 23 stomach mucosa samples obtained from areas uninvolved with cancer in gastric cancer patients showed high-affinity binding sites for bombesin/GRP. This patient was the only one who had Menetrier's disease, a mucosa disorder known to be premalignant. In gastric (36) as well as other cancers such as prostate (34) and small cell lung cancers (37, 38), moderate to very high receptor densities are present on the cells. This would make the system amenable to good target to nontarget differentiation that can be taken advantage of in both scintigraphic imaging and therapy.

For in vivo scintigraphic studies by planar imaging or single photon emission computed tomography (SPECT), ^{99m}Tc is the best radionuclide by virtue of its short 6.02 h half-life, 140 keV photons, a high photon yield per disintegration unaccompanied by significant particulate radiation, a relatively low dose to patients, ready availability in generator form, and low cost. In order to derivatize small biologically active peptides with the metal, a chelating ligand (39) or a specific sequence of amino acids usually including one or more cysteine residues (40) has to be introduced into the peptide to carry the metal. Care has to be taken so that the Tc chelate does not interfere with the pharmacophore of the substrate so as to preserve its biological activity. Of chelating systems available for Tc, the diaminedithiol ligand forms one of the most stable complexes (41–44). To facilitate the incorporation of Tc into biologically active compounds using the DADT ligand system, we developed the two thiolactone derivatives **1** and **2** (Figure 1) (30, 31).

We have evaluated the feasibility of applying the DADT ligand in the form of the two bifunctional chelates as the carrier of the Tc in the derivatization of Lys³-bombesin (Figure 2), a potent bombesin agonist. This analogue of bombesin contained a Lys residue at amino acid position 3 in place of Arg in natural bombesin (Figure 2). In bombesin analogues, the binding site resides in the C-terminal octapeptide sequence (23, 45). Because the Lys residue is further from the binding site, we hypothesized that a Tc chelate attached to the ε-NH₂ group of Lys³ would lead to an analogue that still maintained high-affinity binding to the receptor. Coupling of the BCAs to Lys³-bombesin was performed at pH 9 using a BCA:Lys³-bombesin ratio of 10:1 (Scheme 1). After incubation at room temperature, the excess BCA was removed by extraction with ether and the Lys³-(DADT)-bombesin adduct purified by semipreparative reversed phase HPLC. No side chain protection was necessary since the indole and imidazole groups of Trp and His, respectively, are weak nucleophiles under the coupling conditions. The purified adducts were characterized by mass spectroscopy.

We have prepared both no-carrier-added (^{99m}Tc) and milligram quantities (⁹⁹Tc) of the Tc-derivatized bombesin analogues [Lys³(Tc-DADT)-bombesin]. The compounds were prepared in ligand exchange reactions by incubation of a mixture of the Lys³(DADT)-bombesin adducts with [^{99m}Tc]- or [⁹⁹Tc]glucoheptonate (prepared from glucoheptonate, [^{99m}Tc]- or [⁹⁹Tc]pertechnetate, and stannous ion), respectively, at room temperature (Scheme 1).

Figure 3. Inhibition of [^{125}I -Tyr ^{4}]bombesin binding to the bombesin receptor in rat brain membranes by bombesin analogues.

Table 1. Results of in Vitro Binding Studies of the ^{99}Tc Bombesin Analogues to Rat Brain Membranes

compound	K_i^a (nM)
bombesin	4.3 ± 1.0
Lys ^{3} -bombesin	21.4 ± 5.9
Lys ^{3} (Pm-DADT)-bombesin	24.2 ± 12.3
Lys ^{3} (Hx-DADT)-bombesin	17.9 ± 8.1
Lys $^3(^{99}\text{Tc-Pm-DADT})$ -bombesin-1	3.5 ± 0.7
Lys $^3(^{99}\text{Tc-Pm-DADT})$ -bombesin-2	3.9 ± 1.5
Lys $^3(^{99}\text{Tc-Hx-DADT})$ -bombesin-1	5.2 ± 1.5
Lys $^3(^{99}\text{Tc-Hx-DADT})$ -bombesin-2	7.4 ± 2.0
somatostatin	69500 ± 11200

^a Average $K_i \pm \text{SEM}$ ($n = 3$).

Lys ^{3} -bombesin or the adducts Lys ^{3} (Pm-DADT)-bombesin and Lys ^{3} (Hx-DADT)-bombesin. The affinities of the Lys $^3(^{99}\text{Tc-DADT})$ -bombesin analogues were comparable to that of bombesin ($K_i = 4.3 \pm 1.0$ nM) itself.

BCAs 1 and 2 were designed to affect the biodistribution of the Tc complexes of the resulting adducts as a result of the charge carried by the Tc complex. Tc-DADT complexes contain a $[\text{Tc}(\text{V})\text{-oxo}]^{3+}$ core. Complexes in which at least one of the coordinating nitrogens of the DADT ligand is a secondary amine such as adducts from BCA 2 have neutral complex cores because complexation of Tc results in deprotonation from the two thiols as well as a secondary amine nitrogen (30, 41–44, 46–48). Therefore, Lys ^{3} (Tc-Hx-DADT)-bombesin-1 and Lys ^{3} (Tc-Hx-DADT)-bombesin-2 which are derived from BCA 2 both have neutral Tc complex cores. When both coordinating nitrogens of the ligand are tertiary amines, as is the case for adducts from BCA 1, deprotonation from nitrogen is not possible. Therefore, complexes derived from BCA 1 adducts have a positively charged chelate core (31, 49). These differences in the charge of the Tc complex core are reflected in the biodistribution of the ^{99}Tc analogues (Figure 4A,B). Thus, Lys $^3(^{99}\text{Tc-Hx-}$

Figure 4. Biodistribution of the $^{99\text{m}}\text{Tc}$ -labeled bombesin analogues in normal mice 15 min postinjection (A) and 3 h postinjection (B).

DADT)-bombesin-1 and Lys $^3(^{99}\text{Tc-Hx-DADT})$ -bombesin-2 which are more lipophilic in character showed about 4-fold greater accumulation in the intestines than the Lys $^3(^{99}\text{Tc-Pm-DADT})$ -bombesin-1 and Lys $^3(^{99}\text{Tc-Pm-DADT})$ -bombesin-2 analogues which are derived from BCA 1 and therefore contain positively charged chelate cores. The ^{99}Tc -labeled analogues derived from BCA 1 would therefore be more suitable for imaging in the abdominal area.

The ^{99}Tc -labeled bombesin analogues described above have a potential for use in the in vivo biochemical characterization of bombesin/GRP receptors by scintigraphy. Their application in cancer may allow non-invasive identification of patients that would benefit from therapies based on the disruption of the bombesin/GRP growth promotion pathway as well as early cancer

detection. Use of the agents in this manner would greatly impact patient management. DADT ligands are also capable of forming highly stable complexes with rhenium, the congener of Tc. Therefore, the ^{186}Re and ^{188}Re analogues of the $^{99\text{m}}\text{Tc}$ -labeled bombesin compounds above would be directly applicable for the therapy of many cancers.

Received September 11, 1997; Revised Manuscript Received December 6, 1997

We developed a mass spectrometric method to precisely characterize the structures of the diethyl pyrocarbonate (DEP)-modified amino acid derivatives in intact peptides and proteins. Using acetate-buffered solutions for modification reactions improved the yields of DEP modification. UV quantification of carbethoxylation of angiotensin II was consistent with the degree of mass spectrometrically determined modification. Unequivocal identification of the modification sites in carbethoxylated angiotensin II derivatives was achieved by HPLC separation and mass spectrometric sequencing. With increasing concentrations of DEP, a gradual increase of carbethoxy groups, comprising biscarbethoxylation products, was detected in angiotensin II and in insulin. When using a high molar excess of DEP, histidine carbethoxylation was found together with modifications at α -amino groups and tyrosine residues. The sites of carbethoxylation in insulin were identified by MALDI-MS—peptide mapping analyses of the tryptic digestion mixtures from the nonreduced insulin derivatives and after reduction of disulfide bonds, demonstrating that histidine carbethoxylation was sufficiently stable during disulfide bond reduction and tryptic digestion at pH 7.5. The mass spectrometric identification of mono- and biscarbethoxylated histidine residues in insulin is in agreement with surface accessibilities of imidazolyl nitrogen atoms and seems to reflect the microenvironment of the protein tertiary structure. Thus, mass spectrometric peptide mapping analyses of carbethoxylated protein derivatives allowed both the simultaneous identification of histidine carbethoxylation in the presence of other modified groups and the detection of different chemical behavior of histidine residues by the unambiguous identification of mono- and bismodifications.

INTRODUCTION

Histidine residues are known to be involved in a variety of functions in different proteins such as proton donors and/or acceptors in the catalytic triade of serine proteases, or as metal chelating agents for the central ions of the heme groups, e.g. in myoglobin or in hemoglobin (Creighton, 1993). Functional protein domains and amino acid residues can be detected either by a variety of DNA cloning approaches, including deletion studies, gene fusion, and site-specific mutagenesis (Kornberg and Baker, 1992), or, alternatively, by selective chemical modification of particular amino acid residues in the “wild-type” proteins (Glazer, 1976).

The combination of limited, protein tertiary structure-selective chemical modification and mass spectrometric analyses has been developed as a new approach for both the molecular characterization of the selectivity and the determination of relative reactivities at specific modification sites (Glocker et al., 1994; Suckau et al., 1992). In the general analytical scheme, the precise number of modifications introduced and their distribution in partially modified proteins are first determined by direct mass spectrometric molecular weight analyses. Assignments of the reactivities of modification sites are then

derived from peptide mapping data using mass spectrometry (Przybylski et al., 1993). This method has been successfully employed in proteins, as well as in small peptides, with several specific modification reactions such as amino acylation, tyrosine iodination and nitration, carboxylate amidation, and the bifunctional cysteine modification by arsonous acid derivatives (Glocker et al., 1994, 1996; Przybylski, 1995; Kussmann and Przybylski, 1995; Happersberger et al., 1996; Akashi et al., 1997; Przybylski et al., 1996). Most recently, direct evidence for the conservation of tertiary structures upon selective chemical modification has been obtained for partially acylated derivatives of the ion channel protein porin from *Rhodobacter capsulatus* by mass spectrometric and X-ray crystallographic characterization (Przybylski et al., 1996).

Diethyl pyrocarbonate (DEP)¹ is a reagent commonly used for the specific modification of histidine residues in proteins (Miles, 1977). DEP has been used to demonstrate the importance of histidine residues in enzymes

Figure 1. Pathway of the reaction of histidine imidazolyl groups with an excess of DEP. The molecular mass of the unmodified protein (M) and the additional mass increment (in daltons) caused by the carbethoxylation are indicated for the monomodification (CEt-His) and the bismodification products (FCeT-His or UCeT-His). Constitutional isomers of either CEt-His or FCeT-His carrying the carbethoxy group or the formyl on the opposite ring nitrogen atom are not distinguished by mass spectrometric molecular mass determinations and were not added to this scheme: CEt-His, monocarbethoxyhistidine derivative; FCeT-His, biscarbethoxylated, ring-opened (formyl-CEt) derivative; and UCeT-His, biscarbethoxylated, deformylated (urethane-CEt) derivative.

(Gomi and Fujioka, 1983; Vangrýsperre et al., 1988, 1989; Li et al., 1993), transport systems (Garcia et al., 1982), muscle proteins (Hegyi et al., 1974), and ligand-receptor interactions (Nishino et al., 1980; Glocker et al., 1996). However, in most of these studies, structures of modified histidine residues were not determined but were based on model studies with amino acid derivatives (Mühlrad et al., 1967), and reaction pathways from imidazole derivatives were adopted (Miles, 1977; Avaeva and Krasnova, 1975; Grace et al., 1980). Further, analyses of concurrent side reactions of DEP with other nucleophilic amino acid residues and of histidine bismodification (FCeT-His or UCeT-His) rather than selective monomodification (CEt-His) were frequently lacking in the protein work but were described to occur quite readily with histidine residues and in tri- to pentapeptides (Foti et al., 1991). Recent FAB-MS investigations with deuterium exchange reactions of carbethoxylated imidazole (Kalkum et al., 1995) support the reaction pathway (Figure 1) by which mono- and bis-modified histidine residues are also formed in proteins. The mono- and biscarbethoxylated products lead to different mass adducts so that double mono-modifications ($2 \times$ CEt) can easily be distinguished from bismodification (FCeT or UCeT) by mass spectrometry.

In this report, we describe improved reaction conditions resulting in high yields of carbethoxylated polypeptides and compare UV quantification of the carbethoxylation reaction with the degree of mass spectrometrically determined modification in peptides and proteins. We describe the mass spectrometric characterization and identification of (i) concurrent histidine mono- and bis-carbethoxylated products and (ii) the simultaneous identification of histidine carbethoxylation in the presence of other carbethoxylated amino acid residues in angiotensin II and in insulin. Angiotensin II and insulin, two well-characterized polypeptides, were chosen as models, as in both polypeptides histidine residues are crucial for

bioactivity (Spear et al., 1990; Bovy et al., 1990; Casaretto et al., 1987; Fischer et al., 1985; Nakagawa and Tager, 1986).

MATERIALS AND METHODS

All substances were of the highest grade available. Water from a Millipore water purification system (MilliQ UV Plus) was used for the preparation of aqueous solutions described below.

UV Monitoring of the Carbethoxylation Reaction with Imidazole and Histidine Residues in Angiotensin II Using Diethyl Pyrocarbonate. DEP (2.5 μ mol, Aldrich; from a 1 M stock solution in dried acetonitrile) was added to imidazole (1.24 μ mol, Aldrich), dissolved in either 5 mL of 50 mM potassium phosphate or 50 mM ammonium acetate buffer (pH 6.8). UV spectra of carbethoxylated reaction products were recorded against imidazole solutions as a reference in the range of 200–260 nm with a UV/vis spectrophotometer (UV1202, Shimadzu) at several time points until a maximum absorbance at 230 nm was reached (after 40 min). The pH in the solutions remained constant during the reactions. A molar extinction coefficient for $\lambda = 230$ nm of $2940 \text{ cm}^{-1} \text{ M}^{-1}$ was determined at pH 6.8, which is in good agreement with the molar extinction coefficient of $3000 \text{ cm}^{-1} \text{ M}^{-1}$ at pH 6 (Melchior and Fahrney, 1970). DEP modification of angiotensin II was performed in ammonium acetate buffer. DEP (1 M solution in dried acetonitrile) was added to angiotensin II (0.24 mM solution in 50 mM ammonium acetate at pH 6.8) to yield a molar ratio of 4:1. The time course of the reaction was followed by recording UV spectra in the range of 230–300 nm. The maximum absorbance was observed at 240 nm which is consistent with previous observations (Ovadi and Keleti, 1969), and a molar extinction coefficient for histidine residues from proteins of $3200 \text{ cm}^{-1} \text{ M}^{-1}$ ($\lambda = 240$ nm, pH 6) was used for calculation of the degree of modification.

DEP Modification of Angiotensin II and Insulin for MS Investigations. DEP solutions in dried acetonitrile (0.01 or 1.0 M) were added to aliquots of angiotensin II and insulin solutions in 50 mM ammonium acetate (pH 6.8) to obtain different molar ratios of DEP to polypeptide (0.5:1 to 1000:1) in the reaction mixtures. The protein concentration was 1 $\mu\text{g}/\mu\text{L}$ for angiotensin II and 2.4 $\mu\text{g}/\mu\text{L}$ for insulin. The final concentration of DEP in the reaction mixtures varied from 2 to 10 mM. After the modification reaction (1 h), the angiotensin II samples were used directly for MS analyses and insulin samples were purified from unreacted DEP by ultrafiltration through a microcon 3 microconcentrator (Amicon, MW exclusion of 3000 Da). Retentates were washed three times with 100 μL aliquots of 50 mM ammonium acetate (pH 6.8). All retentates were collected and diluted with 100 μL of 25 mM ammonium acetate.

Tryptic Digestion of Carbethoxylated Insulin Derivatives and Reduction of Disulfide Bonds. Aliquots of 60 μL of purified DEP-modified insulin derivatives and of unmodified insulin (2.2 $\mu\text{g}/\mu\text{L}$) in 50 mM ammonium acetate (pH 6.8) were mixed with 1.4 μL of a trypsin solution in 0.1 N HCl (1 $\mu\text{g}/\mu\text{L}$, trypsin from bovine pancreas, TPCK-treated; Sigma), resulting in an E:S of 1:94. The pH of each digestion mixture was adjusted to 7.5 with 0.1 M ammonium hydrogen carbonate. After 6 h of incubation at 37 $^{\circ}\text{C}$ on a thermomixer (Eppendorf), aliquots were taken for immediate MALDI-MS analyses (1.5 μL). Reduction of disulfide bonds was performed by addition of 10 μL of a 0.1 M β -mercapto-

ethanol (β -ME) solution dissolved in 25 mM ammonium hydrogen carbonate to aliquots of the tryptic peptide mixtures (10 μ L) at 37 °C for 20 min. The molar excess of the reducing agent was approximately 7-fold over thiol groups from insulin.

FAB-MS of Carbethoxylated Angiotensin II. FAB-MS spectra were obtained with a Finnigan MAT 312/AMD 5000 magnetic sector field mass spectrometer (Niehr-Johnson geometry) operated at an acceleration voltage of 3 kV for an extended mass range up to m/z 3500. Spectra were recorded with a scan rate of 14 s/decade, and resolution was set to 2500. Primary ions were produced from a 20 kV Cs⁺ thermoion source. The detector voltage was 2.4 kV. Glycerol was used as a matrix. CsI/glycerol cluster ions were used for calibration in the mass range from m/z 100 to 2500. Solutions containing 20 μ g of carbethoxylated angiotensin II were mixed with 1 μ L of the matrix and concentrated to the matrix volume by evaporation of the solvent.

ESI-MS Analyses of Carbethoxylated Angiotensin II and Insulin. ESI-MS was performed with a Vestec-201A quadrupole mass spectrometer (Vestec, Houston, TX) equipped with a "thermally-assisted" electrospray interface. The spray interface temperature was approximately 40 °C for all measurements. The mass analyzer with a nominal m/z range of 2000 was operated at unit resolution. An electrospray voltage at the tip of the stainless steel capillary needle of 2–2.2 kV and repeller voltages of typically 10–60 V were employed. Spectra were recorded with a scan rate of 7 s/scan with a mass window of m/z 200–2000. Mass calibration was performed with the 8+, 9+, and 10+ charged ions of hen egg white lysozyme, and raw data were analyzed using a Teknivent Vector2 data system (Teknivent, Houston, TX). Protein and peptide solutions were pumped with a Harvard microinfusion pump (Harvard) through a fused silica capillary (inside diameter, 75 μ m) with a flow rate of 2 μ L/min into the ion source. Samples were diluted to a final concentration of 0.1 mg/mL with 2% acetic acid/methanol (9:1, v/v) at pH 3.

On-Line LC-ESI-MS/MS of Carbethoxylated Angiotensin II. The microbore HPLC system consisted of an Applied Biosystems (Foster City, CA) 140B solvent delivery system equipped with an Applied Biosystems 759A absorbance detector which was set at 215 nm. The DEP-modified angiotensin II mixtures (5 μ L aliquots) were separated using a microbore C18 column (Spherisorb, 100 $\times$ 1 mm, 3 μ m). Samples were injected using a Rheodyne (Cotati, CA) injection port (model 8125) equipped with a 5 μ L sample loop. Solvent A was 0.1% TFA in H₂O, and solvent B was 0.07% TFA in acetonitrile. The flow rate was adjusted to 40 μ L/min. After sample injection, the solvent mixture was kept constant at 5% B for 5 min and then was raised to 70% B over a time period of 60 min. On-line ESI-MS was performed on a Perkin-Elmer Sciex API-III triple quadrupole mass spectrometer (Thornhill, ON) in the single quadrupole scanning mode, and ESI-MS/MS was carried out using argon as the collision gas.

MALDI-MS Analyses of Carbethoxylated Angiotensin II and Insulin. MALDI-MS analyses were carried out with a Bruker Biflex linear time-of-flight spectrometer (Bruker-Franzen Analytik GmbH, Bremen, Germany), equipped with a UV nitrogen laser (337 nm) and a dual microchannel plate detector. For the molecular mass determinations, the acceleration voltage was set to 25 kV and spectra were calibrated with insulin, cytochrome c, or myoglobin as internal and external standards. For peptide mapping experiments, the ac-

Figure 2. UV spectra of imidazole carbethoxylation. (A) Reaction in 50 mM phosphate buffer at pH 6.8. (B) Reaction in acetate buffer at pH 6.8. Spectra were recorded after reaction time intervals as indicated. A molar extinction coefficient of 2940 cm⁻¹ M⁻¹ (λ = 230 nm) was used for calculating the amount of carbethoxylated imidazole. Ratios of carbethoxylated products: educts are given.

celeration voltage was set to 10 kV and insulin and neurotensin were used for internal and external mass calibration. Samples (1.5 μ L) were diluted 10-fold with CH₃CH/0.1% TFA (2:1, v/v), and 1 μ L of this solution was mixed with 1 μ L of a saturated HCCA solution [dissolved in CH₃CH/0.1% TFA (2:1, v/v)]. Spectra were recorded after evaporation of the solvent and processed using the X-MASS data system.

PSD-MALDI-MS of Carbethoxylated Angiotensin II. All spectra were obtained using the α -cyano-4-hydroxycinnamic acid matrix and a MALDI-TOF instrument (REFLEX II, Bruker-Franzen Analytik GmbH) equipped with a gridless delayed extraction (GDE) ion source with visualization optics, ion selector, and reflector. Laser powers clearly beyond threshold were used to obtain PSD spectra. The acceleration voltage was 28.5 kV, and the reflector potential was reduced by ca. 25% in steps from 30 to 1 kV. Calibration was carried out using the ACTH clip 18–39. Spectra were recorded after evaporation of the solvent and processed using the X-MASS data system.

Determination of Partial Accessible Surfaces of Insulin from the X-ray Structure. The structure of the Zn-insulin dimer was examined using the corresponding X-ray coordinates (Protein Data Bank entry 5INS) that were obtained from the Brookhaven National Laboratory on a Silicon Graphics Indy workstation with the Molecular Surface Package (MSP) software (Connolly, 1983).

RESULTS

Stoichiometry and Quantification of Monocarbethoxylation at Histidine Residues in Angiotensin II. In initial experiments, we studied the reaction of imidazole with DEP in a commonly used potassium phosphate buffer system and, additionally, in ammonium acetate buffer, as the latter is readily compatible with mass spectrometric analyses. Both buffers were applied at pH 6.8 at a concentration of 50 mM. An imidazole: DEP molar ratio of 1:2 was adjusted, and UV spectra were recorded at several time points (Figure 2) until a maximum absorbance at 230 nm was reached. From the absorbance values of 0.483 in phosphate buffer and of 0.867 in acetate buffer, and the determined molar extinction coefficient of 2940 cm⁻¹ M⁻¹, stoichiometric ratios of carbethoxylated product to imidazole of 0.64:1 and 1.16:1 were calculated, respectively. Thus, by using

Figure 3. UV and MALDI-MS characterization of angiotensin II carboxylation. (A) UV spectra were recorded after reaction time intervals as indicated. A molar extinction coefficient of $3200 \text{ cm}^{-1} \text{ M}^{-1}$ ($\lambda = 240 \text{ nm}$) was used (Ovadi and Keleti, 1969) for calculating the amount of carboxylated angiotensin II. (B) MALDI-MS of the product mixture after 30 min of reaction time. $[M + H]^+$ ions are present for the unmodified angiotensin II, for the monocarboxylated angiotensin II derivative(s), and for the doubly monocarboxylated angiotensin II derivative. Numbers of introduced carboxy groups are given in parentheses. Spectra were recorded using HCCA as a matrix.

acetate buffer, a nearly equimolar consumption of DEP per imidazole molecules was achieved. Predominant monomodification under these conditions was ascertained by NMR analyses of reaction mixtures with equivalent stoichiometries but higher concentrations (data not shown). As quantitative reaction between imidazole and DEP was observed in acetate-buffered solutions, all carboxylation reactions with angiotensin II and insulin were carried out using this buffer system at pH 6.8.

In a first experiment, angiotensin II was carboxylated with DEP using a molar ratio of 1:4 in diluted solutions (the angiotensin II concentration was 0.24 mM), and reaction was followed spectrophotometrically. Reaction was complete after 30 min; no further increase in absorption was observed (Figure 3A). Using the molar extinction coefficient for histidine residues in proteins (Ovadi and Keleti, 1969), a conversion of 43% of histidines to carboxylated histidines was calculated. As an absorption increase at 240 nm gives information only about carboxylation of histidine imidazolyl groups, the reaction mixture was also analyzed mass spectrometrically (Figure 3B). The MALDI mass spectrum shows three signals for molecular ions at m/z 1047, 1119, and 1191. The mass differences of 72 Da are indicative of monocarboxylations (CEt); thus, the observed $[M + H]^+$ ions resemble unmodified, monocarboxylated, and doubly monocarboxylated angiotensin II, respectively. From the relative peak intensities, the respective ion abundances of 45, 41, and 14% were determined. The amount of histidine modification ($41-X\%$) cannot be determined directly by molecular weight determination of the monocarboxylated product. However, α -amino carboxylation ($X\%$) is thought to add only a minor portion ($X \leq 14\%$), since the doubly monocarboxylated derivative was found in only little amounts (14%). Thus, the determined degree of histidine carboxylation by UV (43%) and the mass spectrometrically determined degree of monocarboxylation (41%) are in good agreement.

To distinguish α -amino carboxylation from monocarboxylation at histidine, the products from the carboxylation reaction of angiotensin II were separated by HPLC (Figure 4A). For these studies, the reaction was carried out at a 4-fold higher angiotensin II concentration (0.96 mM) and a molar ratio of DEP: angiotensin II of 1:1 was chosen. Four fractions were obtained by HPLC, and the peptide derivatives were identified by on-line ESI-MS/MS analyses (Table 1).

Figure 4. HPLC and ESI-MS characterization of angiotensin II carboxylation. (A) UV trace of HPLC-separated fractions from angiotensin II carboxylation monitored at 215 nm . Angiotensin II and modified derivatives were identified by on-line ESI-MS/MS analyses (Table 1). Fraction 1 contains unmodified angiotensin II, and fraction 2 contains the His monocarboxylated angiotensin II derivative; fraction 3 corresponds to the α -amino monocarboxylated angiotensin II derivative, and fraction 4 corresponds to the doubly monocarboxylated angiotensin II derivative. (B) ESI-MS of the product mixture. $[M + H]^+$ ions are present for the unmodified angiotensin II, for the monocarboxylated angiotensin II derivative(s), and for the doubly monocarboxylated angiotensin II derivative. Spectra were recorded using 2% acetic acid/methanol (9:1, v/v) at pH 3. Relative intensities of peaks are shown in percent. Numbers of introduced carboxy groups are given in parentheses.

Fraction 1 corresponds to unmodified angiotensin II and represents 44% of the products. Fraction 2 contained the monocarboxylated His derivative, accounting for 37% of the products. Fraction 3 was shown to contain the α -amino carboxylated product and represents 8% of the derivatives. This result verified the assumption that α -amino carboxylation plays a minor role and adds only little to the monocarboxylated angiotensin II derivatives. Finally, fraction 4 resembled the doubly carboxylated angiotensin II derivative (α -amino and His) and represents 11% of the products. The ESI-MS spectrum of the product mixture (Figure 4B) showed three molecular ions resembling unmodified angiotensin II (m/z 1047, 43%) and monocarboxylated (m/z 1119, 43%) and doubly monocarboxylated angiotensin II (m/z 1191, 14%). Peak heights of molecular ion signals were determined for quantification and revealed good correlation of determined degrees of modification between the two methods (Figure 4).

In our hands, DEP-modified angiotensin II derivatives, which were incubated for 48 h at 20°C in aqueous acetate buffers at pH 6–7, showed unchanged intensities of ion signals for the monocarboxylated, doubly monocarboxylated, and unmodified peptides, thus indicating that the carboxylation products were stable under these conditions, consistent with previous studies (Melchior and Fahrney, 1970; Mühlrad et al., 1967). However, at pH 8.5, DEP-modified peptides hydrolyzed to some extent, exhibiting more abundant ion signals for the unmodified rather than the DEP-modified peptides, which is also in agreement with previous results (Miles, 1977; Vangrysterpe et al., 1989).

Mass Spectrometric Identification of Histidine Biscarboxylation and Further Modification Sites in Angiotensin II. Unequivocal identification of the sites of modification in angiotensin II was obtained from the HPLC-separated carboxylated derivatives (Figure 4) by mass spectrometric sequencing using on-line LC-ESI-MS/MS. Angiotensin II and carboxylated derivatives yielded abundant b-type fragment ions (Roepstorff and Fohlmann, 1984; Biemann, 1988) covering the entire sequence (Table 1). For the α -amino carboxylated

^a Nomenclature according to Roepstorff and Fohlmann (1984) and Biemann (1988). ^b A 1:1 angiotensin II:DEP molar ratio was applied. ^c A 1:10 angiotensin II:DEP molar ratio was applied. ^d Observed by LC-ESI-MS/MS; HPLC-separated fractions were analyzed (Figure 4). ^e Observed by PSD-MALDI-MS; parent ions were selected from mixtures by ion extraction (Figure 6). ^f Observed by FAB-MS of the product mixture. ^g Observed by ESI-MS skimmer fragmentation with an elevated repeller voltage (30 V) of the product mixture. ^h Not observed.

derivative (fraction 3 in Figure 4A), a characteristic b2-fragment was observed at m/z 344.4 which is 72 Da higher than that of the corresponding fragment of the unmodified angiotensin II (fraction 1 in Figure 4A, m/z 272.4) and, thus, is indicative of the CEt group attached at the N-terminal Asp residue. Similarly, His modification in the monocarbethoxylated product (fraction 2 in Figure 4A) was ascertained by the b6-fragment which was found at m/z 856.8, whereas the corresponding fragment of the unmodified angiotensin II was found at m/z 784.8. Additionally, between the His and the α -amino carbethoxylated derivative, the b5-, b4-, and b3-fragment ions displayed mass differences of 72 Da which identified the CEt groups attached to His and the α -amino group, respectively. Finally, the doubly monocarbethoxylated angiotensin II derivative (fraction 4 in Figure 4A) showed sequence fragments that were indicative of modification of both the His and the α -amino group (Table 1).

In addition to the above-described carbethoxylations of the histidine residue and the N-terminal α -amino group, a further side reaction with the tyrosine residue in position 4 was observed, when modification was carried out using a 1:10 molar ratio of angiotensin II:DEP (Figure 5A). An ion signal at m/z 1263 which is indicative of a triply monocarbethoxylated (3CEt) derivative was found under these conditions next to the monocarbethoxylated (CEt, m/z 1119) and the doubly monocarbethoxylated (2CEt, m/z 1191) derivative.

The 2CEt and the 3CEt derivatives were sequenced using PSD-MALDI-MS by extracting the precursor ions from the product mixtures prior to fragmentation (Figure 6). Specific a-type and b-type fragment ions were detected in high abundances. The mass differences of 28 Da between a-type and b-type fragment ions, leading to characteristic ion doublets that were also observed in PSD-MALDI spectra of unmodified angiotensin II, are marked by Δ . The spectrum of the doubly CEt-modified angiotensin II derivative allowed determination of the entire sequence, and carbethoxylation at His-6 was clearly identified by the mass difference of 209.2 Da between the b6- and b5-fragment ions (Figure 6A and Table 1). Carbethoxylation at Tyr-4 can be excluded in this derivative, as the mass difference between the b4- and b5-fragment ions of 163.0 Da is indicative of an unmodified Tyr residue. Further abundant ions were found at m/z 589.3, 426.5, and 326.9 which correspond to the b4-, b3-, and b2-fragment ions with an additional loss of 17 amu. The presence of y-type ions in the spectrum confirmed the carbethoxylation at His-6 (y2-

Figure 5. MALDI-MS of carbethoxylated angiotensin II using increasing molar ratios of DEP. (A) Molar ratios of angiotensin II to DEP are increasing from 1:0 up to 1:10. Monocarbethoxylation is indicated by CEt. Carbethoxylation sites are shown for the triply monocarbethoxylated angiotensin II in the sequence. (B) Molar ratios of angiotensin II:DEP are increasing from 1:500 up to 1:5000. Molecular ions due to formation of His bismodification (FCEt) are observed in addition to the monocarbethoxylation products. Signals marked with $\times$ are 18 Da lower than the corresponding $[M + H]^+$ ions. Additional minor peaks were found for sodium adducts, potassium adducts, and matrix adducts. Spectra were recorded using HCCA as a matrix.

and y3-fragment ions, Figure 6A) and also identified the second carbethoxylation site at the α -amino group of Asp-1 by the y7-fragment at m/z 1003.5. In addition to the sequence-specific ions, direct evidence for the modification sites was obtained by PSD-MALDI detection of i-type ions. The triply monocarbethoxylated angiotensin

Figure 6. PSD-MALDI-MS of carbethoxylated angiotensin II. (A) The PSD-MALDI-MS spectrum of doubly monocarbethoxylated angiotensin II shows abundant a-type, b-type (top horizontal dashed line), and y-type fragment ions (bottom horizontal dashed lines) from which the sites of modification can be identified by the characteristic mass differences. The entire sequence of angiotensin II is covered, and m/z values for the most abundant fragment ions are given. The mass difference between a- and b-fragments (28 Da) is marked by Δ . Fragment ions due to additional loss of 17 amu are indicated by $*$. (B) PSD-MALDI-MS spectrum of triply monocarbethoxylated angiotensin II (i-type ion region). The signal for CEt-His is off-scale. The identified sites of modification are indicated in the sequence. Spectra were recorded using HCCA as a matrix.

II yielded i-type ions of CEt-His (m/z 182.2) and CEt-Tyr (m/z 208.2), while CEt- α -amino-Asp (m/z 188.2) was identified as a b1-fragment ion (Figure 6B). The presence of carbethoxylated i-type ions demonstrates that the modification remained stable under the MALDI-MS sequencing conditions, whereas carbethoxy groups are easily lost by using conventional peptide purification procedures for Edman sequencing (Deka et al., 1992). Characteristic fragmentation at particular amide bonds (b6- and b5-fragments, Table 1) of angiotensin II and carbethoxylated products was also observed in ESI spectra with an elevated repeller voltage (front end fragmentation) and produced additional evidence of simultaneous His monocarbethoxylation and α -amino carbethoxylation in the doubly monocarbethoxylated angiotensin II derivative.

For modification of proteins, high DEP excesses (molar ratios of approximately 1:1000 to 1:10000) usually have been chosen. MALDI mass spectra of DEP-modified angiotensin II samples revealed generally higher degrees of modification products with an increasing excess of DEP (Figure 5). When a higher excess of DEP was used for modification of angiotensin II (molar ratios of 1:500 to 1:5000), additional biscarbethoxylation of the histidine

residue, leading to the ring-opened formyl-CEt derivative (FCEt), was observed (Figure 5B; cf. Figure 1). FCEt-His-modified angiotensin II derivatives were detected, together with other carbethoxylation products, at m/z 1281 and 1353, respectively. The FCEt product leads to an additional mass increment of 162 Da and is, thus, easily distinguished from double monocarbethoxylation ($\Delta m = 144$ Da) by molecular weight determination. At these high molar ratios of DEP:angiotensin II, additional, yet unidentified signals with a mass shift Δm of -18 Da were observed besides the signals of the molecular ions of highly modified angiotensin II derivatives.

Identification of Carbethoxylation Sites in Insulin, after Proteolytic Degradation, and after Disulfide Bond Reduction. DEP modification reactions of insulin were carried out using molar ratios of DEP:protein of 50:1 to 1000:1. MALDI-MS molecular weight analyses of unmodified and modified proteins gave characteristic singly and doubly charged ions, which allowed precise determinations of modification degrees. With increasing concentrations of DEP, a gradual increase of up to approximately six carbethoxy groups/insulin was detected comprising mixtures of protein derivatives that carried CEt, FCEt, and UCEt groups (data not shown). Biscarbethoxylation (FCEt and UCEt formation) is characteristic of histidine modification and is clearly identified by mass spectrometric molecular weight analyses of insulin. For the insulin derivatives obtained by carbethoxylation with a 50-fold molar excess DEP, the most abundant molecular ion was observed at m/z 6023, which corresponds to the 4CEt derivative (Table 2). In addition, a molecular ion signal at m/z 6112 was observed for the insulin derivative carrying three CEt modifications and one FCEt modification. After reduction of the disulfide bonds, three major molecular ions were detected. One signal (m/z 2414) corresponded to the a-chain, carrying one CEt group. Two signals were indicative of the b-chain derivatives at m/z 3619 (carrying three CEt groups) and at m/z 3680 (containing two CEt and one UCEt group). These results showed that the modified sites remained carbethoxylated after reduction and during mass spectrometric analyses. However, FCEt was transformed to UCEt under the slightly basic conditions (pH 7.5–8.0) necessary for reduction of disulfide bonds.

The sites of carbethoxylation were identified by MALDI-MS-peptide mapping analyses of the digestion mixtures from the nonreduced insulin derivatives after tryptic cleavage in solution (see Materials and Methods). Insulin has two cleavage sites for trypsin (Arg-22 and Lys-29 in the b-chain, Figure 7A), but additional cleavage due to intrinsic chymotryptic activity of trypsin was observed at Tyr-14 from the a-chain and at Tyr-16 from the b-chain (Figure 7B), showing that these residues were not modified. The corresponding ions of the disulfide-linked N-terminal peptide (1–14)a-S-S-(1–16)b were found modified with up to four CEt groups (m/z 3590) and with three CEt groups and one UCEt group (m/z 3653). The most abundant ion observed (m/z 3518) corresponds to this disulfide-linked peptide carrying three CEt groups. The C-terminal parts from both the a-chain and the b-chain resulted in unmodified peptide ions at m/z 1558 and 860, respectively. Hence, the mass spectrometric peptide mapping data indicated carbethoxylation at His-5, His-10, and both N termini. Under the tryptic (chymotryptic) digestion conditions applied (pH 7.5), FCEt was again transformed to UCEt and partial hydrolysis of carbethoxy groups was detected. This is consistent with previous reports (Deka et al., 1992; Hegyi et al.,

Table 2. MALDI-MS Molecular Weight Determination of Carbethoxylated Insulin^a before and after Reduction of Disulfide Bonds

protein or peptide (modified groups)	[M + H] ⁺ (calcd)	<i>m/z</i> (obsd)	highest degree of modification	most abundant modification species

a-chain (1 × α-NH ₂)	6113 2413	6112 2414	3CEt + 1FCEt 1CEt	1CEt
b-chain (1 × α-NH ₂ , 2 × His)	3617 3679	3619 3680	3CEt 2CEt + UCEt	3CEt

^a Molar ratio DEP: insulin = 50:1.**Figure 7.** Structure representation and MALDI-MS of carbethoxylated insulin. (A) Schematic representation of the insulin monomer. Disulfide bonds are shown as gray bars. Tryptic fragments are indicated by underlining arrows, and calculated molecular masses of tryptic fragments are given. (B) MALDI-MS after tryptic digestion of carbethoxylated insulin at pH 7.5. Molecular ions for the tryptic peptides show multiple monocarbethoxylations (CEt) and formation of UCEt-His in the N-terminal peptide (1-14)a-(1-16)b. (C) MALDI-MS after reduction of disulfide bonds at pH 7.5. The molecular ions for the reduced tryptic peptide (1-16)b show multiple monocarbethoxylations (CEt) and formation of UCEt-His. Spectra were recorded using HCCA as a matrix.

1974; Ovadi and Keletti, 1969) in which proteolytic digestion of carbethoxylated proteins was carried out partly in the presence of a reducing agent (β -mercaptoethanol) without substantial removal of the carbethoxy groups. On the other hand, monocarbethoxylated histidines can be reversed into unmodified histidine residues by addition of excess nucleophiles, such as hydroxylamine (Deka et al., 1992; Miles, 1977). As the observed ions were not baseline-resolved, PSD-MALDI-MS sequencing of the peptide mixture was not carried out and, thus, the sites where partial losses of modifications may have

occurred were not determined. Reduction of the tryptic peptide mixture yielded mixtures of molecular ions for the modified and disulfide bond-cleaved peptides (Figure 7C). Ions for peptide (1-16)b were found at *m/z* 1902 (one CEt), at *m/z* 1974 (two CEt), and at *m/z* 2036 (one CEt and one UCEt), substantiating the fact that His residues and the N terminus were carbethoxylated.

Correlation of Chemical Reactivity with Partial Accessible Surfaces of Histidine Nitrogen Atoms in Insulin. Only one biscarbethoxylation at histidine residues was observed in insulin under the conditions employed. Hence, we assumed that the chemical reactivities of the two His residues in insulin may be different due to different surface structure features. Possible structural parameters for correlation with the relative reactivities (Glocker et al., 1994) of imidazolyl groups are relative (static) surface accessibilities (SA values) defined at a 1.4 Å van der Waals sphere of solvent and were obtained from X-ray crystallography data (Badger et al., 1991) using the insulin dimer structure (Figure 8). For monoderivatization (CEt formation) of histidine residues, only one nitrogen atom of the imidazolyl group has to be exposed on the surface, as is the case for His-5 in both b-chains of the dimer (referred to as the b- and d-chains in Table 3). While in His-5b the ND1 atom shows high solvent accessibility (total area of 11.8 Å²) and NE2 shows little total area (4.1 Å²), the situation is just the opposite for His-5d. Here the total accessible area for NE2 (10.2 Å²) is larger than that of ND1 (1.7 Å²). This suggests that the surface accessibilities of histidine nitrogen atoms in the His-5 residues resemble a "frozen" state in the insulin core structure of an otherwise flexible (but not freely rotating) histidine residue, which can be attacked by chemicals only on one side of the imidazolyl ring. Rotation may be hindered even more after carbethoxylation, and therefore, the His-5 residues may be found mostly CEt-modified. By contrast, ND1 and NE2 atoms of His-10 residues in both b-chains are equally accessible (total areas are 11.5 and 13.4 Å², respectively; Table 3). Thus, it appears likely that the observed FCEt and UCEt derivatives observed in our studies were formed by biscarbethoxylation at His-10, reflecting the chemical behavior of freely rotating histidine residues in nonstructured peptides. As His-5 and His-10 residues are close together in the sequence (Figure 8), they were not separated by proteolytic cleavage; thus, the site of the biscarbethoxylated His residue in insulin was not determined from the above-described results. However, the mass spectrometric peptide mapping analyses of carbethoxylated protein derivatives allowed the simultaneous identification of histidine carbethoxylation in the presence of other modified groups and the detection of the different chemical behavior of histidine residues, providing insight into protein surface structure features.

Figure 8. Schematic representation of the insulin dimer. The ribbon diagram shows the a- and b-chains and His residues are depicted as ball and stick diagrams. The NE2 atoms of His-10 are shown complexed with Zn^{2+} ions of the else freely rotatable residue. His-5 participates in the insulin core structure and shows accessible surface for either ND1 or NE2, depending on the monomer.

Table 3. Static Accessible Surface Areas of Nitrogen Atoms in Insulin His Residues^a

His residue ^b	atom ^c	contact area (Å ²)	reentrant area (Å ²)	total area (Å ²)
5b	ND1	6.4	5.4	11.8
	NE2	0.2	3.9	4.1
10b	ND1	5.2	7.8	13.0
	NE2 ^d	7.2 (0.3)	4.3 (2.3)	11.5 (2.6)
5d	ND1	0.3	1.4	1.7
	NE2	6.1	4.1	10.2
10d	ND1	5.2	8.2	13.4
	NE2 ^d	7.3 (0.5)	4.4 (1.4)	11.7 (1.9)

^a Areas are calculated from histidine residues of both monomers of the homodimeric structure. ^b Sequence positions; d represents the b-chain of the second monomer. ^c Nomenclature according to X-ray data set (Protein Data Bank entry 5INS). ^d Values in parentheses show the accessible areas in the presence of Zn^{2+} .

DISCUSSION

Angiotensin II is a linear octapeptide with a single histidine residue in position 6 that plays an important role in the regulatory angiotensin–renin system. Vasoconstrictive and blood pressure-elevating processes result upon binding of angiotensin II to its receptor. The importance of His-6 for receptor binding has been shown by using cyclized synthetic (Spear et al., 1990) and C-terminally truncated synthetic analogues (Bovy et al., 1990). Our studies show that degrees of His modification in angiotensin II, determined by UV absorption measurements, were in good agreement with modification degrees determined by MALDI-MS. Mass spectrometric determination of modification degrees with peptide mixtures of large proteins seems to have advantages over quantitation by HPLC analysis and/or amino acid analysis of separated fractions (Deka et al., 1992; Vangrýsperre et al., 1989), as complex peptide mixtures may not be

separated completely (Glocker et al., 1996) and coelution of modified and unmodified peptides may obscure quantitative results. However, MALDI-MS seems not to be generally applicable for absolute quantitation, as ion yields may be varying for different analytes. This can be overcome by using internal calibrants with similar chemical properties, providing that signal levels become independent of experimental variables such as inhomogeneous sample distribution and the dependence of laser power for analyte desorption (Tang et al., 1993). Relative quantitations show linear relationships over at least 1 order of magnitude (Nelson et al., 1994). Desorption properties of peptides may be altered upon DEP modification. Thus, to semiquantitatively analyze peptides of interest, especially for proteolytic peptide mixtures from large proteins, we suggest a comparison of the decrease of signal intensity of His-containing unmodified peptides with the ion abundance of peptides that are found unmodified throughout the course of modification experiments (Glocker et al., 1996), thereby not changing the chemical relationships, i.e. ionization efficiencies.

For protein derivatization, large excesses of DEP were usually applied but mostly reversible monomodification of histidines has been reported (Miles, 1977; Gomi and Fujioka, 1983; Garcia et al., 1982; Hegyi et al., 1974; Nishino et al., 1980). This seems in contrast to results from model peptides for which irreversible formation of UCEt and FCEt products was found (Foti et al., 1991). Since most protein modification reactions were carried out in phosphate buffers in which hydrolysis is fast, the actual excess of DEP may have been overestimated. The final degree of histidine modification depends on the total amount of reagent added and on the ratio of the rate constants between carboxylation of amino acid residues and of hydrolysis (Melchior and Fahrney, 1970). As

the rate constant for histidine modification is second-order, the initial protein concentration (i.e. the concentration of modifiable groups) plays a role in the extent of modification observed. Therefore, comparable modification degrees were obtained with angiotensin II when modification was carried out in a 1:4 molar ratio with a low angiotensin II concentration ($0.25 \mu\text{g}/\mu\text{L}$) and in a 1:1 molar ratio with a 4-fold higher angiotensin II concentration ($1 \mu\text{g}/\mu\text{L}$).

Biscarbethoxylation is indicative of histidine modification in proteins and was detected in insulin and in angiotensin II by mass spectrometry together with modification at other nucleophilic groups. This is consistent with very recent studies in which biscarbethoxylation in proteins together with monocarbethoxylation has been reported (Li et al., 1993; Glocker et al., 1996). Insulin is a very well-studied polypeptide hormone for the regulation of glucose homeostasis and is produced by the β -cells of the pancreas in response to nutritional stimuli (Lee and Pilch, 1994). Human insulin encompasses two histidine residues (His-5 and His-10) in the N-terminal part of the b-chain, and this region is necessary for receptor binding (Casaretto et al., 1987; Fischer et al., 1985; Nakagawa and Tager, 1986). In addition, His-10 was found to bind to Zn^{2+} in the crystal structure of porcine insulin (Badger et al., 1991), resulting in noncovalent dimers and hexamers which may structurally resemble the hexamer arrays in which insulin is stored in the pancreatic β -cells. For monoderivatization of histidine residues, only one nitrogen atom of the imidazolyl group needs to be exposed on the surface, as is the case for His-5 in both b-chains of the insulin dimer, as deduced from the X-ray data (Figure 8 and Table 3). By contrast, the His-10 residues of insulin appear to be more similar to histidine residues of nonstructured peptides in solution; i.e. the formation of FCET and/or UCET derivatives should occur more readily. As in our experiments, modification reactions were carried out without addition of cations, both nitrogen atoms of the imidazolyl groups of the His-10 residues should be equally accessible. Thus, it appears likely that the observed FCET and UCET insulin derivatives in our studies may be formed by biscarbethoxylation at His-10. In a recent mass spectrometric study, carbethoxylation of synthetic peptides containing His residues was carried out in the presence of metal ions (Zn^{2+} and Cu^{2+}) and revealed that His residues were partially shielded from carbethoxylation by metal complex formation (Hornshaw and Sutton, 1997). The ability of mass spectrometry to distinguish histidine residues with different chemical behaviors as shown here was also recently demonstrated in studies with a carbethoxylated cytokine and allowed us to distinguish His residues participating in the globular core structure from other His residues located in peptide-like unstructured parts of the protein (Glocker et al., 1996).

In general, chemical reactivity reflects both the protein's surface topology and the amino acid microenvironment. Hence, structural requirements by which histidine imidazolyl groups participate in intact protein core structures may lead to distinct chemical behavior. The ability of mass spectrometry to distinguish histidine residues with different chemical properties, thus, provides insight into protein structural details and structure-function relations.

ACKNOWLEDGMENT

We express our thanks to Prof. Dr. Max L. Deinzer for making his LC-ESI-MS/MS equipment available and to

Dr. Detlev Suckau for assistance with the PSD-MALDI-MS experiments. We thank Prof. Dr. Salvatore Foti for many fruitful discussions on mass spectrometry of carbethoxylated peptides. This work was supported by grants from the Deutsche Forschungsgemeinschaft and by the EU-network "Peptide and Protein Structure Elucidation by Mass Spectrometry".

Molecular Characterization of a Conformational Epitope of Hen Egg White Lysozyme by Differential Chemical Modification of Immune Complexes and Mass Spectrometric Peptide Mapping

Winfried Fiedler, Christoph Borchers, Marcus Macht, Sören-Oliver Deininger, and Michael Przybylski*

Faculty of Chemistry, University of Konstanz, 78457 Konstanz, Germany. Received August 11, 1997; Revised Manuscript Received November 28, 1997

A new approach for the characterization of conformationally dependent epitope structures in protein antigens is described using differential chemical modification of immune complexes in combination with mass spectrometric peptide mapping analysis. Well-established methods for epitope characterization are frequently not applicable to conformationally dependent epitopes, and direct methods of structure analysis such as X-ray crystallography of immune complexes have been successful only in a few cases. Our approach combines tertiary structure-selective chemical modification of immune complexes with the molecular characterization of reaction products by mass spectrometric peptide mapping. The comparison of the modification pattern of free and antibody-bound antigen provides the identification of residues protected from modification by the antibody. These residues hence are characterized as part of the epitope structure. The well-characterized hen egg white lysozyme and a corresponding monoclonal IgM-type antibody were investigated as a model system. Specific modification reactions for arginine, lysine, and tyrosine residues were performed, and the modification sites in free and antibody-bound antigen were determined by mass spectrometric peptide mapping. The R14 residue and residues K13 and K96 in the antibody-bound lysozyme were found to be protected from modification, comprising a surface of spatially adjacent residues by folding of the native protein. In contrast, other K and R residues as well as Y20 and Y23 showed no significant shielding from modification in the immune complex. These results provided an estimation of the molecular epitope surface area of native lysozyme.

INTRODUCTION

Monoclonal antibodies are important tools in biochemistry, molecular biology, medical diagnostics, and immunology (1–4). Molecular structures in protein antigens recognized by antibodies (epitopes) can be classified as linear epitopes (continuous partial sequences of typically 5–10 amino acids) and epitopes dependent on the three-dimensional structure of the antigen (conformational epitopes) (5–9). Conformational epitopes occurring on the native structure of the antigen comprise a multiplicity of amino acid residues spatially assembled by the protein folding. Knowledge of epitope structures is important for predicting and identifying cross-reactivities, for the study of structure–function relationships, and for understanding molecular processes in immunology (1–3).

Several methods for the analysis of linear epitopes have been recently established such as binding analysis of synthetic partial peptides (10–12) and mass spectrometric analysis by epitope extraction or epitope excision (13–18). The characterization of conformational epitopes is considerably more difficult than the characterization of linear epitopes, and as yet, only a few methods are available. Site-specific mutagenesis approaches using binding analyses of recombinant antigen variants have been successfully employed (19, 20), and several recent

X-ray crystallographic determinations of immune complexes have provided structural details of molecular interactions (21–24). Both methods, however, comprise demanding tasks, and site-directed mutagenesis may not provide complete epitope structure data. A further approach employed previously is NMR analysis upon differential deuterium exchange of labile hydrogens in immune complexes (25); the use of synthetic peptides has been successful in a few cases. In previous publications, differential chemical modification was used as an alternative approach for the characterization of conformational epitopes (26–28). This approach applies selective chemical modification by specific reagents to intact immune complexes. As a result of the binding with the antibody, certain residues show significantly diminished reactivity in the immune complex compared to that of the free antigen as a consequence of the shielding by the antibody. However, conventional analysis of the modified antigen by proteolytic digestion and chromatographic separation has limited resolution and provides no direct molecular characterization of the epitope. In addition, this approach requires the use of radioactive reagents.

We have significantly extended this approach by using reactions specific for one type of amino acid, and the precise molecular identification of the sites of modification by mass spectrometry (29, 30). The general analytical scheme employed in this procedure is shown in Figure 1. Reactions used in this study were (i) modification of arginine residues by 1,2-cyclohexanedione (29–32), (ii) acetylation of lysine residues (30, 33, 34), and (iii) tyrosine iodination (34–36). The monoclonal antibody

Figure 1. Analytical scheme for the characterization of conformational epitopes by differential chemical modification of antigen-antibody complexes and mass spectrometric peptide mapping. Modification groups and proteolytic cleavage sites are represented by filled circles and lines, respectively. The white areas represent shielded sequences due to direct interaction with the antibody; light gray areas represent sequences shielded by conformational effects.

employed here was produced in large amounts by cell culture techniques. Binding analysis showed its specific affinity to native HEL,¹ but no significant binding to reduced and denatured HEL which indicated a conformational epitope and native protein structure was required for recognition. This feature was confirmed in this study by the results of the differential chemical modification and mass spectrometric data.

MATERIALS AND METHODS

Materials. All chemicals were of analytical grade or the highest available purity. HEL, TPCK-treated trypsin, and α -cyano-4-hydroxycinnamic acid (HCCA) were purchased from Sigma (St. Louis, MO); cellulose nitrate was from Schleicher & Schuell (Dassel, Germany). 1,2-

Cyclohexanedione (CHD) was from Merck (Darmstadt, Germany); acetic anhydride was from Riedel-de Haën (Hannover, Germany), and iodine was from Aldrich (Milwaukee, WI). Materials and media for antibody production were purchased from Gibco (Eggenstein, Germany). NHS-activated Sepharose columns were obtained from Pharmacia (Freiburg i. Br., Germany).

Antibody Production. A monoclonal antibody (mAb-WF1; IgM) was produced by repeated immunization of Balb/c-mice with native HEL without additives. The antibody concentration in plasma was determined by ELISA. Fusion of isolated spleen cells with a myeloma cell line (X63Ag8.653) was carried out by addition of poly(ethylene glycol), and fusion cells were selected by HAT selection. Single cells of antibody-producing clones were cultivated to ensure a monoclonal cell line. Large amounts of the monoclonal antibody-producing cell line ($>2 \times 10^8$ cells) were grown by the rotating bottle technique (37).

Purification and Characterization of the Antibody. Antibody purification was carried out by affinity chromatography using a column with HEL immobilized on NHS-activated Sepharose according to the manufacturer's instructions (38). Purification was carried out by using cell culture supernatant at pH 7.5, washing with phosphate buffer at pH 7.5, and subsequent elution at pH 3–4. The purified antibody was concentrated and buffered using ultrafiltration units. The purity was assessed by SDS gel electrophoresis, and the activity was determined by ELISA. A sodium ion concentration of 100 mM was required for stable antigen-antibody binding with maximal stability of the complex at pH 7.5. Further characterization of the purified mAb-WF1 showed that it was surprisingly unstable with a complete loss of activity within 10 days. A possible explanation for the lower stability of the IgM antibody compared to IgG stabilities is its high molecular weight and supramolecular structure.

Chemical Modification of Free and Antibody-Bound Antigen. The HEL-mAb immune complex was formed by incubating 1 mg of antibody with 75 μ g of HEL in 1 mL of buffer for 1 h. A 2-fold excess of antibody binding sites was employed to prevent the presence of free antigen. Modification of R residues with 1,2-cyclohexanedione was generally carried out in 200 mM sodium borate buffer and 100 mM NaCl (pH 8). Free HEL was modified according to procedures described previously (29). The reaction was started by addition of 1.56 mmol of CHD and performed for 6 h. The reaction was quenched; the immune complex was dissociated by addition of 30 μ L of acetic acid, and the solution was stored for 12 h at 4 °C. The antibody precipitated under these conditions and was removed by centrifugation. The CHD-modified antigen was purified and isolated by ultrafiltration.

Acetylation of lysine residues was carried out in 500 mM NH_4HCO_3 and 100 mM NaCl (pH 6). The reaction was started by slow addition of acetic anhydride to the solution, and the pH due to hydrolysis of the anhydride was controlled with 1 M NaOH in an automated pH-stat (Titration Controller, Schott, Mainz, Germany). The immune complex was dissociated; the antibody was precipitated by addition of acetic acid until pH 3 was reached, and the solution was stored for 12 h at 4 °C. The precipitated antibody was centrifuged, and the modified HEL was purified by HPLC.

Modification of tyrosine residues was carried out in 100 mM NH_4OAc and 100 mM NaCl (pH 7) by addition of an iodine solution (25 mM KI and 5 mM I_2 in acetate buffer).

¹ Abbreviations: HEL, hen egg white lysozyme; MALDI-MS, matrix-assisted laser desorption/ionization mass spectrometry; ESI-MS, electrospray ionization mass spectrometry; PD-MS, plasma desorption mass spectrometry; HCCA, α -cyano-4-hydroxycinnamic acid; TFA, trifluoroacetic acid; HPLC, high-performance liquid chromatography; IgM, immunoglobulin M; mAb, monoclonal antibody; ELISA, enzyme-linked immunosorbent assay; NHS, *N*-hydroxysuccinimide; CHD, 1,2-cyclohexanedione; DHCH-R, (*N*⁷,*N*⁸-dihydroxy-1,2-cyclohexylidene)-arginine.

The mixture was stirred for 15 min. The reaction was quenched by addition of 30 μ L of acetic acid, and the solution was stored for 12 h at 4 $^{\circ}$ C. The precipitated antibody was centrifuged, and the iodinated HEL was purified by ultrafiltration.

HPLC Purification of Acetylated HEL Derivatives. HPLC purification was carried out on a Waters M510/M45 gradient instrument equipped with a 490E multiwavelength UV detector and a MAXIMA 820 data system, using a 250 $\times$ 4 mm, 6 mm C₄-RP column (Vydac, Hesperia, CA). Gradient elution was carried out with 0.04% aqueous TFA (solvent A) and 0.03% TFA in acetonitrile (solvent B) at 1.5%/min from 10% B and a flow rate of 1 mL/min. Fractions were detected at 220 nm and collected manually.

Proteolytic Digestion. Acetylated and iodinated HEL derivatives were reduced with DTT and alkylated with 4-vinylpyridine as described previously (30, 39). The reaction products were purified by HPLC (acylated derivatives) or by dialysis (iodinated derivatives). Proteolytic digestion with trypsin was carried out at pH 8 and 37 $^{\circ}$ C in the presence of 6 M urea to prevent precipitation of reduced HEL. The enzyme:substrate ratio varied from 1:10 to 1:50. Proteolytic mixtures were directly analyzed by MALDI-MS. Tryptic digestion was also carried out directly on the nitrocellulose target and analyzed by PD-MS as described previously (29, 40, 41).

Mass Spectrometry. PD-MS analysis was carried out with a BIO-ION BIN 20 TOF mass spectrometer (BIO-ION, Uppsala, Sweden) equipped with a 10 μ Ci ²⁵²Cf primary ion source. Spectra were recorded with an acceleration voltage of 17 kV and accumulation of 10⁷ single spectra. Sample preparation was carried out as previously described (16, 30, 40). MALDI-MS was performed with a Bruker Biflex linear TOF mass spectrometer equipped with a SCOUT source and video system (Bruker-Franzen, Bremen, Germany), a nitrogen UV laser (λ_{max} = 337 nm), and a dual-channel plate detector. Sample preparation was performed with 1 μ L of a freshly prepared saturated solution of HCCA in acetonitrile/H₂O (60:40) with 0.1% TFA which was mixed with 1 μ L of the peptide or protein solution. The drop was placed on the target and allowed to dry at 25 $^{\circ}$ C, and the crystals were washed several times with 2 μ L of TFA. Spectra were recorded at an acceleration voltage of 25 kV using an initial deflection pulse of 2 kV perpendicular to the ion flight path and a 1 μ s duration for deflecting matrix ions. Each spectrum was acquired by accumulating 20–100 single laser shots. Calibration was carried out using the singly and doubly protonated ions of bovine insulin as an internal standard. Electrospray ionization mass spectrometry was performed on a Vestec 201 A single quadrupole mass spectrometer (Vestec Corp., Houston, TX) with a Teknivent Vector 2 data system. A desolvation potential of 20 V at a needle voltage of 1.9–2.1 kV and a temperature of 40 $^{\circ}$ C in the spray chamber was used.

RESULTS

Molecular Weight Determination of Lysozyme Derivatives upon Differential Chemical Modification of Immune Complexes. HEL was subjected to selective chemical modification of R, K, and Y residues (i) as the free protein and (ii) as the intact immune complex bound to the antibody. After modification of the immune complexes, the antibody was generally precipitated by acidification and the purified HEL derivatives were subjected to molecular weight determination by

Figure 2. ESI mass spectrometric molecular weight determination of iodinated HEL upon modification of the HEL–antibody complex by I₂ (see Materials and Methods). The spectrum was obtained with a sample concentration of 0.1 μ g/ μ L (7 μ M) in 2% acetic acid containing 10% methanol.

mass spectrometry. The molecular weight determination of the iodinated HEL derivative upon modification of the antibody-bound protein with a 150-fold molar excess of iodine by ESI-MS is illustrated in Figure 2. The spectrum shows the 8–10-fold protonated molecular ions from which an extent of modification by up to five iodines was identified. The relative intensities of the molecular ions provide an estimation of an average modification extent of 2.8. Molecular weights of HEL derivatives partially modified by acetic anhydride and CHD were determined in the same manner by PD-MS and MALDI-MS, respectively.

The molecular weight increase for free and antibody-bound HEL upon iodination, acetylation, and CHD modification as a function of reaction time or molar excess of reagent is shown in Figure 3. For each reaction, the average extent of modification was directly determined from the molecular weight difference between the unmodified and modified protein. In all cases, the mass spectrometric data showed significantly lower modification of antibody-bound HEL compared to that of the free antigen (Figure 3). This result is explained well by the shielding effect of the antibody and by the lower concentration of antigen in the modification reactions with the intact immune complex.

Identification of Modification Sites in Free and Antibody-Bound HEL Derivatives. Modified and purified HEL derivatives were subjected to reductive cleavage of disulfide bonds with DTT and were then digested with trypsin under identical conditions for each protein derivative as described in Materials and Methods. The proteolytic peptide mixtures were directly analyzed by MALDI-MS and PD-MS peptide mapping. From the molecular weight determinations of peptide fragments, the modification sites were determined as described in previous studies of lysozyme derivatives (29, 36). Hence, the comparison of peptides from the free and antibody-bound proteins provided the identification of residues protected from modification by the antibody.

Lysine residues were acetylated by acetic anhydride as described previously (29, 30), with the control of the extent of modification governed by the amount of acidic anhydride present in excess. Since the reactivities of K residues have been previously shown to be primarily dependent on the relative surface accessibilities (36, 42), HEL derivatives with an average extent of modification of four acetyl groups were used to compare the modification pattern of free and antibody-bound protein. Corresponding MALDI-MS peptide mapping analyses of tryptic

Figure 3. Molecular weight increase of HEL derivatives upon chemical modification of R, K, and Y residues as a function of reaction time or molar reagent excess. The open squares denote modification of the free protein and the filled squares the modification of the antibody-bound protein. Molecular weight determinations were performed by ESI-MS and MALDI-MS as described in Materials and Methods: (a) R modification by 1,2-cyclohexanedione, (b) K acetylation with acetic anhydride, and (c) iodination.

fragments are shown in Figure 4. In the case of the acetylated, uncomplexed HEL (Figure 4a), a partial modification of all seven amino groups (N terminus, K1, K97, K13, K33, K96, and K116) was detected by the molecular ions due to the modified peptides. In contrast, no ion signals due to acetylation at K13 and K96 were observed upon acetylation of antibody-bound HEL (indicated by arrows in Figure 4b), whereas modification of all other amino groups was found to be identical in the free protein. Furthermore, modification of the immune complex with an increasing molar excess of acetic anhydride did not yield any acylation at these lysine residues but resulted eventually in precipitation of the antibody and dissociation of the immune complex. The complete protection of these residues from acetylation of the antibody indicates their participation in the epitope structure.

Iodination of tyrosine residues was performed as described previously (35, 36), and the extent of modifica-

Figure 4. MALDI-MS peptide mapping analysis of tryptic peptides (T) of acetylated HEL. The numbers of fragments denote the cleavage positions as shown in Figure 6. Acetylated K residues are indicated: spectrum of (a) peptide fragments from free HEL and (b) peptide fragments from antibody-bound proteins.

tion was controlled again by the molar excess of reagent as described above. Tryptic digestion of iodinated HEL derivatives was performed with a relatively high substrate:enzyme ratio to obtain cleavage at R21 necessary to differentiate between the Y20 and Y23 residues. For comparison of the free and antibody-bound HEL, protein derivatives with an average extent of 2.8 modified residues were selected and peptide mapping analyses were performed by MALDI-MS. Both protein derivatives yielded similar spectra, and no significant differences in the modification pattern were detected (data not shown). The Y20 and Y23 residues were singly and doubly iodinated, whereas only a weak signal was identified for the iodination of Y53. These results suggested that no significant shielding of tyrosine residues was provided by the antibody and hence no participation of these residues in the epitope structure. In the case of Y53, no conclusion was possible because of its low reactivity.

The modification of arginine residues by CHD to (N^7, N^8 -dihydroxy-1,2-cyclohexylidene)arginine (DHCH-R) adducts and the selectivity and reaction mechanism have been described in detail previously (29). Under the conditions described in Materials and Methods, 4 of the 11 arginine residues were found to be modified in the uncomplexed protein. The modification of antibody-bound HEL under identical conditions provided an average extent of modification of three arginine residues, indicating selective shielding of one arginine residue by the antibody. The identification of the modified residues was performed by mass spectrometric peptide mapping

Table 1. Identification of Reactive and Shielded Residues upon Modification at Lys, Arg, and Tyr in Uncomplexed HEL and Antibody-Bound HEL

amino acid	modified residues		shielded residues
	HEL	HEL-mAb complex	
Lys ^a	1, ^d 97, 13, 33, 96, 116 ^e	1, ^d 97, 33, 116 ^e	13, 96
Arg ^b	5, 14, 73, 125 ^f	5, 125, 14	73
Tyr ^c	20, 23, 53	20, 23, (53) ^g	(53) ^g

^a Lysine acetylation with acetic anhydride. ^b Arg modification by 1,2-cyclohexanedione. ^c Tyr iodination. ^d Acetylation at the N terminus was found in uncomplexed HEL and the immune complex. ^e Relative reactivities according to surface accessibilities (28). ^f Unmodified Arg residues in HEL are Arg-21, -45, -61, -68, -112, -114, and -128. ^g Assignment not certain due to low reactivity.

Figure 5. Structure model of HEL indicating the epitope surface estimated from the solvent accessible surface area according to ref 40. The epitope comprising about 400 Å² as a minimum area is marked by the dotted line. R and K residues as part of the epitope are shown in blue; nonepitope residues are marked in red. The Y20 residue adjacent to the epitope surface is shown in orange.

of tryptic fragments for the free and antibody-bound protein. Arginine residues 5, 14, 73, and 125 (Table 1) were selectively modified in the uncomplexed protein which was established in previous studies due to proton acceptor groups in the microenvironment of these residues (16, 29). In contrast, the peptide mapping analysis after CHD modification of antibody-bound HEL showed reactivity only for arginine residues 5, 125, and 73, whereas the ion due to the DHCH-modified peptide containing R14 had disappeared. The selective protection of R14 by the antibody again suggests a protected location of this residue in the epitope structure. However, in the case of the arginine modification, no conclusion could be made about those residues which are unreactive in the uncomplexed protein (29).

