9 (0.50 g, 1.9 mmol) was dissolved in 20 mL of MeOH and deacetylated with an excess of 40% aqueous methanamine (5 mL), evaporated to dryness, and dissolved in water (30 mL). The pH was adjusted to 2 with aqueous hydrogen chloride, and the deprotected 11-mercaptopentadecanoic acid (**10**) was extracted in diethyl ether (3 × 30 mL) and dried with Na₂SO₄. From the crude **10**, a sample (0.070 g, 0.32 mmol) was then dissolved in a mixture of pyridine and MeOH (1:9, 0.9 mL) and added to a solution of **5** (0.2 g, 0.4 mmol) dissolved in a mixture of MeOH and MeCN (1:1, 5 mL), and the solution was stirred at room temperature overnight. The evaporation residue was dissolved in CH₂Cl₂ (5 mL) containing 5%

Et₃N and fractionated on a silica gel column, using a stepwise gradient of MeOH (0 to 5%) in Et₃N/CH₂Cl₂ (5:95) as an eluent. The yield of **11** (starting from **9**) as a triethylammonium salt was 0.15 g (72%). ¹H NMR-(CDCl₃; δ , ppm): 7.46–6.78 (13H, m, DMTr), 3.79 (6H, s, OCH₃), 3.35 (2H, t, J = 7.5 Hz, OCH₂CH₂), 2.85 (2H, t, J = 6.4 Hz, CH₂CH₂S), 2.56 (2H, t, J^3 = 7.7 Hz, CH₂-COO), 2.29 (2H, t, J^3 = 7.3 Hz, SSCH₂), 1.60 (2H, br m, SSCH₂CH₂), 1.25–1.40 (14 H, br m, 7 $\times$ CH₂). The spectrum also exhibited signals of the triethylammonium group. TLC: R_f = 0.74 (5% Et₃N in 9:1 CH₂Cl₂/MeOH), R_f = 0.33 (5% Et₃N in 19:1 CH₂Cl₂/MeOH).

N-[7-[(4,4'-Dimethoxytrityl)oxy]-4,5-dithiaheptanoyl] Supports (S1a–c). Long-chain aminoalkyl controlled pore glass (LCAA-CPG) was treated overnight with 3% dichloroacetic acid in CH₂Cl₂, subjected to successive washings with CH₂Cl₂, 20% Et₃N in MeOH, MeOH, and Et₂O, and finally dried in vacuo. Polystyrene and Tentagel supports were used as received. The supports were suspended in dry pyridine and degassed under reduced pressure (water pump). *N*-Hydroxysuccinimide (2–3 mmol) and 3,3'-dithiodipropionic acid (1–2 mmol, 20–100-fold excess with respect to the support-bound amino groups) were dissolved in pyridine, dried by coevaporation with pyridine, and dissolved again in a minimum amount of pyridine. The resulting solution was added to the suspension of the support in pyridine, and *N,N'*-diisopropylcarbodiimide (2–3 mmol) and a catalytic amount of 4-(dimethylamino)pyridine were added. The suspension was shaken overnight, and the support was washed on a filter with pyridine, CH₂Cl₂, MeOH, and Et₂O. The support dried in the air was suspended in methanol and degassed. DTT (0.30 g, 1.9 mmol) and 30 μ L of a 0.3 mol L⁻¹ solution of Et₃N in methanol were added, and the solution was shaken for several hours. After the mixture was washed with methanol, **5** (0.45 g) was immediately added to the suspension of the support in a mixture of MeOH and MeCN (1:1, 5 mL), and the suspension was shaken overnight. The support was washed on the filter with MeOH. The unreacted amino groups of the support (**S1a–c**) were finally capped by treating the support for 3 $\times$ 10 min with a 1:1 mixture of solutions A and B (A is 1:1:8 acetic anhydride/2,6-lutidine/THF and B is 16:84 *N*-methylimidazole/THF). The loading of the washed and dried support was determined by the dimethoxytrityl cation assay (26). The loadings ranged from 8 to 33 μ mol g⁻¹.

N-[8-[(4,4'-Dimethoxytrityl)oxy]-4,5-dithiaoctanoyl] Supports (S2a–c). These supports were prepared as described for **S1a–c** by using **8** instead of **5**.

N-[16-[(4,4'-Dimethoxytrityl)oxy]-12,13-dithiahexadecanoyl] Supports (S5a,b). 10-Undecenoic acid was attached to amino-modified polystyrene or Tentagel support by the *N*-hydroxysuccinimide and *N,N'*-diisopropylcarbodiimide assisted acylation as described above for supports **S1a–c**. The *N*-acylated support was suspended in dioxane, and thiolacetic acid diluted with dioxane (1:1, 800 μ L) and a few crystals (1–2 mg) of dibenzoylperoxide were added. The suspension was shaken overnight, washed with dioxane, and dried on the filter. The *S*-acetyl group was removed with 1 mol L⁻¹ butylamine in MeOH, and the released mercapto function was coupled with **8** and capped to give supports **S5a,b**, as described for supports **S1a–c**. The loading determined by the dimethoxytrityl cation assay ranged from 7 to 16 μ mol g⁻¹.

N-[15-[(4,4'-Dimethoxytrityl)oxy]-12,13-dithiapentadecanoyl] Supports (S4a,b). These supports were

prepared as described for supports **S5a,b** by using **5** instead of **8**. The support **S4b** was also obtained in two alternative manners. First, the Tentagel support was acylated with the triethylammonium salt of **11**, according to the procedure described for supports **S1a–c** and capped. Second, the Tentagel support was acylated with 11-acetylthioundecanoic acid (**9**), deacetylated with 1 mol L⁻¹ aqueous butylamine, reacted with **5**, and capped.

N-[10-[(4,4'-Dimethoxytrityl)oxy]-7,8-dithiadecanoyl] Support (S3). The support was prepared as described for supports **S5a,b** by using 5-hexenoic acid instead of 10-undecenoic acid and **3** instead of **7**.

Determination of the Hydrolytic Stability of S1–S5. The loading of each batch of **S1–S5** was determined by the dimethoxytrityl cation assay. The supports were then weighed into a synthesizer column and subjected to ammonolysis according to the protocol of manual deprotection and cleavage by a double-syringe method (27). The columns were kept at room temperature for 24 or 48 h. At the end of this period, the ammonia was withdrawn and the support was washed with water, aqueous MeCN, and MeCN, and dried. The dimethoxytrityl cation assay was repeated.

Oligodeoxynucleotide Synthesis. Supports **S4b** were used as supports in the automated oligonucleotide synthesis. The protected oligonucleotides were assembled on an Applied Biosystems 392 DNA synthesizer in 0.2 and 1.0 μ mol scales, using the standard phosphoramidite protocol and unaltered coupling times even when the modified building block (**13**) was introduced (Scheme 6). The support-bound oligonucleotides were deprotected under standard deprotection conditions: treatment with concentrated ammonia (33%) at 55 °C for 8 h or at room temperature for 48 h. The support, still bearing the deprotected oligonucleotide, was washed with water and acetonitrile and dried.

Labeling of the Oligonucleotides on the Solid Support. An appropriate amount of the dried support, containing ~2 OD of oligomer on 0.5 mg of the support, was weighed in a microcentrifuge tube, and the labeling reagent, either 5-(dimethylamino)-1-naphthalenesulfonyl chloride (DNSCl) (7.7 mg, 0.28 μ mol) or **14** (3.0 mg, 3.2 μ mol), from Scheme 6, in 0.05:1:2.95 DBU/MeCN/H₂O (50 μ L, v/v/v) was added (28). The tubes were shaken from 16 to 48 h in the dark at ambient temperature. The solid phase was filtered and washed with water and acetonitrile. The labeled oligonucleotides were detached from the supports with slightly basic 0.5 mol L⁻¹ aqueous DTT (100 μ L, a 3 μ mol L⁻¹ Et₃N/methanol solution in 1 mL of aqueous DTT or DTT in 0.1 mol L⁻¹ Tris buffer at pH 8.4). The reaction was performed either in a synthesizer column by a double-syringe method or in a 1.5 mL microcentrifuge tube. The support was removed by filtration and rinsed with water, aqueous MeCN, and MeCN. The filtrate and washings were combined and evaporated to dryness on a SpeedVac or rotary evaporator. The labeled oligonucleotide conjugate was precipitated with EtOH, and the quality and identity of the product were verified by HPLC. In the case of labeling with **14**, the extent of labeling was determined by releasing Eu(III) ion in solution with a fluorescence enhancement solution and measuring the fluorescence intensity on a time-resolved fluorometer against a europium(III) chloride standard solution (Delfia protocol) (29).

Hybridization Experiments. The hybridization experiments were carried out as described previously (30).

RESULTS AND DISCUSSION

Synthesis of the Supports. Solid supports **S1** and **S2** were prepared as depicted in Scheme 2. Accordingly, the amino functions of polystyrene, Tentagel, and LCAA CPG supports were first acylated with 3,3'-dithiodipropionic acid; the disulfide bond was reductively cleaved with DTT, and the released mercapto function was reacted with either 2-[(4,4'-dimethoxytrityl)oxy]ethyl 2-pyridyl disulfide (**5**; supports **S1a–c**) or 3-[(4,4'-dimethoxytrityl)oxy]propyl 2-pyridyl disulfide (**8**; supports **S2a–c**). The loadings determined by the dimethoxytrityl cation method are listed in Table 1. The 2-pyridyl disulfide-activated ω-[(4,4'-dimethoxytrityl)oxy]thiols, **5** and **8**, were prepared from 2-mercaptoethanol and bis-(3-hydroxypropyl) disulfide, as described in Scheme 3.

The rest of the supports employed (**S3–S5**) were obtained via initial acylation with ω-alkenoic acid, followed by radical addition of thiolacetic acid to the terminal double bond (**31**) (Scheme 4). The *S*-acetyl

group was then removed by aminolysis with butylamine, and the released mercapto group was reacted with **5**. The Tentagel-based support **S4b** was also prepared in two alternative manners shown in Scheme 5. First, the disulfide linker (**11**) was synthesized in solution and attached to the amino-modified Tentagel by an *N*-acylation assisted by *N,N*-diisopropylcarbodiimide, *N*-hydroxysuccinimide, and 4-(dimethylamino)pyridine. Second, 11-(acetylthio)undecanoic acid (**9**) was prepared by radical addition in solution, and only the aminolysis and coupling with **5** were performed on the support (for the loadings, see Table 1).

Hydrolytic Stability of the Disulfide-Tethered Supports (S1–S5). To evaluate the applicability of the supports in machine-assisted oligonucleotide synthesis, they were subjected to ammonolysis. According to the standard protocol, the base moiety protections are removed by treating the support-bound oligomer with concentrated aqueous ammonia for 48 h at room tem-

perature or for 8 h at 55 °C. We applied the double-syringe method for 24–48 h at room temperature. Table 1 records the dimethoxytrityl loadings before and after this ammonolysis. These results indicate that the material of the support is of considerable importance. The loading of the CPG supports, **S1c** and **S2c**, decreased dramatically during the ammonolysis, which in all likelihood may be attributed to partial dissolution of glass.

Scheme 6. Structures of the Modified Phosphoramidite **13** and the Photoluminescent Lanthanide Chelate **14**

Another important factor appears to be the length of the linker molecule; the resistance to ammonolysis increases with the length of the hydrocarbon chain connecting the disulfide group to the carbonyl carbon of the linker. Supports containing a dimethylene bridge are considerably more labile than those containing a nonamethylene bridge. This difference in stability is most clearly seen with the Tentagel-based supports **S2b** and **S5b**. Evidently, the carbonyl function and the disulfide group must be separated by at least three carbon atoms to prevent β -elimination. The distance between the disulfide linkage and the dimethoxytrityloxy group seems to be of lesser importance.

Synthesis of Oligonucleotides on Supports. A model sequence of T₆ was synthesized on those supports

that showed considerable resistance toward ammonolysis. The support-bound oligos were then subjected to ammonia treatment, and after 48 h the ammonia was washed from the supports and collected. These washings were then investigated by ion-exchange HPLC. The oligonucleotide that remained bound to the support was finally released with DTT under mildly basic conditions. The oligomer content of the washings was again determined by HPLC. The general conclusion of these studies was that assembly of an oligonucleotide on the deprotected hydroxy function of the supports still decreased the stability of the disulfide bond toward ammonolysis. Support **S4b**, in particular the batches obtained by route B in Scheme 5, exhibited the desired properties and was selected for further studies. More than 85% of the assembled oligomer remained bonded to the support after ammonolysis and could be released in 84% yield by subsequent reductive cleavage. Furthermore, the released oligomer was more homogeneous than with the other supports tried.

Support **S4b** prepared by route B in Scheme 5 was used to assemble a 15-mer oligonucleotide, 5'-d(GAA-CATCATGGTTCGT)-3', and ammonolyze it in the dimethoxytrityl-on mode. According to RP HPLC, 10% of the full-length tritylated sequences were released during ammonolysis and 90% by the DTT treatment. The latter treatment also resulted in cleavage of the *O*-(2-mercaptoethyl) from the 3'-terminal phosphate group of the released oligomer. This reaction has been suggested to proceed by an intramolecular nucleophilic displacement of the phosphate group by the mercapto function (32). That this really happened under the conditions employed was verified by comparing a dT₆ sequence prepared on **S4b** to an authentic sample of 3'-phosphorylated dT₆ synthesized on a commercially available universal solid support producing oligonucleotide 3'-phosphates. These two materials exhibited identical retention times on ion-exchange HPLC, and when co-injected, gave only a single peak.

Labeling of Oligodeoxyribonucleotides on the Support. The labeling experiments were carried out with an 18-mer sequence, 5'-d(X₂ATATCATCTTTGGTGT)-3', assembled on **S4b** [X = N⁴-(6-aminohexyl)-2'-deoxycytidine] (33). The synthesis gave an average stepwise yield of 99%, calculated by the dimethoxytrityl cation release after the ammonia treatment. The free aliphatic amino groups of the 5'-terminal N⁴-aminoalkylated cytosine bases were labeled either with a prompt fluorophor, 5-(dimethylamino)-1-naphthalenesulfonyl chloride, or a dichlorotriazine derivative of a photoluminescent europium(III) chelate. The appropriate labeling reagent was dissolved in a minimum amount (<50 μ L) of a mixture of DBU [1,8-diazabicyclo(5,4,0)undec-7-ene], water, and MeCN (0.05:1:2.95 v/v/v) and added to 0.5 mg of support-bound oligo (~2 OD) in a microcentrifuge tube. After incubation for 16 h in a shaker, the excess of the reagents was washed, and the support-bound, labeled oligonucleotides were released into solution with dithiothreitol. An ethanol precipitation of the oligonucleotides gave a DTT-free fraction of the labeled oligonucleotide. The extent of labeling of this oligonucleotide conjugate was determined according to the Delfia protocol (29). Accordingly, the europium(III) ion was released in solution and quantified against europium chloride standards. The amount of oligonucleotide was determined spectrophotometrically at 260 nm. The extent of labeling was 1.6, i.e., about 80% of the theoretical value, 2. The presence of the prompt fluorophor (dansyl) was, in turn, verified by measuring the UV spectrum of the ethanol-

Figure 1. Sandwich hybridization on microparticles bearing a sequence complementary to labeled oligonucleotide. The fluorescence signal is measured from one particle as a function of target molecules added to the hybridization reaction mixture. A comparison of in-solution labeled oligo containing five chelates per molecule (line with squares) and solid-phase labeled oligo (maximum of two chelates per oligo) (line with triangles).

precipitated labeled oligo against water. The observed ratio of the absorbance at 360 nm (DNS moiety) and at 260 nm (base moieties) agreed with the almost theoretical extent of labeling. Additionally, the presence of a DNS oligoconjugate was verified with RP HPLC.

Hybridization Properties of the Multilabeled Oligonucleotides. The identity of the oligomer conjugate derived from the photoluminescent europium chelate was further verified by performing two parallel hybridization assays by the previously reported technique based on time-resolved fluorescence detection on microparticles (30). In one of the experiments, an oligonucleotide conjugate prepared in the present work was used. The signal intensity was then compared to that observed when an oligomer labeled previously in solution was used in the same assay (30). As seen from Figure 1, the ratio of the two sets of signals is consistent with the determined extent of labeling.

In summary, the methodology described in the present paper allows preparation of satisfactorily pure oligonucleotide 3'-monophosphates labeled with a photoluminescent europium chelate to the amino groups of N⁴-(aminoalkyl)cytosine residues. The chain assembly and labeling take place on a single solid support, and the resulting conjugate may be purified simply by washing, release in solution, and precipitation with ethanol.

ACKNOWLEDGMENT

The polystyrene and Tentagel particles were a generous gift of Dr. Alex Andrus (Applied Biosystems Inc.). The photoluminescent europium chelate was prepared in the Laboratory of Wallac Oy (Turku, Finland) by Dr. Veli-Matti Mikkala. The authors also thank Mr. Harri Hakala, M.Sc., for the hybridization measurements. Financial support from the Research Council for Natural Sciences, the Academy of Finland, is gratefully acknowledged.

Received October 31, 1997; Revised Manuscript Received January 27, 1998

Several immunotoxins (ITs) were synthesized by the attachment of clavin, a recombinant toxic protein derived from *Aspergillus clavatus*, to the monoclonal antibody Mgr6 that recognizes an epitope of the gp185^{HER-2} extracellular domain expressed on breast and ovarian carcinoma cells. Conjugation and purification parameters were analyzed in an effort to optimize the antitumor activity and stability of the ITs in vivo. To modulate the in vitro and in vivo properties of the immunotoxins, different coupling procedures were used and both disulfide and thioether linkages were obtained. Unhindered and hindered disulfide with a methyl group linkage ethyl S-acetyl 3-mercaptopropionthioimide ester hydrochloride (AMPT) or ethyl S-acetyl 3-mercaptoputylthioimide ester hydrochloride (M-AMPT) were obtained by reaction with recombinant clavin, while the monoclonal antibody Mgr6 was derivatized with ethyl 3-[(4-carboxamidophenyl)dithio]propionthioimide ester hydrochloride (CDPT). To achieve higher hindrance (a disulfide bond with a geminal dimethyl group), Mgr6 was derivatized with the *N*-hydroxysuccinimidyl 3-methyl-3-(acetylthio)butanoate (SAMBA) and clavin with CDPT. To evaluate the relevance of the disulfide bond in the potency and pharmacokinetic behavior of the ITs, a conjugate consisting of a stable thioether bond was also prepared by derivatizing Mgr6 with the *N*-hydroxysuccinimidyl ester of iodoacetic acid (SIA) and clavin with AMPT. The immunotoxins were purified and characterized using a single-step chromatographic procedure. Specificity and cytotoxicity were assayed on target and unrelated cell lines. The data indicate that the introduction of a hindered disulfide linkage into ITs has little or no effect on antitumor activity and suggest that disulfide cleavage is essential for activity; indeed, the intracellularly unbreakable thioether linkage produced an inactive IT. Analysis of IT stability in vitro showed that the release of mAb by incubation with glutathione is proportional to the presence of methyl groups and increases exponentially with the increase in steric hindrance. Analysis of the pharmacokinetic behavior of ITs in Balb/c mice given intravenous bolus injections indicated that ITs with higher in vitro stability were eliminated more slowly; i.e., the disulfide bearing a methyl group doubled the β -phase half-life (from 3.5 to 7.1 h) compared with that of the unhindered, while a geminal dimethyl protection increased the elimination phase to 24 h. The thioether linkage showed its intrinsic stability with a β -phase half-life of 46 h. The thioether linkage also increased the distribution phase from 17 to 32 min. The in vitro characteristics and in vivo stability of Mgr6–clavin conjugates composed of a methyl and dimethyl steric hindered disulfide suggest clinical usefulness.

INTRODUCTION

The potent and highly specific cytotoxic activity of conjugates between monoclonal antibodies and toxins has raised the promise of effective immunotherapy for tumors and graft-versus-host disease. ITs¹ have particular potential in the treatment of leukemias and lymphomas (1, 2), although some evidence suggests they are effective against solid tumors as well (3, 4).

Extremely active ITs have been constructed by covalently linking mAb to bacterial toxins such as *Pseudomonas* exotoxin or to plant toxins such as the ricin A chain, saporin, and gelonin (5–8).

Other interesting ribosome-inactivating proteins (RIPs) with potent antitumor activity such as α -sarcin, restriction, and mitogillin have been isolated from fungi and used to prepare ITs (9–11). RIPs of fungi are extensively homologous in their primary structure (>80%) and have the same catalytic activity, i.e., hydrolysis of the phosphodiester linkage between the G residue at position 4325 and the A residue at position 4326 in 28S rRNA (12).

¹ Abbreviations: ITs, immunotoxins; AMPT, ethyl S-acetyl-propionthioimide; M-AMPT, ethyl S-acetyl-3-mercaptoputylthioimide; CDPT, 3-[(4-carboxamidophenyl)dithio]propionthioimide; SAMBA, *N*-hydroxysuccinimidyl 3-methyl-3-(acetylthio)butanoate; SIA, *N*-hydroxysuccinimidyl ester of iodoacetic acid; RIP, ribosome-inactivating protein; DTNB, Ellman's reagent; DTT, dithiothreitol; TNB, 5-mercaptop-2-nitrobenzoic acid; SDS–PAGE, sodium dodecyl sulfate–polyacrylamide gel electrophoresis; GSH, reduced glutathione; SMPT, 4-[(succinimidyl-oxycarbonyl)- α -methyl- α -(2-pyridyldithio)toluene.

Recently, Parente et al. (13) described the cloning and expression of a new RIP, clavin, from *Aspergillus clavatus*. Clavin was highly active on free ribosomes, inducing low and transient systemic toxicity and a late, low-level antibody response in mice. These characteristics and its availability in large amounts identify clavin as a good candidate for IT preparation.

To selectively target clavin to breast and ovarian carcinoma cells, we used a mAb (Mgr6) that recognizes an epitope of the gp185^{HER-2} extracellular domain (14). The tissue distribution of gp185^{HER-2} in normal human tissues is restricted, and overexpression of the HER-2 oncogene is associated with poor prognosis in breast and ovarian carcinoma patients (15, 16). Existing ITs directed to gp185^{HER-2} have already shown immunotherapeutic promise (17–19).

In this study, we analyzed the conjugation and purification parameters that might yield efficient and stable ITs suitable for preclinical studies.

We prepared various ITs and characterized them with respect to coupling systems (disulfide or thioether linkage). In fact, most of the ITs prepared to date have a reducible disulfide bond which is required for the intracellular release of the toxic moiety (20). The major in vivo limitations of such ITs rest in the instability of the chemical linkage, which restricts the amount of conjugate that is able to bind to target cells (21, 22), and in the potential competition of the released antibody with the intact conjugate since the mAb persists longer in circulation. Previously released antibody may mask tumor antigens, thereby compromising IT potency during multiple-dose treatment regimens.

In an effort to prolong the in vivo half-life of ITs and enhance their antitumor potency, we prepared Mgr6–clavin conjugates using the thioimide cross-linking system which preserves the positive charge on the derivatized proteins and allows modulation of the hindrance on the chemical linkage between clavin and the mAb.

EXPERIMENTAL PROCEDURES

Materials. Anhydrous dichloromethane, Ellman's reagent (DTNB), and all other reagents were from Aldrich (Milwaukee, WI).

Diethyl ether was distilled from lithium aluminum hydride, and dry tetrahydrofuran was obtained by distillation from sodium.

General Procedures. Melting points were determined with a Reichert Kofler apparatus and are uncorrected. ¹H NMR spectra were recorded on a JEOL PMX-60 spectrometer, operating at 60 MHz, with tetramethylsilane as the internal standard. IR spectra were obtained as KBr disks on a Shimadzu FT-IR 8101 M spectrophotometer; wavelengths are given in inverse centimeters. Mass spectra were obtained with a FINNI-GAN-MAT TSQ-700 or with a VG Analytical 70-70 EQ-HF spectrometer. Ultraviolet spectra were recorded on a Beckman DU-70 spectrophotometer.

Reactions were checked on F₂₅₄ silica gel precoated sheets (Merck, Milan, Italy). Purification was carried out by column flash chromatography on silica gel 60 (Merck, 230–400 mesh).

Synthesis of Cross-Linkers. Preparation of Thioimide Ester Hydrochlorides (CDPT, AMPT, and M-AMPT). Hydrogen chloride gas was bubbled through ice-cold ethanethiol (3.25 mL, 0.0435 mol) for 1 h. The nitriles 4-[(2-cyanoethyl)dithio]benzamide, 3-(acetylthio)propionitrile, and 3-(acetylthio)butyronitrile, synthesized

as described by Arpicco (23), were diluted in anhydrous diethyl ether or dry tetrahydrofuran and quickly added to the cold solution with stirring, and the reaction mixture was left overnight at 0 °C. Anhydrous cold diethyl ether was then added, and the reaction mixture was left at –20 °C until a crystalline solid formed. The supernatant was decanted, and the precipitate was washed with anhydrous diethyl ether under argon and dried under reduced pressure at room temperature.

Ethyl 3-[(4-carboxamidophenyl)dithio]propionthioimide ester hydrochloride (CDPT): yield 0.64 g (65%); mp 110–115 °C; ¹H NMR (CD₃OD) δ 7.85 (q, 4H, Ar-H), 3.4–3.15 (m, 6H, SCH₂CH₃ and CH₂CH₂), 1.47 (t, 3H, SCH₂CH₃); IR (KBr) 3500–2200 (NH₂ and NH₂⁺), 1650 (C=O), 1620 (C=N); MS (FAB⁺) 301 (M⁺ + 1).

Ethyl S-acetyl 3-mercaptopropionthioimide ester hydrochloride (AMPT): yield 0.87 g (88%); mp 64–66 °C; ¹H NMR (CDCl₃) δ 3.48 (q, 2H, SCH₂CH₃), 3.26 (m, 4H, CH₂CH₂), 2.38 (s, 3H, SAC), 1.45 (t, 3H, SCH₂CH₃); IR (KBr) 3300–2400 (NH), 1690 (C=O), 1620 (C=N), 1360 (SAC).

Ethyl S-acetyl 3-mercaptoputyrothioimide ester hydrochloride (M-AMPT): yield 0.79 g (75%); mp 112 °C; ¹H NMR (CDCl₃) δ 3.4–3.2 (m, 5H, SCH₂CH₃, CH, and CH₂), 2.43 (s, 3H, SAC), 1.6 (d, 3H, CH₃), 1.43 (t, 3H, SCH₂CH₃); IR (KBr) 3300–2400 (NH), 1690 (C=O), 1620 (C=N), 1360 (SAC); MS-EI *m/z* (relative intensity) 206 (M⁺, 7), 162 (100), 145 (53), 130 (20), 102 (65), 89 (20), 75 (33), 61 (52), 43 (100).

Preparation of N-Hydroxysuccinimidyl 3-Methyl-3-(acetylthio)butanoate (SAMBA). The method of Carroll (24) was used with minor modifications. Briefly, 3-methyl-3-(acetylthio)butanoic acid (1.5 g, 0.0085 mol) dissolved in 12 mL of dry dichloromethane was mixed with 1.3 g of NHS (0.011 mol) in 5 mL of dichloromethane, and dicyclohexylcarbodiimide (2.3 g, 0.011 mol) dissolved in 1 mL of dry dichloromethane was added dropwise. The reaction mixture was stirred at room temperature for 22 h. After filtration and evaporation, the mixture was purified by flash chromatography with elution in hexane/EtOAc (80/20). The ester was obtained as a pale yellow oil that crystallized rapidly at room temperature: yield 1.6 g (70%); mp 63 °C; TLC (80/20 hexane/EtOAc) *R_f* = 0.15; ¹H NMR (CDCl₃) δ 3.23 (s, 2H, CH₂), 2.80 (s, 4H, NHS ester), 2.25 (s, 3H, SAC), 1.6 (s, 6H, CH₃); MS-EI *m/z* (relative intensity) 273 (10), 159 (90), 117 (30), 75 (15), 43 (55).

The N-hydroxysuccinimidyl ester of iodoacetic acid (SIA) was prepared as described (25).

Clavin and Mgr6 Production. For clavin production, a 100 mL culture of *Escherichia coli* HB101 cells carrying the pMRS38 plasmid was used to start the final cultivation step in a Chemap bioreactor with a working volume of 1.5 L. The cultivation was performed in complex medium [20 g/L glucose, 25 g/L yeast extract, 40 g/L casamino acid (Difco), 0.5 g/L NaCl, 5 g/L KCl, 2.6 g/L K₂SO₄, 0.86 g/L MgCl₂·6H₂O, 6.6 mg/L CaCl₂·6H₂O, and trace amounts of oligo elements], supplemented with 100 mg/mL ampicillin. Cultivation parameters such as temperature, pH, and oxygen dissolved in tension (DOT) were computer-controlled. The culture supernatant was recovered by centrifugation and filtered on a Millipore 0.22 μm filter. Clavin was purified as described (13).

Mgr6 hybridoma, directed against the extracellular domain of gp185^{HER-2}, was obtained by immunization of Balb/c mice with the adenocarcinoma cell line CaLu3, and its characterization is described elsewhere (14). mAb Mgr6 was obtained by cultivating hybridoma cells in a

hollow fiber bioreactor (Acusyst R, Endotronics) using a serum-free medium. Medium, prepared in our facilities, consisted of a basal mixture (1/1) of RPMI 1640 and DMEM supplemented with transferrin, insulin, albumin, and Ex-Cite (Miles Inc.) as a lipid source. Additional ingredients were 2-mercaptoethanol, ethanolamine, and sodium selenite.

Cell cultivation was performed as continuous perfusion for approximately 1 month, during which parameters such as glucose and lactic acid concentrations, pH, oxygen and carbon dioxide levels, and antibody production were monitored along with operator responses.

Conditioned media harvested during cultivation were pooled after thawing and adjusted to pH 5.5. Material was diluted and filtered on 4.5 μm filters (Millipore Co., Bedford, MA) before being loaded on a Bakerbond Abx column (Mallinckrodt Baker B. V., Deventer, The Netherlands). The eluted protein peak was desalted on a Sephadex G-25 (Pharmacia-Biotech, Uppsala, Sweden) column and loaded onto a Q-Sepharose FF column (Pharmacia-Biotech). The eluted peak was desalted as indicated above and subjected to the final purification step on a S-Sepharose FF column (Pharmacia-Biotech). Elution was obtained by applying a linear gradient from 20 to 200 mM NaCl in 20 mM phosphate buffer.

Preparation of Immunotoxins. Disulfide Bridge. In a standard preparation, a recombinant clavin solution (357 μM , 1 mL) was stirred with AMPT (122 mM, 30 μL dissolved in ethanol), M-AMPT (98 mM, 30 μL dissolved in ethanol), or CDPT (139 mM, 40 μL in dry dimethylformamide) for 30 min at 25 $^{\circ}\text{C}$ to incorporate an average of 1–1.3 linkers per mole of clavin. The mixture was purified by gel filtration on a 1×20 cm Bio-Gel P6-DG column (Bio-Rad, Hercules, CA) eluted with HBS (0.1 M, 0.2 M NaCl and 1 mM EDTA disodium salt at pH 7.4) at 20 $^{\circ}\text{C}$. The protein solution was concentrated to 1 mL with an Amicon concentrator (Amicon, Beverly, MA) equipped with a Y10 membrane.

mAb Mgr6, dissolved in HBS, was separately reacted with two different cross-linkers, CDPT and SAMBA. The reaction of Mgr6 with CDPT proceeded as follows: CDPT in dry dimethylformamide (13 mM, 40 μL) was added to the mAb in solution (33 μM , 1 mL), and the mixture was stirred for 30 min at 25 $^{\circ}\text{C}$. The Mgr6/CDPT molar ratio was 1/1.1. Derivatization of Mgr6 with SAMBA (11 mM, 30 μL) dissolved in ethanol was carried out for 30 min at 25 $^{\circ}\text{C}$ to introduce two acetylthio groups. In both cases, the mixture was purified by gel centrifugation on a 15×55 mm Bio-Gel P6-DG column preequilibrated in HBS at 20 $^{\circ}\text{C}$.

The number of thioacetylated groups linked to the protein was calculated spectrophotometrically by reaction of the sample with the deacetylating reagent hydroxylamine hydrochloride (0.5 M, 12.5 mM EDTA, pH 7.4) followed by thiol disulfide exchange with DTNB as described (26).

The number of arylthio groups linked to Mgr6 or clavin was determined following the release of the thiolated anion at 313 nm, after incubation of the protein sample (1 mL) with 2-mercaptoethanol in PBS/EDTA (11 mM sodium phosphate and 3 mM EDTA, 50 μL) and NaOH (1 M, 40 μL), to a final pH of 8.8–9.4. The molar absorptivity value of the 4-carboxamidophenylthiolate anion under these conditions at 313 nm was $15\,200 \pm 300 \text{ M}^{-1} \text{ cm}^{-1}$.

All conjugations were performed by mixing the derivatized mAb and RIP in the presence of a solution of hydroxylamine (1/10, v/v). Reactions were allowed to proceed for 5 h at 25 $^{\circ}\text{C}$ followed by 18–35 h at 4 $^{\circ}\text{C}$; at

the end of the reaction, a solution of *N*-ethylmaleimide (20 mM, 20 μL) was added to block free thiol groups.

Thioether Bridge. Clavin (357 μM , 1 mL) was derivatized with AMPT as described above; Mgr6 (33 μM , 1 mL) was reacted with SIA (5.7 mM, 30 μL) dissolved in ethanol, for 30 min at 25 $^{\circ}\text{C}$. The iodoacetyl groups inserted on Mgr6 were identified by reaction with the TNB (5-mercapto-2-nitrobenzoic acid) reagent previously prepared; briefly, 25 mg of dithiothreitol (DTT) was added to 50 mg of DTNB dissolved in 300 μL of 1 M aqueous NaOH under an inert atmosphere. After 30 min, the reaction mixture was acidified with 1 M HCl and the mixture was extracted with diethyl ether under an inert atmosphere. The organic layers were then anhydri-ficated and evaporated under reduced pressure. The residue was washed several times with ethanol to obtain TNB as a dark yellow product.

The Mgr6 derivatization degree was determined by reaction of mAb (3.3 μM , 500 μL) with TNB dissolved in ethanol (3.4 mM, 10 μL) for 90 min at 25 $^{\circ}\text{C}$. After purification by gel centrifugation, the number of iodoacetyl groups was determined spectrophotometrically (TNB molar absorption coefficient was $8800 \text{ M}^{-1} \text{ cm}^{-1}$ at 339 nm). The mean derivatization degree was 1.7.

The derivatized mAb and RIP were mixed in the presence of a solution of hydroxylamine (1/10, v/v). The conjugation reactions proceeded for 18 h at 4 $^{\circ}\text{C}$; at the end of the reaction, a solution of *N*-ethylmaleimide (20 mM, 20 μL) was added to block free thiol groups.

Immunotoxin Purification. Conjugates were purified from unconjugated clavin and Mgr6 in a one-step procedure using CM MemSep cartridges (1000 or 1010) (Millipore) for analytical or preparative application and a Merck-Hitachi 655A-12 HPLC gradient system equipped with an L-5000 LC controller. The eluting fractions were monitored at 280 nm using a L4000 UV detector. Peak heights were recorded and processed on a CBM-10A Shimadzu interface. The mobile phase was sodium acetate buffer (20 mM at pH 5.5) flushed at 1 mL/min. Fractions containing immunoconjugates were dialyzed and concentrated. The purity of the immunotoxins was monitored by sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS–PAGE) using 4–15% precast gels (Bio-Rad) under nonreducing conditions and Coomassie blue staining.

In Vitro Evaluation of Disulfide Bond Stability. The in vitro stability of the bond in the various conjugates was evaluated as follows. Samples (1 mg/mL, 3 μL) were incubated for 1 h at 37 $^{\circ}\text{C}$ with solutions of reduced glutathione (GSH, 3 μL) in increasing excesses (from 3 to 10000-fold), and the reaction was stopped by addition of excess iodoacetamide. Following SDS–PAGE under nonreducing conditions, the 7.5% precast gels (Bio-Rad) were stained with Coomassie blue, dried, and scanned on a Compact 4800 flatbed scanner using Twain compatible software. Band densities were analyzed using ImagePC (Scion Co., Frederick, MD) to calculate the amount of Mgr6 released.

Cell Lines. Human breast carcinoma cell line SKBr3 (ErbB2+) was purchased from ATCC (Rockville, MD), and human melanoma cell line MeWo (ErbB2–) was kindly provided by the late J. Fogh (Memorial Sloan-Kettering Cancer Center, New York). Both cell lines were grown in RPMI 1640 containing 10% fetal calf serum and gentamicin (100 $\mu\text{g/mL}$).

Binding Inhibition Assay. mAb activity after conjugation was assayed as the ability to inhibit binding of [^{125}I]Mgr6 to adherent glutaraldehyde-fixed SKBr3 cells. A fixed amount of [^{125}I]Mgr6 (1 nM) was mixed with serial

dilutions of cold Mgr6 or IT, starting from a 100-fold molar excess. The mixture was added to SKBr3 fixed cells (adherent in 96-well plates) and incubated for 3 h at 37 °C. Cells were washed 10 times with PBS and incubated with 2 N NaOH (100 μ L/well) for 20 min at room temperature. The supernatant was collected and radioactivity determined in a γ -counter (Beckman Instruments, Fullerton, CA).

Percent inhibition was calculated as follows:

$$\% \text{ inhibition} = (1 - C_i/C_{ni}) \times 100$$

where C_i is the average counts per minute in the presence of cold inhibitor and C_{ni} is the average counts per minute without inhibitor.

Inhibition of Protein Synthesis. The assay was carried out essentially as described (13). Briefly, SKBr3 and MeWo cells were suspended in culture medium containing the appropriate concentration of IT, toxin, or mAb alone and incubated for 3 h at 4 °C. Control cells were incubated with medium alone. Cells were centrifuged, resuspended in fresh culture medium, and seeded in 96-well plates (3×10^5 cells/well). After incubation at 37 °C for 48 h, [^{3} H]proline (1 μ Ci/well) was added. After 48 h, cells were washed and [^{3} H]proline incorporation was determined by liquid scintillation in a β -counter. Results are expressed as a percentage of [^{3} H]proline incorporation in control cells.

Radioiodination Procedure. ITs, clavin, and Mgr6 were ^{125} I-labeled using the Iodogen method according to the manufacturer's instructions, to a mean specific activity of 1.5 mCi/mg for ITs, 8.5 mCi/mg for Mgr6, and 4.5 mCi/mg for clavin. The integrity of the radiolabeled protein was tested by ascending paper chromatography in 10% trichloroacetic acid and by SDS–PAGE analysis.

Pharmacokinetic Evaluation. Experiments were performed on 6-week-old female Balb/c mice (Charles River, Como, Italy) maintained according to the provisions of the European Economic Community Council directive 86/209 recognized and adopted by the Italian Government.

Mice received a Lugol solution (0.02% I_2) and 0.6 mg/mL $KClO_4$ in their drinking water 3 days before administration of radioiodinated ITs and throughout the experiments to block free iodine uptake by the thyroid gland and the stomach mucosa. Animals were injected intravenously with a single dose of ^{125} I-labeled IT, ranging from 1.7 to 2.5 μ g/mouse. Blood samples were drawn from the retro-orbital sinus at fixed times after injection. Pharmacokinetic analysis was carried out on serum samples. Each serum sample was diluted 1/20 and run in SDS–PAGE under nonreducing conditions. Gels were fixed, dried, and exposed in a PhosphorImager screen (Molecular Dynamics, Sunnyvale, CA). Densitometric analysis, performed using Image Quant software (Molecular Dynamics), was used to determine the percentage of intact immunoconjugates in the serum at each time point. Pharmacokinetic parameters were calculated using PCNONLIN software (SCI Software, Lexington, KY).

RESULTS

Chemistry. The cross-linkers, prepared as described (23–25), were characterized by NMR, IR, and MS. Before conjugation, the reactivity of the linkers toward the lysyl ϵ -amino groups of IgG as a model protein was evaluated to insert 1–2 groups. Scheme 1 shows the structures of the cross-linkers.

Scheme 1. Structures of Cross-Linkers Used to Produce Mgr6–Clavin ITs

Preparation of Immunotoxins. Four different coupling procedures (Schemes 2 and 3) were followed to compare the relative activity, stability, and in vivo fate of the immunotoxins.

Disulfide Bridge Immunotoxins. Linkers AMPT and M-AMPT were reacted with recombinant clavin to introduce 1–1.3 S-acetylthio groups per protein molecule, whereas a mean value of 1.1 arylthio residues was introduced into Mgr6 with CDPT; the derivatized proteins were coupled in the presence of hydroxylamine to deprotect the acetylthio groups (IT-1 and IT-2 in Scheme 2). Clavin modified with CDPT was reacted with the Mgr6 previously reacted with the hindered *N*-hydroxy-succinimidyl linker SAMBA (IT-4) (Scheme 3).

All coupling reactions were allowed to proceed for 5 h at 25 °C and for 18–35 h at 4 °C; aliquots of the reaction mixtures were analyzed by SDS–PAGE.

Thioether Bridge Immunotoxin. To obtain a thioether linkage, Mgr6 was derivatized with SIA (1.7 iodoacetyl groups) and clavin with AMPT as described above. After addition of hydroxylamine, the reaction proceeded for 18 h at 4 °C (IT-3 in Scheme 2).

The yield of conjugation for the thioether-linked IT was 12%, while for the disulfide-ITs, the yield was approximately 10% for IT-1 and IT-2 and 5% for IT-4. This suggested an inverse correlation between disulfide bond stability and conjugation efficiency. The low yield can be attributed in part to the low (range of 1–1.7) number of reactive groups per protein.

Purification of Immunotoxins. All ITs were purified from the reaction mixture in a single step by HPLC–ion exchange chromatography using a 1010 CM MemSep cartridge.

Figure 1A shows an example of the elution profile of the crude mixture eluted using a discontinuous gradient of sodium chloride ranging from 0 to 250 mM. Fractions from each of the four regions of the elution peaks were separately pooled and subjected to nonreducing SDS–

Scheme 2. Preparation of Mgr6-(CDPT)SS(AMPT)-Clavin (IT-1), Mgr6-(CDPT)SS(M-AMPT)-Clavin (IT-2), and Mgr6-(SIA)CS(AMPT)-Clavin (IT-3)**Scheme 3. Preparation of Mgr6-(SAMBA)SS(CDPT)-Clavin (IT-4)**

PAGE analysis (Figure 1B). By comparison with purified Mgr6 and clavin electrophoresed in parallel, peak 1 was composed only of unreacted Mgr6, peak 2 was 80% IT with a molecular mass of 167 kDa, peak 3 was >99% IT (167 kDa), and peak 4 contained only unreacted clavin (17 kDa).

Disulfide Bond Stability of Conjugates in Vitro.

To test the in vitro stability of the immunotoxins, samples were incubated with reduced GSH in different excesses, subjected to SDS-PAGE, and assessed densitometrically (Figure 2). The profile of the disulfide rupture as a function of GSH excess used is shown in Figure 3. An increase in disulfide stability in relation to the steric hindrance around the disulfide of the conjugates was observed. In comparison, the presence of a thioether bond precluded the breakage by GSH. The increase in stability was exponential, i.e., 10-fold for one methyl group and 100-fold for a geminal dimethyl group. When GSH was used in an excess higher than 7000-fold,

cleavage of the mAb disulfide bond was measurable (data not shown).

In Vitro Activity of ITs. To determine whether Mgr6 retained its binding capacity after derivatization and conjugation, competitive inhibition experiments were conducted with the four ITs. A small, reproducible drop in binding capacity was observed after derivatization that was independent of the cross-linker used (see Figure 4, Mgr6-CDPT curve). All ITs competed with the native [^{125}I]mAb, with a titration similar to that of cold derivatized Mgr6, and no significant differences due to the linkage method adopted were evident (Figure 4).

Each IT was tested for its ability to inhibit protein synthesis in ErbB2-positive SKBr3 cells compared with the inhibition by unconjugated clavin. All ITs specifically inhibited protein synthesis in the SKBr3 cells, whereas none did so in ErbB2-negative MeWo cell. As shown in Figure 5, the IC_{50} s of the conjugates containing a disulfide bridge were similar and ranged between 1 and 4 nM; the

Figure 1. Elution profile of the IT reaction mixture from the CM-MemSep column (A) and SDS-PAGE analysis of eluted fractions (B). For preparative purposes, a MemSep 1010 cartridge eluted in sodium acetate buffer (20 mM at pH 5.5) was loaded with 400 μ L of conjugation mixture, and a step gradient of the same buffer and 1 M NaCl was applied, at a 0.5 mL/min flow rate for the first 12 min and at 2 mL/min thereafter. After 20 min, the gradient was raised over the course of 10 min to 100 mM NaCl and kept constant for another 10 min. To remove unconjugated clavin, the gradient was increased to 250 mM over the course of 10 min and held there for 20 min. The collected fractions (about 3.5 mL) were immediately brought to pH 7.4 by addition of a solution of 1 M PBS (pH 8).

Figure 2. SDS-PAGE analysis of IT-2 incubated with GSH at different concentrations for 1 h at 37 °C.

Figure 3. Release of mAb from the immunoconjugates. The conjugates were incubated with GSH at different concentrations for 1 h at 37 °C. The amounts released were measured by densitometry after SDS-PAGE. Results are the average of three independent experiments (SDs < 10% of the mean).

conjugation to the mAb resulted in a 150–650-fold increase in cytotoxic activity compared to that of clavin alone. No toxicity was observed after treatment with the conjugate containing the thioether bond (IT-3), which cannot be cleaved inside the cell. The specificity of the

Figure 4. Competition of [¹²⁵I]Mgr6 binding to SKBr3 (HER2+) glutaraldehyde-fixed cells with increasing molar concentrations of unlabeled mAb, derivatized mAb, and ITs (SD < 5% of the means).

cytotoxicity was confirmed by the absence of an effect on MeWo cells (IC₅₀s for all ITs are > 1 μ M vs an IC₅₀ of 0.8 μ M for clavin).

Pharmacokinetics. To evaluate the in vivo stability of ITs with a hindered (IT-2 and IT-4) or an unhindered (IT-1) disulfide bond or a thioether bond (IT-3), the pharmacokinetic behavior of each species was evaluated after intravenous bolus administration of ¹²⁵I-labeled IT in groups of three Balb/c mice. Blood samples were collected at various times, and radioactivity was determined. Plasma samples were analyzed by SDS-PAGE, autoradiography, and densitometry. The unhindered disulfide conjugate (IT-1) broke down to release the free

Figure 5. Inhibition of [³H]proline incorporation in SKBr3 target cells. Values represent the arithmetic means of three determinations (SDs < 10% of the means).

antibody in vivo at the fastest rate, and after 6 h, only 12% of the intact IT was present as compared with 35% of the IT-2 at the same time point. Plasma samples collected from IT-4 injected mice contained approximately equal amounts of intact immunotoxin and released mAb 47 h after injection. IT-3 appeared to be stable, and by densitometric analysis, the conjugate represented 86–90% of the total radioactivity 72 h after injection.

Plasma concentrations of IT at each time point were used to construct pharmacokinetic curves for each conjugate (Figure 6). Table 1 lists the parameters obtained from computerized analysis of the clearance data using an open two-compartment pharmacokinetic model. Data for the single components of the ITs are included for comparison. Mgr6 showed a long serum elimination phase, whereas clavin, due to its low molecular mass and relevant charge, was cleared rapidly with only 3% of the initial radioactivity present after 1 h. The clearance values for clavin are shorter than those we reported previously (13) due possibly to the different method used for evaluation.

The elimination curves of the ITs were biphasic, with a similar initial rapid α phase (about 17 min) followed by a slower β phase. The immunoconjugates with higher in vitro stability were eliminated more slowly. Indeed, IT-1 was cleared rapidly; IT-2 doubled the β -phase half-life (from 3.5 to 7.1 h), and IT-4 increased the elimination phase to 24 h. The thioether linkage showed its intrinsic stability, with a β -phase half-life of 46 h. The difference in the elimination rate (144 h for the mAb and 46 h for IT-3) is due only to the presence of the clavin molecule. The thioether linkage stability also increased the distribution phase (from 17 to 32 min).

DISCUSSION

Immunotoxins have shown promise in therapeutic applications for hematological malignancies (1, 2, 27, 28); however, the therapy of disseminated solid tumors has proven to be a greater challenge, and only few trials have provided encouraging results (3, 29). Several investigators used a reduced size IT Fab linked to the toxic domain

Figure 6. Pharmacokinetic serum curves for ITs, clavin, and Mgr6. Mice were injected intravenously with the proteins, and blood samples were obtained at various time intervals. Concentrations were determined by assay of ¹²⁵I radioactivity and by densitometric analysis of SDS–polyacrylamide gels. Note the different clearance times in panels A and B.

of diphtheria toxin or *Pseudomonas* exotoxin to allow sufficient tissue permeation; however, this approach was not efficient in the treatment of solid tumors due to faster increased in vivo clearance (30). We and others have used whole ITs (mAb–RIP) with high potency and good pharmacokinetic properties (6, 10, 31, 32).

In this study, we chose an anti-erbB2 mAb as the RIP targeting component. A large array of murine mAbs directed to HER2 have been generated (33), and several, including Mgr6, induce down-modulation of the oncoprotein and inhibition of tumor growth. The antitumor effect of these and related mAbs is significantly improved by chemical or molecular coupling with toxins (34, 35). A phase I study in breast cancer patients indicated the clinical feasibility of intravenous administration of up to 80 mg of Mgr6 (our unpublished results). Preliminary data in nine breast cancer patients indicate that Mgr6 has a mean elimination half-life of 37 h and does not

induce a human anti-mouse antibody response (manuscript in preparation).

As the toxic agent, we used a novel recombinant RIP, clavin, characterized by a low molecular mass (17 kDa), high in vitro activity, and reduced immunogenicity. The latter is especially relevant because almost all of the RIPs used for IT preparation such as PAP, saporin, momordin, and bryodin are highly immunogenic, and the antibody moiety of most IT conjugates elicits an even stronger immune reaction (36). Those findings are consistent with results obtained in patients receiving IT (37).

Clavin also shows a very low-level, transient, and reversible systemic toxicity on kidney and liver. This aspect is important because one of the major problems in using RIPs, such as PAP-1, PAP-S, RTA, and saporin, is related to their irreversible liver and kidney damage (38, 39).

To be therapeutically effective, ITs composed by type I RIPs must be linked in such a way that they are easily cleaved intracellularly but sufficiently stable in the blood circulation. A stable disulfide bond is essential in maintaining the half-life and potency of ITs, especially for solid tumors. The use of sterically hindered linkers such as SMTP to construct ITs with deglycosylated RTA is widely described, and these ITs are being used in phase I and II clinical studies (1, 2).

We therefore chose a series of thioimide linkers which preserve the positive charge on derivatized proteins and generate both a labile disulfide bond and different steric hindrances. The maintenance of a positive charge is especially important when using toxins such as clavin which is a relatively small molecule with a high positive charge.

Using the thioimide reagents, we prepared three ITs with a disulfide bond and one with a thioether linkage; all were expected to be stable in vivo. A geminal dimethyl hindrance was inserted using the SAMBA reagent because the analogous thioimide linker (in particular its nitrile precursor) tended to polymerize and appeared to be unsuitable for protein derivatization. Since neither SAMBA nor SIA preserved the surface charge, the protein derivatized with these linkers was the mAb which appeared to be less sensitive to surface charge modification (data not shown).

Using a derivatization degree of 1–1.7, we obtained only a 1/1 Mgr6–clavin species of conjugate, reflecting the reactivity of the carboxamidophenylthiolate leaving group presented in the linker CDPT. These conjugation procedures led to a highly homogeneous IT population, which is an advantage in accurately addressing the potency of an IT, but the presence of contaminating unconjugated mAb and RIP remains. The toxin can be removed easily by gel permeation, but this procedure fails to separate IT from free mAb. The amount of free mAb is generally too low to interfere with cytotoxicity assays; however, ITs are cleared more rapidly than unconjugated

mAb from the blood circulation. Moreover, the excess of mAb can compete with the IT for binding to the target antigen and can compromise the effectiveness of the IT in vivo. Several methods for the purification of IT from unconjugated antibody have been reported: ion exchange chromatography (40), high-performance liquid immunoaffinity chromatography (41), chromatography on immobilized Cibacron Blue F3GA (42), and, more recently, a nickel-based resin (Ni-NTA) technique (43) for purifying immunoconjugates containing 10 consecutive histidine residues at the amino terminus of the recombinant toxin.

To increase the yield of conjugate and to minimize the number of purification steps, we focused on an HPLC ion exchange procedure exploiting the high ionic charge ($pI > 10$) on the small surface of clavin, which allows interaction with weak ionic exchanger groups. In fact, isoelectrofocusing of the ITs showed an increase in the pI from 6.2 for the free Mgr6 to 8.2 pH units (data not shown). Further, an HPLC procedure with a membrane cartridge system allows the use of an increased elution flow rate, maintaining high peak resolution. The semistepwise linear salt gradient removes the low-molecular mass reactives (*N*-ethylmaleimide and leaving groups), and Mgr6 eluted in a sharp peak as well as unconjugated clavin. The IT eluted progressively in different peaks, with the first containing small amounts of Mgr6 and the final peaks containing only one pure species, 1/1 mAb–clavin IT.

As confirmed by competitive binding assay, the conjugation procedure and the nature of the linkage did not significantly modify the mAb binding capacity. Conjugates with disulfide bonds showed almost the same cytotoxic activity toward the target SKBr3 cell line, whereas they were ineffective on the nontarget MeWo cell line. The intracellular release of free clavin is necessary for its activity, and the IT linked by a thioether bond was not cytotoxic at all. These data are in agreement with previous findings that the introduction of a hindered disulfide linkage into ITs has little or no effect on pharmacological potency (23), suggesting that disulfide cleavage is not the rate-limiting step in the toxic activity of clavin conjugates on the cell. Moreover, for RIPs with a ribonuclease action, the maintenance of an intracellular easily breakable linkage between mAb and RIP is essential. This behavior is consistent with that described for gelonin and RTA (44) but in contrast with other findings (45) which suggested that gelonin can be delivered efficiently by a thioether linkage with the appropriate anti- α -fetoprotein antibody.

Comparison of the stability among unhindered and hindered disulfide- and thioether-linked ITs showed that the release of mAb by incubation with GSH is proportional to the presence of methyl groups and increased exponentially with the increase in steric hindrance. The in vivo stability of the ITs was verified by studying the

pharmacokinetic behavior after intravenous bolus administration in Balb/c mice.

An exponential correlation was also observed between the clearance rate and steric hindrance for the ITs and Mgr6. These findings underline the importance of inserting a highly stable dimethyl instead of a monomethyl or, obviously, an unhindered disulfide into the clavin IT. This was not so important in the case of RTA ITs (24) where a dimethyl group represented no advantage over a monomethyl, with respect to stability. Moreover, we previously reported (23) a linear correlation in the stability of methyl-substituted disulfide-linked gelonin ITs.

We also prepared a nonreducible thioether linkage to demonstrate the theoretical limit of in vivo linkage stability that can be obtained using Mgr6-clavin ITs. Even the presence of 1 mol of clavin per mole of mAb determined a decrease in elimination time (from 144 to 46 h) due to modification of the surface charge in mAb linked to a highly basic toxin.

The presence of a thioether linkage also affected the distribution phase (α phase) which was doubled compared to that of the three disulfide-linked ITs. In the latter, all three ITs had a similar α phase, suggesting that the reducibility of the linkage is not a limiting factor during the distribution.

We have used the most hindered cross-linking system (SAMBA and CDPT) to obtain an IT which maintains its high potency and specificity and has a slow blood clearance similar to that of RTA-containing ITs used in clinical trials (1, 2, 24). Since even a short half-life IT has been reported to be clinically effective in inducing tumor reduction (29, 30), we speculate that an increase in the half-life to 24 h renders the Mgr6-clavin IT more efficient in inducing in vivo tumor damage.

Temperature-Dependent Associating Property of Liposomes Modified with a Thermosensitive Polymer

Hiroshi Hayashi,[†] Kenji Kono,^{*,‡} and Toru Takagishi[‡]

Shiga Central Research Laboratories, Noevir, Company, Ltd., Yokaichi, Shiga 527, Japan, and Department of Applied Materials Science, College of Engineering, and Department of Applied Bioscience, Research Institute for Advanced Science and Technology, Osaka Prefecture University, Sakai, Osaka 593, Japan. Received August 6, 1997; Revised Manuscript Received December 1, 1997

Novel temperature-sensitive liposomes having surface properties that can be controlled by temperature were designed as liposomes coated with poly(*N*-isopropylacrylamide), which exhibits a hydrated coil to dehydrated globule transition at ca. 32 °C. To obtain the polymer with anchoring groups to the liposome, a copolymer of *N*-isopropylacrylamide and octadecyl acrylate (99:1, mol/mol) was synthesized by radical copolymerization. The copolymer revealed the transition near 30 °C. Liposomes made from various phospholipids were prepared by sonication and coated with the copolymer. When dipalmitoylphosphatidylcholine and distearoylphosphatidylcholine were used as liposome lipids, remarkable aggregation and fusion of the copolymer-modified liposomes took place between the transition temperature of the copolymer and the gel–liquid-crystalline transition temperature (T_c) of the lipid membranes. However, above the T_c , association between the liposomes was much less significant, although the copolymer is still hydrophobic. In the case of the copolymer-modified dilauroylphosphatidylcholine liposome, the membrane of which takes on a liquid-crystalline state under the experimental conditions, association between the liposomes also hardly occurred even when the copolymer became hydrophobic. On the other hand, below the transition temperature of the copolymer, the copolymer-modified liposomes were very stable and aggregation of the liposomes was not observed, irrespective of membrane lipid. Results obtained in this study demonstrate that the copolymer chains fixed on the surface of the liposome with a solid membrane promote aggregation and fusion of the liposomes by hydrophobic interactions between the copolymer chains and/or between the copolymer chains and the liposome membranes above the transition temperature of the copolymer.

INTRODUCTION

Since liposomes made from naturally occurring lipids are biocompatible, their application to drug delivery systems has been extensively attempted (1). To elevate their usefulness, a number of liposomes with various functionalities have been designed. For example, with respect to site specific delivery of drugs, liposomes that release their contents in response to temperature (2, 3), pH (4–6), and light (7–9) have been reported. Also, for cytoplasmic delivery of membrane-impermeable molecules, fusogenic liposomes have been developed (10–14). These liposomes are considered to fuse with the plasma membrane or the endosomal membrane and release their contents into the cytoplasm (14–16). Therefore, fusogenic liposomes are of importance as a carrier of oligonucleotides, nucleic acids, and proteins.

While several approaches to the production of liposomes with functionalities have been attempted, one of the most effective methods is their modification with polymers (17, 18). It was shown that coating of liposomes with polysaccharides improves the stability of the liposomes (19). Also, conjugation of synthetic polymers with

pH sensitivity onto liposomes was shown to provide them with pH-sensitive release and fusion properties (5, 13).

Recently, to obtain liposomes with temperature sensitivity, we (3, 20) and other groups (21–23) designed liposomes modified with poly(*N*-isopropylacrylamide) [poly(NIPAM)].¹ It is well-known that poly(NIPAM) is soluble in water and takes on a hydrated coil state below ca. 32 °C, whereas the polymer is insoluble in water and exhibits a dehydrated globule state above this temperature (24). Already, we have demonstrated that release of contents from the poly(NIPAM)-coated liposomes is enhanced above the coil–globule transition temperature of the polymer (3, 20).

So far, we have focused on the temperature-sensitive release property of the poly(NIPAM)-coated liposomes. However, fixation of the temperature-sensitive polymer onto the liposome surface is also considered to render the nature of the liposome surface temperature-sensitive. The highly hydrated polymer chains will cover the liposome surface below the transition temperature of the polymer. However, above the polymer transition temperature, the polymer chains become hydrophobic and will adsorb onto

¹ Abbreviations: poly(NIPAM), poly(*N*-isopropylacrylamide); copoly(NIPAM–ODS), copolymer of *N*-isopropylacrylamide and octadecyl acrylate; DPPC, 1,3-bis(sn-3'-phosphatidyl)-sn-glycero-3-phosphocholine; DLPC, 1,3-bis(sn-3'-phosphatidyl)-sn-glycero-3-phosphocholine; DSPC, 1,3-bis(sn-3'-phosphatidyl)-sn-glycero-3-phosphocholine; NBD-PE, *N*-(7-nitro-2-benzoxa-1,3-diazol-4-yl)phosphatidylethanolamine; Rh-PE, *N*-(1-issamine rhodamine B sulfonyl)phosphatidylethanolamine; AIBN, azobisisobutyronitrile.

the liposome surface, making the surface hydrophobic. Thus, it is expected that hydrophilicity or hydrophobicity of the liposome surface can be controlled by the ambient temperature. Also, interaction of dehydrated polymer chains with the liposome membrane might reduce the integrity of the membrane structure above the transition temperature of the polymer, which may increase the fusion ability of the liposome.

To examine the influence of surface modification of liposomes with the temperature-sensitive polymer on the nature of the liposomes, we have synthesized a copolymer of NIPAM and octadecylacrylate [copoly(NIPAM-ODA)] as poly(NIPAM) having anchors to liposomal membranes and prepared liposomes coated with the copolymer. Temperature-dependent aggregation and fusion of the copolymer-attached liposomes have been reported.

EXPERIMENTAL PROCEDURES

Materials. L- α -Dipalmitoylphosphatidylcholine (DPPC), L- α -dilauroylphosphatidylcholine (DLPC), and L- α -distearoylphosphatidylcholine (DSPC) were purchased from Sigma. *N*-(7-Nitrobenz-2-oxa-1,3-diazol-4-yl)phosphatidylethanolamine (NBD-PE) and *N*-(lissamine rhodamine B sulfonyl)phosphatidylethanolamine (Rh-PE) were obtained from Avanti Polar Lipids. *N*-Isopropylacrylamide (NIPAM), octadecylacrylate (ODA), and azobis(isobutyronitrile) (AIBN) were from Tokyo Kasei. NIPAM was purified by recrystallization from cyclohexane/*n*-hexane (1:1) before use.

Synthesis of Copoly(NIPAM-ODA). Copoly(NIPAM-ODA) was synthesized as reported previously (3). In brief, NIPAM (9.9 mmol), ODA (0.1 mmol), and AIBN (2.4×10^{-2} mmol) were dissolved in tetrahydrofuran. The solution was degassed with N_2 and kept at 60 °C for 4 h. The copolymer was recovered by precipitation with diethyl ether. The copolymer was dissolved in tetrahydrofuran and reprecipitated with diethyl ether. The copolymer was dissolved in water and lyophilized.

Preparation of Liposomes. Liposomes were prepared as follows: a dry thin membrane of each of the phosphatidylcholines (10 mg) was dispersed in 1.0 mL of 10 mM Tris-HCl-buffered solution of pH 7.4 containing 140 mM NaCl. The lipid dispersion was sonicated for 10 min using a probe-type ultrasonic disruptor (Tomy Seiko, UR-20P). To the liposome suspension (1 mL) was added 0.5 mL of an aqueous solution in which 1 or 5 mg of the copolymer was dissolved, and the mixture was then incubated for 4 h at 5 °C with stirring. Free copolymer was removed by gel permeation chromatography on a Sephacryl S-400 column at 10 °C.

Estimation of the Amount of Copolymer Bound onto Liposome. The amount of the copolymer bound onto the liposome was estimated by high-performance liquid chromatography (HPLC) analysis on an Asahipak GF-310HQ column using methanol as an effluent, as reported previously (20). The copolymer-coated liposome was dried under reduced pressure and then dissolved in methanol. The solution (20 μ L) was injected into the column, and the effluent was monitored by absorbance at 220 nm. For calibration, the copolymer solutions of given concentrations were also injected. From the absorbance of the copolymer separated, the amount of copolymer adsorbed onto the liposome was determined using the calibration curve.

Size Change of Liposomes. Liposomes were prepared as mentioned above except that contamination of large multilamellar liposomes was eliminated by cen-

trifugation (18 000 rpm, 40 min) before incubation with the copolymer. The liposomes were suspended in 10 mM Tris-HCl and 140 mM NaCl solution (0.1 mg of lipid/mL) at pH 7.4 at desired temperatures for 3 min. Mean diameter of the liposome was measured immediately after the incubation or after an additional 10 min of incubation at 20 °C using a laser particle analyzing system (Otsuka Electronics, LPA 3100S).

Fusion of Liposomes. Fusion of liposomes was detected as reported previously (13, 25) by measuring resonance energy transfer between NBD-PE and Rh-PE as reported by Struck et al. (26). Liposomes containing 0.3 mol % of NBD-PE and Rh-PE were prepared according to the above method. The liposomes containing the fluorescent lipids were mixed in a 1:1 mole ratio with probe-free liposomes. The suspension (0.1 mg of lipid/mL) was excited at 475 nm, and fluorescence emission spectra were measured at various time intervals. The *R* value, the ratio of fluorescence intensity at 532 nm to that at 591 nm, was calculated. The ratio was converted into apparent concentration of the fluorophores in the membrane using a standard curve of the reciprocal of the concentration of the fluorophores vs *R* value. The percent fusion was defined as

$$\% \text{ fusion} = (C^0 - C^i)/(C^0 - C^f)$$

where C^0 and C^i are the initial and intermediate concentrations of the fluorophores, respectively. C^f , which equals 0.15 mol % of each fluorophore, represents the concentration at which complete fusion of the liposomes occurs.

Electron Microscopy. The copolymer-modified and the bare DPPC liposomes were suspended in 10 mM Tris-HCl and 140 mM NaCl solution (pH 7.4). The liposome samples were heated at 39 °C for 3 min and returned to room temperature (ca. 20 °C). A small drop of the liposome sample was placed on collodion-coated grids and drawn off with filter paper. A drop of 2% (w/v) phosphotungstic acid was applied to the grid, drawn off with filter paper, and then allowed to dry. The grids were viewed under an electron microscope (JEOL, JEM-2000FEX II).

Other Methods. Nuclear magnetic resonance (NMR) spectra were taken with a JEOL JNM-GX 270 MHz instrument. Differential scanning calorimetry (DSC) was performed with a Seiko Electronics DSC 120 microcalorimeter. The samples were analyzed at a heating rate of 0.5 °C/min. Phospholipid concentration was measured by an assay using Phospholipids B-Test Wako purchased from Wako Pure Chemical Industries. The molecular weight of the copolymer was estimated by HPLC analysis on a Shodex KD-803 column (Showa Denko) using *N,N*-dimethylformamide.

RESULTS AND DISCUSSION

Characterization of Copoly(NIPAM-ODA). To obtain poly(NIPAM) with anchors to liposomal membranes, we synthesized the copolymer of NIPAM and ODA, because a number of studies have shown that hydrophilic polymers with a few hydrophobic groups are fixed onto the liposome membranes through hydrophobic interactions (13, 17, 27). We have previously demonstrated that the NIPAM-ODA copolymer binds onto DPPC and egg yolk phosphatidylcholine liposomes (3).

The copolymer used here was evaluated to contain NIPAM and ODA units in the ratio of 99:1 (mol/mol) by ^1H NMR from the ratio of isopropyl groups in the NIPAM unit (δ 1.2 ppm) to *n*-alkyl groups in the ODA unit (δ 1.3

Figure 1. Microcalorimetric endotherms for aqueous copolymer samples in the absence (A) and in the presence (B) of egg yolk phosphatidylcholine liposome: (A) copolymer solution (0.4 wt %); (B) copolymer solution containing egg yolk phosphatidylcholine liposome (0.4 wt %). The samples (70 μ L) were heated at 0.5 $^{\circ}$ C/min. ΔH for curves (A) and (B) are 4.2 and 4.1 cal/g of the copolymer, respectively.

ppm). The weight-average molecular weight, the number-average molecular weight, and the heterogeneity of the copolymer were determined by gel permeation chromatography to be 12200, 5600, and 2.2, respectively.

It was shown by Schild and Tirrell (28) that the coil-globule transition of poly(NIPAM) can be detected by DSC. Therefore, a DSC measurement was performed to estimate the coil-globule transition temperature of the copolymer (Figure 1). DSC curves of the copolymer in water and in the presence of egg yolk phosphatidylcholine liposomes displayed endotherms with a peak centered at 29.4 $^{\circ}$ C and with a peak centered at 29.7 $^{\circ}$ C, respectively. These values are somewhat lower than the transition temperature of homopolymer of NIPAM, possibly due to the existence of ODA units in the copolymer. It has been previously reported that incorporation of hydrophobic groups into poly(NIPAM) lowers the transition temperature of poly(NIPAM) in water (29).

Fixation of Copoly(NIPAM-ODA) onto Liposomes. In this study, DPPC, DSPC, and DLPC were used as liposomal lipids because membranes of these lipids exhibit the gel-liquid-crystalline phase transition at different temperatures. Liposomes were prepared by sonication and coated with copoly(NIPAM-ODA) by incubation of the liposomes with the copolymer solutions and subsequent gel filtration on a Sephacryl S-400 column. Typical examples of the elution profiles for a DPPC liposome dispersion (A), for the copolymer solution (B), and for DPPC liposomes suspended in the copolymer solution (C) are shown in Figure 2. As is apparent in Figure 2A,B, the liposomes passed through the column more rapidly than the copolymer. Therefore, free copolymer can be removed from the copolymer-attached liposomes by using this column. We collected the effluent of the elution band shown in Figure 2C and used it for experiments.

The amount of the copolymer attached onto the liposome after the gel filtration was quantified by HPLC analysis on an Asahipak column for gel permeation chromatography using methanol as the eluent. Figure 3 shows typical examples of the chromatograms for the copolymer (A), DPPC (B), and copolymer-fixed DPPC liposomes (C). When an aliquot of the copolymer solution was injected into the column, two peaks (7.8 and 13.7

Figure 2. Typical elution profiles through a Sephacryl S-400 column for DPPC liposomes (6.7 mg/mL) (A), copolymer (3.3 mg/mL) (B), and DPPC liposomes incubated in copolymer solution (lipid = 6.7 mg/mL; copolymer = 3.3 mg/mL). Optical density at 220 nm was monitored. The samples (0.5 mL) were loaded onto the column. Flow rate of the effluent was 1 mL/min.

Figure 3. Typical elution profiles through an Asahipak column for copolymer (0.1 mg/mL) (A), DPPC (0.7 mg/mL) (B), and copolymer-fixed DPPC liposome (0.3 mg DPPC/mL) (C). Sample solutions (20 μ L) were injected into the column and eluted with methanol at 0.8 mL/min.

mL) were observed in the chromatogram as shown in Figure 3A. The first and second peaks are attributable to the copolymer and solvent, respectively. It was confirmed that area of the first peak is proportional to the concentration of the copolymer solution under the experimental conditions. When an aliquot of the lipid

Table 1. Preparation of Copoly(NIPAM–ODA)-Modified Liposomes

liposome	copoly(NIPAM–ODA) added (mg/mg of lipid)	copoly(NIPAM–ODA) bound (mg/mg of lipid)	NIPAM unit lipid (mol/mol)
DPPC 1	0.1	0.06	0.38
DPPC 2	0.5	0.16	1.01
DLPC	0.5	0.20	1.07
DSPC	0.5	0.15	1.02

solution was applied into the column, a new peak at 11.4 mL was seen in addition to the solvent peak (Figure 3B). As shown in Figure 3C, the chromatogram for the copolymer-fixed liposomes exhibited three peaks near 7.8, 11.4, and 13.7 mL, corresponding to the copolymer, lipids, and solvent, respectively. The amount of copolymer fixed on the liposomes was evaluated from the chromatograms using a calibration curve that shows the relationship between the area of the copolymer peak and the amount of copolymer.

When DPPC liposomes were incubated with the copolymer in the ratio 0.1:1 (copolymer/lipid, w/w), 0.06 mg of the copolymer was adsorbed onto 1 mg of the liposomal lipid. By increasing the copolymer/lipid ratio to 0.5:1 (w/w) during the incubation, the amount of copolymer adsorbed onto the DPPC liposomes increased to 0.16 mg/mg of lipid. The amounts of copolymer adsorbed on various liposomes are listed in Table 1. When these liposomes are incubated with the copolymer in the ratio 0.5:1 (copolymer/lipid, w/w), the numbers of NIPAM units adsorbed per lipid molecule for DLPC, DPPC, and DSPC liposomes are 1.07, 1.01, and 1.02, respectively, indicating that density of the copolymer on the liposome surface is nearly identical among these liposomes, despite the difference in their membrane fluidities.

Temperature-Dependent Association of Copoly(NIPAM–ODA)-Fixed Liposomes. To investigate the effect of temperature on association of the copolymer-modified liposomes, we first examined size change of liposomes depending on temperature. Liposomes were kept at various temperatures for 3 min, and then the temperature was changed to 20 °C. After 10 min of standing at 20 °C, the diameter of the liposomes was measured. The result is shown in Figure 4. The sizes of the bare DPPC and the bare DSPC liposomes hardly change throughout the range of temperatures we investigated. Also, the copolymer-modified DPPC and the copolymer-modified DSPC liposomes do not change their mean diameters below 30 °C, at which the copolymer bound on the liposomes is hydrophilic.

However, above this temperature when the copolymer is dehydrated and becomes hydrophobic, the size of these liposomes increases greatly. For the copolymer-modified DPPC liposome, a substantial increase in diameter was observed around 39 °C. This temperature appears to be slightly lower than the gel–liquid-crystalline phase transition temperature of DPPC membranes (ca. 41–42 °C) (30). However, it is known that DPPC liposomes made by sonication exhibit the phase transition in a temperature region lower than 41 °C because the membranes of the sonicated liposomes contain packing inhomogeneities caused by their high curvature (31). Thus, it is considered that aggregation of the copolymer-fixed DPPC liposomes is induced most intensively at their phase transition temperature. At the phase transition temperature, the gel and liquid-crystalline phases coexist in the membrane, and hence the membrane contains structural defects. Interaction of the copolymer with the liposome membrane should promote further generation

Figure 4. Mean diameter of various liposomes: (●) copolymer-modified DPPC liposome; (○) bare DPPC liposome; (■) copolymer-modified DSPC liposome; (□) bare DSPC liposome. The liposomes were kept at various temperatures for 3 min and followed by incubation at 20 °C for 10 min, and then diameters of the liposomes were measured at 20 °C. The copolymer-modified DPPC liposome 2 was used (see Table 1).

of defects in the membrane and destabilize the liposome. In addition to the hydrophobic interactions between the copolymers fixed on the liposomes, instability of the defective liposomes might enhance their aggregation, resulting in a significant increase in vesicle size.

In contrast, the increase of the vesicle size was much less significant above 42 °C. It is well-known that liposomes are more stable above the phase transition temperature than below it, where fusion of small vesicles takes place more readily (32).

On the other hand, since the copolymers fixed on the liposome are laterally mobile on the membrane surface above the gel–liquid-crystalline phase transition temperature, they will form aggregates through hydrophobic interactions within the membrane. In addition to the stability of liposomes with a fluid membrane, the difference in mobility of the copolymer on the membrane may also affect the potential of the liposome for association, as mentioned below.

A similar trend can be seen in the case of the copolymer-modified DSPC liposome, except that the most intensive increase in vesicle size occurred near 55 °C, which corresponds to the phase transition temperature of DSPC membrane. These results clearly demonstrate that the size increases of copolymer-modified liposomes are influenced by the fluidity of the liposome membrane as well as the hydrophobicity of the copolymer.

Because the copolymer alters its nature between hydrophobic and hydrophilic states reversibly, responding to the ambient temperature, it is expected that association and dissociation of the copolymer-modified liposomes occur reversibly. Therefore, the reversibility of this process for the copolymer-modified DPPC liposomes was examined. We measured the size of the liposomes immediately after a 3 min incubation at various temperatures, as well as after an additional incubation for 10 min at 20 °C. The results are shown in Figure 5. While in both cases the diameter of the liposome increases significantly near 40 °C, a much greater diameter was observed for the liposomes without additional incubation at 20 °C. This result indicates that liposomes which are associated through hydrophobic

Figure 5. Mean diameter of the copolymer-modified DPPC liposomes. Diameters of the liposomes were measured immediately after 3 min of incubation at various temperatures (●) or after an additional 10 min of incubation at 20 °C (■). The copolymer-modified DPPC liposome 1 was used (see Table 1).

Figure 6. Time courses of fusion of the copolymer-modified DPPC liposomes in 10 mM Tris-HCl-buffered solution containing 140 mM NaCl at various temperatures: (▲) 20 °C; (▼) 30 °C; (●) 39 °C; (■) 45 °C. The copolymer-modified DPPC liposome 1 was used.

interactions between the copolymers can be dissociated when the ambient temperature is lowered below the transition temperature of the copolymer. However, the liposome does not return to its original size, ca. 60 nm, during the 10 min cooling at 20 °C, suggesting that irreversible association of the liposomes also occurs at the same time.

Temperature-Dependent Fusion of Copoly-(NIPAM-ODA)-Fixed Liposomes. As mentioned above, irreversible association between the copolymer-modified liposomes was observed. As such association, fusion of the liposomes is most likely. Thus, we examined the occurrence of fusion by the resonance energy transfer method (26).

Figure 6 shows time courses of fusion of the copolymer-modified DPPC liposomes at various temperatures. Apparently, fusion of the liposomes depends on temperature. The liposomes hardly fuse at 20 °C, whereas intensive fusion takes place at 39 °C, at which a significant increase in vesicle size occurs (Figure 4). Fusion of the liposomes is quite fast and is complete within 1 min.

Figure 7. Percent fusion of various liposomes after 5 min of incubation as a function of temperature: (●) copolymer-modified DPPC liposome 1; (■) copolymer-modified DPPC liposome 2; (○) bare DPPC liposome; (▲) copolymer-modified DLPC liposome; (△) bare DLPC liposome.

The temperature dependence of fusion of various liposomes is shown in Figure 7. For the copolymer-modified DPPC liposomes, the liposomes hardly fuse below 30 °C, whereas above this temperature fusion occurs remarkably. Maximum fusion is seen near 39 °C, followed by a gradual decrease at temperature above 41 °C. This temperature dependence of fusion is similar to that of vesicle size shown in Figure 4. Because the bare DPPC liposomes exhibit a low percent of fusion throughout the experimental temperatures, this fusion property of the copolymer-modified liposomes is apparently controlled by the copolymer. Since the liposome membrane contains structural defects near the gel-liquid-crystalline phase transition temperature, the liposomes will be strongly destabilized by interactions with the hydrophobic copolymer. Moreover, the copolymers fixed on the liposomes facilitate aggregation of the liposomes by their hydrophobic interactions. Thus, fusion of the liposomes is promoted strongly near the transition temperature of the membrane.

When DLPC was used as the liposome lipid, enhancement of fusion hardly occurs above 30 °C. Because a DLPC membrane takes on a liquid-crystalline phase under the experimental conditions, it is suggested that the copolymer does not promote fusion of liposome with a fluid membrane.

To confirm the occurrence of fusion of the copolymer-fixed liposomes, the liposomes were observed by TEM. The copolymer-fixed and the bare DPPC liposomes were incubated at room temperature (ca. 20 °C) or at 39 °C for 3 min and then returned to room temperature and kept for 30 min. Typical TEM images of these liposomes are shown in Figure 8. For the bare DPPC liposomes, diameters of 20–70 nm were observed (Figure 8A). No apparent difference in vesicle size was seen between the liposomes incubated at room temperature and those incubated at 39 °C (result not shown). The size distribution of the liposomes is roughly consistent with the mean diameter (60–70 nm) estimated using dynamic light scattering (Figure 4).

In contrast, a significant difference in diameter was seen between the copolymer-fixed liposomes kept at room temperature and those incubated at 39 °C. When the copolymer-fixed liposomes were incubated at room temperature, liposomes with diameter of ~60 nm were

Figure 8. Negative stain electron micrographs of liposome preparations: bare DPPC liposomes incubated at room temperature (A) and copolymer-fixed DPPC liposomes incubated at room temperature (B) and at 39 °C (C). The bars shown in the (A), (B), and (C) represent 50, 50, and 100 nm, respectively.

observed as shown in Figure 8B. This diameter is similar to that of the bare DPPC liposomes. However, the size of the liposomes treated at 39 °C was quite different. The diameter of a large fraction of the liposomes was much >100 nm (Figure 8C). These results clearly indicate that fusion of the copolymer-fixed liposomes occurred during the incubation at 39 °C.

Temperature-Dependent Associating Property of the Copolymer-Modified Liposomes. As mentioned above, association of the copolymer-modified liposomes was induced above the copolymer transition temperature where the copolymer is hydrophobic. Therefore, it is considered that hydrophobic interactions play an important role in this association. However, association of the copolymer-modified liposomes is affected by the membrane fluidity of the liposomes. This association occurred only at and below the gel–liquid-crystalline transition temperature of the liposome membrane. When the copolymer is bound on the solid membrane, it may exist on the surface of the liposomes even above the transition temperature of the copolymer. However, when the copolymer is bound on the fluid membranes, it should penetrate more easily into the membrane. Therefore, the dehydrated copolymer is considered to be buried partly in the lipid membrane and may not interact with other liposomes effectively.

Ringsdorf et al. showed that hydrophobically modified poly(NIPAM) fixed on a liposome shrinks more efficiently on the surface of the liposome with a liquid-crystalline membrane than on the surface of the liposomes with a gel membrane, because the lateral diffusion of the hydrophobic groups inserted into the membrane is precluded in the gel membrane (33). Similarly, in this study, when the copolymer is fixed on the liposome with a fluid membrane, the copolymer will take a compact conformation above its transition temperature and, as a result, the bare lipid surface will be exposed. However, when the copolymer is fixed on the liposome with a solid membrane, the liposome surface will be covered more effectively by the hydrophobic copolymer chains. The position of the copolymer might also affect the association of the copolymer-modified liposomes, as indicated schematically in Figure 9.

Figure 9. Schematic illustration of temperature-dependent associating property of the copolymer-modified liposomes. Below the copolymer transition temperature, the highly hydrated copolymers cover the liposome surface and stabilize liposome (A). Above this temperature, the liposome surface is covered with the dehydrated copolymers, which enhance association of the liposomes when the liposome has a solid membrane (B). When the copolymer is fixed on a liposome with a fluid membrane, the copolymers shrink effectively and the bare surface is exposed (C).

In addition, it is well-known that the gel phase and liquid-crystalline phase coexist in lipid membranes at the phase transition temperature and that, as a consequence, these membranes contain structural defects. Therefore, it is likely that the dehydrated copolymer destabilized

the liposomes at this temperature and promotes association of liposomes strongly.

CONCLUDING REMARKS

It was found that surface modification of liposomes with copoly(NIPAM-ODA) provided liposomes with a temperature-sensitive associating property: both the aggregation and the fusion of the copolymer-modified DPPC and DSPC liposomes were remarkably enhanced above the transition temperature of the copolymer when these liposomes had a solid membrane.

The copolymer-modified liposomes prepared in this study exhibited temperature response above 30 °C, corresponding to the transition temperature of the copolymer. Since the transition temperature of this type of polymer is controllable by copolymerization with monomers with varying hydrophilicity (34), it is possible to obtain temperature-sensitive polymers with the transition temperature at a desired temperature. Kim et al. recently showed that the transition temperature of copolymers of NIPAM and acrylic acid was elevated as the content of acrylic acid in the copolymers increased. They prepared the copolymer-coated liposomes and showed that release of calcein loaded within the liposomes is enhanced above the transition temperature of the copolymers to some extent (35). In addition, several polymers are known to exhibit transition temperatures slightly higher than physiological temperature (28, 36). If such polymers are fixed on the liposomes, the liposomes are expected to reveal a temperature response near the physiological temperature.

When the liposomes with the temperature-sensitive surface property are injected into the blood stream, their interaction with the blood components, such as plasma proteins and various kinds of cells, should be affected by temperature. Therefore, the distribution of the liposomes in the body may be controlled by temperature. Moreover, the liposomes may deliver their contents into the cytoplasm by fusion with the cellular membranes. Interactions of the liposomes with proteins and cells are currently under investigation.

Alkaline Phosphatase Activatable Polymeric Cross-Linkers and Their Use in the Stabilization of Proteins

Christopher Bieniarz,^{*,†} Michael J. Cornwell,[‡] and Douglas F. Young[‡]

Advanced Drug Delivery, Hospital Products Division, and Diagnostics Division, Abbott Laboratories, Abbott Park, Illinois 60064-3500. Received February 9, 1998

We report the synthesis of polymeric cross-linking agents, poly(glutamic acid) poly(phosphorothioates), and their use in the cross-linking and stabilization of proteins upon treatment with alkaline phosphatase. We have shown that poly(phosphorothioates) are excellent substrates of alkaline phosphatase, yielding thiolated polymers which react covalently with electrophilic groups introduced into the proteins. Three proteins of different structure and function were cross-linked using this method: calf intestinal alkaline phosphatase, glucose oxidase (*Aspergillus niger*), and (R)-phycoerythrin. The cross-linking of alkaline phosphatase is self-catalyzed since this enzyme catalyzes the hydrolysis of phosphates, unmasking thiols which react with the maleimide prederivatized alkaline phosphatase. Incubation of buffered solutions of native alkaline phosphatase at 45 °C for 7–14 days resulted in a 35% higher loss of enzymatic activity compared to that of cross-linked enzyme. The effect of cross-linking glucose oxidase is even more notable, ranging from 800% stabilization at 37 °C and pH 9.0 to 3000% at 37 °C and pH 7.4. (R)-Phycoerythrin cross-linked with 1–3 equiv of poly(phosphorothioates) and incubated at 45 °C for 45 days was 20% more fluorescent than the native (R)-phycoerythrin subjected to the same conditions. The stabilizing effect of cross-linking was confirmed by comparing the rate of loss of quaternary structure of the cross-linked (R)-phycoerythrin with that of the native protein.

INTRODUCTION

The stabilization of proteins is an important field of practical and fundamental research. Enhancement of protein stability against denaturing effects of temperature, pH, and chemical agents has great practical applications in the biosensors, biopharmaceuticals, food, and cosmetic industries. Some of the methods used for stabilizing proteins against unfolding consist of molecular modifications, cross-linking, physical entrapment, surface immobilization, and the use of stabilizing carbohydrates and polymer additives. There is a plethora of reports, patents, and symposia dealing with many aspects of protein stabilization consisting of chemical derivatization and inter- or intramolecular cross-linking of the reactive functionalities on the surface of the proteins, presumably leading to increased conformational stability and enhanced resistance to denaturation (1–9). Unfolding of globular proteins generally involves exposure of buried hydrophobic side chains. Chemical cross-linking of proteins appears to be a particularly efficient stabilization method for minimizing unfolding pathways and preventing changes in the quaternary structure of multimeric proteins. Such unfolding often leads to dissociation into inactive protein subunits. Cross-linking approaches were exploited successfully in the stabilization of proteases, endonucleases, and antibodies (6, 7). Similarly, multimeric enzymes have been stabilized by cross-linking with glutaraldehyde (10). Deliberate polymerization of enzymes with the aim of improving their thermal stability

has also been described (11, 12). Several bifunctional cross-linking agents used in chemical cross-linking and stabilization of proteins were reviewed (13).

The reactive polymeric cross-linkers described in the above references lead to mostly intermolecular cross-linking of the proteins. The resulting polymeric protein often has a molecular weight well in excess of that of its native state. Moreover, the large adducts often have biological activities quite different from those of the native proteins. This is particularly troublesome when the cross-linked proteins are destined for use in immunoconjugates, biosensors, or other biometric applications because of the problems with nonspecific binding and altered solubilities of the cross-linked proteins.

In this paper, we report a novel method of protein cross-linking and stabilization. The cross-linking is based on an alkaline phosphatase activatable linear poly(phosphorothioate). The method is depicted in Scheme 1.

Protein (a) is first derivatized with maleimides. To the derivatized protein (b) is added a poly(phosphorothioate) (c), which is then exposed to the action of alkaline phosphatase (ALP).¹ ALP very efficiently catalyzes the

Scheme 1. ALP-Catalyzed Activation of Poly(phosphorothioate) Polymers and Their Cross-Linking of Proteins

hydrolysis of phosphates, unmasking thiolates on the backbone of the polymer (d). The polymer then reacts with maleimide-derivatized enzyme, resulting in a predominantly intramolecular cross-linking and concomitant stabilization of the protein (e). When the protein (a) is alkaline phosphatase, the process is self-catalyzed in that the very enzyme to be cross-linked catalyzes the hydrolysis of the phosphorothioate bonds and cross-linking of the protein surface.

To show the generality of our cross-linking stabilization method, we present results of ALP-induced cross-linking of three proteins of very different structure and function: calf intestinal ALP, glucose oxidase, and (R)-phycoerythrin. The proteins also vary in the number of subunits, as R-PE is multimeric, ALP dimeric, and GOX monomeric.

EXPERIMENTAL SECTION

Materials. Except as noted, reagents were obtained commercially and used without further purification. All solvents were HPLC grade. Hydrazine monohydrate, ethylenediamine, DTNB, and anhydrous DMF were from Aldrich Chemical Co. PGA, cysteamine S-phosphate, EDC, EDTA, Sephadex G-25, NEM, sodium periodate, sodium cyanoborohydride, glucose, PNPP, BSA, and all buffer components were from Sigma Chemical Co. (St. Louis, MO). SMCC and Traut's reagent (2-iminothiolane hydrochloride) were from Pierce Chemical Co. (Rockford, IL). Concentration membranes, the Centriprep-30 concentrator, and the Centricon-30 concentrator were from Amicon Co. (Beverly, MD). All dialysis tubing was from Spectrum (Houston, TX). Chromatography Econo and Bio-Sil SEC-400 columns and BIO-REX MSZ(D) resin were from Bio-Rad (Hercules, CA). Bovine intestinal ALP and GOX were from Boehringer Mannheim (Indianapolis, IN). R-PE was from Molecular Probes (Eugene, OR). HRPO, 3,5-dichloro-2-hydroxybenzenesulfonic acid sodium salt, and 4-AAP were from Abbott Laboratories (Abbott Park, IL).

General Procedures. Electronic spectra were recorded on a Hewlett-Packard 8452A diode array spectrophotometer. Fluorescence spectra were recorded on a Hitachi F-4010 spectrophotometer. HPLC analyses

were performed on a Spectra-Physics instrument equipped with an SP8490 dual-wavelength detector. All enzyme activity measurements were determined with the initial rate method (14).

Synthesis of Poly(glutamic acid) Poly(phosphorothioate) PGA(SPO₃)₂₄. PGA (MW = 50000–100000, 1.00 g, 14 mmol) and cysteamine S-phosphate (0.26 g, 1.4 mmol) were dissolved in 40 mL of deionized water. EDC (1.00 g, 5.2 mmol) was added in 100 mg aliquots every 30 min for 5 h. The product was purified with a Centriprep-30 concentrator against deionized water and then lyophilized.

Phosphorothioate Analysis. Quantitation of thiolates on poly(phosphorothioates) was achieved with adaptation of Ellman's method as described previously (15, 16). To 1.00 mL of a solution of 5.0 mM PGA(SPO₃)₂₄ in 0.1 M Tris buffer, 1.0 mM MgCl₂, and 0.1 mM ZnCl₂ at pH 7.5 (buffer A) was added 30 mL of 10 mM DTNB in buffer A. The solution was incubated for 5 min, and the absorbance at 412 nm was recorded. No free thiol was detected. ALP (10 mL of a 74.1 mM solution) was added and the mixture incubated until no further increase in 412 nm absorbance was detected (30 min). The concentration of thiol (0.12 mM) was calculated from the final 412 nm absorbance (1.54 AU) and the extinction coefficient of 13 000 M⁻¹ cm⁻¹ of DTNB at pH 7.5. We found there to be 24 equiv of phosphorothioate per mole of polymer.

PGA(SPO₃)₂₄ Cross-Linking of Bovine ALP. To 0.75 mL of an aqueous solution of 74.1 mM ALP was added 1.25 mL of 0.1 M sodium phosphate, 0.1 M NaCl, 1.0 mM MgCl₂, and 0.1 mM ZnCl₂ at pH 7.0 (buffer B). The enzyme was concentrated to 0.2 mL using a Centricon-30 concentrator. The concentrate was rediluted to 2.0 mL with buffer B and then reconcentrated to 0.2 mL, and the procedure was repeated three times. The volume of the enzyme solution was increased to 1.5 mL with buffer B and the mixture placed in a vial. To 75 mL of DMF was added 0.62 mg (1.87 mmol) of SMCC. This solution was added to 1.46 mL of a 35.5 mM solution of ALP (46.7 nmol) and the mixture allowed to react for 1 h at room temperature while being rotated at 100 rpm on a rotary agitator. Coarse Sephadex G-25 that had

been previously rehydrated with 0.1 M sodium phosphate, 0.1 M NaCl, and 0.05% NaN₃ at pH 7.0 (buffer C) was poured to a bed height of 45 cm in a 1 cm × 50 cm Econo column. The column was equilibrated with buffer B. Following the incubation, SMCC-derivatized ALP was applied to the column and the column eluted with buffer B. Fractions with an A₂₈₀ of >0.5 AU were pooled, and the A₂₈₀ of the pool was used to calculate the SMCC-derivatized enzyme concentration. To 300 mL of buffer B was added 2.43 mg (34.7 nmol) of PGA(SPO₃)₂₄, and this solution was added to 1.86 mL of a 1.40 mg/mL solution of SMCC-derivatized ALP (17.4 nmol) and the mixture allowed to react overnight at 5 °C while being rotated on a rotary agitator.

Characterization of PGA-Cross-Linked ALP. PGA-cross-linked ALP was evaluated by size exclusion chromatography using a Bio-Sil SEC-400 column and SDS-PAGE, as described in the Results.

Thermal Stability Evaluation of Cross-Linked ALP. Both the native and the cross-linked enzymes were diluted to 74.1 nM (10 mg/mL) with buffer A. These dilutions were stored at 45 °C in an incubator for the duration of the study. At day 0 and various time points along the course of the study, the activity of the enzymes was evaluated. To separate 1.00 mL volumes of 7 mM PNPP in 0.5 M diethanolamine, 1.0 mM MgCl₂, and 0.1 mM ZnCl₂ at pH 10.2 (buffer D) was added 20 mL of the 74.1 nM ALP dilutions. The rate change in the 412 nm absorbance was calculated over 14 s intervals. The rate generated by the enzyme preparations at the various points was divided by the rate generated by the same enzyme preparation at day 0 to calculate the percentage of residual enzyme activity for the stressed dilution.

PGA(SPO₃)₁₉ Cross-Linking, Characterization, and Thermal Stability Evaluation of GOX from *Aspergillus niger*. GOX experiments were performed in a manner analogous to the ALP procedures except the polymer had an average of 19 phosphorothioate groups. GOX was derivatized with 25, 50, 75, 100, and 150 molar equiv of SMCC as described above for ALP. The stoichiometry of GOX/PGA(SPO₃)₁₉ was 1:1. Hydrolysis of phosphate groups on PGA(SPO₃)₁₉ was the result of externally added micromolar native ALP. Cross-linked GOX was incubated at 37 °C at pH 7.4 and 9.0 and compared to native GOX under the same conditions. Both the native enzyme and the cross-linked enzyme were diluted to 500 mg/mL with 1.0 mM EDTA and 0.1 M NaCl at pH 7.4 (buffer E). These dilutions were stored in a 37 °C incubator for the duration of the study. At day 0 and various time points along the course of the study, the activity of native and cross-linked enzymes was evaluated. Prior to evaluation, the stressed enzyme preparations were diluted to 2 mg/mL using 0.1 M NaCl and 0.1 M sodium phosphate at pH 7.0 (buffer F). Enzyme activity was monitored in a solution of 2 mM 4-AAP and 8 mM 3,5-dichloro-2-hydroxybenzenesulfonic acid in the presence of 1 unit of HRPO and 100 mM glucose in buffer F. The rate changes were monitored at A₅₅₀ over 2 min intervals. Thermal stability evaluations of cross-linked GOX at pH 9.0 were carried out like they were for the sample at pH 7.4 except both the native and the cross-linked enzymes were diluted to 500 mg/mL with 0.1 M sodium phosphate, 1.0 mM EDTA, and 0.1 M NaCl at pH 9.0 (buffer G). Of course, in this application, ALP was added externally to catalyze the hydrolysis of phosphates on PGA(SPO₃)₁₉.

PGA(SPO₃)₁₈ and PGA(SPO₃)₂₈ Cross-Linking of R-PE from *Porphyra tenera*. To 2.5 mL of an aqueous solution of 41.7 mM R-PE was added 2 mL of buffer E.

This solution was transferred to dialysis tubing with a MW cutoff of 12000–14000 and dialyzed for 24 h each against three 4 L changes of buffer E. To a 1.21 mL aliquot of a 24.1 mM solution of dialyzed R-PE (0.292 nmol) was added a solution of 0.49 mg (1.47 nmol) of SMCC in 200 mL of DMF, and the mixture was allowed to react for 1 h at room temperature while being rotated at 100 rpm on a rotary agitator. A Sephadex G-25 column was prepared as above with buffer E, and following the incubation, the SMCC-derivatized R-PE was applied to a Sephadex G-25 column to remove unreacted SMCC. The column was eluted with buffer E, and 0.75 mL fractions were collected. Fractions with an A₅₆₆ of >1.0 AU were pooled, and the A₅₆₆ of the pool was used to calculate the protein concentration of the SMCC-derivatized R-PE. To 1 mL of buffer B was added 10 mg (167 nmol) of PGA(SPO₃)₁₈ (MW = 60 000). To this solution was added 25 mL of 10 mg/mL (1.67 nmol) ALP to deprotect the phosphorothioates. The deprotection reaction was allowed to proceed for 3 h at room temperature while the mixture was being rotated at 100 rpm on a rotary agitator. Following the incubation, a 71 mL (11.5 nmol) aliquot of this solution was added to 1.91 mL of 1.44 mg/mL (11.5 nmol) SMCC-derivatized R-PE and the mixture allowed to react overnight at 5 °C while being rotated at 100 rpm on a rotary agitator. Cross-linking at higher PGA(SPO₃)₁₈:R-PE ratios (2:1 and 3:1 molar ratios) was done analogously.

Characterization of Cross-Linked R-PE. PGA-(SPO₃)₁₈ and PGA(SPO₃)₂₈ cross-linked R-PE were evaluated by size exclusion chromatography using a Bio-Sil SEC-400 column. Detection was at 280 nm. The mobil phase was buffer E running at a flow rate of 1.0 mL/min. The primary population generated had a retention time corresponding to a singlet and doublet cross-linked protein with very little polymerization occurring. The residual fluorescence intensity of the cross-linked R-PE was measured and compared to the fluorescence of the native R-PE under the same conditions. The fluorescence generated by the cross-linked R-PE preparations was divided by the value of fluorescence of the native R-PE to calculate the percentage of residual fluorescence for the cross-linked preparations. The result of this evaluation showed that the cross-linked R-PE had retained 92% of the native protein fluorescence intensity.

Thermal Stability Evaluation of Cross-Linked R-PE by Fluorescence Measurement and by Size. The thermal stability of PGA(SPO₃)₁₈ or PGA(SPO₃)₂₈ cross-linked R-PE was evaluated by measuring fluorescence decay of samples thermally stressed at 45 °C and compared to that of native R-PE under the same conditions, using a λ_{exc} of 488 nm and a λ_{em} of 576 nm. Both the native and the cross-linked proteins were diluted to 100 mg/mL (0.42 mM) with buffer E. These dilutions were stored in a 45 °C incubator for the duration of the study. At day 0 and various time points along the course of the study, the fluorescence intensities of both preparations were evaluated. Prior to evaluation, the stressed protein preparations were diluted to 1 mg/mL (4.2 nM) using buffer E. The fluorescence of the R-PE preparations at various time points was divided by the fluorescence of the same preparation at day 0 to calculate the percentage of residual fluorescence intensity of the stressed protein.

The thermal stability of PGA(SPO₃)₁₈ and PGA(SPO₃)₂₈ cross-linked R-PE was evaluated at 45 °C and compared to that of native R-PE under the same conditions. A Bio-Sil SEC-400 column was used to follow the decomposition of the stressed R-PE into smaller subunits. Detection

Scheme 2. Synthesis of Poly(glutamic acid) Poly(phosphorothioate)

was at 280 nm. The mobile phase was buffer E running at a flow rate of 1.0 mL/min. Both the native protein and the cross-linked protein were diluted to 100 mg/mL with buffer E. These dilutions were stored in a 45 °C incubator for the duration of the study. At day 0 and various time points along the course of the study, the percentage of the total 280 nm absorbance which was due to the small components was evaluated.

RESULTS

Phosphorothioates are excellent substrates for alkaline phosphatase (17, 18). We have exploited this feature for an alkaline phosphatase-catalyzed hydrolysis of phosphorothioate-derivatized polymers. The resulting polymeric cross-linkers display many thiols which in a subsequent step may be reacted with the thiol-reactive electrophilic groups on the protein. Thus, the phosphate may be thought of as a protective group for thiols and alkaline phosphatase as the deprotection reagent. In view of the high reactivity of thiols toward oxidative coupling, the protective phosphate groups prevent disulfide bond formation. Thus, polymers derivatized with phosphorothioates allow access to a new family of cross-linking and conjugating polymers. Moreover, the high polarity of the phosphates ensures the solubility of even very water insoluble, nonpolar polymer backbones.

Although we have prepared several poly(phosphorothioate) polymers, in this work, we focus on cross-linking of three proteins of different structure and function by poly(glutamic acid) poly(phosphorothioate) shown in Scheme 2.

Cross-Linking of Bovine ALP. PGA was activated with EDC, and addition of cysteamine S-phosphate at various stoichiometries afforded polymers with various numbers of phosphorothioate groups per polymer. We found that the optimal level of phosphorothioate groups per polymer was between 18 and 24. The synthesis of $\text{PGA}(\text{SPO}_3)_x$ polymers is shown in Scheme 2.

In preliminary experiments, we ascertained that $\text{PGA}(\text{SPO}_3)_{24}$ is a good substrate for ALP. Virtually all thiols on the polymer were deprotected after 2 h at 5 °C and pH 7.0 using nanomolar quantities of ALP. This was demonstrated by quantitating the number of thiols as a function of time during the deprotection reaction, using Ellmann's reagent (DTNB). In previous work, we demonstrated that the derivatization of ALP with the maleimide heterobifunctional agents did not significantly affect the activity of the enzyme; 90–95% of the native enzyme activity remained after functionalization of the enzyme with various extended linkers (16). We confirmed this result in the current work and found that derivatization of the enzyme with 40 equiv of SMCC per enzyme resulted in a loss of only 5% of its activity. $\text{PGA}(\text{SPO}_3)_{24}$ and ALP were reacted in molar ratios of 1:1, 2:1, 3:1 or 4:1, and 6:1. The ratio of cross-linked multimeric

Figure 1. Dependence of the size of the cross-linked ALP on the stoichiometry of $\text{PGA}(\text{SPO}_3)_{24}$. Cross-linking ALP with 1 equiv of PGA cross-linker yields 82% of the multimeric aggregate of the enzyme (intermolecular cross-linking), while higher ratios of PGA per enzyme yield more singlet enzyme (intramolecular cross-linking).

structures to cross-linked singlets depends on the $\text{PGA}(\text{SPO}_3)_{24}$:ALP stoichiometry. Figure 1 shows that at higher $\text{PGA}(\text{SPO}_3)_{24}$:ALP ratios the cross-linking is prevalently intramolecular, resulting in higher ratios of the surface-cross-linked single enzyme molecule. At low $\text{PGA}(\text{SPO}_3)_{24}$:ALP ratios, multimeric intermolecular cross-linking predominates.

The maleimide-derivatized ALP catalyzes the cross-linking of its own surface in an autocatalytic process which, to the best of our knowledge, is unprecedented.

The cross-linked ALP was also examined by SDS-PAGE using a Phastgel system. Gradient gels of 7 to 10% polyacrylamide were run under nonreducing and reducing conditions. Results from nonreducing conditions showed that the primary population generated was singlet cross-linked enzyme with very little intermolecular cross-linking occurring. Results from the reducing conditions showed that the cross-linked ALP was not monomerized under conditions that were sufficient to monomerize the native ALP. Gel filtration HPLC analysis of the ALP cross-linked with 3 molar equiv of $\text{PGA}(\text{SPO}_3)_{24}$ per ALP using the Bio-Sil SEC-400 column in buffer B showed essentially complete replacement of the peak of the SMCC-derivatized ALP at 11.31 min with a

Figure 2. Thermal stability of ALP cross-linked at 2:1 and 4:1 PGA(SPO₃)₂₄:ALP molar ratios, with NEM capped and uncapped, at 45 °C in 0.1 M Tris buffer (pH 7.5), 0.1 mM ZnCl₂, and 1 mM MgCl₂. The data are normalized to 100% activity at day 0 to better visualize the changes.

new peak at 10.96 min and a small shoulder at a higher molecular weight corresponding to polymerized ALP. The UV-vis detector was set at A_{280} , and the flow rate was 1.0 mL/min. Similar results were observed at 2:1 and 4:1 polymer:enzyme stoichiometries with higher stoichiometries resulting in higher amounts of intramolecular cross-linking and lower multimeric content, as seen in Figure 1.

The cross-linked ALP is significantly stabilized against thermal denaturation. Figure 2 shows the extent of stabilization of cross-linked ALP compared to that of the native enzyme.

A conspicuous feature of the plot is a steep loss of the enzymatic activity during the first 24 h with the cross-linked and native ALP enzymes. Unlike the native enzyme whose activity decreases throughout the incubation, the PGA-cross-linked ALP recovers activity quite rapidly. This striking behavior is discussed later in the text.

The enzyme retains 75–90% of its native activity at day 0. The data in the figure are normalized to better visualize the loss of activity as the result of incubations at 45 °C. We found that *N*-ethylmaleimide capping of the unreacted thiolates left after the cross-linking was not necessary, and in fact led to 10% lower resistance to thermal denaturation. Figure 3 shows that at 5 °C the number of titratable thiols is essentially constant over time for 2:1 and 4:1 PGA(SPO₃)₂₄:ALP ratios. At 45 °C, there is a steady loss of thiolates, probably due to an oxidative dimerization process. Thus, after 5 days at 45 °C, there were only two or three titratable thiols. The PGA(SPO₃)₂₄:ALP ratio used was 2:1, 3:1, and 4:1, yielding 32, 55, or 68 free thiolates, respectively, on the cross-linked ALP at the start of the incubations (only 2:1 and 4:1 stoichiometries are shown in Figure 3). Interestingly, size exclusion HPLC analysis of the cross-linked ALP incubated at 45 °C showed no increase in the higher-molecular weight material despite the observed decrease of the titratable thiols at this higher temperature.

The nature of the maleimide heterobifunctional agent used to derivatize the enzyme is important. Shorter maleimide linkers, i.e. SMCC, resulted in better resis-

Figure 3. Number of thiols of ALP cross-linked at 2:1 and 4:1 ratios with PGA(SPO₃)₂₄ at 5 and 45 °C as a function of time.

Figure 4. Thermal stability of GOX functionalized with 25, 50, 75, 100, and 150 equiv of SMCC, cross-linked at a 1:1 PGA-(SPO₃)₁₉:GOX molar ratio at 37 °C in phosphate buffer (pH 7.4), compared to that of native GOX. The data are normalized to 100% at day 0.

tance of the cross-linked protein to thermal denaturation than the longer 30-atom maleimide conjugating agents (15).

Cross-Linking of GOX. We also applied this cross-linking methodology to GOX (*A. niger*). Figures 4 and 5 show comparisons of the stabilities at 37 °C of the GOX cross-linked to the native enzyme at two different pHs.

The PGA(SPO₃)₁₉:GOX ratio was 1:1. At day 0 after cross-linking, GOX derivatized with 50 equiv of maleimide/enzyme had 85% of the native enzyme activity. The figures above show the very high degree of stabilization for GOX. As in previous figures, the data in Figure 4 are normalized to 100% at day 0 to visualize the effect of thermal stress on the various preparations. Figure 4 shows that, at pH 7.4 and at a fixed 1:1 cross-linking polymer:enzyme ratio, stabilization is dependent on the degree of derivatization of GOX by SMCC. Enzyme derivatized with the lowest stoichiometries of SMCC (25 equiv of SMCC per GOX) showed the lowest degree of

Figure 5. Thermal stability of GOX functionalized with 150 equiv of SMCC, cross-linked at a 1:1 PGA(SPO₃)₁₉:GOX molar ratio at 37 °C in phosphate buffer (pH 9.0), compared to that of native GOX. The data are normalized to 100% at day 0.

stabilization. Derivatization of GOX with a progressively higher number of equivalents of SMCC resulted in correspondingly higher degrees of stabilization.

GOX that is prefunctionalized with 150 molar equiv of SMCC and then cross-linked with PGA(SPO₃)₁₉ in a 1:1 ratio is approximately 8 times more stable than the native enzyme (*t*_{1/2} of 4 vs 0.5 day), as shown in Figure 5. The stabilizing effect of cross-linking is even more pronounced at pH 7.4, which is more compatible with GOX. The progress of the cross-linking reaction was followed by HPLC using a Bio-Rad SEC-400 column and 280 nm detection. Thus, before incubation, GOX derivatized with a 50-fold molar excess of SMCC, in the presence of 1 equiv of PGA(SPO₃)₁₉ and a micromolar level of alkaline phosphatase, had a GPC signal at 12.10 min, but that signal was completely replaced after 16 h by one at 11.37 min (70%) and at 10.25 min (30%) corresponding to a singlet cross-linked GOX and dimeric and trimeric adducts. When higher PGA(SPO₃)₁₉:GOX ratios (3:1 and 5:1) were used, the original signal of GOX was replaced with essentially a single peak at 11.41 min corresponding to a singlet intramolecular cross-linked GOX. Thus, higher ratios of cross-linker per enzyme led to increased content of intramolecular as opposed to intermolecular cross-linking. This trend is consistent with the one observed for ALP shown in Figure 1.

Cross-Linking of R-PE. R-PE, a member of the phycobiliprotein system, is a light-harvesting photosynthetic algal pigment, bilin-protein conjugate with a MW of 240 000 (19, 20). It possesses a complex quaternary structure consisting of 13 subunits organized in subunit architecture (αβ)₆γ. It has 34 bilin chromophores covalently conjugated to cystein residues in the subunits. Due to the multiple bilins, the extremely high absorbance coefficient ($\epsilon = 2.4 \times 10^6 \text{ cm}^{-1} \text{ M}^{-1}$), and the correct mutual orientation of the bilins within the protein domains, R-PE has an exceedingly high fluorescence quantum yield and very large Stokes shift ($\lambda_{\text{ex}} = 495 \text{ nm}$, $\lambda_{\text{em}} = 576 \text{ nm}$). Light absorbed by biliproteins is transferred through a network of pairwise Förster resonance processes (21, 22). The fluorescence characteristics of the phycobiliproteins depend on the mutual orientation of the chromophores within the protein domains.

The top of Figure 6 shows a GPC profile of the chromatographic changes of R-PE stressed at 45 °C with

Figure 6. Chromatographic changes of R-PE stressed at 45 °C in 0.1 M sodium phosphate and 0.1 M NaCl (pH 7.0): (top) native R-PE and (bottom) R-PE cross-linked at a 1:1 PGA-(SPO₃)₁₈:R-PE molar ratio.

Figure 7. Thermal stability of R-PE at 45 °C and pH 7.4. Rate of formation of low-molecular weight subunits of R-PE cross-linked at 1:1 and 4:1 PGA(SPO₃)₁₈:R-PE molar ratios.

0.1 M sodium phosphate and 0.1 M NaCl at pH 7.0. A Bio-Sil SEC-400 column was used to follow the decomposition. Upon incubation, approximately 60% of the protein is fragmented into smaller subunits (α, β, and γ with MWs of 17 000, 18 000, and 30 000, respectively) (20) corresponding to peaks at 14.04 min and an earlier shoulder peak. The bottom of Figure 6 shows a GPC profile of R-PE cross-linked with PGA(SPO₃)₁₈ in 1:1 polymer:R-PE ratio and exposed to the same thermal stress as the native protein. The smaller subunit peaks correspond to approximately 40% of the material, with 60% corresponding to the higher-molecular weight cross-linked material. Thus, cross-linked material displayed a lower tendency to decompose into subunits than the native R-PE.

The changes in the quaternary structure of R-PE are accompanied by a gradual loss of its fluorescence in solution upon exposure to heat.

Figure 7 shows the dependence of the formation of the low-molecular weight fraction in the R-PE solution on the time of incubation at 45 °C and pH 7.4. Clearly, the content of the low-molecular weight component is 30% higher for native R-PE than for R-PE cross-linked with 1 or 4 equiv of PGA(SPO₃)₁₈.

Concomitant with the loss of the quaternary structure of R-PE was a loss of its fluorescence, as shown in Figure 8.

Figure 8. Thermal stability of R-PE at 45 °C and pH 7.4. Rate of fluorescence loss of R-PE cross-linked at a 3:1 PGA(SPO₃)₁₈:R-PE molar ratio. For comparison, native R-PE at 4 and 45 °C is shown. NEM-capped cross-linked R-PE is also shown.

As seen in Figure 8, the fluorescence loss is significantly lower for PGA-cross-linked R-PE than for the native R-PE at 45 °C and pH 7.4. After 18 days at 45 °C, PGA-cross-linked R-PE (open circles) retained 20% more fluorescence than the un-cross-linked, native R-PE (triangles). Capping of the sulfhydryl groups by NEM (solid squares) does not appear to have an effect on the fluorescence.

DISCUSSION

Alkaline phosphatase is frequently employed as a label in enzyme immunoassays. Its widespread use may be attributed to the very high second-order rate constant ($k_{cat}/K_m = 5 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$), the existence of excellent fluorogenic and chromogenic substrates, a pH optimum 9 to 10.5, which is compatible with an optimal signal from fluorogenic and chromogenic substrates, and reasonably good thermal stability (23–25). In this work, we describe a series of new polymeric substrates of alkaline phosphatase. The poly(phosphorothioates) reported here are excellent enzyme substrates and generate thiols upon catalysis. The byproduct of the reaction is phosphate ion, an innocuous material which may be left in the reaction medium and does not interfere with the subsequent use of the polymers as cross-linkers and stabilizers of proteins. Thus, the phosphorothioate functionality may be thought of as a protected thiolate nucleophile. While other protected thiols are widely used in bioconjugations and protein modifications, i.e. SATA and SPDP, these reagents mask thiols as thioacetyl and 2-pyridyl disulfide. The generation of thiols using these reagents is achieved by reductive cleavage of 2-pyridyl disulfide using DTT as a reducing agent which needs to be removed from the reaction medium or by using harsh reaction conditions of 0.2 N NaOH, aqueous NH₃ (26), or hydroxylamine (27) which may be incompatible with base-sensitive haptens or proteins.

The reaction of the polythiolated polymers with the electrophile-derivatized proteins cross-links the surface of the protein and results in protein stabilization. Figure 2 shows that at suitable stoichiometries of PGA(SPO₃)₂₄ the enzyme may be considerably stabilized against thermal denaturation. A striking aspect of this graph is

the precipitous loss of enzymatic activity of this homodimeric protein during the first day of incubation at 45 °C. While the native protein does not recover, the cross-linked ALP recovers its activity. After 72 h, the enzyme activity is similar to the one at the beginning of the incubation. This behavior may be explained in terms of a reversible change in the quaternary structure of the cross-linked dimer versus an irreversible loss of the activity of the native enzyme due to monomerization. Alkaline phosphatases are homodimers in their active forms, and monomers have no detectable enzymatic activity (23, 28). The rate of loss of activity after the third day appears to be similar for the cross-linked and native enzymes. This suggests that the initial loss of activity of the native enzyme is due to a monomerization of the enzyme, a process prevented in the cross-linked protein.

The quantitation of the number of thiols at 5 and 45 °C incubations of ALP cross-linked at 2:1 and 4:1 ratios with PGA is shown in Figure 3. At 5 °C, the number of thiolates measured by spectrophotometric titration with DTNB is reasonably constant for both 2:1 and 4:1 cross-linked enzymes. However, at 45 °C, the number of thiolates decreases rather rapidly, reaching essentially zero after 5 days. The rate of loss of titratable thiols is much faster than the rate of loss of the enzymatic activity shown in Figure 2. HPLC analysis showed that the process is not accompanied by the formation of larger aggregates. HPLC analysis showed that the ratios of multimers to monomeric cross-linked proteins remain constant over the course of 5 days at 45 °C. This suggests intramolecular oxidative disulfide bond formation between the contiguous thiols on the cross-links.

This method of stabilization was also applied to GOX, an oxidoreductase of great importance in biosensor technology and the diagnosis of diabetes (29). As shown in Figure 4, the degree of stabilization of this enzyme is dependent on the level of derivatization of the enzyme with maleimide. The lowest stoichiometries of electrophile resulted in relatively low levels of thermal stabilization, while the highest levels of maleimide resulted in excellent stabilization through reaction with 1:1 PGA-(SPO₃)₁₉. GOX prederivatized with 150 equiv of maleimide and reacted with 1 equiv of PGA retained 58% of the enzymatic activity after 12 days at pH 7.4 and 37 °C, while 50% of the activity remained after 60 days. Under identical conditions, the native enzyme lost 50% of its activity after 2.5 days. Even at an unfavorable pH of 9.0, cross-linking provided a very significant level of stabilization, as shown in Figure 5.

In the past decade, phycobiliproteins such as R-PE have played an increasingly important role as fluorescent labels in single-cell analysis and flow cytometry. Consequently, there has been interest in conjugates of phycobiliproteins and immunoglobulins directed against specific cellular epitopes (30). The high fluorescence of R-PE depends on the preservation of the native quaternary structure of the protein. R-PE is composed of 13 subunits called phycobilisomes organized in an ($\alpha\beta$)₆ γ complex. Each subunit carries one or two bilins for a total of 32 fluorogenic bilins in R-PE. Dissociation of the phycobilisomes occurs as the result of factors which denature the proteins, i.e. low salt, urea, or heat (31–33). The hexamers are known to break down to smaller subunits, including $\alpha\beta$ and $\alpha\beta\gamma$ (34). The effect of cross-linking R-PE is seen in Figures 7 and 8. Clearly, the rate of appearance of the low-molecular weight component is lower for the cross-linked protein than for the unmodified protein, as shown in Figure 7. Similarly, cross-linking has an effect in preserving the intrinsic

fluorescence of R-PE as shown in Figure 8. The congruence of the results in Figures 7 and 8 may be explained by the known dependence of the fluorescence energy transfer and pathways on the three-dimensional structure of phycobiliproteins (20, 35). Denaturing conditions lead to disassembly of the subunits and loss of quaternary structure of the proteins. We believe that stabilizing effects of cross-linking may be attributed to the fact that the intramolecular cross-linking of the protein allows less conformational mobility of the subunits and lessens the degree to which the protein disassembles under the denaturing conditions.

We found that in all cases the use of higher PGA-(SPO₃)_x:protein molar ratios led to increased content of intramolecular cross-linking. This is demonstrated in Figure 1 for the case of alkaline phosphatase-catalyzed auto-cross-linking but was also observed in the case of R-PE and GOX. This may be explained by entropic considerations. The ability to control the degree of cross-linking and the molecular weight of the cross-linked stabilized proteins is a distinct advantage of this method.

The cross-linking process introduces several thiolates into the stabilized protein. These thiolates may serve as functionalities, through which conjugation to other biological molecules or surfaces may be accomplished. We are describing such a bioconjugation in the following paper (36).

SUMMARY

We have presented a new, enzyme-catalyzed cross-linking method based on alkaline phosphatase-catalyzed activation of poly(phosphorothioate) polymers. The cross-linked proteins are considerably stabilized against thermal denaturation in solutions. The method is rapid and in most cases leads to quantitative cross-linking of the protein. The byproducts of the polymer activation and cross-linking are phosphate ions which do not interfere in the biological activity of most proteins. Consequently, it may be left in the reaction medium. Poly(phosphorothioate) polymers are very soluble in water which facilitates the cross-linking process and increases the solubility of the stabilized protein. The method allows easy conjugation of the stabilized cross-linked proteins through reactions of thiolates with electrophilic functionalities on other biomolecules. The chemical and biological properties of the cross-linked proteins are retained. The cross-linking process may be adjusted to individual proteins. Excellent control of the molecular weight of the cross-linked species may be exercised by adjusting the stoichiometries of the cross-linked polymer and proteins.

The method could be adapted for biomolecules other than proteins. Thus, conjugation of oligonucleotides, carbohydrates, and lipids to proteins may be implemented using alkaline phosphatase activation of phosphorothioate-derivatized species. The conjugation to surfaces, i.e. colloidal gold and microchips, in a spatially controlled manner is an intriguing possibility.

ACKNOWLEDGMENT

We thank Dr. Eric Ginsburg of the Abbott Laboratories Advanced Drug Delivery Department for his critical reading of the manuscript.