DISCUSSION

The epitope surface area defined by the binding site of the monoclonal antibody used in this model study with HEL and determined using mass spectrometric epitope mapping is shown schematically in Figure 5. A minimum surface of approximately 400 Å² was estimated from the K and R residues comprising the epitope (K13, K96, and R14), and from corresponding adjacent residues that were found unshielded and hence were modified on the surface of the immune complex (K1, K97, R5, R73, and R125).

Taken together, the results from these modifications and the additional tyrosine iodination define an epitope surface that can be described by conformational arrangement of the intact protein. Near K96, the surface epitope can be located more accurately, because nonepitope residues Y20 and K97 are in close spatial proximity. In contrast, only a rough epitope surface estimation is possible between K1 and R125 because of the lack of suitable reactive residues in the environment of these residues. The distance between the ϵ -amino and guanidino groups of K13 and K96 is 12.5 Å, from K13 to R14 (C atom in the guanidino group) is 9.1 Å, and from K96 to R14 is 13.1 Å. This yields an estimated epitope surface of about 400 Å² which is consistent with the order of epitope surfaces previously determined by X-ray crystallography (ca. 700 Å²) (22, 23, 43). Residues K13, K96, and R14 were frequently found to be involved in epitope structures of HEL with different monoclonal antibodies, and hence can be considered strongly antigenic parts in HEL (45). However, a detailed comparison of the epitope with previously published epitope surfaces is not possible due to the different (IgM) antibody employed in this study.

In conclusion, this study shows that the combination of selective protein chemical modification and mass spectrometric peptide mapping is well suited for the characterization of molecular contact areas in protein-protein interactions. Likewise, this approach can be used to study not only antigen-antibody complexes but also receptor-ligand interactions or complexes of regulatory proteins and hence should constitute a valuable approach which is complementary to X-ray crystallography (36).

ACKNOWLEDGMENT

We thank Professor Volker Ullrich, Dr. Ingrid Kuhlmann, and Renate Sprenger (Faculty of Biology, University of Konstanz) for their kind support and assistance in the preparation of monoclonal antibodies and Klaus Hägele for expert assistance in mass spectrometric procedures. We also gratefully acknowledge the advice of and discussions with Dr. Konrad Kürzinger (Boehringer Mannheim, Penzberg, Germany). This work has been supported by the Deutsche Forschungsgemeinschaft (Bonn, Germany; Forschergruppe "Struktur und Funktionssteuerung an zellulären Oberflächen") and the European Union through the EU network "Peptide and Protein Structure Elucidation by Mass Spectrometry".

Fluorescently Detectable Magnetic Resonance Imaging Agents

Martina M. Hüber, Andrea B. Staubli, Karen Kustedjo, Mike H. B. Gray, John Shih, Scott E. Fraser, Russell E. Jacobs,* and Thomas J. Meade*

Division of Biology and Beckman Institute, California Institute of Technology, Pasadena, California 91125. Received August 13, 1997; Revised Manuscript Received December 12, 1997

This report describes the synthesis, characterization, and in vivo testing of several bifunctional contrast-enhancing agents for optical and magnetic resonance imaging (MRI) of experimental animals. These new agents integrate the advantages of both techniques since they can be visualized simultaneously by light and MRI microscopy. Employing this strategy allows the same biological structures of a specimen to be studied at dramatically different resolutions and depths. The complexes possess a metal chelator for binding a paramagnetic ion, gadolinium (Gd^{3+}), and a covalently attached fluorescent dye. The first class of complexes are low-molecular weight species that are composed of the macrocyclic tetraamine 1,4,7,10-tetraazacyclododecane-*N,N',N'',N'''*-tetraacetic acid (DOTA) as the metal-chelating ligand coupled to tetramethylrhodamine. The second class of MRI-enhancing agents are composed of high-molecular weight polymers that are membrane impermeable and once injected into a cell or cells are trapped inside. These complexes possess multiple copies of both the metal-chelator–diethylenetriaminepentaacetic acid (DTPA) and the tetramethylrhodamine attached to a macromolecular framework of either poly(D-lysine) (pdl) or dextran. Images acquired of single cells after injection with these bifunctional agents enabled us to follow the relative motions and reorganizations of different cell layers during amphibian gastrulation and neurulation in *Xenopus laevis* embryos.

INTRODUCTION

In recent years, two imaging techniques have emerged that have had a major impact upon basic and clinical science: computer-enhanced light microscopy imaging and nuclear magnetic resonance imaging (1–3). Unlike previous approaches that required the processing of fixed tissue samples, both these techniques permit aspects of a living, intact organism to be imaged. With imaging of the organism in defined physiological states, a more realistic picture of developmental processes has begun to emerge.

Computer-enhanced light microscopy permits high-resolution imaging to be accomplished in imperfect preparations, such as whole tissues and organisms. The use of fluorescent indicator dyes visualized with a video or confocal microscope has resulted in several classes of novel experiments. For example, individual cells have been injected with membrane impermeable dyes (e.g., fluorescent dextrans) so that the only cells that are labeled are the original cell and its progeny (1).

MRI offers the potential of true three-dimensional imaging of biological structures and processes at cellular resolution ($\approx 10 \mu m$) (4–7). Typically, the image is based upon the NMR signal from the protons of water where the signal intensity in a given volume element is a function of the water concentration and relaxation times (T_1 and T_2). The paramagnetic ion gadolinium (Gd^{3+}) is used in MRI agents to decrease the local T_1 of water protons and therefore provide increased contrast. The long electron spin relaxation time and high magnetic moment of Gd^{3+} make it an efficient perturbant of T_1 . Through chelation of the Gd^{3+} aqua ion using various ligands, its toxic effects can be minimized (8–10).

While significant results have been obtained employing these techniques, each suffers from inherent constraints.

Light microscopy is limited by optical aberrations and light scattering to the outer 100–300 μm of a specimen. MRI microscopy provides a solution to this limitation by rendering three-dimensional images of opaque specimens, but sacrifices resolution by at least 10–20-fold compared to that of light microscopy. There are a significant number of MRI contrast agents that have been developed for clinical use because they enhance the local image intensity of organs and tissues. However, there are very few examples of agents that have been specifically designed for imaging experimental animals.

Therefore, we have prepared a series of bifunctional contrast-enhancing agents that are designed to integrate the advantages of both techniques. We report the synthesis and in vivo testing of a class of agents that are simultaneously detectable by fluorescence and MRI microscopy, thereby permitting multimodal imaging of experimental animals. The design of these bifunctional contrast agents included the lanthanide chelators DTPA and DOTA, which are known to form lanthanide complexes with high stability and selectivity (9, 11, 12). Conjugation of the fluorescent functionality, tetramethylrhodamine, was achieved either through coupling to the carboxylic acid group of DTPA or by functionalizing the DOTA macrocycle (Figures 1–3) (13–17).

The first class of complexes includes $Gd[p\text{-(aminobenzyl)DOTA}]\text{--tetramethylrhodamine}[Gd(\text{rhoda-DOTA})]$. This agent carries the macrocyclic tetraamine DOTA linked to the fluorochrome in a 1:1 complex and may be used to investigate membrane permeability, fusion, gap-junctional communication, and lesions. The second class includes membrane impermeable agents, such as $Gd\text{-(DTPA)--tetramethylrhodamine--hydroxypropylpoly(D-lysine)}$ (GRIP) and $Gd\text{-(DTPA)--tetramethylrhodamine--aminodextran}$ (GRID). These agents are based on a polymeric scaffold (i.e., pdl and dextran, respectively), carrying several tetramethylrhodamine molecules and $Gd\text{-(DTPA)}$ complexes.

EXPERIMENTAL PROCEDURES

Materials. Unless otherwise noted, all solvents and reagents for organic synthesis were obtained from Aldrich or Fluka and were used without further purification. Dextran and pdl were purchased from Sigma; tetramethylrhodamine-5-isothiocyanate (TRITC) was obtained from Molecular Probes. 2-(*p*-Aminobenzyl)-1,4,7,10-tetraazacyclododecane-*N,N',N'',N'''*-tetraacetic acid (PABD) was synthesized as reported in the literature (13, 14). Doubly distilled deionized water was obtained from a NANO pure II filtration unit to 18 M Ω -cm resistivity and was used throughout to minimize trace-metal contamination of the ligands and chelates. Reactions were performed in oven-dried flasks under positive argon pressure and monitored by analytical thin-layer chromatography (TLC) using E. Merck silica gel 60F plates (0.25 mm). E. Merck silica gel (230–400 mesh) was used for flash chromatography. Samples were purified on PD 10 and NAP 25 prepacked, disposable columns (Pharmacia Biotech). ^1H spectra were recorded at 300 MHz on a GE300 NMR spectrometer. Analytical HPLC was performed with a Waters 600E liquid chromatograph equipped with a 994 diode array detector using a reverse phase VYDAC 201HS54 4.6 mm $\times$ 25 cm, 5 μm C18 column. Samples were eluted with 100 mM triethylammonium acetate with a gradient of 1 to 20% MeCN at a flow rate of 1 mL/min, and products were detected by UV absorption at 260 and 330 nm. FPLC was performed using a Pharmacia Liquid Chromatography Controller LCC 550 unit applying a HR 10/10 Fast Desalting Column and a Superdex 75 column (Pharmacia). Aqueous solutions were injected onto the column and eluted with a 0.15 M sodium phosphate buffer (pH 7) at a flow rate of 1 mL/min. The fluorescence of Gd^{3+} - and tetramethylrhodamine-containing derivatives was analyzed on a Hitachi F-4500 instrument (Gd^{3+} , λ_{ex} = 275 or 280 nm, λ_{em} = 313–335 nm; tetramethylrhodamine, λ_{ex} = 547 nm, λ_{em} = 572 nm). Concentrations of tetramethylrhodamine-containing compounds were determined by UV measurements at 548 nm on a Hewlett-Packard 8452A diode array spectrophotometer using an ϵ of $\approx 100 \times 10^3 \text{ M}^{-1} \text{ cm}^{-1}$ as the molar extinction coefficient.

Fluorescence Microscopy. Survival of the labeled cells was monitored by embryos that were placed in 30% Ringer's solution and transferred to a Sylgard-based plate (Dow Corning Sylgard 182 silicone elastomer, cured and then pretreated with 2% BSA solution) with precut triangular wells. The positions, distributions, and fates of labeled graft progeny were monitored and documented in the living whole mount using a SIT camera (Hamamatsu C2400) mounted on a Zeiss AxioPhot microscope. Bright-field transmitted images were taken on a Zeiss AxioPhot microscope using a Hamamatsu Neuvicon camera. In each case, the images were captured on a 151 image processor (Imaging Technologies, Inc.) and averaged ($n = 8$ frames) before storage on an optical memory disk (Panasonic OMDR 3038) using the VIDIM image-processing software (authored by Belford, Fraser, and Stollberg).

MRI. MR images were acquired using a Bruker AMX500 spectrometer (Bruker Instruments Inc., Billerica, MA) with a microimaging accessory, a homebuilt RF probe with 2.5 and 5 mm ID RF solenoids, a homebuilt low-noise preamplifier, and an Acustar gradient set (Bruker Instruments, Inc., Fremont, CA) capable of producing $\approx 290 \text{ G/cm}$ gradients. For MR imaging, the samples were transferred to 2.5 or 5 mm outside diameter thin-walled glass tubes and maintained at 18 $^\circ\text{C}$ in the

Figure 1. Gd(rhoda-DOTA) (1).

same solution used for growing the embryos. A three-dimensional steady state free precession (SSFP) spin echo imaging sequence with TR/TE = 200 ms/4.4 ms was used to obtain T_1 weighted MR images. The typical isotropic voxel size was 30 μm , although in some cases, data sets with 15 μm voxels were collected. Image visualization was performed on a SGI Indigo*2 workstation (Silicon Graphics, Inc., Mountain View, CA) using VoxelView software (Vital Images, Inc., Fairview, IA).

In Vivo MRI. Imaging studies were performed on *Xenopus laevis* (African frog) embryos. Approximately 10 nL of a buffered aqueous solution containing each compound at a known concentration was injected into the animal pole of one cell in a two-cell embryo. Alternately, ≈ 2 nL of the same solution was injected into a marginal blastomere at the 32–256-cell stage. The distribution and survival of the labeled cells were followed for up to 4 days using MRI and fluorescence microscopy.

Gd(PABD). *Method A.* To a stirred solution of PABD in either water or a 100 mM Na_2CO_3 solution (pH 8) was added $\text{GdCl}_3 \cdot 6\text{H}_2\text{O}$ (0.99 equiv). The reaction mixture was stirred at 80 $^\circ\text{C}$ for 12 h. The solution was concentrated to dryness, redissolved in 100 mM triethylammonium acetate/MeCN, and purified by HPLC.

Method B. To a stirred solution of PABD in water or a 100 mM Na_2CO_3 solution (pH 8) was added Gd_2O_3 (1.3 equiv). The reaction mixture was stirred at 80 $^\circ\text{C}$ for 18 h. The solution was filtered through an Acrodisc (LC 13 PVDF, 0.2 μm) to remove unreacted Gd_2O_3 . The solution was then concentrated to dryness, redissolved in 100 mM triethylammonium acetate/MeCN, and purified by HPLC.

Gd(rhoda-DOTA) (1) (Figure 1). To a stirred solution of Gd(PABD) (1 mg, 1.46 μmol) in 250 μL of DMF was added TRITC (0.72 mg, 1.61 μmol , 1.1 equiv). The solution was covered with aluminum foil and stirred at room temperature for 10 h. The solution was concentrated to dryness, taken up in a 100 mM Na_2CO_3 solution/MeCN, and purified by HPLC. ^1H NMR (D_2O): δ 2.5–3.6 (m, 25 H), 3.25 (s, 12 H), 6.9–7.15 (m, 4 H), 7.27 (d, 2 H), 7.35–7.45 (m, 3 H), 7.5 (d, 2 H), 7.75 (d, 1 H), 8.1 (s, 1 H).

Synthesis of GRIP_c (3–6) (Scheme 1). *DTPA–pdl* (3). To a stirred solution of pdl (2) (50 mg, MW = 3500, 25 000, and 53 000 g/mol) in 12.5 mL of a NaHCO_3 solution (0.5 M, pH 9.5) was slowly added DTPA dianhydride in various amounts (100, 400, or 800 equiv). The pH was maintained at pH 9.5 by addition of a 1 M NaOH solution. After 1 h, the reaction mixture was filtered, concentrated to dryness, redissolved in 1.5 mL of water, and filtered. The solution was applied to a PD10 column and eluted with water, and the collected fractions were concentrated to dryness. The isolated products are referred to as DTPA–pdl_{100ex}, DTPA–pdl_{400ex}, or DTPA–pdl_{800ex} corresponding to the amount of DTPA dianhydride added to the reaction.

Gd–DTPA–pdl (4). To a stirred solution of DTPA–pdl (3) in 1 mL of water at 80 $^\circ\text{C}$ was added $\text{GdCl}_3 \cdot 6\text{H}_2\text{O}$ (10 equiv) dissolved in 0.5 mL of water. After 12 h, the solution was applied to a PD10 column and eluted with

Scheme 1. Synthesis of GRIP_c (6)^a

^a (a) DTPA dianhydride, pH 9.5; (b) GdCl₃·6H₂O or Gd₂O₃, 80 °C, 12 h; (d) β-propiolactone.

water, and the collected fractions were concentrated to dryness.

GRIP (5). Method A. To a stirred solution of Gd-DTPA-pdl_{100ex} (MW = 3500 g/mol) (4) (11 mg, 2.41 μmol) or Gd-DTPA-pdl_{400ex} (MW = 3500 g/mol) (4) (11 mg, 1.95 μmol) in 400 μL of a NaHCO₃ solution (0.5 M, pH 9.5) at 85 °C was added a solution of TRITC (10 equiv) in 200 μL of DMSO/pyridine (50:1). After 24 h, the solution was concentrated to dryness and redissolved in water. The solution was applied to a Sephadex G-25 column and eluted with water, and the collected fractions were concentrated to dryness.

Method B. To a stirred solution of DTPA-pdl (MW = 25 000 g/mol) (3) dissolved in 1 mL of a NaHCO₃ solution (0.5 M, pH 9.5) was added TRITC (30 equiv) dissolved in 50 μL of DMF. After 2 h, the solution was concentrated to dryness and redissolved in water. The solution was applied to a Sephadex G-25 column and eluted with water, and the collected fractions were concentrated to dryness. The intermediate was subsequently redissolved in 1.5 mL of water, and GdCl₃·6H₂O (10 equiv) dissolved in 0.5 mL of water was added. After 12 h, the solution was applied to a Sephadex G-25 column and eluted with water, and the collected fractions were concentrated to dryness.

GRIP_c (6). To a stirred solution of 5 (2.5 mg) in 2 mL of water at 0 °C was first added a 1 N NaOH solution to adjust the pH to 7 and then β-propiolactone (10 equiv) (18). After 10 min, the bath was removed and the reaction solution stirred at ambient temperature for 90 h. The solution was then applied to a PD10 column and eluted with water, and the collected fractions were concentrated to dryness. The crude reaction product was then redissolved in water and purified by FPLC.

Synthesis of GRID (8–11) (Scheme 2). Dex-Am (8). The six-carbon linker 1,6-diaminohexane was at-

tached to dextran via BrCN activation following a literature procedure (19). To a stirred solution of dextran 7 (212 mg, MW = 12 000 g/mol) in 40 mL of water at pH 10.7 (0.1 N NaOH) was slowly added BrCN (50 mg, 0.24 mmol). The reaction mixture was maintained at pH 10.7 by addition of a 0.1 N NaOH solution. After 4 h, the pH of the solution was adjusted to 7.8 by the addition of a 0.1 M HCl solution. To this solution was added 1,6-diaminohexane (500 mg, 4.3 mmol) and the reaction mixture was stirred for 2 h at room temperature. The solution was concentrated to dryness, taken up in water, and purified by FPLC.

Dex-Am-DTPA (9). To a solution of DTPA (360 mg, 90 mmol) in DMSO (40 mL) was added Dex-Am (8) (114 mg, 9 μmol) dissolved in DMSO (5 mL), and the reaction mixture was stirred for 12 h. The solution was concentrated to dryness and purified by FPLC. Dextran: C, 41.3%; H, 6.2%; N, 0%. Dex-Am-DTPA: C, 43.2%; H, 5.75%; N, 6.4%.

Gd-Dex-Am-DTPA (10). To a solution of Dex-Am-DTPA (9) (86 mg, 6.36 μmol) in water (4 mL) was slowly added a solution of GdCl₃·6H₂O (47 mg, 1.27 μmol) dissolved in water (0.4 mL). The pH was adjusted to 5 by the addition of a 0.1 M NaOH solution, and the reaction mixture was stirred for 24 h. The solution was concentrated to dryness and the crude product redissolved in water and purified by FPLC.

GRID (11). TRITC was covalently attached to Gd-Dex-Am-DTPA (10). To a solution of Gd-Dex-Am-DTPA (10) (30 mg, 1.62 μmol) in DMSO (1 mL) was added a solution of TRITC (10 mg, 1.86 μmol) dissolved in DMSO (1 mL) followed by pyridine (5 μL, 0.06 mmol) and dibutyltin dilaureate (3 μL, 5 × 10⁻³ mmol). The reaction mixture was stirred at 80 °C for 24 h. The solution was concentrated to dryness, redissolved in water (2 mL), and

Scheme 2. Synthesis of GRID (11)^a

^a (a) cyanogen bromide; (b) DTPA dianhydride, 12 h; (c) $\text{GdCl}_3 \cdot 6\text{H}_2\text{O}$, 80 °C, pH 5; (d) TRITC, DMSO, dibutyltin dilaureate, 24 h.

applied to a NAP 25 column. The product was eluted with water, and the collected fractions were concentrated to dryness.

RESULTS AND DISCUSSION

PABD was synthesized as described in the literature and purified by HPLC (13–17). The macrocycle was subsequently suspended in either water or a weakly buffered medium (100 mM sodium carbonate) and treated with either Gd_2O_3 or $\text{GdCl}_3 \cdot 6\text{H}_2\text{O}$ over the course of 12–24 h at 80 °C which afforded $\text{Gd}(\text{PABD})$. This complex was then coupled to commercially available TRITC and purified by HPLC to give $\text{Gd}(\text{rhoda-DOTA})$ (**1**) (Figure 1). The highest yields were obtained if the coupling reaction was performed in organic solvents such as *N,N*-dimethylformamide. It is of interest to note that the final product could not be obtained unless the Gd^{3+} was added to PABD prior to the addition of TRITC. This result suggests that the tetramethylrhodamine ligand is sterically shielding the binding cavity of the macrocycle, preventing Gd^{3+} coordination.

GRIP (**5**) and GRIP_c (**6**) were synthesized as illustrated in Scheme 1. The progress of the reaction was monitored by FPLC. The Gd^{3+} concentration of GRIP was determined by fluorescence spectroscopy ($\lambda_{\text{ex}} = 275 \text{ nm}$, $\lambda_{\text{em}} = 313 \text{ nm}$), leading to a ratio of $2 \pm 1 \text{ Gd}^{3+}$ per 3500 MW pdl in the case of GRIP_{100ex} and to a ratio of $4 \pm 1 \text{ Gd}^{3+}$ per 3500 MW pdl in the case of GRIP_{400ex}. An average of two tetramethylrhodamine molecules per pdl were found as estimated by fluorescence and UV–vis spectroscopy.

The synthesis of GRID (**11**) is illustrated in Scheme 2. The number of DTPA chelates (9 ± 2) covalently attached to the dextran backbone was determined by elemental analysis. The number of tetramethylrhodamine molecules (9 ± 4) coupled to the dextran backbone was determined by fluorescence spectroscopy ($\lambda_{\text{ex}} = 547 \text{ nm}$, $\lambda_{\text{em}} = 572 \text{ nm}$) and UV–vis spectroscopy ($\lambda_{\text{max}} = 548 \text{ nm}$, molar extinction coefficient $\epsilon \approx 65\,000 \text{ M}^{-1} \text{ cm}^{-1}$).

In Vivo Imaging Studies with Gd(rhoda-DOTA) (1). $\text{Gd}(\text{rhoda-DOTA})$ (**1**) contains the modified macrocycle DOTA with a pendent *p*-aminobenzyl group linked to one of the methylene carbons. This functional group allows covalent attachment of fluorescent markers such as the commercially available TRITC to the amine. A series of in vitro experiments using $\text{Gd}(\text{rhoda-DOTA})$ (**1**) revealed strong fluorescent and MR signals, and the relaxivity of the complex is comparable to that of $\text{Gd}(\text{DOTA})$. Surprisingly, when similar concentrations of **1** were injected into living embryos, no MR signal was observed while the fluorescence signal from the complex was observable. This may be due to absorption of the relatively hydrophobic molecule into fatty tissues where little or no water exchange with the gadolinium can take place.

In Vivo Imaging with Gd–DTPA–pdl (4) (pdl MW = 3500 g/mol), GRIP (5), and GRIP_c (6). GRIP (**5**) and GRIP_c (**6**) are high-molecular weight, membrane impermeable agents based on pdl as a macromolecular framework. These molecules were designed to be used for embryonic cell lineage analyses. The experiments are performed by single-cell injection of the complex and

Figure 2. In vivo injections of GRIP (5) (pdl MW = 3500 g/mol). (A) *X. laevis* embryo at approximately stage 17 as seen under a fluorescence microscope at the 256-cell stage. GRIP (5) was injected into a single cell. At stage 17, six cells exhibit strong fluorescence, seen as white regions. (B) MRI of the same embryo shown in panel A; semitransparent volume renderings of the embryo, rotated along its long axis (0–180°). Twelve cells produce a strong MRI contrast revealing the presence of the agent.

subsequent monitoring of the descendants of that labeled cell. The polymer contains several DTPA and tetramethylrhodamine molecules linked to the side chain amino groups of lysine. The biodistribution of Gd-DTPA-pdl (4) was studied using *X. laevis* embryos. This system was chosen to test the in vivo behavior of the agents because *X. laevis* cells are extremely sensitive to perturbations during development. If the contrast agents exhibit even minor toxic side effects, the injected cells develop at dramatically different rates compared to neighboring cells.

At the two-cell stage, 10 nL of aqueous solutions (10 mg/mL) of Gd-DTPA-pdl_{100ex} or Gd-DTPA-pdl_{400ex} were injected into the animal pole of the embryos to determine their biodistribution. Gd-DTPA-pdl_{100ex} diffused rapidly and uniformly as revealed by epifluores-

cence microscopy during the first 30 min after injection. Gd-DTPA-pdl_{400ex} did not disperse and remained localized at the site of injection. These observations suggested that the biodistribution correlates with the observed increasing viscosity of the injected solutions (as determined by the increased pressure needed for injections), which is lowest for Gd-DTPA-pdl_{100ex} and highest for Gd-DTPA-pdl_{800ex}. No attempt was made to inject Gd-DTPA-pdl_{800ex}.

In order to evaluate these derivatives as in vivo contrast agents, fluorescence microscopy and MR imaging studies were performed using GRIP (5) and GRIP_c (6) that was microinjected into *X. laevis* embryos. Cell division was monitored, and the embryos developed normally for 24 h after injection of GRIP (5). It was observed that embryo survival could be enhanced by

Figure 3. *X. laevis* embryo (stage 8) with GRIP_c (**6**) injected into the marginal blastomere at the 16-cell stage. (A) The labeled cells populate the prospective mesodermal regions as seen in this confocal fluorescence image. (B) MRI image showing a single slice through the middle of the same embryo shown in panel A. The distribution of labeled cells reveals features and delineates a number of cells that are unobservable by fluorescence techniques because they are too far below the surface. (C) A similarly injected embryo seen at stage 38–39 reveals labeled cells in the somatic mesoderm. The labeled cells, shown in green, are seen to span the length of the somite blocks.

protecting the free amino groups of the high-molecular weight derivatives of pdl by converting the unmodified amino side chains to terminal alcohols with β -propiolactone [GRIP_c (**6**)]. Unmodified pdl is toxic when injected into living cells, and it appears that charge distribution may effect the in vivo toxicity of the pdl derivatives. Similarly, GRIP_{100ex} (**5**) (pdl MW = 3500 g/mol) was injected into a single marginal cell of a *X. laevis* embryo at the 256-cell stage. Later, at stage 17, six fluorescent cells could be detected using fluorescence microscopy (Figure 2A). Figure 2B shows semitransparent volume renderings of MRI data rotated along the long axis of the same embryo at stage 18–19, revealing many more labeled cells at greater depth in the embryo.

Figure 3 depicts a *X. laevis* embryo that was injected with GRIP_c (**6**) (pdl MW = 25 000 g/mol) into a marginal blastomere at the 16-cell stage. Using confocal microscopy (Figure 3A), the labeled cells are seen to populate

the prospective mesodermal regions. The distribution of labeled cells was confirmed using MRI (Figure 3B). In addition, a number of cells that are not visible in the confocal are seen using MRI, demonstrating the unique ability of these agents in cell lineage analysis. The progeny of the labeled blastomere 5 days later at stage ≈ 38 –39 is shown in Figure 3C. Labeled cells in somatic mesoderm are clearly visible and span the length of each somitic block as expected. Cells in the endoderm are labeled in agreement with published fate maps of the 16-cell stage *X. laevis* embryos (20, 21).

In Vivo Imaging Studies with Gd–DTPA–Dextran [GRID (11**)].** GRID (**11**) is a high-molecular weight, membrane impermeable contrast agent based on dextran as a macromolecular framework. The backbone is multiply modified with several DTPA and tetramethylrhodamine molecules. As described above, *X. laevis* embryos were injected with GRID (**11**) and analyzed over

Figure 4. In vivo injections of GRID (11) in *X. laevis* as seen under the fluorescence microscope. (A) Embryo at the 32-cell stage just after injection of GRID (11) into only two cells. (B) The same embryo shown in panel A, however at a much later stage of development (stage 23–24); numerous labeled cells that are descendants of the two injected cells (panel A) can be seen in the embryo's neural axis and in the overlying head ectoderm.

Figure 5. Late stage (26–27) *X. laevis* embryo injected with GRID (11). Panels A and E show fluorescent images of cell progeny labeled with the contrast agent during the 128-cell stage. Panels B–D show the same embryo at the same stage using MRI. Panels A and B reveal the right side of the embryo in fluorescent (A) and MRI (B) views. The eye is brightly fluorescent in panel A and displays a correspondingly strong signal in panel B (e, eye; np, nasal pit). In the top view (C), the difference in signal intensity within the neuraxis is striking. Cells on the left side of the embryo (D and E) are not labeled, as determined using MRI (D) or fluorescence microscopy (E); scale bar = 200 μm ; cg, cement gland which displays intense inherent signal unrelated to the injected contrast agent. The color scale shown in panels B–D is as follows: Yellow represents the most intense signal, red is less intense, and gray is for background. Abbreviations for anatomical structures are as follows: cg, cement gland; e, eye; np, nasal pit; s, somite cell; and sc, skin cell.

time using both fluorescence microscopy and MRI. Cell division could be successfully followed, and the embryos developed normally for several days. Figure 4A shows the *X. laevis* embryo just after injection of GRID (11) into two cells at the 32-cell stage as observed under the fluorescence microscope. The same embryo depicted in Figure 4A is shown in the tail-bud stage (stage 23–24) (Figure 4B). Labeled cells are clearly visible in the embryo's neural axis and in the overlying head ectoderm.

In Figure 5B,C,D, the distribution of the marked cells in the interior of the embryo is visualized by MRI. Figure 5A–D shows a stage 26–27 the *X. laevis* embryo lineage

labeled using GRID (11). Less than 1 nL of the bifunctional agent has been pressure injected into a single dorsal tier-2 blastomere at the 128-cell stage. On the basis of earlier cell lineage studies, the normal fate of this blastomere is expected to be largely anterior neural derivatives.

Panels A and E of Figure 5 reveal low-light-level epifluorescence microscope images that document the distribution of fluorescently labeled cells which are shown in white in this black and white image. On the right-hand side of the animal (Figure 5A), the eye (e) is brightly labeled as is the nasal pit (np) and numerous skin cells

of the head (sc). Cells of the dorsal fin-fold and a few in the somites (s) are also labeled. Because the progeny of the injected blastomere is normally restricted to the right-hand side of the animal, most structures on the left-hand side (Figure 5E), with the exception of the fin-fold, appear unlabeled.

Finally, the distribution of labeled progeny as revealed by fluorescent microscopy is consistent with MR images of the same embryo. The three-dimensional MR data set is shown in the middle three panels (Figure 5B–D) (the labeled cells that were white in the fluorescent image appear in the MR images with a reddish color; as the MR images represent three-dimensional data sets, many more cells deep within the embryo labeled with the bifunctional contrast agent are seen using MR than can be seen with fluorescence microscopy) as right, top, and left views, respectively. Cells that are labeled with the bifunctional agent appear as yellowish regions against a reddish background signal. The right eye and right nasal pit are clearly labeled. The same structures on the left side are not labeled. In the top view, the difference in contrast between the left and right sides is striking. Just below the eye, in the approximate position of the developing mouth, is a structure that displays a high signal in the MR image but appears not to be labeled in the fluorescent image. This structure is the cement gland which typically possesses high contrast and does not represent signal from the injected agent.

In summary, this report describes synthesis and in vivo testing of two new classes of bifunctional contrast-enhancing agents. The agents were designed to integrate the advantages of optical and MR microscopy for studies in experimental animals. As a result, features that are invisible to light microscopes are clearly rendered by MRI microscopy. The complexes contain either one of two Gd^{3+} chelates, DTPA or DOTA as the MRI component, and a fluorescent dye, tetramethylrhodamine. The fluorescent functionality of these agents provides the advantage of allowing us to score the accuracy of labeled specimens immediately after injection, and to follow the initial stages of development using epifluorescence microscopy. Further, after careful analysis of cell divisions and cell lineage distributions of developing embryos, the complexes were shown not to interfere with normal development. Employing this class of agents in the study of embryonic cell lineage permits the acquisition of three-dimensional data sets that are not limited by the nature of the specimen.

Synthesis of Disulfide-Containing Phospholipid Analogs for the Preparation of Head Group-Specific Lipid Antigens: Generation of Phosphatidylserine Antibodies

Cecilia Diaz, Krishnakumar Balasubramanian, and Alan J. Schroit*

Department of Cell Biology, The University of Texas M. D. Anderson Cancer Center, Houston, Texas 77030. Received August 20, 1997; Revised Manuscript Received November 14, 1997[®]

In this report, we describe a new approach for the production of lipid antigens that elicit specific immune responses against phosphatidylserine (PS). Because phospholipids are small nonimmunogenic haptens, PS analogs containing activated coupling groups were synthesized and covalently attached to carrier proteins. Sulfhydryl-reactive PS was generated by acylation of 1-oleoyl-2-(aminocaproyl)-phosphatidylcholine with *N*-succinimidyl-3-(2-pyridyldithio) propionate, converted to PS by phospholipase D-catalyzed base exchange with L-serine, and conjugated to carrier proteins by thiol–disulfide exchange. Antisera to these lipid hapten–protein carrier conjugates were developed in rabbits. Antibodies bound PS but not phosphatidylcholine (PC), phosphatidylglycerol, phosphatidic acid, or phosphatidylethanolamine (PE) when presented together with PC. Inhibition studies using water-soluble lipid analogs and sonicated vesicles indicated that antibody specificity was directed toward the lipid's polar head group. These antibodies also inhibited the PS-dependent prothrombinase activity assay by ~60%. These data show that the covalent coupling of phospholipid haptens to protein carriers via the lipid's fatty acyl side chains preserves its primary head group moiety for the production of specific lipid antibodies.

Antibodies against different membrane components have become an indispensable aid in the study of membrane structure and function. Unlike protein antigens, little attention has been given to the application of lipid-specific antibodies for studying lipid-dependent processes. Because of the inherent difficulty of producing antibodies against small highly conserved lipids, the development of lipid antibodies has progressed slowly. Nonetheless, several laboratories have produced antibodies against certain phospholipid species by immunization with liposomes (Maneta-Peyret et al., 1988, 1989; Benerji and Alving, 1990) or by adsorption of monomeric phospholipids to proteins (Tamamura et al., 1971; Maneta-Peyret et al., 1989), bacteria (Umeda et al., 1989), and acrylamide (Maneta-Peyret et al., 1988, 1989). Due to the apparent lack of specific lipid adsorption, antibodies produced by these methods may cross-react with different lipids (Umeda et al., 1989; Benerji and Alving, 1990) and other phosphate-containing moieties (Alving, 1986).

Because PS¹ can be considered to be a nonimmunogenic hapten, we reasoned that an appropriate lipid–protein

conjugate might elicit a potent and specific immune response. To address this issue and overcome the inherent problems of lipid immunogenicity and cross-reactivity, we designed a lipid–protein conjugate in which the lipid hapten reacts exclusively through a noncritical reactive site at the acyl side chain. In this paper, we report on the synthesis of a phosphatidylcholine analog that contains a “sulfhydryl-activated” coupling group at the end of the 2-position side chain by reacting SPDP with 1-oleoyl-2-(aminocaproyl)phosphatidylcholine (NH₂-PC). The thiolated lipid was then converted into an activated phosphatidylserine derivative by phospholipase D-catalyzed base exchange and then coupled to a sulfhydryl-containing protein carrier and presented to the immune system. This antigen induced the production of PS-specific antibodies which could become potentially useful for the study of lipid-dependent processes and the distribution of specific lipid species in cell membranes.

EXPERIMENTAL PROCEDURES

Materials. PS, PA, PC, PG and PE were purchased from Avanti Biochemicals (Alabaster, AL). *N*-succinimidyl-3-(2-pyridyldithio) propionate (SPDP) and 2-IT were purchased from Pierce (Rockford, IL). BSA, prothrombin, factor X, and analytical reagents were from Sigma (St. Louis, MO). Factor V was purified as previously described (Connor et al., 1989). Phospholipase D (*Streptomyces chromofuscus*) was from Calbiochem (LaJolla, CA), and S2238 was purchased from Kabi Laboratories (Franklin, OH). Human red blood cells (RBCs) were obtained from healthy volunteers by venipuncture into heparinized syringes.

General Procedures. UV adsorption was recorded on a Gilford response spectrophotometer. ELISAs were recorded on a Samtron CERES UV900C instrument at 450 nm. The molecular mass of BSA was assumed to be

[®] Abstract published in *Advance ACS Abstracts*, December 15, 1997.

¹ Abbreviations: 2-IT, 2-iminothiolane; BSA, bovine serum albumin; DTNB, dithiobis(nitrobenzoic acid); DTT, dithiothreitol; NH₂-PC, 1-oleoyl-2-(aminocaproyl)phosphatidylcholine; PA, dioleoylphosphatidic acid; PC, dioleoylphosphatidylcholine; PE, dioleoylphosphatidylethanolamine; PG, dioleoylphosphatidylglycerol; PS, phosphatidylserine; SPDP, *N*-succinimidyl-3-(2-pyridyldithio) propionate; SUV, small unilamellar vesicles; TLC, thin-layer chromatography.

65 kDa. The extinction coefficients used for DTNB and thiopyridine were 14 150 (412 nm) and 8 000 (312 nm), respectively.

The purities of the lipid compounds were assessed after TLC on precoated silica gel 60 plates (Merck). Lipids were purified by silica gel column chromatography. API electrospray mass spectra were recorded by Avanti Polar Lipids (Alabaster, AL) on a HP 5989A mass spectrometer.

Syntheses. *1-Oleoyle-2-(aminocaproyl)phosphatidylcholine (NH₂-PC).* NH₂-PC was synthesized as previously described (Schroit and Madsen, 1983). Briefly, aminocaproic acid was protected by *tert*-butoxycarbonylation, reacted with dicyclohexylcarbodiimide to yield the [(*tert*-Boc)amino]caproic anhydride, condensed with lysophosphatidylcholine to yield [[(*tert*-Boc)amino]caproyl]phosphatidylcholine, and finally deblocked with anhydrous HCl.

1-Oleoyle-2-N-succinimidyl-3-(2-pyridyldithio) Propionyl(aminocaproyl)-PC (SPDP-PC). NH₂-PC (20 μ mol) was dried under N₂ and resuspended in CHCl₃/MEOH/triethylamine (1/2/0.015) (3.0 mL) containing SPDP (40 μ mol) for 16 h at 4 °C. The lipid was extracted by adding CHCl₃ (1 mL) and water (1.8 mL). The organic extract containing the product was dried under reduced pressure. The residue was analyzed by TLC (65/25/4 CHCl₃/MEOH/H₂O) and revealed a single phosphate-positive, ninhydrin-negative spot ($R_f = \sim 0.4$). Mass analysis m/z calcd for C₄₀H₆₉N₃O₉PS₂ (M + Na⁺) 854.08, found 854.7.

1-Oleoyle-2-N-succinimidyl-3-(2-pyridyldithio) Propionyl(aminocaproyl)-PS (SPDP-PS). SPDP-PC (20 μ mol) was dried under N₂ and resuspended in 50% L-serine (1 mL) in acetate buffer (0.1 M, pH 5.6) containing CaCl₂ (0.1 M). Ether (1 mL) and phospholipase D (25 units, 70 μ L) were added, and the suspension was mixed at 45 °C for 3 h. The reaction was stopped by adding EDTA (to 0.2 M). The ether was then evaporated, and the product was resuspended in CHCl₃/MEOH/H₂O (1/2/0.8). The suspension was cooled to 4 °C, and the resulting L-serine precipitate was removed by centrifugation. The product was recovered from the organic phase after the addition of CHCl₃ and water (1 volume each). The organic phase was taken to dryness, dissolved in CHCl₃, and applied to a 2 $\times$ 30 cm column of activated pre-washed silica gel. The column was washed with CHCl₃ (100 mL), followed by 100 mL aliquots of CHCl₃ containing increasing MEOH. Analysis of the product which eluted with CHCl₃/MEOH (6/4) by TLC revealed a single phosphate- and ninhydrin-positive spot ($R_f = \sim 0.2$). The purified product was stored at -70 °C in CHCl₃. Mass analysis m/z calcd for C₃₈H₆₃N₃O₁₁PS₂ (M) 833.02, found 832.7.

Reaction of 2-IT with Carrier Proteins. BSA (10 mg) was solubilized in Tris-EDTA buffer [1 mL, 10 mM Tris (pH 8.0) and 0.1 mM EDTA]. 2-IT was added at a 100-fold molar excess, and the reaction was allowed to proceed for 1 h at 20 °C (Jue et al., 1978). The solution was then dialyzed overnight against deaerated, N₂-flushed Tris-EDTA. The proteins (1 mL) were then mixed with DTT (0.05 mL 0.1 M) for 30 min at 20 °C. The reduced proteins were then purified by exclusion chromatography on a Biogel P6 column (15 $\times$ 500 mm). Peak fractions were collected, and available sulfhydryls and protein concentrations were estimated spectrophotometrically by thiol-disulfide exchange with DTNB as described by Riddles et al. (1983) and by adsorption at 280 nm, respectively.

Coupling of SPDP-PS to Protein Carriers. Reduced, purified, 2-IT-treated BSA (63 nmol in 2 mL, 1300 nmol of SH) was immediately mixed with 1 SH equiv

molar of SPDP-PS in 1/10 volume of ethanol. The efficiency of derivatization was estimated after 10 min by assessing the stoichiometric release of 2-thiopyridine at 343 nm (Grassetti and Murray, 1967). Excess reagents were removed by dialysis against NaCl (0.15 M). The products were stored at -70 °C.

Immunization Protocol. Rabbits were injected in multiple intradermal sites with ~ 1 mg of the lipid-protein conjugates (~ 0.25 mg of lipid hapten) in complete Freund's adjuvant followed by a boost 1 month later in incomplete Freund's adjuvant. The rabbits were bled 2 weeks after the last injection.

Enzyme-Linked Immunoabsorbent Assays (ELISAs). Polystyrene microtiter plates were coated overnight with 30 μ L/well of the indicated phospholipids (200 μ g of lipid/mL) in CHCl₃/MEOH (1/50) at room temperature. The plates containing the evaporated lipids were blocked with goat serum (10% in 0.8% NaCl/20 mM Tris at pH 8.0) for 1 h at room temperature. Antiserum samples prepared in blocking solution were applied to the wells at different dilutions (reported in the figure captions) for 2 h, and binding was assessed by adding anti-rabbit (whole molecule) peroxidase conjugate (1/10 000 dilution in 0.8% NaCl/20 mM Tris at pH 8.0) for 2 h. TMB-ELISA (3,3',5,5'-tetramethylbenzidine base) was used as the substrate, and the ELISA was stopped with H₂SO₄ (1 N). Inhibition of immune serum binding to PS was determined with the head group analogs glycerophosphorylserine (GPS), phosphorylserine (PhoS), serine, glycerophosphorylethanolamine (GPE), phosphorylethanolamine (PhoE), and ethanolamine. Inhibition with SUV (0.5 mg/mL) composed of PS (40 mol % in PC), PE (40 mol % in PC), and PC was achieved by the addition of equal volumes of liposomes to antiserum samples diluted in 10% goat serum. After 1 h of incubation at 37 °C, the ELISA was carried out as described above.

Prothrombinase Activity Assay. The PS-dependent prothrombinase assay was carried out as described previously (Diaz et al., 1996) except that PS SUV were used as the procoagulant surface. Briefly, PS SUV (0.05 mL at 1 mg/mL) were incubated with antiserum or control preimmune serum (0.05 mL) for 1 h at 37 °C. The suspension was then added to prothrombinase assay buffer (0.2 mL) containing Ca²⁺ and the necessary coagulation factors for the period of time indicated. Aliquots of the suspension were then transferred to a cuvette containing EDTA buffer (1 mL) to stop the production of thrombin. The thrombin-dependent chromogen, S2238, was added to the cuvettes (to 0.2 mM), and the rate of chromophore formation was monitored at 405 nm with a Gilford response spectrophotometer employing appropriate kinetic software. The initial rate of thrombin-dependent chromophore production was determined from the slope of the absorbance curve. These rates were plotted on the ordinate against the incubation time.

RESULTS

Preparation of PS-Carrier Conjugates. Because the specificity of lipid antibodies must be directed to the lipid's polar head group, its modification by the attachment of covalent spacers and/or coupling groups will likely generate immune responses that fail to recognize the native lipid. Reactive thiols placed in the fatty acyl chain, however, would not be expected to change the structure of the polar head group and, when incorporated as a heterobifunctional intermediate, could serve as a

Figure 1. Synthesis of PS-carrier conjugates. $\text{NH}_2\text{-PC}$ was reacted with SPDP, converted to the PS derivative with phospholipase D, and coupled by thiol–disulfide exchange to carrier protein: PLD, phospholipase D; 2-TP, 2-thiopyridine.

convenient attachment point for various proteins or peptides via thiol–disulfide exchange reactions. On this basis, we reasoned that phosphatidylcholine could be modified to contain a single reactive amine in an acyl side chain, and that it could be derivatized with an amine- and sulfhydryl-reactive heterobifunctional reagent. Once coupled, the lipid could be readily converted to other lipid species by phospholipase D-catalyzed base exchange without activating the protected thiol-dependent exchange moiety.

To demonstrate the feasibility of this approach, SPDP was first conjugated to $\text{NH}_2\text{-PC}$ **1** as shown in Figure 1. The product, SPDP–PC **2**, containing a protected disulfide β chain, was obtained in >90% yield. This compound was then converted to the PS derivative **3** with phospholipase D in the presence of L-serine. Lipid–protein coupling was accomplished by thiol–disulfide exchange of the activated lipid haptens to proteins treated with 2-IT (1 mol of SPDP–PS per mole of SH). Coupling was stoichiometric as estimated by monitoring the release of 2-thiopyridine. Coupling ratios were typically 20/1.

Reaction of PS Antibodies with Different Lipids.

Antisera obtained from rabbits immunized against PS–BSA were tested by ELISA for their ability to bind unmodified native phospholipids. The data shown in Figure 2A indicate that the antiserum, but not the preimmune serum, reacted with PS. To determine specificity, the antibody was tested against different phospholipid species (Figure 2B). It can be seen that the antibody did not bind PC or the negatively charged phospholipids, PA and PG. The reactivity against PE

Table 1. Phosphate/Head Group Specificity

$\begin{array}{c} \text{HOCH}_2 \\ \\ \text{HOCH} \text{---} \text{O} \\ \quad \parallel \\ \text{H}_2\text{C} \text{---} \text{OPOR} \\ \\ \text{O}^- \end{array}$	glycerophospho- serine ethanolamine
$\begin{array}{c} \text{O} \\ \parallel \\ \text{HOPOR} \\ \\ \text{O}^- \end{array}$	phospho- serine ethanolamine
$\text{R} = \begin{array}{c} \text{NH}_3^+ \\ \\ \text{---CH}_2\text{CH} \\ \\ \text{COO}^- \\ \text{serine} \end{array} \quad \text{or} \quad \begin{array}{c} \text{---CH}_2\text{CH}_2\text{NH}_3^+ \\ \text{ethanolamine} \end{array}$	

was likely an artifact of lipid deposition on the ELISA plates because reactivity was abolished when the lipid was coated as a 50 mol % mixture with PC. The Activity to PS was retained under the same conditions (Figure 2c).

To determine the epitope responsible for PS binding, the reactivity of the antibodies to the lipid's polar head group was assessed by competitive inhibition with water-

Figure 2. Reactivity of PS antiserum with phospholipids. Microtiter plates were coated with 6 μ g of lipid. Bound antibody was quantified by ELISA with peroxidase-conjugated goat anti-rabbit Ig. (A) Binding of control preimmune serum (○) and antiserum (●) to PS-coated plates. (B) Binding of PS antiserum to polystyrene plates coated with 6 μ g of PE (■), PA (▲), PG (▼), and PC (◆) and preimmune serum to PA-, PG-, PC-, and PE (○)-coated plates. (C) Antiserum binding to PS/PC (●) and PE/PC-coated (■) plates.

Figure 3. Inhibition of immune serum binding with soluble head group analogs and vesicles. The binding assays were carried out as described in Figure 2 at a serum dilution of 1/388 ($\log 2^{8.6}$). (A) PS- and (B) PE-coated plates in the presence of GPS, PhoS, serine (S), GPE, PhoE, and ethanolamine (E) at the indicated concentrations. (C) Plates coated with PS and PE were assessed for antibody binding in the presence of SUV (0.5 mg/mL) containing PS, PE, and PC.

soluble lipid analogs (Table 1) and liposomes of different lipid compositions. At 600 μ g/mL, GPS and PhoS inhibited binding to the PS-coated plates by ~80 and ~60%, respectively. Serine, GPE, PhoE, and ethanolamine had no effect (Figure 3A). Similar to the lipid analogs, SUV composed of PS/PC (1/1), but not PE/PC (1/1) or PC inhibited antibody binding by ~50% to PS-coated ELISA plates (Figure 3C). Consistent with the notion that antibody binding to pure PE is an artifact, GPE and PhoE did not inhibit binding to PE-coated plates (Figure 3B). Moreover, unlike the specific inhibition obtained with PS-coated plates, antibody binding to PE was inhibited with vesicles irrespective of their lipid composition.

Because these antibodies bind PS, they should also be able to interfere with PS-dependent processes such as

coagulation. To test this, PS vesicles were preincubated with the antiserum for 1 h at 37 °C and the ability of the vesicles to promote the PS-dependent prothrombinase reaction was assessed. The results presented in Figure 4 show that the initial rates of thrombin-dependent S2238 cleavage after the indicated reaction times were inhibited by ~60% in the antiserum-treated samples (calculated from the slopes of the fitted curve).

DISCUSSION

To preserve the structural integrity of phospholipids, it is important to construct conjugates that do not modify the lipid's polar head group. While the amino lipids seem to be amenable to derivatization with peptide or carrier proteins through their head group (Martin and Papa-

Figure 4. Inhibition of prothrombinase activity. Prothrombinase activity was assessed in the presence of PS-containing vesicles preincubated with the indicated sera. The reaction was stopped at various time points with EDTA, and thrombin production was assessed by determining the initial rates of thrombin-dependent cleavage of the chromogenic substrate. These rates were plotted on the ordinate against the incubation time: preimmune serum (○), antiserum (●).

hajopoulos, 1982; Bate et al., 1993), it is important to realize that such conjugation destroys the lipid's structure. Antibodies obtained with such conjugates cannot be expected to specifically react with natural unmodified phospholipids. Although several laboratories have tried to overcome this problem by using lipids absorbed non-covalently to carriers (Maneta-Peyret et al., 1993; Rote et al., 1993, 1995; Katsuragawa et al., 1995), many of these preparations are not specific and cross-reactivity is common. This may be due to the weak antigenic presentation of the phosphorylated head groups or to the generation of antibodies to diacylglycerol, phosphodiester, and/or fatty acid moieties that are common to all phospholipids.

In an attempt to produce specific PS antibodies, we immunized rabbits with PS covalently coupled to protein carriers via its fatty acid side chain without modifying the crucial phosphoserine moiety. Our data show that the rabbit antibodies specifically recognize PS but not other major phospholipids. The inhibition experiments (Figure 3) show that the presentation of both the serine head group and the phosphate moiety (see Table 1) are required for the specificity of binding to PS. Indeed, the recognition of the serine-phosphate is critical because ethanolamine-phosphate, which is ineffective, differs only by a single carboxyl. These antibodies therefore differ from other lipid antibodies which are partially inhibited by phosphate buffers and phosphorylated nucleotides (Alving, 1986; Banerji and Alving, 1990).

In summary, we have described the synthesis of a novel intermediate sulfhydryl-activated lipid where the coupling group is located on the fatty acyl chain distal from the head group. Thus, the native head group structure is retained even after coupling to carrier proteins. Because the protected intermediate can be used to prepare any glycerophospholipid hapten by phospholipase D-catalyzed base exchange, it should be possible to use this approach for the preparation of other lipid-specific antibodies.

ACKNOWLEDGMENT

The authors thank Dr. Jerald Killion for his kind help and critical comments and Polina Khaskina for technical assistance. This work was supported in part by National Institutes of Health Grant DK 41714.

The synthesis of C-Mel, a cephalosporin carbamate derivative of the clinically used alkylating agent melphalan, is described. C-Mel was designed as an anticancer nitrogen mustard prodrug that releases melphalan upon tumor-specific activation by targeted β -lactamase (bL). The K_m and k_{cat} values for bL hydrolysis of C-Mel were 218 μ M and 980 s^{-1} , respectively. In vitro cytotoxicity assays with 3677 human melanoma cells demonstrated that C-Mel was 40-fold less toxic than melphalan and was activated in an immunologically specific manner by L49-sFv-bL, a recombinant fusion protein that binds to the melanotransferrin antigen on melanomas and on some carcinomas. L49-sFv-bL in combination with C-Mel led to regressions and cures of established subcutaneous 3677 tumors in nude mice. The effects were significantly greater than those of melphalan, which did not result in any long-term regressions in this tumor model. The therapeutic effects were comparable to those obtained in mice treated with the previously described L49-sFv-bL/7-(4-carboxybutanamido)-cephalosporin mustard (CCM) combination. However, C-Mel may be more attractive than CCM for clinical development since the released drug is clinically approved.

INTRODUCTION

Targeting cytotoxic agents to sites of malignancy using monoclonal antibodies (mAb)¹ that bind to tumor-associated antigens has been the subject of a great deal of research. Among the cytotoxic moieties delivered using this strategy are radionuclides (1, 2), protein toxins (3), and chemotherapeutic drugs (4), all of which involve covalent attachment of the targeted molecule to the mAb. An alternative strategy is to use mAb-enzyme conjugates for the activation of anticancer prodrugs. In this two-step process, a mAb-enzyme conjugate is used to convert a prodrug substrate for the targeted enzyme to an active drug in a site-selective manner. Several reviews discussing this approach are currently available (5–7). Earlier work has demonstrated that this approach can generate higher intratumoral levels of drug (8–10) and better therapeutic effects than systemic administration of drug alone (11–15).

β -Lactamases (bL) are enzymes that have been shown to be very effective and versatile for anticancer prodrug activation (8, 11, 13, 15–21). These monomeric enzymes are abundant, available in multiple forms, inexpensive, and retain their activity in vivo. Furthermore, a variety of anticancer drugs can be appended to cephalosporin so that, upon β -lactam hydrolysis, a fragmentation reaction leads to the release of active drug (Scheme 1). Several studies have demonstrated that bL can release phenylenediamine mustard (13, 17), doxorubicin (18), mitomycin C (16), platinum compounds (19), and paclitaxel (20) from

cephalosporin prodrugs. We have previously shown that L6-bL in combination with a cephalosporin doxorubicin prodrug led to antitumor activities in two models of human lung carcinoma (8). Significantly better activities were obtained in melanoma models using either chemically conjugated L49-bL (13, 21) or the single-chain Fv-containing fusion protein L49-sFv-bL (15) in combination with CCM, a prodrug of phenylenediamine mustard. Because of the pronounced activities obtained using alkylating agents in our studies (13, 15, 21) and in others (12, 14), we were prompted to develop cephalosporin prodrugs of a clinically approved nitrogen mustard. One agent that came to our attention was melphalan, an anticancer drug that alkylates DNA, mainly at the N-7 position of guanine residues (22). Since it is known that amide derivatives of melphalan are generally less cytotoxic than the parent drug (23), we reasoned that attachment of melphalan through the primary amine to a cephalosporin via a carbamate linkage would greatly reduce its cytotoxic activity. In this article, we report the synthesis and in vitro and in vivo properties of C-Mel, a cephalosporin prodrug of melphalan.

MATERIALS AND METHODS

Materials. L49 is a mAb that binds to the melanotransferrin antigen expressed on most human melanomas (15). L49-sFv-bL was expressed in *Escherichia coli* and purified as described earlier (15). The bL used was a mutated form of the enzyme from *Enterobacter cloacae* (15, 24). CCM was synthesized as described earlier (17). HPLC analyses were performed on a Perkin-Elmer LC Bio 410 instrument equipped with a 5 μ m C-18 column and a UV detector set at 264 nm. Acetonitrile/0.1 M sodium phosphate (1:1, pH 1.8) was used as the eluting solvent to monitor the enzymatic hydrolysis of the prodrug.

Preparation of 7-(Phenylacetamido)-3-[[[(1',2',2',2'-tetrachloroethoxycarbonyl)oxy]methyl]ceph-3-em-

4-carboxylic Acid 1-Oxide Diphenyl Methyl Ester (2). An ice cold solution of the corresponding thioether (**1**) (25) (7.10 g, 9.80 mmol) in methylene chloride (300 mL) was treated with 3-chloroperoxybenzoic acid (3.05 g, 80% purity). After 15 min, a cold solution containing a 10% sodium bisulfite solution (100 mL) and a 0.1 N sodium bicarbonate solution (100 mL) was added. The biphasic mixture was stirred at 0 °C for 10 min, and the layers were separated. The organic layer was washed with ice cold 0.1 N sodium bicarbonate solution (3 × 100 mL) and saturated NaCl (100 mL), dried over MgSO₄, and concentrated to approximately 80 mL, at which point crystallization occurred. After cooling in ice, the crystalline material was filtered to give 5.20 g (7.01 mmol, 72%) of sulfoxide (**2**) as a white solid. MS (*M* + NH₄⁺): 756 (found), 756 (calcd). ¹H NMR (CDCl₃): δ 7.60–7.24 (m, 15H, ArH), 6.92 (s, 1H, CHCl), 6.69 (d, 1H, *J*_{NH,7} = 9.9 Hz, 7-NH), 6.62 (s, 1H, CHPh₂), 6.11 (dd, 1H, *J*_{6,7} = 4.8 Hz, H-7), 5.61 (d, 1H, *J*_{AB} = 14.1 Hz, CH_{2A}OCO), 4.85 (d, 1H, H-6), 4.54 (d, 1H, H-6), 3.80 (d, 1H, *J*_{AB} = 18.8 Hz, H-2A), 3.67 (d, 1H, CH_{2A}Ph, *J* = 6.3 Hz), 3.60 (d, 1H, CH_{2B}Ph), 3.20 (d, 1H, H-2B). Anal. Calcd for C₃₂H₂₆N₂Cl₄O₈S: C, H, N, S, Cl, 19.15%. Found: C, H, N, S, Cl, 19.87%.

Preparation of C-Mel. To a solution of melphalan (412 mg, 1.35 mmol) in a mixture of 0.25 N sodium bicarbonate (14 mL) and THF (28 mL) was added the activated sulfoxide (**2**) (1.00 g, 1.35 mmol). The resulting suspension turned clear after sonicating at room temperature for 15 min. The reaction mixture was stirred for an additional 10 min at room temperature and cooled in an ice bath; 1 N HCl (5 mL) was added, and the reaction mixture was extracted with ethyl acetate (3 × 40 mL). The combined organic layer was washed with water (80 mL) and brine (80 mL), dried over MgSO₄, and evaporated in vacuo. The resulting residue was suspended in methylene chloride (50 mL) and anisole (5 mL) at 0 °C, and trifluoroacetic acid (5 mL) was added over a period of 5 min. The resulting reaction mixture was stirred at 0 °C for 45 min. Volatile materials were then removed under reduced pressure. The residue was

dissolved in a minimum amount of dichloromethane, and the solution was poured into ice cold hexane (100 mL). The white precipitate formed was filtered and recrystallized from absolute ethanol/methylene chloride (1:1) to give 445 mg (0.60 mmol, 44%) of the title compound as an off-white solid. MS for C₃₀H₃₃Cl₂N₄O₉S (MH⁺): 695 (calcd), 695 (found). ¹H NMR (DMSO-*d*₆): δ 13.80 (br s, 1H, COOH), 12.71 (br s, 1H, COOH), 8.44 (d, 1H, *J* = 8.3 Hz, OCONH), 7.67 (d, 1H, *J*_{NH,7} = 8.3 Hz, 7-NH), 7.32–7.20 (m, 5H, 7-ArH), 7.08 (d, 2H, *J* = 8.6 Hz, 2Ar'H), 6.64 (d, 2H, 2Ar'H), 5.79 (dd, 1H, *J*_{6,7} = 4.8 Hz, H-7), 5.06 (d, 1H, *J*_{AB} = 13.3 Hz, CH_{2A}OCONH), 4.81 (d, 1H, H-6), 4.54 (d, 1H, CH_{2B}OCONH), 4.05–4.01 (m, 1H, NHCHCOOH), 3.78–3.21 (m, 12H, H-2A, H-2B, PhCH₂-CO, 2 NCH₂CH₂Cl), 2.91 (dd, 1H, *J*_{AB} = 13.8 Hz, *J*_{A,X} = 4.4 Hz, CHCH_{2A}Ph-N), 2.70 (dd, 1H, *J*_{B,X} = 10.1 Hz, CHCH_{2B}Ph-N). Anal. Calcd for C₃₀H₃₂Cl₂N₄O₉S·1C₂H₅OH·1H₂O: C, H, N, Cl, S.

Enzyme Kinetics. The hydrolysis of C-Mel by bL was measured as described previously (17). The cleavage of the β-lactam ring results in a loss of absorbance at 260 nm. Initial velocities of β-lactam hydrolysis were determined at room temperature, and a Lineweaver–Burk plot of the data was used to estimate the *K*_m and *k*_{cat} values. The bL concentration was 25 ng/mL, and the C-Mel concentration was 20–100 μM.

In Vitro Cytotoxicity. Type 3677 cells in Iscove's modified Dulbecco's medium containing 10% fetal bovine serum, 60 μg/mL penicillin, and 100 μg/mL streptomycin were plated into 96-well microtiter plates at 10⁴ cells/mL and allowed to adhere overnight at 37 °C. For blocking experiments, the cells were incubated at 4 °C with unconjugated L49 at 2 μM (300 μg/mL) for 30 min prior to treatment with L49–sFv–bL. The cells were then treated with 2 nM L49–sFv–bL (134 ng/mL). After 30 min at 4 °C, the plates were washed four times with antibiotic-free Roswell Park Memorial Institute 1640 media with 10% fetal bovine serum, and then varying concentrations of C-Mel were added. C-Mel and melphalan were also added to cells treated with media alone. After 4 h at 37 °C, cells were washed three times with

Iscove's modified Dulbecco's medium and incubated for approximately 12 h at 37 °C. The cells were then pulsed for 18 h with [^3H]thymidine (1 $\mu\text{Ci}/\text{well}$) at 37 °C, detached by freezing at -20 °C and thawing, and harvested onto glass fiber filter mats using a 96-well harvester. Radioactivity was counted using a LKB Wallac β -plate counter.

Therapy Experiments. Type 3677 tumor-bearing mice (subcutaneous implants, five animals/group, average tumor volume of 110 mm ^{3}) were injected with 1 mg/kg L49-sFv-bL (intravenous, 8 days after tumor implant), followed 18 h later by CCM or C-Mel. Treatment with L49-sFv-bL and CCM or C-Mel was repeated 7 and 14 days later. Control mice were treated with PDM or melphalan. Animals were monitored daily for general health and one or two times per week for body weight and tumor growth. Tumor volume was estimated using the formula (longest length)[(perpendicular dimension) ^{2} /2]. Cures were defined as an established tumor that, after treatment, was not visually detectable for 10 tumor doubling periods (40 days in the 3677 tumor model). MTDs led to less than 10% weight loss and no treatment-related deaths and were within 50% of the dose where such events took place. If an animal was removed from the experiment because of tumor growth, the data set was no longer plotted, but the remaining animals were monitored for tumor size and general health.

RESULTS

Synthesis of C-Mel and Enzymatic Conversion to Melphalan. C-Mel was synthesized by condensing commercially available melphalan with the activated sulfoxide (2) as shown in Scheme 1. Cephalosporin sulfoxide (2) was prepared from 1 (25) by oxidation with 3-chloroperoxybenzoic acid. HPLC analysis revealed that C-Mel was a substrate for bL and released melphalan (data not shown). Enzymatic hydrolysis of C-Mel to melphalan by bL was investigated spectrophotometrically. The K_m was 218 μM , and the k_{cat} was 980 s $^{-1}$. The fast rate of bL hydrolysis of the sulfoxide prodrug C-Mel is comparable to those of other similar cephalosporin sulfoxides (26) and is substantially faster than those of related thioether prodrugs (16).

In Vitro Cytotoxicity. L49-sFv-bL is a recombinant fusion protein containing the sFv fragment of the anti-melanoma mAb L49 and a mutated form of the enzyme bL (24). The protein was expressed in *E. coli* as described earlier and was purified by affinity chromatography (15). The cytotoxic effects of L49-sFv-bL in combination with C-Mel were determined on 3677 human melanoma cells, which express the melanotransferrin (p97) antigen. The experiments were performed by treating the cells with the fusion protein, washing off unbound material, adding various concentrations of C-Mel for 4 h at 37 °C, and using [^3H]thymidine incorporation as a measure of cytotoxic activity. The prodrug C-Mel (IC_{50} = 53 μM) was approximately 40-fold less toxic to 3677 cells than the drug melphalan (IC_{50} = 1.3 μM). As expected, L49-sFv-bL activated C-Mel, and the combination was equivalent in activity to melphalan (Figure 1). This indicates that prodrug conversion was efficient under the conditions tested. In addition, it was found that activation was immunologically specific, since a much lower level of C-Mel activation took place on 3677 cells that were saturated with unconjugated L49 prior to addition of the fusion protein.

Therapeutic Activity. In vivo therapy experiments were performed in which the activities of L49-sFv-bL/

Figure 1. Cytotoxic effects of L49-sFv-bL and C-Mel on 3677 melanoma cells as measured by [^3H]thymidine incorporation. Cells were incubated with L49-sFv-bL, washed, and treated with C-Mel for 4 h. Control cells were treated with melphalan or C-Mel in the absence of L49-sFv-bL or with L49 at saturating amounts prior to L49-sFv-bL addition.

CCM and L49-sFv-bL/C-Mel were compared in nude mice with established subcutaneous 3677 tumors. This particular tumor model has previously been shown to be resistant to treatment with PDM and CCM but was responsive to treatment with the L49-sFv-bL/CCM combination (15). In the experiments reported here, conjugate treatment was initiated 8 days after tumor implant, at which time the tumors were approximately 110 mm ^{3} in volume. CCM or C-Mel was then administered 18 h later, and the treatment protocol was repeated twice more on a weekly basis. This particular time interval was chosen on the basis of the high tumor:nontumor ratios 18 h after L49-sFv-bL administration (15).

The MTD of melphalan (10 mg/kg/injection) led to a delay in tumor outgrowth of 39 days (Figure 2A). More pronounced antitumor activity was seen in mice that received C-Mel (100 mg/kg/injection) after L49-sFv-bL. Therapeutic activity was dose-dependent, as cures (three out of five mice) and complete regressions (two out of five mice) were obtained at a higher C-Mel dose (150 mg/kg/injection). Both of these doses were well tolerated. In the same experiment, it was found that PDM at 3 mg/kg (MTD) had no effect on the growth of the 3677 tumors (Figure 2B). In contrast, animals treated with L49-sFv-bL prior to CCM (100 mg/kg/injection) experienced a tumor growth delay of 63 days, with one out of five cures. L49-sFv-bL followed by CCM (150 mg/kg/injection) resulted in cures (three out of five mice) and partial regressions (two out of five mice). These doses were nontoxic. L49-sFv-bL followed by either C-Mel or CCM at 200 mg/kg was above the MTD. Thus, CCM and C-Mel are equally effective in 3677 tumor-bearing mice that were pretreated with L49-sFv-bL.

DISCUSSION

Among the many prodrugs that have been reported for tumor-selective activation by mAb-enzyme conjugates (5-7), the most pronounced activities have generally been obtained from those containing nitrogen mustards (12-15). Possible reasons for this may be due to the steep dose-response curves displayed by such agents, along with the fact that nitrogen mustards tend not to be cell cycle-specific (22). The alkylating agents employed thus far have been PDM (13, 15, 21) and several benzoic acid mustard derivatives (12, 14), none of which are clinically approved. There may be some advantages in releasing clinically approved agents since their pharmacology and toxicities are well-understood. For this reason, we

Figure 2. Therapeutic effects of L49-sFv-bL in combination with (A) C-Mel or (B) CCM. Nude mice (five mice per group) were treated with L49-sFv-bL at 1 mg/kg followed 15–18 h later by prodrugs. The average tumor volumes were plotted until one or more mice were removed from the experiment due to tumor outgrowth. Melphalan and PDM at the MTDs were also injected without prior L49-sFv-bL treatment.

selected melphalan, a drug that has proven to be useful in the clinical treatment of malignant melanoma and other neoplasias (22, 27).

Melphalan is well-suited for the targeting strategy described here, since acylation of its primary amino group has previously been shown to lead to a reduction in cytotoxic activity (23). Consequently, a prodrug of melphalan was prepared by attaching the drug via its side chain amine to a cephalosporin so that upon bL-catalyzed hydrolysis the parent drug was released. In the prodrug CCM, the primary amine of the phenylenediamine mustard was attached to cephalosporin through a stable carbamate linkage. We therefore decided to append melphalan to cephalosporin using a carbamate linkage. Our starting material for the synthesis of C-Mel was the tetrachloroethyl carbonate **1** (25) in which the cephalosporin carboxylic acid was protected as a diphenyl methyl ester to prevent the otherwise facile lactonization under basic conditions. In designing C-Mel, we decided to oxidize the cephalosporin thioether to a sulfoxide, since this reduces the isomerization of the Δ^2 double bond under the basic conditions used in the coupling reaction (28). Cephalosporin sulfoxides have been shown to be excellent substrates for bL (26), so it was not surprising to find that the k_{cat} value for bL-catalyzed hydrolysis of C-Mel (980 s^{-1}) was quite high. This is substantially higher than the previously reported turnover number of 337 s^{-1} with CCM as the substrate (17).

One of the noteworthy findings in these studies was that significant antitumor activity was obtained in animals treated with a MTD of melphalan (39 day growth delay), while the MTD of PDM was ineffective. The lack of antitumor activity of PDM has been previously noted

(13, 17, 21), and may be due to its high degree of instability under physiological conditions (29). This might lead to the conclusion that the portion of C-Mel that was systemically activated could contribute to therapeutic efficacy, while that of CCM would lead to greater toxicity.

In conclusion, we have demonstrated that C-Mel is a prodrug of melphalan that can be activated in an immunologically specific manner by L49-sFv-bL. All of the tumors in animals treated with L49-sFv-bL and C-Mel at 150 mg/kg/injection underwent complete regressions, and three out of five were eventually cured. Although the therapeutic effects of C-Mel and CCM were equivalent in the tumor model used in these studies, we feel that C-Mel is advantageous since it releases a clinically approved anticancer drug.

Membrane Permeabilization and Efficient Gene Transfer by a Peptide Containing Several Histidines

Patrick Midoux,* Antoine Kichler, Valérie Boutin, Jean-Claude Maurizot, and Michel Monsigny

Centre de Biophysique Moléculaire, CNRS et Université d'Orléans, rue Charles-Sadron,

F-45071 Orléans Cedex 02, France. Received September 4, 1997; Revised Manuscript Received December 10, 1997

We designed a peptide, H5WYG (GLFHAIHFIHGGWHGLIHGWYG), that permeabilizes cell membrane at a slightly acidic pH but not at neutral pH. Absorbance, fluorescence, and circular dichroism spectra showed that H5WYG undergoes a dramatic conformational change between pH 7.0 and 6.0 that correlates with the protonation of the histidyl residues. Cell permeabilization studies monitored by flow cytometry on living cells showed that H5WYG permeabilizes the cell membrane with a great efficiency at pH 6.4 but was not active at neutral pH; at pH 6.8, the peptide permeabilized 50% of the cells at 20 °C within 10 min. H5WYG increased the expression of genes transferred to cells as glycosylated polylysine–DNA complexes, and the transfection efficiency was not impaired in the presence of serum. Therefore, this peptide containing several histidines that become positively charged when the pH decreased to less than 7.0 is a suitable helper for delivering molecules into the cytosol upon either permeabilization of the plasma membrane induced by lowering the extracellular medium to pH 6.4 or permeabilization of the endosomal membrane induced by acidification of endosomes.

INTRODUCTION

The introduction of nucleic acids into cells is of great interest for the development of gene therapy. Various nonviral vectors are available. Cationic lipids such as *N*-[1-(2,3-dioleoyloxy)propyl]-*N,N,N*-trimethylammonium chloride (DOTMA) (1) or dioctadecylamidoglycylspermine (DOGS) (2) and cationic polymers such as polylysine conjugates (3–6) or polyethylenimine (7) are synthetic vectors that form lipoplexes and polyplexes with DNA (8), suitable for gene delivery into eukaryotic cells. Recognition signals, including asialoglycoprotein, transferrin, insulin, immunoglobulins, growth factors, carbohydrates, and metabolites, linked to polylysine (for reviews, see refs 3–6) and to polyethylenimine (9) increased the cell specificity of polyplexes. Cationic lipids and cationic polymers are also suitable for oligonucleotide delivery; DOTMA (10, 11) and polyethylenimine (7) enhanced oligonucleotide cellular uptake. An antisense oligonucleotide complexed with polylysine substituted with either asialoglycoprotein (12), transferrin (13), folate (14), or fucose (15) inhibited hepatitis B viral, *myc*, *myb*, and ICAM-1 gene expression, respectively.

Nucleic acids must be delivered into the cytosol and/or the nucleus. To increase the transmembrane passage of the DNA into the cytosol, several helper molecules, including lipids, chloroquine, glycerol, or fusogenic peptides, were used. Dioleoylphosphatidylethanolamine (DOPE), a neutral fusogenic lipid, was mixed with DOTMA to give lipofectin, which is commonly used for gene and oligonucleotide delivery (1). Chloroquine, a weak base which prevents the delivery of the endosomal content to lysosomes, induces the formation of large endosome-derived vacuoles, and destabilizes their membrane, enhancing the polyfection with transferrin–poly-

lysine (16) and glycosylated polylysine (17, 18); in addition, chloroquine allows the dissociation of glycosylated polylysine–plasmid complexes (19). The inhibition of ICAM-1 gene expression by antisense oligonucleotide–fucosylated polylysine complexes increased drastically in the presence of chloroquine (15). Enhancement of the polyfection with transferrin–polylysine was also reported in the presence of glycerol (20). Amphiphilic peptides exhibiting fusogenic properties in acidic media were used in the development of synthetic virus-like gene-transfer vehicles. Amphiphilic anionic peptides such as GLFEA-IAGFIENGWEGMIDGGGC (21, 22), GLFEAIEGFIENGWEGMIDGWYG (23) derived from the sequence of the N-terminal segment of the HA-2 subunit of the influenza virus hemagglutinin involved in the fusion of the viral envelope with the endosomal membrane, increased the polyfection with transferrin–polylysine complexes. The amphiphilic anionic peptide GLFEAIAEFIEGGWEG-LIEG (E5) corresponding to the N-terminal segment of the HA-2 subunit of the A/PR/8/34 influenza virus hemagglutinin in which G-4, G-8, T-15, and D-19 were replaced by glutamyl residues and M-17 was replaced by a leucyl residue, which induces membrane fusion and permeabilization at acidic pH (24–26), increased the polyfection with lactosylated polylysine (17). Other amphiphilic anionic peptides such as GLFEALLELLESLWELLLEA (27), NPVENYIDEVLNEVLVVPNININSSNC [the sequence of the N-terminal segment of VP1 of HRV2 rhinovirus (28)], or WEAALAEALAEALAEHLAEALAEALAEALAA (GALA) (23, 29) were also found to enhance the gene-transfer efficiency of various polylysine conjugate–DNA complexes. These amphiphilic anionic peptides which contain acid residues (mainly glutamate) are supposed to increase the transmembrane passage of the plasmid into the cytosol upon the membrane disruption of the acidic endocytotic vesicles; this permeabilization is attributed to the protonation of the acid residues of the peptides, and the protonation allows the peptide to

change its conformation from random to α -helix as shown by circular dichroism. Similarly, amphiphilic basic peptides such as melittin (GIGAVLKVLTTGLPALISWIKRKRQQ-NH₂), a peptide isolated from the venom of the european honey bee *Apis mellifera* (30), and GLFKAIAKFIKGGWKGLIKG (K5), an amphiphilic cationic peptide in which the glutamyl residues of the anionic peptide E5 in positions 4, 8, 11, 15, and 19 were replaced by lysyl residues (25), and WKAALAKALAKALAKHLAKALAKALKALAA (KALA) (31) exhibit membrane fusion and permeabilization activities at neutral pH. Melittin coupled to dioleoylphosphatidylethanolamine and complexed with DNA was reported to be efficient in transfecting cells (32). Nevertheless, it is noteworthy to emphasize that those cationic peptides as well as the above-mentioned anionic peptides are inefficient when the transfection step is conducted in the presence of serum.

Knowing that the imidazole group of histidine has a pK of around pH 6.0 and thus becomes cationic in a slightly acidic medium, we hypothesized that changing the lysyl residues of the peptide K5 by histidine residues uncharged at neutral pH but cationic in slightly acidic medium (at a pH close to that found in the lumen of the endocytotic vesicles) will not permeabilize the plasma membrane of the cells under classical conditions, medium at pH 7.4, but will selectively disrupt the membrane of acid vesicles and will lead to the transmembrane passage of plasmids into the cytosol.

In this work, we describe the synthesis and characterization of the peptide GLFHAIHFIHGGWHGLIHGWYG (H5WYG¹), which is analogous to the N-terminal segment (GLFGAIAFGIEGGWTGMIDGWYG) of the HA-2 subunit of the influenza virus hemagglutinin in which G-4, G-8, E-11, T-15, and D-19 were replaced by histidyl residues and M-17 was replaced by a leucyl residue. We show that this peptide exhibits a very efficient membrane permeabilization activity at pH 6.8; at such a very slightly acidic pH, the amphiphilic anionic E5WYG peptide was completely ineffective. We also demonstrate that this peptide increases the gene-transfer efficiency of cells by using glycosylated polylysine-DNA complexes in a pH-dependent manner, and that the efficient gene transfer is not impaired by the presence of serum.

MATERIALS AND METHODS

Chemicals. Luciferin, chloroquine, bafilomycin A₁, and Triton X-100 were from Sigma (St. Louis, MO). L-Glutamine, dimethyl sulfoxide, ATP, glycerol, and MgCl₂ were from Merck (Darmstadt, Germany). Dithiothreitol was from Serva (Heidelberg, Germany). Poly(L-lysine) hydrobromide 30000–50000 (average degree of polymerization of 190) was from Bachem Feinchemikalien (Bubendorf, Switzerland). Poly(L-lysine) hydrobromide (1 g in 200 mL of H₂O) was transformed to its *p*-toluenesulfonic acid salt as described previously (33). Polylysine was partially substituted with an average number of 60 lactosyl residues as previously described (17).

Peptide H5WYG. H5WYG (GLFHAIHFIHGGWHGLIHGWYG) and E5WYG (GLFEAIAEFIEGGWGLIEGWYG) were purchased from Severn Biotech Ltd. (Kidderminster, Worcester, U.K.); alternatively, peptides were synthesized with the Fmoc strategy. E5WYG was

purified as previously described (17). H5WYG was purified by HPLC on a C18 Spherisorb ODS, 5 mm column by using a linear gradient in H₂O containing 0.5% trifluoroacetic acid over the course of 40 min from 0 to 80% acetonitrile. The peptide was eluted with a retention time of 23.4 min. The peptide was characterized by mass spectrometry using a matrix-assisted laser desorption/ionization (MALDI) time-of-flight mass spectrometer (calcd 2584.6 Da, found 2584.7 Da). The peptide concentration was determined by using an $\epsilon_{280\text{ nm}}$ of 12 200 M L⁻¹ cm⁻¹.

Spectrofluorimetry. Fluorescence measurements were performed at 25 °C with a Shimadzu RF-5000 spectrofluorimeter (Roucaire, Courtaboeuf, France). Solutions were contained in a 5 × 5 mm quartz cuvette; their absorbance ($A_{1\text{ cm}}$) was lower than 0.1 at the excitation wavelength.

Circular Dichroism. Circular dichroism measurements were carried out on a Jobin-Yvon Mark IV dichrograph. Data acquisition and analysis were performed on a microcomputer interfaced to the spectrometer. The instrument had been calibrated with camphor-sulfonic acid-*d*₁₀. Optical quartz cells with a path length of 0.1 cm were used under nitrogen. The temperature of the cell was maintained at 20 ± 0.5 °C with a circulating water bath. Curves were signal-averaged with a minimum of four repeats and presented with a similarly signal-averaged buffer baseline subtracted.

Cells and Cell Culture. U937 promonocytic cells (a human histiocytic lymphoma cell line, ATCC CRL 1593, ATCC, Rockville, MD) were cultured in RPMI 1640 medium (Gibco, Renfrewshire, U.K.) supplemented with 10% heat-inactivated fetal bovine serum (FBS) (Gibco); HepG2 cells (a human hepatoma cell line, ATCC 8065 HB) in MEM (Gibco) supplemented with 10% FBS and 1% non-essential amino acids; and Rb-1 cells [rabbit smooth muscle cells, kindly provided by M. Nachtigal (University of South Carolina, Columbia, SC)] (34) and B16 cells (a murine melanoma cell line, ATCC CRL 6322) in DMEM medium (Gibco) supplemented with 10% FBS and new-born calf serum (Gibco), respectively. All the culture media were supplemented with 2 mM L-glutamine (Merck), 100 units/mL penicillin, and 0.1 mg/mL streptomycin (Eurobio, Paris, France). Cells were cultured at 37 °C in a humidified atmosphere (95% air and 5% CO₂). Cells were mycoplasma-free as shown by using the bisbenzimidazole Hoechst 33258 (35) and the BVC-kanamycin A staining methods (36).

Membrane Permeabilization Studies. The membrane permeabilization activity of H5WYG was assessed by using flow cytometry as described previously (26). U937 cells growing in RPMI complete medium were collected in the exponential-growth phase and washed in sheath fluid [134 mM NaCl, 3.7 mM KCl, 15.2 mM NaF, 1.9 mM KH₂PO₄, 16.5 mM Na₂HPO₄, and 0.2% 2-phenoxyethanol (pH 7.4)]. The sheath fluid (1 mL) containing 5 × 10⁵ U937 cells was made 12.5 μ M in ethidium bromide (BET, Molecular Probes, La Jolla, CA) (5 μ L of a 1 mg/mL stock solution in H₂O) at 20 °C and then 36 μ M in H5WYG (50 μ L of a 0.84 mM stock solution in H₂O). The pH of the cell suspension was then lowered by adding aliquots (10–70 μ L) of a 0.3 N HCl solution. The pH values were controlled by using a pH meter. After a 5–15 min incubation, the cell fluorescence intensity was measured by using a FACSort cytometer (Becton Dickinson, Sunnyvale, CA). A 488 nm excitation wavelength was produced by a 15 mW cold air argon laser. A 585 ± 44 nm long-pass filter was used to collect the emitted red fluorescence. The side scatter, the forward

¹ Abbreviations: BET, ethidium bromide; BVC, *p*-[β -[7-(dimethylamino)-1,4-benzoxazin-2-on-3-yl]vinyl]phenylpropenoic acid; E5WYG, GLFEAIAEFIEGGWGLIEGWYG; FBS, fetal bovine serum; H5WYG, GLFHAIHFIHGGWHGLIHGWYG; Lact, lactosyl residue; pLK, poly(L-lysine); RLU, relative light unit.

scatter, and the red fluorescence were simultaneously recorded in the list mode on a minimum of 10 000 cells at 300 events per second. The data were analyzed by using the Cell Quest software (Becton Dickinson).

Plasmid. pSV2LUC plasmid (5 kb), kindly provided by A. B. Brasier (Massachusetts General Hospital, Boston, MA) (37), is an expression vector encoding the firefly luciferase gene under the control of the SV40 T large antigen promoter. pUT650 plasmid (5149 bp) from CAYLA (Toulouse, France) is an expression vector encoding the firefly luciferase gene under the control of the human cytomegalovirus promoter. Supercoiled DNA plasmids were isolated by a standard alkaline lysis method followed by CsCl gradient centrifugation in the presence of BET, extensive extraction with *n*-butanol, and precipitation with ethanol.

Gene Transfer. HepG2 cells (3×10^5 cells per 4 cm² well) and Rb-1 cells (1×10^5 cells per 4 cm² well) were plated (day 0) into 12-well tissue culture plates; B16 cells (8×10^4 cells per 2 cm² well) were plated (day 0) into 24-well tissue culture plates. Polyplexes between a plasmid and lactosylated polylysine (LactpLK) were made with the lowest polymer to DNA molar ratio giving a complete retardation of all the DNA in electrophoresis and used to transfect cells as previously described (18). pSV2LUC or pUT650 (10 μ g, 3 pmol) in 0.7 mL of serum-free DMEM was mixed with LactpLK (30 μ g, 340 pmol) in 0.3 mL of serum-free DMEM, and the solution was kept for 30 min at 20 °C. Then the solution was made either 100 μ M in chloroquine, 10 μ M in E5WYG, or 10 μ M in H5WYG and then supplemented with 1, 20, or 50% FBS, unless otherwise stated. On day 1, the medium was removed and the polyfection solution was added into each well: 1 mL in the case of 12-well tissue culture plates or 0.5 mL in that of 24-well tissue culture plates. After incubation for 4 h at 37 °C in a humidified atmosphere (95% air and 5% CO₂), the medium was removed and cells were further incubated for 48 h at 37 °C in 2 mL of fresh complete culture medium containing 10% serum, in a humidified atmosphere (95% air and 5% CO₂). Experiments were carried out in triplicate.

Luciferase Assay. Luciferase gene expression was measured by monitoring its luminescence activity according to De Wet et al. (38) as previously described (18). The luminescence was recorded for 4 s in a Lumat LB 9501 luminometer (Berthold, Wildbach, Germany). Measurements were carried out in duplicate. The data shown correspond to the number of relative light units (RLU) from 10^6 cells. The number of RLU from a 1 pg/mL luciferase solution was 2000.

RESULTS

Peptide Characterization. The peptide used, GLF-HAIAHFIHGGWHGLIHGWYG (H5WYG), is an analogue of the N-terminal segment (GLFGAIAAGFIEGG-WTGMIDGWYG) of the HA-2 subunit of the influenza virus hemagglutinin in which G-4, G-8, E-11, T-15, and D-19 were replaced by histidyl residues and M-17 was replaced by a leucyl residue. The absorbance and fluorescence spectra of a 16 μ M peptide solution in various buffers in the 9.0–4.5 pH range were studied. The absorbance spectrum of H5WYG depended on the pH of the medium (Figure 1). The absorbance at the maximal wavelength (279 nm) decreased when the pH decreased with a midpoint at pH 5.7, and the ratio of the maximal absorbance at 279 nm to the minimal absorbance between 252 and 260 nm ($A_{\max}/A_{\min}$) increased when the pH decreased with a midpoint at pH 5.7. These data indicate that (i) H5WYG was slightly associated or

Figure 1. pH dependence of the absorbance of H5WYG. A stock solution (1 mg/mL in H₂O) was diluted to 16 μ M with the following buffers: from pH 4.5 to 7.0, 0.15 M NaCl, 50 mM citrate phosphate buffers and 0.15 M NaCl, 50 mM sodium phosphate buffer (pH 7.4); and from pH 8.0 to 9.0, 0.15 M NaCl, 50 mM Tris-HCl buffers. (●) Absorbance at 280 nm and (■) the 280 nm absorbance/255 nm absorbance ratio.

Figure 2. pH dependence of the fluorescence of H5WYG. A stock solution (1 mg/mL in H₂O) was diluted to 16 μ M with the following buffers: from pH 4.5 to 7.0, 0.15 M NaCl, 50 mM citrate phosphate buffers and 0.15 M NaCl, 50 mM sodium phosphate buffer (pH 7.4); and from pH 8.0 to 9.0, 0.15 M NaCl, 50 mM Tris-HCl buffers. The fluorescence spectra were recorded under a 290 nm excitation wavelength. (●) Maximal fluorescence intensity and (■) the wavelength at the maximal emission intensity.

aggregated at neutral pH, (ii) peptide aggregates dissociated between pH 6.5 and 5.0, and (iii) H5WYG was not associated or aggregated at pH <5.0. These statements were confirmed by fluorescence studies (Figure 2). The maximum of the fluorescence spectrum of H5WYG at pH 4.5 was centered at 350 nm, corresponding to solvated tryptophan residues. The wavelength maximum of the spectrum of the peptide shifted from 350 to 338 nm when the pH increased from 5.0 to 7.0 with a midpoint at pH 5.75, indicating the tryptophan residues were in a more hydrophobic environment at neutral pH. In agreement with the absorbance data, the fluorescence data indicated that the peptide was slightly associated or aggregated at neutral pH and not aggregated at pH <5.5. The fluorescence intensity of the peptide decreased when the pH was lowered from pH 7.0 to 5.0 with a midpoint at pH 6.5 (Figure 2). This value, different from that found for the shift of the wavelength maximum, i.e., midpoint at pH 5.75, indicated that the fluorescence quenching of the tryptophan residues (W-14 and W-21) was probably

Figure 3. pH dependence of the circular dichroism of H5WYG. The spectra of 34 μ M H5WYG were measured at either (□) pH 5.0 in 0.15 M NaCl and 10 mM citrate phosphate, (■) pH 6.0 in 0.15 M NaCl and 10 mM citrate phosphate, (▲) pH 7.0 in 0.15 M NaCl and 10 mM sodium phosphate, or (△) pH 9.0 in 0.15 M NaCl and 10 mM Tris-HCl.

related to the ionization state of the surrounding amino acids and especially some of the histidyl residues in relation with the conformation of the peptide at a given pH. Circular dichroism spectra of H5WYG performed at pH 6.0 and 5.0 were similar, while those recorded at pH 7.0 or 9.0 were drastically different (Figure 3). The peptide exhibited a conformational change between pH 7.0 and 6.0, a pH range where the protonation of the histidyl residues does occur. The CD spectra showed that at acidic pH the spectra were surely of unordered structure, but those at neutral and basic pH suggested the presence of some ordered structures, most probably of β -structure.

H5WYG-Induced Membrane Permeabilization.

The membrane permeabilization activity of H5WYG was assessed by a fluorescent method (26). The permeabilization of the plasma membrane of U937 cells was measured by flow cytometry using ethidium bromide, a nonfluorescent and poorly membrane-permeant molecule, which enters the cells upon membrane permeabilization and becomes strongly fluorescent upon binding to DNA. U937 cells incubated in the presence of both BET (12.5 μ M) and H5WYG (36 μ M) became strongly labeled at slightly acidic pH. The membrane permeabilization activity of H5WYG was pH-, time-, and concentration-dependent. In the presence of 36 μ M H5WYG, within 10 min, 97% of the cells were labeled at pH 6.1, 50% at pH 6.8, and <5% at pH 7.1 (Figure 4); the ED_{50} at pH 6.45 was 2.3 μ M (Figure 4 inset), and 89 and 80% of the cells were labeled after 5 min at pH 6.45 in the presence of 36 and 10 μ M H5WYG, respectively (Figure 4 inset).

Effect of H5WYG on the Polyfection with Lactosylated Polylysine. The human hepatoma (HepG2) cells, the murine melanoma (B16) cells, and the rabbit vascular smooth muscle (Rb-1) cells were transfected by using lactosylated polylysine–DNA complexes. Depending on the cell type, complexes were formed between an expression vector encoding the firefly luciferase gene under the control of either the human cytomegalovirus (pUT650) or the large SV40 T antigen (pSV2LUC) promoters and lactosylated polylysine (LactpLK). HepG2, B16, and Rb-1 cells were then incubated for 4 h at 37 °C

Figure 4. pH dependence of H5WYG-induced membrane permeabilization. U937 cells [5×10^5 cells in 1 mL of sheath fluid [134 mM NaCl, 3.7 mM KCl, 15.2 mM NaF, 1.9 mM KH_2PO_4 , 16.5 mM Na_2HPO_4 , and 0.2% 2-phenoxyethanol (pH 7.4)]] were incubated at 20 °C with 12.5 μ M BET in the absence (■) or in the presence (●) of 36 μ M H5WYG. The pH of the cell suspension was lowered by addition of aliquots of a 0.3 N HCl solution. After 10 min, the red cell fluorescence intensity was measured by flow cytometry ($\lambda_{exc} = 488$ nm; $\lambda_{em} = 585 \pm 44$ nm) and the percentage of red labeled cells was determined. (Inset) Concentration dependence of H5WYG-induced membrane permeabilization. U937 cells (5×10^5 cells) in 1 mL of sheath fluid were incubated at 20 °C with 12.5 μ M H5WYG. The pH of the cell suspension was lowered to 6.45 by addition of 40 μ L of a 0.3 N HCl solution. After 10 min, the red cell fluorescence intensity was measured by flow cytometry and the percentage of red labeled cells was determined.

in the presence of either 10 μ M H5WYG, 10 μ M E5WYG, or 100 μ M chloroquine. The efficiency of the gene transfer was evaluated 48 h after the transfection step by measuring the luciferase activity (RLU per 10^6 cells) in the cell lysates (Figure 5). The emitted light was low with any cell line when the transfection was performed in the absence of either H5WYG, E5WYG, or chloroquine. In contrast, when the transfection was performed in the presence of H5WYG, the luciferase activity increased 2150-, 93-, and 630-fold in B16, HepG2, and Rb-1 cells, respectively. In contrast, with E5WYG which was only efficient in HepG2 cells, H5WYG was efficient on all three cell lines; the luciferase activity in Rb-1 and B16 cells transfected in the presence of H5WYG was 63- and 29-fold greater than that in the presence of E5WYG, whereas in HepG2 cells, it was 5.8-fold lower than that in the presence of E5WYG. Depending on the cell type, H5WYG had a better effect than chloroquine; the luciferase activity in Rb-1 cells transfected in the presence of H5WYG was 5-fold greater than that in the presence of chloroquine, whereas in B16 and HepG2 cells, it was 9- and 7-fold lower than that in the presence of chloroquine, respectively. The effect of H5WYG on the transfection efficiency was concentration-dependent; the transfection efficiency of Rb-1 cells was maximal in the presence of 8 μ M H5WYG (Figure 6).

Influence of the Serum on the Polyfection Efficiency in the Presence of H5WYG. The luciferase activity in cells transfected with LactpLK–pUT650 complexes in the presence of H5WYG was not significantly affected when the transfection was performed in the presence of serum from 1 up to 50%. The luciferase activity in B16 cells transfected with H5WYG in the presence of 20 and 50% FBS was 88 and 68%, respectively, of that obtained in the presence of 1% FBS. In

Figure 5. Effect of H5WYG on the polyfection with lactosylated polylysine. HepG2 cells (3×10^5), B16 cells (8×10^4), and Rb-1 cells (1×10^5) were incubated for 4 h at 37 °C in the presence of 1% FBS and of LactpLK–DNA complexes (5 μ g of pUT650 for HepG2 cells, 5 μ g of pSV2LUC for Rb-1 cells, and 2 μ g of pUT650 for B16 cells) in the absence or presence of either 10 μ M H5WYG, 10 μ M E5WYG, or 100 μ M chloroquine in a humidified atmosphere (95% air and 5% CO₂). The cells were washed and incubated in complete culture medium containing 10% FBS in a humidified atmosphere (95% air and 5% CO₂). The gene expression was determined 48 h later by assaying the luciferase activity in cell lysates. RLU, the number of relative light units, represents the luciferase activity in 10^6 cells.

Figure 6. Influence of H5WYG concentration on the polyfection efficiency. Rb-1 cells (1×10^5) were incubated for 4 h at 37 °C in the presence of 1% FBS and LactpLK–pSV2LUC complexes (5 μ g of DNA) in the presence of H5WYG in a humidified atmosphere (95% air and 5% CO₂). The cells were washed and incubated in 2 mL of complete culture medium containing 10% FBS in a humidified atmosphere (95% air and 5% CO₂). The gene expression was determined 48 h later by assaying the luciferase activity in cell lysates. RLU, the number of relative light units, represents the luciferase activity in 10^6 cells.

contrast, the luciferase activity in B16 cells transfected in the presence of serum and of the anionic peptide E5WYG was dramatically reduced. In the presence of E5WYG and 20% FBS, it was only 7% of that obtained in the presence of 1% FBS. In the case of 100 μ M chloroquine and of 20% serum, the luciferase activity in B16 cells was slightly enhanced (120%), while in the presence of 50% serum, the activity dropped to 16%.

Figure 7. Influence of bafilomycin A₁ on the polyfection efficiency in the presence of H5WYG. B16 cells (8×10^4) were incubated at 37 °C with 750 μ L of DMEM containing LactpLK–pUT650 complexes (2 μ g of DNA) and 1% FBS and in the absence or presence of 19 μ M H5WYG and of 200 nM bafilomycin A₁. After 4 h, the medium was removed and cells were incubated in 1 mL of culture medium containing 10% FBS in a humidified atmosphere (95% air and 5% CO₂). The gene expression was determined 48 h later by assaying the luciferase activity in cell lysates. RLU, the number of relative light units, represents the luciferase activity in 10^6 cells.

Influence of the Endosomal pH on the Polyfection Efficiency in the Presence of H5WYG. The capacity of H5WYG, supposed to disrupt endocytotic vesicles containing LactpLK–DNA complexes, was assessed by transfecting B16 cells in the absence or in the presence of bafilomycin A₁, an inhibitor of vacuolar ATPases known to block the endosomal proton pump (39). When the transfection by LactpLK–pUT650 complexes in the presence of H5WYG was performed in the presence of 200 nM bafilomycin A₁, the luciferase activity into B16 cells was 120-fold lower than that obtained in the absence of bafilomycin A₁ and close to that obtained in the absence of H5WYG (Figure 7). Therefore, the inhibition of the endosomal proton pump activity, by impairing the acidification of the endosome lumen, decreased the transfection efficiency in the presence of H5WYG. This indicated that the endosomal membrane disrupting activity of H5WYG occurred in a pH-dependent manner.

DISCUSSION

In this report, we show that the peptide H5WYG has a powerful membrane permeabilization activity at pH 6.4 but not at neutral pH and that it strongly increases the efficiency of cell transfection by glycosylated polylysine–DNA complexes even in the presence of high concentrations of serum.

We chose to synthesize the peptide H5WYG on the following bases. (i) The peptide E5WYG was more active than the peptide E5; this enhanced activity was related to the presence of an additional tripeptide sequence WYG in a C-terminal position as in the native fusogenic peptide (GLFGAIAGFIENGWEGMIDGWYG---) of the influenza hemagglutinin subunit HA-2 (23). (ii) Histidyl residues are expected to be protonated at a pH higher than that for glutamyl residues. Therefore, H5WYG rather than H5 was expected to very efficiently destabilize the endosomal compartments very early upon uptake.

The pH dependence of the absorbance (Figure 1), of the fluorescence (Figure 2), and of the circular dichroism

(Figure 3) spectra of H5WYG indicated that (i) the peptide underwent a drastic conformational change at $\text{pH} < 7.0$, mainly between $\text{pH} 7.0$ and 6.0 , the range corresponding to the protonation of histidyl residues; (ii) at neutral pH , when the histidyl residues are not charged, the peptide was weakly water soluble and was mainly in an aggregated state; (iii) at pH close to 5.0 where all histidyl residues are expected to be protonated, the peptide had a higher solubility and was not aggregated; and (iv) the peptide had unordered structures at acidic pH .

The membrane permeabilization activity of H5WYG was studied on living cells by flow cytometry by using ethidium bromide (BET), a poorly membrane-permeant molecule which is not fluorescent as long as it is free but becomes fluorescent upon binding to nucleic acids. H5WYG permeabilized U937 cells in a pH -, concentration-, and time-dependent manner (Figure 4). It was efficient as soon as the pH was lower than 7.0 . At $\text{pH} 6.85$, the concentration required to obtain 50% permeabilized cells within 10 min, was $2.3 \mu\text{M}$ peptide. H5WYG had a better permeabilizing capacity in slightly acidic pH than the anionic E5CA peptide. By using the same method, the pH had to be lowered to $\text{pH} 6.1$ to reach 50% of permeabilized HL60 cells within 10 min in the presence of $2.5 \mu\text{M}$ E5CA (26). Comparatively, 50% of HL60 cells were permeabilized within 10 min in the presence of $0.5 \mu\text{M}$ melittin (26) as well as in the presence of $5 \mu\text{M}$ K5 (P. Midoux, unpublished results), even when the pH was kept at 7.4 .

We recently showed that the polyfection with glycosylated polylysines was efficient on various cell types. For instance, lactosylated polylysine was highly efficient in transfecting human hepatoma (HepG2) (17, 18) and human normal and cystic fibrosis airway epithelial cells (40); polyfection with mannosylated polylysine was efficient in transfecting human blood monocyte-derived macrophages (41). The capacity of H5WYG to permeabilize membrane in a slightly acid pH but not at neutral pH prompted us to investigate its ability to increase the polyfection with DNA–glycosylated polylysine complexes which are internalized by the cells via receptor (membrane lectin)-mediated endocytosis. H5WYG which permeabilized cells at a pH close to the neutrality ($\text{pH}_{50} = 6.85$) was expected to be effective on endosomal membrane and its membrane disrupting activity might occur in very early endosomes at pH s just below 7.0 , i.e., long before polyplexes could be delivered to lysosomes. The gene-transfer efficiency into a human hepatocarcinoma cell line (HepG2 cells), a murine melanoma cell line (B16 cells), and a rabbit vascular smooth muscle cell line (Rb-1 cells) by using lactosylated polylysine–DNA complexes was clearly enhanced in the presence of H5WYG (Figure 5). In contrast with the effect of the anionic E5WYG peptide which was only efficient into HepG2 cells, H5WYG was efficient on all the three lines used. Anionic peptides which are negatively charged at neutral pH can bind to polylysine-rich DNA complexes (23). DNA–lactosylated polylysine complexes, used in our study, were weakly cationic; the calculated $\pm$ charge ratio was 1.1 – 1.5 (they were made with the lowest polymer to DNA molar ratio inducing a complete retardation of all the DNA in electrophoresis) (18), and the E5WYG peptide did not ionically bind to DNA–lactosylated polylysine complexes (A. Kichler et al., manuscript in preparation). H5WYG which is not negatively charged at neutral pH cannot bind to polyplexes. Therefore, lactosylated polyplexes, E5WYG and H5WYG, were internalized by the cells without direct binding of the peptides to polyplexes.

The extent of the internalization of E5WYG and polyplexes, the luminal pH of endocytotic vesicles containing polyplexes and E5WYG, and their intracellular traffic which depends on the cell type could account for the variability of the effects of E5WYG on the transfection efficiency. HepG2 cells express the hepatocyte membrane lectin specific for β -galactose (asialoglycoprotein receptor) (42); B16 cells and Rb-1 cells do not express a galactose-specific membrane lectin but possess an endogenous lectin (called galectin 3) binding β -galactose also present at the cell surface which is different from the galactose-specific membrane lectin of hepatocytes (ref 43 and V. Boutin et al., unpublished data, respectively). The endocytosis of lactosylated polyplexes is mediated by the galactose-specific membrane lectin of HepG2 cells; the polyplexes are delivered in endosomes with an average luminal pH of 6.0 (19). The peptides H5WYG and E5WYG also reach the endosomes and, because of the low pH of endosomes, induce an efficient permeabilization. In contrast, the lactosylated polyplexes internalized into Rb-1 cells were delivered to endosomes with an average luminal pH of 6.3 (indicating that the majority of the endosomes were weakly acid) (V. Boutin et al., unpublished data), allowing their efficient permeabilization by H5WYG but not by E5WYG. B16 cells which are known to internalize molecules bearing galactose residues (43) took up lactosylated polyplexes probably by a pathway different from that induced by the galactose-specific membrane lectin of HepG2 cells; as in the case of Rb-1 cells, lactosylated polyplexes were delivered in weakly acidic endosomes, allowing their efficient permeabilization by H5WYG but not by E5WYG. Different intracellular traffic of the lactosylated polyplexes and of the peptides in these three cell lines could also account for the differences in efficiency of these two peptides. In the case of Rb-1 and B16 cells, a low amount of E5WYG could reach endosomes (late endosomes) containing polyplexes with a luminal pH , allowing their efficient permeabilization by E5WYG, while H5WYG can already permeabilize endosomal membranes at a less acidic pH (early endosomes). H5WYG elicited its helper effect in gene transfection even in the presence of a high quantity of bovine fetal serum (even at concentration as high as 50%), while E5WYG was almost inactive at a concentration of above a few percent. E5WYG negatively charged at neutral pH could ionically bind to serum proteins and as a consequence had a decreased transfection efficiency, while H5WYG not charged at neutral pH , was not trapped by serum proteins, and kept its activity in the presence of serum.

H5WYG is supposed to disrupt the endosomal membrane containing lactosylated polylysine–DNA complexes. This is supported by the fact that the enhancement of the gene-transfer efficiency was totally abolished in the presence of bafilomycin A_1 , an inhibitor of vacuolar ATPases known to block the acidification of the lumen of endosomes by the endosomal proton pump (Figure 7). The lack of acidification of endosomes prevents the protonation of the imidazole groups of H5WYG and, as a consequence, its membrane permeabilization activity. The membrane permeabilization induced by H5WYG exhibiting an unordered structure in a slightly acidic medium is probably related to its polycationic nature as in the case of the peptide K5 (GLFKAIKFIKGGWKG-LIKG) at neutral pH , an amphiphilic cationic peptide (24, 44, 45), or as in the case of polyhistidine (46, 47), a polypeptide which becomes polycationic at slightly acidic pH . The generation of a polycationic form inside

the early endosomes is supposed to induce the disruption of their membrane and to favor the delivery of large molecules into the cytosol.

Recently, dioleoylphosphatidylethanolamine substituted with an imidazole group was used to make pH sensitive cationic liposomes and to increase the gene-transfer efficiency (48). Similarly, the DNA transfer was helped by using liposomes containing imidazole-substituted lipids (49).

In conclusion, the replacement of glutamyl residues in the GLFEAIAEFIEGGWEGLIEGWYG peptide by histidyl residues leads to a peptide that becomes positively charged when the pH decreases below pH 7.0, and appears to efficiently permeabilize cell membranes at a pH higher than that of the related anionic peptide. In addition, this histidyl-based permeabilization peptide H5WYG is efficient even in cells for which its acidic counterpart E5WYG is almost inefficient. Furthermore, H5WYG keeps its efficiency in the presence of serum, making it a potential tool for transferring genes *in vivo*.

ACKNOWLEDGMENT

We are grateful to Dr. Annie Claude Roche for helpful discussions and critical reading of the manuscript. We thank Sophie Fauvin, who received a fellowship from ANRS (Agence Nationale de Recherche sur le Sida), Philippe Marceau, and Françoise Fargette for their skillful technical help in cell culture and transfection experiments, the synthesis of peptides, and the preparation of plasmids, respectively. This work was partly supported by grants from ANRS (ANRS Grant 97003), "Association pour la Recherche sur le Cancer" (ARC), "Association Française de Lutte contre la Mucoviscidose" (AFLM), "Ministère de la Recherche et de la Technologie" (ACCSV14 Grant 9514104), MERCK/INSERM, and "Ligue Nationale Contre le Cancer". P. Midoux is Research Director at INSERM. A. Kichler received a fellowship from ARC. V. Boutin received a fellowship from MENESRI. J.-C. Maurizot is Research Director at CNRS. M. Monsigny is Professor at the University of Orléans.

Received July 2, 1997; Revised Manuscript Received October 15, 1997

The reducing sugar of an oligosaccharide reacting with the α -amino group of an amino acid is converted to an *N*-oligosaccharyl amino acid which can then be stabilized by *N*-acylation. Oligosaccharides in solution in *N,N*-dimethylformamide reacted with α -glutamyl-*p*-nitroanilide at 50 °C for a few hours, leading to an *N*-oligosaccharylglutamyl-*p*-nitroanilide. Then, the γ -carboxylic group of the glutamyl moiety, activated by adding (benzotriazol-1-yloxy)tris(dimethylamino)phosphonium hexafluorophosphate (BOP), reacted with the substituted α -amino group of the glutamyl residue, leading to an *N*-oligosaccharylpyroglutamyl-*p*-nitroanilide within 0.5 h. Such a one-pot two-step reaction was shown to be very efficient in the case of a disaccharide such as lactose, or pentasaccharides such as lacto-*N*-fucopentaoses, Lewis^a or Lewis^x. The glycosynthons were characterized by chromatography (HPAEC and HPLC); their molecular mass was determined by electrospray ionization mass spectrometry, and the glycosylamides were shown to have a β -anomeric configuration on the basis of their proton NMR. The *N*-oligosaccharylpyroglutamyl-*p*-nitroanilides are quite stable at room temperature over a large pH range. They are easily converted to *N*-oligosaccharylpyroglutamyl-*p*-isothiocyanatoanilides which can be used to prepare glycoconjugates such as cationic glycosylated polylysines suitable for specifically delivering genes or oligonucleotides in a sugar-dependent manner.

INTRODUCTION

The sugar moieties of glycoconjugates are recognition signals which are involved in several important physiological phenomena [for reviews, see Monsigny et al. (1988b,c, 1994b), Lis and Sharon (1991), Drickamer and Taylor (1993), Varki (1993), Karlsson (1995), and Crocker and Feizi (1996)]. To make easier the investigation of the role of those recognition signals, synthetic glycoconjugates have been prepared, including neoglycoproteins, serum albumin substituted with about 25 simple sugar residues as well as glycosylated neutral polymers [for reviews, see Aplin and Wriston (1981), Stowell and Lee (1980), Duncan and Kopecek (1984), Monsigny et al. (1983, 1989, 1994a,b), Lee and Lee (1994a–c), Wong (1995), Roy (1996), and Gabius and Gabius (1997)]. While free mono- or disaccharides usually have a low affinity for lectins, those synthetic glycoconjugates have a high apparent affinity for lectins [Privat et al., 1974; Krantz et al., 1976; Townsend and Stahl, 1981; for reviews, see Stowell and Lee (1980), Monsigny et al. (1994a), Lee and Lee (1994), and Kiessling and Pohl (1996)] because of the presence of a large number of sugar units inducing a multiplicity effect related to avidity. Similarly, complex oligosaccharides have a much higher affinity than their various components. For instance, the galactose-specific hepatocyte lectin binds triantennary oligosaccharides with three Gal β -4GlcNAc β moieties in

a terminal nonreducing position, with an affinity 1000 times higher than that of monoantennary oligosaccharides with a single Gal β -4GlcNAc β moiety in a terminal nonreducing position (Lee et al., 1983). On these bases, neoglycoproteins and glycopolymers bearing a small number of complex oligosaccharides should be more efficient and more specific than those bearing simple sugars. To prepare such glycoconjugates, several methods leading to activated oligosaccharide derivatives suitable to be covalently linked to either a protein, a polymer, or a matrix have been described. These methods belong to three main categories. The first one is a total *de novo* synthesis [for reviews, see Garg et al. (1994), Sinay (1991), Lee and Lee (1992, 1994a–c), Meldal (1994a,b), Roy (1996), Whitfield and Douglas (1996), and Von Itzstein and Colman (1996)] which requires many protection, coupling, and deprotection steps; this approach is time-consuming, and the overall yield remains relatively low. In the second approach, the oligosaccharide can be reversibly converted into a glycosylamine by incubation in the presence of a high concentration of ammonia, an ammonium salt, an aliphatic amine, or an aromatic amine [for reviews, see Ellis and Honeyman (1955), Isbell and Frush (1980), Aplin and Wriston (1981), Kallin (1994), Rice and Corradi Da Silva (1996), and Roy (1996)]. The glycosylamines must be further stabilized by acylation [see, for instance, Isbell and Frush (1958), Thomas (1970), and Likhoshershtov et al. (1986)], the acylating agent being usually an organic compound containing an activated carboxylic group. However, this method suffers from two major disadvantages. One is that it requires several intermediary reactions and purification steps. The second is that there is at least one step in alkaline medium which may release any acyl substituent borne

on the oligosaccharide. The third approach proposed by Gray (1974) is a reductive amination, which allows a one-step glycoconjugate synthesis. This method leads to an altered oligosaccharide, the reducing sugar being transformed into a linear polyol amine derivative.

In a previous paper (Sdiqui et al., 1995), we reported a one-pot two-step synthesis of *N*-glycoamino acids: the first step was the coupling of an oligosaccharide with α -glycyl-*p*-nitroanilide (Gly-*p*NA¹), and the second step was an acylation of the glycosylamine formed. Here, we describe the synthesis of novel glycosylamine derivatives by coupling α -glutamyl-*p*-nitroanilide (Glu-*p*NA) to reducing oligosaccharides. With regard to the previous method described by Sdiqui et al. (1995), this new method has two main advantages. First, the formation of the glycosylamine is faster. Second, the acylation step is an intramolecular reaction involving the γ -carboxylic group of glutamic acid, and as a consequence, it is rapid, efficient, and highly specific. The glycoamino acids obtained can be further coupled to any molecule bearing an amino group.

EXPERIMENTAL PROCEDURES

Materials. α -Glutamyl-*p*-nitroanilide (Glu-*p*NA) was purchased from Bachem (Bubendorf, Switzerland). Poly-(L-lysine) (pLK) HBr salt ($M_r = 95\,100$) with a mean degree of polymerization of 455 (pLK₄₅₅) and ϵ -aminocaproic acid (Aca) were purchased from Sigma (St. Quentin Fallavier, France); pLK, HBr was transformed into pLK, *p*-toluenesulfonate (Derrien et al., 1989) to increase the solubility of the polymer in organic solvents and to avoid the cytotoxic effect of the bromide anion. Lactose and *N,N*-diisopropylethylamine (DIEA) were from Janssen Chimica (Beerse, Belgium); imidazole and dimethyl sulfoxide (DMSO) were from Merck (Darmstadt, Germany). (Benzotriazol-1-yloxy)tris(dimethylamino)phosphonium hexafluorophosphate (BOP) was from Richelieu Biotechnologies (Saint Hyacinthe, Canada). *N,N*-Dimethylformamide (DMF) was freshly distilled in the presence of 0.2 mg/mL (benzyloxycarbonyl)glycyl-*p*-nitrophenyl ester. *N,N'*-Thiocarbamylbisimidazole (TCBI), *p*-toluenesulfonic acid, and δ -gluconolactone were purchased from Aldrich (St. Quentin Fallavier, France); lacto-*N*-fucopentaose II [Lewis^a, Gal β -(Fuc α 4)3GlcNAc β -3Gal β -4Glc] and III [Lewis^x, Gal β -(Fuc α 3)4GlcNAc β -3Gal β -4Glc] (as a mixture) were isolated from human milk (G. Strecker, unpublished data).

Chromatography. Conjugates were purified by gel filtration on a column (2.3 $\times$ 90 cm) of Trisacryl GF 05 (Biosepra, Villeneuve-la-Garenne, France) stabilized in and eluted with 0.1 M acetic acid containing 3% *n*-butanol (flow rate, 8 mL/h).

High-performance anion-exchange chromatography (HPAEC) was performed on a Dionex DX-300 chromatography system (Sunnyvale, CA) which includes a quaternary gradient pump, an eluent degas (He) module, a (4 $\times$ 250 mm) CarboPac PA1 column with a matching guard column, a pulsed amperometric detector (PAD), and a PD40 diode array detector. The flow rate was 1

mL/min. The gradient was obtained by using two solutions (solvent A, 0.1 N sodium hydroxide; and solvent B, 1 M sodium acetate in 0.1 N sodium hydroxide). The column was equilibrated with solution A and eluted with solution A for 5 min and linear gradients of solution B up to 20% over the course of 10 min and then up to 100% over the course of 15 min.

High-performance liquid chromatography (HPLC) analysis was performed on a reverse phase (4 $\times$ 250 mm) column (LiChrospher 100 RP-18, 5 μ m, Merck) to monitor the reduction of *N*-(β -lactosyl)-pGlu-*p*NA into *N*-(β -lactosyl)-pGlu-*p*-aminoanilide and its conversion into *N*-(β -lactosyl)-pGlu-*p*-amidophenyl isothiocyanate [*N*-(β -lactosyl)-pGlu-*p*-amidoPITC]; a reverse phase (3.9 $\times$ 150 mm) cartridge column (Nova-Pak C18, 4 μ m, Waters) was used to monitor the coupling of Aca with *N*-(β -lactosyl)-pGlu-*p*-amidoPITC. The HPLC system included a dual pump system monitored by a Waters 600 Controller linked to a Waters 996 photodiode array detector. The mobile phase was solvent C [0.1 M triethylammonium acetate (TEAA, pH 7.0) and 5% acetonitrile] and solvent D [acetonitrile and 0.1 M TEAA (5%)]. The flow rate was 1 mL/min. The column was equilibrated with a mixture of solvents C and D (95:5, v/v). After the sample (20 μ L) was injected, the column was eluted for 5 min with a 95% C/5% D mixture; solvent D then increased linearly from 5 up to 30% over the course of 30 min.

Electrospray Ionization Mass Spectrometry (ESI-MS). The positive ion electrospray mass spectra were obtained using a Platform quadrupole mass spectrometer (VG Biotech, Fisons Instruments, Altrincham, U.K.) equipped with an electrospray atmospheric pressure ionization source. The capillary voltage was set at 3 kV, and the cone voltage was adjusted at 25 V. The analyzer was calibrated for *m/z* from 400 to 1200 in the positive ion mode using a cesium iodide solution. The sample was dissolved in an acetonitrile/1% formic acid mixture (1:1, v/v) at 20–50 pmol/mL.

¹H NMR Spectroscopy. For ¹H NMR analysis, compounds were dissolved at room temperature in deuterated water at 5 mg/mL, once with D₂O containing 99.9% D and, after freeze-drying, a second time with D₂O containing 99.96% D (Sigma). ¹H NMR spectroscopy was performed at 300 MHz on a Bruker AM-300 spectrometer (Wissembourg, France). Chemical shifts were measured with acetone ($\delta = 2.225$ ppm in D₂O) used as an internal reference and were expressed in parts per million downfield from internal sodium 4,4-dimethyl-4-silapentane-1-sulfonate (DSS).

Synthesis, Purification, and Characterization of *N*-(β -Oligosaccharyl)-pGlu-*p*NA. (1) *N*-(β -Lactosyl)-pGlu-*p*NA (4). In a typical experiment, 5 mg (15 μ mol) of lactose (2, peak 2 in Figure 2A), 7.8 mg (30 μ mol) of Glu-*p*NA, and 4 mg (60 μ mol) of imidazole (1, peak 1 in Figure 2A) were dissolved in 250 μ L of DMF. The solution was kept at 50 $^{\circ}$ C for 8 h.

Without any purification, the *N*-(β -lactosyl)-Glu-*p*NA (3, peak 3 in Figure 2) was further intramolecularly *N*-acylated at room temperature by adding 14.6 mg (33 μ mol) of BOP and 4 mg (60 μ mol) of imidazole. The formation of lactosylpyroglutamyl-*p*-nitroanilide, *N*-(β -lactosyl)-pGlu-*p*NA (4, peak 4 in Figure 2), monitored by HPAEC, was found to be complete within 30 min (Figure 2).

N-(β -Lactosyl)-pGlu-*p*NA (4) was purified by gel filtration. The reaction mixture diluted up to 10 mL with solvent E (0.1 M acetic acid containing 3% *n*-butanol) was introduced onto a Trisacryl GF 05 column (2.3 $\times$ 90 cm) using solvent E as an eluent at a flow rate of 8 mL/h.

¹ Abbreviations: Aca, ϵ -aminocaproic acid; BOP, (benzotriazol-1-yloxy)tris(dimethylamino)phosphonium hexafluorophosphate; DIEA, *N,N*-diisopropylethylamine; DMF, *N,N*-dimethylformamide; DMSO, dimethyl sulfoxide; Glu-*p*NA, α -glutamyl-*p*-nitroanilide; Gly-*p*NA, α -glycyl-*p*-nitroanilide; HOBt, 1-hydroxybenzotriazole; HPAEC, high-performance anion-exchange chromatography; pA, *p*-aminoanilide; PITC, phenyl isothiocyanate; pLK, poly(L-lysine); pNA, *p*-nitroanilide; TCBI, *N,N'*-thiocarbamylbisimidazole; TEAA, triethylammonium acetate.

Figure 1. Synthesis of glycoamino acid species: I, coupling; and II, cyclization. (a) Reducing oligosaccharide. (b) α -Glu derivative, Glu-pNA when R is *p*-nitroanilide ($\text{NHC}_6\text{H}_4\text{NO}_2$). (c) *N*-Oligosaccharyl-Glu-pNA. (d) *N*-Oligosaccharyl-pGlu-pNA.

The glycoamino acid came out first; the other reagents and the coupling solvent came out later. As shown by HPAEC, the purified product still contained some imidazole. The glycoconjugate was made free of imidazole by precipitation from its water solution upon adding 9 volumes of ethanol. Using electrospray ionization mass spectrometry, the mass of the molecular ion was 574.2 (Figure 3A), equal to that calculated for $\text{C}_{23}\text{H}_{31}\text{N}_3\text{O}_{14}$ [($\text{M} + \text{H}$) $^+$, 574.1]: ^1H NMR (300 MHz, D_2O) δ 8.29 and 7.75 (4H, 2d, *H* aromatic), 5.23 (1H, d, $J_{1,2} = 8.25$ Hz, *H*-1, β -D-Glc), 4.65 (1H, d, $J_{1,2} = 7.83$ Hz, α CH pGlu), 4.37 (1H, d, $J_{1,2} = 7.51$ Hz, *H*-1 β -D-Gal), 2.83 (1H, m, γ CH_2 pGlu), 2.56 (2H, m, γ' CH_2 and β CH_2 pGlu), 2.28 (1H, m, β' CH_2 pGlu).

(2) *Lewis*^a/*Lewis*^x-pGlu-pNA. *Lewis*^a/*Lewis*^x oligosaccharides were treated under the conditions described for the synthesis of lactosyl-pGlu-pNA.

The mass of the molecular ion, using an electrospray ionization mass spectrometer [calculated for $\text{C}_{43}\text{H}_{64}\text{N}_4\text{O}_{28}$ ($\text{M} + \text{H}$) $^+$, 1085.4], was found to be 1085.6 (Figure 3B). The assignment of the *Lewis*^a/*Lewis*^x-pGlu-pNA ^1H NMR spectrum in D_2O was as follows: resonances common to the two glycopeptides δ 8.33 and 7.79 (4H, 2d, *H* aromatic), 4.90 (2H, m, *H*-5 α -L-Fuc), 4.67 (1H, d, $J_{1,2} = 7.32$ Hz, *H*-1 β -D-GlcNAc), 4.63 (1H, d, α CH pGlu), 4.37 (1H, d, $J_{1,2} = 7.42$ Hz, *H*-1 β -D-Gal^{im}), 4.16 (1H, s, *H*-4 β -D-Gal^{im}), 2.83 (H, m, γ CH_2 pGlu), 2.58 (2H, m, γ' and β CH_2 pGlu), 2.33 (H, m, β' CH_2 pGlu), 2.05 and 2.04 (6H, 2s, CH_3 Ac β -D-GlcNAc), 1.22 and 1.21 (6H, 2s, CH_3 α -L-Fuc); *Lewis*^a-specific δ 5.05 (1H, d, *H*-1 α -L-Fuc); 4.53 (1H, d, *H*-1 β -D-Gal); *Lewis*^x-specific δ 5.24 (1H, d, $J_{1,2} = 7.2$ Hz, *H*-1 α -L-Fuc); 4.50 (1H, d, *H*-1 β -D-Gal).

Stability of Glycosyl-pGlu-pNA. To assess the stability of the glycosyl-pGlu-pNA derivatives, we exposed the lactosyl-pGlu-pNA (4) at various pHs. The

Figure 2. Conversion of lactose to *N*-(β -lactosyl)-pGlu-pNA. HPAE chromatography analysis monitored using (A) amperometry and (B) absorbance at 316 nm: (a) after 10 min, (b) after incubation for 6 h, and (c) after the cyclization step. Peak 1, imidazole; peak 2, lactose; peak 3, *N*-(β -lactosyl)-Glu-pNA; peak 4, *N*-(β -lactosyl)-pGlu-pNA; and peak 5, HOBT.

Figure 3. Electrospray ionization mass spectra of (A) *N*-(β -lactosyl)-pGlu-pNA (4) and (B) *Lewis*^a/*Lewis*^x-pGlu-pNA.

formation of putative degradation products was monitored by HPAEC, using sorbitol as an internal standard. The conjugate (1 mg/mL) and sorbitol (500 $\mu\text{g/mL}$) were maintained up to 48 h at either 25 or 90 $^{\circ}\text{C}$ in an acidic environment (50 mM sodium acetate buffer at pH 3.6), in a neutral medium (50 mM sodium phosphate buffer at pH 7.0), or in a basic environment (50 mM sodium carbonate buffer at pH 9.0).

Reduction of *N*-(β -Lactosyl)-pGlu-pNA (4) and Conversion into *N*-(β -Lactosyl)-pGlu-p-amidophen-

Figure 4. Time course of the formation of (●) *N*-(β-lactosyl)-Glu-pNA and comparison with the formation of (▼) *N*-(β-lactosyl)-Gly-pNA (inset). Each reaction was performed in DMF at 50 °C in the presence of imidazole. The conjugate formation was monitored by HPAE chromatography.

Figure 5. Preparation of *N*-(β-lactosyl)-pGlu-p-amidoPITC, monitored by HPLC analysis at 290 nm. Reduction of *N*-(β-lactosyl)-pGlu-pNA (4) into *N*-(β-lactosyl)-pGlu-paA (6) and conversion to *N*-(β-lactosyl)-pGlu-p-amidoPITC (7).

yl Isothiocyanate [7, *N*-(β-Lactosyl)-pGlu-p-amido-PITC]. *N*-(β-Lactosyl)-pGlu-pNA (4) (5 mg, 8.7 μmol) was dissolved in 1 mL of a water/methanol mixture (1:1, v/v). To this solution was added 2 mg of 10% palladium on charcoal (Merck). The suspension was stirred for 3 h under hydrogen (1 atm) at room temperature. Both *N*-(β-lactosyl)-pGlu-pNA (4, peak 4 in Figure 5) and its reduced derivative *N*-(β-lactosyl)-pGlu-p-aminoanilide [*N*-(β-lactosyl)-pGlu-paA] (6, peak 6 in Figure 5) were monitored by HPLC at 290 nm.

The palladium on charcoal was removed by centrifugation. The methanolic solution was treated at room temperature with 23 μL of a TCBI (13 μmol) solution at 100 mg/mL in chloroform. After the mixture was stirred for 30 min, the *N*-(β-lactosyl)-pGlu-p-amidoPITC (7, peak 7 in Figure 5) was obtained in a good yield, as shown by HPLC at 290 nm (Figure 5). One volume of chloroform was added to extract the excess of TCBI. The organic phase was removed upon centrifugation (3000g for 5 min). Then methanol was removed under reduced pressure.

Lewis^a/Lewis^x-pGlu-pNA was reduced according to the same procedure.

Coupling of ε-Aminocaproic Acid (Aca) with *N*-(β-Lactosyl)-pGlu-p-amidoPITC (7). Three milligrams

Figure 6. Time course of the coupling of ε-aminocaproic acid (5 equiv) with *N*-(β-lactosyl)-pGlu-p-amidoPITC (1 equiv) monitored by HPLC at 290 nm: after (a) 1 min, (b) 45 min, and (c) 100 min. Peak 7 is *N*-(β-lactosyl)-pGlu-p-amidoPITC, and peak 8 is ε-[*N*-(β-lactosyl)-pGlu-p-amidophenylthioureido]caproic acid.

(5.2 μmol) of *N*-(β-lactosyl)-pGlu-p-amidoPITC (7, peak 7 in Figure 6) was added to Aca (3.4 mg, 25 μmol) in 800 μL of 0.3 M NaCl, 0.1 M sodium bicarbonate buffer at pH 9.3. The mixture was stirred at room temperature and monitored by HPLC at 290 nm. The glycosylated Aca, ε-[*N*-(β-lactosyl)-pGlu-p-amidophenylthioureido]caproic acid (8, peak 8 in Figure 6) was obtained after 100 min in 90% yield as calculated from HPLC. The pure compound was isolated by collecting the corresponding HPLC peak and evaporation of the solvent. The mass of the molecular ion using an electrospray ionization mass spectrometer [calculated for C₃₀H₄₄N₄O₁₄S₁ (M + H)⁺, 717.3] was 717.2: ¹H NMR (300 MHz, D₂O) δ 7.56 and 7.34 (4H, 2d, *H* aromatic), 5.22 (1H, d, *H*-1 β-D-Glc), 4.63 (1H, d, α *CH* pGlu), 4.40 (1H, d, *H*-1 β-D-Gal), 3.57 (2H, m, CH₂-6 Aca), 2.83 (1H, m, γ CH₂ pGlu), 2.58 (2H, m, γ' CH₂ and β CH₂ pGlu), 2.28 (1H, m, β' CH₂ pGlu), 2.22 (2H, t, CH₂-2 Aca), 1.61 (4H, m, CH₂-3 and 5 Aca), 1.38 (2H, m, CH₂-4 Aca).

Preparation of the (Lewis^a/Lewis^x)₁₀₀-pLK⁴⁵⁵ Conjugate. Lewis^a/Lewis^x-pGlu-p-amidoPITC (8 mg, 7.4 μmol) was added to *p*-toluenesulfonate poly(L-lysine) (9.0 mg, 0.0655 μmol) dissolved in 1 mL of DMSO in the presence of DIEA (8.2 μL, 58 μmol). The mixture was stirred overnight at room temperature. The glycosylated pLK was precipitated by adding 10 volumes of 2-propanol and centrifuged (1800g for 15 min). The pellet was washed with 2-propanol, collected upon centrifugation (1800g for 15 min), solubilized in distilled water, and freeze-dried. The average number of Lewis^a/Lewis^x residues bound per pLK molecule was determined using the colorimetric resorcinol sulfuric acid method (Monsigny et al., 1988a).

RESULTS

Synthesis of *N*-(β-Lactosyl)-pGlu-pNA. The general scheme for the synthesis is shown in Figure 1. The first step (I) was the coupling between a reducing oligosaccharide (a) and α-glutamyl-*p*-nitroanilide (b) in the presence of imidazole. Efficient and rapid coupling between the hemiacetal hydroxyl group of the reducing saccharide and the α-amino group of glutamic acid occurred by dehydration. The second step (II) was an intramolecular *N*-acylation (d) of the glycoamino acid

derivative. The reaction was monitored by HPAEC by using two detectors (amperometric and UV). Chromatograms in panels A and B of Figure 2 showed that the amount of *N*-(β -lactosyl)-Glu-pNA (**3**, peak 3 in Figure 2A,B), eluted at 29.2 min, increased as the reaction proceeded; concomitantly, the amount of lactose (**2**, peak 2 in Figure 2A), which came out at 4.9 min, decreased. The time course of the coupling between Glu-pNA and lactose, as monitored by HPAEC, showed that the formation of *N*-lactosyl-Glu-pNA was fast; after 2 h, 80% of the lactose was already converted into lactosyl-Glu-pNA, and after 6 h, 95% was converted (Figure 4). Comparatively, the time course of the coupling between lactose and Gly-pNA was much slower (Figure 4, inset); 120 h was required to reach the 95% level of reaction (Sdiqui et al., 1995). Stabilization of the glycopeptide with 1.1 equiv of BOP and an additional 2 equiv of imidazole led to *N*-(β -lactosyl)-pGlu-pNA (**4**, peak 4 in Figure 2A,B) which came out at 23 min (Figure 2A,B, chromatograms c).

Stability of *N*-(β -Lactosyl)-pGlu-pNA (4**).** The lactosyl-pyroglutamate conjugate maintained at 25 °C for 48 h at pH 7.0, 3.6, or 9.0 was quite stable; neither a decrease in the *N*-(β -lactosyl)-pGlu-pNA (**4**) nor the appearance of a new compound could be detected. At 90 °C, the *N*-(β -lactosyl)-pGlu-pNA (**4**) was stable as long as the pH was either slightly acidic (pH 3.6) or neutral (pH 7.0), and no degradation product could be detected even after 5 h. In contrast, in alkaline medium (pH 9.0), the concentration of *N*-(β -lactosyl)-pGlu-pNA (**4**) decreased according to a first-order kinetics with a constant of $1.25 \times 10^{-4} \text{ s}^{-1}$; a second, still unidentified compound (retention time, 11.5 min) appeared, and its amount increased correlatively.

Reduction of *N*-(β -Lactosyl)-pGlu-pNA (4**), Conversion into *N*-(β -Lactosyl)-pGlu-p-amidoPITC (**7**), and Its Reaction with ϵ -Aminocaproic Acid.** The pure product **4** [*N*-(β -lactosyl)-pGlu-pNA, peak 4 in Figure 5] was quantitatively reduced into **6** [*N*-(β -lactosyl)-pyroglutamyl-*p*-aminoanilide [*N*-(β -lactosyl)-pGlu-paA, peak 6], in the presence of palladium (10% Pd) on charcoal under a hydrogen pressure of 1 atm. The reduced derivative **6** then reacted with TCBI and was converted into *N*-(β -lactosyl)-pyroglutamyl-*p*-isothiocyanatoanilide [*N*-(β -lactosyl)-pGlu-p-amidoPITC], compound **7** (peak 7 in Figure 5), within 30 min. The arylisothiocyanate group was further corroborated by infrared spectroscopy (ν , 2120 cm^{-1}) and by UV spectroscopy on the basis of its maximal absorbance at 290 nm. To test the reactivity of this compound with an ω -alkylamine, the coupling reaction between **7** [*N*-(β -lactosyl)-pGlu-p-amidoPITC] and ϵ -aminocaproic acid (Aca) was monitored by HPLC at 290 nm (Figure 6). A complete disappearance of **7**, *N*-(β -lactosyl)-pGlu-p-amidoPITC, occurred within 2 h, leading to the formation of **8** [ϵ -[*N*-(β -lactosyl)-pGlu-p-amidophenylthioureido]caproic acid]. Compound **8** was collected and characterized by electrospray ionization mass spectrometry and proton magnetic resonance (^1H NMR). Both spectra were consistent with the expected product (see Experimental Procedures).

Synthesis of Lewis^a/Lewis^x-pGlu-pNA and Preparation of pLK-Lewis^a/Lewis^x. Lewis^a/Lewis^x oligosaccharides were reacted with α -glutamyl-*p*-nitroanilide using the conditions described for the *N*-(β -lactosyl)-pGlu-pNA synthesis. This one-pot two-step procedure was also found to be very successful with such relatively complex oligosaccharides. The purified products were obtained, as described in detail in Experimental Procedures, upon gel filtration on a Trisacryl GF05 column and ethanolic

precipitation. The purified compound, Lewis^a/Lewis^x-pGlu-pNA, was shown to be the expected glycoamino acid derivative by ^1H NMR spectroscopy (see Experimental Procedures) and ESI-MS analysis, with a molecular ion peak at m/z 1085.6 (Figure 3B) corresponding to the calculated value.

Under the experimental conditions used for *N*-(β -lactosyl)-pGlu-pNA, Lewis^a/Lewis^x-pGlu-pNA was quantitatively reduced to the Lewis^a/Lewis^x-pGlu-p-aminoanilide and then, upon reaction with TCBI, was converted to the Lewis^a/Lewis^x-pGlu-p-amidoPITC.

The coupling of Lewis^a/Lewis^x-pGlu-p-amidoPITC with pLK₄₅₅ under the conditions described above was achieved with a yield leading to a poly(L-lysine) substituted with 100 Lewis^a/Lewis^x per pLK molecule.

DISCUSSION

Natural oligosaccharides isolated from biological fluids or released by enzymatic or chemical means from natural glycoconjugates can be used for many purposes, especially to synthesize conjugates such as glycopolymers, neoglycoproteins, neoglycolipids, or even glycosylated prodrugs. Among the various described methods, the transformation of reducing oligosaccharides to glycosylamines or glycosylamine derivatives is quite attractive.