TECHNICAL NOTES

Thermally Stabilized Immunoconjugates: Conjugation of Antibodies to Alkaline Phosphatase Stabilized with Polymeric Cross-Linkers

Christopher Bieniarz,^{*,†} Douglas F. Young,[‡] and Michael J. Cornwell[‡]

Advanced Drug Delivery, Hospital Products Division, and Diagnostics Division, Abbott Laboratories, Abbott Park, Illinois 60064-3500. Received February 9, 1998

A method of conjugating poly(glutamic acid) poly(phosphorothioate)-cross-linked alkaline phosphatase to maleimide-derivatized immunoglobulin is described. Intramolecular autocatalyzed cross-linking of alkaline phosphatase at 2:1 to 4:1 polymer:enzyme ratios introduced 32–68 thiols on the surface of the enzyme. Depending on the stoichiometry of polymer to enzyme, the cross-linked alkaline phosphatase retained 75–90% of its native catalytic activity. The cross-linked thiolate-functionalized alkaline phosphatase was conjugated to maleimide-derivatized immunoglobulin. Compared to a control prepared using non-cross-linked alkaline phosphatase, these conjugates were smaller in size and more stable to heat. The enzymatic activity of the cross-linked conjugates after incubation at 45 °C and pH 7.5 for 25 days was 35% higher than those of the highest-activity control conjugates. The conjugation process could be controlled by varying the stoichiometries of poly(glutamic acid) poly(phosphorothioate), alkaline phosphatase, and immunoglobulin.

INTRODUCTION

Alkaline phosphatase is one of the enzymes most frequently employed in ELISA¹ (1, 2). ALP popularity can be attributed to its relatively high stability, its high turnover number, the sensitivity of its enzyme assays (3), and the existence of excellent fluorogenic and chromogenic substrates (4, 5). Although many bioconjugation methods have been developed for efficient conjugation of ALP and other enzymes to antibodies (6–9), there is a continuing need for development of conjugation methods which preserve the chemical and biological properties of those biomolecules in the conjugate. Although ALP is considered to have good thermal stability, in our experience, prolonged storage of ALP–IgG conjugates leads to gradual loss of the enzymatic signal.

In the preceding paper (10), we describe stabilization of proteins via novel polymeric cross-linkers, poly(phosphorothioate) polymers, activated by alkaline phosphatase. The protein is first derivatized with thiol-reactive electrophiles e.g., maleimides. The poly(phosphorothioate) polymer is then exposed to the action of ALP which very efficiently catalyzes the hydrolysis of the phosphates to unmask thiols on the polymeric back-

bone. The thiols on the polymer then react with the electrophiles on the surface of the protein, resulting in predominantly intramolecular cross-linking and concomitant stabilization of the protein. When the protein is ALP, the process is self-catalyzed in that the very enzyme to be cross-linked catalyzes the hydrolysis of the phosphorothioate bonds and the cross-linking of the protein surface.

Here we describe the application of the ALP-catalyzed auto-cross-linking to the construction of stabilized alkaline phosphatase–anti-TSH conjugates. These conjugates are crucially important in enzyme immunoassays for the immunodiagnostic assessment of the function of the thyroid gland. Stabilization of these immunoconjugates against thermal denaturation is of great practical interest because of the prolonged storage requirements for such immunoreagents.

EXPERIMENTAL SECTION

Materials and General Procedures. The synthesis and analysis of poly(glutamic acid) poly(phosphorothioate) PGA(SPO₃)₂₄, materials, and other reagents were as described in the preceding paper (10). Monoclonal anti-TSH was from Abbott Laboratories (Abbott Park, IL). STMCC 30-atom heterobifunctional maleimide-active ester linker was synthesized as described previously (11).

Conjugation of Anti-TSH IgG to PGA(SPO₃)₂₄ Cross-Linked Bovine Alkaline Phosphatase. (a) *Derivatization of Anti-TSH IgG.* To 1 mL of 6.6 mg/mL anti-TSH IgG (44.0 nmol) was added 1 mL of buffer composed of 0.1 M sodium phosphate, 0.1 M NaCl, 1.0 mM MgCl₂, and 0.1 mM ZnCl₂ at pH 7.0 (buffer B). The antibody was concentrated to approximately 0.2 mL using a Centricon-30 concentrator with a MW cutoff of 30 000. The concentrate was rediluted to 2 mL using

¹ Abbreviations: ELISA, enzyme-linked immunosorbent assay; ALP, alkaline phosphatase; TSH, thyroid-stimulating hormone; DMF, dimethylformamide; PGA, poly(L-glutamic acid); STMCC, succinimidyl tris(caproamido) 4-(N-maleimidomethyl)cyclohexane-1-carboxylate; SMCC, succinimidyl 4-(N-maleimidomethyl)cyclohexane-1-carboxylate.

Scheme 1. Conjugation of Poly(phosphorothioate)-Cross-Linked ALP to IgG

buffer B and then reconcentrated to 0.2 mL. This concentration–dilution cycle was repeated three times. The volume of the antibody solution was increased to 1 mL with buffer B and the mixture placed in a vial. The concentration of the protein was 5.3 mg/mL (35 mM by A_{280}). To 50 mL of DMF was added 0.56 mg (831 nmol) of succinimidyl tris(caproamido) 4-(*N*-maleimidoethyl)-cyclohexane-1-carboxylate (STMCC), a 30-atom hetero-bifunctional maleimide active ester cross-linking agent (11). This solution was added to 0.47 mL of the 35 mM solution of IgG (16.6 nmol) with a 50-fold molar excess of STMCC linker to protein. The solution was reacted for 1 h at room temperature while being rotated at 100 rpm on a rotary agitator. The reaction solution was passed through a Sephadex G-25 column which was eluted with buffer B. Fractions with an A_{280} of >0.5 were pooled. The concentration of IgG in the pooled fractions was 0.83 mg/mL (5.5 nM). The antibody pool was stored on ice until it was conjugated.

(b) *Conjugation of STMCC-Derivatized Anti-TSH IgG to PGA(SPO₃)₂₄ Cross-Linked Bovine ALP.* To a 0.72 mL aliquot of 0.83 mg/mL (4 nmol) STMCC linker-derivatized anti-TSH IgG was added 0.69 mL of 1.30 mg/mL (3.3 nmol) PGA(SPO₃)₂₄ cross-linked ALP prepared as described in the preceding paper (10). The resulting solution was allowed to react overnight at 5 °C while being rotated at 100 rpm on a rotary agitator. The progress of the conjugation was followed by gel permeation HPLC using a Bio-Rad Bio-Sil SEC-400 column and pH 7.0 buffer containing 0.1 M sodium phosphate and

0.1 M NaCl (buffer C) at a flow rate of 1.0 mL/min (detector at A_{280}). After 12 h, the reaction was essentially complete with $>80\%$ of the protein conjugated. Conjugates were concentrated to a volume of 200 mL with 30 000 MW cutoff Amicon membranes. The process was repeated three times. The concentration of the protein was 3.2 mg/mL as determined by A_{280} .

As a control experiment, the thermal stability and GPC profile of the PGA(SPO₃)₂₄-cross-linked ALP–anti-TSH conjugate was compared to that of the highest-activity and stability un-cross-linked ALP–anti-TSH control conjugate. Derivatization of ALP with iminothiolane hydrochloride and its conjugation to STMCC-derivatized anti-TSH IgG were carried out as described previously (11).

Thermal Stability Evaluation of the Conjugates.

Stock solutions of PGA(SPO₃)₂₄-cross-linked ALP–anti-TSH IgG conjugates from above were diluted with pH 7.5 buffer containing 0.1 M Tris, 1.0 mM MgCl₂, and 0.1 mM ZnCl₂ to a concentration of 10 mg/mL. These dilutions were stored at 45 °C in an incubator for the duration of the study. The values of the enzyme activity of all the conjugates were normalized to 100% at the start of the incubation. Progressive changes in the enzyme activity of the conjugates were monitored as described in the preceding paper (10).

RESULTS AND DISCUSSION

Scheme 1 shows the conjugation of PGA(SPO₃)₂₄-cross-linked, stabilized ALP to IgG derivatized with the 30-

Figure 1. Thermal stability of PGA(SPO₃)₂₄-cross-linked ALP-anti-TSH IgG conjugates at 45 °C in pH 7.5 buffer containing 0.1 M Tris, 1.0 mM MgCl₂, and 0.1 mM ZnCl₂. Decay of enzyme activity in the best conjugate based on Traut reagent-derivatized ALP and conjugated to STMCC-derivatized IgG, compared with conjugates of ALP cross-linked at 2:1 and 4:1 stoichiometries with PGA(SPO₃)₂₄.

atom heterobifunctional coupling agent STMCC. We have shown before that the performance of this longer maleimide active ester is significantly better than the performance of the shorter analogues (11).

Self-catalyzed cross-linking of ALP by PGA(SPO₃)₂₄ is shown in Scheme 1A. Poly(glutamic acid) poly(phosphorothioate) is incubated in the presence of SMCC-derivatized ALP. This enzyme catalyzes the hydrolysis of phosphate and unmask thiol in the polymer, which react with the maleimides on the surface of ALP. Between 32 and 68 thiols are thus introduced into the ALP, lowering the activity of the enzyme by 10–25%. In the preceding paper, we have presented data which show that PGA-cross-linked ALP is considerably stabilized against thermal denaturation (10). The stoichiometries of PGA(SPO₃)₂₄:ALP may be varied from 1:1 to 6:1. As shown in the preceding paper (10), higher PGA(SPO₃)₂₄:ALP ratios result in predominantly intramolecular cross-linking of ALP. The cross-linking process generates a multiplicity of thiols in the cross-linked protein. These unreacted thiols are used to further conjugate the thermally stabilized enzyme to anti-TSH IgG. Scheme 1B shows derivatization of the antibody with the 30-atom heterobifunctional coupling agent SMCC. The maleimides introduced into the antibody molecule react in the final step with the thiols on the PGA-cross-linked ALP.

The thermal stability of the conjugates is shown in Figure 1. After 8 days at 45 °C in a pH 7.5 buffer containing 0.1 M Tris, 1.0 mM MgCl₂, and 0.1 mM ZnCl₂, the best cross-linked ALP-anti-TSH conjugates (2:1 and 4:1 PGA(SPO₃)₂₄:ALP) had a normalized enzyme activity 15% higher than that of the unmodified native ALP and 30% higher than that of the most active control conjugates based on un-cross-linked ALP, made using the Traut method (12). Notably, the conjugates prepared with the cross-linked ALP also had better thermal stability than the native unconjugated ALP. In our experience, the enzyme thermal stability of ALP conjugates is generally lower than that of the unconjugated ALP. Unlike PGA-cross-linked ALP, in which the cross-

Figure 2. GPC chromatograms of the conjugation: (A) native IgG, (B) native ALP, (C) unfractionated cross-linked ALP, (D) the unfractionated cross-linked ALP-IgG conjugate, with 1:1 enzyme:IgG stoichiometry, and (E) unfractionated Traut reagent-derivatized ALP conjugated to STMCC-derivatized IgG.

linked enzyme experiences a dramatic loss of activity followed by a quick recovery within the first 72 h of incubation at 45 °C (10), the cross-linked ALP conjugates do not show similar behavior. If the loss of activity followed by the recovery, observed in the first 72 h in the cross-linked ALP, is due to the reversibility of the changes in the quaternary structure, the conjugated IgG molecule may have a stabilizing effect which prevents such transient changes in the quaternary structure possibly because of the presence of covalent cross-links to IgG and the contiguity of the IgG and ALP molecules.

All conjugates were prepared from antibodies derivatized with a 50-fold molar excess of STMCC linkers and ALP cross-linked with 2 or 4 equiv of PGA(SPO₃)₂₄. As described in the Experimental Section, the ratio of IgG to cross-linked enzyme was 1:1. The data in Figure 1 are normalized to 100% at day 0 to visualize the effect of thermal stress on various preparations. *N*-Ethylmaleimide-capped conjugates underwent thermal denaturation at a faster rate than the uncapped conjugates (data not shown).

The progress of the conjugations was followed by HPLC using a Bio-Sil SEC-400 column. The ALP enzyme activity of 1:1 ALP-IgG conjugates at day 0 was between 65 and 80% of that of the native enzyme. Panels A–E of Figure 2 show GPC profiles of IgG, native ALP, unfractionated 4:1 PGA-cross-linked ALP, the crude unfractionated IgG-cross-linked ALP conjugate, and the best crude unfractionated conjugate based on the Traut method. Chromatogram D appears to consist predominantly of the conjugated IgG. The crude conjugates at 10.11 min and higher molecular weights all show enzymatic activity, as demonstrated by careful fractionation of this material. The shoulder peak at 11.15 min shows ALP activity and has retention times virtually identical to that of PGA-cross-linked ALP.

As seen in Figures 2E and 1, the most active unfractionated Traut ALP-IgG conjugate yields material with a much higher molecular weight whose thermal stability is considerably lower than that of the cross-linked material.

Free thiols on the enzyme do not lead to aggregation of the conjugates as demonstrated by GPC analysis of the incubated materials. In view of the decrease in the number of titratable thiols in the cross-linked ALP (10), the constant size of the conjugates can possibly be attributed to the exhaustion of the thiols through some oxidative process, i.e. intramolecular disulfide bond formation.

CONCLUSIONS

Auto-catalyzed cross-linking of maleimide-derivatized alkaline phosphatase with poly(glutamic acid) poly-(phosphorothioate) stabilizes the protein against the thermal denaturation and introduces multiple thiolates on the surface of the enzyme. The stabilized enzyme is then conjugated to an the immunoglobulin molecule through the reaction of thiolates with maleimides in the IgG. The conjugation process is highly controllable; conjugate size may be adjusted by selection of appropriate stoichiometries of the cross-linking polymer, enzyme, and immunoglobulin. The method leads to thermally stabilized conjugates.

ACKNOWLEDGMENT

We thank Dr. Eric Ginsburg of the Abbott Laboratories Advanced Drug Delivery Department for his critical reading of the manuscript.

Synthesis of 6 β -[(2'-Aminoethyl)carboxamidomethyl]estradiol and Preparation of Estradiol Probes

Maciej Adamczyk,* Donald D. Johnson, and Rajarathnam E. Reddy

Division Organic Chemistry Research (9NM, AP20), Diagnostic Division, Abbott Laboratories, 100 Abbott Park Road, Abbott Park, Illinois 60064-3500. Received November 28, 1997; Revised Manuscript Received February 13, 1998

Reformatsky reaction of 3,17 β -bis[(2-trimethylsilyl)ethoxymethyl]-1,3,5(10)-estratrien-6-one (**2**) with bromoethyl acetate and zinc gave the ester (**3**) in 60% yield which upon treatment with methanesulfonyl chloride in pyridine afforded the olefinic esters (**4** and **5**) as an endo and exo mixture (67:33 ratio) in 81% yield. Hydrolysis of the SEM protective groups in compounds **4** and **5** followed by hydrogenation of the resulting hydroxy compounds **6** and **7** using 10% Pd/C afforded an epimeric mixture (β : α = 79:21) of 6-[(ethoxycarbonyl)methyl]estradiol (**8a** and **8b**) in 95% yield. Hydrolysis of the ethyl esters (**8a** and **8b**) using sodium hydroxide gave the acid (**9a** and **9b**) in 81% yield. The epimeric mixture of acids (**9a** and **9b**) was activated, treated with *tert*-butyl-*N*-(2-aminoethyl)carbamate (**10**), and purified by HPLC to afford 6 β -[[[(2-*tert*-butoxycarbonyl)amino]ethyl]carboxamidomethyl]estradiol (**11**) in 39% yield as the major isomer. Hydrolysis of the BOC group in compound **11** using TFA afforded the desired 6 β -[(2-aminoethyl)carboxamidomethyl]estradiol **12** in 50% yield. The biotinylated estradiol probe **14**, fluorescent probe **16**, and chemiluminescent probe **18** were prepared from 6 β -[(2'-aminoethyl)-carboxamidomethyl]estradiol (**12**) and the corresponding biotin, 5-carboxyfluorescein, and 10-(3-sulfopropyl)-*N*-tosyl-*N*-(3-carboxypropyl)acridinium-9-carboxamide *N*-succinimidyl esters (**13**, **15**, and **17**) in 65–74% yield and 99% purity.

INTRODUCTION

Estradiol (E₂, **1**) is a hormone which controls the differentiation, growth, and function of the reproductive system in females. It also plays an important role in the growth of estrogen-dependent tumors and other endocrinological disorders (1–3). A variety of E₂ (**1**) derivatives have been used to study estrogen binding proteins (i.e., estrogen receptors or antibodies) and for assaying E₂ (**1**) in serum or other human body fluids (4–7). Typically, the existing hydroxyl groups at the C3 (8–10) or C17 (9) positions of the estradiol nucleus were modified. This, of course, had the disadvantage of blocking those critical binding determinants. Introduction of an auxiliary functionality at the C6 or C7 of the estradiol molecule can address this drawback. Among the many available labels, fluorescein and biotin have often been chosen for the construction of probes at the C6 (11–15), C7 (16–18), and C17 positions (19–21) of estradiol (**1**). Increasingly, chemiluminescent isoluminol (9) conjugates at the C3, C6, and C17 positions and acridinium phenyl esters at the C3 position (8–10) have been employed.

During the past few years in clinical diagnostics, nonradioactive immunoassays have gained tremendous popularity in contrast to the radioimmunoassay (RIA) (22) method, because of their simplicity and ease for automation. In nonradioactive immunoassays, a variety of probes are used for measurement of an analyte depending upon the assay format. The desired probes for the development of competitive nonradioactive immunoassays are those bearing biotin-, fluorescein-, and acridinium-labeled conjugates. A chief reason for using biotin in different assay formats is its specific and high-

affinity interaction with avidin/streptavidin (23). One of the most widely used homogeneous immunoassay formats for low-molecular weight compounds (<2000 Da) is the fluorescence polarization immunoassay (FPIA) which requires a fluorescein conjugate for signal generation (7, 24). Recently, in addition to these methods, the need for higher sensitivity and throughput has spurred the development of chemiluminescent immunoassays (CLIAs) (8–10, 25). The CLIA method is based on the measurement of light which is emitted as result of a chemical reaction, and using this technology, one can measure the analyte concentration down to high femto-gram (10⁻¹⁵ g) per milliliter levels (26). The chemiluminescent probes containing 9-acridinium derivatives have numerous advantages (26). First, the chemical reaction is simplified without the need for a catalyst. The light reaction is rapid, thereby providing an increased counting efficiency, and low background. Also, a major advantage lies in the fact that a portion of the 9-acridinium conjugate bound to the protein (antibody) is cleaved and separated from the light-emitting moiety during the oxidation process which eliminates the inhibition of the light yield and thereby maximizes the sensitivity (26). Thus, in the development of immunoassays, the choice of the label which is conjugated to the ligand will vary depending on the format and requirements of the assay.

Recently, we described the synthesis of fluorescent probes from 6 α -aminoestradiol for studies on the estrogen binding proteins (27). However, in these E₂ probes (27), the native electronic environment on the phenyl ring might be altered due to the electron-withdrawing nature of the amide functionality at the C6 position. We envisioned that, after a label is attached at the C6 position of E₂ (**1**) through an alkyl functionality, the electronic effect on the phenyl ring will be reduced and

the resulting probes would more closely mimic the unmodified E₂. In this paper, we describe a stereoselective synthesis of 6 β -[(2-aminoethyl)carboxamidomethyl]-estradiol (**12**) and the preparation of its biotinylated (**14**), fluorescent (**16**), and chemiluminescent (**18**) conjugates for use as estradiol probes.

EXPERIMENTAL PROCEDURES

General Methods. ¹H NMR spectra were recorded on a varian Gemini spectrometer (300 MHz). Mass spectra were obtained on a Nermang 3010 MS-50 or JEOL SX102-A mass spectrometer or Perkin-Elmer Sciex API 100 electrospray mass spectrometer. Thin-layer chromatography was performed on precoated Watman MK6F silica gel 60 Å plates (layer thickness of 250 μ m) and were visualized with UV light and/or using a KMnO₄ solution [KMnO₄ (1.0 g) and NaOH (8.0 g) in water (200 mL)] or the phosphomolybdic acid reagent (20 wt % solution in ethanol), unless otherwise noted. Column chromatography was performed on silica gel, Merck grade 60 (230–400 mesh). THF was freshly distilled from a purple solution of sodium and benzophenone, and CH₂-Cl₂ was freshly distilled from CaH₂ under nitrogen. All reagents were purchased from Aldrich Chemical Co. (Milwaukee, WI) or Sigma Chemical Co. (St. Louis, MO) and used without further purification, except where noted. All the solvents employed were of HPLC grade and purchased from EM Science (Gibbstown, NJ) and used as received. After workup, the solvent was dried using anhydrous Na₂SO₄ and concentrated on a rotary evaporator at 40 °C (bath temperature). Reverse phase (RP) analytical HPLC was performed using a Waters μ Bondapak C18 10 μ m (8 mm $\times$ 100 mm) column eluting at 2 mL/min with MeCN/0.1% aqueous trifluoroacetic acid (v/v ratio reported) with UV light at 225 nm unless otherwise stated. Preparative RP HPLC was performed using a Waters μ Bondapak C18 10 μ m (40 mm $\times$ 100 mm) column eluting at 45 mL/min with MeCN/0.1% aqueous trifluoroacetic acid (v/v ratio reported) with UV light at 225 nm unless otherwise stated.

3,17 β -Bis[(2-trimethylsilyl)ethoxymethyl]-6-hydroxy-6-[(ethoxycarbonyl)methyl]estra-1,3,5(10)-triene (3**).** In a dry single-necked round-bottom flask, 3,17 β -bis[(2-trimethylsilyl)ethoxymethyl]-1,3,5(10)-estratrien-6-one (**2**) (2.31 g, 4.22 mmol) was dissolved in a mixture of dry ether and benzene (1:1 ratio, 120 mL). Ethyl bromoacetate (1.41 mL, 12.7 mmol, 3.0 equiv) and zinc powder (1.93 g, 29.5 mmol, 7.0 equiv) were added, and the mixture was gently refluxed for 21 h under a nitrogen atmosphere. The reaction mixture was cooled to room temperature, the mixture filtered, and the filtrate concentrated. The residue was diluted with ethyl acetate (25 mL) and hexane (105 mL), and the mixture was stirred at room temperature for 15 min and filtered. The filtrate was concentrated, and the crude product was purified by silica gel column chromatography (20% ethyl acetate in hexane) to afford 1.85 g of **3** (69%) as a colorless thick oil (73:27 mixture of epimers). ¹H NMR (CDCl₃): δ 7.26–7.16 (m, 2 H), 6.97–6.90 (m, 1 H), 5.27–5.15 (m, 2 H), 4.69 (s, 2 H), 4.26–4.15 (m, 2 H), 3.74–3.58 (m, 5 H), 3.04–2.80 (m, 2 H), 2.30–1.20 (m, 16 H), 0.98–0.92 (m, 4 H), 0.82 (s, 73/100, 3 H), 0.78 (s, 27/100, 3 H), 0.22 (s, 9 H), 0.00 (s, 9 H). ESMS: 652 (M + NH₄)⁺, 1286 (2 $\times$ M + NH₄)⁺.

3,17 β -Bis[(2-trimethylsilyl)ethoxymethyl]-6-[(ethoxycarbonyl)methyl]estra-1,3,5(10),6-tetraene (4**, and Also Compound **5**).** The epimeric mixture of the hydroxy compound (**3**, 1.74 g, 2.74 mmol)

was dissolved in pyridine (35 mL), and methanesulfonyl chloride (2.12 mL, 27.4 mmol, 10.0 equiv) was added at room temperature under a nitrogen atmosphere. The mixture was heated at 60 °C for 2.5 h, and the pyridine was removed on a rotary evaporator. The residue was diluted with ethyl acetate (100 mL) and water (100 mL), and the aqueous layer was separated and extracted with ethyl acetate (2 $\times$ 100 mL). The combined organic layers were washed with brine (100 mL), dried, and concentrated. The crude compound was purified by silica gel column chromatography (10% ethyl acetate in hexane) to afford 1.34 g (81%) of compounds **4** and **5** as a thick oil (63:37 mixture of endo and exo isomers). Analytical RP HPLC (90:10 MeCN/0.1% aqueous acetic acid, 2.0 mL/min, 225 nm, relative intensity): t_R 17.63 (76%), 29.2 min (20%). ¹H NMR (CDCl₃): δ 7.32–6.90 (m, 3 H), 6.26 (s, 0.37/1 exocyclic olefinic H), 5.92 (s, 0.63/1 endocyclic olefinic H), 5.22 and 5.19 (s, s, 2 H), 4.7 (s, 2 H), 4.21–4.15 (m, 2 H), 3.80–3.25 (m, 6 H), 2.34–1.20 (m, 15 H), 0.99–0.92 (m, 4 H), 0.79 (s, 63/100, 3 H), 0.77 (s, 37/100, 3 H), 0.02 (s, 9 H), 0.00 (s, 9 H). ESMS: 634 (M + NH₄)⁺.

6-[(Ethoxycarbonyl)methyl]-3,17 β -dihydroxyestra-1,3,5(10),6-tetraene (6**, and Also Compound **7**).** The mixture of olefinic compounds (**4** and **5**, 1.24 g, 2.01 mmol) was dissolved in acetonitrile (75 mL), and 48% HF (4.2 mL) was added dropwise at room temperature. After the mixture was stirred for 2 h, it was then concentrated on a rotary evaporator to an about 20 mL volume and diluted with water (100 mL). The mixture was extracted with ethyl acetate (3 $\times$ 100 mL), and the combined organic layers were dried and concentrated. The crude compound was purified by silica gel column chromatography (5% methanol in CH₂Cl₂) to afford 0.447 g (62%) of compounds **6** and **7** present as a 2:1 mixture of endo and exo isomers. Analytical RP HPLC (60:40 MeCN/0.1% aqueous formic acid, 1.0 mL/min, 225 nm, relative intensity): t_R 6.55 (67.8%), 7.91 min (31.2%). ¹H NMR (CDCl₃): δ 7.22–6.66 (m, 3 H), 6.24 (s, 33/100, H), 5.92 (s, 67/100 H), 4.24–4.10 (m, 2 H), 3.80–3.30 (m, 2 H), 2.40–1.20 (m, 15 H), 0.76 and 0.75 (2 s, 3 H). ESMS: 357 (M + H)⁺, 374 (M + NH₄)⁺.

6 β / α -[(Ethoxycarbonyl)methyl]-3,17 β -dihydroxyestra-1,3,5(10)-triene (8a** and **8b**).** The mixture of olefinic compounds (**6** and **7**, 0.434 g, 1.22 mmol) was dissolved in a mixture of ethyl acetate/methanol (2:1, 24 mL), and 10% Pd/C (0.0130 g) was added. The mixture was stirred under a H₂ atmosphere using balloon at room temperature for 16 h. The mixture was then filtered through Celite power, and the catalyst was washed with methanol (10 mL) and the filtrate concentrated to afford 0.415 g (95%) of compounds **8a** and **8b** as an epimeric (β : α = 79:21) mixture. Analytical RP HPLC (60:40 MeCN/0.1% aqueous formic acid, 1.0 mL/min, 225 nm, relative intensity): t_R 7.49 min (91.02%). ¹H NMR (CDCl₃): δ 7.18–7.40 (m, 1 H), 6.70–6.35 (2, H), 4.24–4.12 (m, 2 H), 3.78–3.70 (m, 1 H), 3.40–3.62 (m, 1 H), 2.86–1.20 (m, 18 H), 0.81 (s, 79/100, 3 H), 0.75 (s, 29/100, 3 H). ESMS: 376 (M + NH₄)⁺.

6 β / α -(Carboxymethyl)-3,17 β -dihydroxyestra-1,3,5(10)-triene (9a** and **9b**).** Aqueous NaOH (10%, 3.6 mL, 8.96 mmol, 8.0 equiv) was added to a solution of the epimeric mixture of esters (**8a** and **8b**) (0.401 g, 1.12 mmol) in methanol (7 mL) at room temperature and the mixture stirred for 1.5 h. The reaction mixture was then diluted with water (50 mL), and the pH was adjusted to 3.0 using 1 M HCl. The mixture was extracted with ethyl acetate (3 $\times$ 50 mL), and the combined organic layers were washed with brine (50 mL), dried, and concentrated to afford 0.370 g (81%) of acid **9a** and **9b** as a mixture

(β : α = 79:21) mixture. Analytical RP HPLC (50:50 MeCN/0.1% aqueous formic acid, 1.0 mL/min, 225 nm, relative intensity): t_R 4.92 min (91.8%). ^1H NMR (CD_3OD): δ 7.10 (d, 1 H, J = 9.0 Hz), 6.68–6.55 (m, 2 H), 3.70–3.60 (m, 1 H), 3.20–3.25 (m, 1 H), 2.84–1.22 (m, 18 H), 0.80 (s, 79/100, 3 H), 0.75 (s, 29/100, 3 H). ESMS: 329 (M – H).

6 β -[[[(2-*tert*-Butoxycarbonyl)amino]ethyl]carboxamidomethyl]-3,17 β -dihydroxyestra-1,3,5 (10)-triene (11a). The epimeric mixture of acids (**9a** and **9b**) (0.360 g, 1.09 mmol) was dissolved in CH_2Cl_2 (20 mL), and *N*-hydroxysuccinimide (HOSu, 0.251 g, 2.18 mmol, 2.0 equiv) was added followed by ethyl-3-[(dimethylamino)propyl]carbodiimide (EDAC, 0.418 g, 2.18 mmol, 2.0 equiv) at room temperature under nitrogen. The mixture was stirred for 16 h and diluted with water (100 mL). The pH of the solution was adjusted to 4.0 using 1 M HCl, and the solution was extracted with CH_2Cl_2 (3 $\times$ 300 mL). The combined CH_2Cl_2 extracts were washed with brine (100 mL), dried, and concentrated to afford 0.509 g of the corresponding succinimidyl esters.

The above-prepared crude mixture of succinimidyl esters was dissolved in DMF (10.0 mL) and treated with *tert*-butyl *N*-(2-aminoethyl)carbamate (**10**, 0.179 g, 1.09 mmol, 1.0 equiv) followed by triethylamine (0.304 mL, 2.18 mmol, 2.0 equiv) at room temperature under a nitrogen atmosphere. After the mixture was stirred for 3 h, the solvent was removed on a rotary evaporator in vacuo. The residue was purified by preparative RP HPLC [Waters μ Bondpak C18 10 μm column (40 mm $\times$ 100 mm) with 60:40 MeOH/0.1% aqueous acetic acid, 25.0 mL/min, 225 nm]. The solvent was removed on a rotary evaporator and dried azeotropically using a mixture of toluene and methanol (1:1, 3 $\times$ 10 mL) to afford 0.201 g of 6 β -[[[(2-*tert*-butoxycarbonyl)amino]ethyl]carboxamidomethyl]estradiol (**11a**) in 39% yield as a colorless powder. Analytical RP HPLC (70:30 MeOH/0.1% aqueous acetic acid, 1.0 mL/min, 225 nm, relative intensity): t_R 10.02 min (93%). ^1H NMR (CD_3OD): δ 8.10 (dist t, 1 H), 7.32–7.06 (m, 1 H), 6.60–6.50 (m, 2 H), 3.65 (t, 1 H, J = 8.4 Hz), 3.22–3.36 (m, 2 H merged with CD_3OD peak), 3.20–3.10 (m, 2 H), 2.80–1.05 (m, 16 H), 1.43 (s, 9 H), 0.81 (s, 3 H). ESMS: 473 (M + H) $^+$.

Also isolated was 0.055 g (10%) of the minor isomer, 6 α -[[[(2-*tert*-butoxycarbonyl)amino]ethyl]carboxamidomethyl]estradiol (**11b**). Analytical RP HPLC (70:30 MeOH/0.1% aqueous acetic acid, 1.0 mL/min, 225 nm, relative intensity): t_R 7.68 min (95.3%). ^1H NMR (CD_3OD): δ 7.10 (d, 1 H, J = 8.4 Hz), 6.64 (d, 1 H, J = 2.5 Hz), 6.57 (dd, 1 H, J = 8.7 and 2.5 Hz), 3.63 (t, 1 H, J = 8.7 Hz), 3.22–3.36 (m, 2 H merged with CD_3OD peak), 3.14 (t, 2 H, J = 6.6 Hz), 2.77–2.72 (m, 1 H), 2.32–1.05 (m, 15 H), 1.43 (s, 9 H), 0.74 (s, 3 H). ESMS: 473 (M + H) $^+$.

6 β -[(2-Aminoethyl)carboxamidomethyl]-3,17 β -dihydroxyestra-1,3,5(10)-triene (12). Trifluoroacetic acid (4.0 mL) was added at room temperature to a solution of 6 β -[[[(2-*tert*-butoxycarbonyl)amino]ethyl]carboxamidomethyl]estradiol (**11a**, 0.180 g, 0.381 mmol) dissolved in anhydrous CH_2Cl_2 (4.0 mL). After the mixture was stirred for 30 min, the solvent was removed on a rotary evaporator to afford 0.217 g of crude amine (**12**). The crude compound (**12**) was purified by preparative RP HPLC [Waters μ Bondpak C18 10 μm column (25 mm $\times$ 100 mm) with 25:75 MeCN/0.1% aqueous trifluoroacetic acid, 9.0 mL/min, 225 nm]. The product was collected, the solvent removed on a rotary evaporator in vacuo, and the residue dried azeotropically using a mixture of toluene and methanol (1:1, 3 $\times$ 10 mL) to afford 0.092 g

of 6 β -[(2-aminoethyl)carboxamidomethyl]-3,17 β -dihydroxyestra-1,3,5(10)-triene [**12**, 6 β -[(2'-aminoethyl)carboxamidomethyl]estradiol] in 50% yield. Analytical RP HPLC (75:25 MeCN/0.1% aqueous trifluoroacetic acid, 1.0 mL/min, 225 nm, relative intensity): t_R 8.65 min (98.6%). ^1H NMR (CD_3OD): δ 7.10 (d, 1 H, J = 8.1 Hz), 6.57–6.61 (m, 2 H), 3.68 (t, 1 H, J = 8.4 Hz), 3.58–3.38 (m, 2 H), 3.05 (t, 2 H, J = 6.3 Hz), 2.60–1.12 (m, 16 H), 0.81 (s, 3 H). ESMS: 373 (M + H) $^+$.

3,17 β -Dihydroxyestra-1,3,5(10)-triene-6 β -(Methylcarboxamidoethyl)biotinamide (14). Biotin succinimidyl ester (**23**) (**13**, 0.0102 g, 0.03 mmol, 1.2 equiv) and diisopropylethylamine (0.043 mL, 0.25 mmol, 10.0 equiv) were added sequentially to the solution of amine **12** (0.0094 g, 0.025 mmol) in anhydrous DMF (0.6 mL) at room temperature under nitrogen. After the mixture was stirred for 16.5 h, the solvent was removed on a rotary evaporator and dried on a vacuum pump. Purification of the crude product by preparative RP HPLC [Waters μ Bondpak C18 10 μm column (40 mm $\times$ 10 mm) with 25:75 MeCN/0.1% aqueous trifluoroacetic acid, 45 mL/min, 225 nm] and lyophilization afforded 0.011 g of the biotinylated probe (**14**) in 74% yield as a colorless powder. Analytical RP HPLC (30:70 MeCN/0.1% aqueous trifluoroacetic acid, 2.0 mL/min, 225 nm, relative intensity): t_R 4.56 min (99%). ^1H NMR (CD_3OD): δ 7.10 (d, 1 H, J = 9.0 Hz), 6.59–6.55 (m, 2 H), 4.44–4.41 (m, 1 H), 4.25–4.22 (m, 1 H), 3.65 (t, 1 H, J = 8.7 Hz), 3.35–3.15 (m, 4 H merged with CD_3OD), 2.90–2.65 (m, 2 H), 2.55–1.14 (m, 25 H), 0.81 (s, 3 H). ESMS: 599 (M + H) $^+$.

3,17 β -Dihydroxyestra-1,3,5(10)-triene-6 β -(Methylcarboxamidoethyl)-5-carboxyfluoresceinamide (16). The amine **12** (0.010 g, 0.021 mmol) was dissolved in anhydrous DMF (0.6 mL), and 5-carboxyfluorescein succinimidyl ester (**29**) (**15**, 0.010 g, 0.021 mmol, 1.0 equiv) was added followed by triethylamine (0.072 mL, 0.071 mmol, 3.4 equiv) at room temperature under a nitrogen atmosphere. The flask was covered with aluminum foil, and the mixture was stirred for 18 h. The solvent was removed on a rotary evaporator and dried on a vacuum pump. Purification of the crude product by preparative RP HPLC [Waters μ Bondpak C18 10 μm column (25 mm $\times$ 10 mm) with 40:60 MeCN/0.1% aqueous acetic acid, 9.0 mL/min, 225 nm]. The acetonitrile was removed on a rotary evaporator and the remaining material was lyophilized to afford 0.0106 g of the fluorescent probe (**16**) in 69% yield as an orange powder. Analytical RP HPLC (40:60 MeCN/0.1% aqueous acetic acid, 2.0 mL/min, 225 nm, relative intensity): t_R 11.96 min (99.9%). ^1H NMR (CD_3OD): δ 8.45 (s, 1 H), 8.24–8.18 (m, 1 H), 7.31 (d, 1 H, J = 8.1 Hz), 7.09 (d, 1 H, J = 8.4 Hz), 6.73–6.54 (m, 8 H), 3.65–3.45 (m, 5 H), 2.58–2.24 (m, 3 H), 2.10–1.90 (m, 3 H), 1.70–1.06 (m, 10 H), 0.78 (s, 3 H). ESMS: 731 (M + H) $^+$.

Acridinium-9-carboxamide Probe (18). The acridinium succinimidyl ester (**30**, **31**) (**17**, 0.014 g, 0.021 mmol, 1.0 equiv) and triethylamine (0.010 mL, 0.072 mmol, 3.4 equiv) were added to a solution of amine **12** (0.010 g, 0.021 mmol) in anhydrous DMF (0.6 mL) at room temperature under nitrogen. The flask was covered with aluminum foil, and the mixture was stirred for 15 h. The solvent was removed on a rotary evaporator and dried on a vacuum pump, and the crude product was purified by preparative RP HPLC [Waters μ Bondpak C18 10 μm column (25 mm $\times$ 10 mm) with 35:65 MeCN/0.1% aqueous formic acid, 9 mL/min, 225 nm]. The acetonitrile was removed on a rotary evaporator, and the remaining material was lyophilized to afford 0.013 g of the acridinium-9-carboxamide probe (**18**).

Scheme 2

dinium probe (**18**) in 65% yield. Analytical RP HPLC (25: 75 MeCN/0.1% aqueous formic acid, 1.0 mL/min, 225 nm, relative intensity): t_R 8.02 min (>99%). ¹H NMR (CD₃-OD): δ 8.98–8.86 (m, 2 H), 8.46–8.38 (m, 2 H), 8.20–7.60 (m, 6 H), 7.18–6.98 (m, 3 H), 6.60–6.40 (m, 2 H), 5.76–5.66 (m, 2 H), 4.32–4.23 (m, 1 H), 3.68–3.12 (m, 8 H, merged with CD₃OD), 3.00–1.05 (m, 22 H), 2.35 (s, 3 H), 0.80 and 0.69 (2 s, 3 H). ESMS: 939 (M)⁺.

RESULTS AND DISCUSSION

The strategy for the synthesis of 6 β -[(2'-aminoethyl)-carboxamidomethyl]estradiol (**12**) involves (Schemes 1–3) a stereoselective introduction of carboxymethyl group at the C6 position of estradiol (**1**) and further elaboration of the spacer arm with an ethylenediamine linker. Thus, Reformatsky reaction of 3,17 β -bis[(2-trimethylsilyl)-ethoxymethyl]-1,3,5(10)-estratrien-6-one (**2**) with bromoethyl acetate and zinc and dehydration of the resulting hydroxy compound (**3**) gave the mixture of endo and exo esters (**4** and **5**) in a 67:33 ratio. Previously, Ghosh et al. (28), in their studies on pentacyclic steroids, obtained a mixture of endo and exo olefinic esters in an 85:15 ratio from 17 β -acetoxy-3-methoxyestra-1,3,5(10)-trien-6-one, a

differentially protected estradiol derivative. In the ¹H NMR spectra of **4**, the endo olefinic proton appeared at 5.92 ppm and the exo olefinic proton in **5** at 6.26 ppm which are consistent with the structures. The exo compound (**5**) appeared to be present as a single isomer by ¹H NMR (olefinic proton at 6.26 ppm), and since the double bond in ester (**5**) be reduced in the subsequent steps, no further effort was made to determine its geometry. It is noteworthy that, unlike the acetate group (28), both the C17 and C3 SEM protective groups in compound **3** were stable under the dehydration conditions; however, they were easily hydrolyzed in esters **4** and **5** using HF in MeCN (27). The resulting endo/exo mixture (**6** and **7**) was hydrogenated using 10% Pd/C to afford 6 β/α -[(ethoxycarbonyl)methyl]estradiol (**8a** and **8b**) in a 79:21 epimeric ratio as determined by ¹H NMR. The stereochemistry of the major product (**8a**) was determined to be β -isomer on the basis of the mode of hydrogenation and comparison to the previous observations by Ghosh et al. (28). In their studies (28), hydrogenation of the mixture of 17 β -hydroxy-3-methoxy-1,3,5-(10),6-estratetraene-6-acetic acid and its exo isomer gave a major β -isomer, 17 β -hydroxy-3-methoxy-1,3,5(10)-es-

Scheme 3

tratriene-6 β -acetic acid. Thus, the hydrogenation of esters **6** and **7** took place from the sterically less hindered α -face of the steroidal molecule, giving the major β -isomer. In the ¹H NMR spectra, the C17 methyl group of the β -isomer (**8a**) appeared at 0.81 ppm, whereas in the α -isomer (**9b**), the C17 methyl group appeared at 0.75 ppm.

The ethyl esters in **8a** and **8b** were hydrolyzed to the corresponding acids (**9a** and **9b**) using sodium hydroxide in 81% yield and a 79:21 ratio (β : α). Activation of the acids (**9a** and **9b**) followed by the treatment with *tert*-butyl *N*-(2-aminoethyl)carbamate (**10**) and HPLC separation afforded the pure β -isomer (**11a**) and the minor α -isomer (**11b**) in 39 and 10% yields, respectively. Finally, hydrolysis of the BOC group in **11a** using TFA in methylene chloride afforded the desired hapten, 6 β -[(2'-aminoethyl)carboxamidomethyl]estradiol (**12**), in 50% yield after purification by preparative HPLC. The hapten (**12**) was then treated with the *N*-succinimidyl active esters of biotin (**13**) (23), 5-carboxyfluorescein (**15**) (29), and 10-(sulfopropyl)-*N*-tosyl-*N*-(3-carboxypropyl)acridinium-9-carboxamide (**17**) (30, 31) in DMF to produce the corresponding biotinylated (**14**), fluorescent (**16**), and

chemiluminescent (**18**) E₂ probes, respectively, in 65–74% yield and >99% purity.

In preparation of a suitable ligand for label conjugation, the selection of the appropriate functionality on the steroidal backbone, site of substitution, and control of stereocenters all play an important role. A C6-functionalized E₂ in which the sp³ nature of C6 is retained would more closely mimic the unmodified E₂ and therefore be a more suitable hapten for preparing immunoreagents for the detection of E₂. In addition, the substitution of a label at the C6 position of E₂ (**1**) prevents the metabolic hydroxylation at this position. When a chiral center is introduced at C6, the stereochemistry and the electronic nature of the substituent at that position become critical because of its spacial disposition to the C18 methyl and C17 hydroxyl groups and the electronic effect on the phenyl ring.

Thus, in this paper, we have described the synthesis of 6 β -[(2'-aminoethyl)carboxamidomethyl]estradiol (**12**), a C6-alkyl-substituted estradiol hapten from 6-oxoestradiol (**2**). The three critically needed estradiol probes (**14**, **16**, and **18**) containing biotin, fluorescein, and acridinium-9-carboxamide, respectively, were prepared from

the amine **12** for studies on estradiol binding proteins and for development of assays for E₂ (**1**).

Received September 12, 1997; Revised Manuscript Received January 14, 1998

Chlorophyll *a* was adsorbed to a synthetic smectite intercalated by poly(vinylpyrrolidone) (PVP) to form the chlorophyll–PVP–smectite conjugate (Chl–PVP–SME) having an absorption maximum at 677 nm. The conjugate was found to be stable toward light illumination in comparison with chlorophyll–smectite, chlorophyll–PVP, and free chlorophyll *a*. Chl–PVP–SME had a photoinduced activity for catalyzing the reduction of methyl viologen. Furthermore, the evolution of hydrogen gas was observed when an aqueous suspension containing Chl–PVP–SME, methyl viologen (an electron carrier), 2-mercaptoethanol (an electron donor), and hydrogenase was illuminated by visible light.

INTRODUCTION

Chlorophyll molecules bind to proteins to form chlorophyll–protein conjugates in the layered thylakoid membrane of chloroplasts and exhibit physiological functions: the photolysis of water and the reduction of NADP (1) under visible light illumination.

A large number of investigations on photosensitization have been published using photocatalytic inorganic compounds such as titanium oxide in the presence of ultraviolet ray (2). To enhance the efficacy of the photocatalytic reactions, Domen et al. (3, 4) demonstrated that a series of layered metal oxide, perovskite, catalyzes overall water splitting. In addition, Miyata et al. (5) prepared viologens intercalated into the layered space of bentonites in relation to their photochromic behavior.

From the viewpoint of solar energy conversion, however, photocatalysts such as chlorophyll and porphyrin derivatives which work under visible light illumination are indispensable. Okura et al. (6, 7) observed photoinduced hydrogen evolution using zinc *meso*-tris(sulfonatophenyl)porphyrin as a photosensitizer in the presence of an electron donor and an electron carrier under visible light illumination. Chlorophyll, however, has been seldom used as a photocatalyst because the natural pigment loses its photostability by extraction with an organic solvent.

We prepared chlorophyll *a* adsorbed onto bentonite (8) and onto smectite (9). Each conjugate was found to be photostable, and its adsorption maximum was shifted to a longer wavelength by increasing the amount of chlorophyll *a* adsorbed onto clay minerals. Bentonite and smectite minerals, which consist of two-dimensional silicate layers separated by hydrated exchangeable cations, swell with a variety of molecules and form inter-

calated complexes (10). Recently, we reported that the chlorophyll–bentonite conjugate exhibited a high photosensitizing activity for reducing nitro blue tetrazolium, through the formation of superoxide anion (11).

This paper deals with preparation of a chlorophyll–PVP–smectite conjugate having high photostability against light. Furthermore, the conjugate evolves hydrogen gas effectively in the presence of an electron donor, an electron carrier, and a catalyst under visible light illumination.

EXPERIMENTAL PROCEDURES

General. Chlorophyll *a* purified from *Spirulina*, poly(vinylpyrrolidone) (PVP)¹ with an average molecular weight of 10 000, and methyl viologen (1,1-dimethyl-4,4-bipyridinium chloride) were purchased from Wako Pure Chemical Industries, Ltd. (Osaka, Japan). Smectite powder (hectorite), which was hydrothermally synthesized, was obtained from Co-op Chemical Co., Ltd. (Tokyo, Japan). Its properties are as follows: elemental composition Si 8.00, Mg 5.65, Li 0.70, Na 1.05; transmittance 95% in 1% aqueous solution at 500 nm; and methylene blue adsorption 101 mequiv per 100 g. Hydrogenase was isolated from *Desulfovibrio vulgaris* according to Yagi's method (12). Other reagents were of analytical grade.

Chlorophyll–PVP–Smectite. The chlorophyll–PVP–smectite conjugate (Chl–PVP–SME) was prepared to test the photostability of chlorophyll *a* as follows. At first, smectite was suspended in a 3% NaCl aqueous solution for 24 h three times to make Na-smectite. Na-smectite was then stirred in a PVP aqueous solution (5%) with a 3:2 weight ratio of PVP and Na-smectite, and the mixture was freeze-dried to form a PVP–smectite con-

¹ Abbreviations: PVP, poly(vinylpyrrolidone); Chl–PVP–SME, chlorophyll–poly(vinylpyrrolidone)–smectite conjugate; PVP–SME, poly(vinylpyrrolidone)–smectite conjugate; Chl–PVP, chlorophyll–poly(vinylpyrrolidone) conjugate; Chl–SME, chlorophyll–smectite conjugate.

jugate (PVP-SME) according to the method of Miyata et al. (5). Two milliliters of chlorophyll *a* dissolved in benzene (9.8 mg/mL) was added to PVP-SME (600 mg). The suspension was then shaken for 1 h at 25 °C to establish the adsorption equilibrium between chlorophyll *a* and PVP-SME. The Chl-PVP-SME thus prepared was collected by centrifugation and was dried under reduced pressure. The amount of chlorophyll *a* adsorbed to PVP-SME was spectrophotometrically determined by using the molar extinction coefficient of chlorophyll *a* ($9.25 \times 10^4 \text{ M}^{-1} \text{ cm}^{-1}$ at 661.6 nm in acetone) (13). One gram of smectite powder in the conjugate adsorbed 12.5 mg of chlorophyll *a* and 1.5 g of PVP. The absorption spectrum of Chl-PVP-SME in 50 mM Tris-HCl buffer (pH 7.8) was measured with a Shimadzu MPS-2000 multipurpose spectrophotometer (Kyoto, Japan) (14). The photostability of chlorophyll *a* was tested as follows. Chl-PVP-SME together with Chl-SME, Chl-PVP in water, and free chlorophyll *a* in benzene was illuminated with a 60 W incandescent lamp at a distance of 9.5 cm, with a light intensity of $200 \text{ J m}^{-2} \text{ s}^{-1}$, at 30 °C.

Chlorophyll-PVP-Smectite Intercalated by Methyl Viologen. Chl-PVP-SME intercalated by methyl viologen was prepared to test whether the conjugate causes photoreduction of methyl viologen by visible light. First, an aqueous solution (17 mL) of methyl viologen (101 mg) was added to powdered PVP-SME (580 mg), and the mixture was stirred for 48 h. After centrifugation, the precipitate was washed with methanol and dried (the conjugate contained 21 mg of methyl viologen). PVP-SME intercalated by methyl viologen was then added to chlorophyll *a* (19.6 mg) dissolved in benzene (2 mL), and the suspension was shaken for 1 h at 25 °C to establish the adsorption equilibrium between chlorophyll *a* and PVP-SME intercalated by methyl viologen. The Chl-PVP-SME intercalated by methyl viologen was collected by centrifugation and was dried under reduced pressure. The conjugate was composed of Chl, PVP, SME, and methyl viologen at a weight ratio of 1:178:130:16.

Photoreduction of Methyl Viologen. Photoreduction of methyl viologen intercalated into Chl-PVP-SME was tested in the presence of 2-mercaptoethanol. The conjugate (17.3 mg; 0.06 μmol as chlorophyll *a*, 4.6 μmol as methyl viologen) was suspended in 3 mL of 25 mM Tris-HCl buffer (pH 7.4) containing 1 mmol of 2-mercaptoethanol. The sample mixture was deaerated by repeated freeze-pump-thaw cycles and was illuminated with a 60 W incandescent lamp at a distance of 3.5 cm, with a light intensity of $1500 \text{ J m}^{-2} \text{ s}^{-1}$, at 30 °C. The photochemical reduction of methyl viologen was observed by measuring the absorbance increase at 605 nm, using the molar extinction coefficient of $1.65 \times 10^4 \text{ M}^{-1} \text{ cm}^{-1}$.

Evolution of Hydrogen Gas. Hydrogen evolution by Chl-PVP-SME intercalated by methyl viologen in the presence of 2-mercaptoethanol and hydrogenase was tested according to the method of Okura et al. (6, 7). The reaction system (3 mL) consisted of 47.5 mg of Chl-PVP-SME intercalated by 2.5 mg of methyl viologen (50 mg; 0.17 μmol as chlorophyll *a*, 3 μmol as methyl viologen) suspended in 25 mM Tris-HCl buffer (pH 7.4) in the presence of 2-mercaptoethanol (1 mmol) and a hydrogenase solution (40 μL). The sample mixture in a Pyrex cell (17.5 cm^3) was deaerated by repeated freeze-pump-thaw cycles, and the upper space of the cell (14.5 cm^3) was filled with argon gas. The sample in the cell equipped with a magnetic stirrer was illuminated with a 200 W tungsten lamp (light intensity of $200 \text{ J m}^{-2} \text{ s}^{-1}$). Light at wavelengths of $<390 \text{ nm}$ was eliminated by a

Toshiba L-39 filter (Tokyo, Japan). A portion of the evolved hydrogen gas was collected via a sampling valve of the cell and was analyzed by gas chromatography.

RESULTS AND DISCUSSION

Photostability of Chl-PVP-SME. In this study, we prepared three kinds of chlorophyll conjugates, chlorophyll-poly(vinylpyrrolidone) (Chl-PVP), chlorophyll-smectite (Chl-SME), and chlorophyll-poly(vinylpyrrolidone)-smectite (Chl-PVP-SME). These chlorophyll conjugates became colloidal solutions with green color by the addition of water. Using these chlorophyll *a* conjugates in water together with chlorophyll *a* in benzene, the photostability was tested by illumination with visible light, which is shown in Figure 1a. Chlorophyll *a* dissolved in benzene is rapidly bleached by light (curve A). On the other hand, the absorbance decreases of the conjugates are much slower as shown by curves B (Chl-PVP), C (Chl-SME), and D (Chl-PVP-SME). Among them, Chl-PVP-SME (curve D) is the most stable. The absorption spectra of chlorophyll *a* in benzene and Chl-PVP-SME in aqueous solution are shown in Figure 1b (curves A and D, respectively). The wavelength of the absorption maximum is located at 665 nm for chlorophyll *a* in benzene and at 677 nm for Chl-PVP-SME in aqueous solution. Table 1 represents the relation between the absorption maximum and the stabilization of these chlorophyll conjugates with chlorophyll in intact leaves. As is clear from the table, chlorophylls in intact leaves have the absorption maximum at 678 nm (14) and are quite stable against light illumination. On the contrary, chlorophyll *a* in benzene has the absorption maximum at 665 nm. It is noteworthy that the shift in

Figure 2. Photoreduction of methyl viologen by Chl-PVP-SME (light intensity of $1500 \text{ J m}^{-2} \text{ s}^{-1}$) at 30°C . (Curve A) The reaction system (3 mL) consists of methyl viologen (0.85 mg) intercalated into Chl-PVP-SME (16.45 mg) and 2-mercaptoethanol (1 mmol). (Curve B) PVP-SME (16.45 mg) was used instead of Chl-PVP-SME in the above reaction system. The hatched pattern in the figure indicates a period in the dark.

absorption maximum of each conjugate to a longer wavelength from 665 nm of chlorophyll *a* is accompanied by an increase in the stability of chlorophyll *a*.

Inamura et al. prepared water-soluble chlorophyll by the addition of macromolecules, such as poly(vinyl alcohol), poly(vinylpyrrolidone), poly(ethylene glycol), and bovine serum albumin (15–17). These chlorophyll preparations were reported to be photostable, and their absorption maxima shifted to longer wavelengths. Kathleen et al. (18) and Sakoda et al. (19) prepared smectite-porphyllin conjugates with similar shifts of the absorption maxima.

Photoreduction of Methyl Viologen and Evolution of Hydrogen Gas. A next series of experiments was conducted to test whether Chl-PVP-SME induces the reduction of methyl viologen by light illumination and also the evolution of hydrogen gas. Figure 2 represents the photoreduction of methyl viologen by Chl-PVP-SME. When a suspension containing Chl-PVP-SME intercalated by methyl viologen is illuminated in the presence of 2-mercaptoethanol, the absorbance at 605 nm increases with illumination time, indicating the reduction of methyl viologen (Figure 2, curve A). When the light is turned off, the absorbance at 605 nm decreases gradually, probably due to the oxidation of reduced methyl viologen by a trace amount of oxygen existing in the reaction system. The decreased absorbance in dark increases again by the second illumination. On the other hand, methyl viologen is hardly reduced with PVP-SME in place of Chl-PVP-SME (curve B). In the absence of 2-mercaptoethanol in the reaction system, no photoreduction of methyl viologen occurs, even by light illumination (data not shown).

As the standard oxidation–reduction potential of methyl viologen is -0.44 V , the photoreduction system containing Chl-PVP-SME intercalated by methyl viologen is expected to reduce two hydrogen ions into a hydrogen

Figure 3. Hydrogen gas generation by Chl-PVP-SME intercalated by methyl viologen in the presence of 2-mercaptoethanol and hydrogenase under illumination with visible light (light intensity of $200 \text{ J m}^{-2} \text{ s}^{-1}$) at 30°C . (Curve A) The reaction system (3 mL of 25 mM Tris-HCl buffer at pH 7.4) consists of Chl-PVP-SME (47.5 mg) intercalated by methyl viologen (2.5 mg), 2-mercaptoethanol (1 mmol), and hydrogenase (40 μL). The chlorophyll content in this reaction system was $0.17 \mu\text{mol}$. (Curve B) In the absence of 2-mercaptoethanol. (Curve C) In the dark.

molecule according to Scheme 1 (6, 7). Figure 3 shows the hydrogen gas evolution by Chl-PVP-SME intercalated by methyl viologen in the presence of 2-mercaptoethanol (electron donor) and hydrogenase under illumination with visible light. The amount of hydrogen gas evolved from the reaction system increases with the illumination time, with a delay of about 60 min which is shown by curve A in Figure 3. After illumination of the mixture for 6 h, approximately $0.16 \mu\text{mol}$ of hydrogen gas is evolved from the reaction system, and the reaction is still in progress. It indicates that $0.32 \mu\text{mol}$ of hydrogen ion, which is twice the amount of chlorophyll *a* ($0.17 \mu\text{mol}$) on the smectite, is reduced to hydrogen molecules. Therefore, the chlorophyll conjugate appears to serve as a photoactivated system for transferring electrons from 2-mercaptoethanol to a more reductive hydrogen molecule (6, 7). A similar experiment is conducted in the absence of 2-mercaptoethanol or in the dark, but hydrogen gas is not evolved in each case shown by curves B and C, respectively. The reason the hydrogen evolution could not be observed during the initial 60 min is not clarified yet. It would probably take time to reduce the metal ions (Fe^{3+} , Ni^{3+}) in the active center of hydrogenase to activate the enzyme (20). From the results obtained above, the chlorophyll conjugate excited by illumination ($\text{Chl}^*\text{-conj.}$) releases an electron and changes to a cationic chlorophyll conjugate ($\text{Chl}^+\text{-conj.}$). The electron reduces methyl viologen dication (MV^{2+}) to methyl viologen cation radical (MV^+), which reduces hydrogen ion to hydrogen gas by the catalytic action of hydrogenase. On the other hand, the $\text{Chl}^+\text{-conj.}$ is reduced by 2-mercaptoethanol to reproduce chlorophyll conjugate (Scheme 1).

Scheme 1

In conclusion, chlorophyll molecules gained high stability against light illumination by conjugating with poly-(vinylpyrrolidone) and/or smectite, and the chlorophyll conjugates exhibited high photosensitizing activity during the long-period illumination. Further experiments are now in progress to stabilize the chlorophyll conjugate against light and to enhance the efficacy of photoenergy conversion. We believe that, soon, the chlorophyll molecules conjugated with multilayered compounds could be designed to allow the artificial photosynthetic reactions such as water splitting and carbon dioxide fixation.

A Method for the ^{32}P Labeling of Peptides or Peptide Nucleic Acid Oligomers

Igor A. Kozlov,[†] Peter E. Nielsen,[‡] and Leslie E. Orgel^{*,†}

The Salk Institute for Biological Studies, P.O. Box 85800, San Diego, California 92186, and Center for Biomolecular Recognition, IMBG, The Panum Institute, Blegdamsvej 3c, DK-2100 N Copenhagen, Denmark.
Received March 24, 1998

A novel approach to the radioactive labeling of peptides and PNA oligomers is described. It is based on the conjugation of a deoxynucleoside 3'-phosphate with the terminal amine of the substrate, followed by phosphorylation of the 5'-hydroxyl group of the nucleotide using T4 polynucleotide kinase and [γ - ^{32}P]ATP.

During the course of work on chimeras of DNA and peptide nucleic acids (PNAs), we needed to synthesize conjugates of 2'-deoxycytidine 3'-phosphate (dCp) and PNAs. Reaction between 2'-deoxycytidine 3'-phosphorimidazolid (dCpIm) and the free terminal amino group of PNA was found to proceed with almost quantitative yield. We found that the conjugate could then be phosphorylated using T4 polynucleotide kinase (Maniatis et al., 1982) as efficiently as an oligonucleotide. This is not surprising since T4 polynucleotide kinase is known to phosphorylate nucleoside-containing substrates with a free 5'-OH group and an esterified phosphate group at the 3'-position (Richardson, 1981). Our experiments show that T4 polynucleotide kinase will accept a substrate in which the 3'-phosphomonoester is replaced by

an analogous 3'-phosphoamide. We have now extended our procedure to the phosphorylation of other amine-containing molecules and have used it to label the N terminus of a peptide.

2'-Deoxycytidine 3'-phosphorimidazolid (dCpIm) was synthesized from dCp by an obvious modification of a published procedure in almost quantitative yield (Joyce et al., 1984). The PNA molecule $\text{H}_2\text{N-ATGCTCTGC-CONH}_2$ (PNA-1) with a free terminal amino group and a protected carboxyl group was obtained by solid phase synthesis using a published procedure, and its identity was confirmed by mass spectroscopy (Christensen et al., 1995; Hyrup and Nielsen, 1996). The peptide molecule $\text{H}_2\text{N-WQFEQQ-CONH}_2$ (P-1) containing a free terminal amino group and a protected carboxyl group was synthesized at the Salk Institute for Biological Studies.

To synthesize the PNA-dCp conjugate, a solution of PNA-1 (1 mM) and dCpIm (0.1 M) in 0.1 M Im buffer, at pH 7.7, was kept at room temperature for 2 days. The peptide-dCp conjugate was prepared in the same way

Figure 1. (A) Scheme for the synthesis of a conjugate of PNA with dCp. (B) Scheme for the synthesis of a conjugate of a peptide with dCp: (i) 0.1 M Im buffer at pH 7.7 and (ii) T4 polynucleotide kinase and ATP, under routine conditions (Maniatis et al., 1982).

Figure 2. (A) Synthesis (a and b) and phosphorylation (c and d) of the conjugate between PNA-1 and dCp: (a) starting PNA-1, (b) reaction mixture after 2 days, (c) purified conjugate, (d) reaction mixture after phosphorylation of the conjugate, (1) starting PNA-1, (2) conjugate of PNA-1 with dCp and (3) 5'-phosphorylated conjugate. HPLC analysis was performed on an RPC5 column as previously described (Joyce et al., 1984; Schmidt et al., 1996). Reaction products were eluted with a linear gradient of NaClO_4 (pH 12, 0 to 0.06 M over the course of 60 min) and monitored by UV absorption at 254 nm. (B) Synthesis (a and b) and phosphorylation (c and d) of the conjugate of peptide P-1 with dCp: (a) starting peptide, (b) reaction mixture after 2 days, (c) purified conjugate, (d) reaction mixture after phosphorylation of the conjugate, (1) starting peptide P-1, (2) conjugate of P-1 with dCp and (3) 5'-phosphorylated conjugate. HPLC analysis (a and b) was performed on a C18 RP-HPLC column using a linear gradient of 0 to 40% acetonitrile in water (0.1% TFA) over the course of 30 min. Reaction products were monitored by UV absorption at 220 nm. HPLC analysis (c and d) was performed on an RPC5 column as previously described (Joyce et al., 1984). Reaction products were eluted with a linear gradient of NaClO_4 (pH 8, 0 to 0.06 M over the course of 60 min) and monitored by UV absorption at 220 nm. We did not study the nature of the material that eluted ahead of compound 2 in part c since the peak appears in a control experiment from which the substrate peptide was omitted. We believe that the large peak that elutes ahead of compounds 2 and 3 in part d corresponds to a component of the phosphorylation reaction mixture.

but using 3 mM peptide P-1 in place of 1 mM PNA. The reaction sequence is shown in Figure 1. The PNA-dCp conjugate was purified by HPLC on an RPC5 column at

pH 12 (Joyce et al., 1984; Schmidt et al., 1996) (Figure 2A, part b) and then dialyzed against water (Spectrum dialysis membranes). The peptide-dCp conjugate was

Figure 3. Analysis of ^{32}P -labeled conjugates between (A) PNA-1 and dCp and (B) peptide P-1 and dCp by electrophoresis on a 20% polyacrylamide gel. Separations were run for about 2 h at a constant current of 18 mA on a denaturing gel (8 M urea). The elution buffer was 50 mM Tris-borate (pH 8.3) containing 1 mM ethylenediaminetetraacetic acid (EDTA). Xc and Bpb are the positions of markers xylene cyanol and bromophenol blue, respectively.

purified by RP-HPLC on a C18 column (Figure 2B, part b). The fraction containing the product was neutralized with 1 N sodium hydroxide and then dialyzed against water. The molecular weights of the conjugates were determined using a Bruker Esquire-LC electrospray ionization mass spectrometer (PNA-dCp conjugate, calcd for $\text{C}_{105}\text{H}_{135}\text{N}_{52}\text{O}_{35}\text{P} - \text{H}^+$ 2714, found 2715; peptide-dCp conjugate, calcd for $\text{C}_{49}\text{H}_{65}\text{H}_{14}\text{O}_{17}\text{P} - \text{H}^+$ 1151.4, found 1150.9). The chemical structures of the conjugates were confirmed by their hydrolysis in 0.1 N HCl at 37 °C (2 h) which gave the initial PNA or peptide. These conditions are specific for the acid hydrolysis of phosphoamide linkages in nucleotide-peptide conjugates (Rjabova et al., 1965; Shabarova, 1970).

The conjugates were phosphorylated using T4 polynucleotide kinase (Maniatis et al., 1982) (Figure 1). The reaction products were analyzed by HPLC on an RPC5 column at pH 12 for PNA (Figure 2A, part d) and pH 8 for peptide (Figure 2B, part d). Virtually complete phosphorylation of the PNA-dCp conjugate was achieved in 5 min, but complete phosphorylation of the peptide-dCp conjugate required an initial 30 min of incubation with the enzyme followed by incubation for a further 30 min with a fresh portion of the enzyme. The ^{32}P -labeled PNAs and peptides could be analyzed by electrophoresis

on 20% polyacrylamide gels under standard conditions (Maniatis et al., 1982) (Figure 3). The three negative charges introduced by the terminal nucleotide are sufficient to transform a PNA or peptide molecule into a molecule suitable for electrophoretic analysis.

The procedure described above should be applicable to the ^{32}P labeling of biopolymers containing primary amino groups. dCp could be replaced by any other 2'-deoxynucleoside 3'-phosphate. Peptides that include lysyl residues are likely to undergo multiple conjugations. Some selectivity might be achieved by carrying out reactions at low pH. ^{32}P labeling of biopolymers that lack amino groups should be possible using appropriate linkers if sulfhydryl or carboxyl groups are available.

Other procedures for the ^{32}P labeling of peptides and PNA oligomers have been described. They involve the attachment of short peptides that are substrates of protein kinases to the target molecules (Kemp and Pearson, 1991; Koch et al., 1995). The nature of the potential application will determine the method of choice.

1. INTRODUCTION

The need to maintain substances in blood is one of the main goals in therapeutic and diagnostic applications, which are often hampered by the short in vivo half-life of administered compounds. Many factors are involved in the removal of substances from the circulation: proteins and peptides are rapidly eliminated by proteolytic degradation, renal filtration, and/or immunogenic and antigenic reactions, while renal excretion and inactivation reactions by blood enzymes (especially the hydrolytic action of esterases) are the main causes for the brief plasma residence time of low-molecular mass (MW)¹ nonprotein drugs.

Many methods have been studied in the last three decades in an effort to find a means for prolonging the permanence of substances in circulation. To review this complex matter, we decided to report separately here the

three most interesting strategies: covalent conjugation of drugs to polymers, drug encapsulation in liposomes, and drug physical entrapment in particles. As will become clearer later, polymers are currently the "last word" of all these approaches, since they are used not only for direct conjugation to drugs but also as further stabilizers of drug-loaded liposomes and particles. The additional combination of various strategies has led to the creation of drug carrier systems which are very similar to "Russian dolls", the smallest doll (represented by the innermost drug) surrounded by a larger doll (liposome or particle), in turn protected by the largest one of all (the polymer). In this review, particular emphasis is therefore given to polymers, with a brief description of their chemical structure, properties, and methods of activation.

Another approach to the stabilization of molecules in the circulation is the use of natural carriers such as cells, bacteria, or virus envelopes. These carriers will not be reviewed here, since emphasis is primarily given to strategies based on chemical approaches.

2. POLYMER CONJUGATION

2.1. Introduction. Modification of biologically active compounds with polymers is one of the methods for altering and controlling their pharmacokinetics, biodistribution, and often toxicity (1). The preparation of drug-polymer conjugates has been extensively reported in many reviews (2–14). Ringsdorf first proposed using polymers as drug carriers in the mid-1970s (15), and the possibility of creating drug delivery systems able to determine both controlled release of the drug, through optimization of its pharmacokinetics, and drug targeting, through a moiety able to drive the carried drug to specific organs and tissues, rapidly became a primary goal, especially in cancer chemotherapy. Since then, polymers with varying chemical and biological properties have been investigated in an effort to achieve long circulation times, slow release, and/or targeting of the conjugated drugs, thus improving their therapeutic use.

The following sections review (a) the properties and activation methods of polymers used for drug derivatization and (b) the characteristics of both protein and nonprotein drug conjugates. Special attention will be paid to poly(ethylene glycol) (PEG) and its adducts, since it is still the most widely used polymer for drug conjugation.

2.2. Properties and Methods of Activation of Polymers for Drug Conjugation. The general requirements for any polymer carrier (natural or synthetic) to be used for drug conjugation are water solubility, biocompatibility, lack of immunogenicity, biological inertia, and the presence of functional groups for allowing covalent conjugation to drugs and targeting moieties.

2.2.1. Natural Polymers. Natural polymers have the advantage of easy availability and biocompatibility, although their preparation may be restricted by the need for several purification steps and their use is limited by their high immunogenicity. However, polymers such as polysaccharides (dextran) and albumin are widely used.

Dextran. Dextran is an uncharged, water-soluble polymer of α -D-glucose, presenting 95% of α -1,6-linked linear units and 5% of α -1,3-linked moieties as side chains. High-molecular mass branched dextrans, first used as plasma expanders, were unfortunately associated with toxicity and allergic reactions, later avoided by using linear dextrans, obtained from *Leuconostoc mesenteroides*. However, in this case, a long purification procedure

was required, including an initial hydrolysis step for obtaining polymers with a range of different molecular masses and a size fractionation step for purifying dextrans of 40, 70, and 110 kDa. Polymers with molecular masses outside this range are useless, since the smaller ones pass through the glomerulus and are secreted and the larger ones cause erythrocyte aggregation and hypersensitivity reactions (6).

Dextrans in the 40–110 kDa molecular mass range have been studied for drug modification; for this purpose, dextran vicinal diols can be activated to electrophilic groups able to react with protein and drug amino groups. Reactive imidocarbonate groups, introduced via cyanogen bromide (16–18), or dialdehyde-dextran, obtained by oxidation with sodium periodate (19–21), are used for either protein or conventional drug modification at the amino groups. Both methods have advantages and disadvantages. Imidocarbonate-dextran reacts in a one-step reaction but is unstable in aqueous solution, and its reagents and byproducts are toxic; dialdehyde-dextran is relatively stable in aqueous solution but requires a later step for reductive amination.

Human Serum Albumin (HSA). This protein is very easily available from blood banks, and is widely used to modify proteins of therapeutic interest. Its polyfunctionality allows a variety of derivatives to be prepared, but it is also responsible for intra- and intermolecular cross-linkages, with the final formation of heterogeneous products. HSA may also sometimes confer immunogenic properties on the conjugated drug, thus limiting its use as a carrier. Drug modification by HSA is performed in aqueous buffer in the presence of cross-linking agents such as glutaraldehyde, carbodiimide, and sodium periodate.

2.2.2. Synthetic Polymers. Synthetic polymers offer the opportunity for preparing tailor-made carriers, properly designed, and presenting all the desired features and moieties, such as targeting residues, peptidyl spacers as sites for enzymatic cleavage, and pH-sensitive linkers. Although the favorable biological properties of some polymers may sometimes be combined with the main use of the carried drug to create a synergic effect, the toxicity of others often strongly limits their in vivo use. *N*-(2-Hydroxypropyl)methacrylamide copolymers (HPMA), poly(styrene-co-maleic acid/anhydride) (SMA), poly(divinyl ether maleic anhydride) (DIVEMA), poly(*N*-vinylpyrrolidone) (PVP), poly(*N*-acryloyl)morpholine (PACM), and poly(ethylene glycol) (PEG) are some of the investigated polymers, whose chemical structures are reported in Figure 1.

***N*-(2-Hydroxypropyl)methacrylamide Copolymers (HPMA).** HPMA is a water-soluble, biocompatible polymer, which was developed in Czechoslovakia as a plasma expander (22). It is biologically well tolerated, nonimmunogenic (23), and nontoxic at the maximum administrable dose of 30 g/kg. Conjugate synthesis (24–30) consists of reacting HPMA copolymers, containing side chains terminating in reactive ester groups, to the aliphatic amino groups on the drug. The reaction may be carried out sequentially in organic and aqueous solutions to introduce drugs, prodrugs, antibodies, and peptides, according to their solubility, along the polymer backbone (14). However, these chemical procedures do not allow one-point attachment of the polymer chain to the surface of a protein, resulting in multiple attachment reactions. To create a polymer molecule with only one point of modification, semitelechelic poly-HPMA (ST-HPMA) containing one amino endgroup is synthesized by radical polymerization in the presence of 2-amino-

ethanethiol as a chain transfer agent and used to modify the surface of nanospheres (31).

Poly(styrene-co-maleic acid/anhydride) (SMA). SMA is an interesting polymer introduced by Maeda and co-workers (7, 32) containing alternating linkages of styrene and maleic acid. SMA is prepared with 30–50% maleic acid in the form of reactive anhydride and half the free groups butylated to confer hydrophobicity (32, 33). The anhydride group of the polymer reacts with the amino groups of the protein, while the styrene side chain provides hydrophobicity and hindrance to the conjugate.

Poly(divinyl ether maleic anhydride) (DIVEMA). The 1:2 divinyl ether maleic anhydride cyclic alternating copolymer (DIVEMA) is well-known for the variety of its biological activities. It possesses antitumor, antiviral, antibacterial, and antifungal activity. It is an anti-coagulant, anti-inflammatory agent, and immunopoten-

tiator. It induces the formation of interferon, increases the rate of phagocytosis, activates macrophages selectively, and inhibits RNA-dependent DNA polymerase (34). Studies on the relationship between polymer MW and toxicity have been performed using DIVEMA in the 2500–44800 Da range; great differences in acute toxicity were not observed, whereas toxicity measured by other criteria (levels of serum glutamic pyruvate transaminase, inhibition of drug metabolism, and sensitization to endotoxins) increased with increasing molecular mass. All toxicity tests were positive for polymers with a molecular mass over 15000 Da (34, 35). The biocompatibility of DIVEMA in the 2500–15000 Da range, its solubility, and the numerous anhydride groups available along its backbone have allowed its use for drug modification. Because of its own pharmacological effects, it has been exploited for conjugation to biologically interesting proteins and drugs, in view of the synergic effect of the new adducts. Moreover, the high negative charge of this polymer confers on the conjugate affinity toward particular biological structures and molecules, causing a unique in vivo behavior (34–36). The synthesis of DIVEMA–protein conjugates is not simple, since the multifunctional groups of both are involved in cross-linking processes, with a possible decrease in protein activity. However, the cross-linking reaction may be minimized by a pH-reversible protective reagent for the protein amino groups, which randomly restricts the number of protein amino groups available for later conjugation to the polymer (37).

Poly(N-vinylpyrrolidone) (PVP). PVP is a synthetic polymer used in large quantities as a blood expander and is well-known for its lack of toxicity, immunogenicity, and antigenicity (38, 39). One of the methods proposed for its binding to proteins is the opening of some of the pyrrolidinone rings by alkaline treatment, followed by masking of the amino groups and activation of the carboxyl groups as succinimidyl esters for the next reaction to the protein amino groups (40). The inconvenience of this method is the formation of several potentially reactive groups along its chain, with consequent cross-linked, heterogeneous final products. The use of chain transfer techniques during the polymerization of *N*-vinylpyrrolidinones provides a method for the preparation of OH or COOH monofunctionalized PVP with better defined structure (41). The high polydispersivity of the products requires a fractionation step (performed either by gel filtration purification or by fractional precipitation) to separate the PVP oligomers of convenient molecular size (42). These end-hydroxylated oligomers are directly activated into 4-nitrophenyl carbonate derivatives or succinimidyl esters for the subsequent modification of peptide and protein amino groups. Unfortunately, attempts to convert them into carboxylated derivatives by coupling to amino acids have until now resulted in low yields (43).

Poly(N-acryloyl)morpholine (PACM). High-MW polymers of *N*-acryloylmorpholine (PACM) are amphiphilic and nontoxic polymers used in pharmaceutical applications as plasma substitutes (44) and in transdermal applications (45, 46). PACM oligomers, ending at one chain terminus with a reactive OH or COOH function and obtained by radical polymerization of the vinyl monomer *N*-acryloylmorpholine in the presence of functionalized chain transfer agents (47), are synthesized to modify proteins of therapeutic interest.

Poly(ethylene glycol) (PEG). PEG is a linear polyether diol with many useful properties such as biocompatibility (48, 49), solubility in aqueous and organic media (49, 50),

lack of toxicity, very low immunogenicity and antigenicity (51), and good excretion kinetics (52). These properties allow its use in a variety of applications (53), including the biomedical field, after FDA approval for internal administration. It is commercially available in a variety of molecular masses at low dispersivity ($M_w/M_n \leq 1.1$), and activated species are now available from specialized sources (Shearwater Polymers, Inc., Huntsville, AL; and Polymer Laboratories, Inc., Amherst, MA). The most frequently used polymer molecular masses for drug conjugation range from 1000 to 20 000 Da, although lower and higher molecular masses have also been used. The body biodistribution of PEG with different molecular masses (from 31 000 to 277 000 Da) was recently investigated after intravenous (iv) injection into mice bearing a tumor mass (54). The study indicated that PEG does not exhibit specific affinity for any organ and that its accumulation in the tumor tissue is mainly governed by the level of hyperpermeable tumor vasculature (enhanced permeability retention, EPR effect), irrespective of the molecular mass of the polymer and the tumor loading site. Conversely, the higher the molecular mass of PEG, the longer the retention time in the blood. The balance between tumor accumulation rate and blood retention results in maximal accumulation of PEG with a MW of 200 000 Da. This highlights the problem of the toxicity of high-MW PEGs (above 200 000 Da) because of their very long circulation time. However, this problem does not interfere with using PEG for drug modification, since the MWs of PEG used for this purpose are well below the critical value.

The polymer backbone is chemically inert, and the terminal primary hydroxyl groups are available for derivatization. Protein and nonprotein drug conjugates are usually prepared from monomethoxy-PEG (mPEG) which, having only one derivatizable group, minimizes the heterogeneity of conjugates which may rise from cross-linking reactions. The hydroxyl groups on the polymer are sometimes directly bound to the desired molecules in a one-step process, yielding ether (55, 56), ester (57–61), or carbonate (62) linkages. In most cases, the hydroxyl groups are first activated and then reacted with the chosen molecule. Zalipsky (63) and Herman (64) recently and exhaustively reviewed PEG activation methods.

A great deal of work has been (and still is being) carried out on PEG functionalization, for two main reasons: (1) to discover the best synthesis of activated PEGs, reactive in mild conditions and possibly also selective toward different chemical groups on the drug molecule, without affecting its activity, and (2) to investigate the various PEG–drug linkages to establish the relationship between the type of binding and the properties of the new conjugates. Briefly, the most common functionalized PEGs are obtained as follows. (a) *Chloride, bromide, and sulfonate esters* are obtained by conversion of terminal hydroxyl groups by thionyl chloride (57, 65, 66), thionyl bromide (67), or organic sulfonyl chlorides. Reactive sulfonate ester derivatives such as tosylate–PEG (68–71) and mesylate–PEG (72) are used as intermediates in the preparation of amino–PEG (68, 73), thiol–PEG (71), phenylglyoxal–PEG (74), and benzaldehyde–PEG (75). Tresylate–PEG (76) is directly used to modify the desired molecule, especially at the protein amino groups (but thiol groups can also react) (77–79), with the formation of a secondary amine between PEG and the protein (this type of bond is particularly important if the nucleophilicity of the amino group is essential for activity preservation). (b) *Amino–PEGs* can be synthesized from

one of the above intermediates with an excess of ammonia (65, 67, 80, 81) or (to avoid the secondary amine side product) by conversion of the –OH into a *p*-toluenesulfonate ester followed by nucleophilic displacement of tosyl groups by potassium phthalimide and hydrazinolysis of the phthalimide endgroups (73). For quantitative conversion, the halide group can be displaced by azide and the azide group then reduced to primary amine (82). Other methods used to introduce an amino group on PEG are ester formation between the polymer hydroxyl groups and an amino acid carboxyl group (50) or introduction of aromatic amine by reaction of potassium alkoxide–PEG with *p*-nitrobenzyl bromide (83) or chloride (84), followed by reduction of the nitro groups. Conjugates are then obtained by alkylation or acylation reactions and, in the case of aromatic amine, also by a diazo coupling reaction after conversion of the amine into diazonium salts (84). (c) *Hydrazido–PEGs* are prepared by several methods (85–87), including the reaction of alkoxide–PEG with haloacetate ester and successive hydrazinolysis of the resulting ester (88). These activated PEGs form stable hydrazones on reaction with aldehyde-containing compounds and are particularly useful for site-specific modification of glycoproteins (86). (d) *Mercapto–PEGs* are synthesized by reaction of PEG–tosylate with potassium ethyl xanthate and amination of the product by glycine (71), derivatization of mPEG–NH₂ with the heterobifunctional reagent succinimidyl 3-(2-pyridyldithio)propionate (89), or other procedures (90) and used to graft polymer chains onto maleimide-containing liposomes (89). (e) *Carboxyl–PEGs* are obtained by means of several methods: direct oxidation of the hydroxyl groups by permanganate, although unfortunately this may give rise to polymer chain cleavage as a side reaction (91), carboxymethylation with α -haloacetic acid or its esters, especially displacement of bromide in ethyl bromoacetate by PEG–alkoxide (67, 92, 93), use of succinic (or glutaric) anhydride (57, 94–96), reaction with ethyl isocyanatoacetate (71, 82, 97, 98), and hydrolysis of the resulting ethyl esters of the PEG–glycine carbamate. Biological molecules can be covalently bound to carboxyl–PEG via ester or amide bonds (57, 65), dicyclohexylcarbodiimide being used as a carboxyl activator. Succinimidyl esters of carboxymethylated and succinylated PEGs are widely used for protein, lipid, and other substrate modification (99–103), yielding an amide bond between the substrate and the succinate residue. Esters of urethane-linked amino acids are also used for protein modification, the amino acid linker being useful for conjugate characterization; a non-natural amino acid, like norleucine, allows accurate determination of the degree of protein modification by quantitative amino acid analysis of the adduct, thus avoiding the less precise colorimetric or fluorimetric evaluations based on trinitrobenzenesulfonic acid or fluorecamine, respectively (104, 105). (f) *For carbonate-, carbamate-, and chloroformate–PEGs*, PEG can be converted into (imidazolyl-carbonyl)oxy derivatives by reaction with carbonyldiimidazole and successively reacted with protein amino groups forming urethane linkages (106); mPEG carbonate derivatives of *p*-nitrophenyl, 2,4,5-trichlorophenyl (107), and succinimidyl carbonate of PEG (108–111) are also used for protein modification, the latter also having an interesting use in the synthesis of liposome-forming mPEG–stearylamine (112). (g) *Cyanuryl chloride–PEG*, obtained by reaction of mPEG with trichloro-*s*-triazine (cyanuric chloride) (113), has the disadvantage of reacting not only with the amino but also with the hydroxyl and sulfhydryl groups on proteins, thus causing loss of

selectivity and sometimes of biological activity (114). The advantage of this product is that it is obtained by replacement of two of the three reactive chlorides of trichloro-s-triazine with mPEG, leaving the third chloride available for modification of the drug amino group; this provides a branched reagent that is able to introduce double the amount of polymer per number of amino sites modified (115). This aspect is important since, as will be discussed below, some beneficial properties of PEG proteins depend directly on PEG content, but the residual activity of the conjugate may sometimes inversely depend on the number of modified amino groups. (h) *Aldehyde-PEG* is synthesized in several ways. For example, acetaldehyde residues are introduced (116, 117), and the product is used for protein conjugation via reductive amination reaction (118, 119). This procedure is an alternative to using tresylate-PEG in the formation of a secondary amine between the polymer and the protein amino group without modification of the thiol groups. Aromatic aldehydes have also been studied (120), and amination of mPEG-nitrophenyl carbonate with 3-amino-1,2-propanediol followed by periodate oxidation of the diol into aldehyde (121) is used to prepare the copolymer PEG-lysine (122). (i) *Epoxide-PEG*, obtained by reaction with epichlorohydrin (123-125), shows mild reactivity toward hydroxyl and amino groups and better reactivity with thiols, thus being a useful reagent when a low degree of conjugation is desired.

Many other interesting activation methods of PEG have been reported for special uses, such as (j) *a dimethyl anhydride analogue of PEG*, gradually cleaved from the conjugate in physiological conditions (126), (k) *a PEG-imido ester* which forms a positively charged amidine upon reaction with protein amino groups with no consequent change of the total charge balance in the conjugate (127), (l) *a maleimide-PEG* (128, 129) and (m) *a vinyl sulfone-PEG* (130) for specific reaction at the cysteine residues, (n) *a phenylglyoxal-PEG* for selective modification of arginine residues (131), and (o) *heterobifunctional-PEGs* like α -amino- ω -hydroxy-PEG (132) allowing the binding of two different molecules at the two terminal groups (e.g., a drug on one terminus and a target moiety on the other).

Fascinating new PEG derivatives have recently been developed. (p) *PEG2-Lys succinimidyl ester* (133) was synthesized to obtain a two-arm reagent or branched polymer that is able to introduce twice the amount of polymer chains without increasing the number of derivatized protein amino groups. Because of its chemical structure, the reagent avoids the problems of product heterogeneity and loss of activity encountered with the use of the PEG2-trichlorotriazine obtained by Inada and co-workers (134). Interestingly, nature provides some proteins of very complex branched carbohydrate residues which create a protective shield against degradation and inactivation processes. This branched polymer may be thought of as an artificial simulation of the glycosylated cloud naturally provided to proteins. (q) *Comb PEGs*, PEG derivatives possessing a comb-shaped conformation (PM), have been synthesized as copolymers of a PEG derivative and maleic anhydride; the reactive site of the derivative is multivalent, and the molecular mass may vary widely (PM13 and PM100 corresponding to 13 and 100 kDa, respectively, have been studied). Modification with PM introduces many more PEG chains per the number of modified amino groups than either PEG1 or PEG2 (135). To overcome the problem of the limited number of low-molecular mass drug molecules that can be linked to a single chain of PEG, new drug carriers have

been introduced, like (r) *poly(PEG-Lys)*, composed of alternating segments of PEG and lysine bound by urethane linkages (122, 136), and (s) *mPEG-poly(Asp)*, a copolymer with increased drug-loading potentiality (137).

As briefly reviewed above, most of the PEG activation methods are directed toward the amino groups of the molecule to be modified. The use of these methods is justified by the high nucleophilicity and well-defined chemistry of the amino groups and, in the case of proteins, by the high number of residues bearing amino groups present on the protein surface exposed to the solvent. Moreover, protein amino groups usually only play a structural role in conferring solubility to the macromolecule and are only seldom involved in the catalytic process. According to the procedure used for PEG activation, the final conjugate may have amino groups no longer in the nucleophilic form (as in the case of all reactions based on amino group acylation) or amino groups with lower nucleophilicity (all alkylation reactions transforming a primary amino group into a secondary one). This must be taken into consideration when amino group acylation is associated with a decrease or even loss of drug activity.

Other Polymers. Many other polymers have been studied as potential drug carriers, although most of them have not been examined in vivo studies. For some of them, acute and subacute toxicity and immunogenicity have been evaluated, but for most, only in vitro studies have been carried out. Of these, worthy of mention are natural gelatin and polyamino acids and synthetic poly(L-glutamic acid), poly(L-lysine), poly(DL-alanine), poly(hydroxyethyl-L-glutamine), poly(α -malic acid), poly(acrylic acid), poly(vinyl alcohol), polytartrate (138), and poly(1-hydroxymethylethylene hydroxymethylformal) with a hydrolyzable main chain (139). Recently, the reaction between polysuccinimide and hydrazine produced a water-soluble, nontoxic, nonimmunogenic, α,β -polyasparthydrazide polymer which was loaded with 9% of antibacterial ofloxacin via a water-soluble carbodiimide (140). α,β -Poly(*N*-hydroxyethyl)-DL-asparthamide is used to prepare micromatrices loaded with an anti-inflammatory drug, 4-biphenylacetic acid (141). New carrier molecules, $\text{NH}_2\text{OCH}_2\text{CO}-(\text{Gly})_3-[\text{Lys}(\text{H-Ser})]_5-\text{Gly-OH}$ and $\text{HCO-m-C}_6\text{H}_4\text{CH}=\text{NOCH}_2\text{CO}-(\text{Gly})_3-[\text{Lys}(\text{H-Ser})]_5-\text{Gly-OH}$, are synthesized for the preparation of protein conjugates of defined structure. These molecules are able to react either with an aldehyde group introduced on a protein, with the formation of an oxime bond, or with the carboxyl terminus of a polypeptide chain, previously modified with carbonylhydrazide, to give a hydrazone bond (142).

Copolymers. Recently, besides improvements in the activation methods for each of the above polymers, great efforts have been made to create new carriers with more versatile properties. These polymers are usually prepared by combining traditional polymers, like the *N*-(2-hydroxypropyl)methacrylate-vinylpyrrolidone copolymer, PEG-ylated polymers, and block and graft copolymers (143, 144). Among them are (a) the above-mentioned poly(Asp)-PEG copolymers and poly(PEG-Lys); (b) PEG-grafted dextran, obtained by reaction of α -methyl- ω -amino-PEG with epichlorohydrin-activated dextran (145) and similarly synthesized; (c) PEG-poly[*N*-(2-hydroxyethyl)-L-glutamine] (PHEG) (146); and (d) diblock co-poly(ethylene oxide) (PEO)-poly(propylene oxide) (POP) copolymers (proxanols), PEO and POP conferring hydrophilic and hydrophobic properties, respectively, on the copolymer and the final conjugate (144). Proteins can be linked to the copolymer either by a covalent bond (the copolymer is activated as aldehyde and reacted to protein

Figure 2. Potential in vivo problems connected with the therapeutic use of proteins and solutions by polymer modification.

amino groups, with later reduction of the iminium group) or by thermoinduced and high-pressure-induced complexation for a noncovalent adduct; (e) bovine serum albumin (BSA)-PEG copolymers were used to prepare controlled release systems of hydrogels with high water content (>96%) (147).

In general, the number of activatable groups along the polymer chain is of great importance when the polymers are used as drug carriers, since the presence of one or several activatable groups determines the amount of drug loaded along the polymer and therefore the characteristics of the final product. In the case of protein modification, PEG and DIVEMA are two opposite cases, PEG conjugates being easy to characterize well and DIVEMA giving rise to heterogeneous cross-linked conjugates. Although not ideal for medical use, these heterogeneous adducts are useful in biocatalysis, since a high enzyme content per molecule of polymer may be achieved. Among the many strategies studied in the biocatalysis field for increasing enzyme stability to solvents, heat, and denaturants, the multipoint attachment obtained with polyfunctional polymers is an important method.

2.3. Polymer-Drug Conjugates. The above-described polymers are used to modify proteins and non-

protein drugs to improve their therapeutic characteristics. The use of proteins in therapy is often limited by their short plasma half-life due to degradation by proteolytic enzymes, rapid clearance, and immunological reactions (when they are of heterologous origin). Instead, for low-MW nonprotein drugs, the main disadvantages are rapid metabolism by degradation reactions, toxicity, and premature excretion, which may be prevented or reduced by polymer conjugation.

2.3.1. Polymer-Protein Adducts. Peptides and proteins may acquire many advantages after polymer derivatization (Figure 2), including a plasma half-life increased by a factor of 3–500. In general, the more polymer chains attached per protein molecule, the greater the extension of the half-life (106, 148–150), although specific activity may sometimes be proportionally reduced. The increased plasma half-life is due to several mechanisms: (1) increased size of protein conjugates beyond the limit for glomerular filtration (~70 kDa), (2) reduced cell clearance through both the reticuloendothelial system (RES) and/or specific cells which interact through their specific receptors with carbohydrate chains or specific amino acid sequences on the protein (the polymer cloud around the protein masks these sites), (3)

decreased proteolysis due to polymer steric hindrance to proteolytic attack, and (4) reduced immunogenicity and antigenicity. Polymer conjugation causes reduced immunogenicity and antigenicity for polymer shielding of the epitopes and the antigenic determinants on the protein, preventing the raising of antibodies against the conjugate (8) and hindering the ability to interact with antibodies against the unmodified protein. Other new protein properties are sometimes observed upon modification, i.e., increased activity, increased solubility in aqueous and organic solvents, and increased thermal stability.

Various polymers were used to modify therapeutically useful proteins and peptides to improve their pharmacokinetic and immunogenic-antigenic properties. They are briefly reviewed here.

Dextran-Protein Conjugates. Dextran is used for derivatization of various proteins. Carboxypeptidase G and arginase (151), soybean trypsin inhibitor (SBTI) (152, 153), and superoxide dismutase (SOD) (154) conjugated to dextran all have an increased half-life in blood. The dextran-asparaginase conjugate, together with increased circulatory persistence, also shows markedly reduced antigen reactivity (6).

Gelatin-Protein Conjugates. Gelatin, used as a polymer carrier for drugs, has been proven to increase their therapeutic efficacy. Derivatization of recombinant IL-1 α to the natural polymer leads to prolonged retention in the body (155). In the same way, conjugation of succinylated gelatin to SBTI causes a 6-fold increase in circulation time compared to that of the unmodified protein (156).

Albumin-Protein Conjugates. Albumin is one of the natural polymers most frequently used for protein modification. Uricase modified by albumin has an enhanced plasma life (157), and recombinant human granulocyte-colony stimulating factor (rhG-CSF) conjugated to both rat and human serum albumin through a spacer of heterobifunctional maleimidocarboxyl PEG (1:1 albumin-rhG-CSF conjugate) increases its serum stability (158). Modification of earthworm fibrinolytic enzyme with fragmented HSA (10000–30000 Da MW) causes loss of its antigenicity, increased stability toward protease inhibitors in rat plasma, and retention of its potent proteolytic activity (159).

SMA-Protein Conjugates. SMA was developed as an ideal polymer for neocarzinostatin (NCS) modification for the properties described previously (32). NCS is a potent antitumor protein having however high toxicity (bone marrow suppression) and a very short plasma half-life. Conjugation with SMA (both 1.5 and 6 kDa) causes a longer half-life as a result of binding of SMA-NCS to albumin (33) and decreased immunogenicity and toxicity (32, 160, 161). SMA-NCS conjugates have already been evaluated in humans, and great success has been reported in many cases of liver tumors and liver tumor metastasis. Among other drugs modified by SMA, SOD has been successfully conjugated, the SMA-SOD derivative showing an increased half-life (162).

DIVEMA-Protein Conjugates. SOD-DIVEMA is prepared with minimal cross-linkage and minimal loss of activity, due to the use of 2,3-dimethylmaleic anhydride as a pH-reversible, randomly protective reagent for SOD amino groups (37). The circulation time of the conjugate has been greatly improved and immunogenicity reduced with respect to those of the native enzyme (163, 164).

PVP-Protein Conjugates. Conjugation of β -D-N-acetylhexosaminidase A to PVP extends the circulation time of the enzyme (165). Ribonuclease and uricase are

modified by a PVP-succinimidyl ester, yielding conjugates with increased thermostability, stability to proteolysis, reduced immunogenicity, and enhanced blood half-life (166). SOD-PVP has an increased body residence time, reduced antigenicity and immunogenicity, increased solubility in organic solvents, and increased stability toward thermal denaturation (167).

PACM-Protein Conjugates. Tailor-made copolymers of *N*-acryloylmorpholine and *N*-acryloxysuccinimide are prepared by radical copolymerization, the former monomer providing water solubility to the copolymer and the latter reactivity toward protein amino groups. Copolymers are successfully used to modify catalase and ribonuclease A, and the conjugates maintain full enzyme activity (168, 169).

PEG-Protein Conjugates. PEG is used to modify a variety of proteins. In particular, over the last two decades, enzymes have constituted the single largest class of proteins covalently modified by PEG (the following lists are by no means a complete bibliography). All the following proteins have an increased plasma half-life upon modification with PEG, with no or minimal loss of activity: streptokinase (170), tissue plasminogen activator (5), SOD (171, 172), arginase (173), recombinant interleukine-2 (174), tumor necrosis factor (175, 176), kallikrein and α -interferon (177), β -interferon (11), colony-stimulating factor-1 (CSF-1) (178), granulocyte-CSF (179–181), Fab-2 fragment of murine monoclonal antibody A7 (182), and serpins (a family of serine proteinase inhibitors) (183). PEG-adenosine deaminase (ADA) keeps its activity, with neither toxic effects nor hypersensitivity reactions (184, 185). PEG-uricase (a urolytic agent for treatment of hyperuricemia associated with chemotherapy) shows good activity (186). PEG-asparaginase has an increased half-life and increased antitumor activity and is nonimmunogenic, nonantigenic, and nonallergenic (187–193). Lack of immunogenicity is shown by conjugation of PEG to urokinase, cholinesterase, cellulase, and SOD (194), glutaminase-asparaginase (195), β -glucuronidase (196), urate oxidase (197), ribonuclease (107), streptokinase (198), catalase (199), arginase (200), and phenylalanine ammonia lyase (201). Asparaginase and albumin modified by PEG1-trichlorotriazine, PEG2-trichlorotriazine, PM13, and PM100 are all nonimmunogenic, although the percentage of activity depends on the type of polymer and degree of modification (202, 203).

Some important information can be drawn from the literature regarding how the number, molecular mass, and shape of the polymer chains bound to the protein influence body residence time. In SOD-PEG conjugates, there is a direct relation between residence time and number and length of PEG chains. SOD-PEG conjugates are obtained by enzyme modification with PEG of 1900 and 5000 Da. A comparison of derivatives obtained with the same molecular mass polymer but with a different degree of modification indicates that the circulation time increases with the degree of modification (204). Moreover, among the conjugates obtained with the same number of polymer chains per enzyme molecule using PEG with different molecular masses, circulation time increases with the length of the polymer chain (204). In other works, it has been shown that a single PEG chain of sufficiently high molecular mass is enough to reduce the renal excretion of the SOD-PEG conjugate to a level comparable to that obtained by several low-molecular mass polymer chains, without the disadvantage of reduced activity (205, 206). Recent investigations have shown that the molecular mass of PEG used for modification and the degree of modification have in

Table 1. Influence of the Polymer Molecular Mass, the Number of Polymer Chains Bound to the Protein, and the Polymer Shape on the Plasma Half-Life of PEG-Protein Conjugates in Rat or Mouse Circulation

conjugate	moles of PEG linked per mole of protein	half-life in rats (h)	half-life in mice (h)	reference
SOD	—	0.083	0.066	204, 206
SOD-PEG ₁₉₀₀ ^a	3	1.5	—	204

SOD-PEG ₁₀₀₀₀₀	1	—	36	206
asparaginase	—	—	3.8	208
asparaginase— linear PEG ^b	13	—	52.7	208
asparaginase— branched PEG	13	—	65.25	208

^a The subscript number refers to the MW of PEG used in the protein conjugation. ^b Asparaginase-PEG derivatives were obtained with linear PEG with a 10 000 Da MW or branched PEG with a 2 × 5000 Da MW.

themselves a minimum effect on the half-life of SOD, demonstrating that this is mainly determined by the overall molecular size of SOD and its conjugates (207). In this respect, it is important to recall that PEG, due to its flexibility and great degree of hydration, behaves like a protein of approximately twice its molecular mass. This may be quantitatively verified by size-exclusion analysis and comparing the residence time of PEG alone or bound to a peptide or protein. When a protein-conjugate preparation is being designed, it is important to consider that a MW of over 55–60 kDa (such as the albumin MW) is enough for a protein to prolong its retention in the circulation. The shape of the polymer is also related to the final residence time of the modified protein; modification of 70% of the asparaginase amino groups with linear PEG 10000 or branched PEG 10000 (two chains of PEG 5000) indicates an increase in $t_{1/2\beta}$ (the half-time of the elimination phase) from 3.8 h for the native enzyme to 52.7 and 65.25 h for the linear and branched PEG forms, respectively (208). Table 1 shows a comparison of the factors discussed above.

The PEG length/circulation time ratio has also been demonstrated for a lower-molecular mass polypeptide, granulocyte-CSF, whose renal excretion is prevented by a single PEG chain of 30–40 kDa (209).

The great effects of PEG branching on protein residence time, resistance to proteolysis, and immunogenicity (133, 210) compared to those of the linear polymer make this PEG form of great interest for therapeutic applications.

In some cases, PEG modification causes a decrease in protein activity, especially enzymatic activity toward high- or low-MW substrates. For elastase (211), trypsin (212), and chymotrypsin (109), the hindrance created by the polymer around the active site reduces the approach of a macromolecular substrate to the active site itself. This problem may be overcome by carrying out the modification in the presence of a macromolecularized protector of the active site (such as an inhibitor); after enzyme derivatization, the protector can be removed by a change in pH, leaving the active site accessible (213, 214). Besides, some PEGylated enzymes show decreased activity toward low-MW substrates. In this case, modification of the amino groups at the active site may be responsible for the low residual activity of the conjugates. One strategy for avoiding this problem is the conjugation

of enzymes to the above-mentioned branched PEG (PEG2) which, because of its hindrance, does not have access to the amino groups of the active site cleft, leaving them unmodified. In the case of uricase, a 20% modification of its amino groups by linear PEG causes a drop in enzyme activity to 2.5%, while the conjugate with 30% of the amino groups modified by PEG2 retains 32% of the activity (208).

Other Carrier-Protein Conjugates. PEG-grafted polymers, like PEG-dextran and PEG-PHEG described above, are promising and potential carriers for protein and nonprotein molecules, since the introduction of PEG side groups results in reduced liver uptake and slow blood clearance (143). PEO-POP copolymers (2000 MW, aldehyde-activated) are used to modify soybean Bowman-Birk protease inhibitor, and the conjugate experiences a 7.3-fold decrease in total plasma clearance (215). Among the novel molecules used to modify therapeutic proteins, a succinylated keratin fragment (with affinity for cell membrane components and organelles) has been used to conjugate SOD, yielding an adduct with a longer half-life, lower immunogenicity, greater accumulation in the liver, and better therapeutic effects against paraquat toxicity compared to those of native SOD (216).

2.3.2. Polymer-Low Molecular Mass Drug Adducts. Polymer derivatization of nonprotein drugs leads to long-lasting activity due to the increased half-life in the circulation, as a result of protection toward metabolism and/or reduced kidney ultrafiltration because of the increased size of the adduct. Polymer modification also imparts decreased toxicity due to polymer shielding of "toxic" moieties, and the possibility of targeting to specific organs and tissues by introduction of a target molecule along the polymer backbone. This last issue approaches the concept of the "magic bullet" pioneered by Erlich (217) in the ideal project of delivering cancer chemotherapeutic drugs only to tumor cells. The most important examples of polymer-drug conjugates are listed here.

Dextran-Drug Conjugates. In the late 1970s, Bernstein showed that dextran oxidized to a polyaldehyde could be coupled to daunomycin, producing a conjugate with greater therapeutic activity and decreased toxicity (218). Subsequently, doxorubicin (DOX) was coupled to oxidized dextran 70 and the conjugate (OXD-DOX) had a higher plasma level, persisting for a long period, thus creating very effective passive tumor targeting (219). However, the phase I clinical trial of OXD-DOX indicated that the conjugate was significantly toxic: WHO grade IV thrombocytopenia in two of two patients treated with 40 mg/m² (milligrams per meter squared of body surface area) doxorubicin equivalent (DOXe_q), hepatotoxicity in five of five patients, and thrombocytopenia in three of five patients treated with 20 mg/m² DOX (220). Dextran of various molecular masses (10, 70, and 500 kDa) and electrical charges have been conjugated to mitomycin C and the conjugates used to investigate the charge effect on in vivo behavior and renal excretion. It was established that a negatively charged macromolecule is slowly excreted from the negatively charged basal membrane which instead enhances the passage of positively charged polymers. This holds not only for synthetic polymers but also for proteins, their pI being important in this case. Consistent with this principle, anionic conjugates of mitomycin C have a persistently high plasma level, gradually accumulating in peripheral tumors, whereas cationic ones are trapped by the liver and blood vessels and rapidly cleared from circulation, like the unmodified drug (221). Dextran (36 500 Da) is also coupled to oligopeptide derivatives of the antimicrobial

drug norfloxacin to improve their pharmacokinetics (222). The adducts, presenting tetrapeptides Gly-Phe-Ala-Leu or Gly-Phe-Leu-Gly at the piperazine amino group of the drug, show hydrolytic stability under physiological conditions but drug release in the presence of lysosomal enzymes. Dextran (500 kDa) is also used to prolong the blood half-life of the imaging agent ^{99m}Tc (223).

HPMA-Drug Conjugates. Many drugs (and targeting groups) have been linked to the HPMA copolymer backbone, including daunomycin (and galactose) (224), doxorubicin (and galactose) (225, 226), doxorubicin (and the melanocyte-stimulating hormone) (227), melphalan (and sugar residues) (228, 229), and chlorin e6 (and antibodies) (230). One of the most interesting uses of HPMA is the linkage of DOX to the polymer backbone through peptide sequences designed to be extracellularly stable but rapidly cleaved, following pinocytosis, by lysosomal enzymes (225). Targeting groups such as antibodies (231), hormones (227), and sugars (232) are also incorporated. HPMA-DOX has an extended plasma half-life responsible for passive targeting to solid tumors (233). In this case, the polymer plays an important role in inducing cell internalization by endocytosis, whereas drug release is influenced by the chemistry of the binding and the structure of the spacer, planned to be stable to blood enzymes but hydrolyzed by lysosomal cathepsins (9, 14).

DIVEMA-Drug Conjugates. DIVEMA of 7000 Da, a MW in the range of biocompatibility (34), is conjugated to DOX to produce the possible synergic effect of the antitumor properties of both polymer (234) and drug. The adduct causes prolonged retention of the drug in the body (36).

PEG-Drug Conjugates. Conjugation of drugs containing carboxylic acid groups to PEG hydroxyl groups via ester formation is used as an approach to the formulation of long-circulating, slow-released drugs, the rate of hydrolysis depending on the nature of the carboxylic acid, the MW of PEG, the pH, and the temperature. Penicillin V conjugated to mPEG (2000, 3000, and 4000 Da) (235) and poly(PEG-Lys) (50 000 Da) (122) and aspirin conjugated to PEG (400, 1000, and 3000 Da) have been studied. Ibuprofen conjugated to PEG of various MW (200, 900, and 2000 Da) yields a conjugate with long-lasting anti-inflammatory activity (58). Atropine and quinidine are linked to PEG-succinate of various molecular masses (235). In our laboratory, we synthesized a PEG-DOX conjugate with an amino acid or peptide spacer between the polymer and the drug to study tritosomic activity by lysosomal enzymes on the various derivatives. All the conjugates showed great plasma stability and a considerable decrease in toxicity, whereas activities depended on the nature of the amino acid bridge (236). PEG-5-fluorouracil (5FU) conjugates with ester, amide, or ether linkages have been studied (237), with increased stability under physiological conditions ranging from ester and amide to ether. The insoluble drug Taxol, one of the most potent chemotherapeutic agents used in the treatment of breast and ovarian cancers, has been linked to both hydroxyl ends of PEG through an ester bond, producing a highly soluble prodrug. The study indicated that the PEG molecular mass must be of such magnitude so a $t_{1/2}(\text{circulation}) > t_{1/2}(\text{hydrolysis})$ is maintained, a 40 kDa PEG being a good choice for the in vivo behavior of the prodrug (238). Similarly, the potent antitumor natural drug camptothecin has been bound to both hydroxyl groups of 40 kDa PEG, and an increased plasma half-life of the prodrug was obtained. Stability, interaction with plasma proteins, and activity of the conjugates are all strictly

influenced by the nature of the bond between the drug and the polymer (239).

One great limitation of PEG as a drug carrier resides in its mono- or bifunctionality. This characteristic, although useful in the case of PEG conjugation to polyfunctional drugs, preventing the problem of reticulation, restricts the total amount of drug molecules loaded per molecule of polymer in the case of monofunctional drugs. To circumvent this limitation and link a greater number of drug molecules per polymer chain, poly(PEG-Lys) has been synthesized and conjugated to *cis*-4-hydroxy-L-proline (240) and mPEG-poly(Asp) has been used to bind doxorubicin (241). In this latter case, the conjugate forms micelles composed of a drug-containing hydrophobic core with grafted PEG chains on their exterior, causing prolonged circulation in the bloodstream. The PEG derivative mPEG-glycol-poly(L-lysyl)diethylenetriaminepenta acetate monoamide has been used to prolong the circulation time of the imaging agent ^{99m}Tc (242).

Other Polymer-Drug Conjugates. Many other macromolecular drug conjugates have been studied. The alginate (9000 and 40000 Da MW)-*cis*-diamminedichloroplatinum (DDP) complex shows an increased plasma level, especially when high-MW alginate is used (243); the heparin-hepatocyte growth factor complex leads to improved plasma residence time for the drug (244). Other conjugates are under investigation, such as pyran copolymer-DOX (245), poly(aspartic acid)-DOX (248), poly(L-glutamic acid)-DOX, poly(hydroxyethyl-L-glutamine)-DOX (247), albumin-daunorubicin (248), *N*-(2-hydroxyethyl)methacrylate-*N*-vinylpyrrolidone copolymer-daunomycin (249), poly(L-lysine)-daunorubicin (250), polygalacturonic acid and carboxymethylated yeast β -D-glucanarabinoside C (251), poly(α -malic acid)-5-fluorouracil (252), poly(L-lysine)-methotrexate (253), block copolymers of poly(ethylenimine) and palmitic acid-cyclophosphamide derivatives (254), and DIVEMA-cyclophosphamide (255).

Special attention has been recently paid to oligonucleotide conjugates, e.g., poly(L-lysine) oligonucleotides (256), in an attempt to solve the problem of oligonucleotide delivery. The strategy combines reduced excretion of the drug, due to the increased mass of the conjugate, and mutual neutralization of polylysine and oligonucleotide, thus facilitating the crossing of cell membranes.

A potential strategy for regulating gene translation is deactivation of a target gene with oligonucleotides which form triplexes with that gene. However, triplex formation is unstable under the physiological conditions because of the repulsion among phosphate anions in DNA molecules associating in the triplex and duplex. The former use of macromolecular polycations, such as poly(L-lysine) (PLL), revealed an increase in the melting temperature (T_m) of the duplex, but it was associated with a precipitation process due to polyion formation. Comb-type copolymers of PLL with polysaccharide side chains finally proved to be a good solution to the problem (257); the hydrophilic chains of the polysaccharide grant solubility to the complex, while the polycation portion induces stability of the triplex.

2.4. General Considerations on Substance Conjugation. The conjugation of drugs to low-molecular mass molecules based on acetylation, esterification, and phosphorylation reactions is a well-established methodology in prodrug preparation. The use of polymers in drug modification is a more recent approach and, as such, is open to further developments, as described above. The two approaches increase the circulation half-life of drugs

in different ways. The old strategy causes an increase in the residence time of the drug simply by modifying its hydrophilicity and generally protecting it from metabolism. The new approach increases stability to chemicals and metabolic enzymes and prevents renal ultrafiltration because of the high molecular mass of the adduct. Moreover, the hindrance of the polymer around the drug is responsible for other specific advantages, such as the masking effect on immunogenic and antigenic sites, with consequent decreased immunogenicity and antigenicity. In addition, the increased molecular mass of the conjugate allows a targeting process to tumor tissues by means of the EPR effect.

The two main limitations of the polymer conjugation strategy are as follows: (1) the drug must possess chemical groups so that it can be derivatized by the polymer, (2) modification of those groups may lead to the decrease or loss of activity. In some lucky cases, modification does not affect drug activity, although the modified groups are the same ones involved in the explication of activity. However, more frequently, preservation of activity requires the appropriate choice of the chemical groups to be modified, since they must be different from those involved in the activity cascade (from the receptor binding step to the following phases). This choice is easier in the case of polypeptides and proteins which, due to their size, may present conjugation sites which are clearly distinguished from activity sites. Moreover, modification sites can also be introduced by substituting amino acids insignificant for the protein structure and activity with derivatizable amino acids. This explains the great efforts made in this direction by many biotechnological laboratories. The data obtained so far in polypeptide conjugation are now also paving the way for the preparation of new and original polymers that are able to modify selectively a specific amino acid. For the less versatile nonprotein drugs, the lack of anchoring groups can often make impossible the conjugation to polymers. For this case and for proteins that cannot be modified with one of the above strategies, physical entrapment in liposomes or particles is of help.

3. LIPOSOMES

3.1. Introduction. Water-insoluble polar lipids (e.g., phospholipids) in an excess of water give rise to highly ordered assemblages, which eventually arrange themselves into a system of concentric, closed, bilayered membranes called liposomes.

Since they were discovered (258), liposomes have been used as biomembrane models to provide information on the inter-relations of membrane lipid components in the basic bimolecular structure. Protein components of membranes are incorporated into liposomes to investigate lipid-protein interactions in biological membranes and the actions of membrane-active compounds such as ionophores, anesthetics, divalent cations, and antigen-antibody interactions. Liposomes have also emerged for clinical and diagnostic use as nontoxic carriers. This chapter briefly describes (a) properties and methods for entrapment of drugs, (b) liposomes as drug carriers and their *in vivo* fate, and (c) long-circulating liposomes.

3.2. Liposomes: Properties, Methods of Preparation, and Entrapment of Drugs. Various preparation procedures may be used to obtain one or more lipid lamellae liposomes, ranging from the minimum size of about 50 nm (diameter) for the smallest unilamellar vesicles (SUV) to several micrometers for the multilamellar type (MLV).

The classical procedure for preparing liposomes consists of dissolving appropriate concentrations of phos-

pholipids in an organic solvent, evaporating it, and subsequently disrupting the dry lipid layer with excess water or buffer, leading to the spontaneous formation of multilamellar liposomes of heterogeneous size (0.05–1 μm in diameter). Drugs may be entrapped either in the aqueous phase or in the lipid bilayers, depending on their hydrophilicity/hydrophobicity ratio. Substances that are soluble in organic solvents can be mixed with the lipids, ending up as constituents of the membrane structure in the final product, whereas water-soluble substances added to the solution, used in the dry lipid layer disruption step, end up in the aqueous compartment. Subsequent sonication of multilamellar liposomes yields unilamellar liposomes (50–100 nm in diameter) which are separated from the contaminating large ones by gel filtration (259) or ultracentrifugation (260). However, sonication has some disadvantages, like oxidation of unsaturated bonds in the fatty acid chains of phospholipids, with the formation of lyso compounds and free fatty acids, and denaturation and/or inactivation of entrapped molecules (proteins and nucleic acids). SUV may also be prepared by physical procedures, like the passage of large unilamellar vesicles (LUV) through acetylcellulose membranes, forced dialysis, or the French press process. An alternative method for preparing unilamellar liposomes is injection of an organic solution of the lipids into a large aqueous volume containing the substance for entrapment (261). For the preparation of SUV, repeated freezing and thawing may be employed, while LUV (diameter of $\geq 1 \mu\text{m}$) may be obtained from SUV by the addition of a divalent salt (e.g., calcium) which fuses the SUVs and subsequent removal of Ca^{2+} by EDTA.

The stability of phospholipid bilayers may be altered in terms of both rigidity and permeability by incorporating into the liposome structure other lipid soluble compounds such as sterols; alternatively, a charged amphiphile can both render the liposomal surface positively or negatively charged and increase the distance between the bilayers, giving rise to an increased aqueous volume. Size, rigidity, charge, and composition determine liposome fate and residence time in the body.

Depending on the hydrophilic/hydrophobic volume ratio, micelles may alternatively be formed and exploited for drug delivery and diagnostic purposes.

3.3. Liposomes as Drug Carriers and Their *In Vivo* Fate. Liposome carriers can alter drug biodistribution and pharmacokinetics when administered to human or animal models. Since liposomes can be modified at their surface by specific ligands, antigens, antibodies, sugars, and other targeting moieties, the entrapped drug may have quite different *in vivo* properties with regard to the site and rate of disposition and targeting. For this reason, liposomes are used to modify the properties of drugs and diagnostic agents; they can prolong their circulation time, isolate them from the systemic background, reduce their toxicity or side effects, and target them to the desired tissue with increased clinical efficacy (262–269).

The use of liposomes as drug carriers is supported by the following properties. (1) Intravenously administered liposomes are captured by monophagocytes in the reticuloendothelial system (RES) (270, 271) and can be used for efficient delivery of antiparasitic and antimicrobial drugs in treating infections localized in this system (e.g., antimonial drugs against leishmaniasis) (272) or for encapsulation of immunomodulators in activating macrophages to become tumoricidal in tumor models (273, 274). However, the efficient uptake of liposomes by the

RES, probably due to their opsonization by plasma proteins (275), results in their rapid removal from circulation and is the main disadvantage for the possible use of liposomes as delivery systems when the target site is beyond the RES. (2) Thanks to the different disposition and pharmacokinetics of the entrapped drug, liposome formulations can prevent the drug side effects such as the cardiotoxicity of doxorubicin (276, 277) and the nephrotoxicity of amphotericin B (278). (3) Both water-insoluble and amphiphilic drugs entrapped in liposome lipid bilayers have a longer half-life after intravenous administration and can be carried through the bloodstream to the target (279, 280). (4) Water-soluble macromolecules such as cytokines, plasmids, and ribozymes, which are easily inactivated and metabolized in the liver and other tissues, have an increased half-life when encapsulated in the aqueous compartment of liposomes. Liposomal monensin remains in circulation for 2 h, while the free form is cleared in only 15 min (281). Although anticancer agents such as topotecan, camptothecin (CAM), 9-aminocamptothecin (9-NC), and CTP-11 are interesting drugs capable of arresting the growth of a variety of human tumors, the rapid hydrolysis, at physiological pH, of their α -hydroxy lactone ring moiety, essential for biological activity, greatly limits their therapeutic use. Packaging of topotecan in the aqueous compartment (adjusted to pH 5) of distearoylphosphatidylcholine (DSPC) liposomes dramatically enhances its half-life in blood (282). Liposome formulations of CAM and 9-NC have a biological half-life which is 11 times longer than that of the free compounds (283). The use of other compounds such as valproic acid (VPA), an antiepileptic drug capable of crossing the placenta and producing fetal malformations, together with other toxic effects, must be avoided during pregnancy. However, encapsulation of VPA into phosphatidylcholine (PC)/cholesterol/ α -tocopherol liposomes significantly reduces the amount of exposure to the fetus (284). (5) Besides the use of liposome formulations for the reasons described above, many efforts are also directed toward modulating their permeability for sustained or local release of drugs (not discussed in this paper).

The *in vivo* properties of liposomes are determined by administration route, dose, size, formulation, surface charge, and the presence of specific ligands, sugars, antibodies, and other moieties appended along their structure.

Orally administered liposomes protect the encapsulated substances from enzymatic or pH degradation, but they may be partly lysated at pH 2.5, with 10 mM bile salts, by pancreatin and inside enterocytes (285). Local administration routes, intramuscular or subcutaneous, allow slow and sustained release of drugs at the injection site (286), especially from large multilamellar liposomes, whereas small RES-avoiding liposomes pass quickly to the bloodstream when injected subcutaneously (287).

The main liposome applications consist of drug targeting to the site of disease via circulation and controlled drug release at that site. In these applications, the characteristics of liposomes—(1) stability in plasma, (2) sufficient circulation time to interact with target tissues, (3) targeting, and (4) delivery of entrapped drugs into target cells—are important factors to be considered. In general, drugs entrapped in liposomes and retained in circulation are more stable than free drugs because of the liposome coating and stabilization by plasma proteins bound to their surface (288). However, high-density lipoproteins (HDL) are the main cause of liposome instability in plasma because of the transfer of liposomal

lipids to the HDL, with consequent release of the encapsulated material. This transfer is mediated by phospholipid transfer proteins present in plasma (289–294). Low-density lipoproteins may also increase liposomal permeability, taking lipid components from the liposomal membrane, especially when large doses of liposomes are used (295, 296). To solve this problem, several strategies, aimed at manipulating lipid composition and the fluidity of the lipid bilayer, have been used in the preparation steps of liposomes. (1) The incorporation of cholesterol, causing increased packing of phospholipids in the lipid bilayer, reduces the transfer of phospholipids to HDL (297, 298). (2) Liposomes obtained by PC with saturated fatty acyl chains (with a high liquid crystalline transition temperature) or sphingomyelin (SM) are more stable in blood than liposomes prepared by PC with unsaturated fatty acyl chains (299). (3) The use of lipid derivatives, such as PC with carbamyl analogues at the C-2 region (300, 301) or hydroxycholesterol (302), also stabilizes liposomes in the blood.