Glycosylamines have been obtained as crystalline substances arising from sugars dissolved in methanol containing ammonia (Lobry de Bruyn, 1895; Lobry de Bruyn and Franchimont, 1893; Lobry de Bruyn and Van Leent, 1895, 1896). Glycosylamines were also prepared upon incubation of sugars in the presence of a saturated ammonium bicarbonate solution for up to 7 days (Likhoshervostov et al., 1986; Kallin et al., 1989; Otvos et al., 1989; Urge et al., 1991, 1992; Manger et al., 1992a,b; Vetter and Gallop, 1995) or in the presence of 0.2 M ammonium bicarbonate in 16 M aqueous ammonia for 36 h (Lubineau et al., 1995). Alternatively, β -glycosylamines may be obtained from N-type glycoproteins upon hydrolysis of the linkage between the oligosaccharylamine and the β -carboxylic group of the aspartyl residue by N-glycanase under alkaline conditions (Rasmussen et al., 1992; Tarentino et al., 1993). Unfortunately, glycosylamines are readily hydrolyzed in neutral or slightly acidic aqueous solution (Lobry de Bruyn and Van Leent, 1895; Frush and Isbell, 1951; Isbell and Frush, 1958). Glycosylamines were stabilized by acylation using various simple organic acids activated as acid chloride, anhydride, mixed anhydride, *N*-succinimide ester, etc. [for reviews, see Ellis and Honeyman (1955), Thomas (1977), and Garg et al. (1994)]. Alternatively, glycosylamines were stabilized as a glycoamino acid or a glycopeptide [for reviews, see Ellis and Honeyman (1955) and Garg et al. (1994)] by acylation with an activated amino acid (Otvos et al., 1989; Urge et al., 1991, 1992; Gupta and Suroliia, 1994; Tamura et al., 1994; Arsequel et al., 1994; Wadhwa et al., 1995) and/or a peptide bearing a single activated carboxylic group (Anisfeld and Lansbury, 1990; Cohen-Anisfeld and Lansbury, 1993; Wong et al., 1993). Glycosylamines were also stabilized by acylation with a bifunctional organic compound such as acryloyl chloride (Kallin et al., 1989) or disuccinimidyl suberate (Vetter et al., 1995) or with an activated halogeno (bromoacetic, chloroacetic, or iodoacetic) acid (Thomas, 1970; Manger et al., 1992a,b; Wong et al., 1994) or chloroacetic anhydride (Manger et al., 1992a,b), the second function being used later to achieve a further substitution. Glycosylamines may also be acylated by enzymatic β -aspartylation (Mononen et al., 1996).

Glycopeptides may also be obtained by direct coupling of a reducing sugar and a peptide. Dixon (1972) found that N_α -glucosylpeptides were formed upon incubation of glucose and short peptides such as Val-His or Ile-Tyr in the presence of pyridine and acetic acid for 3 days. The conjugate was stable enough to be separated by paper electrophoresis. The equilibrium constant for the dissociation of Glc-Val-His to Val-His in aqueous solution at pH 6.2 was found to be 0.3 M. The relatively high stability of such glycopeptides may be related to the steric hindrance of the side chain of the N-terminal amino acid (Val or Ile) substituted by the glucosyl residue or to the Amadori rearrangement [for reviews, see Hodge (1955), Hodge and Fisher (1963), and Lee and Cerami (1992)]. In contrast, glycosylamino acid such as an oligosaccharidyl-Gly-*p*NA containing a glycyl residue was found to be readily hydrolyzed in neutral aqueous medium (Normand-Sdiqui, 1995; Sdiqui et al., 1995), and an N-acylation was required to stabilize it. To simplify the stabilization step, we developed another class of glycoamino acid derivatives in which a glutamic acid derivative was used. The γ -COOH function of the glutamic acid side chain, upon activation, readily reacts with the α -amino group, leading to a pyroglutamate derivative; this intramolecular cyclization occurred with an excellent yield.

The *N*-glycopyroglutamyl conjugate is perfectly stable at room temperature in aqueous medium tested at any pH in the 3.6–9.0 range. It is also quite stable at high temperatures in a slightly acidic or a neutral medium; no degradation was observed after exposure at 90 °C for 5 h. In contrast, the compound was degraded in alkaline medium (pH 9.0) at 90 °C with a half-life of 85 min.

The main advantage of using a glutamic acid derivative is that the intramolecular cyclization step does not require any additional acylating reagent; the addition of a carboxylic group activator is sufficient. The formation of the pyroglutamyl derivative is very fast and actually stoichiometric, and no other acylation reaction could be detected. This contrasts with the N-acylation of the glyco-Gly-*p*NA which requires the addition of an acetylating agent, leading in some cases to a partial O-acetylation in addition to the expected N-acylation.

The reaction conditions used here to couple lactose with Glu-*p*NA are similar to those used previously for the coupling of lactose with Gly-*p*NA; i.e., the reaction occurs in DMF at 50 °C with 2 equiv of Glu-*p*NA and 4 equiv of imidazole. However, the coupling reaction was faster in the case of Glu-*p*NA than in that of Gly-*p*NA. Indeed, the times required to reach 50% of the reaction leading to *N*-(β -lactosyl)-Gly-*p*NA and to *N*-(β -lactosyl)-Glu-*p*NA were 30 and <2 h, respectively; those required to reach 95% were 120 and 8 h, respectively (Figure 4). Thus, unexpectedly, the use of Glu-*p*NA instead of Gly-*p*NA induced a second advantage in that both steps of the one-pot reaction appeared to be faster.

Under the conditions used, the reducing sugar reacts with the α -amino group of the α -glutamyl-*p*-nitroanilide and leads to a glycosylamine derivative in a β -configuration. Indeed, upon cyclization of the glutamic residue, the NMR spectrum shows that the *H*-1 proton resonance of the glucosyl residue is a doublet with a coupling constant $J_{1,2}$ of 8.25 Hz, in agreement with a β -configuration, and is downfield shifted to δ 5.23 ppm as expected for an *N*-acyl glucosylamide (Vliegthart et al., 1983). Furthermore, the *H*-1 proton intensity of the glucosyl residue and that of the galactosyl residue are identical, showing that the glucosyl residue is quantitatively present as an *N*-acyl- β -glucosylamide. This conclusion

is also supported by the lack of a low $J_{1,2}$ coupling constant doublet resonance between 4 and 6 ppm; such a doublet could correspond to the anomeric resonance of an *N*-acyl- α -glucosylamide or the anomeric resonance of an *N*-acyl- α -mannosylamide which is expected to be further downfield and could be derived from an isomerization process, as it occurs as a minor side product in the formation of glycosylamine in the presence of ammonium bicarbonate (Tamura et al., 1994). Another possible side reaction is the formation of diglycosylamines upon a transglycosylation process [for a review, see Ellis and Honeyman (1955), and for instance a recent paper on the structure of some *N,N*-bisglycosylamines from Linek et al. (1993) and references therein]. Such *N,N*-bis-glycosyl-glutamates, if they were formed, could not be N-acylated because the α -amino group should become a tertiary amine. Another side reaction which could occur is an Amadori rearrangement leading in the present case to the galactopyranosyl- β -4-(1-deoxy-1-pyroglutamyl-*p*-nitroanilide)fructose, in which there is only one anomeric resonance, that of the β -galactosyl residue, the fructosyl residue containing no anomeric proton. The Amadori rearrangement is known to occur when reducing sugars are incubated in the presence of ammonia, amines, amino acids, or protein [for reviews, see Hodge (1955), Hodge and Fisher (1963), and Lee and Cerami (1992)]. Under the conditions used in this paper, that type of isomerization does not occur, and this may be related to the presence of imidazole; imidazole is required to increase the rate of conjugate formation (Sdiqui et al., 1995) and also to give a clean reaction leading to a single conjugate. The quantitative analysis of the NMR spectra shows also that the sugar moiety and the pyroglutamyl anilide moiety are in equal amounts; for instance, the area of the *H*-1 proton resonance of each sugar residue at δ 5.23 or 4.37 ppm is identical to that of the α -CH proton resonance of the pyroglutamyl residue at δ 4.65 ppm.

The *N*-glycopyroglutamyl-*p*-nitroanilide derivatives were rapidly and quantitatively reduced in the presence of hydrogen and Pd on charcoal, leading to a single *p*-aminoanilide derivative, indicating that the pyroglutamyl ring was not altered during this step. The *N*-glycopyroglutamyl-*p*-aminoanilide also reacted rapidly and quantitatively with TCBI, leading to the phenyl isothiocyanate derivative without side reactions. Such a procedure described by Staab and Walther (1962) appeared to be quite efficient also in the case of these new glycoamino acid derivatives. TCBI is more convenient than the classical thiophosgene used previously by us (Roche et al., 1983; Monsigny et al., 1984) and many others because TCBI is not volatile and is less toxic.

The coupling of the glycopyroglutamyl-*p*-amidophenyl isothiocyanate with ϵ -aminocaproic acid as a model was fast and nearly quantitative with regard to the glycoside derivative. In addition, the coupling of an *N*-glycopyroglutamyl-*p*-isothiocynatoanilide to poly(L-lysine) was roughly quantitative.

The synthesis of such glycosynthons appeared to be quite efficient with either simple oligosaccharides such as lactose or more complex oligosaccharides such as fucosylpentaoses. In addition, this procedure is also suitable for the preparation of glycosynthons from oligosaccharides ending with other reducing sugars such as galactose, *N*-acetylglucosamine, and *N*-acetylgalactosamine (N. Normand-Sdiqui, unpublished results). Alternatively, other glutamyl derivatives may also be used instead of the α -glutamyl-*p*-nitroanilide; for instance, other glycosynthons were recently obtained by coupling, under the conditions described above, oligosac-

charides with glutamyl derivatives containing a protected thiol (Quétard et al., 1997).

Such *p*-nitrophenyl sugar derivatives have a large field of applications. They may be used to characterize oligosaccharides by HPLC with a sensitive detection at 375 nm, as in the case of *N*-*p*-nitrophenylglycosylamines (Kurth and Lehmann, 1986), or at 280 nm with *N*-tyrosyloligosaccharylamide [Tamura et al., 1994; see also the review of Rice et al. (1995) and references therein]. The aminophenyl sugar derivatives are suitable for being selectively acylated and converted into diazophenyl or into phenyl isothiocyanate [Buss and Goldstein, 1968; see Reichert et al. (1994) for a review]. The acylation with succinic anhydride leads to a derivative containing a carboxylic group ready for reaction with amino groups of a drug, a protein, a polypeptide, or a matrix bearing amino groups. Alternatively, the aminophenyl group may be acylated by an activated organic acid as in the case of the substitution with an aminobenzylglycoside derivative (Rafestin et al., 1974). The acylation with *N*-succinimidyl 3-(2-pyridylthio)propionate (SPDP) (Carlsson et al., 1978), or with iminothiolane (Tarentino et al., 1993) leads to a glycoconjugate bearing a thiol group suitable for a further substitution.

The diazophenyl derivatives may be used to prepare antigens (Goebel and Avery, 1929), neoglycoproteins, and glycosylated cytochemical markers suitable for visualizing lectins bound to cell surface glycoconjugates [for reviews, see Monsigny et al. (1983, 1989), Lee and Lee (1994a–c), and Gabius and Gabius (1997)]. The phenyl isothiocyanate derivatives may be used to prepare neoglycoproteins (Roche et al., 1983; Monsigny et al., 1984), neutral glycosylated polymers (Derrien et al., 1989), or cationic glycosylated polylysine [Midoux et al., 1993; for reviews, see Monsigny et al. (1984, 1988a,b, 1994a,b), Magnusson et al. (1994), Molema and Meijer (1994), and Reichert et al. (1994)]. Such glycoconjugates have been shown to be quite useful in studying the properties of endogenous lectins and in carrying drugs, oligonucleotides, and genes [for reviews, see Monsigny et al. (1994a,b) and Wadhwa and Rice (1995)]. Cationic glycosylated polylysines are efficient in increasing the biological effect of antisense oligonucleotides (Hangeland et al., 1995, 1997; Stewart et al., 1996) and in allowing gene targeting (Plank et al., 1992; Midoux et al., 1993; Wadhwa et al., 1995; Perales et al., 1994).

The one-pot two-step synthesis preparation of *N*-glycoamino acid derivatives from unprotected complex oligosaccharides bearing a reducing sugar in a terminal position described in this paper is very simple and very efficient and opens another way of preparing conjugates highly specific for endogenous lectins.

ACKNOWLEDGMENT

We thank Yves Plancke (Laboratoire de Chimie Biologique, CNRS, Université des Sciences et Technologies de Lille, Villeneuve d'Ascq, France) and Anita Caille and Henri Labbé (Centre de Biophysique Moléculaire, CNRS, Orléans, France) for recording the NMR spectra and Alain Deroussent (Institut Gustave Roussy, CNRS URA 147, Villejuif, France) for running the electrospray mass spectrometer. This work was supported by grants from the Agence Nationale de Recherches sur le SIDA (ANRS) and from the Association de Recherche sur le Cancer (Grant ARC 6132). C.Q. received a fellowship from the Région Centre Council. S.B. is the recipient of a postdoctoral fellowship from the ANRS. R.M. and G.S. are Research Directors at CNRS. A.C.R. and P.M. are

Research Directors at INSERM. M.M. is a Professor at the Université d'Orléans.

Micropatterned Immobilization of Epidermal Growth Factor To Regulate Cell Function

Yoshihiro Ito,^{*,†,‡} Guoping Chen,[†] and Yukio Imanishi[†]

Department of Material Chemistry, Faculty of Engineering, Kyoto University, Kyoto 606-01, Japan, and PRESTO, JST, Keihanna Plaza, Hikaridai 1-7, Seika-cho, Kyoto 619-02, Japan. Received September 30, 1997; Revised Manuscript Received December 16, 1997

Photoreactive epidermal growth factor (EGF) was synthesized by conjugating mouse EGF with photoreactive polyallylamine, which was synthesized by the coupling reaction of polyallylamine with *N*-[4-(azidobenzoyl)oxy]succinimide. The EGF derivative was pattern-immobilized onto a polystyrene plate by UV irradiation in the presence of a photomask in a prescribed micropattern. The patterned immobilization of EGF on the polystyrene plate was confirmed by immunostaining with anti-EGF antibody. Chinese hamster ovary (CHO) cells overexpressing EGF receptors were cultured on the micropatterned plate. The phosphorylated tyrosine residues of signal proteins, including EGF receptors, were detected only in the cells adhered in the EGF-immobilized area, and cell growth was observed only in the EGF-immobilized area. The cells growing in the EGF-immobilized area were partially stained by anti-phosphotyrosine antibody, when the area of EGF immobilization was smaller than the cell. The partial staining of activated proteins indicates that immobilization of EGF inhibited the free lateral diffusion and internalization of the activated EGF–EGF receptor complex. The enhanced cell growth is due to juxtacrine stimulation realized by immobilized EGF.

INTRODUCTION

Natural and artificial substrata are important in basic bioscience and biotechnology, including cell culture and tissue engineering (1–4). Cellular interactions with the extracellular matrix play critical roles in various biological processes, including migration, morphogenesis, growth, differentiation, and apoptosis (5). On the other hand, selective cell attachment (6–9) and cell shape regulation (10, 11) by micropatterned surface substrata constructed by nanotechnology have been reported. However, those artificial substrata could not transduce biological signals such as for growth and differentiation. Recently, several growth factors, including the epidermal growth factor (EGF), have been reported to regulate cell functions in the transmembrane form by “juxtacrine stimulation” (12, 13). They stimulate cells without internalization. The juxtacrine mechanism was deduced from the studies of intercellular regulation by paraformaldehyde-fixed cells that express the growth factors (13).

In addition to the juxtacrine stimulation, recently some researchers, including our group, demonstrated artificial juxtacrine stimulation by interleukin 2 or insulin immobilized on artificial substrata such as polystyrene and poly(methyl methacrylate) films (14–16). In this investigation, photoreactive EGF conjugate was synthesized and immobilized on a prescribed micropattern of different size to visualize signal transduction without internalization. EGF transduced the signal through the cognate receptor to stimulate the growth of Chinese hamster ovary cells overexpressing EGF receptors (CHO-ER cells).

MATERIALS AND METHODS

Materials. *N,N*-Dimethylformamide (DMF), paraformaldehyde, Triton X-100, and sodium orthovanadate were purchased from Wako Pure Chemicals Ltd. (Osaka, Japan). Dicyclohexylcarbodiimide (DCC) and 4-azidobenzoic acid were purchased from Tokyo Kasei Co. (Tokyo, Japan). *N*-Hydroxysuccinimide was purchased from Protein Institute Inc. (Minoh, Japan). Polyallylamine hydrochloride was purchased from Nittobo (Tokyo, Japan). Bovine serum albumin (BSA) was purchased from Interger Co. (Purchase, NY). Mouse EGF was purchased from Toyobo (Osaka, Japan). Anti-EGF IgG was purchased from Becton Dickinson Labware (Bedford, MA). Anti-phosphotyrosine antibody was purchased from Santa Cruz Biotechnology, Inc. (Santa Cruz, CA). Rhodamine-conjugated antibody was purchased from Protos Immunoresearch (San Francisco, CA). Vectashield mounting medium for fluorescence was purchased from Vector Laboratories, Inc. (Burlingame, CA). Tissue culture polystyrene plates with six wells (Sumilon) were purchased from Akita Sumitomo Bake Co. (Akita, Japan).

Preparation of Photoreactive Polyallylamine and Photoreactive EGF. The preparative scheme of photoreactive polyallylamine and photoreactive EGF is shown in Figure 1a. Photoreactive EGF was synthesized by conjugating mouse EGF with the photoreactive polyallylamine, which was synthesized by the coupling reaction of polyallylamine with *N*-[4-(azidobenzoyl)oxy]succinimide.

N-[4-(Azidobenzoyl)oxy]succinimide was prepared as described by Matsuda and Sugawara (17). A solution of DCC (13.3 g, 64.6 mmol) in tetrahydrofuran (THF, 50 mL) was added dropwise to a solution of *N*-hydroxysuccinimide (7.43 g, 64.6 mmol) and 4-azidobenzoic acid (9.57 g, 58.7 mmol) in THF (150 mL) and then cooled in an ice bath under stirring. After 3 h, the reaction mixture was

Figure 1. Synthetic scheme of photoreactive polyallylamine and photoreactive EGF (a) and microprocessing of patterned immobilization of EGF on a polystyrene plate (b). DMF and PBS represent *N,N*-dimethylformamide and phosphate-buffered saline, respectively.

warmed slowly to room temperature and then stirred overnight. The white solid that formed was filtered off, and the solvent was removed under reduced pressure. The yellow residue obtained was crystallized from isopropyl alcohol/diisopropyl ether.

Polyallylamine (MW = 60 000, 30 mg) dissolved in 10 mL of phosphate-buffered solution (pH 7.0) was added to a DMF solution (20 mL) of *N*-[4-(azidobenzoyl)oxy]succinimide (25.8 mg) being stirred on ice. After incubation at 4 °C for 24 h with stirring, the solution was ultrafiltrated (Millipore MoleCut II, cutoff below 10 kDa) and washed three times with 10 mL of distilled water. The azidophenyl-derivatized polyallylamine was referred to as AzPhPAAm. The amount of azidophenyl groups in the conjugate calculated from the absorbance at 280 nm was 65 mol/mol. The molar extinction coefficient was 1141. The azidophenyl-derivatized polyallylamine was further conjugated with EGF as follows. To a 0.1 M 2-(*N*-morpholino)ethanesulfate-buffered solution (MES, pH 4.5, 10 mL) were added 1-ethyl-3-[3-(dimethylamino)propyl]carbodiimide hydrochloride (water-soluble carbodiimide, WSC, 10 mg), EGF (300 µg), and AzPhPAAm (600 µg), and they were allowed to react at 4 °C for 24 h while being stirred. Then the solution was ultrafiltrated (Millipore MoleCut II, cutoff below 10 kDa) and washed twice with 2 mL of distilled water. The photoreactive EGF conjugate was referred to as AzPhPAAmEGF. The amount of EGF in the AzPhPAAmEGF conjugate was determined by measuring the fluorescence intensity at 345 nm by excitation at 280 nm and by an elemental

analysis. The calibration curve of fluorescence of EGF was measured in the presence of AzPhPAAm before photoirradiation. Both measurements demonstrated that 1.4 molecules of EGF was contained in 1 molecule of AzPhPAAmEGF.

Pattern Immobilization of EGF. The procedure of pattern immobilization of EGF is shown in Figure 1b. An aqueous solution of AzPhPAAm (200 µg/mL, 200 µL) was eluted on a polystyrene plate in the shape of a circle (diameter of 10 mm) and air-dried at room temperature. Then the plate was UV-irradiated using a UV lamp (Koala, 100 W) from a distance of 5 cm for 10 s. The plate was thoroughly washed with diluted hydrochloric acid (pH 3.0) until the absence of released AzPhPAAm was confirmed by ultraviolet absorbance at 280 nm (7 days). Subsequently, the EGF conjugate (200 µg/mL, 50 µL) was cast in a circular shape (diameter of 5 mm) and air-dried at room temperature. The plate was covered with a photomask of a specific pattern and irradiated with an ultraviolet lamp from a distance of 5 cm for 10 s. Finally, the plate was washed with PBS at 4 °C until the absence of released EGF was confirmed by ultraviolet absorbance at 280 nm (7 days).

Immunostaining of Immobilized EGF. The plates immobilized with EGF were immersed in PBS containing 0.02% NaN₃ and 3% bovine serum albumin (BSA) at 4 °C for 24 h and subsequently incubated with anti-EGF IgG antibody diluted in PBS containing 0.02% NaN₃ and 3% bovine serum albumin (2 µg/mL) at 4 °C for 12 h. After being washed with PBS containing 0.02% NaN₃,

Figure 2. Micrographs of photomask (a and c) and the corresponding fluorescence micrographs of EGF immobilized in a stripe pattern (b and d).

the plate was incubated in PBS containing rhodamine-conjugated anti-mouse IgG antibody ($2 \mu\text{g/mL}$) and 0.02% NaN_3 at 4°C for 12 h. The stained plate was washed with PBS, briefly rinsed with distilled water, mounted in Vectashield mounting medium, and observed under a laser fluorescence microscope (Olympus Co., Tokyo, Japan).

Cell Culture and Treatments for Microscopic Observation. CHO-ER cells (2.5×10^5 receptor molecules per cell) were subcultured in Ham's F-12 medium containing 10% (v/v) fetal bovine serum under an atmosphere containing 5% CO_2 at 37°C . After culturing in the absence of serum for 2 days, cells were harvested by incubation at 37°C for 10 min with PBS containing 0.02% (w/v) ethylenediaminetetraacetic acid and pipetting. After being washed twice with Ham's F-12 medium, the cells were suspended in Ham's F-12 medium (1×10^6 cells/mL). The cell suspension was added to six-well tissue culture plates (0.2 mL/well) containing the EGF-immobilized polystyrene plate that had been incubated in the well in the presence of Ham's F-12 medium (5 mL) at 37°C for 2 h. The cells were cultured under a 5% CO_2 atmosphere at 37°C for 48 h and observed with a phase-contrast microscope.

To investigate the tyrosine phosphorylation of signal proteins, the cells were cultured under a 5% CO_2 atmosphere at 37°C for 30 min. Then, the cells were fixed

for 30 min at 4°C with 3% paraformaldehyde in PBS. The fixed cells were washed three times with PBS containing 1 mM Na_3VO_4 . Subsequently, the cells were permeabilized with PBS containing 0.25% Triton X-100 and 1 mM Na_3VO_4 and washed three times with 50 mM Tris-HCl-buffered solution containing 150 mM NaCl and 0.1% Triton X-100 (TBST, pH 7.4) and 1 mM Na_3VO_4 . After an overnight incubation at 4°C in TBST containing 3% BSA and 1 mM Na_3VO_4 , the treated cells were incubated for 2 h at 25°C with a solution of anti-phosphotyrosine mouse IgG diluted to 1/100 with 50 mM Tris-HCl (pH 7.4), 150 mM NaCl, 0.01% Tween 20, 0.02% NaN_3 , and 1 mM Na_3VO_4 (TBS) containing 3% BSA. The cells were washed once with TBS, once with TBST, and once with TBST containing 0.1% BSA. A solution of rhodamine-conjugated anti-mouse IgG antibody was diluted to 1/200 with TBS containing 3% BSA and incubated with the cells for 2 h at 25°C . The cells were washed three times for 5 min each with TBST and three times with PBS, briefly rinsed with distilled water, and then mounted in Vectashield mounting medium. The cells were observed by a laser fluorescence microscope.

RESULTS

Preparation of the Photoreactive EGF Conjugate and Pattern Immobilization of EGF. Photoreactive polyallylamine was synthesized by coupling polyallyl-

Figure 3. Optical (a and c) and the corresponding fluorescence (b and d) micrographs of CHO-ER cells cultured for 30 min on a polystyrene plate with immobilized EGF. For fluorescence microscopy, the cells were stained with anti-phosphotyrosine antibody.

amine with *N*-[4-(azidobenzoyl)oxy]succinimide. The amount of incorporated azidophenyl groups in the conjugate calculated from the absorbance at 280 nm was 65 mol/mol. The azidophenyl-derivatized polyallylamine was further conjugated with EGF to synthesize the photoreactive EGF conjugate. The content of EGF in the AzPhPAAmEGF conjugate determined by measuring the fluorescence intensity at 345 nm by excitation at 280 nm was 1.4 mol/mol. A polystyrene plate was in advance grafted with the photoreactive polyallylamine by UV irradiation. Then, an aqueous solution of the photoreactive EGF was coated on the polyallylamine-grafted polystyrene plate and air-dried, and the plate was UV-irradiated in the presence of a photomask in a prescribed micropattern. Upon UV irradiation, the azidophenyl groups were easily photolyzed to generate highly reactive nitrenes, which spontaneously formed covalent bonds with neighboring hydrocarbons on the polystyrene plate surface. The irradiated areas should be covalently cross-

linked with EGF. The photoreactive EGF in other areas should not be cross-linked and could be removed by washing. A pattern of covalently cross-linked EGF would appear on the polystyrene plate surface.

After the plate was completely washed with PBS, the patterned immobilization of EGF on the polystyrene plate was confirmed by staining with anti-EGF antibody. As shown in Figure 2, the pattern of immobilized EGF was the same as that of the photomask used.

Tyrosine Phosphorylation of Signal Proteins. CHO-ER cells were cultured on the plate pattern-immobilized with EGF for 30 min. The CHO-ER cells were fixed by paraformaldehyde and stained with anti-phosphotyrosine mouse IgG and rhodamine-conjugated anti-mouse IgG antibodies. Figure 3a shows the uniform adherence of cells on the surface of the plate pattern-immobilized with EGF, indicating that cell adhesion was not enhanced by immobilized EGF. However, Figure 3b shows that the phosphorylated tyrosine residue was

Figure 4. Phase-contrast micrograph of CHO-ER cells on EGF immobilized in a stripe pattern with a $100\ \mu\text{m}$ width before culture (a) and after a 48 h culture (b) and on a plate having EGF immobilized in a stripe pattern with a $2\ \mu\text{m}$ width before culture (c) and after a 48 h culture (d).

detected only in the cells adhered on the EGF-immobilized area, indicating a signal transduction occurring only through immobilized EGF.

Panels c and d of Figure 3 show the cells adhering on the plate pattern-immobilized with EGF in a narrow stripe pattern. The contact area (stripes $2\ \mu\text{m}$ in width) between the cells and the immobilized EGF was stained by anti-phosphotyrosine antibody. Since free lateral diffusion and internalization of the bound EGF–EGF receptor complex are prohibited by immobilization of EGF, signal proteins were partially activated. These findings indicate that the biological signal is transduced only to the cells that interact with immobilized EGF.

Cell Growth. CHO-ER cells before and after a 48 h culture on the culture plate with immobilized EGF in a micropattern (100 or $2\ \mu\text{m}$ in width) are shown in Figure 4. When the width of the stripe is larger ($100\ \mu\text{m}$) than the cell, the patterned growth of cells was observed as shown in Figure 4b. The patterned growth may have been caused by the enhancement of cell growth due to

signal transduction from the immobilized EGF. When the pattern width is smaller than the cell ($2\ \mu\text{m}$), all the cells proliferated and patterned growth did not occur (Figure 4d). Considering the absence of cell growth in the EGF-nonimmobilized area (Figure 4b), the partial and lateral diffusion-limited stimulation was sufficient for cell growth.

DISCUSSION

Although the conjugation of a biosignal with an insoluble substratum is an important technique for elucidation of the biosignaling mechanism and molecular design of drugs or medical materials, it has not sufficiently been examined after the pioneering investigation using sepharose gel with immobilized insulin (18, 19). The stimulation of the growth of only the cells on the immobilized EGF region indicated that diffusible EGF was absent in the culture system. The local concentration of EGF on the surface is sufficient to promote effective interaction with the EGF receptors of adsorbed

cells. Recent studies on overlapping of adhesion molecules and growth factors (20), the growth stimulation by noninternalizing EGF receptors (21), and various juxtacrine stimulators (12, 13) suggest that the signal of immobilized EGF was transduced and cell growth stimulated without internalization. With similar methods, it will be possible to manipulate cells and tissues using artificial substrata with covalently conjugated growth factors and cytokines.

ACKNOWLEDGMENT

We thank Dr. T. Matsuda of the National Cardiovascular Center, the Research Institute for their valuable suggestions on the microprocessing technique, Prof. M. Kasuga of Kobe University for providing the authors with CHO-ER cells, and Prof. S. Nakanishi of Kyoto University for critical suggestions on the manuscript.

A Mild and Efficient Solid-Support Synthesis of Novel Oligonucleotide Conjugates

Ivan Habus, Jin Xie, Radhakrishnan P. Iyer, Wen-Qiang Zhou, Ling X. Shen, and Sudhir Agrawal*

Hybridon, Inc., 620 Memorial Drive, Cambridge, Massachusetts 02139. Received July 18, 1997;

Revised Manuscript Received December 16, 1997

Conjugates of oligodeoxyribonucleotide phosphorothioate (ODN-PS) with folic acid, retinoic acid, arachidonic acid, and methoxypoly(ethylene glycol)propionic acid have been synthesized. The procedure involved the initial solid-phase preparation of 5'-amino-functionalized ODN-PS using *N*-pent-4-enoyl-derived (PNT) nucleoside phosphoramidites followed by conjugation of the oligonucleotide either to the ligand acids, using 1-[3-(dimethylamino)propyl]-3-ethylcarbodiimide as a coupling reagent, or to their corresponding succinimidyl derivatives. Subsequent exposure of the support to aqueous ammonium hydroxide (28%, 2 h, 55 °C) resulted in the release of the fully deprotected ODN conjugates, which were purified by reversed-phase HPLC or by preparative polyacrylamide gel electrophoresis. The identity of the oligonucleotide conjugates was confirmed by MALDI-TOF mass spectral analysis.

INTRODUCTION

Oligodeoxynucleotides (ODNs) are widely used as research tools for inhibiting gene expression and as diagnostic agents and are being developed as potential therapeutic agents (1, 2). In recent years, considerable efforts have been devoted to the synthesis of chemically modified ODNs to improve their stability against nucleases, to enhance their binding affinity with the complementary target, and to facilitate their uptake by cells (3–7). In this context, phosphorothioate (PS) ODNs in which one of the nonbridging oxygens in an internucleotidic phosphodiester linkage is replaced by sulfur have emerged as a promising first-generation antisense therapeutic. Studies on the *in vivo* pharmacokinetics in rodents reveal that PS-ODNs are widely distributed in tissues and are slowly cleared primarily by urinary excretion.

In the development of antisense ODNs as potential anticancer therapeutics, it would be desirable to achieve high intracellular concentration of the ODN at the tumor site. One approach to achieve this objective is to conjugate oligonucleotides to tissue-specific carriers, which would facilitate "carrier-mediated uptake" of the oligonucleotides. In our earlier studies, we had conjugated ODNs to β -cyclodextrin, and its analogues (8, 9), as well as to adamantane (10) to facilitate cellular uptake of ODNs. In the present study, it was envisioned that the dual objectives of tissue-specific targeting and facilitated intracellular delivery could potentially be achieved by conjugating ODNs to ligands such as folic acid (FA) (1), retinoic acid (RA) (2), arachidonic acid (AA) (3), and methoxypoly(ethylene glycol)propionic acid (PEG-A) (4) (Chart 1). Indeed, several papers have described the facilitated intracellular delivery of proteins (11) and other macromolecules (12) as well as liposomes containing entrapped drugs (13) by folate complexation. Presumably, folic acid-receptor-mediated endocytosis is operative in these cases. Recently, a conceptually similar idea was explored in which antisense ODNs were complexed with FA–polylysine conjugate (14, 15). The regulation of RA-

induced proliferation and differentiation of various cancerous cells *in vitro* has been attempted by the use of antisense ODNs (16, 17), peptide nucleic acids (PNA) (18), stable transformant antisense RNA (19), and antisense-transfected clones (20). Similarly, numerous roles have been suggested for AA and its metabolites in cellular function, and antisense ODNs have been employed in studies aimed at delineating these roles (21, 22).

In analogy with these studies, we hoped to achieve tissue-specific targeting and facilitated intracellular delivery of ODN conjugates by receptor-mediated endocytosis mechanism, since the receptors for certain growth factors, vitamins, and hormones are overexpressed in rapidly dividing tumor cells (23–26). Conjugation of ODNs with the lipophilic PEG-A was expected to facilitate their cellular uptake, perhaps by passive diffusion, and reduce their protein binding. PEG is also nontoxic and is a pharmacopoeia-approved excipient for topical and oral dosage forms (27).

For our studies, we employed an 18-mer ODN sequence targeted against the RI α subunit of protein kinase A (PKA). The down-regulation of the RI α PKA isoform was reported to cause inhibition of tumor growth in a number of experimental *in vivo* tumor models (28).

RESULTS AND DISCUSSION

Synthesis of the Conjugates. A number of methods have been reported for conjugating ODNs to various ligands (29). Two approaches that are commonly employed are as follows: (a) the attachment of the ligand at the 5'-end of the ODN by incorporating the corresponding phosphoramidite during solid-phase ODN synthesis and (b) postsynthetic conjugation of an appropriately functionalized ODN with a ligand. Initially, we attempted to attach FA to the amino-functionalized ODN 5 (Chart 2) by following a procedure for preparation of liposome–FA conjugates (18). The requisite *N*-hydroxysuccinimide (NHS) ester 6 of FA (1) was prepared and isolated as reported (18). However, in our hands, attempts to synthesize the FA–ODN conjugate 7, by the reaction between 5 and 6, failed to reveal significant product formation when analyzed by reversed-phase

OLIGONUCLEOTIDE = ODN-PS, 5'-GCGTGCCTCCTCACTGGC-3'

HPLC and PAGE (data not shown). In a separate model study, we synthesized the amino-functionalized TT phosphodiester (TT PO) **8** and phosphorothioate (TT PS) **9** dinucleotides. Again, the reaction of **8** and **9** with the NHS ester **6** and analysis of the products by reversed-phase HPLC did not show the formation of the expected conjugate in isolable yields, but instead revealed a complex mixture of products (data not shown).

We then examined an alternate solid-phase approach in which a support-linked functionalized ODN was coupled to the ligands using 1-[3-(dimethylamino)propyl]-3-ethylcarbodiimide (DEC) as a coupling reagent. Since folic acid, arachidonic acid, and retinoic acid are known to be heat- and light-sensitive molecules, mild deprotection conditions had to be employed during the preparation of the requisite ODN conjugates. This precluded the use of nucleosides that carry conventional protecting groups for the synthesis of the ODN conjugates as they require harsh deprotection conditions for their removal. In the present study, we employed *N*-pent-4-enoyl-

derived (PNT)-protected nucleoside monomers (31). However, nucleosides that carry other base-labile protecting groups, e.g., *N*-tert-butylphenoxyacetyl (*t*-Pac) (32), can also be employed. As a model study, we prepared the support-linked 5'-amino-terminated dinucleotides TT PO **8a** and TT PS **9a** (Scheme 1). The synthesis of **8a** and **9a** was carried out on a 10 μ mol scale in an automated DNA synthesizer. During their synthesis, the oxidation of the internucleotidic phosphite linkage was done using a solution of iodine, and the oxidative sulfurization was achieved using a 2% solution of 3*H*-1,2-benzodithiole-3-one 1,1-dioxide (30) in acetonitrile. For the attachment of the 5'-amino linker, the column was removed from the synthesizer and exposed to an acetonitrile solution of the 5'-amino-modifier phosphoramidite C6. Oxidation and capping, followed by the removal of the monomethoxytrityl (MMT) group, gave the support-linked dinucleotides **8a** and **9a**. The dimers **8a** and **9a** were then reacted with a solution of FA in anhydrous DMF in the presence of DEC as the coupling agent for 24 h.

Chart 3

After successive washing with DMF and acetonitrile, the support was exposed to aqueous ammonium hydroxide (28%, 2 h, 55 °C) to release the fully deprotected dinucleotide conjugates **10–13** (Chart 3). The crude reaction mixtures were analyzed by HPLC (Figure 1) and purified by preparative HPLC. Although the analytical HPLC chromatograms of the purified conjugates revealed the apparent presence of only one product peak, derived from **8** and **9**, the MALDI-TOF mass spectra showed two sets of molecular ions presumably corresponding to mono-

and bisconjugates **10** and **11** (calcd for **10**, *m/z* 1149.0, found, *m/z* 1147.0; calcd for **11**, *m/z* 1856.6, found, *m/z* 1854.0), as well as **12** and **13** (calcd for **12**, *m/z* 1181.13, found, *m/z* 1181.8; calcd for **13**, *m/z* 1920.84, found, *m/z* 1923.5) derived from **8a** and **9a**, respectively. Also, the presence of the FA moiety in each of the conjugates **10–13** was ascertained by UV–VIS spectra, which revealed the presence of characteristic bands for folic acid chromophore at λ_{290} to λ_{390} nm (Figure 2). The formation of the monoconjugates **10** and **12** as well as the bisconju-

Figure 1. Reversed-phase HPLC profile of the reaction mixture between support-bound **8a** (A), **9a** (B), and between FA and isolated product mixture of **10** and **11** (C) and **12** and **13** (D). The solid-phase reaction was carried out as follows: A mixture of **8a** or **9a** on solid support (250 mg of CPG), **1** (0.5 mmol), DEC (2.5 mmol), and anhydrous DMF (10 mL) was shaken at room temperature for 24 h under nitrogen atmosphere. The CPG was filtered off and washed successively with DMF and acetonitrile. The products were released from the solid support, deprotected in ammonium hydroxide for 2 h at 55 °C, and after evaporation to dryness purified by reversed-phase HPLC. HPLC was carried out using a Waters 600E system controller, a 996 photodiode array detector, an NEC PowerMate 486/33i, and a Millennium 2010 chromatography manager. For further details see Experimental Procedures.

gates **11** and **13** is consistent with the expected reaction of **8** and **9** with one and two carboxylic functions of FA, respectively. Furthermore, according to the HPLC analysis (Figure 1A,B), the integral ratio of the area under the

respective peaks corresponding to the dinucleotides and the derived conjugates were 1:5 for **8**:(**10** + **11**) and 1:7 for **9**:(**12** + **13**), reflecting an overall conversion of 80–85% for the conjugation step.

Chart 4

At this juncture, we did not develop procedures for the separation of the mono- and bisconjugates, but applied the methodology for ODN conjugate synthesis. The principal advantage of this solid-phase approach was that all nucleophilic sites remained fully protected while the nucleophilic amino terminus reacted with the ligands in a chemoselective fashion. Consequently, a relatively high yield of the desired conjugates was obtained by this approach compared to the alternate solution-phase approach. Thus, the corresponding fully protected support-bound ODN PS **5** was synthesized on a 10 μ mol scale using PNT-protected nucleoside phosphoramidites, and dC^{PNT} nucleoside was anchored to succinylated controlled pore glass (CPG) on an automated DNA synthesizer. The attachment of the 5'-amino-modifier C6 was performed manually on a solid support. After oxidative sulfurization and capping, the MMT group was removed, and the CPG-bound ODN **5** was reacted with FA, RA, and AA in anhydrous DMF and PEG-A in anhydrous pyridine for 24–72 h. After successive washing with DMF or pyridine and acetonitrile, the support-bound conjugates were treated with aqueous ammonium hydroxide (28%, 2 h, 55 °C) and purified by reversed-phase HPLC or, alternatively, by preparative PAGE, to give the corresponding ODN conjugates **7** and **14–17** (Chart 4).

Upon analysis by PAGE, it was found that the conjugation reaction of ODN **5** with FA on solid support gave two products, **7** and **17**. The products **7** and **17** were

isolated and examined by MALDI-TOF mass spectrometry. The major product **7** (faster moving band on the PAGE, Figure 3) had one molecule of FA attached to the ODN (found, m/z 6319.1, calcd, m/z 6319.50) (Figure 4A). The minor product **17** (slower moving band on PAGE, Figure 3) had two ODNs bridged with one molecule of FA (MALDI-TOF spectrum showed a broad molecular ion between m/z 11900 and 13500 and centered approximately at m/z 12351.1; calcd, m/z 12197.54). To further ascertain their structural identity, we synthesized the ODN PS **18** (36-mer, twice as long as the sequence **5**) as a standard. Upon analysis by PAGE the electrophoretic mobilities of both **17** and the 36-mer **18** were found to be similar (Figure 3). Interestingly, the formation of the bisconjugate **17** could be minimized by reducing the reaction time from 72 to 24 h and/or by replacing the C6 amino linker with the C3 amino linker. This way, we could isolate a single product with C6 amino linker or **19** with C3 amino linker (found, m/z 6277.31, calcd, m/z 6277.40).

The crude ODN conjugates **14–16** (derived from RA, AA, and PEG-A, respectively) were also purified by preparative HPLC. The conjugates **14** and **15** showed a single sharp band by PAGE analysis (Figure 3), while the PEG oligoconjugate **16** showed a somewhat dispersed band presumably because the PEG used in the present study was a mixture of polymers with an average molecular weight of 5245. MALDI-TOF mass spectrom-

Figure 3. PAGE of the oligonucleotide conjugates (lanes): **16** (A), **17** (B), **18** (C), xylene cyanol (D) (marker dye), **15** (E), **14** (F), **7** (G), and **5** (H). The oligonucleotide conjugates (0.2 A_{260} unit) were analyzed by electrophoresis on a 20% polyacrylamide gel containing 8 M urea and visualized by UV shadowing.

etry analysis revealed the expected mass ions for **14** (found, m/z 6177.4, calcd, 6178.52) (Figure 4B) and **15** (found, m/z 6180.6, calcd, 6182.55) (Figure 4C). A sample of **16** gave a positive ion MALDI-TOF spectrum showing a broad peak unresolved pseudomolecular ion signal between approximately m/z 10000 and 13000 and centered at 11413 (calcd, 11179.07). Figure 5 shows the CGE profiles of the oligonucleotide conjugates **7**, **14**, **15**, **16**, **17**, and **19**.

The ODN conjugates **7** and **14–16** were studied for hybridization properties with the complementary RNA (30-mer) (Table 1). Hybridization studies indicated that incorporation of FA slightly increased the stability of the duplex formed ($\Delta T_m = 1.8$ °C) relative to the unconjugated control ODN, while incorporation of RA and AA had a slight destabilizing effect on duplex formation, $\Delta T_m = -3.3$ and -2.5 °C, respectively. The incorporation of PEG-A caused more significant reduction in binding ($\Delta T_m = -4.9$ °C; Table 1), presumably due to destabilization of the duplex by steric interference by the large polymer such as PEG (MW $\sim$ 5245).

While our work was in progress, a synthetic route for conjugation of ODNs, with cholic acid, FA, lipoic acid, and pantothenic acid, through thioether and disulfide bonds was reported (34), involving the initial multistep synthetic preparation of solid-support derivatized with cysteine. Also, recently, Kranz and co-workers reported successful conjugation of FA to N-terminal amino groups of protein using DEC (35).

In conclusion, we have successfully demonstrated a simple and efficient method for ODN conjugation on solid support. The combination of solid-support ODN synthesis by employing PNT-protected (or other suitable base-labile-protected) nucleoside phosphoramidites and conjugation of the ODN on the solid support has the following advantages: (a) The conjugation could be

Figure 4. MALDI-TOF mass spectra of folic acid-ODN conjugate **7** (A), retinoic acid-ODN conjugate **14** (B), and arachidonic acid-ODN conjugate **15** (C). The molecular ions were at 6319.1, 6177.4, and 6180.6, respectively.

performed at essentially neutral conditions. (b) Both the 5'- and 3'-ends of an amino-linked ODN could be conjugated, which is dependent on the use of the 3'- or 5'-phosphoramidites. (c) Because the PNT group can be removed using multiple deprotection strategies ranging from neutral to mildly basic conditions (32), the use of this base-protecting group allows flexibility in the synthesis of ODN analogues, as well as in the structurally diverse molecules that could be conjugated to ODN. (d) Conjugation on solid support facilitated the removal of excess reactants and made it easier to isolate the products. The ODN conjugates, thus synthesized, formed stable duplexes with complementary RNA target.

EXPERIMENTAL PROCEDURES

Materials and Methods. MALDI-TOF mass spectrometry was performed using a PerSeptive Biosystems Voyager Elite Biospectrometry research station coupled with a delayed extraction laser desorption mass spectrometer, using hydroxypicolinic acid as a matrix.

UV-VIS measurements were recorded on a Perkin-Elmer Lambda 2 spectrometer. T_m measurements were recorded on a GBC 920 UV-VIS spectrometer, supplied with GBC Thermocell.

Oligonucleotides were assembled on CPG, carrying the leader PNT nucleoside (31), using an Expedite Nucleic Acid Synthesis System equipped with an NEC Image 466es and CTX monitor.

A Waters 650E Advanced Protein Purification System equipped with a Waters 600E system controller, a Dyanmax model UV-C absorbance detector, and 746 data module was used for purification of the oligonucleotides.

Figure 5. CGE profiles of oligonucleotide conjugates **7** (A), **17** (B), **19** (C), **14** (D), **15** (E), and **16** (F).

For the analysis of the oligonucleotides, a Waters chromatographic system equipped with a 600E system controller, a 996 photodiode array detector, an NEC Power Mate 486/33i, and a Millennium 2010 chromatography manager was used. Preparative reversed-phase HPLC

was done using a column (300 mm length, 10 mm diameter) packed with bulk preparative C_{18} matrix (125 Å, 55–105 μ m). For analytical HPLC, a Waters Radial-Pak cartridge was used. Buffers used were (A) 0.1 M ammonium acetate and (B) acetonitrile/A, 20:80. For

Entry	Oligonucleotide	T_m^b , (°C)	ΔT_m , (°C)
1	5'-GCGTGCCTCCTCACTGGC-3' ODN PS	62.8	-
2	 7	64.6	+1.8
3	 14	59.5	-3.3
4	 15	60.3	-2.5
5	 16	57.9	-4.9

^a T_m determinations were done using complementary RNA (5'-ACGCGCCGAGGAGGACGACGCCUU-3'). ^b Absorbance vs temperature profiles were obtained using a 1 μ M concentration for each strand, in 1 mL of buffer (100 mM Na⁺, 10 mM phosphate, 0.1 mM EDTA, pH 7.4).

preparative HPLC, a linear gradient was used: 100% A, 0% B for 5 min, 0–20% B for 15 min, 20–35% B for 30 min, 35–100% B for 15 min; flow rate of 10 mL/min. For analytical HPLC, a linear gradient was used: 100% A, 0% buffer B for 2 min, 0–20% buffer B for 30 min, 20–60% buffer B for 30 min; flow rate of 1.5 mL/min; detection at λ_{254} nm.

CGE analysis was carried out using the Beckman System Gold Personal chromatograph P/ACE system 2200, equipped with P/ACE UV absorbance detector and eCAP ssDNA 100 gel column, 47 cm in length. The oligonucleotides were electrokinetically loaded onto the column and analyzed by applying a voltage of 14.1 kV for 60–100 min and using tris–borate 7 M urea buffer for elution with the detector set at 254 nm.

DNA and RNA reagents, RNA phosphoramidite monomers (32), and the LCAA–CPG for the synthesis of oligodeoxy and oligoribonucleotides were obtained from PerSeptive Biosystems GmbH and CPG Inc., respectively. The 5'-amino modifier—C6 and C3 phosphoramidites—and 3H-1,2-benzodithiole-3-one 1,1-dioxide were purchased from Glen Research and R. I. Chemicals Inc., respectively. PNT phosphoramidites were synthesized and analyzed as described before (31). Folic acid, retinoic acid, and arachidonic acid were obtained from Aldrich Chemical Co. The HPLC grade solvents were obtained from Fisher Scientific Co. PEG-A (MW 5000) was purchased from Shearwater Polymers, Inc., and used as received.

Protocol for Oligonucleotide Conjugate Synthesis. The synthesis of the oligonucleotide phosphorothioate (ODN PS, 18-mer) sequence targeted against the RI α subunit of protein kinase A (PKA) (28) was carried out on a 10 μ mol scale on a CPG support (40 μ mol/g) in conjunction with PNT β -cyanoethyl 3'-phosphoramidites on an automated DNA synthesizer. A 2% solution of 3H-1,2-benzodithiole-3-one 1,1-dioxide in acetonitrile was used for PS oxidative sulfurization. The last DMT was manually removed on the synthesizer, and the deblocking solution was thoroughly rinsed out of the column with

acetonitrile. The CPG column was removed from the synthesizer and purged with argon. 5'-Amino modifier C6 or C3 phosphoramidite (250 mg) was dissolved in anhydrous acetonitrile (1 mL) and transferred into a luer tip syringe. The syringe was then attached onto the CPG column with another syringe containing 4 mL of standard activator solution. Both solutions of phosphoramidite and activator were swished back and forth through the column for 5 min. The CPG column was then installed back into the DNA synthesizer and washed with acetonitrile, followed by oxidation and capping. The MMT group was then removed using deblocking solution. After thorough washing with acetonitrile, followed by washing with anhydrous pyridine (20 mL) and acetonitrile, the CPG oligonucleotide was dried overnight in vacuo over P₂O₅.

(a) *Oligonucleotide Conjugates of Folic Acid, Retinoic Acid, and Arachidonic Acid.* A mixture of CPG oligonucleotide (250 mg), folic acid (1), retinoic acid (2), or arachidonic acid (3) (0.5 mmol), 4-(dimethylamino)pyridine (DMAP) (0.05 mmol), triethylamine (40 μ L), DEC (2.5 mmol), and anhydrous DMF (10 mL) was shaken in a septum-fitted round-bottom flask (25 mL) at room temperature for 24–72 h under nitrogen atmosphere. The CPG–oligonucleotide conjugate was filtered off and washed successively with DMF and acetonitrile.

(b) *PEG-A Oligonucleotide Conjugate.* A mixture of CPG-bound oligonucleotide (250 mg), methoxy-PEG succinimidyl propionate (4, 0.1 mmol), and anhydrous pyridine (5 mL) was shaken in a septum-fitted round-bottom flask (25 mL) at room temperature for 24 h under nitrogen atmosphere. The CPG–oligonucleotide conjugate was filtered off and washed successively with pyridine and acetonitrile.

The CPG-bound oligonucleotide conjugates were treated with aqueous ammonium hydroxide (28%, 2 h, 55 °C) and evaporated to dryness, and the crude conjugates **7**, **17**, **19**, and **14–16** were purified by reversed-phase HPLC and/or PAGE. Oligonucleotide conjugates **7** (257 A₂₆₀ units), **17** (55 A₂₆₀ units), and **19** (157 A₂₆₀ units) were

purified by PAGE, while **16** (172 A_{260} units, 30% overall yield) was purified by reversed-phase HPLC. Oligonucleotide-conjugates **14** (195 A_{260} units) and **15** (90 A_{260} units) were purified by both techniques to obtain pure samples.

Characterization of Interpolyelectrolyte Complexes between Double-Stranded DNA and Polylysine Comb-Type Copolymers Having Hydrophilic Side Chains

Atsushi Maruyama,* Hiromitsu Watanabe, Anwarul Ferdous, Maiko Katoh, Tsutomu Ishihara, and Toshihiro Akaike

Department of Biomolecular Engineering, Faculty of Bioscience and Biotechnology, Tokyo Institute of Technology, 4259 Nagatsuta, Midori, Yokohama 226-8501, Japan. Received August 11, 1997; Revised Manuscript Received January 29, 1998

The polyionic interaction between DNA and polycations grafted with hydrophilic dextran side chains was evaluated. The comb-type copolymers, poly(L-lysine)-*graft*-dextran, were successfully prepared by employing a reductive amination reaction between ϵ -amino groups of poly(L-lysine) (PLL) and the reductive ends of dextran (Dex). A coupling efficacy on the order of 70% was obtained regardless of intrinsic philicities of the solvents used, either aqueous buffer or DMSO. The resulting graft copolymers, which varied in the degree of grafting and the length of hydrophilic side chains, formed a soluble complex with DNA. They also affected the melting behavior of double-stranded DNA (dsDNA) in different ways. Copolymers having a high degree of grafting thermally stabilized dsDNA without affecting its reversible transition between single-stranded and double-stranded forms. However, copolymers with a low degree of grafting or with a high degree of grafting of short dextran chains impeded the reversibility of this transition. Furthermore, highly grafted copolymers also accelerated the hybridization of DNA strands in a low-ionic strength medium. It is of particular note that these copolymers scarcely altered circular dichroic signals of dsDNA even when the copolymers were added in excess. This suggested that the copolymer interacted with dsDNA without affecting its native structure or physicochemical properties. Finally, the copolymer even formed a stable complex with a short oligonucleotide (20 bases). We, therefore, concluded that, by regulating the degree of grafting and the molecular weight of grafted side chains, it would be possible to design novel different graft copolymers capable of acting as carriers of functional genes to target cells or tissue.

INTRODUCTION

Polycations interact with polyanions strongly to form polyanion complexes (PICs) or interpolyelectrolyte complexes (IPECs). Although both polyanions and polycations are readily soluble in water, when combined in solution they form complexes, such as coacervates or precipitates, which separate out of aqueous media (1–4). IPECs have been investigated as biocompatible (5–8), membrane- (5) and enzyme-immobilization (9), and microencapsulation (10–12) materials. More recently, complexes between DNA and polycation derivatives have been used as artificial carriers of poly(oligo)nucleotides, including genes and antisense oligonucleotides (13). However, applications of IPECs are limited due to their irreversible and insoluble behavior. As a result, regulation of both properties and structures of IPECs is needed to expand the functional applications of these polymer complexes.

While complex formation in mixtures of linear polyanions and polycations has frequently been observed, little is known about IPEC formation between polyion segments in mixed block (14–16) or graft copolymers. In specific, complex formation is poorly understood between graft copolymers of one polyion and polymers of the opposite charge (17, 18). We previously reported that the graft copolymer consisting of a poly(L-lysine) (PLL)

backbone and dextran (Dex) graft chains forms a soluble complex with DNA and stabilizes DNA triple helices of poly(dA)·2poly(dT) (17). Without the copolymer, these triple helices were unstable under physiological conditions (19). Despite the graft copolymers' considerable elevation of the triple helix melting temperature (T_m), they did not disturb reversible transition between the triplex and its constituent single-stranded DNAs (ssDNAs).

The main aim of this study was to understand and to control the interaction between polyanionic DNA and various graft copolymers consisting of a PLL backbone and hydrophilic graft side chains of Dex. PLL-*graft*-Dex (PLL-*g*-Dex) copolymers with various degrees of grafting and lengths of Dex chains were synthesized, and their interaction with DNA was evaluated by turbidity assays, UV-melting temperature assays (UV- T_m), circular dichroism (CD) measurements, and gel electrophoresis assays. We found that the graft copolymers formed basically two categories of soluble complexes. The first category of graft copolymer–DNA complexes allowed the reversible transition between duplex and its ssDNAs. Such copolymers were also capable of thermal stabilization of dsDNA. The second category included mostly irreversible complexes. Our results suggest that, by changing the molecular weight, degree of grafting, and the properties of the graft chains, we were able to control the associating properties of these polyions.

^a The reaction was carried out in the borate buffer (runs 1–7) or in DMSO (runs 8–12). ^b M_n = the number-average molecular weight; M_w = the weight-average molecular weight. M_n and M_w were determined as described in Materials and Methods. ^c Determined by ¹H NMR. ^d Mol % = 100(fraction of lysine units coupled with Dex). ^e Coupling efficacy = [Dex]_{copolymer}/[Dex]_{in feed}.

**Figure 1.** Structural formula of the polylysine-graft-dextran copolymer.

MATERIALS AND METHODS

Materials. Poly(L-lysine) (PLL) was purchased from Sigma-Aldrich Japan (Tokyo, Japan) or Peptide Institute, Inc. (Tokyo, Japan). Dextran T-10 (M_n = 5900), poly(dA), and poly(dT) were obtained from Pharmacia Biotech (Uppsala, Sweden). Oligonucleotides were a HPLC-purified grade obtained from Grainer Japan Co. (Tokyo, Japan). Dextran 4 (fraction with a MW of 4000–6000) was purchased from Funakoshi Chemical Co. (Tokyo, Japan). Calf thymus DNA (t-DNA) was obtained from Sigma-Aldrich Japan. Other solvents and chemicals were reagent grade, were obtained from Wako Pure Chemical Industries, Ltd. (Osaka, Japan), and were used without further purification.

Synthesis of the Poly(L-lysine)-graft-Dextran Copolymer. Comb-type copolymers, poly[(L-lysine)-graft-(α -1,6-D-glucopyranoside)] (PLL-g-Dex), were synthesized by a reductive amination reaction of PLL·HBr with dextran (Dex) (17, 20). Either borate buffer or DMSO was used as a solvent for the reaction. The conditions for the synthesis are described in Table 1. The resulting copolymers were isolated by ultrafiltration to remove unreacted Dex. The ultrafiltration was carried out using a Millipore UFV2BGC10 centrifugal filter device (MW cutoff of 10 000, Millipore Corp., Bedford, MA) or a Q0100 ultrafilter (MW cutoff of 10 000, Advantec Toyo Filter Ltd., Tokyo, Japan). Finally, the copolymers were lyophilized.

¹H NMR of the copolymers in D₂O was recorded on a Varian VNMR 4.3 spectrometer and used to determine the composition of the resulting copolymers. The structural formulas of the comb-type copolymer are shown in Figure 1. Hereafter, we designate the copolymers as PLL-Dex(X-Y), where X and Y represent the molecular weight (number average) and the content (mole percentage) of Dex chains in the copolymers, respectively.

Gel Permeation Chromatography (GPC) and Molecular Weight Determination of Polymers.

The resulting copolymers were analyzed using a gel permeation chromatography system (GPC, Jasco model 800, Tokyo, Japan) on Waters Ultrahydrogel 250 and 500 columns connected with a multiangle light scattering detector (Dawn-DSP, Wyatt Technology, Santa Barbara, CA) and a differential refractive index (RI) detector (Jasco, model 830-RI). An aqueous solution of 0.5 M acetic acid and 0.2 M Na₂SO₄ was used as a mobile phase at 1.0 mL/min. An aliquot (200 μ L) of graft copolymer solution (1 mg/mL) was injected into the column. The molecular weight and its distribution were determined according to the instruction manual of Dawn-DSP on the basis of Zimm's equation (eq 1).

$$\frac{R_\theta}{K^*c} = MP(\theta) - 2A_2cM^2P^2(\theta) \quad (1)$$

where c is the concentration of solute molecules in the solvent r , M is the weight-average molecular weight, A_2 is the second virial coefficient, $P(\theta)$ is a theoretically derived factor and is a function of the molecule's z -average size, shape, and structure, $R(\theta)$ is the Rayleigh ratio at the individual scattering angle, and K^* is an optical constant [$=4\pi^2n_0^2(dn/dc)^2\lambda_0^{-4}N_A^{-1}$, where n_0 is the refractive index of the solvent at the incident radiation wavelength (nanometers), N_A is Avogadro's number, and dn/dc is the differential refractive index increment of the solvent/solute solution with respect to a change in solute concentration].

By extrapolating the value of θ to 0, we derived eq 2 from eq 1.

$$\frac{R_{\theta=0}}{K^*c} = M - 2A_2cM^2 \quad (2)$$

By neglecting the second term, we determined M with a R_θ/K^*c versus $\sin^2(\theta/2)$ plot (Debye plot) for θ approaching 0. M was calculated at each second of the elution period using c monitored by the RI detector. The estimated values of M at each 1 s slice in the GPC were then used to determine weight- and number-average molecular weights of polymers.

Turbidity Measurements of the DNA/Copolymer Mixture. Calf thymus DNA was dissolved in Milli Q water at 1.4 mg/mL and sonicated twice for 8 min on ice with a 80 W output at a 20% interval using a probe-type generator (Tomy UD-201, Tokyo, Japan). The approxi-

mate molecular weight of the sonicated DNA fragments was 1 kbp as determined by agarose gel electrophoresis (data not shown). The DNA solution was diluted to 30 $\mu\text{g/mL}$ with 10 mM sodium phosphate buffer solution (PBS, pH 7.2) containing 150 mM NaCl (buffer I). To the DNA solution was added a stock solution (1 mg/mL) of the graft copolymer in buffer I at various polymer/DNA charge ratios ($P/D = [\text{amino group}]_{\text{polymer}}/[\text{phosphate group}]_{\text{DNA}}$). The final DNA concentration was adjusted to 27.4 $\mu\text{g/mL}$. After the solution was vigorously mixed with a vortex mixer, it was allowed to stand at 4 °C. Turbidity measurements were carried out after 1, 4, and 14 days at 340 nm with Beckman DU 640 spectrophotometer with a 1 cm path length.

CD and UV- T_m Measurements. Stock solutions were prepared by dissolving nucleotides in 10 mM PBS (pH 7.2) containing 150 mM NaCl and 0.1 mM EDTA (buffer II). Concentrations of the stock solutions were calculated using molar extinction coefficients of 8900 at 257 nm for poly(dA) and 9000 at 265 nm for poly(dT) (21). Solutions for CD and UV- T_m measurements were prepared by diluting the stock nucleotide solutions (final concentration of 36 $\mu\text{mol/L}$) and the comb-type copolymer solution at various P/D ratios into buffer II. The mixtures were heated at 90 °C for 30 min, gradually cooled, and allowed to stand for 16 h at room temperature.

UV spectra and UV melting curves were recorded with a Beckman DU-640 spectrometer equipped with a micro-melting temperature apparatus (Beckman). The UV melting curves were recorded at 0.2 K/min as heating and cooling rates. The differential absorbance ($\Delta A = A_{260} - A_{340}$) was calculated to correct for baseline shift. The first derivative $[d(\Delta A)/dT]$ was calculated from the melting curve data. Peak temperatures in the derivative curves were designated T_m .

CD spectra were measured with a Jasco model J-600 spectropolarimeter. Each spectrum shown was the average of more than three scans that have been smoothed.

Analysis of DNA-Polymer Complex Formation by Gel Electrophoresis. An increasing amount of each of the copolymers was added to 3 μg of pSV plasmid DNA (6.8 kbp) in buffer I from a stock solution. The mixture was diluted with buffer I to a final plasmid concentration of 43.4 $\mu\text{g/mL}$, followed by incubation for 24 h at room temperature. The mixture was then analyzed by running it on a 1% agarose gel in Tris-acetate buffer (40 mM, pH 8.0) containing 1 mM EDTA. The gel was then stained with ethidium bromide to visualize the DNA bands.

The complex formation between a 20-mer oligonucleotide (ODN) and the graft copolymer was analyzed as follows. The ODN (500 ng) in 50 mM Tris-acetate (pH 7.0), 100 mM NaCl, and 10 mM MgCl_2 was heated at 65 °C for 10 min to disrupt self-associated chains and then quickly cooled on ice. The copolymer was then added at the indicated P/D ratio and the mixture incubated for 12 h at room temperature. The mixture was then electrophoresed on a 15% polyacrylamide gel for 16 h at constant voltage (8 V/cm). The resulting bands were visualized by staining with Stain-all (Nacalai Tesque, Inc., Kyoto, Japan). A competition assay was also performed as described above, except that the ODN was incubated with or without copolymer at a P/D ratio of 1. Samples were electrophoresed in the presence or absence of an excess (ca. 10 times) amount of sonicated calf thymus DNA.

RESULTS AND DISCUSSION

Successful Preparation of PLL-g-Dex with High Coupling Efficacy. Semitelechelic prepolymers which

Figure 2. GPC profiles of PLL, Dex, and the resulting copolymers. Copolymers prepared from Dex having a M_n of 2600 (a) and a M_n of 5900 (b) were analyzed on Waters Ultrahydrogel 250 and 500 columns connected with a multiangle light scattering detector and a differential refractive index (RI) detector (see the text for details). An aqueous solution containing 0.5 M acetic acid and 0.2 M Na_2SO_4 was used as a mobile phase at a rate of 1.0 mL/min.

have a reactive group at their one chain end are required in the preparation of graft copolymers by the polymer coupling method. Polysaccharides are suitable prepolymers for graft copolymer preparation, since most polysaccharides possess one reductive end. Their semitelechelic character is preserved even after chemical or enzymic hydrolysis of the glycosyl bonds of the polysaccharide chains. Thus, by combining the hydrolysis and coupling reactions, we can obtain graft copolymers having polysaccharide chains with various molecular weights. In this study, the reductive end of Dex was directly coupled to the ϵ -amino groups of PLL by a reductive amination reaction using NaBH_3CN as a reductant. Figure 2 shows GPC profiles of PLL, Dex, and the copolymers. These reactions show an apparent increase in molecular weight. Furthermore, since there is no corresponding Dex peak in the copolymer formulations, they can be assumed to be free of unreacted Dex. The results of the coupling reaction are summarized in Table 1 with the number-average molecular weight of the polymers estimated by static light scattering. At a lower feed ratio (<20 mol %) of Dex/PLL, the efficacy of coupling of Dex to PLL was $>70\%$ regardless of the molecular weight of Dex and solvents used in the coupling process. The polymer composition calculated from the molecular weight was in good agreement with that determined from ^1H NMR measurements (Figure 3). This result indicated that no detectable side reactions that may cause cross-linking or degradation of the resulting copolymers occurred. As reported elsewhere, the coupling reaction between PLL and other polysaccharides, including amylose (20), hyaluronic acid (22), and arabinogalactane (manuscript in preparation), were found to be successful, indicating the validity of the coupling polysaccharide conjugates with PLL.

Turbidity of the DNA/Copolymer Mixture and the Melting Behavior of DNA in the Mixture. Polycationic homopolymers such as polylysine and polyarginine form precipitates or coacervates when they are mixed with polyanions such as DNA in aqueous media. The strong electrostatic attraction between oppositely charged macromolecules causes them to be drawn together and

Figure 3. ^1H NMR spectra of PLL-g-Dex copolymers in D_2O . The indicated run numbers were the same as those indicated in Table 1.

Figure 4. Turbidity of DNA/polymer mixtures (P/D ratio = 1) in phosphate-buffered saline (PBS). To a $30\text{ }\mu\text{g/mL}$ sonicated calf thymus DNA solution in PBS was added a 1 mg/mL PBS solution of graft copolymers prepared with Dextran 4 ($M_n = 2600$, $\circ$) or Dextran T-10 ($M_n = 5900$, $\bullet$) at a P/D ratio of 1. The mixture was diluted with buffer I to a final DNA concentration of $27.4\text{ }\mu\text{g/mL}$. After the mixture was vigorously mixed with a vortex mixer, the turbidity of the solution was measured as the optical density (OD) at 340 nm .

react ionically, releasing their associated counterions as free salt (1, 23). The counterion release caused a significant loss in solubility due to a loss in osmotic pressure of the complex. The important characteristic of the comb-type graft copolymer is the fact that they form soluble complexes with DNAs as estimated by turbidity measurements of DNA/graft copolymer mixtures (Figure 4). The mixture of linear polylysine and DNA shows significant turbidity in 10 mM PBS containing 150 mM NaCl; however, the turbidity decreases with an increasing degree of grafting of Dex side chains. No turbidity is observed at higher degrees of grafting even after storage for 4 weeks at $4\text{ }^\circ\text{C}$. The grafted dextran chains seem to be responsible for protecting the DNA-polycation complex from self-aggregation and precipitation. In support of our argument, we have seen, using fluorescence microscopy, that this protective effect also occurs in large (166 kbp) DNA sequences of T4 phage (data not shown).

The solubility of such complexes minimized the effect of turbidity and/or precipitation and enabled us to evaluate their interaction with DNA by UV- T_m measurements. Figure 5 shows the UV- T_m curves of double-helical poly(dA)·poly(dT) in the absence or presence of the comb-type copolymers with various Dex contents. Poly(dA)·poly(dT) alone undergoes double helix to single

Figure 5. UV- T_m profiles (upper panel) and its derivative curves (lower panel) of the poly(dA)·poly(dT) duplex in the presence ($P/D = 1$) of PLL-g-Dex copolymers having various degrees of grafting and lengths of Dex in buffer II. The differential absorbance ($\Delta A = A_{260} - A_{340}$) was plotted. Poly(dA) and poly(dT) were dissolved in buffer II. To a 1/1 mixture of poly(dA) and poly(dT) was added the copolymer at a P/D ratio of 1. After dilution to a final DNA concentration of $36\text{ (bp) }\mu\text{mol/L}$ with buffer II, the mixtures were heated at $90\text{ }^\circ\text{C}$ for 30 min , cooled to room temperature, and allowed to stand for 16 h . The UV- T_m curves were recorded at 0.2 K/min as heating and cooling rates with a DU-640 spectrometer (Beckman) equipped with a micro-melting temperature apparatus. The differential absorbance ($\Delta A = A_{260} - A_{340}$) was used to correct for background variation. First-derivative curves were obtained from absorbance data.

strand transition at $72\text{ }^\circ\text{C}$ in PBS. In the presence of the comb-type copolymers either with lower-molecular weight Dex, PLL-Dex(2600-7, -14, and -34) (Figure 5a), or with lower Dex content, PLL-Dex(5900-7) (Figure 5b), the complete melting of the double helix was not observed. In the presence of PLL-Dex(5900-7), although partial melting of the double-helical DNA to single strands was observed, reassociation of the ssDNA to form the double helix was incomplete in the cooling process. These results suggest that copolymers having lower degrees of grafting or shorter Dex chains interact firmly with the DNAs and prevent them from reversible duplex-single strand transition. This is in agreement with the previously reported finding that polycations such as polylysine and polyarginine irreversibly interacted with DNA (3, 4). Like PLL homopolymers, the PLL backbone

in the copolymers with a lower degree of grafting is assumed to interact irreversibly with DNA, leading to considerable stabilization of DNA double helices or inhibition of ssDNAs to form double helices. In other words, the Dex chains of these copolymers do not considerably hinder the interaction between DNA and the PLL backbone; however, they effectively increase the solubility of the complex.

As seen in Figure 5, UV absorbance at 260 nm that is attributed to DNA in the mixture is decreased compared with that of free DNA. Similar behavior was previously observed in DNA/PLL mixtures (24), although significant turbidity was detected in this case. It seems that the polycationic backbone triggers a conformational change of the DNA to a dense globular structure (25–27), leading to a loss in UV absorption. However, we believe that further study on the assembly process between DNA and these copolymers is needed to understand the exact nature and behavior of the resulting complex.

In contrast to the results obtained with the graft copolymers with lower degrees of grafting, the double-helical DNA undergoes complete melting and reassociation when associated with the graft copolymer [PLL–Dex(5900–21)] with a higher degree of grafting (Figure 5b). The T_m of the dsDNA increased by more than 15 °C in the presence of an electrostatically equivalent amount ([amino group]_{polymer}/[phosphate group]_{DNA} = 1) of PLL–Dex(5900–21). It can be concluded that PLL–Dex(5900–21) is capable of thermally stabilizing the poly(dA)·poly(dT) double helices without interfering with their interpolynucleotide recognition and assembly. The abundant Dex graft chains (90 wt %) in PLL–Dex(5900–21) may prevent close association of the DNA to the PLL backbone, leading to weak PLL–DNA interactions. This weak interaction still allows the copolymer to thermally stabilize the DNA double helices possibly by reducing the electrostatic repulsion between negatively charged DNA strands. PLL–Dex(2600–34), for which the degree of grafting is higher than that of PLL–Dex(5900–21), does not allow the DNA to melt. Thus, both the degree of grafting and the length of graft chains are parameters by which we could regulate reversible melting of dsDNA.

Stabilizing Effect of PLL–Dex(5900–21) on the Poly(dA)·Poly(dT) Double Helix. The stabilizing effect of the graft copolymer, PLL–Dex(5900–21), having a higher Dex content was further evaluated by changing the polymer/DNA ratio. Figure 6 shows the copolymer/DNA ratio ([amino group]_{polymer}/[phosphate group]_{DNA} = P/D) effects on the melting of the poly(dA)·poly(dT) double helix in the presence of PLL–Dex(5900–21). The melting temperature of the dsDNA gradually increases with an increasing P/D ratio. It is notable that an excess amount of the copolymer did not affect the reversibility of the DNA melting and reassociation. Since the ionic strength of the media is a factor that affects interpolyion interaction, we assessed the melting behavior of the double helix in a low-salt medium. Figure 7 shows the melting profiles of poly(dA)·poly(dT) duplex in 1/100 diluted buffer I (0.1 mM PBS with 1.5 mM NaCl). Under these conditions, poly(dA)·poly(dT) alone melted at 48 °C and did not exhibit obvious reassociation in the cooling process, indicating a considerably slower rate in double-helix formation. Upon addition of the copolymer, the melting temperatures significantly increased and double-helix reassociation also became more prominent. We concluded that the copolymer permits reassociation of DNA even under low-ionic strength conditions and promotes annealing of dsDNA. In the presence of a small amount of the copolymer, the DNA T_m surpassed 45 °C,

Figure 6. P/D ratio dependency of thermal dissociation and reassociation of poly(dA)·poly(dT) in the presence of PLL–Dex(5900–21) in buffer II: (a) change in absorbance at 260 nm and (b) first-derivative curves. The measurements were performed according to the same procedure described in Figure 5, except using different P/D ratios.

Figure 7. P/D ratio dependency of dissociation and reassociation of poly(dA)·poly(dT) in the presence of PLL–Dex(5900–21) in 1/100 diluted PBS: (a) change in absorbance at 260 nm and (b) first-derivative curves. The measurements were performed according to the same procedure as that described in Figure 6, except that the 1/100 diluted buffer II was used in these experiments.

leading to the same T_m observed in undiluted buffer I. The T_m value reached a plateau at a P/D ratio of 1, supporting the assumption that the graft copolymer and DNA form a stable association in buffer I. Further evidence supporting stable graft copolymer association is shown in Figures 6 and 7, where poly(dA)·poly(dT) melted in a bimodal manner at a P/D ratio of <1 , indicating a dissociation rate of the copolymer from DNA

Figure 8. Circular dichroism spectra of calf thymus DNA in the presence of varying amounts of PLL (a and c) or PLL-Dex(5900-21) (b and d). To 1 mL of 100 $\mu\text{g/mL}$ calf thymus DNA in Dulbecco's PBS (a and b) or 1/100 diluted PBS (c and d) was added the appropriate amount of polymers from a 10 mg/mL stock solution at room temperature. The mixtures were diluted to 2.5 mL, followed by CD measurement at room temperature (ca. 20 $^{\circ}\text{C}$). The P/D ratios are indicated above the graphs.

considerably slower than that of the dsDNA to ssDNAs. Oligomeric cations, such as spermine, are reported to elevate the T_m of poly(dA)·poly(dT) in low-ionic strength media (21). Spermine, however, failed to stabilize the duplex in physiological saline (17), indicating a weak association to the duplex. In contrast to spermine, the graft copolymer stably associates with the duplex, leading to T_m elevation in high- and low-salt media.

The graft copolymer, PLL-Dex(5900-21), was previously reported to be an effective stabilizer of triple-helical DNA of poly(dA)·2poly(dT) (17), which is unstable under physiological conditions (19).

The Grafting Copolymer PLL-Dex(5900-21) Does Not Change the CD Signal of Duplex DNA. The unique effect of PLL-Dex(5900-21) in the DNA melting process prompted us to further analyze the polymer's effects on the secondary structure of DNA. Figure 8a shows CD spectra of calf thymus DNA mixed with various amounts of PLL homopolymer or PLL-Dex(5900-21) in buffer I. CD signals do not change for the DNA/PLL homopolymer mixture at a P/D ratio from 1 to 10 due to precipitation of the complex. Although a transparent solution of the PLL/DNA mixture was obtained at P/D ratios of >15 , the CD signal was considerably different when compared to that of free DNA. The change in CD signals in the PLL/DNA mixtures has been explained by distortion and base tilting of the B conformation (3). X-ray diffraction results, however, indicated that DNA in these complexes remains essentially in the untilted B conformation, characteristic of free DNA in solution (3). The abnormal CD pattern was attributed to micellar or liquid crystal structure in the complex. CD signals observed at a wavelength of >300 nm indicated the formation of chiral aggregates (28–31). On the other hand, the graft copolymer does not induce a significant change in CD signals as shown in Figure 8b, suggesting only a slight effect on the DNA secondary structure. Similar results were also obtained even in the presence of large excesses of the copolymers. The CD measurements were also carried out in 1/100 diluted buffer I.

Figure 9. Circular dichroism spectra of poly(dA)·poly(dT) in the absence (dotted line) or presence (solid line) of PLL-Dex(5900-21) ($P/D = 2$). The samples were prepared according to the same procedure as that described in Figure 5. The spectra were recorded on a Jasco J-600 apparatus using a 1 cm long quartz cell with 20 nm/min as a scanning speed, 0.1 nm/point as a wavelength step, and 1 s/point as a time step. Each spectrum shown was the average of three scans and has been smoothed. The CD signal attributed to PLL-g-Dex was negligible under these conditions.

Although the PLL/DNA mixture was a transparent solution, probably due to a lower salting out effect, modified CD signals were recorded at all P/D ratios as shown in Figure 8c. The copolymer did not induce a significant change in CD signals even in low-ionic strength media (Figure 8d), in which ionic interactions should be significantly enhanced.

The CD study was further carried out with the poly(dA)·poly(dT) duplex as shown in Figure 9. Results similar to those obtained with calf thymus DNA were observed; namely, PLL-Dex(5900-21) addition did not significantly change the CD signals of poly(dA)·poly(dT). It was confirmed that the graft copolymers with higher Dex content did not change the secondary structure of DNA double helices, while it elevated the T_m .

Gel Electrophoresis of the DNA/Copolymer Mixture. The stability of the complex between DNA and the graft copolymer, PLL-Dex(5900-21), was assessed by gel electrophoresis of plasmid DNA (6.8 kbp) or a 20-mer oligodeoxynucleotide (ODN). As shown in Figure 10, migration of the plasmid DNA slowed as the P/D ratio increased. The graft copolymer completely inhibited migration of the plasmid DNA into the agarose gel at a nearly electrostatically equivalent point. Since the molecular weight of polyelectrolytes should be a factor which determines the stability of its IPECs, we then evaluated the complex of PLL-Dex(5900-21) with oligonucleotides. The migration of a 20-mer ODN (Figure 11A), which bears 19 phosphate anions in a molecule, into a 15% polyacrylamide gel was also impeded by the copolymer at a P/D ratio of 1 as shown in Figure 11B. PLL-Dex(5900-21) forms a stoichiometric complex even with a 20-mer ODN which bears considerably fewer negative charges than the plasmid DNA. Although the interaction between PLL-Dex(5900-21) and DNA seemed to be weaker than the interaction between the PLL homopolymer and the copolymers with a lower degree of grafting or length, it retained an ability to form a relatively stable complex with DNA.

The property of the complex was further estimated by a gel electrophoresis assay where an excess of thymus DNA (t-DNA) was added to the preformed complex. The ODN was completely and rapidly released from the complex by the addition of excess t-DNA (Figure 11C), while slight dissociation was observed with the PLL/ODN mixture (data not shown). Thus, PLL-Dex(5900-21)

Figure 10. Analysis of complex formation between plasmid DNA (pSV) and PLL-Dex(5900-21) by agarose gel electrophoresis. The increasing amount of the copolymer was added to 3 μ g of pSV plasmid (6.8 kbp) in PBS from a stock solution. The mixture was diluted with PBS to a final plasmid concentration of 43.4 μ g/mL, followed by incubation for 24 h at room temperature. The mixture was then analyzed on a 0.8% agarose gel in Tris-acetate buffer (40 mM, pH 8.0) containing 1 mM EDTA. The plasmid was finally stained with ethidium bromide to visualize it. M marks the columns with low- and high-molecular weight markers.

stably retains the ODN but allows rapid exchange between DNA molecules. This unique behavior of the copolymer seems to be related to the reversible dissociation and association of the DNA duplex and triplex. The copolymer thus allows DNA molecules in the complex to recognize and hybridize to each other.

CONCLUSION

Although the graft copolymer forms a soluble complex with DNA, physicochemical properties of DNA in the complex were significantly changed with the degree of grafting and length of graft chains. Graft copolymers with lower degrees of grafting firmly interacted with DNA, and probably condensed DNA into a globular conformation. This phenomenon was supported by a fluorescent dye exclusion assay using ethidium bromide and fluorescence microscopic observation of giant T4 DNA (data not shown). However, graft copolymers with higher degrees of grafting increased the T_m of the poly-(dA)·poly(dT) duplex by nearly 20 °C without affecting the reversible dissociation and reassociation of dsDNA. DNA associated with graft copolymers considerably accelerated hybridization of DNA strands in low-ionic strength media. The copolymers with higher degrees of grafting did not induce severe conformational changes of DNAs; furthermore, they still maintained the ability to form stoichiometric complexes with ODN. Thus, it can be concluded that grafting hydrophilic chains to PLL allows the regulation of the physicochemical properties of DNA-PLL copolymer complexes.

Several conjugates between polycations and biological ligands have been examined as carriers of DNA, including genes and ODNs. DNA delivery by these carriers, however, lacks high efficiency. To improve DNA delivery using such conjugates, it is crucial to understand the structure-function relationships of DNA carriers and their complexes with DNA. Regulation of physicochemical properties and assembling structures of DNA-carrier complexes with graft copolymers may provide new knowledge for effective DNA delivery and may lead to remarkable progress in this field. We have recently found that the PLL graft copolymers with cell-specific polysaccharide chains permits cell-specific delivery and expression of a

TECHNICAL NOTES

Synthesis of Heterobifunctional Poly(ethylene glycol) with a Reducing Monosaccharide Residue at One End

Teruo Nakamura, Yukio Nagasaki, and Kazunori Kataoka*

Department of Materials Science and Technology, Science University of Tokyo, Noda 278, Japan.
Received September 15, 1997; Revised Manuscript Received December 15, 1997

A new synthetic method for a heterobifunctional poly(ethylene glycol) (PEG) having a monosaccharide moiety at one end was created. PEG with a reducing monosaccharide residue at the α -end, which is linked to a defined position of the sugar molecule, could be prepared via the anionic polymerization of ethylene oxide (EO) initiated with a potassium alkolate of a protected monosaccharide such as 1,2;5,6-di-*O*-isopropylidene- β -D-glucopyranose (DIGL), 1,2;3,4-di-*O*-isopropylidene- β -D-galactopyranose (DIGA), and 1,2-*O*-isopropylidene-3,5-*O*-benzylidene- β -D-glucopyranose (IBGL). The resulting PEGs possess the corresponding sugar molecule at the α -chain end and a hydroxyl group at the ω -chain end. The ω -chain end could be converted to several functional groups such as allyl, amino, and hydroxycarbonyl groups in high yield. Such heterobifunctional PEGs possessing a reducing monosaccharide residue at the α -end are one of the promising tools for bioconjugate chemistries.

INTRODUCTION

Poly(ethylene glycol) (PEG) is a polymer possessing peculiar physicochemical properties such as high water solubility and flexibility. In addition, its bioinert characteristic increases an opportunity for biomedical applications. Chemical modification of biologically active compounds with PEG, designated PEGylation, led to alteration of their pharmacokinetics (1). As we reported previously, polymeric micelles, composed of PEG–poly(peptide) block copolymers, behave as long-circulating vehicles of antitumor agents in vivo (2). The hydrophilic character of the PEG outer shell along with the small size of the micelle (approximately tens of nanometers) confers a reduced nonspecific uptake to reticuloendothelial systems. By installing homing devices onto the surface of the micelles, we enhanced cellular uptake at a target tissue. Carbohydrates are known as one of the promising candidates for a homing moiety. Recent progress in glycobiology revealed that carbohydrate–protein interaction requires a ligand with well-defined structural compatibility (3). For instance, the permeability of intestinal epithelium to macromolecular substances was improved by installing a reducing glucose residue rather than a nonreducing moiety on them (4). This enhanced permeability may be attributed to receptor-mediated endocytosis via glucose transporters, mediating the facilitative diffusion of glucose, through specific binding with the reducing glucose residue. This result suggests that the designed sugar moieties can be utilized as a targeting device. However, to design a sugar derivative as a homing unit, regiospecific conjugation as mentioned above and spatial arrangement of plural sugar residues are key factors in demonstrating the target function. If an accommodating spacer, such as PEG, can

be introduced at a sugar residue site-specifically, it will provide a superior device for incorporating a potent targeting moiety into the compounds desired to be delivered.

Thus, we report herein a new synthetic route for a heterobifunctional PEG with a reducing monosaccharide residue at one end with a defined position linkage of PEG and the sugar moiety. A functional group was introduced at the other end for further derivatization. Our strategy is to initiate anionic polymerization of ethylene oxide (EO) from the hydroxyl of site-specifically protected sugar molecules.

EXPERIMENTAL PROCEDURES

Polymerization of EO from Protected Sugars. To a solution of 1,2;5,6-di-*O*-isopropylidene- β -D-glucopyranose (DIGL) (5) (260 mg, 1 mmol) in tetrahydrofuran (THF) was added potassium naphthalene (1 mmol) as a THF solution to convert a hydroxyl group at the C-3 position to a potassium salt. EO (115 mmol) was added to the solution via a cooled syringe, and the mixture was stirred in a water bath for 2 days. The reaction mixture was then poured into ice-cold ether (approximately 1 L) to obtain a white precipitate. Polymerizations of EO with the potassium alkolate form of 1,2;3,4-di-*O*-isopropylidene- β -D-galactopyranose (DIGA) (5) and 1,2-*O*-isopropylidene-3,5-*O*-benzylidene- β -D-glucopyranose (IBGL) (6) were carried out in a procedure similar to the DIGL-initiated EO polymerization.

Removal of Protective Groups from the Sugar End Group. PEG with a sugar derivative end group was dissolved in 8:2 (v/v) trifluoroacetic acid–water and allowed to stand for 1 h at room temperature. The reaction solution was diluted with water, and the solvent was removed under reduced pressure followed by lyophilization from water.

ω -End Functionalization of Sugar-PEG. After the polymerization of EO (115 mmol) initiated with DIGL (130 mg, 0.5 mmol) in THF, a THF solution of potassium naphthalene (1 mmol) was added to the polymerization mixture and the mixture stirred at room temperature for 30 min. To the solution was added allyl bromide (0.43 mL, 5 mmol) via a syringe, and the mixture was stirred at room temperature for 4 h. Then, the reaction solution was mixed with chloroform and washed with a saturated NaCl aqueous solution several times to eliminate impurities from the PEG derivative. The organic phase was dried with sodium sulfate followed by concentration and then poured into ice-cold ether. The resultant white precipitate was dried in vacuo. Under these reaction conditions, the conversion of the ω -end from potassium alkoxide to the allyl group was almost complete, forming DIGL-PEG-allyl heteroPEG quantitatively.

For the introduction of an amino group at the ω -end, 100 mg of DIGL-PEG-allyl and a 100-fold molar excess of 2-aminoethanethiol hydrochloride were dissolved in degassed water containing 10 wt % sodium chloride and the mixture was stirred in a water bath at 40 °C for 3 h. Purification was carried out in the same way as the sugar-PEG-allyl preparation.

RESULTS AND DISCUSSION

As we reported previously, potassium alkoxide possessing an acetal moiety initiates the polymerization of EO to yield PEG with an acetal group at the α -end without any side reaction (7). If the potassium salt of DIGL acts as an initiator for EO polymerization, then a heterobifunctional PEG with sugar derivative at the α -end should be obtained. To confirm the hypothesis, synthesis of α -DIGL- ω -hydroxyl-PEG was attempted. The precipitate obtained after polymerization was dried in vacuo and was analyzed by gel permeation chromatography (GPC) as shown in Figure 1. The resultant material had a number average molecular weight (M_n) of 4300 with a unimodal and narrow molecular weight distribution (MWD) of 1.09 (M_w/M_n). Results of polymerization using DIGL as an initiator under several conditions are summarized in Table 1. The value of the

Table 1. Results of Polymerization of Ethylene Oxide (EO) Initiated with Potassium Alkoxide of DIGL^a

^a M_n and M_w/M_n were determined by GPC.

Figure 2. 400 MHz ^1H NMR spectra of PEGs with a sugar residue at the α -end in D_2O . DIGL-PEG (upper) and deprotected product Glc(3)-PEG (lower).

M_n could be controlled by the initial monomer/initiator ratio while retaining a narrow MWD.

Removal of protective groups from the sugar derivative at the PEG chain end was achieved under acidic condition (8). Figure 2 shows the ^1H NMR spectrum of the PEG before and after the TFA treatment. In the lower spectrum, anomeric protons of the reducing glucose residue at 4.66 ppm [H-1(β)] and 5.23 ppm [H-1(α)] were clearly observed at the same time as the disappearance of signals at 1.24, 1.40, 1.45, and 1.52 ppm originating from isopropylidene groups, observed in the upper spectrum, indicating the complete deprotection of the sugar derivative at the end of the polymer. Typical protons of the free sugar residue in Figure 2 (lower) further supported the achievement of cleavage. Worth noticing, revealed by the ^1H NMR spectrum of the deprotected polymer, was an increased ratio of α -anomer to β -anomer of the glucose residue on coupling with PEG. The α/β ratio from the ^1H NMR spectrum of the polymer is estimated to be 45/55; on the other hand, the ratio is 37/63 for intact glucose. The reason for this increased stability of the α -anomer may be the intramolecular interaction of the PEG chain with the sugar moiety.

EO polymerizations with IBGL and DIGA as the initiators were also carried out to obtain sugar-ended PEGs with a different linkage position and a different sugar residue, respectively (see Scheme 1). In the case of IBGL, PEG with a hydroxyl group at both chain ends was produced in approximately 35% as a byproduct due to a trace amount of water in IBGL. The larger M_n of the polymer with hydroxyl ends permitted the isolation of PEG with a sugar end group by gel filtration. In the DIGA case, the polymerization succeeded in producing the targeted compound adequately. Removal of protective groups on the sugar derivative on these polymers was also achieved by TFA treatment to convert them to

Scheme 1

reducing types. On the whole, the polymerization of EO proceeded smoothly with the sugar derivative initiators.

The chances of exploiting the sugar-PEG for drug targeting or surface modification can be improved by ω -end derivatization to an appropriate function. The living nature of the propagating end of the PEG chain allows the introduction of an additional functionality to the ω -end via a successive chemical reaction in the same reaction vessel.

The product obtained after ω -end allylation was analyzed by GPC to reveal the formation of the polymer having an M_n of 6000 with a unimodal MWD ($M_w/M_n = 1.06$) (Figure 3). In the ^1H NMR spectrum of the polymer (Figure 4), signals that can be attributed to DIGL and the allyl group were observed. The signal intensities of methyl protons in the isopropylidene unit, oxymethylene protons in PEG, and methine protons in the allyl end group along with C-1 protons in the sugar moiety were 12, 590, and 2.2, respectively. The M_n of the polymer was then calculated to be 6500, assuming one sugar residue per each polymer chain, which is in good agreement with that from the GPC measurements. This result is consistent with the formation of heterobifunctional PEG possessing sugar and allyl groups at the α - and ω -termini, respectively.

The allyl end can be converted to an amino group or a carboxyl group by radical addition of thiol compounds possessing the corresponding functional group. Although the procedure using a radical initiator at 70 °C in anhydrous DMF was previously reported for preparing amino-ended PEG (9), addition of thiols to the allyl group under mild conditions without any catalyst (10) should be attractive from the standpoint of polymer end-group derivatization. With the procedure described herein, the conversion to the amine end was accomplished in 91% yield, estimated by the intensity ratio of isopropylidene to the allyl unit from the ^1H NMR spectrum (Figure 4), which was proved by the appearance of two methylene protons of the 2-aminoethanethiol unit at 2.85 and 3.20

Figure 3. GPC chromatogram of PEG with α -DIGL and α -allyl end groups.

ppm with suitable intensities. On the contrary, amination in pure water was achieved in 26% conversion. Formation of a PEG-solute complex may change the chain conformation in the vicinity of the ω -end, enhancing the possibility of thiol access to the allyl group. Derivatization using mercaptoacetic acid proceeded under the same conditions. From the ^1H NMR spectrum of the resultant polymer, there was no signal to assign to the allyl group, while the methylene proton of the mercaptoacetic acid unit was clearly observed at 3.25 ppm as a singlet. A great excess of mercaptoacetic acid in the reaction solution, however, partially cleaved isopropylidene on the sugar derivative. The ω -end amina-

tion or hydroxycarbonylation of sugar-PEGs increases their usefulness in the preparation of a variety of bioconjugates.

In conclusion, the successful synthesis of a heterobifunctional PEG with a sugar end via EO polymerization using a sugar derivative as an initiator was demonstrated. The sugar residue was introduced onto PEG without any linkage reagent, and the PEG linking

position on the sugar was defined by protective groups introduced to the hydroxyl on the sugar molecule. The procedure reported here can be applied to an array of carbohydrates to provide a series of sugar-PEGs. Furthermore, ω -end functionalization of the sugar-PEG was attained. These sugar-PEGs may be applicable to preparation of a wide variety of bioconjugates as well as polymeric micelles with many sugar residues on their surface, which should be quite useful in active targeting of drugs and biologically active compounds.

Cascade Liposomal Triggering: Light-Induced Ca^{2+} Release from Diplasmerylcholine Liposomes Triggers PLA_2 -Catalyzed Hydrolysis and Contents Leakage from DPPC Liposomes

Nathan J. Wymer, Oleg V. Gerasimov, and David H. Thompson*

Department of Chemistry, Purdue University, West Lafayette, Indiana 47907-1393. Received January 7, 1998;
Revised Manuscript Received February 19, 1998

We have previously reported a direct triggering approach [Thompson, D. H., et al. (1996) *Biochim. Biophys. Acta* 1279, 25–34; Gerasimov, O. V., et al. (1997) *Biochim. Biophys. Acta* 1324, 200–214] based on the facile degradation of plasmerylcholine and diplasmerylcholine vinyl ether linkages by either photooxidation or low-pH environments. This report describes a novel, cascade-type triggering technique that utilizes liposome photooxidation and contents release to activate an enzyme capable of destabilizing conventional phosphatidylcholine liposomes. Our application of this concept employs a mixture of two different liposome populations, one composed of synthetic diplasmerylcholine (1,2-dihexadec-1'-enyl-*sn*-glycero-3-phosphocholine, DPPIsCho) containing Ca^{2+} as a signaling agent for phospholipase A_2 (PLA_2) and the second composed of 1,2-dihexadecanoyl-*sn*-glycero-3-phosphocholine (DPPC) with encapsulated calcein as the reporter molecule. Bacteriochlorophyll (BChl)-sensitized photorelease of Ca^{2+} from PLA_2 -resistant DPPIsCho liposomes activates extravesicular PLA_2 , thereby promoting catalyzed DPPC hydrolysis in a secondary triggering reaction, leading to calcein release. BChl/DPPIsCho/DHC/DPPE-PEG5000/ $\text{Ca}^{2+}_{\text{IN}}$ (0.5:85:10:5) liposomes can be phototriggered using 800 nm excitation, resulting in Ca^{2+} release ($t_{50\% \text{ release}} = 15 \text{ min}$) that cocatalyzes the release of calcein ($t_{50\% \text{ release}} = 40 \text{ min}$) from DPPC liposomes (1.5 mM total lipid in DPPIsCho liposomes, 0.18 mM DPPC, 210 μM final Ca^{2+} concentration, 90 units of PLA_2/mL , 50 mM calcein, and 36 μM EDTA). No appreciable calcein release occurs in the absence of either PLA_2 or BChl/DPPIsCho/DHC/DPPE-PEG5000/ Ca_{IN} liposomes. The implications of this cascade triggering technique on drug delivery approaches are briefly discussed.

Triggered release from liposomal carriers has been the subject of numerous studies (1, 2). We have previously reported a triggering approach (3), based on the facile degradation of plasmerylcholine vinyl ether linkages by either photooxidation (3a–d) or low environmental pH (3a,d,e), that utilizes plasma-stable liposomes having long blood circulation times in a murine model (1b) and

efficiently delivers water-soluble drugs to the cytoplasm of target cells (3e). Plasmerylcholines and diplasmerylcholines, however, suffer from higher costs compared with egg or soy lecithins and from liposome processing restrictions due to the involvement of vinyl ether degradation reactions. In an attempt to mitigate these limitations, we investigated a novel, cascade-type triggering technique that utilizes liposome photorelease to activate an enzyme capable of destabilizing conventional phosphatidylcholine liposomes. Inexpensive phosphatidylcholine

Figure 1. Schematic view of cascade triggering in a binary liposomal system. Calcium ions are shown as shaded circles, and calcein is shown as diamonds. Hydrolyzed/photolyzed lipid molecules are shown as one-tail species, as opposed to intact two-tail molecules.

(lecithin) liposomes are intended to serve as a main payload carrier, while phototriggerable liposomes containing a signaling substance will be ideally present in a small proportion. To demonstrate the feasibility of this approach, we present a system (Figure 1) which employs a mixture of two different populations of liposomes, one composed of synthetic diplasmenylcholine (4) (1,2-hexadec-1'-enyl-*sn*-glycero-3-phosphocholine, DPPIsCho¹) containing calcium ions as a signaling agent and the second composed of 1,2-dihexadecanoyl-*sn*-glycero-3-phosphocholine (DPPC) with encapsulated calcein as the reporter molecule. Photorelease of Ca²⁺ from diplasmenylcholine liposomes, therefore, should activate extravesicular calcium-dependent phospholipase A₂ (PLA₂) and promote catalyzed DPPC hydrolysis in a secondary triggering reaction, leading to calcein release (5).

Bacteriochlorophyll (BChl)-sensitized photooxidation of semisynthetic plasmenylcholine (1-alk-1'-enyl-2-hexadecanoyl-*sn*-glycero-3-phosphocholine) liposomes has previously been used as a phototriggering mechanism (3c,d); however, due to the presence of an *sn*-2 acyl substituent in this phospholipid, liposomes formed from it can also serve as a PLA₂ substrate. DPPIsCho, containing 1'-hexadecenyl ether linkages in both the *sn*-1 and *sn*-2 positions, was chosen to form the photosensitive liposome fraction since its resistance to PLA₂-catalyzed hydrolysis would help us avoid complications that could arise from PLA₂-induced background calcium leakage before illumination. In addition, a protective, steric-stabilization layer of poly(ethylene oxide) was added to the DPPIsCho liposomes, in the form of 5 mol % DPPE-PEG5000, to

Figure 2. Photorelease of Ca²⁺ from DPPIsCho liposomes. BChl/DPPIsCho/DHC/DPPE-PEG5000 liposomes (0.5:85:10:5 mole ratio, 10 μ mol of total lipid) were prepared by extrusion (9). Briefly, lipids and BChl were dissolved in CHCl₃ in a cryovial and after chloroform removal (N₂ flow followed by ≤ 100 μ m vacuum for ≥ 6 h) were hydrated in 0.1 M CaCl₂ by multiple freeze-thaw cycles and extruded through two stacked 0.1 μ m Poretics polycarbonate filters. The extraliposomal Ca²⁺ was then replaced by 150 mM NaCl on a 1 $\times$ 20 cm Sephadex G50M column. Illumination was carried out with a Spectra Diode Labs SDL820 laser emitting at 800 nm (incident light power of 1 W/cm², 1 cm path length) in an unstoppered 3 mL (1 $\times$ 1 cm) glass cuvette thermostated at 37 $^{\circ}$ C, the contents of which were continuously stirred to aerate the liposome solution. Illumination was ceased after 15 min due to complete photobleaching of BChl. The release of Ca²⁺ was monitored by taking a 100 μ L aliquot and diluting it in 2 mL of 0.2 mM Arsenazo III solution in HBS. The absorbance of the solution at 656 nm was then measured before and after the addition of 1 drop of a 10% Triton X-100 solution. Concentrations used in the experiments presented here were as follows: lipid (total) = 1.2 mM and Ca²⁺ = 120 μ M (bulk concentration when completely released) in HBS.

prevent PLA₂ contact with them (6), since PLA₂ adsorption might, in principle, destabilize the DPPIsCho bilayer and induce contents release even in the absence of lipid hydrolysis (7). Dihydrocholesterol (DHC, 10 mol %) was also included in the DPPIsCho liposome formulation (3e) to further suppress the dark leakage rate of calcium ions (8).

The results shown in Figure 2 indicate that 0.5:85:10:5 (mole ratio) BChl/DPPIsCho/DHC/DPPE-5000/Ca²⁺_{IN} liposomes can be phototriggered using 800 nm excitation, yielding Ca²⁺ release rates that were comparable to those reported for calcein release from semisynthetic plasmalogen liposomes under similar conditions (3c). Subsequent control experiments demonstrated that pure DPPC liposomes loaded with 50 mM calcein are stable at 37 $^{\circ}$ C in the presence of PLA₂ for at least 20 min, yet they rapidly release calcein in the presence of 50 μ M Ca²⁺ (Figure 3). These results suggested that the individual liposomes in mixtures of BChl/DPPIsCho/DHC/DPPE-5000/Ca²⁺_{IN}, DPPC/calcein, and PLA₂ would retain their contents until the solution was illuminated. Liposome-compartmentalized Ca²⁺ and calcein are, in fact, retained until 800 nm irradiation induces the onset of calcein leakage (Figure 4), presumably via a cascade mechanism involving calcium ion photorelease and PLA₂-catalyzed hydrolysis. Control experiments showed that appreciable calcein release from DPPC liposomes was not observed in the absence of either PLA₂ or BChl/DPPIsCho/DHC/DPPE-5000/Ca²⁺_{IN} liposomes.

The two coupled chemical reactions of the cascade triggering mechanism (Figure 1) are DPPIsCho photooxidation and DPPC hydrolysis catalyzed by Ca²⁺-activated

Figure 3. PLA_2 -induced calcein release from DPPC liposomes in the presence of 50 μM EDTA and varying concentrations of Ca^{2+} at 37 $^\circ\text{C}$. The DPPC liposomes were prepared by extrusion (9) (after hydrating dry DPPC in a 50 mM calcein solution), followed by gel filtration on a 1×40 cm Sephadex G50M column, equilibrated with 150 mM NaCl. Calcein release was monitored by measuring the solution luminescence intensity at 520 nm ($\lambda_{\text{ex}} = 475$ nm) (10). Concentrations (in HBS) were as follows: [DPPC] = 120 μM , [PLA_2] = 15 units/mL, [EDTA] = 50 μM , and [Ca^{2+}]_{added} = (●) 50 μM , (■) 60 μM , and (▲) 100 μM , resulting in 0, 10, and 50 μM free Ca^{2+} , respectively.

PLA_2 . BChl-sensitized photooxidation of DPPCsCho, which initiates the entire triggering sequence, is a well-documented reaction for the case of semisynthetic plasmenylcholine (3c,d). By analogy, singlet oxygen-mediated cleavage of the DPPCsCho vinyl ether bonds would produce a water-soluble bisformyl-*sn*-glycerophosphocholine fragment and 2 equiv of the single-chain surfactant, pentadecanal:

Accumulation of these surfactant photolysis products in the liposomal membrane leads to increased membrane permeability and Ca^{2+} release (11). Once the photoreleased Ca^{2+} concentration exceeds the EDTA concentration, PLA_2 activation occurs, leading to the catalytic degradation of DPPC and the production of the single-chain surfactants, lysophosphatidylcholine and hexadecanoic acid, in a subsequent consecutive reaction. DPPC hydrolysis, therefore, increases the liposome bilayer permeability (12) and initiates calcein leakage in a manner analogous to that of photooxidized DPPCsCho liposomes.

It should be noted that bee venom PLA_2 activation requires the presence of bulk calcium ion concentrations in the micromolar range (13). We achieved these relatively high concentrations of photoreleased Ca^{2+} by using concentrated solutions of DPPCsCho liposomes. Therefore, in its present form, the DPPCsCho content required to elicit a detectable cascade triggering response from DPPC liposomes is approximately 8:1; presumably, this may be improved by increasing the Ca^{2+} concentration within the DPPCsCho liposome population.

Figure 4. Kinetics of cascade-triggered calcein photorelease in the system comprised of two different liposomal populations described in Figures 2 and 3. Concentrations used were as follows: [BChl/DPPCsCho/DHC/DPE-PEG5000 (0.5:85:10:5 mole ratio)] = 1.5 mM (total lipid in the diplasmenylcholine liposome population), [Ca^{2+}] = 210 μM (total Ca^{2+} concentration), [PLA_2] = 90 units, [EDTA] = 36 μM , and [DPPC] = 0.18 mM.

While we have not yet reached our goal of reducing the amount of DPPCsCho required for photorelease of water-soluble materials from liposomal carriers (i.e. cascade amplification), these results clearly indicate new possibilities for cascade liposomal triggering. Incorporation of novel photochemical and cascade triggering properties into standard liposomal formulations that previously released their contents via passive diffusion is now feasible (14). Although this work focused on PLA_2 -mediated release from DPPC liposomes, in principle, calcium ion photorelease from DPPCsCho liposomes may be used to activate any Ca^{2+} -dependent enzyme or other calcium-requiring agent (15). It is also conceivable that this system could be used with minor modifications (i.e. encapsulation of small phototriggerable, Ca^{2+} -containing DPPCsCho liposomes within larger PLA_2 - and drug-containing phosphatidylcholine liposomes) to assemble a complete autonomous vesicular drug delivery vehicle that is photoresponsive. Structures such as these (vesicles inside vesicles with external diameters of $\sim 1 \mu\text{m}$) have been described recently by Zasadzinski and co-workers (16). Another system, based on lecithin liposomes microencapsulated in much larger particles ($> 100 \mu\text{m}$) of an alginate poly(L-lysine)-containing gel in which contents release rates on a week time scale was modulated by the presence of co-encapsulated PLA_2 , has been reported by Langer et al. (17). These and related enzyme-activated systems (18), in principle, can now be actively triggered using this cascade triggering approach.

ACKNOWLEDGMENT

We thank Dr. Y. Rui for the synthesis of diplasmenylcholine and Mr. J. Boomer for assistance with manuscript preparation. Financial support from the Purdue Research Foundation and INEX Pharmaceuticals, Inc., is gratefully acknowledged.

 - (5) This reaction sequence is analogous to the cascade amplification pathways involving intracellular Ca^{2+} release and calcium-dependent PLA_2 activation in mammalian cell signal transduction cascades [Dennis, E. A. (1994) *J. Biol. Chem.* 269, 13057–13060; Clark, J. D., Schievella, A. R., Nalefski, E. A., and Lin, L. L. (1995) *J. Lipid Mediators Cell Signalling* 12, 83–117].
 - (6) Addition of PEG-conjugated lipids is a common strategy for reducing protein adsorption onto the liposome surface (see ref 14a).
 - (7) It has been reported that PLA_2 isozymes, while lacking PLA_2 activity, can cause leakage of carboxyfluorescein from phosphatidylcholine liposomes [Shimohigashi, Y., et al. (1995) *J. Biochem.* 118, 1037–1044]. This means that PLA_2 can, in some cases, cause leakage simply by disturbing bilayer structure upon contact. We found that the presence of PEG reduced dark leakage of Ca^{2+} from DPPHsCho liposomes but did not affect their photosensitivity.
 - (8) EDTA was present in the solution (~0.25 equiv of EDTA/equiv of Ca^{2+}) to chelate any Ca^{2+} that may have leaked passively before the illumination started. EDTA was included as a precautionary measure even though appreciable dark calcium leakage was not observed from any batches of DPPHsCho/DHC/DPPE-PEG5000/ Ca^{2+} liposomes (cf. Figure 2). Its presence did not affect the performance of either the phototriggering or PLA_2 hydrolysis reactions once the free (i.e. photoreleased) calcium ion concentration exceeded the EDTA concentration.

Application of Cystamine and *N,N'*-Bis(glycyl)cystamine as Linkers in Polysaccharide–Protein Conjugation

Odo de Weers,[†] Michel Beurret, Leo van Buren, Lukas A. Oomen, Jan T. Poolman,[‡] and Peter Hoogerhout*

National Institute of Public Health and the Environment (RIVM), Laboratory of Vaccine Development and Immune Mechanisms, P.O. Box 1, 3720 BA Bilthoven, The Netherlands. Received October 31, 1997; Revised Manuscript Received February 10, 1998

Pneumococcal polysaccharide type 6B, 14, or 23F (35–70 kDa) was activated with cyanogen bromide and modified with cystamine. After reduction of the spacer, the thiol-containing (i.e. cysteamine-modified) polysaccharide obtained was added in a 5–10-fold molar excess to bromoacetylated tetanus toxoid to give thioether-linked polysaccharide–protein conjugates in a yield of 10–20%. This approach failed for preparing a type 19F polysaccharide–protein conjugate, possibly due to intramolecular elimination of cysteamine from the reduced 19F polysaccharide. When *N,N'*-bis(glycyl)cystamine was introduced as a spacer molecule, the elimination of the reduced spacer was suppressed, thus allowing preparation of a 19F polysaccharide–tetanus toxoid conjugate (15%).

INTRODUCTION

Many bacterial capsular polysaccharides (PS¹), for example, from *Haemophilus influenzae* type b, *Neisseria meningitidis*, and *Streptococcus pneumoniae*, can be used as vaccines. However, PS vaccines are poorly immunogenic in infants due to their T cell-independent nature as antigens. Conjugation of the PS to proteins (1–5) gives T cell-dependent antigens which on immunization induce anti-polysaccharide immunoglobulin G responses and immunological memory. This approach has been applied successfully for the preparation of protective vaccines, in particular against *H. influenzae* type b (6–9) and, more recently, against *S. pneumoniae* (7, 10–13).

Conjugation of PS and a protein can be performed directly, for example, by reductive amination of a terminal reducing sugar or of periodate-activated PS (14–16),

or indirectly, by first modifying activated PS with spacers such as cystamine, diaminobutane (5, 17), or 6-amino-hexanoic acid (18). Cystamine has been used for introduction of a masked thiol group into carboxylic acid-containing carbohydrates by carbodiimide-mediated coupling reactions (19–21). The compound has also been coupled to proteins (22) and synthetic oligonucleotides (23).

We have incorporated cystamine into (carboxylic acid-devoid) polysaccharides after classical activation with cyanogen bromide (24). In this paper, we illustrate this approach by preparation of cystamine-modified PS of pneumococcal types 6B,² 14, and 23F (cf. Scheme 1 for the PS structures). After reduction of the spacer, the thiol-PS obtained was coupled to bromoacetylated tetanus toxoid (BrAc-TTd) to give thioether conjugates. Furthermore, it is reported that this approach failed in preparing a type 19F PS–TTd conjugate but that this problem can be solved by using *N,N'*-bis(glycyl)cystamine as a spacer molecule.

EXPERIMENTAL PROCEDURES

Tetanus toxoid was obtained from the Laboratory of Vaccine Production of RIVM. The material met the requirements of the World Health Organization for human administration. Purified pneumococcal polysaccharides were purchased from the American Type Culture Collection (Rockville, MD) or obtained from the Laboratory of Product and Process Development of RIVM. The polysaccharides met the requirements of the European Pharmacopoeia. Solvents, reagents, and standards were purchased and were of analytical or higher grade, and used without purification.

² The Danish nomenclature for pneumococcal serotype classification is being used.

^a After incorporation of cystamine or *N,N'*-bis(glycyl)cystamine. ^b After DTE reduction of the linker. ^c In the pooled fractions (12–16) containing the conjugate, after purification over Sephacryl S-400 HR. ^d Based on the starting amount of PS. ^e Using cystamine as the linker. ^f Using *N,N'*-bis(glycyl)cystamine as the linker. ^g During purification over Sephacryl S-400 HR, about 10% of the nonconjugated PS 23F (67 kDa) coeluted with the selected conjugate-containing fractions nos. 12–16. For the three other conjugates, this was less than 2%.

Bromoacetylated Tetanus Toxoid. The cysteamine-modified Pn PS 6B [12 mg in 1.4 mL of 0.1 M sodium phosphate buffer, containing 5 mM EDTA (pH 7)] was mixed with BrAc-TTd [5 mg in 1.8 mL of 0.1 M sodium phosphate buffer, containing 5 mM EDTA (pH 7)], at a PS:TTd molar ratio of 7.5:1, at room temperature under a helium atmosphere. Conjugation was monitored by GP–HPLC analysis. After 91 h, essentially no uncoupled BrAc-TTd was left, and the main GP–HPLC peak had moved to a higher M_w . The remaining thiol groups on the PS were capped with bromoacetamide (8.1 mg, i.e. a 10-fold molar excess based on the initial amino group content, as measured on the PS before reduction) for 6 h at room temperature. The remaining bromoacetyl groups on BrAc-TTd were capped with 2-aminoethanethiol hydrochloride (17.0 mg, i.e. a 2.5-fold molar excess based on the amount of bromoacetamide added previously) overnight at room temperature. The conjugate was purified at room temperature by low-pressure GPC on a Sephacryl S-400 HR (Pharmacia) column (100 × 1.6 cm) using PBS as the eluent at a flow rate of 1 mL/min. The appropriate fractions (8 mL) were analyzed for carbohydrate (phenol/sulfuric acid assay) and protein content, sterile-filtered over a 0.2 μ m membrane, and stored at ~4 °C.

Preparation of Pn PS 14– and Pn PS 23F–TTd Conjugate Vaccines Using Cystamine. Starting from Pn PS 14 (ATCC lot 2016107) and Pn PS 23F (ATCC lot 2009269), these conjugates were prepared as described above for the Pn PS 6B–TTd conjugate. Table 1 shows the results.

***N,N'*-Bis[(*tert*-butyloxycarbonyl)glycyl]cystamine [N,N'-Bis(Boc-Gly)cystamine] (36).** *N,N*-Dimethylacetamide (42 mL) and *N,N*-diisopropylethylamine (14.6 mL, 83.8 mmol) were added to a mixture of *N'*-succinimidyl *N*-(*tert*-butyloxycarbonyl)glycinate, Boc-Gly-ONSu (11.4 g, 41.9 mmol), and cystamine dihydrochloride (3.77 g, 16.7 mmol). The suspension was stirred overnight at room temperature (cystamine dihydrochloride dissolved gradually in a few hours). The clear solution was diluted with water (16.7 mL), which caused phase separation. After the mixture was stirred for 1 h, diethyl ether (170 mL) was added and the mixture obtained was washed with water (170 mL). After phase separation, the water layer was extracted with diethyl ether (85 mL). The organic phases were combined, washed with 1 M NaHCO₃ (3 × 85 mL), water (3 × 85 mL), and 1 M NaH₂PO₄ (3 × 85 mL), successively, and dried with MgSO₄. The MgSO₄ was removed by filtration, and the filtrate was concentrated in vacuo to give *N,N'*-bis(Boc-Gly)cystamine (4.81 g, 62%) as a “glassy” solid.

***N,N'*-Bis(glycyl)cystamine (Dihydrotrifluoro Acetate) (36).** *N,N'*-Bis(Boc-Gly)cystamine (4.81 g, 10.3 mmol), as obtained in the previous step, was dissolved in dichloromethane (16.7 mL). The solution was stirred,

and trifluoroacetic acid (16.7 mL) was added. Formation of isobutene and carbon dioxide was visible for about 5 min. After a total period of 30 min, the reaction mixture was added dropwise to a powerfully stirred mixture of diethyl ether (170 mL) and pentane (170 mL). Stirring was ceased, and the precipitate was allowed to settle for 5 min. Diethyl ether/pentane was removed by decantation, and the solid was washed with a mixture of diethyl ether (50 mL) and pentane (50 mL). Again, diethyl ether/pentane was removed by decantation. The hygroscopic solid was dissolved in water (40 mL). Traces of diethyl ether/pentane were removed in vacuo at room temperature. Thereafter, the solution was lyophilized to give *N,N'*-bis(glycyl)cystamine dihydrotrifluoro acetate (4.93 g, 97%). Finally, the compound was dissolved in water at a concentration of 1.0 M and stored frozen at –20 °C.

Preparation of the Pn PS 19F–TTd Conjugate Vaccine Using *N,N'*-Bis(glycyl)cystamine. *Partial Depolymerization of Pn PS 19F.* Pneumococcal polysaccharide serotype 19F (RIVM, lot 19FEXP2A/S13; 275 mg, ~90% polysaccharide by colorimetric assay) was dissolved in 20 mL of water and sonicated for a total of 125 min, as described for Pn PS 6B. The M_w of the PS was reduced from ~980 to 49 kDa (from ~1700 to ~85 RU). The solution was filtered over a 0.45 μ m membrane and stored frozen at –20 °C.

*Modification of Pn PS 19F (49 kDa) with *N,N'*-Bis(glycyl)cystamine.* For the modification, 3.25 mL of a Pn PS 19F solution in water (6.15 mg/mL by colorimetric assay) was mixed with an equal volume of a 1 M sodium carbonate solution (pH 12). The mixture was cooled to ~2 °C. While the mixture was stirred, 250 μ L of the CNBr reagent (100 mg/mL in acetonitrile) was added. After 10 min, the solution was buffer-exchanged over Sephadex G-25 M with 0.2 M sodium carbonate/bicarbonate buffer at pH 9.25 and ~4 °C. The PS-containing fraction was mixed with 4.73 mL of a precooled solution of 0.2 M sodium carbonate/bicarbonate buffer (pH 9.25)/1.0 M *N,N'*-bis(glycyl)cystamine (dihydrotrifluoro acetate) (1/1, v/v). The pH dropped to 6.5 and was readjusted to 9.3 with 6 M sodium hydroxide. Over the course of 1.5 h, the pH was checked occasionally and, if necessary, readjusted. Thereafter, the mixture was kept at ~4 °C overnight. Finally, the sample was buffer-exchanged against 0.1 M sodium phosphate buffer, containing 5 mM EDTA (pH 8), and concentrated to a volume of 2 mL on a Centriprep-10 concentrator. Analysis of primary amino groups gave 1 NH₂/4.2 RU (TNBS assay).

*Reduction of *N,N'*-Bis(glycyl)cystamine-Modified Pn PS 19F.* *N,N'*-Bis(glycyl)cystamine-modified Pn PS 19F [13 mg in 1.75 mL of 0.1 M sodium phosphate buffer, containing 5 mM EDTA (pH 8)] was reduced by adding an 11-fold molar excess (based on NH₂ groups introduced into the PS) of DTE (8.9 mg). After incubation overnight at room temperature, the sample was buffer-exchanged over Sephadex G-25 M with 0.1 M sodium phosphate

Scheme 2. Activation of a Polysaccharide (PS) with Cyanogen Bromide, Followed by Modification with Cystamine, Reduction, and Conjugation to Bromoacetylated Tetanus Toxoid (BrAc-TTd)

buffer, containing 5 mM EDTA (pH 7, deaerated with helium), and concentrated to a volume of 3.5 mL on a Centriprep-10 concentrator. Analysis for sulfhydryl groups gave 1 SH/8.5 RU (Ellman assay).

Conjugation of *N*-(Glycyl)cysteamine-Modified Pn PS 19F and Bromoacetylated Tetanus Toxoid. The *N*-(glycyl)cysteamine-modified Pn PS 19F (11.5 mg) and BrAc-TTd (5 mg) were conjugated in a similar manner as described for cysteamine-modified Pn PS 6B and BrAc-TTd. The appropriate fractions (8 mL) from the Sephacryl S-400 HR purification were analyzed for carbohydrate (anthrone assay) and protein content, sterile-filtered over a 0.2 μm membrane, and stored at $\sim 4^\circ\text{C}$.

RESULTS AND DISCUSSION

A cystamine spacer was easily incorporated into the pneumococcal 6B, 14, and 23F PS. To this end, the PS was randomly activated with cyanogen bromide in sodium carbonate at pH 12 (35). Although the reaction pathway is more complicated (24) than depicted in Scheme 2, the major product (apart from immediate hydrolysis) is a highly reactive cyanate ester which, after lowering the pH to 9.25, was coupled with cystamine to give an isourea derivative. The reaction conditions applied allowed the incorporation of one cystamine per 1–3 repeating units (RU) as determined by measurement of the amino group content of the PS (Table 1).

After reduction of the disulfide bond of cystamine with an excess of dithioerythritol (DTE) and purification by ultrafiltration, thiol-PS (i.e. cysteamine-modified PS) was obtained. The thiol content of the PS varied from 1 SH per 7–33 RU (Table 1), which is lower compared to the amino content found in the previous step. A 5–10-fold molar excess of thiolated type 6B, 14, or 23F PS was used for conjugation to bromoacetylated tetanus toxoid (BrAc-TTd) at pH 7. Figure 1 shows a representative GP-HPLC analysis of the conjugation of the Pn PS 6B. The peak representing BrAc-TTd disappeared from the chromatogram in the course of about 4 days, whereas a protein-containing product (the carbohydrate is not detected by UV absorption at 280 nm) with a higher molecular mass was formed. This peak shift indicated

Figure 1. Gel permeation-HPLC of the conjugation of thiolated pneumococcal polysaccharide 6B (Pn PS 6B) to bromoacetylated tetanus toxoid (BrAc-TTd) at $t = 0$, 1 h, 1 day, and 4 days, monitored by UV detection at 280 nm. The bold arrow near the horizontal axis indicates where nonconjugated thiolated Pn PS 6B (as detected by refractive index in a separate run) as well as nonconjugated BrAc-TTd eluted. It should be noted that polysaccharide is not detected at 280 nm and that BrAc-TTd alone is stable for 4 days under the conditions used for the conjugation (i.e. overlapping with the conjugate mixture profile at $t = 0$).

Figure 2. Purification of the pneumococcal type 6B polysaccharide-tetanus toxoid conjugate over a Sephacryl S-400 HR column (100×1.6 cm) using phosphate-buffered saline as the eluent: (+) protein content as determined by colorimetric assay and (●) carbohydrate content as determined by phenol/sulfuric colorimetric assay. The left arrow indicates which fractions (12–16) were pooled for immunological experiments. The right arrow indicates where nonconjugated Pn PS 6B eluted from this column (i.e. fractions 16–20). The conjugate content (not shown), as determined by a specific immunochemical assay, correlated with the protein content.

complete conjugation of the protein, since BrAc-TTd, in the absence of thiol-PS, does not shift to a higher molecular mass under the reaction conditions within 4 days. After the remaining thiol and bromoacetyl groups were capped, the conjugates were purified by low-pressure gel filtration over Sephacryl S-400 HR. As shown for the Pn PS 6B-TTd conjugate (Figure 2), the elution profiles of the conjugate (as determined by the protein assay) and carbohydrate (phenol/sulfuric acid

Scheme 3. Synthesis of *N,N'*-Bis(glycyl)cystamine and Its Use for Preparing Thiol-Modified Polysaccharide, Which Is Conjugated to BrAc-TTd

assay) did not coincide, indicating the presence of uncoupled PS. Samples from the fractions were also analyzed by conjugate-specific enzyme-linked immunosorbent assays (ELISA).³ An elution profile derived from the intensity of the ELISA readings coincided with the profile based on the protein content in the fractions (data not shown). Only the conjugate-containing fractions which were (almost) devoid of free PS were pooled (in all cases, fractions 12–16, Figure 2) and used for immunization experiments.⁴ Yields and PS:TTd ratios are summarized in Table 1.

Cystamine-modified Pn PS 19F containing one cystamine per 2–5 RU was easily obtained as described above for modification of type 6B, 14, and 23F PS. However, immediately after reduction with DTE and purification, a dramatically low thiol content was measured (less than 1 SH/100 RU). On incubation of the DTE-reduced Pn PS 19F with BrAc-TTd for several days, as described above, a peak shift correlated to conjugation of the protein was not observed by GP–HPLC analysis. Possible explanations for the low thiol content of the 19F PS are (a) incomplete reduction, (b) reoxidation during purification, (c) elimination of cysteamine by intermolecular attack on the isourea bond, for instance, by the excess of DTE present during reduction, and (d) intramo-

lecular elimination of cysteamine. Repeated reduction of the modified Pn PS 19F and thorough precautions to avoid reoxidation did not improve the thiol content of the PS. To rule out the third possibility, Pn PS 19F was activated with cyanogen bromide and then incubated with diaminobutane instead of cystamine. The diaminobutane-modified Pn PS 19F proved to be stable to DTE treatment; its amino content kept almost constant (loss of <5%, data not shown). Therefore, it was concluded that the loss of cysteamine might be caused by intramolecular attack of the thiol on the isourea bond. Although this hypothesis was not investigated mechanistically, intramolecular elimination of cysteamine should proceed via a favorable five-membered ring transition state with a low activation energy. This would suggest that elimination of elongated linkers should be more difficult, for instance, if a less favorable eight-membered ring transition state would be required for elimination.

This suggestion was tested by using *N,N'*-bis(glycyl)-cystamine for modification of cyanogen bromide-activated Pn PS 19F (Scheme 3). The modified PS contained an average of 1 linker per 4.2 RU. After DTE reduction, *N*-(glycyl)cysteamine-modified Pn PS 19F containing 1 thiol per 8.5 RU was obtained. This degree of functionalization proved to be satisfactory, since conjugation to BrAc-TTd was readily achieved. Elution profiles of the conjugate on GP–HPLC and Sephacryl S-400 HR were comparable to profiles for the Pn PS 6B–TTd conjugate as shown in Figures 1 and 2, respectively.

CONCLUSIONS

Type 6B, 14, and 23F pneumococcal polysaccharides were conveniently activated with cyanogen bromide and subsequently modified by coupling of cystamine. After reduction, thiolated polysaccharides were obtained and conjugated to bromoacetylated tetanus toxoid. This procedure failed for the 19F polysaccharide, possibly due to elimination of cysteamine by an intramolecular reaction. Although it remains unclear why elimination of the linker from the 19F polysaccharide is apparently much faster than that from the 6B, 14, and 23F polysaccharides, the problem could be solved by incorporating *N,N'*-bis(glycyl)cystamine into the 19F polysaccharide. The

³ Briefly, in case of types 6B, 14, and 19F, microtiter plates were coated with polyclonal sheep anti-tetanus toxoid antibodies. Thereafter, the plates were successively incubated with the sample (containing the PS–TTd conjugate), poly (type 14) or monoclonal (types 6B and 19F) mouse anti-pneumococcal PS antibodies, peroxidase-conjugated polyclonal goat anti-mouse antibodies, a substrate (3,3',5,5'-tetramethylbenzidine), and sulfuric acid. The conversion of the substrate, as measured by the optical density at 450 nm, is related to the amount of conjugate present in the sample. For 23F, a reversed assay proved to be more convenient and sensitive. In this case, polyclonal rabbit anti-PS 23F antibodies were coated onto a microtiter plate. Thereafter, the plates were successively incubated with the sample, peroxidase-conjugated polyclonal horse anti-tetanus toxoid antibodies, the substrate, and sulfuric acid.

⁴ The results of the immunological experiments will be described elsewhere. The conjugates induce anti-PS IgG antibodies and immunological memory in mice and/or rats. The first results will appear in ref 39.

use of cystamine and *N,N'*-bis(glycyl)cystamine as linkers allows preparation of a tetravalent pneumococcal polysaccharide–tetanus toxoid conjugate vaccine.

ACKNOWLEDGMENT

We thank Mrs. Danny Schijf and Dr. Wim Jiskoot from the Laboratory of Product and Process Development of RIVM for providing purified pneumococcal polysaccharide type 19F.

Detection of Oligonucleotide Hybridization on a Single Microparticle by Time-Resolved Fluorometry: Quantitation and Optimization of a Sandwich Type Assay

Harri Hakala,* Esa Mäki, and Harri Lönnberg

Department of Chemistry, University of Turku, FIN-20014 Turku, Finland. Received October 24, 1997; Revised Manuscript Received January 22, 1998

Uniformly sized (50 μm) porous glycidyl methacrylate/ethylene dimethacrylate particles (SINTEF) were used as the solid phase in a sandwich type mixed-phase hybridization assay based on time-resolved fluorescence detection on a single particle. These particles were coated with oligodeoxyribonucleotide probes by conventional phosphoramidite chain assembly. An oligodeoxyribonucleotide bearing a photoluminescent europium(III) chelate, $\{2,2',2'',2'''-\{4'-\{4'''-[(4,6\text{-dichloro-}1,3,5\text{-triazin-}2\text{-yl)amino]phenyl}\}-2,2':6',2''\text{-terpyridine-}6,6''\text{-diyl}\}\text{bis(methylenenitrilo)}\}\text{tetrakis(acetato)}\}\text{europium(III)}$, was hybridized to a complementary sequence of the target oligonucleotide, and the resulting duplex was further hybridized to the particle-bound probes. The latter binding was quantified by time-resolved measurement of the emission signal of a single particle. Kinetics of hybridization and the effect of the concentration of the target oligomer and the fluorescently tagged probe on the efficiency of hybridization were studied. The intensity of the emission signal was linearly related to the concentration of the target oligomer over a range of 5 orders of magnitude. The length of the complementary region between the target oligomer and the particle-bound probe was varied, and the effect of point mutations and deletions on the hybridization efficiency was determined in each case. The maximal selectivity was observed with 10–16-base pair complementary sequences, the optimal length depending on the oligonucleotide loading on the particle. Discrimination between the complete matches and point mismatches was unequivocal, a single point mutation and/or deletion decreasing the efficiency of hybridization by more than 2 orders of magnitude.

INTRODUCTION

Solid supports bearing immobilized oligodeoxyribonucleotide probes are a useful tool in analyzing the base sequence of nucleic acids (1–10). This kind of mixed-phase assay combined with efficient amplification techniques, such as polymerase chain reaction (PCR; 11), has gained increasing popularity in clinical diagnostics. These assays are usually based on arrays of allele-specific oligonucleotides attached to a solid support, hybridization of fluorescently or radioactively labeled PCR-amplified sequences to the support-bound probes, and detection of the hybridized sequences by location of the label spots on the support (12–14). We have recently tried to evaluate the feasibility of an alternative approach based on the following principle (15). A mixture of microscopic particles, each of which bears a given allele-specific oligonucleotide and a reporter group defining the particle category, is used as the solid phase. After hybridization, individual particles are separately subjected to two parallel measurements: one identifies the particle category (reporter groups on the particle), and the other quantifies the fluorescently tagged oligonucleotide hybridized to the particle-bound probes. The fluorescent markers employed for labeling of oligonucleotides are photoluminescent lanthanide chelates. Such markers have advantages over organic fluorophores, since their long-lived fluorescence allows the usage of the time-

resolved mode in the measurement, and this, in turn, allows efficient elimination of the prompt background fluorescence. Furthermore, the difference between the wavelength of excitation and emission is large, and the emission bands are narrow (16, 17). Lanthanide chelates have earlier been utilized in highly sensitive immunoassays (18–20) and also in studying nucleic acid hybridization (19–24). However, none of the previous hybridization assays is based on a single-particle approach similar to that used in this work. In other words, they do not form a basis for development of a multiparametric assay.

We have previously described several methods for covalent immobilization of oligonucleotide probes to uniformly sized polymer particles (25) and shown that the same particles may also, after appropriate derivatization, be used as a solid support in automated oligonucleotide synthesis (26). In fact, the postsynthetic immobilization of purified oligonucleotide probes appears to offer no advantage over the more convenient direct chain assembly on the particles. With both types of particles, the intensity of the emission signal measured directly from the particle surface is proportional to the concentration of the fluorescently tagged oligomer in solution over a concentration range of 5 orders of magnitude. About 10^4 oligonucleotides hybridized to a single particle is sufficient for reliable quantitation. To show that the particles obtained by direct chain assembly also exhibit excellent selectivity of hybridization, although they bear a considerable amount of truncated sequences, we now report on quantitation of a sandwich type hybridization assay on these particles. The principle of the assay is described in Figure 1. The results show that

proper adjustment of the length of the complementary region between the target oligonucleotide and the particle-bound probes allows an unequivocal discrimination between a complete match and a point mismatch (mutation and/or deletion) over a wide concentration range. Under optimal conditions, a single mismatch reduces the efficiency of hybridization by more than 2 orders of magnitude.

EXPERIMENTAL PROCEDURES

Oligonucleotide-Coated Particles (1). The particles were porous uniformly sized beads ($\varnothing = 50 \mu\text{m}$) made of a copolymer of glycidyl methacrylate (40%) and ethylene dimethacrylate (60%) (37% matrix) and derivatized with bis(3-aminopropyl)amine, yielding a 1 mmol g^{-1} density of primary amino functions (SINTEF). They were derivatized for oligonucleotide synthesis as described previously (26), and the sequence 5'-d(CCTATGATGAATATAGTTT)-3' was assembled with the normal phosphoramidite strategy. According to the DMTr cation response (27), the loadings of the full-length oligonucleotide sequence on three separate batches prepared (1) were 2, 5, and $10 \mu\text{mol g}^{-1}$. After conventional ammonolysis and washings, the particles were dried under reduced pressure, removed from the column, and washed with the buffer used in the hybridization assays.

Oligonucleotides and Their Fluorescent Conjugates. The unlabeled oligodeoxyribonucleotides used as targets in the sandwich assays were synthesized with the conventional phosphoramidite strategy and purified by ion exchange and RP-HPLC and desalted. Table 1 lists the oligomers studied.

Two fluorescently tagged oligonucleotides were used in the hybridization assays: 5'-d(X₅ATATCATCTTTGGTGT)-3' (**20**) and 5'-(X₂₀ATCATCTTTGGT)-3' (**21**). Here X stands for a N⁴-(6-aminoethyl)-2'-deoxycytidine unit tethered to a photoluminescent europium(III) chelate, {2,2',2'',2'''-[[{4'-{4'''-[(4,6-dichloro-1,3,5-triazin-2-yl)-amino]phenyl}-2,2':6',2''-terpyridine-6,6''-diyl}bis(methylenenitrilo)}tetrakis(acetato)]europium(III) (**28**). These oligonucleotide conjugates were prepared as described previously (29). Probes **20** and **21** were observed to bear 5 and 17 labels per oligomer, respectively, when assayed according to the DELFIA protocol (18). In other words, the extent of labeling of the aliphatic amino functions was 1.0 with **20** and 0.85 with **21**.

Hybridization Assays. The hybridization assays were carried out in a Tris buffer (50 mmol L^{-1} at pH 7.5, 0.01% Tween 20 and 0.5 mol L^{-1} NaCl). Usually, 50 particles were incubated in $10 \mu\text{L}$ of the buffer containing a known amount of the target oligonucleotide (**2–19**) and the fluorescently labeled probe (**20** or **21**). The reaction

time was typically 24 h. However, on examination of the kinetics of hybridization, 500 particles in a total volume of 100 μL was used, from which aliquots of 10 μL were withdrawn. In these experiments, the concentration of the target oligonucleotide (**2**) was 5 nmol L^{-1} and that of the labeled oligonucleotide (**20**) 17 nmol L^{-1} . The particles were washed twice with 200 μL of glycine buffer (50 mM at pH 10), containing 20% propanol, and then transferred into a quartz capillary tube for measurement. However, in the experiments of kinetics of hybridization, particles were washed once with 300 μL . The fluorescence emission of each particle was determined separately on a time-resolved microfluorometer as described previously (30). A delay time of 296 μs was used, and the signal was collected for 300 μs , which allowed complete elimination of the prompt background fluorescence. Typically, 5–10 individual particles were measured, the standard deviation ranging from 5 to 10%.

RESULTS

Quantitation of the Sandwich Type Hybridization. Particles **1** bearing the sequence 5'-d(CCTATGATGAATATAGTTT)-3' (three batches with loadings of 2, 5, and 10 $\mu\text{mol g}^{-1}$) were used as the solid support in all hybridization studies. The target oligonucleotides (**2**–**19**) were 28–36 nucleotides long. They contained at their 5'-terminus an 8–16-nucleotide sequence complementary to the particle-bound probe (indicated by bold letters in Table 1) and at their 3'-terminus a 16- or 12-nucleotide sequence (indicated in italics in Table 1) complementary to the fluorescently tagged oligomers **20** [5'-d(X₂₀ATATCATCTTTGGTGT)-3'] or **21** [5'-d(X₂₀ATCATCTTTGGT)-3'], respectively. The labeled oligomer (**20** or **21**) was used in excess compared to the target (**2**–**19**) to ensure quantitative hybridization of the target to the labeled probe. With **20**, which has a 16-nucleotide sequence complementary to the target, no excess is really needed. The emission signal measured was independent of the concentration of **20**, as long as this concentration was at least equal to that of the target. With **21**, which has only a 12-nucleotide sequence complementary to the target, a 15-fold excess was needed to obtain a maximal emission signal. For this reason, **20** was used as the fluorescent probe in most of the measurements. Unspecific adsorption of **20** or **21** to the particles was estimated by treating the particles with the labeled probe in the absence of the target oligomer. The unspecific binding represented in all the cases less than 1% of the total amount of the labeled probe. The resulting background signal was determined at each concentration of **20** (or **21**) employed and subtracted from the signal obtained in the presence of the target. Throughout this paper, only these corrected signals referring to sequence-selective hybridization are given.