Once the problem of the release of drugs in plasma has been solved with one of the above strategies, due to their new acquired stability, clearance of the encapsulated drug depends on the clearance of the liposome itself (303). Liposomes administered systemically tend to accumulate in the RES (especially liver and spleen), with consequent rapid removal from the blood (304–307).

It is well-known that liposome composition, size, and charge can influence RES uptake; cholesterol-rich liposomes have low uptake by the RES (308), and SUV have a half-life longer than the 500–5000 nm MLV. Negatively charged liposomes have a shorter half-life in blood than neutral liposomes (289, 309) (although several studies report the opposite), due to immunological recognition (310–312) or activation of the complement system [fragments of complement component C3 may be deposited on the surface of unmodified liposomes, thus acting as opsonins (313, 314)]. Instead, positively charged liposomes are toxic and quickly removed from circulation (315).

3.4. Long-Circulating Liposomes. RES trapping of liposomes is the main problem in distributing encapsulated drugs to various organs. The first approach to the development of stabilized liposomes, later called “stealth liposomes” or “ninjasomes”, used SUV composed of saturated phospholipids such as DSPC and cholesterol (289, 309, 316, 317). Since they had the disadvantage of low aqueous entrapment volume, two more successful strategies are used to reduce internalization [due to one of the following processes: (1) immune recognition of negatively charged liposomes, (2) liposome opsonization, and (3) receptor-mediated phagocytosis] and consequent RES trapping. The first strategy is to prepare liposomes mimicking the erythrocyte membrane to be recognized by the RES as “self” instead of “foreign” structures; since the sialic acid portion of erythrocyte glycoproteins is thought to be important for immune recognition, liposomes are modified by gangliosides and sialic acid derivatives such as monosialoganglioside (GM1) (318–321). The second strategy consists of increasing the hydrophilicity of the liposomal surface, with a consequent decrease in opsonization, receptor-mediated phagocytosis, and RES entrapping (Figure 3); for this goal, poly(ethylene glycol) (PEG) was successfully introduced into liposome structures as PEG–phosphatidylethanolamine (PE) (102, 322, 323). Although PEG is still the best-known material for this aim, many other polymers have been investigated as liposome stabilizers.

Long-circulating liposomes are particularly important

Figure 3. Different behaviors of plain and polymer-modified liposomes or nanoparticles toward proteins (opsonins and/or dysopsonins) and/or cells (macrophages) involved in the pre-RES uptake phases.

for passive targeting to tumor tissues. Because of their longer circulation time and the very permeable vasculature and low development of lymph channels (which recover extravasated molecules) in tumor tissues, long-circulating liposomes can pass through leaky endothelium tissue by passive convective transport better than conventional liposomes. This behavior is the basis for

the numerous studies now in progress in tumor targeting for both therapy and imaging.

3.4.1. GM1 and Glucuronide Liposomes. Several glycolipids are used to prepare liposomes to be studied for their RES uptake after iv injection. Only GM1 causes a decrease in RES uptake. The addition of GM1 to liposomes composed of rigid lipids increases the blood/RES ratio by 1 order of magnitude. It should be noted that rigid liposomes themselves increase this ratio by 1 order of magnitude compared to fluid lipids of all sizes (321). The effect of size in the biodistribution of GM1-containing liposomes was studied in mice bearing EMT6 solid tumors (324). Liposomes with a diameter in the 90–200 nm range have longer blood retentions, with consequent accumulation in tumor tissues, than those on either side of this range (324). Large liposomes with a diameter of >300 nm preferentially accumulate in the spleen, whereas those with a diameter of <40 nm probably deeply penetrate the interstitial spaces of liver. Unfortunately, the effect of GM1 liposomes in prolonging half-life in blood has only been observed in the mouse system, no long-circulating activity being shown in rats (325) and rabbits (326). Among other gangliosides, only GM3 prolongs liposome circulation in the rat system (327).

Studies of GM1 liposomes are an important step in the understanding and development of long-lasting liposomes. To investigate the mechanism of GM1 liposome RES avoidance, liposomes containing various gangliosides at 10 mol % (GM1, GM2, GM3, GD1a, and GD1b) and asialoganglioside GM1 liposomes, obtained by the sialidase treatment, were incubated with cultured macrophages (328). It was demonstrated that only GM1 reduced macrophage uptake, whereas the other gangliosides neither reduced nor stimulated the uptake. The degree of macrophage uptake depended on the concentration of GM1 in PC liposomes; a concentration of 10 mol % decreased RES uptake by 90%. This RES-avoiding effect was reversed by the removal of the sialic acid moiety, demonstrating the important role played by this molecule in RES-trapping avoidance. Sialic acid-modified liposomes prolong blood retention not only in mice but also in rats (325).

From all the above results, two possibilities were proposed to explain the mechanism of RES avoidance by ganglioside liposomes. (1) Specific moieties (i.e., GM1, but not other gangliosides in mice) bound to the liposome surface reduce the opsonization which occurs in plasma prior to recognition by the RES. (2) These moieties bind dysopsonins, reducing recognition by the RES. It was also suggested that the topology of carboxyl groups on the liposome surface plays an important role in liposome circulation time (329).

One problem for the extensive use of sialic acid is its cost, a fact which stimulated the investigation of other derivatives, including glucuronic acid. Palmitylglucuronide (PG1cUA) and palmitylgalacturoide were synthesized for incorporation into liposomes and to test whether RES-avoiding activity was specific to uronates in general or to glucuronate in particular (330, 331). It was demonstrated in mice that RES-avoiding activity is specific to uronates in general (331), that the liposome structure remains intact during their long half-life in blood (303), and that the mouse macrophage cell line J774 neither binds nor incorporates PG1cUA liposomes (332–334). Doubly labeled PG1cUA liposomes ($[^3\text{H}]$ -inulin in the inner aqueous space and cholesteryl $[^{14}\text{C}]$ -oleate in the bilayer) accumulate in tumor tissues (303) as a result of passive targeting, although the specific

interaction of tumor tissues and glucuronate cannot be excluded; this interaction is not due to a lower RES function in tumor-bearing mice, since liver accumulation is similar to that seen in normal mice. These long-circulating liposomes are probably not taken up by tumor cells but concentrated around them, as suggested by the comparable recovery of ^{14}C and ^3H , indicating that cholesteryl oleate is not degraded in the tumor.

3.4.2. PEG Liposomes. On the basis of the fact that increased hydrophilicity of the liposome surface prevents opsonization by serum proteins and interaction of liposomes with macrophages, liposomes have been modified with PEG in several laboratories to increase their circulation time (102, 322, 323). PEG prevention of serum protein and opsonin binding to the liposome surface and consequent RES trapping are related to its ability to mask the liposome surface under a hydrophilic, water-rich layer. X-ray diffraction analysis is used to measure structural organization and interbilayer repulsion for lipid/cholesterol (2/1) bilayers by incorporating 4 mol % of a PEG 1900 lipid. Analysis shows that the grafted polymer moiety extends ~ 50 Å from the lipid surface and gives rise to strong, slowly decaying, repulsive pressure between membranes, thus hindering their close approach (335). Recent studies indicate that the critical protective property of a PEG-coated liposome surface lies in its "self-similarity", i.e., the fractal characteristics of the spatial variations or fluctuations in the density of the polymer cloud. Self-similarity means that parts of the surface must resemble the whole surface over a prescribed range of spatial scales (336). The steric barrier created by PEG is also proven by the use of biotinyl-PE liposomes; the addition of avidin causes liposomes, but not PEG 5000-modified liposomes, to aggregate (337). However, PEG 2000 and PEG 550 provide only partial steric inhibition to the avidin-induced aggregation, while GM1-modified liposomes freely aggregate after the addition of avidin (338). The stability conferred on liposomes by PEG incorporation is due not only to the MW of the bound polymer but also to its considerable conformational flexibility (free rotation of individual units around interunit linkages) (339); a more rigid polymer like dextran, grafted to liposomes and used in similar quantities, does not cause liposome-protein interaction.

Distearoylphosphatidyl-*N*-(methoxy polyoxyethylene succinyl)ethanolamine-PEG 1900 (DSPE-PEG, 10 mol %) modification of SM/PC/cholesterol, DSPC/cholesterol, or PC/cholesterol liposomes produces increased blood residence time in all cases. It also indicates that the in vivo fate of PEG liposomes is affected little by the fluidity, the net charge on the liposome surface, the coupling method, or the hydrophobic anchoring group of PEG lipids; residence time is affected by the density of sterically active hydrophilic headgroups (340). More detailed studies testing the influence of the lipid anchor and the chemical stability of succinate, carbamate and amide linkages between mPEG derivatives and the amino headgroup of PE on circulation lifetime shows that a strong membrane anchor (DSPE) and a chemically stable conjugate bond (amide) result in retention of the polymer coating and greatly enhance circulation lifetimes (341).

The amount of PEG necessary to avoid RES activity is evaluated in the range of 5–7 mol % of PEG-DSPE in SM/PC/cholesterol liposomes, with no changes up to 20 mol %. The dependence of circulation time on PEG molecular mass indicates that a MW of 1000–2000 Da prolongs the circulation time of fluid lipid liposomes while

one of 5000–12000 Da is necessary to prolong the blood half-life of solid lipid liposomes (342). The size effect of 1/1/0.2 SM/PC/cholesterol/PEG 1900-DSPE liposomes on blood level shows that large (diameter of >300 nm) and small (diameter of <70 nm) liposomes accumulate in spleen and liver, respectively, while those of intermediate size remain in the blood (343).

The effect of PEG in liposome interactions with macrophages has been studied in vitro and indicates reduced uptake beginning at 5 mol % of PEG 1900-PE and reaching 95% reduction with 10 mol % (328). Liposomes uptake by human monocytes is also suppressed by PEG modification. These modified liposomes adhere to the cells, few being internalized by endocytosis (322).

The pharmacokinetics and biodistribution of PEG-DSPE liposomes have also been examined after subcutaneous administration. This route of administration may become very important, especially for patient self-administration and sustained release of drugs in vivo (287). Small liposomes (<120 nm diameter) appear intact in circulation after moving down lymph node chains (draining the site of injection), with up to 30% of in vivo label appearing in the blood 12–24 h postinjection. In the absence of PEG-DSPE, 4-fold lower levels of small liposomes are found in blood, probably due to macrophage uptake at the site of injection or along the lymph nodes, particularly evident when low doses are administered. These results therefore promote further investigations on the use of PEG liposomes for this new administration route of the liposome pharmaceutical form.

These novel PEG derivatives are regarded as key components of second-generation long-circulating liposomes (344). Liposomes are prepared from DSPC and cholesterol (1/1) containing 6 mol % of various PEG derivatives. The activity of the cholesterol derivative of PEG in prolonging the circulation time of liposomes is proportional to the average PEG molecular mass, i.e., 4800 Da $>$ 2600 Da $>$ 1700 Da $\gg$ 800 Da; the blood level increases from 7.8 to 32.9% as the polymer MW increases from 800 to 4800 Da. α -Methoxy- ω -(1,2-dioctadecenoyloxy glyceryl)polyoxyethylene (DO-PEG) 1000 and α -methoxy- ω -(1,2-ditetradecenoyloxy glyceryl)polyoxyethylene 1000, in which PEG is directly linked to glycerol, prolong circulation time as effectively as DSPE-PEG. Liposomes containing PEG derivatives with a functional group at the PEG terminal, such as distearoylphosphatidyl-*N*-(3-carboxypropionyl polyoxyethylene succinyl)ethanolamine (DSPE-PEG-COOH 3600 and 2400) and α -(dipalmitoylphosphatidyl)- ω -hydroxypolyoxyethylene (DPP-PEG-OH 1000), show higher blood levels than those containing DSPE-PEG 1000 (50.9, 43.3, 39.1, and 25%, respectively), suggesting that increased hydrophilicity and/or the presence of a steric barrier at the liposome surface, provided by PEG, play an important role. It should be noted that the incorporation of PEG derivatives does not change membrane fluidity and decreases the uptake by the murine macrophage-like cell line J774.

3.4.3. Other Polymers Used in the Preparation of Long-Circulating Liposomes. Other flexible, amphiphilic, functionalized oligomers are studied as PEG substitutes to obtain long-circulating liposomes. Among these, PVP and PAcM are activated as succinimidyl esters and bound to PE for liposome preparation. The plasma half-lives of unmodified liposomes, linear PEG, branched PEG (PEG2), PAcM, and PVP-modified liposomes (3% of polymer) are 10, 80, 140, 90, and 40 min, respectively (345). For all of the modified forms, a

comparable polymer molecular mass of around 5000–6000 Da (2×5000 Da for PEG2) is used. Captation by the liver follows the same pattern.

SUVs with 100 nm diameters are coated with poly(vinyl alcohol) (PVA) or a modified PVA bearing a long alkyl chain at the end of the molecule (PVA-R) to improve stability. Doxorubicin is encapsulated as a model drug to study the *in vivo* stability of polymer-coated liposomes. Both PVA- and especially PVA-R-coated liposomes are more stable in serum and have a longer survival time in systemic circulation than noncoated liposomes (346). Similar PVA and PVA-R mucoadhesive liposomes (347) are loaded with insulin (348); the faster decrease of glucose in blood and the long-lasting lowered glucose level caused by coated liposomes versus uncoated ones indicate good mucoadhesion and longer stability of modified liposomes.

Polyglycerols of various molecular masses are also investigated as potential liposome stabilizers. Polyglycerols are bound to dipalmitoylphosphatidic acid (DPP) and used for liposome preparation. Modified liposomes have high RES avoidance, which depends on the length of the polymer chains (349).

The lipid conjugates of two long-known but little exploited amphipathic polymers, poly(2-methyl-2-oxazoline) (PMOZ) and poly(2-ethyl-2-oxazoline) (PEOZ), are obtained by reaction of the glutarate esters of the polymers with DSPE or by termination of the polymerization process with DSPE. The products are used to prepare surface-modified liposomes, conferring low liver uptake and long circulation time on them to an extent similar to that for PEG, so far the best-known material for this purpose (350).

One of the newest methods proposed for protecting liposomes from external stimuli and degradation by lipases, lipooxidases, and/or serum proteins is coating their surface with hydrophobized polysaccharides, a method which mimics the role of polysaccharides in the wall of plant cells and bacterial cell membranes. Preliminary studies include the use of cholesterol-bearing pullulan with various degrees of substitution, monoalkyl (hexadecyl)-bearing pullulan, dialkyl (α,α' -dodecyl diglycerol diether)-bearing pullulan, cholesterol-bearing dextran, and cholesterol-bearing mannan. The cholesteryl moiety is the best hydrophobic anchor for such polysaccharides (351).

It has recently been found that injected polysialic acids (PSA) have long half-lives in the circulation of mice and may be used to extend the half-life of conjugated drugs (352). A low-molecular mass PSA (colominic acid, $M_n = 17000$ or 7800), already coupled to asparaginase and catalase to prolong circulation time, is coupled to the surface of SUV, increasing the liposome plasma half-life after intravenous injection (353).

A comparison of long-circulating liposomes coated with various types of polymers is reported in Table 2.

Last, a new strategy for further improving liposome pharmacokinetics is transient suppression of macrophage functions obtained by preadministration of liposome-encapsulated drugs, especially clodronate, which extends the circulation time of subsequently administered liposomes, even when they are long-circulating (354).

3.4.4. Active Targeted, Thermosensitive, pH-Sensitive Long-Circulating Liposomes. Long-circulating liposomes are ideal for active targeting. Monoclonal antibody 3A4, which binds a glycoprotein antigen, gp112, on the luminal surface of mouse lung capillary endothelium, is incorporated into PC/cholesterol liposomes containing 4 mol % of either GM1 or PEG 5000–

Table 2. Influence of the Type and Amount of Polymer Used for Liposome Coating on the Retention of Liposomes in Rat or Mouse Circulation

^a The molecular masses of PEG, PEG2 (branched PEG), PVP, and PACM used in this preparation were 5000, 10000 (2×5000), 6000, and 6000 Da, respectively. The polymer content (3 or 7 mol %) is calculated as a fraction of PE residues. The retention in mouse circulation is expressed as half-life (minutes) (345). ^b Diglycerol (PG2) with a MW of 166 Da and hexaglycerol (PG6) with a MW of 500 were used for the preparation of dipalmitoylphosphatidylpolyglycerols (DPP-PG) of different length chains. The retention in mouse circulation is expressed as the percent injected dose in blood 6 h postinjection (349). ^c The MWs of PEOZ, PMOZ, and PEG used in this experiment were 5000, 4000, and 2000 Da, respectively. The retention in rat circulation is expressed as half-life (hours) (350). ^d The two small poly(sialic acid)s used (colominic acid, CA) had MWs of 17000 and 7800 Da, respectively. The retention in mouse circulation is expressed as half-life (hours) (353).

PE (355–357). GM1 incorporation enhances lung binding up to 52% and decreases liver uptake to 25%, indicating that GM1 is a suitable molecule for prolonging the blood life of immunoliposomes. Instead, PEG 5000 creates a general steric barrier, preventing both lung and liver uptake (decreased to 25%), PEG chain length thus turning out to be an important parameter in immunoliposome design (337). The problem may be overcome by (1) using shorter PEG chains [PEG 1900 (358) and PEG 2000 (359)], (2) introducing a long spacer arm between the liposome surface and the antibody, or (3) conjugating the antibody directly to the ends of long PEG chains (360). Many methods are available for attaching proteins to the liposome surface, a convenient one being the formation of a thioether bond (359).

Poly(ethylene glycol)-grafted liposomes with oligopeptide or oligosaccharide ligands appended to the termini of the polymer chains have recently been synthesized (361). In this case, the structure of long-circulating liposomes, obtained using DSPE as a lipid anchor and heterobifunctional PEG (2000 Da) as a linking moiety, is exploited to bind a cell-adhesive ligand, like YIGSR peptide and the Sialyl Lewis^x oligosaccharide, ligands for laminin cell surface receptors involved in metastasis and angiogenesis processes and for E-, P-, and L-selectin involved in inflammation-related tissue injury, respectively. This study highlights the fact that long-circulating liposomes may be used as a basic structure on whose external portion biologically active ligands can be attached. In general, this approach is useful both as a ligand-mediated targeting system and as a carrier for

small biologically active substances, which, in their free form, have high clearance from circulation.

Liposomes modified with a bioadhesive polymer are proposed as carriers for drugs to be driven to lymphocyte-rich sites such as inflamed sites. Cyclosporin is encapsulated in liposomes modified with various types of bioadhesive polymers (Carbopol 941, 940, 1342, and 934P). The drug has enhanced residence time in systemic circulation and delivery to spleen and liver which is twice as effective as that of the drug without liposome encapsulation (362).

Thermosensitive liposomes may be obtained by adding to the lipid mixture a high percentage of a component with a transition temperature slightly above body temperature. Delivery of encapsulated drugs to the target site may thus be enhanced, since warming above the critical transition temperature promotes drug leakage. Local hyperthermia, already used to promote tumor regression, may be combined with long-circulating thermosensitive liposomes, which are able to accumulate in tumor by penetration through the leaky vasculature of the tumor tissues. Thermosensitive GM1 liposomes (363) and PEG liposomes (364, 365), both containing doxorubicin and tested on C-26 colon carcinoma, show tumor regression and an increase in life span when the hyperthermia is applied at the tumor site to release the liposome content. Thermosensitive magnetoliposomes (TMs) are a further development of thermosensitive liposomes. In the attempt to treat diseases such as malignant tumors by warming humans and animals systemically or locally, capacitive heating is normally used. Since this method can achieve only broadly distributed and nonselective heating, hyperthermic materials such as magnetic particles, seeds, and needles have been used for more selective heating. The combination of this new technology with the use of thermosensitive liposomes has successfully led to dextran magnetite-incorporating thermosensitive liposomes, namely TMs (366).

pH-sensitive (367–369) and target-sensitive immunoliposomes (370, 371) have also been developed, the former entering cells via endocytosis and releasing the entrapped drug after fusion of liposomal and endosomal membranes at the acidic pH of the endosomes and the latter releasing their contents upon destabilization induced by liposomes binding to target cells. Sterically stabilized pH-sensitive liposomes are prepared by addition of PEG–PE to the membrane of cholesteryl hemisuccinate/dioleoylphosphatidylethanolamine liposomes, encapsulating a charged water-soluble fluorophore, calcein (372). These liposomes have better stability than those lacking PEG–PE and an unaltered ability to release calcein intracellularly. The antitumor agent methotrexate is entrapped into pH-sensitive long-circulating liposomes prepared with PEG–PE. Their plasma stability increases with the percentage of PEG–PE introduced, without losing pH sensitivity. Liposomes are destabilized in cancer tissues by the low pH in cells, with consequent release of the drug (373). Antisense oligonucleotides usually show decreased activity in biological fluids because of the strong lytic process by nucleases. To avoid this problem, they are encapsulated into pH-sensitive liposomes (374) that protect a 15-mer phosphodiester oligonucleotide from degradation in plasma and cause increased plasma concentrations. Sterically stabilized pH-sensitive liposomes may therefore be potentially useful for the *in vivo* intracellular delivery of highly negatively charged molecules such as genes, antisense oligonucleotides, and ribozymes for the treatment of various diseases (375).

3.4.5. Long-Circulating Liposomes for Tumor Diagnosis and Cancer Chemotherapy. The passive targeting of long-circulating liposomes to tumor tissues strongly supports their use in tumor imaging. [^{67}Ga]-Desferoxamine or [^{111}In]bleomycin is incorporated into hydrogenated PC/cholesterol liposomes containing a small molar fraction of GM1 or hydrogenated phosphatidylinositol. The *iv* injection of these liposomes into mice bearing B16 melanoma, J6456 lymphoma, or LS174T human colon carcinoma causes a tumor accumulation increase of up to 40-fold, 24 h after injection (376). Effective tumor imaging is successful because of the site receiving the implanted tumor cells (e.g., a hind leg), since most of the radioactivity accumulates in the bulk of the body, including the RES. [^{67}Ga]Desferoxamine is also encapsulated into PEG liposomes (377). The level of [$^{99\text{m}}\text{Tc}$]diethylenetriaminetetraacetic acid encapsulated into PG1cUA liposomes detected in blood and consequently in tumor tissue is higher than that of the marker in dipalmitoylphosphatidylglycerol (DPPG) liposomes, which preferentially accumulate in liver (378), indicating that DPPG liposomes are not suitable for tumor imaging when the tumor is close to liver.

The positive correlation between liposome circulation time and their localization in tumors makes the use of long-circulating liposomes for delivery of cancer drugs very promising. Enhanced tumor accumulation and antitumor activity, together with decreased toxicity, are reported for liposomal doxorubicin and epirubicin in mice bearing intraperitoneally injected lymphoma (379), subcutaneously (sc) injected colon carcinoma (380, 381), or sc injected Meth A sarcoma (382). Doxorubicin entrapped in PEG liposomes suppresses metastasis (383, 384) and shows a therapeutic effect in models of human ovarian carcinoma xenografts, HEY (385), and human prostate carcinoma PC-3 xenografts (386). To understand the mechanism of liposome uptake in various tissues, sterically stabilized liposome preparations with encapsulated colloidal gold particles and applied silver enhancement of the colloidal gold have been prepared to monitor the *in vivo* fate of liposomes by optical and electron microscopy (387). Results indicated that sterically stabilized small liposomes containing DSPE–PEG or GM1, with a half-life of 12–24 h, are able to traverse the endothelium of small blood vessels in tumors and extravasate into interstitial spaces; in liver and bone marrow, they are endocytosed primarily by cells of the mononuclear phagocyte system. Furthermore, the encapsulated drug, being able to diffuse much more through the tumor mass than the macromolecular carrier itself, can probably reach distant tumor cells within the same area where liposomes have extravasated and exert its cytotoxic effect there.

3.5. General Considerations on Substance Entrapment in Liposomes. Entrapment of substances in liposomes is a general procedure for obtaining long-circulating pharmaceutical or diagnostic forms. From a technological point of view, it also is an easier procedure when compared with the conjugation strategy, since chemical steps, available only to specialists, are avoided. Moreover, the drug undergoes more delicate treatment particularly important for substances which are easily susceptible to degradation.

However, when the use of liposome formulations is planned, the fact that great changes in drug pharmacokinetics and biodistribution and a limited increase in circulation half-life are often observed must be taken into consideration.

Moreover, the main limitations of this strategy are (1)

the reduced level of drug loading, especially in the case of lipophilic drugs which may disrupt the liposome double layer, and (2) the difficulty of obtaining a general viable form of liposomes for delivery and marketing. Many of these disadvantages may be overcome by the potentials of stealth liposomes and the new synthetic phospholipids which are becoming available.

In the delivery of biotechnological drugs, one problem which may remain is their antigenicity, which is not prevented but enhanced by liposome entrapment. Polymer conjugation is the only way to solve this problem, and the possibility of entrapping polymer-conjugated polypeptides in liposomes, thus exploiting the best of both techniques, must be suggested. This procedure is still to be properly investigated.

4. PARTICLES

4.1. Introduction. The use of particles as drug carriers has been developed as a method for improving drug bioavailability and for reaching two important therapeutic aims: controlled drug release and drug targeting. Both natural (e.g., red and white blood cells) and artificial particles (mostly obtained by synthetic polymers) have been used as drug carriers. Artificial particles are classified as microparticles (diameter of 1–50 μm) or nanoparticles (diameter of 10–1000 nm) according to their size and as spheres or capsules according to the presence of the polymer in the whole structure of the particle or only in its exterior portion. It is important to note that in literature the words microspheres and microcapsules are often used as synonyms.

Microparticles belong to the first generation of drug carriers. Although they deliver the active substance to the target, they cannot be considered true carriers, since they must be implanted as close as possible to their target (388). Instead, nanoparticles belong to the second generation of particulate drug carriers, since they are capable of not only releasing the active molecule at the target site but also carrying it there. Their size makes them suitable for systemic use, as they can pass capillaries. This review briefly describes the use of microparticles; a more extensive report on nanoparticles involves (a) their properties and methods of preparation, (b) nanoparticles as drug carriers, and (c) long-circulating nanoparticles.

4.2. Microparticles. Microparticles may circulate in the blood and pass through the heart, but they cannot pass through capillaries because of their size. On the basis of this property, biodegradable microspheres prepared from starch (389), albumin (390), or poly(lactic acid) (391) and nonbiodegradable microcapsules of ethylcellulose (392, 393) have been studied for chemoembolization; with this procedure, drugs localize in the nearby tissue surrounding the capillaries where microparticles accumulate by upstream intra-arterial injection. Their spherical shape, calibrated size, and capacity to carry and protect the desired drug are the major advantages of microparticles compared with natural emboli.

Microspheres are also used as depot systems, especially subcutaneous but also intravenous or intraperitoneous. In this case, the advantage of their size allows easy administration by injection, while the entrapped drug is slowly and continuously released into circulation from a system that protects it from degradation. The rate of drug release may be designed by properly choosing the polymer, i.e., pore size, degradation, and swelling properties. Polymer hydrophobicity is also an important issue since it protects the drug from hydrolytic or oxidative degradation. The best example of this application is the release from polylactide microcapsules of peptides used

to treat prostate cancer, both somatostatin analogue RC-160 (394) and LH-RH antagonist SB-75 (395). Systems releasing contraceptive drugs for more than 1 year have also been described.

Poly(lactic-co-glycolic acid) (PLGA) microspheres loaded with recombinant human growth hormone stabilize the protein and allow continuous drug release for 30 days under in vitro physiological conditions (396). PLGA is also used to prepare injectable gel implants of methotrexate. When PLGA is injected into sarcoma 180-bearing mice, drug plasma levels are sustained for more than 2 weeks (397). Somatostatin analogue RC-160 is encapsulated in PLGA microspheres for sustained drug release (398). Microspheres, recently prepared from new biodegradable polyesters with the ABA block structure, containing hydrophobic poly(lactide-co-glycolide) (A) blocks and hydrophilic poly(ethylene oxide) (B) blocks are now under therapeutic investigation (399). To stabilize microparticles for drug delivery and vaccine formulation, poly(ethylene glycol)-dextran (PEG-DEX) conjugates have been used as combined stabilizers and surface modifiers to produce reabsorbable PLGA microparticles, in which the PEG component provides an anchor to the microparticle surface while the dextran component extends from the particle surface, providing steric stabilization (400). A novel lipid microsphere (LM) emulsified by lecithin with saturated fatty acids was investigated as a drug carrier (401). Compared with yolk phospholipids LM, much slower plasma clearance was observed when dipalmitoylphosphatidylcholine LM was administered iv to rats.

4.3. Properties and Methods of Preparation of Nanoparticles. Various methods and polymers can be used for particle preparation (388). (A) The first is polymerization of a monomer. Polyalkylcyanoacrylate (PACA) nanospheres of around 150 nm can be prepared by an emulsion polymerization process, in which droplets of water-insoluble monomers are emulsified in an aqueous phase (402). Anionic polymerization is initiated by water hydroxyl ions and takes place in micelles where monomer molecules diffuse through the water phase. Drugs dissolved in the polymerization medium can be entrapped in nanospheres either before or after polymerization. PACA and polyisobutylcyanoacrylate (PIBCA) nanocapsules of 200–300 nm are formed by interfacial polymerization, in which an organic phase (including an ethanol solution of the monomer, the oily core material, the lipophilic drug to be encapsulated, and soybean lecithin as an additional surfactant) is slowly dropped into a double volume of an aqueous phase (solution of an anionic surfactant) (403, 404). (B) The second is use of macromolecules. Submicronic macromolecular particulates can be obtained from preformed (natural or synthetic) macromolecules such as polymers, proteins, or polysaccharides. Nanospheres are prepared according to one of the following procedures. (1) The solution emulsification technique produces polymer (e.g., polylactide) (405, 406) and nonpolymer (albumin) nanospheres (407). In the former case, the polymer is dissolved in an organic volatile solvent immiscible in water and the organic phase is dispersed in an aqueous phase by conventional emulsification techniques. The polymer particles are formed from oil-in-water droplets by removal of the organic solvent following distillation under reduced pressure. In the latter case, albumin is dissolved in water and the solution dispersed in an oily phase to form a W/O emulsion which, poured into oil heated to more than 100 °C, causes denaturation of the protein and evaporation of the aqueous phase. The limitations of these methods

are the difficulty of entrapping lipophilic drugs in the first case and thermolabile drugs in the second. (2) The desolvation method, consisting of the precipitation of polymers from their solution by addition of a third component (nonsolvent or salts), is optimized to yield polymer and nonpolymer nanospheres. For polymer nanospheres, the first simple method proposed consists of preparing low-dispersed 200 nm particles by adding an organic solution of the polymer to a miscible nonsolvent and evaporating the volatile solvent (408). This method is successfully applied to polymers such as polylactide, polylactide-co-glycolide, poly- ϵ -caprolactone, ethylcellulose, cellulose acetophthalate, PACA, poly(vinyl chloride)-co-acetate, and polystyrene. Nonpolymer gelatin nanospheres are prepared by controlled desolvation of an aqueous solution of gelatin by adding a desolvating agent (409). Albumin nanospheres are obtained by adapting Fessi's method (410). Both procedures are mild, and labile drugs can be entrapped in the nanoparticles. (3) The spontaneous emulsification technique (411) is adapted (412) to yield polymer nanocapsules with 200–5000 nm diameters; the polymer is dissolved in an organic solvent in association with an oily phase, which then becomes the core of the nanocapsule, and with the drug to be loaded. This organic solution is then poured into a nonsolvent of both polymer and oily core, leading to the formation of nanocapsules. (4) The recently described emulsification–diffusion technique (413) involves the formation of an O/W emulsion with a partially water-soluble solvent containing the polymer and an aqueous phase containing a stabilizer. The subsequent addition of water to the system causes the solvent to diffuse into the external phase, with consequent aggregation of the polymer held in the globules for forming nanoparticles.

4.4. Nanoparticles as Drug Carriers. The reticuloendothelial system (RES) is responsible for eliminating nanoparticle drug carriers from circulation with the following biodistribution: 80–90% in liver, 5–8% in spleen, and 1–2% in bone marrow. Many drugs have been loaded into nanoparticles to be targeted to the above organs. Examples are PACA nanospheres-DOX, used for M5076 hepatic metastases, with a higher plasma level (414, 415), lower toxicity, and stronger uptake by the liver, associated with lower clearance from liver (416), than those of the free drug; and the lipophilic immunomodulator MDP–L-alanylcholesterol (MDP–Chol), entrapped in PIBCA nanocapsules to prolong its biological half-life (417).

However, nanoparticle uptake by the phagocytic system puts limits on a more general applicability, as already described for liposomes. Formulations of long-lasting nanoparticles are therefore under investigation.

4.5. Long-Circulating Nanoparticles. Many attempts have been made to prolong the circulation time of drugs entrapped in particulate systems after iv injection. The main strategy is reduction of particle affinity to RES cells (particularly Kupffer cells), a phenomenon that greatly limits their use to tissues other than liver, spleen, and lung.

The removal of drugs entrapped in particles from circulation depends mostly on the parameters regulating the removal of the carrier system itself. Particles with polar and charged surfaces have an increased circulation time and reduced uptake by the RES organs (418). Amino-modified polystyrene nanoparticles ranging from 100 to 1000 nm are labeled with [^{14}C]formaldehyde, and their fate in blood, liver, spleen, and lung is monitored (419). Half-life in blood ranges from 1.36 to 4.92 min;

Figure 4. Methods for particle surface modification by polymers: (a) adsorption, (b) incorporation, and (c) covalent binding.

particles are mainly taken up by liver, larger particles being taken up faster than smaller ones. Amino-bearing polystyrene particles stimulate the phagocytic uptake mechanism to a lesser extent than polystyrene particles without amino groups, and consequently have a longer half-life (419).

One of the most successful strategies for obtaining long-circulating nanoparticles is polymer anchoring, especially poly(ethylene glycol) (PEG), at the particle surface, for creating a hydrophilic cloud reducing interactions with the proteins and cells responsible for their low blood residence time. The modification of nanoparticle surface by polymers can be performed by polymer adsorption, incorporation during the production of nanoparticles, or covalent attachment to the nanoparticle surface (Figure 4).

Uptake of particulate carriers by liver and/or isolated Kupffer cells may be prevented by coating particles with a hydrophilic surface based on PEG-type materials, like block copolymers of ethylene oxide/propylene oxide (POE/POP) or poloxamine-908 (420–424), which are either adsorbed or covalently bound to the particles. Adsorption of poloxamine-908 to polystyrene microspheres prolongs microsphere circulation time after iv injection into rabbits (420). Possible important factors for such increased retention in blood are (1) the thickness of the adsorbed layer (425); (2) the decrease in surface hydrophobicity,

causing limited phagocytosis (426); (3) the reduced opsonization due to the hydrophilic coating layer, with consequent decrease of particle recognition by RES phagocytes (427–429); and (4) the binding of plasma dysopsonins (suppressive substances from plasma and serum) which minimizes interaction with phagocytes (430–432) (Figure 3).

To investigate all these hypotheses, colloidal gold particles (117 nm diameter) and polystyrene microspheres (60 nm diameter) are used as models for poloxamine-908 coating (433). Since preopsonization of gold particles in plasma results in immobilization of fibrinectin on their surface (429, 434), stimulating the uptake of gold particles by isolated Kupffer cells via a peripheral membrane-bound C-reactive protein [a particle-galactose-specific receptor (434, 435)], coating them with poloxamine-908 reveals how the steric barrier of poloxamine affects the opsonization process. Moreover, since the uptake of latex microspheres by macrophages in the presence of plasma or serum is suppressed and regulated by dysopsonins (426, 430), their use in this kind of experiment highlights the role of dysopsonins in clearing poloxamine-coated particles. The study indicates that poloxamine-908 coating blocks opsonization but still allows dysopsonization (433).

Poly(lactic acid) (PLA)–monomethoxypoly(ethylene glycol) (PEG) copolymers (PLA–PEG) are used to modify the surface of biodegradable poly(lactide-co-glycolide) (PLGA) and polystyrene (PS) nanoparticles (used as controls) and to compare these particles with those obtained by modification with poloxamine-908 (436). PLA–PEG copolymer (3/4) (PEG MW of 2000 Da), 2/5 PLA–PEG (PEG MW of 5000 Da) copolymers, and poloxamine-908 produce coating layers of ~3, 7, and 9 nm, respectively. Coating particles with any of the stabilizing copolymers significantly decrease albumin adsorption, which is attributed to folding of the PEG chain into the hydrated layer. For polystyrene nanoparticles, coating with either 2/5 PLA–PEG or 3/4 PLA–PEG reduces the rapid clearance from circulation observed for uncoated nanoparticles, although the reduction is greater for poloxamine-908. PLA–PEG-coated PS nanoparticles are removed from circulation by liver to the same extent as uncoated ones, but higher clearance by spleen is observed. Coating PLGA nanoparticles with PLA–PEG copolymers results in extended circulating levels, comparable with those obtained with poloxamine-908, and decreased liver uptake. The different clearance and organ distributions of polystyrene and PLGA nanoparticles, both coated with PLA–PEG, may be attributed to the difference in stability of PLA–PEG coatings on polystyrene and PLGA nanoparticles. The PLA portion of PLA–PEG copolymers is a better anchor group when they are adsorbed on the surface of a similar structure, i.e., that of PLGA nanoparticles, providing a coating layer stable to desorption and displacement which prevents any gradual adsorption of plasma proteins (436). The lymph node localization of biodegradable PLGA nanoparticles may be dramatically enhanced by coating their surface with PLA–PEG copolymers or by producing coprecipitate nanoparticles of PLGA and PLA–PEG (437).

Other copolymers are being investigated for coating nanoparticles, like a nontoxic PEG–polycyanoacrylate copolymer for preparing PEG-coated PACA nanoparticles (438). Nanospheres are prepared by emulsion–polymerization of isobutylcyanoacrylate in water in the presence of PEG of different chemical structure (PEG, methoxy-PEG, and bimethoxy-PEG) to evaluate the role

Table 3. Influence of Different Polymer Coatings of Polystyrene (PS) and/or PLGA Nanoparticles on Their Permanence in Rat Circulation

particles	MW of the copolymer (Da)	retention in rat circulation	reference
PS	—	6	436 ^a
PS/PLA–PEG ₅₀₀₀ (2/5)	9500	36	436
PS/PLA–PEG ₂₀₀₀ (3/4)	5400	58	436
PS/poloxamine-908	25000	108	436
PLGA	—	4.8	436
PLGA/PLA–PEG ₅₀₀₀ (2/5)	9500	13.2	436
PLGA/PLA–PEG ₂₀₀₀ (3/4)	5400	60	436
PLGA/poloxamine	25000	93	436
PLGA	—	3.7	437 ^b
75% PLGA/PLA–PEG ₇₅₀ (1.5/0.75)	2219	7.0	437
65% PLGA/PLA–PEG ₇₅₀ (1.5/0.75)	2219	8.7	437
55% PLGA/PLA–PEG ₇₅₀ (1.5/0.75)	2219	12.0	437
PF	—	—	438 ^c
PF/poloxamine-908	—	0.75	438
PF/PF–PEG ₅₀₀₀	—	3	438

^a PEG 5000 and 2000 were used for the preparation of 2/5 and 3/4 PLA–PEG, respectively. The coated nanospheres were obtained by the precipitation–solvent evaporation method. The retention in rat circulation is expressed as half-life (minutes) (436).

^b The nanospheres were obtained by coprecipitation of a mixture of PLGA and PLA–PEG, in which PLGA ranged from 75 to 55%. The retention in rat circulation is expressed as the percent injected dose in blood 6 h postinjection (437). ^c The nanoparticles were coated with the poloxamine-908 (MW of 25000 Da) or PF–PEG (5% PEG chains of 5000 Da) copolymer. The retention in rat circulation is expressed as half-life (hours) (438).

of the various configurations of PEG on these potential stealth-type, rapidly biodegradable carriers (439).

The poly(phosphazene)–poly(ethyleneoxide) (PF–PEO₅₀₀₀) copolymer is used for surface modification of poly(phosphazene) nanoparticles (440). In this case, poly(phosphazene) nanoparticles are modified with both PF–PEO and poloxamine-908. Biodistribution in rat has been studied; nanoparticles with a poloxamine-908 coating are mainly captured by liver, although delayed clearance from systemic circulation was noted. In contrast, nanoparticles coated with PF–PEO have a prolonged blood circulation profile, and only small amounts of nanoparticles are sequestered by liver. This stresses the importance of the nature of both the anchoring group and the particle surface in determining the biological behavior of the system.

ST-PHPMA polymers with different molecular masses and containing an amino end group (31) are covalently bound via amide bonds to the surface of nanospheres based on copolymers of methyl methacrylate, maleic anhydride, and methacrylic acid. Such modified nanospheres show decreased *in vitro* adsorption to proteins, decreased accumulation in liver after *iv* administration in rats, and increased intravascular half-life. Changes in these properties increase with increasing polymer molecular mass (31).

Retention in blood of various long-circulating nanoparticles is reported in Table 3.

4.6. General Considerations on Substance Entrapment in Particles. Encapsulation of drugs in micro- or nanoparticle appears to be the simplest and technologically most suitable method for prolonging the body residence time of drugs, as compared with polymer conjugation and liposome entrapment. This is particularly due to the availability of many new tailor-made polymers. However, there are many problems in encaps-

sualting biotechnological products, since the organic solvents and heating procedures, often required in the entrapment step, may denature the proteins. This limitation does not apply to polymer conjugation and liposome strategies.

Once the drug has been encapsulated, two other main problems may be encountered. (1) Hydrolytically labile compounds may be damaged by water diffusing inside the matrix, unless very hydrophobic polymers are used. (2) The release of large peptides and proteins may be limited by the matrix pore size of biodegradable polymers used.

As for liposomes, the new biodistribution pattern acquired by the encapsulated drug must be taken into consideration in planning particle use, especially for microparticles which do not pass through capillaries.

The use of microparticles may become a very attractive strategy if new polymers are introduced, conferring specific characteristics on the system, e.g., adhesive polymers for direct delivery of drugs to deep aerial pathways.

5. ADDITIONAL STRATEGIES

Other strategies are applied to increase the stability of substances in circulation. For a brief review of what has been achieved in various fields and for very different purposes, a few examples are given here.

Other Long-Circulating Polymer-Coated Systems. Lipid emulsions stabilized with emulsifiers, such as phospholipids, represent an interesting system for delivering lipophilic drugs. Unlike liposomes, O/W emulsions have only one layer of amphipathic molecules (e.g., phosphatidylcholine) and a hydrophobic core which can be filled with a considerable amount of lipophilic drug. Moreover, together with the characteristics of biodegradability, biocompatibility, and physical stability, they can be prepared on a large industrial scale and are relatively stable below 25 °C for prolonged periods (441). Rhizoxin palmitoyl derivative RS-1541 in O/W emulsions has a lengthy circulation time in blood after iv injection and stability against lipoprotein lipase (442). The main problem in using O/W emulsions is rapid clearance from blood by the RES system after parental administration (443, 444), a process involving apolipoprotein E (445). PEG is again proposed as a solution to this problem. Inclusion of PEG derivatives such as Tween-80 or dioleoyl *N*-[monomethoxypoly(ethylene glycol) succinyl]phosphatidylethanolamine (mPEG-PE) as a coemulsifier in emulsions composed of Castor oil and phosphatidylcholine decreases their RES uptake and prolongs circulation in blood. PEG derivatives increase circulation time depending on the chain length of the polymer (PEG 2000 $\geq$ PEG 5000 > PEG 1000 and Tween-80) and PEG density on the emulsion surface (446). A submicrometer lipid emulsion coated with amphipathic poly(ethylene glycol) for parental administration of paclitaxel (Taxol) is an alternative formulation for the drug (447), which is usually prepared in ethanol and Cremophor EL (Diluent 12), a solvent system associated with severe side effects.

Polymer micelles are another interesting class of potentially useful drug carriers. Although their structure is quite different from that of liposomes, they are related to them by the similarity in structural elements, and their formation is based on a thermodynamic equilibrium. The small size of micelles, between that of single molecules and that of the smallest liposomes (50 nm), means that they are of great interest as carriers for drugs or imaging agents, since they can reach body sites not accessible to any other particle system. Micelles based

on the copolymers of poly(ethylene oxide) (PEO) and poly(aspartic acid) [p(Asp)] with covalently bound adriamycin (ADR) are prepared (241, 448) and have long circulation times, which increase according to the PEO MW/p(Asp) MW ratio: 1000/4800 < 5000/8700 < 5000/2100 < 12000/2100. This behavior is attributed to the low level of interaction of the PEO corona region of the micelles with various biocomponents (proteins and cells). Low uptake levels of PEO-[p(Asp)-(ADR)] in liver and spleen are reported. Biodistribution depends on micelle stability, since unstable micelles form free polymer chains which undergo renal excretion.

Micelles are also prepared from comb copolymers based on stearyl methacrylate and acrylate derivatives of PEG. Micelles may be formed by homogeneous dispersion of comb copolymers in aqueous solutions and the sizes adjusted by sonication. These micelles are now being investigated to confirm their expected high circulation half-lives due to the attachment of PEG on the copolymers (449).

Novel reactive polymer micelles for potential use as drug carriers are obtained with heterobifunctional AB block copolymers consisting of PEG and PLA containing an acetal group at the PEG chain end. This block copolymer forms polymer micelles (30 nm diameter) in aqueous media. The acetal groups are transformed into aldehyde groups, which conjugate with targeting moieties such as sugar molecules and antibodies (450).

Micelles with 10–50 nm diameters are obtained from PEO and successfully incorporated with amphiphilic ¹¹¹In and gadolinium chelates for percutaneous lymphography (451). New trends in preparing contrast-loaded micelles are also under investigation, e.g., the application of amphiphilic polychelating polymers (452).

Glycosylation. Glycosylation of SOD with monosaccharides such as galactose and mannose influences enzyme renal disposition, reducing tubular reabsorption and enhancing exposure to the luminal surface (453).

Hydrolytically Stable Peptide Analogues. Many peptide analogues have been prepared to improve the pharmacokinetics of natural peptides. An example is somatostatin, a peptide which binds to specific receptors in various target tissues and inhibits the release of growth hormone from pituitary cells. Several analogues have been synthesized, including the octapeptide analogue octreotide (Sandostatin). This has a similar high affinity for specific receptors with an IC₅₀ in the subnanomolar range but is much better under in vivo conditions, having a longer duration of action, specificity, and potency, unlike its different distribution, metabolism, and excretion behavior (454).

Antibody Fragments. In the development of tumor diagnosis and drug-targeting strategies, monoclonal antibodies play an important role as agents in directing drugs to specific tumor tissues (455). Limitations connected with using intact antibodies, like long half-life (which does not allow discrimination between tumor target and background in tumor imaging) and relatively large molecular mass (which inhibits the rate of immunoconjugate extravasation and the extent of tumor penetration), are avoided by using antibody fragments such as F(ab) or F(ab')₂ (which associates better with target cells than the monovalent fragment). These antibody fragments are generated by proteolysis of intact Ig or Fv fragments, comprising the variable domains only of H and L chains, approximately half the size of a F(ab) fragment, obtained by genetic engineering (456). In the latter case, the spontaneous separation of VH and VL chains, which are in dynamic equilibrium in solution, are

deleterious to stability, probably because the isolated VH chain is highly susceptible to denaturation (457). Bis-FvCys conjugates prepared from murine anti-lysozyme Fv fragments (458) and antcarbohydrate antigen, occurring in many human tumors (459, 460), both have better stability and a significantly longer serum half-life than univalent Fv analogues.

Lipophilization. ^{99m}Tc is an important imaging agent in nuclear medicine as mentioned above. [^{99m}Tc]Exam-etazime and its stabilized form containing CoCl_2 (461) are well-established radiopharmaceutical drugs, mainly used to study regional cerebral blood flow by single-photon emission tomography and to radiolabel leukocytes for imaging focal sites of infection and/or inflammation (462–465). On its first pass through the brain, lipophilic [^{99m}Tc]exametazime is removed from the blood by cerebral extraction and rapidly converted to a more hydrophilic species which is retained in cerebral blood long enough for the acquisition of images over the following few hours (462).

Lecithinization. Lecithinization has been investigated as an alternative method for improving protein pharmacokinetics; both SOD (466) and interleukine-6 (467) derivatives have longer persistence in blood than unmodified forms.

Lipidization. A new technique recently introduced in the drug delivery field is reversible lipidization of polypeptides. Conjugation with fatty acids decreases the level of proteolytic degradation (468) and increases the plasma half-life of polypeptide drugs (469, 470). This method seems very innovative, although critical aspects such as immunogenicity and toxicity are still to be properly investigated.

Microemulsions. The formation of macroscopically homogeneous, stable, fluid, optically transparent W/O microemulsions is being evaluated for the production of new drug carriers. The influence of various counterions added to W/O microemulsions (containing lecithin as a surfactant and water/propylene glycol at various pH values as an internal phase) on the permeation of methotrexate across intact hairless mouse skin has been studied (471). Increased permeation of the drug as a consequence of methotrexate lipophilization due to ion pair formation is noticed when dodecyl sulfate and dioctyl sulfosuccinate are used.

Dendrimers. Many efforts have been made in the field of dendrimer synthesis, characterization, and modification to obtain polymer “boxes” for potential use as nanoscopic molecular containers (472). The latest dendritic boxes are formed by the reaction of a fifth-generation poly(propylene imine) dendrimer with a bulky, hydrogen-bonding group such as a protected phenylalanine, which forms a rigid shell around the dendrimer. Modification of the shell gives boxes of various porosity, and shape-selective release of “guests” is possible. The reaction of terminal amino groups with alkanolic acids yields medium-tunable boxes, which are closed in polar media (collapsed alkyl chains) and open in apolar media (swollen alkyl chains) (473). Complexes of oligonucleotides with polyamidoamine starburst dendrimers show that dendrimers cause 50-fold enhancement in the level of cell uptake of oligonucleotides, supporting further evaluation of dendrimers for oligonucleotide delivery in cell cultures and in vivo (474).

Cyclodextrins. Inclusion complexation of unstable guests with cyclodextrins has also been proposed as a new method for stabilizing and solubilizing a variety of molecules. At this stage, researchers are still studying the kinetic parameters regulating complex formation and

degradation (475), but the system potentially represents one of the future methods for carrying molecules in circulation while avoiding degradation processes.

Niosomes. To reduce renal clearance of doxorubicin modified with HPMA and thus increase tumor accumulation, a nonionic surfactant vesicle (niosome) formulation has been developed (476). These DOX–HPMA-containing niosomes are stable in the presence of plasma, releasing only 0.2% DOX over 72 h; in the presence of a lysosomal enzyme preparation (tritosomes), the polymer conjugate is cleaved, releasing 8% DOX over 72 h.

Biological Carriers. This review does not include reports on natural carriers, since attention is focused on methods that involve chemical approaches. However, one example must be briefly reported, since it is an interesting combination of biological and chemical procedures in the preparation of a carrier. Among potential natural carriers, erythrocytes are the most widely used, since they are easy to obtain and can be pretreated to inactivate their two major proteolytic systems, Ca^{2+} -dependent neutral proteinases and acid endopeptidases (477). The specific phosphatases in their structure are exploited for slow release of prodrugs entrapped in the cells. Erythrocytes loaded with azidothymidine derivatives act in vitro as bioreactors, ensuring sustained and potentially useful release of drugs (478). Chemical modification of the erythrocyte surface may also prolong and/or target entrapped drugs to different organs. These positive advantages have already allowed successful clinical testing.

6. CONCLUSIONS

Retention of drugs in circulation is a key step in drug design and delivery. Even the most active compound in vitro is useless if it does not reside in vivo in the blood long enough to reach its target, while managing to avoid to some extent premature metabolism, immunological reactions, toxicity, rapid excretion, and captation by undesired tissues. In the last few decades, the combination of a better understanding of cell and tissue properties and the development of tailor-made polymers, liposomes, and nanoparticles has led to the production of interesting systems which have increased drug residence time in circulation.

Starting from the pioneering proposal of multivalent polymers by Ringsdorf in the 1970s, many complex tools were later developed in the design of drugs covalently bound to polymers. Great importance was given to drug stability, polymer properties and targeting to specific tissues, and protease susceptibility of the peptide spacer between polymer and drug. This approach has already yielded successful clinical results, especially with the two antitumor drug carriers SMA and HPMA, and it is now therefore considered a general strategy which may be applied to new polymers and drugs.

So far, the most widely studied polymer is PEG, which is certainly still the best characterized material for this goal. PEG has a much simpler structure than SMA, HPMA, or other polymers, and it possesses incredibly favorable in vivo properties which have encouraged many studies especially with it as a protein and peptide carrier. Many tests have been carried out on the chemistry of this polymer, reported in both academic and proprietary publications, particularly with regard to activation methods which allow its binding not only to protein and nonprotein drugs but also to liposomes and particles, to convey long-lasting properties. Chemistry is still the important issue for new discoveries in this approach to

drug delivery; it is essential both for the synthesis of new polymers and for the preparation of copolymers, in which the properties of hydrophilicity and hydrophobicity, charge, and shape of different polymers can be variously combined.

In the field of drug encapsulation, besides the classical liposomes, particles, and their long-circulating versions obtained by polymer coatings, interesting new structures are being developed, such as niosomes and dendrimers. The latter structures have rapidly demonstrated their great potential in drug delivery, thanks to the complex but extremely precise architecture of their huge synthetic structure. Another area of study, which only chemical investigations can bring to mature application, is the derivatization of fullerene for yielding products of precise size but with still undiscovered although fascinating delivery potentials.

The development of biological studies is also of primary importance, not only for evaluation of the *in vivo* behavior of the carried drugs but also for further experimentation with cells and viruses as carriers.

In conclusion, although many important goals have been already reached in the stabilization of substances in circulation, many other fascinating chemical and biological combinations must be explored, with the final goal of reaching the ambitious possibility of tailoring the most suitable strategy for any drug delivery or targeting need.

Revised Manuscript Received April 6, 1998

Synthetic human MUC1 peptides are important candidates for therapeutic cancer vaccines. To explore whether a human MUC1 peptide BP25 (STAPPAHGVTSPAPDTRPAPGSTAPP) can be rendered immunogenic by incorporation in liposomes, the effects of physical association of the peptide with liposomes on immune responses were investigated. Lipid conjugated and nonconjugated MUC1 peptides were incorporated in liposomes with a composition of distearoylphosphatidylcholine/cholesterol/dimyristoylphosphatidylglycerol (3:1:0.25, molar ratio) containing monophosphoryl lipid A (1% w/w of the total lipids). Liposomes were characterized for peptide retention by HPLC and for surface peptide display of MUC1 epitopes by flow cytometry. C57BL/6 mice were immunized with lipopeptide alone, peptide mixed with peptide-free liposomes, and peptide associated with liposomes in entrapped or surface-exposed forms. T cell proliferative responses, cytokine patterns, and antibody isotypes were studied. Results showed that immune responses were profoundly influenced by the liposome formulations. Physically associated, either encapsulated or surface-exposed, peptide liposomes elicited strong antigen-specific T cell responses, but not lipopeptide alone or peptide mixed with peptide-free liposomes. Analysis of the cytokines secreted by the proliferating T cells showed a high level of IFN- γ and undetectable levels of IL-4, indicating a T helper type 1 response. Thus, physical association of the peptide with liposomes was required for T cell proliferative responses, but the mode of association was not critical. On the other hand, the nature of the association significantly affected humoral immune responses. Only the surface-exposed peptide liposomes induced MUC1-specific antibodies. A domination of anti-MUC1 IgG2b over IgG1 (94 versus 6%) was observed. Our results support the hypothesis that different immune pathways are stimulated by different liposome formulations. This study demonstrated that a liposome delivery system could be tailored to induce either a preferential cellular or humoral immune response.

INTRODUCTION

MUC1 mucin is a high-molecular weight glycoprotein consisting of tandem repeats of the 20-amino acid unit PDTRPAPGSTAPPAHGVTSA (1). It is expressed by normal secretory epithelial cells and adenocarcinomas (2). MUC1 mucin produced by adenocarcinomas is underglycosylated in comparison to its normal counterpart. This results in exposure of certain core peptide epitopes of MUC1 to the immune system (3–6). Such epitopes may elicit anticancer immune responses in cancer patients, providing a rationale for the design of therapeutic MUC1 peptide cancer vaccines (7–9). Evidence for the protection against breast cancer through natural immunization by MUC1 epitopes during pregnancy suggests such vaccines may also have prophylactic applications (10–12). However, the problem of low immuno-

genicity of synthetic MUC1 peptides must be overcome for the development of effective cancer vaccines. Synthetic MUC1 peptides coupled with a carrier protein have been shown to induce anticancer immune responses in mice and in cancer patients in phase I clinical studies (13; unpublished results). We have chosen liposomal delivery of MUC1 synthetic peptides as an alternate approach for enhancing immunogenicity.

The immunoadjuvant properties of liposomes have long been recognized (14) and repeatedly demonstrated for humoral and cell-mediated immunity (15, 16). The nature of the physical association of protein antigens with liposomes can influence immune responses to a significant degree depending on the route of administration and antigen characteristics (17–20). In contrast to many studies on liposome-associated protein antigens, little work has been done with synthetic peptides, especially linear and hydrophilic peptides. Recently, a liposomal MUC1 peptide antigen delivery system containing monophosphoryl lipid A (MPLA) has been developed (21). It elicited strong antigen-specific T cell responses; however,

no MUC1-specific antibodies were induced. Our working hypothesis is that the nature of physical association of MUC1 peptide with liposomes will influence the type of immune responses. The goal of this work was to evaluate the effects of the association of the MUC1 peptide with liposomes on antibody production and T cell responses.

EXPERIMENTAL PROCEDURES

Materials. Mouse MUC1 peptide SP1-020 (DSTSS-PVHSGTSSPATSAPEDSTS) and human MUC1 peptides BP16 (GVTSAPDTRPAPGSTA), BP24 (TAPPAHGVT-SAPDTRPAPGSTAPP), and BP25 (STAPPAHGVTSA-PDTRPAPGSTAPP) were constructed using the solid-phase approach of Merrifield (22) on an automated peptide synthesizer (MilliGen/Bioscience model 9050). LCP25 (laurylcys-STAPPAHGVTSA-PDTRPAPGSTAPP) was synthesized using laurylcysteine as the N-terminal amino acid. Laurylcysteine was presynthesized in solution phase by coupling lauric acid to the amino group of cysteine. Monoclonal antibodies (mAb) B248.7R2 specific for MUC1 peptide sequence APPAHGVTS and B80.3 (specific for PSA, prostate-specific antigen) were produced and provided by Biomira Inc. (Edmonton, AB). Distearoylphosphatidylcholine (DSPC), cholesterol (CHOL), and dimyristoylphosphatidylglycerol (DMPG) were obtained from Princeton Lipids (Princeton, NJ).

Peptide Liposome Formulations. Five formulations with equimolar peptide content (2 nmol per 50 μ L of liposomes; 5 μ g of BP25 or 5.6 μ g of LCP25) were prepared for immune response studies. Multilamellar vesicles with a final lipid concentration of 30 mM, composed of DSPC/CHOL/DMPG (3:1:0.25, molar ratio) and MPLA (1% w/w of the total lipids) (Ribi Immunochem Inc., Hamilton, MT), were prepared by a modified freeze-and-thaw (FAT) method (23, 24). Briefly, lipids were dissolved in chloroform and coated onto the walls of a 100 mL round-bottom flask by rotary evaporation, and the residual solvent was removed by overnight vacuum desiccation at 43 °C. The desiccated lipid film was dispersed in filter-sterilized PBS containing BP25 to form "liposomal BP25" at 65 °C followed by five cycles of FAT. Freezing was carried out in a dry ice/acetone bath for 5 min, and thawing occurred at room temperature for 50 min followed by incubation for 5 min at 65 °C. Free peptides in supernatants were removed after centrifugation at 150000g for 12 min (Beckman model L8-55 ultracentrifuge). Lipopeptide LCP25 was incorporated by mixing it with the lipids in chloroform prior to rotary evaporation, followed by hydration of the film with sterile PBS, forming liposomal LCP25. The entrapment of BP25 and LCP25 in liposomes was quantified by HPLC. Peptide-free liposomes ("empty") containing 1% MPLA were similarly prepared, except that only PBS was used for hydration. The "BP25 mixed" group was formulated by adding a specific amount of BP25 to empty liposomes. A control formulation of lipopeptide LCP25 ("LCP25 alone") was made by mixing it with 1% (w/v) MPLA in a PBS solution containing 0.1% (w/v) triethylamine.

Determination of Peptide Leakage from Liposomes. Aliquots of 200 μ L of liposome-encapsulated BP25 or LCP25 were incubated in a shaking water bath at 37 °C for 24 h. At various time intervals, liposome samples were centrifuged and analyzed by HPLC for MUC1 peptide in the supernatant and the pellet.

Liposome Size Determination. Liposome size was determined by dynamic light scattering (Brookhaven Instruments, Holtsville, NY). Samples were diluted 300 times with buffer and measured at 25 °C.

HPLC Analysis. Liposome pellets were dissolved in 25% absolute ethanol and then mixed with the internal standard phenol solution and PBS. A Waters 625-746 HPLC system with a C-18 reverse-phase radial-pak cartridge (8 mm $\times$ 100 mm) was used for HPLC analysis. Peptides were eluted using a gradient aqueous mobile phase consisting of eluent A [10% acetonitrile and 0.1% trifluoroacetic acid (TFA)] and eluent B (70% acetonitrile and 0.085% TFA). The flow rate was 1 mL/min. Peptides were detected by UV absorbance at 210 nm. Quantification of MUC1 peptides was done using a calibration curve based on peak areas ($R^2 > 0.9991$).

Flow Cytometric Analysis. To determine the surface exposure of MUC1 peptides, liposome samples (empty liposomes, BP25 mixed with empty liposomes, BP25 liposomes, and LCP25 liposomes) were incubated with B248.7R2 (MUC1-specific mAb) or B80.3 (negative control mAb) for 45 min at 4 °C, washed, and incubated with FITC-conjugated goat anti-mouse IgG1 (Southern Biotechnology Associates Inc., Birmingham, AL) at 4 °C for 30 min. After washing, liposomes were analyzed using a FACSsort flow cytometer (Becton Dickinson, Mountain View, CA) under standard conditions.

Immunization Procedures. Normal serum samples were collected from C57BL/6 mice (female, 7–8-week-old) 1 day before immunization by tail vein bleeding.

Single Immunization. On day 0, five groups of mice (seven in each group) were immunized subcutaneously (sc) in the left hind footpad with 50 μ L of the following five formulations: empty, BP25 mixed with empty liposomes, LCP25 alone, liposomal BP25, and liposomal LCP25. On day 10, blood was collected from each mouse by cardiac puncture and the draining popliteal lymph nodes were collected for the T cell proliferation assay.

Two Immunizations. On day 0, another five groups of mice were immunized sc in the left thigh with the same formulations as above. On day 14, an identical second immunization was given intraperitoneally (ip). On day 26, blood and the draining inguinal lymph nodes were collected.

T Cell Proliferation Assay and Cytokine Collection. Chemically inactivated syngenic spleen cells from naïve mice were used as antigen-presenting cells (APCs). Mitomycin C (Sigma Chemical Co., Mississauga, ON) was added at a dose of 60 μ g per 20 million spleen cells and the mixture incubated for 100 min at 37 °C in 5% CO₂. T cells were isolated from the lymph node cells by the nylon wool purification method (25). T cells (2.5×10^5 /well) and APCs (5×10^5 /well) were cultured in a total volume of 300 μ L in 96-well flat-bottom Costar microtiter plates (Fisher Scientific, Fair Lawn, NJ) in the presence of media alone (peptide-free background), SP1-020 (negative control), and BP24 or BP25 at 20 μ g/well for a period of 3 days at 37 °C in 5% CO₂. Each group was cultured in quadruplicate. On day 3, the cultures were pulsed with 1 μ Ci of [³H]thymidine (Amersham Canada Ltd., Oakville, ON) at 50 μ L/well for 21 h. Incorporation of [³H]-thymidine into the proliferating cells was measured after harvesting the cells on filters (Skatron model 11055 microcell harvester) and counting the filters (Beckman model LS 60001C liquid scintillation counter) in the presence of 4 mL of scintillation fluid (Cytoscint Research Production Division, Costa Mesa, CA). The stimulation index (SI) was defined as the ratio of the counts per minutes (cpm) of the peptide-stimulated cultures to the background cpm of peptide-free cultures. Separate parallel cultures under identical conditions were set up for collection of cytokines produced during T cell prolifera-

Figure 1. FACS analysis of liposomal BP25 (A and B) and LCP25 (C and D) for the presence of MUC1 epitopes on the surface. Liposomes were incubated with negative control mAb B80.3 specific for PSA (A and C) or MUC1-specific mAb B248.7R2 specific for the amino acid sequence APPAHGVSTA (B and D), subsequently incubated with an appropriate FITC-labeled secondary antibody, and analyzed by FACS. The bars represent fluorescence signal above background noise.

tion. Culture supernatant was collected from separate plates at 24, 48, and 72 h.

Cytokine Analysis. Levels of INF- γ and IL-4 in the above culture supernatants were separately estimated at 24, 48, or 72 h by a sandwich type enzyme-linked immunosorbent assay (ELISA) (26, 27). The 96-well Nunc ELISA plates were coated with antibodies R46.A2 and 11B11 (Biomira Inc.) for IFN- γ and IL-4, respectively, by incubation at 37 °C for 30 min, followed by washing with TPBS (PBS with 0.05% Tween 20 at pH 7.4). Culture supernatants or recombinant reference standards (rIFN- γ , concentration range of 5000–156 pg/mL; rIL-4, 1666–52 pg/mL; PharMingen, San Diego, CA) were added and the mixtures incubated at 37 °C for 45 min. After washing with TPBS, second antibodies (for IFN- γ , XMGI.2 biotinylated, Biomira Inc.; for IL-4, BVD6-24G2 biotinylated, PharMingen) were added and the mixtures incubated for 45 min at 37 °C. After washing, the wells were incubated with horseradish peroxidase (HRPO)-conjugated streptavidin (Jackson ImmunoResearch Lab Inc., Bar Harbor, ME) at 37 °C for 30 min and washed in TPBS. Finally, a HRPO substrate solution freshly prepared by mixing equal volumes of a TMB (3,3',5,5'-tetramethylbenzidine) solution [0.4 g/L in an organic base, Kirkegaard and Perry Laboratories Inc. (KPL), Gaithersburg, MD] and a H₂O₂ solution (0.02% in citric acid buffer, KPL) were added to the wells (100 μ L/well). The optical density (OD) at 650 nm was read immediately using a microplate reader (Molecular Devices, Menlo Park, CA) in a kinetic mode. A final OD reading was made at 450 nm after adding 100 μ L of 1 M phosphoric acid to each well. Cytokine levels in the culture supernatants were determined on the basis of the standard curves generated for the reference standards.

Antibody Analysis. Nunc maxisorb microplates were coated with 100 μ L/well BP16-HSA (human serum albumin) and HSA (negative control) at a concentration of 5 μ g/mL at 4 °C overnight. After washing with TPBS, the wells were blocked by incubation with bovine serum

albumin (1% in phosphate buffer, 200 μ L/well, KPL) at 37 °C for 30 min and washing with TPBS. Then serial dilutions of test serum samples (pooled for each immunization group) were added to the wells (100 μ L/well) and the mixtures incubated at room temperature for 1 h. A pooled normal serum sample (from unimmunized mice) was used as the negative control. Serum samples containing anti-MUC1 IgG and IgM from mice immunized with BP-16 conjugated to KLH (13) were used as positive controls (serial dilutions for IgM, 1:80 to 1:5120; for IgG, 1:2500 to 1:160000). The plates were then washed with TPBS. Goat anti-mouse IgG and IgM antibodies labeled with HRPO (KPL) at a 1:2000 dilution in PBS or subtype-specific goat anti-mouse IgG1, IgG2a, IgG2b, and IgG3 antibodies labeled with HRPO (Southern Biotechnology Associates Inc.) at a 1:4000 dilution in PBS were added to each well (100 μ L/well). After incubation at room temperature for 1 h and subsequent washing with TPBS, a HRPO substrate solution freshly prepared by mixing equal volumes of an ABTS [2,2'-azinobis(3-ethylbenzthiazoline sulfonate)] solution (0.6 g/L in glycine buffer, KPL) and a H₂O₂ solution (0.02% in citric acid buffer, KPL) were added to the wells (100 μ L/well). The wells were incubated at room temperature for 15 min, and the OD was read at 405 nm using a microplate reader (Molecular Devices).

RESULTS

Physical Characterization of Liposomes Containing Peptide versus Lipopeptide Antigen. FACS analysis of liposomal LCP25 with a mAb B248.7R2 (specific for the amino acid sequence APPAHGVSTA of human MUC1 mucin) clearly showed that the MUC1 peptide epitopes were present on the surfaces of liposomes, whereas no MUC1 epitopes were detected on liposome surfaces in the rest of the formulations (Figure 1). An irrelevant mAb B80.3 (specific for PSA) did not bind with LCP25 liposomes, establishing the antigen specificity of the FACS analysis. BP25 and LCP25

Figure 2. Retention of BP25 and LCP25 in liposomes with a lipid composition of 3:1:0.25 DSPC/CHOL/DMPG at 37 °C in PBS over the course of 24 h. Error bars indicate the standard deviation (SD) ($n = 3$).

liposomes leaked less than 10% of the entrapped peptides over the course of 24 h at 37 °C (Figure 2). The mean diameters of BP25 and LCP25 liposomes were 0.8 ± 0.1 and 0.9 ± 0.1 μm , respectively.

Physical Association of the MUC1 Peptide with Liposomes Was Required for T Cell Responses. Antigen-specific T cell priming induced by liposomal formulations was studied by T cell proliferation assays. T cell responses (SI) were significantly stronger ($P < 0.01$) in groups of mice immunized with the peptide-associated liposomes (encapsulated or surface-exposed) than in the rest of the formulations (Figure 3). There were no significant differences ($P > 0.01$) between the encapsulated and surface-exposed liposomes or between the two different immunization procedures (Figure 3). Antigen specificity was established by the observation that T cells responded to both recall human MUC1 peptides BP24 and BP25 but not to the irrelevant mouse MUC1 peptide SP1-020.

Cytokine Analysis Indicated a T Helper Type 1 (Th1) Response. T cell responses were further characterized by analyzing the cytokine secretion profiles of the proliferating T cells. No evidence of IL-4 was present in the T cell cultures following one or two immunizations, at 24, 48, or 72 h (all below the detectable level of 52 pg/mL; data not shown). However, there were significant levels of IFN- γ in the cell cultures that correlated with T cell responses (Figures 3 and 4). The amount of IFN- γ was found to be highest at 72 h. These results are indicative of Th1 responses (28).

Surface-Exposed but Not Encapsulated MUC1 Peptide Liposomes Induced Antibody Production. MUC1-specific humoral immune responses were evaluated by ELISA using BP16-HSA as the solid phase. BP16 contains the immunodominant B cell epitopes of MUC1 tandem repeat sequences in mice (13). The positive control serum for IgG and IgM was from mice immunized with BP16-KLH (keyhole limpet hemocyanin). There were no detectable levels of IgG or IgM after one immunization (Figure 5). However, high titers of IgG and IgM were detected in the sera pooled from the group of mice immunized twice with liposomal LCP25, but not with other formulations (Figure 6). This serum was further analyzed for IgG subclasses IgG1, IgG2a, IgG2b, and IgG3. Results showed a domination of IgG2b over IgG1 (94 versus 6%) (Figure 7). There were no detectable levels of IgG2a or IgG3.

DISCUSSION

Our results showed that physical association of the MUC1 peptide with liposomes containing MPLA was

necessary for induction of immune responses. Both encapsulated and surface-displayed formulations of peptides induced T cell responses, whereas an aqueous solution of lipopeptide containing MPLA or free peptide mixed with liposomes failed to induce antibodies or T cell responses. For most protein antigens, potent humoral responses may be induced by a variety of liposomal formulations, where protein antigens are entrapped, surface-linked, or even mixed with liposomes (29–31). Protein antigens containing hydrophobic domains may physically associate with lipid bilayers even by simple mixing with liposomes. Hydrophilic peptides such as MUC1 peptides used in our study are unlikely to associate with lipid bilayer. This is confirmed by the lack of MUC1-specific antibody binding with BP25 encapsulated liposomes. Since short peptides are quickly degraded by peptidases and rapidly cleared, they are unlikely to induce immune responses unless they are delivered in physical association with liposomes. The ability of the liposomes to retain more than 90% of the MUC1 peptides at 37 °C suggests that a major fraction of the peptides will be delivered to the immune system in an associated rather than released form.

MUC1 peptide delivery by both encapsulated or surface-exposed liposome formulations was equally effective in priming T cell responses *in vivo*. Induction of T cell responses requires antigen uptake by professional APCs and presentation of the antigenic peptide in association with MHC molecules: MHC class II presentation for CD4⁺ T helper (Th) cells and MHC class I presentation for CD8⁺ cytotoxic T lymphocytes (CTLs) (32). Liposomes are efficient vehicles for antigen delivery to professional APCs (33). Phospholipids have been shown to facilitate antigen presentation by enhancing peptide binding to MHC class II molecules possibly by inducing conformational changes in MHC class II molecules (34). Liposomes are also efficient vehicles for induction of CTLs (35, 36). The strong antigen-specific T cell proliferation in response to MUC1 peptides *ex vivo* is an indication of successful *in vivo* priming of Th cells by immunization with the liposomal formulations. It is possible that CD8⁺ CTLs also might have contributed to the proliferative responses *ex vivo*. However, further studies on the CD4/CD8 profile of the activated T cells and MHC-restricted lysis of MUC1⁺ target cells are required to confirm *in vivo* priming of CTLs by immunization with the liposomal MUC1 peptide formulations.

The cytokine secretion pattern (IFN- γ but not IL-4) of the MUC1-specific T cells indicates that the immune responses induced by both liposomal formulations were of the T helper 1 (Th1) type (28). It has been previously proposed that liposome surface-exposed antigen preferentially follows a Th1 and encapsulated antigen follows a Th2 activation pathway on the basis of the immunoglobulin (Ig) isotype profiles (37). Another report has suggested that both encapsulated and surface-linked formulations induce a Th1 type immunity (31). The exact mechanisms by which our formulations bias the immune responses toward a Th1 type have not been examined. We hypothesize that antigen delivery by these formulations results in induction of IL-12, a key cytokine initiator of the Th1 pathway of immune response. Phagocytosis of liposomes by professional APCs may induce secretion of IL-12. Uptake of particulate materials has been reported to induce IL-12 secretion by macrophages and dendritic cells (38). Further, MPLA adjuvant may favor Th1 responses by induction of IL-12 secretion by APCs (39).

The mode of physical association of MUC1 peptide with

Figure 3. T cell responses induced by MUC1 peptide formulations after one or two immunizations (peptide dose, 2 nmol/mouse). T cells purified from lymph nodes were cultured along with antigen-presenting cells alone or in the presence of human MUC1 peptides (BP24 or BP25) or an irrelevant mouse MUC1 peptide (SP1-020) as shown. The stimulation index (SI) was defined as the ratio of counts per minute (cpm) of the peptide-stimulated cultures to the background cpm of peptide-free cultures. Error bars indicate the SD ($n = 4$).

Figure 4. Levels of IFN- γ in the 72 h T cell cultures from groups of mice immunized with the MUC1 peptide formulations. T cells purified from lymph nodes were cultured along with antigen-presenting cells alone or in the presence of human MUC1 peptides (BP24 or BP25) or an irrelevant mouse MUC1 peptide (SP1-020) as shown. Error bars indicate the SD ($n = 4$).

Figure 5. Anti-MUC1 IgG and IgM analysis from sera pooled from each group of mice immunized once (sc) with MUC1 peptide formulations. The polyclonal antiserum from BP16-KLH-immunized mice served as the positive control. The optical density (OD) was determined at a wavelength of 405 nm. Error bars indicate the SD ($n = 3$).

liposomes was found to be a key element for the humoral immune response induction. Only one formulation, LCP25 (N-terminally acylated BP25) liposomes with

surface-exposed MUC1 epitopes, elicited antibody production. No detectable antibody responses were induced by the BP25 encapsulated formulation, even though the

Figure 6. Anti-MUC1 IgG and IgM analyses from sera pooled from each group of mice immunized twice (sc and ip, 14 days apart) with MUC1 peptide formulations. The polyclonal antiserum from BP16-KLH-immunized mice served as the positive control. The optical density (OD) was determined at a wavelength of 405 nm. Error bars indicate the SD ($n = 3$).

Figure 7. Anti-MUC1 IgG isotype analyses from sera of the group of mice immunized twice with liposomal LCP25. The optical density (OD) was determined at a wavelength of 405 nm. Error bars indicate the SD ($n = 3$).

immunization routes (sc followed by an ip booster) were chosen to favor antibody production. These results are consistent with our previous studies where a MUC1 24mer peptide (BP24) encapsulated within liposomes also failed to induce detectable antibodies at a comparable dose ($5 \mu\text{g}/\text{mice}$) after three sc immunizations (21). White et al. (35) reported that a gp120 V3 loop peptide (P18) encapsulated in liposomes induced CTL responses, but not detectable antibody responses (35). Induction of antibody responses against V3 loop epitopes required presentation of the epitopes on the liposome surface. Antibody responses are initiated by B cell recognition of antigens through Ig receptors on their surface (40, 41). The lack of antibody responses against liposome-encapsulated MUC1 peptide may be due to the lack of antigen accessibility to the Ig molecules on B cells. Both encapsulated and surface-exposed peptide liposomes would be expected to be phagocytosed and processed by professional APCs such as dendritic cells and macrophages; however, only the liposomes with surface-exposed peptide would interact with B cells. Dal Monte and Szoka demonstrated that soluble and liposome surface-exposed but not encapsulated pigeon cytochrome c (PCC) antigen was processed and presented by B cells *in vitro* (42), whereas the encapsulated PCC was phagocytosed and

presented by macrophages (43). Thus, the lack of antibody responses against the liposome-encapsulated MUC1 peptide may be due to the lack of antigen accessibility to the Ig molecules on B cells. Another important factor influencing antibody responses is the epitope repetitiveness. Repetitiveness of viral epitopes is a key factor responsible for efficient cross linking of surface Ig receptors leading to strong B cell responses, including isotype switching (44). The LCP25 liposomes would be expected to present multiple surface-exposed MUC1 epitopes to B cells, leading to efficient B cell activation through cross-linking of surface Igs. B cell recognition of MUC1 epitopes in BP25 liposomes would be dependent on the slow release of the encapsulated peptide, which would be detected only as monomers. Another factor influencing the differential B cell responses might be the higher *in vivo* stability of the lipopeptide in comparison to the unmodified peptide (BP25) (45, 46).

Immunoglobulins induced by liposomal LCP25 included IgM and IgG, with a domination of IgG2b over IgG1 (94 versus 6%) and no detectable levels of IgG2a or IgG3. The induction of Ig isotypes is influenced by many factors, including antigen location, adjuvants, mice strain, and route of administration (18, 19, 47). Immunomodulatory properties of adjuvants can affect Ig isotype distribution. Enhanced expression of IgG2b over IgG1 was observed by using lipid-soluble MDP (muramyl dipeptide) liposome-encapsulated protein antigens, but not with water-soluble MDP liposomes (48). Using liposomal surface-conjugated peptides, Friede et al. also observed a predominant production of IgG2b over IgG1 (49). Dominance of IgG2a and/or IgG2b over IgG1 is associated with Th1 type immune responses and is augmented by IFN- γ (50, 51). The ratio of IgG2a:IgG2b titers is influenced by the mouse strain, with a predominance of IgG2a in A/J mice and a predominance of IgG2b in C57BL/6 mice (47, 52). The gene corresponding to IgG2a in C57BL/6 mice (IgG2c) is significantly different from that in Balb/c, and the commercial reagents for murine IgG2a might not cross-react substantially with this isotype in C57BL/6 strains (53, 54). Therefore, IgG2b responses are a better indicator of Th1 responses

in C57BL/6 mice. Thus, the isotype distribution of humoral immune responses also confirmed that Th1-associated immune responses were induced by liposomal LCP25.

In summary, immune responses were profoundly influenced by characteristics of the liposome formulations. This study demonstrated that liposome delivery systems could be tailored to induce preferential cellular or humoral immune response. Our results suggest that encapsulation of peptide antigens in liposomes offers an approach to selective induction of T cell responses without activation of the humoral responses. Alternatively, surface display of peptides on liposomes would allow activation of humoral responses without compromising T cell responses. Such selective immune manipulations are useful in defining the protective immune responses against infections and cancer and are of special significance to therapeutic cancer vaccines. The results of this study are also relevant to vaccine design in general.

ACKNOWLEDGMENT

We thank Ms. Deborah Sosnowski, Ms. Ann Burrell, Ms. Brenda Christian, and Mr. Aldo Ritacco for their excellent technical assistance. Financial support for Ms. Holly Guan was provided by a Province of Alberta Postgraduate Fellowship. We thank the Medical Research Council of Canada for financial support of this work through a research grant to Dr. John Samuel (MT-13261).

Kinetic Studies on the Immobilization of Antibodies to High-Performance Liquid Chromatographic Supports

Matthew R. Oates, William Clarke, Elizabeth M. Marsh, and David S. Hage*

Department of Chemistry, University of Nebraska, Lincoln, Nebraska 68588-0304. Received August 17, 1997; Revised Manuscript Received January 14, 1998

Several factors can potentially affect the rate of immobilization of proteins onto solid supports, such as those used in affinity-based high-performance liquid chromatography. This study examined several of these factors and their influence on the coupling of periodate-treated rabbit immunoglobulin G antibodies to dihydrazide-activated silica. Items considered included the number of potential coupling sites on the antibodies, the density of activated sites on the support, the relative amount of antibody combined with the support, and the density of the overall reaction slurry. In each case, the rate of change in the solution-phase antibody concentration gave biphasic behavior which could be described by two competing pseudo-first-order reactions. The overall immobilization rate was essentially independent of the density of the support's activated sites (when present at a coverage of 0.1–0.4 $\mu\text{mol}/\text{m}^2$) but was strongly influenced by the number of available coupling groups on the antibodies. Increasing the slurry density had no appreciable effect on the immobilization rate, and the reaction rate showed only a small change when using different types of reagents for support activation (e.g., adipic vs oxalic dihydrazide). These results are consistent with a mechanism in which the rate-limiting step during immobilization is the covalent attachment of antibodies to the support and not mass transfer of antibodies to the support's surface.

INTRODUCTION

Affinity chromatographic supports, such as those based on immobilized antibodies, are playing an ever-increasing role in the development of new separation and analysis methods for compounds of biological, industrial, or environmental interest (1–5). In recent years, the development of high-efficiency supports with good biocompatibility (e.g., diol-bonded silica or perfusion-type media) has promoted the use of various affinity ligands in high-performance liquid chromatography (HPLC)¹ (1–7). This, in turn, has made affinity supports even more attractive for advanced analytical methods such as immuno-analytical assays, on-line monitoring methods for biotechnology or environmental testing, and multidimensional schemes in which affinity extraction is coupled with methods like reversed-phase or size-exclusion chromatography (3–5). There are a variety of procedures available for attaching proteins and other ligands to HPLC supports for use in affinity columns (1–3, 7). However, there is little information available in the literature regarding the immobilization kinetics of these methods. Such data would be valuable in the design and optimization of new HPLC affinity media, particularly as the demand for more efficient supports and more rapid method development increases. There have been numerous studies in the past that have examined the kinetic processes behind the physical adsorption of proteins to various solid matrixes (8–21), including chromatographic materials such as silica (e.g., see refs 17–21). The general kinetic model used in these studies involves two

initial steps: (1) mass transfer of protein to the liquid–solid interface and (2) adsorption of the protein to unoccupied regions on the support's surface; a similar model would be expected to hold for covalent protein immobilization but with the adsorption step now being replaced with one involving the coupling of protein to the surface of the support. In many cases, the physical adsorption of proteins to silica and other supports has been reported to occur at a rate that is limited mainly by protein mass transfer to the surface (i.e., a diffusion-limited system) (8, 14–17), but there have also been cases in which adsorption has been noted to be the rate-limiting step (10, 12). The relative importance of these steps in determining the overall rate for the covalent immobilization of antibodies will be one item investigated in this work.

This study will examine the rate of antibody immobilization onto HPLC-grade media by using periodate-treated rabbit immunoglobulin G as the model ligand and dihydrazide-activated silica as the model support. This particular system is of practical importance since antibodies are frequently used as ligands in affinity-based HPLC (3–5), and dihydrazide-activated supports are commonly used for their immobilization (7, 22–25). Furthermore, previous work has shown that several important experimental variables, such as the number of potential coupling sites available on each antibody and the surface coverage of active sites on the support, can be controlled in this system through the proper selection of conditions for the periodate oxidation of antibodies (24, 25) or for the preparation of dihydrazide-activated silica (23). Along with these variables, other factors that will be considered in this study with regard to immobilization rates will include the effect of varying the relative amount of antibody in contact with the support and the density of the overall reaction slurry. Such work should

provide information on the overall importance of these factors in determining the net rate of antibody immobilization. The same data should also provide clues regarding the roles played by mass transfer versus covalent attachment in the immobilization kinetics of antibodies and other proteins.

EXPERIMENTAL PROCEDURES

Reagents. Oxalic dihydrazide, adipic dihydrazide, and Lucifer yellow CH (LyCH) were from Aldrich (Milwaukee, WI). HPLC-grade Nucleosil Si-1000 silica (7 μ m particle diameter, 1000 Å pore size, 25 m²/g surface area) was obtained from Alltech (Deerfield, IL). The rabbit immunoglobulin G (IgG), *p*-periodic acid reagent (i.e., periodic acid), and 2,4,6-trinitrobenzenesulfonic acid (TNBS) were from Sigma (St. Louis, MO). Ethylene glycol and Triton X-100 were obtained from Fisher Scientific (Pittsburgh, PA). Reagents for the bicinchoninic acid (BCA) protein assay were from Pierce (Rockford, IL). All other chemicals were reagent-grade or better. All aqueous solutions were prepared using deionized water from a Nanopure water system (Barnstead, Dubuque, IA).

Apparatus. Samples for the manual BCA protein assay and TNBS assay were analyzed using disposable polystyrene cuvettes (Fisher Scientific) and a Shimadzu UV160U absorbance spectrophotometer (Kyoto, Japan). The degree of antibody oxidation was determined by labeling the oxidized antibodies with LyCH (26) and analyzing the degree of LyCH conjugation by flow injection analysis (FIA), as described previously (27). The application buffer for the FIA system was delivered by a Xper-Chrom model 400 pump from P. J. Cobert (St. Louis, MO); the BCA reagent for the same system was delivered by a model J120 cassette pump from Manostat (New York, NY). The LyCH label was detected at 428 nm on the FIA system by using a SM3100X absorbance detector from LDC/Milton Roy (Riviera Beach, FL), and the colored BCA product was detected at 562 nm using a V⁴ absorbance detector from ISCO (Lincoln, NE). The FIA samples were injected using a Rheodyne 7012 injection valve (Cotati, CA) equipped with a 20 μ L sample loop. The BCA reagent was combined with samples in the FIA system by using a standard mixing tee (Upchurch, Oak Harbor, WA), followed by passage of the mixture through a serpentine type II reaction chamber made from 1.0 m $\times$ 0.5 mm inner diameter PTFE tubing (28). This reaction chamber was immersed in an adjustable water bath set at 80 °C.

Methods. The diol-bonded silica and dihydrazide-activated supports were prepared from Nucleosil Si-1000, according to the scheme shown in Figure 1. The final diol coverage of the Nucleosil prior to activation by dihydrazide groups was 62 ± 4 μ mol of diol per gram of silica, as determined in triplicate by an iodimetric capillary electrophoresis method (29). The oxalic and adipic dihydrazide-activated supports were both prepared from the same batch of diol-bonded silica. Various degrees of dihydrazide coverage were obtained on these supports by controlling the amount of diol oxidation that was used during support preparation, as described in ref 23. The final coverage of activated sites on each support was determined by reacting the final material with an excess of TNBS, followed by washing away of the excess reagent and measurement of the resulting colored product by suspending the treated silica in a saturated sucrose solution and determining the absorbance of the suspension at 425 nm (23).

Table 1. Oxidation Conditions Used To Generate Rabbit IgG Antibodies with Various Levels of Potential Coupling Sites

pH	[periodic acid] (mM)	oxidation time (min)	degree of oxidation (mol of LyCH/mol of IgG) ^a
5.0	0.05	10	0.6 (± 0.1)
7.0	10.0	10	0.9 (± 0.1)
5.0	10.0	30	2.0 (± 0.1)
4.0	10.0	60	3.6 (± 0.1)
3.0	10.0	60	4.6 (± 0.1)

^a The numbers in parentheses represent a range of ± 1 SD. The value of moles of LyCH per mole of IgG is a measure of the average number of reactive aldehyde groups per IgG molecule that are available for coupling to a hydrazide-containing reagent (24).

The number of potential coupling sites on the rabbit IgG antibodies was varied by altering the pH and time used to treat the antibodies with periodic acid (24). All antibody oxidation was carried out at 25 °C using a rabbit IgG concentration of 1 mg/mL in 0.02 M sodium acetate buffer containing 0.15 M sodium chloride; Table 1 lists the other conditions that were used for antibody oxidation. After each oxidation mixture had been reacted for the appropriate length of time, ethylene glycol was added to quench the reaction. The ethylene glycol and remaining periodate were then removed by size-exclusion chromatography and dialysis, as described earlier (26); during this process, the antibodies were placed into a pH 6.0, 0.10 M phosphate buffer for the immobilization step. The final oxidized antibody preparations were either used immediately or stored for short periods of time at 4 °C prior to being used.

Antibody immobilization was carried out by mixing each oxidized antibody preparation with a fixed amount of dihydrazide-activated silica suspended in pH 6.0, 0.10 M phosphate buffer. This mixture was vortex-mixed, placed onto an inversion shaker, and allowed to react for various lengths of time at 4 °C. Aliquots were periodically removed from this mixture and centrifuged to remove the supernatant from the silica. The protein content in the supernatant was then determined in duplicate by a manual BCA assay (30), with rabbit IgG being used as the standard. Similar control studies were performed with nonoxidized antibodies in the presence of diol-bonded or dihydrazide-activated silica and with oxidized antibodies in the presence of diol-bonded silica.

Figure 2. Immobilization rate of rabbit IgG when the coverage of activated groups on the surface of adipic dihydrazide-activated silica was (Δ) 3.0, ($\diamond$) 5.8, (+) 7.3, or ($\blacksquare$) 10.5 μmol of reactive hydrazide groups per gram of silica.

RESULTS AND DISCUSSION

Effect of Support Active Site Coverage on Antibody Immobilization Rate. The first series of studies examined the effect on the rate of antibody immobilization when the support's surface coverage of active sites to which the antibody could be attached was changed. In our model system, the coverage of active hydrazide groups was varied by adjusting the amount of periodate used in converting diol-bonded silica into an aldehyde-activated form (i.e., see the second step in Figure 1) prior to reaction of this support with a dihydrazide reagent (23). The conditions used in this work involved converting 25–100% of the available diol groups into aldehydes for reaction with adipic dihydrazide; under these conditions, the final coverages obtained for active hydrazide groups ranged from 3 to 10.5 $\mu\text{mol/g}$ of silica, or 0.12–0.42 $\mu\text{mol/m}^2$, in agreement with previously reported results (23).

Figure 2 shows the results obtained when a constant amount of oxidized rabbit IgG was reacted with fixed amounts of several silica samples that had various surface coverages of active hydrazide groups. The IgG was oxidized under conditions that produced two available aldehyde groups per antibody (see conditions in Table 1 for 2.0 mol of LyCH/mol of IgG); the total amount of added antibody was 2.2 $\mu\text{mol/L}$ or 0.33 g/L (5 mg in 15 mL), and the amount of silica in the reaction slurry was 13.3 g/L (200 mg in 15 mL). Under these conditions, the active hydrazide groups were present in a 13–67-fold molar excess versus the antibodies, and the maximum degree of antibody immobilization that could be achieved was approximately 0.3 monolayer. It can be seen from Figure 2 that essentially the same rate of antibody immobilization was observed for each surface coverage of active hydrazide groups. The consistency of these results implies that, under these particular conditions, the immobilization rate of IgG was independent of the silica's active group coverage. In other words, the immobilization rate appears to have had a zero-order dependence on the surface concentration of the support's active sites. Similar control studies performed with nonoxidized rabbit IgG in the presence of either diol-bonded silica or the dihydrazide-activated silica did not give rise to any observable immobilization; this indicated that the results in Figure 2 were due to specific covalent attachment rather than a process involving nonspecific physical adsorption of the antibodies to the silica surface (23).

Figure 3. Immobilization rate observed for rabbit IgG for reaction mixtures containing ($\blacksquare$) 2.2, ($\diamond$) 1.1, or (Δ) 0.33 g/L IgG and 13.3 g/L adipic dihydrazide-activated silica. The total amount of IgG used in these experiments corresponded to maximum theoretical coverages on the support of approximately 2.0, 1.0, or 0.3 monolayers, respectively.

Although it may at first be surprising that the immobilization rate is essentially independent of the support's active group coverage, this can be explained by considering the relative size of an antibody versus the average area occupied by an active site on the support. For example, rabbit IgG (MW of 150 kDa) has a Stoke's diameter of approximately 100 Å (31), which gives this protein a cross-sectional area of about 7900 Å² when it is described as a spherical molecule. In contrast to this, a support with an active site coverage of 0.1–0.4 $\mu\text{mol/m}^2$, as used in this work, would have an average area per active site ranging from 1600 to 400 Å², respectively. This means that each rabbit IgG molecule will cover an area occupied by about 19–20 active sites (at 400 Å²/site) or 4–5 active sites (at 1600 Å²/site). The fact that there is a large molar excess of these active sites versus each antibody, and that these active groups are nonmobile, supports a model in which the coverage of these groups is not an important factor in limiting the number of effective collisions between the antibodies and the support during the immobilization process. At much lower surface coverages of the active sites, some dependence of the immobilization rate on active site coverage would be expected, but it is anticipated that the conditions required to achieve this are well below those typically used in affinity supports for HPLC (e.g., 0.02 μmol of active groups/ m^2 would be needed to obtain an average of only one active hydrazide site per 7900 Å², the approximate cross-sectional area of rabbit IgG).

Effect of Antibody Concentration on Immobilization Rate. A second factor considered in these immobilization studies was the role played by antibody concentration in determining the net rate of reaction. Figure 3 illustrates how antibody concentration affected the immobilization rate for rabbit IgG on adipic dihydrazide-activated silica. As in the previous section, the oxidized IgG contained about two available aldehyde groups per antibody and the amount of silica in the reaction slurry was 9–13 g/L; the degree of support activation was 3.0 μmol of hydrazide groups/g of silica for the 0.33 g/L IgG data and 10–11 $\mu\text{mol/g}$ for the 1.1–2.2 g/L IgG results. The initial amount of rabbit IgG in solution for the experiments shown in Figure 3 ranged from 0.33 to 2.2 g/L; these levels correspond to maximum theoretical coverages on the support of 0.3–2 monolayers (i.e., antibody amounts that ranged from below that

Figure 4. Relative change in solution-phase antibody concentration as a function of time for the immobilization of rabbit IgG to adipic dihydrazide-activated silica. The initial IgG concentration was 0.33 g/L; the level of silica was 13.3 g/L, and the degree of antibody oxidation was 2.0 reactive aldehydes/mol of IgG. In this graph, $[P]_t$ represents the molar concentration of protein in the supernatant at time t , $[P]_0$ is the initial protein concentration in the supernatant, and $[P]_\infty$ is the amount of protein remaining in the supernatant after the immobilization reaction has reached completion. The inset shows an enlarged view of the data points obtained over the first 10 h of the reaction.

needed to saturate the support's surface to amounts in excess of the surface area available for immobilization).

The reaction profiles in Figure 3 (and also those shown earlier in Figure 2) are typical of those seen throughout our immobilization studies with rabbit IgG. Such profiles generally included a fast rate of antibody immobilization during the first day of the reaction, followed by a slower rate that proceeded over much longer times. This type of biphasic behavior has been noted over a shorter time scale for the physical adsorption of human serum albumin (9), lysozyme, β -lactoglobulin, and hemoglobin to silica (21) and for the adsorption of bovine serum albumin, IgG, fibrinogen, and polylysine to poly(vinyl chloride) or methylacrylic-methacrylate copolymers (13).

The immobilization reaction in this study was essentially complete after 12–14 days when working with antibody levels at or below a theoretical support coverage of 1 monolayer (see Figure 2 and data in Figure 3 at 0.33 and 1.1 g/L IgG). For higher amounts of antibody (see data in Figure 3 for 2.2 g/L IgG), the reaction was also complete after 12–14 days, with the excess antibodies remaining in solution as a nonimmobilized fraction. This time frame is several orders of magnitude longer than that observed in any previous studies for the physical adsorption of proteins (including antibodies and silica supports) under mass-transfer-limited conditions (8, 14–21) and suggests a reaction mechanism in which the overall immobilization rate is controlled mainly by the rate of covalent attachment of antibodies to the support.

A more detailed analysis of the antibody immobilization data by using log concentration versus time plots consistently gave a response with two linear regions (see Figure 4). This fits a model in which the net rate of antibody immobilization to dihydrazide-activated silica can be described by two competing pseudo-first-order processes; a similar model has previously been used by others to describe the physical adsorption of various proteins to silica (21). The data obtained by these plots for studies at relatively low antibody levels (e.g., the results in Figure 4 at 0.33 g/L rabbit IgG and 13.3 g/L

silica) gave an apparent first-order rate constant for the fast immobilization reaction of approximately (1.9 ± 0.3) (one SD) $\times 10^{-5} \text{ s}^{-1}$ (half-life, 10 h); the same data gave an apparent first-order rate constant for the second, slower immobilization reaction of (4 ± 1) (one SD) $\times 10^{-6} \text{ s}^{-1}$ (half-life, 2 days). Similar rate constants were obtained at each of the other antibody levels that were tested in this study.

As mentioned earlier, control experiments with diol-bonded or dihydrazide-activated silica and nonoxidized rabbit IgG did not give rise to any observable antibody immobilization. This indicated that neither the fast nor slow immobilization reactions seen in Figure 4 were due to physical adsorption of the antibodies to the support. However, it was found that the combination of oxidized antibodies with diol-bonded silica did give rise to antibody attachment. In this case, a plot of the log of the antibody concentration versus time gave linear behavior (correlation coefficient = 0.9813 for 18 data points obtained over 0–1.2 days), as seen earlier for the dihydrazide-activated supports, indicating that the reaction of oxidized antibodies with diol-bonded silica was also a pseudo-first-order process. Furthermore, the apparent rate constant for the oxidized antibody–diol-bonded silica reaction $[(1.7 \pm 0.1) \times 10^{-5} \text{ s}^{-1}]$ was statistically identical to the value obtained in Figure 4 for the fast reaction of oxidized antibodies with dihydrazide-activated silica. This suggests that it is the remaining diol groups on the silica (and also perhaps primary alcohols that are generated in the third step of the reaction scheme in Figure 1) that are responsible for the fast immobilization process on both types of supports. Although further work is needed to conclusively identify the mechanism for this fast process, one strong possibility is that the aldehyde groups on the oxidized antibodies are forming acetal or hemiacetal linkages with secondary and primary alcohols on the surface of the silica. Regardless of whether this is the actual mechanism for the fast reaction, the results of this control study do indicate that the second, slower immobilization process seen for dihydrazide-activated silica is the one that actually represents the attachment of oxidized antibodies to active hydrazide groups on this support.

Effect of Antibody Coupling Sites on Immobilization Rate. Besides antibody concentration, this report also considered how varying the number of potential coupling sites on an antibody affected its net rate of immobilization. This factor was controlled by varying the oxidation conditions used during the periodate treatment of antibodies prior to immobilization. As discussed in detail previously (24, 25), using different times, temperatures, pHs, or periodate concentrations for antibody oxidation can lead to the production of various amounts of active aldehyde groups on an antibody's carbohydrate residues. This, in turn, leads to different numbers of sites at which hydrazide groups on the support can attach to the antibodies for immobilization.

Figure 5 shows the results obtained for adipic and oxalic dihydrazide-activated silica supports when they were reacted with rabbit IgG containing an average of 0.6–4.6 available aldehyde groups per antibody molecule, as prepared according to the oxidation conditions shown in Table 1. The total amount of antibody used in each case was 0.33 g/L, and the silica content in the reaction slurry was 13.3 g/L. The coverages of active hydrazide groups on the adipic and oxalic dihydrazide-activated supports were both in the range of 5–6 $\mu\text{mol/g}$ of silica (23). The general behavior of the plots in Figure 5 was the same as that noted in the previous studies (see

Figure 5. Immobilization rates observed for rabbit IgG containing various amounts of potential coupling sites in the presence of (a) adipic dihydrazide-activated silica or (b) oxalic dihydrazide-activated silica. In panels a and b, the number of potential coupling sites on the antibodies was (∇) 0.6, ($\blacksquare$) 0.9, (+) 2.0, ($\diamond$) 3.6, or ($\times$) 4.6 aldehydes per IgG.

Figures 2–4) in which a fast rate of antibody immobilization occurred during the first day of the reaction, followed by a slower immobilization rate over longer reaction times. Similar rates were observed for the oxalic and adipic dihydrazide supports when antibodies containing 0.6 available aldehyde per IgG were used, but a slightly faster immobilization rate was seen for the oxalic dihydrazide-activated support with antibodies that contained an average of 0.9–4.6 aldehydes per IgG. The exact reason for this apparent difference is still under investigation, but it is probably related to the different local environments that are known to be present for the immobilized oxalic and adipic dihydrazide groups. For example, it has been shown previously that these two reagents yield different fractions of active hydrazide residues as the density of aldehyde groups on silica surface is varied; this behavior is, in turn, related to the different chain lengths of these dihydrazide reagents and their different tendencies to undergo bifunctional attachment to aldehyde-activated silica (23).

It can be seen in Figure 5 that, when the average number of aldehyde groups per antibody was less than one (e.g., 0.6 or 0.9 aldehyde/IgG), a significant fraction of antibodies remained in solution after 14 days of reaction. This occurred because not all of the antibodies possessed coupling sites (i.e., aldehyde groups) under such conditions. For example, the data obtained when working with antibodies that had an average of 0.6 aldehyde per IgG might represent a situation in which

Figure 6. Plots of (a) the relative change in solution-phase antibody concentration as a function of time for the immobilization of rabbit IgG to adipic dihydrazide-activated silica for antibodies containing (∇) 0.6, ($\blacksquare$) 0.9, (+) 2.0, or ($\diamond$) 3.6 available aldehyde groups per IgG and (b) the change in the apparent pseudo-first-order rate constant (k_{app}) for the slow immobilization reaction as a function of the degree of antibody oxidation. The data used in generating these plots were obtained from Figure 5a. All abbreviations used on the y-axis in panel a are the same as those defined in Figure 4.

just under half of the antibodies had no aldehyde groups and the remainder had only one such group per IgG (e.g., if all oxidation took place at only terminal sialic acid residues) (24). Because of this, it was only at higher degrees of oxidation (2.0–4.6 aldehydes per IgG) that essentially complete immobilization of all antibodies was observed.

Examples of first-order kinetic plots that were obtained for the data in Figure 5 are shown in Figure 6. As discussed earlier, the general trend seen was one in which the reaction obeyed pseudo-first-order kinetics with respect to antibody concentration, with two competing reactions (one fast and one slow) being present. However, one interesting feature now observed was the fact that the reaction rates showed a strong dependence on the number of aldehyde groups available on the antibodies for coupling to the dihydrazide-activated support. This was most clearly seen for the slower immobilization process, in which the apparent pseudo-first-order rate constant increased with the average number of aldehyde groups per IgG (see Figure 6b). Such behavior is an indication of the importance of an antibody having the correct orientation in obtaining an effective collision with the support for immobilization. In addition, this result further supports a mechanism in which the net rate of immobilization is controlled by the rate of covalent coupling between the antibody and the support.

Figure 7. Change in the immobilization rate for rabbit IgG when using silica amounts in the reaction slurry of (+) 20, (◇) 13, (x) 6.7, or (Δ) 3.3 g/L.

Effect of Slurry Density on Antibody Immobilization Rate. A final study was performed to determine the effect of varying the slurry density of the reaction mixture on the observed rate of antibody immobilization. The results are shown in Figure 7. These graphs were generated using antibodies containing an average of 2 aldehyde groups per IgG. The support was adipic dihydrazide-activated silica that contained 10–11 μmol of hydrazide groups per gram of silica. The slurry density was varied by adjusting the volume of buffer present in the reaction mixture while keeping a constant mass of added antibodies and silica (i.e., a ratio of 1 mg of rabbit IgG per 40 mg of silica or a maximum theoretical coverage of 0.3 monolayer for IgG on the silica's surface).

The data in Figure 7 show that only random changes occurred in the immobilization rate when support concentrations of 3.3–20 g/L and IgG concentrations of 0.08–0.5 g/L were used. Kinetic plots made with these data gave the same type of biphasic behavior seen in Figures 4 and 6a; the pseudo-first order rate constants obtained also agreed with those given in the previous sections. The consistency of the results in Figure 7 indicates that the slurry density was not an important factor in controlling the rate of antibody immobilization. This is again consistent with a reaction mechanism in which the net rate of rate of immobilization is controlled mainly by the rate of antibody attachment rather than by antibody mass transfer to the surface of the support.

CONCLUSIONS

This work considered several factors that can potentially affect the immobilization rate of antibodies onto HPLC supports, using rabbit IgG and dihydrazide-activated silica as a model system. The overall immobilization rate was essentially independent of the density of the support's activated sites (when present at a coverage of 0.1–0.4 $\mu\text{mol}/\text{m}^2$) but was strongly influenced by the number of available coupling groups on the antibodies. Increasing the slurry density of the support and antibodies in the reaction mixture had little or no effect on the immobilization rate, and the reaction rate showed only a small change when different types of reagents were used for support activation (e.g., adipic vs oxalic dihydrazide).

In each case studied, the rate of change in the solution-phase antibody concentration gave biphasic behavior which could be described by two competing pseudo-first-order reactions. One of these reactions was relatively fast (half-life, 10 h), while the second proceeded at a much

slower rate (half-life, 2 days). Through control experiments, it was found that both processes required the presence of antibody oxidation, indicating that these reactions were due to covalent linkages rather than due to simple physical adsorption. It was further determined that the fast and slow reactions were most likely the result of the coupling of oxidized antibodies with (1) secondary or primary alcohols on the support and (2) active hydrazide residues on the support, respectively.

The results of this study provide some interesting insights into the kinetics of antibody immobilization and the factors which are most important in influencing the rates of such reactions. For example, the results of this work consistently indicated that antibody attachment (vs mass transfer) was the rate-limiting step in controlling the overall immobilization process; this behavior is much different from that generally seen for the physical adsorption of proteins to surfaces, a reaction which often tends to be mass-transfer-limited (8, 14–17). It is expected that many of the trends reported in this work apply not only to antibodies but also to other proteins during their immobilization to small diameter supports. The data provided in this study should also be useful in providing some initial guidelines regarding the selection of conditions for the preparation of affinity-based HPLC media.

Use of N^{α} -Fmoc-cysteine(*S*-thiobutyl) Derivatized Oligodeoxynucleotides for the Preparation of Oligodeoxynucleotide–Peptide Hybrid Molecules

Sommay Soukchareun,* Jim Haralambidis, and Geoffrey Tregear

The Howard Florey Institute of Experimental Physiology and Medicine, University of Melbourne, Parkville, Victoria 3052, Australia. Received January 14, 1998; Revised Manuscript Received April 17, 1998

The chemical modification of antisense oligodeoxynucleotides (ODNs) by conjugating synthetic peptides of known membranotropic activities to the 3' and/or 5' terminus of ODNs may serve two functions that are important for increasing their bioavailability by protecting the ODNs from exonuclease digestion and facilitated delivery into cells. We have previously reported the preparation of ODN–peptide conjugates by the total synthesis approach. However, by such technology the preparation of ODN–peptide conjugates in amounts sufficient for in vitro functional analysis is at present limited to the syntheses of peptides containing residues without acidolytic deprotection. Requisite to the alternative method of site-specific conjugation, the segment coupling approach is the derivatization of an ODN with a nucleophilic moiety. In this paper, we describe a novel method of functionalizing synthetic ODNs by incorporating *S*-thiobutyl-protected N^{α} -Fmoc-cysteine to aminopropyl-functionalized CPG by standard N^{α} -Fmoc SPPS methodology. The derivatized solid support can be used to synthesize an ODN of any sequence by the phosphoramidite chemistry, and the removal of the *S*-thiobutyl side chain function can be conveniently affected by the standard aminolytic deprotection of ODNs containing 1 M DTT. The purified cysteine-derivatized ODN was shown to react specifically and efficiently with two types of synthetic peptides corresponding to regions within the glycoprotein (gp) of HIV that have been shown to have membranotropic activities: a 18 residue maleimide-derivatized Tat peptide of the transactivator (*tat*) of HIV and a 22 residue peptide corresponding to the carboxyl terminus of gp41(Ca-gp41).

INTRODUCTION

The potential of antisense oligodeoxynucleotides (ODNs) as chemotherapeutic agents for the treatment of AIDS as well as for the control of other viral infections lies in the predictability and specificity by which the antisense ODNs interact with the target mRNA to inhibit protein expression (1). Many instances of specific antisense inhibition have been documented (2, 3). However, the low intracellular bioavailability of ODNs, due to both their susceptibility to enzymatic degradation and their low penetration into cells, are two well-recognized factors that limit their therapeutic potential. To overcome these limitations, a class of chemically modified antisense ODNs was designed that contained peptides covalently linked at the 3'- or 5'-terminus of ODNs. The tethered peptides, usually chosen for their membranotropic activities, serve to protect ODNs from exonuclease digestion and to facilitate intracellular uptake.

There are two general methods for the preparation of structurally discrete and well-characterized ODN–peptide hybrid conjugates: the fragment coupling strategy and the total synthesis method, which requires the consecutive assembly of the peptide and then the ODN on a solid support that has been functionalized with a base-labile handle. With few exceptions (4), the assembly of the peptide is achieved by the N^{α} -fluoren-9-ylmethoxycarbonyl solid-phase peptide synthesis (Fmoc SPPS)

chemistry (5, 6). After the peptide is assembled and the N^{α} -Fmoc group of the terminal amino acid residue is deprotected, reaction with a heterobifunctional linker converts the N-terminus to a protected hydroxyl functionality suitable for solid-phase DNA synthesis. Using such method, we recently reported the synthesis of ODN–peptide conjugates containing the gp41 fusion peptide by the use of α,ω -hydroxycarboxylic acid linker (7). De la Torre et al. (4) extended this approach to the synthesis of a hybrid conjugate containing a nuclear targeting signal peptide. However, one of the major shortcomings of the total synthesis approach is that the chemistry used for the deprotection and cleavage of the peptide and ODN is often incompatible. Thus, the deprotection of peptides by acidolysis, essential to the chemical syntheses of peptides prepared by the N^{α} -Fmoc or N^{α} -Boc chemistry, may also induce depurination and degradation of the preformed ODNs (8, 9).

One way of circumventing the problems associated with the incompatible deprotection chemistry is to prepare conjugates by the classical segment coupling strategy whereby the peptides and ODNs are separately synthesized by standard solid-phase methods and derivatized with functionalities that are mutually reactive. The reaction between the functionalized ODN and peptide components is achieved in solution, after which the conjugate is purified. Methods for the derivatization of synthetic ODNs at the 5'- or 3'-terminus follow two basic routes. The first is performed largely in aqueous solutions, and it involves the conversion of the 5'-hydroxyl groups of the deprotected ODNs to an amino (10, 11), sulfhydryl (12, 13), aldehyde (14), or hydrazide group (15)

by postsynthetic derivatization reaction. In an alternative approach, a suitably protected linker containing a masked nucleophilic function such as 5'-mercapto-5'-deoxynucleoside phosphoramidite (16), aminoalkyl alcohol derivatives (17, 18), or triphenylmethyl-*O*-methoxymorpholinophosphite derivatives of 3-mercaptopropanol and 6-mercaptohexanol (19) is incorporated on the 5'-terminus of the ODNs in the last cycle of DNA synthesis.

Although many combinations of chemical groups can be used to achieve chemoselective coupling, the nucleophilic power and specificity of reaction of the thiol functional groups have been used to afford specific and rapid reaction with a wide variety of substrates that have been derivatized with electrophilic groups such as maleimides, isothiocyanates, bromomethyl aromatics, and haloacetamides (20).

Although recent evidence indicates that endonuclease activity in cells is also a significant determinant of ODN stability, the investigations of the stability of antisense oligonucleotides in the presence of cell culture media (21, 22) and cellular lysates (22) indicated that the predominant degradative activities were mediated by enzymes directed toward the 3'-terminus of ODNs. In the development of ODN–peptide conjugates as improved antisense inhibitors, chemical modification strategies that prolong the biological half-life of ODNs may be achieved by ligating a peptide to the 3'-terminus of ODNs. However, existing methods used to introduce a nucleophilic function at the 3'-terminus of synthetic ODNs are laborious. Zuckerman et al. described the synthesis of 3'-thiolated ODNs by linking 3,3'-dithiodipropanol derivatives of thymidine to AP-CPG solid support by a disulfide exchange reaction (23). The modified thiol nucleoside used in this reaction was prepared from the 5'-dimethoxytrityl (DMT) protected thymidine. Phosphorylation of the nucleoside with 2-chlorophenyl-*O,O*-bis(1-benzotriazolyl) phosphate activated the nucleoside for subsequent reaction with 3,3'-dithiodipropanol giving rise to a thiol-containing thymidine (protected as a disulfide), which was subsequently coupled to aminopropyl CPG that was then used to synthesize DNA by the phosphoramidite or phosphotriester chemistry. After DNA synthesis, the exocyclic amino protecting groups of the bases of the 3'-disulfide-containing ODN were deprotected by standard methods. The purified 3'-thiolated ODN was further reacted with 2,2'-dithiodipyridine to form the 3'-*S*-thiopyridyl oligonucleotide derivative, which was subsequently shown to react efficiently with thiolated fluorescein or to cross-link with cysteine-derivatized *Staphylococcal* nuclease protein to generate a hybrid deoxyribonuclease. Functionalizing the 3'-terminus of synthetic ODNs by this technique is laborious since the protocol requires the preparation of four different solid supports, each individually derivatized with a disulfide-linked nucleotide. A similar and more versatile method is the coupling of an activated AP-CPG support with an *O*-DMT-6-mercaptohexanol derivative via a disulfide linkage. Activation of the CPG starts with the reaction of the thiol-derivatized CPG with 2,2'-dithiobis(5-nitropyridine) (DNTP). The DNTP-activated support is then reacted with *O*-DMT-6-mercaptohexanol, giving rise to 3'-thiolated ODNs that are subsequently used to synthesize DNA. The reactivity of the 3'-thiol-derivatized ODN was demonstrated by its efficient conjugation to pyrenyl maleimide (24, 25). The method of native chemical ligation by chemoselective coupling of two protected peptides has been described (26). In this approach, the carboxyl terminus of one peptide is functionalized with a thioester, and the other is functionalized with a cysteine

residue. Thioester exchange produces an unstable thioester-linked intermediate that subsequently rearranges to form a stable peptide bond. An extension of this technique was described that involved the template-directed fusion of 3'-amine-terminated DNA with the DNA–peptide intermediate containing a thioester linkage, resulting in an oligonucleotide–peptide hybrid containing an amide bond (27).

In this paper, we describe the development of a novel strategy for incorporating the thiol nucleophile at the 3'-terminus of an ODN. This method offers several advantages over existing approaches. The masked sulphydryl function is incorporated onto the solid support by standard *N*^α-Fmoc SPPS, using a commercially available *N*^α-Fmoc derivative of thiobutyl-protected cysteine. The cysteine-derivatized solid supports can then be used to synthesize ODNs of any sequence. After DNA synthesis, the protecting groups on the nucleotide bases of the ODNs and the pendant cysteine residue are conveniently removed by treating the support with a mixture of DTT in concentrated aqueous ammonia.

EXPERIMENTAL PROCEDURES

General. Derivatization of AP-CPG as well as the synthesis of the Ca-gp41 and the Tat peptide were performed on the Biolynx 4175 peptide synthesizer (LKB Biochrom, Cambridge, England) using continuous-flow solid-phase peptide synthesis (SPPS) protocols. Automated DNA synthesis was carried out on an Applied Biosystems 380A DNA synthesizer using standard β -cyanoethyl nucleoside phosphoramidites. Amino acid analyses were carried out on a Beckman system 6300 analyzer after hydrolysis of the samples in evacuated, sealed tubes for 24 h at 130 °C with 6 N hydrochloric acid/0.1% phenol. Preparative and analytical reversed-phase high-performance liquid chromatography (RP-HPLC) was carried out on a Waters liquid chromatography system consisting of a Waters 600 multisolvent delivery system connected to a variable wavelength detector. The ODN-(ϵ Ahx)₂-Cys were purified with either a Synchropak semipreparative RP-C18 column (10 × 250 mm, 300 Å pore diameter, 6.5 μ m particle size, Synchrom, Lafayette, IN) with flow rates of 3 mL/min at 260 nm detection. The peptides were purified using a Vydac semipreparative C18 column (10 × 250 mm, 300 Å pore diameter, 6.5 μ m particle size) with buffers composed of aqueous trifluoroacetic acid (0.1% TFA) and acetonitrile in 0.1% TFA. The gel filtration column was connected to an LKB 2138 UV-ICORD detector, and the eluate was dispensed directly into an LKB 7000 Ultrafrac fraction collector. The ODN–peptides were 5'-end labeled using polynucleotide kinase and γ -³²P-[ATP] according to established procedures (7, 28) and analyzed by polyacrylamide gel electrophoresis (PAGE).

Materials. All reagents, unless otherwise stated, were of analytical grade. Controlled pore glass resin (CPG, 200–400 mesh, pore size of 500 Å, Catalog No. 27720) was obtained from Fluka. *N*^α-Fmoc pentafluorophenyl (pfp) esters of amino acids, *N*-Fmoc-cysteine(*S*-thiobutyl)-OH, benzotriazol-1-yl-oxy-tris-pyrrolidinophosphonium hexafluorophosphate (PyBOP), DMF (peptide synthesis grade), and trifluoroacetic acid (TFA, peptide synthesis grade) were from Auspep (Melbourne, Australia).

Derivatization of Controlled Pore Glass Resin with Fmoc- ϵ Ahx. Controlled pore glass (CPG) was first aminated with 3-aminopropyltriethoxysilane (Scheme 1), then two residues of aminohexanoic acid (ϵ Ahx) were coupled to this aminopropyl-CPG (AP-CPG) using Fmoc-

Scheme 1. Preparation of the CPG Resin for Peptide Synthesis

ϵ Ahx-OH by *in situ* activation of the amino acid using PyBOP (benzotriazol-1-yl-oxy-tris-pyrrolidinophosphonium hexafluorophosphate) by continuous-flow Fmoc SPPS as described (7). Briefly, the AP-CPG resin (**1**, Scheme 1) (6 g, 0.9 mmol of amino groups) was coupled *in situ* with a mixture of Fmoc- ϵ Ahx (2.7 mmol, 3 equiv), PyBOP (2.7 mmol, 3 equiv), 1-hydroxybenzotriazole (HOBt) (2.7 mmol, 3 equiv), and *N*-methylmorpholine (NMM) (4.5 mmol, 5 equiv) for 30 min. The resin was washed with dimethylformamide (DMF, 10 min), treated with 20% (v/v) piperidine in DMF (10 min), and washed again prior to coupling with Fmoc- ϵ Ahx. After 30 min acylation, the loading was determined to be 250 μ mol/g by Fmoc test. After the resin was washed, any free residual amino groups were acetylated with acetic anhydride (250 μ L, 1.25 mmol) and 4-*N,N*-(dimethylamino)pyridine (DMAP, 50 mg, 0.4 mmol) in pyridine (1 mL). The resin was washed, deprotected (20% piperidine, 10 min), and reacted with the *p*-nitrophenyl ester of *O*-pixyl-4-hydroxybutyric acid (**2**, Scheme 2), thereby converting the amino terminus to a protected primary aliphatic hydroxyl group. Reaction with the pixyl linker synthon **2** (3 g, 0.45 mmol) was achieved in the presence of HOBt (1.3 mmol, 3 equiv). A pixyl assay (7) performed on a small amount of resin (**3**) indicated a loading of 75 μ mol/g after coupling for 1–2 h. Any free residual amino groups were blocked by acetylation as described above and then washed. Prior to the coupling with *N* $^{\alpha}$ -Fmoc-cysteine(*S*-thiobutyl), removal of the pixyl protecting group was afforded by treatment with 3% (v/v) dichloroacetic acid in dichloromethane (DCM, 10 min). The resin was washed extensively with DCM (10 min) and then DMF.