To convert the microfluorometry signals to the number of fluorescently labeled oligonucleotides hybridized to the particle, a calibration line was determined. Two sets of hybridization reactions were carried out, in which the concentrations of the target (**2**) and fluorescent probe (**20**) were varied from 0.17 to 50 nM. After incubation for 20 h, one set of particles was subjected to measurement by microfluorometry, while from the other set, europium(III) ions were released in solution and determined according to the DELFIA protocol (18). The calibration line obtained (data not shown) was essentially similar to that described previously (25, 26) for the direct hybridization of a fluorescently tagged oligonucleotide to the same particles, and it was used throughout this work

Figure 2. Kinetics of formation of a sandwich hybrid on particles **1**, having an oligonucleotide loading of 2 $\mu\text{mol g}^{-1}$. The concentration of the target oligonucleotide (**2**) was 5 nmol L^{-1} and that of the fluorescently tagged probe (**20**) 17 nmol L^{-1} . The particle density was 5 particles/ μL and the temperature 25 $^{\circ}\text{C}$.

to convert the microfluorometry signals to the number of fluorescently labeled oligonucleotide molecules.

Figure 2 shows the hybridization kinetics observed with particles **1**, having an oligonucleotide loading of 2 $\mu\text{mol g}^{-1}$. The concentration of target (**2**) was 5 nmol L^{-1} (3×10^{11} molecules in 100 μL) and that of the fluorescently tagged oligonucleotide (**20**) 17 nmol L^{-1} . The kinetics of this sandwich type hybridization are very similar to those observed previously (26) for direct hybridization of fluorescently labeled oligonucleotides to the same particles. Evidently, hybridization of **2** to **20** is, in the excess of the latter, quantitative and fast compared to the hybridization of the resulting duplex to the solid phase. The latter sandwich hybridization obeys first-order kinetics. The curve indicated in Figure 2 represents the best least-squares fit obtained on the basis of this model. The kinetics were similar also when **21** was used as the labeled probe (data not shown).

The dependence of the intensity of the emission signal on the concentration of the target oligomer was studied by keeping the concentration of the fluorescent probe (**20**) constant and varying that of the target (**2**): [**20**] = 166 pmol L^{-1} when [**2**] = 0.5–100 pmol L^{-1} , and [**20**] = 50 nmol L^{-1} when [**2**] = 0.1–166 nmol L^{-1} . The oligonucleotide loading of the particles was 10 $\mu\text{mol g}^{-1}$. This experiment mimics the real assay of amplified oligomers, because then the amount of target is unknown and a constant higher concentration of the labeled probe must be used. The results obtained are shown in Figure 3. As seen, the linear range is wide, 5 orders of magnitude. However, the entire range cannot be utilized by using a single constant probe concentration, because at the lowest target concentrations the unspecific binding of the probe becomes too high compared to the specific hybridization signal. The excess of the fluorescent probe cannot be larger than 1000-fold.

Although the intensity of the emission signal is linearly related to the concentration of the target oligomer in solution over a range of 5 orders of magnitude, the slope of this correlation line is not exactly unity but 1.05. At least apparently the efficiency of hybridization increases with the increasing concentration of the target. At the lowest concentration of **2**, the efficiency [(amount of **2** hybridized)/(total amount of **2**)] is only 16% but at the highest concentration 85%. In this respect, the sandwich hybridization seems to differ from the direct hybridization of the labeled probe to the particles. As shown previously (26), in the latter case, the hybridization efficiency remains constant over the entire concentration range of 5 orders of magnitude.

Figure 3. Intensity of the emission signal measured from a single microparticle plotted against the concentration of the target oligonucleotide (**2**). The concentration of the fluorescently tagged probe was $0.166 \text{ nmol L}^{-1}$ when $[\mathbf{2}] < 0.1 \text{ nmol L}^{-1}$ and 50 nmol L^{-1} at higher concentrations of **2**.

Effect of the Length of the Complementary Region on the Hybridization Efficiency. To determine the minimal length of the complementary sequence between the target oligonucleotide and the particle-bound probe that allows hybridization with maximal efficiency, a set of target oligomers (**2**, **6**, **9**, **12**, **15**, **18**, and **19**) having sequences of 16, 14, 13, 12, 10, 9, and 8 bases complementary to the particle-bound oligonucleotide were hybridized to **1**. Panels A and B of Figure 4 refer to oligonucleotide loadings of 10 and $2 \mu\text{mol g}^{-1}$ on the particles, respectively. With both types of particles, the intensity of the emission signal is increased linearly with the increasing concentration of target, as long as the concentration of the target oligomer remains lower than that of the labeled probe. As seen, the concentration-dependent signal levels are identical as long as the complementary region is 12 nucleotides or longer. With shorter sequences, the signal level gradually decreases. Similar results were obtained when target **2** was allowed to hybridize with particles bearing probes shorter than **1** (data not shown). Comparison of the curves in panels A and B of Figure 4 reveals that decreasing the length of the complementary sequence has a more dramatic effect on the efficiency of hybridization when the oligonucleotide loading on the particles is low. Table 2 contains the hybridization efficiencies observed at high target concentrations, i.e. at concentrations exceeding the one required to make the signal independent of the target concentration ($17\text{--}170 \text{ nmol L}^{-1}$). The data obtained with an oligonucleotide loading of $5 \mu\text{mol g}^{-1}$ are included in the same table. These results indicate that the minimum length of complementarity needed for maximal efficiency of hybridization is 10 nucleotides when the oligonucleotide loading on the particle is $5 \mu\text{mol g}^{-1}$ or higher and 12 nucleotides for particles where the oligonucleotide loading is $2 \mu\text{mol g}^{-1}$.

Selectivity of Hybridization. To determine how sensitive the efficiency of hybridization is to the presence of a single mismatch within a complementary sequence of variable length, a set of target oligonucleotides containing a single point mutation or deletion was prepared and hybridized to particles **1**. The length of the complementary region was varied from 10 to 16 nucleotides, and the mismatch was placed approximately in the center of this region to obtain a maximal discrimination between

Figure 4. Effect of the length of the complementary sequence between the target and the particle-bound probes (**1**) on the hybridization efficiency. The intensity of the emission signal measured from a single microparticle plotted against the concentration of the target (**2**, **12**, **15**, **18**, and **19**). The concentration of the fluorescently tagged probe was 17 nmol L^{-1} . Panels A and B correspond to oligonucleotide loadings of 10 and $2 \mu\text{mol g}^{-1}$, respectively.

matches and mismatches (12, 31). The concentration of these targets (**3**–**5**, **7**, **8**, **10**, **11**, **13**, **14**, **16**, and **17**) was varied from 0.17 to 170 nmol L^{-1} in the hybridization assays, and that of the fluorescent probe (**20**) was 17 nmol L^{-1} . Particles **1** with all three different oligonucleotide loadings (2 , 5 , and $10 \mu\text{mol g}^{-1}$) were used as a solid phase. Figure 5 shows an example of the results: the effect of a single point mutation (**13**) and deletion (**14**) on the concentration-dependent hybridization efficiency of a target having 12 bases complementary to the particle-bound oligomers (loading of $10 \mu\text{mol g}^{-1}$). As seen, both mismatches reduce the hybridization efficiency

Figure 5. Effect of a single point mutation or deletion on hybridization of a target oligonucleotide (**12**) having a 12-nucleotide sequence complementary to the particle-bound probes of particles **1** (loading of $10 \mu\text{mol g}^{-1}$). The concentration of the fluorescently tagged probe was 17 nmol L^{-1} .

by more than 2 orders of magnitude. Table 3 summarizes the entire data for point mutations and Table 4 for point deletions. As seen, the oligonucleotide loading on particles slightly affects the discrimination of matches and mismatches. If the loading on particles is low ($2 \mu\text{mol g}^{-1}$), a point mutation may unequivocally be distinguished from the unmutated sequence when the length of the complementary sequence falls in the range of 10–14 bases, and rather clearly even when this sequence is 16 nucleotides long. With higher oligonucleotide loadings, the complementary sequence should not be longer than 13 bases, preferably 12 bases. There are no significant differences between the effects of mutations in C•G or A•T base pairs. The effects of point deletions

on the hybridization efficiency are rather similar to those of point mutations.

DISCUSSION

A sandwich type hybridization assay may be carried out on microparticles in two different manners. Either the mutation-specific probe is immobilized to the particles, as described in Figure 1, or the fluorescently tagged oligomer is mutation-specific. Of these two approaches, the former was applied in this study, since it is more convenient to coat the particles with various mutation-specific probes than to prepare a large selection of fluorescently tagged oligonucleotides, each having a different sequence.

The results presented above clearly show that porous polymer particles bearing 3'-attached oligonucleotide probes (**1**) constitute a good solid support for sandwich hybridization assays. The dynamic range achieved with the single-particle technique described is exceptionally large; the intensity of the emission signal measured from a single particle is linearly related to the concentration of the target oligonucleotide over a concentration range of 5 orders of magnitude (Figure 3). The main reasons for the wide linear range include (i) the high capacity of porous particles, (ii) the almost negligible concentration quenching of the photoluminescent europium(III) chelate used as a fluorescent marker, and (iii) the efficient elimination of the prompt background fluorescence by the use of the time-resolved mode in the measurement.

The sensitivity of the sandwich assay described is high. On using 5 particles/ μL , the detection limit for the target oligonucleotide is less than 1.7 pmol L^{-1} . In other words, about 3×10^4 probes (0.05 amol) hybridized to a single particle becomes detected (signal $> 2 \times$ standard deviation). In terms of concentration, the detection limit may still be decreased; decreasing the number of particles per volume increases the signal measured from a single particle, but the time required to reach the equilibrium is simultaneously increased. To some extent, the sensitivity may also be increased by increasing the number of lanthanide chelates per probe (21). Even as it is, the sensitivity is excellent compared to that of other reported assay systems, including those based on radioactive detection (32).

The major shortcoming of the methodology introduced is relatively slow hybridization. Up to 20 h was needed to reach the equilibrium on using 5 particles/ μL . Our previous results (26) on direct hybridization of a fluorescently tagged oligomer on the same particles, however, suggest that the reaction time may be reduced to less than $1/10$ of the value by increasing the number of particles in a given volume of the sample. Unfortunately, this simultaneously decreases the sensitivity of detection, since the same amount of target oligonucleotides is then distributed among a larger number of particles.

The selectivity of hybridization is good. However, a prerequisite for this is a proper adjustment of the length of the complementary region between the target oligonucleotide and the particle-bound probe. The minimum length required for maximal hybridization efficiency somewhat depends on the loading of the probes on particles, ranging from 10 (loading of $10 \mu\text{mol g}^{-1}$) to 12 (loading of $2 \mu\text{mol g}^{-1}$) nucleotides. When this minimal length of complementarity is used, a single point mutation or deletion near the center of the hybridizing sequence decreases the efficiency of hybridization to less than 1% of the original value. However, even complementarity 3 to 4 nucleotides longer gives selectivity that

is almost as good (Tables 3 and 4). Accordingly, the method appears not to be too sensitive to the length of the mutation-specific probes.

ACKNOWLEDGMENT

The particles employed were a generous gift of Dr. Ruth Schmid (SINTEF). The photoluminescent marker was prepared in the Laboratory of Wallac Oy (Turku, Finland) by Dr. Veli-Matti Mikkala and Dr. Harri Takalo. We also thank Mr. Harri Salo, M.Sc., for his help in oligonucleotide synthesis. Financial support from the Academy of Finland, the Research Council for Natural Sciences and Technology, is gratefully acknowledged.

Streptavidin in Antibody Pretargeting. 2. Evaluation of Methods for Decreasing Localization of Streptavidin to Kidney while Retaining Its Tumor Binding Capacity

D. Scott Wilbur,^{*,†} Donald K. Hamlin,[†] Kent R. Buhler,[‡] Pradip M. Pathare,[†] Robert L. Vessella,[‡] Patrick S. Stayton,[§] and Richard To[§]

Departments of Radiation Oncology, Urology, and Bioengineering, University of Washington, Seattle, Washington 98195. Received October 10, 1997; Revised Manuscript Received January 28, 1998

An investigation has been conducted to determine if the kidney localization of recombinant streptavidin can be decreased to improve its characteristics in pretargeting protocols. Three different methods of accomplishing this were evaluated. The first method, blocking kidney uptake with a preadministration of recombinant streptavidin in which biotin occupied all of the binding sites, was unsuccessful. In a second method, L-lysine administration was used to block kidney localization. This method worked well, decreasing the concentration to 29% of the unmodified amount at 8 h postinjection. However, this method suffered from a requirement for constant infusion of lysine during the period of observation. A third method, use of succinylated recombinant streptavidin, was found to be the best approach. Succinylation of streptavidin was readily accomplished with very good protein recovery. With the succinylated streptavidin, the kidney concentration was only 14% of that of nonmodified streptavidin at 4 h postinjection. While these results demonstrated that the concentration of streptavidin could be decreased in the kidney, it was important to assess whether the tumor colocalization of streptavidin with biotinylated antibody was affected under those conditions. As part of our continuing investigation of pretargeting, a new water-solubilized biotinidase-stabilized biotinylation reagent was prepared. Using that reagent in a pretargeting experiment, an equivalent quantity of succinylated recombinant streptavidin as biotinylated antibody Fab' was localized in a tumor xenograft model. In that experiment, the kidney concentration was decreased to less than 10% of that obtained with unmodified recombinant streptavidin at 24 h postinjection. The results of our investigation have demonstrated that succinylation of streptavidin improves its distribution characteristics for pretargeting applications. The fact that succinylated streptavidin has no specific tissue localization should allow its use as a carrier of radioactivity in "two-step" pretargeting protocols.

INTRODUCTION

A number of research groups are investigating a monoclonal antibody (mAb)-based approach for systemic delivery of therapeutic radionuclides to cancer cells in patients termed "tumor pretargeting" (1–15). The pretargeting approach uses mAb conjugates to target cancer cells *in vivo* prior to administration of the radionuclide in a "two-step" or "three-step" protocol (16). The key to the pretargeting approach is that the molecule carrying the radionuclide bind tightly to the preadministered antibody conjugate. Our pretargeting studies have fo-

cused on a three-step approach. In that approach, three reagents are administered as sequential steps in a protocol designed to maximize the tumor radiation dose while minimizing radiation doses to bone marrow and other nontarget tissues. The reagents used in our three-step pretargeting approach include a biotinylated mAb Fab' fragment, recombinant streptavidin (r-SAv), and a radiolabeled biotin derivative. Although only one of the reagents carries the radionuclide, the distributions of all three reagents are important as each reagent binds *in vivo* with the next reagent administered. Thus, the tissue distribution observed for the administered radionuclide is a composite of the combination of distributions of the three components, and the adducts they form *in vivo*.

As part of our pretargeting studies, we have investigated the tissue localization of each of the three components used. Our reasons for conducting the studies are to gain a better understanding of the distribution of radioactivity and to determine if the reagents or conditions used might be optimized to provide more favorable radiation dosimetry for patient therapy. The results obtained from the tissue distribution of one of the components used, r-SAv, indicated that localization to kidney might be a problem in the pretargeting approach (11, 17). Biodistribution studies conducted with radioiodinated r-SAv have shown that a high concentration (25–35% ID/g) is localized in kidney within 4 h of

injection, and the concentration of radioactivity does not decrease appreciably over a 72 h period. Importantly, no other specific tissue localization appears to occur with r-SAv. Similar kidney localization has been observed for two r-SAv mutants and two commercially available SAv proteins (17). High kidney localization is a general characteristic of SAv proteins, although reported concentrations of SAv in kidney have varied greatly (7, 8, 18–21).

The importance of the concentration of SAv in pretargeting may be questioned since it is not radiolabeled in most protocols. Indeed, if SAv localized in kidney does not result in a specific binding of the radiolabeled biotin molecule in that tissue, then there is no problem. Unfortunately, our (unreported) studies of the localization of radiolabeled biotin molecules have not provided a clear answer to the question of kidney binding of radiolabeled biotin. The results obtained have been complicated by the issue of biotinidase cleavage (22–25) of the biotin derivatives used, by issues relating to endogenous biotin (26), and by the fact that renal clearance is the normal route of excretion of the radiolabeled biotin derivatives. This issue cannot be readily resolved from literature reports either, as many other investigators have not addressed it directly or have not provided data that could be used to assess the localization quantitatively. Recently, Sharkey et al. (15) reported that specific kidney localization occurred when large quantities (i.e. 100–500 μ g) of SAv were administered. Additional studies in our laboratory will be directed at kidney localization of radioiodinated biotin derivatives.

Aside from the issue of localization of radiolabeled biotin in the three-step pretargeting approach, the high kidney concentrations of SAv have kept it from being used as a carrier of radioactivity in a two-step pretargeting approach. Although there are distinct advantages for using radiolabeled biotin derivatives for many radionuclides, it may be advantageous to use a two-step approach with certain radionuclides if kidney localization can be circumvented. For example, the very fast blood clearance of small biotin derivatives results in a low percentage of the injected dose being delivered to the tumor. The longer serum half-life of a radiolabeled SAv molecule would likely result in more of the injected dose being bound at the tumor. This might be a favorable situation for very expensive radionuclides such as the α -emitting therapeutic radionuclide At-211 (27). Decay of the short path length α -emitter in blood might prove to be less toxic than if it is excreted in a high concentration through a critical organ such as liver or kidney.

Our concern regarding kidney localization of radiolabeled biotin, and the desire to use radiolabeled r-SAv as a carrier of radionuclides in pretargeting protocols, led to an investigation of methods of blocking or decreasing the kidney localization of SAv. In the investigation, three different methods were evaluated: (1) blocking with r-SAv that was saturated with biotin, (2) blocking by administering L-lysine, and (3) decreasing the pI of r-SAv through chemical modification. The latter two methods were found to be effective in decreasing kidney localization of radioiodinated r-SAv. On the basis of those results, additional biodistribution studies were conducted to evaluate the tissue distribution and localization of radiolabeled r-SAv to a human tumor xenograft model in athymic mice. The biodistribution results indicated that equivalent tumor concentrations were obtained with L-lysine treatment and through the use of succinylated r-SAv as obtained with the standard protocol. However, chemical modification (succinylation) provided the best

combination of retaining tumor localization while decreasing kidney localization. The results obtained from our investigation of methods for decreasing kidney localization of r-SAv are reported herein.

EXPERIMENTAL PROCEDURES

General. All chemicals purchased from commercial sources were analytical grade or better and were used without further purification unless noted. Chloramine-T (ChT), *d*-biotin, and phosphate-buffered saline (PBS) were obtained from Sigma (St. Louis, MO). HABA [2-(4'-hydroxyazobenzene)benzoic acid] and avidin were obtained from Pierce (Rockford, IL). (Methoxycarbonyl)-maleimide, **6**, was obtained from Fluka Chemical Corp. (Ronkonkoma, NY). Succinic anhydride, di-*tert*-butyl dicarbonate, and most other chemicals were obtained from Aldrich Chemical Co. (Milwaukee, WI). Solvents for HPLC analysis were obtained as HPLC grade and were filtered (0.2 μ m) prior to use. Biotin derivatives **1** and **2** (Scheme 1) were prepared as previously described (25). Tetrafluorophenyl trifluoroacetate (TFP-OTFA) was prepared as previously described (28). A6H Fab' was obtained as previously described (11). r-Streptavidin was obtained as previously described (29). Biotin deficient, egg white-enriched (avidin rich) mouse chow (catalog no. 5836 test diet from basal diet catalog no. 5755) was obtained from Purina Test Diets (Richmond, IN). Centricon-10 and Centricon-30 centrifugation concentrators were obtained from Amicon (Beverly, MA). NAP-10 (Sephadex G-25) size exclusion columns were obtained from Pharmacia Biotech AB (Uppsala, Sweden).

Na¹²⁵I and Na¹³¹I were purchased from NEN/Dupont (Billerica, MA) as high-concentration, high-specific activity radioiodide in 0.1 N NaOH. Measurement of ¹²⁵I and ¹³¹I was accomplished on the Capintec CRC-15R or a Capintec CRC-6A radioisotope calibrator. Tissue samples were counted in a LKB 1282 gamma counter with the following window settings: channels 35–102 (20–90 keV) and channels 165–185 (300–450 keV) when ¹²⁵I and ¹³¹I were counted together.

Spectroscopic Data. ¹H NMR spectra were obtained on Bruker AF-200 (200 MHz) instrument. The chemical shifts are expressed as parts per million using tetramethylsilane as an internal standard (δ = 0.0 ppm). IR data were obtained on a Perkin-Elmer 1420 infrared spectrophotometer. Mass spectral data were obtained on a VG 70SEQ mass spectrometer with a 11250J data system. Fast atom bombardment (FAB⁺) mass spectral data were obtained at 8 kV using a matrix of 90% thioglycerol, 9% DMSO, and 1% TFA (DMIX) or propylene glycol 600 containing thioglycolate.

Analytical Chromatography. Equipment. HPLC separations of compounds were obtained on a Hewlett-Packard quaternary 1050 gradient pumping system with a variable wavelength UV detector (254 nm) and a Vares ELSD MKIII evaporative light-scattering detector. Analyses of the HPLC data were conducted on Hewlett-Packard HPLC ChemStation software.

Biotin Compounds. All reactions for synthesizing the biotinylation reagent, **7**, were monitored by HPLC. Reversed-phase HPLC was carried out on an Alltech Altima C-18 column (5 μ m, 250 $\times$ 4.5 mm) using a gradient solvent system at a flow rate of 1 mL/min. Solvent A in the gradient was methanol. Solvent B was aqueous 1% HOAc. Starting from 40% solvent A, the initial solvent mixture was maintained for 2 min, then the gradient was increased linearly to 100% A over the next 10 min, and 100% A was maintained for 5 min.

Scheme 1. Synthesis of the Biotinidase-Stabilized, Water-Solubilized Maleimidobiotin Derivative Used for Biotinylation of A6H Fab' ^a

^a (a) Sarcosine methyl ester, DMF, Et₃N, rt, 2–3 h, 1 N NaOH/MeOH, rt, 1 h; (b) TFP-OAc, Et₃N, 20 min, not isolated; (c) 4, DMF, rt, 1.5 h; (d) TFA, rt, 30 min, saturated NaHCO₃, 0 °C, **6**, 10 min, 57%.

Retention times (*t_R*) for biotin derivatives using these conditions were as follows: **5**, *t_R* = 10.9 min; and **7**, *t_R* = 8.6 min (see Supporting Information).

Proteins. Size exclusion chromatography was performed on all A6H Fab' and r-SAv modifications. Proteins were evaluated on a TosoHaas G3000SW column (10 μm, 7.5 mm × 30 cm) run isocratically at 0.75 mL/min eluting with 50 mM sodium phosphate buffer (pH 6.8) which contained 300 mM NaCl, 1 mM EDTA, and 1 mM sodium azide. Retention times (*t_R*) for the various proteins using this system were as follows: biotinylated A6H Fab', *t_R* = 29.7 min; r-SAv, *t_R* = 28.7 min; perbiotinylated r-SAv, *t_R* = 28.7 min; and succinylated r-SAv, *t_R* = 27.8 min.

Radiolabeled Proteins. Size exclusion chromatography was also used to evaluate the radioiodinated proteins. The equipment and conditions for elution were as previously reported (11).

N-(tert-Butoxycarbonyl)-4,7,10-trioxa-1,13-tridecanediamine (4). To a solution of 4,7,10-trioxa-1,13-tridecanediamine (50.45 g, 229 mmol) in 200 mL of CH₂Cl₂ was added *tert*-butyl dicarbonate (2 g, 9.2 mmol). The reaction mixture was stirred at room temperature for 12 h, and the solvent was removed under vacuum. The residue was extracted into CHCl₃ (300 mL) and was washed with H₂O (2 × 25 mL). The CHCl₃ solution was dried over anhydrous Na₂SO₄, and the CHCl₃ was removed under vacuum to yield 2.74 g (92%) of **4** as an oil. ¹H NMR (MeOH-*d*₄): δ 4.9 (s, 1H), 3.1–3.3 (m, 13H), 2.7 (m, 3H), 2.5 (m, 2H), 1.3–1.5 (m, 4H), 1.1 (s, 9H). IR (Nujol): 3280, 2920, 2860, 1760, 1650, 1450, 1380, 940 cm⁻¹. HRMS: Calcd for C₁₅H₃₂N₂O₅ (M + H) 321.2389, found 321.2395.

13-N-(tert-Butoxycarbonyl)-4,7,10-trioxatridecanyl-1-N-methylglycine Biotinamide (5). To a solution of *N*-methylglycine biotinamide, **2** (0.5 g, 1.59 mmol), in 12 mL of DMF was added TFP-OTFA (0.5 g, 1.92 mmol) followed by Et₃N (200 μL). The reaction mixture was stirred at room temperature for 20 min (monitored by HPLC) to obtain **3**, and then **4** (0.509 g, 1.59 mmol) was added in 5 mL of DMF. The reaction mixture was stirred at room temperature for 0.5 h (monitored by HPLC), and the DMF was removed under vacuum. The residue was

extracted with CHCl₃ (300 mL) and washed with H₂O (2 × 25 mL). The CHCl₃ solution was dried over anhydrous Na₂SO₄ and then evaporated under vacuum. The isolated **5** was dried under vacuum to yield 0.8 g (82%) of an oil. ¹H NMR (MeOH-*d*₄): δ 4.5 (m, 1H), 4.3 (m, 1H), 4.0 (d, *J* = 9.4 Hz, 2H), 3.4–3.7 (m, 14H), 3.1–3.3 (m, 8H), 2.8–3.0 (m, 3H), 2.7 (d, *J* = 13 Hz, 1H), 2.2–2.4 (m, 2H), 1.4–1.8 (m, 19H). IR (Nujol): 3280, 2920, 2860, 1760, 1650, 1450, 1380, 940 cm⁻¹. HRMS: Calcd for C₂₈H₅₁N₅O₈S (M + H) 618.3537, found 618.3530.

13-N-Maleimido-4,7,10-trioxatridecanyl-1-N-methylglycine Biotinamide (7). A 400 mg (0.774 mmol) quantity of biotinamide **5** was dissolved in 2 mL of TFA and the mixture stirred at room temperature for 0.5 h. The TFA was removed under vacuum. The residue was dissolved in 5 mL of saturated aqueous NaHCO₃ and cooled with ice–H₂O. *N*-(Methoxycarbonyl)maleimide, **6** (0.239 g, 1.55 mmol), was added, and the reaction mixture was stirred at 0 °C for 10 min. A 25 mL aliquot of H₂O was added to the reaction mixture, and stirring was continued at room temperature for an additional 15 min. The mixture was extracted with CHCl₃ (4 × 100 mL). The combined CHCl₃ extracts were washed with H₂O (2 × 50 mL) and dried over anhydrous Na₂SO₄, and the CHCl₃ was removed under vacuum. The isolated product was dried under vacuum to yield 220 mg (57%) of **7** as an oil. ¹H NMR (MeOH-*d*₄): δ 6.7 (s, 2H), 4.4 (m, 1H), 4.2 (m, 1H), 3.9 (d, *J* = 10.6 Hz, 2H), 2.9–3.5 (m, 23H), 2.6 (d, *J* = 12.8 Hz, 1H), 2.2–2.4 (m, 2H), 1.3–1.7 (m, 11H). IR (KBr): 3280, 2920, 2860, 1760, 1650, 1450, 1380, 940 cm⁻¹. HRMS: Calcd for C₂₇H₄₄N₅O₈S (M + H) 598.2899, found 598.2910.

Biotinylation of A6H Fab'. To 120 μL of a 17 mg/mL solution of A6H F(ab')₂ (2 mg, 4 × 10⁻⁵ mmol) was added 5 μL of 100 mM DTT in H₂O. After 1 h at room temperature, the entire solution was added to a NAP-10 column that had been equilibrated in 20 mM sodium phosphate buffer (pH 6.5) containing 1 mM EDTA and was eluted with the same buffer. The protein-containing fractions were pooled (monitored by UV). The combined fractions sat at room temperature for 1 h prior to adding 0.24 mg (4 × 10⁻⁴ mmol) of **7** in 100 μL of H₂O. After 30 min at room temperature, the entire mixture was placed

in a Centricon-30 apparatus and concentrated to 200 μ L. That solution was then eluted on a NAP-10 column that had been equilibrated in 100 mM PBS. The protein-containing fractions were pooled and concentrated with a Centricon-30 concentrator. The final concentration was determined by UV (A_{280} ; 1 mg/mL = 1.1). Protein recovery yields for the A6H Fab' biotinylations with **7** have ranged from 71 to 89%. Immunoreactivities of the biotinylated Fab' were assessed as described previously (11) and were found to be equivalent to the those of nonbiotinylated A6H Fab'.

Quantitation of Biotins on A6H Fab'. The number of biotin molecules per protein was determined by measuring the decrease in absorbance at 500 nm for a solution containing avidin and HABA after the biotinylated protein was added. The HABA method used was adapted from a Pierce biotinylation kit (catalog no. 21430). Briefly, to a 1 mL aliquot of 1 mg/mL avidin in PBS was added 0.94 mL of PBS, followed by 60 μ L of 10 mM HABA in 10 mM NaOH for preparing the avidin/HABA solution. The UV absorbance at 500 nm was measured for 900 μ L of the avidin/HABA solution. Then 100 μ L of a diluted biotinylated protein was added. After 1 min, the absorbance was again measured. The number of biotin molecules was determined from the difference in absorbance measured by the following equation (simplified from the Pierce equation). The number of biotins per antibody is $(A/3400)/B$, where $A = [0.9(A_{500} \text{ of the HABA/avidin solution}) - (A_{500} \text{ of the HABA/avidin solution plus the sample})]$ and $B = \text{the sample molar concentration}$. Using this method of assay, the number of biotins per Fab' obtained with **7** ranged from 1.2 to 3.8.

Perbiotinylation of Streptavidin. To 67 μ L of a 15 mg/mL solution of r-SAv (1 mg, 1.9×10^{-5} mmol) was added 200 μ L of a 2.5 mg/mL biotin solution (0.5 mg, 2×10^{-3} mmol) in 20 mM sodium phosphate (pH 6.8). The biotin binding was allowed to proceed at room temperature for 30 min, and then the reaction mixture was added to a Centricon-10 filtration unit and concentrated to 50 μ L. PBS (500 μ L) was added, and the solution was again concentrated to 50 μ L. This wash step was repeated five times to remove excess biotin. The final concentration of perbiotinylated r-SAv was 1.3 mg/mL (A_{280} ; 1 mg/mL = 2.56) with a protein recovery of 59%.

Succinylation of Streptavidin. A 185 μ L aliquot of a 5.4 mg/mL solution of r-SAv (1 mg, 1.9×10^{-5} mmol) was added to 370 μ L of 50 mM NaHCO₃ buffer (pH 8.5). To this solution was added 95 μ g (1×10^{-3} mmol) of succinic anhydride in 20 μ L of DMSO. After 30 min at room temperature, the contents were transferred to a Centricon-10 apparatus and concentrated to 50 μ L. PBS (500 μ L) was added, and the solution was again concentrated to 50 μ L. This wash step was repeated five times. The final concentration was determined to be 3.5 mg/mL with a protein recovery of 88%.

Radioiodination of Proteins. In a typical radioiodination, 2 μ L of Na¹²⁵I or Na¹³¹I in 0.1 N NaOH was added to 25 μ L of sodium phosphate (0.5 M, pH 7.4). To this solution was added 1.0 mg of r-SAv in 185 μ L of PBS, followed by the addition of 20 μ L of a 1 mg/mL ChT solution in H₂O. After 1 min at room temperature, the reaction was quenched by the addition of 2 μ L of a 10 mg/mL aqueous sodium metabisulfite solution. The entire reaction solution was then placed on a NAP-10 column that was equilibrated in 0.9% saline and eluted with 0.9% saline. The protein fractions were combined and the concentrations and specific activities determined using UV₂₈₀ and a dose calibrator.

Labeling Yields. The radiochemical yields for five r-SAv radioiodinations ranged from 73 to 95%, and the specific activity ranged from 0.82 to 1.76 mCi/mg. Succinylated r-SAv was radioiodinated in the same manner with yields of 76–78% (specific activity of 0.47–1.1 mCi/mg). Perbiotinylated r-SAv was radioiodinated with a yield of 80% (specific activity of 1.6 mCi/mg). Radioiodinations of the biotinylated A6H Fab' were also conducted in the same manner, with radiochemical yields ranging from 82 to 87% (specific activities of 0.84–1.3 mCi/mg).

Biodistribution Studies. General. Animal use and procedures were approved by the University of Washington's Animal Care Committee. Animal care and use was conducted in accordance with the NIH guidelines.² Male athymic mice (BALB/c nu/nu), 4–5 weeks of age, were obtained from Simonsen Laboratories (Gilroy, CA). Mice were housed for 1 week in the animal facility prior to beginning the study. All injections of reagents were administered to mice in a total volume of approximately 100 μ L (injectate weighed) via the lateral tail vein. Injections and sacrifice of the animals were done at predetermined times. The tissues excised are shown in the tables, and the average animal weight in a biodistribution and average tumor weights for groups involving mice bearing tumor xenografts are provided in the table footnotes. Blood samples were obtained by cardiac puncture immediately before sacrifice. Urine samples were obtained with a syringe bladder tap at the time the tissues were excised. Excised tissues were blotted free of blood, weighed, and counted. In those studies employing human tumor xenografts, small tumor pieces (5–10 mg) of TK-82 renal cell carcinoma (RCC) (30) were implanted sc over the right shoulder of the mice. The implants were allowed to grow for 3–4 weeks or until the average size was approximately 100 mg. In the studies involving localization of r-SAv to tumors, the mice were placed on a biotin deficient diet 5 days prior to initiation. Calculation of the percent injected dose (%ID) and percent injected dose per gram (%ID/g) in the tissues was based on internal standards containing 1 μ L of the injected dose. The counts obtained were compensated for decay, and where dual radionuclide counting was required, the ¹²⁵I counts were compensated (13.5%) for spillover counts from the ¹³¹I. The total blood volume was estimated to be 8% of body weight for the calculations (31). Statistical analysis of the data was conducted using the paired Student's *t* test. Differences were considered statistically significant when the *p* value was less than 0.04.

r-SAv Blocking Study. In this study, variations of blocking were evaluated in three groups of athymic mice. In group 1, five mice were injected with 15 μ g of r-[¹²⁵I]-SAv, and then at 4 h *pi*, 15 μ g of r-[¹³¹I]-SAv was injected. In group 2, five mice were injected with 15 μ g of perbiotinylated r-[¹²⁵I]-SAv, and then at 4 h *pi*, 15 μ g of r-[¹³¹I]-SAv was injected. In group 3, five mice were co-injected with 15 μ g of perbiotinylated r-[¹²⁵I]-SAv and 15 μ g of r-[¹³¹I]-SAv was injected. Mice were sacrificed at 28 h *pi* for groups 1 and 2 and 24 h *pi* for group 3. Biodistribution results from this study are provided in Table 1.

L-Lysine Blocking Studies. In the initial study, L-lysine blocking was evaluated in two groups of five athymic mice. All mice were injected with 30 μ g of r-[¹³¹I]-SAv and sacrificed 5 h *pi*. The blocking group was treated with

² NIH guidelines are described in NIH Publication 86-23 (Guide for the Care and Use of Laboratory Animals).

Table 1. Distribution of Radioactivity in Athymic Mice after Administration of r-[¹²⁵I]SAv or Perbiotinylated r-[¹²⁵I]SAv Followed by Administration of r-[¹³¹I]SAv^a

^a Values shown are the percentage of the injected dose per gram ± standard deviation. Mice were on a biotin deficient diet for 4 days prior to the study. Data were obtained for five mice per group; the average animal weight was 27.69 ± 1.65 g. Injections were made in the lateral tail vein; all animals received a total of 30 μg of r-SAv in approximately 100 μL of 0.9% sterile saline. ^b Each animal received 15 μg of [¹²⁵I]SAv with a specific activity of 1.76 μCi/μg and after 4 h 15 μg of [¹³¹I]SAv with a specific activity of 1.15 μCi/μg. Animals were sacrificed 24 h after the second injection. ^c Each animal received 15 μg of perbiotinylated [¹²⁵I]SAv with a specific activity of 1.6 μCi/μg and after 4 h 15 μg of [¹³¹I]SAv with a specific activity of 1.15 μCi/μg. Animals were sacrificed 24 h after the second injection. ^d Each animal received a co-injection of 15 μg of perbiotinylated [¹²⁵I]SAv and 15 μg of [¹³¹I]SAv. Animals were sacrificed at 24 h postinjection. ^e Urine was collected with a syringe bladder tap after sacrifice. Statistical analysis of the controls r-[¹³¹I]SAv (groups 1 and 2), the pretreatment reagents, r-[¹²⁵I]SAv (group 1) and r-[¹²⁵I]SAv and biotin (group 2), and the co-injected reagents, r-[¹²⁵I]SAv and biotin and r-[¹³¹I]SAv (group 3), produced no significant differences in the data when $p < 0.04$.

Table 2. Comparison of the Biodistribution of r-[¹³¹I]SAv (Study 1) with r-[¹³¹I]SAv after L-Lysine Treatment and (Study 2) with Succinylated r-[¹²⁵I]SAv in Athymic Mice^a

^a Values shown are the percentage of the injected dose per gram ± standard deviation; Injections were made in the lateral tail vein. ^b Two groups of animals (five in each group) were used; the average animal weight was 29.99 ± 2.38 g. A 30 μg quantity of r-SAv was injected into each mouse. One group (control) had no L-lysine administered, and the second group was injected intravenously with 30 mg of L-lysine at $t = 0, 1, 2$, and 3 h. All animals were sacrificed 5 h after the initial injection. ^c Data were obtained for five mice 4 h after co-injection of 15 μg of r-[¹³¹I]SAv and 15 μg of succinylated r-[¹²⁵I]SAv in a 100 μL volume; the average animal weight was 23.34 ± 1.59 g. ^d Urine was collected with a syringe bladder tap after sacrifice. Statistical analysis was not conducted on these data due to the differences in the study parameters.

30 mg of L-lysine by *ip* injection³ at 10 min prior to administration of r-[¹³¹I]SAv and at 1, 2, and 3 h *pi*. The results from this study are provided in Table 2 (study 1). A second study involved athymic mice bearing the TK-82 human RCC xenografts. Two groups of five mice were used (with and without the L-lysine treatment). All mice were administered 30 μg of biotinylated A6H [¹²⁵I]-Fab', and after 24 h, 30 μg of r-[¹³¹I]SAv was administered. Half of the mice (group 2) were treated with four injections of 30 mg of L-lysine each (in 100 μL of saline) at 10 min prior to and 1, 2, and 3 h after injection of r-[¹³¹I]SAv. All animals were sacrificed at 48 h *pi* of the

^a Values shown are the percentage of the injected dose per gram ± standard deviation. Injections were made in the lateral tail vein. Mice were on a biotin deficient diet for 5 days prior to the study. Data were obtained for five mice per group. The average animal weight was 28.72 ± 2.04 g; the average tumor weight was 0.210 ± 0.033 g. Animals received 30 μg of biotinylated [¹²⁵I]Fab' in approximately 100 μL of 0.9% sterile saline and 24 h later 30 μg of r-[¹³¹I]SAv in 100 μL of 0.9% sterile saline. Animals in group 2 received intravenous injections of 30 mg of L-lysine in 200 μL of saline at -0.1, 1, 2, and 3 h after the injection of r-[¹³¹I]SAv. All animals were sacrificed 48 h after the Fab' injection. ^b Tumor xenografts were TK-82 renal cell carcinoma. ^c Urine was collected with a syringe bladder tap after sacrifice. ^d Statistical analysis comparing the two [¹²⁵I]Fab' data sets and comparing the r-[¹³¹I]SAv with and without L-lysine data sets indicated that there were no significant differences (where $p < 0.04$) except for the following: * $p = 0.0004$, ⁺ $p = 0.01$, [#] $p = 0.02$, ^{*} $p = 0.01$, and [@] $p = 0.0007$.

Fab' (24 h *pi* of r-SAv). The results from this study are provided in Table 3.

Succinylated r-SAv Studies. In the initial study, one group of five mice were co-injected with succinylated r-[¹²⁵I]SAv and r-[¹³¹I]SAv and then sacrificed 4 h *pi*. The biodistribution data are shown in Table 2 (study 2). A second study involved athymic mice bearing TK-82 human RCC xenografts. Two groups of five mice were used (comparing succinylated r-SAv with r-SAv). All mice were administered 30 μg of biotinylated A6H [¹²⁵I]-Fab', and after 24 h, 30 μg of r-[¹³¹I]SAv or succinylated r-[¹³¹I]SAv was administered. All animals were sacrificed at 48 h *pi* of the Fab'.

³ No difference was noted in kidney localization of r-SAv whether the L-lysine was administered by intraperitoneal or by intravenous injection (unreported results).

RESULTS

Preparation of Reagents. *Biotinylation of r-SAv.* Saturation of the biotin binding sites of r-SAv was accomplished by addition of 100 molar equiv of biotin and incubating at room temperature for 30 min. The excess biotin was removed by exchanging the solvent (PBS) five times in size exclusion ultrafiltration concentrators.

Synthesis of Biotinylation Reagent (7). We have previously described the synthesis and application of a water-solubilized, sulfhydryl-reactive biotinylation reagent (11). However, that reagent is not stabilized toward cleavage by the enzyme biotinidase (25). Due to the concern for biotinidase cleavage of our biotinylation reagent, and other commercially available reagents, we designed and synthesized another water-solubilized, sulfhydryl-reactive biotinylation reagent that also contains a *N*-methyl moiety for blocking biotinidase. The synthesis of the new biotinylation reagent is shown in Scheme 1. Synthesis of biotin derivatives 1–3 has been previously reported (25). Reaction of the tetrafluorophenyl (TFP) ester of *N*-methylglycine adduct 3 (formed in situ) with mono-*t*Boc protected 4,7,10-trioxa-1,13-tridecanediamine, 4, yielded biotin derivative 5 in high yield. Reaction of 5 with trifluoroacetic acid provided the deprotected biotin derivative with a free terminal amine, and reaction of that compound with (methoxycarbonyl)maleimide, 6, gave the desired maleimidobiotin derivative, 7, in good yield.

Biotinylation of A6H Fab'. This procedure was conducted as previously described for the non-biotinidase-stabilized biotinylation reagent (11). A6H Fab' was prepared by reductive cleavage of A6H F(ab')₂ with DTT over a 1 h period. After the excess DTT was removed and a period of 1 h passed, 10 molar equiv of the biotinylation reagent, 7, was added. Recovery of biotinylated Fab' was high. All characterizations (HPLC, SDS–PAGE, IEF, and immunoreactivity assay) of the biotinylated Fab' indicated that biotinylation had a minimal effect on it.

Succinylation of r-SAv. Succinylation of r-SAv was accomplished by reacting 50 molar equiv of succinic anhydride in aqueous solution at a pH of 8.5 or 9.5 for 30 min at room temperature. The succinylation decreased the *pI* of r-SAv from 7–7.3 (17) to 4.0–4.3 as shown in the scanned IEF gel provided as Figure 1. As no difference in *pI* or protein heterogeneity was noted between the succinylations at the two pH values, the pH of choice for running the reaction is 8.5. Good recovery of succinylated r-SAv was obtained after removing the excess succinic anhydride/succinic acid. Assessment of the biotin binding capacity of the succinylated r-SAv indicated that it had not changed from the nonmodified r-SAv (data not shown).

Kidney Blocking with r-SAv and Perbiotinylated r-SAv. Blocking of kidney localization of r-SAv was evaluated in athymic mice. Three different combinations of reagents and conditions were evaluated for decreasing kidney concentrations of r-SAv by preinjected r-SAv. These combinations included (1) pre-injection of an equal amount (i.e. 15 μ g) of r-SAv 4 h prior to a second injection, (2) pre-injection of an equal amount of r-SAv that had been saturated with biotin (perbiotinylated) 4 h prior to the second injection, and (3) co-injection of equal quantities of r-SAv and perbiotinylated r-SAv. Dual isotope labeling allowed us to distinguish the two r-SAv proteins in vivo. The distribution of radioactivity was evaluated 24 h after the first injection. The results are shown in Table 1 as group 1–3, respectively. The results in group

Figure 1. Digitized image of an IEF gel showing succinylated and nonsuccinylated r-SAv. The gel (PhastGel IEF 3–9) was run on a PhastSystem electrophoresis apparatus (Pharmacia LKB, Uppsala, Sweden) using the optimized method for IEF described in Separation Technique File #100. Protein staining was accomplished by the silver stain method described in Development Technique File #210: lane 1, IEF standards (Isoelectric Calibration Kit, broad *pI* of 3–10) run in the opposite direction of application of the sample (e.g. top to bottom); lane 2, r-SAv succinylated at pH 8.5; lane 3, r-SAv succinylated at pH 9.5; lane 4, r-SAv that has not been modified; and lane 5, IEF standards run in the direction of application (bottom to top).

1 show that pre-injection of r-SAv does not affect the distribution of a second injection of r-SAv 4 h later. Similarly, results from group 2 indicate that pre-injection of r-SAv which has been saturated with biotin does not affect the distribution of a second injection of r-SAv 4 h later. Co-injection of perbiotinylated r-SAv with r-SAv demonstrated that they have essentially identical distributions.

L-Lysine Blocking of Kidney Localization. Two experiments were conducted to assess blocking of kidney localization of r-SAv with the use of L-lysine administration. The first experiment was conducted to determine if four hourly injections (at *t* = –10 min and 1, 2, and 3 h) of 30 mg of L-lysine hydrochloride would decrease the kidney concentration of r-[¹³¹I]SAv in athymic mice at 5 h *pi*. A dramatic drop in kidney concentrations was obtained (16–4.7% ID/g) without affecting the distribution in other tissues (Table 2, study 1). Because of the encouraging results obtained, a second study was conducted to determine if the lysine treatment affected the tumor localization properties of r-SAv in a pretargeting protocol. In the study, two groups of athymic mice bearing RCC tumor xenografts were pretargeted with biotinylated A6H [¹²⁵I]Fab' over a 24 h period, and then both groups were administered r-[¹³¹I]SAv. In one group, L-lysine was administered just prior to the administration of r-[¹³¹I]SAv and administered again 1, 2, and 3 h later. The results of that study (Table 3) clearly demonstrated that tumor localization of r-[¹³¹I]SAv was equivalent to the tumor localization of biotinylated [¹²⁵I]Fab' with or without lysine treatment. The localization of r-[¹³¹I]SAv was also equivalent between the groups of mice in most

Table 4. Distribution of Radioactivity for A6H [¹²⁵I]Fab' and r-[¹³¹I]SAv or Succinylated r-[¹³¹I]SAv in Athymic Mice Bearing Human Tumor Xenografts^a

^a Values shown are the percentage of the injected dose per gram ± standard deviation. Injections were made in the lateral tail vein. Mice were on a biotin deficient diet for 5 days prior to the study. Data were obtained for five mice in each group. The average animal weight was 26.34 ± 2.12 g; the average tumor weight for group 1 was 0.210 ± 0.167 g, and the average tumor weight for group 2 was 0.110 ± 0.033 g. Both groups of animals received 30 μg of biotinylated [¹²⁵I]Fab' in approximately 100 μL of 0.9% sterile saline and 24 h later 30 μg of r-[¹³¹I]SAv or succinylated r-[¹³¹I]SAv in 100 μL of 0.9% sterile saline. All animals were sacrificed 48 h after the Fab' injection. ^b Tumor xenografts were TK-82 renal cell carcinoma. ^c Urine was collected with a syringe bladder tap after sacrifice. ^d Statistical analysis comparing the two [¹²⁵I]Fab' data sets and comparing the r-[¹³¹I]SAv/r-[¹³¹I]SAv-succ data sets indicated that there were no significant differences (where $p < 0.04$) except for the following: * $p = 0.03$, ⁺ $p = 0.005$, [#] $p = 0.0001$, and [&] $p = 0.02$.

other tissues. The relevant exception was the kidney, which was decreased from 28 to 11% ID/g.

Decreasing Kidney Concentration with Succinylated r-SA_v. Succinylated r-SA_v was evaluated as a reagent for decreasing kidney localization in two animal distribution studies. The initial study compared the tissue distribution of dual isotope-labeled, co-injected succinylated r-[¹²⁵I]SAv with that of unmodified r-[¹³¹I]SAv. The results of that study are shown in Table 2 (study 2). A dramatic decrease in the kidney concentration of the succinylated r-SA_v was noted in comparison with that of the unmodified r-SA_v (i.e. 16% ID/g decreased to 2% ID/g). The decreased kidney localization was accompanied by an increase in the blood concentration of the succinylated r-SA_v. In a second study, the application of succinylated r-SA_v in tumor pretargeting was compared with application of unmodified r-SA_v. The results of that study are shown in Table 4. In both study groups, the tumor localization of r-SA_v was equivalent to that of the A6H Fab'. Most importantly, the succinylated r-SA_v retained equivalent tumor localization while decreasing the kidney localization from 29% ID/g to 2% ID/g.

DISCUSSION

Streptavidin is an important component in many of the "tumor pretargeting" studies being conducted throughout the world (3, 5–13, 15). Although we use recombinant SA_v in our studies, all of the truncated or "core" SA_v proteins evaluated in our laboratory appear to have similar distributions (17). The prominent feature in the SA_v distribution is its propensity to localize in kidney. This kidney localization of SA_v is of concern when it is used in pretargeting, as it may cause an increased localization of radiolabeled biotin in that tissue. Further, the high kidney localization of SA_v has precluded its use as the carrier of radionuclides. This is unfortunate as

there may be advantages to using radiolabeled SA_v rather than a radiolabeled biotin derivative. These factors led to our investigating methods of reducing the propensity for SA_v to localize in kidney.

Renal accumulation of SA_v most likely proceeds in the same manner as that of other small proteins, i.e. glomerular filtration followed by uptake in proximal tubular cells (32). Although the tubular uptake of small proteins is considered a high-capacity process, some proteins may interact with receptors on the peritubular side. Depending on the rate of endocytosis of a receptor-bound SA_v molecule, it could be available for binding with the administered radiolabeled biotin molecule. We were particularly concerned about a slow endocytosis process as we had noted in previous biodistributions of SA_v proteins that the concentration of r-[¹³¹I]SA_v did not change appreciably from the 4 h to the 24 or 48 h time points (11, 17). While this could be due to a slow catabolism in the lysosomes of tubular cells, there could also be a receptor-mediated process for internalizing SA_v. Further, if SA_v proved to be saturable, administration of SA_v that had all the biotin binding sites occupied (perbiotinylated) would preclude binding of radiolabeled biotin molecules. Wilchek et al. (33, 34) have postulated that renal accumulation of SA_v is related to the "universal recognition sequence" (RGD) which is present in fibronectin and other adhesion proteins that bind with cell surface integrins. Their hypothesis is that the RYD sequence found in SA_v mimics the RGD receptor domain of fibronectin and could cause receptor binding with tubular cells (33). However, they also recognized that the kidney accumulation could simply be due to a slow degradation of the proteolytically stable SA_v in lysosomes (34). The results of the studies reported herein appear to indicate that the long retention time of radioiodinated SA_v in kidney is due to its resistance to degradation. The kidney blocking studies using preadministered r-SA_v clearly show that, if it is a receptor-mediated process, it is not saturable at the quantities investigated. The total amount accumulated in the kidney appears to be dependent on the initial blood concentration.

Another hypothesis for renal tubular reabsorption of proteins was presented by Mogensen and Solling (35). They believed that the "initial event in the normal tubular protein reabsorption is binding between a free positive amino- or guanidino-group in the protein molecule and a negative site on the tubular cell surface". This hypothesis led to the discovery that lysine and other positively charged substances could block tubular absorption of proteins. The fact that this methodology for blocking tubular absorption could be applied to humans without undue toxicity (36–40) provided an impetus for evaluating its use in decreasing kidney accumulation of antibody Fab (41–44) and Fv (45) fragments. Our studies demonstrated that L-lysine also blocks the absorption of SA_v. Although administration of L-lysine did not affect the tumor localization of r-SA_v, it has a major shortcoming in that a constant infusion of a high concentration is necessary to keep the kidney localization low.

Constant infusion of L-lysine was not desired, so we continued to investigate alternative methods for decreasing kidney accumulation of SA_v. We had noted in an earlier investigation of r-SA_v distribution in mice that radioiodination with *N*-hydroxysuccinimidyl *p*-[¹²⁵I]iodobenzoate ([¹²⁵I]PIB) that there was a significant decrease (i.e. by 25%) in the kidney accumulation compared to that of the same protein labeled by the chloramine-T method (17). It appeared that the only difference in these two

proteins was that one was modified by adding an iodine atom to tyrosine (ChT-labeled) and the other was modified by conjugation on a lysine amine (PIB-labeled). This led us to hypothesize that chemical modification of the surface lysine amines had resulted in decreased kidney localization. It was known that glomerular permeability of macromolecules is a function of their overall charge. Positively charged macromolecules cross the glomerular wall more readily than neutral macromolecules, and negatively charged macromolecules are restricted from crossing (46, 47). On the basis of this, we thought that chemical modification of r-SAv that makes it more anionic (i.e. lower *pI*) might block its accumulation in kidney.

Rosebrough and Hartley previously described (48) chemical modification of SAv and avidin to evaluate the effect on their *in vivo* properties. Galactosylation of amino groups on SAv was shown to decrease its *pI* to less than 5.1. They noted that galactosylated SAv had increased hepatic uptake (as expected) and retained its biotin binding capacity when less than 50 equiv of the galactosylation reagent was used, but they did not indicate how this affected kidney localization. Because of the highly positive nature of avidin [e.g. *pI* = 10 (49)], they modified the amino groups with the *N*-hydroxysuccinimide ester of acetic acid (NHS-Ac). Modification with 50–75 equiv of NHS-Ac resulted in decreasing the *pI* to below 4.7. They also evaluated the distribution of avidin that had been deglycosylated. The combination of deglycosylation and treatment of NHS-Ac resulted in low levels of avidin accumulating in liver and kidney. Further evidence that modification of the lysine amines might result in decreased kidney accumulation of SAv was obtained from studies of avidin that was modified by succinic anhydride reported by Jeong et al. (50). They demonstrated that conjugation of succinic acid moieties with lysine amines decreased the *pI* of avidin to 4.0–4.8 and decreased the kidney concentrations from 19 to 1.7% ID/g. Prior to those studies, succinylation of avidin had been shown to reduce its binding with membranes without significantly altering its biotin binding properties (51). Our studies with succinylated r-SAv demonstrated a dramatic decrease in kidney localization. Most importantly, no difference was noted in binding with biotinylated Fab' localized in a tumor xenograft model between succinylated and unmodified r-SAv.

Summary. Three methods of decreasing kidney localization of r-SAv were examined in this investigation. The first method investigated, pre-injection of a dose of r-SAv that was saturated with biotin, did not alter the kidney uptake. The second method investigated, use of four hourly injections of L-lysine, was successful in reducing kidney localization. However, when the lysine dosing was discontinued, the kidney concentrations of r-SAv rose. The third method investigated, chemical modification of r-SAv through succinylation of lysine amines, demonstrated a dramatic and prolonged decrease in kidney concentrations of r-SAv. Both lysine treatment and succinylation of r-SAv had no effect on its binding with biotinylated Fab' in the tumor. On the basis of the results of this study, succinylated r-SAv will be used in our pretargeting protocols. The decrease in kidney accumulation will alleviate the concerns about binding of radiolabeled biotin derivatives and will permit its use as a carrier of radioactivity when that is desired.

Solution Structure of a DNA Complex with the Fluorescent Bis-Intercalator TOTO Modified on the Benzothiazole Ring

Michael Petersen and Jens Peter Jacobsen*

Department of Chemistry, Odense University, Odense M, DK-5230 Denmark. Received July 21, 1997;
Revised Manuscript Received December 3, 1997

We have used two-dimensional ^1H NMR spectroscopy to determine the solution structure of the DNA oligonucleotide $d(5'\text{-CGCTAGCG-3}')_2$ complexed with the bis-intercalating dye 1,1'-(4,4,8,8-tetramethyl-4,8-diazaundecamethylene)bis-4-[3-ethyl-2,3-dihydro(benzo-1,3-thiazolyl)-2-methylidene]quinolinium tetraiodide (TOTOEt). The determination of the structure was based on a total relaxation matrix analysis of the NOESY cross-peak intensities. DQF-COSY spectra were used to obtain coupling constants for the deoxyribose ring protons. The coupling constants were transformed into angle estimates. The NOE-derived distance and dihedral restraints were applied in restrained molecular dynamics calculations. Twenty final structures each were generated for the TOTOEt complex from both A-form and B-form double-stranded (ds) DNA starting structures, giving a total of 40 final structures. Since many NOE contacts were observed between TOTOEt and dsDNA, the resulting structure has a fairly high resolution and allows determination of local features in the dsDNA structure after TOTOEt binding. The root-mean-square (rms) deviation of the coordinates for the 40 structures of the complex was 0.52 Å. The local DNA structure is distorted in the complex. The helix is unwound by 80° and has an overall helical repeat of 12 base pairs, caused by bis-intercalation of TOTOEt. The benzothiazole ring system is twisted relative to the quinoline in the uncomplexed TOTOEt molecule. The site selectivity of TOTOEt for the CTAG-CTAG site is explained by its ability to adapt to the base pair propeller twist of dsDNA to optimize stacking and the hydrophobic interaction between the thymidine methyl group and the benzothiazole ring. The polypropylene amine linker chain is located in the minor groove of dsDNA. The *N*-ethyl group on the benzothiazole of TOTOEt is placed in the major groove pointing toward the center of the oligonucleotide and the dyad symmetry axis of the complex. This orientation seems to make it feasible to create a TOTO analogue with a linker connecting the two chromophores in the major groove. The design of such an analogue and a macrocyclic analogue with a linker in both the major groove and the minor groove seems to be straightforward.

INTRODUCTION

Progress in cancer research indicates that neoplasia is a malady of genes (Bishop, 1987). Although several potent antitumor drugs do not interact with nucleic acids, there is accumulating evidence that suggests that the malignant transformation of cells is due to alterations of particular genes. Thus, the development and investigation of DNA-interacting substances is called for. A prominent class of DNA-targeting drugs are intercalators and bis-intercalators (e.g. amsacrine, daunomycin, and

Scheme 1. TOTO and TOTOEt Numbering Scheme

adriamycin). To gain knowledge of the often subtle features that govern drug–DNA recognition, the need for high-resolution structures of drug–DNA complexes is imperative.

Recent research in our laboratory has focused on the bis-intercalating drug TOTO¹ (Scheme 1). We have examined both the sequence specificity and the kinetics

of association and dissociation for dsDNA complexes with both TOTO and a number of TOTO analogues (Faridi et al., 1997; Hansen et al., 1996; Jacobsen et al., 1995; Spielmann et al., 1995b; Stærk et al., 1997). TOTO bis-intercalates into dsDNA by nearest neighbor intercalation and shows sequence selectivity toward the (5'-CTAG-3')₂ site (Hansen et al., 1996; Jacobsen et al., 1995). The structure of the complex implies that modifications on the benzothiazole nitrogen would be expected to be positioned in the major groove on complex formation with dsDNA (Spielmann et al., 1995b). However, the binding of TOTO has been shown to be very sensitive to even small modifications on the oligonucleotide (Hansen et al., 1996). Consequently, there is a risk that slight changes of the chromophore of TOTO would destroy the binding affinity and selectivity of the molecule.

Our long-term objective is to design a TOTO analogue with a linker connecting the two chromophores in the major groove, subsequently with a linker in both the major groove and the minor groove. As a primary modification, the *N*-methyl group of TOTO was substituted with a *N*-ethyl group to give the compound 1,1'-(4,4,8,8-tetramethyl-4,8-diazaundecamethylene)bis-4-[3-ethyl-2,3-dihydro(benzo-1,3-thiazolyl)-2-methylidene]-quinolinium tetraiodide (TOTOEt, Scheme 1). We have used ¹H NMR spectroscopy to determine the solution structure of the DNA oligonucleotide d(5'-CGCTAGCG-3')₂ complexed with the bis-intercalating TOTOEt. The determination of the structure was based on the protocol described by James and co-workers (Schmitz and James, 1995) combined with inclusion of dihedral angle estimates obtained from coupling constants in the deoxyribose ring protons. This study was carried out to investigate whether this modification implied a dramatic change of the binding and selectivity of the molecule. Furthermore, this structural study was aimed at determining the position of the *N*-ethyl group in a dsDNA complex and the feasibility of substituting larger groups than ethyl, eventually a linker, at the benzothiazole nitrogen while still maintaining proper affinity and selectivity with respect to dsDNA.

EXPERIMENTAL PROCEDURES

Sample Preparation. TOTOEt was a gift from E. B. Pedersen (Department of Chemistry, Odense University, Denmark). The purified oligonucleotide d(CGC-TAGCG)₂ was purchased from DNA technology (Århus, Denmark) and used without further purification. The numbering scheme for the double-stranded oligonucleotide is

TOTOEt is almost insoluble in water, and the complexes with dsDNA were therefore made with the procedure described earlier (Jacobsen et al., 1995). The NMR samples were prepared by dissolving the complexes in 0.5 mL of 10 mM sodium phosphate buffer (pH 7.0), 0.05 mM Na EDTA, 0.01 mM NaN₃, and 0.1 mM DSS. For experiments carried out in D₂O, the solid complex, lyophilized three times from D₂O, was redissolved in 99.96% D₂O (Cambridge Isotope Laboratories). A mixture of 90% H₂O and 10% D₂O (0.5 mL) was used for experiments examining exchangeable protons. The sample was kept in a NMR tube under nitrogen. The final concentration of the complex was 2 mM.

NMR Experiments. NMR experiments were performed on a Varian Unity 500 spectrometer at 27 °C

unless otherwise stated. NOESY spectra of the complex were acquired in D₂O using 1024 complex points in *t*₂ and a spectral width of 5000 Hz. A total of 512 *t*₁ experiments were recorded using the States phase cycling scheme. The residual signal from HOD was removed by presaturation. NOE buildups were obtained by recording NOESY spectra with mixing times of 50, 100, 150, and 200 ms with 64 scans acquired for each *t*₁ value and a repetition delay of 2.8 s between each scan. The NOESY spectra were obtained sequentially without removing the sample from the magnet. TOCSY spectra of the complex with mixing times of 30 and 90 ms were obtained in the TPPI mode using 1024 complex points in *t*₂ and 512 *t*₁ experiments with 64 scans each. DQF-COSY spectra were recorded using the States phase cycling scheme with 1024 complex points in *t*₂ and 1024 *t*₁ experiments with 64 scans each. Removal of the residual HOD signal was in either case carried out with presaturation. A NOESY spectrum of the complex in H₂O with a mixing time of 160 ms was obtained by using a NOESY pulse sequence where the last 90° pulse is replaced by a 1-1 jump-return pulse to suppress the solvent signal (Guéron and Plateau, 1982). A Watergate NOESY spectrum in H₂O with a mixing time of 50 ms was recorded on a Varian Unity+ 500 spectrometer. Both NOESY spectra in H₂O were acquired with a spectral width of 10 000 Hz in 2048 complex points using 512 *t*₁ experiments with 64 scans acquired in each *t*₁ experiment. A ¹H, ¹³C HSQC spectrum in D₂O was recorded on a Varian Unity+ 500 spectrometer. A NOESY spectrum with mixing time of 500 ms was recorded of the free TOTOEt in DMSO-*d*₆.

The acquired data were processed using FELIX (version 2.35, Biosym/MSI, San Diego, CA). All spectra were apodized by a skewed sine bell squared function in both dimensions. The four spectra used in the buildup study were zero-filled to 2K points to enhance digital resolution and baseline corrected by first-order standard polynomial fits in both dimensions. The NOESY spectrum recorded in H₂O was baseline corrected by a third-order standard polynomial in *F*₂ and seventh-order one in *F*₁. The DQF-COSY spectrum was zero-filled to 4K points. The spectra were assigned by conventional methods (Wüthrich, 1986; Feigon et al., 1983; Hare et al., 1983; Scheek et al., 1983, 1984; Boelens et al., 1985).

Distance and Angle Restraints. The structure determination was performed using the protocol described by James and co-workers (Schmitz and James, 1995) combined with inclusion of dihedral angle estimates obtained from coupling constants in the deoxyribose ring protons in the following way. The upper and lower diagonal parts of each of the four NOESY buildup spectra were integrated separately with FELIX, yielding a total of eight peak intensity sets. The RANDMARDI procedure (Liu et al., 1995) of the complete relaxation matrix analysis method MARDIGRAS (Borgias et al., 1990; Borgias and James, 1990) was used to calculate interproton distance RMD bounds from the resulting integrated peak intensities. In the calculations, a noise level of 5 times the integrated intensity of the smallest cross-peak was used as the "noise" range. The dynamic range of observed cross-peak intensities was 2000. In the RANDMARDI procedure, 30 different intensity sets from each experimental data set were generated, and MARDIGRAS calculations were performed on all of them. Resulting distances were then averaged together to form one bounds file for each of the eight data sets. The bounds files from all of the mixing times were then combined into a single bounds file from which the RMD restraint file was generated. Upper and lower bounds

were average interproton distances $\pm$ one standard deviation calculated from all of the MARDIGRAS runs.

An additional 22 distance restraints were included to mimic Watson–Crick hydrogen bonding throughout the calculations. Three hydrogen bonds were included for each of the six G•C base pairs and two hydrogen bonds for each of the A•T base pairs with lower and upper bounds of 1.7 and 2.1 Å, respectively.

The H1' to H2' and H2'' region of the DQF-COSY spectrum was used as input to CHEOPS to obtain *J* coupling information for the H1', H2', H2'', and H3' deoxyribose ring protons (Gochin et al., 1990; Macaya et al., 1992). The ring conformations were analyzed using the PSEUROT procedure (de Leeuw and Altona, 1983).

Restrained Molecular Dynamics. TOTOEt was manually docked into the model of either A-form or B-form DNA in INSIGHTII (version 95.0, Biosym/MSI) to obtain the starting models for the structure refinements. The TOTOEt molecule was built using INSIGHTII. The potentials for both DNA and TOTOEt were assigned by the AMBER force field, modified to accommodate the benzothiazole sulfur atom of TOTOEt. Partial charges for TOTOEt were calculated using ab initio GAUSSIAN94 calculations.

The distance restraints obtained from RANDMARDI and dihedral angle restraints from PSEUROT were incorporated into energy minimization and an RMD procedure using DISCOVER (version 95.0, Biosym/MSI). An initial energy minimization was followed by 28 ps of restrained molecular dynamics, at 600 K for 4 ps, followed by cooling to 200 K in 50 K steps of 3 ps each. The final structure was then energy minimized to a maximum derivative of 0.01 Å.

The pseudo-energy terms used to enforce the restraints were

$$E_{\text{NOE}} = \begin{cases} k_1(r - r_1)^2 & \text{when } r_1 > r \\ 0 & \text{when } r_2 \geq r \geq r_1 \\ k_1(r - r_2)^2 & \text{when } r > r_2 \end{cases}$$

$$E_{\text{dihedral}} = \begin{cases} k_2(\theta - \theta_1)^2 & \text{when } \theta_1 > \theta \\ 0 & \text{when } \theta_2 \geq \theta \geq \theta_1 \\ k_2(\theta - \theta_2)^2 & \text{when } \theta > \theta_2 \end{cases}$$

where r_1 and r_2 are the lower and upper distance bounds determined from the cross-peak volumes, respectively, k_1 and k_2 are the force constants, and θ_1 and θ_2 are the lower and upper dihedral angle bounds determined from the DQF-COSY spectral simulations, respectively. For NOE-derived distance restraints a force constant k_1 of 50 kcal/(mol Å²) was employed and for dihedral angle restraints a force constant k_2 of 25 kcal/(mol Å²). The width of the flat region of the potential well reflects the accuracy of a given constraint. A distance-dependent dielectric ($\epsilon = r$) was employed to account for solvent effects. Helix parameters were calculated with the program CURVES 5.1 (Lavery and Sklenar, 1988, 1989).