Coupling of N^α -Fmoc-Cysteine (S-thiobutyl) and Fmoc- ϵ Ahx spacer residues. N^α -Fmoc-cysteine(S-thiobutyl)-OH (0.45 mmol, 6 equiv) was introduced to the ϵ Ahx-derivatized resin **3** (1 g) as the symmetrical anhydride, preactivated with diisopropyl carbodiimide (DIC) (0.225 mmol, 3 equiv) as described previously (7). DMAP (0.045 mmol, 0.3 equiv) dissolved in 0.5 mL of DMF was used as a catalyst. Fmoc test of aliquots of resin **4** gave a loading of $42 \pm 1 \mu\text{mol/g}$ after 1 h acylation. The resin was washed (DMF, 10 min), and then the residual resin-bound hydroxyl groups were inactivated by acylation with DMAP and acetic anhydride as described above. The resin was washed and then deprotected. Fmoc- ϵ Ahx-Pfp (0.168 mmol, 4 equiv) was then coupled in the presence of 4 equiv of HOBt (0.168 mmol, 30 min). The resin was acetylated as described above. Another Fmoc- ϵ Ahx-Pfp residue was coupled in the same way. After Fmoc deprotection, the pixyl linker synthon (**2**) (0.168 mmol, 4 equiv) was coupled in the presence of equimolar amounts of HOBt (0.168 mmol). The pixyl test of resin **5** was determined to be $26 \pm 1 \mu\text{mol/g}$ after 1 h coupling. The

resin was acetylated as before, washed (DMF, 10 min) and then DCM, and dried under reduced pressure.

DNA Synthesis. The Cys(S-thiobutyl)-functionalized solid support **5** was used directly in solid-phase DNA synthesis using β -cyanoethyl phosphoramidite by the trityl-on method (Scheme 3). Acetylation was affected by 0.1 M acetic anhydride/tetrahydrofuran (THF) and 0.1 M imidazole/THF. After DNA synthesis, the resin was recovered by filtration and treated with concentrated ammonia containing 1 M DTT at 55 °C for 6 h to simultaneously affect deprotection of the side chain of the cysteine residue as well as cleavage of the ODN- ϵ Ahx₂Cys (**7**) from the resin. The resin was removed by filtration and rinsed with concentrated ammonia. In vacuo evaporation of the combined filtrate resulted in a clear residue containing the ODN- ϵ Ahx₂Cys and DTT, which was subsequently redissolved in water prior to purification by HPLC.

Peptide Synthesis. The Tat and Ca-gp41 peptides were synthesized by continuous-flow SPPS on ethylenediamine-treated PepsynK resin (Auspep, Melbourne, Australia) derivatized with hydroxymethylphenolacetic acid using established protocols (29, 30). All acylations were of 30 min duration, and *N*-Fmoc deprotection was affected by 20% (v/v) piperidine in DMF for 10 min. The first residue of the Tat peptide (PTSQSRGDPTGPKE) as well

Scheme 3. DNA Synthesis and Deprotection^a

^a Key: (a) 3% DCA/ CH_2Cl_2 ; (b) **6**, tetrazole; (c) Ac_2O , DMAP; (d) I_2 , H_2O ; (e) repeat steps a–d n times, (f) concentrated NH_3 , rt, 6 h. (g) 1 M DTT, concentrated NH_3 , 55 °C, 6 h.

as the Ca-gp41 peptide (DRVIEVVQGAYRAIRNIPRR-IRQG) were coupled as its symmetrical anhydride using established protocols (30). With the exception of Fmoc-Arg(Pmc)-OH, which was coupled by in situ activation using PyBop, NMM, and HOBt, the remaining amino acids were coupled as their Pfp esters in the presence of HOBt (1.18 mmol, 4 equiv of each). The side chain protecting groups were as follows: *tert*-Bu for Glu, Thr, Asp, and Ser; Boc for Lys, and Pmc for Arg. All acylation reactions were essentially complete within 30 min (as determined by TNBSA test of aliquots of the resin), with the exception of Ile and Val (residues 21 and 22) on the Ca-gp41 peptide, which required at least two consecutive couplings of 30 min duration each (7). The peptide was derivatized by reacting with succinimido-3-maleimidopropanoate (**31**) (1.18 mmol, 4 equiv) in the presence of HOBt (1.18 mmol, 4 equiv) for 1 h. The Ca-gp41 peptide was deprotected and cleaved by a mixture that consisted of ethane dithiol, H_2O , thioanisole, and TFA (5:5:5:85 v/v), while deprotection and cleavage of the Tat peptide was affected by thioanisole in TFA (5:95, v/v). Both deprotection reactions were at room temperature for 2 h.

Both the maleimide-derivatized Ca-gp41 and Tat peptides were purified by RP-HPLC using aqueous 0.1% (v/v) TFA and 0.1% (v/v) TFA in acetonitrile. RP-HPLC purification of the cysteine-derivatized ODNs used buffers consisting of triethylammonium acetate (0.1 M TEAA, pH 7.0) and acetonitrile using a modified protocol (7) that was found to be critical for the efficient removal of DTT: after the sample was injected, an isocratic mode (100% buffer A) was maintained for 15 min before initiating the programmed gradient. After the target peak was collected, two aliquots (200 μL each) of the fraction were put aside. One was diluted with buffer A to 1.5 mL, and the purified ODN was quantified by spectrophotometric

absorbance at 260 nm. The other aliquot was rechromatographed to assess homogeneity. The remainder of the purified cysteine-derivatized ODN was immediately added to the maleimide-derivatized peptide.

Conjugation of Cysteine-Derivatized ODNs with Maleimide–Peptides. Accurately weighed amounts of the maleimide-derivatized Ca-gp41 or Tat peptides were dissolved in TEAA (0.1 M, pH 7.0) at a concentration of 10 mg/mL. For the maleimide-derivatized Ca-gp41 peptide, SDS was added at the concentration of 0.25–0.5% (w/v) prior to the addition of cysteine-derivatized ODN since this was necessary to prevent the nonspecific polymerization of the peptide to the negatively charged backbone of the ODN, with the resultant precipitation of the complex (results not shown). The HPLC eluate containing the cysteine-derivatized ODN (typically 1 mg/10 mL, based on spectrophotometric reading of the purified ODN) was mixed with approximately 10–15 molar excess of maleimide-derivatized peptide. The 10–15 molar excess of maleimide–peptide was found to be optimal for rapid reaction. To monitor the reaction, at timed intervals, aliquots of the reaction mixture (typically 7 μg of the reaction mixture) were lyophilized, resuspended in 30 μL of a solution containing equal volume of H_2O and formamide, and fractionated by denaturing PAGE. When the reaction was deemed complete, the entire reaction mixture was transferred to a stoppered flask and detritylated by treating the reaction mixture with an equal volume of glacial acetic acid at room temperature for 20 min with occasional agitation. The solvents were evaporated in vacuo and dissolved in 3 mL water.

Polyacrylamide Gel Electrophoresis. Assessment of the efficiency of the conjugation reaction was carried out on denaturing 20% (w/v) acrylamide gel containing 0.089 M Tris, 0.089 M boric acid, 2 mM EDTA (TBE), and 7 M urea. The gel was stained with 0.05% (w/v) methylene blue dye (30 min) and washed by immersion in water over 8 h duration (with five changes of water) before being photographed.

Purification of Conjugates by Gel Filtration. The H1- ϵAhx_2 -Cys(Tat) conjugate was purified using a gel filtration column (2 cm width $\times$ 45 cm height) containing Sephadex G-75 gel matrix equilibrated with TEAA (0.1 M, pH 6.7). The flow rate was 250 $\mu\text{L}/\text{min}$.

RESULTS

Derivatization of ODNs with a N^α -Fmoc-Cys(S-thiobutyl) residue. The demonstration that ODN–peptide conjugates was efficiently incorporated to the 3'-terminus of ODNs by the total synthesis method (7) prompted us to investigate the feasibility of synthesizing a simple 3'-polyamide containing a cysteine residue on a CPG support as a novel approach to the derivatization of ODNs with a sulfhydryl function. The success of the strategy depends on several factors: the stability of the S-thiobutyl group to the conditions of both peptide and DNA synthesis and the ease by which it was removed under mild conditions at the end of DNA synthesis. The efficient DNA synthesis (by the phosphoramidite chemistry) onto an AP-CPG support that was functionalized with the 3,3'-dithiodipropyl derivative (**23**) or *O*-dimethoxytrityl-6-mercaptohexanol (**24**) containing a disulfide bond were previously reported, suggesting that protection of the sulfhydryl function by a disulfide bond was stable to conditions of SPSS and DNA synthesis.

In the technique described herein, the AP-CPG support was first derivatized with an acid-labile linker, such as the α,ω -hydroxybutyric acid derivative (**2**, Scheme 3).

Standard *N*^α-Fmoc SPPS was used to incorporate *N*-Fmoc-Cys(*S*-thiobutyl) onto the resin (**4**). At this point, the resin can be coupled with the pixyl linker synthon, thereby converting the amino terminus to an aliphatic hydroxyl group suitable for automated DNA synthesis. However, we discovered that the conjugation reaction between the resultant deprotected cysteine-derivatized ODN (ODN-Cys) and maleimide-derivatized peptide was sluggish (results not shown), possibly because the pendant ODN sterically hindered the accessibility of the thiol group on the side chain of cysteine residue. To investigate this possibility, two aminohexanoic spacer residues were coupled to the *N*-terminal of the Cys(*S*-thiobutyl) residue, prior to reacting with the pixyl linker synthon **2**, as described in the Experimental Procedures. The derivatized support was then used to synthesize a 20mer (GCGTACTCACCAGTCGCCGC) complementary to the primer binding site of HIV-1 mRNA (**7**) by solid-phase DNA synthesis. After DNA synthesis, the resin was treated with concentrated ammonia in the presence of DTT to affect the simultaneous deprotection of the exocyclic bases of the ODNs and the thiol side chain protection of the pendant cysteine (Scheme 3). Removal of DTT is achieved by RP-HPLC, after which the ODN-(ϵ Ahx)₂Cys can be used to ligate with a maleimide peptide in solution. DNA synthesis of resin **5** appeared to proceed well with high coupling efficiency (typically 99%). Chromatographic analysis of the crude product produced a clean profile with the predominant trityl-on peak eluting at 25 min (34% CH₃CN) (Figure 1, panel I) and the detritylated product emerging at 22 min (Figure 1, panel II). The overall yield of ODN-(ϵ Ahx)₂Cys, after RP-HPLC was typically 20 ± 4% based on the initial resin substitution. Ion-spray mass spectrometry of the purified ODN-(ϵ Ahx)₂Cys gave the correct molecular ion (results not shown), suggesting that disulfide protection of the cysteine by the *S*-thiobutyl group was stable to conditions of solid-phase peptide and DNA synthesis. The purified ODN-(ϵ Ahx)₂Cys fraction was used in the solution-phase conjugation with maleimide-derivatized peptides.

Derivatization of Peptides with Succinimido-3-maleipropanoate. Analytical RP-HPLC of the purified Ca-gp41peptide (peak at 20 min, panel I) and that of the crude Tat peptide (peak at 20 min, panel II) are represented in Figure 2. Amino acid analyses of the purified Ca-gp41 peptide and that of the crude Tat peptide showed the correct peptide composition (Tables 1 and 2). These peptides were subsequently used to conjugate with the cysteine-derivatized oligonucleotides.

Conjugation of H1-(ϵ Ahx)₂Cys with the Maleimide-Derivatized Tat Peptide. Evidence for the rapid conjugation reaction of the H1-(ϵ Ahx)₂Cys (1 mg, 10 mL) with approximately 15-fold molar excess of crude maleimide-derivatized Tat peptide is presented in Figure 3. Fractionation of the reaction mixture on denaturing PAGE showed that after 1 min (lane A) virtually all of the H1-(ϵ Ahx)₂Cys had disappeared and a slower migrating band, presumably corresponding to the H1-(ϵ Ahx)₂Cys(Tat) conjugate, had appeared (lane A, arrow 2). In addition, another weaker band (lane A, arrow 1) was obvious, migrating slightly slower than the putative conjugate band. Subsequent studies using a mock reaction with purified H1-(ϵ Ahx)₂Cys (without the peptide nor DTT) (results not shown) indicated that this band corresponds to a small proportion of H1-(ϵ Ahx)₂Cys that had dimerized. That the slower migrating band was ODN dimers was confirmed by the apparent absence of this putative dimerized ODN in lane B, which contains purified H1-(ϵ Ahx)₂Cys in the presence of DTT. Lane

Figure 1. Reversed-phase chromatogram of the crude H1-(ϵ Ahx)₂Cys (trityl-on, panel I) and after detritylation with glacial acetic acid (panel II). Chromatographic conditions: Synchropak C18 column. Flow rate, 1.5 mL/min. Buffer A, TEAA (0.1 M, pH = 7). Buffer B, acetonitrile. Gradient, 0–40% B over 30 min.

C correspond to the normal, unmodified ODN (i.e., H1 ODN with no 3'-polyamide). These results indicate that the ODN-(ϵ Ahx)₂Cys was reactive, and emphasize the importance of immediately mixing the reactive thiol-ODN (after RP-HPLC purification) to the maleimide-peptide solution in order to minimize the loss of the H1-(ϵ Ahx)₂Cys through dimerization. Amino acid analysis of the putative H1-(ϵ Ahx)₂Cys(Tat) product (lane A, arrow 2) after being purified by denaturing PAGE indicates that the amino acid composition was consistent with that of the Tat peptide (Table 1). These results indicate that the solution-phase segment coupling of the H1-(ϵ Ahx)₂Cys with the maleimide-Tat peptide was rapid, specific, and efficient. However, an approximately 2-fold molar excess of the peptide (quantified by amino acid analysis) was observed as compared to the ODN content. The disproportionate peptide-ODN ratio de-

Figure 2. Reversed-phase chromatogram of purified, maleimide-derivatized Ca-gp41 peptide (panel I) and crude maleimide-derivatized Tat peptide (panel II). rived from amino acid hydrolysates of the ODN–peptide does not necessarily indicate that a 1:1 peptide–ODN ratio does not exist. In our previous paper, we also observed disproportionate amino acid to ODN ratios, yet ion-spray mass spectroscopic analyses of the conjugates unequivocally indicated the correct molecular weight (7). The disparity in the peptide and ODN ratio may be related to the different techniques used to quantify the

two components of the hybrid molecule, i.e., amino acid analyses for peptides and spectrophotometric absorbance of ODNs.

The RP-HPLC chromatogram of the reaction mixture taken at different time points showed a peak that eluted at the same time as the starting H1–(ϵ Ahx) $_2$ Cys (results not shown), thus making the purification of the H1–(ϵ Ahx) $_2$ Cys(Tat) conjugates by RP-HPLC problematic. The coelution of the H1–(ϵ Ahx) $_2$ Cys(Tat) conjugate and H1–(ϵ Ahx) $_2$ Cys under RP-HPLC conditions is perhaps not surprising given that the Tat peptide is hydrophilic and uncharged. Because the Tat peptide is electrically

Figure 4. Size-exclusion chromatography using Sephadex G-75. Panel I: The samples (shown superimposed) were analyzed separately. Dextran sulfate (peak A, $\lambda = 220$ nm), H1-(ϵ Ahx)₂Cys (peak B, $\lambda = 254$ nm), maleimide-Tat peptide (peak C, $\lambda = 220$ nm). Panel II: The crude reaction mixture containing H1-(ϵ Ahx)₂Cys and maleimide Tat peptide ($\lambda = 220$ nm). Peak D is the H1-(ϵ Ahx)₂Cys(Tat) conjugate, and peak E corresponds to excess peptide. Chromatographic conditions: Buffer, TEAA (0.1 M, pH = 6.7). Flow rate, 250 μ L/mL.

neutral, the use of ion-exchange liquid chromatography to isolate the conjugate product from the unmodified cysteine-derivatized ODN is also precluded. Taking advantage of the large MW difference between the H1-(ϵ Ahx)₂Cys(Tat) conjugate (approximate MW of 8500 Da) and the maleimide-derivatized Tat peptide (approximate MW of 1400), the removal of excess peptide from the reaction mixture by size exclusion gel filtration was attempted. The separate analyses of the ODN and the tat peptide using identical chromatographic conditions showed that the ODN was well separated before the Tat peptide (Figure 4, panel I), suggesting that it was feasible to use size-exclusion chromatography to purify the H1-(ϵ Ahx)₂Cys(Tat). Importantly, the gel filtration profile of the reaction mixture containing the H1-(ϵ Ahx)₂Cys and the Tat peptide with detection at 220 nm clearly showed two well resolved peaks (Figure 4, panel II). One peak, D, presumably corresponded to the higher MW components of the reaction mixture [i.e., the conjugates and any remaining unreacted H1-(ϵ Ahx)₂Cys], and the other, peak E, corresponded to excess maleimide-Tat peptide. Denaturing PAGE analyses of the purified fractions showed that peak D contained ODN material, presumably the H1-(ϵ Ahx)₂Cys(Tat) conjugate (Figure 5, lane C) that migrated with lower electrophoretic mobility than the H1-(ϵ Ahx)₂Cys reactant (lane A). To

Figure 5. Denaturing PAGE analysis of fractions from Sephadex G-75 gel filtration. Lane A: H1-(ϵ Ahx)₂Cys, in the presence of DTT. Lane B: Peak E from Figure 4 (presumably containing only the Tat peptide) loaded at 5 times the concentration of the sample shown on lane C. Lane C: Peak D from Figure 4 is the putative H1-(ϵ Ahx)₂Cys(Tat) conjugate. The gel was stained with methylene blue dye and photographed.

further demonstrate that the peptides were efficiently removed from the conjugate, peak E (theoretically containing only the maleimide-Tat peptide) was worked up to the same concentration as peak A, based on absorbance reading at 260 nm but loaded on the gel at 5-fold the amount of peak D (Figure 5, lane B). The absence of a band in this lane clearly indicates that no ODN was present in this fraction. However, since the peptide is not visible under these denaturing PAGE conditions, the presence of a band with a lower electrophoretic mobility alone, although suggestive of the presence of H1-(ϵ Ahx)₂Cys(Tat) conjugate (Figure 5, lane C), does not necessarily demonstrate complete removal of the excess peptide by gel filtration. Amino acid analysis of fraction D showed that the amino acid composition (Table 1) as well as the peptide and ODN molar ratio (2:1) were within acceptable levels. However, the comparative ratio of ODN to peptide, for reasons already discussed, does not provide unambiguous determination of the actual ratio present. We attempted to analyze the purified conjugate by ion-spray mass spectrophotometry. However, due to reasons that are not entirely clear to us, we did not obtain a usable spectra. The yield of conjugates after gel filtration purification, as assessed by spectrophotometric absorbance of the products at 260 nm, was typically 34–42%. This yield is perhaps low, but since it was determined by spectrophotometric absorbance of the resulting conjugate after purification, the lower than optimal yields may also reflect inevitable losses due to sample isolation and handling.

To further demonstrate the reactivity of the cysteine-derivatized ODNs, the H1-(ϵ Ahx)₂Cys (200 μ g, 2 mL) was also reacted with 14 molar excess of the maleimide-derivatized Ca-gp41 peptide [500 μ g in 500 μ L 0.1 M TEAA containing 0.3% (w/v) SDS]. In this reaction, it was necessary to add 0.3% (w/v) SDS to the peptide mixture prior to the addition of the ODN reactant in order to abrogate the electrostatic interaction of the positively charged Ca-gp41 peptide and the negatively charged ODN, which otherwise would lead to the aggregation and insolubility of the ODNs (results not shown). Due to problems associated with aggregation and insolubility of the ODN-peptide, assessment of the reaction kinetics by RP-HPLC was problematic (results not shown). Twenty-four hours after the commencement of the reaction, an aliquot of the reaction mixture (after ethanol precipitation to remove SDS, which inhibits the

Figure 6. Denaturing PAGE analysis of 5'-end labeled H1- ϵ Ahx₂Cys (lane A) and that of the reaction mixture consisting of H1- ϵ Ahx₂Cys and maleimide Ca-gp41 peptide (containing 0.5% (w/v) SDS after ethanol precipitation, lane B).

PNK reaction) was labeled with γ -[³²P]-ATP and fractionated by denaturing PAGE. The loss of a band that comigrated with ODN-(ϵ Ahx)₂Cys (Figure 6, lane B), concomitant with the emergence of a band that migrated with retarded mobility (Figure 6, lane A) suggested complete reaction. Amino acid analysis of the putative conjugate product (i.e., the band with retarded mobility) after purification by PAGE showed an amino acid composition that was consistent with the Ca-gp41 peptide (Table 2). The low Ile and Val values are probably due to incomplete hydrolysis; the high glycine is probably related to the presence of the ODN (7). The purified sample, after extensive dialyses, was subjected to mass spectrophotometric analyses. However after several attempts, a reliable spectrum could not be attained. It should be noted that at the time that this study was undertaken, mass spectrophotometric analysis of ODNs of this length was still experimental, and the failure to obtain a reliable spectrum might be related to technical difficulties in analyzing this type of ODN–peptide conjugates.

DISCUSSION

Two different types of peptides, the 14 residue segment of the HIV transactivator (*tat*) protein (Tat), and the 24 residue segment of the carboxyl terminus of the gp41 of HIV (Ca-gp41) were used to conjugate with cysteine-functionalized ODNs. Although the precise function of the highly conserved Ca-gp41 peptide remains to be clarified, several lines of evidence suggested a role for this peptide in HIV-mediated cytopathy (32–34). Furthermore, the Ca-gp41 peptide is among the most highly amphiphilic α -helices documented to date (35), and this structural feature was shown to impart membranotropic activities by causing the fusion and lysis of artificial membranes (36–38). The 86 residue *tat* protein of HIV is produced in the cytoplasm of the HIV-infected cell and subsequently translocated into the nucleus where it binds to the long terminal repeats (LTR) of the provirus and promotes transcription of HIV genes (39). The *tat* protein consists of several structurally well-defined domains. A 14 residue segment at the carboxyl terminus of *tat* was shown to be important in promoting the virus' internalization into cells (40), and conjugation of this 14 residue synthetic peptide corresponding to immunoglobulin Fab fragments, which are normally poorly internalized, enhanced the cellular internalization of the pendant Fab fragments in carcinoma cells (41). The known membranotropic activity of the Ca-gp41 and *tat* peptide suggested

that conjugating these peptides to cysteine-derivatized ODNs might enable the passage of ODNs across cell membranes.

The preparation of ODN–peptide hybrid conjugates of a defined structure by the solution-phase chemical ligation approach necessitates the functionalization of ODNs and peptides with mutually reactive moieties. Because solid-phase DNA synthesis normally proceeds in the 3' to 5' direction, documented procedures describing the functionalization of the 3'-terminus of ODNs with a sulfhydryl group are tedious and require the derivatization of the solid support with a chemical synthon that contains a suitably protected sulfhydryl function. At present, techniques suitable for the preparation of 3'-thiol functionalized ODNs are relatively rare as compared to the plethora of techniques describing the functionalization of synthetic ODNs at the 5'-terminus. Furthermore, existing methodologies describing the introduction of a sulfhydryl function at the 3'-termini of ODNs are arduous. For example, the method described by Zuckerman et al. required multiple steps, involving the derivatization of nucleotide monomers with 3,3'-dithiodipropyl followed by its reaction with S-2-thiopyridyl-2-mercaptoethanol (23). Functionalizing the 3'-terminus of synthetic ODNs by this technique requires the preparation of four different solid supports, each individually derivatized with a disulfide-linked nucleotide (i.e., deoxyadenosine, deoxyguanosine, deoxycytidine, and thymidine). A simpler method of functionalizing synthetic ODNs involves the derivatization of CPG with mercaptohexyl derivatives reported by Kumar et al. (24, 25). Another method of synthesizing ODN–peptide hybrids whereby the peptide was ligated to 3'-end of ODNs was by the template-directed two-step reaction involving site-specific ligation of amine-terminated ODN to ODN–peptide linked by thioester linkage (27).

As a novel method for derivatizing synthetic ODNs, the thiobutyl-protected cysteine-derivatized CPG resin described in this study offers several distinct advantages. The derivatized resin can be used to efficiently synthesize ODN of any sequence by standard methods of solid-phase DNA synthesis. The ability to synthesize the ODN by the trityl-on method and the ease by which the DMT group is removed by mild acid treatment also enable ready purification without the need for additional treatment with silver nitrate to affect removal of the trityl group as described for the synthesis of C6 modifier developed by Conolly et al. (19). In addition, *N*^α-Fmoc-thiobutyl-protected Cys is commercially available, is stable to the conditions of DNA synthesis and base deprotection, and can be efficiently incorporated into the 3'-polyamide by standard *N*^α-Fmoc SPPS chemistry.

The HI ODN-(ϵ Ahx)₂Cys described in this study was shown to react specifically and rapidly with maleimide-derivatized peptides. We also attempted to conjugate the 20 residue highly hydrophobic maleimide-derivatized gp41 peptide with the H1 ODN-(ϵ Ahx)₂Cys. However, attempts at the conjugation were not successful due to the insolubility of the peptide. Results of the conjugation reactions described in this study highlight a well recognized caveat of the solution-phase segment coupling approach to the chemical synthesis of ODN–peptide conjugates, that is, the poor solubility properties of some peptides may undermine the efficiency of the conjugation reaction. The conjugation of the Ca-gp41 peptide exemplifies this. Although soluble in aqueous solvents, in the absence of SDS the Ca-gp41 peptide nevertheless interacts with and precipitates the cysteine–ODN. Furthermore, the precipitation of ODNs induced by the Ca-gp41

peptide which is not hydrophobic illustrates the possibility that precipitation of the ODN-peptide conjugate is not necessarily only confined to hydrophobic, poorly soluble peptides per se but extends also to peptides that bind avidly to ODNs.

The present study demonstrated that the success of the segment coupling approach depends on the establishment of appropriate chromatographic systems that are capable both of monitoring the progress of the conjugation reactions but can also be used as a purification tool to remove excess peptide reactants from the conjugates. Although methodologies for RP-HPLC of peptides and ODNs are well established, thus far techniques for the efficient purification of all types of ODN-peptide hybrids are not established. The major problem associated with adapting currently accepted protocols for HPLC purification of peptides and ODNs to the purification of ODN-peptide conjugates is that RP-HPLC analyses of ODNs and peptides uses incompatible buffers. Whereas isolation of peptides by RP-HPLC uses acidic TFA-based buffers with detection at 214 nm/220 nm, RP-HPLC of ODNs uses TEAA at neutral pH with detection at 260 nm. Furthermore, since RP-HPLC fractionate compounds based predominantly on hydrophobic interactions, for conjugate products in which the peptide moiety is small and/or hydrophilic, RP-HPLC analysis may be of limited value (7). Although gel filtration has certain disadvantages (slow flow rate, poor resolution), it offers the advantage of having a chromatographic support and buffer system (TEAA) that can accommodate monitoring and separation of both peptides and ODNs simultaneously. As demonstrated in this paper, for the purification of the H1 ODN-(ϵ Ahx)₂Cys(Tat) conjugate, size-exclusion chromatography may be useful in isolating the conjugate from excess peptide.

Received December 22, 1997; Revised Manuscript Received April 3, 1998

The polyampholyte comb-type copolymers consisting of a poly(L-lysine) (PLL) main chain, a DNA binding site, and hyaluronic acid (HA) side chains, cell-specific ligands, have been prepared as the DNA carrier targeting sinusoidal endothelial cells of liver. The reducing end of HA and ϵ -amino groups of PLL were covalently coupled by reductive amination to obtain the resulting comb-type copolymers (PLL-graft-HA). The chain length of HA was controlled by the enzymatic hydrolysis of high-molecular weight HA. Since HA formed polyion complexes with PLL, the coupling reaction was carried out with high-ionic strength media to suppress polyion complex formation. The reaction proceeded in a homogeneous system, leading to a high efficiency of coupling (>70%) of HA onto the PLL backbone. By using the enzymatic hydrolysis of HA and the reductive amination reaction between HA and PLL with high-ionic strength media, it is possible to prepare the various comb-type copolymers with a defined density and a defined length of HA side chains. Furthermore, we also find that these polyampholyte comb-type copolymers vary their assembling structure in water in response to two kinds of environmental factors, i.e., ionic strength and pH. Finally, a ¹H NMR study reveals that the PLL backbone efficiently interacts with DNA molecules despite the presence of HA side chains having negative charges.

INTRODUCTION

Polycations have been used for the nonviral gene carriers because the polycations and DNAs form stable complexes in a noncovalent manner (1–3). The polycations, e.g., poly(L-lysine) (PLL¹), are reported to be conjugated with several ligands for targeted gene delivery (4–8). The physicochemical properties of the DNA complexes have been described as factors which influence transfection activity (9–11). However, the general method controlling and optimizing the complex properties has not been established yet.

We have reported on several comb-type copolymers consisting of a PLL backbone and hydrophilic dextran side chains for controlling the assembling structure of DNA–copolymer complexes (12, 13). The dextran chains grafted onto PLL are found to reduce the aggregation of the resulting complexes and increase the solubility of the complexes. Furthermore, the grafting degree of the

copolymer affects the DNA conformation in the complex, enabling us to regulate DNA compaction. The comb-type copolymers with a higher degree of grafting induce little compaction of DNA and stabilize DNA duplexes and triplexes by shielding the repulsion between phosphate anions of DNA. Moreover, the grafted chains reduce the nonspecific interaction of the PLL backbone with proteins (14). The comb-type copolymers therefore fulfill several requirements for the cell-specific carrier of DNA, if the copolymers are provided with cell-specific ligands.

Hyaluronic acid (HA) is an unbranched high-molecular weight polysaccharide consisting of alternating *N*-acetyl- β -D-glucosamine and β -D-glucuronic acid residues linked at the 1–3 and 1–4 positions, respectively (15). Liver sinusoidal endothelial cells (SECs) possess the receptors that recognize and internalize HA (16, 17). More than 90% of HAs in the blood stream are known to be taken up and metabolized by SECs. We have therefore chosen HA as the ligand for delivering the DNA to the SEC. Our recent study shows that the complexes between PLL–HA conjugates and reporter genes were distributed exclusively in SECs, leading to gene expression in vivo (18).

The binding affinity of the HA receptor is reported to increase as the chain length of HA is increased (19). In addition, the density and length of HA chains grafted onto PLL are expected to be the factors which affect the assembling structure of PLL–DNA complexes in the context of the efficiency of both targeting and transfection in vivo. The various comb-type copolymers consisting of a PLL backbone and HA side chains would be useful in

investigating the structure–function relationship and optimizing the complex structure.

In this study, we have prepared the PLL-*graft*-HA comb-type copolymers with various chain lengths of both PLL and HA segments and the densities of HA *grafts*. For the synthesis of the comb-type copolymers, high-molecular weight HA was hydrolyzed, and then the HAs were covalently coupled with ϵ -amino groups of PLL at their reducing end by reductive amination. This paper describes the synthesis and characterization of the PLL-*graft*-HA comb-type copolymers in the context of their physicochemical properties and complex formation with DNA.

EXPERIMENTAL PROCEDURES

Materials. PLL, obtained as its chloride or bromide salt, was purchased from Peptide Institute, Inc. (Osaka, Japan). High-molecular weight HA (5.9×10^5), obtained as its sodium salt (sodium hyaluronate), was kindly provided by Denki Kagaku Kogyo Co., Ltd. (Tokyo, Japan). Bovine testicular hyaluronidase (EC 3.2.1.35, type I-S) was purchased from Sigma Chemical Co. (St. Louis, MO), and sodium cyanoborohydride (NaBH_3CN) was from Wako Pure Chemical Industries, Ltd. (Osaka, Japan). Salmon sperm DNA (approximately 300 base pairs) was kindly provided by Nissan Chemical Industries, Ltd. (Tokyo, Japan). All other chemicals of a special grade were used without further purification.

Enzymatic Hydrolysis of HA. High-molecular weight HA was partially degraded by hyaluronidase to low-molecular weight fragments (20). Hyaluronidase (20 mg) and HA (1 g) were added together in 120 mL of water. The solution was stirred at 50 °C for a desired time (1–20 h). Then, the solution was boiled for 5 min to terminate the reaction and allowed to cool to room temperature. After the filtration of the cooled mixture through a 0.45 μm filter (New Steradisc 25, KURABO, Osaka, Japan), the resulting HA fragments were obtained by freeze-drying.

Synthesis of PLL-*graft*-HA Comb-Type Copolymers. The obtained HA fragments were conjugated to PLL by reductive amination using NaBH_3CN as a reducing agent (Scheme 1). The NaBH_3CN was added to the mixture of HA (100–300 mg) and PLL (60–120 mg) in 15 mL of sodium borate buffer (0.1 M, pH 8.5) containing 0.4–1 M NaCl at a final concentration of 0.3 M. The reaction mixture was incubated at 40 °C for 3 days while it was stirred constantly, followed by dialysis against a 0.5 M NaCl aqueous solution using a Spectra/Por 7 membrane (molecular weight cutoff of 25 000) to remove unreacted HA. Then, the solution was desalted by dialysis against distilled water, and the resulting copolymer was obtained by freeze-drying.

Gel Permeation Chromatography (GPC). GPC was carried out using a JASCO 880-PU pumping system (Tokyo, Japan) at the flow rate of 1.0 mL/min at 25 °C with Ultrahydrogel 500 and Ultrahydrogel 250 columns (Japan Waters Ltd., Tokyo, Japan). The aqueous solution containing 0.2 M Na_2SO_4 and 5 mM sodium phosphate buffer (pH 8.0) was used as a mobile phase. Two hundred microliters of each sample was picked up from the reaction mixture and was injected into the columns. Eluate was detected by a refractive index (RI) detector (830-RI, JASCO) and a multiangle light scattering (LS) detector (Dawn-DSP, Wyatt Technology Co., Santa Barbara, CA). RI and LS signals were transferred to the computer to calculate the number-average (M_n) and

Scheme 1. Synthesis of PLL-*graft*-HA Comb-Type Copolymers

weight-average (M_w) molecular weight according to the instruction manual (Wyatt Technology Co.) for Dawn-DSP.

^1H NMR Spectroscopy. Each copolymer was dissolved in D_2O (99.95 at. % D; Merck, Darmstadt, Germany) containing 0.35 M NaCl. ^1H NMR spectra (400 MHz) were obtained with a Varian Unity 400plus spectrometer (Palo Alto, CA), at a probe temperature of 298 K. The chemical shifts are expressed as parts per million using internal HDO molecules ($\delta = 4.7$ ppm in D_2O) as a reference.

Turbidity Measurement of PLL-*graft*-HA Solutions. The copolymer was dissolved in 3 mL of distilled water at a concentration of 1.0 mg/mL. The ionic strength of the solution was increased by the stepwise addition of a 5 M NaCl solution. The pH of the solution was varied by adding a 0.1 M solution of HCl or NaOH. The turbidity change of the solution at different ionic strengths or pHs was monitored as the absorbance at 500 nm with a Beckman DU-640 spectrophotometer (Fullerton, CA).

Estimation of the DNA-PLL-*graft*-HA Interaction by ^1H NMR Spectroscopy. The stock solution of DNA (1 mg/mL) in 10 mM sodium phosphate buffer (pH 7.2) containing 0.5 mM EDTA and 1 M NaCl was mixed with the PLL-*graft*-HA solution (1 mg/mL) in 1 M NaCl at a copolymer/DNA charge ratio ($[\text{amino group}]_{\text{copolymer}}/[\text{phosphate group}]_{\text{DNA}}$) of 1.0. The mixture was then desalted by step-down dialysis using a Spectra/Por 7 membrane (molecular weight cutoff of 1000), followed by freeze-drying. The resulting sample was dissolved in D_2O . The ^1H NMR spectrum was obtained as described above.

RESULTS AND DISCUSSION

Synthesis of PLL-*graft*-HA Comb-Type Copolymers. Most polysaccharides are useful for the synthesis of comb-type copolymers using the coupling reaction because they have one reducing end per molecule; namely, they are semitelechelic polymers (21, 22). The polysaccharides whose glycosyl bonds are hydrolyzed

Figure 1. Time course of the hydrolysis of HA by hyaluronidase. HA (5.9×10^5 ; 1 g) was hydrolyzed by hyaluronidase (20 mg) at 50 °C. The M_n of HA was determined by GPC. The inset shows the change in the molecular weight distribution (M_w/M_n).

Figure 2. Gel permeation chromatograms of the isolated PLL-graft-HA copolymer (solid line) and the reaction mixture of PLL ($M_n = 9.7 \times 10^4$; 39 mg) and HA ($M_n = 2.2 \times 10^3$; 94 mg) at 0 h (dotted line) or 9 days (dashed line): column, Ultrahydrogel 500 and 250; eluent, 0.2 M Na_2SO_4 and 5 mM sodium phosphate buffer (pH 8.0); flow rate, 1.0 mL/min; temperature, 25 °C; and detection, RI.

enzymatically or chemically are also semitelechelic. Therefore, the comb-type copolymers with the different densities and lengths of polysaccharide side chains would be available by combining enzymatic hydrolysis and the conjugation of the reducing end to the main chain polymer (Scheme 1).

To regulate the molecular weight of HA, we hydrolyzed high-molecular weight HA with hyaluronidase for the indicated time period (Figure 1). The molecular weight of HA decreased and the molecular weight distribution narrowed with the increase in digestion time. When the time for enzyme reaction was controlled, the HAs with the desired molecular weight, i.e., chain length, were isolated.

The hydrolyzed HA fragment was then grafted onto PLL by reductive amination between the reducing end of HA and ϵ -amino groups of PLL using NaBH_3CN as a reducing agent. The HA polyanion can form the polyion complex, which prevents the conjugating reaction, with the PLL polycation. To suppress this polyion complex formation, the ionic strength of the medium was increased (0.4–1 M NaCl). The increase in the NaCl concentration resulted in the reaction proceeding in a homogeneous system (see Figure 4a).

Figure 2 shows the representative GPC profile of the reaction mixture and the resulting copolymer. After the reaction, the peak area of PLL increased while that of HA decreased. Although an obvious elution volume shift

Figure 3. ^1H NMR spectra of PLL (a), HA (b), and PLL-graft-HA (c) in D_2O . For the PLL-graft-HA, D_2O containing 0.35 M NaCl was used.

was not observed in the chromatogram owing to some interaction between the polymers and column packing, the molecular weight determined by the LS detector increased drastically after the reaction, being 2.3×10^5 for the resulting copolymer in comparison with 9.7×10^4 for the original PLL. The incubation of HA or PLL alone with NaBH_3CN under the same conditions caused no change in GPC profiles, which suggested that neither degradation nor intermolecular side reaction occurred (results not shown). When HA was incubated with PLL in the presence of a 10-fold molar excess of lactose or sucrose with respect to the reducing end of HA, not sucrose, the nonreducing sugar, but lactose, the reducing one, inhibited HA consumption (results not shown). Therefore, it can be concluded that the HA was conjugated with PLL at its reducing end through the reductive amination reaction (23). Figure 2 also shows that the comb-type copolymer was isolated from unreacted HA by dialysis.

As shown in Figure 3, the ^1H NMR spectra of the comb-type copolymer showed the characteristic signals of both PLL and HA moieties: PLL, δ 1.4–1.8 (β , γ , δ - CH_2), 3.0 (ϵ - CH_2), 4.3 (α -CH); HA, δ 2.0 (NAc- CH_3), 3.3–3.9 (H-2,3,4,5,6), 4.4–4.6 (H-1). From the signal ratio of methyl protons (2.0 ppm) of the *N*-acetyl groups of the HA-grafts to ϵ -methylene protons (3.0 ppm) of the PLL backbone, the content (wt % and grafting %) of HA in the copolymer was determined. The results of the synthesis of PLL-graft-HA comb-type copolymers are summarized in Table 1. The coupling efficiency was more than about 70%. Consequently, we have easily prepared the various PLL–HA conjugates with a well-defined comb-type structure by combining enzymatic hydrolysis and reductive amination.

Polyampholyte Properties of the PLL-graft-HA Comb-Type Copolymer. The resulting PLL-graft-HA comb-type copolymer consists of a polycation backbone and polyanion side chains. The polyampholyte property of the comb-type copolymer was examined by measuring the turbidity of the copolymer solution. Figure 4a shows that the turbidity of the PLL-graft-HA solution varied with the change of NaCl concentration at neutral pH; namely, the solubility of the PLL-graft-HA markedly

Figure 4. Polyampholyte properties of the PLL-*graft*-HA comb-type copolymer (sample 1). (a) Effect of ionic strength on the solubility of the copolymer at neutral pH. (b) Effect of pH on the solubility of the copolymer in the absence (●) or presence (○) of 400 mM NaCl. The turbidity was monitored as the absorbance at 500 nm.

varied in water in response to the ionic strength of the medium. The PLL-*graft*-HA suddenly precipitated out of the aqueous medium at a particular ionic strength but became soluble again at higher ionic strengths.

It should be noted that the PLL-*graft*-HA seems to be soluble at lower ionic strengths where the comb-type copolymers should form polyion complexes. Since the net charge of the PLL-*graft*-HA used in the experiment is positive at neutral pH, the copolymers were probably dispersed in the medium as colloidal particles without undergoing particle aggregation. The increase in the ionic strength of the medium presumably reduced the electrostatic repulsion among the colloidal particles, inducing particle aggregation (salting out) to exhibit turbidity. However, the further increase in the ionic strength of the medium over 350 mM NaCl probably

dissociated the polyion complex between PLL and HA chains, resulting in the complete disappearance of turbidity. To assess the solution behavior at the lower ionic strength, we varied the pH of the solution (24). As seen in Figure 4b, the sudden increase in turbidity was observed when the pH of the medium was increased to 9.0, where the deprotonation of the ϵ -amino groups of PLL was initiated (25). The partial deprotonation of the PLL moiety presumably decreased the repulsive force among colloidal particles and increased their hydrophobicity, triggering interparticle aggregation. Finally, the solution became transparent again above pH 11, owing to the complete dissociation of the polyion complex, due to the thorough deprotonation of PLL, between PLL and HA. These results suggest that the PLL-*graft*-HA formed its intramolecular polyion complex under low-ionic strength conditions (in 0 mM NaCl) and dissociated its polyion complex under high-ionic strength conditions (>350 mM NaCl).

DNA-PLL-*graft*-HA Polyion Complex. The DNA was mixed with the PLL-*graft*-HA ($[\text{amino group}]_{\text{copolymer}}/[\text{phosphate group}]_{\text{DNA}} = 1$), and the ionic strength of the medium was gradually decreased from 1 to 0 M NaCl by step-down dialysis (26). The transparent solution obtained after dialysis was then lyophilized, dissolved in D₂O, and analyzed by ¹H NMR. The ¹H NMR spectra of the copolymer with or without DNA are shown in Figure 5. It is worth noting that the signals of ϵ -methylene protons of the PLL moiety in the PLL-*graft*-HA broadened in the presence of DNA (Figure 5c). This is probably caused by polyion complex formation between the PLL moiety and DNA. Although the PLL signals broadened, the HA signals remained unchanged, or rather became sharper. The sharp signals of HA in the presence of DNA under low-ionic strength conditions (Figure 5c) seem to be similar to those of PLL-*graft*-HA alone at high ionic strengths (Figures 3c and 5a), where the PLL-*graft*-HA did not form polyion complex; i.e., HA chains were free. These results suggest that the PLL backbone selectively formed the polyion complex with DNA even in the presence of the HA side chains. The preferential complex formation was further demonstrated by the acrylamide gel electrophoresis analysis of a PLL-*graft*-HA-oligoDNA mixture, as will be reported elsewhere (27). In addition, the PLL-*graft*-HA-DNA complex may form the multiphase structure in which the hydrophobic PLL-DNA complex is surrounded by the hydrated shell of free HA (28, 29). Complex formation with free HA chains is considered to be essential for directing the complex to target cells.

Figure 5. Effect of DNA on the ^1H NMR spectra of the PLL-graft-HA comb-type copolymer: PLL-graft-HA alone in D_2O containing 350 mM NaCl (a) and PLL-graft-HA in the absence (b) or presence (c) of DNA in D_2O without NaCl. The signal of ϵ -methylene protons of PLL (3.0 ppm) and the H-2 signal of glucuronic acid of HA (3.3 ppm) are represented.

Conclusion. In this study, we have prepared the various PLL-graft-HA comb-type copolymers with a defined density and a defined length of HA side chains. The synthesis of the comb-type copolymers has been achieved by (1) the control of the HA chain length by enzymatic hydrolysis, (2) the suppression of formation of a polyion complex between HA and PLL in high-ionic strength media during the coupling reaction, and (3) the relatively high coupling efficiency of the reductive amination between the reducing end of HA and ϵ -amino groups of PLL.

By using the various PLL-graft-HA comb-type copolymers, it would be possible to control the properties of the DNA complex such as complex size, solubility, and the degree of DNA compaction (13, 30). The resulting comb-type copolymers are, therefore, useful in investigating the relationship between DNA complex properties and the efficiency of both targeting and transfection. Furthermore, the efficient conjugation of the HA chains to other materials (31–40) can offer unique tools for studying the biological and biochemical properties of HA.

ACKNOWLEDGMENT

We are grateful to Dr. Teruzo Miyoshi and Dr. Koichi Takahashi of Denki Kagaku Kogyo Co., Ltd., for supplying hyaluronic acid and for their help in the preparation of the manuscript. We thank Dr. Anwarul Ferdous of the Tokyo Institute of Technology for his helpful discussions.

Recombinant Immunocytokines Targeting the Mouse Transferrin Receptor: Construction and Biological Activities

Torsten Dreier,[†] Holger N. Lode,[†] Rong Xiang,[†] Carrie S. Dolman,[†] Ralph A. Reisfeld,^{*,†} and Angray S. Kang[‡]

Department of Immunology and Department of Molecular Biology, The Scripps Research Institute, 10550 North Torrey Pines Road, La Jolla, California 92037. Received February 16, 1998; Revised Manuscript Received May 7, 1998

Localized cytokine therapies with recombinant monoclonal antibody-cytokine fusion proteins, designated immunocytokines, have become of increasing interest for tumor immunotherapy, since they direct immunomodulatory cytokines into the tumor microenvironment. To investigate their mechanisms of action in a variety of syngeneic tumor models, recombinant mouse cytokines IL2 and GM-CSF were engineered as fusion proteins to the carboxyl terminus of a chimeric rat/mouse antitransferrin receptor antibody, ch17217 and expressed in stable-transfected Chinese hamster ovary cells. The recombinant immunocytokines were readily purified by affinity chromatography and their binding characteristics were identical to those shown for the ch17217 antibody. The IL2 immunocytokine had an activity similar to recombinant mouse IL2, whereas the GM-CSF immunocytokine had enhanced cytokine activity relative to recombinant mouse GM-CSF. The clearance rates of ch17217 and the GM-CSF and IL2 immunocytokines were relatively similar with elimination phases ($t_{1/2\alpha}$) of 1.8 h and distribution phases ($t_{1/2\beta}$) of 83, 88, and 91 h, respectively. Both immunocytokines demonstrated effective antitumor activity by suppressing the growth of hepatic metastases of mouse neuroblastoma and pulmonary metastases of mouse colon carcinoma in syngeneic A/J and BALB/c mice, respectively. These results indicate that biologically effective IL2 and GM-CSF immunocytokines combine the targeting ability of an antitransferrin receptor monoclonal antibody with the immunomodulatory functions of each cytokine. Because of the universal expression of the transferrin receptor on mouse tumor cell lines, these constructs should prove useful to determine their efficacy in a wide variety of syngeneic mouse tumor models and to perform detailed studies of their modes of action.

INTRODUCTION

The increased availability of recombinant cytokines in pharmacologic quantities has stimulated a number of research efforts to assess the effect of these immunomodulatory molecules on the host immune response to cancer. Among a variety of cytokines, IL2 has been most widely applied, since it is one of the most potent antitumor cytokines with biological activities that include the stimulation of proliferation of such antitumor effectors as cytotoxic T cells, natural killer (NK) cells, and macrophages (1, 2). This cytokine has been applied with some success for the treatment of patients with melanoma and renal carcinoma (3). However, the systemic administration of IL2 is limited by serious side effects, even at nanomolar concentrations (4). Therefore, investigators started to focus on local cytokine treatments, e.g., intratumoral cytokine injection or cytokine gene therapy which, in contrast to systemic application, comply with the paracrine mode of action of these immunomodulators being optimally effective within a few cell diameters from their cell of origin (5).

Gene therapy, i.e., the *ex vivo* transfection of cytokine genes into autologous tumor cells that are subsequently injected into a host, has been widely applied in clinical trials and preclinical animal models. When such cyto-

kines, including IL2 and GM-CSF, are produced by the transfected tumor cells, they induce a local inflammatory response, resulting in some cases, in a systemic immune response effective against challenge with wild-type tumor cells (6, 7). Some encouraging preclinical and early clinical data were obtained with this strategy (8); however, the feasibility of its broad clinical application as a cancer therapy is limited by its patient-specific nature.

We have developed an alternative approach for tumor immunotherapy by using immunocytokines with the unique ability to direct multifunctional cytokines to the tumor microenvironment (9). This approach conforms with the paracrine function of most cytokines and is not limited by systemic toxicities or patient specificity. We previously demonstrated in syngeneic mouse tumor models of neuroblastoma (10), colon carcinoma (11), and melanoma (12) that recombinant immunocytokines comprised of different tumor-specific antibodies and IL2 can eradicate established disseminated tumor metastases, followed in some cases by a long-lived tumor-protective immune response (11). However, the antibody specificity for one distinct target antigen limited the use of such constructs to only a small number of syngeneic mouse tumor models.

Here, we describe the construction, characterization and biological activity of two recombinant immunocytokines comprised of a monoclonal antibody against mouse transferrin receptor and mouse IL2 and GM-CSF, respectively. In both cases, the antigen-binding capacity and cytokine functions were maintained, and effective suppression of metastasis was demonstrated in two

syngeneic models of mouse neuroblastoma and colon carcinoma. The universal expression of the transferrin receptor on mouse tumor cell lines should make these immunocytokines applicable to ascertain their antitumor activity in all syngeneic mouse tumor models and to perform in-depth studies of their underlying effector mechanisms.

EXPERIMENTAL PROCEDURES

Antibodies and Cell Lines. The rat hybridoma R17217, secreting an antibody of IgG2b isotype, directed against the mouse transferrin receptor (Tf-R), was kindly made available by Dr. Jayne F. Lesley (Salk Institute, La Jolla, CA). This antibody was extensively characterized and demonstrated not to affect functions of Tf-R involved in iron transport into cells or to inhibit the growth of tumor cells (13, 14).

The GM-CSF-dependent acute mouse hematopoietic stem cell line 32D(G) was kindly provided by Dr. D. Santoli (Wistar Institute, Philadelphia, PA). The IL-2-dependent mouse leukemia CTLL-2 and CHO cell lines were obtained from the American Type Culture Collection (Rockville, MD).

Mice. Syngeneic female A/J and BALB/c mice were obtained at 6–8 weeks of age from Jackson Laboratory (Bar Harbor, ME). The mice were maintained under specific pathogen-free conditions. All experiments were performed according to NIH Guidelines for Care and Use of Laboratory Animals.

Construction of Immunocytokines. The variable region of the rat immunoglobulin chains were amplified by RT-PCR using mRNA isolated from R17217 hybridoma as a template. To access the VL chain, a 5'-primer was designed according to sequence information available for these regions (15). We selected GAYGTNCARATGACNCARTCNCC as the 5'-primer for amplification of the variable region of the rat VL. The 3'-primer was designed to anneal to the rat κ light chain region (GGATGATGTCTTATGAACAA). In a second PCR reaction, the OKT3-leader sequence was added upstream and a *Nar*I site downstream of the primary VL PCR product. The construction of the chimeric rat-mouse light chain was completed by joining this VL via the *Nar*I site with a mouse C κ fragment (Figure 1A).

The variable heavy chain (VH) was amplified in a similar manner. Briefly, we used the 5'-primer GAGGTGCARCTNGTNGAATCNGGAGGAGG and selected the 3'-primer from the region of the rat J-minigene (GGTGACCATGGTTCCTGGGCCCCAGAAGTC). In a second PCR, the N418 hamster immunoglobulin-derived leader sequence was added upstream and a *Csp*45I site downstream of the original VH-PCR-product, respectively (Figure 1A). This VH construct was ligated to a mouse IgG2a constant heavy-chain backbone via the *Csp*45I site, which had been engineered at the 5' end of the IgG2a. The mouse IgG2a backbone was constructed with an *Sma*I site located seven amino acids upstream of the original 3' end of mouse IgG2a. In the case of the recombinant antibody, we introduced a synthetic oligonucleotide in this *Sma*I site, providing a stop codon followed by an *Eco*RI site. For the construction of the immunocytokines, the mature sequences of the mouse cytokines IL-2 and GM-CSF were amplified from the RNA of Concanavalin-A stimulated mouse splenocytes by RT-PCR with the following primers: GGACCCCGG-GAGCACCCACTTCAAGCTCC (IL-2 5'); CTGAATTCT-TATTGAGGGCTTGTTGAGATGATGC (IL-2 3'); GGAC-CCCGGGAGCACCCACCCGCTCACCC (GM-CSF 5'); and

CTGAATTCTGGGCTTCCTCATTTCCTGGCTTGG (GM-CSF 3'). The resulting PCR products were inserted as *Sma*I-*Eco*RI fragments at the 3' end of the heavy chain construct.

Construction of the Expression Vectors. For expression purposes, the light-chain construct was cloned into the multiple cloning site of the pcDNA3.1/zeo vector (Invitrogen, Carlsbad, CA) using the *Nhe*I and *Xho*I restriction sites. The heavy-chain constructs were cloned as *Nhe*I to *Eco*RI fragments into the pBK-CMV vector (Stratagene, La Jolla, CA). The entire heavy-chain expression unit was isolated after digestion with *Nsi*I followed by blunt ending with mung bean nuclease and a *Mlu*I digest. A double expression vector was constructed by cloning the heavy-chain expression unit into the pcDNA3.1/zeo vector containing the light-chain expression unit using *Sca*I and *Mlu*I restriction sites (Figure 1B), thus sacrificing the ampicillin gene used for selection in prokaryotic cells. However, the selectable zeocin marker is retained.

Cell Culture and Transfection. Chinese hamster ovary (CHO) cells were maintained in Dulbecco's modified Eagle's medium (DMEM) containing 10% fetal bovine serum and 1% nonessential amino acid solution (Biowhittaker, Walkersville, MD). Transfection with the double expression vectors was done at cell densities of 70–80% using SuperFect (Qiagen, Chatsworth, CA) according to the manufacturer's protocol. Twenty-four h after transfection, the cells were transferred to 96-well plates and drug selection was initiated by supplementing the media with 200 μ g/mL zeocin (Invitrogen, Carlsbad, CA). Zeocin-resistant colonies developed within 2 weeks after transfection. The supernatants of these colonies were assayed for mouse IgG2a production by ELISA and dot blot analyses. The highest producers (10–20 μ g/mL) were expanded to produce the desired immunocytokines.

Production and Purification of Immunocytokines. For ease of purification, the medium of 90% confluent cells cultured in roller bottles was changed to serum-free IS-CHO medium (Irvine Scientific, Santa Ana, CA) and culture continued in this medium for another 10 days. The immunocytokines produced were isolated from the spent culture media by protein A Sepharose chromatography and concentrated by ultrafiltration to a final concentration of 1–2 mg/mL. The molecular size and purity of the proteins was analyzed by SDS-PAGE.

Immunoassays. Identification of the chimeric antibodies or immunocytokines was performed by ELISA and dot blot analyses. The capture antibody used in the ELISA was an Fc-specific goat anti-mouse antibody, and the detection antibody was an alkaline phosphatase-labeled κ -chain-specific goat anti-mouse antibody (Sigma, St. Louis, MO). An alkaline phosphatase-labeled goat anti-mouse antibody was used for dot blots. The mouse IgG2a antibody UPC10 (Sigma, St. Louis, MO) served as a positive control and the supernatant of nontransfected CHO cells as a negative control.

Cytokine Activity Assays. IL-2 activity was measured by a mouse T-cell proliferation assay (16). Briefly, the IL-2 dependent murine leukemia cell line CTLL-2 (ATCC) was cultured for 48 h without IL-2. Then, 3×10^4 cells were incubated for 24 h with serial dilutions of either recombinant murine (rm) IL-2 or the ch17217-IL-2 immunocytokine, respectively, in a total volume of 200 μ L. GM-CSF activity was detected in a proliferation assay with the GM-CSF-dependent cell line, 32D(G). The cells were added to 96-well plates (5000 cells/well) together with serial dilutions of either rmGM-CSF or the

Figure 1. Schematics depicting DNA constructs encoding for the ch17217-IL2 and GM-CSF immunocytokines and their expression vector. (A) Schematic of heavy and light chains; the variable region of the rat R17217 light chain (VL) was constructed downstream of an OKT3 leader sequence (OL) and subsequently cloned upstream of the constant region of a mouse κ light chain ($C\kappa$) using the *NarI* restriction site. The variable region of the rat R17217 heavy chain (VH) was combined with a hamster-derived N418 leader sequence (NL) and introduced in the heavy-chain backbone of mouse Ig2a by using the *Csp 45I* restriction site. (B) Double expression vector with heavy and light chains. The ch17217 light-chain expression unit was cloned into the multiple cloning site of the pcDNA 3.1/zeo vector as an *NheI XhoI* fragment. Heavy-chain expression units for each fusion protein were introduced as *ScaI MluI* fragments, generated as described in the Experimental Procedures. The zeocin resistance gene remained intact as a functional selection marker in both eukaryotic and prokaryotic cells.

ch17217-GM-CSF immunocytokine and incubated for 24 h. [*methyl*- ^3H]Thymidine uptake was measured 16 h after addition of 0.5 μCi /well. All samples were tested in triplicate.

Radiolabeling. Radiolabeling with ^{125}I was performed, as previously described (17). Briefly, 1 mg of the respective protein was incubated for 30 min on ice with 1 mCi of ^{125}I (100 mCi, 3.75 Gbq/mL (Amersham, Arlington Heights, IL) in polystyrene tubes coated with 100 μg of Iodo-Gen reagent (Pierce, Rockford, IL). Non-incorporated ^{125}I was removed by gel filtration on PD10 columns (Pharmacia, Piscataway, NJ).

Saturation Binding Assays. Binding assays were performed with ch17217 and both immunocytokines on several mouse tumor cell lines (RENCA, NXS2, CT26). Although all of these cell lines expressed Tf-R, we selected RENCA mouse renal carcinoma cells for our analyses, since these were adherent and provided the most reproducible saturation binding data. For that purpose, 9×10^4 cells were added to 24-well microtiter plates and cultured for 24 h. Saturation binding was then determined by adding the respective ^{125}I -radiolabeled proteins at various concentrations to the cells followed by incubation on ice for 2 h. Cells were washed three

times with ice cold PBS and 1% BSA, and cell-bound radiolabel was determined in a γ -scintillation counter. Nonspecific binding was determined for all proteins in the presence of a 200-fold excess of unlabeled mAb R17217. The number of binding sites and the binding constants for each construct were determined by Scatchard plot analysis (18).

Pharmacokinetics. Six week old BALB/c mice were used to determine the blood clearance of mAb ch17217 and immunocytokines, ch17217-IL2 and ch17217-GM-CSF. Groups of four mice each were injected into the lateral tail vein with 25 μ g of each of these radiolabeled proteins (specific activity of 0.2 μ Ci/ μ g). Blood samples were collected from the orbital sinus at 0.5, 1, 2, 4, 8, 24, 48, and 72 h after injection of the radiolabeled proteins and assayed for ^{125} I activity in a γ -scintillation counter. Elimination ($t_{1/2\alpha}$) and distribution ($t_{1/2\beta}$) phase half-lives were calculated assuming exponential clearance according to the formula $A = A_0 e^{-kt}$ using the two earliest and latest time points, respectively (19).

Syngeneic Tumor Models. Pulmonary colon carcinoma and hepatic neuroblastoma metastases were induced in syngeneic BALB/c and A/J mice, respectively, as described previously (10, 11). Briefly, 1×10^5 or 1×10^4 NXS2 mouse neuroblastoma cells were injected into the lateral tail vein of A/J mice to induce hepatic metastases. CT26 mouse colon carcinoma cells (1×10^4) were injected intravenously (i.v.) for induction of pulmonary metastases. Mice were treated 24 h after tumor cell inoculation with daily i.v. injections ($\times 7$) of either PBS, 5 and 30 μ g ch17217-IL2, or 30 μ g of ch17217-GM-CSF. Macroscopic metastases to livers and lungs were determined 24–28 days after tumor cell inoculation. Since the metastatic foci appeared fused, metastases were scored according to the percentage of lung and liver surface involvement.

Statistics. The statistical significance of differential findings between experimental groups of mice was determined by the nonparametric Mann–Whitney rank sum test. Results were regarded significant if two-tailed P values were <0.05 .

RESULTS

Expression of Immunocytokines. The construction of immunocytokines between the ch17217 antibody and mouse IL2 or mouse GM-CSF is described in the Experimental Procedures and shown schematically in Figure 1. The mature IL2 or GM-CSF protein sequences were directly fused to the carboxyl terminus of the CH3 exon of the mouse C γ 12a gene from which the three penultimate amino acids were deleted. The proteins secreted by these transfectants assembled into complete antibody molecules with the cytokine linked to the IgH chains. In both cases, mouse IL2 and GM-CSF retained their biological activities. The expression levels of the transfectants ranged from 10 to 20 μ g/mL.

Purification and Analysis of Immunocytokines. Purification was achieved by passing spent culture medium of stable-transfected CHO cells over a protein A Sepharose column. The purity of both immunocytokines was documented by SDS–PAGE analysis for chain composition and assembly under reducing conditions. Figure 2A indicates that under reducing conditions the ch17217 antibody dissociated into heavy (H) and light (L) chains of the size corresponding to that of the R17217 antibody. The H chains of the GM-CSF and IL2 immunocytokines showed higher apparent molecular masses of ~68 and ~62 kDa, consistent with the fusion of GM-

Figure 2. Analysis of ch17217 anti-mouse transferrin receptor antibody and its IL2 and GM-CSF immunocytokines. (A) Proteins were diluted in gel sample buffer, boiled under reducing conditions and analyzed on a 10% polyacrylamide gel containing SDS. Purified R17217 (lane 2) and ch17217 (lane 3) were compared to immunocytokine ch17217-GM-CSF (lane 4) and ch17217-IL2 (lane 5). Molecular weight markers are shown in lane 1. (B) Samples were also analyzed on SDS–PAGE under nonreducing conditions. Purified R17217 (lane 2) and ch17217 (lane 3) were compared to immunocytokines ch17217-IL2 (lane 4) and ch17217-GM-CSF (lane 5).

CSF and IL2, respectively. Figure 2B shows the electrophoretic profile of the same constructs on SDS–PAGE under nonreducing conditions. The molecular size of each immunocytokine and antibody was as expected, with ch17217-GM-CSF showing the highest molecular size, followed by ch17217-IL2 and the antibodies in that order.

The effect which fusion of the cytokines exerted on the antigen-binding activity of ch17217 was determined by flow cytometry and direct binding in saturation-binding assays. Flow cytometry using NXS2 neuroblastoma cells indicated equal binding of ch17217 and its IL2 and GM-CSF fusion protein to Tf-R expressed on these cells (data not shown). A representative saturation-binding assay with RENCA cells, followed by Scatchard analysis using all three constructs, is depicted in Figure 3. Essentially identical binding constants (K_D) for ch17217 and its IL2 and GM-CSF immunocytokines were demonstrated with K_D values ranging from $(2 \text{ to } 4.5) \times 10^{-9}$ M and the number of Tf-R binding sites expressed on RENCA cells ranging from $(3 \text{ to } 5) \times 10^5$ per cell in three separate experiments.

Biological Activities of Immunocytokines. The IL2 activity of ch17217-IL2 was measured in a proliferation assay with the IL2-dependent mouse CTLL-2 cell

Figure 3. Scatchard plot of saturation binding analysis. Serial dilutions of ^{125}I -labeled ch17217-IL2 (A) and GM-CSF (B) immunocytokines were compared with ch17217 antibody (C) in a saturation-binding assay using mouse RENCA cells. Binding constants of each construct was calculated from corresponding Scatchard plots. Inserts depict the respective Scatchard plots.

Figure 4. Biological activity of immunocytokines. (A) Proliferation activity assays of recombinant mouse (rm) IL2 standard and purified ch17217-IL2 immuno-cytokine were performed at several dilutions using the IL2-dependent mouse leukemia cell line CTLL-2. (B) Proliferation activity assay of recombinant mouse (rm) GM-CSF standard and purified ch17217-GM-CSF immunocytokine. This was performed as above with the GM-CSF-dependent mouse hematopoietic stem cell line 32D (G).

line. When compared on a protein basis to recombinant mouse IL2, produced in bacteria, the immunocytokine required essentially equal concentration to achieve the same level of proliferation when assayed in the range of 1–10 ng/mL (Figure 4A). The GM-CSF activity of the ch17217-GM-CSF immunocytokine, tested in a proliferation assay with the GM-CSF-dependent mouse hemo-

poietic stem cell line 32D(G), required less material than the rmGM-CSF standard (produced in bacteria) when assayed in the range 0.1–1 ng/mL.

Pharmacokinetics. In vivo blood clearance was measured by intravenous injection of ^{125}I -labeled, purified immunocytokines into BALB/c mice. Analyses of blood samples collected at various time intervals (see Experi-

Figure 5. Blood clearance of ch17217 antibody and immunocytokines. Groups of four mice were injected with 25 μ g of ^{125} I-labeled ch17217 antibody or each immunocytokine. Blood samples were collected at various time intervals and assayed for ^{125} I activity in a γ -scintillation counter. Each data point represents the mean value of four individual mice. Standard deviations were always less than $\pm 2\%$ of injected dose/mL blood.

Table 1. Half-Lives of the α and β Phases of the Free Antibody and Immunocytokines

	$t_{1/2}$, h	
	α	β
ch17217	1.9	83
ch17217-GM-CSF	1.8	88
ch17217-IL2	1.8	91

mental Procedures) indicated very similar clearance rates for ch17217 and the GM-CSF and IL2 immunocytokines (Figure 5). Table 1 indicates that the elimination ($t_{1/2\alpha}$) and distribution ($t_{1/2\beta}$) phases for all three constructs are in a similar range.

Antitumor Activity of Immunocytokines. The antitumor activities of the IL2 and GM-CSF immunocytokines were demonstrated by their ability to effectively suppress the growth of either hepatic metastases of NXS2 mouse neuroblastoma in syngeneic A/J mice or pulmonary metastases of CT26 mouse colon carcinoma in syngeneic BALB/c mice. Treatment with daily i.v. injections ($\times 7$) was initiated 24 h after i.v. injection of the respective tumor cells, and animals were sacrificed and analyzed for macroscopic tumor growth 24–28 days after tumor cell inoculation. The data shown in Figure 6A indicate that treatment with 30 μ g ($\times 7$) of ch17217-IL2 completely suppressed the growth of hepatic neuroblastoma metastases in 6/6 animals, whereas 5 μ g ($\times 7$) was only partially effective ($p < 0.02$). This is in contrast to control animals injected with PBS that uniformly showed extensive hepatic metastases. Administration of 30 μ g ($\times 7$) of the ch17217-GM-CSF immunocytokine completely suppressed the growth of hepatic neuroblastoma metastases in 5/6 mice. By comparison, all control mice injected with PBS exhibited extensive metastases. The data shown in Figure 6B indicate that administration of 30 μ g ($\times 7$) of the ch17217-IL2 immunocytokine completely suppressed pulmonary metastases of colon carcinoma in 6/8 mice, and an equal dose of the ch17217-GM-CSF immunocytokine achieved this same effect in 5/8 animals. In both cases, two mice exhibited partial suppression of pulmonary metastases following administration of ch17217-GM-CSF immunocytokine, as compared to all control animals injected with PBS that showed extensive metastases.

Figure 6. Antitumor activity of ch17217 immunocytokines in syngeneic tumor models of mouse neuroblastoma and colorectal carcinoma. Mice were injected intravenously with 1×10^5 (closed symbols) or 1×10^4 (open symbols) NXS2 mouse neuroblastoma cells (A) or 1×10^4 CT26 mouse colorectal carcinoma cells (B). Treatment with either PBS(n), ch17217-IL2 (l, 5 μ g; s, 30 μ g) or ch17217-GM-CSF fusion protein (m, 30 μ g) was initiated 24 h after inoculation by daily intravenous injections ($\times 7$). Animals were sacrificed 24–28 days after inoculation. Liver or lung metastases were staged according to the percentage of metastatic liver or lung surface: Liver: 0 = 0%, 1 = 0–25%, 2 = 25–50%, 3 = 50–75%, 4 = $\geq 75\%$; Lung: 0 = 0%, 1 = 0–5%, 2 = 5–50%, 3 = $\geq 50\%$. Differences in metastatic scores between mice treated with fusion protein compared to untreated controls were all statistically significant ($P < 0.02$).

DISCUSSION

The rapid development of recombinant DNA technologies during the past decade facilitated the construction of antitumor antibody-cytokine fusion proteins (20). These constructs, called immunocytokines, combine the unique targeting ability of monoclonal antibodies with the multifunctional biological activities of cytokines and effectively direct these immunomodulatory molecules to the tumor microenvironment. Since most cytokines are paracrine factors that function optimally within a few cell diameters from their cell of origin, they are most effective in activating and proliferating immune effector cells to kill tumor cells when concentrated in the tumor microenvironment.

The systemic administration of cytokines, such as IL2, has led to improvements in the treatment of some patients with melanoma and renal carcinoma (1–4); however, a number of toxic side reactions were dose limiting (4) and led investigators to focus on local cytokine treatment strategies. This included the development of cytokine gene therapy largely by ex vivo transfection of a variety of cytokine genes, including IL2 and GM-CSF, into patients' autologous tumor cells or fibroblasts (6–8). Unlike systemic administration of cytokines, gene therapy with cytokines takes advantage of their paracrine nature. In a number of early clinical trials, this type of immunotherapy resulted in improvements in the treatment of some cancer patients (8). In preclinical experiments, gene therapy with cytokines induced an inflammatory response at the site where transduced tumor cells were injected, resulting in their rejection, which, in some cases, was followed by a systemic immune response capable of rejecting a challenge of wild-type tumor cells (5–7). However, the

patient-specific nature of this type of therapy will likely limit its widespread, broad clinical application.

We (9–12) and others (20, 21) developed several recombinant immunocytokines as an alternative approach for cancer immunotherapy that conforms with the paracrine nature of cytokines and is not limited by being patient specific. In all of these experiments, an antigen expressed preferentially on human or mouse tumor cells served as a docking site for directing immunocytokines to the tumor microenvironment. In a number of experiments, the gene encoding for a human tumor-associated antigen was transduced into mouse tumor cells which then became uniquely specific targets for immunocytokines in syngeneic hosts that completely lacked this same tumor-associated antigen in their organs and tissues (11, 12).

Here, we applied a distinctly different strategy by selecting the mouse transferrin receptor (Tf-R) as a target, which is universally expressed on most mouse tumor cells, as well as on a variety of normal organs and tissues. These include, in particular, liver, kidney, and spleen. In fact, the anti-mouse Tf-R antibody R17217 used in this study was shown to follow this pattern of biodistribution and was predominantly detected in the spleen. It is presently not known whether this is entirely due to its specific binding to Tf-R or to uptake by the reticuloendothelial system (13).

We wanted to test the hypothesis that even under these somewhat unfavorable conditions, anti-TfR antibody-IL2 and GM-CSF immunocytokines could still effectively suppress the growth of pulmonary and hepatic metastases of mouse colon carcinoma and neuroblastoma in syngeneic mice. We purposely selected the rat anti-mouse Tf-R antibody R17217 of IgG2b isotype, since it was shown *not* to block Tf-R functions involved in iron transport and thus proved incapable of inhibiting the growth of mouse tumor cells (14).

We demonstrated purity of the IL2 and GM-CSF immunocytokines by SDS–PAGE analysis under reducing conditions and showed that these constructs secreted by transfected CHO cells were capable of assembling into complete antibody molecules with IL2 and GM-CSF fused to the Ig heavy chain (Figure 2). Construction of these immunocytokines did not affect their antigen-binding affinities as saturation-binding studies and Scatchard plot analyses of these data indicated that the binding constant (K_D) of the chimeric anti-Tf-R antibody ch17217 was in the same range, i.e., $(2–4.5) \times 10^{-9}$ M, as those of its GM-CSF and IL2 immunocytokines. When tested on a mouse renal carcinoma cell line (RENCA), these immunocytokines bound Tf-R sites expressed on these cells essentially in the same range of $(3–5) \times 10^5$ sites/cell as ch17217. Apparently, the deletion of the three penultimate carboxyl terminal amino acids of Ig H chains of the two immunocytokines did not measurably affect their binding affinities.

The IL2 activity of ch17217-IL2 was found to be essentially the same as that of the recombinant mouse IL2 standard produced in bacteria. This was true for a concentration range of 1–10 ng/mL required to achieve proliferation of the IL2-dependent mouse leukemia cell line CTLL-2 (Figure 4A). By contrast, the GM-CSF activity of ch17217-GM-CSF was greater in the 0.1–1 ng concentration range than that of the recombinant mouse GM-CSF standard produced in nonglycosylated form in bacteria (Figure 4B). Apparently, the GM-CSF moiety of the ch17217-GM-CSF immunocytokine has more activity than the nonglycosylated GM-CSF standard. This

could be due to its expression in CHO cells where it becomes fully glycosylated (22).

An examination of the pharmacokinetics of ch17217 and its GM-CSF and IL2 immunocytokines in BALB/c mice revealed quite similar values for $t_{1/2\alpha}$ (elimination phase) and the $t_{1/2\beta}$ (distribution phase). These data are of interest when compared with those obtained previously by us in athymic *nu/nu* mice with human/mouse chimeric anti-ganglioside GD₂ antibody (ch14.18) and its respective immunocytokines with recombinant human GM-CSF and human IL2. In this case, the $t_{1/2\alpha}$ phases were 7.5, 1.4, and 0.3 h, and the $t_{1/2\beta}$ phases were 59, 30, and 28 h, respectively (23). In the present study, $t_{1/2\beta}$ (distribution phase) values were considerably extended, ranging from 83 to 91 h. Importantly, these values far exceed those of native GM-CSF, which was reported to be 50–85 min following bolus injection into humans (24) and that of rhIL2 reported as 13–24 min under the same conditions (25). The increase in $t_{1/2\beta}$ phases of ch17217-mouse GM-CSF over that of the ch14.18-huGM-CSF immunocytokine is noteworthy, since mouse GM-CSF has considerably higher affinity for the mouse GM-CSF receptor than human GM-CSF (26). The more extended $t_{1/2\beta}$ phases of the ch17217-IL2 and GM-CSF immunocytokines may also be influenced by their accumulation in the liver, kidney and spleen of mice (13).

However, the most important question to answer was whether the two immunocytokines under study were effective in directing IL2 and GM-CSF to the tumor microenvironment to mediate cellular immune responses capable of suppressing the growth and dissemination of tumor metastases. It is quite evident from our data (Figure 6) that this is indeed the case in neuroblastoma and colon carcinoma metastasis models in syngeneic mice. It is noteworthy that growth and dissemination of hepatic neuroblastoma metastases and pulmonary colon carcinoma metastases could be effectively suppressed in contrast to all control animals that developed extensive metastases.

On the basis of the data obtained thus far, it is most likely that the two immunocytokines described here can be used in a wide variety of syngeneic mouse tumor models to critically evaluate their efficacy in suppressing growth and dissemination of tumor metastases. More importantly, it is likely that these immunocytokines will lend themselves very well for in-depth studies of immunological effector mechanisms involved in their anti-tumor activities.

ACKNOWLEDGMENT

We wish to thank Dr. Ekke Liehl (NOVARTIS, Vienna, Austria) for a generous gift of recombinant murine GM-CSF. The authors express their appreciation to Ms. Lynne Kottel for preparation of this manuscript and to Ms. Lucia Morkes for technical assistance. This work was supported by NIH Grant CA37641. T.D. and H.N.L. were supported by a training grant of the Deutsche Forschungsgemeinschaft. This is The Scripps Research Institute's manuscript 11419-IMM.

Cell-Specific Modulation of Drug Resistance in Acute Myeloid Leukemic Blasts by Diphtheria Fusion Toxin, DT388-GMCSF

Arthur E. Frankel,^{*,†} Philip D. Hall,[‡] Chris McLain,[†] Ahmad R. Safa,[§] Edward P. Tagge,^{||} and Robert J. Kreitman[⊥]

Received February 4, 1998; Revised Manuscript Received April 10, 1998

Radiochemotherapy-resistant blasts commonly cause treatment failure in acute myeloid leukemia (AML), and their resistance is due, in part, to overexpression of multidrug resistance (mdr) proteins. We reasoned that targeted delivery of protein synthesis inactivating toxins to leukemic blasts would reduce the cellular concentrations of relatively short half-life resistance proteins and sensitize the cells to cytotoxic drugs. To test this hypothesis, we employed human granulocyte-macrophage colony-stimulating factor fused to truncated diphtheria toxin (DT388-GMCSF). The human AML cell line HL60 and its vincristine-resistant sublines, HL60Vinc and HL60VCR, were incubated *in vitro* for 24 h with varying concentrations of toxin. Doxorubicin was added for an additional 24 h, and cell cytotoxicity was assayed by thymidine incorporation and colony formation in semisolid medium. DT388-GMCSF sensitized HL60Vinc and HL60VCR but not HL60 to doxorubicin. Combination indices for three log cell kill varied from 0.2 to 0.3. In contrast, pretreatment with doxorubicin followed by toxins failed to show synergy. At least in the case of the vincristine-resistant cell lines, modulation of drug resistance correlated with reduction in membrane P-glycoprotein concentrations based on immunoblots with C219 antibody, flow cytometry with MRK16 antibody, and cell uptake of doxorubicin. These observations suggest clinical trials of combination therapy may be warranted in patients with refractory AML. Further, targeted toxins may represent a novel class of cell-specific modulators of drug resistance for a number of malignancies.

INTRODUCTION

There were 9200 new cases of acute myeloid leukemia (AML) in the U.S. in 1996 (1), and, even with complete remission rates of 50–70% and effective consolidation and intensification regimens including allogeneic bone marrow transplantation, over 80% of patients will die from complications of the disease and its treatment (2). Radiochemotherapy resistant blasts are a frequent cause of treatment failure in AML patients (3). In many cases, multidrug resistance (mdr) is due in part to overexpression of resistance proteins which alter drug accumulation, metabolism, and apoptotic thresholds. Modification of resistance protein function has been hampered by the finding that many resistance proteins are expressed by normal human tissues, and noncell specific modulation leads to significant toxicities. For example, the substrate analogues (quinine, cyclosporine, and PSC833) of the P-glycoprotein drug efflux transporter resistance protein have been tested in AML therapy trials and have produced toxicities to marrow and other organs, marked alterations in cytotoxic drug pharmacodynamics and minimal effects on disease-free survival or overall sur-

vival (4). Hence, there is a need for new reagents with a unique mechanism of action to modulate drug resistance specifically in AML blasts.

Three resistance proteins (P-glycoprotein, glutathione S-transferase π , and Bcl2) have been shown to have rapid turnover (24 h or less) (5–7), and the blast concentrations of these proteins correlate with clinical response rates and remission durations (8–10). These proteins could serve as targets for cell-specific inhibitors of protein synthesis such as targeted toxins. Targeted toxins are polypeptide drugs consisting of tumor cell-directed ligands covalently linked to protein synthesis inactivating peptide toxins.

A number of studies both *in vitro* and *in vivo* have shown supraadditive cell killing with combinations of immunotoxins and cytotoxic drugs (11–20). Anti-CD19-ricin A chain and anti-CD22-ricin A chain conjugates with either cyclophosphamide, doxorubicin, or camptothecin incubated with Burkitt's lymphoma cells show synergistic cell kill (11). Similarly, anti-CD19-blocked ricin conjugate combined with etoposide or doxorubicin yielded synergistic cell killing of a B-lymphoma cell line and a retrovirally transfected B-lymphoma cell line expressing mdr-1 (12). Finally, anti-p43 epithelial antigen-recombinant ricin A chain conjugate combined with thiotepa or cisplatin showed synergistic cell killing of ovarian carcinoma cell lines (13). When anti-CD19-ricin A chain and anti-CD22-ricin A chain were administered with doxorubicin, cyclophosphamide, or camptothecin to scid mice bearing Burkitt's lymphoma cells, schedule dependence for supraadditive cell killing was observed

(14). Only when immunotoxins were given before or at the same time as cytotoxic drugs was synergy seen. With modulating doses of anti-p43-ricin A chain conjugate on ovarian carcinoma cells and anti-CD19-blocked ricin on *mdr-1* expressing B-lymphoma cells, concentrations of resistance proteins decreased (12, 13). The ovarian carcinoma cells showed decreases in glutathione S-transferase activity, and the B-lymphoma had decreases in membrane P-glycoprotein. While additional studies report coalitive interactions of immunotoxins with cytotoxic drugs in T-acute lymphoblastic leukemia (15), B-lymphoma (16), colon carcinoma (17), and B-acute lymphoblastic leukemia (18), no similar efforts to modulate drug resistance in AML with targeted toxins have been reported.

We chose to use human granulocyte-macrophage colony-stimulating factor fused to truncated diphtheria toxin (DT388-GMCSF) to inhibit protein synthesis in myeloid blasts. We and others had previously reported potent protein synthesis inhibition by this fusion toxin on leukemic blasts (19–21). We reasoned that short half-life resistance protein concentrations should be reduced, sensitizing the cells to cytotoxic drugs. Further, GMCSF receptors are expressed on the majority of AML patients' blasts (24). We chose doxorubicin as the cytotoxic drug for study since anthracyclines are a critical component of AML induction regimens. The cell lines selected were HL60 and its vincristine-resistant sublines HL60Vinc and HL60VCR (25, 26). HL60 is a well-characterized human AML cell line displaying GMCSF receptors. The latter two sublines show different degrees of multidrug resistance, and each overexpresses P-glycoprotein. The goals of the present study were to examine the ability of the fusion toxin to modulate doxorubicin sensitivity in the three cell lines, determine the schedule dependency of any observed modulation, and correlate modulation with changes in P-glycoprotein concentration. We believed such a study was a requisite step prior to examination of resistance modulation with fresh leukemic blasts.

MATERIALS AND METHODS

Materials. DT388-GMCSF was prepared as previously described (20) and stored at -20°C until used. DT390mGM-CSF was a kind gift of Dr. Daniel Vallera and was stored at -20°C until used (38).

Cell Culture. HL60 human leukemia cells were a gift from M. Center, Kansas State University. The cells were grown in RPMI1640 plus 15% fetal calf serum. All media and components were purchased from Irvine Scientific (Santa Ana, CA). HL60Vinc, a vincristine-resistant subline of HL60 (26), was a gift from M. Center and maintained in RPMI1640 plus 15% fetal calf serum. The HL60VCR vincristine-resistant subline was developed by stepwise exposure of HL60Vinc to increasing concentrations of vincristine (A. R. Safa, unpublished data) and maintained in RPMI1640 plus 15% fetal calf serum plus $1\text{ }\mu\text{g/mL}$ vincristine (Eli Lilly, Indianapolis, IN). WT19 mouse leukemia cells were a gift of Dr. Andrew Kraft, University of Colorado Medical Center (41). The cells were grown in RPMI1640 plus 15% fetal calf serum with 10% WEHI cell conditioned medium.

GMCSF Receptor Density. Ten aliquots of two million cells in RPMI1640 plus 2.5% bovine serum albumin (BSA) plus 0.2% sodium azide plus 20 mM Hepes, pH 7.2, in a total volume of $150\text{ }\mu\text{L}$ were incubated with different concentrations of [^{125}I]GMCSF (Amersham, Arlington Heights, IL) in the presence or absence of 1500

ng of unlabeled human GMCSF (Immunex, Seattle, WA) for 30 min at 37°C with shaking. The cell suspensions were then layered onto $200\text{ }\mu\text{L}$ of phthalate oil mixture (1.5 parts dibutylphthalate and 1 part dioctylphthalate) in 1.5 mL Eppendorf tubes, centrifuged at 12 000 rpm in a microfuge at room temperature for 1 min and both cell pellets and cell supernatants counted in an LKB-Wallac 1260 multi-gamma counter gated for ^{125}I with 50% counting efficiency. Scatchard plots of specific bound/free versus specific bound counts per minute were made. Receptor density/cell was calculated as the value for the x-intercept divided by (specific activity in microcuries per microgram times the cell number times 4.2×10^{-8}). K_d was calculated as the x-intercept times 2.7×10^{-13} divided by the product of the y-intercept and the specific activity.

Thymidine Incorporation Cytotoxicity Assays. A total of 5×10^4 cells (HL60, HL60Vinc, HL60VCR, or WT19) were incubated in $100\text{ }\mu\text{L}$ RPMI1640 plus 15% fetal calf serum in Costar 96 well flat-bottomed plates. Twelve different concentrations of DT388-GMCSF or DT390mGM-CSF were added to each column in $50\text{ }\mu\text{L}$ of media and the cells maintained at $37^{\circ}\text{C}/5\%\text{ CO}_2$ for 24 h. Then, eight different concentrations of doxorubicin (Pharmacia, Kalamazoo, MI) were added to each row in a total volume of $25\text{ }\mu\text{L}$, and incubation continued for another 24 h at $37^{\circ}\text{C}/5\%\text{ CO}_2$. Then $1\text{ }\mu\text{Ci}$ [^3H]thymidine (NEN DuPont, Boston, MA) in $25\text{ }\mu\text{L}$ of medium was added to each well and incubated at $37^{\circ}\text{C}/5\%\text{ CO}_2$ for an additional 18 h. Cells were then harvested by a Skatron Cell Harvester (Skatron Instruments, Lier, Norway) onto glass fiber mats and ^3H counts per minute was counted in an LKB liquid scintillation counter gated for ^3H . The calculated IC_{90} , IC_{99} , and $\text{IC}_{99.9}$ were the concentrations of toxin, doxorubicin, or combination which inhibited thymidine incorporation by 90, 99, or 99.9% compared to control wells. To determine whether the cytotoxic effect of combination treatment was additive, antagonistic, or synergistic, an analysis using the combination index (CI) for each level of cytotoxicity was calculated using the equation: $\text{CI} = A/A_e + B/B_e$, where A and B are the concentrations of toxin and drug that in combination kill 90, 99, or 99.9% of cells and A_e and B_e are the concentrations of the toxin and drug, respectively, extrapolated from their individual killing curves capable of killing 90, 99, or 99.9% of cells alone (27). For $\text{CI} > 1$, antagonism is present; for $\text{CI} = 1$, additivity is present; for $\text{CI} < 1$, synergy is present.

Clonogenic Cytotoxicity Assays. To evaluate inhibition of colony formation as another measure of cell kill, $70\text{ }\mu\text{L}$ aliquots containing 2×10^4 cells were collected from the wells with toxin and doxorubicin described above after 48 h incubation. The cells were dispersed in 3 mL of RPMI1640 plus 15% fetal calf serum with 50 ng/mL GMCSF (Immunex), GCSF (Amgen, Thousand Oaks, CA) and 0.2% agarose (SeaPlaque, FMC Bioproducts, Rockland, ME) in 35 mm gridded polystyrene Petri dishes. After 20 min of solidification at 4°C , dishes were incubated 7 days at $37^{\circ}\text{C}/5\%\text{ CO}_2$ in a humidified incubator. Colonies containing >20 cells were counted on an inverted microscope. IC_{90} , IC_{99} , and $\text{IC}_{99.9}$ were the concentrations of toxin, doxorubicin, or combination, which inhibited colony formation by 90, 99, or 99.9% compared to control wells. CIs were calculated as for thymidine incorporation inhibition.

Reversed Schedule Thymidine Assay. Aliquots of $100\text{ }\mu\text{L}$ of medium with 5×10^4 cells were incubated first with $25\text{ }\mu\text{L}$ of medium containing eight different concentrations of doxorubicin. After 24 h, $50\text{ }\mu\text{L}$ of medium

containing 12 different concentrations of DT388-GMCSF was added, and incubation continued another 24 h at 37 °C/5% CO₂. [³H]Thymidine was then added (1 μ Ci in 25 μ L/well) and incubation and harvesting done as described above. CIs were again calculated as above.

Cell Uptake of Doxorubicin. Aliquots of one million cells in 100 μ L RPMI1640 plus 15% fetal calf serum with or without 50 μ M verapamil (Sigma) were mixed with or without 2.8 μ g/mL doxorubicin for 60 min at 37 °C/5% CO₂ and then washed with PBS/BSA/azide and then resuspended in 500 μ L of PBS/BSA/azide and run on the EPICS-XL with scatter gating and rhodamine fluorescence detection.

P-Glycoprotein Content of Cells. A total of 5×10^6 HL60, HL60Vinc or HL60VCR cells in 10 mL of RPMI1640 plus 15% fetal calf serum with or without modulating concentrations of toxin (4×10^{-9} M DT388-GMCSF) were incubated 48 h at 37 °C/5% CO₂. Cells were then harvested by centrifugation at 1000 rpm for 7 min, washed twice with 10 mL of PBS, and resuspended in 10 mM NaCl, 10 mM Tris-HCl, pH 8.0, 1 mM PMSF, and 50 μ g/mL leupeptin, and left on ice for 10 min. Cells were then sonicated, and nuclei and debris removed by centrifugation at 2500 rpm for 15 min. Membranes were isolated by centrifugation at 25 000 rpm for 60 min and resuspended in 1 mM Tris, pH 8.0, 0.1 mM EDTA, 1 mM PMSF, and 50 ng/mL leupeptin. Protein concentrations were determined by Bradford assay using the Bio-Rad protein assay kit and BSA standards. Aliquots equivalent to 1.3×10^6 cells (50–100 μ g of protein) were diluted in reducing sample buffer and subjected to 8% reducing SDS-PAGE along with Bio-Rad kaleidoscope high molecular weight protein standards. Proteins were transferred to nitrocellulose sheets using a Bio-Rad Semi-dry Transblot apparatus in Towbin buffer following the recommendations of the manufacturer. The blots were blocked with 10% nonfat dry milk solution/PBS/0.1% Tween-20/0.1% BSA/0.1% sodium azide for 3 h at room temperature with gentle shaking, washed three times with PBS plus 0.05% Tween-20 and once with PBS, incubated with 2 μ g/mL C219 anti-P-gp monoclonal antibody (Signet Labs, Dedham, MA) or 1:1000 rabbit anti-GLUT1 polyclonal antibody (a kind gift of Dr. Ian Simpson, NIDDK) in PBS plus 0.05% BSA overnight, rewashed, and incubated with 1:2000 goat anti-mouse Ig conjugated to horseradish peroxidase (Santa Cruz Biotechnology, Santa Cruz, CA) or 1:3000 donkey anti-rabbit Ig conjugated to horseradish peroxidase (Amersham). The blots were again washed, and immune complexes detected by chemiluminescence (Amersham) following the manufacturer's recommendations. Lumograms were scanned on an IBAS automatic image analysis system (Kontron, Germany) and relevant band intensities compared. KB-V1 vincristine-resistant epidermoid carcinoma cells were used as a control for P-gp and were a gift of Dr. Mark Willingham, Wake Forest University, Winston-Salem, NC.

A separate assay for the concentration of P-glycoprotein on the surface of leukemic blasts was performed by flow cytometry as previously described (39). Briefly, one million HL60 and HL60VCR cells in 5 mL of RPMI1640 plus 15% fetal calf serum with or without 4×10^{-8} M DT388-GMCSF were incubated 60 h at 37 °C/5% CO₂. Cells were harvested by centrifugation at 1000 rpm for 7 min, washed once with 0.5 mL of Hank's balanced salt solution (Gibco) with 1% fetal calf serum and 0.05% sodium azide (HFN), reacted in 100 μ L of HFN with or without 4 μ L MRK16 antibody (Kamiya, Seattle, WA) for 20 min on ice, rewashed, resuspended in 100 μ L HPN

with 2 μ L biotinylated goat anti-mouse Ig (Southern Biotech, Birmingham, AL), and incubated for 20 min on ice. The cells were washed again, resuspended in 1 mL of goat serum for 10 min on ice, rewashed in HFN, resuspended in 100 μ L of HFN plus 1.5 μ L of Texas Red-streptavidin (Molecular Probes, Eugene, OR), and incubated 20 min on ice. Finally, the cells were washed and suspended in 1 mL of PBS plus 0.2% bovine serum albumin and 0.01% sodium azide and run on an EPICS XL flow cytometer (Coulter, Hialeah, FL) with gating for live cells and detection of the FL2 fluorescence. Background fluorescence with isotype matched control antibody was subtracted.

RESULTS

To evaluate the ability of targeted toxins to modulate doxorubicin resistance in AML cell lines, we first had to define the variables that affect sensitivity of AML blasts to toxins and drug. In this study, parameters that we evaluated included the cell surface GMCSF receptor density and the amounts and function of P-glycoprotein on the three cell lines.

GMCSF Receptor Density and Ligand Affinity. Scatchard plots of [¹²⁵I]GMCSF binding to AML cell lines revealed high-affinity receptor densities of 320/cell, 123/cell, and 172/cell for HL60, HL60Vinc, and HL60VCR based on linear regression (Figure 1). The K_d s were calculated as 2×10^{-11} , 1.4×10^{-11} , and 8×10^{-12} M for HL60, HL60Vinc, and HL60VCR, respectively.

P-Glycoprotein Concentrations. Immunoblots with C219 included KB-V1 control and showed relative densities for HL60, HL60Vinc, and HL60VCR of 0.07, 0.28, and 2.75 based on equal cell loading on SDS-PAGE (Figure 2 and Table 5). Immunoblots of control protein, GLUT1, revealed bands at 45 and 55 kDa for HL60, HL60Vinc, and HL60VCR and bands at 43 and 53 kDa for KB-V1. Flow cytometry of HL60 and HL60VCR cells for surface P-gp showed minimal P-gp on HL60 cells (20% above background) and marked P-gp on HL60VCR cells (360% above background).

Doxorubicin Uptake by AML Cell Lines. The mean channel rhodamine fluorescence of AML cell lines increased from 3 without doxorubicin incubation (auto-fluorescence) to 15 for HL60 cells, 10 for HL60Vinc, and 7 for HL60VCR cells with 1 h incubation with 5×10^{-6} M doxorubicin.

Cell Cytotoxicity Measured by Thymidine Incorporation of DT388-GMCSF, DT390mGM-CSF, and Doxorubicin Alone. Table 1 shows the IC₅₀, IC₉₉, and IC_{99.9} for inhibition of thymidine incorporation after one or two day incubations with DT388-GMCSF and doxorubicin alone for each of the three AML cell lines. Doxorubicin sensitivity is most for HL60 cells, intermediate for HL60Vinc cells, and least for HL60VCR cells. Forty-eight hour incubation increased toxicity of DT388-GMCSF but not doxorubicin. DT390mGM-CSF was nontoxic to HL60 and HL60VCR cells (IC₅₀ > 4×10^{-8} M), but showed potent cytotoxicity to WT19 mouse leukemia cells (IC₅₀ = 5×10^{-12} M).

Cell Cytotoxicity Measured by Clonogenic Assay with DT388-GMCSF and Doxorubicin Alone. Table 2 displays the IC₅₀, IC₉₉, and IC_{99.9} for inhibition of colony formation in semisolid medium for DT388-GMCSF and doxorubicin on each of the AML cell lines. There was an excellent correlation with the 48 h thymidine incorporation inhibition assay results.

Modulation of Doxorubicin Resistance with DT388-GMCSF. The effects of preincubation with

^a Each assay performed at least twice. IC values above 4×10^{-8} M for DT388-GMCSF and 2×10^{-4} M for doxorubicin projected from curves. Methods as in text.

Figure 2. Immunoblot of AML cell membrane extracts reacted with C219 monoclonal anti-P-glycoprotein antibody. The experimental method is described in the text. Kladeiscope high molecular mass marker migration is depicted by arrows (203, 126, and 71 kDa). Lane 1, KB-V1 cells; lane 2, HL60VCR cells; lane 3, HL60Vinc cells; lane 4, HL60 cells.

DT388-GMCSF on doxorubicin sensitivity of thymidine incorporation and colony formation for the AML cell lines was analyzed by isobolograms (Figure 3) and calculation of the combination index (CI). CIs for colony inhibition and thymidine incorporation inhibition were similar. Modulation was greater for three log cell kill than one or two log cell kill. Concave isoboles were observed for three log cell kill of HL60Vinc and HL60VCR. CIs for

IC99.9	1×10^{-7}	5×10^{-6}	4×10^{-5}

^a Assays performed as described in text. IC values above 4×10^{-8} M for DT388-GMCSF, and 2×10^{-4} M for doxorubicin extrapolated from curves.

the different cell lines are shown in Table 3. In each case, the CI was less for three log cell kill than one log cell kill.

The scheduling of toxin and drug were critical. Higher CIs at three log cell kill were observed when drug treatment preceded toxin exposure except in the case of HL60 cells (Table 4).

Effects of Modulating Concentrations of DT388-GMCSF on P-gp Concentrations. At modulating concentrations of toxins (4×10^{-9} M DT388-GMCSF), the concentrations of P-gp in HL60Vinc and HL60VCR were reduced 6–27-fold relative to untreated cells based on

^a Immunoblots developed with C219 anti-P-gp monoclonal antibody and calibrated with 1.3×10^6 cell membrane extract of untreated cells. Modulating concentrations were 4×10^{-9} M for DT388-GMCSF for 48 h incubation. HL60 cells had no detectable P-gp under all incubation conditions.

densitometry of immunoblots (Figure 4 and Table 5). Control protein GLUT1 concentrations were altered by toxins under the conditions producing maximal modulation of drug resistance but to a much lesser degree (Figure 5).

Flow cytometry showed a 2-fold reduction in P-gp surface membrane concentration of HL60VCR cells after fusion toxin exposure.

Examination of toxin- and doxorubicin-treated apoptotic cell populations revealed that toxin pretreatment was associated with increased intracellular concentrations of doxorubicin (Table 6).

DISCUSSION

Novel treatment strategies for patients with relapsed or refractory AML have focused on circumventing multidrug resistance. Allogeneic bone marrow transplant has produced a significant fraction of durable remission in patients less than 55 years old, in part due to a graft-versus-leukemia effect (28). However, most AML patients are older than 55 years old. Chemotherapeutic agents which are not substrates for the common resis-

Figure 3. Isobologram for concentrations of DT388-GMCSF and doxorubicin yielding a 99% reduction in thymidine incorporation of HL60VCR cells. Cells were incubated for 24 h with DT388-GMCSF and then doxorubicin added for an additional 24 h, followed by an 18 h labeling with [³H]thymidine, harvesting and counting. Thymidine incorporation was compared to untreated cells. The concentration of DT388-GMCSF alone producing 99% reduction in thymidine incorporation, A_e , was 4×10^{-8} M. The concentration of doxorubicin yielding a 99% reduction in thymidine incorporation, B_e , was projected at 130 μ g/mL. The dotted line shows the additivity isobole. Concave lines beneath the additivity isobole show synergy, and convex lines above the additivity isobole show antagonism. The CI was 0.2.

Figure 4. Immunoblot of AML cell membrane extracts reacted with C219 antibody. Standard protein markers were the same as Figure 4. Lane 1, HL60VCR control; lane 2, HL60VCR treated with 4×10^{-9} M DT388-GMCSF for 48 h; lane 3, HL60Vinc control; lane 4, same as lane 2 with HL60Vinc.

tance phenotypes have been tested. The nucleoside analogue fludarabine produced responses in relapsed patients in combination with cytosine arabinoside (29). The topoisomerase I inhibitor topotecan showed activity as a salvage agent alone and with cytarabine, but at the cost of moderate to severe oropharyngeal mucositis (30). The hypomethylating agent decitabine yielded remissions in drug-resistant AML patients, but the patients had prolonged myelosuppression (31). Finally, nonspecific modulators of P-gp such as cyclosporine have been combined with anthracyclines as salvage therapy (32). Responses were seen, but the modulation of P-gp in liver and kidney led to altered drug pharmacokinetics and enhanced toxicities to marrow, kidney, and central nervous system. The novel antibody-drug conjugate, anti-CD33-calicheamicin, showed minimal toxicities with

Figure 5. Immunoblot of AML membrane extracts detected with anti-GLUT antibody as described in the text. Low molecular mass prestained protein standards (105, 71, and 41.8 kDa) are shown by arrows. Membrane extracts in lanes 1–4 are the same as in Figure 4. Relative densities of the 45 kDa GLUT1 bands were 1, 1.5, 1, and 0.8, respectively, for lanes 1–4.

Table 6. Doxorubicin Intracellular Concentrations in AML Cell Lines

cell line	condition	mean rhodamine fluorescence channel ^a		
		media alone	doxorubicin	doxorubicin + verapamil

	DT388-GMCSF	3	17	25
HL60VCR	control	3	7	19
	DT388-GMCSF	4	61	68

^a Cells were incubated for 60 min with 5 μ M doxorubicin with or without 50 μ M verapamil, washed, and run on an EPICS-XL gated for apoptotic cells by forward and 90° light scatter. Modulating concentrations of DT388-GMCSF as described in Table 5.

complete remissions in 4/35 patients, but most patients failed to respond due to active drug efflux (35). Thus, new reagents with unique mechanisms of action which can directly modify the apoptotic threshold of resistant malignant blasts are needed.

Targeted toxins are a novel class of therapeutics which may be useful for relapsed/refractory AML. Previous clinical trials of targeted toxins in T-cell and B-cell lymphomas have shown a number of partial and complete responses; however, clinical benefit has been limited by toxicity to vascular endothelium (33).

We had previously engineered a targeted toxin for AML, DT388-GMCSF (19, 20), but we anticipated vascular leak syndrome as the dose-limiting toxicity in man (34). We sought to overcome both the problem of drug-resistant leukemic blasts and endothelial injury of targeted toxins by administering combinations of targeted toxins and cytotoxic drugs. We hypothesized that targeted toxins would be synergistic with cytotoxic drugs based on previous studies in vitro with lymphoma and ovarian carcinoma cells (11–14). Thus, with combination therapy, lower doses of both targeted toxin and cytotoxic drug would be needed. Both vascular leak and some of the toxicities of cytotoxic drugs may be ameliorated. To test our hypothesis, we performed a systematic study of the optimal delivery of DT388-GMCSF with doxorubicin on three AML cell lines.

The first interesting finding was the variations in sensitivity to fusion toxin independent of receptor status. The resistance of the HL60Vinc cells to DT388-GMCSF may be due to antiapoptotic protein expression as we have previously reported (19). The results of the clonogenic assays in our study paralleled the results of the thymidine assays. Specificity was confirmed by the lack of toxicity of the diphtheria fusion toxin, DT390mGM-CSF, for HL60 and HL60VCR cells.

Synergy was observed primarily at higher log cell kill ($IC_{99.9}$) reflecting a mechanism requiring significant inhibition of protein synthesis. This observation is consistent with the requirement to reduce the intracellular concentrations of some short half-life proteins to modulate resistance.

The less pronounced synergy on HL60 cells versus HL60Vinc and HL60VCR suggests a significant impact of *mdr-1* on this process. This finding is also compatible with our model of modulation by reducing short half-life resistance proteins. Further support for the model was observed with the immunoblots, flow cytometry, and doxorubicin uptake studies showing reduced antigen and functional activity for *mdr-1* in the toxin modulated cells. The differences in the concentrations of P-gp after fusion toxin exposure assayed by immunoblots or flow cytometry may reflect different rates of metabolism of intracellular and cell surface protein.

The dependence of synergy on toxin followed by cytotoxic drug, rather than the reverse, is also evidence for the proposed molecular mechanism. Our findings confirm the schedule dependency in vivo reported by Ghetie et al. (14).

Our experiments suggest a potential for targeted toxins such as DT388-GMCSF as cell-specific modulators of drug resistance in relapsed/refractory AML patients. However, further studies will be needed to confirm these observations on fresh resistant AML blasts.

Since drug resistance contributes to treatment failure for a number of human malignancies (36) and targeted toxins have been designed for many different cell types (37), this approach, both as detailed in this study and in previous reports (11–20), may yield additional cancer therapeutic strategies.

ACKNOWLEDGMENT

We wish to thank James Nicholson for imaging analysis and Dr. Ian Simpson, NIDDK, for antibody to GLUT1.

Received December 26, 1997; Revised Manuscript Received April 15, 1998

Interposition of a metabolizable linkage has been performed to reduce the hepatic radioactivity levels of radiolabeled antibodies. To estimate the validity of this strategy, a radioiodination reagent (HML) that provides a stable attachment for *m*-iodohippuric acid with proteins in plasma while facilitating rapid and selective release of the compound after lysosomal proteolysis in the liver was conjugated with a monoclonal antibody (mAb) against osteogenic sarcoma (OST7, IgG₁). Radiolabeled OST7 conjugates with a plasma-labile ester bond for releasing *m*-iodohippuric acid (MIH), plasma-stable amide bonds for releasing radiometabolites of hepatobiliary excretion (MPH), or slow elimination rates from hepatocytes ([¹¹¹In]EMCS-Bz-EDTA) were prepared with similar conjugation chemistry. The four radiolabeled OST7 conjugates were characterized both in vitro and in vivo. All the radiolabeled OST7 conjugates had similar radiochromatograms on size-exclusion HPLC and similar antigen binding affinities. While MIH-OST7 indicated accelerated clearance of radioactivity from the blood due to the release of *m*-iodohippurate, the rest of the three radiolabeled OST7 conjugates remained stable in serum incubation studies and had similar radioactivity elimination from the blood in vivo. When injected into normal mice, HML-OST7 demonstrated tissue-to-blood ratios of radioactivity similar to those of MIH-OST7 and significantly lower than those of the other two radiolabeled OST7 conjugates. In biodistribution studies in nude mice, both HML-OST7 and MIH-OST7 exhibited tumor-to-liver or tumor-to-intestine ratios of radioactivity higher than those of [¹¹¹In]EMCS-Bz-EDTA-OST7 or MPH-OST7, respectively. HML-OST7, MPH-OST7, and [¹¹¹In]EMCS-Bz-EDTA-OST7 indicated there were no changes in the radioactivity levels in the tumor between 24 and 48 h postinjection, whereas MIH-OST7 significantly decreased the radioactivity levels in the tumor at these time points. HML reduced the radioactivity levels in nontarget tissues without impairing the tumor radioactivity levels delivered by OST7. These findings indicated that the design of a radiolabeled mAb that is stable in plasma and liberates the radiometabolite of rapid urinary excretion constitutes an effective strategy for achieving target-selective radioactivity delivery.

INTRODUCTION

The localization of radioactivity in nontarget tissues such as the liver after administration of radiolabeled monoclonal antibodies (mAbs)¹ constitutes a serious problem for clinical applications of radiopharmaceuticals. Although the precise mechanisms of mAb accumulation in the liver are still uncertain, target-selective radioactivity localization could be amplified if the radiolabeled mAbs bound to the target remain stable while the radioactivity in nontarget tissues is excreted in the urine.

This approach was first reported by Haseman et al., who introduced a diester bond between an antibody and an ¹¹¹In chelate of benzyl-EDTA as a "metabolizable linkage" to liberate the radiolabeled compound with a low molecular weight after lysosomal proteolysis in nontarget tissues (1). A variety of radiolabeled mAbs with metabolizable linkages have been developed (2–8), and some

studies demonstrated enhanced target-to-nontarget ratios of the radioactivity in animal models.

In most studies, ester bonds have been used as the metabolizable linkage of choice due to rapid cleavage of the linkage in nontarget tissues such as the liver and kidney where high esterase activity levels have been reported (9). However, since ester bonds are cleaved by both chemical and enzymatic hydrolyses not only in nontarget tissues but also in plasma, use of ester bonds as the metabolizable linkage impaired the radioactivity levels in the target (1, 5, 10, 11). In addition, while the cleavage of the ester bond in plasma may cause only a slight decrease in the radioactivity levels in the target tissues in animal models, due to the presence of large tumor masses in a small body, the plasma-labile characteristics of ester bonds may significantly decrease the target radioactivity levels in humans where much smaller tumor masses are located in much higher distribution volumes.

On the other hand, recent metabolic studies of radiolabeled polypeptides demonstrated that the radiometabolites generated after lysosomal proteolysis of polypeptides play a critical role in the radioactivity levels in the liver (12–17). These findings support the rationale of the radiochemical design of antibodies using a metabolizable linkage to reduce the nontarget radioactivity levels. Furthermore, recent advances in genetic engineering have provided mAbs with less immunogenicity (e.g., humanized mAbs) and more favorable pharmacokinetic characteristics (e.g., single-chain Fv fragment) (18–21). Monoclonal antibodies directed against endothelial cells in solid tumors may also facilitate higher accumulation in target tissues within shorter postinjection intervals (22–24). These classes of mAbs would potentially solve various problems associated with the clinical applications of radiolabeled murine mAbs. These findings and developments prompted us to further assess the validity of the radiochemical design of mAbs with metabolizable linkages for reducing the nontarget radioactivity levels of radiolabeled mAbs.

To estimate the validity of the design, the metabolizable linkages should be stable enough in plasma to deliver radioactivity to both target and nontarget tissues equivalent to nonmetabolizable linkages. Furthermore, the radiometabolite generated after cleavage of the metabolizable linkage should be excreted rapidly from the nontarget tissues into urine without redistribution into other tissues. We have recently developed a radioiodination reagent for proteins with L-lysine as the metabolizable linkage, 3'-iodohippuryl *N*^ε-maleoyl-L-lysine (HML). In our previous studies using galactosyl-neoglycoalbumin (NGA) as a model polypeptide, [¹³¹I]-HML-NGA selectively liberated *m*-iodohippuric acid after lysosomal proteolysis in hepatocytes. In addition, the peptide bond of [¹³¹I]HML-NGA remained stable in human serum and murine plasma (25). Such chemical and biological characteristics would render HML useful for estimating the validity of the chemical design of mAbs for reducing the nontarget radioactivity localization.

In this study, HML was radioiodinated with Na¹²⁵I or Na¹³¹I and conjugated with a mAb against osteogenic sarcoma (OST7, IgG₁). For comparison, radioiodinated OST7 conjugates with an ester bond or an amide bond were prepared using maleimidoethyl 3'-iodohippurate (MIH) or *N*-(5-maleimidopentyl) 3'-iodohippuric acid amide (MPH), respectively. ¹¹¹In-labeled OST7 was also prepared using 1-[4-[(5-maleimidopentyl)amino]benzyl]-ethylenediaminetetraacetic acid (EMCS-Bz-EDTA) as a bifunctional chelating agent. The chemical structures of

Figure 1. Chemical structures of radiolabeled OST7 conjugates. All the reagents were conjugated with OST7 molecules with maleimide–thiol chemistry after reducing the disulfide bonds in OST7.

radiolabeled OST7 conjugates used in this study are illustrated in Figure 1. All the reagents were attached to OST7 with similar conjugation chemistry using maleimide–thiol chemistry. Prior studies showed that all the reagents provided radiolabeled polypeptides stable against *in vivo* deiodination or transchelation (14, 25–27). Radiometabolites generated after lysosomal proteolysis of radiolabeled NGAs using the respective reagent were well characterized in previous studies (11, 14, 25, 26). While MIH liberates *m*-iodohippuric acid as the sole radiometabolite in hepatic parenchymal cells at a rate similar to that of HML, the ester bond in MIH is hydrolyzed with time in buffered solutions at neutral pH and in plasma. MPH generates radiometabolites with hepatobiliary excretion after lysosomal proteolysis in the murine liver. NGA-[¹¹¹In]EMCS-Bz-EDTA generates a cysteine adduct as the predominant radiometabolite in hepatocytes, and the metabolite was eliminated from the liver at a rate that was the slowest of the four reagents. All the radiolabeled OST7 conjugates were characterized *in vitro*, and the radioactivity distribution was compared in normal mice and nude mice bearing osteogenic sarcoma. The validity of the radiochemical design of mAbs using the metabolizable linkage to achieve target-selective radioactivity localization will be discussed.

MATERIALS AND METHODS

Reagents and Chemicals. Na¹³¹I and Na¹²⁵I were obtained from Daiichi Radioisotopes Laboratories (Tokyo)

and Daiichi Kagaku (Tokyo), respectively, and were diluted with 0.1 M PB (pH 7.4) to 7.4 MBq (0.2 mCi)/ μ L and 3.7 MBq (0.1 mCi)/ μ L, respectively. $^{111}\text{InCl}_3$ [74 MBq (2 mCi)/mL in 0.02 N HCl] was kindly supplied by Nihon Medi-Physics (Nishinomiya, Japan). The stannyl precursors of HML, 3'-(tri-*n*-butylstannyl)hippuryl-*N* ϵ -maleoyl-L-lysine (SHML), MPH, *N*-(5-maleimidopentyl) 3'-(tri-*n*-butylstannyl)hippuric acid amide (SMPH), and MIH, maleimidoethyl 3-(tri-*n*-butylstannyl)hippurate (SMIH), were synthesized as reported previously (25, 26). EMCS-Bz-EDTA was purchased from Dojindo Laboratories (Kumamoto, Japan). Size-exclusion HPLC and RP-HPLC were performed using Cosmosil Diol-300 (7.5 $\times$ 600 mm, Nacalai Tesque, Kyoto, Japan) and Cosmosil 5C₁₈-AR (4.6 $\times$ 250 mm, Nacalai Tesque) columns, respectively. Size-exclusion HPLC and RP-HPLC columns were equilibrated and eluted with 0.1 M PB (pH 6.8) and with a mixture of 0.1% aqueous phosphoric acid/acetonitrile (7:3), respectively, at a flow rate of 1 mL/min. Other reagents were of reagent grade and were used as received.

Tumor and mAbs. KT005-cloned human osteogenic sarcoma was maintained by serial subcutaneous transplantation in athymic mice. Pieces (1–2 mm³) of tumor tissue (ca. 0.3–0.9 g) at 2 weeks postplantation were used for the *in vivo* study. Single-cell suspensions from xenografted tumors were used for the *in vitro* study. The mAb against osteogenic sarcoma (OST7, IgG₁), generated by standard hybridoma techniques, was purified by ammonium sulfate precipitation with subsequent protein A affinity chromatography (Pharmacia Biotech Co., Ltd., Tokyo) as reported previously (2, 11, 28).

Preparation of Radioiodinated OST7 Conjugates. SHML, SMPH, and SMIH were radioiodinated in the presence of NCS as previously described (11, 25, 26). Briefly, SHML was dissolved in methanol containing 1% acetic acid (0.64 mg/mL), and 22 μ L (0.021 μ mol) of this solution was mixed with 6.04 μ L of NCS in methanol (0.5 mg/mL) in a sealed vial, followed by an addition of Na¹³¹I (3 μ L). After incubation at room temperature for 45 min, the reaction was quenched with aqueous sodium bisulfite (2.92 μ L, 0.72 mg/mL). The radiochemical yields of [¹³¹I]-HML were determined by TLC developed with a mixture of chloroform/methanol/acetic acid (40:5:2). The solvent was removed by a flow of N₂ prior to the subsequent conjugation reaction with OST7. Radioiodination of SHML with Na¹²⁵I was performed as described above except using Na¹²⁵I instead of Na¹³¹I.

Conjugation of [¹³¹I]HML with OST7 was performed by reducing the disulfide bonds of OST7, as described previously (2, 11). Briefly, OST7 (250 μ L, 5 mg/mL) in well-degassed 0.1 M PB (pH 7.0) containing 2 mM EDTA was allowed to react with a 1000-fold molar excess of 2-ME at room temperature for 30 min. Excess 2-ME was removed by a centrifuged column procedure (29) using Sephadex G-50 (Pharmacia Biotech Co., Ltd.) equilibrated and eluted with 0.1 M PB (pH 6.0) containing 2 mM EDTA. Aliquots of this mixture were sampled for estimation of the number of thiol groups with 2,2'-dithiopyridine (11, 30, 32). The filtrate (90 μ L) was then added to a reaction vial containing crude [¹³¹I]HML. After gentle agitation of the reaction mixture for 1.5 h at room temperature, 39 μ L of iodoacetamide (10 mg/mL) in 0.1 M PB (pH 6.0) was added. The reaction mixture was further incubated for 30 min to alkylate the unreacted thiol groups. [¹³¹I]HML-OST7 was subsequently purified by the centrifuged column procedure, equilibrated, and eluted with 0.1 M PBS (pH 6.0). [¹²⁵I]HML-OST7 was prepared with similar procedures.

[¹²⁵I]MIH-OST7 and [¹²⁵I]MPH-OST7 were also prepared by experimental procedures similar to those used for [^{125/131}I]HML-OST7 except using SMIH or SMPH in place of SHML. Direct radioiodination of OST7 was performed by the chloramine T method (11, 31). To 200 μ L aliquots of OST7 (0.25 mg/mL) in 0.3 M PB (pH 7.5) was added 5 μ L of Na¹²⁵I. Chloramine T (0.1 mg/mL, 25 μ L), freshly prepared in the same buffer, was then added. After incubation of the mixture for 10 min at room temperature, the reaction was terminated by addition of 6 μ L of aqueous sodium bisulfite (0.7 mg/mL). [¹²⁵I]OST7 was then purified by the centrifuged column procedure.

Radiochemical purities of the radioiodinated OST7 conjugates were determined by size-exclusion HPLC, TLC, and CAE. CAE was run at an electrostatic field of 0.8 mA/cm for 45 min in veronal buffer (*I* = 0.06, pH 8.6).

Preparation of [¹¹¹In]EMCS-Bz-EDTA-OST7. OST7 was also labeled with ¹¹¹In using EMCS-Bz-EDTA as the bifunctional chelating agent. EMCS-Bz-EDTA was conjugated to OST7 by reducing the disulfide bonds in OST7 with procedures similar to those used for [¹³¹I]HML conjugation, as previously reported (11). EMCS-Bz-EDTA-OST7 was purified from unreacted low-molecular weight compounds by the centrifuged column procedure using Sephadex G-50 equilibrated and eluted with 20 mM MES-buffered saline (pH 6.0). The number of EMCS-Bz-EDTA molecules introduced per molecule of OST7 was determined by measuring the thiol groups before and after conjugation reaction using 2,2'-dithiopyridine, as previously described (11, 32).

The purified EMCS-Bz-EDTA-OST7 was labeled with ¹¹¹In according to the procedure of Brechbiel et al. (33) with slight modifications as previously noted (12, 32). Briefly, 5 μ L of ¹¹¹InCl₃ in 0.02 N HCl was added to a mixed solution (5 μ L) of 1 M sodium acetate and 1.75 N HCl (4:1). After 3 min, 40 μ L of EMCS-Bz-EDTA-OST7 (1 mg/mL) was added, and the reaction solution was kept at room temperature (23 $^{\circ}$ C) for 1 h. A 13 μ L aliquot of 2 mM EDTA in 0.1 M acetate buffer (pH 5.0) was then added to the reaction solution. After incubation for an additional 30 min at room temperature, [¹¹¹In]EMCS-Bz-EDTA-OST7 was purified by the centrifuged column procedure using Sephadex G-50 equilibrated with 0.1 M PBS (pH 6.0). The radiochemical purity of [¹¹¹In]EMCS-Bz-EDTA-OST7 was determined by CAE and size-exclusion HPLC.

Immunoreactivity Measurement. The immunoreactivity of the four radiolabeled OST7 conjugates was determined as described previously (2, 11, 28). Tumor cells (2 $\times$ 10⁴ to 1 $\times$ 10⁷) suspended in 100 μ L of Dulbecco's PBS were incubated with 100 μ L of radiolabeled OST7 in microcentrifugation tubes (5.7 mm $\times$ 46 mm) for 2 h at 4 $^{\circ}$ C. After centrifugation at 10000*g* for 5 min, the supernatant was discarded, and the radioactivity was determined using a well counter (ARC 2000, Aloka, Tokyo).

Stability Estimation of Radiolabeled OST7 Conjugates in Human Serum. Each radiolabeled OST7 was diluted to 0.5 mg/mL with 0.1 M PBS (pH 6.0), and 20 μ L of each solution was added to 230 μ L of freshly prepared human serum (11). After incubation for 1, 3, 6, or 24 h at 37 $^{\circ}$ C, samples were taken from the solutions, and the percentages of radioactivity released from the three radioiodinated OST7 conjugates were determined by PC (no. 50, Advantec Toyo, Tokyo) and TLC. The percentages of the radioactivity released from [¹¹¹In]EMCS-Bz-EDTA-OST7 were determined by size-

Scheme 1^a

^a (a) *N*-Chlorosuccinimide, Na^{131/125}I, 1% AcOH/MeOH, room temperature, 45 min; (b) 2-mercaptoethanol, 0.1 M PBS/2 mM EDTA (pH 6.0), room temperature, 30 min; (c) 0.1 M PBS/2 mM EDTA (pH 6.0), 1.5 h; (d) iodoacetamide, 0.1 M PB (pH 6.0), room temperature, 30 min.

exclusion HPLC, as reported previously (32). Each value was calculated by dividing the antibody-bound radioactivity at various intervals by the radiochemical purity of the respective freshly prepared antibody. PC was developed with a mixture of methanol/water (8:2), and TLC was developed with a mixture of chloroform/methanol/water (15:8:1). Under these conditions, protein-bound radioactivity, free iodine, *m*-iodobenzoic acid, and *m*-iodohippuric acid had *R_f* values of 0, 0.6–0.65, 0.9–0.95, and 0.9–0.95 on PC and 0, 0.1, 0.4, and 0.25 on TLC, respectively.