RESULTS

Spectral Analysis. The 1D spectrum of the dsDNA–TOTOEt complex exhibits sharp lines, with line widths as small as those observed for the dsDNA–TOTO complex. There is no sign whatsoever of any minor forms. We therefore conclude that TOTOEt has a strong preference for the (5'-CTAG-3')₂ site. Observation of lines for just one dsDNA strand and one thiazole orange chromophore shows that the dyad symmetry of the d(CGC-

Figure 1. (a) H1'–aromatic part of the 150 ms NOESY spectrum of the TOTOEt complex. The sequential H1'–H6/H8–H1' connectivity pathway is indicated by a solid line. The interrupted connectivities at the 5'-C3pT4-3' and 5'-A5pG6-3' base pair steps due to intercalation sites are indicated by dotted lines. It is also possible to follow the H3'–H6/H8–H3' connectivity pathway with similar interrupted connectivities. A few of the observed cross-peaks between TOTOEt and the oligonucleotide are also marked. It is noteworthy that the cross-peak between TOTOEt H15 and A5 H1' has a measured volume which is approximately 100 times smaller than the observed cross-peak between TOTOEt H8 and H16. This demonstrates the large dynamic range and precision of the measured volumes that can be obtained from the spectra. (b) Methyl–aromatic part of the 160 ms NOESY spectrum recorded in H₂O. The assignments of the C3 and A5 amino protons, the thymidine methyl protons, and some of the TOTOEt protons are indicated. Cross-peaks between TOTOEt CH₃(6) and the amino protons of C3 and A5 unambiguously place the benzothiazole *N*-ethyl group in the major groove of the dsDNA.

TAGCG)₂ oligonucleotide is retained on complex formation with TOTOEt.

The NOESY spectrum of this complex exhibits the characteristic features of dsDNA sequential connectivities. However, the sequential pathways are interrupted at the 5'-C3pT4-3' and 5'-A5pG6-3' base pair steps. This is clear evidence of bis-intercalation (Hansen et al., 1996; Jacobsen et al., 1995; Spielmann et al., 1995b). Parts of the NOESY spectra are shown in Figure 1. The NOESY spectra of the complex also contain a multitude of intermolecular cross-peaks between dsDNA and TOTOEt as well as intramolecular TOTOEt cross-peaks. These were assigned in a similar way as previously

published (Jacobsen et al., 1995; Spielmann et al., 1995b). The DQF-COSY spectrum was used for the assignment of proton resonances in the linker of TOTOEt. The combined use of DQF-COSY spectra and NOESY spectra with short mixing times allows unambiguous assignments of the H2' and H2'' resonances. The HSQC spectrum was used to completely establish the assignments of the H3' and H4' protons. The chemical shift values of the protons in the complex are given in Table 1.

The NOESY spectra of the complex recorded in H₂O contain the normal Watson–Crick NOE connectivity pattern justifying the inclusion of 22 hydrogen bond distance restraints. Chemical shift values of labile protons are included in Table 1. Furthermore, the spectra in H₂O contain distinct cross-peaks between the thymidine imino proton (T4–H3) and the amino protons of the base-paired adenosine (A13–H6). These peaks are absent in normal dsDNA at room temperature due to exchange. The lowering of the exchange rates of the adenosine amino protons on complex formation is a consequence of the bis-intercalation. Similarly, exchange cross-peaks between water and the thymidine imino protons are absent at room temperature, and only very small ones are observed for the G6 and G14 imino protons. The G2 and G10 imino protons yield an exchange cross-peak to water of normal intensity.

Studies of the conformation of the free TOTOEt in DMSO-*d*₆ using NOESY and DQF-COSY spectra reveal that the relative conformation of the two ring systems in each chromophore is close to that indicated in Scheme 1. This is a consequence of a prominent NOESY cross-peak between H8 and H16. We have found an identical conformation of the aromatic ring systems in the dsDNA–TOTOEt complex. The relative conformation of the aromatic ring systems about the cyanine methine bonds in the chromophores is therefore not affected by intercalation into dsDNA.

Cross-peaks in the NOESY spectra unambiguously show that the poly(propylene amine) linker is positioned in the minor groove. This is demonstrated by a large number of cross-peaks. The H2 of the adenines gives cross-peaks to the linker protons H21, H22, and H23 and the H1' proton of G6 to the linker H19, H21, and H22 protons, and the H4' of the adenines and the guanines

The puckering amplitude was kept constant at 36°. ^f G2 and G6's sugar pucker could not be analyzed due to spectral overlap in the DQF-COSY spectrum. ^g No minimum could be found for the sugar pucker parameters for this nucleotide; see the following discussion.

in the binding site also shows cross-peaks to linker protons.

Cross-peaks between TOTOEt CH₃(6) and CH₂(6) and the amino protons of C3 and A5 unambiguously place the benzothiazole *N*-ethyl group in the major groove of the dsDNA. The relative intensities of these cross-peaks in the NOESY spectrum recorded in H₂O with a short mixing time (50 ms) established that the *N*-ethyl group is pointing toward the center of the oligonucleotide.

Deoxyribose Ring Conformations. Due to the dyad symmetry of the TOTOEt–d(CGCTAGCG)₂ complex, only eight spectroscopically distinct deoxyribose residues are observed in the DQF-COSY spectrum. Two of these, G2 and G6, are hampered by severe overlap of the H2' and H2'' resonances, making use of cross-peaks from these residues impossible. For the remaining six residues, CHEOPS simulations of the DQF-COSY spectrum returned values that correlated well (>0.93) with the experimental spectrum (Macaya et al., 1992). The *J* coupling constants returned by CHEOPS were used as input for PSEUROT. The PSEUROT minimization converged for five of the six residues analyzed by CHEOPS, producing the values given in Table 2.

Structure Calculations. More than 450 NOE cross-peaks were observed in the NOESY spectrum with a

^a The restraints were derived from MARDIGRAS calculations unless otherwise stated. Restraints derived from the NOESY spectrum recorded in H₂O are tabulated in parentheses. The 193 NOE connectivities gave a total of 386 symmetry-related distance restraints; 22 distance restraints ensuring Watson-Crick base pairing were also included in the RMD calculations. ^b One of the restraints was derived directly from inspection of the spectra and used with loose bounds.

mixing time of 200 ms. Some of these resulted predominantly from spin diffusion and were consequently not observed in NOESY spectra with shorter mixing times. The accuracy of the integration of some cross-peaks was hampered by spectral overlap. These cross-peaks were therefore not included in the MARDIGRAS calculations. The integrated intensities from a total number of 3056 in eight sets of 382 NOESY cross-peak intensities were used in the total relaxation matrix analysis. Of these, 2880 cross-peak intensities (360 per set) corresponded to interproton distances that are not covalently fixed in either the dye or the dsDNA in the complex. Cross-peak integrals that corresponded to fixed distances in the dsDNA were not converted into distance restraints for use in the RMD simulations. The RANDMARDI calculations returned 362 interproton distances based on the eight sets of 382 NOE cross-peak intensities. These were distributed as given in Table 4.

MARDIGRAS uses internal calibration when it iteratively fits the data to a model of the molecule. In particular, fixed distances were used to normalize the other distances. These fixed distances include the H5-H6 distance in cytosine, the 5-methyl-H6 distance in thymidine, and the H2'-H2'' distance in deoxyribose. NOE intensities for these known distances are used to normalize the NOE intensities in the model. The program does not reset covalently determined proton-proton distances within TOTOEt because these distances intentionally were left out of the reference file. The magnetization transfer for these protons is calculated and

provides a check of how well the RANDMARDI procedure is working. Good agreement between the actual distances of the fixed bonds and the experimentally determined distances indicates that the RANDMARDI procedure yields accurate interproton distances (Table 3).

The MARDIGRAS calculations were performed with various values of the correlation time for the complex in the range of 2–5 ns. The results were fairly insensitive to the actual value, and a correlation time of 3.75 ns was chosen for the final calculation. No symmetry was enforced during the RANDMARDI procedure. The bounds for symmetry-related restraints were calculated by averaging the symmetry-related upper and lower bounds. An additional 0.2 Å was added to all upper bounds of the distance restraints returned by RANDMARDI for use in the RMD calculations to circumvent any problem that may occur due to an incomplete description of the relaxation matrix (cf. Table 3). No additional symmetry was enforced during the RMD calculations.

The range of differences between the upper and lower bounds for the 362 NOE-derived distance restraints used was between 0.27 and 3.13 Å with an average flat well potential width of 1.19 Å. This range between the upper and lower bounds represents the accuracy of the restraints calculated from the NOESY data. Weak NOESY cross-peaks that arose primarily from spin diffusion had the greatest difference between their upper and lower bounds.

Interproton distances involving exchangeable DNA amino and imino protons were derived from the NOESY spectrum of the complex recorded in H₂O with a mixing time of 160 ms. The "jump-and-return" delay was chosen to give optimal excitation of the amino protons. The volume integral for each cross-peak was integrated and normalized for the sinusoidal excitation profile of the jump-and-return pulse sequence. The normalized volume for the cross-peak between C7H5 and C7H6 was used as a reference (2.45 Å) for calculating the interproton distances involving exchangeable protons using the isolated spin pair approach. Due to the inherent error in this approach, upper and lower bounds of ± 1 Å were assigned to all distance restraints. An additional 0.8 Å was added to the upper bounds for restraints involving methylene protons, and 1.0 Å was added to upper bounds for methyl protons. A total of 28 distance restraints derived from the NOESY spectrum recorded in H₂O were included in the RMD simulation. In addition, a few restraints with loose bounds were derived by inspection of the spectra in D₂O to give a grand total of 408 distance restraints incorporated into the RMD simulations (Table 4).

Dihedral angle restraints for the H1'-C1'-C2'-H2', H1'-C1'-C2'-H2'', H2'-C2'-C3'-H3', and H2''-C2'-C3'-H3' deoxyribose angles were obtained by the angles returned for the most populated conformation by PSEUROT. Upper and lower bounds of $\pm 3^\circ$ were assigned giving a flat well potential width of 6° . A total of 20 dihedral angle restraints were included in the RMD simulations.

Twenty final structures each were generated for the TOTOEt complex starting from either an A-form or B-form DNA. All the structures converged to one family of conformations. The root-mean-square (rms) deviation of the coordinates of the 40 structures was 0.52 Å. The sum of violations was 11.4 Å for the A-form starting structure and 10.9 Å for the B-form starting structure. We observed three violations of >0.3 Å with none being >0.6 Å. These violations involved backbone H5' and H5'' protons of A5, perhaps an indication of unresolved

Figure 2. Stick plot of one of the calculated TOTOEt-DNA structures showing the helix axis. (a) View from the side of the helix. (b) View perpendicular to the view in panel a. Deoxyribose protons have been omitted for clarity.

dynamics of the phosphate backbone of the central part of the oligonucleotide. Different views of the structure are presented in Figures 2–4.

The reliability of the structure calculations was carefully evaluated. RMD calculations in which the force constants of the distance restraints, k_1 , were lowered to 25 kcal/Å² generated structures that converged to exactly the same family of structure as with the higher force constants, although the rmsd was slightly higher. The structure obtained is not strongly dependent on the exclusion of any of the restraints. In particular, calculations performed without including the Watson-Crick restraints yielded exactly the same structure, although the rmsd value was slightly higher.

Helix Parameters. Helical parameters for the 40 final structures were thoroughly analyzed with the program CURVES 5.1 (Lavery and Sklenar, 1988, 1989). The CURVES algorithm allows the determination of local structural parameters and the overall helical axis for irregular nucleic acid structures. Plots of some of the global helical parameters for the TOTOEt complex are shown in Figure 5. The structural parameters for canonical A-DNA and B-DNA are included in Figure 5 for comparison.

DISCUSSION

Binding Mode and Selectivity of TOTOEt. The 1D ¹H NMR spectrum of TOTOEt bound to d(CGCTAGCG)₂ exhibits sharp lines (line widths ≈ 7 Hz) indicating that there is no chemical exchange between different binding sites. TOTOEt binds to the (5'-CTAG-3')₂ site by bis-intercalating in the CT and AG base steps with an affinity more than 100 times higher than that to any other possible site in the oligomer. There seems to be some evidence that the binding of TOTOEt to dsDNA is even more selective and tighter than that to TOTO.

The chemical shift values of the dsDNA protons at the binding site in the TOTOEt complex reflect intercalation of the aromatic chromophores. Compared to the free dsDNA, the T4 CH₃(6) protons are shifted 0.8 ppm upfield. This is in agreement with the structure of the complex that shows that this methyl group is positioned exactly above the benzothiazole ring and thus exposed to a large ring current effect. Similar strong shifts are observed for A5 H1', A5 H2'', C3 H6, and T4 H6, consistent with the positions of these protons either above

or below a ring system of the intercalating chromophore or near the intercalation site.

Description of the Structure. The structure of the TOTOEt-dsDNA shows that TOTOEt bis-intercalates in the (5'-CTAG-3')₂ site with the benzothiazole ring system sandwiched between the pyrimidines and the quolinium ring system between the purines. The *N*-ethyl group on the benzothiazole is placed in the major groove pointing toward the center of the oligonucleotide and the dyad symmetry axis of the complex to avoid a steric clash with the thymidine methyl group. The linker between the two chromophores is positioned in the minor groove, crossing from one side of the groove to the other. This is similar to what has been observed in other TOTO analogues (Spielmann et al., 1995b; Stærk et al., 1997).

In the complex, the TOTOEt chromophores extend across the dsDNA helix. T4 and T12 unstack from A5 and A13 and move into the major groove to maximize van der Waals contacts with the benzothiazole ring of TOTOEt. The thymidine methyl groups are positioned right on top of the benzothiazole ring of TOTOEt. The observed imino proton cross-peaks, including the cross-peaks to the adenine amino protons and interstrand cross-peaks between adenine H2 and thymidine H1', prove the existence of normal Watson-Crick base pairing in the intercalation site. So even though the thymidines are unstacked from the neighboring adenines, the base pairings of the thymidines with the complementary adenines do not appear to be appreciably disturbed. This is similar to what was observed in the TOTO complex (Spielmann et al., 1995b).

Sugar Conformations. In B-form DNA, the deoxyribose ring adopts an *S*-type conformation described by a pseudorotation angle P of $180 \pm 90^\circ$, while the deoxyribose residues of A-form DNA adopt an *N*-type conformation described by a pseudorotation angle P of $0 \pm 90^\circ$. The results from the PSEUROT calculations resulted in *S*-type sugar conformations for all residues analyzed except for C3 in a purity above ~80% with the pseudorotation angle P_s between 120 and 175° corresponding to C1'-exo and C2'-endo conformations, respectively. For the C3 sugar part, no minimum could be found by the PSEUROT procedure, indicating that the dynamical processes governing the C3 sugar conformation are complex and cannot be described by the two-state model applied by PSEUROT. The C3 nucleotide is flanking one of the intercalated TOTOEt chromophores on the 5' side. Similar complex dynamics were found for the nucleotides flanking the intercalation side of psoralen monoadducted and cross-linked to a DNA oligomer (Emsley et al., 1993). It should be noted, though, that the sugars of the two nucleotides trapped between the TOTOEt chromophores are found to be in relatively pure *S*-type conformations (Table 2).

Helix Parameters. There are three major categories of helical parameters: axis-base pair, intra-base pair, and inter-base pair parameters (Dickerson et al., 1989). These parameters are discussed for the TOTOEt complex with respect to the calculated global helix axis below. However, the parameters reported for the terminal base pairs of the complex are not reliable because of dynamic processes and are included only for completeness. Spectroscopically, the complex was found to possess *C2* symmetry. The small deviation of the structure and the calculated helical parameters from this symmetry reflects the level of uncertainty in the data.

Global Helix Axis. The global helix axis in the dsDNA-TOTOEt complex is not straight but exhibits a pronounced kink at the intercalation site (Figure 2). The

Figure 3. Stereoview of a superposition of 10 randomly chosen structures of the 40 structures obtained by RMD calculations for the TOTOEt-DNA complex. Deoxyribose protons have been omitted for clarity.

Figure 4. Stacking of the TOTOEt chromophore in the CpT-GpA binding site viewed from the side. Only nucleobases and the TOTOEt chromophores are shown. It is evident that the benzothiazole *N*-ethyl group protrudes into the major groove. The following coloring scheme is used: TOTOEt chromophore, red; benzothiazole *N*-ethyl, yellow; adenine base, green; and thymine base, blue.

helix axis can be divided into different parts. The T4-A5 segment is almost parallel to the terminal parts at both the 5' and 3' ends of the helix, while the intermediate parts, G2-T4 and A5-C7, describe a slip dislocation of these segments caused by the bis-intercalated TOTOEt. The effects of the slip dislocations of the helix axis are demonstrated by the helical parameters. Besides the pronounced kink, the helix axis of the TOTOEt complex shows a small bend ($\sim 5^\circ$) into the minor groove.

We believe that the kink of the global helix axis in the dsDNA-TOTOEt complex is not a mere artifact of the

structure determination. We support this conclusion with the fact that the artifact of distance restraints that are too short applied in the RMD protocol normally produces bends into the major groove due to the larger density of restraints in the major groove of dsDNA (Spielmann et al., 1995a). Furthermore, the distribution of restraints applied in the structure determination of the TOTOEt complex is fairly isotropic around the intercalation site, diminishing the effects of foul distance restraints.

The kink of the helix axis occurs around the TOTOEt intercalation site, and we believe the benzothiazole *N*-ethyl group is responsible for this as the dsDNA-TOTO complex shows no kinks or bends of the helix axis. It has recently been demonstrated that the placement of bulky groups in the minor groove of dsDNA can induce pronounced bending into the major groove (Chen et al., 1996). The benzothiazole ring system does not stack exactly coplanar with T4 but is twisted slightly relative to the nucleobase and thus inducing the kink in the helix axis.

Axis-Base Pair Parameters. *X*-axis displacement, *Y*-axis displacement, inclination, and tip are the parameters minimized to obtain the global helix axis (Lavery and Sklenar, 1988). These parameters thus describe how the base pairs are positioned in the helix relative to the global helix axis.

The *X*-axis displacement and *Y*-axis displacement are both close to the values for B-DNA, while inclination shows significant deviations with an evident C2 symmetry. The value for tip shows large and correlated changes from the B-DNA values, changing from negative to positive going from C3 to G6; this is a direct consequence of the geometry of the kinking helix axis.

Intra-Base Pair Parameters. The values obtained for shear, stretch, stagger, and opening are partly determined by the constraints introduced to mimic Watson-Crick base pairing. However, in the central part of the oligonucleotide, the numerous dsDNA-TOTOEt NOEs

Figure 5. Helical parameters for the TOTOEt complex calculated using CURVES and compared with those of canonical A-DNA (•••) and B-DNA (---).

lock the conformation of the structure. The TOTOEt ligand extends across the duplex and hence makes NOE contacts to both strands. This contributes significantly to the determination of the above parameters.

The shear changes from negative to positive across the intercalation site, compensating for the intercalation of the TOTOEt chromophores. The shear introduced possibly stems from the A5 maximizing the overlap with one

ring of the quinolinium ring system and the T4 moving into the major groove to maximize van der Waals forces with the benzothiazole ring system. There is only a slight net shear introduced in the helix. This was also observed for the dsDNA-TOTO structure (Spielmann et al., 1995b). The stretch is essentially that of B-DNA.

Base opening is almost symmetrically disposed around the T4-A5 base step. An opening angle larger than that of standard DNA narrows the minor groove. It is seen that the T4 moves into the major groove and the minor groove subsequently narrows, probably also due to van der Waals interactions between the linker *N*-methyl groups and electrostatic attractions between the anionic DNA phosphates and the linker nitrogens. The opening observed for the central base pairs is not as large as that found in the dsDNA-TOTO complex. This is a consequence of the near coplanarity of the two ring systems of the TOTOEt chromophores. For the TOTO complex, it was found that the chromophores were twisted about the quinoline-C8-thiazole bond by an angle of 22°. In the dsDNA-TOTOEt complex, this angle is 6°. A GAUSSIAN94 calculation performed on the free TOTOEt shows an angle of 22° between the two planes of the chromophores. The decrease of this angle from the free TOTOEt to the bound is due to clamping of TOTOEt by the nucleobases in the complex.

The slight twisting of the TOTOEt chromophores is mirrored in the parameters for buckle and propeller twist. It is reported that intercalation can induce buckling in dsDNA as the base pairs adjacent to the intercalation site buckle to maximize van der Waals contacts with the chromophore(s) of the intercalating agent (Williams and Gao, 1992). TOTOEt introduces almost no buckle in the dsDNA, indicating that the nucleobases of the complex can maximize van der Waals contacts and stacking with the TOTOEt chromophores without the propensity to introduce buckling.

The propeller twists of the two central base pairs are essentially that of B-DNA. A large propeller twist is introduced into the C3-G14 and G6-C11 base pairs. This is because the G6-G14 remains coplanar with the quinolinium ring system, while C3-C11 stacks with G2-G10.

Inter-Base Pair Parameters. The roll, slide, and shift in regular A-DNA and B-DNA conformations are essentially zero. These parameters show large and correlated changes from the equilibrium values in the TOTOEt complex. There are shifts for the two intercalation sites with opposite signs that cancel each other in terms of the overall helix. The slide exhibits correlated and compensatory changes for the C3-T4 and T4-A5 base pair steps to accommodate the dye intercalation. The shift and slide values are exact mirrors of the lateral displacements of the global helix axis.

The central base pair step T4-A5 has a positive roll. Positive roll opens the angle between base pairs toward the minor groove, resulting in a bend into the major groove. A negative roll results in a bend into the minor groove. The central base pair T4-A5 is clamped between the two thiazole orange chromophores to maximize van der Waals contacts. The bases roll to open the minor groove. The base pair steps flanking the intercalation sites show almost zero rolls, while the G2-C3 and G6-C7 base pair steps one step away from the intercalation site exhibit significant negative roll. This is to compensate for the kinking of the helix axis at the C3-T4 and A5-G6 base pair steps.

The helix is unwound by 80° and has an overall helical repeat of 12 base pairs in the complex, consistent with the bis-intercalation of TOTOEt. It is noteworthy that

the unwinding is largely confined to the two base pair steps defining the intercalation site.

CONCLUSION

The results obtained in this work show that TOTOEt binds selectively to dsDNA with (5'-CTAG-3')₂ as the preferred binding site. Compared to TOTO, this implies that modification of this drug on the benzothiazole N atom system is possible while still maintaining or even enhancing the selectivity and binding affinity. Our study showed that an extremely well defined complex between TOTOEt and (5'-CGCTAGCG-3')₂ was obtained. The complex seems to be even more well defined than that in the case of TOTO, indicating that TOTOEt has a higher affinity and selectivity toward dsDNA. This is possibly caused by the benzothiazole *N*-ethyl group clamping the drug to the dsDNA.

The *N*-ethyl group on the benzothiazole of TOTOEt is placed in the major groove pointing toward the center of the oligonucleotide and the dyad symmetry axis of the complex. This is exactly the orientation that is required for a TOTO analogue with a linker connecting the two chromophores in the major groove. Consequently, it seems rather straightforward to design such an analogue, the only remaining problem being the length of the linker. Direct measurement of the structure indicates the linker in the major groove should be slightly shorter than the linker in the minor groove. After the proper linker in the major groove has been found, it seems obvious from the structure that the subsequent design of a TOTO analogue with a linker in both the major groove and the minor groove is straightforward. This would probably yield a selective dsDNA binding drug with an extremely high binding affinity and vanishing kinetic abilities.

ACKNOWLEDGMENT

We are grateful to Dr. E. B. Pedersen (Department of Chemistry, Odense University, Denmark) for providing TOTOEt. Professor H. Peter Spielmann is acknowledged for supporting this work with spectrometer time on a Varian Unity+ 500 NMR spectrometer and many helpful discussions.

The high expression level of receptors for low-density lipoprotein (LDL) on tumor cells makes LDL an attractive carrier for selective delivery of drugs to these cells. The aim of this study is to allow incorporation of oncogene-directed antisense oligodeoxynucleotides (ODNs) into the lipid moiety of LDL. Therefore, ODNs were conjugated with oleic acid, cholesterol, and several other steroid lipids. These latter steroid lipids were synthesized starting from bile acids and were varied in lipophilicity by attaching oleic acid ester structures. The lipid structures, activated as pentafluorophenyl esters, were conjugated in solution phase to 3'-amino-tailed ODNs. The ODNs conjugated with lithocholic acid, oleic acid, and cholesterol could easily be purified by reversed phase (RP)-HPLC. However, the ODNs conjugated with the oleoyl steroid ester structures irreversibly bound to the column material. These highly lipidic ODNs were separated from the nonconjugated ODN by electrophoresis in a 1% low-melting agarose gel containing 0.1% Tween 20. This method was found to be very effective in isolating the ODNs conjugated to the oleoyl steroid ester structures. The ODNs conjugated with cholesterol and the oleoyl esters of lithocholic and cholenic acid associated readily and nearly completely with LDL. However, the less lipidic ODNs and the ODN conjugated with the dioleoyl ester of chenodeoxycholic acid did not and did incompletely associate, respectively. Lithocholic acid and oleic acid are probably not sufficiently lipophilic to induce association with LDL, whereas the dioleoyl ester structure is probably too bulky and extended to allow partitioning into the lipid moiety of LDL. We conclude that several of the lipid-ODNs can associate readily with LDL, enabling delivery of oncogene-directed antisense ODNs via the LDL receptor pathway.

INTRODUCTION

The so-called first-generation antisense ODNs,¹ mostly phosphorothiate ODNs, were primarily designed to stabilize the nuclease-sensitive phosphodiester backbone of unmodified ODNs. Numerous reports have shown their effectiveness both in vitro and in vivo (1, 2). The success in preclinical research has led to approval of several antisense ODNs for clinical trials (2). Although the phosphorothioate ODNs and other backbone-modified ODNs are very promising in antisense research, cellular uptake of these modified ODNs still remains an inefficient process.

Lipophilic moieties, conjugated to ODNs at either the 3'- or the 5'-end, stabilize the ODN and significantly enhance their cellular uptake (3–6). This can subsequently lead to improved antisense inhibition, as has been shown for cholesteryl-derivatized ODNs (7–11). The increased antisense efficacy of these ODNs may be a direct result of the affinity of the lipophilic moiety for membrane structures leading to a more efficient uptake, probably via a process of adsorptive endocytosis (4, 8, 10).

Alternatively, binding to the low-density lipoprotein (LDL) may also play a role, as it has been demonstrated that upregulation of the LDL receptor (LDLr) on cells increases the cellular uptake and effectiveness of cholesteryl-derivatized antisense ODNs (10).

LDL is the main cholesterol-transporting vehicle in the human circulatory system. It is a spherical particle with a mean diameter of 23 nm, and it consists of an apolar core of cholesteryl esters and triglycerides, which is surrounded by a shell of cholesterol and phospholipids (12). A large part of the surface is covered by apolipoprotein B100, which is responsible for recognition by the LDLr. Binding of LDL to its receptor is followed by internalization of the particle. There is evidence that many malignant cells, like leukemia cells, take up large amounts of LDL via the LDLr. The LDL particle may therefore constitute an attractive carrier for selective and highly efficient intracellular delivery of antineoplastic drugs to tumor cells. The LDLr-mediated therapeutic approach has already been explored for conventional lipophilic antitumor drugs (13–16) but may also be applied for lipophilic oncogene-directed antisense ODNs. Earlier studies established the potential of receptor-mediated endocytosis to mediate effective internalization of ODNs, thereby increasing the antisense efficacy (17, 18).

We and others have shown before that attachment of a cholesteryl moiety to the 5'-end allows association of ODNs with LDL in vitro. Association presumably occurs by partitioning of the relatively rigid cholesteryl moiety into the lipoprotein's lipid shell (10, 19). In analogy,

conjugation of an alkyl chain was also shown to induce association of ODNs to LDL (20).

In this study, we examine the ability of several lipophilic moieties to induce spontaneous association of ODNs to LDL. *c-myb* antisense ODNs were conjugated in solution phase at the 3'-end with lipidic structures which are composed of oleic acid and steroids. The antisense ODNs used in this study are directed to the *c-myb* proto-oncogene which is abundantly expressed in leukemic cells (21, 22). Numerous reports already showed the therapeutic potential of these ODNs in leukemic malignancies (23–25). Association of the lipid-ODNs to LDL is anticipated to enhance the cellular uptake, leading to an improved efficacy of the antisense ODN.

EXPERIMENTAL SECTION

Reagents. An 18-mer antisense ODN complementary to the *c-myb* proto-oncogene (5'-G*T*G* CCG GGG TCT TCG GGC-3'), provided with a seven-carbon 3'-amine linker and three phosphorothioate linkages (*) at the 5'-end, and a corresponding 28-mer sense ODN (5'-CCA TGG CCC GAA GAC CCC GGC ACA GCA T-3') were from Eurogentec (Seraing, Belgium). Low-melting multipurpose (LM-MP) agarose and Agarase from *Pseudomonas atlantica* were obtained from Boehringer (Mannheim, Germany). Tween 20 was from Merck (Darmstadt, Germany). Hionic Fluor and Emulsifier Safe scintillation cocktails and Soluene-350 were from Packard (Downers Grove, IL). Pyridine and DCE were dried by refluxing with CaH₂ and were distilled. DMF was stirred with CaH₂ prior to distillation under reduced pressure. These and other solvents (analytical grade) were stored over molecular sieves (4 Å). Oleoyl chloride was distilled under reduced pressure before use. Na¹²⁵I (carrier-free) and ³H₂O were purchased from Amersham (Buckinghamshire, U.K.). DiPEA (99.5%, redistilled) was purchased from Aldrich (Milwaukee, WI). All other chemicals were of analytical grade.

General Procedures. ODN concentrations were determined by UV spectroscopy at 260 nm. All reactions were run at ambient temperature, unless otherwise stated. Reactions were monitored by TLC on silica gel 60 F₂₅₄ aluminum sheets (Merck). Compounds were visualized under UV (254 nm) or by spraying with MnCl₂ for detection of steroids (26) or cresol green for carboxylic acids. Short column chromatography was performed on silica gel 60 (Merck, 230–400 mesh). ¹H NMR spectra were measured at 200 MHz using a JEOL JNM-FX 200 spectrometer with tetramethylsilane as an internal standard. ¹³C NMR spectra were measured at 50.3 MHz on the same apparatus, with CDCl₃ as an internal standard. ¹³C NMR spectra were monitored using the attached proton test technique. ¹⁹F NMR spectra were measured at 282 MHz with CFCl₃ as an internal standard on a Bruker WM-300 spectrometer. FAB mass spectrometry was carried out using a JEOL JMS SX/SX-102A four-sector mass spectrometer.

5-Cholenic Acid 3 β -Ol (4-Bromobenzoyl)methyl Ester 1b. To a solution of 250 mg (0.67 mmol) of cholenic acid **1a** in 10 mL of DMF were added 205 mg (0.74 mmol) of dibromoacetophenone and 240 mg (0.74 mmol) of Cs₂CO₃. After completion of the reaction, monitored by TLC (DCM), the mixture was filtered, and DMF was evaporated under reduced pressure. The product was purified by column chromatography using *n*-hexane/DCM (3:7, v/v) as the eluent, yielding 364 mg (0.64 mmol, 95%) of **1b**. ¹H NMR [parts per million (ppm)]: δ 7.78, 7.63 (4H,

dd, J = 8.9 Hz, ArH), 5.30 (3H, m, COCH₂O and vinyl H), 3.51 (1H, m, H-3). ¹³C {¹H} NMR (ppm): δ 71.7 (C-3), 65.7 (COCH₂O), 121.6 (C-6), 132.2, 129.3 (CH Ar), 133.0, 129.1 (qC Ar), 173.6 (C-24), 191.5 (C=O ketone).

5 β -Cholanic Acid 3 α -Ol (4-Bromobenzoyl)methyl Ester 2b. Compound **2b** was prepared with the procedure described for **1b**, starting from 865 mg (2.30 mmol) of lithocholic acid **2a**. The product was purified by column chromatography with MeOH/DCM (1:99, v/v) as the eluent, yielding 1.31 g (2.28 mmol, 99%) of **2b**. ¹H NMR (ppm): δ 7.74 and 7.59 (4H, dd, J = 8.6 Hz, ArH), 5.26 (2H, m, COCH₂O), 3.57 (1H, m, H-3). ¹³C {¹H} NMR (ppm): δ 65.3 (COCH₂O), 70.7 (C-3), 128.5, 132.3 (qC Ar), 128.8, 131.6 (CH Ar), 173.3 (C-24), 191.4 (C=O ketone).

5 β -Cholanic Acid 3 α ,7 α -Diol (4-Bromobenzoyl)methyl Ester 3b. Compound **3b** was prepared with the procedure described for **1b**, starting from 500 mg (1.27 mmol) of chenodeoxycholic acid. The product was purified by column chromatography with DCM $\rightarrow$ MeOH/DCM (1:25, v/v) as the eluent, yielding 650 mg (1.10 mmol, 87%) of **3b**. ¹H NMR (ppm): δ 7.79, 7.67 (4H, dd, J = 8.6 Hz, ArH), 5.28 (2H, m, COCH₂O), 3.45 (1H, m, H-3). ¹³C {¹H} NMR (ppm): δ 65.4 (COCH₂O), 67.8 (C-7), 71.4 (C-3), 128.6, 132.6 (qC Ar), 129.0 and 131.8 (CH Ar), 173.2 (C-24), 191.2 (C=O ketone).

3 β -(Oleoyloxy)-5-cholenic Acid (4-Bromobenzoyl)methyl Ester 1c. To a solution of 200 mg (0.35 mmol) of **1b** and 47 mg (0.39 mmol) of DMAP in 10 mL of pyridine, kept under a N₂ atmosphere, was added dropwise 116.5 mg (0.40 mmol) of oleoyl chloride. After being stirred for 6 h, the mixture was concentrated in vacuo. The residue was dissolved in DCM and the mixture washed with 1 N HCl and brine. The organic layer was dried over MgSO₄ and evaporated to dryness. The product was purified by column chromatography using *n*-pentane/DCM (2:5, v/v) as the eluent, yielding 170 mg (0.20 mmol, 58%) of **1c**. ¹H NMR (ppm): δ 7.68, 7.52 (4H, dd, J = 8.6 Hz, ArH), 5.26 (5H, m, COCH₂O and vinyl H), 4.50 (1H, m, H-3). ¹³C {¹H} NMR (ppm): δ 14.1 (CH₃-oleoyl), 65.6 (COCH₂O), 73.6 (C-3), 122.4 (C-6), 129.2, 132.1 (CH Ar), 129.0, 132.9 (qC Ar), 129.7, 129.9 (CH=oleoyl), 139.6 (C-5), 173.2 (C=O oleoyl ester), 173.5 (C-24), 191.4 (C=O ketone).

3 α -(Oleoyloxy)-5 β -cholanic Acid (4-Bromobenzoyl)methyl Ester 2c. Compound **2c** was prepared with the procedure described for **1c**, starting from 470 mg (0.82 mmol) of **2b**. The product was purified by column chromatography using *n*-pentane/DCM (2:3, v/v) as the eluent, yielding 650 mg (0.78 mmol, 95%) of **2c**. ¹H NMR (ppm): δ 7.78 and 7.63 (4H, dd, J = 8.2 Hz, ArH), 5.34 (4H, m, COCH₂O and vinyl H), 4.75 (1H, m, H-3). ¹³C {¹H} NMR (ppm): δ 14.0 (CH₃-oleoyl), 65.6 (COCH₂O), 73.9 (C-3), 129.2, 132.1 (CH Ar), 129.0, 132.9 (qC Ar), 129.7, 129.9 (CH=oleoyl), 173.2 (C=O oleoyl ester), 173.5 (C-24), 191.3 (C=O ketone).

3 α ,7 α -Bis(oleoyloxy)-5 β -cholanic Acid (4-Bromobenzoyl)methyl Ester 3c. To a solution of 340 mg (0.58 mmol) of **3b** in 10 mL of pyridine were added 155 mg (1.3 mmol) of DMAP and 451 mg (1.5 mmol) of oleoyl chloride. After the mixture was stirred for 2 h, another portion of 100 mg of DMAP and 226 mg of oleoyl chloride were added. After being stirred overnight, the mixture was concentrated in vacuo. The residue was dissolved in DCM, and the organic layer was washed with 1 N HCl and brine. The organic layer was dried over MgSO₄. The product was purified by column chromatography using DCM as the eluent, yielding 150 mg (0.13 mmol, 23%) of the dioleate **3c** and 210 mg (0.27 mmol, 46%) of the monooleate (C-3-esterified). ¹H NMR (ppm): δ 7.78 and

7.62 (4H, dd, $J = 8.9$ Hz, ArH), 5.34 (6H, m, COCH₂O and vinyl H), 4.89 (1H, m, H-7), 4.60 (1H, m, H-3). ¹³C {¹H} NMR (ppm): δ 14.0 (CH₃-oleoyl), 65.6 (COCH₂O), 70.8 (C-7), 73.7 (C-3), 129.1, 132.1 (CH Ar), 129.0, 132.9 (qC Ar), 129.1, 129.9 (CH=oleoyl), 172.9, 173.2, 173.4 (2 $\times$ C=O oleoyl ester, C24).

3 β -(Oleoyloxy)-5-cholenic Acid 1d. To a solution of 170 mg (0.20 mmol) of **1c** in 20 mL of DCM/HAc (1:1, v/v) was added 100 mg of Zn (powder). After being stirred overnight, the mixture was filtered over Hyflo and concentrated in vacuo. The product was purified by column chromatography using MeOH/DCM (1:99, v/v) as the eluent, yielding 124 mg (0.19 mmol, 97%) of **1d**. ¹H NMR (ppm): δ 5.32 (3H, m, vinyl H), 4.60 (1H, m, H-3). ¹³C {¹H} NMR (ppm): δ 14.1 (CH₃-oleoyl), 73.6 (C-3), 122.4 (C-6), 129.7, 129.9 (CH=oleoyl), 139.6 (C-5), 173.3 (C=O oleoyl ester), 180.3 (C-24). MS(FAB): 637.5 (M - H). HRMS: Calcd for C₄₂H₆₉O₄ 637.5196, found 637.5189.

3 α -(Oleoyloxy)-5 β -cholanolic Acid 2d. Compound **2d** was prepared with the procedure described for **1d**, starting from 650 mg (0.78 mmol) of **2c**. The product was purified by column chromatography using MeOH/DCM (from 1:99 to 1:66, v/v) as the eluent, yielding 460 mg (0.72 mmol, 92%) of **2d**. ¹H NMR (ppm): δ 11.06 (1H, m, COOH), 5.33 (2H, m, vinyl H), 4.72 (1H, m, H-3). ¹³C {¹H} NMR (ppm): δ 14.0 (CH₃-oleoyl), 74.0 (C-3), 129.7, 129.9 (CH=oleoyl), 173.4 (C=O oleoyl ester), 180.5 (C-24). MS(FAB): 639 (M - H). HRMS: Calcd for C₄₂H₇₁O₄ 639.5352, found 639.5399.

3 α ,7 α -Bis(oleoyloxy)-5 β -cholanolic Acid 3d. Compound **3d** was prepared with the procedure described for **1d**, starting from 150 mg (0.13 mmol) of **3c**. The product was purified by column chromatography using MeOH/DCM (from 1:99 to 2:99, v/v) as the eluent, yielding 96 mg (0.10 mmol, 80%) of **3d**. ¹H NMR (ppm): δ 5.34 (4H, m, vinyl H), 4.89 (1H, m, H-7), 4.59 (1H, m, H-3). ¹³C {¹H} NMR (ppm): δ 13.9 (CH₃-oleoyl), 70.8 (C-7), 73.7 (C-3), 129.5, 129.8 (CH=oleoyl), 172.8, 173.1 (2 $\times$ C=O oleoyl ester), 179.5 (C-24). MS(FAB): 920 (M - H). HRMS: Calcd for C₆₀H₁₀₃O₆ 919.7755, found 919.7819.

3 β -(Oleoyloxy)-5-cholenic Acid Pentafluorophenyl Ester 1e. To a solution of 90 mg (0.14 mmol) of **1d** in 10 mL of DCE was added 30 mg (0.16 mmol) of pentafluorophenol, and the mixture was cooled to 0 °C. Subsequently, 35 mg (0.17 mmol) of DCC was added. After 0.5 h, the mixture was allowed to warm to room temperature. After precipitation of dicyclohexylurea, the mixture was filtered and concentrated in vacuo. The product was purified by column chromatography using hexane/DCM (11:9, v/v) as the eluent, yielding 110 mg (0.14 mmol, 98%) of **1e** as a colorless oil. ¹H NMR (ppm): δ 5.34 (3H, m, vinyl H), 4.59 (1H, m, H-3), 0.88 (3H, t, CH₃-oleoyl). ¹³C {¹H} NMR (ppm): δ 73.6 (C-3), 122.4 (C-6), 129.7, 129.9 (CH=oleoyl), 139.7 (C-5), 169.9 (C-24), 173.2 (C=O oleoyl ester). ¹⁹F NMR (ppm): δ -151.1 (m), -156.5 (t), -160.7 (m).

3 α -(Oleoyloxy)-5 β -cholanolic Acid Pentafluorophenyl Ester 2e. Compound **2e** was prepared with the procedure described for **1e**, starting from 260 mg (0.41 mmol) of **2d**. The product was purified by column chromatography with hexane/DCM (2:3, v/v) as the eluent, yielding 325 mg (0.40 mmol, 98%) of **2e** as a colorless oil. ¹H NMR (ppm): δ 5.34 (2H, m, vinyl H), 4.73 (1H, m), 0.88 (3H, t, CH₃-oleoyl). ¹³C {¹H} NMR (ppm): δ 14.1 (CH₃-oleoyl), 74.0 (C-3), 129.7, 130.0 (CH=oleoyl), 169.9 (C-24), 173.3 (C=O oleoyl ester). ¹⁹F NMR (ppm): δ -151.1 (m), -156.5 (t), -160.7 (m).

3 α ,7 α -Bis(oleoyloxy)-5 β -cholanolic Acid Pentafluorophenyl Ester 3e. Compound **3e** was prepared with

the procedure described for **1e**, starting from 96 mg (0.10 mmol) of **3d**. The product was purified by column chromatography with hexane/DCM (1:3, v/v) as the eluent, yielding 77 mg (0.07 mmol, 68%) of **3e** as a colorless oil. ¹H NMR (ppm): δ 5.33 (4H, m, vinyl H), 4.90 (1H, m, H-7), 4.60 (1H, m, H-3), 0.88 (3H, t, CH₃-oleoyl). ¹³C {¹H} NMR (ppm): δ 14.0 (CH₃-oleoyl), 70.8 (C-7), 73.7 (C-3), 129.6, 129.9 (CH=oleoyl), 169.8 (C-24), 172.9, 173.1 (2 $\times$ C=O oleoyl ester). ¹⁹F NMR (ppm): δ -151.1 (m), -156.5 (t), -160.7 (m).

5 β -Cholanolic Acid 3 α -Ol Pentafluorophenyl Ester 2f. To a solution of 150 mg (0.40 mmol) of lithocholic acid **2a** in 5 mL of DCE/DMF (4:1, v/v) was added 88 mg (0.44 mmol) of pentafluorophenol, and the mixture was cooled to 0 °C. Subsequently, 99 mg (0.44 mmol) of DCC was added. After 0.5 h, the mixture was allowed to warm to room temperature and stirring was continued until dicyclohexylurea precipitated. The mixture was filtered and concentrated in vacuo. The product was purified by column chromatography using DCM/MeOH (98:2, v/v) as the eluent, yielding 194 mg (0.36 mmol, 89%) of **2f** as a white solid. ¹H NMR (ppm): δ 3.73 (1H, m, H-3). ¹³C {¹H} NMR (ppm): δ 73.6 (C-3), 122.4 (C-6), 129.7, 129.9 (CH=oleoyl), 139.7 (C-5), 169.9 (C-24), 173.2 (C=O oleoyl ester). ¹⁹F NMR (ppm): δ -151.1 (m), -156.6 (t), -160.7 (m).

Oleic Acid Pentafluorophenyl Ester 4b. Compound **4b** was prepared with the procedure described for **2f**, starting from 200 mg (0.71 mmol) of oleic acid **4a**. The product was purified by column chromatography with *n*-hexane/DCM (9:1, v/v) as the eluent, yielding 230 mg (0.51 mmol, 72%) of **4b** as a colorless oil. ¹H NMR (ppm): δ 5.35 (2H, m, vinyl H), 0.88 (3H, t, CH₃-oleoyl). ¹³C {¹H} NMR (ppm): δ 14.04 (CH₃-oleyl), 129.63 and 130.06 (CH=oleyl), 169.52 (C=O). ¹⁹F NMR (ppm): δ -151.1 (m), -156.6 (t), -160.7 (m).

Radiolabeling of ODN by Hydrogen-Tritium Exchange. The 3'-amine ODN was tritiated by the procedure of Graham et al. (27), with slight modifications. After 0.50 mg of the 3'-amine ODN was dissolved in 200 μ L of 50 mM sodium phosphate buffer (pH 7.8), containing 0.1 mM EDTA, the solution was freeze-dried. The lyophilized material was dissolved in 200 μ L of ³H₂O (0.6 Ci), and 4.2 μ L of β -mercaptoethanol was added. The solution was covered with 400 μ L of mineral oil and was incubated in a gasketed vial in an oil bath kept at 90 °C. After 6 h, the radiolabeled ODN was desalted and depleted of ³H₂O by repetitive centrifugation and resuspension in ¹H₂O using a Microcon-3 concentrator (Amicon, Witten, Germany). To remove final traces of ³H₂O, the concentrated [³H]ODN was taken up in 50 μ L of H₂O and precipitated with 500 μ L of 3% LiClO₄ in acetone. Finally, the precipitate was taken up in H₂O, and after the A₂₆₀ and radioactivity were measured, the ODN was stored at -20 °C. We did not detect any significant exchange of radioactivity upon 6 months of storage at -20 °C. The total yield was 0.28 mg (56%). The specific activity of the [³H]ODN was 80 $\times$ 10⁶ dpm mg⁻¹ (0.5 $\times$ 10⁹ dpm μ mol⁻¹).

Synthesis and Purification of 3'-Lipid-ODN. The 3'-amine ODN was precipitated as a Li salt with 10 volume equiv of 3% LiClO₄ in acetone. Next, the ODN was dissolved in H₂O and precipitated again with 10 volume equiv of acetone to remove final traces of LiClO₄. In a typical derivatization experiment, 15 nmol of ODN was dissolved in 350 μ L of H₂O/DMF/dioxane (1:4:2, v/v/v). Subsequently, 1 μ mol of the activated lipid dissolved in 100 μ L of dioxane and 35 μ mol of DiPEA were added. The mixture was incubated for 48 h at 56 °C for lipids

1e, **2e**, and **3e** or at 37 °C for **2f**, **4b**, and cholesterol chloroformate. Solvents were removed in a speed-vac concentrator, and the residue was taken up in 200 μ L of DCM and 200 μ L of H₂O. The layers were separated by centrifugation, and the organic layer was washed twice with 200 μ L of H₂O. The H₂O fractions were combined and freeze-dried. Derivatization of [³H]ODN was performed as described above with 2 nmol of [³H]ODN and 4 nmol of unlabeled ODN.

ODNs conjugated with lithocholic acid, oleic acid, or cholesterol were purified by reversed phase (RP)-HPLC on a Waters C4 column (5 μ m, 300 Å, 300 $\times$ 3.9 mm), applying a gradient of 1% CH₃CN/min in 50 mM triethylammonium acetate (pH 7.0) at a flow rate of 1 mL/min. The gradient (5 to 50%) was started after elution for 5 min at 5% CH₃CN. ODNs were detected at 260 nm. All other lipid-conjugated ODNs were purified by gel electrophoresis in a 1% LM-MP agarose gel containing 0.1% Tween 20, in 0.5 $\times$ TBE [45 mM Tris-borate and 0.1 mM EDTA (pH 8.4)]. After separation of the lipid-ODN from the nonconjugated ODN, the gel slice containing the lipid-ODN was melted for 5 min at 65 °C. The agarose was digested with Agarase (40 units per milliliter of gel) at 45 °C in 30 mM Bis-Tris and 10 mM EDTA for 2 h. The lipid-ODNs were precipitated with 10 volume equiv of acetone. To remove traces of undigested agarose, the precipitate was taken up in 200 μ L of H₂O and passed over a filter paper (no. 589, Schleicher and Schüll). Lipid-conjugated ODNs were isolated in a yield of 35–75%.

Determination of Melting Temperatures. Melting temperatures of hybrids of the antisense 3'-lipid-ODNs with an 28-mer sense ODN were determined using a Perkin-Elmer spectrophotometer equipped with a PTP-6 thermal programmer. Equimolar amounts of both ODNs were dissolved in PBS (pH 7.4) to a concentration of 3.6 μ M, denatured at 96 °C for 2 min, and subsequently cooled to room temperature to anneal slowly. Then, the temperature was adjusted to 35 °C, and hybrids were melted by increasing the temperature to 95 °C at a rate of 0.5 °C min⁻¹. Duplicate runs produced *T*_ms within 1 °C.

Isolation and Radiolabeling of LDL. LDL was isolated from the serum of fasted volunteers by density gradient ultracentrifugation (28) and was dialyzed against PBS containing 1 mM EDTA (pH 7.4). Radioiodination was performed at pH 10.0 with carrier-free ¹²⁵I as described by McFarlane (29). Protein concentrations of LDL were determined by the method of Lowry (30) with bovine serum albumin as a standard.

Determination of the Association of Lipid-ODNs with LDL. Equimolar amounts of [¹²⁵I]LDL and lipid-[³H]ODNs (1.7 μ M), dissolved in PBS and 1 mM EDTA (pH 7.4), were incubated for 2 h at 37 °C. For these experiments, the molecular weight of an LDL particle was related to the molecular weight of the apoprotein B-100 (31), as each LDL particle contains only one copy of the apoprotein. The molecular weights of the lipid-ODNs were taken from Table 1. Aliquots of the incubation mixtures were subjected to gel electrophoresis in a 0.75% (w/v) agarose gel in 75 mM Tris-hippuric acid buffer (pH 8.8). After electrophoresis, the gel was cut into slices, and after addition of 0.5 mL of Soluene-350, the ¹²⁵I radioactivity was counted. After 24 h, 3 mL of Hionic Fluor was added and samples were evaluated for ³H radioactivity. The measured values of ³H radioactivity were corrected for the contribution of ¹²⁵I radioactivity.

^a Melting temperatures (degrees Celsius) were calculated from duplicate runs with a 28-mer unmodified DNA strand as the target sequence in PBS. ^b Lipid-ODNs were analyzed by ES mass spectrometry. The exact mass data were calculated from at least four multiply charged ions. ^c Cholesteryl chloroformate.

RESULTS AND DISCUSSION

Synthesis of Activated Lipid Structures. Starting points for the design of the lipids to be conjugated to the *c-myc* specific ODNs were the studies of Firestone et al. (13, 14). These studies show that aliphatic lipids with at least one cis double bond and oleoyl steroid esters facilitate reconstitution of LDL with lysosomotropic agents and nitrogen mustards. The lipid structures in this study were synthesized, as shown in Scheme 1, starting from oleic acid **4a** and the bile acids cholenic acid **1a**, lithocholic acid **2a**, and chenodeoxycholic acid **3a**. Bile acids were selected because they contain both a carboxylic acid functionality which can be used for conjugation to ODNs bearing nucleophilic moieties and hydroxyl groups that can be esterified with fatty acids. The lipophilicity of the bile acids was enhanced by introducing one oleic acid chain (**1d** and **2d**) or two oleic acid chains (**3d**). The bile acids lithocholic acid **2a** and cholenic acid **1a** differ in the configuration of the hydroxyl at the 3 position and the rigidity of the steroid rings. First, the carboxylic acids of the bile acids were protected with 4-bromophenacyl bromide. Then, the hydroxyls were esterified with oleoyl chloride in the presence of DMAP, resulting in the oleoyl steroid esters **1c** and **2c** in a yield of 58–95%. Synthesis of **3c** afforded the dioleoyl ester in a low yield (23%), compared to those of the monooleoyl esters **1c** and **2c**.

Characterization of the reaction products formed during synthesis of **3c** revealed two main products: the dioleoyl ester **3c** and the monooleoyl steroid ester esteri-

Scheme 1. Synthesis of Activated Lipid Structures^a

fied at the 3-OH. The 7-OH monooleoyl ester could not be detected as a main product. The 3-OH of chenodeoxycholic acid thus appears to react more easily with oleoyl chloride than the 7-OH, presumably because this position is more readily accessible. Upon formation of the oleic acid ester at the 3-OH, the 7-OH may become even less accessible for esterification, due to steric hindrance. We also attempted to synthesize the dioleoyl steroid ester of deoxycholic acid (3-OH and 12-OH). However, compared to the 7-OH of chenodeoxycholic acid, the 12-OH of deoxycholic acid was found to be even more difficult to esterify.

After esterification of the hydroxyls of the steroids, the bromophenacyl group could easily be removed by overnight stirring in HAc/Zn. All synthesized lipids were activated with pentafluorophenol to allow coupling to 3'-amino-tailed ODNs.

Conjugation of ODNs with Lipid Structures. We performed synthesis of the lipid-ODNs in solution phase, since in the alternative approach, solid phase synthesis, the steroid ester structures would be disrupted by the standard ammonia cleavage of the ODN from the solid support (32, 33). However, earlier studies have proven that the covalent attachment of large lipids to ODNs in solution phase is a difficult task. The lipids and the ODNs have very different solubility properties, and the amphiphilic properties of the resulting lipid-ODNs often lead to isolation problems and consequently low yields (34-36). To achieve a high conjugation efficiency for our

lipids, we have tested several protocols described in the literature. Derivatization of ODNs with lipids in aqueous buffer solutions (pH 8-10) has been reported to be the most successful derivatization method (32, 33). However, the low solubility of most of our lipids in these mixtures resulted in very low yields of the conjugated ODN. Lipophilic cations such as CTAB or PMDBD have been used to dissolve and subsequently derivatize ODNs with lipids in organic solvents such as DMSO and $CHCl_3$ (34, 35, 37, 38). Unfortunately, this approach failed for derivatization of our lipids. We found that derivatization in a mixture of H_2O and the aprotic solvents DMF and 1,4-dioxane (1:4:4, v/v/v), in which DiPEA was present to create mildly basic conditions, is far superior to the other two methods (39). The presence of dioxane in this mixture improved the solubility of the steroid lipids, and DMF appeared to be a crucial component. When DMF was replaced by dioxane, resulting in a mixture of H_2O and dioxane only (1:8, v/v), the conjugations were unsuccessful, although both the ODN and the activated lipid could be dissolved. Derivatization of the 3'-amino ODN could efficiently be accomplished in the H_2O /DMF/dioxane mixture for 48 h at 37 °C for the lipids **2f**, **4b**, and cholesteryl chloroformate. The activated lipids **1e**, **2e**, and **3e** were conjugated in the same mixture, but the temperature was raised to 56 °C to ensure complete solubility of these activated steroid lipids.

After conjugation of the ODN and removal of the reaction mixture solvents, excess reactive lipids were

extracted with DCM. Without this extraction step, recoveries of the conjugated ODNs were very low. Separation of the ODNs conjugated with lithocholic acid, oleic acid, and cholesterol (ODN-2, ODN-3, and ODN-4, respectively) from the nonconjugated ODNs was accomplished by RP-HPLC (Waters C4 column, 5 μ m, 300 Å) using an CH₃CN gradient from 5 to 50% in 50 mM triethylammonium acetate (pH 7.0). The retention time of ODNs increased significantly from 17 min for the nonconjugated ODN to 23.7 min for ODN-2 and 34.5 min for ODN-3 and ODN-4. When a C8 HPLC column was utilized, the cholesteryl-derivatized ODN had a much higher retention time than the oleic acid-derivatized ODN. The C4 column was preferred since it led to higher recoveries of the ODNs (overall recoveries of up to 80%).

Purification of the ODNs conjugated with the oleoyl steroid ester structures (ODN-5, ODN-6, and ODN-7) was not possible by RP-HPLC; no conjugated products could be recovered. Several RP-HPLC columns (C4, C8, and C18) were tested, and very high concentrations of the organic modifier (CH₃CN and tetrahydrofuran up to 95%) were used. Only small amounts (<30%) of the non-derivatized ODNs could be recovered. Attempts to purify the lipid-ODNs by PAGE gave comparable results. The lipid-ODNs are readily soluble in water after the DCM/H₂O extraction, but since no lipid-ODN could be detected by RP-HPLC, we assume that the highly lipidic ODN-5, ODN-6, and ODN-7 bind irreversibly to the column material. The limitations of RP-HPLC for purification of lipid-ODNs have already been shown by Manoharan et al. (40). These authors observed a linear correlation between the percentage of acetonitrile needed to elute lipid-ODNs from a HPLC C18 column and the number of carbon atoms in the lipid conjugated to the ODN. This indicates that RP-HPLC analysis is restricted to lipidic ODNs of limited hydrophobicity. PAGE of ODN-5, ODN-6, and ODN-7 suggests formation of large structures, since none of the conjugated ODNs migrated into the gel. Only a small amount of the underivatized ODN could be detected. This was also observed by Farooqui et al. (11) for ODNs conjugated with two cholesteryl groups. Bourtoune et al. (36) reported similar isolation problems with fullerene (C60)-conjugated ODNs by both RP-HPLC and PAGE. They solved the problem by separating the fullerene-ODN from the nonconjugated ODN by electrophoresis in a 1% agarose gel containing 0.1% Triton X-100. Separation is based on the formation of micelles between lipid-ODNs and a nonionic detergent such as Tween 20 or Triton X-100. We applied this method to separate the nonconjugated ODN from the ODNs conjugated to the oleoyl steroid esters (ODN-5, ODN-6, and ODN-7). As can be seen in Figure 1, these lipid-ODNs migrate more slowly than the nonconjugated ODNs in a gel matrix of LM-MP agarose and Tween 20. The lipid-ODNs could be isolated by treatment of the ODN-containing gel slices with Agarase and subsequent precipitation of the ODNs by acetone. The yields of the derivatized ODNs purified by this method varied from 35 to 65% (based upon starting material, as judged from both the radioactivity and the A₂₆₀ of the isolated ODNs). Surprisingly, oleic acid- and lithocholic acid-conjugated ODNs (ODN-2 and ODN-3), which were readily isolated by RP-HPLC, could not be separated from the nonconjugated ODN by this gel electrophoresis method. An interesting feature of the cholesteryl-conjugated ODNs is that they could be purified by RP-HPLC as well as by agarose/detergent gel electrophoresis. When agarose gel-purified cholesteryl-conjugated ODNs were analyzed by

Figure 1. Analysis of reaction mixtures of ODNs conjugated with steroid lipids. Reaction mixtures were subjected to electrophoresis in a 1% agarose/0.1% Tween 20 gel in 0.5× TBE [45 mM Tris-borate and 0.1 mM EDTA (pH 8.4)]. ODNs were visualized by UV shadowing: lanes 1 and 8, xylene cyanol (marker); lanes 2 and 7, ODN-1; lane 3, reaction mixture ODN-6; lane 4, reaction mixture ODN-7; lane 5, reaction mixture ODN-5; and lane 6, reaction mixture ODN-4.

RP-HPLC, the retention time was exactly the same as that for the HPLC-purified cholesteryl-conjugated ODNs.

All purified lipid-ODNs were analyzed by electrospray mass spectrometry. The exact molecular weights were calculated from at least four multiply charged ions in the mass spectrum and are listed in Table 1. The calculated molecular weights agree very well with the measured values which confirms the chemical structures of the isolated products.

Interaction of Lipid-ODNs with Their Target Sequences. To ascertain that the attached lipid structures do not negatively interfere with the interaction of the antisense ODN with the target sequence, we determined the melting temperatures of antisense and sense hybrids. The 28-mer sense ODN possessed five overhang nucleotides at both the 3'- and 5'-end for assessing a possible interaction of the lipid with the single-stranded part of the hybrid. Although the steroid lipids, and in particular the oleoyl steroid esters, are relatively bulky, our data indicate that interference of the lipids with the overhang nucleotides of the target sequence is minimal, since only a slight difference of maximally 2 °C in T_m was observed (Table 1). These findings are consistent with other reports on lipid-ODNs (41, 42).

Interaction of Lipid-ODNs with LDL. After conjugation of the lipids to the ODN, we determined the association of these conjugates with native LDL. The ODN was specific to the *c-myc* proto-oncogene. The association of these oncogene-directed ODNs with LDL is highly relevant, as it has been shown that various tumor cells express elevated levels of the LDLr (15). The use of LDL as a carrier particle may therefore facilitate cellular uptake of oncogene-directed ODNs, and thus enhance antisense activity.

To examine which of the synthesized lipids were able to associate the ODN with native LDL, radioiodinated LDL was incubated for 2 h at 37 °C with equimolar amounts of lipid-[³H]ODN. Incubation mixtures were analyzed by agarose gel electrophoresis in 75 mM Tris-hippuric acid buffer (pH 8.8) (Figure 2). The electrophoretic mobility (R_f) of native LDL (relative to bromophenol blue) in this gel matrix is 0.2, whereas the nonassociated ODN and lipid-ODNs have R_f values close to 1.0. These complexation experiments reveal that ODNs conjugated with cholesterol and the oleoyl esters

Figure 2. Association of lipid-ODNs with LDL; analysis by agarose gel electrophoresis. Equimolar amounts of [^{125}I]LDL and lipid-[^3H]ODNs (1.7 μM), dissolved in PBS and 1 mM EDTA (pH 7.4), were incubated for 2 h at 37 $^{\circ}\text{C}$. Aliquots of the incubation mixtures were subjected to gel electrophoresis in a 0.75% (w/v) agarose gel in 75 mM Tris-hippuric acid buffer (pH 8.8). After electrophoresis, the gel was cut into slices that were assayed for ^3H radioactivity ($\circ$) and ^{125}I radioactivity ($\bullet$). The results are expressed as a percentage of the recovered radioactivities. Recoveries were $>95\%$.

of lithocholic acid and cholenic acid associate spontaneously and almost completely with LDL. More than 95% of the [^3H]ODNs conjugated with these steroids comigrated in the gel with radioiodinated LDL at an R_f of 0.2. These steroids meet the structural requirements for LDL anchors as defined by Firestone (13). Association of the lipid-ODNs with LDL also slightly broadened the band of LDL in the gel. This is probably due to an increase of the overall negative charge of the complex. When ODNs were associated at higher molar ratios, the increase in the electrophoretic mobility was more clear (data not shown). The association of cholesteryl-derivatized ODNs with native LDL has been shown before (10, 19), but the use of oleoyl steroid esters to induce association of ODNs with LDL is novel.

In Figure 2, the fact that not all lipids can induce spontaneous association of the ODN with LDL is also illustrated. Lithocholic acid and oleic acid proved not to be effective as a LDL anchors in our experiments. This also applies for the bis-oleoyl steroid ester. Only a small proportion of the ODN conjugated to this steroid ester (ODN-6) comigrated with LDL, and more than 50% of the ^3H radioactivity was found at an R_f of >0.2 . The aberrant migration pattern for ODN-6 may indicate that this lipid-ODN has formed an aggregate during incubation with LDL or that it slowly dissociates from the LDL during electrophoresis. The lipid moiety of ODN-6 probably does not partition with its complete steroid structure into the lipids of LDL, but only with the two oleoyl chains. The complete bis-oleoyl steroid ester structure may be too bulky to associate spontaneously with LDL. How-

ever, this ODN might be an interesting candidate to use in the recently developed artificial LDL-like carrier systems (43, 44). In this system, lipid-ODNs are incorporated during vesicle formation, in contrast to the spontaneous association with LDL in this study. The lack of association of ODN-3 with LDL was not expected, since complexation of a 5'-palmitoylated 16-mer phosphorothioate ODN with LDL was already reported by Mishra et al. (20). The structural difference between oleic acid and palmitic acid may explain the difference in LDL association. In fact, Svinarchuk et al. (8) reported that small structural differences of fatty acids can change their binding characteristics for membrane structures significantly. Alternatively, the inability of the oleoyl chain to associate ODNs with LDL may be caused by different methods of analysis of complexation.

Concluding Remarks. We have efficiently conjugated ODNs to several lipid structures in solution phase. The conjugates could easily be purified in high yields, either by RP-HPLC or by electrophoresis in a 1% agarose gel in the presence of 0.1% detergent. Several of the lipid-ODN conjugates associate readily with LDL, which opens the possibility of utilizing the lipid structures for specific delivery of oncogene-directed ODNs to tumor cells via the LDLr pathway. To be effective, however, the ODNs need to escape from the endosomal/lysosomal compartment. We speculate that lipid-ODNs can exit these compartments, since it has been shown by several authors that lipid-ODNs can bind to membrane structures which may facilitate transport. Indeed, enhanced activity of lipid-ODNs, which may be the result of

increased transport across the cellular membrane, has been described (7, 9).

ACKNOWLEDGMENT

Muthiah Manoharan and Kathleen Tivel at ISIS Pharmaceuticals (Carlsbad, CA) and Sven Wagner at the DKFZ (Heidelberg, Germany) are acknowledged for mass analyses of the ODNs. Dr. S. van Zwanenbergstichting is acknowledged for financial support for presenting part of this work at the 12th IRT (1996, La Jolla, CA).

Terbium Chelate Membrane Label for Time-Resolved, Total Internal Reflection Fluorescence Microscopy of Substrate-Adherent Cells

Sam Phimphivong and S. Scott Saavedra*

Department of Chemistry, University of Arizona, Tucson, Arizona 85721. Received September 11, 1997;
Revised Manuscript Received March 6, 1998

A chelating agent conjugated to a lipid was synthesized by reacting the dianhydride form of diethylenetriaminepentaacetic acid sequentially with 4-aminosalicylate and dioleoylphosphatidylethanolamine. The product, DOPE-YAS-Tb, exhibits photophysical properties characteristic of a chelated Tb³⁺ ion bound to an organic triplet donor: an excitation maximum at 310 nm, narrow emission bands at 490, 545, 590, and 625 nm, and a lifetime of 1.57 ms. The suitability of DOPE-YAS-Tb as a membrane-staining agent for morphological studies of cultured cells using total internal reflection fluorescence microscopy (TIRFM) was investigated. Swiss albino mouse 3T3 cells were cultured on silica and polystyrene substrates. Time-resolved detection was employed to reject short-lived background emission (autoemission from the cells and/or the polymer substrate), which allowed the long-lived Tb³⁺ emission to be selectively imaged. The results show that time-resolved TIRFM of cells stained with DOPE-YAS-Tb is an effective method of quantitatively examining the cell morphology in situations where background due to autoemission from cells and/or the substrate material is problematic.

INTRODUCTION

Total internal reflection fluorescence microscopy (TIRFM), in which an evanescent wave is used to selectively excite fluorophores near a solid-liquid interface, was first used by Axelrod to visualize cell-substrate contact regions by labeling the plasma membrane with an amphiphilic fluor (1). TIRFM has since been used widely to study cell adhesion phenomena. Examples include morphological studies of chick heart cells (2), *Dicytostelium* amoebae (3), bovine aortic endothelial cells (4, 5), and rat myotubes (6), Fc receptors in rat basophilic leukemia cells (7), the angiotensin-converting enzyme in endothelium (8), and the structural organization of interphase fibroblasts (9). A thorough review is provided in a recent paper by Burmeister et al. (10).

Several groups have shown that digital TIRFM can be used to determine separation distances between the plasma membrane and the substrate in cell-substrate contact regions (5, 9–11), which allows the technique to be used for quantitative studies of cell adhesive interactions. For example, Burmeister et al. (10) examined relationships between contact area and adhesion strength in endothelial cells cultured on biomaterial surfaces and performed real-time measurements of the cell-substrate separation distance as a function of applied shear stress.

However, quantitative conversion of a digital TIRFM image to a map of contact region morphology can be compromised by extraneous emission from the cell and/or the substrate (5). The emission spectra of conventional membrane labels such as DiIC₁₈ and lipid-conjugated fluorescein and rhodamine overlap with cellular autofluorescence at wavelengths of less than 600 nm (12, 13), which can be problematic if the label density is relatively low and/or the separation distance is large. Furthermore,

the autofluorescence and Raman scattering background from many polymers, including those of biomedical interest, is usually more intense than that of a silica substrate.

Methods for correcting steady-state fluorescence measurements on cells for autofluorescence have been described (13–15). Typically, correction factors are determined on a cell-by-cell basis by making a second measurement of emission intensity at a wavelength that is both spectrally resolved from the label emission and shown to be correlated with autoemission intensity within the label emission band.

Time-resolved detection using an extrinsic label having decay kinetics much slower than those of the sources of background emission is an alternative approach. Since the radiative lifetime of cellular autofluorescence is less than 100 ns, it can be temporally discriminated from the emission of lanthanide metals such as Eu³⁺ and Tb³⁺, which have lifetimes in the millisecond range. Principles and applications of time-resolved fluorometry using lanthanide probes have been reviewed elsewhere (16, 17). Briefly, following excitation of a sample with a light pulse, photon detection is delayed to allow the short-lived background emission to decay to a negligible level. The detection system is activated thereafter to record only the signal from the long-lived label.

We previously examined the use of two Tb chelates as staining agents for time-resolved TIRFM of substrate-adherent cells (18). The results showed that elimination of short-lived cellular autofluorescence permitted selective detection of the long-lived label fluorescence. However, the chelates were found to stain not only the plasma membrane but also cytoplasmic regions, including the nucleus. Thus, interpretation of the TIRF image was somewhat ambiguous due to the nonselective localization of the label. Here we describe the synthesis of another Tb chelate, DOPE-YAS (dioleoylphosphatidylethanolamine conjugated to diethylenetriaminepentaacetyl-4-

* Corresponding author. Phone: (520) 621-9761. Fax: (520) 621-8407. E-mail: saavedra@u.arizona.edu.

aminosalicylic acid), and its use as a long-lived probe for time-resolved TIRFM of cells. The utility of this label in cell adhesion studies where background emission is problematic is demonstrated by performing TIRFM on stained cells cultured on polystyrene. Although this material is a ubiquitous cell culture substrate, in comparison to silica, it is a relatively poor material for TIRF studies due to inherently high levels of Raman scattering and autoluminescence (19).

EXPERIMENTAL SECTION

Chemicals and Cell Culture Supplies. 1,2-Di-*cis*-9-octadecenoyl-*sn*-glycero-3-phosphoethanolamine (DOPE), Dulbecco's modified Eagle's medium (DMEM) without phenol red, trypsin, Hank's balanced salt solution (HBSS) without phenol red, fetal bovine serum, penicillin (100 units/mL), streptomycin sulfate, and Tris hydrochloride were obtained from Sigma. Diethylenetriaminepentaacetic acid dianhydride (YdA), 4-aminosalicylate, sodium salt (pAS), pyridine, anhydrous dimethyl sulfoxide (DMSO), terbium(III) chloride hexahydrate, polystyrene (secondary standard, $M_w = 240\,000$), potassium bromide, and spectral-grade chlorobenzene were obtained from Aldrich. All chemicals were used as received. Deionized water was obtained from a Barnstead Nanopure system.

Preparation and Characterization of DOPE-YAS. YdA was reacted with pAS to produce the YAS monoanhydride, as previously described (20, 21). DOPE-YAS was synthesized by reacting YAS monoanhydride with DOPE, following the general procedure of Nayar et al. (22). DOPE (53.7 μmol) was placed in a 100 mL round-bottom flask and dried under high vacuum for 2 h to remove residual chloroform. The dried lipid was redissolved in 10 mL of freshly distilled pyridine containing 537 μmol of YAS anhydride. The reaction mixture was stirred under a N_2 atmosphere at 60 $^\circ\text{C}$ for 24 h. Excess YAS anhydride was hydrolyzed by adding 2 mL of 1:2:0.8 $\text{CHCl}_3/\text{CH}_3\text{OH}/0.58\% \text{ NaCl}$ (v/v). Thin-layer chromatography of the unpurified product (using a mobile phase of 65:25:4 $\text{CH}_3\text{Cl}/\text{MeOH}/\text{H}_2\text{O}$ and ninhydrin staining) showed a nearly complete conversion of DOPE to DOPE-YAS.

Unreacted DOPE and DOPE-YAS were recovered by repeated extraction with a 1:1 mixture of $\text{CH}_3\text{Cl}/0.58\% \text{ NaCl}$. The saline solution was buffered at pH 2 with 100 mM phosphate (note that DOPE-YAS is insoluble in water at pH 2). The CH_3Cl fractions, which contained DOPE, DOPE-YAS, methanol, and pyridine, were pooled, dried on a rotary evaporator, and redissolved in 50 mL of 1:9 $\text{CH}_3\text{Cl}/\text{CH}_3\text{OH}$. DOPE-YAS was removed from this solution by repeated extraction with a 1:1 mixture of $\text{CH}_3\text{Cl}/0.58\% \text{ NaCl}$. In this step, the saline solution was buffered at pH 8 with 100 mM phosphate (note that DOPE-YAS is slightly soluble in water at pH 8). The progress of the extraction was monitored by adding a few drops of the organic phase to a solution of TbCl_3 dissolved in Tris buffer at pH 7.4. When DOPE-YAS was present in the organic phase (i.e., had not been quantitatively extracted), the interface between the droplets and the TbCl_3 solution fluoresced green under illumination from a mercury lamp. The extraction was repeated until no fluorescence could be visually detected. The aqueous fractions were then pooled, washed three times with CH_3Cl , and lyophilized to yield the DOPE-YAS product.

The product was characterized by UV-visible and infrared absorbance spectrometry, using a Hewlett-Packard 8452A spectrophotometer and a Nicolet 510P

FT-IR spectrometer, respectively. Steady-state fluorescence spectroscopy of dissolved DOPE-YAS-Tb was performed using a Spex Fluorolog fluorometer (Spex Industries, Inc., Edison, NJ). Fluorescent lifetime measurements on samples of dissolved DOPE-YAS-Tb were performed using the time-resolved fluorescence spectroscopic system that was described previously (18).

Substrates. Fused silica slides (Dynasil, Berlin, NJ) were cleaned by light mechanical scrubbing with cotton in 2% PCC-54 detergent (Pierce) and sonicated first in hot (ca. 60 $^\circ\text{C}$) 2% PCC-54 for 15 min, then in methanol for 10 min, and finally in deionized water for 10 min. Slides were rinsed with deionized water between sonications and then dried overnight at 120 $^\circ\text{C}$. Fused silica slides coated with polystyrene (PS) were prepared by spin coating at 1500 rpm, using an 8% (w/w) solution of PS dissolved in chlorobenzene, as described previously (23). After the slides were coated, films were dried at 70 $^\circ\text{C}$ for 24 h. The thickness and refractive index were determined by measuring prism coupling angles that produced waveguided modes in the film at 514.5 nm, as described previously (23). The typical thickness and refractive index of a PS film prepared in this manner were 0.84 μm and 1.59, respectively. These values differed by no more than 5% when measured at several different spots on a single slide. Among a batch of PS-coated slides prepared on a given day, the variation in film thickness and refractive index was also no more than 5%.

Cell Culture and Labeling. Cells were cultured as described previously (18). Briefly, Swiss albino mouse 3T3 cells (American Type Culture Collection, Rockville, MD) were cultured in 90% DMEM, supplemented with 10% fetal bovine serum, 100 $\mu\text{g}/\text{mL}$ streptomycin, and 100 units/mL penicillin. Cells were grown, usually to confluence, in a 75 cm^2 culture flask (Costar, Cambridge, MA) at 37 $^\circ\text{C}$ in a 5% $\text{CO}_2/95\%$ air atmosphere. Cells were passaged by washing with HBSS, detached by incubation with 2 mL of a trypsin solution (diluted to 1:20 from the stock solution) for 5 min, and resuspended in supplemented medium at a density of ca. 10^5 cells/mL. Passage numbers 10–30 were used in experiments described herein.

For fluorescence spectroscopy and microscopy, cells were plated at a density of approximately 10^3 cells/mL on either fused silica slides or PS-coated fused silica slides, with the planar substrate mounted in a Lucite chamber which also functioned as a TIRF cell. The plating time was 24 h on fused silica slides and 48–72 h for PS-coated slides. Longer times were required on PS because the cells adhered poorly to it and growth was relatively slow, which is well-known for PS that has not been oxidized (24).

After plating, the adherent cells were washed with HBSS, fixed in 3.7% formaldehyde at room temperature for 7 min, and rinsed with deionized water. Labeling with Tb was performed using a two-step procedure. Cells were incubated with DOPE-YAS (16 μM in Tris buffer at pH 7.4) for 60 min, rinsed with deionized water, incubated with TbCl_3 (16 μM in Tris buffer at pH 7.4) for 10 min, and then rinsed with deionized water.

Fluorescence Microscopy of Cultured Cells. Fluorescence microspectroscopy and microphotography were performed using the instrumentation described previously (18). Briefly, the sample is excited in a TIR geometry at a 70 $^\circ$ incidence angle with the 325 nm beam (about 1 mW) of a helium-cadmium laser (Liconix model 3207N). The beam is mechanically chopped at 400 Hz and adjusted to transverse electric (s) polarization with

Figure 1. Absorbance spectra of pAS (8 μ M, solid line) and DOPE-YAS (84 μ M, dashed line) dissolved in 0.1 M Tris buffer at pH 7.

Figure 2. Infrared spectra of pAS, DOPE, and DOPE-YAS (KBr pellet). Spectra were scaled for presentation.

reaction product. Figure 2 shows IR spectra of pAS, DOPE, and DOPE-YAS. In the pAS spectrum, the phenolic O-H stretch appears as a broad band at 3650–3200 cm^{-1} and overlaps the asymmetric (3372 cm^{-1}) and symmetric (3290 cm^{-1}) N-H stretching modes of the amine. This phenolic O-H stretch is also observed in the spectrum of the product, consistent with incorporation of the pAS moiety.

In Tris buffer at pH 7.4 containing an equimolar amount of Tb^{3+} , DOPE-YAS exhibits a fluorescent excitation maximum at 308 nm, similar to its absorption spectrum, and sharp emission maxima at 490, 545, 590, and 625 nm (uncorrected) which are characteristic of the Tb^{3+} ion (data not shown). The fluorescence emission decay is first-order with a lifetime of 1.57 ms (data not shown). These properties are very similar to those of YAS-Tb (18, 20, 21), which shows that the electronic properties of YAS-Tb are not significantly altered by conjugation to DOPE. The quantum yield of DOPE-YAS-Tb was not measured. However, since the struc-

Figure 3. Images of a 3T3 cell cultured on a fused silica substrate for 24 h, fixed, and labeled with DOPE-YAS-Tb: (A) phase-contrast image, (B) steady-state TIRF image, and (C) time-resolved TIRF image. The image size is 160 $\mu\text{m} \times 118 \mu\text{m}$.

ture of the chelating group is very similar to YAS-Tb, the quantum yield of DOPE-YAS-Tb is not expected to be significantly different from 0.1, the value reported previously for YAS-Tb (21).

Fluorescence Microscopy. Cell Adhesion on Fused Silica. Shown in Figure 3 are phase-contrast and TIRF images of a 3T3 cell plated on a fused silica substrate, fixed 24 h later, and stained with DOPE-YAS-Tb. Under steady-state excitation (Figure 3B), the cell exhibits spatially distributed patches of green fluorescence. The brightest patches are in regions adjacent to the nucleus and at the cell periphery (identified from the

Figure 4. Steady-state (upper curve) and time-resolved (lower curve) TIRF spectra of a 3T3 cell cultured on a fused silica substrate for 24 h, fixed, and stained with DOPE-YAS-Tb.

phase-contrast image). A steady-state emission spectrum of this cell is shown in Figure 4. The emission bands at 490, 545, and 590 nm which can be attributed to the Tb label are superimposed on a broad background emission, which is due to cellular autofluorescence (18) that occurs over the entire 400–600 nm region.

The corresponding time-resolved TIRF image of the same cell is shown in Figure 3C. Although the pattern is similar, the emission intensity is reduced relative to that of the steady-state image (Figure 3B). The corresponding time-resolved TIRF spectrum is displayed in Figure 4. It is apparent that gating the detection system essentially eliminates the broad-band autofluorescence present in the steady-state spectrum (Figure 4, upper curve), leaving the characteristic Tb^{3+} emission bands superimposed on a relatively flat background. Thus, the emission pattern in the time-resolved image (Figure 3C) arises almost entirely from the DOPE-YAS-Tb label. Elimination of the autofluorescence occurs because its lifetime is considerably shorter [in the nanosecond range (18)] than the delay period before the liquid crystal shutter was opened to expose the CCD.

The percentage of DOPE-YAS incorporated into the membranes of fixed cells via the labeling procedure described above was not determined. The percentage of incorporated DOPE-YAS molecules that were complexed with Tb^{3+} was also not determined. However, on the basis of a formation constant of 10^{17} reported previously for YAS-Tb (21), the affinity of binding of Tb^{3+} to DOPE-YAS is likely to be very strong, and thus, the percentage of incorporated DOPE-YAS molecules that are complexed with Tb^{3+} is probably near unity. Furthermore, the fluorescence emission intensity from fixed cells incubated with $16 \mu\text{M}$ TbCl_3 for 10 min followed by rinsing with deionized water (i.e., the cells were not stained with DOPE-YAS) was indistinguishable from the background intensity due to cellular autofluorescence. This result shows that, in the absence of DOPE-YAS labeling, fixed 3T3 cells have relatively little binding affinity for Tb^{3+} .

Cell Adhesion on a Polystyrene-Coated Fused Silica Substrate. The steady-state TIRF spectrum of an unstained 3T3 cell that was fixed 72 h after being plated on a fused silica substrate coated with polystyrene (PS) is shown in Figure 5A. The broad emission band with a maximum near 450 nm in the steady-state spectrum is due to autoemission from both the cell and the polymer film [the emission maximum of the PS itself was near

Figure 5. (A) Steady-state (upper curve) and time-resolved (lower curve) TIRF spectra of a fixed, unstained 3T3 cell cultured on a PS-coated silica substrate for 72 h. (B) Steady-state (upper curve) and time-resolved (lower curve) TIRF spectra of a 3T3 cell cultured on a PS-coated silica substrate for 72 h, fixed, and stained with DOPE-YAS-Tb.

520 nm (spectrum not shown)]. The time-resolved TIRF spectrum, also plotted in Figure 5A, shows that both sources of autoemission are essentially eliminated when time-resolved detection is implemented.

Phase-contrast and TIRF images of a 3T3 cell plated on a PS-coated fused silica substrate, fixed 72 h later, and stained with DOPE-YAS-Tb are shown in Figure 6. The steady-state TIRF image shows spatially distributed patches of green fluorescence similar to those present in the images of the stained cell that adheres to fused silica (Figure 3). The steady-state emission spectrum of the cell shown in Figure 6 is plotted in Figure 5B and shows the Tb emission bands superimposed on the autoemission background which arises from the cell and the polymer film. The corresponding time-resolved TIRF image and spectrum of the same cell are shown in Figures 6C and 5B, respectively. A comparison of the two spectra shows that time-resolved detection essentially eliminates the background. Thus, with the background removed, the time-resolved image represents the actual spatial distribution of the Tb label in the cell.

Steady-state and time-resolved TIRF spectra were also acquired from the three subcellular regions outlined by the boxes shown in Figure 6A. The spectra are plotted in Figure 7. In regions 1 and 2, the steady-state emission intensities at 545 nm are approximately 1.9×10^4 and 1.6×10^4 counts per second, respectively. However, the

Figure 6. Images of a 3T3 cell cultured on a PS-coated silica substrate for 72 h, fixed, and labeled with DOPE-YAS-Tb: (A) phase-contrast image, (B) steady-state TIRF image, and (C) time-resolved TIRF image. The image size is $176\ \mu\text{m} \times 176\ \mu\text{m}$. The regions outlined by the boxes in panel A represent an area of $865\ \mu\text{m}^2$ each.

time-resolved emission intensities, which more accurately reflect the relative number densities of DOPE-YAS-Tb in the two regions, are nearly equal at 545 nm. Thus, the difference observed in the steady-state mode is due primarily to differences in background intensity between the two regions. This comparison illustrates the fact that quantitative conversion of a digital TIRFM image to a map of contact region morphology can be compromised by extraneous emission from the cell and/or the substrate. The severity of the problem may be greater when the label emission intensity is much lower, such as in region 3, in which the mean cell-substrate gap is presumably larger than that in regions 1 and 2.

Assessment. In a previous paper (18), we showed that background emission in TIRFM of substrate-adherent cells due to cellular autofluorescence could be rejected using a Tb chelate as a staining agent coupled with time-resolved detection. However, the Tb chelates examined in that study stained not only the plasma membrane but also cytoplasmic regions, including the nucleus, which made interpretation of the TIRF images somewhat ambiguous. Since the Tb chelate described in this study is a modified lipid, it was expected to exhibit greater selectivity for the membranes of substrate-adherent cells. The TIRF images shown in Figures 3 and 6 are consistent with this expectation. The spatial distribution of fluo-

rescence emission is similar to that observed for cells labeled with DiI (data not shown) and with TIRF images of substrate-adherent cells that have appeared in the literature (3–5, 9). Since the penetration depth of the evanescent wave used to generate the TIRF images shown in Figures 3 and 6 is less than 100 nm, the images presumably represent the ventral membrane topography of the cells. However, to identify particular regions as (for example) focal contacts, a complementary technique should be employed, such as immunofluorescence staining for a protein known to be present in these regions [e.g., vinculin (4, 26)].

Cell adhesion, growth, and motility on polymeric materials is a very active area of research because these materials are widely used in implantable devices (24, 27–30). However, the use of TIRFM in studying cell adhesion behavior on biomedical polymers has been very limited to date, which is due in part to the high background emission characteristic of these materials. As noted above, converting a digital TIRFM image to a quantitative map of cell-substrate contact region morphology requires that the background emission be minimal or be removed (5). The results described herein show that the use of DOPE-YAS-Tb as a membrane-staining agent eliminates the background problem for polystyrene, which is a relatively poor substrate material for TIRFM

Figure 7. Steady-state and time-resolved TIRF spectra (upper and lower curves, respectively, in each pair of spectra) acquired from three subregions of the cell shown in Figure 6. The numbers on each pair of spectra correspond to the labeled subregions shown in Figure 6A.

studies due to its intrinsic autoluminescence and Raman scattering (19). This technique may therefore be useful in TIRFM studies of cell adhesion on other types of polymers, although we have not yet tested materials other than PS.

Finally, we note that the TIRFM experiments described above were performed on fixed cells. The degree to which live cells internalize DOPE-YAS was not investigated. Internalization is undesirable since it produces fluorescence emission from regions of the cell other than the plasma membrane. In the presence of significant emission originating from the cell interior, the use of digital TIRFM to quantitatively assess cell-substrate separation distances would be problematic (10).

A series of 6-(ω -methanesulfonylthioalkoxy)-2-*N*-methyl-1,2,3,4-tetrahydroisoquinolines (**7a–d**) was prepared and characterized as SH-reactive molecular yardsticks useful in probing α_2 -adrenergic receptors. Rapid displacement of the methanesulfonyl group by a cysteine residue in dilute aqueous solution with concomitant formation of a disulfide conjugate was verified by MALDI-TOF mass spectrometric analysis of the reaction of **7a** with a cysteine-containing decapeptide. **7a–d** all showed a marked affinity for the three different variants of human α_2 -adrenergic receptors: H α_{2A} wt, H α_{2B} -wt, and mutant H α_{2A} Ser201Cys197. However, only the mutated receptor (H α_{2A} Ser201Cys197) was irreversibly inactivated, and the extent of inactivation in this case was linearly dependent on the length of the side chain of **7a–d**. These results show that the molecular yardstick approach tested here can provide useful information for modeling receptor proteins.

INTRODUCTION

The α_2 -adrenergic receptors, for which there are three distinct subtypes in humans (α_{2A} , α_{2B} , and α_{2C}) (1–3), mediate many of the physiological and pharmacological effects of norepinephrine and epinephrine. As typical G-protein-coupled receptors, each consists of a single polypeptide chain spanning the cell membrane seven times with three intra- and three extracellular loops (4). The seven transmembrane segments are believed to be conserved α -helical elements forming the binding site for not only the endogenous transmitters but also small molecule analogues, such as oxymetazoline, chlorpromazine, UK 14,304, dexmedetomidene, and alkylated tetrahydroisoquinolines. All these compounds show a different pattern of subtype selectivity, and hence different pharmacological actions (5, 6).

Elucidation of the structural details of the binding domain of receptor proteins can facilitate the development of new therapeutic agents, exhibiting improved selectivity. However, primarily because of their membrane protein nature, direct structural studies (e.g., X-ray crystallography or NMR) on these receptors have so far not yielded high-resolution data despite considerable efforts. In attempts to obtain experimental information on receptor structure, mutagenesis studies in combination with pharmacological characterization have been popular, with over 200 literature references in the area

of G-protein-coupled receptors. However, these studies suffer from the limitation that noncovalent interactions are involved which introduces uncertainty in the interpretation stage. So far and because of their importance to the pharmaceutical industry, molecular modeling by a variety of means has been used to produce crude models, but there is still no consensus as to which residues line the binding cavity.

In a previous study, a new biochemical approach for mapping the binding site crevice of the human α_2 -adrenergic receptors (α_2 -ARs) was introduced by us (7). Based on a three-dimensional (3D) receptor model, each of the residues (197–201 and 204) in the fifth transmembrane domain (TM5) of the human α_{2A} -AR was changed to cysteine (Cys). Subsequently, the irreversible binding of chloroethylclonidine (CEC), an alkylating derivative of the α_2 -adrenergic agonist clonidine, was used as a criterion for identifying the introduced Cys residues as being exposed in the binding cavity. Thus, the results supported a model in which Val197, Ser200, Cys201, and Ser204 are exposed to the binding cavity and residues Ile198, Ser199, Ile202, and Gly203 face the lipid bilayer of the plasma membrane. To extend the utility of this approach, a molecular yardstick approach series of new synthetic receptor ligands was designed and synthesized. The new compounds (**7a–d**) have a *N*-methyl-1,2,3,4-tetrahydroisoquinoline core conferring α_2 -AR affinity, a methanesulfonylthio group making them Cys-reactive, and an alkyl linker of variable length connecting the two functional moieties. The basic assumption is that varying the length of the linker affects the alkylating properties of **7a–d** by placing distance constraints on the receptor–ligand interaction. This paper describes the synthesis, molecular modeling, and initial characterization of the set of 6-(ω -methanesulfonylthioalkoxy)-2-*N*-methyl-1,2,3,4-tetrahydroisoquinolines (**7a–d**) as site-specific labeling agents providing information that is useful for further improving the reliability of 3D models

of α_2 -ARs, as well as other closely related receptors. A similar chemistry has very recently been applied by Berglund et al. (8) to obtain a series of chemically modified cysteine mutants of subtilisin.

EXPERIMENTAL PROCEDURES

General Methods. Chromatographic purifications were carried out on Kieselgel 60 (Merck) silica gel and TLC analyses on Alufolien Kieselgel 60 F₂₅₄ (Merck) TLC plates, using the following eluent systems: system A, 8:92 methanol/dichloromethane (v/v); system B, 1.5:98.5 methanol/dichloromethane (v/v); and system C, 7:93 triethylamine/dichloromethane (v/v). The NMR spectra were recorded on JEOL JNM-GX 400, JEOL JNM-A 500, or Bruker AW 80 NMR spectrometers. The chemical shifts are given in parts per million from internal TMS. The mass spectra of small molecular compounds were recorded on a 7070E VG mass spectrometer, and that of the peptide conjugate was recorded on a Finnigan MAT Lasermat mass spectrometer. Pyridine was dried by refluxing with CaH₂ and then stored over 4 Å molecular sieves. [³H]RX821002 [2-(2-methoxy-1,4-benzodioxan-2-yl)-2-imidazoline] was from Amersham (Buckinghamshire, U.K.; specific activity of 52 Ci/mmol). Phentolamine and CEC were from Research Biochemicals Inc. (Natick, MA). Cell culture reagents were supplied by Gibco (Gaithersburg, MD). The construction of expression vectors and receptor production have been described elsewhere (7). Saturation isotherms of [³H]RX821002 binding when analyzed by LIGAND (9) gave the following receptor affinities (K_d) and receptor densities (B_{max}): 0.60 ± 0.02 nM (B_{max} = 595 ± 2 fmol mg⁻¹) for H α_{2A} wt, 6.12 ± 0.46 nM (B_{max} = 1870 ± 111 fmol mg⁻¹) for H α_{2B} wt, and 0.53 ± 0.05 nM (B_{max} = 295 ± 22 fmol mg⁻¹) for H α_{2A} -Ser201Cys197 (7).

The radioligand binding assays were performed with cell homogenates in potassium phosphate buffer as previously described (10). Competition and inactivation studies were carried out using [³H]RX821002 concentrations that were close to its affinity constant (K_d) at each receptor and 10–13 concentrations of the competitors.

The receptor inactivation was investigated in parallel assays with CEC and **7a–d**. The concentrations used for inactivation were 2–3 K_i (inhibition constant) for each compound. The cell homogenates were first incubated with CEC (1 μ M) or **7a–d** (5 μ M) in 2.5 mL of potassium phosphate buffer for 45 min at 37 °C. The protein content was 0.3–0.5 mg/mL. The cell membranes were then pelleted at 40000g for 15 min at 4 °C, washed twice with 2.5 mL of ice-cold potassium phosphate buffer, and rehomogenized with the Ultra-Turrax homogenizer. Residual α_2 -AR binding was assessed by incubating the membranes (0.1–0.2 mg of protein/assay tube) with 2.5 nM [³H]RX821002. Nonspecific binding was determined by including 10 μ M phentolamine in parallel assays.

Molecular Modeling. The Tripos program Sybyl was used to perform molecular modeling on a Silicon Graphics Indigo 2 machine fitted with 128 megabytes of memory. The starting structure of each of the compounds in the series had the reactive side chain in a fully extended conformation and the amine nitrogen atom assigned an N4 atom type. Energy minimization was performed using the Tripos force field without electrostatics. Conformational dynamics were calculated using the Tripos force field without electrostatics, at 310 K, for a 1 ns time period, with a step size of 1 fs, saving coordinates every 50 fs. The dynamic trajectory frames were read into standard Sybyl tables, where atom–atom distances were calculated and statistical analysis was performed.

6-Methoxy-2-N-methyl-1,2,3,4-tetrahydroisoquinoline 2. 6-Methoxy-1,2,3,4-tetrahydroisoquinoline (**1**) (1.28 g, 7.8 mmol) was dissolved into a mixture of formic acid (1.5 mL) and formaldehyde (1.4 mL of a 40% aqueous solution). The reaction mixture was first warmed to 30 °C and, when the formation of CO₂ was ceased, to 80 °C. After 4 h, the reaction mixture was made acidic (pH ~ 3) with dilute aqueous hydrogen chloride and then washed with diethyl ether. The aqueous solution was made alkaline with aqueous sodium hydroxide and extracted with diethyl ether. The organic layer was separated, dried on Na₂SO₄, and evaporated to dryness. Yield: 1.1 g (80%). MS(EI) (relative intensity): 176 (100, M⁺ – 1), 161 (20), 134 (93). ¹H NMR (400 MHz, CDCl₃): 6.93 (d, 1H, *J* = 8.4 Hz), 6.69 (dd, 1H, *J* = 2.6 Hz, *J* = 8.4 Hz), 6.64 (d, 1H, *J* = 2.6 Hz), 3.77 (s, 3H), 3.52 (s, 2H), 2.90 (t, 2H, *J* = 6.0 Hz), 2.66 (t, 2H, *J* = 6.0 Hz), 2.45 (s, 3H). ¹³C NMR (100 MHz, CDCl₃): 29.5, 46.1, 52.8, 55.2, 57.5, 112.0, 113.2, 127.0, 127.3, 134.9, 157.9.

6-Hydroxy-2-N-methyl-1,2,3,4-tetrahydroisoquinoline 3. **2** (1.07 g, 6.0 mmol) was dissolved in 25 mL of 47% aqueous HBr and refluxed for 4 h under nitrogen. The solution was evaporated to dryness, and **3** was recrystallized from ethanol as hydrobromide. A total of 1.2 g (81%) of white crystals was obtained. MS(EI) (relative intensity): 162 (100, M⁺ – 1), 120 (60). ¹H NMR (400 MHz, DMSO-*d*₆): 9.88 (s, 1H), 9.53 (s, 1H), 6.99 (d, 1H, *J* = 8.4 Hz), 6.68 (dd, 1H, *J* = 2.6 Hz, *J* = 8.3 Hz), 6.62 (d, 1H, *J* = 2.5 Hz), 4.37 (d, 1H, *J* = 14.4 Hz), 4.16 (dd, 1H, *J* = 8.2 Hz, *J* = 14.4 Hz), 3.62 (m, 1H), 3.29 (m, 1H), 3.07 (m, 1H), 2.97 (m, 1H), 2.91 (d, 3H, *J* = 4.3 Hz). ¹³C NMR (100 MHz, DMSO-*d*₆): 25.1, 41.9, 50.3, 53.5, 114.3, 114.5, 118.4, 127.6, 131.9, 156.8.

The hydrobromide of **3** (1.0 g, 4.1 mmol) was dissolved in water, and 2 mol L⁻¹ aqueous sodium hydroxide (2.0 mL, 4.1 mmol) was added. The precipitated product was filtered, washed with a small amount of water, and dried under reduced pressure. Yield: 0.52 g (77%). MS(EI) (relative intensity): 162 (100, M⁺ – 1), 120 (66). ¹H NMR (400 MHz, DMSO-*d*₆): 9.07 (s, 1H), 6.80 (d, 1H, *J* = 8.3 Hz), 6.49 (dd, 1H, *J* = 2.5 Hz, *J* = 8.3 Hz), 6.46 (d, 1H, *J* = 2.2 Hz), 3.33 (s, 2H), 2.69 (t, 2H, *J* = 5.7 Hz), 2.50 (t, 2H, *J* = 5.7 Hz), 2.28 (s, 3H). ¹³C NMR (100 MHz, DMSO-*d*₆): 29.3, 46.2, 52.8, 57.5, 113.4, 114.9, 125.5, 127.4, 135.0, 155.7.

6-(Triphenylmethoxy)-1-hexanol 8d. Triphenylmethyl chloride (10.0 g, 36 mmol) was dissolved in dry pyridine, and 10.6 g (90 mmol) of 1,6-hexanediol was added. After 16 h, the reaction mixture was diluted with dichloromethane, washed with aqueous sodium bicarbonate and brine, dried on Na₂SO₄, and evaporated to dryness. The product was purified by silica gel chromatography (system B). Yield: 11.9 g (92%). ¹H NMR (80 MHz, CDCl₃): 7.10–7.50 (m, 15H), 3.60 (t, 2H, *J* = 5 Hz), 3.05 (t, 2H, *J* = 5 Hz), 1.20–1.70 (m, 8H).

5-(Triphenylmethoxy)-1-pentanol 8c was prepared from 1,5-pentanediol as previously described for **8d**. Yield: 84%. ¹H NMR (80 MHz, CDCl₃): 7.10–7.50 (m, 15H), 3.60 (t, 2H, *J* = 5 Hz), 3.05 (t, 2H, *J* = 5 Hz), 1.25–1.70 (m, 6H).

4-(Triphenylmethoxy)-1-butanol 8b was prepared from 1,4-butanediol as previously described for **8d**. Yield: 90%. ¹H NMR (80 MHz, CDCl₃): 7.10–7.50 (m, 15H), 3.60 (t, 2H, *J* = 5 Hz), 3.10 (t, 2H, *J* = 5 Hz), 1.55–1.75 (m, 4H).

3-(Triphenylmethoxy)-1-propanol 8a was prepared from 1,3-propanediol as previously described for **8d**. Yield: 65%. ¹H NMR (400 MHz, CDCl₃): 7.2–7.5 (m,

15H), 3.77 (t, 2H, $J = 5.8$ Hz), 3.28 (t, 2H, $J = 5.8$ Hz), 1.86 (m, 2H).

6-[(6-Hydroxyhexyl)oxy]-2-*N*-methyl-1,2,3,4-tetrahydroisoquinoline 5d. **3** (0.50 g, 3.1 mmol) was dissolved in THF. **8d** (1.5 g, 4.3 mmol) and triphenylphosphine (0.96 g, 3.7 mmol) were added. To this solution was added dropwise 0.57 mL (3.7 mmol) of diethyl azodicarboxylate (DEAD), and the mixture was left to stand for 24 h. After completion of the reaction (TLC, system A), dichloromethane was added and the solution was washed with aqueous sodium bicarbonate, dried with Na_2SO_4 , and evaporated. **4d** was dissolved in 25 mL of 1 mol L^{-1} aqueous hydrogen chloride, and the mixture was refluxed for 1 h, allowed to cool to room temperature, and washed with ethyl acetate. Aqueous sodium hydroxide solution was added, and the product was extracted to ethyl acetate, dried on Na_2SO_4 , and evaporated. The product was purified by silica gel chromatography (system C). Yield: 0.53 g (66%). MS(EI) (relative intensity): 262 (100, $\text{M}^+ - 1$), 220 (12), 162 (36), 120 (45). ^1H NMR (400 MHz, CDCl_3): 6.92 (d, 1H, $J = 8.5$ Hz), 6.68 (dd, 1H, $J = 2.4$ Hz, $J = 8.5$ Hz), 6.63 (d, 1H, $J = 2.2$ Hz), 3.92 (t, 2H, $J = 6.6$ Hz), 3.65 (t, 2H, $J = 6.6$ Hz), 3.51 (s, 2H), 2.89 (t, 2H, $J = 5.8$ Hz), 2.65 (t, 2H, $J = 5.8$ Hz), 2.44 (s, 3H), 1.74–1.81 (m, 2H), 1.56–1.63 (m, 2H), 1.38–1.52 (m, 4H). ^{13}C NMR (100 MHz, CDCl_3): 25.6, 25.9, 29.3, 29.5, 32.7, 46.1, 52.9, 57.5, 62.8, 67.8, 112.5, 113.9, 126.8, 127.3, 134.9, 157.5.

6-[(5-Hydroxypentyl)oxy]-2-*N*-methyl-1,2,3,4-tetrahydroisoquinoline 5c was prepared from **3c** as previously described for **5d**. Yield: 62%. MS(EI) (relative intensity): 248 (100, $\text{M}^+ - 1$), 206 (11), 162 (49), 120 (57). ^1H NMR (400 MHz, CDCl_3): 6.92 (d, 1H, $J = 8.3$ Hz), 6.68 (dd, 1H, $J = 2.4$ Hz, $J = 8.6$ Hz), 6.63 (d, 1H, $J = 2.2$ Hz), 3.92 (t, 2H, $J = 6.4$ Hz), 3.65 (t, 2H, $J = 6.4$ Hz), 3.51 (s, 2H), 2.89 (t, 2H, $J = 5.9$ Hz), 2.66 (t, 2H, $J = 5.9$ Hz), 2.44 (s, 3H), 1.75–1.82 (m, 2H), 1.59–1.66 (m, 2H), 1.45–1.55 (m, 2H). ^{13}C NMR (100 MHz, CDCl_3): 22.4, 29.1, 29.5, 32.5, 46.1, 52.8, 57.5, 62.7, 67.8, 112.5, 113.9, 126.8, 127.3, 134.9, 157.4.

6-[(4-Hydroxybutyl)oxy]-2-*N*-methyl-1,2,3,4-tetrahydroisoquinoline 5b was prepared from **3b** as previously described for **5d**. Yield: 67%. MS(EI) (relative intensity): 234 (93, $\text{M}^+ - 1$), 192 (7), 162 (63), 120 (100). ^1H NMR (500 MHz, CDCl_3): 6.92 (d, 1H, $J = 8.4$ Hz), 6.69 (dd, 1H, $J = 2.6$ Hz, $J = 8.4$ Hz), 6.64 (d, 1H, $J = 2.5$ Hz), 3.97 (t, 2H, $J = 6.3$ Hz), 3.71 (t, 2H, $J = 6.3$ Hz), 3.52 (s, 2H), 2.89 (t, 2H, $J = 6.0$ Hz), 2.67 (t, 2H, $J = 6.0$ Hz), 2.44 (s, 3H), 1.84–1.89 (m, 2H), 1.72–1.77 (m, 2H). ^{13}C NMR (100 MHz, CDCl_3): 25.9, 29.4, 29.6, 46.0, 52.7, 57.4, 62.6, 67.9, 112.5, 114.0, 126.8, 127.3, 134.9, 157.4.

6-[(3-Hydroxypropyl)oxy]-2-*N*-methyl-1,2,3,4-tetrahydroisoquinoline 5a was prepared from **3a** as previously described for **5d**. Yield: 73%. MS(EI) (relative intensity): 220 (100, $\text{M}^+ - 1$), 178 (29), 162 (46), 120 (50). ^1H NMR (400 MHz, $\text{DMSO}-d_6$): 6.87 (d, 1H, $J = 8.3$ Hz), 6.6 (m, 2H), 3.92 (t, 2H, $J = 6.3$ Hz), 3.49 (t, 2H, $J = 6.1$ Hz), 3.33 (s, 2H), 2.72 (t, 2H, $J = 5.6$ Hz), 2.49 (t, 2H, $J = 5.9$ Hz), 2.26 (s, 3H), 1.73–1.83 (m, 2H). ^{13}C NMR (100 MHz, $\text{DMSO}-d_6$): 29.0, 32.2, 45.8, 52.3, 56.9, 57.3, 64.4, 112.3, 113.5, 126.8, 127.0, 134.8, 156.8.

6-(6-Methanesulfonyloxyhexoxy)-2-*N*-methyl-1,2,3,4-tetrahydroisoquinoline 6d. **5d** (0.26 g, 1.0 mmol) was dissolved in a small amount of dry pyridine, and 10 mg of (dimethylamino)pyridine and 0.21 g (1.2 mmol) of methanesulfonyl anhydride were added. After completion of reaction (TLC, system A), dichloromethane was added and the solution was washed with aqueous sodium bicarbonate. The organic layer was dried on Na_2SO_4 and evaporated.

The product was purified by silica gel chromatography (system A). Yield: 0.20 g (59%). MS(EI) (relative intensity): 340 (100, $\text{M}^+ - 1$), 298 (19), 244 (14), 162 (35), 120 (48).

6-(5-Methanesulfonyloxypropoxy)-2-*N*-methyl-1,2,3,4-tetrahydroisoquinoline 6c was prepared from **5c** as previously described for **6d**. Yield: 61%. MS(EI) (relative intensity): 326 (100, $\text{M}^+ - 1$), 284 (21), 230 (15), 162 (47), 120 (64).

6-(4-Methanesulfonyloxybutoxy)-2-*N*-methyl-1,2,3,4-tetrahydroisoquinoline 6b was prepared from **5b** as previously described for **6d**. Yield: 52%. MS(EI) (relative intensity): 312 (100, $\text{M}^+ - 1$), 270 (23), 216 (14), 162 (38), 120 (33).

6-(3-Methanesulfonyloxypropoxy)-2-*N*-methyl-1,2,3,4-tetrahydroisoquinoline 6a was prepared from **5a** as previously described for **6d**. Yield: 62%. MS(EI) (relative intensity): 298 (100, $\text{M}^+ - 1$), 256 (15), 202 (10), 162 (40), 120 (50).

6-(6-Methanesulfonylthiohexoxy)-2-*N*-methyl-1,2,3,4-tetrahydroisoquinoline 7d. **6d** (0.18 g, 0.5 mmol) was dissolved in ethanol, and 0.15 g (1.1 mmol) of sodium methanethiosulfonate was added. The reaction mixture was incubated for 65 h at 50 °C and then diluted with dichloromethane. After being washed with aqueous sodium bicarbonate, being dried on Na_2SO_4 , and evaporation, the product was purified by silica gel chromatography (system A). Yield: 82 mg (42%). MS(EI) (relative intensity): 356 (100, $\text{M}^+ - 1$), 278 (24), 162 (33), 146 (11), 120 (39). ^1H NMR (500 MHz, CDCl_3): 6.93 (d, 1H, $J = 8.4$ Hz), 6.69 (dd, 1H, $J = 2.6$ Hz, $J = 8.4$ Hz), 6.63 (d, 1H, $J = 2.5$ Hz), 3.92 (t, 2H, $J = 6.3$ Hz), 3.59 (s, 2H), 3.32 (s, 3H), 3.18 (t, 2H, $J = 7.4$ Hz), 2.92 (t, 2H, $J = 6.1$ Hz), 2.74 (t, 2H, $J = 6.1$ Hz), 2.50 (s, 3H), 1.76–1.82 (m, 4H), 1.49–1.51 (m, 4H). ^{13}C NMR (120 MHz, CDCl_3): 25.5, 28.3, 29.0, 29.1, 29.5, 36.4, 45.7, 50.6, 52.6, 57.1, 67.6, 112.7, 113.9, 126.2, 127.4, 134.6, 157.5.

6-(5-Methanesulfonylthiopentoxo)-2-*N*-methyl-1,2,3,4-tetrahydroisoquinoline 7c was prepared from **6c** as previously described for **7d**. Yield: 39%. MS(EI) (relative intensity): 342 (100, $\text{M}^+ - 1$), 264 (36), 162 (68), 146 (18), 120 (68). ^1H NMR (400 MHz, CDCl_3): 6.93 (d, 1H, $J = 8.6$ Hz), 6.68 (dd, 1H, $J = 2.7$ Hz, $J = 8.6$ Hz), 6.63 (d, 1H, $J = 2.2$ Hz), 3.94 (t, 2H, $J = 6.3$ Hz), 3.60 (s, 2H), 3.32 (s, 3H), 3.20 (t, 2H, $J = 7.3$ Hz), 2.93 (t, 2H, $J = 6.1$ Hz), 2.75 (t, 2H, $J = 6.1$ Hz), 2.51 (s, 3H), 1.77–1.87 (m, 4H), 1.59–1.64 (m, 2H). ^{13}C NMR (120 MHz, CDCl_3): 25.2, 28.6, 29.1, 29.3, 36.3, 45.7, 50.7, 52.7, 57.2, 67.4, 112.7, 113.9, 126.2, 127.4, 134.6, 157.4.

6-(4-Methanesulfonylthiobutoxy)-2-*N*-methyl-1,2,3,4-tetrahydroisoquinoline 7b was prepared from **6b** as previously described for **7d**. Yield: 36%. MS(EI) (relative intensity): 328 (100, $\text{M}^+ - 1$), 250 (21), 162 (62), 146 (12), 120 (38). ^1H NMR (400 MHz, CDCl_3): 6.93 (d, 1H, $J = 8.3$ Hz), 6.68 (dd, 1H, $J = 2.4$ Hz, $J = 8.3$ Hz), 6.63 (d, 1H, $J = 2.4$ Hz), 3.97 (t, 2H, $J = 5.9$ Hz), 3.59 (s, 2H), 3.33 (s, 3H), 3.26 (t, 2H, $J = 7.3$ Hz), 2.93 (t, 2H, $J = 5.9$ Hz), 2.74 (t, 2H, $J = 5.9$ Hz), 2.51 (s, 3H), 1.89–2.00 (m, 4H). ^{13}C NMR (100 MHz, CDCl_3): 26.5, 28.0, 29.0, 36.2, 45.7, 50.8, 52.6, 57.1, 66.9, 112.7, 113.9, 126.4, 127.4, 134.3, 157.1.

6-(3-Methanesulfonylthiopropoxy)-2-*N*-methyl-1,2,3,4-tetrahydroisoquinoline 7a was prepared from **6a** as previously described for **7d**. Yield: 14%. MS(EI) (relative intensity): 314 (100, $\text{M}^+ - 1$), 162 (39), 146 (19), 120 (24). ^1H NMR (500 MHz, CDCl_3): 6.93 (d, 1H, $J = 8.4$ Hz), 6.68 (dd, 1H, $J = 2.6$ Hz, $J = 8.3$ Hz), 6.64 (d, 1H, $J = 2.6$ Hz), 4.05 (t, 2H, $J = 7.4$ Hz), 3.57 (s, 2H), 3.37 (t, 2H, $J = 7.1$ Hz), 3.32 (s, 3H), 2.93 (t, 2H, $J = 6.0$

Hz), 2.72 (t, 2H, *J* = 6.0 Hz), 2.48 (s, 3H), 2.46 (m, 2H). ¹³C NMR (125 MHz, CDCl₃): 29.2, 29.4, 33.2, 45.8, 50.4, 52.6, 57.2, 65.3, 112.6, 113.9, 126.9, 127.5, 134.9, 156.9.

Hydrolysis of 7a-d. The rates of hydrolyses of **7a-d** were measured at 37 °C in potassium phosphate buffer (50 mM, pH 7.4). The aliquots of 40 μ L were withdrawn at suitable intervals and analyzed immediately by HPLC [Purospher RP-18e column, 0.050 mol L⁻¹ ammonium acetate buffer at pH 4.7, flow rate of 0.75 mL min⁻¹; elution, 85:15 buffer/MeCN for **7a-b**, 80:20 buffer/MeCN for **7c**, and 75:25 buffer/MeCN for **7d**; detection, 276 nm; *t_R*(**7a**) = 6.8 min, *t_R*(**7b**) = 12.6 min, *t_R*(**7c**) = 9.9 min, and *t_R*(**7d**) = 8.6 min]. The first-order rate constants were 4.3×10^{-4} , 3.7×10^{-4} , 3.2×10^{-4} , and 2.8×10^{-4} s⁻¹ for **7a-d**, respectively.

Reaction of 7a with Peptide YVISSCIGSF. One milligram (0.93 μ mol) of the 10-mer oligopeptide Tyr-Val-Ile-Ser-Ser-Cys-Ile-Gly-Ser-Phe was dissolved in 10 mL of 50 mmol L⁻¹ potassium phosphate buffer (pH 7.4 at 21 °C), and 2 equiv of **7a** (0.58 mg, 1.86 μ mol) was added. The reaction mixture was incubated for 60 min at 37 °C. Analysis by MALDI-TOF mass spectroscopy verified the conjugation. MS(MALDI): 1313.7. The reaction of **7a** with YVISSCIGSF was further studied by HPLC. The peptide (0.3 μ mol mL⁻¹) was treated with 1 equiv of **7a**, and the aliquots withdrawn were immediately chromatographed on a Purospher RP-18e column (0.050 mol L⁻¹ ammonium acetate buffer at pH 4.7, flow rate of 0.75 mL min⁻¹; elution, 85:15 buffer/MeCN; detection, 276 nm).

RESULTS

Synthesis of 6-(ω -Methanesulfonylthioalkoxy)-2-N-methyl-1,2,3,4-tetrahydroisoquinolines. 6-Methoxy-1,2,3,4-tetrahydroisoquinoline (**1**) was prepared as described earlier (11); the nitrogen atom was methylated by an Eschweiler-Clarke reaction (**2**), and the 6-methoxy group was converted to a 6-hydroxy group with boiling of aqueous 48% hydrogen bromide under nitrogen (**3**). The phenolic hydroxy function of **3** was then displaced with an appropriate monotritylated α,ω -diol by Mitsunobu reaction, and the product (**4a-d**) was detritylated to give **5a-d** (Scheme 1).

Several alkyl methanethiosulfonates have previously been prepared from alkyl halides by S_N2 substitution

Scheme 2^a

^a (i) Methanesulfonic anhydride/Py, 20 h; (ii) sodium methanethiosulfonate, EtOH, 50 °C, 65 h; (iii) *p*-toluenesulfonyl chloride/Py.

with sodium methanethiosulfonate. Accordingly, conversion of **5a-d** to the corresponding tosylates, followed by displacement with sodium methanethiosulfonate, was considered to be a viable route to **7a-d**. However, all attempts to convert **5a-d** to tosylates were unsuccessful. By contrast, less reactive mesylates **6a-d** could be easily obtained. Use of mesyl anhydride, instead of the more commonly used mesyl chloride, proved to be essential, since **6a-d** reacted surprisingly easily with the chloride ion released to the reaction mixture upon the S_N2 displacement. Compounds **6a-d** turned out to be relatively unstable. To obtain reasonable yields of **7a-d**, the reaction with sodium methanethiosulfonate had to be started immediately after silica gel purification of **6a-d** (Scheme 2).

Covalent Coupling of 7a to Model Peptide YVISSCIGSF. The applicability of **7a-d** in protein labeling, and hence as useful agents in α_2 -adrenergic receptor mapping, was demonstrated by reacting one of them with a cysteine residue of model peptide YVISSCIGSF. This peptide is part of the TM5 region of the human α_{2A} -AR. Two equivalents of **7a** was added to the solution of the model peptide in 0.050 mol L⁻¹ potassium phosphate buffer (pH 7.4 at 21 °C) at 37 °C, and after 1 h, a matrix-assisted laser desorption mass spectrum was recorded from the reaction mixture. The disappearance of the signal referring to peptide YVISSCIGSF and the appearance of a new signal at higher field by 235 mass units indicated that **7a** had formed a covalent conjugate with the peptide (Figure 1). The half-lives for the hydrolysis of **7a-d** were observed to be 27 (**7a**), 31 (**7b**), 36 (**7c**), and 41 min (**7d**) under the conditions employed in the conjugation with the peptide. When the model peptide was treated at a 0.3 mmol L⁻¹ concentration with 1 equiv of the most labile labeling agent (**7a**), the HPLC signal of **7a** qualitatively disappeared in 2 min at 37 °C. Accordingly, the hydrolysis of **7a-d** is slow enough to ensure efficient conjugation with the peptide.

Molecular Modeling. Table 1 presents a summary of intramolecular atom-atom distances between the ω -sulfur and both the phenoxyl oxygen and the quaternary ammonium nitrogen occurring in the molecular dynamics trajectory of **7a-d**. The maximal distance from the ether oxygen to the ω -sulfur in the side chain (*n* = 3–6) spans from 5.3 to 8.7 Å and that from the amine nitrogen to sulfur from 11.6 to 14.5 Å. The successive increment per methylene group is about 1 Å (the theoretical upper limit of the distance resolution by a molecular yardstick approach). Whereas the average distance for the O–S atom pairs is incremental, the average distance for the N–S atom pairs is not. This is a result of folding back of the linker in the longer (*n* = 6) side

Figure 1. MALDI-TOF spectra of peptide YVSSCIGSF (A) and its conjugate formed upon reaction with **7a** (B). The peaks at m/z 1078.0 and 1115.1 represent the peptide and its potassium adduct, and that at 1313.6 represents the peptide conjugate formed by the displacement of the methanesulfonyl group of **7a** by the peptide.

chain such that the shortest N–S distance of 3.4 Å is shorter than that of the other compound ($n = 3$), 4.8 Å.

Binding Affinity of CEC and **7a–d.** The CEC-resistant wild-type receptor H α_{2B} , the mutant H α_{2A} -Ser201Cys197, and H α_{2A} wt were all capable of binding CEC and **7a–d** (approximate K_i values of 34–2789 nM). Table 2 shows the results of competition binding assays, where CEC and **7a–d** were allowed to compete with the radioligand [^{3} H]RX821002 for binding to H α_{2A} wt, H α_{2B} -wt, and H α_{2A} Ser201Cys197 receptors. The K_i values

Figure 2. Effect of treatment with CEC and **7a–d** on binding activity of human α_2 -AR subtypes. CHO cells expressing human α_2 -AR subtypes H α_{2A} wt, H α_{2B} wt, and H α_{2A} Ser201Cys197 were incubated in the absence (control) and presence of CEC (1 μ M) or **7a–d** (5 μ M) for 45 min at 37 °C, followed by two washes. The residual α_2 -AR binding capacity was determined by incubation with 2.5 nM [^{3} H]RX821001. The nonspecific binding was determined with 10 μ M phentolamine. The results are expressed as the percentage of specific [^{3} H]RX821002 binding left after treatment with CEC or **7a–d**. The results are means $\pm$ SE of three or four experiments, each performed in duplicate.

obtained do not accurately represent competitive affinities of binding of the test compounds to the receptors; in the case of H α_{2A} wt and H α_{2A} Ser201Cys197 receptors, some irreversible binding is also taking place at this reaction temperature (25 °C). In any case, the results show that compounds **7a–d** have quite high affinities for the receptors tested, comparable to that of CEC.

Receptor Inactivation Studies. The alkylating effect of **7a–d** was tested on three H α_2 -AR variants (H α_{2A} wt, H α_{2B} wt, and the mutant H α_{2A} Ser201Cys197). Incubation of cell homogenates in the absence (control) and presence of CEC was performed for control purposes and as a reference for **7a–d**. CEC treatment reduced the binding capacity of H α_{2A} wt and H α_{2A} Ser201Cys197 by 61 and 91%, respectively, while H α_{2B} wt (lacking an exposed Cys residue) was not alkylated by CEC (Figure 2). In experiments with **7a–d**, the mutant H α_{2A} -Ser201Cys197 receptor was inactivated to a significant extent. Moreover, the degree of inactivation was linearly related to the length of the linker.

DISCUSSION

This study is part of a series of studies aimed at providing geometric constraints from biochemical studies for improving the structural modeling of α_2 -adrenergic receptor subtypes, which are important drug target sites. Previously, we have shown that amino acid residues Val197, Ser200, Cys201, and Ser204 of the human α_{2A} -AR are accessible inside the binding cavity using cysteine substitution and covalent labeling with chloroethylclonidine (CEC) (7). Thus, a hypothetical three-dimensional model of the receptor, albeit admittedly rather crude, was supported. As an alkylating agent, CEC reacts via a reactive aziridinium ion species and is expected to be of use in the identification of amino acid residues located inside the binding cavity within the fourth, fifth, and sixth transmembrane helical elements. The development of the 6-(ω -methanesulfonylthioalkoxy)-2-*N*-methyl-1,2,3,4-tetrahydroisoquinoline series is expected to aid in exploring regions of the receptor toward and outside the entrance of the binding cavity.

Previous chemical studies with simple alkyl methanesulfonothiolates, RSSO_2Me , show that the mercapto-methyl side chain of proteins is able to displace rapidly and quantitatively the methanesulfonyl group in dilute aqueous solution with concomitant formation of a disulfide linkage (12, 13). The specificity of this reaction for cysteine residues over other amino acid residues has also been demonstrated. Here, a pilot study was carried out on a 10-mer peptide with the sequence YVISCIGSF, part of the sequence of the fifth transmembrane-spanning segment of the human α_{2A} -AR, to determine the reaction conditions needed for biochemical inactivation studies of the receptor. The methanesulfonylthio group was the preferred labeling agent compared to more commonly used SH-reactive functions (including pyridyl disulfide, maleimido, and bromoacetyl groups) because it does not carry a formal charge, is relatively hydrophilic, and appears to be sterically less demanding. These features were attractive as they were considered less likely to affect pharmacophore interactions, as was borne out by similar binding affinities of the series.

Three receptors were chosen for these studies; $\text{H}\alpha_{2A}$ -wt (Cys in position 201), $\text{H}\alpha_{2B}$ -wt (Ser in position 177 corresponding to 201), and the mutant $\text{H}\alpha_{2A}\text{Ser201Cys197}$ (Cys in position 197 close to the extracellular surface of the plasma membrane and Ser in position 201 in place of the wild-type Cys 201) (7). Inactivation of the $\text{H}\alpha_{2A}\text{Ser201Cys197}$ indicates that the series of compounds **7a–d** bind to α_2 -ARs in a manner similar to that of CEC, with the quaternary amine group of the tetrahydroisoquinoline core forming an ion pair with Asp113 of the third transmembrane helical element (TM3), and the benzene ring occupying the cavity region formed by TM4–TM5–TM6. Assuming that the methanesulfonylthioalkyl groups of **7a–d** ($n = 3–6$) react with a cysteine thiol group at similar rates and with a similar mode of binding, then the linear relationship from $n = 3$ to $n = 6$ probably reflects a progressive distance approach of the reactive methanesulfonylthioalkyl headgroup toward Cys197. This is interpreted here as locating this residue position about 8.6–14.5 Å from the position of Asp113, with the lower and upper limit corresponding to the average and maximum distances, respectively, indicated by molecular dynamics for compound **7d** (Table 1).

We did not yet explore compounds with a chain length of greater than 6 as already at this length the molecular dynamics showed that for this chain length there is a

significant proportion of folded conformation accessed. Although a rigid side chain would have helped in the interpretation of the results, it is less likely to be accommodated by the receptor through unfavorable steric interactions.

Unlike CEC, none of the **7a–d** series inactivated the human $\text{H}\alpha_{2A}$ -AR, containing Cys201. In our previous study, we found that the relative rate of receptor inactivation by CEC was dependent on the location of the exposed Cys residue in the binding crevice. The Cys residues located close to the extracellular surface of the plasma membrane were alkylated significantly more avidly than those located deeper in the binding site pocket formed between the seven α -helical TM domains of the receptor protein. The $\text{H}\alpha_{2B}$ -wt receptor, which is resistant to the alkylating effect of CEC, was used as a negative control. However, as can be seen in Figure 2, a moderate level of inactivation was observed with the compounds where $n = 5$ and 6. This was possibly a result of covalent coupling to reactive residues in the loop region of the extracellular surface, which includes a cysteine residue in the loop between TM6 and TM7. That binding occurs before inactivation is indicated by comparison with a study on the D2 dopamine receptor by Javitch et al. (14). This study involved introduction of unique cysteine residues into the receptor followed by covalent labeling with a nonspecific cysteine methanesulfonylthio alkylating reagent. Concentrations in the millimolar range were required to cause receptor inactivation as opposed to the micromolar concentrations used in this study.

In summary, we show that the 6-(ω -methanesulfonylthioalkoxy)-2-*N*-methyl-1,2,3,4-tetrahydroisoquinolines have a binding mode similar to that of the human α_{2A} -AR as CEC, the binding mode in each case being supported by covalent coupling. In terms of a molecular yardstick approach, this preliminary study shows that compounds **7a–d** retain affinity at α_{2A} -ARs and that a linear relationship exists between linker length and target site inactivation.

Disulfide-Tethered Solid Supports for Synthesis of Photoluminescent Oligonucleotide Conjugates: Hydrolytic Stability and Labeling on the Support[†]

Harri Salo,* Andrei Guzaev,[‡] and Harri Lönnberg

Department of Chemistry, University of Turku, FIN-20014 Turku, Finland. Received November 10, 1997; Revised Manuscript Received March 11, 1998

Several new disulfide-tethered solid supports (**S1–S5**) were synthesized, and their resistance against ammonolysis was tested. Among these supports, only the one bearing an *N*-[15-[(4,4'-dimethoxytrityl)-oxy]-12,13-dithiapentadecanoyl] linker (**S4b**) tolerated ammonolysis and exhibited properties compatible with the oligonucleotide synthesis by phosphoramidite strategy. The applicability of this disulfide linker structure in postsynthetic oligonucleotide labeling on the support was demonstrated by introduction of two photoluminescent lanthanide chelates or two dansyl groups to the *N*⁴-(6-aminoethyl) amino-modified cytosine residues at the 5' end of the oligonucleotide sequence. Subsequent release of the resulting conjugates as their 3'-phosphates was achieved by reductive cleavage of the disulfide bond and precipitation of the conjugate from the solution with ethanol. The fluorescently tagged oligomer obtained showed hybridization properties similar to those of oligonucleotides labeled in solution.

INTRODUCTION

The introduction of polymerase chain reaction (PCR) (1) has been a launching pad for the development of an increasing number of hybridization assays for the detection of gene mutations. Methods utilizing fluorescent oligonucleotide conjugates have become the subject of particular interest (2–7). Besides organic fluorophores, photoluminescent lanthanide chelates have recently been exploited as markers in hybridization assays (8–13). These chelates offer some obvious advantages over conventional fluorescent dyes: (i) the luminescence lifetime is long (≈ 1 ms), allowing utilization of time-resolved measurement, (ii) the difference between the wavelength of excitation and main emission is large, (iii) the emission bands are narrow, and (iv) the concentration quenching is almost negligible (14). The most serious drawback is the rather laborious preparation of the oligonucleotide conjugates. Usually an oligonucleotide bearing a nucleophilic functionality, such as an aliphatic amino group, is reacted in solution with an isothiocyanatophenyl or 4,6-dichloro-1,3,5-triazin-2-ylaminophenyl group of the chelate (15). This necessarily leads to somewhat complicated chromatographic purifications. To simplify the purifications and to increase the efficiency of labeling, Kwiatkowski et al. (16) have prepared phosphoramidite building blocks that are compatible with the automated solid-phase synthesis of oligonucleotides and bear the desired ligand of the photoluminescent chelate in a fully protected form. After chain assembly and deprotection of the ligand and base moieties, the oligomer is released in solution, and the lanthanide ion is introduced by treat-

ment with lanthanide citrate. The final purification then includes desalting on NAP-10 Sephadex and RP FPLC.

While the labeling method described above undoubtedly is highly useful, it still depends on synthesis of a separate nucleosidic phosphoramidite building block for each luminescent chelate used as a marker. For some purposes, coupling of an activated chelate to a functional group of the oligomer that is still bound to the support would constitute a more versatile strategy. Obviously, the latter approach put high demands for the linker tethering the 3'-terminal nucleoside to the solid support. It should withstand, in addition to the conditions of the chain assembly, deprotection of the completed oligomer and reaction of the activated chelate with the appropriate conjugate group on the oligomer. Both of these steps are usually carried out under rather basic conditions. Furthermore, the linker should undergo cleavage under such mild conditions that the labeled oligomer is not modified upon the release in solution, and the final purification remains as simple as possible. Several linkers that allow synthesis of fully deprotected oligonucleotide on solid support and postsynthetic derivatization have been introduced, but in most cases their cleavage requires rather drastic conditions (17, 18). Disulfide-based tethers, however, may be expected to meet the requirements of solid-phase labeling with lanthanide chelates. They have been successfully used in automated oligonucleotide synthesis (19–24); they withstand basic conditions rather well, and they readily undergo reductive cleavage. Unfortunately, no data on postsynthetic transformation reactions of disulfide-immobilized oligonucleotides appear to exist. We now report on derivatization of polymeric solid supports (**S1–S5**) with a number of disulfide linkers. The stability of these linkers under basic conditions has been compared, and the best candidates (**S4b**) have been used in labeling of the *N*⁴-(6-aminoethyl)cytosine residues of the support-bound oligonucleotide with a 4,6-dichloro-1,3,5-triazin-2-ylaminophenyl-acti-

Scheme 1. General Scheme for Labeling of Oligonucleotides on the Support

vated europium(III) chelate. The general protocol of this idea is presented in Scheme 1.

EXPERIMENTAL PROCEDURES

General. The reagents of oligonucleotide synthesis were products of Cruachem and Glen Research. The amino-modified polystyrene and Tentagel supports were from Applied Biosystems Inc. *N*⁴-(*N*-Trifluoroacetyl-6-aminoethyl)-2'-deoxycytidine 3'-(*N,N*-diisopropyl-*O*-cyanoethyl)phosphoramidite (**13**) and the photoluminescent europium chelate {2,2',2'',2'''-[4'-{4'''-[(4,6-dichloro-1,3,5-triazin-2-yl)amino]phenyl}-2,2':6',2''-terpyridine-6,6''-diyl]-bis(methylenenitrilo)}tetrakis(acetato)}europium(III) were received from the laboratory of Wallac Oy. Adsorption column chromatography was performed on Silica Gel 60 (Merck). All the other reagents were purchased from Aldrich. NMR spectra were recorded on a JEOL GX-400 spectrometer operating at 399.8 and 100.5 MHz for ¹H and ¹³C, respectively. The oligonucleotides were analyzed by ion-exchange and RP HPLC (columns, Synchropak AX-300, 4.0 mm × 250 mm, Synchrom Inc., for the ion exchange, and Hypersil ODS 5 μm, 4.0 mm × 250 mm and Nucleosil 300-5C18, 4.0 mm × 250 mm, Macherey-Nagel, for the RP HPLC). Elemental analyses were performed on a Perkin-Elmer 2400 Series II instrument.

2-[(4,4'-Dimethoxytrityl)oxy]ethyl 2-Pyridyl Disulfide (5). Bis(2-pyridyl) disulfide (1.1 mmol, 250 mg) was dissolved in a mixture of pyridine and MeOH (10 mL, 1:99, v/v). 2-Mercaptoethanol (1.0 mmol, 72 μL) was added dropwise to the stirred solution, and the mixture was left to stand at ambient temperature until no 2-mercaptoethanol could be detected by TLC. The reaction mixture was evaporated to dryness and coevaporated three times with dry pyridine. The residue (**4**) was dissolved in dry pyridine (10 mL); 4,4'-dimethoxytrityl chloride (1.1 mmol, 375 mg) was added, and the reaction mixture was left to stand overnight at ambient temperature. The reaction was stopped by adding MeOH (0.5 mL) and aqueous NaHCO₃ (5 mL of a 5% solution). The mixture was evaporated to an oil in vacuo, dissolved in CH₂Cl₂ (40 mL), washed with water (2 × 20 mL), and dried over Na₂SO₄. The solvent was removed in vacuo, and **5** was separated on a silica gel column (30 mm ×

100 mm), eluting with a stepwise gradient system of CH₂-Cl₂ in hexane containing 0.1% pyridine (from 75 to 100% CH₂Cl₂). The overall yield was 81%. ¹H NMR (CDCl₃; δ, ppm): 8.41 (1H, m, Pyr H6), 7.68 (1H, m, Pyr H4), 7.54 (1H, m, Pyr H5), 7.43 (2H, m, DMTr), 7.32–7.15 (6H, m, DMTr), 7.04 (1H, m, Pyr H3), 6.83–6.78 (5H, m, DMTr), 3.77 (6H, s, OMe), 3.38 (2H, t, *J*³ = 6.4 Hz, DMTrOCH₂), 2.94 (2H, t, *J*³ = 6.4 Hz, PyrSSCH₂). TLC: *R*_f = 0.88 (19:1 CH₂Cl₂/MeOH), 0.62 (49:1 CH₂Cl₂/MeOH). MS: *m/z* at 489 (M⁺).

3-[(4,4'-Dimethoxytrityl)oxy]propyl 2-Pyridyl Disulfide (8). Bis(3-hydroxypropyl) disulfide (**25**) (5.76 mmol, 1.05 g) was coevaporated with pyridine (3 × 20 mL) and dissolved in dry pyridine (50 mL). 4,4'-Dimethoxytrityl chloride (10.2 mmol, 3.45 g) in pyridine (50 mL) was added to the stirred solution and the mixture left to stand overnight at ambient temperature. The resulting **6** was worked up as described for **5** and used without further purification. **6** (0.6 g, 0.8 mmol) was dissolved in CH₂Cl₂ (10 mL), and methanolic DTT (0.8 mmol in 3 mL) was added. The reductive cleavage of **6** to **7** was followed by TLC. The reaction mixture was evaporated, dissolved in CH₂Cl₂, washed with water, dried, and concentrated to an oil. The oil was immediately added to a solution of bis(2-pyridyl) disulfide (1.6 mmol, 0.35 g) in MeOH (10 mL). After being stirred for 4 days at ambient temperature, the reaction mixture was evaporated to an oil and dissolved in a mixture of hexane and CH₂Cl₂ (25:75) containing 0.1% pyridine. **8** was isolated on a silica gel column (30 mm × 100 mm), eluting with a gradient of CH₂Cl₂ (75 to 100%) in hexane. The overall yield was 40%. ¹H NMR (CDCl₃; δ, ppm): 8.44 (1H, m, Pyr H6), 7.68 (1H, m, Pyr H4), 7.59 (1H, m, Pyr H5), 7.41 (2H, m, DMTr), 7.30–7.16 (6H, m, DMTr), 7.06 (1H, m, Pyr H3), 6.84–6.80 (5H, m, DMTr), 3.78 (6H, s, MeO), 3.14 (2H, t, *J*³ = 7.3 Hz, DMTrOCH₂), 2.93 (2H, t, *J*³ = 6.0 Hz, PyrSSCH₂), 1.98 (2H, q, *J*³ = 7.3 Hz CH₂CH₂CH₂). TLC: *R*_f = 0.88 (19:1 CH₂Cl₂/MeOH), 0.60 (49:1 CH₂Cl₂/MeOH). MS: *m/z* at 503 (M⁺).

15-[(4,4'-Dimethoxytrityl)oxy]-12,13-dithiapentadecanoic Acid (11). To a solution of thiolacetic acid (13 mmol, 1.0 g) in dioxane (1 mL) was added a few crystals (1–2 mg) of dibenzoylperoxide. The solution was mixed with a solution of 10-undecenoic acid (6.6 mmol, 1.21 g) in dioxane (20 mL), and the mixture was stirred overnight at ambient temperature. The completeness of the reaction was checked by TLC; water (20 mL) was added, and the mixture was acidified with aqueous hydrogen chloride. Extraction with ethyl acetate (2 × 30 mL) gave 11-acetylthioundecanoic acid (**9**) as a white solid (1.63 g, 95%). Anal. (C₁₃H₂₄O₃S): C, H, S. ¹H NMR (CDCl₃; δ, ppm): 2.86 (2H, t, *J*³ = 7.4 Hz, SCH₂CH₂), 2.35 (2H, t, *J*³ = 7.4 Hz, CH₂COOH), 2.32 (3H, s, SC(=O)CH₃), 1.63 (2H, q, *J*³ = 7.4 Hz, CH₂CH₂COOH), 1.56 (2H, q, *J*³ = 7.0 Hz, SCH₂CH₂), 1.31 (12H, br m, (CH₂)₆CH₂COOH). TLC: *R*_f = 0.60 (1:2 EtOAc/hexane).