In Vivo Studies. In vivo studies were performed after simultaneous administration of a mixed solution of [¹³¹I]-HML-OST7 and [¹²⁵I]MIH-OST7 or [¹²⁵I]MPH-OST7. A 3 mL solution of 0.1 M PB (pH 6.0) containing 1.12 mg of unmodified OST7 was mixed with 12 μ L each of [¹³¹I]HML-OST7 (14.6 μ Ci) and [¹²⁵I]MIH-OST7 or [¹²⁵I]MPH-OST7 (9.3 or 10.0 μ Ci) prior to administration. For comparison of the radioactivity distribution of [¹²⁵I]HML-OST7 and [¹¹¹In]EMCS-Bz-EDTA-OST7, 12 μ L (10.9 μ Ci, 42 μ g) of [¹²⁵I]HML-OST7 and 63 μ L (10.5 μ Ci, 42 μ g) of [¹¹¹In]EMCS-Bz-EDTA-OST7 were added to 3 mL of unmodified OST7 (1.12 mg) prior to administration. Blood clearance of radioactivity after intravenous administration of each mixture in 6-week-old male ddY mice (34) was determined. Groups of five mice, each receiving 100 μ L of the radiolabeled OST7 conjugate solution, were sacrificed 1, 3, 6, 24, 48, 72, and 96 h postinjection. Organs of interest were removed and weighed, and the radioactivity was determined with a well counter (ARC 2000). A window from 29 to 97 keV was used for counting ¹²⁵I while one from 280 to 440 keV for ¹³¹I and from 168 to 568 keV for ¹¹¹In. Correlation factors for eliminating crossover of ¹³¹I or ¹¹¹In activity into ¹²⁵I were determined by counting the ¹³¹I or ¹¹¹In standard in each window. The crossover of ¹²⁵I into the ¹³¹I or ¹¹¹In channels was negligible. Samples of urine and feces were collected for 96 h, and the radioactivity was determined. Twenty-four hours after injection of [¹²⁵I]HML-OST7, urine samples were collected and analyzed by TLC as described above. The urine samples were also analyzed by RP-HPLC after filtration through a 10 kDa cutoff ultrafiltration membrane (Microcon 10, Amicon Grace, Tokyo). In RP-HPLC analysis, free iodine, *m*-iodohippuric acid, and *m*-iodobenzoic acid had retention times of 2.9, 9.4, and 30.8 min, respectively.

Athymic mice bearing osteogenic sarcoma were also treated intravenously with 100 μ L of a mixed solution of [¹³¹I]HML-OST7 and [¹²⁵I]MIH-OST7, [¹³¹I]HML-OST7 and [¹²⁵I]MPH-OST7, and [¹²⁵I]HML-OST7 and [¹¹¹In]-EMCS-Bz-EDTA-OST7, prepared as described above. The animals were sacrificed 24 and 48 h postinjection (five mice in each group). Organs of interest were removed and weighed, and the radioactivity in each tissue was determined (ARC 2000).

Statistical Analysis. Data are expressed as means $\pm$ standard deviation where appropriate. Results were statistically analyzed using the unpaired *t* test for in vitro studies and the paired *t* test for in vivo studies. Differences were considered statistically significant when the *p* value was less than 0.05.

RESULTS

Preparation of Radiolabeled OST7 Conjugates.

Radioiodination of SHML was performed in 1% AcOH/MeOH in the presence of NCS as an oxidant (Scheme 1). After reaction for 45 min at room temperature, [¹²⁵I]HML and [¹³¹I]HML were obtained with radiochemical yields of 80.2 and 78.9%, respectively, as determined by TLC. Similar procedures were employed for the radioiodination of SMIH and SMPH, which provided [¹²⁵I]MIH and [¹²⁵I]MPH with radiochemical yields of 79.8 and 88.7%, respectively. All the radioiodinated compounds were treated with sodium bisulfite to quench any residual NCS, preventing the iodine species from reacting with tyrosine residues of the antibody molecule. Neutralization of NCS also prevented exposure of the protein to the oxidant.

Conjugation of [^{125/131}I]HML with OST7 was performed by reactions of thiolated antibodies with the maleimide group of [^{125/131}I]HML. 2-ME reduction of OST7 exposed 6.2 thiol groups per molecule of OST7, and subsequent conjugation reactions with [^{125/131}I]HML were performed at a maleimide-to-thiol molar ratio of 1:1. After the conjugation reaction, the unreacted thiol groups were capped with iodoacetamide. The reaction steps are summarized in Scheme 1. The radiochemical yield of [¹³¹I]HML-OST7 was 46.8%, as determined by CAE. After purification by the centrifuged column procedure, [¹³¹I]HML-OST7 was obtained with a radiochemical purity and specific activity of 96.0% and 348 μ Ci/mg,

Figure 2. Size-exclusion HPLC profile of the radioactivity of [^{131}I]HML-OST7. More than 97% of the radioactivity was eluted at a retention time identical to that of unmodified OST7. Under these conditions, thyroglobulin (670 000), OST7 (IgG), bovine serum albumin (68 000), and cytochrome *c* (13 000) were eluted at retention times of 11.4, 15.4, 16.8, and 21.0 min, respectively.

respectively, for subsequent studies. With similar procedures, [^{125}I]HML-OST7, [^{125}I]MIH-OST7, and [^{125}I]MPH-OST7 were obtained with radiochemical yields of 67.1, 72.3, and 81.9%, respectively. The radiochemical purity and specific activity were 95.1% and 261 $\mu\text{Ci}/\text{mg}$, 98.7% and 223 $\mu\text{Ci}/\text{mg}$, and 99.4% and 238 $\mu\text{Ci}/\text{mg}$ for [^{125}I]HML-OST7, [^{125}I]MIH-OST7, and [^{125}I]MPH-OST7, respectively. Direct radioiodination of OST7 with Na^{125}I produced [^{125}I]OST7 with a radiochemical purity and specific activity of 97.3% and 74 $\mu\text{Ci}/\text{mg}$, respectively.

The EMCS-Bz-EDTA-OST7 conjugate was prepared with maleimide-thiol chemistry using the maleimide group of EMCS-Bz-EDTA and the thiol groups of OST7, generated by reducing the disulfide bonds. The number of EMCS-Bz-EDTA molecules attached per molecule of OST7 was 3.7, as determined by measuring the thiol groups before and after the conjugation reaction. After the centrifuged column procedure, [^{111}In]EMCS-Bz-EDTA-OST7 was obtained with a radiochemical purity and specific activity of 91.9% and 250 $\mu\text{Ci}/\text{mg}$, respectively, as determined by CAE.

Figure 2 shows the size-exclusion HPLC profile of [^{131}I]HML-OST7. More than 97% of the radioactivity was observed in fractions similar to those of unmodified OST7. Similar results were observed with all the radiolabeled OST7 conjugates used in this study (data not shown).

Serum Stability of Radiolabeled OST7 Conjugates. Table 1 shows the percentages of the protein-bound radioactivity of the respective radiolabeled OST7 conjugate after incubation in freshly prepared human serum at 37 $^{\circ}\text{C}$. [^{131}I]HML-OST7, [^{125}I]MPH-OST7, and [^{111}In]EMCS-Bz-EDTA-OST7 released only ca. 2–3% of the initial antibody-bound radioactivity after incubation for 24 h. However, [^{125}I]MIH-OST7 released a significantly higher amount of the radioactivity with incubation time, and half of the initial radioactivity was released from OST7 after incubation for 24 h. The radioactivity released from [^{125}I]MIH-OST7 was an indication of R_f values identical to those of *m*-iodohippuric acid when analyzed by TLC and PC.

Figure 3. Organ-to-tumor ratios of the radioactivity 6 h (A) and 72 h (B) after injection of [^{125}I]HML-OST7, [^{131}I]HML-OST7, [^{125}I]MIH-OST7, [^{125}I]MPH-OST7, and [^{111}In]EMCS-Bz-EDTA-OST7 in normal mice. Since no significant differences were observed between [^{125}I]HML-OST7 and [^{131}I]HML-OST7, these results were combined and expressed as the results for [$^{125/131}\text{I}$]HML-OST7.

Immunoreactivity. The binding of [^{131}I]HML-OST7, [^{125}I]HML-OST7, [^{125}I]MIH-OST7, [^{125}I]MPH-OST7, [^{111}In]EMCS-Bz-EDTA-OST7, and [^{125}I]OST7 to KT005 cells was examined as a function of cell number. No significant differences were observed in the cell-bound radioactivity among the six radiolabeled OST7 conjugates (data not shown).

Biodistribution Studies in ddY Mice. The time courses of the radioactivity in the blood after intravenous administration of radiolabeled OST7 conjugates in ddY mice are summarized in Table 2. Since [^{131}I]HML-OST7 and [^{125}I]HML-OST7 had similar radioactivity distributions in the three experiments, these results were combined and presented as [$^{125/131}\text{I}$]HML-OST7 in Table 2. While no significant differences were observed in the radioactivity elimination from the blood up to 96 h postinjection among [$^{125/131}\text{I}$]HML-OST7, [^{125}I]MPH-OST7, and [^{111}In]EMCS-Bz-EDTA-OST7, [^{125}I]MIH-OST7 showed a significantly rapid disappearance of the radioactivity from the blood from 24 h postinjection onward. The liver-to-blood and intestine-to-blood ratios of the radioactivity 6 (A) and 72 h (B) postinjection of

the four radiolabeled OST7 conjugates in ddY mice are shown in Figure 3. No significant differences in the radioactivity ratios were observed between [¹³¹I]HML-OST7 and [¹²⁵I]MIH-OST7 at either postinjection time point. However, [¹²⁵I]MPH-OST7 had significantly higher liver-to-blood ratios at 72 h and intestine-to-blood ratios at both 6 and 72 h than [¹³¹I]HML-OST7. Significantly higher radioactivity ratios were also observed with [¹¹¹In]EMCS-Bz-EDTA-OST7 at 6 h for the liver and at 6 and 72 h for the intestine when compared with those of simultaneously administered [¹²⁵I]HML-OST7.

Figure 4 shows the RP-HPLC and TLC radioactivity profiles of urine obtained 24 h after injection of [¹³¹I]HML-OST7. RP-HPLC indicated that more than 93% of the radioactivity in the urine was eluted at a retention time identical to that of *m*-iodohippuric acid. TLC analysis also indicated a single radioactivity peak (>98%) at an *R_f* value identical to that of *m*-iodohippuric acid.

Table 3 summarizes the cumulative radioactivity excreted in the urine and feces 96 h after injection of the five radiolabeled OST7 conjugates. [¹²⁵I]MIH-OST7 showed the fastest excretion rate of radioactivity from the body. While both [¹²⁵/¹³¹I]HML-OST7 and [¹²⁵I]MIH-OST7 showed more than 95% excreted radioactivity in the urine, [¹²⁵I]MPH-OST7 excreted an almost equal amount of radioactivity in urine and feces. [¹¹¹In]EMCS-Bz-EDTA-OST7 exhibited the slowest excretion rate of radioactivity from the body.

Biodistribution Studies in Nude Mice. Table 4 shows the biodistribution of radioactivity after simultaneous administration of [¹³¹I]HML-OST7 and [¹²⁵I]MIH-OST7 in athymic mice bearing osteogenic sarcoma. Although similar radioactivity levels in the tumor were observed with both radioiodinated OST7 conjugates 24 h postinjection, [¹²⁵I]MIH-OST7 indicated a significant

Figure 4. Radioactivity profiles of murine urine 24 h after injection of [¹³¹I]HML-OST7 on RP-HPLC (A) and TLC (B). The major radioactivity (>93% for RP-HPLC and >98% for TLC) was detected at a retention time and *R_f* value similar to those of *m*-iodohippuric acid.

decrease in the radioactivity levels in the tumor 48 h postinjection. Although [¹²⁵I]MIH-OST7 indicated significantly higher tumor-to-liver and tumor-to-intestine ratios of radioactivity at both postinjection time points, no significant differences were observed between the two

^a Values are the means (SD) of five animals for each point. Mean weights (SD) of mice and tumors in grams: 20.69 (0.77) and 0.54 (0.22) at 24 h and 20.46 (1.92) and 0.51 (0.21) at 48 h, respectively. ^b $p < 0.005$ compared to that for [¹³¹I]HML-OST7.

radioiodinated OST7 conjugates when the liver-to-blood and intestine-to-blood ratios of the radioactivity were calculated.

The biodistributions of radioactivity after simultaneous administration of [¹³¹I]HML-OST7 and [¹²⁵I]MPH-OST7 in athymic mice bearing osteogenic sarcoma are summarized in Table 5. Both radioiodinated OST7 conjugates showed no changes in radioactivity levels in the tumor between the two postinjection time points. No significant differences were observed in the radioactivity levels in the tumor and in the blood when the two radioiodinated OST7 conjugates were compared 24 and 48 h postinjection. However, while [¹³¹I]HML-OST7 and [¹²⁵I]MPH-OST7 had similar tumor-to-liver ratios of radioactivity, significantly higher tumor-to-intestine ratios were achieved by [¹³¹I]HML-OST7 at both postinjection time points.

The biodistributions of radioactivity after simultaneous administration of [¹²⁵I]HML-OST7 and [¹¹¹In]EMCS-Bz-EDTA-OST7 in athymic mice are shown in Table 6. [¹²⁵I]HML-OST7 and [¹¹¹In]EMCS-Bz-EDTA-OST7 had similar radioactivity levels in the tumor and blood both

24 and 48 h postinjection. However, [¹²⁵I]HML-OST7 had significantly higher tumor-to-liver ratios of radioactivity both 24 and 48 h postinjection and tumor-to-intestine ratios 48 h postinjection when compared with [¹¹¹In]EMCS-Bz-EDTA-OST7.

DISCUSSION

All the radiolabeled OST7 conjugates were prepared using similar conjugation chemistry. All exhibited similar radiochromatograms on size-exclusion HPLC (Figure 2) and similar affinities for KT005 cells. In addition, high stability against in vivo deiodination or transchelation of all the radiolabeled OST7 conjugates was well demonstrated in this study and in previous studies (11, 12, 14, 25–27, 32, 35). Thus, the differences in the localization of the radioactivity from the four radiolabeled OST7 conjugates in vivo could be primarily attributed to the differences in stability of the metabolizable linkage of the respective radiolabeled OST7 and the in vivo behavior of radiometabolites derived from each reagent.

The plasma-labile characteristic of the ester bond in MIH (Table 1) was reflected in the biodistribution studies in normal mice, and the fastest elimination rate of radioactivity from the blood (Table 2) and the highest excretion of the radioactivity from the body (Table 3) were observed with [¹²⁵I]MIH-OST7. Despite this, however, no significant differences were observed in the organ-to-blood ratios of the radioactivity between [¹³¹I]HML-OST7 and [¹²⁵I]MIH-OST7 (Figure 3), indicating that [¹³¹I]HML-OST7 liberated *m*-iodohippuric acid after lysosomal proteolysis in nontarget tissues at a rate similar to that of [¹²⁵I]MIH-OST7. This was supported by the results of the urine analyses where the radioactivity was excreted as *m*-iodohippuric acid after administration of [¹³¹I]HML-OST7 (Figure 4).

Since similar radioactivity levels in the blood were observed after simultaneous administration of [¹³¹I]HML-OST7 and [¹²⁵I]MPH-OST7 (Table 2), similar amounts of radiolabeled OST7 would be delivered to the liver. Thus, significantly higher radioactivity levels in

	48	33.39 (7.06)	5.47 (1.02)	8.41 ^c (3.09)	75.68 ^b (10.06)

^a Values are the means (SD) of five animals for each point. Mean weights (SD) of mice and tumors in grams: 20.44 (1.41) and 0.37 (0.10) at 24 h and 20.88 (0.52) and 0.47 (0.25) at 48 h, respectively. ^b $p < 0.05$ compared to that for [¹³¹I]HML-OST7. ^c $p < 0.005$ compared to that for [¹³¹I]HML-OST7.

these tissues after administration of [^{125}I]MPH-OST7 (Figure 3) would reflect the slower hepatic elimination rate of the radiometabolites derived from MPH and subsequent hepatobiliary excretion, as also observed in a previous study using NGA (25). Similarly, the slowest hepatic elimination rate of the radiometabolites derived from [^{111}In]EMCS-Bz-EDTA-OST7 would be responsible for the highest liver-to-blood ratios of the radioactivity of this radiolabeled OST7. This was supported by the lowest radioactivity excretion levels of this radiolabeled OST7 (Table 3). These findings using OST7 were consistent with those of previous studies using NGA as a model polypeptide, reinforcing the fact that *in vivo* behavior of radiometabolites generated after lysosomal proteolysis of radiolabeled mAbs plays a critical role in the hepatic radioactivity levels. These findings also indicated that, when applied to mAbs, HML provided rapid and selective release of *m*-iodohippuric acid after accumulation in nontarget tissues such as the liver, while providing a stable attachment for *m*-iodohippuric acid with the mAb in plasma.

To further estimate the validity of the radiochemical design of mAbs with metabolizable linkages, two radiolabeled OST7 conjugates that liberate *m*-iodohippuric acid as the sole radiometabolite after lysosomal proteolysis at a similar rate, [^{131}I]HML-OST7 and [^{125}I]MIH-OST7, were simultaneously administered to nude mice bearing osteogenic sarcoma. Similar radioactivity levels in the tumor 24 h after injection of the two radiolabeled OST7 conjugates would be attributable to the similar radioactivity levels in the blood at this postinjection time and the similar affinities for the tumor cells of the two radioiodinated OST7 conjugates. The significantly lowered radioactivity levels in the blood 48 h after injection of [^{125}I]MIH-OST7 would be caused by the enzymatic and chemical hydrolysis of the ester bond in the blood, followed by the urinary excretion of the resulting *m*-iodohippuric acid. On the other hand, the formation of antigen-antibody complexes on the tumor cell surface provides steric hindrance to esterase access, which stabilized the ester bond of [^{125}I]MIH-OST7 (11). Thus, while chemical hydrolysis of the ester bond in [^{125}I]MIH-OST7 would be predominantly responsible for the elimination of radioactivity from the tumor, both chemical and enzymatic hydrolyses takes place in the blood, which enhances the target-to-nontarget ratios of the radioactivity with time after injection (Table 4). Since the peptide bond of [^{131}I]HML-OST7 was stable both in the blood and on the tumor cell surface, neither accelerated clearance of the radioactivity from the blood nor decreased radioactivity levels in the tumor were observed. Although [^{125}I]MIH-OST7 provided significantly higher tumor-to-nontarget ratios of the radioactivity, these results would be most likely caused by the presence of large tumor masses compared to their small distribution volume in the animal model. When the much lower and delayed accumulation of the radioactivity of radiolabeled mAbs in clinical studies is considered (36-39), the plasma-labile characteristics of the ester bond in MIH may cause a significant decrease in the radioactivity levels in the tumor in clinical studies. Thus, the animal model may have underestimated the plasma-labile characteristics of the ester bond in MIH in the radioactivity delivery to the target by the mAb. Similar nontarget-to-blood ratios of the radioactivity after administration of [^{131}I]HML-OST7 and [^{125}I]MIH-OST7 in normal and nude mice also suggested that the higher tumor-to-nontarget ratios of the radioactivity with [^{125}I]MIH-

OST7 are characteristic of the animal model (Figure 3 and Table 4).

The ability of HML to provide target-selective radioactivity localization using mAbs as vehicles was clearly demonstrated in the comparative biodistribution studies of [$^{125/131}\text{I}$]HML-OST7 with [^{125}I]MPH-OST7 or [^{111}In]EMCS-Bz-EDTA-OST7 (Tables 5 and 6). Similar radioactivity levels in the blood and the tumor both 24 and 48 h after injection of the three radiolabeled OST7 conjugates coincided well with the similar plasma stabilities and tumor cell affinities of the three radiolabeled OST7 conjugates. Significantly higher radioactivity levels in the intestine of [^{125}I]MPH-OST7 and in the liver and intestine of [^{111}In]EMCS-Bz-EDTA-OST7 reflected the *in vivo* behavior of radiometabolites derived from the respective reagent. These findings indicated that the radiochemical design of mAb conjugates that provides a stable attachment for the radiolabel in plasma while facilitating rapid and selective release of the radiometabolite of urinary excretion would be useful in achieving target-selective radioactivity localization using mAbs as vehicles.

Recently, efforts have been directed toward increasing the accumulation of radiolabeled mAbs by hyperthermia or biological response modifiers (40-43). Antibody fragments and mAbs that recognize the antigens present on the vascular wall in the tumoral tissues offer promise for achieving target-selective radioactivity localization within short postinjection intervals (18, 20-24). Since the radiochemical design of mAb conjugates using metabolizable linkages is complementary to these approaches, combinations of these different approaches would render the radiolabeled mAbs attractive radiopharmaceuticals for both diagnostic and therapeutic nuclear medicine.

In conclusion, the peptide bond of HML-conjugated OST7 remained stable in plasma but rapidly liberated *m*-iodohippuric acid after lysosomal proteolysis in nontarget tissues. As a result, HML-conjugated OST7 decreased the radioactivity levels in nontarget tissues without impairing those in the target delivered by the mAb. These findings strongly supported the validity of the radiochemical design of antibodies using metabolizable linkages that provide a stable attachment of radiolabels with mAbs in plasma while facilitating selective release of radiometabolites of rapid urinary excretion. The well-correlated hepatic radioactivity levels between radiolabeled mAbs and radiolabeled NGAs also indicated that the biological method using NGA as the model polypeptide would be highly useful in estimating newly designed radiolabeling reagents for reducing hepatic radioactivity levels of radiolabeled mAbs.

ACKNOWLEDGMENT

We are grateful to Dr. I. Yomoda of Daiichi Radioisotope Laboratories (Tokyo) for providing Na^{131}I . We also thank Nihon Medi-Physics for their kind gift of $^{111}\text{InCl}_3$. This study was supported in part by Grants-in-Aid for Developing Scientific Research (08557135 and 09672279) from the Ministry of Education, Science, Culture and Sports of Japan.

A New Photoactivatable Reagent Capable of Transferring a Radiolabel to Target Proteins. Application to the Human Growth Hormone–Rat Liver Prolactin Receptor Interaction

Néstor T. H. Masckauchán, José M. Delfino,* and Horacio N. Fernández†

Instituto de Química y Físicoquímica Biológicas, Universidad de Buenos Aires, CONICET, Buenos Aires, Argentina. Received November 14, 1997; Revised Manuscript Received March 15, 1998

A new photoactivatable cross-linking reagent, 1-(2'-dithiopyridyl)-2-(5'-azidosalicylamido)ethane (ASDPE), was synthesized. This probe can be easily labeled with ^{125}I in the azidosalicylamido ring and contains an activated disulfide bridge. After reaction of [^{125}I]ASDPE with proteins, the radiolabeled moiety of the probe becomes attached to cysteine residues. Upon partial reduction of human growth hormone (hGH) with dithiothreitol, its C-terminal disulfide bond between residues 182 and 189 was cleaved and the nascent thiol groups were modified with [^{125}I]ASDPE to yield [^{125}I]ASET–hGH [1-(thio-hGH)–2-(3'-[^{125}I]iodo-5'-azidosalicylamido)ethane]. After binding of this hormone derivative to rat liver microsomes, followed by photolysis and subsequent reduction of disulfide bridges, the specific transfer of the radiolabeled moiety to prolactin receptor (PRL-R) was achieved. Partial purification of the radiolabeled receptor by size exclusion chromatography was performed. We anticipate that [^{125}I]ASDPE will be generally useful in pursuing structural and functional studies of target proteins which interact specifically with protein ligands.

INTRODUCTION

After their introduction as photoaffinity reagents in 1969 (1), aryl azides became the most commonly used photoreactive compounds in biochemistry, mostly due to the simplicity of their synthesis (2). Cleavability of the reagent is an additional advantage, because it allows further analysis of the target of the cross-link by separating the photoreacted (and radiolabeled) head, which remains attached to the acceptor molecule, from the rest of the ligand. Certain photoactivatable probes of the azidosalicylamido kind, which may be cleaved by reduction of a disulfide bridge, have been employed to transfer a radioactive label between peptidic species (3, 4). This technique shows great promise for both identification and purification of ligand-binding proteins and further study of the binding site by fragmentation and peptide analysis. Herein, we synthesized and characterized ASDPE,¹ a new photoreagent useful for these purposes.

Rat liver PRL-R consists of a single polypeptide chain with an M_r of 42K. This species, by far the most abundant PRL-R form present in this tissue, has been the subject of previous cross-linking studies (5, 6). At present, a complete view of the transduction pathways following the initial step of binding of a lactogenic hormone to the PRL-R still has to be elucidated. In this work, we demonstrated the transfer of a radiolabel from hGH, a natural ligand of PRL-R, derivatized with [^{125}I]ASDPE to this receptor. This opens the possibility of

studying modifications of the PRL-R occurring along its intracellular transit, including degradation and/or phosphorylation. In addition, a receptor radiolabeled in this way could serve as a tracer in pursuing its purification and in studying the association with other membrane or intracellular molecules.

MATERIALS AND METHODS

General Procedures. The ^1H NMR spectra were recorded on a Bruker WM 300 NMR spectrometer, FTIR spectra on a Bruker IFS 25 infrared spectrometer, mass spectra on a Shimadzu GCMS QP-1000 mass spectrometer, and UV/visible spectra on a JASCO 7850 spectrophotometer. Thin layer chromatography (TLC) was routinely performed on 5.0 cm $\times$ 1.6 cm plates of silica gel 60 F₂₅₄ (E. Merck, Darmstadt, Germany). Different solvent systems were employed: solvent 1, benzene/acetic acid (9:1, v/v); solvent 2, tetrahydrofuran/ethanol/acetic acid (4.5:4.5:1); and solvent 3, dichloromethane/ethanol/acetic acid (6:3:1). All reagents employed were of analytical grade and were purchased from Aldrich, Sigma, or Fluka. Na ^{125}I (15–17 Ci/mg) was purchased from New England Nuclear (Boston, MA). Samples were irradiated at 254 nm in quartz cuvettes or in a Petri dish with a Desaga UVIS setup 3 cm from the lamp for the times indicated.

Synthesis and Characterization of Compounds. **5-Azidosalicylic Acid (3).** 5-Aminosalicylic acid (**1**, 200 mg, 1.3 mmol) was dissolved in 7.5 mL of 0.94 M H₂SO₄ and the mixture cooled to 4 °C, and NaNO₂ (110 mg, 1.6 mmol) dissolved in 1 mL of distilled water was then added. The reaction mixture was gently shaken at 0 °C for 20–30 min. The resulting diazonium salt (**2**) was not isolated. NaN₃ (420 mg, 6.5 mmol) dissolved in 10 mL distilled water was added next. From this step on, care was taken to avoid direct sunlight; thus, the following synthetic procedures were performed under dim yellow light. The reaction was allowed to proceed for 48 h at 4

† Died August 2, 1995.

¹ Abbreviations: ASDPE, 1-(2'-dithiopyridyl)-2-(5'-azidosalicylamido)ethane; PRL-R, prolactin receptor; hGH, human growth hormone; [^{125}I]ASET–hGH, 1-(thio-hGH)–2-(3'-[^{125}I]iodo-5'-azidosalicylamido)ethane.

°C with gentle stirring. After the test for diazonium salt turned negative, compound **3** was filtered and purified by recrystallization from ethanol. After 24 h at 4 °C, the crystalline material was filtered and dried. The yield of product was 67%. TLC (silica, solvent 1): $R_f = 0.34$. MS (EI, 70 eV): m/e (relative intensity) 180 (4.9, $M + 1$), 179 (4.6, M), 152 (3.2, $M + 1 - N_2$), 151 (3.3, $M - N_2$). UV (1 mM HCl in methanol): λ (nm) 371 (min), 330 (max), 290 (min), 257 (max).

1-(2'-Dithiopyridyl)-2-aminoethane (6). 2,2'-Dithiodipyridine (200 mg, 0.91 mmol) was dissolved in 0.5 mL of 10% (v/v) acetic acid in ethanol, and 2-aminoethanethiol hydrochloride (**5**, 50 mg, 0.44 mmol) dissolved in 1 mL of ethanol was then added. The reaction mixture was incubated at 25 °C for 16–24 h under a nitrogen atmosphere. At the end, the mixture was centrifuged and the clear supernatant was dried under vacuum and dissolved in 0.25 mL of methanol. The product **6** was precipitated by the addition of 0.5–0.75 mL of diethyl ether and left overnight at –20 °C. After filtration and drying under vacuum, large prismatic crystals of compound **6** were obtained. Further purification was achieved by an additional recrystallization step from the same solvent mixture. The yield of pure product was 55%. TLC (silica, solvent 2): $R_f = 0.57$. MS (EI, 70 eV): m/e (relative intensity) 157 (5.5), 143 (16.4), 112 (6.3), 111 (34.2).

1-(2'-Dithiopyridyl)-2-(5'-azidosalicylamido)ethane (ASDPE, 7). A fresh batch of ASDPE can be synthesized starting from compounds **3** and **6**, which can be stored for months in the dark at 4 °C. Compound **3** (40 mg, 0.22 mmol) was dissolved in 0.35 mL of tetrahydrofuran while the mixture was gently shaken. To this solution were added *N*-hydroxysuccinimide (27 mg, 0.24 mmol) and dicyclohexylcarbodiimide (50 mg, 0.24 mmol), and the reaction mixture was stirred for 24 h at room temperature. At the end, the precipitate was separated by filtration or centrifugation, and to the clear supernatant containing the *N*-hydroxysuccinimidyl ester of 5-azidosalicylic acid (**4**) were added pyridine (20 μ L, 0.25 mmol) and a solution of compound **6** (49 mg, 0.22 mmol). The reaction was allowed to proceed under a nitrogen atmosphere while the mixture was gently shaken for 1 week at 25 °C. The progress of the reaction was followed by TLC using solvent 3. The workup procedure was as follows. The mixture was centrifuged, and the supernatant was separated. The remaining residue was washed with 0.4 mL of tetrahydrofuran, and this solution was pooled with the supernatant. Finally, the solvent was evaporated under reduced pressure. Purification was achieved by column silica gel chromatography employing straight chloroform as the solvent. Fractions (2–3 mL) were collected and analyzed by TLC; those containing compound **7** were pooled together, and the solvent was evaporated under reduced pressure. The yield of pure product was 91%. TLC (silica, solvent 3): $R_f = 0.95$. ^1H NMR (CDCl_3 , 300 MHz): δ 3.22 (m, 2H), 3.98 (m, 2H), 7.23–7.68 (complex, 5H), 7.85 (m, 1H), 8.74 (m, 1H), 9.28 (s broad, 1H), 12.53 (s broad, 1H). ^1H NMR (CDCl_3 and D_2O): δ 3.22 (t, $J = 5.4$ Hz, 2H), 3.97 (t, $J = 5.4$ Hz, 2H), 7.23–7.68 (complex, 5H), 7.85 (m, 1H), 8.73 (m, 1H). FTIR (film): wavenumber (cm^{-1}) 3337 (br, m), 2115 (s), 1643 (m), 1597 (m), 1577 (m), 1558 (m), 1492 (m), 1418 (s), 1291 (m). After photolysis in a chloroform solution, the bands at 2115 and 1291 cm^{-1} diminished significantly. MS (EI, 70 eV): m/e (relative intensity) 319 (4.1, $M - N_2$), 176 (3.2), 135 (3.8), 134 (2.9), 112 (4.8), 111 (26.5), 79 (5.3), 78 (8.2). UV (ethanol): λ (nm) 338 (max), 312 (min), 275 (sh), 233 (max). Changes that occurred

Figure 1. Time course of photolysis of ASDPE. UV spectra of compound **7** ($t = 0$ s) and the photolysis reaction mixture at the times (in seconds) indicated with numbers. The sample was irradiated at 254 nm in ethanol. The inset shows the decay of the absorbance at 233 nm as a function of the time of photolysis. The data were adjusted with the equation $A = A_1 \exp(-kt) + A_2$, where A_1 is the difference between the absorbance values at 233 nm for $t = 0$ and $t = \infty$, A_2 is the absorbance at $t = \infty$, and k is the apparent rate constant for the decay in absorbance where $A_1 = 0.496 \pm 0.015$, $A_2 = 1.483 \pm 0.010$, and $k = 0.060 \pm 0.004 \text{ s}^{-1}$.

upon photolysis of this compound (Figure 1) are discussed in the Results and Discussion.

1-(2'-Dithiopyridyl)-2-(3'-[^{125}I]iodo-5'-azidosalicylamido)ethane ([^{125}I]ASDPE, 8). ASDPE (2 μ L of a 2.5 mM solution in CHCl_3) was dried in the bottom of a 3 mm $\times$ 40 mm tube under a nitrogen stream, and 10 μ L of a 0.3 M sodium phosphate buffer (pH 7.4), 0.5 mCi of Na^{125}I (1.5 μ L), 2 μ L of distilled water, and 2 μ L of 1.2 mg/mL chloramine T were successively added. The mixture was stirred, and the reaction was allowed to proceed for 15 min. Then, 2 μ L of dimethylformamide and 30 μ L of benzene were added. After vigorous shaking and centrifugation, the organic phase containing the product (**8**) was separated carefully and dried under a nitrogen stream. The solid residue was dissolved in 100 μ L of anhydrous ethanol. There was no need for purification, since an autoradiography of a TLC analysis of the reaction mixture showed a single spot (**8**) with a mobility similar to that of unlabeled ASDPE. The radioiodinated probe (35 Ci/mmol) was used immediately for the derivatization of hGH.

Modification of hGH with [^{125}I]ASDPE. hGH (200 μ g) was dissolved in 200 μ L of 10 mM sodium phosphate buffer (pH 8.4), and 2 μ L of 25 mM dithiothreitol was added under an inert atmosphere. After 40 min at room temperature, the reaction mixture was sampled on a Sephadex G-100 column ($V_t = 0.9$ mL) using 10 mM sodium phosphate buffer (pH 7.0) and 0.01 mM EDTA as the eluent. Fractions of 200 μ L were collected under nitrogen. A sample of the fraction (50 μ L) containing reduced hGH was tested for the content of thiol groups by estimating the absorbance at 343 nm after (i) the addition of 5 μ L of 5 mM 2,2'-dithiodipyridine, (ii) incubation for 15–20 min, and (iii) dilution with water to a 600 μ L final volume. The remaining partially reduced hGH (150 μ L) was reacted with iodoacetamide (5.5 μ L of a 1 mM solution, equivalent to a 0.5-fold molar

content of thiol groups) over the course of 30 min at room temperature. The resulting partially reduced and blocked hGH was modified with [^{125} I]ASDPE as follows. The probe (100 μ L of the ethanolic solution) was dried under a nitrogen stream; the residue was dissolved in anhydrous ethanol (1 μ L) and propylene glycol (1 μ L), and the hGH solution (10 μ L) was then added. After being carefully shaken, the mixture was incubated at room temperature for 1 h under nitrogen. Next, 60 μ L of iodoacetamide-treated BSA [1 mg/mL BSA in 10 mM sodium phosphate buffer (pH 7.0) and 0.01 mM EDTA, reacted with a 0.05 mM iodoacetamide solution] was added. Finally, [^{125} I]ASET-hGH was purified by gel filtration on a Sephadex G-100 column (V_i = 100 mL) equilibrated with 10 mM sodium phosphate buffer (pH 6.0) and 0.05 mM EDTA. To minimize radiolysis and/or reduction, this photoderivative was prepared immediately before use. For the purpose of characterization, ASET-hGH was synthesized from unlabeled ASDPE and hGH in the same fashion. UV (25 mM NaHCO₃, pH 8.0): λ (nm) 351 (max), 311 (min), 270 (max), 257 (min).

Binding of [^{125} I]ASET-hGH to Rat Liver Mitochondria. Mitochondria (1.2 mg of protein), prepared as described by Bonifacino et al. (7), were incubated in flat-bottom plastic tubes in the presence of 3.5 ng of [^{125} I]ASET-hGH (approximately 9×10^4 cpm) in a total volume of 160 μ L with or without a 1000-fold molar excess of unlabeled hGH. Samples were run in triplicate. The incubation medium was 25 mM Tris-HCl, 10 mM CaCl₂, 10 mM MgCl₂, and 0.25 mg/mL BSA (pH 7.5). Samples were incubated in the dark for 3 h at 25 $^{\circ}$ C. Binding was stopped by addition of 0.5 mL of cold buffer, and the suspension was then irradiated at 254 nm for 6 min while it was gently shaken and finally centrifuged for 5 min at 2500g. The resulting pellet was suspended in 0.5–1 mL of buffer and kept at -20° C until it was used. The protein content was evaluated (8) after boiling a sample for 20 min in 1 M NaOH.

Partial Purification of PRL-R after Radiolabel Transfer with [^{125} I]ASET-hGH. Mitochondria (0.5 mL, 0.9 mg of protein) bound to [^{125} I]ASET-hGH were centrifuged, and the pellet obtained was dissolved in 0.5 mL of 42 mM Tris-HCl buffer (pH 7.0), 1.8% (w/v) SDS, 3 mM EDTA, and 0.8% (v/v) 2-mercaptoethanol. The mixture was incubated overnight at room temperature and then applied to a Sephadex G-100 column (V_i = 14 mL), equilibrated with 3.5 mM Tris-HCl buffer (pH 7.0), 0.15% (w/v) SDS, and 0.25 mM EDTA. Fractions (220 μ L) were collected, freeze-dried, and analyzed by SDS-PAGE.

Gel Electrophoresis and Autoradiography. Samples (0.10–0.15 mg of protein) were boiled at 100 $^{\circ}$ C for 3 min in the presence of sample buffer [1.5% (w/v) SDS, 5% (v/v) glycerol, 25 mM EDTA, and 35 mM Tris-HCl buffer (pH 7.3)] and 5% (v/v) 2-mercaptoethanol. Proteins were separated by SDS-PAGE on 6.5 to 12% T [1.5% C and 0.2% (w/v) SDS] gradient gels (9). Gels were then stained with Amido Black, destained, and dried. Radioactive bands were visualized by exposure of gels on Kodak X-Omat XAR-5 films at -70° C for 5–20 days with the aid of intensifying screens.

Western Blot Analysis. After SDS-PAGE [10% T, 1.5% C, and 0.1% (w/v) SDS], rat liver mitochondria were blotted onto a nitrocellulose membrane for 2 h at 100 V in 25 mM Tris and 193 mM glycine buffer with 20% (v/v) methanol. After being blocked for 2–3 h with 4% (w/v) dry fat-free milk in buffer [PBS and 0.1% (v/v) Tween 20 (pH 7.3)], the nitrocellulose membrane was rinsed four times for 10 min with buffer and incubated overnight at

^a (a) NaNO₂, aqueous H₂SO₄, 0 $^{\circ}$ C; (b) NaN₃, aqueous H₂SO₄, 4 $^{\circ}$ C; (c) N-hydroxysuccinimide, dicyclohexylcarbodiimide, tetrahydrofuran, 25 $^{\circ}$ C; (d) 2,2'-thiopyridine, acetic acid/ethanol, 25 $^{\circ}$ C; (e) pyridine/tetrahydrofuran, 25 $^{\circ}$ C; (f) Na¹²⁵I, chloramine T, sodium phosphate buffer, pH 7.4.

room temperature with T6 mouse IgG anti-PRL-R mAb (4 g/mL, purchased from Affinity Bioreagents, Golden, CO) (10) in buffer with 1% (w/v) BSA. Next, the membrane was rinsed four times for 15 min with buffer and incubated for 1 h with a donkey anti-immunoglobulin G antibody [1/5000 dilution in buffer and 2% (w/v) BSA]. Finally, the membrane was rinsed in PBS and revealed by an enzymic chemiluminescent assay (ECL, Amersham International).

RESULTS AND DISCUSSION

Among the wide variety of photoactivatable reagents available, only a relatively limited set has the added capability of carrying a radioactive label and of transferring it between molecules. Herein, we describe the synthesis and use of the novel photoactivatable probe ASDPE (7, Scheme 1). ASDPE includes the photoreactive azidosalicylamido headgroup at one end and the thiol-reactive function dithiopyridine at the other end. The linkage between these moieties is accomplished through a short ethylene bridge. ASDPE can be radiolabeled with ¹²⁵I to yield [^{125} I]ASDPE (8, Scheme). In turn, this compound is reacted with natural cysteine residues present in proteins or those introduced by site-directed mutagenesis, to yield a stable disulfide bridge. Next, the derivatized protein interacts with its target molecule, and upon photolysis, the azido group generates a highly reactive nitrene species which inserts readily into different functional groups present in the environment around the headgroup. At variance with other reagents of this class (3, 4, 11), it is noteworthy that the phenol group para with respect to the azido group orients the substitution of the bulky ¹²⁵I in meta, thus minimizing steric hindrance in the addition reactions of the nitrene. The expectation is that this feature will result in improved yields of photoadduct.

A convergent strategy for the synthesis of ASDPE is described in Scheme 1. The starting materials were 5-aminosalicylic acid (1) and mercaptoethylamine (5). We attempted to optimize yields at each step to avoid unnecessary purifications whenever possible. For analytical purposes, a small sample of each compound was routinely purified before the final characterization was carried out. The azido group was built in place of the amino substituent in 1 through a diazonium salt intermediate 2. On the other hand, 5 was reacted with 2,2'-

Figure 2. Reductive cleavage of ASDPE. (A) UV spectrum of a 0.05 mM solution of ASDPE in 5 mM sodium phosphate buffer (pH 7.4) (curve 1). To this solution was added 2-mercaptoethanol (1 mM final concentration), and the scanning of the spectrum was repeated after 1 min (curve 2) and 16 min (curve 3). (B) Autoradiography of a thin layer chromatogram (silica, chloroform) of a 0.2 mM solution of [^{125} I]ASDPE in ethanol ($R_f = 0.35$, lane a) and its reaction mixtures with 0.2 mM 2-mercaptoacetic acid ($R_f = 0.0$, lane b) or 0.2 or 2 mM 2-mercaptoethanol ($R_f < 0.1$, lanes c and d, respectively).

dithiodipyridine and the resulting amine **6** was coupled to 5-azidosalicylic acid (**3**), conveniently activated as the *N*-hydroxysuccinimidyl ester **4**, to yield ASDPE (**7**). The reagent, as a dry powder, is stable in the dark for months. Finally, an efficient protocol, involving a two-phase reaction, for radiolabeling ASDPE was developed to yield **8**. Thus, our reagent is able to withstand the oxidative conditions of this reaction medium with little or no appearance of byproducts (Figure 2B, lane a).

The UV spectrum of ASDPE (Figure 1) showed characteristic absorption bands with maxima at 233 and 338 nm and a shoulder at 275 nm, all these transitions related to the azido group (2). Upon irradiation, the first band decayed exponentially with a half-life of 11.6 ± 0.8 s in our photolysis setup (Figure 1, inset), while there were lesser changes in the region of 250–290 nm. Although there was a concomitant decrease of the band at 338 nm, accurate measurement in this spectral region was hampered by the appearance of UV-absorbing byproducts of the photolysis at longer irradiation times (>20 s). This is consistent with the lack of a clear isosbestic point at around 280 nm. The FTIR bands at 2115 and 1291 cm^{-1} , characteristic of the azido group (12), disappeared after photolysis (not shown).

The reactivity of ASDPE with thiol groups was tested against selected mercaptans. The reaction of ASDPE with 2-mercaptoethanol produced an almost immediate (<1 min) increase in the absorbance at 342 nm (Figure 2A), corresponding to the generation of thiopyridone. This arises as a consequence of the nucleophilic attack of the thiol group on the disulfide bridge of the probe. This reaction was routinely performed as a control assay for the integrity of the disulfide bond in the reagent, prior to the radioiodination step. The TLC analysis of the reaction mixture of [^{125} I]ASDPE and 2-mercaptoacetic acid (equimolar amount) or 2-mercaptoethanol (equimolar and 10-fold excess amounts) allowed the direct determination of the mixed disulfide products (Figure 2B). The appearance of new spots of lower mobility, consistent with the higher polarity of the parent thiol compounds, was evident, an indication of the generation of stable disulfides.

Figure 3. Radiolabel transfer from [^{125} I]ASET-hGH to rat liver PRL-R as analyzed by SDS-PAGE and autoradiography. Microsomes (1.2 mg of protein) were incubated with 1×10^{-9} M [^{125} I]ASET-hGH in the absence (lane a) or in the presence of a 600-fold molar excess of unlabeled hGH (lane b), as described in Materials and Methods. The values of radioactivity bound to microsomes were 37.4 and 12.1%, respectively. After photolysis, transfer of radioactive label occurred when, prior to electrophoresis, microsomes were incubated with sample buffer combined with 2-mercaptoethanol. Partially purified PRL-R from a sample of microsomal proteins reacted with [^{125} I]ASET-hGH and further reduced before gel filtration through Sephadex G-100 is shown (lane c). Western blot analysis of rat liver microsomal proteins incubated with an anti-PRL-R mAb (T6) is also shown (lane d). See Materials and Methods for details. The bar on the left indicates the 42 kDa band.

A suitable target protein for modification with [^{125} I]-ASDPE was partially reduced hGH, which yields [^{125} I]-ASET-hGH. Under the conditions described in Materials and Methods, reduction of the C-terminal disulfide bridge between residues Cys 182 and Cys 189 takes place. In addition, treatment of this sample with an equimolar amount of iodoacetamide with respect to hGH, prior to modification with [^{125} I]ASDPE, blocked on average one of these nascent thiol groups. The purpose of this was to minimize restoration of the disulfide link between the Cys residues, and therefore increase the stability of the resulting photoderivative. In addition to the absorption bands characteristic of the protein chromophores, the UV spectrum of purified ASET-hGH had an absorption band with a maximum at 351 nm, indicative of the presence of the azidosalicylamido group (results not shown).

The new photoderivative presented herein, i.e., [^{125} I]ASET-hGH, was successfully cross-linked, and able to transfer, after reduction, the radioactive label to PRL-R present in rat liver microsomes (42 kDa band in Figure 3, lane a). This band disappeared when the photoderivative was incubated in the presence of a 600-fold molar excess of unlabeled hGH (lane b), indicating that the interaction between these proteins is specific. After solubilization of microsomes, purification of PRL-R thus labeled was achieved by gel filtration. The analysis by SDS-PAGE of pooled fractions containing the receptor showed a single band corresponding to a labeled protein of 42 kDa (lane c). Its identity was assessed by Western blot analysis and reaction with the anti-PRL-R monoclonal antibody T6 (lane d).

Consistent with results presented herein, a noncleavable photoderivative of hGH, involving the modification of the same cysteine residues, namely, azidophenacyl-hGH ([^{125} I]AP-hGH, 21 kDa), was capable of cross-linking specifically to PRL-R in rat liver membranes to yield a 63 kDa adduct (13) as well as to a receptor-associated protein (14). To pursue future studies on the supramolecular structure of PRL-R, we are currently preparing a new photoderivative starting from a single cysteine mutant of hGH (C182S-hGH).

The novel photoactivatable reagent ASDPE can be easily synthesized in very good yield. Furthermore, it is radioiodinated at a high specific activity in a straightforward manner and can be linked to free thiol groups conveniently placed at selected locations in proteins. Cross-linking and transfer of the radioactive label to a specific target molecule make it possible to trace it along its purification. A related reagent, [^{125} I]-*N*-[4-(*p*-azido-

salicylamido)butyl]-3'-(2'-pyridyldithio)propionamide ([¹²⁵I]-APDP), was tested before as a valuable tool in the characterization of neighboring proteins in a complex such as the *Escherichia coli* ribosome (4, 15, 16). This molecule exhibits a cross-linking length of 21.1 Å in its fully extended form (4), comparable to the radius of an average protein (for hGH, this value is around 23 Å). Conceivably, the capabilities of ASDPE extend beyond its use in tagging the target protein after radiolabel transfer, including the potential for a detailed analysis of protein-protein interfaces. Given its short span (the distance between the Cβ of the modified cysteine and the proximal nitrogen of the azido group is 10.4 Å), this reagent may enhance the geometrical resolution around the site of the cross-link. Such analysis would involve radiolabel transfer, subsequent fragmentation of the target protein, and microsequencing of the resulting peptides.

In conclusion, we believe that ASDPE presents useful traits which complement the set of known photoactivatable cross-linking reagents.

Sequence-Specific DNA Minor Groove Binders. Design and Synthesis of Netropsin and Distamycin Analogues

Christian Bailly^{*,†} and Jonathan B. Chaires[‡]

INSERM U-124 et Laboratoire de Pharmacologie Antitumorale Moléculaire du Centre Oscar Lambret, IRCL, Place de Verdun, 59045 Lille, France, and Department of Biochemistry, University of Mississippi Medical Center, 2500 North State Street, Jackson, Mississippi 39216-4505. Received January 13, 1998; Revised Manuscript Received May 5, 1998

Over the past two decades, impressive advances have occurred in the understanding of how a normal cell transforms into a tumor cell. Molecular and cellular studies have shown that point mutations, deletions, translocations, and other types of rearrangements in DNA affect either the expression or the biochemical function of specific genes, be it an oncogene or a tumor-suppressing gene. By designing a drug capable of recognizing a specific sequence in DNA, it may be possible to specifically inhibit the expression of certain oncogenes and thereby to control the development of tumor cells. The message provided by the molecular biologist is that specific DNA sequence changes can switch on the malignant transformation of a cell. The goal of the pharmacologist is to find a drug to switch it off.

The possibility that low molecular weight ligands might bind to specific sequences in DNA was raised long ago (1, 2). The antiviral antibiotics netropsin (Net) and distamycin (Dst) were arguably the first drugs discovered that bound selectively to AT-rich sequences in the minor groove of DNA. So far, >20 high-resolution structures obtained by NMR and X-ray crystallography have been reported for a variety of oligonucleotide sequences complexed with netropsin, distamycin, and related minor groove binders (Table 1) (3–19). Quantitative footprinting methods have been used to analyze the sequence

netropsin

distamycin

preference (20–25). Computational studies have contributed information that provides a rational explanation for the selective fit of these crescent-shaped ligands into the minor groove of DNA (26, 27). Thermodynamic studies of Net and Dst binding to DNA, and their effects on the formation of protein/DNA complexes, have also been thoroughly investigated (28–40). Since the pioneer discoveries of the AT-selective binding of Net and Dst to DNA (41), a considerable number of physicochemical, biochemical, and biological studies have been reported to increase our understanding of the details of the mechanisms by which these two antibiotics bind to and recognize double-stranded DNA sequence (42). This detailed information has been exploited by medicinal chem-

ists to develop molecules capable of reading specific DNA sequences and, most importantly, to establish molecular rules for the design of sequence recognition elements. Although studies are still in progress, it is already clear that the design of sequence-specific ligands promises to be one of the great success stories of pharmacology. A brief survey of the story is reviewed here. This review is mainly concerned with the different categories of netropsin and distamycin derivatives synthesized during the past 15 years.

1. GENERAL MECHANISM OF GROOVE BINDING

The general mechanism of groove binding is shown schematically in Figure 1. Conceptually, the binding process may be divided into at least two parts. First, the groove binding agent undergoes a hydrophobic transfer from solution into the DNA minor groove. If the groove binder is positively charged, this event will be accompanied by the release of condensed counterions that surround the DNA. Once in the minor groove, specific molecular interactions may then form, including van der Waals attraction and the formation of hydrogen bonds.

The detailed energetics of groove binding reactions have yet to be fully elucidated, but the following elements are minimal contributions that must be considered. The formation of any bimolecular complex contains a substantial unfavorable free energy contribution resulting from the loss of rotational and translational degrees of freedom as two reactants form a single complex. Other, energetically favorable, contributions must then balance and overwhelm this entropic cost of forming the complex. The favorable contribution from the hydrophobic transfer process to the free energy is expected to be large and may largely balance the entropic penalty. Smaller, but no less important, favorable contributions come from the polyelectrolyte contribution to the free energy, arising from counterion release and from the formation of the various noncovalent molecular interactions. Whereas such molecular interactions are usually very much the focus of high-resolution structural studies, it must always be kept firmly in mind that such interactions are the culmination of a complex, multistep reaction mechanism. The stability of the final complex arises from an often delicate balance of favorable and unfavorable free energy contributions at each step along the reaction pathway.

2. THE LEXITROPSINS: MONOMERS AND DIMERS

Three main factors are thought to contribute favorably to the stability between AT sequences and netropsin or distamycin: (i) hydrogen bonding between the amide NH of the drug and thymine O-2 and adenine N-3 atoms; (ii) an overall shape complementarity resulting in close ligand-DNA van der Waals contacts; and (iii) polyelectrolyte interactions between the polyanionic DNA and the cationic drugs. It is assumed that the van der Waals interactions are pivotal in the sequence recognition (43).

The first design strategy employed to generate new compounds was to extend the length of the groove binding agents in hopes of extending the length of the binding site. Tris, tetra, penta, and hexa *N*-methylpyrrolecarboxamide derivatives of Net and Dst can bind to sequences containing five, six, seven, and eight contiguous A•T base pairs, respectively. The binding site size for an analogue containing $n - 1$ pyrrole rings or n amide bonds is $n + 1$ base pairs long in terms of occluding base pairs (or n in terms of contacted base pairs) (44, 45). This rule is valid for analogues containing up to six *N*-methylpyrrolecarboxamide residues but not for longer

molecules. A hepta *N*-methylpyrrolecarboxamide derivative does not fit very well with the natural twist of the DNA, presumably because the molecule gets out of phase with the base pairs along the minor groove floor of the double helix. Indeed, the pyrrolecarboxamide unit is $\approx 20\%$ longer than required to match perfectly the base pair rise in the minor groove (46). Two alternative strategies have been envisaged to circumvent the poor phasing between the DNA and *N*-methylpyrrolecarboxamide-containing ligands.

The first consists of joining two netropsin or distamycin molecules by a linker of suitable length to permit bidentate binding to DNA. A considerable number of bis-(netropsin)s containing different types of linkers have been elaborated (47–51). Bis(netropsin)s coupled by a polymethylene tether (**1**) can engage in bidentate binding

providing that the connector contains at least three methylene groups. However, owing to the flexibility of the aliphatic connector, monodentate binding of such bis-(netropsin)s is also possible. In contrast, bis(netropsin)s possessing conformationally rigid linkers (**2**) can readily bind to sequences containing 8–10 consecutive AT base pairs without the unwanted monomer binding to shorter sequences (52, 53). For chiral bis(netropsin)s, the stereochemistry of the linker is critical and may be used for controlling the directionality in binding to DNA (54). Recently, two bis(distamycin) derivatives possessing a 3,5-*m*-pyridyl or a *trans*-vinyl linker were found to be the

Figure 1. Schematic representation of hypothetical steps in the reaction pathway from DNA groove binding: (A) A groove binding agent is hydrophobically transferred from solution into the minor groove. If the ligand is positively charged, condensed counterions territorially bound to the DNA will be released. (B) Once in the minor groove, the ligand can form a variety of molecular interactions, including hydrogen bonds and van der Waals attractions.

most effective bis-linked lexitropsins at inhibiting transcription by HIV-1 reverse transcriptase (55). The linker can also play an active role in the DNA recognition process. For example, the bis(netropsin) analogue **3**, in

which the two netropsin residues are connected by a disulfide bond between two Gly-Cys-Gly peptides, binds more strongly to sequences containing a central GC step such as (AT)₃(GC)₂(AT)₃ than to strictly homologous (AT)_n sequences (56, 57).

The second strategy consists of replacing the carboxamide bond in netropsin and distamycin with shorter keto or amino linkages. Molecular modeling predicts that isohelical molecules such as **4** and **5** (called isolexins) would bind more tightly in the minor groove than their corresponding carboxamide analogues (46, 58). As for the lexitropsins (see below), the use of imidazole or furan rings would favor recognition of GC sequences. In the same way, the computational studies predict that the replacement of the carboxamide bond of netropsin with an ethylene bond (compound **6**) would permit an optimum

fit to the minor groove surface (59). According to the computational measurements, molecules called vinyllexins containing both $-C=C-$ linkages and imidazole and/or furan heterocycles (e.g., compound **7**) would display a considerable preference for GC-rich sequences (60). Although these suggestions are very promising, so far neither the isolexin nor the vinyllexin strategy has been experimentally tested.

The guanine 2-amino group protrudes into the minor groove and obstructs the access of drugs to the floor of the groove. The fact that the 2-amino group constitutes a critical negative recognition element for binding of small molecules, including Net and Dst, in the minor groove of DNA has now been unambiguously demonstrated using DNA molecules in which that group has been either deleted from guanines and/or added to adenines (61–65). Given both the strategic position of the guanine 2-amino group in the minor groove and its hydrogen bonding capacity (it is the only H bond donor exposed in the minor groove), it was proposed that the introduction of an H bond acceptor heteroatom in the pyrrole rings of netropsin might permit the drug to bind to GC sequences (46). Lown and co-workers have extensively exploited this concept and synthesized an impressive number of molecules christened “lexitropsins” or information reading oligopeptides structurally related to netropsin and distamycin (66, 67). By substituting imidazole, thiazole, triazole, pyrazole, or oxazole heterocycles for the *N*-methylpyrrole rings of netropsin, one can design drugs capable of binding to sequences containing one or two G·C pairs embedded in an AT sequence (Figure 2). Among the numerous lexitropsins synthesized so far, imidazole lexitropsins such as compounds **8–10** display the most pronounced capacity for binding

Figure 2. (A) Representation of the binding to DNA of netropsin; (B) proposed representation of a model lexitropsin molecule with guanine residues in DNA. Heavy arrows are hydrogen bonds, from donor to acceptor. Dashed lines mark close van der Waals nonbonded contacts between DNA and drug.

to GC-containing sequences (68–79). Thiazole lexitropsins either accept or avoid a G·C base pair in their binding sites, depending on the position of the sulfur atom (80–83). For example, the lexitropsin **11** with the sulfur atom directed into the minor groove does not bind to GC-containing sites, whereas the lexitropsin **12** containing two thiazole rings with the sulfur atoms directed outward from the minor groove binds best to alternating purine–pyrimidine sequences such as 5'-TATGAC and

5'-TGCATGC (84). The same type of result was obtained with the furan-containing lexitropsin **13** (85). To summarize, the lexitropsin approach based on a 1:1 complex has led to minor groove binders with increased tolerance for G·C base pairs in the binding site but did not lead to the design of a purely GC-specific molecule. According to computational studies, the observation that most lexitropsins can accommodate both AT- and GC-containing sequences comes in part from the fact that the electrostatic potential in the minor groove of AT-rich regions is very negative (86). The electrostatic interactions between AT sites and the positively charged end groups in the lexitropsins presumably provide the initial attraction. The binding of mono- and dicationic minor groove binders to AT-rich regions has a significant electrostatic component (87–89). However, the fact that neutral lexitropsins show the same interaction with AT sequences as the monocationic distamycin tripeptide argues against the dominant role of electrostatics in sequence selectivity (90). A recent comprehensive spectroscopic and thermodynamic study of the interaction of the minor groove binder Hoechst 33258 with the d(CG-CAAATTTGCG)₂ duplex suggested that the hydrophobic

thiazole-lexitropsins

furan-lexitropsin

pyridine-lexitropsin

transfer of the drug from solution into the duplex binding site provides the major driving force for the binding reaction (91).

An alternative approach to design minor groove binders capable of binding GC pairs is to connect a netropsin-like molecule with GC-recognizing elements. For example, substitution of the terminal formamido-methylpyrrole group of distamycin for a pyridine group (compound **14**) permits interaction with a G•C base pair. However, as for the imidazole lexitropsin, the binding to pure AT sequences is not abolished (92, 93). The bithiazole moiety of the antitumor drug bleomycin has offered opportunities for binding to GC sites. The netropsin moiety of the conjugate **15** drives the drug to AT sites and allows the appended bithiazole unit to contact a pyrimidine-G-pyrimidine motif (94).

The discovery in 1990 that the minor groove of DNA can expand slightly to accommodate two distamycin molecules associated side-by-side in an antiparallel head-to-tail orientation has rekindled interest in the design of lexitropsin compounds (9, 10, 15–17, 95). The 2:1 drugs/DNA motif has been observed with different distamycin analogues including a carbamoyl tetrapyrrole derivative (96). This landmark discovery immediately inspired the design of homo- and heterodimeric ligands.

Imidazole- and pyridine-containing lexitropsins (compounds **16** and **17**) were combined side-by-side so as to

permit direct interaction with G•C pairs via hydrogen bonding with the 2-amino group of guanines (13, 97–99). The imidazole-containing homodimer (**18**) binds specifically to GCGC sequences. This was the first instance of a minor groove binding lexitropsin being directed uniquely to GC sites (100). Combination of side-by-side pyrrole and imidazole rings permits G•C base pairs to be differentiated from C•G base pairs (101). The sequence selectivity, affinity, and geometry of the drug/DNA 2:1 complex can be optimized by choosing appropriate pairs of ligand molecules with complementary recognition properties and by covalently linking the two DNA reading elements (compounds **19** and **20**) (102–111).

3. HAIRPIN POLYAMIDES: A TRIUMPH IN THE DESIGN OF SEQUENCE-SPECIFIC DNA MINOR GROOVE BINDERS

The ambitious goal of rationally designing ligands capable of binding tightly and specifically to any desired target sequence of double-stranded DNA has recently been realized. Hairpin polyamides that consist of two covalently linked lexitropsin molecules connected end-to-end via a γ -aminobutyric acid linker residue, offer promising possibilities for high-affinity specific recognition of a broad sequence repertoire in the minor groove of DNA (112–121). For examples, hairpin pyrrole–imidazole polyamides **21** and **22** bind specifically to 5'-(A,T)GG(A,T)₂ (112, 113) and 5'-AAAAAGACAAAAA (107), respectively. Hairpin polyamides can exhibit affinities and specificities for DNA comparable with transcription factors and other DNA binding regulatory proteins (122). These molecules, which can be built by solid-phase synthesis (123), can discriminate between GC-rich sequences such as GCGC and GGCC, for example (124, 125). The specificity is sufficiently stringent to target a 7 base pair sequence in the minor groove of DNA (126). Antiparallel pairing of an imidazole (Im) opposite a pyrrole (Py) residue recognizes a G•C base

pair, whereas a Py/Im combination recognizes a C•G pair (Figure 3) (127).

Discrimination of T•A versus A•T base pair was an obstacle because a pyrrole/pyrrole (Py/Py) pair is degenerate. The problem has now been resolved. A major breakthrough has been achieved with the rational design of new series of hairpin polyamides that can efficiently discriminate T•A from A•T base pairs (128). Replacement of the pyrrole unit with a bulkier 3-hydroxypyrrole enables hairpin polyamide molecules to break the degeneracy, allowing the ligand to distinguish A•T and T•A pairs (Figure 3). Apparently the increased specificity of hydroxypyrrole(Hp)-containing hairpin polyamides does not arise from enhanced interactions at specific sites but mainly comes from enhanced destabilization of interactions on unselected sequences. Placement of Hp

opposite an adenine residue provokes steric hindrance that destabilizes polyamide binding. In addition, the newly introduced OH group of Hp may engage in hydrogen-bonding interaction with O-2 of a thymine (128).

Judicious combinations of the three aromatic amino acids pyrrole (Py), imidazole (Im), and hydroxypyrrole (Hp) should permit precise recognition of A·T (Py/Hp), T·A (Hp/Py), G·C (Im/Py), and C·G (Py/im) base pairs (Figure 3) and therefore the targeting of specific sequences. Moreover, the affinity and specificity of hairpin polyamides can be further enhanced via optimization of the γ -turn linker that tethers the two minor groove binding units placed face to face. Replacement of the conventional γ -aminobutyric acid linker with analogues equipped with functional groups (e.g., amino group) can reinforce significantly the affinity as well as the specificity. Stereochemical control of the ligand–DNA interaction has recently been reported using (R)- and (S)-diaminobutyric acid linker, as depicted in Figure 4 (129). Studies of hairpin polyamides are close to success in manipulating gene expression with small molecules. A few problems remain to be solved (e.g., targeting of longer sequences, cellular uptake), but there is no doubt that polyamides are on their way to a promising future as gene-specific control agents (130–134).

By combining the end-to-end with the side-by-side dimeric motifs, one will perhaps succeed in targeting 15–17 base pairs of unique sequence in a biological system (135, 136). For the first time, it has been shown that an eight-ring hairpin polyamide [ImPyPy- γ -ImPyPyPy- β -Dp] targeted to the binding site of the transcription factor TFIIIA entered into the nucleus of cultured frog fibroblast cells and specifically inhibited transcription of the 5S RNA gene (137). Without doubt, with the demonstration of such precise engineering of the hairpin polyamides, a decisive step has been realized toward the targeting of any designated DNA sequence with small molecules.

The repertoire of sequences targeted by artificial ligands can be further extended by combining an oligonucleotide with a netropsin-like (138) or a hairpin polyamide derivative (139). For example, the affinity of the conjugate (23) for the 18 base pair target site 5'-TGACATTAAAAAGAAA-3' is 150-fold higher than that of the unlinked subunits (140). A related ligand consisting of a pyrimidine oligonucleotide 11 bases in length covalently tethered to an imidazole-containing polyamide cooperatively binds as a dimer to 27 noncontiguous base pairs of double-helical DNA via the formation of a 2:1 ligands/DNA complex (139). In both cases, the recognition process involves simultaneous recognition of the minor and major grooves of the double helix, thus mimicking the function of certain sequence-specific DNA binding proteins.

Despite the elegant design strategy for lexitropsin/DNA complexes, the biological activity of minor groove binders has not been much improved. So far, the lexitropsin approach has not led to clinically useful drugs, although certain monomeric and dimeric lexitropsins exhibit interesting antiviral or anticancer activities in vitro and sometimes in vivo (55). Some retroamide distamycin analogues exhibit promising antiviral and antiprotozoal activities (141).

A considerable number of antitumor agents, including some of clinical value, induce DNA damage either directly by alkylation or cleavage of DNA or indirectly via inhibition of topoisomerase activities. The DNA lesions induced by these different categories of drugs are presumably responsible for their cellular toxicity. Irrevers-

ible damage of the genetic material in cells has been considered as the basis of the antitumor effect, but it is more likely responsible, to some extent, for the toxic side effects toward normal cells (genotoxicity). Consequently, there is currently intense interest in the development of sequence-directed DNA damaging agents with a view to improving the therapeutic value of the drugs by virtue of a gene-specific recognition. The following sections describe some examples of netropsin/distamycin conjugates rationally designed to bind tightly to DNA and/or to produce irreparable damages at precisely defined genomic locations.

4. LINKAGE TO POLYAMINES

Bruce and co-workers have elaborated a series of molecules they call *microgonotropens* in which the methyl substituent on the central pyrrole ring of distamycin is replaced with a branched polyamine (142–148). The polyamine substituent on the dien- (24) and tren-microgonotropens (25) projects outward from the minor

dien-microgonotropen

tren-microgonotropen

groove and acts as a hook to increase the affinity for DNA via interaction with the phosphodiester backbone or with the major groove of DNA. The tren [$-\text{NHCH}_2\text{CH}_2\text{N}(\text{CH}_2\text{CH}_2\text{NH}_2)_2$] microgonotropen (25, $n = 4$) is more effective than distamycin in promoting DNA bending and straightening (149). Such compounds can also efficiently compete with the sequence-specific binding of regulatory proteins to DNA (150). The microgonotropen strategy represents a new avenue in the design of minor groove reading ligands having a very high affinity for DNA. In addition, the metal-chelating properties (151) of the dien and tren substituents may be exploited for the design of catalysts for sequence-selective hydrolysis of DNA, that is, for the design of artificial nucleases (152).

5. LINKAGE TO DNA-ALKYLATING AGENTS

Most alkylating drugs react with DNA via an electrophilic attack on purine residues, in particular on guanines. Classical alkylating agents such as chlorambucil (153) and *cis*-platin as well as the pluramycin antibiotics (154) react within the major groove of DNA at the N-7 position of guanines. In contrast, mitomycin C (155) and anthramycin (156, 157) form adducts with the exocyclic amino group of guanine. Minor groove interactions also occur with the adenine-specific alkylators duocarmycin A and CC-1065 (158–160).

The accessibility of the major groove and the high intrinsic nucleophilicity of the N-7 heteroatom position contribute to the preferential alkylation of guanine residues by nitrogen mustards. However, the alkylation patterns of nitrogen mustards and nitrosoureas can be modified by linking the reactive group to a DNA reading element. The first generation of alkylating lexitropsins consisted of netropsin and distamycin analogues equipped with *N*-chloroacetyl (26) and *N*-bromoacetyl (27) substituents

agents or with bis(chloroethyl)amino substituents (e.g., 28–30) (161, 162). *N*-Bromoacetyl distamycin (35) reacts with a single adenine in the sequence 5'-GTTTA•5'-TA•AAC within a 167 base pair restriction fragment

(163, 164). The second generation of alkylating lexitropsins contains benzoyl (31, 32) or benzyl mustards (33,

34) (165–170). Following the discovery of the aforementioned antiparallel side-by-side motif, bis(mustard) cross-linked lexitropsins such as **35** were synthesized (171).

Distamycin analogues equipped with DNA alkylating

functionalities such as compounds **31–34** show a remarkable sequence selectivity with, in some cases, an almost exclusive alkylation of adenines in the minor groove with no detectable guanine N-7 reaction. The lead compound in the series is the bis(2-chloroethyl)aminobenzoyl derivative of distamycin FCE24517 (**31**), also known as tallimustine, which demonstrates significant anticancer activity in animal models and is currently undergoing clinical trials (172–178). The antitumor activity of tallimustine is dependent on its capacity to interact with DNA. The drug alkylates the 3'-purine residue within the consensus sequence 5'-TTTTGPy-3' (167, 175). Recently, novel tallimustine derivatives have been synthesized, and some of them, such as the pyrazole derivative **36**, proved to be significantly more active than

tallimustine (179, 180). Fifty years after they were introduced into medical practice in the treatment of neoplastic diseases (181), nitrogen mustards are still among the most clinically useful anticancer drugs. With the rational design of tumor active drugs such as FCE24517, there is good reason to believe that nitrogen mustards will remain of major clinical importance for a considerable time.

Other series of distamycin conjugates equipped with alkylating functionalities have been synthesized. Lown and collaborators have synthesized a series of lexitropsin cyclopropylpyrroloindole (CPI) hybrids (182). The CPI-*N*-methylpyrrolocarboxamide derivative (**37**) exhibits an exceptional cytotoxic potency against KB tumor cells in vitro (IC₅₀ = 0.76 fg/L) and forms stable covalent adducts in the minor groove of DNA (183). The pharmacophore found in CC-1065 and the duocarmycins has been exploited for the design of conjugates **38** and **39**. Compound **38**, containing a stable 3-(chloromethyl)-6-hydroxy-2,3-dihydroindole, binds covalently to AT-rich sequences in DNA (184). Church et al. (185) have synthesized chloroethylnitrosourea-lexitropsin conjugates such as **40**, which alkylates adenine residues in the minor groove. Zhang et al. (90) have prepared a series of noncationic *N*-methylpyrrole dipeptides incorporating sulfonate ester terminal groups (**41**, **42**). Here also, efficient alkylation

at adenine N-3 in the minor groove was observed. An elegant way to provoke DNA-DNA cross-links has been reported using a distamycin analogue coupled to a 2,3-bis(hydroxymethyl)pyrrole function, which in part mimics the functionality present in reductively activated mitomycins or oxidatively activated pyrrolizidine alkaloids. Compound **43** efficiently produces interstrand cross-links by bridging the 2-amino groups of two paired CpG steps (186, 187). More recently, Walker et al. (188) have designed netropsin-anthracycline conjugates such as the chimera **44**, which is expected to recognize the sequence RGAAAA from the HIV-1 polypurine tract. Gupta et al. recently reported the synthesis, DNA binding, sequence specificity, and biological evaluation of DNA-directed alkylating agents comprising naphthalimide,

nitrogen mustard, and lexitropsin moieties (e.g., compound **45**). However, in this case alkylation still occurred at N-7 guanine, indicating that the bulky intercalative naphthalimide mustard does not enhance sequence specificity (189).

6. LINKAGE TO A PHOTSENSITIVE GROUP

A few psoralen derivatives (e.g., 8-methoxypsoralen) are used in phototherapy for the treatment of human skin diseases, chronic leukemia, and some infections connected with AIDS. The biological effect probably arises from intercalation into DNA. When exposed to UV light, intercalated molecules react covalently with DNA to form cyclobutane links to pyrimidine bases, predominantly at the 5'-TpA step (190). Psoralen (**46**, **47**) and coumarin (**48**) derivatized minor groove binding oligopeptides have been used to induce light-dependent sequence-specific reaction with DNA (191, 192). Pyrene-lexitropsin con-

jugates such as (49) were also synthesized (193). The cytotoxicity of this sequence-selective photosensitizer is significantly enhanced upon irradiation. The photoinduced DNA lesions apparently result from the production of singlet oxygen. Using a similar approach, Herfeld et al. (194) have synthesized netropsin–isoalloxazine conjugates such as compounds 50 and 51. Upon photoactivation in the presence of molecular oxygen, the flavin chromophore oxidizes and generates oxy radicals capable of causing DNA breaks. The linkage of netropsin to a flavin chromophore leads to AT selective strand cleavage reaction (195, 196). Quinone–netropsin hybrids (e.g., 52) have been also designed. These conjugates are capable of inducing UV-mediated strand breaks (197).

Cationic porphyrins can also act as DNA photosensitizers (198). Molecular modeling predicts that the porphyrin moiety of the conjugate 53 intercalates into DNA (199, 200). UV-sensitive *p*-nitrobenzoyl groups attached to netropsin–acridine hybrids also act as photocleavers. Matsumoto et al. (201) have synthesized a series of oligo-(*N*-methylpyrrolecarboxamide) derivatives linked to halogenated heteroaromatic groups. Photoinduced DNA cleavage by the bromofuran–netropsin conjugate 54 is not mediated via active oxygen species ($\text{OH}^\bullet$) but may be due to the reaction of an aryl radical produced upon photolysis of the carbon–halogen bond (201). A similar mechanism with drug radical production has been proposed for X-ray-sensitive nitroaromatic compounds. Metronidazole and misonidazole are typical examples of radiosensitizing agents used in the treatment of anaerobic infections and are under continuing investigation regarding their use in cancer therapy, acting as markers for hypoxic regions in tumors (202). These two sensitizers only react only weakly with DNA, presumably via an electron-seeking radical (203, 204). Targeting of a nitroarene moiety to DNA via a minor groove binder is expected to increase the sensitizer concentrations at

defined sites on DNA (205–207). The affinity of the 2-nitroimidazole–netropsin conjugate (**55**) for DNA is

~200-fold superior to that of misonidazole, but despite the improved interaction with DNA and improved cellular uptake capacity, the radiosensitization efficiency remains relatively poor and not better than that of misonidazole (206). Photoinduced DNA cleavage has been reported with oligo-*N*-methylpyrrolecarboxamide derivatives substituted with a benzylsulfonamido group such as the *p*-chlorobenzenesulfonamide–netropsin hybrid **56**. In this case, the efficiency of single-strand cleavage under UV-A irradiation clearly depends on the length of the pyrrolecarboxamide chain. Tetrapyrrole-sulfonamide conjugates are more efficient DNA cleavers than the corresponding analogues containing three or two pyrrole units, and conjugates with only one pyrrole are practically inactive (208). The same conclusion was drawn for simple oligopeptides such as **57** and **58**, which do not possess special side chains sensitive to UV light but which, nevertheless, can induce DNA cleavage under UV-A irradiation (209). Conversely, for nitrated oligopyrrolecarboxamide derivatives such as **59** and **60**, the DNA photocleavage efficiency is higher for the monopyrrole compounds than for the bis- and tris(peptide)s (210).

The netropsin–platinum–netropsin conjugate (**61**) represents another type of netropsin conjugate capable of inducing DNA cleavage upon X-ray ionization (211). According to footprinting experiments, the drug binds selectively to 9 base pair long AT-rich sites with the two netropsin moieties extended along the minor groove. Recently it was shown that along with the extended conformation, hairpin conformation can coexist with the pyrrole rings of one netropsin-like element stacked on the pyrrole rings of the other. This structure is remi-

niscant of the parallel hairpin polyamide motif described above (212). X-irradiation of drug/DNA complexes yields discrete cutting sites near the center of the platinum–bis(netropsin) binding sites. The cleavage would result from the rupture of the deoxyribose residues upon attack by Auger electrons generated by the irradiated platinum atom. Such conjugate compounds capable of triggering sequence-specific DNA degradation might be of interest for X-ray therapy of tumors.

7. LINKAGE TO A METAL/COMPLEX

Endonucleases, such as DNase I, are generally employed to map ligand binding sites on DNA (213, 214), but the preequilibrated ligand/DNA complex can be subjected to the nicking activity of a chemical nuclease, such as Dervan's reagent methidiumpropyl-EDTA complexed with iron (MPE·Fe^{II}). It is also possible to equip the ligand with its own DNA-cleaving functionality, for example, to attach an Fe·EDTA complex to the test drug. This method, termed DNA-affinity cleaving, has proved

to be very successful in analyzing binding sites for distamycin via the use of EDTA–distamycin conjugates such as compound **62** (214–216). The technique has been

extensively exploited to study oligo(*N*-methylpyrrolecarboxamide) derivatives containing up to 12 pyrrole units as well as a variety of monomer and dimer lexitropsins (217–222). Upon chemical activation with a reducing agent (e.g., dithiothreitol) the iron–EDTA portion generates hydroxyl radicals, which react with the deoxyribose residues to produce DNA strand cleavage. In contrast to Fe•EDTA footprinting, the active oxygen species are produced directly in the vicinity of the ligand binding sites on DNA and so are less susceptible to diffusion.

Metal complexing peptides can serve as a source of oxygen radicals. The growth-modulating tripeptide glycyl–histidyl–lysyl (GHK) and the related tripeptide glycyl–glycyl–L-histidine (GGH) both form complexes with copper and upon activation can generate oxygen active species (223–226). Linkage of the metal-complexed GHK peptide to minor groove binding drugs has been considered as a means of inducing sequence selective cleavage. Compound **63** was synthesized. The peptide moiety not only cleaves DNA but also contributes positively to the DNA binding reaction (227, 228). Non-peptidic metal complexes have been utilized. Recently, Dst was linked to a bis(salicylidene)ethylenediamine derivative to give the distamycin–salen conjugate **64**. However, the cleavage remained largely nonspecific (229).

The best characterized natural model for sequence-specific DNA cleavage is bleomycin, which remains one of the most useful antitumor drugs. The bleomycin•Fe(II) complex combines with O₂ to produce a reactive oxygenated metalbleomycin species, which is capable of abstracting a hydrogen atom from the C4' position of deoxyriboses in DNA. Bleomycin generates mainly single-strand breaks at pyrimidine residues 3' to a guanine residue (i.e., at 5'-GpC and 5'-GpT sequences) (230). The long established clinical utility of bleomycin sparked tremendous interest in its mechanism of action and in the design of compounds based on its structure. A considerable number of bleomycin analogues and related structures have been designed, including some equipped with DNA reading elements based on netropsin and distamycin. The structure of the antibiotic has been simplified to yield analogues such as PYML (231), and AMPHIS (232–234), which mimic efficiently the metal-chelating/oxygen activation domain of bleomycin.

Attachment of PYML (235, 236) and AMPHIS (237–241) to lexitropsin carriers gave bleomycin-like conjugates such as compounds **65–68** endowed with interesting sequence-specific DNA recognition properties. For bleomycin, the whole molecule spanning from the pyrimidine region to the bithiazole terminus appears to be responsible for specific recognition of DNA (242–244). In contrast, the lexitropsin moiety is only responsible for specific base recognition of man-designed bleomycin conjugates. The fact that the synthetic PYML–distamycin hybrid **67** is more toxic than bleomycin itself toward L1210 leukemia cells in vitro encourages the design of other related bleomycin-like molecules tailored with DNA reading elements.

8. LINKAGE TO AN ENEDIYNE LIGAND

The discoveries in the late 1980s of the antitumor activity of enediyne antibiotics rapidly elicited extensive research activity into their chemistry. An impressive number of synthetic analogues of dynemicin, neocarzinostatin, calicheamicin, and esperamicin have been described (245–247). Upon activation, enediynes trigger a Bergman reaction, which leads to highly reactive benzenoid diradicals and causes severe DNA damage (247). Enediyne antibiotics are among the most cytotoxic compounds known so far, and their activity is likely attributable to their effect on DNA. The excessive reactivity of the enediyne moiety prompted the development of analogues containing DNA delivery systems. To this end, netropsin was coupled with the neocarzinostatin chromophore (**69**) (248) and distamycin was attached to a dynemicin model (**70**) (245). More recently, the synthesis and biological activity of new netropsin–enediyne hybrids such as **71** was reported. The addition of the binding domain improved the DNA cleavage potency considerably (up to 100-fold), but a concomitant increase in potency against tumor cells was not observed (249).

Simple cyclic enediynes attached to netropsin moieties have also been elaborated (250). The linkage of the two functionalities via acetate and crotonate (**72**) tethers results in a hybrid series in which the cleavage efficiency is strongly enhanced (up to 1000-fold compared to the

Amphis-netropsin

PYML(6)-(AHM)-distamycin

PYML(6)-(APA)-distamycin

neocarzinostatin-netropsin

dymecicin-distamycin

(72)

TMM-netropsin

enediyne alone) (251). These encouraging results pave the way for the design of simpler related structures capable of triggering effective DNA cleavage via a radical mechanism. In this context, Bregant et al. (252) synthesized the netropsin analogue **73** equipped with a trimethylenemethane group (TMM), which can undergo cycloaddition to electron deficient alkenes. Upon photolysis of the diazene moiety, the TMM-netropsin conjugate can transform to a diyl radical and cleaves DNA, predominantly at AT-rich regions (253). Propargylic sulfones are small synthetic molecules that mimic the

chemical action of enediynes. They can cleave DNA in a pH-dependent fashion. Here again, linkage of lexitropsin carriers to propargylic sulfones (**74**, **75**) may permit the cleavage to be directed to specific sequences in DNA (254). It is worth mentioning here the netropsin-

quinocarcin conjugate **76**, which can efficiently cleave DNA at AT-rich sequences via the production of a nondiffusible oxidant (255).

9. LINKAGE TO AN INTERCALATING AGENT: THE COMBILEXINS

A large number of intercalating drugs, including some of major clinical value, possess a heterocyclic chromophore substituted with peptide, alkyl, or carbohydrate side chains that participate in DNA recognition. These chains represent a kind of hook for sequence-selective interaction within the minor groove of DNA. For example, the antitumor drug actinomycin intercalates between base pairs, leaving the two pentapeptide lactones lying in the minor groove of the double helix (256–258). The symmetrically disposed cyclic peptides participate in the specific recognition of GpC sites by actinomycin. Similar observations can be made for a variety of tumor active intercalating drugs. Anthracyclines such as daunomycin and nogalamycin contain carbohydrate residues that serve as DNA recognition elements (259, 260). The peptide rings of the quinoxaline antibiotics echinomycin and triostin A are prime determinants for sequence-specific recognition by the drug (261). The enediyne antibiotics dynemicin A (262) and neocarzinostatin (263) bind to DNA by intercalation of their chromophore (naphthoate for neocarzinostatin and anthraquinone for dynemicin), placing their reactive enediyne-containing bicyclic core moiety in the minor groove in a suitable position for selective DNA cleavage. Such considerations indicate that in many cases drugs usually referred to as “intercalators” in fact exhibit mixed modes of binding to DNA and therefore should be considered as intercalator–minor groove reading hybrid molecules or naturally occurring *combilexins* (thus called by analogy with the *lexitropsins*) (264, 265).

Using actinomycin D as a model compound, Krivtsora et al. (266) designed a series of hybrid molecules called

distactins in which the phenoxazine chromophore is substituted at positions 1 and 9 with one, two, or three *N*-methylpyrrolecarboxamide units. Bidentate reaction with DNA involving intercalation of the chromophore and minor groove binding of the DNA reading element was observed with distactins bearing one or two pyrrole rings but not with the analogues having three units. The model was reconsidered two years later (45). DNA affinity cleaving studies of the bis(EDTA–distamycin)–phenoxazine conjugate molecule **77** revealed a major

distactin (**77**)

[bis-(EDTA–distamycin)]–phenoxazine

NetMitox (**78**)

cleavage site flanking the 10 base pair sequence 5'-TATAGGTAA, suggesting thus that intercalation of the tricyclic nucleus at the central GG step is accompanied with minor groove binding of the distamycin moieties at the flanking (A·T)₄ sites. Additional single cleavage loci were also observed. Depending on the recognized sequence, only one or both recognition elements engage in contact with DNA (45). Similar results were recently obtained with the bis(netropsin)-anthraquinone combilexin **78**. Intercalation of the mitoxantrone-derived chromophore is hindered by the appended minor groove elements. The anthraquinone not only provides extra strength of binding but notably influences the DNA recognition by the minor groove element (267).

Bis(pyrrolicarboxamide) moieties were linked to a 9-aminoacridine chromophore by alkyl linkers of variable length (268). Optimum fit to DNA was obtained with the combilexin **79** with a butyryl tether. This biscationic hybrid exhibits a strict AT preference as for distamycin. A structurally related acridine-distamycin ligand equipped with a photoactivatable *p*-nitrobenzoyl (**80**)

group has been synthesized (269). This conjugate can cut DNA upon activation with UV light (310 nm) with a preference for AT sequences (270). The selectivity for AT sites was found to be significantly decreased when a truncated netropsin moiety was linked to a glycyanilinoacridine chromophore structurally related to the antileukemic drug amsacrine. In this case, the rigid connector between the bis(pyrrole) unit and the acridine nucleus of the combilexin molecule **81** does not permit optimal intercalation of the acridine and apparently slightly restricts the netropsin moiety fitting deeply into the minor groove (271, 272). However, this compound is a potent topoisomerase II inhibitor and exhibits moderate antitumor activities in vivo (273, 274). Two functional domains were identified in the combilexin **81**: the anilino group can be regarded as a skeletal core to which are

connected, on the one side, the tricyclic acridine moiety, which represents the DNA binding domain, and, on the other side, the *N*-methylpyrrolicarboxamide moiety, which constitutes the topoisomerase II-targeted domain (275).

Covalent linkage of distamycin to a GC-selective ellipticine derivative (276) afforded a monocationic hybrid molecule Distel(1+) (**82**), capable of bidentate binding to DNA. The reaction with DNA was primarily driven by the charged ellipticine moiety of the hybrid (277–279). The ellipticine chromophore has markedly reinforced the affinity of the ligand for DNA, but the effect is at the expense of DNA sequence selectivity. Computational studies suggested that the addition of a positively charged group on the distamycin terminal group would favor binding to AT sequences (277). The calculation proved to be correct. Indeed, the substitution of the terminal formamido group of Distel(1+) for an aminopropionamido group charged at neutral pH [Distel(2+) (**83**)] was the

correct way to proceed to convert a nonspecific conjugate into a highly AT-specific DNA reader (280). In contrast to Distel(1+), the interaction of Distel(2+) with DNA seems to be driven as much by the distamycin moiety as by the ellipticine residue. Of the two distamycin-

ellipticine hybrids **82** and **83**, only the monocationic hybrid Distel(1+) (**82**) proved to be a topoisomerase inhibitor. Its biscationic analogue Distel(2+) (**83**) showed practically no effect on both topoisomerase I and topoisomerase II, despite its superior DNA binding properties (281). The poisoning of topoisomerase I by Distel(1+) contributes to the cytotoxic effect since P388CPT5 cells resistant to camptothecin (a powerful topoisomerase I inhibitor) display a notable cross-resistance to Distel(1+) (281).

A different situation has been reported with a biscationic netropsin conjugate containing an oxazolopyridocarbazole chromophore derived from the ellipticines. The Net-OPC (**84**) hybrid ligand adopts different configurations according to the sequence to which it binds. At GC sites, the OPC chromophore intercalates into DNA but the netropsin remains unbound. At AT sites, the most energetically favored complex has both the netropsin and the OPC moieties inserted in the minor groove of a 7 base pair long sequence. In contrast, the second favored complex at (A·T)₄ sites involved intercalation of the OPC ring and minor groove recognition by the bispyrrole moiety (282–285). A somewhat similar coexistence of an intercalative and a nonintercalative binding mode was reported for the netropsin–porphyrin conjugate **53** (199). The connecting group between the two DNA binding elements plays a critical role in the DNA recognition process (200). These typical examples illustrate the difficulties encountered in designing combilexin molecules. It is a challenging exercise that demands consideration of the notions of geometrical compatibility, hydrogen bonding capability, and the overall electronic properties of the interacting species.

A moderate antitumor activity *in vivo* was observed with the bifunctional molecule **85**, which combines features of both the lexitropsin and combilexin approaches. This hybrid ligand, in which are conjugated the thiazole lexitropsin (**12**) and the intercalating anilinoacridine chromophore, binds to DNA via a bimodal process involving minor groove binding of the lexitropsin moiety and intercalation of the acridine moiety (286).

A second generation of combilexins has now been designed. Unlike compound **81**, the netropsin–amsacrine hybrid (**86**) bears a positively charged terminal side chain, which contributes significantly to the ATT selectivity of such ligands and retains the *m*-methoxy and methanesulfonamide substituents on the anilino ring, which constitute key elements for the interference with topoisomerases, the maintenance of redox properties, and the biological properties of amsacrine. The netropsin moiety is connected to the acridine ring via a 4-carboxamide side chain, whereas it was previously attached directly to the anilino group. Linkage of a carboxamide side chain to position 4 of the acridine ring of amsacrine has earlier been shown to convert the drug from a classical intercalator to a threading intercalator (287, 288). Structural and kinetic studies have revealed that the conjugate threads through the DNA double helix so as to intercalate its acridine chromophore, leaving the netropsin moiety and the methanesulfonanilino group positioned within the minor and major grooves of the double helix, respectively (289). In addition, the hybrid retains the susceptibility to copper-dependent oxidation and to generate DNA-damaging oxygen radicals (290). It also stimulates the formation of cleavable complexes with DNA in the presence of topoisomerase II, but its netropsin-like moiety confers little or no influence on the reaction with the topoisomerase (290).

Thus far, the combilexin strategy has concerned netropsin- or lexitropsin-like minor groove binders attached to different intercalating chromophores. In 1995, the strategy was extended to another category of minor groove binders, namely, 1,3-diaryltriazenes derived from the antiviral and antiprotozoal drug berenil. The acridine–triazene combilexin (**87**) exhibits a distinct preference for AT base tracts rather than GC-rich sequences and is ~40-fold more cytotoxic than the triazene or acridine subunits toward L1210 mouse leukemia and A2780 human colon cancer cell lines (291). These results on combilexin molecules obtained so far encourage us to believe that this approach to DNA-targeted pharmacology has the potential to yield important developments in the search for new classes of topoisomerase inhibitors and perhaps for new and better anticancer drugs.

The epipodophyllotoxins etoposide (VP-16-213) and teniposide (VM-26) are very potent topoisomerase II inhibitors and are mainly used in chemotherapy for the treatment of small cell lung cancer, testicular cancer, lymphoma, and leukemia. These compounds stabilize DNA/topoisomerase II complexes but interact only weakly, if at all, with DNA in the absence of the enzyme. Lown and co-workers have attempted to direct epipodophyllotoxins to specific sequences via the conjugation with lexitropsins. A series of 4'-demethylepipodophyllotoxin–lexitropsin conjugates such as compound **88** were syn-

thesized, but these compounds were found to be much less cytotoxic than the parent compounds (292). In the same vein, a pyrroloquinoline nucleus of the topoisomerase II inhibitor makaluvamine A has been linked to mono-, bis-, and tris(pyrrolocarboxamide) moieties. Hybrids such as compound **89** show significant cytotoxicity against different tumor cell lines (293).

10. CONCLUSION

Netropsin and distamycin have greatly contributed to our understanding of the molecular basis of drug–DNA recognition. The understanding of how these two antibiotics recognize and bind to AT sequences in DNA provided perceptions of how to design sequence-specific DNA binding molecules and stimulated the synthesis of several classes of new compounds of potential use in cancer chemotherapy. As shown in this review, the chemical structure of netropsin-like DNA reading elements may be varied in many synthetically convenient fashions to produce different repertoires of sequence-selective DNA binding molecules with a range of functionalities. Sterically demanding groups can be attached to netropsin and distamycin without abolishing their sequence recognition properties. The fact that certain netropsin analogues can readily recognize a specific sequence in DNA (e.g., lexitropsins forming 2:1 complexes and hairpin polyamides) shows that DNA targeting with minor groove binding drugs is no longer merely a possibility but a practical reality. The fact that certain netropsin conjugates capable of inducing DNA damage at specific sequences exhibit potent antitumor activities (e.g., netropsin–nitrogen mustard conjugates) shows that this DNA-targeting strategy has the potential to yield new and efficient antitumor agents. There is good reason to believe that netropsin and distamycin will continue to inspire the development of new anticancer agents (294–297). However, it is important to bear in mind that at the present day no-one can certify that chemotherapeutic selectivity will be improved by virtue of an increase in sequence selectivity.

In the many examples presented in this review, netropsin and distamycin are almost always used to deliver cytotoxic drugs to specific sequences in DNA, but they can also be used to deliver DNA to cells. Gene transfer with netropsin–lipid conjugates has been attempted (298). Moreover, netropsin and distamycin analogues can also be used independently of their capacity to bind to AT-rich DNA sequences. For example, sulfonated and phosphonated ureido dimers of netropsin such as compound **90**, containing six sulfonic acid units, and the phosphonic acid-containing ligand **91** represent a new class of surface acting antiviral agents. Their mechanism of action apparently does not require binding to DNA but may involve the disruption of the virus attachment to CD4⁺-susceptible cells via an effect on CD4-gp120 interactions (299).

Although there are a few netropsin conjugates under clinical or preclinical evaluation, medicinal chemists still have much to do to design new clinically useful drugs endowed with the aptitude for reading any given DNA sequence and inducing the required DNA modification to obtain the desired biological response. Computer-based methods will increasingly serve to delineate more precisely the molecular rules that govern drug–DNA recognition. The increasing evidence that DNA binding proteins such as topoisomerases and transcription factors mediate the effects of drugs suggests that in addition to elucidating the structures of drug/DNA complexes it will be necessary to examine in detail the effects of drugs on

protein/DNA complexes. Close collaboration between medicinal chemists and molecular biologists will be necessary if we are to gain an improved understanding of the mechanisms whereby antitumor drugs affect the function of particular oncogenes.

Over the past 15 years, research on small molecules acting on nucleic acids has not only led to therapeutically useful drugs but also provided an invaluable source of structural and biological information on nucleic acids. The recent discovery of new tumor active compounds, such as those based on netropsin and distamycin reported here, has perhaps restored small molecules to the forefront of cancer therapy. It is still premature to state that netropsin and distamycin derivatives will provide new generations of sequence-specific antitumor drugs. However, the results obtained thus far are suggestive and promising. They augur exciting developments for years to come.

Synthesis and in Vitro T-Cell Immunogenicity of Conjugates with Dual Specificity: Attachment of Epitope Peptides of 16 and 38 kDa Proteins from *Mycobacterium tuberculosis* to Branched Polypeptide

Katalin A. Wilkinson, Hans Vordermeier,[†] R. J. Wilkinson,[†] Juraj Ivanyi,[†] and Ferenc Hudecz*

Research Group of Peptide Chemistry, Hungarian Academy of Sciences, Eötvös L. University, H-1518 Budapest, Hungary, and Tuberculosis & Related Infections Unit, MRC Clinical Sciences Center, Imperial College School of Medicine, Hammersmith Hospital, London W12 0NN, U.K. Received August 21, 1997; Revised Manuscript Received January 16, 1998

T-cell epitope containing peptides covalently attached to macromolecular carriers can be considered as synthetic immunogens for the development of skin-test diagnostics and of vaccines. As a carrier, an amphoteric branched chain polypeptide, poly[Lys-(Glu₇-DL-Ala_m)] (EAK) with poly(L-lysine) backbone has been used. This polypeptide with free α -amino and γ -carboxyl groups at the end of the side chains was conjugated with peptides representing two immunodominant regions of the 16 and 38 kDa proteins of *Mycobacterium tuberculosis*, respectively. Peptide C⁹¹SEFAYGSFVRTVSLPVGAD¹¹⁰ was elongated by Cys at the N-terminal and attached to the carrier containing protected SH groups to form disulfide bridges. Peptide ⁶⁵FNLWGPAFHERYPNVTITA⁸³ was conjugated to the 3-(2-pyridyldithio)propionic acid *N*-hydroxysuccinimide ester (SPDP) modified and acetylated EAK by introducing amide bond between the free α -amino group of peptide and the free γ -COOH group of Glu at the terminal position of the branches. This strategy lead to chemically well-defined synthetic immunogens that contain two different epitopes in multiple copies covalently linked to a synthetic branched polypeptide carrier. In vitro T-cell immunogenicity of a prototype conjugate was studied using T-cell hybridomas, lymph node cells from 38 kDa protein immunized mice, and human peripheral blood mononuclear cell (PBMC) cultures from sensitized individuals. These data document that the specific T-cell stimulatory effect of each mycobacterial epitope was maintained in this conjugate. Taken together, these findings suggest that it is feasible to use a biodegradable polymeric polypeptide for producing macromolecular bioconjugates for the stimulation of T-cell responses.

INTRODUCTION

Immunogenic peptides covalently attached to macromolecular carriers have extensively been used in experimental animals to elicit antibody responses or to induce protection against microbial or parasitic pathogens (1, 2, 3). However, this approach was applied to enhance or modulate T-cell responses sporadically (4). Recently, T-cell epitope containing peptides conjugated to various compounds have been used for the induction of antibody responses against lysozyme (5), gangliosides (6), or polysaccharides of bacterial origin (7, 8).

As a carrier, a synthetic, biodegradable branched polypeptide with poly(L-lysine) backbone has been used (9, 10). Linear and branched (multichain) polymeric peptides with controlled composition was first suggested by Sela (11), while branched polypeptides with simplified chemical structure invented by Szekerke (12, 13) provide a rational basis for its use as an immunological carrier. Recently, new bioconjugates were prepared and used successfully for constructing synthetic immunogens/antigens (14) with a phenyl-oxazolone hapten (15, 16),

B-cell epitope peptides of epithelial mucin (17), or herpes simplex virus (type I) glycoprotein D (18).

In tuberculosis, both protection and pathogenesis have generally been attributed to the actions of host T-cells (19). It is, therefore, of interest to construct synthetic immunogens with a capability to dissect *Mycobacterium tuberculosis* specific T-cell responses and to use for the development of skin-test diagnostics or vaccine. A partially purified protein mixture with lipophilic adjuvant (20) or cell wall components entrapped in liposomes (21) or the recombinant 38 kDa protein included into poly(DL-lactide-co-glycolide) microparticles (22) has been studied as subunit vaccine candidates. Bioconjugate immunogens containing T-cell epitope peptides of *M. tuberculosis* origin can be considered as specific skin-test reagents.

The 38 kDa glyco-lipoprotein of *M. tuberculosis* is a major secreted antigen with known amino acid sequence (23, 24). This protein is recognized prominently by sera from patients with multibacillary (19) or pulmonary tuberculosis (25). Several T-cell stimulatory regions were identified within the 374 amino acid residue protein using synthetic 20-mer peptides in murine (26, 27), bovine (28), and human (29) systems. Peptide 65–83 (⁶⁵FNLWGPAFHERYPNVTITA⁸³) stimulated strong proliferative responses of T-cells from mice which had been

Figure 1. Schematic representation of conjugate K2 containing two different epitope peptides from *M. tuberculosis* proteins $^{65}\text{FNLWGPAFHERRYPNVTITA}^{83}$ and $^{\text{C}91}\text{SEFAYGSFVRTVSLPVGAD}^{110}$ attached to branched polypeptide EAK by amide and disulfide bond, respectively.

presensitized with either live or killed organisms or with the recombinant 38 kDa protein (26). This peptide is also recognized by T-cells from PPD¹-positive humans (29).

The 16 kDa protein of 144 amino acid residues (30) is a major membrane constituent (31). It serves as a molecular chaperone and may be involved in bacterial stasis (32). It can induce in vitro T-cell proliferative responses as well as DTH reactions in mice and guinea pigs (33). T-cell responses with murine lymph node cells suggested that peptide 91–110 ($^{\text{C}91}\text{SEFAYGSFVRTVSLPVGAD}^{110}$) contains a T-cell epitope (34), which was stimulatory also for human PBMC from PPD sensitized healthy subjects and patients with active tuberculosis (35).

For the construction of conjugates to be utilized as potentially useful *M. tuberculosis* specific skin test diagnostics, poly[Lys-(X_i-DL-Ala_m)] (XAK) type poly- α -amino acids were used as synthetic carriers (9). X is either glutamic acid (EAK) (13) or *N*- α -acetyl glutamic acid (AcEAK) (36). EAK is an amphoteric polypeptide in which two types of functional groups (α -amino and γ -carboxyl groups) are available for conjugation. Consequently, this molecule seems to be ideal for well-defined attachment of two different entities with suitable selected reactive groups (Figure 1).

In this paper we describe (i) the synthesis and characterization of the epitope-EAK conjugate with dual specificity and of several epitope-AcEAK conjugates and (ii) the epitope-related T-cell immunoreactivity of the conjugates. The results presented here demonstrate that the strategy outlined leads to chemically well-defined synthetic antigens which contain two different epitopes in multiple copies covalently linked to a synthetic branched polypeptide carrier. In vitro data from assays using a specific murine hybridoma T-cell line (38.H6), mouse

lymph node cells and human PBMC cultures from sensitized individuals indicate that T-cell stimulatory capacity of each mycobacterial epitope was maintained or even enhanced in the prototype conjugate.

MATERIAL AND METHODS

Chemicals. DL-Alanine, glutamic acid, *N* ϵ -Z-lysine, imidazole, and acetic anhydride were purchased from Reanal (Budapest, Hungary). *N,N*-Diisopropylethylamine (DIEA), 1-hydroxy benzotriazole (HOBt) and bis-(trichloromethyl) carbonate were Fluka products (Buchs, Switzerland), while benzotriazol-1-yl-oxy-tris(dimethylamino)phosphonium hexafluoro-phosphate (BOP) was from Bachem (Bubendorf, Switzerland). Dimethylformamide (DMF) was stored over molecular sieves. Protected amino acids, peptide 38.G, and resins were purchased from Bachem (Bubendorf, Switzerland) or Novabiochem (Laenfeldingen, Switzerland), unless otherwise stated.

Synthetic Peptides. Peptides $^{\text{C}91}\text{SEFAYGSFVRTVSLPVGAD}^{110}$ (16.10), $^{\text{C}91}\text{SEFAYGSFVRTVSLPVGAD}^{110}$ (C-16.10), and $^{65}\text{FNLWGPAFHERRYPNVTITA}^{83}$ (38.I) were synthesized in our laboratory by the solid-phase methodology using 4-methyl-benzhydrylamine resin. All amino acids were coupled as *N* α -tert-butyloxycarbonyl derivatives. As side-chain protecting groups cyclohexyl for Glu and Asp, benzyloxymethyl for His, benzyl for Ser, and Thr and mesitylene sulfonyl for Arg were applied. Coupling was carried out using 1-hydroxy-benzotriazole/diisopropylcarbodiimide method in DMF:DCM = 1:1 (v/v). The reactions were monitored by ninhydrin assay (37) or bromophenol-blue method (38). After the completion of the synthesis, the α -amino groups were deprotected with 33% TFA/DCM and peptides were cleaved from the resin using hydrogen fluoride containing *p*-cresol and DL-dithiothreitol (DTT) [peptide: *p*-cresol:DTT = 1:1:0.1 (mol/mol/mol)].

The crude products were purified by RP-HPLC using a DELTA-PACK column (7.8 mm $\times$ 30 cm, C18-300 Å, 15 μm , Spherical, Nixon Waters Ltd., Tokyo, Japan) and gradient elution (0.1%TFA/H₂O as eluent A and 0.1%TFA/80%MeCN/20% H₂O as eluent B). Homogeneity of the pure peptides was confirmed by analytical RP-HPLC and the primary sequences were verified by amino acid analysis and mass spectrometry measured on a VG-ZA-2SEQ tandem mass spectrometer (Fisons, Loughborough, U.K.) equipped with a Cs⁺ gun (25 keV).

Branched Polypeptides. Abbreviations for amino acids and their derivatives follow the revised recommendation of the IUPAC-IUB Committee on Biochemical Nomenclature, entitled Nomenclature and Symbolism for Amino Acids and Peptides (39). The nomenclature of branched polypeptides is used in accordance with the recommended nomenclature of graft polymers (40). For the sake of brevity, codes of branched polypeptides were constructed by us using the one-letter symbols of amino acids. All amino acids are of the L-configuration unless otherwise stated.

The average degree of polymerization ($\overline{\text{DP}}_n$) of the polylysine used for the synthesis of branched polypeptides and conjugates was estimated by sedimentation analysis (41). Sedimentation analysis was carried out in a MOM3170 ultracentrifuge. The average relative molar mass of the branched polypeptides (EAK and AcEAK) was calculated from $\overline{\text{DP}}_n$ of the poly[Lys] backbone and from the amino acid ratios Glu:Ala:Lys as described earlier (12, 41). Visking tubes with a 12 000–14 000 Da

cutoff (Fisons, Loughborough, U.K.) were used for the dialysis of polymer products.

Poly[Lys-(Glu_{1,0}-DL-Ala_{3,1})] (EAK), was synthesized as previously described (13). Briefly, poly[L-Lys] ($\overline{DP}_n = 70$) was prepared by the polymerization of *N*^α-carboxy-*N*^ε-(benzyloxycarbonyl)-lysine anhydride. After cleavage of the protecting groups with HBr in glacial acetic acid, poly[Lys-(DL-Ala_{3,1})] (AK) was formed by grafting of short oligomeric DL-alanine side chains onto the ε-amino groups of polylysine using *N*-carboxy-DL-alanine anhydride. Attachment of Z-Glu(OBzl)-OPcp to AK was carried out in a water/DMF solvent mixture in the presence of HOBt and 4-methyl morpholine at pH 7–8. The protecting groups were cleaved with a HBr/acetic acid mixture, and their absence was verified by UV spectroscopy. EAK was purified by extensive dialysis and then freeze-dried.

Poly[Lys-(AcGlu_{1,0}-DL-Ala_{3,1})] (AcEAK) (36) was obtained by the use of acetic anhydride and imidazole in DMF in the presence of triethylamine (42). Briefly, EAK was dissolved in water/DMF (1:5, v/v) and equimolar TEA was added. Mixture of acetic anhydride and imidazole [1:1 (mol/mol)] was added to the polymer solution. After 1 h at 0 °C and overnight at room temperature, the product was purified by dialysis as described above. No ninhydrin positive reaction was observed in the ninhydrin test (37).

Synthesis of Epitope Peptide-AcEAK Conjugates.

AcEAK (10 mg, 20 μmol) was dissolved in 1 mL of deionized water and diluted with 4 mL of DMF. BOP reagent (8.9 mg, 20 μmol), 3.3 mg (25 μmol) of HOBt, and 7 μL (40 μmol) of *N,N*-diisopropylethylamine (DIEA) were dissolved in 1 mL of DMF, representing a molar ratio of BOP:HOBt:DIEA = 1:1:2 (mol/mol/mol). The activating mixture was added to the polymer solution and stirred for 20 min. Epitope peptide (0.5 mmol) (calculated for the side chains of the polymer) was dissolved in 3 mL of DMF at a concentration of 2.5 mg/mL, and 0.5 mmol of DIEA was added to this solution followed by addition to the preactivated polymer solution. The coupling was performed at room-temperature overnight under stirring. The solution was then dialyzed against deionized water for 3 days. Finally, the product was isolated by freeze-drying. The average molar substitution ratio was calculated according to the amino acid composition of the conjugate obtained from amino acid analysis (Table 1).

Synthesis of Epitope Peptides-EAK Conjugate with Amide and Disulfide Bonds. This was achieved in four steps: first, the α-amino group of the glutamic

acid side chains in the EAK polypeptide was modified by 3-(2-pyridyldithio)propionic acid *N*-hydroxy-succinimide ester (SPDP) (17,43) to obtain (SSP)EAK, and second, the remaining free α-amino groups were acetylated (42). In the third and fourth steps the conjugation of peptides was performed.

Poly[Lys-(SSP_x-Glu_i-DL-Ala_m)]_n, (SSP)EAK. EAK (100 mg, 215 μmol) was dissolved in 7.5 mL of PBS (0.1 M, pH 8, adjusted with 1 M NaOH). SPDP (20 mg, 64.0 μmol) SPDP (Sigma, Poole, U.K.) was dissolved in 2 mL of abs. methanol and added dropwise to the solution of the polypeptide. The reaction mixture was stirred for 30 min at room temperature and dialyzed for 24 h against distilled water. To determine the degree of 2-pyridyl-disulfide group incorporation, 400 μL of (SSP)EAK solution was reacted with 200 μL of DL-dithiothreitol (DTT) (2.5 mg/mL PBS), and after 5 min, the absorbance of the released pyridine-2-thione was measured at λ = 343 nm and ε = 8080 M⁻¹cm⁻¹ (44). The calculated degree of substitution was 19.3%. (SSP)EAK was isolated by freeze-drying.

Poly[Lys-(Ac_y,SSP_x-Glu_i-DL-Ala_m)]_n, (Ac,SSP)EAK. (SSP)EAK (110 mg, 235 μmol) was dissolved in 1 mL of distilled water and diluted to 5 mL with DMF at 4 °C. In the meantime, 312 μL (3.3 mmol) of acetic anhydride and 224 mg (3.3 mmol) of imidazole were mixed in 1 mL of DMF at 4 °C and stirred for 10 min. The two solutions were then mixed, and acetylation was continued for 2 h at room temperature. After dialysis against distilled water, the product was isolated by freeze-drying. The blocking of free amino groups was verified by the ninhydrin assay.

Poly[Lys-(Ac_y,SSP_x-Glu_i(Peptide₁)-DL-Ala_m)]_n, (Ac,SSP)E(Peptide₁)AK. (Ac,SSP)EAK (10 mg, 19 μmol) (calculated on the basis of 19.3% 2-pyridyl-disulfide group content, and 80.7% acetyl group content) was dissolved in 1 mL of water and diluted five times with DMF. BOP (8.9 mg, 20 μmol), 3.3 mg (25 μmol) of HOBt, and 7 μL (40 μmol) of DIEA were dissolved in 1 mL of DMF. The activating mixture was added to the polymer solution and stirred for 20 min. Peptide 38.I (10 mg, 4.5 μmol) (representing 0.25 mol of peptide/polymer side chain) was dissolved in 4 mL of DMF at a concentration of 2.5 mg/mL DMF, and mixed with 4.5 μmol of DIEA.

The peptide solution was added to the preactivated polymer solution and allowed to couple for 24 h at room temperature under stirring. The solution was then dialyzed against distilled water for 48 h as described

above, and the conjugate was isolated by freeze-drying. The average degree of substitution was calculated from amino acid analysis shown in Table 1.

The presence of the 2-pyridyl-disulfide groups was verified by reacting 400 μ L of (Ac,SSP)E(38.I)AK with 200 μ L of DTT (2.5 mg/1 mL of PBS) as described above and proved to be unmodified (19.5%). The preparation of (Ac,SSP)E(38.G)AK was performed according to a similar protocol.

Poly[Lys-(Ac₂,Peptide₂)-Glu₁(Peptide₁)-DL-Ala_m], (Ac,Peptide₂)E(Peptide₁)AK. (Ac,SSP)E(38.I)-AK conjugate (10 mg) (containing 3 μ mol protected thiol groups) was dissolved in 1 mL of distilled water. Peptide (10 mg, 4.5 μ mol) peptide C-⁹¹SEFAYGSFVRTVSLPVG-AD¹¹⁰ (C-16.10) dissolved in 1 mL of PBS (pH 8.0, adjusted with 1 M NaOH) was added to the conjugate solution. The reaction mixture was stirred for 30 min at room temperature, followed by dialysis against distilled water for 48 h and freeze-dried. The average degree of substitution was calculated from amino acid analysis and presented in Table 1.

(Ac,16.10)E(38.G)AK conjugate was prepared in a similar way. The characteristic data of these conjugates are shown in Table 1.

Amino Acid Analysis. The amino acid composition of peptides, branched polypeptides (EAK, AcEAK), and conjugates was determined from amino acid analysis using a Beckman (Fullerton, USA) model 6300 amino acid analyzer. Prior to analysis, samples were hydrolyzed in 6 M HCl in sealed and evacuated tubes at 110 °C for 24 h.

Analysis of Conjugates by RP-HPLC. The composition of the conjugates was tested by RP-HPLC, using a Delta-Pak RP C₁₈ column (7.8 mm $\times$ 30 cm) packed with spherical 15 μ m silica of 300 Å pore size (Nixon Waters Ltd., Tokyo, Japan) and the eluent system of 0.1% TFA in water (eluent A) and 0.1% TFA in acetonitrile/water = 80/20 v/v (eluent B) using high-purity (Analar) solvents and distilled, deionized water. The gradient elution was applied between 10 and 100% eluent B, for 35 min. The injection volume was 100 μ L containing 10 μ g of conjugate, polymer, or peptide. Compounds were dissolved in eluent immediately before application and filtered through 0.45 μ m Spartan 13 (Schleicher and Schuell, Dassel, Germany) filters. Free peptide or polymer polypeptide samples were run as standards, and their retention times were determined. UV absorbance was monitored at a wavelength of 220 nm. All analyses were carried out at ambient temperature with a flow rate of 1.0 mL/min. As a control, in some cases, the HPLC profile of peptide/conjugate mixture was also recorded.

The HPLC system consisted of a M600E quaternary gradient solvent delivery system with PowerLine control of programmable UV detector (model 490E), autosampler (model 717 plus), and of a Millennium 2010 chromatography manager (all from Waters, Milford, USA).

Recombinant Proteins. The recombinant 38 kDa protein produced in *Escherichia coli* and purified as described previously (45) was obtained from the WHO protein bank (Braunschweig, Germany). It is neither glycosylated nor lipoylated and lacks the first 11 amino acids of the native protein.

Cells, Mice. The HT2 cells were obtained from the European Cell Culture Collection (Porton Down, U.K.). The BW5147 cells were a gift from Dr. W. Born, Denver, CO. C57BL/10 (H-2^b) mice were obtained from Olac Harlem Ltd. (Shaws Farm, Bicester, Oxon, U.K.). Mice were age (6–10 weeks old) and sex (female) matched for each experiment.

Murine Hybridoma T-Cell Proliferation Assay. T-cell hybridomas specific for peptide 65–83 of 38 kDa protein [38.H6/1] and for peptide 91–110 of 16 kDa protein [16.10.7] were established and tested as described earlier (27, 46). Prior to use, hybridoma cells were washed with medium to remove HT and then assayed by incubating 5×10^4 cells/well of 96-well microtiter plates in the presence of 3×10^5 /well irradiated antigen presenting spleen cells and compounds at appropriate concentrations [$(5 \text{ and } 25) \times 10^{-6}$ M, calculated on the basis of epitope content]. After 24 h, culture supernatants (100 μ L/well) were removed and tested for IL-2 content using the IL-2-dependent, indicator cell line HT2 (10^4 cells/well, 100 μ L). Twenty-four hours later, 0.5 μ Ci/well [³H]thymidine (Amersham, U.K.) was added to the cells and harvested 4 h later onto glass fiber paper. The radioactivity was determined by standard liquid scintillation counting. Results are expressed as means of triplicates, in counts per minute (cpm).

Immunization and Mouse Lymph Node (LN) Proliferation Assay. Mice (5 animals/group) were immunized subcutaneously in each hind footpad with 40 μ g of recombinant 38 kDa protein emulsified in incomplete Freund's adjuvant (IFA, Difco, Detroit). Control animals were immunized with phosphate-buffered saline (PBS) emulsified in IFA. After 8 days, draining popliteal lymph nodes were removed and cell-suspensions prepared in culture medium [RPMI-1640 medium supplemented with 10% fetal calf serum (FCS, Gibco, Paisley, U.K.), 5×10^{-5} M 2-mercaptoethanol, 2 mM L-glutamine, 100 units/mL penicillin, 100 μ g/mL streptomycin sulfate, and 1% HEPES buffer 1 M (Gibco BRL, U.K.)]. Triplicate cultures of 4×10^5 cells/well were incubated in the presence of conjugate, free synthetic peptides and branched polypeptide ($c = 25 \times 10^{-6}$ M calculated on the basis of epitope content) in flat bottomed 96-well plates (Nunc, Roskilde, Denmark) at 37 °C in an atmosphere of 5% CO₂. [³H]thymidine (0.5 μ Ci/well) (Amersham International, Amersham, U.K.) were added to the cells on the third day of culture and harvested 6 h later onto glass fiber filter paper. The incorporated radioactivity was determined by standard liquid scintillation counting. The proliferation experiments were performed in triplicate, and the average value obtained from these three results was calculated. Standard deviation was <20%. The obtained data were represented as stimulation indices (SI) (cpm with peptide/cpm without peptide).

Human T-Lymphocyte Proliferation Assay. Blood was drawn from healthy PPD positive individuals. Peripheral blood mononuclear cells (PBMCs) were isolated by diluting whole citrated blood, 1:1 (v/v) in PBS and centrifuged on a Ficoll-Hypaque (Pharmacia, Sweden) density gradient. PBMCs were suspended in RPMI-1640 supplemented with 2 mM L-glutamine, 100 units/mL penicillin, 100 μ g/mL streptomycin, 5% AB positive human serum, and 0.025 M HEPES buffer (Gibco BRL, U.K.). Cells were cultured at 1.5×10^5 /well in 96-well round-bottomed microtiter plates (Nunc, Denmark) in the presence of the test peptide [$(0.2\text{--}25) \times 10^{-6}$ M]. Purified protein derivative (PPD) at 10 units/mL was used as a specific, and ConA at 5 μ g/mL was applied as a nonspecific positive control. After 6 days of incubation at 37 °C in 5% CO₂ cells were labeled with 1 μ Ci of [³H]thymidine (Amersham International, Amersham, U.K.) and harvested after 16 h onto glass fiber filters. The incorporated radioactivity was determined by standard liquid scintillation counting. The proliferation experiments were performed in triplicate and the average value obtained

Figure 2. Outline of the synthesis of conjugates containing two different epitope peptides (peptide 1 and peptide 2) and branched polymeric polypeptide EAK.

from these three results was calculated and expressed as stimulation indices (SI) (cpm with peptide/cpm without peptide).

In Vivo Toxicity Assay. In vivo toxicity of AcEAK was evaluated by observing mice using specified pathogen free BDF1 for 20 days after single i.p. injections at doses of up to 50 mg/kg body weight. All mice were alive at the end of this period, and no body weight loss or any noticeable toxic effect was detected.

RESULTS AND DISCUSSION

Preparation of Conjugates Containing Two Different Epitope Peptides and Branched Polypeptide EAK. To prepare structurally well-defined conjugates with two different and uniformly oriented peptide epitopes, the following strategy was developed (Figure 2). As carrier, branched polypeptide EAK containing free α -amino and γ -carboxyl groups was selected and two epitope peptide amides from *M. tuberculosis* proteins were prepared by solid-phase methodology (Table 1). For conjugation, peptide ⁶⁵FNLWGPAFHERYPNVTITA⁸³ (peptide 1) from 38 kDa protein possessing free α -amino group at the N-terminal was used without modification, while the second epitope peptide originating from 16 kDa protein was elongated with an N-terminal Cys [⁹¹SEFAYGSFVRTVSLPVGAD¹¹⁰] (peptide 2).

Our aim was to form two different types of covalent linkage between the polymer and the peptides. One of these bonds was an amide between the γ -COOH of EAK and α -NH₂ of peptide 1, while the second was a disulfide bridge introduced between the α -NH₂ of EAK and SH of peptide 2 (Figure 1).

In the first step, the α -amino-group of Glu in the side chain of EAK was modified by the heterobifunctional reagent SPDP to introduce protected SH groups into the polymer structure [(SSP)EAK] (43,17). The extent of 2-pyridyldisulfide group incorporation was determined spectrophotometrically from the amount of pyridine-2-thione released by reduction with DTT (44), and the average degree of substitution was 19.3%. To produce polypeptide (Ac,SSP)EAK, the free α -amino groups of Glu in the branches were blocked by acetylation using a mixture of acetic anhydride and imidazole (42). In the next step, peptide 1 was coupled to (Ac,SSP)EAK. This was achieved by the BOP reagent-based activation method in which the γ -carboxyl group of glutamic acid of (Ac,SSP)EAK was linked to the α -amino group of phenylalanine residue in peptide 1 to provide isopeptide (γ , α -type amide) bonding. After isolation of the product, the presence of the 2-pyridyldisulfide groups was verified as described above and proved to be unchanged (19%).

In the last step, disulfide bridge was introduced by the substitution of the protecting group of SH of the polymer by peptide 2 (C⁹¹SEFAYGSFVRTVSLPVGAD¹¹⁰). The completion of the reaction between (Ac,SSP)E(peptide1)-AK and peptide 2 was checked spectrophotometrically as mentioned above. The average degree of incorporation of peptide 2 was 19.5%. Data obtained from amino acid analysis suggest that the protected thiol groups of the polymer were fully transformed into disulfide link between peptide 2 and branches of the polymer (Table 2). Similar procedure was applied for the preparation of conjugate K1, which contains peptide ³⁵⁰DQVHFQPLP-PAVVKLSDALI³⁶⁹ from 38 kDa protein. However, it should be noted that the Lys residue in position 363 of the peptide ³⁵⁰DQVHFQPLPPAVVKLSDALI³⁶⁹ was unprotected during the coupling. Therefore, this conjugate might have not only γ , α -bond between γ -COOH of the polymer and α -NH₂ of the peptide but also γ , ϵ -type linkage with ϵ -NH₂ of Lys³⁶³ in the peptide (Table 2).

Preparation of Epitope Peptide-AcEAK Conjugate. Conjugates containing multiple copies of only one kind of epitope peptide (⁶⁵FNLWGPAFHERYPNVTITA⁸³, ³⁵⁰DQVHFQPLPPAVVKLSDALI³⁶⁹, or ⁹¹SEFAYGSFVRTVSLPVGAD¹¹⁰) and branched polypeptide AcEAK derived from EAK were also prepared and used in control immunological experiments.

In AcEAK, the α -amino group of Glu in the branches are acetylated, and therefore, this polypeptide contains γ -carboxyl groups suitable for reacting with amino groups of the peptide to be attached. Coupling was performed by activation of COOH groups using BOP reagent-based method as described earlier for a GnRH antagonist peptide (42). In conjugates with peptides 16.10 or 38.I, γ , α amide bonds are expected. Due to the presence of unprotected ϵ -NH₂ of Lys³⁶³ in ³⁵⁰DQVHFQPLPPAVVKLSDALI³⁶⁹ (Table 2), an additional γ , ϵ -type peptide linkage cannot be excluded in the 38.G-AcEAK conjugate.

Characterization of the Conjugates. After extensive dialysis, products were isolated and RP-HPLC studies were carried out to access free peptides in the conjugate preparation. The retention time for peptides (Table 1) as well as for conjugates and carriers, absorbing at 220 nm, was determined. Free AcEAK was detected at 21.5 min, whereas the *t_R* values for K1 and K2 were 23.5 and 23 min, respectively. Quantitative analysis indicated less than 1% of free peptide in the conjugate samples.

The amino acid composition of conjugates K1 and K2 after the third and the last step of the synthesis and of

^a On the basis of the single letter code of branched polypeptides (EAK, AcEAK) and on the peptide-codes (16.1, 38.1, 38.G). ^b Peptide: polymer molar ratio calculated from the amino acid composition determined by amino acid analysis. ^c Average degree of substitution expressed as percent of modified side chains of the carrier polypeptide calculated from the average degree of polymerization of the polylysine ($DP_n = 70$) and from the side chain composition of the conjugate. ^d Average molecular weight of the macromolecule, calculated from $DP_n = 70$ for polylysine and from the side-chain composition.

all purified AcEAK conjugates was determined by amino acid analysis.

On the basis of the 2-pyridyldisulfide group content of conjugates K1 and K2 after the third step of the synthesis and on the amino acid composition data obtained from conjugates, free carrier, and of the free peptides, the average degree of molar substitution (DS) was calculated.

The characteristic data are shown in Table 2. DS values for AcEAK-based conjugates show that, depending on the amino acid sequence and composition of the epitope peptide, 14–33.5% of the side chains can be modified by this method under conditions applied. These values are in good agreement with our previous experience with GnRH antagonist (42) and mucin 1 peptides (17). It is interesting to observe that the DS values combined for the two different epitope peptides in conjugates K1 and K2 fall also into this range (30.8 and 26.5%, respectively). It should be noted that the incorporation of peptide ³⁵⁰DQVHFQPLPPAVVKLSDALI³⁶⁹ in conjugate K1 was higher than that of peptide ⁶⁵FNLWGPAFHERYPNVTITA⁸³ in conjugate K2 (12.7 vs 7.0%). This variation might be attributed again to the possibility of an additional amide bond formation between the ϵ -NH₂ Lys³⁶³ of 38.G and the carboxyl group of the polymer in conjugate K1.

Immune Responses to Conjugates Containing Two Different Peptides. To investigate the effect of covalent attachment, specific T-cell responses were analyzed with one selected prototype conjugate K2. In this conjugate peptide ⁹¹SEFAYGSFVRTVSLPVGAD¹¹⁰ from the 16 kDa protein and peptide ⁶⁵FNLWGPAFHERYPNVTITA⁸³ from the 38 kDa protein were coupled with polymeric branched polypeptide, EAK. This macromolecular construct together with relevant AcEAK-based conjugates was tested by using (1) murine T-cell hybridomas (clones 16.10.7 and 38H6/1), (2) lymph node (LN) cells proliferation assays, and (3) PBMC cultures of PPD-positive individuals.

Stimulation of T-Cell Hybridomas with Conjugate K2. Conjugate K2, the free peptides (⁹¹SEFAYGSFVRTVSLPVGAD¹¹⁰ and ⁶⁵FNLWGPAFHERYPNVTITA⁸³), their AcEAK conjugates, and unsubstituted branched polypeptides (AcEAK and EAK) were tested using the murine T-cell hybridomas 38H6 and 16.10.7. The results expressed as stimulation indices at two concentrations [$c = (5 \text{ and } 25) \times 10^{-6} \text{ M}$] are summarized in Figures 3 and 4. The concentration of conjugates was calculated according to respective peptide content.

Figure 3. T-cell recognition of conjugate K2 by hybridoma [38.H6/1] specific for ⁶⁵FNLWGPAFHERYPNVTITA⁸³ (38.1). Cells were incubated with conjugate K2 and control compounds (peptides 38.1 and 16.10, conjugate 38.1-AcEAK and AcEAK) at $c = 5$ and $25 \times 10^{-6} \text{ M}$ in the presence of irradiated C57BL/10 spleen cells. Culture supernatants were tested with the cell line HT2. Results are expressed as stimulation indices (SI = cpm with peptide/cpm without peptide).

The 65–83 specific T-cell hybridoma, 38.H6/1 obtained from recombinant 38 kDa protein immunized mice was recognized by conjugates K2 and 38.1-AcEAK as well as free ⁶⁵FNLWGPAFHERYPNVTITA⁸³ peptide (Figure 3). As expected, peptide ⁹¹SEFAYGSFVRTVSLPVGAD¹¹⁰ corresponding to the immunodominant region of the 16 kDa protein did not induce response. The synthetic branched polypeptides AcEAK (Figure 3) and EAK (data not show), used for the preparation of conjugates, were not found stimulatory at the concentrations studied. These findings suggest that the 38 kDa protein-specific T-cell epitope in peptide ⁶⁵FNLWGPAFHERYPNVTITA⁸³ was efficiently recognized not only in its free but also in its polypeptide conjugated form.

The activity of peptide ⁹¹SEFAYGSFVRTVSLPVGAD¹¹⁰ from the 16 kDa protein was investigated using T-cell hybridomas obtained from peptide 91–110 immunized mice. ⁹¹SEFAYGSFVRTVSLPVGAD¹¹⁰ conjugated either to EAK through a disulfide bond (in conjugate K2) or to AcEAK with an amide bond was able to induce T-cell stimulation (Figure 4). Specificity has been proved by the lack of effect of free 38.1 or branched polypeptides (AcEAK or EAK) on these cells.

These findings suggest that the conjugate K2 containing two distinct T-cell epitopes are able to induce epitope-specific responses in hybridoma cells. Thus, the capa-

^a Cells were incubated with conjugate K2 and control compounds (16.10-AcEAK and 38.I-AcEAK) at $c = 25 \times 10^{-6}$ M (calculated on the basis of epitope content). ^b The background cpm observed in the absence of peptide treatment. ^c Results are expressed as stimulation index (SI) = cpm with peptide/cpm without peptide and represent the average of triplicate cultures. Values > 2.5 were considered as responder. Purified protein derivative (PPD, 10U) was used as positive control, and a response of SI > 10 was obtained in each case. ^d Background.

Figure 4. T-cell recognition of conjugate K2 by hybridoma [16.10.7] specific for ⁹¹SEFAYGSFVRTVSLPVGAD E¹¹⁰ (16.10). Cells were incubated with conjugate K2 and control compounds (peptides 16.10 and 38.I, conjugate 16.10-AcEAK and AcEAK) at $c = 5$ and 25×10^{-6} M in the presence of irradiated C57BL/10 spleen cells. Culture supernatants were tested with the cell line HT2. Results are expressed as stimulation indices (SI = cpm with peptide/cpm without peptide).

bility of epitope peptides to initiate T-cell stimulation was preserved after their well-defined covalent attachment to a synthetic polymeric polypeptide.

Proliferative Response of Lymph Node Cells from Mice. The prototype conjugate K2 was also tested in a proliferation experiments using LN cells from mice immunized with the recombinant 38 kDa protein. Draining popliteal LN cells were stimulated in vitro by conjugate K2, the free peptides (⁶⁵FNLWGPAFHERYP-NVTITA⁸³, ⁹¹SEFAYGSFVRTVSLPVGAD E¹¹⁰) and the unconjugated branched polypeptide, EAK at $c = 25 \times 10^{-6}$ M. As negative control, LN cells from PBS immunized mice were used and tested with the same set of compounds resulting SI values of <1.3 (data not shown). LN cells of 38 kDa immunized mice were stimulated with the conjugate K2 and the peptide from the 38 kDa protein (38.I) used as a positive controls (SI = 5.2 for K2 and SI = 5.7 for 38.I) (Figure 5). No T-cell stimulation was observed using peptide ⁹¹SEFAYGSFVRTVSLPVGAD E¹¹⁰ from the 16 kDa protein or by the free polypeptide.

Proliferative Response of Human Peripheral Blood Mononuclear Cells. We have studied conjugate K2 as well as AcEAK-based derivatives of peptides 38.I and 16.10 in proliferation assays using PBMC cultures of PPD-positive individuals (Table 3). Cells were stimulated in vitro by conjugates at $c = 25 \times 10^{-6}$ M or free carrier. Incubation with unsubstituted branched polypeptide resulted in SI values of <1.5 (data not shown). Using SI > 2.5 as cutoff, 6 out of 11 subjects responded to conjugate K2, while AcEAK conjugates of 38.I or 16.10

Figure 5. T-cell recognition of peptide conjugate K2 by LN cells from mice immunized by recombinant 38 kDa protein. LN cells were stimulated with conjugate K2 and control compounds (peptides 38.I and 16.10 and branched polypeptide EAK) at $c = 25 \times 10^{-6}$ M (calculated on the basis of epitope content). Results are expressed as stimulation indices (SI = cpm with peptide/cpm without peptide). PBS/IFA injected mice gave SI < 1.3. Values > 2 were considered as positive.

were recognized slightly less efficiently (4 out of 11 and 5 out of 11, respectively). The analysis of these cultures has also indicated differences among individuals in recognition of conjugates containing 16 or 38 kDa related epitopes. Interestingly, only three individuals responded to both 38.I-AcEAK and 16.10-AcEAK conjugates, but PBMC samples from each group were capable to proliferate upon incubation with conjugate K2 possessing dual specificity.

CONCLUSION

Taken together, these data suggest that the strategy outlined results in bioconjugates in which two different peptides are attached covalently and uniformly in multiple copies to a biodegradable polymeric polypeptide possessing free amino and carboxyl groups. The immunological analysis presented suggest that the prototype conjugate bearing two different T-cell epitope peptides from *M. tuberculosis* proteins were well recognized and that the epitopes sustained the specific T-cell stimulatory potential after attachment to EAK. In light of these promising findings, it is feasible to develop further macromolecular branched polypeptide bioconjugates for T-cell response based immunodiagnosis.

ACKNOWLEDGMENT

Thanks are due to Dr. D. Gaál (National Institute of Oncology, Hungary) for performing the in vivo toxicity assays. This work was supported by grants from WHO

(T9/181/133), the Hungarian Academy of Sciences (OTKA T 014964, W 015596), and from the Ministry of Education (FKFP 0101/1997).

Catalytic Properties of Galactose Oxidase to Liposome-Forming Amphiphiles Which Have Many Pendent Galactose Residues[†]

Kohji Ohno and Hiromi Kitano*

Department of Chemical and Biochemical Engineering, Toyama University, Toyama 930, Japan.

Received September 15, 1997; Revised Manuscript Received May 5, 1998

A galactose-carrying vinyl monomer [2-(methacryloyloxy)ethyl β -D-galactopyranoside, MEGal] was polymerized by using a lipophilic radical initiator. The amphiphiles obtained (DODA-PMEGal) formed stable liposomes by mixing with phospholipids, and the galactose residues on the liposome surface were effectively recognized and oxidized by galactose oxidase. The affinity (estimated by the $1/K_m$ value) of galactose oxidase for the galactose residues on the liposomes was higher than those for free galactose and MEGal and dependent on the length of galactose-carrying polymer chains on the liposome surface and the fluidity of the membranes, whereas not significantly influenced by the surface density of galactose residues on the liposomes. The affinity of galactose oxidase for the galactose-carrying linear polymers, which were prepared by using an ordinary azo-type radical initiator and a chain-transfer reagent, was also higher than those for free galactose and MEGal and dependent on the degree of polymerization of MEGal. The affinity was, however, relatively much smaller than those for DODA-PMEGals incorporated in liposomes.

INTRODUCTION

Recently, studies on carbohydrate chains have been making rapid progress, and the importance of carbohydrate chains in vivo (e.g., fertilization, immunological protection system, nervous system, virus infection) has become well understood (1–4). Carbohydrates conjugated to a variety of materials, including proteins, lipids, and synthetic polymers, have been also studied and applied in a wide area of disciplines (5, 6). For instance, novel techniques of medical treatments such as artificial organs or drug delivery system (DDS) have been developed by ingeniously taking advantage of the recognition processes of carbohydrates by cell in vivo, and by extensively investigating their therapeutic effects on diseases (7, 8). We have been studying the recognition between sugar-carrying liposomes and sugar receptors at liquid–lipid and solid–lipid interfaces (9, 10).

Galactose oxidase oxidizes exposed primary hydroxyl groups in nonreducing, terminal galactose and *N*-acetyl-galactosamine residues (11). The galactose oxidase/ NaB^{3}H_4 method is well-known and widely used as a technique to label cell-surface glycoconjugates (12–14). It has been found that only a portion of glycolipids is available to galactose oxidase, and different glycolipids vary in their susceptibilities to the enzyme (15–18). Lampio et al. and Masserini et al. previously reported the interaction of galactose oxidase with the major red-cell glycolipid (globoside) and GM_1 ganglioside, respectively, in liposome suspensions (17, 18).

Recently, using a lipophilic radical initiator and galactose-carrying vinyl monomer, 2-(methacryloyloxy)ethyl β -D-galactopyranoside (MEGal),¹ we prepared novel galactose-carrying amphiphiles (galactolipids) with various degrees of polymerization (10). By incorporating the galactose-carrying amphiphiles in liposome, we could

examine the recognition of amino group-carrying liposomes by galactose-carrying liposomes that had been treated with galactose oxidase beforehand, as a model system of induction of lymphocyte cytotoxicity (19). In that experiment, we found a very interesting property of galactose oxidase that its affinity for the galactose residues in the polymer chains on the liposome surface was much higher than that for free galactose.

To verify what happens in the catalytic reaction of enzyme to the carbohydrate chains on the membrane surfaces, galactose-carrying homopolymers and copolymers and galactose-carrying amphiphiles were prepared by using the galactose-carrying vinyl monomer (MEGal) in this study. We examined kinetic analyses on the catalytic behavior of galactose oxidase at various reaction fields including liposome surfaces. It will be described below why galactose oxidase exhibits enhanced affinity to the galactose residues on the membrane surfaces.

EXPERIMENTAL PROCEDURES

Materials. A lipophilic radical initiator (DODA-501, Figure 1a) was synthesized from *N,N*-dioctadecylamine (DODA, Fluka, Switzerland) and 4,4'-azobis(cyanovaleric

acid) (V-501, Wako Pure Chemicals, Osaka, Japan) as described previously (20). A galactose-carrying vinyl monomer, 2-(methacryloyloxy)ethyl β -D-galactopyranoside (MEGal, Figure 1(b)), was prepared by trans-glycosylation between lactose and 2-hydroxyethyl methacrylate (HEMA) catalyzed by β -galactosidase (from *Escherichia coli*, 340 units/mg, Sigma, St. Louis, MO) in a phosphate buffer (1/15 M, pH 6.4) (21) in the presence of hydroquinone (polymerization inhibitor). 1,3-Di-O-hexadecylglycerol was synthesized by the reaction of epichlorohydrin and 1-hexadecanol in the presence of sodium hydride at 80 °C overnight (22). A polymerizable lipid, bis(*trans,trans*-2,4-octadecadienyl)-phosphatidylcholine (DDPC), was kindly donated by the Japan Fat and Oil Co., Tokyo, Japan. Galactose oxidase (from *Dactylium dendroides*, 240 units/mg) was from Sigma. Other reagents were commercially available. Deionized water was distilled before use.

Preparation of Galactose-Carrying Homopolymer. A homogeneous polymerization of MEGal was carried out using 4,4'-azobis(cyanovaleric acid) (V-501) and cysteamine hydrochloride as initiator and chain-transfer reagent, respectively, in methanol-water (1:3) at 70 °C for 24 h. After evaporation of the solvent, the oily product was washed several times with acetone and dried in vacuo. The slightly yellow powder obtained was dissolved in water again and repeatedly ultrafiltered with water (Amicon Model 8010; membrane, YM-1; exclusion limit, 1000) to remove other small impurities. The solution retained above the membrane was lyophilized. Further, the filtrate which contained the products with a lower degree of polymerization was concentrated, purified by passage through a GPC column (Sephadex G-10, 1.5 cm i.d. $\times$ 25 cm; mobile phase, water), and lyophilized. The syntheses of polymer and/or oligomer with different degrees of polymerization (DPs) were carried out under conditions with fixed concentrations of initiator and monomer and varying amount of chain-transfer agent. The DP values of MEGal homopolymers were determined by the conductometric titration of an amino group at the end of the polymers with a N/100 NaOH aqueous solution.

Preparation of Poly[acrylamide-co-2-(methacryloyloxy)ethyl β -D-galactopyranoside]. A copolymerization of MEGal (151 mg, 0.514 mmol) and acrylamide

(AAM, 37 mg, 0.514 mmol) was carried out using V-501 (2.9 mg, 0.01 mmol) and cysteamine hydrochloride (5.8 mg, 0.051 mmol) as initiator and chain-transfer reagent, respectively, in methanol-water (1:3) at 70 °C. The polymers with different DP values were synthesized as described in the preparation of homopolymer, namely, under conditions with fixed concentrations of initiator and monomer and varying amount of chain-transfer agent. The product was purified in the same way as the homopolymers described above. The molecular weight of the copolymer was determined conductometrically. The monomer ratio (MEGal:AAM) in the copolymers was evaluated by elemental analyses and ¹H NMR (in D₂O): After the molecular weight of a copolymer sample was estimated to 1200 by conductometric titration, the monomer ratio (MEGal:AAM) in the copolymer was determined to be 1:7.6 by the ratio of integrals of ¹H NMR (calculated from the signals of 1.1–1.3 and 1.4–1.9 ppm corresponding to methyl protons of MEGal unit and methylene protons of AAM, respectively). Furthermore, the validity of supposed chemical structure was clarified by elemental analysis. Anal. Calcd. for C₂H₈NCIS(C₁₂H₂₀O₈)_{1.3}(C₃H₅-ON)_{9.7}·4H₂O: C, 44.67; H, 7.29; N, 12.00. Found: C, 44.09; H, 7.27; N, 12.20.

Preparation of Galactose-Carrying Amphiphiles by Polymerization. Details of the preparation were described elsewhere (9, 10, 19). Briefly, MEGal and DODA-501 were dissolved in THF, and after N₂ gas was bubbled for several minutes, the solution mixture was incubated in a tightly sealed test tube at 70 °C for 24 h. After evaporation of the solvent in vacuo, the viscous oil was washed with *n*-hexane several times to remove unreacted initiator by centrifugation at 15 000 rpm and 20 °C for 15 min. After decantation, the precipitate was dried in vacuo and dispersed in water. The suspension was purified by passage through a GPC column (Sephacryl S-200, 2 cm i.d. $\times$ 18 cm; mobile phase, water) and lyophilized. The DP value of the amphiphile (Figure 1c) was determined by elemental analysis. DODA-PMEGal (DP = 8.5) Anal. Calcd. for C₄₂H₈₂N₂O(C₁₂H₂₀O₈)_{8.5}: C, 55.51; H, 8.15; N, 0.90. Found: C, 55.43; H, 8.42; N, 0.91.

Preparation of Galactose Lipid by Using Trichloroacetimidate of Carbohydrate. The preparation procedure followed the method of Minamikawa et al. (23): To molecular sieves 4 Å (200 mg, dried in vacuo prior to use), 1,3-di-O-hexadecylglycerol (300 mg, 0.55 mmol) and 2,3,4,6-tetra-O-D-acetylgalactopyranosyl 1- α -trichloroacetimidate (273 mg, 0.55 mmol) in dry dichloromethane (10 mL) were added. The solution was cooled at 0 °C, and trimethylsilyl trifluoromethanesulfonate (123 mg, 0.55 mmol) was added dropwise to the solution. After the solution was stirred at 0 °C for 6 h, anhydrous pyridine (40 mL) was added dropwise at 0 °C and the solution was diluted with ethyl acetate (20 mL) at room temperature. After filtration, the filtrate was washed with a saturated sodium bicarbonate solution (30 mL) and saturated aqueous sodium chloride solution (30 mL) successively. The organic layer was dried over anhydrous sodium sulfate, and the solvent was removed under reduced pressure. The residual oil was purified by silica gel chromatography (toluene:acetone = 4:1) to give 1,3-di-O-hexadecyl-2-O-(β -D-tetraacetylgalactopyranosyl)-glycerol (157 mg). A 28% methanol solution of sodium methoxide (50 mL) was added to 1,3-di-O-hexadecyl-2-O-(β -D-tetraacetylgalactopyranosyl)glycerol (150 mg) in a mixture of dry methanol (2.5 mL) and dry DMF (2 mL). The reaction was complete after 2 h at room temperature. The solution was neutralized with ion-exchange resins (Dowex 50W-X4, H⁺ form), filtered, and evaporated. The

residue was chromatographed by silica gel chromatography (chloroform:methanol = 7:1). The compound was further purified by recrystallization from methanol to give 1,3-di-*O*-hexadecyl-2-*O*-(β -D-galactopyranosyl)glycerol (DHDG-Gal, Figure 1d) as a white powder (54 mg). ^1H NMR (CDCl_3): δ 0.88 (t, 6H, CH_3), 1.1–1.4 (m, 52H, CH_2 of alkyl chains), 1.57 (br, 4H, OCH_2CH_2), 2.8–4.1 (m, 19H, protons of galactose moiety, that of glycerol moiety, and OCH_2CH_2), 4.43 (d, $J = 7.6$ Hz, 1H, anomeric proton of pyranose ring). IR (KBr, cm^{-1}): O–H stretching of galactose moiety, 3350–3500; ν_{as} C–H, 2917; ν_{s} C–H, 2850; C–O–C stretching of glycerol moiety, 1040–1130. Anal. Calcd. for $\text{C}_{41}\text{H}_{82}\text{O}_8$: C, 70.02; H, 11.78. Found: C, 70.01; H, 11.83.

Preparation of Galactose-Carrying Liposomes. DDPC (24 mg) was dissolved in chloroform (2 mL) in a small, round-bottomed flask. After evaporation of the solvent, the thin lipid membrane was dispersed in an *N*-(2-hydroxyethyl)piperazine-*N'*-2-ethanesulfonic acid (HEPES) buffer (pH 6.5, 10 mM, 3 mL) in which DODA-PMEGal (6 mg) had been dispersed beforehand. The dispersion was sonicated (Astrason W-385, Heat System-Ultrasonics, Inc., New York) for 3 min while N_2 gas was passed through the suspension. To remove large aggregates, the liposome suspension obtained was passed through a membrane filter (SLGV025LS, Gelman Sciences; pore size, $0.22\ \mu\text{m}$) and irradiated in a quartz cell by a UV lamp (HB-251A, Ushio, Tokyo, Japan) at room temperature for 4 h to polymerize the dienoyl groups of DDPC. The progress of polymerization was followed by the decrease in absorbance at 258 nm by using a UV–vis spectrophotometer (Ubest-35, Japan Spectroscopic Co., Tokyo, Japan). Unpolymerized galactose-carrying liposome was also prepared without UV irradiation.

Characterization of Liposomes. Formation of liposomal structure was confirmed by the fluorescence dye incorporation technique using Eosin Y as a probe (20, 24) (excitation at 305 nm, emission at 571 nm, FP-777, Japan Spectroscopic Co.). Hydrodynamic diameter of the liposomes was estimated as 1200 Å on average by the dynamic light scattering (DLS) technique (DLS-7000, Otsuka Electronics, Hirakata, Japan; light source He–Ne laser, 632.8 nm).

Enzyme Activity Measurements. The oxidation reaction of galactose residues catalyzed by galactose oxidase was followed using a spectrophotometric method (25, 26): Hydrogen peroxide produced by the oxidation of galactose was reduced by the reaction with 4-aminoantipyrine and phenol catalyzed by horseradish peroxidase (HRP), and the increase in optical density at 500 nm due to the production of quinoneimine dye was measured for 5 min by the spectrophotometer thermostated at 25 °C. The initial increase in optical density per minute was calculated from the initial linear portion of the curve ($\epsilon = 12\ 000$). One unit of galactose oxidase causes the formation of $1\ \mu\text{mol}$ of hydrogen peroxide/min at 25 °C. The stock solution of galactose oxidase was diluted to the appropriate concentration, and the catalytic activity of the enzyme was checked just prior to use.

Kinetic Analyses. The initial velocities of oxidation of galactose at various reaction fields were measured by using the spectrophotometric method described above, in which sufficient amount of HRP, aminoantipyrine, and phenol were added in the reaction system, that is, the reaction of galactose oxidase to galactose residues is the rate-determining step. The substrate concentrations at various reaction fields were standardized on the basis of the number of galactose residues. Previous report showed that the galactose-carrying amphiphiles were preferen-

Figure 2. Hanes-Woolf plot for the catalytic reaction of galactose oxidase to a galactose-carrying homopolymer (PMEGal, DP = 16). In the HEPES buffer (10 mM, pH 6.5). [Enzyme] = 0.05 units/mL.

tially (about 80%) distributed in the outer layer of DDPC liposomes (19). Therefore, in the case using sugar-carrying liposomes as a substrate, we determined the substrate concentration based on the number of all galactose-carrying lipids incorporated inside and outside the liposome. The V_{max} and K_m values of the enzyme reaction were determined by the Hanes-Woolf plot (eq 1) (27):

$$[S]/v = (1/V_{\text{max}})[S] + K_m/V_{\text{max}} \quad (1)$$

where $[S]$ is the concentration of substrate (total concentration of galactose residues in the reacting solution), v is the initial reaction velocity, V_{max} is the limiting value of initial reaction velocity, and K_m is the Michaelis constant. Graphing $[S]/v$ vs $[S]$ yields a straight line where the slope is $1/V_{\text{max}}$, the y-intercept is K_m/V_{max} , and the x-intercept is $-K_m$. The data in the figures and table represent the mean values of two measurements. The uncertainties of the kinetic parameters were within 10%.

RESULTS AND DISCUSSION

A. Catalytic Behavior of Galactose Oxidase for Galactose-Carrying Polymers. After the incubation of galactose-carrying homopolymer with a solution of galactose oxidase, the production of H_2O_2 was confirmed by the spectrophotometric method. Figure 2 shows a typical example of Hanes-Woolf plot for the catalytic reaction of galactose oxidase to a galactose-carrying homopolymer (PMEGal, DP = 16). The affinity (estimated by $1/K_m$ values) of galactose oxidase for PMEGal was larger than those for free galactose and β -D-galactopyranosides (MEGal, lactose, PNPG and MG) (Table 1). Furthermore, by varying the degree of polymerization of PMEGal, we could examine the effect of the length of polymer chains on K_m (Figure 3a). The larger the molecular weight of PMEGal was, the larger the affinity of galactose oxidase. These results suggest that galactose oxidase can effectively recognize and oxidize galactose residues which are suspended repeatedly from the polymer chain, probably because the enzyme can easily access the galactose moiety in the vicinity of galactose which has been just oxidized. This phenomenon is consistent with the previous report that the galactose oxidase from *Polyporus circinatus* has a high affinity for galactomannan guaran (polysaccharide constituted from galactose and mannose) (26).

To verify the enhancement of the affinity of galactose oxidase for the substrates sequentially distributed, the similar experiment was carried out by using copolymers of MEGal and acrylamide (inert monomer for galactose oxidase). The affinity of galactose oxidase for the galactose residues in the copolymers with large DP values was

^a In the HEPES buffer (10 mM, pH 6.5) at 25 °C. The ranges of substrate concentration in the experiments using low molecular weight substrates, polymers, and liposomes were 1–100 mM, 0.01–10 mM, and 10^{-4} –0.1 mM, respectively. In the case of lactose, the range was 1 mM to 1 M. Substrate concentrations were standardized on the basis of the number of galactose residues (see Experimental Procedures). The concentrations of enzyme in the experiment using liposomes and other all substrates were 0.25 and 0.05 units/mL, respectively. ^b Degree of polymerization.

^c Determined by the conductometric method. ^d MEGal:AAM = 1:7.6. ^e MEGal:AAM = 1:1:1. ^f MEGal:AAM = 1:1:1. ^g MEGal:AAM = 1:5.7. ^h DHDG-Gal was used in place of DODA-PMEGal.

ⁱ Not detected. ^j Determined by the elemental analysis.

Figure 3. Effect of the degree of polymerization of homopolymer (PMEGal) on K_m and k_{cat}/K_m values at 25 °C. In the HEPES buffer (10 mM, pH 6.5). [Enzyme] = 0.05 units/mL.

comparable to those in the homopolymers with comparable DP values (Table 1), whereas the affinity for the galactose residues in the copolymer with a small DP value seemed to be smaller than that in the homopolymer with a comparable DP value. Since the spatial density of galactose residues existing in the copolymer chain is smaller than that in the homopolymer, the unexpectedly large affinity of the enzyme for the galactose residues in the copolymers with a large DP value shows that the distance between MEGal residues in the copolymers (as

for the copolymer with the monomer ratio 1:5.7, for example, 17 Å on average) is still small enough for the enzyme to access the galactose moieties one after another.

Furthermore, the k_{cat}/K_m value which represents the catalytic efficiency of galactose oxidase for PMEGal increased with the degree of polymerization of homopolymers (Figure 3b), which strongly suggests that the catalytic behavior of galactose oxidase represents an increased efficiency for the PMEGal due to the localization of substrates along the polymer chain.

B. Catalytic Behavior of Galactose Oxidase for Galactose-Carrying Liposomes. Next, to examine catalytic behavior of galactose oxidase at lipid bilayer–liquid interfaces, we prepared the galactose-carrying amphiphiles (DODA-PMEGal), which have galactose-carrying polymer chain as a hydrophilic group, from the lipophilic radical initiator and MEGal. A lipid carrying only one galactose residue (DHDG-Gal) was used as a reference.

When the galactose-carrying liposome consisted of DHDG-Gal and polymerized lipid (DDPC) was incubated with the solution of galactose oxidase, no production of H_2O_2 was confirmed by the spectrophotometric method, which is in a contrast to the results for β -D-galactopyranosides with small molecular weights (Table 1). Previously, Lampio et al. showed that galactose oxidase cannot oxidize the galactosyl residue of ceramide dihexoside in liposomes, probably because its carbohydrate moiety is too close to the membrane surface (17). Since the galactose residue of DHDG-Gal is directly attached to the glyceryl group, galactose oxidase would not easily approach the substrate, and therefore, our result is understandable.

When the similar experiment was carried out on the liposomes carrying the DODA-PMEGal, on the other hand, the production of H_2O_2 was definitely confirmed spectrophotometrically, which shows that the galactose-carrying polymer chain functions as a substrate for galactose oxidase not only in bulk solution but also at the lipid bilayer–liquid interface. The K_m value for the galactose-carrying liposome [DODA-PMEGal (DP = 8.5), 0.0030 mM] was much lower than that for the galactose-carrying homopolymer [PMEGal (DP = 16), 0.35 mM] (Table 1). Despite the steric disadvantage that the reaction field is above the lipid bilayer surface, the affinity of galactose oxidase for the galactose-carrying polymer chains on the liposome surface is much higher than that for PMEGal in bulk solution.

The galactose-carrying liposomes prepared here probably bring about the phase separation (or in other words, cluster formation) of the galactose-carrying amphiphiles in the liposomes by the two-dimensional photopolymerization of DDPC molecules (28). To verify clustering of galactose-carrying polymers on the liposome surface, we carried out a differential scanning calorimetry (DSC) with DODA-PMEGal/DDPC (unpolymerized) mixed liposomes. This experiment showed a sharp calorific change around 25 °C which is the temperature of the midpoint of gel–liquid crystal transition (T_m) of DDPC, indicating the phase separation due to the respective lipid molecules. If the different lipid molecules are compatible, the DSC curve would exhibit a broad calorific change. Therefore, the DODA-PMEGal/DDPC mixed liposome system is expected to show the phase-separated structure below 25 °C, even in the case when DDPC molecules are not polymerized. More importantly, when the DDPC molecules are polymerized, the Gal-carrying liposomes would show the phase-separated structure. This phase separation might make galactose oxidase, which has attacked

Figure 4. Effect of the degree of polymerization of DODA-PMEGal on K_m and k_{cat}/K_m values at 25 °C. [Enzyme] = 0.25 units/mL.

the amphiphile, surrounded by the galactose residues localizing on the liposome surface and, consequently, decrease the K_m value. This result is in agreement with the report by Masserini et al. (18) that the K_m value of G_{M1} ganglioside in vesicle was smaller than that of Des G_{M1} (oligosaccharide portion of G_{M1} ganglioside) in bulk solution.

The k_{cat} value, which is defined as the number of substrate molecules converted into product per enzyme molecule per unit time, of galactose oxidase for the DODA-PMEGal/polymerized DDPC liposomes was lower than those of free galactose and PMEGals, whereas the k_{cat}/K_m value, which represents the catalytic efficiency of an enzyme, of galactose oxidase for the liposomes was larger than those for free galactose and MEGal and comparable to that for PMEGals (Table 1). Since the galactose-carrying polymer chains at liquid-polymerized liposome interface are clustered, the motion of the enzyme molecule attaching the PMEGal domain above the liposome surface might be restricted, and therefore, it is understandable that the turnover number (k_{cat}) of galactose oxidase for DODA-PMEGal was smaller than those for galactose, MEGal and PMEGal. However, the clustering of the galactose-carrying polymer chains might enhance further the affinity of the enzyme for the substrate, which would consequently make the catalytic efficiency (k_{cat}/K_m) of galactose oxidase for the galactose-carrying liposomes larger than those for small molecular weight β -D-galactopyranosides.

Furthermore, the effect of the degree of polymerization of DODA-PMEGal on the catalytic behavior of galactose oxidase was examined. As shown in Figure 4a, the K_m value decreased with the degree of polymerization of DODA-PMEGal. Since the distance from the liposome surface to the end galactose residues increased with the DP value, galactose oxidase would be able to more easily approach the substrates above the liposome surface as the DP value becomes larger. It is worth noting that the increase in the degree of polymerization enhanced the affinity of galactose oxidase for galactose residue not only in the bulk solution but also at the lipid bilayer-liquid interfaces. The k_{cat}/K_m showed an increase with the DP

Figure 5. Effect of the content of DODA-PMEGal in the liposome on K_m and k_{cat}/K_m values at 25 °C. [Enzyme] = 0.25 units/mL.

value of DODA-PMEGal (Figure 4b), due to the decrease in the K_m value with DP.

Next, by varying the weight percents of DODA-PMEGal (DP = 8.5) included in the liposome, we could examine the effect of surface concentration of galactose-carrying amphiphiles on the affinity of galactose oxidase. Figure 5a shows that the K_m value was not significantly dependent on the surface concentration of galactose-carrying amphiphiles (DP = 8.5) above 10 wt % (3.4 mol %). Previously, Masserini et al. and Cestaro et al. investigated the catalytic properties of galactose oxidase and neuraminidase, respectively, for gangliosides on the liposome surface (18, 29). They showed that the greatest rates of enzymatic reaction were obtained at an optimal proportion of gangliosides in the liposome. These phenomena were explained by the enhanced hydrogen-bonding interaction between the carbohydrate residues of adjacent ganglioside molecules with an increase in the percentage of the ganglioside. The hydrophilic group of DODA-PMEGal used in our experiment is a polymethacrylate chain and would be more flexible than ganglioside. Therefore, the interaction between carbohydrate residues on the liposomes composed of DODA-PMEGal is probably smaller than that between gangliosides, thus, the optimum content of DODA-PMEGal in the liposome for the enzymatic reaction would not be observed in our experiment. We also think that this phenomenon is partly because the local concentration of galactose residue which the galactose oxidase can recognize is similar at any surface concentration due to the phase separation of DODA-PMEGal on the surface of polymerized DDPC liposome.

Furthermore, the k_{cat}/K_m value increased with the content of DODA-PMEGal in the galactose-carrying liposome (Figure 5b), which means that the enzyme effectively and repeatedly catalyzes oxidation of the substrates which exist on the surface of the same liposome. This is probably because it is not necessary for the enzyme molecule to migrate urgently from the liposome surface catalyzing presently to other liposome surfaces, and the enzyme only needs to oxidize the galactose residues on the same liposome.

Figure 6. van't Hoff and Arrhenius plots of enzymatic reaction for various galactose residues. In the HEPES buffer (10 mM, pH 6.5). [Enzyme] = 0.25 and 0.05 units/mL for liposomes and free galactose, respectively. Contents of DODA-PMEGal (DP = 8.5) in the liposome, 20 (w/w) %. (○) polymerized liposome. (●) unpolymerized liposome; (○) free galactose. The units of K_m and k_{cat} are (molarity) and (millimolar milliliters per minute units), respectively.

Moreover, by using galactose-carrying liposome with unpolymerized DDPC, we could examine the effect of membrane fluidity on the catalytic behavior of galactose oxidase. As shown in Figure 6a, the K_m value of galactose oxidase for the unpolymerized galactose-carrying liposome was larger than that for the polymerized galactose-carrying liposome above the T_m of unpolymerized DDPC (25 °C) and comparable below 25 °C. The similar tendency was observed in the Arrhenius plots of k_{cat} (Figure 6b).

The membrane fluidity of the unpolymerized galactose-carrying liposome above 25 °C would be higher than that of polymerized one, which makes it difficult for galactose oxidase to face the domain of the galactose-carrying polymer chains on the unpolymerized fluid liposome surface, because the PMEGal chains would not be localized above 25 °C. Previously, we examined the effect of temperature on the inhibition of trypsin by soybean trypsin inhibitor at lipid–lipid interfaces (30). The recognition processes at interfaces were strongly dependent on the gel–liquid crystal-phase transition temperature of the liposomes, which supports the importance of fluidity of liposome membranes in the oxidation of MEGal residues by the enzyme at lipid bilayer–liquid interfaces.

In conclusion, the recognition of galactose residues on the liposome surface by galactose oxidase was more effective compared to those of free galactose and other small β -D-galactopyranosides. The affinity of galactose oxidase for sugar residues on the surface of liposomes was dependent on the length of galactose-carrying polymer chain and cluster formation of the amphiphiles on the liposome surface, but not significantly influenced by the surface density of galactolipids on liposomes. The present study indicates that the spatial distribution of substrates significantly affects the catalytic behavior of the enzyme. More importantly, the clustering-effect of sugar residues enhances the affinity of sugar-recognizing

proteins not only lectins but also enzymes, which would be valuable information in carbohydrate chain chemistry and polymer science.

ACKNOWLEDGMENT

We thank Misses Y. Murasaki and A. Sugayama of this department for their technical assistance. We are grateful to Wako Pure Chemicals for the kind donation of V-501. The Japan Fat and Oil Co. is greatly appreciated for the kind donation of DDPC. Sequence-Specific Photomodification of DNA by an Oligonucleotide-Phenanthrodihydrodioxin Conjugate

Kestutis G. Bendinskas,* Andreas Harsch,^{†‡} R. Marshall Wilson,[‡] and W. Robert Midden

Center for Photochemical Sciences, Department of Chemistry, Bowling Green State University, Bowling Green, Ohio 43403 . Received December 19, 1997; Revised Manuscript Received May 22, 1998

We introduce a new member of a family of photochemically active oligonucleotide conjugates. A Phenanthrodihydrodioxin (PDHD)-based agent was synthesized and covalently linked to a 5'-end of the 9-mer oligonucleotide via a hexamethylene linker. The conjugate hybridized to a complementary 30-nucleotide-long target and efficiently cleaved it in a sequence specific manner. Up to 67% of target was specifically damaged (51% cross-links and 16% direct cleavage). While the photosensitizer alone nonspecifically damaged only Gs in a single-stranded target, its conjugate cross-linked to and damaged also A, T, and C sites in a target in agreement with duplex and triplex formation.

INTRODUCTION

Therapeutic potential of covalently modified oligonucleotides has driven the search for agents that can be coupled to DNA, are easy to control, and damage specific DNA target sites (1). One of the most frequently used classes of such agents has been photosensitizers since they offer the advantage of controlling the timing of the chemical inactivation event (2).

Several photoreactive groups have been covalently linked to oligonucleotides and their analogues (3). For example, psoralens (Pso)¹ that are able to form inter-strand cross-links or monoadducts in double-stranded DNA (4), often have been used as photosensitizers coupled to oligonucleotides. Pso-pN₁₃ was covalently linked to target DNA and irreversibly inhibited *bla* gene transcription in *Escherichia coli* in vitro (5). Psoralen-methylphosphonate conjugate cross-linked with rabbit globin mRNA 50–100% and specifically inhibited translation to the extent of 40–60% at oligomer concentrations of 5–20 μ M (6). Pso-pN₁₆ inhibition of *Dra*I digestion of HIV-I DNA was 95% at 7 μ M oligonucleotide concentration (7, 8). Pso-pN₁₀ induced 100-fold more frequent mutations in a specific region of the λ genome (9). After UV irradiation, Pso-pN₁₅ cross-linked and inhibited transcription of the α -subunit of the interleukin 2 receptor in vivo (10).

Another class of photosensitizers, porphyrins, linked to oligonucleotides, produced various types of photodamage on a complementary target DNA (11–13). This included oxidation of G and cross-linking of the porphyrin conjugate to the target sequence. Both reactions gave 57% yield of total modification (20% oxidized G, and 37%

cross-linking). Guanines located close to the porphyrin macrocycle were the most altered (11). Up to 7% of target DNA was cross-linked, and up to 23% was cleaved by the conjugate of sapphyrin, an extended porphyrin that damages DNA upon irradiation with 300 and >620 nm light (13). The conjugates of 3-azidoflavine (14) and *p*-azidophenacyl (15) were photo-cross-linked to the single- and double-stranded 27-mers and induced cleavage after piperidine treatment. A small fraction of ellipticine derivative photo-cross-linked with double-stranded DNA (16). Eosin has been linked to oligonucleotides and produced damage in double-stranded targets (17). Proflavin-linked oligonucleotide was able to induce 12% cleavage after irradiation followed by piperidine treatment (18). Uranyl UO₂²⁺ photooxidation induced cleavage at the ends of oligodeoxynucleotides. However, its conjugates failed to do so (19). Aryl azide/biotin/oligonucleotide derivative cross-linked to its target and was used to quantitate triple-helix formation (20).

Considering potential benefits of photosensitizer-DNA conjugates, it is important to search for and study new kinds of photoreactive groups that could give high yields of specific target DNA inactivation.

The purpose of this investigation was to prepare a PDHD–DNA conjugate and investigate its sequence-specific DNA damage potency. PDHDs were designed as photoactivatable DNA-damaging agents (21–26), and this study is a first attempt to couple them to a molecule that will give them sequence specificity.

PDHDs are masked *o*-quinones: they can be made from and release phenanthrenequinone (PAQ) when irradiated with 425–514 and 350 nm light, respectively (Scheme 1) (21). This release of parent PAQ is believed to be responsible for DNA damage and cleavage. Several PDHD analogues carrying ionic groups to make them soluble in water have been prepared. PDHDs with cationic groups bind to DNA with typical binding constants $K_{\text{ass}} = 2.5 \times 10^4 \text{ M}^{-1}$. They show hyperchromism and a 3–7 nm bathochromic shift in the presence of DNA which is consistent with intercalation and/or groove binding. Cationic PDHDs efficiently relax supercoiled Φ X 174 FR I DNA upon irradiation with low doses of 365 nm light under both oxygen-rich and oxygen-free conditions. Cationic PDHDs inactivate up to 4 logs of

Scheme 1. Schönberg Reaction: Forward Reaction with Visible Light (425–514 nm), Reverse Reaction with UV Light (350 nm)

Vaccinia virus. Results of transient spectroscopy, quenching of DNA cleavage with dithiothreitol (DTT), and irradiation of PDHDs in the presence of cytochrome *c* and superoxide dismutase support a mechanism of DNA damage which involves the release of excited PAQ that is capable of hydrogen abstraction or electron transfer and the involvement of superoxide and other radicals (21, 27). Other mechanisms of DNA damage by cationic PDHDs, including involvement of singlet oxygen, are possible. The relative efficiencies of different DNA-cleaving mechanisms for different PDHDs is being investigated and will be a subject of a separate publication.

No information was available about sequence specificity of PDHDs. Due to the small size, little if any specificity was expected. Because of the relatively low DNA binding affinity [10 times lower than ethidium bromide, 1000 times lower than tripyridyl ruthenium (27)] PDHDs are good candidates for use as DNA conjugates since they should allow sequence-specific recognition by the targeting oligonucleotide, increasing its binding slightly, but not so much as to alter the site-specificity provided by the sequence-recognizing oligonucleotide group.

EXPERIMENTAL PROCEDURES

Preparation of Oligonucleotides. Regular oligonucleotides were synthesized on PerSeptive Biosystems Expedite Synthesizer using standard phosphoramidite chemistry at the DNA Core Facility at the University of Cincinnati. All oligos were purified by reverse-phase columns and PAGE and dissolved in water to make a 20 μ M solution. Target DNA was labeled at the 5'-end using [γ - ^{32} P]ATP and T4 polynucleotide kinase. Its purity and labeling efficiency were checked by 20% polyacrylamide gel electrophoresis.

Synthesis of 2-[4-(6-(*tert*-Butyldimethylsilyloxy)-hexyloxy)phenyl]-2-[4-methoxy-phenyl]-2,3-dihydrophenanthro-[9.10-b]-1,4-dioxin (2, Scheme 2). Dihydrodioxin **1** (Scheme 2) (0.0827 g, 0.19 mmol) was placed in a 5 mL one-necked flask and dissolved in 1.5 mL of HPLC-grade acetonitrile, followed by the addition of 0.06 g (0.23 mmol) 18-crown-6, 0.032 g (0.23 mmol) of potassium carbonate, and 0.078 g (0.23 mmol) of 6-(*tert*-butyldimethylsilyloxy)-1-iodohexane. The reaction was allowed to stir under nitrogen for 12 h and was then diluted with chloroform. The solids were removed by filtration and the solvent was evaporated. The crude reaction mixture was purified by rotary chromatography (7.5% ethyl acetate, 92.5% hexanes). The product **2** was isolated as a colorless oil. Product $C_{41}H_{48}O_5Si$; molar mass: 648.9 g/mol; yield 0.0993 g (0.153 mmol), 80.5%. ^1H NMR ($CDCl_3$) δ (ppm): 8.56 (m, 2H), 8.43 (d, J = 7.5

Hz, 1H), 8.12 (m, 1H), 7.67–7.42 (m, 8H), 6.83 (d, J = 8.6 Hz, 2H), 6.81 (d, J = 8.6 Hz, 2H), 4.75 (s, 2H), 3.88 (t, J = 6.5 Hz, 2H), 3.74 (s, 3H), 3.59 (t, J = 6.2 Hz, 2H), 1.72 (m, 2H), 1.54–1.35 (m, 6H), 0.88 (s, 9H), 0.03 (s, 6H). ^{13}C NMR ($CDCl_3$) δ (ppm): 158.8, 133.4, 133.1, 132.8, 132.5, 128.2, 128.1, 127.9, 126.9, 126.7, 126.6, 126.5, 126.2, 124.7, 122.4, 122.3, 120.8, 120.7, 114.3, 113.8, 79.3, 70.4, 67.8, 63.1, 55.2, 32.8, 29.2, 25.9, 25.8, 25.6, 18.4, –5.3. Synthesis of 2-[4-(6-Hydroxyhexyloxy)phenyl]-2-[4-methoxy-phenyl]-2,3-dihydrophenanthro-[9.10-b]-1,4-dioxin (3, Scheme 2). In a 5 mL round-bottom flask, 0.0993 g (0.153 mmol) of **2** was dissolved in distilled THF. The solution was cooled in an ice bath, then 0.184 mL of a 1 M solution of tetrabutylammonium fluoride in hexanes (0.184 mmol) was added dropwise via syringe. The reaction mixture was allowed to stir for 4 h at 0 $^{\circ}C$. Thin-layer chromatography showed complete disappearance of the protected alcohol. The solution was diluted with 10 mL of chloroform and washed twice with water. The organic layer was collected and filtered through magnesium sulfate, and the solvent was evaporated. Purification was achieved by rotary chromatography (70% ethyl acetate, 30% hexanes). The product was isolated as a highly viscous oil. Product $C_{35}H_{34}O_5$; molar mass 534.7 g/mol; yield 0.0664 g (0.124 mmol), 81.2%. ^1H NMR ($CDCl_3$) δ (ppm): 8.56 (m, 2H), 8.43 (d, J = 8.3 Hz, 1H), 8.11 (m, 1H), 7.67–7.41 (m, 8H), 6.83 (d, J = 8.3 Hz, 2H), 6.79 (d, J = 8.3 Hz, 2H), 4.74 (s, 2H), 3.86 (t, J = 6.3 Hz, 2H), 3.72 (s, 3H), 3.61 (t, J = 6.4 Hz, 2H), 1.77–1.49 (m, 8H), 1.27 (s, 1H). ^{13}C NMR ($CDCl_3$) δ (ppm): 159.2, 158.7, 133.4, 133.1, 132.8, 132.5, 128.2, 127.8, 126.9, 126.7, 126.6, 126.4, 126.2, 124.8, 122.5, 122.4, 120.8, 120.7, 114.3, 113.7, 79.3, 70.4, 67.7, 62.8, 55.2, 32.7, 29.2, 25.9, 25.5. IR ($CHCl_3$): 3622, 3080, 2938, 2881, 1633, 1610, 1512, 1454, 1350, 1335, 1250, 1178, 1118, 1089, 1040, 949, 832 cm^{-1} .

Synthesis of 2-[4-(6-(*N,N*-Diisopropyl)[cyanoethyloxy]phosphoroxy-hexyloxy)phenyl]-2-[4-methoxy-phenyl]-2,3-dihydrophenanthro-[9.10-b]-1,4-dioxin (4, Scheme 2). A solution of 0.0296 g (0.055 mmol) of **3** and 0.019 mL (0.11 mmol) *N,N*-diisopropylethylamine in 0.5 mL of distilled methylene chloride was placed in a 2 mL microscale flask. The flask was purged with argon, then 0.013 mL (0.058 mmol) of 2-cyanoethyl *N,N*-diisopropylchlorophosphoramidite was added via syringe. The reaction was stirred at room temperature for 10 min, then diluted with chloroform, and the organic layer was washed twice with small portions of water. The organic solution was filtered through magnesium sulfate,

THF/pyridine/water, then carefully dehydrated, and dissolved in acetonitrile to make a 0.1 M solution.

Synthesis of an Oligonucleotide–PDHD Conjugate (5, Scheme 2). The 9-mer TTTTCTTTT was synthesized in the DNA Core Facility at the University of Cincinnati by standard synthesis on a 1 μ M scale using a ABI 394 synthesizer with the following changes: an easily deprotected phosphoramidite of dC was used, and, after the 5'-end deprotection step of the oligonucleotide, TCA was washed from the column with acetonitrile for 2 min (4 times longer than usual) to minimize exposure of the photosensitizer to acid. The coupling of this resin-bound oligonucleotide to PDHD–phosphoramidite was performed in 0.5 M tetrazole in acetonitrile for 3 min (6 times longer than usual) to increase coupling efficiency. Instead of standard 0.1 M I_2 , 20 mM I_2 in THF/pyridine/water was used for the oxidation step. The detritylation step, since it involves the use of TCA, was excluded at the end of the program. After cleaving from the column in aqueous ammonia, the conjugate was deprotected for 1 h at room temperature, purified using a reversed-phase

Figure 3. Fluorescence spectra of 2.5 μ M PDHD, excitation at 354 nm.

cartridge, and checked using PAGE. The conjugate's UV–vis and fluorescence spectra were recorded with a Hewlett Packard 8452A Diode Array Spectrophotometer and SPEX 1680 0.22M Double Spectrometer, respectively. Mass spectrum of the conjugate was taken on PerSeptive Biosystems Voyager-DE MALDI-TOF as the sum of 64 nitrogen laser shots at 336 nm using 3-hydroxypicolinic acid as a matrix.

Unless stated otherwise, all chemicals for syntheses were purchased from Aldrich. Solvents were purified according to standard procedures. ^1H and ^{13}C and ^{31}P -NMR spectra were recorded with a Bruker AC 250. IR spectra were recorded with a Perkin-Elmer 1600 Series FTIR in a solution cell (path length, 0.2 mm). Low resolution mass spectra were taken with a Hewlett-Packard HP 5995, electron impact 70 eV or a Finnigan Mat LCQ Ion Trap, high-resolution mass spectra were obtained on a Kratos MS 801-DS 55. Unless stated otherwise, preparative chromatography separations were performed using centrifugal chromatography with a Chromatotron and plates were coated with E. Merck silica gel 60-PF254.

UV-Melting Experiments. The change of absorbance at 260 nm was measured with a Cary 219 Spectrophotometer interfaced to an IBM computer with an Intel 80386 processor that also controlled a Haake A80 circulating water bath and collected temperature data from a thermocouple using custom software. The sample chamber was purged with N_2 . DNA was dissolved in SCP (1 M NaCl, 10 mM sodium phosphate, pH 7.4) buffer, heated to 98 $^{\circ}C$, and cooled slowly, at 0.5 $^{\circ}C/min$ rate, to 4 $^{\circ}C$.

Maxam and Gilbert Chemical Sequencing. The target DNA was sequenced using standard procedures (28) with the following changes: both, GA and TC reactions with formic acid and hydrazine, respectively, were incubated for 2 h at room temperature, and the treatment with 10% piperidine was performed at 90 $^{\circ}C$ for 60 min for GA and for 50 min for TC reaction.

Photochemical Cleavage Reaction. Radioactively labeled target DNA at 10 nM concentration was mixed with PDHD or PDHD-conjugate at 0–10 μ M in 20 μ L of SCP buffer. Carrier calf thymus DNA (2 μ g) was included where indicated. Samples were heated at 55 $^{\circ}C$ for 1 min, cooled to 4 $^{\circ}C$ at the rate of 1 $^{\circ}C/min$ in a thermal cycler, and incubated for 1 h at 4 $^{\circ}C$. All of the

Figure 4. Irradiation of the target **30A** DNA with and without PDHD **6**/conjugate **5** for different times and concentrations. Lanes: (1) GA Maxam-Gilbert reaction of the target, (2) TC Maxam-Gilbert reaction, (3 and 12) target irradiated for 12 h and treated with piperidine (as the rest of the lanes, unless otherwise indicated), (4 and 11) target not irradiated and not treated, (5–10 and 13–20) target irradiated ($h\nu$) for indicated times with indicated concentrations of PDHD or PDHD-conjugate.

above were performed with dimmed lights. Samples were placed on Parafilm on a glass table surrounded by SCP buffer and enclosed in a Pyrex glass dish. Samples were irradiated for 1–12 h at 4 °C in a RAYONET Preperative Type RS Photochemical Reactor equipped with a cooling fan and heated-cathode 350 nm emission lamps from Southern New England Ultraviolet Co. Irradiance at the sample was 2 mW/cm². The reaction was stopped by turning off the lamps. Radicals were quenched by addition of 2 μ L of 0.1 M DTT. DNA was treated in 10% piperidine for 1 h, triple-lyophilized, redissolved in 10 μ L of 80% formamide loading buffer, and run on 20% polyacrylamide, 8 M urea gel. After electrophoresis, the gel was covered with saran wrap and exposed to Kodak X-ray film. Films were scanned using a Bio-Rad GS-670 imaging densitometer. The data were processed on an IBM computer with an Intel 80386 processor using Molecular Analyst software.

RESULTS AND DISCUSSION

The M13 genome was chosen as a target for the studies. The sequence AAAAGAAAA (between bases 5983 and 5992 of M13, traditional numbering) was selected for several reasons. It is a unique site in the genome. It is a potential site not only for double-strand but also for triple-strand formation. It is a part of the *lac i* gene which enables blue/white plaque screening for later studies. A 30-mer 5'-TCTCGCTGGTGAAAAGA-AAAACCACCCTGG-3' (**30A**, Scheme 3a) containing the target sequence AAAAGAAAA was synthesized and labeled with ³²P at the 5'-end. The conjugate that binds to such a target should have a polypyrimidine sequence 5'-TTTTCTTTT-3' to be capable of both double- and triple-strand formation (Scheme 3b). The hexamethylene linker was used to give the photosensitizer PDHD some degree of freedom to interact with the target. Two oligonucleotides complementary to the target were syn-

Figure 5. Quantitation of product formation for Figure 4. The amount of cross-links (Crossl), undamaged 30-mer (30-mer), specific cleavage in the region between bases A19 and C27 (Spec), damage to G16 (Gmid), and damage in the region between bases G8 and G11 (Other) was measured by scanning densitometry. Irradiation times and reagent concentrations are as indicated.

thesized, a 30-mer **30T** and a 9-mer **9T** (Scheme 3a) for the appropriate control experiments.

The PDHD derivative **1** (Scheme 2) was synthesized in a five step procedure (27). This synthesis will be reported elsewhere. Subsequent functionalization of **1** was achieved using an etherification method described by Fedorynski et al. (29). The reaction was carried out in the presence of potassium carbonate and 18-crown-6, allowing mild deprotonation of the phenolic compound **1**. The alkylating agent was 6-(*tert*-butyldimethylsiloxy)-1-iodohexane. It was prepared according to a published procedure by Heslin et al. (30). Introduction of the hexyl side chain yielded the PDHD derivative **2** (Scheme 2) in approximately 80% yield. Subsequent cleavage of the silyl ether by treatment with tetrabutylammonium fluoride afforded the alcohol **3** (Scheme 2) in good yield. This compound was then reacted with a 2-cyanoethyl *N,N*-diisopropylchlorophosphoramidite (**31**) in the presence of *N,N*-diisopropylethylamine, yielding the desired PDHD-phosphoramidite **4** (Scheme 2) in 84% yield. Its structure was verified by complete spectral characterization. Due to the lability of the dihydrodioxin ring system, the M^+ ion of **4** could not be observed using EI or FAB. However, ESI provided the molecular ion peak, $(M + H)^+$.

The PDHD oligonucleotide conjugate **5** (Scheme 2) was prepared by standard synthesis of TTTTGTTTT at 1 μ M scale and coupling this oligonucleotide to PDHD-phosphoramidite using special precautions and the manual adjustment of standard synthesis procedures to avoid any damage of the conjugate by light, acid, or harsh treatment during deprotection (see Experimental Procedures). The yield after purification through a reversed-phase column was 191 μ g.

The PDHD dication **6** (Scheme 2) was prepared for comparison of the effects of the free photosensitizer versus the effects of the conjugate. This synthesis will be reported elsewhere.

The synthesis of the conjugate **5** was confirmed using UV-vis, fluorescence, PAGE, and MALDI-TOF. The 200–400 nm spectra of **9T** DNA alone, PDHD **6**, and the conjugate **5** were compared. The spectra of the conjugate has the peaks of both DNA and PDHD (Figure 1), indicating the presence of both substances in the product. Covalent linkage of PDHD to the oligonucleotide was confirmed by electrophoresis of PDHD **6**, PDHD **6** with **9T** DNA and the conjugate **5** on 8% polyacrylamide 8M urea gel (Figure 2). DNA and PDHD were visualized by UV-shadowing. As expected, PDHD in the first lane migrated out of the gel because it has a positive charge.

Figure 6. Irradiation of the target **30A** DNA with and without PDHD **6**/conjugate **5** with and without piperidine treatment. Lanes: (1) GA Maxam-Gilbert reaction of the target, (2) TC Maxam-Gilbert reaction, (3) target not treated, (4) target irradiated for 12 h (as the rest of the samples) and treated with piperidine, (5 and 6) without piperidine treatment, (7 and 8) with piperidine treatment, (5 and 7) with 10 μ M PDHD, and (6 and 8) with 10 μ M conjugate.

Although it is electrostatically bound to DNA, it also migrated out of the second lane that contained both PDHD and **9T** DNA. The gray band in this lane is **9T** DNA. Only the lane containing the conjugate exhibited the strong dark blue (about 400–440 nm) fluorescence that is observed at 420 nm with PDHD alone (Figure 3). This proves that PDHD is covalently linked to **9T** DNA in the conjugate. Notably, the conjugate migrates more slowly on the gel because of the higher molecular weight and because of the lower charge to molecular weight ratio (PDHD is an approximate equivalent of one and a half nucleotides with no charge) (Figure 2). The covalent linkage was clearly confirmed by the MALDI-TOF spec-

Figure 7. Irradiation of the target **30A** DNA with and without PDHD **6**/conjugate **5** in the presence of carrier DNA, at different concentrations of NaCl and different pH. Lanes: (1) GA Maxam–Gilbert reaction of the target, (2) TC Maxam–Gilbert reaction, (3) target not treated, (4–6) with 2 μ g of calf thymus carrier DNA, (4) target irradiated for 12 h and treated with piperidine (as the rest of the lanes, unless otherwise indicated), (5 and 7) with 10 μ M PDHD, (6 and 8–13) with 10 μ M conjugate, (8) 0 M NaCl, (9) 0.1 M NaCl, (10) 0.25 M NaCl, (11) 0.5 M NaCl, (12) 0.75 M NaCl, (13) 1.0 M NaCl, pH 7.4, (14) pH 6.0, (15) pH 8.8.

trum of the conjugate $[(m/z) (M - H)^-]$ observed, 3255.1; calculated, 3256.3].

To assess how PDHD in a conjugate affects DNA–DNA binding, UV-melting experiments were performed. **30A** was premixed with **30T**, **9T**, and a conjugate **5** at 1:1 molar ratio in SCP buffer, heated to 98 °C, and cooled slowly to 4 °C to anneal. Multiple UV-melting curves were collected, and melting temperatures of duplexes were determined at the maximum of the calculated dA/dT curve [data not shown, (32)]. The melting temperature for the duplex of **30A** and **30T** was 80.8 °C ($\sigma = 0.1$ °C). The duplex of **30A** and **9T** melted at 20.1 °C ($\sigma = 0.5$ °C). The duplex of **30A** and a conjugate **5** had a melting temperature of 21 °C ($\sigma = 0.5$ °C). This is the

expected result indicating very little, if any, stabilization of the duplex by the conjugated PDHD.

Irradiation of the ss 30-mer target **30A** with and without a PDHD conjugate **5** and dication PDHD **6** was performed in SCP buffer for 1–12 h at 350 nm at about 2 mW/cm² at 4 °C. The concentration of the radioactively labeled target was constant at 10 nM. The concentration of the conjugate and photosensitizer was varied from 0 to 10 μ M. The reactants were premixed, heated to 55 °C, and cooled to 4 °C at a rate of 1 °C/min and incubated at 4 °C for 1 h in the dark before irradiation. After irradiation, the radical reaction was quenched by 10 mM DTT. Then the sample was treated with 10% piperidine at 90 °C to cleave the single stranded target at damaged

bases. Results were analyzed by electrophoresis on denaturing polyacrylamide gels. To determine which bases were damaged, Maxam–Gilbert chemical sequencing was performed. Two controls were also included: the target that was not irradiated and the target that was irradiated and treated with piperidine, to determine the background cleavage that is not due to PDHD and PDHD conjugate.

The following can be concluded from Figure 4. Free PDHD damages specifically only Gs in ss DNA (lane 5 vs lane 3). In contrast, the conjugate specifically cleaves A21 and C22 (lane 10 vs lane 5). This can be explained only by ds formation (Scheme 3b). Notably, the conjugate also specifically damages T7, T10, and A12 (lane 18 vs lane 17), sites that are consistent with triplex formation (Scheme 3b). The conjugate protects from nonspecific cleavage G16, which is in the middle of the binding region (lane 16 vs lane 15). The conjugate nonspecifically damages other Gs (G8, G9, and G11 in lane 16 vs lane 15). The conjugate also forms cross-links with the target forming two new bands of higher MW (**30A** with a conjugate via ds formation and **30A** with two conjugates via triplex formation, lane 9).

Damage to the target was quantitated by scanning densitometry. The total amount of cross-links, undamaged 30-mer, specific cleavage in the region between bases A19 and C27, and damage of G16 and damage in the region between bases G8 and G11 was estimated (Figure 5). As time of irradiation was increased from $\frac{1}{2}$ to 12 h, cross-links increased from 4 to 26%, specific damage increased from 2 to 17% (Figures 4 and 5). The irradiation time for all further studies was set at 12 h. The concentration of PDHD and the conjugate were varied in the range 2.5–50 μ M. There was little specific damage and cross-links by the conjugate formed at 2.5 μ M concentrations. These products increased at 10 μ M concentrations. Further increases in concentration only increased nonspecific damage (Figures 4 and 5). Thus, the concentration of damaging agents was set at 10 μ M for all further experiments.

When ss target was irradiated with PDHD or PDHD conjugate, but not treated with piperidine, little cleavage at Gs was observed with free PDHD (lane 5 vs lane 7, Figure 6), and there were more cross-links than cleavage with the conjugate (lane 6 vs lane 8, Figure 6). This indicates that PDHD is damaging Gs, but not cleaving them, and that the conjugate primarily forms cross-links that are later partially cleaved by piperidine.

When ss target was irradiated with a large amount of carrier DNA (2000 carrier, 1 target), PDHD cleaved the target severalfold less (lane 5 vs lane 7, Figure 7), indicating complete nonspecificity, while the conjugate cleaved with almost the same efficiency as it cleaved in the absence of carrier DNA (lane 6 vs lane 13, Figure 7). Specific cleavage increased when the concentration of NaCl was increased (0, 0.1, 0.25, 0.5, 0.75, and 1.0 M in lanes 8–13, Figure 7, and lanes 10–15, Figure 8). This is consistent with increased double-strand stability at higher salt concentrations. Slight variation of pH (7.4, 6.0, and 8.8 in lanes 13–15, Figure 7) did not affect cleavage significantly. Triplex cleavage was not detected under these conditions. The maximum site-specific modification achieved was 67% (51% of cross-links and 16% of direct cleavage) in a sample that was not treated with piperidine (lane 3, Figure 8).

Four separate irradiations of the target with the conjugate at standard conditions (10 nM target, 10 μ M conjugate, 12 h of irradiation, piperidine treated) gave an average of 40% site-specific modifications: 23% ($\sigma =$

Figure 8. Quantitation of product formation for Figures 6 and 7. Samples: (1–3) DNA alone, with PDHD and with the conjugate, no piperidine treatment, (4–6) DNA alone, with PDHD and with the conjugate, piperidine treated, (7–9) DNA alone, with PDHD and with the conjugate, with 2 μ g of calf thymus carrier DNA present, 10–15 NaCl concentrations of 0, 0.1, 0.25, 0.5, and 1 M, respectively, (15) pH 7.4, (16) pH 6, (17) pH 8.8.

3%) cross-links and 17% ($\sigma = 3\%$) direct cleavage (lanes 5 and 9, Figure 5, and lanes 6 and 15, Figure 8).

While the damage at double-strand formation sites was always consistent, the damage at triple-strand sites was observed in a few cases, in conditions where it was strongly favored. Some evaporation of the samples, even though compensated by the addition of water, may have affected product formation.

As compared to other photosensitizers that were conjugated to DNA (2, 3), PDHD seems to have desirable qualities. The wavelength of excitation is 350 nm, above the absorbance of DNA and proteins although still much shorter than the 700 nm that is more useful for phototherapy. PDHD conjugate gives high yields (up to 67%) of specific damage, which places it second after psoralens (6) in efficacy of damage. PDHD conjugate is capable of photo-cross-linking to or damaging all four bases in a target DNA, while most other sensitizers damage only a limited set of bases (4, 13). Besides the site-specific damage, the current generation of PDHD conjugates induce nonspecific damage of Gs around the targeted sequence. This can hopefully be eliminated by attaching the sequence-recognizing unit to the quinone rather than the olefin-derived moiety, thus preventing damage to nearby sequences through migration of released PAQ.

In conclusion, the photochemical cleavage studies prove that the PDHD–oligonucleotide conjugate binds to the complementary target. It efficiently and site-specifically cleaves the designated target, thus, the incorporation of the oligonucleotide sequence recognizing unit onto the PDHD converts a nonspecific photochemical reagent into a sequence specific one.

In future studies, the ss PDHD conjugate will be tested as a selective photochemical M13 virus inactivating agent by measuring inactivation of the *lac i* gene. A variety of improvements of PDHDs are currently under investigation.

ACKNOWLEDGMENT

We sincerely thank the DNA Core Facility at the University of Cincinnati for providing all oligonucleotides and performing the DHD–oligonucleotide coupling reaction. R.M.W. thanks the NSF (CHE-9122141) for financial support.

Polycaprolactone-*b*-poly(ethylene Oxide) Block Copolymer Micelles as a Novel Drug Delivery Vehicle for Neurotrophic Agents FK506 and L-685,818

Christine Allen,[†] Yisong Yu,[†] Dusica Maysinger,^{*,‡} and Adi Eisenberg^{*,†}

Department of Chemistry, McGill University, 801 Sherbrooke Street West, Montreal P.Q, Canada H3A 2K6, and Department of Pharmacology and Therapeutics, McGill University, 3655 Drummond St., Montreal, P.Q. Canada H3G 1Y6. Received December 19, 1997; Revised Manuscript Received May 7, 1998

Micelles formed from polycaprolactone-*b*-poly(ethylene oxide) (PCL-*b*-PEO) diblock copolymers were investigated as a novel drug delivery system. The affinity of the micelles for hydrophobic solubilizates was assayed by determining the partition coefficient for the lipophilic compound, pyrene, between the micelles and water; the partition coefficient was found to be on the order of 10^2 . The Trypan blue and Alamar blue survival assays were used to assess the in vitro biocompatibility of the micelles with PC 12 cells, MCF-7 breast cancer cells, and primary cultures of human microglia, astrocytes, and cortical neurons. The micelles were then studied as a delivery vehicle for the neurotrophic agents FK506 and L-685,818 in PC 12 cell cultures. In both cases, the micelle-incorporated drugs, in the presence of nerve growth factor (5 ng/mL), were able to promote the degree of differentiation of the PC 12 rat pheochromocytoma cells.

INTRODUCTION

Colloidal drug delivery vehicles such as liposomes, microspheres, nanospheres, and block copolymer micelles have recently been shown to increase the therapeutic index and improve the selectivity of various potent drugs (1–8). These vehicles have been shown to optimize the therapeutic efficacy of drugs by preventing their rapid elimination from the body (4), reducing their systemic toxicity (4), delaying their degradation, and optimizing their metabolism (3, 4). In addition, they also provide for effective delivery of drugs to specific target sites (3) and aid in overcoming both transport limitations and defense mechanisms associated with the multidrug resistance phenotype (5).

In the recent past, there has been increasing interest in the use of micellar delivery systems formed from block copolymers (4, 6, 8). The use of block copolymers in drug delivery was first proposed by Ringsdorf's group in the early 1980s (11). Recently, the work of Kabanov's group and Kataoka's group has greatly enhanced the development of block copolymer micelles as drug delivery vehicles (4–6). These micelles are formed from individual block copolymer molecules, each of which contains a hydrophobic block and a hydrophilic block. The amphiphilic nature of the block copolymers enables them to self-assemble to form nanosized aggregates of various morphologies in aqueous solution such that the hydrophobic blocks form the core of the micelle which is surrounded by the hydrophilic blocks, which form the outer shell (12). The inner core of the micelle creates a hydrophobic microenvironment for the nonpolar drug, while the hydrophilic shell provides a stabilizing interface between the micelle core and the aqueous medium. The properties of the hydrophilic shell, which in most cases

consists of poly(ethylene oxide), can be adjusted to both maximize biocompatibility and avoid reticuloendothelial system uptake. The size of the micelles is usually between 10 and 100 nm (4). This size is small enough to allow access to small capillaries while avoiding reticuloendothelial system uptake (4). Micelles in this size range are also large enough to escape renal filtration, which increases their blood circulation time. Most of the existing block copolymer micelle systems are based on poly(ethylene oxide)-*b*-polypropylene oxide-*b*-poly(ethylene oxide) triblock copolymer or from block copolymers which have a polypeptide or polylactic acid core forming block and a poly(ethylene oxide) block which forms the hydrophilic corona (4–6, 8–10).

In this paper, we introduce a novel block copolymer micelle system, formed from polycaprolactone-*b*-poly(ethylene oxide) (PCL-*b*-PEO) diblocks as a potential drug delivery vehicle. The individual block components, polycaprolactone and poly(ethylene oxide), have been explored previously for a variety of biomedical applications (13–19). Polycaprolactone, the hydrophobic core-forming block of the micelles is a synthetic semicrystalline biodegradable polymer. Due to the biodegradability of the polycaprolactone homopolymer, it has been tried both as a structural material in the production of medical devices, such as implants, sutures, stents, and prosthetics, and as a carrier for a variety of drugs (13, 14). Polycaprolactone pastes have been developed as a drug delivery system for the anti-cancer agent taxol (15) and the antineoplastic agent bis(maltolato)oxovanadium (16). Nanoparticle, nanocapsule, and microparticle drug carriers made of polycaprolactone have been assayed for the ocular delivery of indomethacin (17). Poly(ethylene oxide), the hydrophilic shell forming block of the micelles, is commonly used to impart blood compatibility to a material surface (18, 19).

Triblocks of polycaprolactone-*b*-poly(ethylene oxide)-*b*-polycaprolactone have been used to form tablets, which were studied in terms of their biocompatibility and

biodegradation (20). In addition, recently matrixes to be used as implantable drug delivery systems have been formed from the triblock copolymer polycaprolactone-*b*-poly(ethylene oxide)-*b*-polycaprolactone (PCL₆-*b*-PEO₉₀-*b*-PCL₆) (21).

To our knowledge, there has only been one previous report on the use of diblock copolymer micelles of polycaprolactone-*b*-poly(ethylene oxide) as a drug delivery system (22). The novelty associated with the present application is largely due to the length of the polycaprolactone blocks. To date, diblocks with long blocks of polycaprolactone had not been synthesized; now, however, owing to a new synthetic method, longer blocks are possible (23). The longer caprolactone blocks should create a larger hydrophobic microreservoir enabling the incorporation of a greater amount of lipophilic drug. It is also anticipated that control over the degree of incorporation and the release kinetics can be gained by varying the length of the polycaprolactone block. The degree of drug incorporated and the release kinetics of that drug are largely a function of the interaction between the drug and the core forming block. Since polycaprolactone is more hydrophobic than other polymers, commonly used as core-forming blocks (e.g., polypropylene oxide), this system may be have a larger capacity for the most hydrophobic drugs.

The polycaprolactone micellar core is suitable for the incorporation of a variety of neutral, lipophilic drugs. In this paper, we focus on the drugs FK506 and its analogue, L-685,818. FK506, otherwise known as tacrolimus, has been effectively used to achieve immunosuppression in organ transplant recipients (24). FK506 binds to the immunophilin FKBP12 to form a complex which binds to and inhibits calcineurin; this, in turn, results in immunosuppression (25). Recently, FK506 has been found to promote neuronal outgrowth, which has been demonstrated in terms of the enhancement of neurite extension in PC 12 (rat pheochromocytoma) cell cultures (26) and explant cultures of rat sensory ganglia (27). The use of FK506 for the treatment of neurodegenerative diseases is limited by its immunosuppressant activity. However, L-685,818, the structural analogue to FK506, has retained the neurotrophic action of FK506 but lost its immunosuppressant action (27). The structural difference between FK506 and L-685,818 is only in the addition of a hydroxyl group on the analogue at C-18 and the substitution of an ethyl group for an allyl group at C-21 (27). Recently, L-685,818 has been of interest for its potential use in the treatment of neurodegenerative diseases, as it has been shown to "enhance functional and morphologic recovery in rats with crushed sciatic nerves" (27).

At present, FK506 is administered either orally, in a capsule, or by injection as a sterile solution. In addition to this, a microemulsion formulation of FK506 has also been developed (24). However, to our knowledge, this is the first delivery system which has been introduced for the FK 506 analogue, L-685,818.

In this communication, we report on studies which explore the potential of the PCL-*b*-PEO copolymer micelles as drug delivery vehicles. To establish this system as a suitable drug carrier, we studied a range of the micelle's characteristics including effective diameter, size population distributions, as well as their in vitro stability in various cell culture media. The micelle's affinity for lipophilic compounds was evaluated by determining the partition coefficient for the highly lipophilic compound, pyrene, between the PCL-*b*-PEO micelles and water. Though each of the components, polycaprolactone and

poly(ethylene oxide), are biocompatible, it was also necessary to assess the biocompatibility of the block copolymer as a whole. The in vitro biocompatibility of the copolymer was assayed by incubation of the micelles with PC 12 cells (26) and MCF-7 breast cancer cells as well as primary cultures of human microglia, astrocytes, and cortical neurons. Finally, the neurotrophic drugs FK506 and L-685,818 were incorporated into the PCL-*b*-PEO micelles, and the in vitro delivery was assayed by monitoring the degree of differentiation achieved in cultures of PC 12 rat pheochromocytoma cells.

2. EXPERIMENTAL SECTION

2.1. Materials. The block copolymers were synthesized by anionic polymerization, the method has been described in detail elsewhere (23). GPC results revealed that the polydispersity (PD) of the block copolymers was 1.16, with a symmetrical mono modal distribution. In all cases, following purification of the block copolymer, there was no homopolymer present. The polycaprolactone-*b*-poly(ethylene oxide) copolymers employed have identical poly(ethylene oxide) block lengths (44 ethylene oxide units) but different polycaprolactone block lengths; 14 or 20 units. These polymers are designated as PCL₁₄-*b*-PEO₄₄ and PCL₂₀-*b*-PEO₄₄, respectively. All chemicals for the synthesis were purchased from Aldrich Chemical Co.

FK 506 (Prograf) was purchased from Fujisawa Pharmaceutical, Osaka, Japan. The FK 506 analogue L-685 818 was supplied by Merck Inc. The MCF-7 cells and primary cultures of human microglia, astrocytes, and cortical neurons were supplied by Dr. Antel at the Montreal Neurological Institute. The tissue culture reagents were all purchased from Gibco BRL. The Alamar blue was purchased from Biosource Camarillo and the Trypan blue from Gibco BRL.

2.2. Methods. **2.2.1. Characterization of the PCL-*b*-PEO Micelles.** **2.2.1.1. Micelle Preparation.** The PCL-*b*-PEO copolymer was dissolved in DMF and stirred overnight at room temperature. Micellization was achieved by the addition of water in a dropwise fashion to the block copolymer solution to form a micelle solution. The micelle solution was stirred overnight and then dialyzed against milli-Q distilled water using dialysis tubing. The water was changed every hour for the first 4 h and then every 3 h for the next 12 h.

2.2.1.2. Micelle Size Distribution. Dynamic laser light scattering (DLS) measurements on the PCL-*b*-PEO block copolymer micelles were carried out using a Brookhaven laser light scattering instrument (Brookhaven Instruments Corporation, New York), with a uniphase 125 mW micro green laser at a wavelength of 532 nm at 25 °C. A scattering angle of 90° was used for all measurements. The concentration of the samples ranged from 0.01 to 0.2% w/w in filtered (0.8 μm filter) deionized distilled Milli Q water.

2.2.1.3. In Vitro Micelle Stability Studies. The 1% w/w PCL-*b*-PEO block copolymer micelle solutions prepared as described above were freeze-dried and dissolved in Dulbecco's Modified Eagle Medium (DMEM, Gibco), RPMI medium, and water to produce both 0.01 and 0.1% w/w solutions. Dynamic laser light scattering (DLS) measurements on the solutions were carried out on a weekly basis over a 3 month period.

2.2.2. Determination of the Partition Coefficient for Pyrene between the PCL-*b*-PEO Block Copolymer Micelles and a DMF/H₂O Solvent Mixture. The fluorescence method used to determine the partition

coefficient for pyrene between a mixed water/DMF solvent mixture (60–90% water content) and block copolymer micelles (concentration PCL₂₀-*b*-PEO₄₄ ranges from 1×10^{-6} to 1×10^{-2} g/g), at 25 °C, has been described in detail elsewhere (5b, 28, 29a). The incorporation of pyrene into the micelle core has been described as a partition equilibrium between a micellar phase and a solvent phase (29). Briefly, the intensity ratio of vibrational band three to vibrational band one (I_3/I_1) in the fluorescence emission spectrum of pyrene reflects the polarity of the surrounding environment of the probe molecules. The I_3/I_1 ratio can thus be used to calculate the concentration of pyrene incorporated into the micelles and from this concentration as well as the total amount of pyrene in solution we can calculate the partition coefficient (K_v) for pyrene between the PCL-*b*-PEO micelles and the H₂O/DMF solvent mixtures. The semi-logarithmic plot of the K_v versus the water content can then be extrapolated to 100% water content.

2.2.2.1. Preparation of Solutions for the Determination of the Partition Coefficient. Sample solutions were prepared by adding known amounts of pyrene in acetone to each of a series of empty vials, following which the acetone was evaporated. The amount of pyrene was chosen so as to give a pyrene concentration in the final solution of 1.5×10^{-9} mol/g. Different amounts of PCL₁₄-*b*-PEO₄₄ copolymer in DMF were then added. The initial volumes of the solutions were ca. 2 mL. Micellization of the polymer was achieved by adding water at a rate of 1 drop every 10 s. The addition of water was continued until the desired water content was reached. All the sample solutions were stirred overnight before fluorescence measurements were taken.

2.2.2.2. Fluorescence Measurements. Steady-state fluorescent spectra were measured using a SPEX Fluorolog 2 spectrometer in the right-angle geometry (90° collecting optics). For the fluorescence measurements, ca. 3 mL of solution was placed in a 1.0 cm square quartz cell. All spectra were run on air-equilibrated solutions. For fluorescence emission spectra, λ_{ex} was 339 nm. Spectra were accumulated with an integration time of 1 s/0.5 nm.

2.2.3. Studies Involving the PCL-*b*-PEO Micelles and PC 12 Cells. **2.2.3.1. Cell Cultures.** PC 12 cells were maintained in DMEM supplemented with 10% horse serum, 5% fetal calf serum, 500 µg/mL penicillin, 500 µg/mL streptomycin, and 290 µg/mL.

2.2.3.2. In vitro Biocompatibility of the PCL-*b*-PEO Micelles. PC 12 cells and the MCF-7 breast cancer cells were maintained at 37 °C in 5% CO₂. The cells were plated in 96-well plates and cultured in RPMI medium supplemented with 5% fetal bovine serum. Aliquots of the 10% and 1% PCL-*b*-PEO micelle solutions (PCL₁₄-*b*-PEO₄₄ and PCL₂₀-*b*-PEO₄₄) were added to the wells to make the final concentration of micelles in the wells to range from 0.02 to 1% (w/v). In each case, there were controls which consisted of cells without any micelles added to the wells. The cells were incubated with the micelles for both a 24 and 48 h period at which point the Trypan blue and Alamar blue survival assays were employed to assess cell viability in the presence of the PCL-*b*-PEO micelles.

2.2.3.3. Cell Survival Assays: (a) Trypan Blue Exclusion Assay. Following the 24 or 48 h incubation period, the cells were detached with 0.025% Trypsin. The cell suspension was mixed with 75 µL of PBS and 25 µL of Trypan blue. The number of viable cells was determined by using a light microscope (Nikon, objective 20×). The percentage of viable cells was expressed as the number of viable cells divided by the total number of cells.

(b) Alamar Blue Assay. A 10 µL aliquot of the Alamar blue was added to each cell well following a 24 or 48 h incubation period. Following incubation with the dye, 50 µL of the contents of each well was then transferred to a new 96-well plate and the absorbance at 570 nm was measured by a microplate reader (Bio-rad, Mode 550). Cell viability was expressed as the inverse of the absorbance. The value obtained for the controls was considered to be 100% survival.

2.2.3.4. Cell Uptake of Pyrene-Incorporated Micelles. Pyrene-incorporated micelles were prepared such that a total of 2×10^{-7} mol/L of pyrene had been added to the 1% (w/w) micelle (PCL₁₄-*b*-PEO₄₄) solution. An aliquot of the micelle solution was incubated with PC 12 cells cultured in DMEM at 37 °C, 5% CO₂. At time 0, 4, 8, and 24 h, the fluorescence intensity (Perkin-Elmer LS 50) of the supernatant was measured at 390 nm in order to determine the amount of pyrene remaining in the supernatant. Controls consisting of medium or medium and micelles alone were also measured. Following the removal of the aliquot of supernatant at each time point, the remaining supernatant was removed and the cells were washed three times with 100 µL of phosphate buffer saline. The cells were then gently scraped and fixed with aquamount on a slide and analyzed using a fluorescence microscope (Olympus BH-2).

2.2.4. Effect of the FK 506- and L-685,818-incorporated PCL-*b*-PEO Micelles.

2.2.4.1. Preparation of the FK506 and L-685,818-Incorporated PCL-*b*-PEO Micelles. Stock solutions of each drug were prepared by dissolving the drug in acetone. An aliquot of the stock solution was then added to an empty sample vial, the acetone was evaporated, and preparation proceeded as described above. The FK506 drug was received as a sterile solution (Prograf, Fujisawa Pharmaceutical, Osaka, Japan), and thus, it had to be isolated prior to use. The drug was then dissolved in acetone to produce a 5.6×10^{-4} mol/L stock solution. An aliquot of the stock solution was added to an empty sample vial, and the acetone was evaporated off. The PCL₂₀-*b*-PEO₄₄ block copolymer was added to the vial along with DMF, then water was added dropwise and the solution was dialyzed (as described above) to produce a 1.1×10^{-5} mol/L concentration of drug in a 1% (w/w) block copolymer solution. For the L-685,818 analogue, the concentration of the stock solution was 5.6×10^{-4} mol/L. The L-685,818 micelle-incorporated solution was produced in the same manner but the final concentration of the analogue was 2.3×10^{-5} mol/L in the 1% (w/w) PCL₂₀-*b*-PEO₄₄ micelle solution. It should be noted that, for both the FK506 and L-685,818 micelle solutions, the concentration mentioned is the maximum quantity of drug incorporated into the micelles; some will be lost in the dialysis process.

2.2.4.2. In Vitro Studies of Free Form FK506 and L-685,818 and Micelle-Incorporated FK506 and L-685,818. Cell Differentiation Assay. PC 12 cells were plated in 24-well plates at 37 °C in 5% CO₂ and incubated in DMEM supplemented with 5% fetal bovine serum and the treatments described below. Neurite-like outgrowth in PC 12 cells was detected after a 48 h period using a Nikon light microscope. For each data point, five fields of 250–300 cells/well were analyzed. For the quantitation of neurite-like outgrowth the PC 12 cells were considered to have outgrowth if their processes were longer than the length of the diameter of the cell.

2.2.4.3. Dose-Response Curves for NGF, FK 506 or L-685,818 Alone and the Combinations of FK 506 or L-685,818 with NGF. A range of concentrations of either NGF (0.1–50 ng/mL), FK506 (1–500 nM), or L-685–818

(1–500 nM) alone or combinations of 0.5 or 5 ng/mL of NGF with either FK506 (5–500 nM) or L-685,818 (50 nM to 10 μ M) were incubated with the PC 12 cells for a 48 h incubation period. The wells with untreated cells were used as controls.

2.2.4.4. In Vitro Effect of Micelle-Incorporated FK506 and L-685,818 along with NGF. The unfiltered solution of the micelle incorporated drug was added to the cell wells at different concentrations: a 10 μ L aliquot of a FK506-micelle solution was added to each 0.5 mL cell well. The 10 μ L aliquot was produced by diluting the 1.1×10^{-5} mol/L FK506-PCL₂₀-*b*-PEO₄₄ micelle (1% w/w) stock solution. The final concentration of FK506 in the cell well was made to range 1–1000 nM. In the same manner, a 10 μ L aliquot of the L-685,818 micelle solution was added to each 0.5 mL cell well, such that final concentration in the well was made to range from 10 nM to 1 μ M. In each case, 5 ng/mL NGF was also added to each cell well. Several controls were also used where the cells were treated with 5 ng/mL of NGF alone, 1% (w/w) PCL₂₀-*b*-PEO₄₄ micelles alone, 1% (w/w) PCL₂₀-*b*-PEO₄₄ micelles containing 1 nM FK 506 without NGF or 1% (w/w) PCL₂₀-*b*-PEO₄₄ micelles containing 10 nM L-685,818 without NGF.

3. RESULTS

3.1. Micelle Size Distributions. The Dynamic Light Scattering instrument was used to measure the effective diameter of the micelles and Contin Analysis was employed to determine the population distribution of the micelles in terms of their size. The effective diameter of 0.1% (w/w) solutions of the micelles when a 0.45 μ m filter is used is 62 nm for the PCL₂₀-*b*-PEO₄₄ and 55 nm for the PCL₁₄-*b*-PEO₄₄. Figure 1 shows the population distributions obtained for unfiltered solutions of the PCL₂₀-*b*-PEO₄₄ micelles (0.02 and 0.1% w/w, panels a and b in Figure 1, respectively). Figure 1a shows the bimodal population distribution present in the unfiltered micelle solution; the small aggregates were approximately 50 nm in diameter and the larger aggregates were $\sim$ 500 nm (Figure 1a). The effect of dilution, following the preparation, on this bimodal population distribution was examined as the concentration was varied from 0.01 to 0.2% (w/w). In all cases, the 500 nm population was most prevalent at the higher concentration range, while dilution resulted in a gradual shift in favor of the 50 nm population.

3.2. In Vitro Stability Studies. The micelles were monitored on a weekly basis by DLS in order to determine their relative stability in different sterile media. Over a 3 month period, both the effective diameter of the micelles and the population size distribution remained unchanged (as per above).

3.3. Determination of the Partition Coefficient for Pyrene. Pyrene was used as a model hydrophobic compound. Figure 2a shows the I_3/I_1 ratio of pyrene in micelle solutions of different PCL-*b*-PEO copolymer concentrations over a range of water contents in the DMF/H₂O solvent mixtures. The I_3/I_1 ratio (Figure 2a) increases with increasing water content within the solvent mixture for a constant copolymer concentration. Likewise, for a particular water content within the solvent mixture, the I_3/I_1 ratio increases as the copolymer concentration is increased. Figure 2b shows the partition coefficients calculated for pyrene between the PCL-*b*-PEO micelles and the DMF/H₂O solvent mixtures. The extrapolation of this plot to 100% water content gives a value of the order of 10^2 for the partition coefficient for pyrene between the PCL-*b*-PEO (20-*b*-44) micelles and H₂O.

Figure 1. (a) Particle size distribution of a 0.02% (w/w) solution of the PCL₂₀-*b*-PEO₄₄ copolymer micelles. (b) Particle size distribution of a 0.1% (w/w) solution of the PCL₂₀-*b*-PEO₄₄ copolymer micelles.

3.4. Cell Survival in the Presence of the PCL-*b*-PEO Micelles. The incubation of the micelles with several different cell lines and primary cultures was employed as a means of testing the biocompatibility of the PCL-*b*-PEO micelles. Primary cultures of human microglia, astrocytes, and cortical neurons were incubated with micelles formed from PCL₁₄-*b*-PEO₄₄ and PCL₂₀-*b*-PEO₄₄. In the cell cultures tested, the PCL₁₄-*b*-PEO₄₄ induced 10–20% cell death whereas the micelles formed from the larger polycaprolactone block (PCL₂₀-*b*-PEO₄₄) did not cause any noticeable damage. For the incubation of the micelles with the PC 12 and MCF-7 cells, the results from the Trypan blue and Alamar blue survival assays found the micelles to cause little or no cell death when compared with the control wells of untreated cells. Figure 3 shows the results of the Alamar blue assay for the incubation of the PCL-*b*-PEO micelles with PC 12 cells over a 48 h period. At almost every concentration, the micelles formed from the PCL₁₄-*b*-PEO₄₄ block copolymer appeared to have a slightly lower cell survival than the 20-*b*-44 micelles.

3.5. Cell Uptake of Pyrene Incorporated Micelles. Figure 4 shows the fluorescence intensity found for both the supernatant at 390 nm and the cells at the 0, 4, 8, and 24 h time points. The fluorescence intensity of pyrene in the various aliquots of supernatant was found to decrease over the 24 h incubation period, indicating a decrease in the amount of pyrene remaining

Figure 2. (a) The I_3/I_1 ratio for pyrene in a solution of PCL₁₄-*b*-PEO₄₄ copolymer micelles and a DMF/H₂O solvent mixture. (b) The semilogarithmic plot of the partition coefficient for pyrene in a solution of the PCL-*b*-PEO micelles and a range of H₂O/DMF solvent mixtures.

Figure 3. The in vitro biocompatibility of the PCL-*b*-PEO (14-*b*-44 and 20-*b*-44) micelles (0.02–1% w/v) as determined by the Alamar Blue survival assay. The results were confirmed by the Trypan Blue assay. Each data point represents the average of three independent experiments, from 6 to 8 wells.

in the external medium. The relative fluorescence intensity at zero time was taken as 1 while, after 4 h, it had decreased to 0.70 (± 0.05), after 8 h, 0.60 (± 0.05),

Figure 4. The change in the relative emission intensity of pyrene in the supernatant (■) and cells (○) at 390 nm, over a 24 h period. PC 12 cells were exposed to PCL₁₄-*b*-PEO₄₄ micelles containing pyrene and the change in the fluorescence intensity was measured at 4, 8, and 24 h time points.

Figure 5. The degree of neurite-like outgrowth in PC 12 cells incubated with either NGF, FK506 or L-685,818, over a 48 h period ($n = 3-4$). The concentration of NGF incubated with the cells was C1 = 0.1, C2 = 0.5, C3 = 1, C4 = 5, C5 = 50 ng/mL, the concentrations of FK506 or L-685,818 were C1 = 1, C2 = 5, C3 = 10, C4 = 100, C5 = 500 nM. The degree of differentiation in the control (absence of any treatment) is taken to be 100% differentiation.

and finally, after 24 h, the intensity was 0.55 (± 0.05) (Figure 4). The cells were isolated at each time point and analyzed by fluorescence microscopy. The contrast relative to the intensity of fluorescence in the cells increased over the 24 h period, from nondetectable at time zero to the maximum (arbitrarily set at 1) after 24 h.

3.6. In Vitro Studies of Free Form FK506 and L-685,818 and Micelle-Incorporated FK506 and L-685,818. In each case, the degree of neurite-like outgrowth was taken to be 100% in the control wells of untreated PC 12 cells. The degree of differentiation in cell wells in the presence of NGF and/or drug is expressed as a percentage relative to 100% for the control.

3.7. Dose-Response Curves for NGF, FK506 and L-685,818 without Micelles. Figure 5 shows the degree of neurite-like outgrowth obtained over 48 h incubation of PC 12 cells with either NGF, FK506, or L-685,818. The

Figure 6. The effect of micelle-incorporated FK 506 and NGF (5 ng/mL) on the neurite-like outgrowth in PC 12 cells over a 48 h period ($n = 3-4$). Control = PC 12 cells in the absence of any treatment. Bars 1-9 are PC 12 cells treated with the following: bar 1 = 5 ng/mL NGF, bar 2 = PCL₂₀-*b*-PEO₄₄ micelles, bar 3 = micelle-incorporated FK506 (1 nM), bars 4-6 = FK506 (bars 4, 5, and 6 = 1, 10, 100 nM, respectively) along with 5 ng/mL NGF; bars 7-9 = micelle-incorporated FK506 (bars 7, 8, and 9 = 1, 10, 100 nM, respectively) along with 5 ng/mL NGF.

degree of outgrowth in the wells where NGF had been added was found to increase from 110 to 260% as the concentration of NGF incubated with the cells increased. In wells incubated with FK506 or L-685,818 alone, the degree of outgrowth did not vary with the concentration of drug added, rather it oscillated slightly around the 100% value.

3.8. Dose-Response Curves for the Combined Effect of NGF and FK506 or L-685,818 without Micelles. The neurite-like outgrowth for cells incubated with 5 ng/mL of NGF was found to be $180 \pm 6\%$. As shown in Figure 6, the degree of outgrowth in cells incubated with NGF (5 ng/mL) along with FK506 (1-100 nM) increased from 220 to 380% with increasing concentration of FK506. Figure 7, shows that in cells incubated with NGF (5 ng/mL) along with L-685,818 (10-1000 nM) the degree of outgrowth increased from 200 to 350% as the concentration of drug was increased.

3.9. In Vitro Effect of Micelle-Incorporated FK506 and L-685,818 along with NGF. Figure 6 shows the degree of differentiation in PC 12 cells which have been incubated with PCL-*b*-PEO-incorporated FK506 and 5 ng/mL NGF following a 48 h incubation period. The degree of neurite-like outgrowth in cells incubated with 5 ng/mL of NGF was $160 \pm 5\%$. In cell wells incubated with micelle-incorporated FK506 (1 to 100 nM) along with 5 ng/mL of NGF the neurite-like, outgrowth ranged 170-300%. In Figure 6, we see no significant difference between untreated cells and cells treated with either PCL-*b*-PEO micelles without drug or cells treated with micelle-incorporated FK506 (control vs bars 2 and 3). There was also no significant difference between cells treated with 5 ng/mL NGF and those treated with micelle incorporated FK506 (1 nM) along with 5 ng/mL NGF (bar 1 vs bar 7). However, there was a significant difference ($p < 0.01$) between cells treated with 5 ng/mL NGF and cells treated with 10 or 100 nM of micelle incorporated FK506 (bar 1 vs bars 8 and 9).

Figure 7. The effect of micelle-incorporated L-685,818 and NGF (5 ng/mL) on the neurite-like outgrowth in PC 12 cells over a 48 h period ($n = 3-4$). Control = PC 12 cells in the absence of any treatment. Bars 1-9 are PC 12 cells treated with the following: bar 1 = 5 ng/mL NGF, bar 2 = PCL₂₀-*b*-PEO₄₄ micelles, bar 3 = micelle-incorporated L-685,818 (10 nM), bars 4-6 = L-685,818 (bars 4, 5, and 6 = 10, 100, 1000 nM, respectively) along with 5 ng/mL NGF; bars 7-9 = micelle-incorporated L-685,818 (bars 7, 8, and 9 = 10, 100, 1000 nM, respectively) along with 5 ng/mL NGF.

Figure 7 shows the degree of differentiation in PC 12 cells which have been incubated with PCL-*b*-PEO incorporated L-685,818 and 5 ng/mL NGF following a 48 h incubation period. The degree of differentiation seen in cells incubated with the micelle incorporated L-685,818 along with 5 ng/mL NGF increased from 163 to 290% as the concentration of drug increased from 10 nM to 1 μ M. In Figure 7, there is no significant difference between the untreated cells and the cells treated with micelles alone or 10 nM of micelle incorporated L-685,818 (control vs bar 2 or bar 3). Also, no significant difference was found between cells treated with 5 ng/mL of NGF and 10 nM micelle incorporated L-685,818. There was a significant difference ($p < 0.01$) between cells treated with 5 ng/mL NGF and cells treated with 100 nM and 1 μ M of micelle incorporated L-685,818 (bar 1 vs bars 8 and 9).

4 DISCUSSION

4.1. Characterization of the PCL-*b*-PEO Micelles.

In this study, we explored the potential of the novel PCL-*b*-PEO micelles as a drug delivery vehicle for lipophilic drugs. The PCL-*b*-PEO micelles cannot be prepared in water alone due to the hydrophobicity of the polycaprolactone core-forming block. For this reason, the block copolymer is first dissolved in DMF, and micellization is induced by the dropwise addition of water, followed by dialysis. The micelles formed by this method of preparation were studied by dynamic light scattering in order to measure their effective diameter and their population distribution in terms of size. Figure 1 shows the population distribution of the micelles calculated by Contin analysis of the dynamic light scattering measurements. Figure 1a shows the bimodal population distribution found in a 0.02% (w/w) of PCL₂₀-*b*-PEO₄₄. The larger population, at approximately 500 nm, consists of aggregates of the small individual micelles, which we see at 50 nm. Figure 1b shows the population distribution

in terms of size of a 0.1% (w/w) of PCL₂₀-*b*-PEO₄₄. Comparing panels a and b in Figure 1, we see that as the solution is diluted, decreasing the concentration from 0.1 to 0.02%, the population of the larger aggregates is decreased in favor of the smaller (50 nm) population. This suggests that the larger aggregates are composed of aggregates of small individual micelles. Micelles with a coronal shell formed from PEO are frequently seen to form larger aggregates in solution. Winnik's group suggested the large associates of PS-*b*-PEO to be either onion-like aggregates or aggregates of small individual micelles (29). Kataoka's group agreed with the latter suggestion when explaining the large associates they observed with the PEO-*b*-PBLA micelles (6b). They suggest the aggregates of individual micelles may form due to either hydrophobic-hydrophobic interactions or van der Waals interactions between the exposed cores of the individual micelles.

In our case, we had specifically chosen the PEO block to be 44 units in length, since this has most commonly been the length of the PEO stabilizing moieties employed for the steric stabilization of liposomes. However, most likely the length of the PEO blocks is too short to outweigh the hydrophobic-hydrophobic or van der Waals interactions between the exposed polycaprolactone cores. We are now studying the relationship between the PEO chain length and the degree of aggregation achieved in the micelle solution.

Dynamic light scattering measurements were also used to monitor the in vitro stability of the micelles in water and the cell culture media DMEM and RPMI. Over a 3 month period, the micelles were still intact and the population distribution of the micelles in terms of size remained relatively constant. These studies are still ongoing since the in vitro stability of the micelles will determine the extent to which they are suitable for various applications.

4.2 Determination of the Partition Coefficient for Pyrene between the PCL-*b*-PEO Micelles and Water. The affinity of the PCL-*b*-PEO micelles for lipophilic compounds was assayed by the determination of the K_v for the hydrophobic model compound, pyrene, between the PCL-*b*-PEO micelles and water. This method was described in an earlier communication where it had been used to determine the K_v of pyrene between polystyrene-*b*-poly(acrylic acid) micelles and water. This fluorescence method is based on pyrene's sensitivity to the hydrophobicity of its microenvironment. This is reflected in changes in the ratio of the I_3/I_1 bands of its emission spectrum. The method requires the measurement of the I_3/I_1 ratio for pyrene in micelle solutions of various DMF/H₂O solvent mixtures. Figure 2a shows the increase in the I_3/I_1 ratio which accompanies an increase in the water content in the solvent mixture. The increase in the water content within the solvent mixture provides a driving force promoting the entry of pyrene into the more hydrophobic environment of the polycaprolactone micelle core. The I_3/I_1 ratio for pyrene in the many solutions was then used to calculate the partition coefficient for pyrene in each solution. Figure 2b shows the partition coefficients obtained for pyrene in the various micelle solutions, extrapolation of this plot to 100% water content provides the value for the K_v of pyrene between the PCL-*b*-PEO micelles and water. The partition coefficient of pyrene in this micelle system was found to be on the order of 10^2 ; this is low in comparison to a partition coefficient of the order of 10^5 found for pyrene between the polystyrene-*b*-poly(acrylic acid) (PS-*b*-PAA) micelles and water (28). The high value for the K_v of pyrene between the

PS-*b*-PAA micelles and water is thus due to the highly hydrophobic nature of both pyrene and the polystyrene core. The polycaprolactone core, though hydrophobic, is clearly less hydrophobic than polystyrene. However, this value of K_v for pyrene between the PCL-*b*-PEO micelles and water is on the same order of magnitude as that for pyrene in a solution of PEO_{*m*/2}-*b*-PPO_{*n*}-*b*-PEO_{*m*/2} ($m = 51$, $n = 38$) and water at the same temperature (20 °C) (4b).

It should be noted that our measurements for the determination of the partition coefficient for pyrene between the PCL-*b*-PEO micelles and water were all performed at 20 °C. Previously, it was found that the partition coefficient for pyrene between micelles formed from PEO-*b*-PPO-*b*-PEO and water increased by an order of magnitude when the temperature was increased from 20 to 37 °C. This increase is said to be due to the decrease in the degree of hydration of the core-forming block at the higher temperature. Due to the nature of the polycaprolactone core-forming block, we also anticipate an increase in the partition coefficient for pyrene at higher temperatures.

Many studies, have revealed that the greatest degree of solubilization of a compound within a micelle core is achieved when there is a close match between the degree of the polarity and hydrophobicity of the compound and the micelle core (30–32). For this reason, we are now exploring the incorporation of various hydrophobic drugs into micelles with a longer polycaprolactone core forming block. Overall, the incorporation of the highly hydrophobic compound, pyrene, reveals the suitability of this micelle system as a potential carrier for even the most lipophilic compounds.

4.3. In Vitro Biocompatibility of the PCL-*b*-PEO Micelles. The in vitro biocompatibility of the PCL-*b*-PEO micelles (14-*b*-44, 20-*b*-44) was tested by incubating the micelles with a wide range of cell lines for both 24 and 48 h periods. The Trypan blue and Alamar blue survival assays were then used to quantitate the survival rates in the presence of the PCL-*b*-PEO micelles. Figure 3 shows the percent survival obtained for the incubation of the PCL-*b*-PEO micelles [0.02–1% (w/v)] with PC 12 cells over a 24 h period. The survival in the presence of micelles was between 85 and 100%, except for the 70% survival obtained for the incubation of the PCL₁₄-*b*-PEO₄₄ micelles at the lowest concentration. In Figure 3, we see that at several concentrations the survival obtained with the PCL₁₄-*b*-PEO₄₄ is slightly lower than that obtained with the PCL₂₀-*b*-PEO₄₄. For this reason, the 20-*b*-44 PCL-*b*-PEO system, rather than the 14-*b*-44 system, is investigated as the delivery system for FK506 and L-685,818.

The in vitro biocompatibility studies have shown us that addition of a PCL₂₀-*b*-PEO₄₄ micelle solution to the cell well causes little or no cell death. However, the actual destination of the micelles following their addition to the cell well is still unknown. There are several possibilities; they all remain in the supernatant, they all enter the cell, possibly only the small micelles can enter the cell while the larger aggregates remain in the supernatant, or the micelles may aggregate at the cell surface. We are currently investigating the destination of the micelles since this will largely affect the types of drugs which will most effectively be delivered by this system.

4.4. Cell Uptake of Pyrene-Incorporated Micelles. The capability of the PCL-*b*-PEO micelle system to deliver a hydrophobic compound was first tested in vitro using pyrene as a model compound. The pyrene-incorporated PCL-*b*-PEO micelles were incubated with

PC 12 cells over a 24 h period. At 0, 4, 8, and 24 h, samples of the supernatant were studied by fluorescence in order to determine the quantity of pyrene remaining in the supernatant at each time point. Likewise, at each time point, cells were isolated and their fluorescence was examined under the fluorescence microscope, to determine if the decrease in the fluorescence within the supernatant was accompanied by an increase in fluorescence within the cells. Figure 4 shows the pronounced decrease in the fluorescence of the supernatant at the 4 h time point; this decrease was found to be more gradual over the rest of the 24 h period. A similar trend was also seen for the fluorescence of the isolated cells where the fluorescence increases gradually over the 24 h period. At the 24 h time point, the fluorescence is quite intense and appears to be localized in small spherical aggregates.

The cell uptake studies reveal that the addition of pyrene incorporated micelles to the cells does, in fact, result in the accumulation of pyrene within the cells. However, once again, it is unknown whether the micelles have simply remained in the supernatant or have somehow facilitated the entry of pyrene into the cells. Since the partition coefficient for pyrene between water and the PCL-*b*-PEO micelle system is on the order of 10^2 , it seems likely that the micelles either enter the cells themselves or possibly attach themselves to the surface of the cell, enabling the drug to enter the cell without having to enter the hydrophilic cell medium.

4.5. PCL-*b*-PEO Micelles as a Delivery System for FK506 and L-685,818. The size of the PCL-*b*-PEO micelles as well as their in vitro stability, in vitro biocompatibility, and their loading capacity for lipophilic compounds such as pyrene merited further study of this system as a delivery system for hydrophobic drugs. We have chosen FK506 and L-685,818 as the first hydrophobic candidate drugs to be delivered by the PCL-*b*-PEO micellar system.

As mentioned, FK506 and L-685,818 have both been shown to potentiate the effect of NGF on the outgrowth of PC 12 cells (24). To compare the effect of the micelle-incorporated FK506 and L-685,818 with the free drugs, it was necessary to construct dose-response curves for NGF, FK506, and L-685,818 alone as well as the combinations of NGF with FK506 or L-685,818. Figure 5 shows the dose-response curves for each of NGF, FK506, and L-685,818 alone. Clearly, the degree of differentiation of the PC 12 cells increases with increasing concentration of NGF; however, the concentration of either FK506 or L-685,818 alone was found to have no effect on the degree of differentiation (Figure 5). These findings support previous results which have been reported in the literature (27).

Figure 6 shows the degree of differentiation obtained in cells treated with micelle-incorporated FK506 along with NGF and Figure 7 shows that for cells treated with micelle-incorporated L-685,818. The PCL-*b*-PEO-incorporated FK506 and L-685,818 were both found to potentiate the effect of NGF on neurite-like outgrowth in PC 12 cell cultures. Thus, the ability of both FK506 and L-685,818 to potentiate the effect of NGF on neuronal outgrowth was retained despite their incorporation into the PCL-*b*-PEO copolymer micelles (Figures 6 and 7, bars 7–9). The degree of neurite-like outgrowth achieved in cell cultures treated with 5 ng/mL NGF and either micelle-incorporated FK506 or L-685,818 (Figure 6 and 7, bars 7–9) was in both cases less than that obtained when the cells were treated with 5 ng/mL NGF and free FK506 or L-685,818 (Figure 6 and 7, bars 4–6). This may be due to the limited 48 h incubation period over

which time only a fraction of the drug will be released from the micelles. It should be noted that, in vitro, a dose of FK506 as low as 1 nM, is adequate to potentiate neurite-like outgrowth in PC12 cell cultures (Figure 6). Also, in several in vivo studies on rats, it was found that 1 mg/kg of FK506 was an effective dose (33). This micellar delivery system is able to incorporate much higher concentrations of FK506, which will later be released slowly over time. In this way, it will prevent some of the damaging effects that high doses would induce.

In summary, the preliminary results obtained for the novel PCL-*b*-PEO micelle system reveal it to be a promising drug delivery vehicle for the delivery of various lipophilic drugs. The small size and indefinite in vitro stability of the micelles suggest that they may be useful for a wide variety of biomedical applications. Their loading capacity for the very hydrophobic compound, pyrene, encourages the incorporation of many different compounds with a high degree of hydrophobicity. Studies involving the degree of aggregation encountered in the micelle solutions are now underway with special effort placed on limiting the degree of aggregation. Also, now that the in vitro biocompatibility of the micelles has been established, it will be assayed in vivo.

ACKNOWLEDGMENT

The authors would like to thank NSERC for support of this research; in addition, C.A. is grateful to NSERC for financial assistance provided in form of a fellowship. Thanks are also due to Andrea Bardel for her help with the measurement of neurite outgrowth in PC 12 cells. Also the help of Dr. Matthew Moffitt in teaching C.A. the use of dynamic light scattering is deeply appreciated.

Nuclease-resistant aptamers identified from randomized nucleic acid libraries represent a novel class of drug candidates. Aptamers are synthesized chemically and therefore can be readily modified with functional groups that modulate their properties. We report here on the preparation, initial characterization, and functional properties of a nuclease-resistant vascular endothelial growth factor (VEGF) aptamer anchored in liposome bilayers through a lipid group on the aptamer. While the high-affinity binding to VEGF is maintained, the plasma residence time of the liposome-anchored aptamer is considerably improved compared with that of the free aptamer. The lipid group attachment and/or liposome anchoring leads to a dramatic improvement in inhibitory activity of the aptamer toward VEGF-induced endothelial cell proliferation in vitro and vascular permeability increase and angiogenesis in vivo.

INTRODUCTION

Nucleic acids are capable of folding into stable and intricate three-dimensional structures. Randomized nucleic acid libraries therefore contain molecules with many shapes in which functional groups capable of hydrogen bonding, hydrophobic, and charge–charge interactions are arranged in a defined spatial orientation. By taking advantage of iterative cycles of affinity selection and amplification, the SELEX¹ process has emerged in recent years as a highly efficient method of identifying rare nucleic acid ligands (aptamers) from random libraries that bind to other molecules with high affinity and specificity (1–4). The advent of nuclease-stabilized libraries, such as the 2'-amino- or 2'-fluoropyrimidine RNA, has recently increased the utility of the SELEX process as a tool for identifying drug candidates (5–8).

We have recently used the SELEX process to identify 2'-aminopyrimidine RNA aptamers that bind to vascular endothelial growth factor (VEGF) (9), a potent inducer of angiogenesis. Angiogenesis, the growth of new blood vessels from existing vessels, accompanies physiological processes such as wound healing and reproductive cycles and is tightly controlled in healthy adults by opposing effects of positive and negative regulators. Under certain pathological conditions, including proliferative retinopathies, rheumatoid arthritis, psoriasis, and cancer, positive

regulators prevail and angiogenesis contributes to disease progression (reviewed in ref 10). VEGF is unique among angiogenic growth factors described to date in that it specifically stimulates endothelial cell proliferation (11–13) and induces a transient increase in blood vessel permeability with respect to macromolecules (hence, its alternative and original name, vascular permeability factor) (14–16). Increased vascular permeability and the resulting deposition of plasma proteins in the extravascular space assist the new vessel formation by providing a provisional matrix for the migration of endothelial cells (17). Hyperpermeability is indeed a characteristic feature of new vessels (17). In addition, compensatory angiogenesis induced by tissue hypoxia is now known to be mediated by VEGF (18, 19). Most tumors and tumor cell lines are capable of producing and secreting VEGF, and inhibition of VEGF activity leads to the reduced rate of tumor growth as well as the reduced incidence of metastases. Together, these observations have led to the assertion that VEGF is the crucial positive regulator of angiogenesis (20, 21). VEGF is a secreted disulfide-linked homodimer that occurs in four forms (VEGF-121, VEGF-165, VEGF-189, and VEGF-206) as a result of alternative splicing of the VEGF gene, with VEGF-165 being the most abundantly occurring form (22, 23). The biological effects of VEGF are mediated through two tyrosine kinase receptors (Flt-1 and Flk-1/KDR) whose expression is highly restricted to cells with endothelial and hematopoietic origins (24–27).

In the 2'-aminopyrimidine RNA aptamer, the subnanomolar binding affinity for VEGF-165 is encoded in a sequence of 24 nucleotides (9). We have achieved additional resistance to nuclease degradation by adding short phosphorothioate caps at the 3' and 5' ends and by substituting 2'-O-methylpurine nucleotides at all purine positions (10 out of 14) that tolerate such a substitution without loss of binding affinity. Such an aptamer (NX213 = 5'-dT^sdT^sdT^sdT^smAaCaCaCaUrGrAaUmGrGaUmAmGrAaCmGaCaCmGmG mGmGaUmGdT^sdT^sdT^sdT^sdT-3', where prefixes d, r, a, and m denote deoxy-, ribodeoxy-, 2'-amino-, and 2'-O-methylnucleotides and a superscript

s denotes phosphorothioate internucleoside linkages) inhibited the binding of [^{125} I]VEGF to receptors expressed on human umbilical vein endothelial cells (HUVECs) with an EC_{50} of ≈ 1 nM, suggesting that the aptamer could be an inhibitor of VEGF-mediated effects (9). However, compared to its very good stability in biological fluids in vitro (9), the residence time of NX213 in plasma in vivo was found to be very short (see below), mostly as a consequence of rapid renal clearance (S. C. Gill and R. Fielding, unpublished results). Since aptamers in the 20–35-nucleotide size range have molecular masses of ≈ 7 –12 kDa, one obvious way of increasing their plasma residence times is by associating them with large, inert entities. Liposomes represent a class of supramolecular assemblies that could be used for this purpose. We report here on the synthesis and initial characterization of a lipid (dialkylglycerol, DAG) derivative of the VEGF aptamer (DAG–NX213) in which the lipid group is used to anchor the aptamers in liposome bilayers. The preparation of liposome-anchored aptamers is essentially as straightforward as the preparation of unloaded liposomes. Importantly, both the addition of the DAG group and liposome anchoring do not interfere with the ability of the aptamer to bind to VEGF with a high affinity. The plasma residence time of the liposome-anchored aptamer (DAG–NX213-L) is considerably longer than that of NX213. We also show that DAG–NX213 and/or DAG–NX213-L exhibit enhanced inhibitory activity compared with the free aptamer toward VEGF-induced endothelial cell proliferation in vitro and vascular permeability increase and CAM angiogenesis in vivo.

EXPERIMENTAL PROCEDURES

Preparation of the DAG Phosphoramidite Reagent. Tetraethylene Glycol Monotosylate (2). Tetraethylene glycol (200 mL, 1.15 mol) was dissolved in 500 mL of pyridine, cooled to 0 °C, and treated with 22.0 g (0.115 mol) of *p*-toluenesulfonyl chloride. Once the solution was formed, the reaction mixture was stored in the refrigerator overnight, and then concentrated in vacuo. The residue was dissolved in 800 mL of EtOAc and extracted with 3 $\times$ 600 mL of H₂O. The H₂O fractions were back-extracted with EtOAc, and the combined EtOAc fractions were extracted with saturated aqueous Na₂HPO₄. The organic phase was dried over MgSO₄ and concentrated to a colorless oil. The oil was purified by flash chromatography using 800 mL of silica gel and eluting with hexane, then 25% EtOAc/50% EtOAc in hexane, then EtOAc, and then 10% MeOH/20% MeOH in EtOAc to afford 23.7 g (60%) of pure product and 11% of product containing a minor impurity: ^1H NMR (300 MHz, CDCl₃) δ 7.77 (d, J = 8.1 Hz, 2H), 7.32 (d, J = 8.1 Hz, 2H), 4.13 (t, J = 4.8 Hz, 2H), 3.68–3.53 (m, 14H), 2.58 (t, J = 5.6 Hz, 1H), 2.42 (s, 3H); ^{13}C NMR (75 MHz, CDCl₃) δ 168.2, 158.3, 144.8, 135.9, 133.8, 132.0, 129.9, 128.0, 127.7, 126.6, 123.1, 113.0, 85.9, 73.0, 70.6, 70.4, 70.0, 69.7, 67.8, 64.4, 55.1, 37.1; low-resolution MS m/z calculated for C₁₅H₂₄O₈S (M + 1) 349.1 Da.

Tetraethylene Glycol Monophthalimide (3). To a stirred solution of 31.96 g (0.092 mol) of **2** in 400 mL of anhydrous DMF were added 14.2 g (1.05 equiv) of phthalimide and 14.4 mL (1.05 equiv) of 1,8-diazabicyclo[5.4.0]undec-7-ene. The solution was heated at 70 °C for 18 h and then concentrated in vacuo. The crude yellow oil was purified by flash chromatography using 1600 mL of silica gel and eluting with 25% EtOAc/50% EtOAc/75% EtOAc in hexane, then EtOAc, and then 10% MeOH/20% MeOH in EtOAc to afford 23.8 g (80%) of **3** as an oil. Upon standing, **3** became a waxy white solid: ^1H NMR (300

MHz, CDCl₃) δ 7.84–7.78 (m, 2H), 7.70–7.66 (m, 2H), 3.86 (t, J = 5.6 Hz, 2H), 3.70 (t, J = 5.6 Hz, 2H), 3.64–3.51 (m, 12H), 2.67 (bs, 1H); ^{13}C NMR (75 MHz, CDCl₃) δ 168.2, 133.8, 132.0, 123.1, 72.4, 70.5, 70.4, 70.2, 70.0, 67.8, 61.6, 37.2.

Synthesis of Compound 4. A solution of 15 g (0.0464 mol) of **3** in 150 mL of THF and 15 mL of DMF was cooled to 0 °C under Ar. Allyl bromide (6.0 mL, 1.5 equiv) was added to the solution, followed by addition of 1.76 g (1.5 equiv) of NaH as a solid. The opaque yellow suspension was stirred at 0 °C for 30 min and then at room temperature for 18 h. MeOH (50–100 mL) was added, and the mixture was concentrated in vacuo. The crude material was purified by flash chromatography using 1500 mL of silica gel and eluting with 25% EtOAc/50% EtOAc/75% EtOAc in hexane, then EtOAc, and then 10% MeOH in EtOAc to afford 11.05 g (65%) of **4** as a yellow oil: ^1H NMR (300 MHz, CDCl₃) δ 7.84–7.80 (m, 2H), 7.72–7.67 (m, 2H), 5.94–5.84 (m, 1H), 5.28–5.14 (m, 2H), 3.99 (d, J = 5.61 Hz, 2H), 3.88 (t, J = 5.85 Hz, 2H), 3.72 (t, J = 5.76 Hz, 2H), 3.64–3.54 (m, 13H); ^{13}C NMR (75 MHz, CDCl₃) δ 168.0, 134.6, 133.7, 131.9, 123.0, 116.9, 72.0, 70.4, 69.9, 69.2, 67.7, 37.0.

1-(Dimethoxytrityl)-3-(phthalimidotetraethylene glycolyl)-rac-glycerol (5). To a stirred solution of **4** (10.13 g, 0.0279 mol) in 100 mL of acetone and 1 mL of H₂O was added 3.98 g (1.22 equiv) of *N*-methylmorpholine *N*-oxide. To this suspension was added 1.75 mL (0.005 equiv) of OsO₄ as a 2.5% solution in i -PrOH. After addition of the OsO₄ solution, the reaction mixture became clear yellow. After TLC analysis indicated complete conversion of **4** (ca. 16 h), the reaction mixture was treated with 1.5 g of sodium hydrosulfite and 5.0 g of florisil and stirred for 30 min. The suspension was filtered through florisil, and the filtrate was concentrated to an oil. This crude product was combined with another batch prepared in the same manner from 1.0 g of **4**. Two 100 mL portions of pyridine were coevaporated from the combined lots, and the residue was dissolved in 300 mL of pyridine. The solution was cooled to 0 °C, and 10.89 g (1.05 equiv) of 4,4'-dimethoxytrityl chloride was added. A drying tube was placed into the flask, and the reaction mixture was stirred at room temperature for 16 h. The solution was treated with 20 mL of MeOH and concentrated in vacuo, keeping the temperature of the water bath below 40 °C. The crude oil was purified by flash chromatography using 1100 mL of silica gel (wet-packed onto the column using 3% triethylamine in hexane) and eluting with 10–100% EtOAc in hexane (all containing 3% triethylamine) to give 21.3 g (89% after two steps) of **5** as a yellow oil: ^1H NMR (300 MHz, CDCl₃) δ 7.80–7.77 (m, 2H), 7.66–7.64 (m, 2H), 7.39–7.22 (m, 9H), 7.20–6.76 (m, 4H), 3.97 (bs, 1H), 3.84 (t, J = 5.97 Hz, 2H), 3.74 (s, 6H), 3.68 (t, J = 5.7 Hz, 2H), 3.60–3.49 (m, 14H), 3.13–2.76 (m, 2H), 2.00 (bs, 1H); ^{13}C NMR (75 MHz, CDCl₃) δ 168.2, 158.3, 144.8, 135.9, 133.8, 132.0, 129.9, 128.0, 127.7, 126.6, 123.1, 113.0, 85.9, 73.0, 70.6, 70.4, 70.0, 69.7, 67.8, 64.4, 55.1, 37.1; low-resolution MS m/z calculated for C₄₀H₄₅O₁₀N (M + NH₄⁺) 717.5 Da.

1-(Dimethoxytrityl)-3-(aminotetraethylene glycolyl)-sn-glycerol (6). Compound **5** (5.2 g, 7.2 mmol) was taken up in 50 mL of 40% methylamine in H₂O, and 10 mL of methanol was added to solubilize the starting material. The reaction mixture was heated at 50 °C for 5 h and then concentrated in vacuo and coevaporated with toluene. The crude material was purified by flash chromatography on 200 mL of silica gel, eluting with 15% methanolic ammonia in dichloromethane. **6** (3.94 g, 96%) was collected as a pale yellow oil: ^1H NMR (300 MHz,

CDCl_3) δ 7.46–7.21 (m, 9H, DMT), 6.81 (d, 4H, DMT), 4.00 (m, 1H), 3.80 (s, 6H), 3.70–3.49 (overlapping m, 18H), 3.20 (dd, $J = 9.24, 5.49$ Hz, 1H), 3.12 (dd, $J = 9.21, 6.0$ Hz, 1H), 2.84–2.80 (m, 3H); ^{13}C NMR (75 MHz, CDCl_3) δ 158.30, 144.82, 136.01, 129.95, 128.04, 127.66, 126.61, 112.95, 85.85, 73.46, 72.85, 70.55, 70.45, 69.99, 69.51, 64.43, 55.10, 41.40; low-resolution MS m/z calculated for $\text{C}_{32}\text{H}_{44}\text{O}_8\text{N}$ ($M + 1^+$) 570.353 Da, found 570.4 Da.

Chloroformate 7. To a stirred solution of 3 g (5.03 mmol) of 1,2-di-*O*-octadecyl-*sn*-glycerol in 60 mL of toluene was added 20 mL of a 1.93 M solution of phosgene. Additional phosgene solution (2×10 mL, total of 15.4 equiv of phosgene) was added until no further alcohol starting material remained (by ^1H NMR analysis of concentrated aliquots). The excess phosgene and HCl was removed with an aspirator, and the reaction mixture was concentrated in vacuo to afford 3.3 g (98%) of the desired chloroformate **7** as a white powder: ^1H NMR (300 MHz, CDCl_3) δ 4.45 (dd, $J = 11.22, 3.69$ Hz, 1H), 4.34 (dd, $J = 11.22, 6.15$ Hz, 1H), 3.65 (m, 1H), 3.56–3.40 (m, 6H), 1.53 (m, 4H), 1.24 (m, 62H), 0.87 (t, $J = 6.36$ Hz, 6H); ^{13}C NMR (75 MHz, CDCl_3) δ 75.90, 71.91, 71.35, 70.93, 69.36, 31.99, 29.96–29.44 (overlapping signals from hydrocarbon chains), 26.13, 26.04, 22.76, 14.18.

Conjugate 8. To a stirred solution of 2.25 g (3.95 mmol) of **6** in 60 mL of pyridine was added 2.6 g of the distearyl glycerol chloroformate **7**. ^1H NMR analysis of a concentrated aliquot after 2 h revealed no remaining chloroformate, and the mixture was concentrated in vacuo. The crude residue was combined with material similarly prepared from 0.5 g (0.88 mmol) of **6** and 0.58 g of the chloroformate **7**, and the combined lots were purified by flash silica gel chromatography on a column of 100 mL of silica gel (packed in hexanes containing 2% triethylamine) eluting with 200 mL hexanes, and then 250 mL each of 10–20 and 30% EtOAc in hexanes and 500 mL of 40% EtOAc in hexanes, then 250 mL each of 50, 60, 70, and 80% EtOAc in hexanes, and finally with 250 mL of EtOAc. The product-containing fractions were concentrated to afford 3.3 g (57%) of the conjugate **8**.

Phosphoramidite 9. To a stirred solution of 3.8 g (3.26 mmol) of conjugate **8** in 25 mL of CH_2Cl_2 were added 1.14 mL (6.52 mmol) of diisopropylethylamine and then 1.09 mL (4.88 mmol) of 2-cyanoethyl *N,N*-diisopropylchlorophosphoramidite. After 2 h, the mixture was diluted with CH_2Cl_2 and washed with a saturated NaHCO_3 solution, dried over Na_2SO_4 , and concentrated. The crude residue was purified by flash silica gel chromatography on a column of 125 mL of silica gel (packed in hexanes containing 2% triethylamine) eluting with 100 mL hexanes, then 250 mL each of 10 and 20% EtOAc in hexanes and 500 mL of 30% EtOAc in hexanes, and then 250 mL of 50% EtOAc in hexanes. The product-containing fractions were concentrated to afford 4.2 g (95%) of the phosphoramidite **9**: ^{31}P NMR (CDCl_3) δ 151.52, 151.08.

Preparation of DAG–Aptamers. The VEGF aptamer (NX213) and its scrambled analogue (scNX213) were prepared by standard solid phase oligonucleotide synthesis protocols as described (ref 9 and references therein). For DAG-conjugated aptamers, phosphoramidite **9** dissolved in CH_2Cl_2 (acetonitrile was not an adequate solvent) was added as the last coupling step to the 5' end of the aptamers (two 30 min coupling cycles using a 4-fold excess of the amidite; coupling efficiency $\approx 90\%$, by dimethoxytrityl absorbance). The DAG–aptamer was purified by reverse phase HPLC (PRP-1 column, Hamilton, Reno, NV) using a 100 mM triethylammonium acetate/acetonitrile gradient followed by desalting and

salt (Na^+ for triethylammonium) exchange (PRP-1 column). Following purification, $>99\%$ of the oligonucleotide contained the DAG moiety. Electrospray mass spectroscopic analysis of DAG–NX213 indicated two major components with m/z values of 11 714.2 and 11 699.2 Da (calculated mass of DAG–NX213 = 11 715.3 Da). The m/z 11 699.2 Da component (≈ 16 Da less than calculated) is probably due to incomplete oxidation by the sulfurizing reagent (Glen Research, Sterling, VA), resulting on average in seven instead of eight phosphorothioate internucleoside linkages per molecule.

Preparation of Liposome-Associated Aptamers.

A spray-dried mixture of 1,2-distearoyl-*sn*-glycero-3-phosphatidylcholine (DSPC) and cholesterol (2 mol:1 mol) was placed in a 14 mL Pyrex glass centrifuge tube (50 mg of total lipid) and suspended in a 1 mL solution containing 1 mg/mL (0.12 mol %) DAG–NX213 or DAG–scNX213 in 9% sucrose buffered to pH 7.4 with 25 mM sodium phosphate. The lipid suspension was incubated for 5–15 min at 65 °C, gently mixed until evenly suspended, and sonicated with a 0.125 in. microtip probe at 65 °C with an approximately 215 W input power using a model 475 Virsonic power supply (Virtis, Gardiner, NY). The progress of the sonication was followed by particle sizing using dynamic light scattering (Leeds Northrop MicroTrac Model 150 Particle Analyzer, Honeywell, Ft. Washington, PA). Liposome sizing was determined by the volume of distribution method using the manufacturer's protocol (MicroTrac). Sonication was typically stopped when the liposomes reached an essentially unimodal distribution with a mean vesicle diameter of approximately 50–65 nm. The final liposome product is sterilized by filtration through a 0.2 μm syringe filter (Supor Acrodisc 25, Gelman Sciences, Ann Arbor, MI). The total concentration of aptamer in the liposomal formulation was determined from the absorbance value at 260 nm ($\epsilon_{260} = 27 \text{ au mg}^{-1} \text{ mL}^{-1}$) in a 0.1% sodium dodecyl sulfate solution. In all experiments with the liposome-anchored aptamer, the total aptamer concentration was used without a correction for the orientation of the aptamer in the liposome bilayer (see below).

Ribonuclease T₁ Digestion of the Free and Liposomal Aptamers. All digests were performed with ^{32}P 3' end-labeled DAG–NX213 at 8 pmol/ μL and 20 units/ μL RNase T₁ in 25 mM sodium phosphate buffer (pH 7.4) containing 9% sucrose. The digests were terminated by adding an equal volume of gel loading solution (80% formamide, 89 mM Tris borate, 1 mM EDTA, 2% sodium dodecyl sulfate, and 0.7 M β -mercaptoethanol), followed by heating at 95 °C for 2 min and cooling on ice before loading on a 20% polyacrylamide/7 M urea gel.

Plasma Pharmacokinetics. The pharmacokinetic properties of VEGF aptamers NX213, DAG–NX213, and DAG–NX213-L were determined in Sprague-Dawley rats. In each study, the aptamer was diluted in PBS to a concentration of 1.0 mg/mL on the basis of UV absorption at 260 nm and an extinction coefficient of 0.037 mg of oligo/mL. In all studies, six rats received 1.0 mg of oligonucleotide/kg of animal weight by bolus tail vein injection and EDTA plasma samples were taken at various times from 2 min to 4 h. The standards, plasma samples, and quality control samples were analyzed using a hybridization assay. The hybridization assay utilized a capture oligonucleotide that contains a complementary sequence at the 5' end of the VEGF aptamer conjugated to an iron oxide (FeO) bead [FeO -spacer-3'-d(GCCTTAGTCACTT)-5' where spacer = (dT)₈] and a detection oligonucleotide containing two biotin molecules at the 5' end [biotin-biotin-5'-d(spacer-CGGATGTATAAG-

CA)-3', where spacer = (dT)₈]. After incubation of the capture and detection probes with a plasma sample containing VEGF aptamers, the amount of the biotin oligonucleotide hybridized to the bead was quantitated with the streptavidin-linked alkaline phosphatase, using CSPD-Sapphire (Tropix, Bedford, MA) as the luminescent substrate. For each aptamer, the standard curve and quality control samples were matched to the aptamer being analyzed. Standard curves were fit using a four-parameter logistic equation (PRISM, version 2.00, Graph-Pad, San Diego, CA). Sample and quality control concentrations were extrapolated from the standard curve and corrected for dilution. Data for each formulation were pooled, and the pharmacokinetic parameters were analyzed using two-compartment compartmental analysis (weighting $1/y^2$, WinNonlin Pro, version 1.1.12, Scientific Consulting, Inc., Apex, NC).

Competition Electrophoretic Mobility Shift Assay. ³²P 5' end-labeled NX213 (1.5 nM) was incubated in binding buffer (phosphate-buffered saline with 0.01% human serum albumin) at 37 °C for 20 min in the presence of VEGF-165 (R&D Systems, Minneapolis, MN; 0.33 nM) and competitor oligonucleotide (5 pM to 0.33 μM). The [³²P]NX213-VEGF complex was resolved from the free [³²P]NX213 by electrophoresis on an 8% polyacrylamide gel (19:1 acrylamide/bisacrylamide, Tris-borate, 89 mM, and 1 mM EDTA as the running buffer). The intensity of the band corresponding to the [³²P]-NX213-VEGF complex at varying competitor concentrations was quantitated by phosphorimager analysis. Data normalized for the amount of complex formed in the absence of competitor were fitted by the least-squares method to a competition binding equation that describes the mutually exclusive binding of two species to the same target (28).

Receptor Binding Inhibition. Confluent cultures of HUVECs in 24-well plates were incubated with [¹²⁵I]-VEGF-165 (Amersham, Arlington Heights, IL; 20 ng/mL) and varying amounts of aptamers for 2 h at 4 °C. At the end of the 2 h incubation period, the supernatant was aspirated and the wells were washed two times with cold PBS. HUVECs were then lysed with 1% Triton X-100, and the amount of cell-associated [¹²⁵I]VEGF was determined by γ counting.

[³H]Thymidine Incorporation Assay. HUVECs (population doubling of 4–12) were plated at a density of 10⁴/well on 96-well plates in MEM supplemented with 10 mM HEPES (pH 7.4) and 1 μg/mL heparin (from porcine lungs, Sigma, St. Louis, MO). Following a 4–5 h attachment period, quiescence was induced by overnight incubation in MEM containing 0.5% fetal bovine serum and 1 μg/mL heparin. VEGF was then added to the cell cultures in the presence or absence of aptamers for a period of 48 h. [³H]Thymidine was added in the last 24 h of incubation, and the amount of DNA-associated [³H]thymidine was determined by scintillation counting.

Dermal Vascular Permeability Assay. The ability of the test aptamers to attenuate VEGF-induced changes in the permeability of the dermal vasculature (Miles assay) was performed as previously described (15, 29) with minor modifications. Briefly, adult female guinea pigs (three per study) were anesthetized with isoflurane, and the hair on the dorsal and lateral back areas was removed with clippers. Evans Blue dye (2.5 mg/guinea pig) was administered intravenously. Injection solutions (PBS, VEGF, and aptamers) were prepared ≥30 min in advance and comixed where indicated. Each solution shown was then injected intradermally (duplicate injec-

tions for each guinea pig, 40 μL/site) in a randomized manner in a grid pattern drawn on the clipped area. Guinea pigs were allowed to recover from anesthesia and were sacrificed by CO₂ exposure 30 min after completion of the intradermal injections. The skin was harvested, trimmed free of subcutis, and transilluminated. Images were then captured using a color CCD camera (Hitachi Denshi KP-50U) and Image-Pro Plus software (version 3.1, Media Cybernetics, Silver Springs, MD). Each skin sample was normalized for intensity with each injection site analyzed for optical density and the area involved.

Chicken Allantoic Membrane (CAM) Assay. The effect of various VEGF aptamers on VEGF-induced angiogenesis was tested in CAMs. Angiogenesis was induced in CAMs by placing filter disks saturated with VEGF on 10-day-old embryos. Coded test compounds (1 μM) or an equal amount of the carrier buffer (100 μL) was injected into the vessels on the following day. CAMs were resected on day 3 and analyzed using an Olympus stereomicroscope. The number of branching blood vessels infiltrating under the disk were counted and photographed. The average number of blood vessels under the disks soaked in buffer alone were subtracted from all groups.

RESULTS

Preparation of Liposome-Anchored VEGF Aptamers. To allow stable membrane anchoring, we used the solid phase phosphoramidite method to prepare a lipid derivative of the VEGF aptamer in which two 18-carbon saturated unbranched hydrocarbon chains were attached via glycerol ether linkages. The dialkylglycerol (DAG) phosphoramidite containing a tetraethylene glycol spacer was synthesized in seven steps and introduced at the 5' end of the VEGF aptamer (Figure 1A,B). DAG-NX213 was readily purified by reverse phase HPLC since the retention time of the lipid-containing aptamer is considerably greater than that of the aptamer without the lipid group. To incorporate DAG-NX213 into the bilayer of liposomes, we sonicated a solution of DAG-NX213 (1 mg/mL) in 25 mM sodium phosphate buffer (pH 7.4) containing 9% sucrose in the presence of a 50 mg/mL spray-dried hydrated mixture of distearoylphosphatidylcholine (DSPC) and cholesterol (2 mol:1 mol). The ratio of DAG-NX213 to lipids was chosen arbitrarily and is not optimized for any purpose. On the basis of size exclusion chromatography, all of the DAG-aptamer was found to be associated with the liposome fraction following sonication. Importantly, aptamer fragments were not observed following liposome preparation, either by size exclusion chromatography or by HPLC, indicating that the DAG-aptamer is stable to sonication conditions (data not shown). In a typical preparation, liposomes with a mean diameter of ≈50–65 nm were obtained (Figure 2A). Liposomes prepared in this manner were visualized by electron microscopy in freeze-fracture preparations (30) (Figure 2B). Assuming surface areas of 44.5 Å for DSPC and 39 Å for cholesterol (31), for spherical liposomes with a homogeneous lipid distribution [2 mol of DSPC (MW = 790.2) per mole of cholesterol (MW = 386.7)] and a membrane thickness of 50 Å, we calculated the number of lipids per liposome to be 3.02×10^4 and 4.88×10^4 for liposomes with 50 and 65 nm diameters, respectively. On the basis of these values, we estimate that there are on average approximately 34–60 aptamers per liposome for 50–65 nm liposomes.

In the absence of the DAG-NX213 aptamer, liposomes with a comparable size distribution were obtained using

Figure 2. Characterization of physical properties of the liposomal VEGF aptamer (DAG-NX213-L). (A, top left) The size of DAG-NX213-L particles was determined by quasi-elastic light scattering using a Leeds & Northrup Model Microtrack UPA 150 particle analyzer (Horsham, PA). The distribution by liposome volume as a function of diameter is shown. (B, bottom left) Freeze-fracture electron micrograph of DAG-NX213-L. (C, top right) Accessibility of DAG-NX213 to ribonuclease T₁ as a function of formulation. RNase T₁ digests of DAG-NX213 alone (lanes 1–4), DAG-NX213 mixed with preformed liposomes (lanes 5–8), and DAG-NX213 incorporated into liposomes by sonication (DAG-NX213-L, lanes 9–12) are shown resolved on a 20% polyacrylamide/7 M urea gel. In the first lane of each set (lanes 1, 5, and 9), no RNase was added. In the second lane of each set (lanes 2, 6, and 10), the gel loading solution (which inactivates the RNase) was added to the samples prior to adding RNase. In the third lane of each set (lanes 3, 7, and 11), the samples were incubated with RNase T₁ for 30 min at 20 °C. In the fourth lane of each set (lanes 4, 8, and 12), the samples were incubated with RNase T₁ for 30 min at 20 °C in the presence of 0.1% Triton X-100. (D, bottom right) Schematic representation of liposome-anchored aptamers.

increase was studied in guinea pigs (Figure 7). Test aptamers at various concentrations were coinjected intradermally with VEGF (20 nM) in guinea pigs preinjected with Evans blue dye. Because the recovery of the dye by organic solvent extraction is generally very inefficient, we have developed a quantitation method that measures the absorption of light through the skin. NX213 at concentrations up to 10 μ M was not able to inhibit the vascular permeability activity of VEGF. DAG-NX213 and DAG-NX213-L, on the other hand, inhibited about 60 and 90% of the VEGF-induced permeability increase, respectively, at the highest aptamer concentration tested (10 μ M), with comparable IC₅₀ values of 0.3–0.5 μ M. Sequence-scrambled analogues of these compounds were not inhibitory (data not shown).

Effect of VEGF Aptamers on VEGF-Induced Angiogenesis in Chicken Chorioallantoic Membranes (CAMs). VEGF is a potent inducer of angiogenesis in a number of in vivo model systems. The effect of various VEGF aptamers on VEGF-induced angiogenesis was tested in CAMs. Capillary vessel formation within the CAMs has been used extensively as a convenient in vivo model system for studying the angiogenic and angiostatic activity of various compounds (32). Angiogenesis was induced in CAMs by placing filter disks saturated with VEGF on 10-day-old embryos. Coded test compounds (1 μ M) or an equal amount of the carrier buffer (100 μ L) was injected into the vessels on the following day. CAMs were resected on day 3 and analyzed using a stereomicroscope. The number of branching blood vessels infil-

Figure 3. Plasma pharmacokinetic properties of NX213, DAG-NX213, and DAG-NX213-L in Sprague-Dawley rats. Aptamers were administered by intravenous injection via the tail vein, at a dose of 1 mg of aptamer per kilogram of animal weight. EDTA plasma samples were analyzed using a double-hybridization assay: NX213 (○), DAG-NX213 (◇), and DAG-NX213-L (□). Data from two to five animals were used per data point ($\pm$ SEM).

Table 1. Summary of Aptamer Pharmacokinetic Parameters in Plasma after Intravenous Bolus Administration in Sprague-Dawley Rats Determined from the Data Shown in Figure 3 (Compartmental Analysis)

parameter	NX213	DAG-NX213	DAG-NX213-L
total AUC ($\mu\text{g min}^{-1} \text{mL}^{-1}$) ^a	147	202	531
C, $t = 0$ min ($\mu\text{g/mL}$)	14.59	23.16	16.95
C, $t = 2$ min ($\mu\text{g/mL}$)	15.31	14.08	15.74
$\alpha(t_{1/2})$ (min)	7	3	13
$\beta(t_{1/2})$ (min)	49	67	113
clearance ($\text{mL kg}^{-1} \text{min}^{-1}$)	6.80	4.95	1.88
V_{ss} (mL/kg)	72	251	152

^a AUC = area under the curve.

Figure 4. Binding affinities of NX213, DAG-NX213, and DAG-NX213-L and their sequence-scrambled analogues for VEGF. A competition electrophoretic mobility shift assay was used to determine the binding affinities of NX213 (○), DAG-NX213 (◇), and DAG-NX213-L (□) and their sequence-scrambled analogues scNX213 (●), DAG-scNX213 (◆), and DAG-scNX213-L (■). In all cases, competitor concentration refers to the total concentration of oligonucleotide (without a correction for aptamer accessibility).

trating under the disk were counted and photographed. The average number of blood vessels under the disks soaked in buffer alone was subtracted from all groups. The only compound that effectively blocked VEGF-induced angiogenesis was DAG-NX213-L, while NX213, DAG-NX213, and DAG-scNX213-L had a smaller effect or no effect (Figure 8).

DISCUSSION

The SELEX process has recently emerged as an efficient method of identifying aptamers with high affinities

Table 2. Relative Binding Affinities of NX213, DAG-NX213, DAG-NX213-L, and Their Sequence-Scrambled Analogues^a

aptamer	$K_d^{\text{aptamer}}/K_d^{\text{NX213}}$ ^a
NX213	(1.0)
DAG-NX213	1.6 ± 0.3
DAG-NX213-L	4.7 ± 0.7
scNX213	$(1.3 \pm 0.9) \times 10^3$
DAG-scNX213	$(5.0 \pm 0.7) \times 10^2$
DAG-scNX213-L	$(3.1 \pm 3.4) \times 10^3$

^a The value of K_d for NX213 binding to VEGF calculated from the competition binding experiment is $(3.2 \pm 0.2) \times 10^{-10}$ M.

Figure 5. Effect of NX213, DAG-NX213, and DAG-NX213-L aptamers and their sequence-scrambled analogues on the binding of [¹²⁵I]VEGF to cell surface receptors expressed on human umbilical vein endothelial cells (HUVECs). Confluent cultures of HUVECs were incubated with 20 ng/mL [¹²⁵I]VEGF and varying amounts of NX213 (○), DAG-NX213 (◇), and DAG-NX213-L (□) and their sequence-scrambled analogues scNX213 (●), DAG-scNX213 (◆), and DAG-scNX213-L (■). Data points represent averages of two determinations.

for a variety of molecular targets. As chemically synthesized molecules, aptamers are uniquely amenable to a wide range of chemical modifications. In attempts to develop aptamer-based drug candidates, many such modifications have been aimed at improving the functional efficacy of the aptamers in vivo. For example, the affinity, specificity, and nuclease resistance have been substantially improved by the introduction of a series of 2'-O-methylpurine substitutions (9). Hicke et al. have recently shown that poly(ethylene glycol)-derivatized L-selectin DNA aptamers have improved pharmacokinetic properties and that this translated into more effective inhibition of lymphocyte trafficking in vivo (33).

Here we have shown that a lipid group such as DAG can be introduced into a prototypic aptamer with minimal effects on the binding affinity. Although we have employed the solid phase phosphoramidite method to conjugate the DAG group to the aptamer, solution coupling methods as well as other types of coupling chemistries are clearly feasible. Indeed, it has been demonstrated previously that hydrophobic groups can be introduced into oligonucleotides by a variety of methods and that such lipid-oligonucleotide conjugates have altered physical and pharmacokinetic properties (34–38). Lipid groups such as DAG permit stable anchoring into bilayers of liposomes. This notion has been recognized previously and exploited for improving the circulating levels in plasma of low-molecular weight molecules such as small peptides and carbohydrates (39, 40).

The plasma circulating time of the lipid-modified VEGF aptamer (DAG-NX213) is somewhat improved compared to that of the underivatized aptamer (NX213),

Figure 6. Effect of NX213, DAG-NX213, and DAG-NX213-L aptamers and their sequence-scrambled analogues on VEGF-induced HUVEC proliferation. (A) Dose response of VEGF added to the culture medium. (B) The effect of NX213 (○), DAG-NX213 (◇), DAG-NX213-L (□), DAG-scNX213-L (◆), and DAG-NX213-L (■) on HUVEC proliferation induced with 3 ng/mL VEGF. Values are the mean (five determinations) $\pm$ SEM.

Figure 7. Effect of NX213, DAG-NX213, and DAG-NX213-L aptamers on VEGF-induced vascular permeability increase. The local extravasation of Evans blue dye was determined 30 min after injection of VEGF (0.8 pmol) in the presence or absence of aptamers by transillumination of harvested skin. Values are the mean (two to ten determinations) $\pm$ SEM. An asterisk indicates that $P < 0.05$ compared with that for VEGF alone.

as has been observed with other lipid-modified nucleic acids (38). This is probably the result of the association of DAG-NX213 with lipoproteins in plasma (38). Liposome anchoring of the DAG-NX213 aptamer, however, clearly leads to a further substantial increase in its plasma lifetime. Liposomes with the same lipid composition and size as those used in this work in which the unconjugated aptamer (NX213) was encapsulated in the interior of the liposome exhibit considerably longer plasma residence times (total AUC $\approx 4900 \mu\text{g min}^{-1} \text{mL}^{-1}$, clearance $\approx 0.2 \text{ mL kg}^{-1} \text{min}^{-1}$; see Table 1) compared with liposomes that carry DAG-NX213 in their bilayers (data not shown). Thus, like peptides and

Control CAM

DAG-NX213-L-treated CAM

Figure 8. Effect of NX213, DAG-NX213, and DAG-NX213-L aptamers and their sequence-scrambled analogues on VEGF-induced angiogenesis in CAMs. VEGF-saturated filter disks were used on 10-day-old CAMs to induce angiogenesis. Test compounds or buffer (PBS) was injected intravascularly on the following day, and the number of branching blood vessels infiltrating the disks were counted on day 3. Five to twelve CAMs were studied for each compound, and the experiments were repeated at least two times with similar results. (A, top) Relative angiogenesis scores normalized to the number of new blood vessels observed in the group of CAMs containing the VEGF-saturated disks and treated with PBS alone ($\pm$ SEM). An asterisk indicates that $P < 0.05$ compared with that of the control (PBS) group alone, and two asterisks indicate that $P < 0.05$ compared with that of NX213 or DAG-NX213. (B, bottom) Representative CAMs containing VEGF-saturated disks (covering the entire CAM) treated with buffer alone (upper panel) or DAG-NX213-L (lower panel).

antibodies (39, 41), surface-immobilized aptamers appear to reduce the plasma residence times of liposomes.

Liposome anchoring of DAG-NX213 causes a small apparent reduction in the binding affinity for VEGF (Figure 4) which is probably due in part to the fact that

some of the aptamer is anchored in the inner leaflet of the bilayer and is therefore inaccessible to VEGF in solution. However, since liposome anchoring also creates a multivalent display of the aptamer (which is expected to increase the apparent affinity) in addition to imposing steric and orientational constraints on binding (which may reduce the apparent affinity), a straightforward interpretation of affinity is not possible from the data. Like NX213, DAG-NX213 and DAG-NX213-L aptamers inhibited the binding of VEGF to its endothelial cell receptors, albeit at ≈ 5 -fold reduced potency compared with that of NX213. In contrast to the modest reduction in the binding affinity for VEGF and in the receptor binding inhibitory activity, DAG-NX213 and DAG-NX213-L exhibited a considerably greater potency in inhibiting VEGF-induced DNA synthesis in endothelial cells compared with NX213 (NX213 showed no inhibition up to $1 \mu\text{M}$). Similar inhibitory activity enhancement was observed with DAG-NX213 and DAG-NX213-L compared to that with NX213 in the vascular permeability assay, with DAG-NX213-L showing the most complete inhibition and NX213 being ineffective up to $10 \mu\text{M}$. In the CAM angiogenesis assay, DAG-NX213-L was the only aptamer that showed effective inhibition of VEGF-induced angiogenesis.

The reason for the inhibitory activity enhancement of DAG-NX213 and DAG-NX213-L in vitro and in vivo remains to be elucidated. It will be important to establish whether DAG-NX213 and DAG-NX213-L (or similar preparations) associate with cellular plasma membranes in the mitogenicity assay and whether the larger size of these aptamers (especially of the liposomal aptamer) results in slower diffusion and therefore greater concentration at the site of injection in the Miles assay. In the mitogenicity and Miles assays, since VEGF is administered along with the aptamers in a confined space, the longer plasma circulating times of DAG-NX213 and DAG-NX213-L compared with that of NX213 are obviously not relevant. However, this may be important in the CAM assay where the aptamers were administered intravenously.

The association of aptamers with liposomes in a manner described here may have several applications of general utility. The advantages of such formulations include (i) improving the plasma pharmacokinetics of aptamers, (ii) presenting aptamers in a multivalent array with the aim of increasing the avidity of interaction with their targets, (iii) combining two or more aptamers with different specificities in the same liposome particle, (iv) enhancing the delivery of aptamers to tumors by taking advantage of the intrinsic tumor targeting properties of liposomes, and (v) using the high affinity and specificity of aptamers to guide liposomal contents to specific targets, which has to date primarily been accomplished with antibodies (41–43). Aptamers are well-suited for the kinds of preparations described here since, unlike most proteins, the denaturation of aptamers by heat, various molecular denaturants, and organic solvents is readily reversible. Given the rapidly increasing availability of aptamers with different specificities, similar liposome-anchored aptamers to the ones described here will be tested soon.

ACKNOWLEDGMENT

We thank Drs. Paul Schmidt, Eric Forssen, and Gary Fujii for many useful discussions. We also thank Jeffrey Walenta, Joelle Brown, and Sarah O'Rourke for expert technical assistance, Chandra Vargeese and Philippe

Bridonneau for assistance with large-scale oligonucleotide synthesis and purification, Julie Wolf for performing statistical analyses, and David Tinnermeier for performing electrospray mass spectroscopy analyses.

A Novel Ternary Ligand System for ^{99m}Tc -Labeling of Hydrazino Nicotinamide-Modified Biologically Active Molecules Using Imine-N-Containing Heterocycles as Coligands

Shuang Liu,* D. Scott Edwards,* and Anthony R. Harris

The DuPont Merck Pharmaceutical Company, Radiopharmaceuticals Division 331 Treble Cove Road, North Billerica, Massachusetts 01862. Received January 25, 1998; Revised Manuscript Received June 8, 1998

A hydrazinonicotinamide-functionalized cyclic platelet glycoprotein IIb/IIIa (GPIIb/IIIa) receptor antagonist [HYNICTide, cyclo(D-Val-NMeArg-Gly-Asp-Mamb(5-(6-(6-hydrazinonicotinamido)hexanamide)))] was labeled with ^{99m}Tc using tricine and a series of imine-N-containing heterocycles as coligands. The imine-N-containing heterocycles include *N*- ω -Acetylhistamine (HIS-AC), *N*-(2-hydroxyethyl)isonicotinamide (ISONIC-HE), isonicotinic acid (ISONIC), isonicotinoyl-L-aspartic acid dimethyl ester (ISONIC-L-Asp-OMe₂), 4-methyl-5-thiazoleethanol (MTE), nicotinic acid (NIC), 3-nitro-1,2,4-triazole (NTZ), 4-pyridylacetic acid (PA), 4-pyridineethanesulfonic acid (PES), and 3-pyridinesulfonic acid (PSA). The synthesis of these new ternary ligand [^{99m}Tc]HYNICTide complexes can be performed in one or two steps in high yield and high specific activity ($\geq 10\,000$ Ci/mmol HYNICTide). For example, the reaction of HYNICTide, [^{99m}Tc]pertechnetate, nicotinic acid, stannous chloride, and tricine at pH ~ 5 and 100 $^{\circ}\text{C}$ for 20 min results in the complex [^{99m}Tc (HYNICTide)(tricine)(NIC)] in $\geq 90\%$ yield as determined by radio-HPLC. It was found that ternary ligand technetium complexes, [^{99m}Tc (HYNICTide)(tricine)(L)] (L = ISONIC, ISONIC-L-Asp-OMe₂, ISONIC-HE, MTE, PA, PES, and PSA) are formed as equal mixtures of two isomeric forms. Complex [^{99m}Tc (HYNICTide)(tricine)(L)] (L = HIS-AC and NTZ) showed more than two well-resolved radiometric peaks at the retention times of interest, suggesting that they may have more than two forms in solution due to different bonding modalities of HIS-AC and NTZ. By a chirality experiment, it was found that the presence of two radiometric peaks is a result of the resolution of the two diastereomers which are formed by the combination of the chiral HYNICTide and the chiral technetium chelate. The formation of two diastereomers was also observed when a chiral imine-N-containing coligand was used for the radiolabeling of HYNIC-BA. The new ternary ligand [^{99m}Tc]HYNICTide complexes were found to be stable for up to 6 h in the reaction mixture. The high solution stability is attributed to their kinetic inertness. The composition of these complexes was determined to be 1:1:1:1 for Tc:HYNICTide:L:tricine (L = imine-N-containing heterocycles) through a series of mixed ligand experiments on the tracer (^{99m}Tc) level. The lipophilicity of the ternary ligand [^{99m}Tc]HYNICTide complexes can be systematically varied by the choice of polyaminocarboxylate and imine-N-containing coligands. Using the combination of tricine and an imine-N-containing coligand, HYNIC-derivatized peptides or other small molecules can be labeled with ^{99m}Tc in high specific activity and high stability for potential use as radiopharmaceuticals.

INTRODUCTION

Recently, Abrams and co-workers (1, 2) reported the use of organic hydrazines such as hydrazinonicotinamide (HYNIC) in labeling polyclonal IgG with ^{99m}Tc for imaging focal sites of infection. This technology has also been used for the ^{99m}Tc -labeling of chemotactic peptides (3–9), somatostatin analogues (10, 11), and antisense DNA oligonucleotides (12–14). Since the HYNIC group can only occupy one or two coordination sites in the technetium coordination sphere, a coligand such as glucoheptonate or tricine is required. It has been shown that the specific activity of the ^{99m}Tc -labeled polyclonal IgG using tricine as a coligand is much higher than that obtained using glucoheptonate (15, 16).

We have used tricine as the coligand in the ^{99m}Tc -labeling of a HYNIC-modified cyclic platelet glycoprotein IIb/IIIa (GPIIb/IIIa) antagonist (HYNICTide, Chart 1).

Very high specific activity ($\geq 20\,000$ mCi/ μmol) can be achieved for the [^{99m}Tc]HYNICTide complex when tricine

Chart 2. Water-Soluble Phosphines and Imine-N-Containing Heterocyclic Coligands

is used as the coligand (17). However, the use of tricine as the coligand suffers two major disadvantages: the solution instability of the complex [^{99m}Tc(HYNICtide)-(tricine)₂], and the presence of many isomeric forms in solution. Similar phenomena were seen when glucoheptonate was used as a coligand in the ^{99m}Tc-labeling of a HYNIC-modified chemotactic peptide (18).

To minimize the number of isomeric forms and increase the solution stability of the [^{99m}Tc]HYNICtide complex, we have used water soluble phosphines (Chart 2: TPPTS, trisodium triphenylphosphine-3,3',3''-trisulfonate; TPPDS, disodium triphenylphosphine-3,3'-disulfonate; TPPMS, sodium triphenylphosphine-3-monosulfonate) as second coligands (19). We found that the combination of HYNICtide, tricine, and a monodentate phosphine produces a unique and versatile ternary ligand system which forms technetium complexes [^{99m}Tc(HYNICtide)-(tricine)(L)] (L = TPPTS, TPPDS, and TPPMS) with high solution stability and only two detectable isomeric forms. As a continuation of this study, we now present a new ternary ligand system, in which imine-N-containing heterocycles (Chart 2) are used as second coligands instead of water-soluble phosphines and its application in the ^{99m}Tc-labeling of a cyclic platelet GPIIb/IIIa HYNICtide. We describe the synthesis, HPLC characterization, and stability of new ternary ligand complexes, [^{99m}Tc(HYNICtide)(tricine)(L)] (L = HIS-AC, ISONIC, ISONIC-L-Asp-OMe₂, ISONIC-HE, MTE, NIC, NTZ, PA, PES, and PSA). This new ternary ligand system can also be used for the ^{99m}Tc-labeling of other HYNIC-conjugated biologically active small molecules.

EXPERIMENTAL SECTION

Materials. *N*-ω-Acetylhistamine (HIS-AC), *N*-(2-hydroxyethyl)isonicotinamide (ISONIC-HE), isonicotinic

acid (ISONIC), isonicotinoyl chloride hydrochloride, 4-methyl-5-thiazoleethanol (MTE), nicotinic acid (NIC), 3-nitro-1,2,4-triazole (NTZ), 4-pyridylacetic acid (PA), 4-pyridineethane-sulfonic acid (PES), 3-pyridinesulfonic acid (PSA), salicylaldehyde, tricine, 2-amino-2-(hydroxymethyl)-1,3-dihydroxypropane (tris), and trisodium triphenylphosphine-3,3',3''-trisulfonate (TPPTS) were purchased from Aldrich Chemical Co. TPPTS was purified according to the literature method (20) before use for radiolabeling. Succinimidyl 6-(2-sulfobenzaldehydehydrazono)nicotinate sodium salt was prepared according to the literature method (21). ¹H-NMR spectra were recorded on a 270 MHz Bruker spectrometer. The ¹H-NMR data were reported as δ (ppm) relative to TMS. FAB-MS analyses were performed using a Finnigan MAT 8230 mass spectrometer. Electrospray MS analyses were performed using a VG Quattro mass spectrometer. Na^{99m}TcO₄ was obtained from a Technelite ⁹⁹Mo/^{99m}Tc generator, DuPont Merck Pharmaceutical Co., North Billerica, MA. Deionized water was obtained from a Millipore MilliQ Water System and was of >18 MΩ quality. The synthesis and biological properties of the cyclic GPIIb/IIIa HYNICtide have been reported elsewhere (22).

Instruments and Methods. The high-performance liquid chromatography (HPLC) methods used a Hewlett-Packard Model 1050 instrument with radiometric detector using a sodium iodide probe. The instant thin-layer chromatography (ITLC) method used Gelman Sciences silica gel strips and a 1:1 mixture of acetone and saline as eluant.

HPLC method 1 used a Zorbax C₁₈ column (4.6 mm × 250 mm, 80 Å pore size) at a flow rate of 1 mL/min with a gradient mobile phase starting from 88% A (0.01 M phosphate buffer, pH 6) and 12% B (acetonitrile) to 85% A and 15% B at 30 min.

HPLC method 2 used a Zorbax C₁₈ column (4.6 mm × 250 mm, 80 Å pore size) at a flow rate of 1 mL/min with a gradient mobile phase starting from 88% A (0.01 M phosphate buffer, pH 6) and 12% B (acetonitrile) to 80% A and 20% B at 30 min.

HPLC method 3 used a Zorbax C₁₈ column (4.6 mm × 250 mm, 80 Å pore size) at a flow rate of 1 mL/min with a gradient mobile phase starting from 88% A (0.01 M phosphate buffer, pH 6) and 12% B (acetonitrile) to 86% A and 14% B at 20 min and to 80% A and 20% B at 30 min.

HPLC method 4 used a Hewlett-Packard model 1090 instrument, a Zorbax C₁₈ column (4.6 mm × 250 mm, 80 Å pore size) at a flow rate of 1 mL/min with a gradient mobile phase starting from 80% A (0.01 M phosphate buffer, pH 6) and 20% B (acetonitrile) to 60% A and 40% B at 30 min.

Synthesis of N-Benzyl-6-(2-sulfobenzaldehydehydrazono)nicotinamide Sodium Salt (HYNIC-BA).

To a solution of succinimidyl 6-(2-sulfobenzaldehydehydrazono)nicotinate sodium salt (1.0 g, 2.27 mmol) in dry DMF (20 mL) was added benzylamine (0.243 g, 2.27 mmol). The resulting mixture was stirred at room temperature for 24 h. Solvent was removed under reduced pressure, and the residue was triturated with methanol (3 mL) to give a pale-yellow solid. The solid was collected by filtration, washed with diethyl ether, and dried under vacuum. The yield was 0.9 g (92%). The title compound was recrystallized twice from methanol before use for radiolabeling. Electrospray MS (in negative mode): *m/z* 432.1 (M - 1, [C₂₀H₁₇N₄O₄NaS]⁺) and *m/z* 409.1 (M - Na, [C₂₀H₁₇N₄O₄S]⁻). ¹H NMR (DMSO-d₆): 4.48 (d, 2H, PhCH₂, *J* = 5.6 Hz); 7.20–7.41 (m, 8H,

Ph); 7.80 (dd, 1H, Py); 8.05 (d, 1H); 8.14 (dd, 1H, Py); 8.72 (d, 1H, $J = 2.0$ Hz, Py); 8.98 (t, 1H, amide NH); 9.04 (s, 1H, N=CH); and 11.40 (s, 1H, hydrazone NH).

Synthesis of *N*-((*R*)-(+)- α -Methylbenzyl)-6-(2-sulfobenzaldehyde hydrazone)nicotinamide Sodium Salt (HYNIC-MBA). To a solution of succinimidyl 6-(2-sulfobenzaldehydehydrazone)nicotinate sodium salt (1.0 g, 2.27 mmol) in dry DMF (10 mL) was added (*R*)-(+)- α -methylbenzylamine (0.35 g, 2.89 mmol). The resulting mixture was stirred at room temperature for 24 h. Removal of the solvent under reduced pressure gave an oily residue, which was redissolved in ethanol (5 mL). Trituration with diethyl ether gave a pale-yellow precipitate. The precipitate was collected by filtration, washed with diethyl ether, and dried in air. The yield was 0.95 g (94%). Recrystallization of the title compound from methanol gave an off-white powder. Electrospray MS (in negative mode): m/z 445.1 ($M - 1$, $[\text{C}_{21}\text{H}_{19}\text{N}_4\text{O}_4\text{NaS}]^-$) and m/z 423.1 ($M - \text{Na}$, $[\text{C}_{21}\text{H}_{19}\text{N}_4\text{O}_4\text{S}]^-$). ^1H NMR ($\text{DMSO}-d_6$): 1.48 (d, 3H, CH_3 , $J = 7.1$ Hz); 5.16 (m, 1H, PhCHMe); 7.20–7.41 (m, 8H, Ph); 7.76 (dd, 1H, Py); 8.05 (d, 1H, Ph); 8.10 (dd, 1H, Py); 8.69 (s, 1H, Py); 8.69 (t, 1H, amide NH); 9.01 (s, 1H, N=CH); and 11.38 (s, 1H, hydrazone NH).

Synthesis of Isonicotinoyl-L-aspartic Acid Dimethyl Ester (ISONIC-L-Asp-OMe₂). To a solution of L-aspartic acid dimethyl ester hydrochloride (2.0 g, 10 mmol) in acetonitrile (100 mL) were added isonicotinoyl chloride hydrochloride (1.8 g, 10 mmol) and triethylamine (3.0 mL, 21.5 mmol). The reaction mixture was stirred at room temperature for 24 h and was then refluxed for 2 h. The solution was filtered and the filtrate was evaporated under reduced pressure to give a whitish oil. This residue was extracted with diethyl ether (2×75 mL). The organic fractions were combined, and the solvent was removed to give the product as a whitish oil. Electrospray MS: m/z 267 ($M + 1$, $[\text{C}_{12}\text{H}_{14}\text{N}_2\text{O}_5]^+$). ^1H NMR (CDCl_3): 2.91–3.17 (m, 2H, CH_2), 3.69 (s, 3H, COOCH_3); 3.78 (s, 3H, COOCH_3); 4.99–5.05 (m, 1H, CH); 7.38–7.41 (d, 1H, NH); 7.62–7.65 (m, 2H, aromatic H) and 7.82–7.84 (m, 2H, aromatic H).

Synthesis of 2-Salicylimino-2-hydroxymethyl-1,3-propanediol (Saltris). To a solution of tris (2.4 g, 19 mmol) in hot methanol (30 mL) was added slowly salicylaldehyde (2.5 g, 20.5 mmol) in the same solvent (10 mL). The resulting mixture was refluxed for 30 min and was then cooled to room temperature. Upon addition of diethyl ether (50 mL), the reaction mixture was kept standing at room temperature for 2–3 h, during which time bright-yellow microcrystals were formed. The bright-yellow solid was collected by filtration, washed with diethyl ether, and dried in a vacuum. The yield was 4.0 g (~86%). The schiff base was used for further reaction without further purification.

Synthesis of 2-(2-Hydroxybenzyl)amino-2-hydroxymethyl-1,3-propanediol (Hbtris). Saltris (5.0 g, 21.6 mmol) was suspended in 50 mL of methanol. Potassium borohydride (KBH_4) was added in small portions until the yellow color totally disappeared. The reaction mixture was refluxed for an additional 10 min. The solvent was removed under reduced pressure. To the residue was added ammonium chloride (2 g) in 15 mL of water to give a milky solution, which became clear upon heating. The mixture was condensed on a rotary evaporator until a thick milky liquid was formed. Upon cooling in an ice-bath, the aqueous solution was discarded. To the residue was added 30 mL of absolute ethanol while a white solid formed. The solid was collected by filtration, washed with cold ethanol (5 mL) and diethyl ether

(10 mL), and dried in air. The product was purified by recrystallization from a mixture of water and methanol (50:50). The yield was 2.6 g (~52%). FAB-MS: m/z 228 ($M + 1$, $[\text{C}_{11}\text{H}_{18}\text{NO}_4]^+$). ^1H NMR (CD_3OD): 3.70 (s, 6H, CH_2); 3.80–4.20 (m, 2H, benzyl- CH_2); and 6.50–7.40 (m, 4H, aromatic hydrogens).

Synthesis of Ternary Ligand [^{99m}Tc]HYNICTide Complexes. Two-Step Synthesis. To a 10 mL vial was added 0.2–0.4 mL of the HYNICTide solution (50–100 $\mu\text{g/mL}$ in 25 mM succinate buffer, pH 5.0), 0.4 mL of tricine solution (100 mg/mL in 25 mM succinate buffer, pH 5.0), 0.2–0.5 mL of $^{99m}\text{TcO}_4^-$ solution (100–200 mCi/mL in saline), and 25 μL of $\text{SnCl}_2 \cdot 2\text{H}_2\text{O}$ solution (1.0 mg/mL in 0.1 N HCl). The reaction mixture was allowed to stand at room temperature for 30 min. The HPLC (method 1) showed radiochemical purity (RCP) of $\geq 95\%$ for the resulting complex [$^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})_2$]. To the solution was added 0.2 mL of the imine-N-containing coligand solution (10–50 mg/mL in 25 mM succinate buffer, pH 5.0). The reaction mixture was heated at 100 °C for 15–20 min. After cooling at room temperature for 10 min, an aliquot of the reaction mixture was analyzed by radio-HPLC and ITLC. The [^{99m}Tc]HYNICTide complex migrates while the [^{99m}Tc]colloid remains at the origin of the ITLC strip.

One-Step Synthesis. To a 10 mL vial was added 0.4 mL of tricine solution (50–100 mg/mL in 25 mM succinate buffer, pH 5.0), 0.2–0.4 mL of HYNICTide solution (50–100 $\mu\text{g/mL}$ in 25 mM succinate buffer, pH 5.0), 0.2 mL of coligand solution (10–50 mg/mL in 25 mM succinate buffer, pH 5.0), 0.2–0.5 mL of $^{99m}\text{TcO}_4^-$ solution (100–200 mCi/mL in saline), and 25 μL of $\text{SnCl}_2 \cdot 2\text{H}_2\text{O}$ solution (1.0 mg/mL in 0.1 N HCl). The reaction mixture was heated at 100 °C for 15–20 min. After cooling at room temperature for 10 min, the reaction mixture was analyzed by radio-HPLC and ITLC. The [^{99m}Tc]HYNICTide complexes prepared by this approach were shown by HPLC to be identical to those prepared by the two-step synthesis. The radiolabeling yields for [^{99m}Tc]HYNICTide complexes along with their HPLC data are summarized in Table 1.

Composition Studies of [^{99m}Tc]HYNICTide Complexes. Determination of the Number of HYNICTide Ligands. To a 10 mL vial was added 0.4 mL of tricine solution (100 mg/mL in 25 mM succinate buffer, pH 5.0), followed by 0.2 mL of PSA solution (30 mg/mL in 25 mM succinate buffer, pH 5.0), 0.4 mL of HYNICTide solution (50 $\mu\text{g/mL}$ in 25 mM succinate buffer, pH 5.0), 0.1 mL of *N*-(6-hydrazinonicotinyl)-(*R*)-(+)- α -methylbenzylamine solution (50 $\mu\text{g/mL}$ in 25 mM succinate buffer, pH 5.0), 0.2 mL of $^{99m}\text{TcO}_4^-$ solution (250 mCi/mL in saline), and 25

μL of $\text{SnCl}_2 \cdot 2\text{H}_2\text{O}$ solution (1.0 mg/mL in 0.1 N HCl). The reaction mixture was heated at 100 °C for 20 min, and was then analyzed by HPLC (method 1).

Determination of the Number of Heterocyclic Coligands. To a 10 mL vial was added 0.4 mL of HYNICTide solution (50 $\mu\text{g}/\text{mL}$ in 25 mM succinate buffer, pH 5.0), 0.4 mL of tricine solution (100 mg/mL in 25 mM succinate buffer, pH 5.0), 0.2 mL of PSA solution (25 mg/mL in 25 mM succinate buffer, pH 5.0), 0.2 mL of ISONIC-HE solution (25 mg/mL in 25 mM succinate buffer, pH 5.0), 0.2 mL of $^{99\text{m}}\text{TcO}_4^-$ solution (250 mCi/mL in saline), and 25 μL of $\text{SnCl}_2 \cdot 2\text{H}_2\text{O}$ solution (1.0 mg/mL in 0.1 N HCl). The reaction mixture was heated at 100 °C for 20 min, and was then analyzed by radio-HPLC (method 1).

Determination of the Number of Tricine Coligands. To a 10 mL vial was added 0.4 mL of HYNICTide solution (100 $\mu\text{g}/\text{mL}$ in 25 mM succinate buffer, pH 5.0), 20 μL of tricine solution (100 mg/mL in 25 mM succinate buffer, pH 5.0), 0.5 mL of Hbtris [10 mg/mL in a mixture of 50:50 (v:v) ethanol and 25 mM succinate buffer, pH 5.0], 0.2 mL of NIC solution (25 mg/mL in 25 mM succinate buffer, pH 5.0), 0.3 mL of $^{99\text{m}}\text{TcO}_4^-$ solution (~170 mCi/mL in saline), and 25 μL of $\text{SnCl}_2 \cdot 2\text{H}_2\text{O}$ solution (1.0 mg/mL in 0.1 N HCl). The reaction mixture was heated at 100 °C for 20 min. After cooling to room temperature, the reaction mixture was filtered using a Millex-GV 0.22 μm filter. The filtrate was analyzed by radio-HPLC (method 3).

Chirality Experiments. *Chiral Center on the HYNIC Ligand.* To a 10 mL vial was added 0.4 mL of tricine solution (100 mg/mL in 25 mM succinate buffer, pH 5.0), followed by 0.2 mL of PSA solution (30 mg/mL in 25 mM succinate buffer, pH 5.0), 0.2 mL of HYNIC-BA solution (100 $\mu\text{g}/\text{mL}$ in 25 mM succinate buffer, pH 5.0), 0.2 mL of HYNIC-MBA solution (100 $\mu\text{g}/\text{mL}$ in 25 mM succinate buffer, pH 5.0), 0.2 mL of $^{99\text{m}}\text{TcO}_4^-$ solution (250 mCi/mL in saline), and 25 μL of $\text{SnCl}_2 \cdot 2\text{H}_2\text{O}$ solution (1.0 mg/mL in 0.1 N HCl). The reaction mixture was heated at 100 °C for 20 min, and was then analyzed by HPLC (method 1).

Chiral Center on the Imine-N-Containing Coligand. To a 10 mL vial was added 0.4 mL of tricine solution (100 mg/mL in 25 mM succinate buffer, pH 5.0), followed by 0.2 mL of HYNIC-BA solution (100 $\mu\text{g}/\text{mL}$ in 25 mM succinate buffer, pH 5.0), 0.1 mL of ISONIC-HE solution (40 mg/mL in 25 mM succinate buffer, pH 5.0), 0.2 mL of ISONIC-L-Asp-OMe₂ solution (10 mg/mL in 50% EtOH), 0.2 mL of $^{99\text{m}}\text{TcO}_4^-$ solution (250 mCi/mL in saline), and 25 μL of $\text{SnCl}_2 \cdot 2\text{H}_2\text{O}$ solution (1.0 mg/mL in 0.1 N HCl). The reaction mixture was heated at 100 °C for 10 min, and was then analyzed by HPLC (method 4).

Solution Stability Studies. *Solution Stability of [$^{99\text{m}}\text{Tc}$]HYNICTide Complexes in Kit Matrix.* [$^{99\text{m}}\text{Tc}$]HYNICTide complexes in the kit matrix were analyzed by HPLC (method 1 or method 2) without dilution. Aliquots of the reaction mixture were placed in six autosampler vials and analyzed sequentially over 6 h.

Solution Stability of Complexes [$^{99\text{m}}\text{Tc}$ (HYNICTide)-(tricine)(L)] (L = ISONIC and ISONIC-HE) in the Presence of Cysteine in Kit Matrix. Complexes [$^{99\text{m}}\text{Tc}$ (HYNICTide)(tricine)(L)] (L = ISONIC and ISONIC-HE) were synthesized using the procedure above. To the reaction mixture was added cysteine in succinate buffer (pH 5.0) to give a concentration of 1 mg/mL. The resulting solutions were kept at room temperature and were analyzed by radio-HPLC (method 1) with four injections over 6 h.

Solution Stability of HPLC Purified [$^{99\text{m}}\text{Tc}$]HYNICTide Complexes. The [$^{99\text{m}}\text{Tc}$]HYNICTide complexes were pre-

pared first and were then purified by HPLC using either method 1 or method 2. The collected fractions were evaporated to dryness under reduced pressure, and the residues were diluted to 10 mCi/mL with deionized water. Aliquots of the diluted solution were placed in six autosampler vials and analyzed sequentially over 6 h.

Solution Stability of HPLC Purified [$^{99\text{m}}\text{Tc}$]HYNICTide Complexes in the Presence of Excess TPPTS. The complex [$^{99\text{m}}\text{Tc}$ (HYNICTide)(tricine)(PSA)] was prepared, and purified by HPLC using method 1. Volatiles from the collected fraction were removed under reduced pressure. The residue was diluted to 5 mCi/mL with a TPPTS (1.0 mg/mL) solution in water. The resulting solutions were kept at room temperature, and were analyzed at $t = 0, 1, 2,$ and 3 h by radio-HPLC.

Solution Stability of the Two Isomeric Forms of the Complex [$^{99\text{m}}\text{Tc}$ (HYNICTide)(tricine)(NIC)]. The complex was prepared, and the two radiometric peaks were collected into two separate flasks. After removal of solvents, NIC solution in phosphate buffer (pH 6) was added to each flask to give a concentration of 1 mg/mL for NIC and 3–4 mCi/mL for the complex [$^{99\text{m}}\text{Tc}$ (HYNICTide)(tricine)(NIC)]. These two solutions were kept at room temperature and monitored by HPLC (method 1).

RESULTS AND DISCUSSION

There is a great current interest in the development of receptor-based target specific radiopharmaceuticals by the $^{99\text{m}}\text{Tc}$ -labeling of biologically active molecules such as antibodies (1, 2) and small peptides. Peptides used for $^{99\text{m}}\text{Tc}$ -labeling include chemotactic peptides (3–9, 18) and tuftsin receptor antagonists (22–24) for imaging focal infection or inflammation, somatostatin analogues for imaging tumors (10, 11, 26–30), and platelet GPIIb/IIIa receptor antagonists for imaging thrombosis (31–38). The $^{99\text{m}}\text{Tc}$ -labeling of highly potent small peptides (39), and the pharmacokinetics of $^{99\text{m}}\text{Tc}$ -labeled small peptides (40) have been reviewed recently.

Small peptides are of interest because of their favorable metabolic and pharmacokinetic characteristics as compared to antibodies and their fragments. Peptides are necessary elements in many fundamental biological processes, and in some cases, the affinities of small peptides for their receptors are significantly greater than that of antibodies or their fragments. Small peptides are easy to synthesize and modify, less likely to be immunogenic, and can have rapid blood clearance. The faster blood clearance results in adequate T/B ratios earlier so that it is practical to use $^{99\text{m}}\text{Tc}$, which is the preferred radionuclide for diagnostic nuclear medicine.

To label a small peptide with $^{99\text{m}}\text{Tc}$, a bifunctional coupling agent (BFCA) is often needed. The BFCA can be attached to the C-terminus or N-terminus via a linker, if needed. It can also be attached to the side-chain of the peptide or incorporated in the peptide backbone (31–34) provided that incorporation of the BFCA does not significantly affect the receptor-binding affinity of the peptide. The radiolabeling can be achieved either by direct reduction of $^{99\text{m}}\text{TcO}_4^-$ in the presence of a BFCA-peptide conjugate or by ligand exchange with an intermediate $^{99\text{m}}\text{Tc}$ complex such as [$^{99\text{m}}\text{Tc}$]glucoheptonate. For very potent small peptides with IC₅₀ values in the nanomolar range, the $^{99\text{m}}\text{Tc}$ -labeling must be accomplished with high specific activity. Therefore, the choice of a BFCA is very important for the success of the radiolabeling. As a matter of fact, one of the challenges for the development of peptide-based radiopharmaceuticals is to design new ligand systems that have very high

Chart 3. Synthesis of [^{99m}Tc]HYNICTide Complexes

labeling efficiency (rapid labeling and high yield) and form technetium complexes with high solution stability and less isomerism.

Various chelators have been used as BFCAs in labeling proteins and biologically active small molecules with ^{99m}Tc and ^{186}Re . These include DTPA (41), N_2S triamidedithiols (42–44), N_2S_2 diamidedithiols (44–47), N_2S_2 monoamidemonoaminedithiols (48), N_2S_2 diaminedithiols (49–54), BATOs (55, 56), PnAO (26), tetraamines (27), and HYNIC (1–18). Among these BFCAs, HYNIC is of particular interest due to its very high labeling efficiency. Also, the use of various coligands with HYNIC allows the hydrophilicity of the technetium complex to be modified in order to improve the pharmacokinetics of the ^{99m}Tc -labeled peptide.

Recently, we reported the use of tricine and water soluble phosphines (Chart 2: TPPTS, TPPDS, and TPPMS) as the coligands to label a cyclic GPIIb/IIIa HYNICTide with ^{99m}Tc (19). The combination of HYNICTide, tricine, and a monodentate phosphine (TPPTS, TPPDS, and TPPMS) produces a unique and versatile ternary ligand system that forms [^{99m}Tc]HYNICTide complexes with high solution stability and only two detectable isomeric forms. It is amazing that the use of a simple monodentate phosphine ligand dramatically reduces the number of isomeric forms from more than 10 for [^{99m}Tc](HYNICTide)(tricine) $_2$ to only two for [^{99m}Tc](HYNICTide)(tricine)(TPPTS)] and significantly increases the solution stability of the [^{99m}Tc]HYNICTide complex at the same time.

Phosphine-P is known as a soft donor, and binds strongly to metal ions in their lower oxidation state, such as Tc(III). When bonded to the Tc, it uses its 3p electron lone-pair to form a Tc–P σ -bond. The empty 3d orbitals can be used to accept the electrons from 4d orbitals of the Tc and form $d\pi$ – $d\pi$ back-bonding. This suggests that monodentate ligands with other soft donors such as imine-N may also be used as the second coligands to stabilize [^{99m}Tc]HYNICTide complexes. We now report the discovery of a new ternary ligand system, in which five- or six-membered imine-N-containing heterocycles, such as thiazole and pyridine derivatives (Chart 2), are used as the second coligands in the ^{99m}Tc -labeling of a GPIIb/IIIa receptor antagonist, HYNICTide (Chart 1).

Synthesis of [^{99m}Tc]HYNICTide Complexes. Synthesis (Chart 3) of ternary ligand [^{99m}Tc]HYNICTide complexes can be achieved either in two steps, in which

the complex [^{99m}Tc](HYNICTide)(tricine) $_2$ is formed first and then reacts with a imine-N-containing coligand, or in one step by direct reduction of [^{99m}Tc]pertechnetate with stannous chloride in the presence of HYNICTide, tricine, and an imine-N-containing coligand. For example, the reaction of HYNICTide, [^{99m}Tc]pertechnetate, nicotinic acid, stannous chloride, and tricine at pH $\sim$ 5 and 100 $^\circ\text{C}$ for 20 min results in the complex [^{99m}Tc](HYNICTide)(tricine)(NIC)] in $\geq$ 90% yield as determined by radio-HPLC. Successful radiolabeling at lower temperatures (50–80 $^\circ\text{C}$) requires longer heating time ($>$ 30 min). The tricine concentration can range from 20 to 60 mg/mL. Using lower tricine concentration ($<$ 20 mg/mL) may result in the formation of a significant amount of [^{99m}Tc]colloid. For pyridine analogues, the coligand concentration is 5–10 mg/mL while the concentration of imidazole, thiazole or triazole analogues is 1–5 mg/mL. Low concentration ($<$ 1.0 mg/mL) of imine-N-containing coligand may result in either incomplete conversion of [^{99m}Tc](HYNICTide)(tricine) $_2$ to the corresponding ternary ligand [^{99m}Tc]HYNICTide complexes in the two-step synthesis or the formation of [^{99m}Tc](HYNICTide)(tricine) $_2$ as a radioimpurity in the one-step synthesis. The concentration of the HYNICTide can range from 5 to 50 $\mu\text{g/mL}$. When pyridine derivatives, particularly those with strong electron-withdrawing groups, are used as coligands, the higher HYNICTide concentration may result in formation of the bis-HYNICTide complex since HYNICTide itself contains a pyridine-N donor and a hydrazine group. The labeling yields (Table 1) are usually 85–95% for complex [^{99m}Tc](HYNICTide)(tricine)(L)] (L = ISONIC, ISONIC-L-Asp-OMe $_2$, ISONIC-HE, MTE, PA, PES, and PSA) as determined by HPLC. Very high specific activity ($\geq$ 10 000 mCi/ μmol HYNICTide) can be achieved without post labeling purification. Therefore, the procedure described in this report for the preparation of ternary ligand [^{99m}Tc]HYNICTide complexes is amenable for clinical application.

HPLC Characterization. The HPLC methods for the characterization of these new ternary ligand [^{99m}Tc]HYNICTide complexes are very similar to those used for the complex [^{99m}Tc](HYNICTide)(tricine)(TPPTS)] (19). Like the phosphine coligands such as TPPTS, imine-N-containing heterocycles react with [^{99m}Tc](HYNICTide)(tricine) $_2$ and form a ternary ligand complex [^{99m}Tc](HYNICTide)(tricine)(L)] (L = ISONIC, ISONIC-L-Asp-OMe $_2$, ISONIC-HE, MTE, PA, PES, and PSA), which show only two radiometric peaks in their HPLC chromatograms. Table 1 summarizes the radio-HPLC data for these ternary ligand [^{99m}Tc]HYNICTide complexes. Under ideal conditions, most of them show two well-resolved peaks with the area ratio being approximately 1:1. Figure 1 shows two representative HPLC chromatograms for [^{99m}Tc](HYNICTide)(tricine)(ISONIC)] (bottom) and [^{99m}Tc](HYNICTide)(tricine)(PES)] (top). Chromatograms of complex [^{99m}Tc](HYNICTide)(tricine)(L)] (L = HIS-AC and NTZ) showed more than two well-resolved radiometric peaks (Figure 2) at the retention times of interest, suggesting that these complexes may have more than two forms in solution, probably due to different bonding modalities of the substituted imidazole and 1,2,4-triazole coligands. It should be noted that the retention time and separation of the two radiometric peaks for complexes [^{99m}Tc](HYNICTide)(tricine)(L)] (L = ISONIC, ISONIC-L-Asp-OMe $_2$, ISONIC-HE, MTE, PA, PES, and PSA) are very much dependent on the model of HPLC, column type, column age, and HPLC method used for the characterization of these [^{99m}Tc]HYNICTide complexes.

Figure 1. Radio-HPLC chromatograms (method 1) of ternary ligand technetium complexes: $[^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})(\text{ISONIC})]$ (top) and $[^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})(\text{PES})]$ (bottom).

Figure 2. Radio-HPLC (method 2) chromatograms of ternary ligand technetium complexes: $[^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})(\text{NTE})]$ (top) and $[^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})(\text{HIS-AC})]$ (bottom).

Composition Studies of $[^{99m}\text{Tc}]\text{HYNICTide}$ Complexes. A mixed ligand experiment was performed to determine the number of HYNICTides bonded to the Tc. In this experiment, the HYNICTide and a model compound, N-(6-hydrazinonicotiny)-(R)-(+)- α -methylbenzylamine (HYNIC-MBA), were used in the same reaction mixture. After the radiolabeling, the reaction mixture was analyzed by radio-HPLC (method 1). If only one HYNICTide is bonded to the Tc, the chromatogram is expected to show two sets of peaks, one from $[^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})(\text{PSA})]$ and the other from $[^{99m}\text{Tc}(\text{HYNIC-MBA})(\text{tricine})(\text{PSA})]$. If there were two HYNIC-containing ligands in each $[^{99m}\text{Tc}]\text{HYNICTide}$ complex, a third set of peaks from the mixed ligand complex $[^{99m}\text{Tc}(\text{HYNICTide})(\text{HYNIC-MBA})(\text{tricine})(\text{PSA})]$ would be expected. The presence of only two pairs of peaks in the radio-HPLC chromatogram (Figure 3) demonstrates clearly that there is only one HYNICTide bonded to the Tc in $[^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})(\text{PSA})]$, and by inference in the other $[^{99m}\text{Tc}]\text{HYNICTide}$ complexes with tricine and an imine-N-containing heterocycle as coligands.

The number of PSA coligands in $[^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})(\text{PSA})]$ was determined in a fashion similar to

Figure 3. Radio-HPLC chromatogram (method 1) for the mixed HYNIC-ligand experiment. The peaks at 16.2 and 17.0 min are due to the complex $[^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})(\text{PSA})]$, and the peaks at 19.6 and 20.8 min are due to the complex $[^{99m}\text{Tc}(\text{HYNIC-MBA})(\text{tricine})(\text{PSA})]$.

Figure 4. Radio-HPLC chromatogram (method 1) for the mixed ligand experiment. The peaks at 16.2 and 17.0 min are due to the complex $[^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})(\text{PSA})]$, and the peaks at 22.5 and 23.8 min are due to the complex $[^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})(\text{ISONIC-HE})]$.

Figure 5. Radio-HPLC chromatogram (method 1) for the mixed ligand experiment. The peaks at 11.2 and 12.0 min are due to the complex $[^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})(\text{NIC})]$, and the peaks at 27.6 and 28.1 min are due to the complex $[^{99m}\text{Tc}(\text{HYNICTide})(\text{Hbtris})(\text{NIC})]$.

that for the HYNICTide using PSA and ISONIC-HE as competing coligands. Figure 4 shows the radio-HPLC chromatogram of the resulting reaction mixture. The presence of two sets of distinctive peaks at ~ 16.0 and ~ 23.5 min for $[^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})(\text{PSA})]$ and $[^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})(\text{ISONIC-HE})]$, respectively, demonstrates clearly that there is only one PSA coligand in the complex $[^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})(\text{PSA})]$, one ISONIC-HE coligand in the complex $[^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})(\text{ISONIC-HE})]$, and by inference, one imine-N-containing coligand in other $[^{99m}\text{Tc}]\text{HYNICTide}$ complexes.

The number of tricine coligands in $[^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})(\text{PSA})]$ was determined similarly using tricine and Hbtris as competing coligands. Hbtris was prepared by KBH_4 reduction of Saltris, which was synthesized from the reaction of salicylaldehyde with tris in methanol. Hbtris has been characterized by ^1H NMR and mass spectroscopy. We used a 2:1 molar ratio of Hbtris to tricine in the reaction mixture because of the low labeling efficiency of Hbtris as compared to tricine. Figure 5 shows the radio-HPLC chromatogram (method 3) of the resulting reaction mixture. The peaks at 11.2 and 12.0 min are due to $[^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})(\text{NIC})]$ and the

Figure 6. Radio-HPLC chromatogram (method 1) for the chirality experiment. The single peak at 12.5 min is due to the complex $^{99m}\text{Tc}(\text{HYNIC-BA})(\text{tricine})(\text{PSA})$, and the peaks at 19.8 and 20.4 min are due to the complex $^{99m}\text{Tc}(\text{HYNIC-MBA})(\text{tricine})(\text{PSA})$.

peaks at 27.6 and 28.1 min are from $^{99m}\text{Tc}(\text{HYNICTide})(\text{Hbtris})(\text{NIC})$. This clearly demonstrates that there is only one tricine coligand in the complex $^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})(\text{NIC})$, one Hbtris coligand in the complex $^{99m}\text{Tc}(\text{HYNICTide})(\text{Hbtris})(\text{NIC})$, and by inference, one tricine or Hbtris in the other ternary ligand ^{99m}Tc -HYNICTide complexes.

On the basis of these data, we conclude that these ternary ligand technetium complexes contain one HYNICTide, one tricine, and one imine-N-containing heterocyclic coligand.

Chirality Experiment. For quite a long time, we have been puzzled by the presence of two radiometric peaks in the radio-HPLC chromatograms of complex $^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})(\text{L})$ ($\text{L} = \text{ISONIC}$, $\text{ISONIC-L-Asp-OMe}_2$, ISONIC-HE , MTE , PA , PES , and PSA). The ratio of these two forms is always close to 1:1. Several possible explanations can be envisaged for the existence of two isomeric forms of these complexes, including the resolution of diastereomers resulting from the chiral centers on both the cyclic peptide backbone and the technetium chelate and different geometric orientations of the diazenido ligand due to restricted rotation around the $\text{Tc}=\text{N}$ and $\text{N}=\text{N}$ bonds.

To understand the presence of these two isomeric forms, a chirality experiment was designed. In this experiment, two closely related HYNIC derivatives, *N*-benzyl-6-(2-sulfobenzaldehydehydrazono)nicotinamide (HYNIC-BA) and *N*-((*R*)-(+)- α -methylbenzyl)-6-(2-sulfobenzaldehydehydrazono)nicotinamide (HYNIC-MBA), were used in the same reaction mixture and PSA was used as coligand. HYNIC-MBA contains a chiral center, and HYNIC-BA has no chiral center. They were prepared by reacting the corresponding free amine with succinimidyl 6-(2-sulfobenzaldehydehydrazono)nicotinate sodium salt in DMF. The ternary ligand complexes $^{99m}\text{Tc}(\text{HYNIC-BA})(\text{tricine})(\text{PSA})$ and $^{99m}\text{Tc}(\text{HYNIC-MBA})(\text{tricine})(\text{PSA})$ were synthesized by reacting ^{99m}Tc pertechnetate, tricine, PSA, HYNIC-BA and HYNIC-MBA in the presence of stannous chloride at 100 °C for 20 min. The resulting solution was analyzed by HPLC (method 1).

If the existence of two isomeric forms were due to different geometric orientations of the substituted pyridine ring in the HYNICTide because of restricted rotation around the $\text{Tc}=\text{N}$ and $\text{N}=\text{N}$ bonds, there would be two pairs of peaks in the radio-HPLC chromatogram: one from $^{99m}\text{Tc}(\text{HYNIC-BA})(\text{tricine})(\text{PSA})$ and the other from $^{99m}\text{Tc}(\text{HYNIC-MBA})(\text{tricine})(\text{PSA})$. On the contrary, the radio-HPLC chromatogram (Figure 6) of the reaction mixture shows a single peak at 12.5 min due to the complex $^{99m}\text{Tc}(\text{HYNIC-BA})(\text{tricine})(\text{PSA})$, and a pair of peaks at 19.8 and 20.4 min due to the complex $^{99m}\text{Tc}(\text{HYNIC-MBA})(\text{tricine})(\text{PSA})$. These data provide strong

Figure 7. Radio-HPLC chromatogram (method 4) for the chirality experiment. The single peak at 11.9 min is due to $^{99m}\text{Tc}(\text{HYNIC-BA})(\text{tricine})(\text{ISONIC-HE})$, and the doublet at 21.5 and 26.5 min is from the complex $^{99m}\text{Tc}(\text{HYNIC-BA})(\text{tricine})(\text{ISONIC-Asp-OMe}_2)$.

evidence that the isomerism seen in these ternary ligand ^{99m}Tc -HYNICTide complexes is due to the formation of two diastereomers.

In another chirality experiment, HYNIC-BA was used as the ligand and the two pyridine analogues (ISONIC-HE without a chiral center and $\text{ISONIC-L-Asp-OMe}_2$ with a chiral center) were used as coligands. Synthesis of $\text{ISONIC-L-Asp-OMe}_2$ was carried out by reacting isonicotiny chloride hydrochloride with aspartic acid dimethyl ester hydrochloride in acetonitrile in the presence of excess triethylamine. $\text{ISONIC-L-Asp-OMe}_2$ was isolated as a whitish oil and has been characterized by $^1\text{H-NMR}$ and electrospray mass spectroscopy. The ternary ligand complexes $^{99m}\text{Tc}(\text{HYNIC-BA})(\text{tricine})(\text{ISONIC-HE})$ and $^{99m}\text{Tc}(\text{HYNIC-BA})(\text{tricine})(\text{ISONIC-L-Asp-OMe}_2)$ were prepared by reacting ^{99m}Tc pertechnetate, tricine, HYNIC-BA, ISONIC-HE , and $\text{ISONIC-L-Asp-OMe}_2$ in the presence of stannous chloride at 100 °C for 10 min. The resulting solution was analyzed by HPLC (method 4). The radio-HPLC chromatogram (Figure 7) shows a single peak at 9.0 min due to the complex $^{99m}\text{Tc}(\text{HYNIC-BA})(\text{tricine})(\text{ISONIC-HE})$ and a pair of peaks at 21.4 and 26.4 min due to the complex $^{99m}\text{Tc}(\text{HYNIC-MBA})(\text{tricine})(\text{ISONIC-L-Asp-OMe}_2)$. The area ratio of these two peaks is always close to 1:1, suggesting that they are indeed a result of resolution of the two diastereomers of the complex $^{99m}\text{Tc}(\text{HYNIC-MBA})(\text{tricine})(\text{ISONIC-L-Asp-OMe}_2)$.

The technetium chelate moiety is chiral, due to the tricine ligand being pro-chiral, and should be formed in an equal mixture of *D* and *L* enantiomers. These enantiomers in combination with the chiral centers on cyclic peptide backbone of HYNICTide or on the imine N-containing coligand result in the formation of diastereomers. If there is no chiral center on the imine N-containing coligand or the HYNIC-conjugated small molecules, the corresponding ternary ligand ^{99m}Tc -HYNICTide complex is expected to show only one radiometric peak unless a chiral chromatographic method is employed.

Solution Stability of ^{99m}Tc -HYNICTide Complexes. We examined the solution stability of four ^{99m}Tc -HYNICTide complexes, $^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})(\text{L})$ ($\text{L} = \text{ISONIC}$, ISONIC-HE , PES , and PSA), in the kit matrix. The stability was assessed by radio-HPLC (method 1 or 2) by performing six injections over 6 h. Figure 8 shows the plot of RCP (radiochemical purity) vs time for these four ^{99m}Tc -HYNICTide complexes. In all the cases, there is no significant RCP drop over 6 h within the experimental error. It is clear that the ternary ligand complex $^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})(\text{L})$ ($\text{L} = \text{ISONIC}$, ISONIC-HE , PES , and PSA) is stable for ≥ 6 h in solution. It is amazing that three different ligands (HYNICTide, tricine, and imine-N-containing heterocycle)

Figure 8. Plot of RCP (%) versus time (h) for $[^{99m}\text{Tc}]\text{HYNICTide}$ complexes in the kit matrix.

Figure 9. Plot of RCP (%) versus time (h) for $[^{99m}\text{Tc}]\text{HYNICTide}$ complexes in the presence of cysteine in the kit matrix.

combine with Tc and form a technetium complex with only two detectable isomers and with high solution stability.

Since cysteine is a native chelating ligand in biological systems, we decided to study the solution stability of two $[^{99m}\text{Tc}]\text{HYNICTide}$ complexes, $[^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})(\text{L})]$ (L = ISONIC and ISONIC-HE), in the presence of cysteine in the kit matrix. The cysteine challenging experiment is rather aggressive because of the high affinity of technetium in its intermediate or lower oxidation state for thiol ligands. In this experiment, the two $[^{99m}\text{Tc}]\text{HYNICTide}$ complexes were prepared first and then cysteine was added to the resulting reaction mixture to give a concentration of 1 mg/mL. The resulting solutions were kept at room temperature and monitored by radio-HPLC (method 1). Figure 9 shows the plot of RCP of the two $[^{99m}\text{Tc}]\text{HYNICTide}$ complexes in the presence of cysteine. It is quite clear that both complexes remain stable for ≥ 6 h in the kit matrix in the presence of cysteine.

We also examined the stability of four HPLC-purified ternary ligand complexes, $[^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})(\text{L})]$ (L = NIC, MTE, PES, and PSA). The collected fractions were evaporated under reduced pressure, and the residues were redissolved in water to a concentration of 10 mCi/mL. Since the HPLC mobile phase contains phosphate buffer (pH 6.0), no additional buffer was used for

Figure 10. Plot of RCP (%) versus time (h) for the HPLC purified $[^{99m}\text{Tc}]\text{HYNICTide}$ complexes in succinate buffer (pH 5).

dilution. These solutions were monitored over 6 h by radio-HPLC (method 1 or 2). Figure 10 shows the plot of RCP vs time for the HPLC-purified complexes. It was found that the complex $[^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})(\text{MTE})]$ is stable for at least 6 h in solution (pH 6.0). For complex $[^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})(\text{L})]$ (L = PSA and PES), there was a slight drop in the RCP in the first hour, and it remained relatively unchanged over the next 5 h. For the complex $[^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})(\text{NIC})]$, the RCP drops steadily over 6 h from 100% to about 90%.

Compared to TPPTS, PSA is a much weaker coligand in binding to the Tc. For example, when PSA (15–20 mg/mL, ~ 100 mM) and TPPTS (1–2 mg/mL, 2–3 mM) were used in the same reaction mixture, the yield for $[^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})(\text{PSA})]$ is only 8–10% and the major product is $[^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})(\text{TPPTS})]$ with $\sim 80\%$ yield. Considering the electron-withdrawing sulfonate group on the pyridine ring and the overall weak donating capability of PSA, it is surprising that the HPLC purified $[^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})(\text{PSA})]$ remained stable in solution for more than 6 h. That lead us to examine the solution stability of $[^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})(\text{PSA})]$ in the presence of excess TPPTS.

The complex $[^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})(\text{PSA})]$ was first synthesized and HPLC purified. Volatiles in the collected fraction were removed under reduced pressure, and the residue was redissolved in phosphate buffer (pH 6.0) to give a concentration of about 5 mCi/mL $[^{99m/99}\text{Tc}(\text{HYNICTide})(\text{tricine})(\text{PSA})] \approx 3 \times 10^{-8}$ M. Upon addition of TPPTS (1 mg/mL $\approx 2 \times 10^{-3}$ M), the solution was kept at room temperature and monitored by radio-HPLC (method 1). To our surprise, there is no ligand exchange between TPPTS and PSA at room temperature over 3 h.

The fact that $[^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})(\text{PSA})]$ remains intact in the presence of ≥ 50000 -fold excess of TPPTS, which is a much stronger coligand than PSA, is significant. This suggests that the ligand-exchange reaction is not dependent on the concentration of the entering ligand and dissociation of the Tc–N (PSA) bond is the rate-limiting step. Therefore, the high stability of these new ternary ligand $[^{99m}\text{Tc}]\text{HYNICTide}$ complexes is probably due to their kinetic inertness. It also suggests that these complexes most likely have a common distorted octahedron coordination geometry around the Tc since 5- or 7-coordinated complexes are often kinetically labile and undergo facile associative-addition or dissociative-elimination reactions.

For the complex $^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})(\text{NIC})$, we also isolated the two peaks. Solutions of the two isolated peaks were kept at room temperature and monitored by HPLC (method 1) over 6 h. It was found that there is no interconversion between the two isomeric forms although the typical decomposition seen for the HPLC purified $^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})(\text{NIC})$ was observed. This suggests that as soon as the NIC coligand is dissociated the intermediate complex, $^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})$ decomposes. Should the coordinated tricine undergo the conformational change via partial dissociation, there would be interconversion between the two isomeric forms of the complex $^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})(\text{NIC})$.

It should be noted that the solution stability of a ternary ligand ^{99m}Tc HYNICTide complex depends on the nature of the imine-N-containing coligand. For MTE, which contains a thiazole ring, the complex $^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})(\text{MTE})$ remains stable in solution for over 6 h without any decomposition. For a pyridine analogue such as NIC, however, the complex $^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})(\text{NIC})$ decomposes slowly in solution. In general, the solution stability of ternary ligand ^{99m}Tc HYNICTide complexes follows the order of phosphines $\geq$ thiazoles/imidazoles $\gg$ pyridines. This is consistent with the σ -bonding capability of phosphine-P, thiazole-N, and pyridine-N.

Like that of phosphines, the bonding of the imine-N-containing coligand to the Tc dramatically reduces the number of isomeric forms of the ^{99m}Tc HYNICTide complexes and significantly increases the solution stability of ^{99m}Tc HYNICTide complexes. The hydrophilicity of ^{99m}Tc HYNICTide complexes with the new ternary ligand system can be tuned by changing the substituents on the heterocyclic ring. Among the coligands used in this study, ISONIC-HE and MTZ are of particular interest because of their neutrality. If the peptide is not charged, the resulting ternary ligand complex will be neutral, which may allow the complexes to cross the cell membranes and potentially bind to intracellular receptors. However, there are also limitations using this new ligand system. For example, this new ligand system may not be suitable for ^{99m}Tc -labeling of biologically active molecules containing one or more disulfide linkages because the use of SnCl_2 and high-temperature heating may destroy the S–S disulfide bonds and cause adverse effect on the biological properties of the HYNIC conjugate.

When a heterocycle such as MTE contains only one imine-N donor atom, it forms a ternary ligand complex $^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})(\text{MTE})$ with two isomeric forms. Thiazole-S is a much weaker donor than imine-N and does not impose a challenge in bonding to the Tc. However, if a heterocyclic coligand such as NTZ contains more than one imine-N donor, it may form a ternary ligand ^{99m}Tc HYNICTide complex with more than two isomeric forms because of different bonding modalities of the heterocyclic coligand. In addition, when triazole or imidazole is bonded to the Tc center, the hydrogen on the secondary amine-N may become deprotonated. An ideal imine-N-containing coligand is that which forms a ternary ligand technetium complex with only two diastereomers if the HYNIC-conjugated small molecule has a chiral center.

The HYNICTide contains a pyridine-N donor atom and a hydrazine group. Theoretically, HYNICTide itself can act as a monodentate coligand with the pyridine-N bonding to the Tc or as bidentate ligand using both pyridine-N and terminal hydrazine-N to form a five-membered chelate ring with Tc. It is not surprising that

on the macroscopic (^{99}Tc) level the reaction of ^{99}Tc tricline complex with 2 equiv of HYNIC-D-Phe-OMe results in formation of two technetium complexes: $^{99}\text{Tc}(\text{HYNIC-D-Phe-OMe})(\text{tricine})^-$ and $^{99}\text{Tc}(\text{HYNIC-D-Phe-OMe})_2(\text{tricine})_2^-$ (57). It was also reported that reaction of 2-hydrazinopyridine, a model compound for HYNIC, in its dihydrochloride form with pertechnetate or perrhenate in methanol produced bis-hydrazide complexes (58). A structural study of $[\text{ReCl}_3(\text{HN}=\text{NC}_5\text{H}_4\text{N})(\text{N}=\text{NC}_5\text{H}_4\text{NH})]$ showed that the $\text{HN}=\text{NC}_5\text{H}_4\text{N}$ moiety is a neutral and bidentate pyridyldiazene while the $\text{N}=\text{NC}_5\text{H}_4\text{NH}$ moiety is a monodentate pyridiniumdiazenido.

On the tracer level, however, the complex $^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})(\text{NIC})$ is formed in $\sim 90\%$ yield from the reaction of HYNICTide, ^{99m}Tc pertechnetate, tricine, and NIC, which is a close analogue of HYNIC. In the radio-HPLC chromatogram (Figure 1), the two peaks at 13.2 and 14.8 min are due to the two isomeric forms of the complex $^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})(\text{NIC})$ while some of the later peaks at 18–30 min are probably due to the bis-HYNICTide complex. The area percentage of these peaks is usually $\leq 2\%$. This is due to the fact that the NIC concentration ($5 \text{ mg/mL} = 4 \times 10^{-2} \text{ M}$) is ~ 1000 -fold in excess over that of the HYNICTide ($40 \text{ }\mu\text{g/mL} \approx 4 \times 10^{-5} \text{ M}$). Since these later peaks are less than 2%, no further characterization was performed.

On the basis of the mixed-ligand experiments, it is quite clear that the ternary ligand ^{99m}Tc HYNICTide complexes described in this study contain one HYNICTide, one tricine, and one imine-N-containing coligand. The technetium oxidation state and the exact nature of bonding between these ligands (HYNIC, tricine, and imine-N-containing heterocycle) and the Tc metal center still remains unclear. It has been proposed that the technetium oxidation state in the ^{99m}Tc tricline complex is +5 (15, 16, 57). However, the oxidation state might change when the HYNIC group and imine-N are bonded to the Tc center since 2-hydrazinopyridine, which is a close analogue of HYNIC, has been shown to act as a reducing agent for pertechnetate or perrhenate (58, 59). Furthermore, the technetium oxidation state largely depends on how the HYNIC group binds to the Tc and how one counts the charge on the HYNIC ligand.

Complexes containing Tc-hydrazido and Tc-diazenido bonds have been previously reported and characterized by X-ray crystallography (58–66). Recently, Davison and co-workers (58, 59) reported a series of technetium(III) and rhenium(III) complexes of 2-hydrazinopyridine. It was found that, unlike phenylhydrazine, 2-hydrazinopyridine has several bonding modalities: neutral bidentate pyridyldiazene (58, 59), neutral monodentate pyridiniumdiazenido (58), and anionic monodentate pyridyldiazenido (59). Various Tc–Re complexes can be prepared depending upon the starting material and reaction conditions. For example, the reaction of $\text{NH}_4[\text{TcO}_4]$ with 2-hydrazinopyridine dihydrochloride in methanol produces a complex $[\text{TcCl}_3(\text{HN}=\text{NC}_5\text{H}_4\text{N})(\text{N}=\text{NC}_5\text{H}_4\text{NH})]$. The reaction of the complex $[\text{ReCl}_3(\text{HN}=\text{NC}_5\text{H}_4\text{N})(\text{N}=\text{NC}_5\text{H}_4\text{NH})]$ with triphenylphosphine (PPh_3) in the presence of a base such as diisopropylethylamine gives a complex $[\text{ReCl}_2(\text{PPh}_3)(\text{N}=\text{NC}_5\text{H}_4\text{N})(\text{N}=\text{NC}_5\text{H}_4\text{NH})]$, in which the $\text{N}=\text{NC}_5\text{H}_4\text{N}$ moiety was found to be an anionic monodentate pyridyldiazenido (67).

When the HYNICTide binds to the Tc, it likely occupies one site of the Tc coordination sphere by forming either a Tc–hydrazido or Tc–diazenido bond. If one assumes that the coordination geometry around the Tc is distorted octahedral, the tricline coligand is expected to be tetradentate. The technetium chelate is chiral, due to the

Chart 4. Eight Isomeric Forms from Bidentate HYNICTide and Tridentate Tricine in the Ternary Ligand [^{99m}Tc]HYNICTide Complexes

asymmetrical binding of the tricine coligand and should be formed in an equal mixture of D and L enantiomers. These enantiomers in combination with the chiral centers on the cyclic peptide backbone of HYNICTide (DLL) result in the diastereomers DDLL and LDLL. Therefore, it is not surprising that HYNIC-conjugated small molecules with one or more chiral centers form ternary ligand [^{99m}Tc]-HYNICTide complexes showing two radiometric peaks in their radio-HPLC chromatograms, as demonstrated in the chirality experiment, while HYNIC-conjugated small molecules without a chiral center form the corresponding ternary ligand [^{99m}Tc]HYNICTide complexes showing only one radiometric peak in their radio-HPLC chromatograms, as was observed for [^{99m}Tc](HYNIC-BA)(tricine)-(PSA)].

If HYNICTide bonds to the Tc center as a bidentate ligand (Chart 4), the tricine coligand has to be tridentate to complete the octahedral coordination sphere. Due to the relative geometric arrangement of these three different ligands, there are eight possible isomeric forms: four facial and four meridional (Chart 4). Each of these eight isomers has its enantiomer. This, in combination with the chiral centers of the HYNICTide, would result in total of 16 diastereomers, which should be at least partially resolvable under the chromatographic conditions used in this study. The fact that ternary ligand complexes [^{99m}Tc](HYNICTide)(tricine)(L)] (L = ISONIC, ISONIC-HE, MTE, PA, PES, and PSA) show only two radiometric peaks in their radio-HPLC chromatograms strongly suggests that these complexes have a common 6-coordinate distorted octahedron coordination geometry

with a monodentate HYNICTide, a tetradentate tricine, and a monodentate imine-N-containing coligand.

Recently, HYNIC has been used for the ^{99m}Tc -labeling of somatostatin analogues with a β -alanine or diaminobutanesuccinyl linker (10, 11). Tricine was used as the only coligand. It was found that these ^{99m}Tc -labeled somatostatin analogues are specific for the SRIF receptor, and show comparable tumor uptake to ^{111}In -DTPA-D-Phe-1-Octreotide (^{111}In -OctreoScan). One major drawback is the high level of blood activity. It was proposed that the high blood activity might be due to serum protein binding (11). The serum protein binding was also observed for the ^{99m}Tc -labeled DNA oligonucleotides when HYNIC was used as a bifunctional coupling agent (14). However, there was no evidence to prove the assumption. In this study, we clearly demonstrated that imine-N-containing heterocycles such as HIS-AC can react with the binary ligand complex [^{99m}Tc](HYNICTide)(tricine) $_2$ and form the stable ternary ligand technetium complex [^{99m}Tc](HYNICTide)(tricine)(HIS-AC)]. Since blood proteins contain many histidine amino acid residues, it is quite possible for the binary complex [^{99m}Tc](HYNIC-linker-Octreotide)-(tricine) $_2$ to react with the imidazole moiety of histidine residues from blood proteins, and form a stable bonding between the [^{99m}Tc]HYNIC-Octreotide complex and protein molecules. The results from this study provide direct evidence to support the assumption that the high level blood activity is indeed due to serum protein binding.

The coligand, ISONIC-Asp-OMe $_2$, is of particular interest because it contains two ester groups which can be enzymatically hydrolyzed in biological systems. Since ISONIC-Asp-OMe $_2$ carries no charge, it forms neutral technetium complexes, which can cross the cell membrane and potentially bind to intracellular receptors, if the biologically active molecule carries no charge. Once inside the cell, enzymatic hydrolysis of the ester groups forms negatively charged ^{99m}Tc species, which cannot be easily washed out. In this way, the target uptake may be significantly improved. If ester groups are hydrolyzed in the blood, the negatively charged ^{99m}Tc species is expected to have faster renal clearance than the neutral precursor. Therefore, the introduction of two ester groups has two potential advantages: increasing target uptake and decreasing background.

CONCLUSIONS

In this report, we described the use of a new ternary ligand system in the ^{99m}Tc labeling of a cyclic GPIIb/IIIa HYNICTide. The new ternary ligand system is composed of HYNICTide, tricine, and an imine-N-containing heterocycle. The imine-N-containing heterocyclic coligands include *N*- ω -acetylhistamine, *N*-(2-hydroxyethyl)isonicotinamide, isonicotinic acid, 4-methyl-5-thiazoleethanol, nicotinic acid, 3-nitro-1,2,4-triazole, pyridine, 4-pyridineethanesulfonic acid, 3-pyridinesulfonic acid, and 4-pyridylacetic acid. The ternary ligand complex [^{99m}Tc](HYNICTide)(tricine)(L)] (L = HIS-AC, ISONIC, ISONIC-HE, MTE, NTZ, PA, PES, PSA, and PY) was prepared in high yield and high specific activity ($\geq 10\,000$ Ci/mmol HYNICTide). We found that the ternary ligand complex [^{99m}Tc](HYNICTide)(tricine)(L)] (L = ISONIC, ISONIC-HE, MTE, PA, PES, PSA, and PY) is formed as equal mixtures of two isomeric forms. Using a chirality experiment, we demonstrated that the presence of two equal intensity radiometric peaks in their HPLC chromatograms is due to the resolution of two diastereomers which are formed as a result of the chiral centers on the cyclic peptide backbone and the formation of a mixture of

enantiomers for the technetium chelate when tricine is bonded to the Tc as a tetradentate ligand. We also found that these new ternary ligand [^{99m}Tc]HYNICTide complexes are stable for up to 6 h in the reaction mixture, and the high solution stability was due to their kinetic inertness. The composition of these complexes was determined to be 1:1:1:1 for Tc:HYNICTide:L:tricine (L = imine-N-containing heterocycle) through a series of mixed ligand experiments on the tracer (^{99m}Tc) level. The lipophilicity of the [^{99m}Tc]HYNICTide complexes can be systematically varied by the choice of polyaminocarboxylate and imine-N-containing coligands depending on the pharmacokinetic requirements. Using the combination of tricine and an imine-N-containing coligand, HYNICT-derivatized peptides or other small molecules can be labeled with ^{99m}Tc in high specific activity and high stability for potential use as radiopharmaceuticals.

Optimization and Immunological Characterization of a Photochemically Coupled Lysergic Acid Diethylamide (LSD) Immunogen

Sarah Kerrigan[†] and Donald. E. Brooks*

Departments of Chemistry and Pathology and Laboratory Medicine, 2211 Wesbrook Mall, University of British Columbia, Vancouver, British Columbia, Canada V6T 2B5 . Received March 18, 1998; Revised Manuscript Received June 30, 1998

A photoreactive heterobifunctional linker was used to prepare an immunogen in which lysergic acid diethylamide was indirectly coupled to keyhole limpet hemocyanin at multiple sites on the drug. It was possible to attach approximately 35 drug molecules to each protein using approximately equal amounts of both species during the reaction. The presence of buffer components or water severely compromised reaction efficiency, as estimated from the molar substitution ratio. Factors such as excess linker, pH, irradiation of dry matrix in the absence of buffer, and the drug/protein ratio used during photolysis were shown to have pronounced effects on reaction efficiency. Structural insights regarding immunogen coupling were obtained by determining the specificities of antibodies which were raised against the immunogen. Cross-reactivity data indicated that haptenation of protein likely occurred at positions N1 and N6 of lysergic acid diethylamide, which is plausible given the electrophilicity of the photogenerated aryl nitrene.

INTRODUCTION

The haptenation of protein for the purpose of raising antibodies to small molecules such as drugs or toxins influences the immune response at the T-cell level (1). The production of antibody is sterically influenced by the site of attachment between drug and carrier molecule. In practice, this effect is generally observed in cross-reactivity studies as decreased antibody specificity in the vicinity of the linkage. The chemistry of the linker moiety and the hapten density affect both the intensity and the character of the immune response, as does the nature of the carrier molecule (2). In theory, a superior antiserum is obtained following immunization with a highly immunogenic conjugate in which drug is attached to the carrier protein via an extended spacer arm to improve specificity. This approach allows the hapten to be held a short distance away from the protein surface, thus increasing the possibility that lymphocytes can distinguish the haptenic determinant at the site of attachment. Immunogen design, therefore, has a profound effect on the affinity, specificity, and overall characteristics of the antiserum. The quality of the antibody reagent can have a pronounced effect on the performance of immunoassays, which are frequently used to determine the concentration of a drug in a biological specimen.

Lysergic acid diethylamide (LSD)¹ is a controlled drug which is abused for its potent psychoactive properties. A typical dose is only between 50 and 100 μ g as a result of its unusually high potency, relative to other common hallucinogens such as psilocybin or mescaline. As a result of the small dose ingested and its rapid biotransformation, LSD detection in biological matrixes can be a formidable task for drug detection agencies. Immunoassay methodologies which rely on competitive binding principles require highly sensitive antibodies for successful measurements in the sub-microgram-per-liter region of forensic interest.

There have been surprisingly few developments in LSD immunogen design spanning the history of the drug's use. By far the most successful and widely used technique has been to couple the indole nitrogen of LSD to a carrier protein using a type of Mannich condensation, first described 25 years ago (3, 4). Protein haptenation has also been accomplished via carbodiimide-mediated linkage at the carboxyl group of lysergic acid (5, 6). The incorporation of a carbon spacer between the drug and carrier has been described for chemical linkages at both these reactive sites on the drug molecule (7, 8). At the present time, there are no known reports of LSD immunogens which utilize chemical linkages at sites other than N1 or C8, due to the complex chemistry of the drug and the limited number of reactive sites.

Recently, a new LSD immunogen was prepared using a novel haptenation procedure, whereby drug was coupled to the carrier protein in a nonspecific manner at a number of possible sites (9). Polyclonal antibodies raised against this immunogen were used to detect picogram quantities of LSD in urine by enzyme-linked immunosorbent assay (ELISA) (10). It is believed that the improved detection limits toward unmetabolized LSD were the results of multisite attachment of drug to carrier protein, which produces a theoretically superior antiserum (11). When LSD is coupled to keyhole limpet hemocyanin (KLH) using a photoreactive heterobifunc-

¹ BSA, bovine serum albumin; DMSO, dimethyl sulfoxide; DTT, dithiothreitol; ELISA, enzyme-linked immunosorbent assay; IgG, immunoglobulin G; KLH, keyhole limpet hemocyanin; LAMPA, lysergic acid methyl-*N*-propylamide; LSD, lysergic acid diethylamide; MSR, molar substitution ratio; NHS, *N*-hydroxysuccinimide; PBS, phosphate-buffered saline; SASD, sulfosuccinimidyl-2-(*p*-azidosalicylamido)ethyl-1, 3'-dithiopropionate; TMB, 3,3',5,5'-tetramethylbenzidine.

Figure 1. Schematic illustration of immunogen synthesis. The *N*-hydroxysuccinimide ester end of the photoreactive heterobifunctional linker, SASD, was coupled to amine residues on the protein, KLH, by nucleophilic substitution in the dark. After removal of excess hydrolyzed linker and buffer components by dialysis, LSD was added. Derivatized KLH and LSD were freeze-dried and the aryl azide was photoactivated under UV light. After the reaction, excess unbound drug was removed by dialysis.

tional linker, covalent attachments are the result of the relatively nonselective reactivity of the aryl azide moiety. Upon photoactivation, a highly reactive aryl nitrene is produced, which can react with neighboring drug molecules in a number of ways. This approach facilitates multisite attachments at positions on the drug molecule which would not normally be possible using group-specific coupling reagents. This technique reduces the chance that epitopes at the site of attachment are not recognized by the immune system, making more epitopes available for recognition and, therefore, increasing antiserum sensitivity.

Using the heterobifunctional linker sulfo succinimidyl-2-(*p*-azidosalicylamido)ethyl-1,3'-dithiopropionate (SASD), a two-step conjugation procedure was described for the synthesis of the LSD immunogen, KLH-SASD-LSD (9). In the first step, primary amines in KLH were coupled to the *N*-hydroxysuccinimide ester end of the linker in the absence of light. Following removal of excess linker, LSD was photochemically coupled to the aryl azide moiety of the modified protein, as outlined schematically in Figure 1.

This work describes a number of variables which were found to affect the conjugation procedure, in particular the overall efficiency of the reaction which was estimated from the molar substitution ratio (MSR). A theoretical discussion of feasible linkages is provided with respect to aryl azides. Finally, immunological characterization of the antiserum in a cross-reactivity study was used to obtain some structural insight into the possible sites of attachment during haptenation.

EXPERIMENTAL SECTION

Materials. Keyhole limpet hemocyanin, sulfo succinimidyl-2-(*p*-azidosalicylamido)ethyl-1,3'-dithiopropionate, and Slide-A-Lyzer dialysis cassettes were obtained from Pierce (Rockford, IL). Coomassie Brilliant Blue G-250 was supplied by Eastman Kodak (Rochester, NY). Fluorescamine [4-phenylspiro[furan-2(3H),1'-phthalan]-3,3'-dione], dithiothreitol (DTT), 3,3',5,5'-tetramethylbenzidine (TMB), and goat anti-rabbit IgG peroxidase were obtained from Sigma (St. Louis, MO). ACS grade inorganic salts, glycine, acids, organic solvents, and hydrogen peroxide were supplied from Fisher Scientific

(Edmonton, AB). Dimethyl sulfoxide (DMSO) was dried over molecular sieves prior to use.

Iso-LSD and lysergic acid methyl-*N*-propylamide (LAM-PA) were supplied by Dr. Kevin Gormley through the National Institute on Drug Abuse (NIDA) Drug Supply Program (Rockville, MD). Dr. Haro Avdovich of the Bureau of Drug Research (BDR), Health Canada, (Ottawa, ON) supplied *d*-lysergic acid diethylamide, dimethyltryptamine, *d*-lysergic acid, and lysergic acid amide. Ergonovine maleate, α -ergocryptine, ergotamine tartarate, lysergol, and *N*-demethyl-LSD (nor-LSD) were purchased from Sigma (St. Louis, MO). Research Biochemicals Inc. (Natick, MA) supplied ergocornine, ergocryptine, methylegonovine maleate, methysergide maleate, and *d*-lysergic acid diallylamide tartarate. Finally, 2-oxo-3-hydroxy-LSD was purchased from Radian International (Austin, TX).

Disposable flat-bottomed 96-well polystyrene microtiter plates were purchased from Corning (New York, NY). A solution of Carnation nonfat skim milk powder (5%) in 150 mM, pH 7.4, phosphate-buffered saline (PBS) was routinely used as the blocking solution in enzyme-linked immunosorbent assays. The TMB substrate solution (12), which was prepared immediately before use was made up as follows. Deionized water (16 mL) was added to pH 6.0 acetate/citrate buffer (4 mL) after which 200 μ L of 3,3',5,5'-tetramethylbenzidine in dimethyl sulfoxide (10 mg/mL) and 20 μ L hydrogen peroxide (3%) were added. The acetate/citrate buffer was made by adding 200 mM citric acid to 200 mM sodium acetate to give a final pH of 6.0. The Bradford dye binding reagent (13) was prepared by dissolving Coomassie Brilliant Blue G-250 (10 mg) in 5 mL of ethanol after which 10 mL of phosphoric acid (85%) was added and the total volume made up to 100 mL with deionized water.

Modification of Protein with SASD at Varying pH. The reaction efficiency of SASD with protein at different pH values was estimated by measuring the decrease in the number of amines before and after the reaction. Quantitative determination of primary amine residues was performed using fluorescamine as previously described (14). Briefly, a sample containing primary amines (1.5 mL) was vortex mixed with 0.5 mL fluorescamine (0.3 mg/mL) in acetone. After 10 min, the fluorescence was measured using a Turner model 430 Spectrofluorometer at excitation and emission wavelengths 395 and 475 nm, respectively. Glycine was routinely used as the standard to compensate for changes in fluorescence intensity over a range of pH.

It was necessary to remove the photoreactive aryl azide group of the derivatized protein prior to the fluorescamine assay. This was achieved by cleavage of the disulfide group using the reducing agent dithiothreitol (DTT). The percent of protein residues which were modified with SASD over a range of pH was measured using BSA in place of KLH, to minimize solubility problems. In the absence of light, 100 μ g of BSA was reacted with SASD (0.14 mg in dry DMSO) for 2 h in 50 mM phosphate or carbonate buffer between pH 7.0 and 9.5. Samples containing BSA in the absence of SASD were run in parallel for use as the blanks. DTT (0.06 mg in deionized water) was added to each sample and reacted for 1 h, after which excess linker and the photoreactive end were removed by centrifugal filtration (Centricon-10, Amicon, Oakville, ON). After isolation of the high molecular weight fraction of interest, the number of lysines which were underivatized was estimated from the ratio of fluorescence measurements before and after reaction at

different pH values. The percent of amines that were coupled to SASD was calculated by difference.

Derivatization of KLH with SASD. The *N*-hydroxysuccinimide ester of SASD was coupled to the carrier protein KLH by nucleophilic substitution at optimal pH. An improvement in yield was observed when the first conjugation step was performed directly in the dialysis cassette. This obviates the need for sample transfer after the reaction. The same cassette was rinsed and reused for dialysis in the second conjugation step to reduce additional sample loss due to adsorption on the membrane.

All steps preceding photolysis were performed in complete darkness or in the presence of a red safety light. SASD (5.0 mg) was dissolved in 50 μ L of DMSO which had been dried over molecular sieves. KLH (2.0 mg) dissolved in 1.5 mL of 100 mM, pH 8.0, phosphate buffer was injected into a 3 mL Slide-A-Lyzer dialysis cassette. SASD in DMSO was injected through a second port into the cassette with gentle agitation. A small air bubble (0.5 mL) was injected to facilitate mixing, and the cassette was taped to an oscillating table and allowed to react for 2 h in the dark. The cassette was then mounted on a floatation device and dialyzed against deionized water or PBS in the dark for 2.5 h with half-hourly water changes to remove the excess unreacted linker or its hydrolysis products. The high molecular weight solution containing the modified protein was removed from the dialysis cassette and stored in the dark until use. LSD (2.2 mg) was added and the mixture was freeze-dried in the absence of light prior to the photoactivation step.

Photoactivation with LSD. KLH which had been derivatized with SASD was photoactivated with LSD using different conditions. Due to the nonselective nature of the photocoupling reaction, the molar ratio of LSD to KLH during the reaction was investigated. The reaction was performed using modified KLH and LSD which had been freeze-dried in the absence of light. The photocoupling step was also performed in solution, in the presence of either water or buffer (PBS). Photoactivation was performed using a Chromato-Vue C3 viewing box (UltraViolet Products Inc., San Gabriel, CA). Samples were placed 10 cm from two long wave (General Electric G15T8, 15W) germicidal lamps and two short wave (Sylvania Blacklite F15T8-BL, 15W) phosphor-coated lamps, which emit light at 254 and 365 nm, respectively. A reaction time of 20 min was sufficient for photoactivation of the aryl azide of SASD, as determined by the 45% decrease in the absorption maximum (10) in accordance with the literature (15–17). Unbound LSD was removed by extensive dialysis over 24 h in a Slide-A-Lyzer cassette. TLC of the purified immunogen indicated that noncovalent incorporation of LSD into the protein was negligible.

Estimation of the Molar Substitution Ratio (MSR). Concentrations of LSD and KLH in the antigen were estimated using spectrofluorometry and colorimetric protein assays, respectively, as previously described (9). The purified immunogen was poorly soluble so antigen preparations were allowed to stand overnight at 4 °C, after which the clear supernatant layer containing the soluble fraction was removed for analysis. Quantitative estimates of LSD in the immunogen were based on the assumption that there was no change in the native fluorescence of LSD before and after reaction. The fluorescence spectrum of the soluble immunogen indicated the excitation and emission wavelengths were unchanged ($\lambda_{\text{ex}} = 322$ nm, $\lambda_{\text{em}} = 412$ nm), although it is not known how the intensity of the LSD fluorescence is

affected once the drug was bound. However, there was a good correlation between this method and the more widely used UV absorption method as demonstrated previously (3, 9). The drug content, therefore, was estimated directly from the spectrofluorometric calibration of LSD. The concentration of KLH in the soluble antigen was estimated by the Bradford method (13) in which dye-binding reagent (200 μ L) and sample (100 μ L) were mixed in a microtiter plate. The absorbance was measured using an SLT microtiter plate reader EAR 400 AT (SLT-Labinstruments, Austria) at 550 nm and the concentration of KLH in the immunogen was interpolated directly from the calibration graph.

Investigation of Immunogen Structure. Structural insights regarding the sites at which LSD was coupled to KLH in the immunogen were obtained by measuring the cross-reactivity of the polyclonal antiserum produced in rabbits which were immunized with the conjugate. A standard immunization protocol was used whereby 150 μ g of immunogen was injected subcutaneously in Freund's complete adjuvant followed by intramuscular booster injections in Freund's incomplete adjuvant at monthly intervals (18). The specificity of the antiserum toward a number of structurally related analogues to LSD was measured using a competitive binding ELISA (10). Polystyrene microtiter plates were coated overnight at 4 °C with 100 μ L BSA–LSD conjugate (10 mg/L in PBS) prepared by the Mannich reaction (3, 4). After treating uncoated sites on the well with 150 μ L of blocking solution (5% skim milk powder in PBS) for 30 min at 37 °C, wells were washed thoroughly with PBS. LSD or related compounds were diluted in blocking solution (10^{-7} – 10^{-12} M), and 50 μ L was added to the plate. An additional 50 μ L of rabbit anti-LSD in blocking solution was added, such that the overall serum dilution was 1:50. After incubation for 2.5 h at 37 °C, the plate was rinsed with PBS and 100 μ L goat anti-rabbit IgG peroxidase (1:1000) in blocking solution was added. Following a 30 min incubation at 37 °C, wells were washed with PBS and 100 μ L TMB substrate solution was added. After 5 min, the reaction was stopped using 50 μ L of 1 M sulfuric acid and the absorbance was measured at 450 nm using 620 nm as the reference using a microtiter plate reader.

RESULTS AND DISCUSSION

Derivatization of Protein with Linker. The incorporation of sufficient LSD for immune recognition is dependent on the successful modification of KLH with aryl azides. Only the unprotonated amines on the protein are reactive toward the NHS ester region of the linker; therefore, it is necessary to use a pH at which a significant number of amines are uncharged. Fluorescamine was used to determine the pH conditions at which the availability of unprotonated amines was maximized (Figure 2). A shift in pH from neutral to alkaline pH increased fluorescence, which is linearly related to the number of primary amines, more than 3-fold. This is in accordance with the deprotonation of lysine residues ($pK_a \approx 10$) which is the principal source of primary amines in the protein.

Fluorescence measurements before and after reaction were used to estimate the number of lysines which had been derivatized with SASD at different pH values. Figure 2 illustrates the delicate balance between competing aminolysis and hydrolysis reactions. Increasing stoichiometry with increasing pH is the result of deprotonation of amine groups whereas the decrease in reac-

Figure 2. Effect of pH on availability of primary amines using the fluorescamine assay. BSA, 6.25 μg (diamonds), KLH, 25 μg (squares). The fluorescence signal, which is linearly related to the number of amines, was calculated relative to glycine, at the same pH. (Below) Effect of pH on reaction efficiency using BSA and SASD (circles). The percentage of amines coupled to linker was determined by difference using fluorescamine, before and after reaction.

tion efficiency at elevated pH is the result of NHS ester hydrolysis. A shift of 1 pH unit from 7.0 to 8.0 increased the derivatization of lysines by more than a factor of 2. Therefore, a pH of 8.0 was chosen as a compromise between the number of available amines and the lability of the ester. The ester moiety of SASD although stable at acid pH, hydrolyzes to *p*-azidosalicylamido-1,3'-dithiopropionate and *N*-hydroxysuccinimide (NHS) under alkaline conditions. The half-life of NHS-esters at pH 9, 7.5, and 5 is reported to be 1, 14, and >90 min, respectively (19). Optimum substitution is achieved when a large molar excess of linker is used to overcome inefficiencies due to hydrolysis (20, 21). When a 20 molar excess of linker to primary amines on KLH was used at pH 8.0, approximately 45% of the lysine residues were coupled to SASD. Assuming there to be about 689 lysine residues in the KLH molecule, this corresponds to a total of about 310 photoreactive linker moieties attached to each protein, assuming a molecular mass of 3×10^6 Da (9, 22).

Photochemical Coupling and the Molar Substitution Ratio. Estimation of the molar substitution ratio using LSD fluorescence and protein quantitation provided useful insight into the effect of photocoupling conditions on reaction efficiency. Most of the typical methods used for determining substitution ratios could not be used due to the very large size of KLH [350–13 000 kDa (23)] and the poor solubility of the immunogen ($\sim 5 \mu\text{g/mL}$). UV spectroscopic determination was not possible due to the overlapping absorption of SASD with both KLH and LSD. Indirect spectroscopic techniques,

such as the use of trinitrobenzene sulfonic acid (TNBS) allow the colorimetric determination of unreacted amino groups in the milligram per milliliter concentration range. Radiolabeled haptens can be used to measure the extent of coupling directly, by measuring the associated radioactivity of the conjugate. However, this technique is not advocated for photochemical coupling due to non specific ("dark") labeling or photodeiodination (15, 24). Mass spectrometry, particularly electrospray and matrix-assisted laser desorption ionization techniques, have become increasingly useful for the characterization of conjugates which are soluble at sufficient (approximate micromolar) concentration (25–27).

Characterization of the LSD immunogen in which relatively few drug molecules are attached to a protein with a molecular mass of several million is not an easy task. The fluorescence technique was the only method suitable for sensitive and specific estimation of LSD bound to KLH in the immunogen (9).

The combined fluorescence and Bradford dye-binding methods provides only a comparative approximation of the LSD content in the soluble immunogen fraction since it is dependent on a number of assumptions. The photolytic approach to immunogen synthesis likely results in a number of high molecular weight products with varying degrees of substitution. The first assumption is that the LSD content of the soluble fraction is representative of the entire sample, which might not be true. Solubility is likely to decrease with increasing substitution of protein which might result in the least soluble complexes (which have higher MSRs) precipitating out.

Optimization of Photocoupling Conditions. As expected, removal of excess unreacted linker prior to photoactivation was essential. Its presence in the reaction mixture severely compromised reaction efficiency by competing with drug for the limited number of aryl azide moieties. Liquid-phase photoactivation also decreased the MSR of the immunogen. When photolysis was performed in aqueous solution rather than on a freeze-dried sample, there was more than a 40% decrease in efficiency. Removal of water from the reaction mixture is preferred because the nitrene can react with water to form hydroxylamine (28), which decreases the substitution ratio. Despite reports of poor reaction efficiencies due to photolysis in aqueous solvents (16), there are no known reports in the literature of conjugation by dry photoactivation, as was routinely employed in this study.

Molar substitution ratios were measured over 2 orders of magnitude using dry photoactivation under various conditions. The covalent coupling of aryl azides on KLH with neighboring molecules is nonspecific. Therefore, to increase the chance of reaction with LSD, a large excess of drug was used. Figure 3 summarizes the results of 12 immunogen preparations performed over a number of weeks in which the molar ratio of LSD to KLH employed during photoactivation was varied. Dried down buffer components were present in the reaction matrix during irradiation. Clearly, the initial LSD/KLH ratio employed during photolysis determined the degree of substitution in the immunogen. There was a good correlation between increased concentration of LSD during photolysis and increasing molar substitution ratio ($r = 0.958$). The use of large excesses of drug during photolysis is a definite drawback, however, considering that LSD is a controlled substance which is available in limited supply. Reaction conditions which produced optimum substitution under these conditions could not

Figure 3. Effect of excess LSD on molar substitution ratio (MSR). Immunogen was prepared by irradiation of freeze-dried modified protein and LSD in the presence of dried buffer components (squares) and in the absence of buffer (circles).

be employed on a preparative scale for immunization of rabbits, because the quantity of drug required was too large.

However, dialysis of the immunogen matrix against deionized water prior to photoactivation showed improved performance (Figure 3). A dramatic increase in reaction efficiency was observed when buffer components were removed prior to irradiation. By this method, molar substitution ratios of 20–50 were attainable using only slight excesses of drug. This suggests that buffer components in the reaction matrix compete with LSD for the limited number of reactive nitrenes on the protein. In the absence of buffer, photoactivation of approximately equal amounts of KLH and LSD by weight produced conjugates with average substitution ratios of about 35.

Reaction Efficiency. The efficiency of the reaction was calculated from the percentage of lysine residues on KLH that were eventually coupled to LSD. The average two-step reaction efficiency for the injected immunogen was 5% assuming 35 LSDs attached to each KLH molecule, which contains about 689 lysine residues/ 3×10^6 Da molecule (9). It was estimated that only about 45% of the total lysines on KLH were derivatized with SASD. Therefore, the reaction efficiency of the photolysis step toward LSD using optimized conditions was approximately 11%, which is quite favorable considering the nonselective nature of the photochemical coupling. This is likely the result of solvent and buffer removal prior to photolysis and the presence of nucleophilic groups on LSD which attract the electrophilic nitrene. Typical efficiencies of photoreactive linkers which are used to couple high molecular weight species are generally low due to the nonspecific nature of the reaction. Reaction efficiencies of 15% using conventional aryl azide photoprobes such as SASD are considered good (29).

Reaction efficiencies vary greatly, depending on the type of linker used. The recent introduction of polyfluorinated phenyl azide heterobifunctional linkers, which generate strongly electrophilic nitrenes, result in greater efficiencies (30, 31) typically reported between 20 and 60% (32). The use of a fluorinated photoreactive linker and a carrier protein which contains more lysine residues would improve efficiency. The availability of primary amines on KLH and BSA at pH 8.0 was determined using the fluorescamine assay. Following linear regression analysis, a direct comparison of the slopes for BSA (0.233 ± 0.009 , $r = 0.997$) and KLH (0.057 ± 0.004 , $r = 0.987$)

Figure 4. Important reactions of the aryl azide group.

indicated that KLH had only $25 \pm 3\%$ of the lysines available on BSA by weight. This finding suggests that overall higher reaction efficiencies might be achieved using albumin, although the immunogenicity of the derivatized BSA conjugate may be lower than that of KLH.

Theoretical Considerations. Insertion of aryl azides in model systems such as cyclohexane or diethylamine is well documented (33), although investigation of protein conjugates is rarely attempted. The relationship between insertion characteristics of the nitrene in a model system compared to a macromolecule is extraordinarily difficult due to the variety of functional groups and environments in the protein (16). The complex photochemistry of aryl azides involves three excited states and at least six short-lived ground-state intermediates. Photolysis of phenyl azides usually results in multiple reaction pathways of highly amorphous products which make interpretation and identification often difficult. To complicate things further, the products are highly variable, depending on reaction conditions such as an inert or reactive solvent systems, characteristics of the light source and substituent groups on the aryl azide ring. To gain some insight into the reactivity of the derivatized protein toward neighboring molecules, some important reactions of aryl azides are summarized in Figure 4. These include insertion into NH bonds to form hydrazines (1), reduction of the azido group (2), nucleophilic ring expansion to form azepines (3), formation of azobenzene (4), insertion into CH bonds (5), and addition across double bonds to form aziridines (6).

It should be noted, however, that the most favorable reaction pathways are primarily dependent on the electrophilic character of the nitrene and its environment. CH insertion products are produced using very strongly electrophilic nitrenes, such as polyfluorinated phenyl azides. Strong electron-withdrawing groups increase the

reactivity of the nitrene toward CH bond insertion. Aryl azides without such substituents are more likely to react with other groups, such as nucleophiles, especially if they are embedded in a nucleophilic environment, such as a protein molecule.

The lifetime of a reactive nitrene is about 10^{-4} s (34), although this depends on the substituent groups attached to the aryl ring (35). Aryl nitrenes or their intermediates may react with C—H, N—H, and aryl groups, which are present in the LSD molecule. The nitrene is one of the few reactive species that can react with C—H by abstraction and insertion, therefore allowing covalent attachment in the absence of any particular functional group. Because the species is particularly reactive toward nucleophilic groups, it is likely that a large part of the nitrene reactivity on the modified protein will be self-directed. However, the 19 Å spacer arm of SASD increases the likelihood of a bimolecular reaction (35).

An inherent disadvantage of the photocoupling technique is its low efficiency compared to most site-specific bioconjugation techniques. Yields resulting from photo-reactive linking of unsubstituted aryl azides are generally low, and efficiencies less than 10% are considered acceptable (20). Efficient coupling requires not only a reactive nitrene but also a favorable orientation toward the target molecule. To partly compensate for this, it is necessary to use a large excess of LSD to improve the probability that the photogenerated species is in proximity to a drug molecule.

Perhaps the most important difference between the literature reports of aryl nitrene chemistry and the system we describe is the use of a solid matrix for photoactivation. There have been only a few reports of the effect of temperature and phase on aromatic nitrene chemistry. Although the simple systems examined do not resemble our immunogen reaction matrix, a number of interesting observations have been made. In a restricted environment, such as solid state or ligand bound to macromolecule, radical coupling may predominate due to limited movement of the reactive species (36). It was suggested that the increase in CH insertion products via radical recombination in a "rigid" matrix was due to trapping aryl azides in the hydrophobic crevices of the protein, which resulted in higher protein labeling efficiencies (16).

Photoactivation of the aryl azides on KLH in the presence of LSD likely results in a great many products given the complexity of the reaction matrix and the diversity of functional groups which are present. A mixture of both favorable and unfavorable reaction products are contained in the high molecular weight fraction.

The most desirable reactions are those which take place between modified KLH and LSD, of which there are a number of hypothetical products (Figure 4). Azepine type conjugates (3) may result from the reaction between the electrophilic nitrene and nucleophilic substituents on LSD. Lone pairs on amino nitrogen and other nucleophiles are known to attract the nitrene. In LSD, the nitrogen in the 6 position is strongly basic due to the presence of three electron-donating alkyl groups. The indole nitrogen, which is less basic due to the aromaticity of the indole ring, could also react with a nitrene to form an azepine. Addition across double bonds (6) could also occur at a number of sites on the LSD molecule, although there are very few reports of stable aziridine products from such reactions (28). Singlet nitrenes can insert into CH bonds (5) with varying efficiencies depending on the CH bond strength. A possible site for this reaction could

be the acidic hydrogen in the 2 position, which would lead to formation of an amine. Phenyl azides are also capable of NH insertion reactions (1) which could take place at the indole nitrogen to produce a hydrazine product. In summary, there are a number of hypothetical reaction sites on LSD which would result in covalent attachment of the drug to the modified protein.

However, there are many undesirable reactions which might occur in the reaction matrix between aryl azide and neighboring amino acid residues. The reactivity of aryl nitrenes toward functional groups found in biological molecules is unquestionable. In particular, reactivity with aryl (Phe, Tyr, Trp, His), N—H (Lys, His, *N*-termini), O—H (Ser, Thr, Try), and S—H (Cys) has been suggested (37). In one report, photolysis of [^{125} I]SASD in the presence of BSA indicated incorporation of radiolabel into His, Thr, Lys, Cys, Glu, and Asp (38). It is quite likely that the bulk of the nitrene reactivity is directed toward these residues and not the target molecule, LSD. For this reason, it is necessary to use an excess of drug during photolysis, so that LSD is utilized as a "scavenger". These species are used in conventional photoaffinity labeling to preferentially react with photogenerated intermediates at places other than the ligand-binding site between protein and receptor. Nucleophilic molecules such as tris and *p*-aminobenzoic acid have been used for this purpose (35). In a sense, LSD which contains a number of groups which are reactive toward electrophilic nitrenes, is utilized as a scavenger to bind nonspecifically with photolabeled protein.

Poor efficiencies of photoreactive conjugation processes have been attributed to the unwanted reactions which occur between the aryl azide and water or buffer components in the mixture (35). Other unwanted reactions involve the formation of aniline (2) or azobenzene (4) type products. With respect to the latter case, the reaction between two aryl azide moieties in the immunogen is unlikely due to the limited number of reactive nitrenes and the restricted mobility of the derivatized protein in the solid-phase matrix. However, intramolecular cross-linking may occur if the two aryl azide groups are in close enough proximity.

Antibody Specificity and Immunogen Structure.

The cross-reactivity of anti-LSD antisera raised against the photocoupled immunogen was measured by ELISA. Regions of the drug molecule which demonstrate reduced specificity indicate that molecular transformation or conjugation may have taken place. An antibody will not recognize a particular epitope if it has not been exposed to it during immunization. This occlusion may occur as a result of the chemical linkage which exists between the hapten and carrier. Depending on the size of the protein and the distance between it and the hapten, areas surrounding the point of attachment may be obscured from the immune system. This is of particular importance for small molecules such as drugs of abuse, for which immunogen design plays a fundamental role in determining the overall antibody specificity (39–41). As a result, cross-reactivity studies can provide valuable insights into possible structural attachments which have taken place in the immunogen.

Antiserum cross-reactivity toward LSD analogues is illustrated in Figure 5. The approximate percent cross-reactivity was estimated from the concentration of analogue, which produced a signal equivalent to 1.55 nM LSD (0.5 ng/mL), which is the generally accepted cutoff concentration for LSD by immunoassay. The highest cross-reactivity was toward BSA-LSD coupled via the indole nitrogen (100%), 6-nor-LSD (52%) and LAMPA

Figure 5. The specificity of the antibody raised against the immunogen was measured by ELISA. The approximate percent cross-reactivity was calculated from the concentration of analogue which produced a signal equivalent to 1.5 nM LSD. Measured cross-reactivities of 0.08% or greater are shown in parentheses.

(34%). In LAMPA, the two ethyl substituents on the amide side chain of LSD are replaced with propyl and methyl groups which do not significantly change the electronic properties of the drug. It is, therefore, no surprise that LAMPA cross-reacts with the antiserum to such an extent. A number of other compounds tested had structural differences at the amide position. When ethyl groups were replaced with hydrogen, in lysergic acid amide, no recognition occurred. In the same way, α -ergocryptine, ergocornine, ergocryptine, ergonovine, ergotamine, and methylethylgonovine, all of which are modified with large hydrocarbon groups at the amide position, do not significantly cross-react with the antiserum. When C_2H_5 is replaced with $CH_2-CH=CH_2$ in lysergic acid diallylamide, only minimal cross-reactivity was observed (<3%). The replacement of electron-donating ethyl groups with electron-withdrawing allyl groups makes the nitrogen less basic and significantly changes the properties of the molecule in such a way as to prevent effective antibody recognition.

Further insight is provided by analogues which differ from LSD at the C8 position. Replacement of the amide substituent with carboxylic acid or alcohol in *d*-lysergic acid and lysergol produced no cross-reaction and *iso*-LSD, which is a stereoisomer of LSD, cross-reacted only 0.05%. The antiserum recognizes the change in spatial arrangement of diethylamide in *iso*-LSD, thus producing a poor fit between the antibody-binding site and the drug. Overall, the antiserum exhibits good specificity in the vicinity of C8 and the amide. This suggests that, not only did conjugation not occur here but an epitope exists in this region.

Significant cross-reactivity was observed with nor-LSD which is modified in the N6 position. However, it has been shown that replacement of alkyl groups with hydrogen in the amide substituent sufficiently changed the properties of the drug, preventing effective antibody recognition. This not being the case in the N6 region might be suggestive of a covalent attachment having taken place. The reactive nitrene tends to be electrophilic in nature, thus having a preference for regions of high electron density, such as double bonds or lone pairs (28). The nitrogen at the 6 position is a tertiary amine, with three electron-donating groups. It is feasible that the electron-deficient nitrene is attracted to the lone pair on this basic nitrogen which subsequently results in covalent attachment at this point. Further evidence for the proposed reactivity between the aryl azide and nitrogen

is provided by the cross-reactivity of antibody with BSA-LSD, in which LSD is derivatized at the indole nitrogen (3). The indole nitrogen is less basic than the tertiary amine because of the electron-withdrawing double bonds of the indole ring. However, if the nitrene was attracted to the lone pair of electrons on the indole nitrogen, the subsequent chemical linkage would explain the failure of the antibody to distinguish the derivative from the parent drug. In addition to this, the hydrogen atom adjacent to the indole nitrogen is reactive. The removal of this acidic hydrogen results in a nucleophilic carbon in the 2 position which could also attract an electrophilic nitrene. A small cross-reactivity (3%) toward 2-oxo-3-hydroxy-LSD was observed. However, given the likelihood of an attachment at the indole nitrogen, it is possible that this cross-reaction is the result of the nearby linkage which depreciates immune recognition of the drug at adjacent positions.

Structural attachments within the immunogen are almost impossible to determine by conventional means due to the size and poor solubility of the immunogen. Therefore, the cross-reactivity of LSD-like substances provided valuable insight into possible sites of attachment in the immunogen. These data suggest that multisite attachment did occur between LSD and KLH, most likely at positions 1 and 6 of the drug, which is plausible given the reactivity of the photogenerated nitrene.

Preparation of a Spermine Conjugate of the Bis-phenanthroline Ligand Clip-Phen and Evaluation of the Corresponding Copper Complex

Marguerite Pitié and Bernard Meunier*

Laboratoire de Chimie de Coordination du CNRS, 205 route de Narbonne, 31077 Toulouse Cedex 4, France.
Received March 23, 1998; Revised Manuscript Received July 2, 1998

We described the synthesis of conjugates of *N,N*-diethylethylenediamine and spermine with Clip-Phen, a new ligand with two 1,10-phenanthrolines linked by serinol. The ability of the copper complexes of these Clip-Phen conjugates to cleave Φ X174 DNA when activated by a reductant in the presence of air was compared to that of 1,10-phenanthroline copper complexes. The results indicated that Clip-Phen–spermine with copper was the most active DNA cleaver. Comparison with a conjugate having only one phenanthroline unit linked to spermine showed that the high activity of Clip-Phen–spermine–Cu was not only due to the presence of spermine, which increases the affinity of the Clip-Phen entity for the DNA, but was effectively due to the presence of the two bridged phenanthroline entities. The DNA cleavage activity of (Clip-Phen–spermine) CuCl_2 was analyzed on a 167 bp restriction fragment and a 45-mer double-stranded oligonucleotide.

INTRODUCTION

Transition-metal complexes endowed with redox properties and DNA affinity have been developed as chemical cleavers of nucleic acids for the last two decades. Their ability to cleave DNA has several possible applications that include probing structural variations in nucleic acids, identification of binding sites of DNA ligands, design of artificial DNA cleavers, and potential chemotherapeutic agents. Typical examples are Fe^{III} -EDTA, manganese^{III}-porphyrin, Co, Rh or Ru complexes of phenanthroline or bipyridine, and the classical $[(\text{Phen})_2\text{Cu}^{\text{II}}]^{2+}$ complex (1–4).

1,10-Phenanthroline is a versatile ligand able to chelate copper to give mono-Phen or bis-Phen copper complexes at the oxidation state I or II (5). The $(\text{Phen})_2\text{Cu}^{\text{I}}$ complex in the presence of hydrogen peroxide efficiently cleaves DNA by oxidative attack on deoxyribose units from the DNA minor groove (6, 7). The Phen– Cu^{I} complex is less efficient (8). DNA cleavage products include 5'- and 3'-monophosphate ester termini, free bases, 5-methylenefuranone, and a small amount of 3'-phosphoglycolate (9–11). Hydrogen peroxide can be generated closely to the DNA by the $(\text{Phen})_2\text{Cu}^{\text{II}}$ itself in the presence of a reductant and molecular oxygen. $(\text{Phen})_2\text{Cu}$ cleaves double-stranded DNA at all nucleotides, but some preferences have been observed for particular conformations of B-DNA, lac-operon control region, or TAT triplets (12–15).

Different conjugates between phenanthroline and targeting DNA ligands have been prepared in order to enhance the cleavage specificity but also the reactivity

of the corresponding copper complexes by increasing their affinity for the DNA. For example, 1,10-phenanthroline has been conjugated to oligonucleotides, minor groove binders such as Hoescht-33258 or DNA binding proteins (16–22). But all these chimeric compounds contain only one phenanthroline unit, which is not the best situation for DNA cleavage, since the higher cleavage activities have been observed with a Phen/Cu ratio of 2–1.

We have recently prepared Clip-Phen (Scheme 1), a new ligand with two 1,10-phenanthroline entities linked via their C2-carbon by a short flexible arm adapted for having both phenanthrolines on the same copper ion (23). In the presence of copper(II) and a reductant and air, we observed on Φ X174 a better DNA cleavage activity for Clip-Phen than for 1,10-phenanthroline. Furthermore, this ligand has an exogenous primary amine to facilitate the attachment of different possible vectors in order to increase and to modulate the binding domain of this DNA cleaver.

We report here the synthesis of new conjugates of Clip-Phen with *N,N*-diethylethylenediamine (DEEDA) or spermine (sp) and the DNA cleavage activity of the corresponding copper complexes. We chose DEEDA in order to have a new amine-containing ligand with a terminal tertiary amine attached to Clip-Phen. Since DEEDA is easily protonated in physiological conditions, the presence of the terminal tertiary amine should be an additional favorable factor for DNA interactions of this molecule (Clip-Phen-DEEDA **2**, Scheme 1). We also used spermine to create another Clip-Phen conjugate (Clip-Phen-sp **3**, Scheme 1) which should have an enhanced DNA affinity compared to Clip-Phen itself, since this natural polyamine, protonated in physiological conditions, exhibits a strong DNA affinity (24–28). Spermine has been successfully used in different conjugates to enhance their affinity for DNA and consequently their reactivity (29–33). Since the conjugate Clip-Phen-spermine was particularly active (see below), we also decided to prepare a Phen–spermine conjugate (Phen-sp **6**, Scheme 1) with only one phenanthroline unit linked to

¹ Abbreviations: BOP, benzotriazol-1-yloxy-tris(dimethylamino)phosphonium hexafluorophosphate; bp, base pair; DEEDA, *N,N*-diethylethylenediamine; HOBt, 1-hydroxybenzotriazole; MPA, mercaptopropionic acid; ODN, oligodeoxyribonucleotide; Phen, 1,10-phenanthroline (also abbreviated as oP); sp, spermine = *N,N'*-bis(3-aminopropyl)-1,4-butanediamine.

Scheme 1. Reaction Pathways for Preparation of the Different Clip-Phen Conjugates^a

^a Yields of each steps are given in brackets. Numbering corresponds to NMR assignments (a) Serinol, NaH in DMF (72%). (b) Succinic anhydride in chloroform (79%). (c) BOP, HOBT, *N*-methylmorpholine, DEEDA, in dichloromethane (100%). (d) BOP, HOBT, *N*-methylmorpholine in DMF, then spermine in DMF/water (86%). (e) Ethanolamine, NaH in DMF (55%). (f) Succinic anhydride in chloroform (88%). (g) BOP, HOBT, *N*-methylmorpholine in DMF, then spermine in DMF/water (63%).

spermine in order to confirm that the high DNA cleavage activity of Clip-Phen-sp was effectively due to the presence of the two phenanthroline entities. The DNA cleavage activity of (Clip-Phen-spermine) Cu^{II} was analyzed with different modes of activation (dioxigen and a reductant, hydrogen peroxide, etc.) on phage ΦX174 , a restriction fragment and an oligonucleotide and was compared to that of (Clip-Phen) Cu^{II} and (Phen) $_2\text{Cu}^{\text{II}}$ complexes.

MATERIALS AND METHODS

General Methods. Proton NMR spectra were recorded on Bruker 250 MHz. UV-vis spectra were recorded on a Hewlett-Packard 8452A diode array spectrophotometer using cuvettes of 1 cm path length. Syntheses has been monitored by thin-layer chromatography on Macherey-Nagel Alugram Sil G/UV 254, eluted by toluene/methanol (7:3, v/v) with saturation of the cuve by ammoniac (3 mL of concentrated NH_4OH in a small open flask), and spots were visualized with UV-light (violet spots at 254 nm and blue fluorescence at 365 nm for derivatives of the Clip-Phen family). DMF was dried on calcium sulfate and CH_2Cl_2 on basic aluminum oxide. Other commercial reagents were used without purification.

Synthesis. 2-Chloro-1,10-phenanthroline (34, 35) and Clip-Phen (23) have been prepared as previously described.

2-Succinoyl-amino-1,3-bis(1',10'-phenanthrolin-2'-yl-oxy)propane [Clip-Phen-COOH (1)]. To a solution of Clip-Phen (396 mg, 0.88 mmol) in chloroform (100 mL) was added succinic anhydride (254 mg, 2.4 mmol) and the

mixture was heated at reflux for 1 h. After evaporation of the solvent, the crude product was redissolved in hot methanol (250 mL), precipitated at -20°C , and centrifuged for 20 min at 3000 rpm. The product was then dissolved in chloroform and precipitated with diethyl ether to give Clip-Phen-COOH (1) as a white powder (377 mg, 79%). ^1H NMR (CDCl_3 , 250 MHz) δ 2.69 (m, 4H, H5 and H6), 5.00 (m, 5H, H1 and H2), 7.12 (d, 2H, J = 8.7 Hz, H3'), 7.59 (dd, 2H, J = 8.1, 4.5 Hz, H8'), 7.64 (d, 2H, J = 8.7 Hz, H6'), 7.72 (d, 2H, J = 8.7 Hz, H5'), 8.07 (d, 2H, J = 8.7 Hz, H4'), 8.23 (dd, 2H, J = 8.1, 1.65 Hz, H7'), 8.96 (d, 1H, J = 6.6 Hz, H3), 9.13 (dd, 2H, J = 4.5, 1.65 Hz, H9'). MS (CDI, NH_3): m/z (%) 548 ($M + 1$, 1.3), 530 (4.5), 504 (7.5), 448 (3), 352 (4), 308 (3), 252 (31.5), 197 (100). UV (CH_3OH): 226 (ϵ = 78 400 $\text{M}^{-1}\text{cm}^{-1}$), 274 nm (ϵ = 53 000).

2-Succinoyl-amino-1,3-bis(1',10'-phenanthrolin-2'-yl-oxy)propane-*N,N*-diethyl Ethylenediamine Conjugate [Clip-Phen-DEEDA (2)]. To 1 (210 mg, 0.38 mmol) in dry CH_2Cl_2 (20 mL), *N*-methylmorpholine (120 μL , 1.09 mmol), BOP (485 mg, 1.09 mmol), HOBT (200 mg, 1.48 mmol) and *N,N*-diethylethylenediamine (508 μL , 3.61 mmol) was added. After stirring 40 min at ambient temperature, triethylamine (508 μL , 3.64 mmol) was added and the mixture was stirred at room temperature for 20 h. The reaction mixture was diluted with water and the product was extracted three times with CH_2Cl_2 (3×100 mL). The organic phase was dried with sodium sulfate, and after concentration under vacuum, the product was precipitated with diethyl ether to give Clip-Phen-DEEDA 2 as a yellow powder (254 mg, 100%). ^1H NMR (CD_2Cl_2 , 250 MHz): δ 1.16 (t, 6H, J = 7.5 Hz, H13), 2.49 and 2.94

(2t, 2 × 2H, H5 and H6), 3.19 (m, 6H, H10 and H12), 3.66 (dd, 2H, H9), 4.78 (m, 2H, H1), 4.98 (m, 3H, H1 and H2), 7.25 (d, 2H, $J = 9$ Hz, H3'), 7.51 (m, 1H, H8), 7.74 (dd, 2H, $J = 8.0, 4.0$ Hz, H8'), 7.78 and 7.87 (AX, 2 × 2H, $J = 9.0$ Hz, H5' and H6'), 8.25 (d, 2H, $J = 9.0$ Hz, H4'), 8.42 (dd, 2H, $J = 8.0, 2.0$ Hz, H7'), 9.03 (dd, 2H, $J = 4.0, 2.0$ Hz, H9'), 10.00 (d, 1H, $J = 6.0$ Hz, H3). MS (ES, positive mode) m/z 646.3 ($M + 1$) (calcd for $C_{37}H_{39}N_7O_4 = 645.76$). UV (CH_3OH): 226 ($\epsilon = 58\,800$), 274 nm ($\epsilon = 38\,200$).

2-Succinoyl-amino-1,3-bis(1',10'-phenanthroline-2'-yl-oxy)propane-spermine Conjugate [Clip-Phen-sp (3)]. To **1** (200 mg, 0.36 mmol) in dry DMF (40 mL), *N*-methylmorpholine (2 mL, 18.2 mmol), BOP (485 mg, 1.09 mmol), and HOBT (200 mg, 1.48 mmol) were added, and after 40 min at 50 °C, this mixture was added during 20 min on a solution of spermine (1.5 g, 7.74 mmol) in water (40 mL) and stirred at 50 °C for 15 h. The reaction mixture was diluted with water (60 mL) and extracted with CH_2Cl_2 (3 × 100 mL). The organic phase was dried on sodium sulfate and evaporated. The product was redissolved in CH_2Cl_2 and precipitated with diethyl ether to give Clip-Phen-sp (**3**) as a white powder (230 mg, 86%). ^1H NMR (CD_2Cl_2 , 250 MHz): δ 1.59 and 1.70 (2 m, 2 × 4H, H10, H19 and H14, H15), 2.49 (t, 2H), 2.55–3.10 (m, 10H), 3.28 (m, 2H, H9), 4.83 (m, 5H, H1 and H2), 7.12 (d, 2H, $J = 6.5$ Hz, H3'), 7.47 (m, 1H, H8), 7.64 (dd, 2H, $J = 8.0, 4.5$ Hz, H8'), 7.70 and 7.77 (AX, 2 × 2H, $J = 8.5$ Hz, H5' and H6'), 8.16 (d, 2H, $J = 8.5$ Hz, H4'), 8.27 (dd, 2H, $J = 8.5, 1.5$ Hz, H7'), 9.09 (dd, 2H, $J = 4.5, 1.5$ Hz, H9'), 9.27 (d, 1H, $J = 6.5$ Hz, H3). MS (ES, positive mode): m/z 732.5 ($M + H$) (calcd for $C_{41}H_{49}N_9O_4 = 731.90$). UV (CH_3OH): 226 ($\epsilon = 70\,700$), 274 nm ($\epsilon = 46\,800$).

2-Amino-1-(1',10'-phenanthroline-2'-yloxy)ethane (4). To sodium hydride (688 mg, 17.17 mmol) in dry DMF (10 mL) on ice bath were added 2-chloro-1,10-phenanthroline (500 mg, 2.33 mmol) and ethanolamine (200 μ L, 3.26 mmol), and the mixture was stirred 24 h with return to room temperature. The crude product was then dissolved with DMF (30 mL), ethanol (10 mL), and water (100 mL), and the volume was reduced to 75 mL before to be extracted with CH_2Cl_2 (3 × 75 mL). The product was dried under vacuum, redissolved in CH_2Cl_2 and precipitated with diethyl ether to give **4** as a pale yellow powder (304 mg, 55%). ^1H NMR ($CDCl_3$, 250 MHz): δ 3.17 (t, 2H, $J = 5.3$ Hz, H2), 4.77 (t, 2H, $J = 5.3$ Hz, H1), 7.14 (d, 1H, $J = 8.5$ Hz, H3'), 7.56 (dd, 1H, $J = 8.0, 4.4$ Hz, H8'), 7.64 and 7.73 (AX, 2H, $J = 8.6$ Hz, H5' and H6'), 8.11 (d, 1H, $J = 8.5$ Hz, H4'), 8.21 (dd, 1H, $J = 8.0, 1.6$ Hz, H7'), 9.14 (dd, 1H, $J = 4.4, 1.6$ Hz, H9'). MS (CDI, NH_3): m/z (%) = 240 ($M + 1$, 100), 197 (10.8). UV (CH_3OH): 228 ($\epsilon = 40\,200$), 274 ($\epsilon = 26\,900$). Anal. Calcd for $C_{14}H_{13}N_3O \cdot 1/2H_2O$: C, 67.73; H, 5.68; N, 16.92. Found: C, 67.59; H, 5.31; N, 17.31.

2-Succinoyl-amino-1-(1',10'-phenanthroline-2'-yloxy)ethane (5). To a solution of **4** (200 mg, 0.84 mmol) in chloroform (180 mL) was added succinic anhydride (232 mg, 2.2 mmol), and the mixture was heated at reflux for 1 h. A precipitate was formed during the reaction which was filtrated after cooling, dried under vacuum, and reprecipitated in hot methanol to give **5** as a white powder (231.5 mg, 88%). ^1H NMR (DMSO- d_6 , 250 MHz): δ 2.56 (s, 4H, H5 and H6), 3.70 (dd, 2H, $J = 5.5, 5.3$ Hz, H2), 4.71 (t, 2H, $J = 5.5$ Hz, H1), 7.39 (d, 1H, $J = 8.6$ Hz, H3'), 7.86 (dd, 1H, $J = 8.3, 4.3$ Hz, H8'), 7.98 and 8.08 (AX, 2H, $J = 8.7$ Hz, H5' and H6'), 8.53 (d, 1H, $J = 8.6$ Hz, H4'), 8.59 (dd, 1H, $J = 8.3, 1.7$ Hz, H7'), 8.64 (t, 1H, $J = 5.2$ Hz, H3), 9.23 (dd, 1H, $J = 4.3, 1.7$ Hz,

H9'), 12.21 (s, 1H, COOH). MS (CDI, NH_3): m/z (%) 340 ($M + 1$, 100), 296 (3), 240 (4), 197 (10). UV (CH_3OH): 226 ($\epsilon = 47\,100$), 274 nm ($\epsilon = 32\,700$). Anal. Calcd. for $C_{18}H_{17}N_3O_3 \cdot 1/2H_2O$: C, 62.01; H, 5.16; N, 12.05. Found: C, 61.84; H, 4.50; N, 11.99.

2-Succinoyl-amino-1-(1',10'-phenanthroline-2'-yloxy)ethane-spermine Conjugate (Phen-sp (6)). To **5** (200 mg, 0.59 mmol) in dry DMF (68 mL), *N*-methylmorpholine (3.4 mL, 30.92 mmol), BOP (822 mg, 1.85 mmol), and HOBT (340 mg, 2.50 mmol) were added. After 40 min at 50 °C, the mixture was added during 20 min on a solution of spermine (2.54 g, 12.53 mmol) in water (68 mL) and the mixture was stirred at 50 °C for 15 h. The reaction mixture was diluted with water (100 mL) and alcalinized to pH 13 with NaOH before extraction with $CHCl_3$. After evaporation of the organic phase, the product was redissolved in $CHCl_3$ and precipitated with diethyl ether to give Phen-sp **6** as a white wax (195 mg, 63%). ^1H NMR (DMSO- d_6 , 250 MHz): δ 1.48 (m, 4H, H14 and H15), 1.58 (m, 2H, H8 and H19), 2.45 (m, 2H), 2.55 (m, 8H), 3.16 (m, 4H), 3.69 (m, 2H, H2), 4.70 (t, 2H, $J = 5.5$ Hz, H1), 7.37 (d, 1H, $J = 8.6$ Hz, H3'), 7.86 (dd, 1H, $J = 8.0, 4.3$ Hz, H8'), 7.98 (m, 1H, H8), 7.98 and 8.08 (AX, 2H, $J = 8.8$ Hz, H5' and H6'), 8.53 (d, 1H, $J = 8.6$ Hz, H4'), 8.59 (dd, 1H, $J = 8.0, 1.7$ Hz, H7'), 8.66 (t, 1H, $J = 5.13$ Hz, H3), 9.23 (dd, 1H, $J = 4.3, 1.7$ Hz, H9'). MS (ES, positive mode): $m/z = 524.3$ ($M + H$) (calcd for $C_{28}H_{41}N_7O_3 = 523.68$). UV (CH_3OH): 226 ($\epsilon = 36\,400$), 276 nm ($\epsilon = 24\,300$).

DNA Cleavage Experiments. Metalations by $CuCl_2$ of the different ligands used in DNA cleavage experiments were performed by using 1 or 2 equiv of the desired ligand in a DMF/water mixture (1:1, v/v; the final copper concentration being 1 mM) during 4 h at room temperature before dilution of the corresponding complex with water.

Comparison of the DNA Cleavage Activity of the Copper Complexes of 2, 3, and 6 by Cleavage of Φ X174. To 10 μ L of Φ X174 (7 nM, 40 μ M in bp) in 80 mM sodium phosphate buffer (pH 7.2), 100 mM NaCl, 20 mM $MgCl_2$ were added 5 μ L of the desired complex (4 μ M). After 30 min at room temperature, DNA cleavage was initiated by addition of an aqueous solution of MPA (5 μ L, 20 mM) and samples were incubated for 1 h at 37 °C. Of a solution of 50% (v/v) glycerol/40 mM Tris-Cl buffer (pH 8) and 0.05% bromophenol blue (w/v), 75 μ L, was then added, and samples were immediately loaded on agarose gel (0.8%) containing 1 μ g/mL of ethidium bromide. Electrophoresis was run at constant current (25 mA for 15 h) in TBE buffer. Bands were located by UV light (254 nm), photographed and quantified by microdensity. The correction coefficient 1.47 was used for the decrease of stainability of form I DNA versus forms II and III (36). A Poisson distribution was used to describe cleavage reactions. The average number of strand scissions per DNA phage, μ , is equal to $-\ln$ (fraction of form I). When only DNA forms I and II are formed, this number equals the average number of single-stranded cuts per molecule of phage DNA. When form I was not observable, μ was considered to be superior to 4.6 (value corresponding to 1% of form I).

Cleavage of a Restriction Fragment by (Clip-Phen-sp)Cu. pBR322 plasmid (12.5 μ g) was opened with *Eco*RI (100 units) and labeled on the 5'-termini with T4 polynucleotide kinase (10 units) and [γ - ^{32}P]ATP (10 pmol) in an exchange buffer. A 167 bp fragment, uniquely labeled on the template strand, was created by secondary restriction with *Rsa*I (100 units) and purified on 8% polyacrylamide gel before to be desalted on G25

Figure 1. Comparison of Φ X174 cleavage efficiency between Phen, Clip-Phen, Clip-Phen-COOH, Clip-Phen-DEEDA, Clip-Phen-sp and Phen-sp in the presence of CuCl_2 1 μM and MPA 5 mM. Lane 1: Phen 1 μM . Lane 2: Phen 2 μM . Lane 3: Clip-Phen 1 μM . Lane 4: Clip-Phen-COOH 1 μM . Lane 5: Clip-Phen-DEEDA 1 μM . Lane 6: Clip-Phen-sp 1 μM . Lane 7: Phen-sp 1 μM . Lane 8: Phen-sp 2 μM . Lane 9: control DNA. Lane 10: control DNA plus MPA 5 mM. Lane 11: CuCl_2 1 μM , MPA 5 mM without ligand. Lanes 12, 13, and 14: Phen 2 μM , Clip-Phen 1 μM and Clip-Phen-sp 1 μM , respectively, with MPA 5 mM but without CuCl_2 . Single-strand breaks were expressed as μ values representing $-\ln(\text{fraction of form I})$.

Scheme 2. Sequence of the *Eco*RI–*Rsa*I Restriction Fragment (167 bp) and of the ODN 1-ODN 2 Duplex (45-mer) (the ODN 1 Sequence in the *Eco*RI–*Rsa*I Restriction Fragment Is Underlined)

superfine Sephadex by elution with water. The sequence of the restriction fragment is indicated in Scheme 2.

Cleavage experiments were performed as follows: to a 8 μL solution of [^{32}P]DNA fragment, 40 μM per base pair of sonicated calf thymus DNA in 80 mM sodium phosphate buffer (pH 8), 100 mM NaCl, and 20 mM MgCl_2 was added 4 μL of (Clip-Phen-sp)· CuCl_2 complex 4, 2, 0.4, or 0.2 μM . After 1 h at room-temperature cleavages were initiated by addition of 2 μL of ascorbate (0.8 mM) and 2 μL of H_2O_2 (0.8 mM) aqueous solutions and samples were incubated 1 h at 37 $^\circ\text{C}$. Sodium acetate buffer (20 μL) (3 M, pH 5.2) and 0.5 μL of yeast tRNA (10 mg/mL) were then added and samples were precipitated with 200 μL of ethanol. Pellets were rinsed with ethanol and lyophilized. Fragments of DNA were analyzed by denaturing 8% polyacrylamide gel electrophoresis.

After collecting the data on the 167 bp restriction fragment, we decided to investigate in more detail the sequence specificity of these DNA cleavers on the section of the restriction fragment corresponding to the more intense breaks. This sequence (45 bases, named ODN 1 and ODN 2 for its complementary strand) has been underlined on the sequence of the 167 bp fragment in Scheme 2.

Comparison of the DNA Cleavage Activity of Clip-Phen-sp, Clip-Phen, and 1,10-Phenanthroline Complexes of CuCl_2 . The 5'-end of ODN 1 was labeled by ^{32}P using a standard procedure with T4 polynucleotide kinase and [γ - ^{32}P]ATP. All oligonucleotides were desalted on columns of G25 Sephadex DNA grade equilibrated with water. ODN 1 (labeled on its 5'-end) and ODN 2 were annealed in 312 μL of sodium phosphate buffer (0.1 M, pH 7.2) by heating at 90 $^\circ\text{C}$ for 5 min followed by slow cooling to room temperature. 5 M NaCl (8 μL) and 80 μL of 0.1 M MgCl_2 were then added. Double-stranded oligonucleotide concentration was 0.2 μM .

For cleavage experiments, to an 8 μL solution of the ODN 1-ODN 2 duplex was added 4 μL of the desired complex (4 μM). After 30 min at room temperature, cleavages were initiated by addition of 4 μL of an aqueous solution of MPA (20 mM) or ascorbate (0.4 mM) or by addition of 2 μL of ascorbate (0.8 mM) and 2 μL of H_2O_2 (0.8 mM) aqueous solutions and samples were incubated for 1 h at 37 $^\circ\text{C}$. 20 μL of sodium acetate buffer (3 M, pH 5.2) and 0.5 μL of yeast tRNA (10 mg/mL) were then added and samples were precipitated with 200 μL of ethanol. Pellets were rinsed with ethanol and lyophilized. One part of the samples was then redissolved in 50 μL of piperidine 1 M and heated 30 min at 90 $^\circ\text{C}$ before to be precipitated with 50 μL of sodium acetate buffer (3 M, pH 5.2) and 500 μL of ethanol, rinsed with ethanol, and lyophilized. Fragments of DNA were analyzed by denaturing 15% polyacrylamide gel electrophoresis.

RESULTS AND DISCUSSION

Synthesis. To enhance the DNA cleavage activity of Clip-Phen, a new ligand with two connected 1,10-phenanthrolines (23), we prepared two different conjugates: Clip-Phen-sp (3) and Clip-Phen-DEEDA (2), having a spermine or a *N,N*-diethylethylenediamine motif, respectively. Phen-sp (6) was prepared to compare its cleavage activity with Clip-Phen-sp in order to measure the benefit of having a chelating ligand containing two Phen entities linked together. The different steps of the preparation of these conjugates are described in Scheme 1.

The introduction of a carboxylic function and additional flexibility on Clip-Phen was easily performed by using succinic anhydride to give Clip-Phen-COOH (1). This precursor was conjugated with DEEDA (which has a rather low affinity for nucleic acids) to give Clip-Phen-DEEDA (2) after activation of the carboxylic function of 1 by BOP/HOBT. The yield of the coupling reaction was quantitative (nearly 100% after an easy purification step

Figure 3. Cleavage of ODN 1 × ODN 2 by CuCl₂ complexes of Clip-Phen, Clip-Phen-sp and Phen. The target, labeled on the 5'-end of ODN 1, was 0.1 μM. CuCl₂ was 1 μM. Lanes 1 and 2: Maxam–Gilbert, A + G and G, respectively. Lanes 3, 5, and 7: Clip-Phen 1 μM with MPA 5 mM, ascorbate 0.1 mM, or ascorbate 0.1 mM plus H₂O₂ 0.1 mM, respectively. Lanes 9, 11, and 13: Clip-Phen-sp 1 μM with MPA 5 mM, ascorbate 0.1 mM, or ascorbate 0.1 mM plus H₂O₂ 0.1 mM, respectively. Lanes 15, 17, and 19: Phen 2 μM with MPA 5 mM, ascorbate 0.1 mM or ascorbate 0.1 mM plus H₂O₂ 0.1 mM, respectively. Lanes 4, 6, 8, 10, 12, 14, 16, 18, and 20: as lanes 3, 5, 7, 9, 11, 13, 15, 17, and 19 with a piperidine treatment, respectively.

specific site of cleavage might generate additional single-strand breaks in the vicinity of the initial DNA cleavage sites leading to form III before the total disappearance of form I). To know if the high DNA cleavage activity of Clip-Phen-sp resulted only from a better affinity for DNA due to the presence of spermine, Phen-sp (**6**), a conjugate with a spermine but only one phenanthroline entity, was prepared and its DNA cleavage activity compared to **3** (lanes 7 and 8 for a 1:1 and a 2:1 ligand/copper ratio, respectively). In the same experimental conditions used for **3**, no DNA cleavage was observed with **6**. The absence of activity of compound **6** could not be explained by the fact that the spermine was linked to phenanthroline by the C2-carbon, a position known to decrease dramatically the reactivity of substituted phenanthroline copper complexes (17), since Clip-Phen-sp with a linker between the C2-carbons had a good DNA cleavage activity. So, this result indicated that the activity of Clip-Phen-sp was not only due to spermine but was also due to the chelating properties of the two phenanthrolines of the Clip-Phen entity.

So, the Clip-Phen entity has an affinity for DNA and is able to chelate efficiently copper, and its copper complex has a redox activity leading to single-strand

breaks on DNA. Its DNA cleavage activity is increased by using ascorbate or the association of a reductant with H_2O_2 (data not shown). When MPA was replaced by the more active reductant ascorbate (0.1 mM) or by the association ascorbate/ H_2O_2 (0.1 mM for both concentrations), the obtained results indicated clearly that (Phen-sp)Cu had a detectable DNA cleavage activity at $1\ \mu\text{M}$ concentration. But in the same conditions, only 50 nM of (Clip-Phen-sp)Cu was necessary to cleave efficiently ΦX174 (data not shown). However, it must be noted that, when using ascorbate/ H_2O_2 conditions of activation, metal ion traces present in buffer solutions or in the agarose gel were able in the presence of metal-free Clip-Phen derivatives to induce a weak DNA cleavage activity that complicated the comparative studies. This last phenomenon can also explain the low DNA cleavage activity observed with Phen-sp was used in control experiments without addition of a copper salt (lane 14).

Cleavage of a Restriction Fragment by (Clip-Phen-sp)Cu. To further characterize the sequence specificity aspects of the DNA cleavage by the most active conjugate, (Clip-Phen-sp)Cu was used to cleave a double-stranded DNA fragment corresponding to a *EcoRI*-*RsaI* 167 bp restriction fragment of pBR322 plasmid labeled

by ^{32}P at the 5'-end. The target was incubated in the presence of a random double-stranded calf thymus DNA to have the same base pair concentration (20 μM) than for ΦX174 cleavage experiments. Various concentrations of (Clip-Phen-sp)Cu ranging from 1 to 0.05 μM were tested. Cleavage was initiated by addition of ascorbate (0.1 mM) and H_2O_2 (0.1 mM) because preliminary results showed that the cleavage pattern was the same with MPA (5 mM), ascorbate (0.1 mM), or ascorbate/ H_2O_2 (0.1 mM/0.1 mM), but increased with this last mode of activation (results not shown). Cleavage experiments were conducted for 1 h at 37 °C, and cleavage patterns were analyzed by high-resolution gel electrophoresis. Cleavage sites were determined with a Maxam–Gilbert sequencing reaction (results are shown in Figure 2).

Cleavage was observed at nearly all nucleotides of the sequence with a small preference for some sites. From these data, it was not easy to propose a rule for this limited sequence preference since these breaks were observed on TAT, CATGT, or TGT sequences which are known to be preferential cleavage sequence for phenanthroline copper complexes (14, 15) or near a py-pu-py triplet. (Clip-Phen-sp)Cu cleaved double-stranded DNA in a roughly nonspecific fashion as generally observed for Phen–Cu complexes. These results could be also explained by the nonspecific interaction of spermine within the minor groove of DNA (24, 26, 27, 29).

Comparison of the DNA Cleavage Specificity of Clip-Phen, Clip-Phen-sp, and Phen copPer Complexes. The DNA cleavage activity of (Clip-Phen)Cu, (Clip-Phen-sp)Cu, and (Phen) $_2$ Cu complexes were compared with the ODN 1-ODN 2 target. This double-stranded 45-mer was selected from the 167 bp restriction fragment because of some specific breaks observed with (Clip-Phen-sp)Cu $^{\text{II}}$ on this restriction fragment. The length of this oligonucleotide was small enough to allow a high-resolution analysis of the extremities of cleavage fragments by electrophoresis on denaturing polyacrylamide gel. For these experiments, the target (0.1 μM) labeled on the 5'-end of ODN 1 was incubated with 1 μM (in copper) of each different complex. The activation was performed with MPA (5 mM), ascorbate (0.1 mM), or ascorbate (0.1 mM) plus H_2O_2 (0.1 mM) for 1 h at 37 °C. Figure 3 summarizes the obtained results.

The three conjugates induced roughly the same cleavage patterns: a smear and a cleavage at all nucleotides of the target with just a little preference for some sequences. More intense breaks were observed at T_{26} , T_{28} , and T_{30} with (Clip-Phen-sp)Cu (Figure 3, lanes 11 and 13), as previously observed on the restriction fragment, and at G_{29} with (Phen) $_2$ Cu (lanes 17 and 19, for example). Since all these direct cleavage fragments migrated like the Maxam–Gilbert scale, it can be assumed that they have a 3'-phosphate extremity and resulted from deoxyribose oxidation as previously observed for 1,10-phenanthroline–copper complexes (1).

To study the smears, we decided to further analyze the cleavage patterns after piperidine treatment (30 min at 90 °C) of the nicked DNA samples. The smears of cleavage products were transformed into discrete bands with 3'-phosphate extremity and the intensity of the band corresponding to the uncleaved target was decreased. Further studies should show if this phenomenon results of oxidation of the sugars or of alkali-sensitive base damage of the DNA target.

Moreover, these experiments allowed comparison of the efficiency of the different activation modes of these copper complexes. MPA was clearly the less active activator. As previously observed for (Phen) $_2$ Cu, ascorbate was

more efficient (8). Addition of H_2O_2 increased the DNA cleavage activity of the reduced complex. This result could be explained by the fact that activation of the copper(II) complex by a reductant generates first a low-valent Cu(I) species which reacts then with dioxygen to produce superoxide and then hydrogen peroxide via a copper-catalyzed dismutation of superoxide. These catalytic cycles reduce the concentration of the copper(I) complex able to react with hydrogen peroxide to generate hydroxyl radicals via a Fenton-type reaction. So, when H_2O_2 is initially present in solution the DNA cleavage efficiency increased because of the higher concentration of H_2O_2 compared to that obtained by copper-catalyzed processes.

In conclusion, we described the preparation of phenanthroline conjugates based on the Clip-Phen entity which containing two covalently linked Phen units via a serinol bridge. An elongation of the tether with a terminal carboxylic function allowed us to prepare amine conjugates (with a spermine or a diethylethylenediamine, respectively Clip-Phen-sp and Clip-Phen-DEEDA). The copper derivative of Clip-Phen-sp is a highly efficient DNA cleaver. The nonspecific cleavage observed with these Clip-Phen derivatives will make them suitable for specific DNA cleavage after attaching the Clip-Phen motif to oligonucleotides or proteins, since the recognition of nucleic acids by these vectors will not be perturbed by the cleaver itself.

Received April 6, 1998; Revised Manuscript Received July 6, 1998

Two different methods were developed to prepare an adduct of a poly(ethylene glycol)-lysine copolymer with either cysteamine or 1-amino-2-methyl-2-propanethiol. Cysteine-containing peptides could then be disulfide-linked to the thiol groups on the polymer in a facile manner. In the described procedures, a coupling ratio of about 8 peptides/molecule of poly(ethylene glycol)-lysine copolymer ($M_w = 27\,000$) was typically attained. The products were stable at neutral pH, but the peptides could be released from the polymer in a physiologically relevant reducing environment. The release rate was highly dependent on the linker used for forming the disulfide bond. To illustrate the potential biomedical usefulness of this polymer carrier, a Tat peptide-PEG conjugate was shown to inhibit expression of a reporter gene fused to the TAR element of human immunodeficiency virus in a model cell assay.

INTRODUCTION

Covalent attachment of water-soluble polymers can be used to manipulate the pharmacologic properties of a drug (1). Poly(ethylene glycol) (PEG)¹ can be derivatized with various functional groups for appending drug molecules (2). For example, appending PEG chains to a protein can increase its circulating half-life and minimize its immunogenic properties (3). With regard to low-molecular-weight drugs, Kohn and colleagues have designed a PEG-lysine copolymer having multiple attachment sites (4). They then prepared conjugates through either biostable or biodegradable linkages (4), but they did not investigate the biodegradable disulfide linkage. The disulfide linkage might be especially useful for drug delivery into cells, due to the stronger reducing environment within cells than in extracellular fluids. Stein and colleagues prepared a PEG derivative having a terminal thiol protected by disulfide linkage with 2-thiopyridine (5). They showed its usefulness by making a conjugate with papain, which was linked to PEG through its active-site cysteine residue, thereby keeping this enzyme in an inactive state until release from the polymer by a reducing agent. We now report the preparation and release

properties of a PEG-lysine copolymer having multiple 2-thiopyridine-protected attachment sites for cysteine-containing peptides, including those having appended biotin moieties as cellular uptake enhancers.

MATERIALS AND METHODS

Materials. Cysteamine hydrogen chloride, Ellman's reagent [5,5'-dithiobis(2-nitrobenzoic acid)], and glutathione (reduced form) were obtained from Sigma Chemicals (St. Louis, MO). Dithiothreitol (DTT) was obtained from Pierce (Rockford, IL). 2,2'-Dipyridyl disulfide, 1-amino-2-methyl-2-propanethiol, diisopropylethylamine (DIEA), and silica gel, 70–230 mesh, 60A were obtained from Aldrich Chemical (Milwaukee, WI). Hydroxybenzotriazole (HOBt), benzotriazol-1-yloxytris(dimethylamino)phosphonium hexafluorophosphate (BOP), and dimethylformamide (DMF) were obtained from PerSeptive Biosystems (Boston, MA). Dichloromethane (DCM) and methanol (MeOH) were HPLC grade and obtained from Fisher Scientific (Pittsburgh, PA). Sephadex was obtained from Pharmacia LKB Biotechnology (Piscataway, NJ). Poly(ethylene glycol)-lysine copolymer ($M_w = 2.69 \times 10^4$, 2198/repeating unit), which was synthesized according to a published procedure (4), was kindly supplied by John Kemnitzer and Joachim Kohn.

Peptide Synthesis. The peptide *N*-acetyl-Phe-Arg-Arg-Arg-Cys-NH₂ (abbreviated as FR₃C) was synthesized at the Louisiana State University (LSU) core facility using Fmoc chemistry, purified by reversed-phase HPLC, and confirmed for structure by mass spectral analysis. The peptides *N*-acetyl-Arg-Lys-Lys-Arg-Arg-Gln-Arg-Arg-Arg-Cys-NH₂ (Tat9-Cys) and *N*-acetyl-Arg-Lys-Lys-Arg-Arg-Gln-Arg-Arg-Arg-Lys(ϵ -biotin)-Cys-NH₂ [Tat9K(bio)-Cys] were manually synthesized using Fmoc chemistry. For radiolabeling, the assembled peptide on the solid support was allowed to react with tritiated acetic anhydride in the presence of the coupling activation reagents BOP, HOBt, and DIEA. Acetylation of the peptide was com-

Scheme 2

pleted by chasing with an excess of nonradioactive acetic anhydride. After cleavage from the solid support and ether precipitation, the radiolabeled peptide was purified by chromatography on Sephadex G-10 using PBS (0.15 M NaCl, 20 mM potassium phosphate buffer, pH 7.4) for elution.

Preparation of PEG-Cysteamine-TP by Scheme 1. To a solution of cysteamine hydrogen chloride (0.50 g, 4.4 mmol) dissolved in 15 mL of degassed buffer (0.1 N sodium acetate adjusted to pH 4.0 with acetic acid, 0.3 M sodium chloride, and 1 mM EDTA) was added 2,2'-dithiodipyridine (3.5 g, 15 mmol) dissolved in 18 mL of MeOH. The mixture was stirred at room temperature under N₂. The reaction, which was monitored with thin-layer chromatography (ammonium hydroxide/MeOH/DCM, 2/10/90), was complete after 4 h. The MeOH was removed in vacuo and the residue was made basic by saturating with sodium carbonate. The residue was extracted into DCM (3 × 50 mL) and the combined DCM was washed with water (2 × 40 mL) and brine (40 mL) and then dried over magnesium sulfate. The magnesium sulfate was filtered and the filtrate was concentrated in vacuo to an oily residue. The product, cysteamine-TP, was purified by flash chromatography on a silica gel column (ammonium hydroxide/MeOH/DCM, 2/10/90). Yield: 0.30 g (yellow oil) (36%). ¹H NMR (CDCl₃): δ 8.4–8.5 ppm (m, 1H), 7.7–7.6 ppm (m, 2H), 7.15–7.0 ppm (m, 1H), 3.0–2.7 ppm (m, 4H), 0.9 ppm (b, 2H).

PEG-lysine copolymer (0.20 g, 91 μmol of lysine) was dissolved in 2.5 mL of degassed DMF. Cysteamine-TP (0.5 mmol), BOP (0.5 mmol), HOBT (0.5 mmol), and DIEA (25 μL) were added to the PEG copolymer solution and stirred under N₂ overnight. The product was precipitated with cold ether, washed with cold ether, and then dried by Speedvac (Savant Instrument Co., Farmingdale, NY) to a gellike residue. The product was dissolved and purified on a Sephadex G-75 column (48 mL bed volume) using 0.1 N acetic acid. Appropriate fractions were combined and lyophilized. Yield: 0.11 g (colorless solid).

Preparation of PEG-Cysteamine-TP by Scheme 2. Cysteamine hydrogen chloride was first converted to the disulfide-linked dimer by overnight stirring of an aqueous solution (0.3 g in 15 mL) adjusted to pH 8.6 with triethylamine. Ellman's assay indicated less than 1% remaining free thiol. To the mixture was added a saturated solution of sodium carbonate to pH 10, followed by extracting into DCM (5 × 20 mL), drying over magnesium sulfate, filtering, and concentrating on a rotary evaporator. PEG-lysine copolymer (0.20 g, 91 μmol of lysine) was dissolved in 2.5 mL of degassed DMF. Cysteamine dimer (650 μmol), BOP (650 μmol), HOBT (650 μmol), and DIEA (25 μL) were added to the PEG copolymer solution and stirred under N₂ overnight. The product was precipitated with cold ether, washed with cold ether, and then dried by Speedvac to a gellike residue. The product was purified on a Sephadex G-75

gel filtration column, as above. Appropriate fractions were combined and lyophilized to yield 70 mg of colorless solid, which was dissolved in degassed PBS (pH 7.4). DTT (10 molar equivalents based on lysine) was then added and the reduction reaction proceeded under N_2 overnight. The product was purified on a G-75 column (48 mL bed volume) using 0.1 N acetic acid containing 1 mM EDTA for elution. Appropriate fractions were combined and lyophilized to yield 60 mg of colorless solid, which was dissolved in 4 mL of degassed buffer (0.1 N sodium acetate adjusted to pH 4 with acetic acid, 0.3 M sodium chloride, 1 mM EDTA). 2,2'-Dithiodipyridine (270 μ mol) dissolved in 3 mL of degassed MeOH was added, and the reaction mixture was stirred under N_2 for 2 h. The MeOH was removed on a rotary evaporator, and the product was purified on a Sephadex G-75 column (bed volume 48 mL) using 0.1 N acetic acid for elution. Appropriate fractions were combined and lyophilized to yield 30 mg of colorless solid. A similar procedure was used to prepare the PEG derivative of the sterically hindered cysteamine analogue 1-amino-2-methyl-2-propanethiol.

Determination of the 2-Thiopyridine Content in PEG-Cysteamine-TP. The concentration of a PEG-cysteamine-TP solution was determined by acid hydrolysis and measurement of the released lysine using an Applied Biosystems amino acid analyzer (LSU core facility). Varying amounts of PEG-cysteamine-TP (100, 200, and 400 μ L) of a 4 mg/mL (ca. 2 μ mol/mL of lysine) solution in water were reacted separately with an excess of DTT (200 μ L of 26 μ mol/mL in water) and diluted to a final volume of 1.0 mL with PBS. The amount of 2-thiopyridone liberated was quantitated using a molar extinction coefficient of 7.06×10^3 at 343 nm (6).

Preparation of PEG-cysteamine-Peptide. PEG-cysteamine-TP, dissolved in water (8 μ mol/mL of lysine), was mixed with an equal volume of PBS containing 1 mM EDTA. To 3 mL of this solution was added 1 equiv [as determined by Ellman's assay for thiols (7)] of the peptide FR_3C . The reaction, which was monitored by absorbance at 343 nm on aliquots of the mixture, was complete after 15 min of stirring under N_2 . The product was purified on a Sephadex G-75 column, using PBS as eluent. Appropriate fractions were pooled. The extent of peptide derivatization of the copolymer was determined by amino acid analysis (LSU core facility). Other combinations of a PEG carrier and a peptide, including radiolabeled peptides, were prepared similarly.

Release of Peptides from PEG-S-S-Peptide Conjugates. The disulfide-linked conjugate $PEG-(cysteamine-FR_3C)_n$ was added to a solution of reduced glutathione (3 mM in PBS) to a final peptide concentration of 0.3 mM and then incubated under N_2 at room temperature. A sample was taken at each time point, acidified by adding an aliquot of 5% TFA, and applied to a G-75 column in 0.1% TFA (7 mL bed volume) to separate PEG-conjugated peptide from free peptide. Appropriate fractions in the high-molecular-weight region were pooled, and the extent of peptide derivatization at each time point was determined by amino acid analysis. For measuring the release of radiolabeled peptide, each time point aliquot was acidified to pH 3.5 with sulfuric acid. The PEG-conjugated peptide and the free peptide were then separated using ultrafiltration on Centricon-10 (Amicon/Millipore, Bedford, MA). To ensure complete separation, the retentate was diluted and ultrafiltered two more times. Radioactivity in the retentate and combined filtrate was quantitated by scintillation counting.

Inhibition of Protein Expression from a TAR-CAT Plasmid. Details of this assay have been published (8). Briefly, Jurkat cells were stably transfected with a recombinant plasmid comprising the HIV-1 long terminal repeat (LTR), which contains the TAR (transactivator response element) domain, linked to the chloramphenicol acetyltransferase (CAT) gene on the pRep10 episomal vector (Invitrogen, Carlsbad, CA) (S. Stein, B. Beiss, and A. B. Rabson, unpublished results). For expression of Tat protein, which transactivates transcription after binding to the TAR RNA domain of nascent transcripts, cells were transfected with pAR(Tat), which comprises the HIV-1 LTR and viral sequences encoding the 72 amino acid form of Tat. CAT protein in harvested cells was measured using an immunoassay kit from Boehringer-Mannheim (Indianapolis, IN). In this assay, cells were transfected with pAR(Tat) at $t = 0$, and the cells were incubated in 10% fetal calf serum under 95% air/5% carbon dioxide. The Tat-peptide inhibitor, either free or appended to the PEG carrier, was added at various concentrations at $t = 18$ h, and the cells were harvested for CAT immunoassay at $t = 42$ h.

RESULTS

Preparation of PEG-S-S-Peptides. The synthetic routes are given in Schemes 1 and 2. In Scheme 1, cysteamine was first converted into the mixed disulfide with 2-thiopyridine. The cysteamine-TP reagent was purified by silica gel chromatography, and its structure was confirmed by ^1H NMR. It was necessary to use this reagent immediately for coupling to the PEG-lysine copolymer, since the 2-thiopyridine group would react back to 2,2'-dipyridyl disulfide, as evaluated by NMR, at a rate of about 15%/day. Amide bond formation between the carboxylate groups on the PEG-lysine copolymer and the amino group on cysteamine was accomplished using reagents typically used for coupling in peptide synthesis (Scheme 1). In Scheme 2, cysteamine was first converted to the symmetric disulfide, then appended to the PEG-lysine copolymer, and finally converted to the 2-thiopyridine derivative. Preparation of the PEG-1-amino-2-methyl-2-propanethiol-TP derivative by Scheme 2 was as facile as that of the cysteamine version.

The disulfide bond between 2-thiopyridine and cysteamine appended to PEG was stable to cleavage in PBS (pH 7.4), as determined by absence of absorbance at 343 nm after 24 h at room temperature. However, upon addition of a cysteinyl-peptide, FR_3C , reaction was complete within several minutes, as determined by the released 2-thiopyridone measured at 343 nm (Figure 1). This coupling reaction was about 100 times slower for the polymer in which 1-amino-2-methyl-2-propanethiol was substituted for cysteamine.

To determine the stoichiometry, the amount of 2-thiopyridone released from a given amount of PEG-cysteamine-TP solution by an excess of reducing agent (DTT) in PBS was measured. Then, 1 equiv (as defined by thiol groups measured by Ellman's assay) of the peptide, FR_3C , was added to an aliquot of PEG-cysteamine-TP solution, and essentially complete release of 2-thiopyridone was observed. Purification of the product, PEG-S-S-peptide, by gel filtration chromatography gave complete separation from released 2-thiopyridone and, presumably, from any residual unreacted peptide (Figure 2).

Acid hydrolysis, followed by amino acid analysis, was used to determine the concentration of the PEG-lysine

Figure 1. Spectroscopic analysis of the reaction of PEG-cysteamine-TP with the peptide FR₃C. The UV spectrum of a solution of PEG-cysteamine-TP is shown (solid line). Addition of the peptide results in release of 2-thiopyridone, which is observed as a peak with a maximum at 343 nm (dashed line).

copolymer, and treatment with an excess of DTT was used to determine the amount of coupled cysteamine-TP on that same sample. By this procedure, it was determined that $66 \pm 8\%$ of the lysine carboxylate groups had been derivatized with cysteamine-TP on a sample of PEG-cysteamine-TP prepared by Scheme 1. Acid hydrolysis, followed by amino acid analysis was also used to determine the extent of derivatization by the peptide, FR₃C. Duplicate analyses gave a ratio of Phe:Lys of 0.64 and 0.55 and a ratio of Arg:Lys of 2.0 and 1.8. Therefore, the extent of peptide derivatization, based on lysine groups in the copolymer backbone, was $62 \pm 4\%$. In another sample prepared by Scheme 1, the peptide coupling ratio was found to be $66 \pm 5\%$. In a sample prepared by Scheme 2, the peptide coupling ratio was found to be $78 \pm 9\%$.

Release Studies. Release of the peptide FR₃C by reductive cleavage of its disulfide linkage to PEG-cyste-

amine was evaluated using 3 mM glutathione in PBS (pH 7.4) at room temperature. At each time point, an aliquot was withdrawn and acidified to halt the disulfide interchange reaction. Released peptide was removed from PEG-peptide conjugate by gel filtration chromatography, and the ratio of PEG (i.e., Lys residues) to peptide (i.e., Phe or Arg residues) was determined by amino acid analysis. Release was found to be relatively rapid, with a half-time of about 3 min (data not shown). The presence of glycine and glutamic acid in the high-molecular-weight fraction from glutathione-treated samples (data not shown) indicates that glutathione replaces the released peptide on the PEG copolymer.

Release kinetics were also studied using the disulfide-linked radiolabeled peptides, Tat9-Cys and Tat9K(bio)-Cys. Released peptide was removed from PEG-peptide conjugate by ultrafiltration. The half-time of release in PBS containing 3 mM glutathione was found to also be about 3 min for either peptide (Figure 3).

To achieve a slower release rate, as previously suggested for linking antibodies to toxins (9), the PEG derivative of the sterically hindered cysteamine analogue, 1-amino-2-methyl-2-propanethiol, was synthesized. Analysis of the release rate of radiolabeled Tat9K(bio)-Cys gave a half-time of about 40 min in the presence of 30 mM glutathione (Figure 4). Since the disulfide cleavage rate is proportional to glutathione concentration (10), the sterically hindered linker has a release rate about 100-times slower than does the cysteamine linker. Thus, the release rate can be readily controlled by selection of the linker between the PEG backbone and the appended peptide.

Cell Assay. The ability to achieve a biological effect was tested using the peptide Tat9K(bio)-Cys, which represents the TAR RNA-binding domain of the Tat protein encoded in the human immunodeficiency virus (HIV-1) genome. The rationale is that Tat protein interacts with TAR, which comprises the 5'-terminus of nascent transcripts, to potentiate transcription elongation, and that a Tat-binding domain peptide might interfere with this transactivation process (8). Indeed, the Cys(S-biotin) analogue of this peptide has been shown to inhibit viral replication in infected cells, thereby being a candidate therapeutic agent for AIDS (8). The ap-

Figure 2. Purification of the product from a reaction mixture of PEG-cysteamine-TP and the peptide FR₃C by gel filtration chromatography. Note the presence of the released 2-thiopyridone in the low-molecular-weight fractions according to absorbance at 343 nm.

Figure 3. Time course of release of the radiolabeled peptide Tat9K(bio)-Cys from PEG-cysteamine-peptide by 3 mM glutathione in PBS. The data are presented as a semilog plot. Essentially the same release kinetics were obtained in two additional experiments.

Figure 4. Time course of release of the radiolabeled peptide, Tat9K(bio)-Cys, from PEG-1-amino-2-methyl-2-propanethiol-peptide in PBS by 30 mM glutathione. The dashed line is a theoretical plot of $C = C_{\text{initial}}e^{-kt}$. A semilog plot of the early time point data is shown in the inset. Essentially the same release kinetics were obtained in two additional experiments.

pendent biotin moiety has been found to increase cell uptake of the peptide (8). The Lys(ϵ -biotin) analogue of this peptide, used in the present study, has been found to bind to TAR RNA with similar avidity and specificity as the Cys(S-biotin) analogue and to inhibit gene expression (Figure 5) in a model cell assay (8), and it would be expected to inhibit HIV-1 replication similarly. A conjugate comprising multiple copies of this peptide disulfide-linked to PEG, PEG-[cysteamine-Tat9K(bio)-Cys]_n, was not only active in the model cell assay but also resulted in an increase in potency (Figure 5).

DISCUSSION

Although peptides and peptide mimetics are potential therapeutic agents, a major limitation to their utility is the requirement of parenteral rather than oral administration, due to degradation and/or poor absorption in the gastrointestinal tract. The necessity of frequent injections of a therapeutic peptide, due to the rapid

Figure 5. Inhibition of protein expression from a TAR-CAT plasmid. The biotinylated Tat-peptide inhibitor, either free or appended to the PEG carrier, was added at each indicated concentration. Each point is the average of three separate cell cultures. The data for the low concentrations of free and appended peptide were obtained in a side-by-side experiment, whereas the data for the high concentrations were obtained in separate experiments. Note the repetition of one concentration of free Tat-peptide in the high and low concentration sets of experiments; this is indicative of the assay-to-assay variability. The remaining 20–25% of CAT Activity at high inhibitor concentrations most likely represents CAT protein already synthesized prior to addition of the inhibitor to the culture medium and its uptake into the cells.

clearance of low-molecular-weight compounds, can be overcome by using PEG as a carrier (4). In this report, we describe an approach for preparing a reversible conjugate of a peptide on a PEG polymer. The reversible linkage is the disulfide bond, which can be cleaved by glutathione, a physiologically relevant reducing agent. This concept has recently been reported using hemoglobin as the carrier, with disulfide linkage to a cysteine residue in the peptide (10). In that study (10), mathematical modeling was presented to show the influence of various kinetic parameters on the blood level of released peptide.

In our studies, release of the peptide from the polymer was studied in PBS containing reduced glutathione, which is present in most tissues at a concentration of approximately 3 mM (11). Since the concentration of reduced glutathione in blood is on the order of 10 μM (12), the appended peptide molecules should remain mostly bound to the PEG carrier in the extracellular environment, but they should be released from the carrier upon entry into cells. Thus, this disulfide-based PEG delivery approach may be especially advantageous for intracellularly targeted drugs.

We now speculate that a PEG carrier loaded with multiple copies of the peptide, Tat9K(bio)-Cys (or a peptidase-resistant version), could be a particularly useful therapeutic product. Owing to its low clearance rate and resistance to disulfide exchange in extracellular fluids, this conjugate would be parenterally administered at, perhaps, daily or weekly intervals. The multiple biotin moieties appended to each PEG molecule, as well as the high density of positive charges on the side chains of the basic amino acids, might have an additive or synergistic effect on cell uptake efficiency. Indeed, preliminary cell culture experiments indicate that the peptide is more potent when added to the culture medium as a disulfide-linked PEG conjugate. Although we have not yet experimentally determined the basis for this apparent increase

in potency, we hypothesize that it is due to enhanced cellular uptake. Whatever the reason, it is clear that both an uptake enhancer (biotin) and a PEG carrier contribute markedly to enhanced potency for a peptide that has an intracellular target. In conclusion, our approach provides a method for reaching intracellular disease-related targets using peptide mimetics and other polar organic compounds that would otherwise not have the requisite pharmacologic properties.

ACKNOWLEDGMENT

We thank Dr. Joachim Kohn and Dr. John Kemnitzer for their advice and for supplying the PEG-lysine copolymer. S.P. was supported by NIH training grant GM55145.

Cathepsin Substrates as Cleavable Peptide Linkers in Bioconjugates, Selected from a Fluorescence Quench Combinatorial Library

James J. Peterson and Claude F. Meares*

Department of Chemistry, University of California, One Shields Avenue, Davis, California 95616-5295.
Received June 4, 1998

Several extended peptide substrates for the human liver enzymes cathepsin B and cathepsin D have been selected as cleavable linkers for lysosomal proteolysis of bioconjugates. A one-bead-one-peptide combinatorial library of 9⁴ fluorogenic substrates was employed. We designed this library to explore a set of substrates containing nonionizable/nonoxidizable groups to meet the requirements of prelabeling [Li et al. (1994) *Bioconjugate Chem.* 5, 101–104] as well as to yield stable conjugates whose preparation is straightforward.

INTRODUCTION

Insertion of a labile lysosomal endoprotease substrate site into drug delivery agents has found several applications (1–5). For example, there is promise that insertion of a peptide substrate between a radiolabeled chelate and its targeting moiety (e.g., an antibody) may lead to expedited clearance of undesirable radioactivity from the liver during radioimmunotherapy and imaging (6, 7). Further development of the peptide linkers to include compatible amino acid residues beyond the simple Gly₃-Phe sequence introduced by Li and Meares (6) is warranted. Two likely candidates for intracellular cleavage of peptide linkers are the cysteine protease cathepsin B (8) and the aspartic acid protease cathepsin D (9, 10).

Our initial aim was to select a number of appropriate substrates as lead compounds, so that some would ultimately satisfy the additional constraints posed by radioimmunoconjugate synthesis, solubility, and metabolism. We excluded ionizable and oxidizable residues from this study in order to simplify incorporation of chelate and isothiocyanate functionalities as well as to conform to the requirements of "prelabeling" (11), which enables removal of nonradiolabeled chelate via ion exchange prior to conjugation of radiolabeled chelate to a targeting moiety. The literature is rich in ionizable cathepsin B substrates (12–16) and cathepsin D substrates (17, 18), and a few nonionizable substrates also have been identified (4, 19).

Rational, or iterative, design of protease substrates or inhibitors can yield unexpected results: the interdependency effects of perturbing existing proteolytic substrates with different amino acids have been documented (20, 21). Similarly, rational designs based on the crystal structure of the protease active site are not always successful (45).

Combinatorial strategies, wherein all positions are varied independently, offer a promising alternative. Sensitive intramolecular fluorescence quenching experiments using resonance energy-transfer donor/acceptor

pairs (22–24) are well-suited to the identification of endoprotease substrates where the features imparting lability are not fully characterized. This is particularly true with substrates for enzymes having extended binding sites. We have employed the one-bead-one-peptide strategy developed by Meldal et al. (25), which combines powerful target isolation (26) with the sensitivity of intramolecular fluorescence quenching using the anthranilamide/3-nitrotyrosine donor/acceptor pair (24). After partial digestion of the peptide bead, cleavage is signaled by visible blue fluorescence, but enough of the unmodified peptide remains on the bead so that all of the information is conserved and decodable via Edman sequencing. Substrates with donor/acceptor pairs having critical distances for energy transfer (R_0) as large as 50 Å have been studied (24). Related variations of the procedure have been used to optimize substrates for subtilisin Carlsberg (25) and Cruzipain (27).

The lysosomal endoproteases cathepsin B and D are not absolutely dependent on the identity of any particular amino acid at any given subsite,¹ P_n-P_n', although some trends have been described (17, 28, 29, 45). Full characterization of lysosomal endoprotease substrates requires study of an extended substrate-binding site—particularly in the case of cathepsin D, which is known to be unresponsive to substrate motifs of <5 residues (29). Study of extended substrates is particularly appropriate in our case, since it can be inferred that increased length of the substrate is a favorable characteristic for linkers (4, 30).

The solubility properties of the PEGA² support allow enzyme permeability in an aqueous environment and are critical to the success of this combinatorial library technique (25, 27). This support consists of bis(2-acrylamidoprop-1-yl) poly(ethylene glycol) cross-linked dimethyl acrylamide and mono-2-acrylamidoprop-1-yl [2-aminoprop-1-yl] poly(ethylene glycol) (800), which we have confirmed is fully accessible to cathepsins B and D.

¹ For example, a peptide substrate NH₂-G-A-L-T-CO₂H, if cleaved between A and L, would be described in terms of the following subsites: G is in P₂; A is in P₁; L is in P₁'; T is in P₂'.

Scheme 1. Synthesis Strategy

This study incorporates one of the following amino acids at each of four variable positions: Phe, Tyr, Ala, Gly, Asn, Gln, Ser, Thr, Val (Scheme 1).

² Abbreviations: Abz, o-aminobenzoyl; Abz-OH, o-aminobenzoic acid; BTEE, N-benzoyl tyrosine ethyl ester; Bop, (benzotriazolyl)tris-(dimethylamino)phosphonium hexafluorophosphate; Boc, tert-butoxycarbonyl; t-Bu, tert-butyl; DCC, N,N'-dicyclohexylcarbodiimide; dhbt, 3,4-dihydro-4-oxo-1,2,3-benzotriazo-3-yl; DIEA, diisopropylethylamine; DMF, N,N-dimethylformamide; DTT, dithiothreitol; DOTA, 1,4,7,10-tetraazacyclododecane-N,N',N'',N'''-tetraacetic acid; EtOH, ethanol; EtOAc, ethyl acetate; EDTA, ethylenediaminetetraacetic acid; Fmoc, fluorene-9-ylmethoxycarbonyl; HOBt, 1-hydroxybenzotriazole; NO₂Phe, p-nitrophenylalanine; NO₂Tyr, 3-nitrotyrosine; NMP, 1-methyl-2-pyrrolidone; PEGA, bis(2-acrylamido-1-yl)poly(ethylene glycol) (800) cross-linked dimethyl acrylamide and mono-2-acrylamidoprop-1-yl [2-aminoprop-1-yl]poly(ethylene glycol); pfp, pentafluorophenol; THF, tetrahydrofuran; trt, trityl.

MATERIALS AND METHODS

Reagents. Anhydrous DMF, anhydrous NMP, HOBt, Boc₂O, Et₃N, piperidine, redistilled DIEA, anhydrous CH₂Cl₂, DCC, dhbt-OH, anthranilic acid, CF₃COOH, fluorescamine, and bovine pancreas α -chymotrypsin type II were purchased from Aldrich Chemical Co. EtOAc, CH₃CN, CH₃OH, and THF were purchased from Fisher; THF was freshly redistilled over Na(s) before use. Bop, Fmoc-Ala-OH, Fmoc-Asn(trt)-OH, Fmoc-Gly-OH, Fmoc-Gln(trt)-OH, Fmoc-Lys(Boc)-OH, Fmoc-Phe-OH, Fmoc-Ser(t-Bu)-OH, Fmoc-Thr(t-Bu)-OH, Fmoc-Tyr(t-Bu)-OH, Fmoc-NO₂Tyr-OH, and Fmoc-Val-OH were purchased from Bachem California. Amino-PEGA resin and human liver cathepsin D were purchased from Calbiochem-Novabiochem Corp. The solid-phase assay ninhydrin analytical reagent kit was purchased from ABI. Human liver cathepsin B was purchased from Sigma.

Scheme 2. Multiple Peptide Synthesis Apparatus^a

^a (A) For <0.25 g of resin, use Bio-Rad catalog no. 731-1550; punch a 1/4 in. hole in Chemglass catalog no. 3022-06 septum as seal/reducer. For <0.05 g of resin, use Bio-Rad catalog no. 732-6008; (B) aluminum donut (top of clamp); I.D. = 16.3 cm, O.D. = 24 cm, thickness = 7 mm (1/4 in.); (C) 8 1/4 in. lag bolts with wing nuts; (D) aluminum base (bottom of clamp); D = 24 cm, thickness = 7 mm; (E) inner flexible Teflon tubing leading to solvent recovery reservoir; (F) outer glass inlet for inert gas; (G) machined 3/4 in. Teflon plate (For column orifices, use a 5/16 in. drill followed by a 21/32 in. mill. Do not mill through. Leave a minimum of 3/16 in. step for Bio-Rad catalog no. 732-6008); (H) desiccator/primary reservoir.

Spectroscopy. NMR spectra were recorded on a General Electric QE 300 spectrometer at 300 MHz. IR spectra were recorded on a Mattson Galaxy Series FTIR 300. UV spectroscopy was performed on a Hewlett-Packard model 8450 UV-vis spectrophotometer.

Adaptable Scale Multiple Column Peptide Synthesizer. This apparatus (Scheme 2) was designed to be economical, scale-versatile, and simple. A 160 mm Pyrex glass vacuum desiccator was used as the primary solvent recovery reservoir. A 3/4 in. thick sheet of machine-grade Teflon was shaped and milled to allow interface with a variety of polypropylene-fritted "Bio-spin" and "econo-pac" chromatography vessels purchased from Bio-Rad. Aluminum plates were cut and drilled to provide the sealing clamp. Positive N₂ pressure regulated at <5 psig was used to bubble-stir reactions and washes. Soft Teflon forms an excellent seal with snugly fitting columns and glass inlets, avoiding the need for rubber seals.

Sequencing. Edman sequencing was performed on an ABI model 477A sequencer equipped with an ABI 120 HPLC column. Data were analyzed using ABI system 610 software.

Peptide Synthesis and Analysis. 2-*tert*-Butyloxy-carbonylamino benzoic acid (*Boc*-Abz-OH) (**1**) was synthesized according to literature (24). The reaction and purification were monitored by TLC. Stationary phase: Kieselgel 60 F₂₅₄, EM Science. Mobile phase EtOAc:CHCl₃:CH₃OH, 1:1:1, *R*_f = 0.8; 25.7% yield. ¹H NMR (CDCl₃): δ 1.55 (s, 9H), 7.03 (m, 1H), 7.56 (m, 1H), 8.10 (d, 1H), 8.46 (d, 1H), 10.03 (s, 1H), 10.9 (broad s, 1H). IR (KBr pellet): Broad acid-OH from 2500 to 3500 cm⁻¹. Carbamate CO stretch at 1667 and 1731 cm⁻¹. Sharp NH stretch at 3320 cm⁻¹. These properties conform to those previously reported (24).

3,4-Dihydro-4-Oxo-1,2,3-benzotriazol-3-yl 2-*tert*-butyloxycarbonylamino benzoate (*Boc*-Abz-ODhbt) (**2**) was synthesized according to literature (24), 77.5% yield. TLC (CH₂Cl₂:CHCl₃ 50:50) *R*_f = 0.5. ¹H NMR (CDCl₃): δ 1.47 (s, 9H), 7.12 (m, 1H), 7.66 (m, 1H), 7.85 (m, 1H), 8.02 (m, 1H), 8.25 (d, 1H), 8.35 (d, 1H), 8.40 (d, 1H), 9.55 (s, 1H); IR (KBr pellet): intense ester CO stretch centered at 1724 cm⁻¹. Disappearance of broad acid OH stretch from 2500 to 3500 cm⁻¹. These properties conform to those previously reported (24).

Fmoc-(*L*)-Lys-(*ε*-*Boc*)-PEGA (**3**). Amino-PEGA resin (1 g, 0.3 mmol) was delivered to a 30 mL fritted reaction vessel. (*Precoupling wash*) The slurry was washed 4 times (5 min each) with 15 mL aliquots of reagent grade

DMF. A final wash with dry DMF was carried out, and excess DMF was pushed from the swollen resin with dry N₂. (*Preactivation*) To a separate 15 mL pear-bottom flask fitted with a rubber septum, 1.2 mmol of α-Fmoc-(*L*)-Lys-(*ε*-*Boc*)-OH, 1.2 mmol of HOBt, and 1.8 mmol of DIEA were dissolved in 2.4 mL of dry DMF. Bop (0.531 g, 1.2 mmol) was dissolved separately in 0.8 mL of DMF, then added at RT. (*Coupling*) After 10 min of preactivation (31), all but ~50 μL of the HOBt ester was added via baked syringe to the swollen resin. With the remaining 50 μL, an approximate concentration of active species of 0.24–0.35 M was confirmed via amine-masking fluorescamine assay (see below). Coupling was allowed to proceed for 2 h. Complete acylation of free amines was confirmed by ninhydrin analysis. The resin was given a *postcoupling* wash of 5 vol of DMF and 5 vol of CH₂Cl₂.

Fmoc-(*L*)-Phe-(*L*)-Lys-(*ε*-Abz-*Boc*)-PEGA (**4**). The *ε*-Boc group was removed from **3** with 15 mL of 50% CF₃COOH in CH₂Cl₂ for 20 min at RT. The resin was immediately washed twice with 10 mL aliquots of CH₂Cl₂, twice with 15 mL aliquots of 2.5% DIEA in CH₂Cl₂, and once with 15 mL of CH₂Cl₂. The amine substitution was measured by quantitative ninhydrin assay (230 μmol/g). The resin was then given a *precoupling* wash.

Boc-Abz-ODhbt, 0.382 g (**2**, 1 mmol), and DIEA, 87 μL (0.5 mmol), were dissolved in 7 mL of DMF and added to α-Fmoc-Lys-PEGA just swollen in dry DMF. After 2 h, complete coupling was confirmed by ninhydrin assay. The resin was then washed 5 times with 15 mL aliquots of DMF, treated with 20 mL of 20% piperidine in DMF for 20 min, and given a *precoupling* wash.

Fmoc-Phe was coupled via the above Bop-preactivation procedure. The resin was then given a *postcoupling* wash and stored overnight in CH₂Cl₂ at 4 °C.

Fmoc-NO₂Tyr-Www-Xxx-Yyy-Zzz-Phe-Lys-(*ε*-Abz-*Boc*)-PEGA (**5**). Resin **4** was divided equally into nine separate 10 mL graduated polypropylene Bio-Rad "Bio-spin" columns, washed once with 5 mL of DMF/column, treated with 5 mL of 20% piperidine in DMF for 20 min, and given a *precoupling* wash. A common Bop/DMF solution (4.5 mL, 0.444 M) was prepared and metered from a 15 mL polypropylene conical tube fitted with a rubber septum. For each 25 μmol peptide-resin slurry, a preactivated HOBt ester (2 mL, 0.222 M) was prepared from its respective Fmoc-amino acid as before and, after 10 min, added to the appropriate column. Coupling times ranged 1.5–2 h. After checking for complete coupling, the resins were given a *postcoupling* wash, and if necessary, stored overnight at 4 °C in CH₂Cl₂. The resin then was pooled, thoroughly mixed in a 50 mL polypropylene conical tube, redistributed into the nine columns, and the deprotection/coupling cycle repeated. This was accomplished at a rate of 1–2 residues/day. Finally, *Fmoc*-NO₂Tyr was coupled to all the peptides.

Fmoc-NO₂Tyr-Www-Xxx-Yyy-Zzz-Phe-Lys-(*ε*-Abz)-PEGA (**6**). A 500 μL sample of **5** (equilibrated in CH₃OH) was treated with 1 mL of 50% CF₃COOH/45% CH₂Cl₂/5% thioanisole for 30 min and washed with 5 mL of CH₂Cl₂.

CF₃CO-NO₂Tyr-Www-Xxx-Yyy-Zzz-Phe-Lys-(*ε*-Abz)-PEGA (**7**). A 700 μL sample of **5** (equilibrated in DMF) was first treated with 1.1 mL of 20% piperidine, washed, and swollen in 1.2 mL of CH₂Cl₂. Pentafluorophenol (1 g, 5.4 mmol), DIEA (1.5 mL) and trifluoroacetic anhydride (0.7 mL, 4.2 mmol) were dissolved in 2 mL of DMF in a separate flask. After 15 min, the active solution was added to the swollen resin. After 1 h, the resin was completely negative to ninhydrin. Boc then was removed as above.

$\text{NO}_2\text{Tyr-Www-Xxx-Yyy-Zzz-Phe-Lys}(\epsilon\text{-Abz})\text{-PEGA}$ (**8**). The remaining PEGA library **5** was treated first with 20 mL of 20% piperidine for 20 min, washed 5 times with 15 mL of DMF, 5 times with 15 mL of CH_2Cl_2 , then treated with $\text{CF}_3\text{COOH}/\text{CH}_2\text{Cl}_2$ /thioanisole as above for 1 h.

Amine-Masking Active Ester Assay. Active esters were assayed for acylating activity as follows: 5 μL of a solution of 0.30 M alanine amide and 0.3 M DIEA in NMP was added to 10 conical wells of a polypropylene microtiter plate. After preactivation, 1–10 μL of active ester solution was added to each well and allowed to react for 20 min. Then, 10 μL of 350 μM fluorescamine in acetone was added and allowed to react for 10 min. Under a 365 nm UV lamp, bright green fluorescence indicates any deficiency of acylating activity and permits an estimate of active species concentration.

Enzymatic Fluorometric Analysis and Bead Capture. Throughout the experiments, the library was stored in CH_3OH at 4 $^\circ\text{C}$, and amounts were measured by spinning aqueous suspensions of beads down to a swollen volume of 25–250 μL as measured on a graduated spin filter, catalog no. 2000–600, purchased from Bio-101 Inc.³

False-positive, blue-glowing beads were carefully removed from the library of quenched, dark beads prior to each enzymatic assay. This was accomplished with a pipet while suspending a portion of the library in 60% $\text{EtOH}/5\text{mM}$ Et_3N ⁴ in a screening dish (polypropylene pipet tip box lid) under a UV lamp.

A shielded UV-254 short wave lamp was used in conjunction with a Nikon SU-B model S microscope to visualize and collect enzymatically cleaved, fluorescing beads. Positive beads were manipulated, first via polypropylene pipet, into a 5 cm Petri dish, and finally captured using microtweezers. Tweezer ends were flared slightly to grip the bead firmly without damaging it. Beads were placed onto 1.2 cm CF_3COOH -pretreated glass fiber filters, coated with 15 μL of dilute biobrene solution (20 $\mu\text{g}/\mu\text{L}$) to firmly fix the bead, and submitted for sequencing.

Library Quality Control Test. One untreated, fully quenched bead was chosen at random, removed from the library, and submitted for Edman sequencing. The bead was found to contain the sequence $\text{NO}_2\text{Tyr-Asn-Tyr-Ala-Ser-Phe-Lys}$. The quantity of peptide on this single bead was estimated as $\leq 10^{-9}$ mol.

Enzyme Preparation and Storage. Human liver cathepsin B (25 μg) in 50 mM NaOAc and 1 mM EDTA, pH 5, was diluted to 1 mL with the same buffer. The solution was divided into 100 μL portions, snap-frozen with liquid N_2 , and stored at -80°C . An aliquot was thawed and its activity determined to be 1.4 units/mL (13).

Lyophilized human liver cathepsin D (25 μg) was dissolved in 600 μL deionized water. Aliquots were snap frozen and stored at -80°C . An aliquot was thawed and its activity determined to be 0.95 units/mL (32, 33).

α -Chymotrypsin Control Digestions. Fmoc-protected resin **6** (50 μL) was divided equally into two separate spin eppendorfs and washed 5 times with 200 μL buffer A (50 mM Tris(hydroxymethyl)aminomethane-

HCl, pH 8.1 and 10 mM CaCl_2). One reaction was carried out in buffer A alone at RT. A second reaction was carried out in 200 μL of buffer A containing α -chymotrypsin [0.94 mg/mL; 52 units/mg BTEE (34)] at RT. After 3 h, the resins were washed 5 times with 500 μL of H_2O , and 5 times with 500 μL of 10% CH_3CN in 0.1% aqueous CF_3COOH , delivered to a polypropylene screening dish, dissolved in 60% $\text{EtOH}/5\text{mM}$ Et_3N , and visualized under 254 nm. None of the beads in either experiment were positive. After 15 h, two of the buffer control beads were faintly positive. Of the chymotrypsin-treated beads, only one clearly positive bead and 25–37 faintly positive blue-rimmed beads were found. The same procedure was repeated on the *N*-trifluoroacetylated resin **7**; the resulting supernatant was faintly colored and only about 10% of the beads were positive after digestion.

Fmoc was cleaved from remaining resin **6** with 20% piperidine to yield beads **8** that were bright orange at pH 8. Another 25 μL of resin was treated as above with chymotrypsin and washed. Within 1.25 h, the supernatant turned distinctly yellow, and over 85% of the beads was clearly fluorescent. This experiment was repeated using a lower enzyme concentration. Two separate 200 μL aliquots of PEGA-library **8** were used. One aliquot was treated with 32 μL of buffer A alone; the other was treated with chymotrypsin (0.48 $\mu\text{g}/\mu\text{L}$) in 32 μL of buffer A and gently stirred overnight. After 1 h, hundreds of beads had become fluorescent in the chymotrypsin treated aliquot; after 15 h, over 90% of the chymotrypsin beads were fluorescent, but none of those in the control. The final absorbance at 426 nm of the chymotrypsin treatment supernatant was 0.3, and that of the buffer-only control was <0.1 .

Cathepsin B Assays. Library resin **8** ($2 \times 250 \mu\text{L}$) was washed 5 times with 500 μL of buffer B (50 mM NaOAc and 1 mM EDTA, pH 5.4). To one of the centrifuged/swollen resin suspensions, 195 μL of buffer B and 5 μL of 1 M DTT were added and the resin incubated at 37 $^\circ\text{C}$. To the other resin bed, 100 μL of freshly thawed cathepsin B, 95 μL of buffer B, and 5 μL of 1 M DTT were added and incubated at 37 $^\circ\text{C}$. After the first 1.5 h of treatment, the resin beds were centrifuge filtered, the supernatant saved, and the resin washed 5 times with 0.5 mL of 0.1 N NaOAc, pH 6; 5 times with 0.5 mL of 20% $\text{CH}_3\text{CN}/80\%$ 0.1 N NaOAc, pH 6; and 5 times with 0.5 mL of H_2O . No positive beads were found during treatment of resin with buffer alone, while the cathepsin-treated resin bed yielded two positive beads, which were submitted for sequencing. A 100 μL aliquot of the slightly colored supernatant from this treatment was diluted to 1.1 mL with 0.1 N KHCO_3 , pH 9, and found to have an absorbance of 0.11 at 426 nm. The remaining unreacted beads from this batch of resin were recovered, and another round of proteolytic treatment was repeated for an additional 195 min, yielding an absorbance at 426 nm of <0.1 for the diluted supernatant, and two more positive beads. A final round was performed over 17 h: the diluted supernatant gave an absorbance of 0.16, and 6 positive beads were collected. Results from these and subsequent treatments are summarized in Tables 1 and 2.

Cathepsin D Assays. Treatment of 250 μL resin beads **8** with 180 μL of freshly thawed enzyme and 20 μL buffer C (1 N sodium formate, pH 3.8) for 24 h at 37 $^\circ\text{C}$ resulted in >100 positive beads for the enzymatic resin bed and three positives for the buffer control. A milder treatment on a fresh library sample was performed using 50 μL of freshly thawed enzyme, 20 μL of buffer C, and 130 μL of water at 37 $^\circ\text{C}$ for 15.5 h. This yielded eight

³ Using a small mechanic's rule, swollen beads were estimated to have a range of diameters from 75 to 200 μm in 60% EtOH . Accordingly, a 200 μL packed resin bed represents $\approx 80\,000$ beads.

⁴ The pH must be >6 to deprotonate the NO_2Tyr and completely quench the fluorophore.

^a Lysine with free ϵ -amine is detected (25). ^b Cathepsin B from human placenta. ^c Edman incomplete. Very low level of peptide detected. Doublet of Phe is inferred, since a Phe was inserted into the mother resin Phe-Lys(Abz)-PEGA. ^d Cleavage between two Phe residues. ^e Valine in position P2. ^f NO₂Tyr in P2 of second cleavage site. ^g QXV detected (19). ^h Three beads with identical sequences isolated.

clearly positive beads, and no positive beads for the buffer control. Unfortunately, only two of these contained sufficient peptide to be sequenced. The assay was repeated, using 50 μ L of cathepsin D, 20 μ L of buffer C, and 170 μ L of water for 14 h at 37 °C. At this time, six positive beads were collected, five of which could be sequenced. These procedures were repeated as necessary to accumulate a statistically relevant number of sequences.

Substrate Sequence Analysis. Pratt version 2.1 sequence pattern analysis software (52) was utilized online to search for consensus sequences for cathepsin B and cathepsin D substrates selected from the library. Amino-terminal fragments (Table 2) of substrates for both enzymes were entered as variable amino acids, except for NO₂Tyr, which was entered as an ancillary letter code to set off the relative position of the N-terminus of the aligned results without being considered as part of any pattern by the algorithm. There were too few carboxyl-terminal fragments composed of variable amino acids to be statistically significant. The "C-option" stringency was set to 25% for cathepsin B and 67% for cathepsin D. Two patterns were identified and scored for cathepsin B: G-X(0,1)-V-[AGQ]⁵ where V occupies P2 (fitness score = 10.5), and A-X(0,1)-G where A occupies P3 and/or P2 (fitness score = 7.8). Two patterns were identified and scored for cathepsin D: G-X(1,2)-F, where Gly occupies either P4 or P3, and Phe occupies P1 (fitness

score = 7.8), and T-X(0,1)-F, where Thr occupies P3 or P2, and Phe occupies P1 (fitness score = 7.8).

RESULTS AND DISCUSSION

During control experiments, we found that a free amino-terminus on the peptide bead was essential for cleavage with chymotrypsin. All peptides in the library were potential chymotrypsin substrates, yet Fmoc-protected resin-peptides were not digested by chymotrypsin. Acylation of the N-terminus with the less hydrophobic trifluoroacetyl group did not result in a significant improvement. In contrast, the library with free N-termini was efficiently hydrolyzed by chymotrypsin. These observations correlate with the findings of others using this technique. For example, Del Nery et al. (27) discovered that an unbiased library of peptide nonamers was poorly hydrolyzed by Cruzipain and ionizable substrates seemed to be preferred. In our library of heptamers, chymotrypsin was capable of cleaving nearly all the peptides, and biases in enzyme accessibility due to the presence of ionizable groups were avoided because such residues were not included in the library. Even the comparatively large cathepsin D, at 42 kDa, was capable of cleaving substrates in a way that is characteristic of this enzyme.

It should be noted that all of the peptide beads were not indefinitely stable in aqueous media. Nitrotyrosine-containing chromophores elute from the resin over time, and batches of resin incubated only with buffer produce a small but significant number of beads that become fluorescent without intentional exposure to enzymes. Therefore, any set of beads collected from proteolytic

⁵ The nomenclature for this pattern is translated as follows: Gly is followed by either 0 or 1 variable amino acids, which is followed by Val, which is followed by either Ala, Gly, or Gln.

^a Phe*-Lys(Abz) is present at the C-terminus of all members of the library. Substrates in **Bold** were selected independently three times.

digests may contain a small percentage of false positive sequences, underscoring the need for appropriate buffer-only controls.

About 10% of the beads submitted for Edman sequencing contained too little peptide to be sequenced. Beads collected from our first cathepsin D digestion contained particularly small amounts of peptide. A strategy where the supernatant absorbance at 426 nm was repeatedly monitored and positive beads periodically removed was found useful.

It was possible that extensive proteolysis might result in the total loss of the N-terminal portion of the peptide. On the other hand, insufficient cleavage might not produce enough product to reveal the cleavage site. Fortunately, 50–60% of beads submitted for Edman degradation contained the proper balance of cleaved and uncleaved peptide to identify both uncleaved peptide and sites of cleavage. Indeed, in some cases, two sites of cleavage were discernible from the pattern of multiple peaks resulting from Edman sequencing.

Cathepsin B Results. The results in Tables 1 and 2 correlate well with the literature on substrate specificity. For example, the presence of a hydrophobic residue in position P2 is a frequently cited characteristic of papain-like proteinases such as cathepsin B (3, 35, 46). In 27

clearly assignable cleavage sites, only one anomalous hydrophilic Thr is found here. P2 is shared about equally by Val, NO₂Tyr, and Ala. A modestly preferred N-terminal substrate consensus sequence was derived (52): G-X-V-[AGQ], where Gly occupies P4, P3 has high variability, Val occupies P2, and Ala, Gly, or Gln occupies P1. The aromatic residues Phe and Tyr were not found at P2 as might have been expected (46).

We infer from our cathepsin B results that small side chains are somewhat favored in P1, with the following ranking: Gly > Gln > Ala. Our literature search revealed that Phe and Tyr are disfavored in P1, while the equally hydrophobic O-benzyl-Thr derivative is beneficial here, for detailed steric reasons (41).⁶

Tyr, Phe, and Asn are all distinctly underrepresented for cathepsin B in *all* variable positions in our combinatorial context. Amino acid analysis of a sample of untreated library shows that Asn, Phe, and Tyr each fall within 1 standard deviation ($\pm 11\%$) of the average level of incorporation. This particular bias was not observed during cathepsin D treatment of the same library (where, for example, Phe dominates P1). These observations are

⁶ It has since been shown that the benzyl group probably occupies the adjacent S1' pocket (42).

consistent with the expectation that this procedure reveals the intrinsic preferences of the cathepsins.

Among cathepsin B substrates, the preference for the constant penultimate C-terminal Phe at P1' was notable. Menard et al. (12) note a preference for large hydrophobic residues such as Phe and Leu at P1', and this is supported by evidence from the crystal structure (42, 43). However, this alone may not explain the fact that library cleavage occurs primarily toward the C-terminus of the substrate, where only two residues occupy the S' sites. Table 2 shows that when cleavages occur elsewhere, they are almost exclusively found *in addition* to cleavages at this position for the same substrate and two residues distant.⁷ Most of the multiply cut cathepsin B substrates in Table 2 have the following characteristics: another hydrophobic residue (NO₂Tyr) occupies P2, a small residue is again found in P1, and a small residue is found in P3'. The crystal structure for cathepsin B suggests that there is narrowing of the active-site cleft at S3', which is nearly spanned by Leu181 on one side and His111 of the "occluding loop" on the other (42, 43). His110 and His111 side chains in this loop are implicated in cathepsin B's pH-controlled carboxydipeptidase activity (44). The almost exclusive preference for the C-terminal 2-amidoprop-1-yl-PEG interface, or small residues Gly, Gln, and Ala at P3' in the solution set is consistent with a model whereby the preferred site of endoprotease activity is influenced by the occlusion at S3'.

The sequence Q-X-V occurs at least 5 of 27 times in the N-terminal portions of the selected substrates for cathepsin B (Table 1). This is reminiscent of the highly conserved QXVXG motif found in the hydrophobic loops of cystatin inhibitors of papain-like proteases (36). Labile substrates based on the crystal structure of cathepsin B and certain "wedge" regions of the cystatin inhibitors have been characterized (37, 38). Substrates based on the conserved segments of the cystatins were discovered by chance and were unexpected (19) because the cystatin inhibition mechanism is reversible and does not involve peptide cleavage of the inhibitor. A literature substrate based on the central portion of this wedge, Abz-QVVAG-EDDnp, has $k_{\text{cat}}/K_m = 2.5 \times 10^4 \text{ M}^{-1} \text{ s}^{-1}$ for cathepsin B (19). Gln occupies P4 in this substrate, as it does in at least six of our selected substrates for cathepsin B.

Cathepsin D Results. Cathepsin D proved to be a far more selective enzyme, as expected (46–48). Pratt sequence software was able to identify two conserved patterns in 67% of the solution set in Table 2, as compared to only 25% for cathepsin B. *Identical* substrates were selected independently on three different beads (Table 1) for each of two unique sequences, -Gly-Thr-Gln-Phe-Phe and -Gly-Ser-Thr-Phe-Phe. Cleavage of these substrates occurs between the doublet of Phe residues. It should be remembered that the library contained an invariant Phe at its C-terminus, which appears at P1' in these sequences. Both triply selected substrates are closely related to the N-terminal consensus sequences derived from Pratt analysis: G-X(1,2)-F and T-X(0,1)-F. The preferential cleavage between Phe residues in substrates of pepsin-like proteinases such as cathepsin D is well established (29, 35, 39). For example, cathepsin D substrates based upon this common (but not exclusive) phenomenon have been characterized: Lys-Pro-Ile-Leu-Phe-NO₂Phe-Arg-Leu, $k_{\text{cat}}/K_m = 1.61 \times 10^6$

$\text{M}^{-1} \text{ s}^{-1}$ (17); and Phe-Ala-Ala-NO₂Phe-Phe-Val-Leu, $k_{\text{cat}}/K_m = 4.1 \times 10^5 \text{ M}^{-1} \text{ s}^{-1}$ (40). Like cathepsin B, cathepsin D cleaves primarily at the position prior to the constant Phe. This position in the library is unique in that one-ninth of all library substrates will have a doublet of Phe here. A preference for Thr in P3 is consistent with preferences as found for both human cathepsin D (49) and the homologous porcine pepsin (39), but the predicted preference for Val, Ala, and Asn at P2 was not observed. Instead hydrophilic, hydrogen-bonding residues seem to be preferred despite the large, mainly hydrophobic pocket at S2 (51). Others have found that inhibitors designed to fill this pocket with correspondingly large hydrophobic side chains failed to produce the desired result, the explanation being attributed to overall entropic penalties for the enzyme-inhibitor complex (45).

Another behavior that has eluded prediction by analogy (39), modeling assumptions (45), and historical techniques (17, 49) is the clear preference for small or hydrophilic residues Gly > Ala > Gln in P4. This again suggests a lack of complementarity to the hydrophobicity of the putative enzyme subsite.

CONCLUSIONS

The scope of this peptide library ($9^4 = 6561$) was necessarily limited due to the practical constraints imposed by constructing a peptide-linked radiolabeled chelate with protein modification functionality and by prelabeling antibodies for radiopharmaceutical use. Even so, the results were found to be not only consistent with, but supplementary to many characteristics outlined in the literature.

For cathepsin B, we found that (1) the size of the hydrophobic residue at P2 was not as important as expected, as demonstrated by the frequent acceptance of Ala here; (2) the preference for a small residue in P1 is confirmed; (3) Asn, Phe, and Tyr are statistically under-represented in positions P4–P1; (4) there may be a preference for Gln or Gly in P4; and (5) bioconjugates dependent upon the endoprotease activity of cathepsin B may benefit from a substrate design which considers the "occlusion" at the predicted P3' position.

For cathepsin D, cleavage between a doublet of Phe residues is the dominant characteristic, in accord with both statistical prediction for the homologous pepsin (39) and experiment (17, 49). The preference for Thr in P3 is similarly expected. However, our results are not in total agreement with predictions based on either the homologous porcine pepsin or structure-based modeling. We observe a preference for hydrogen-bonding residues in P2 and a distinct preference for Gly > Ala > Gln in P4. This demonstrates that even the more remote subsites may have a significant effect on substrate properties.

These results must be interpreted with deference to the unquantified role of solubility in this selection process. Study of two enzymes was found useful in this regard: substrates with clearly different sequences were selected. So while differences in solubility might not be negligible for these experiments, they do not mask the specificity of the enzymes.

The fluorescence quench one-bead-one peptide methodology is sufficiently simple and straightforward to explore new alternatives even in highly specialized drug targeting contexts such as radioimmunotherapy, and it may provide improvements on the simple Gly₃Phe linker

⁷ A similar substrate "shift" has been proposed for penicillopepsin (50). A pattern of multiple cleavage was not observed for cathepsin D.

used previously (6). To this end, we are preparing several new DOTA-peptide-antibody conjugates for biological tests.

TECHNICAL NOTES

Modification of the Thiourea Linkage of a Fluorescein–Oligonucleotide Conjugate to a Guanidinium Motif during Ammonia Deprotection

Igor Dubey, Geneviève Pratviel, and Bernard Meunier*

Laboratoire de Chimie de Coordination du CNRS, 205 route de Narbonne, 31077 Toulouse Cedex 4, France.
Received December 30, 1997; Revised Manuscript Received June 8, 1998

During the preparation of a fluorescent conjugate based on a manganese cationic porphyrin carboxylate derivative linked to a 5'-amino-3'-fluorescein-labeled oligonucleotide, we observed the chemical transformation of the thiourea linkage to a guanidinium function during the deprotection in ammonia of the 3'-fluorescein–oligonucleotide from CPG support. We also noted a secondary reactivity of the activated carboxylate group of the metalloporphyrin precursor with the fluorescein entity of the conjugated oligonucleotide.

INTRODUCTION

Fluorescein is one of the most sensitive and popular fluorescent dyes and a usual nonradioactive label for nucleic acids. Modifications of oligonucleotides (ODN)¹ with this fluorescent compound are now well-established (1–8). To monitor the cell penetration of manganese-porphyrin–oligonucleotide conjugates, we decided to use 3'-fluorescein labeled oligonucleotides with the 5'-end available for the linkage of the metalloporphyrin derivative (for recent references on metalloporphyrin conjugate, see ref 9–12). In the present work, the fluorescent label was introduced at the 3'-end of an oligonucleotide by using a polymer support for solid-phase synthesis of 3'-fluorescein-labeled oligonucleotides that is commercially available. We used a polymer from Glen Research with a thiourea linker Flu-NH-CS-NH designed to provide the same fluorescein-type structure (Figure 1) as that obtained with standard fluorescein isothiocyanate reagent (FITC). However, during the synthesis of these 5'-Mn-Por-ODN-3'-Flu conjugates (and also for ODN-3'-Flu conjugates), we found that the classical thiourea linkage of the ODN-3'-Flu was modified to a guanidinium function during the deprotection step in ammonia. This not yet published modification has been evidenced by electrospray ionization mass spectrometry (ESI-MS).

EXPERIMENTAL PROCEDURE

Synthesis and Purification of 3'-Fluorescein-5'-amino-link Oligonucleotide. Solid-phase oligonucleo-

Figure 1. Structure of the commercial fluorescein-CPG support used in the present study.

tide synthesis was performed on a Cyclone Plus DNA synthesizer (Milligen/Bioscience) using a standard β -cyanoethyl phosphoramidite approach and all the necessary commercially available reagents (Perseptive). Cleavage of ODN from support required 2 h at room temperature with 32% ammonium hydroxide and base deprotection was performed by a further overnight incubation at 55 °C in the same ammonium hydroxide solution. Analyses were performed by anion-exchange HPLC using a Protein Pak DEAE 8HR column (Waters) followed by a diode-array detector (DAD 440, Kontron) with a linear gradient 0–500 mM NaCl in 25 mM Tris/HCl buffer, pH 8.5, over 45 min, at a flow rate of 0.7 mL/min. Fluorescein CPG support (0.2 μ mol cartridge from Glen Research) was used for the synthesis of 3'-fluorescein-labeled oligonucleotide. After chain elongation was over, 5'-functionalization with 1,6-diaminohexane as aminoalkyl linker was performed under usual conditions (13). The 3'-fluorescein-labeled and the 5'-amino-linked corresponding oligonucleotides were purified by anion-exchange HPLC using a Protein Pak DEAE 8HR column under the same condition as that described for analysis (R_t , 45 and 43 min for ODN–Flu and 5'-amino-linked ODN–Flu, respectively). Desalting of the product was performed

on Sep-Pak cartridges (Waters): elution of salts with 25 mM TEAA buffer, pH 6.5, followed by washing with a mixture of 100 mM TEAA, pH 6.5, with (70/30, v/v) acetonitrile. Spectrophotometric data of the 3'-fluorescein-modified oligonucleotide were as follows: the OD₄₉₄/OD₂₆₀ nm absorbance ratio at pH 8 for the fluorescein-oligonucleotide conjugate was 0.35, which is in full agreement with calculated values (ϵ of fluorescein at 494 and 260 nm: 75×10^3 and $25 \times 10^3 \text{ M}^{-1} \text{ cm}^{-1}$ respectively) (8). Concentrations of oligonucleotides were determined by UV measurements from the calculated molar extinction coefficient (14) (ϵ at 260 nm: $185 \times 10^3 \text{ M}^{-1} \text{ cm}^{-1}$ for ODN or $210 \times 10^3 \text{ M}^{-1} \text{ cm}^{-1}$ for ODN-Flu) (Table 1).

Synthesis of the Metalloporphyrin Precursor.

The manganese(III) 5-[(4-(5-carboxy-1-butoxy)phenyl)-10,15,20-tris(4-*N*-methylpyridiniumyl)-porphyrin] precursor was prepared as previously described (15). UV-vis spectral data of the manganese-porphyrin precursor in water are as follows: λ nm (ϵ , $\text{M}^{-1} \text{ cm}^{-1}$): 260 (3×10^4) and 468 (1×10^5).

Synthesis of the Mn(III) Porphyrin Conjugate of 3'-Fluorescein-Labeled Oligonucleotide. According to published procedures (16–18), activation of the manganese(III) 5-[(4-(5-carboxy-1-butoxy)phenyl)-10,15,20-tris(4-*N*-methylpyridiniumyl)porphyrin] precursor (0.038 mmol) was performed in the presence of BOP (0.27 mmol, 7 eq), HOBT (0.27 mmol, 7 eq) and *N*-methyldimorpholine (3.75 mmol, 15 eq) in 25 mL of dry DMF for 45 min at 40 °C. To hydrolyze the excess of BOP/HOBT reagent, 10 mL of 20 mM MOPS buffer (pH 7.5) was added and the mixture was warmed for 10 min at 40 °C. Then this solution was mixed with 40 μL of the purified 5'-amino-3'-fluorescein-labeled oligonucleotide (7.5 nmol, 1.4 OD₂₆₀) dissolved in 20 mM MOPS buffer (pH 7.5). Coupling reaction was allowed to proceed for 45 min at 40 °C. Addition of 150 μL of methanol and incubation at –20 °C for 20 min precipitated the conjugated product. After a centrifugation step, the pellet was washed twice with 50 μL of methanol, dried, and dissolved in 50 μL of 0.5 M sodium acetate (pH 5) at 60 °C. The product was then precipitated with 180 μL of ethanol, cooled to –20 °C and centrifuged again. The pellet was washed twice with 50 μL of ethanol, dried under vacuum, and dissolved in water. The crude product was purified by anion-exchange HPLC (R_t , 33 min for 5'-Mn-Por-ODN-3'-Flu), desalted on Sep-Pak cartridge and dissolved in water for quantification. After purification and desalting the product yield was about 40% (based on starting 5'-amino-linked oligonucleotide). The vis/UV absorbance ratios of conjugate were OD₄₆₈/OD₂₆₀ = 0.6 to account for the covalent attachment of one manganese(III) porphyrin moiety onto oligonucleotide and OD₄₉₄/OD₂₆₀ = 0.3 due to 3'-fluorescein chromophore that is in good agreement with calculated values (Table 1).

Preparation of a Fluorescein Isothiocyanate Adduct with 4-Aminobutanol and Behavior in Ammonia. Fluorescein isothiocyanate (29 mg, 0.075 mmol) was dissolved in 300 μL of freshly distilled DMF, and 4-aminobutanol (0.15 mmol, 14 μL) was added. After 4

h at ambient temperature, acetonitrile (3 mL) was added, the mixture cooled, and precipitate centrifuged. The dye material was dissolved in 5% NaHCO₃ and precipitated carefully with diluted HCl, centrifuged, washed with water, and dried. It was purified by chromatography on a silica gel column (elution with chloroform/acetone, 1:1). Yield = 19 mg (61%). TLC (Kieselgel 60F254 plates from Merck): R_f = 0.13 (CHCl₃/MeOH, 9/1, v/v), 0.80 (CH₃CN/water, 5/1), 0.82 (EtOH). ESI-MS: m/z 479.1 ($\text{M} + \text{H}^+$), 389.8 [$\text{M} - \text{NH}(\text{CH}_2)_4\text{OH}$]⁺. Fourteen milligrams of this compound (0.03 mmol) was dissolved in 1 mL of 32% ammonia and kept at 55 °C for 24 h. All starting material was transformed into a product having a value of R_f = 0.05 (CH₃CN/water, 5/1), 0.32 (EtOH). The reaction mixture was dried by Speed-Vac; the remaining material was dissolved in a small volume of diluted ammonia, precipitated with diluted HCl, and centrifuged. The pellet was washed with cold water ($3 \times 300 \mu\text{L}$) and dried. Nine milligrams of orange powder were recovered (yield = 67%). ESI-MS: m/z 462.2 ($\text{M} + \text{H}^+$), 373 [$\text{M} - \text{NH}(\text{CH}_2)_4\text{OH}$]⁺.

Electrospray MS. Electrospray ionization mass spectra were obtained using a quadrupole LC-MS spectrometer (Perkin-Elmer SCIEX API 100) equipped with an ionspray source. The ionization voltage was 5 kV in the positive mode and –4.5 kV in the negative mode. The orifice voltage was set to +50 or –50 V in the positive or negative mode, respectively. Sample solutions were introduced into the ionspray source at a rate of 5 $\mu\text{L}/\text{min}$ using a Harvard Apparatus syringe pump. The background noise recorded with the solvent used for ESI-MS analysis was subtracted when specified in the figure legends.

Electrospray MS of Oligonucleotides. Purified oligonucleotides were treated with ammonium acetate and precipitated with ethanol for displacement of sodium ions as described in ref 19. Analysis was performed in the negative mode. The injected solution consisted of 50 μL of at least 25 pmol/ μL concentration of ODN derivative dissolved in a water/acetonitrile mixture (50/50) containing 0.1% triethylamine.

Electrospray MS of the Fluorescein Isothiocyanate Adduct with 4-Aminobutanol and Its Guanidinium Analogue. Analysis was performed in the positive mode. The injected solution consisted of 50 μL of at least 25 pmol/ μL concentration of the adduct dissolved in a water/methanol mixture (50/50) containing 0.1% of trifluoroacetic acid.

RESULTS AND DISCUSSION

Preparation of the 5'-Mn-Por-ODN-3'-Flu Conjugate. In the present work, modified oligonucleotides were prepared having a fluorescent marker and/or an artificial nuclease moiety. The covalent attachment of a cationic porphyrin moiety at the 5'-end of an oligonucleotide labeled at the 3'-end by a fluorescein was performed via an amide bond resulting from the reaction in solution between an activated ester of the porphyrin carboxylate precursor and a 5'-amino-linked oligonucleotide (Figure 2). The sequence of the oligonucleotide was 5'-GTTGTAAACGACGCGCAT-3'. It is directed toward the coding region of the *Escherichia coli* β -galactosidase messenger RNA (349–411 region). The absorption maximum of fluorescein dye (492–494 nm at pH 8) is situated in a region close to that of the manganese-porphyrin core (Mn-Por) (468 nm), but the fluorescence maximum (520 nm) is far from the absorption maximum of Mn-Por.

The synthesis of the 5'-amino-linked ODN-3'-Flu was performed using the phosphoramidite method with the

Figure 2. Structure of 3'-fluorescein oligonucleotide (ODN-3'-Flu) and 5'-manganese porphyrin-3'-fluorescein oligonucleotide (5'-Mn-Por-ODN-3'-Flu) conjugates. The oligonucleotide sequence is 5'-GTTGTAAAACGACGGCAT-3'.

Figure 3. UV-vis spectrum of 5'-Mn-Por-ODN-3'-Flu.

fluorescein-CPG support shown in Figure 1. Derivatization on the 5'-position by an amino-linker was performed on the ODN still attached on the CPG cartridge, and the resulting 5'-amino-linked-ODN-3'-Flu product was cleaved from support, deprotected by ammonolysis, and purified before further reaction with the activated ester of Mn-Por precursor. We hydrolyzed the excess BOP/HOBT reagent after activation of the Mn-Por precursor, but before its addition to the 5'-amino-linked ODN-3'-Flu. During the coupling reaction, the starting 5'-amino-linked-ODN-3'-Flu was consumed to completion, and a side product corresponding to two Mn-Por moieties covalently bound to the ODN was observed. It could be transformed to the desired conjugate by mild acidic treatment, e.g., solubilization of the methanol precipitate of the coupling reaction in 0.5 M sodium acetate (pH 5). So, the reprecipitation of coupling reaction mixture after incubation in sodium acetate (pH 5) is essential to obtain good coupling product yield. The most probable way of formation of this side product is the covalent modification of fluorescein entity by the activated ester of Mn-Por during the coupling reaction. We ruled out some strong noncovalent interaction between porphyrin and fluorescein by control experiments where the ODN-3'-Flu and the nonactivated Mn-Por precursor were incubated and submitted to chromatography together. Fluorescein has two nucleophilic centers that are able to react with the excess of the activated ester of Mn-Por: the OH group of the carboxylic or phenolic functions. But the reaction of the fluorescein carboxylic group would lead to a mixed anhydride which should be unstable and would hydrolyze immediately during the isolation of the product. The

second possibility is the fixation of a second Mn-Por on the phenolic group of the 3'-fluorescein. In peptide synthesis, active esters of carboxylic acids are known to acylate phenolic hydroxyl of tyrosine and even aliphatic OH-group of serine, especially in the presence of HOBT as powerful catalyst of O-acylation (20–22). Furthermore, efficient acylation of alcohols by BOP/HOBT-activated carboxylic acids was recently described (23, 24). Since phenolic OH are more reactive than aliphatic alcohol functions, the reaction of the phenolic group of fluorescein with the activated ester of the Mn-Por precursor is highly probable. Its product, an aryl ester of carboxylic acid, should be rather stable under neutral conditions, but could be prone to acid or basic hydrolysis. Under acidic conditions, the protonation of the oxygen atom of the pyrone ring of fluorescein makes the fluorescein residue a good leaving group, and this may account for the transformation of the side product containing two Mn-Por entities into the desired conjugate with one Mn-Por per oligonucleotide. The UV-vis spectra of the 5'-Mn-Por-ODN-3'-Flu conjugate nicely showed the manganese-porphyrin (468 nm), oligonucleotide (260 nm), and fluorescein (492–494 nm) absorption bands (Figure 3).

Modification of the Linker between the 3'-Flu Entity and the ODN. Electrospray mass spectra were recorded in order to confirm the structure of ODN-3'-Flu and 5'-Mn-Por-ODN-3'-Flu conjugates. The mass spectra are shown in Figure 4. Figure 4B is the spectrum of 5'-Mn-Por-ODN-3'-Flu. In the mass range m/z 600–1500, four ions of the series $(M - nH)^{-n}$ appear for charged states $n = 5$ –8: 1423.2, 1186.2, 1016.5, and

NH-C(NH ₂) ⁺ -NH, calcd	889.9	1016.9	1186.2	1423.3	7126.3	C ₂₆₂ H ₃₀₄ N ₈₆ O ₁₁₆ P ₁₈ Mn
Mn-Por-ODN-Flu, observed	889.5	1016.5	1186.2	1423.2	7126.3 ± 0.9	

889.5, respectively (see Table 2). The calculated mass of the analyzed product was 7126.3 ± 0.9 . The calculated mass of the conjugate containing a thiourea linkage corresponding to C₂₆₂H₃₀₂N₈₅O₁₁₆P₁₈MnS is 7142.4. The calculated *m/z* values of this compound for *n* = 5–8 are 1426.6, 1188.7, 1018.8, and 891.3, respectively (Table 2). These values differ from the observed ones by ~0.25%, which is above the experimental errors expected for ESI-MS (19, 25). We suspected that the difference was due to the possible transformation of the thiourea function -NH-CS-NH- in the fluorescein linker on the CPG support into a guanidinium group -NH-C(NH)-NH- during the ammonolysis of the 3'-fluorescein labeled ODNs, with a loss of molecular mass of 17 or 16 whether the guanidine function is neutral or protonated, respectively. Indeed the calculated mass corresponding to the guanidinium-linked product, C₂₆₂H₃₀₃₍₄₎N₈₆O₁₁₆P₁₈Mn, is 7125.3 (7126.3 if guanidinium is protonated) and should show *m/z* peaks at the values listed in Table 2 (1423.3, 1186.2, 1016.9, and 889.9) that differ by only 0.02% from the observed values. The same discrepancy between observed spec-

trum and theoretical values was noted for the simple ODN-3'-Flu (Figure 4A). The observed *m/z* values were 1233.1, 1027.5, 880.5, 770.4, 684.4, and 616.1 for charged states *n* = 5–10, respectively, and led to a molecular mass of 6170.7 ± 0.2 . These values could not account for a product with a thiourea linkage C₂₀₆H₂₄₈N₇₆O₁₁₃P₁₈S that has a calculated molecular mass of 6186.3 but rather to a guanidinium-linked conjugate of molecular formula of C₂₀₆H₂₄₉₍₂₅₀₎N₇₇O₁₁₃P₁₈ and of calculated molecular mass of 6169.3 (6170.3 if protonated) (Table 2). It is known that thioureas react with ammonia or amines to form guanidines (26–28). To check this possibility, we have synthesized the conjugate of fluorescein isothiocyanate (FITC) with 4-aminobutanol (mass of the thiourea fluorescein isothiocyanate adduct = 478) and applied it to the ammonolysis procedure (the molecular mass of this fluorescein-aminobutanol adduct was 462 after protonation). So, electrospray mass spectra confirmed the guanidine structure of the fluorescein linker after ammonolysis with a reduction of molecular mass of 16 (or 17 if the guanidine is not protonated) units

compared to the starting thiourea fluorescein derivative. So, the same process also takes place during the deprotection of fluorescein-oligonucleotide conjugates explaining the difference between calculated and observed molecular mass of fluorescein-ODN conjugates. However, we verified that the thiourea function was completely stable when incubated for 24 h in a 32% ammonia solution used for deprotection at room temperature.

In conclusion, this chemical transformation should appear each time NH-CS-NH linkage of modified nucleotides is subjected to a 55 °C overnight deprotection in ammonia, in particular when using 3'-fluorescein-CPG supports. It may not affect the general properties of conjugated molecules, yet introduces an extra positive charge on it and the change in its molecular mass may be misleading. This chemical transformation can be avoided for fluorescein label when the coupling of the dye can be performed after deprotection (29, 30) or when deprotection is performed under mild conditions (24 h in ammonia at room temperature). Fluorescein activated by succinimidyl esters of 5- (or 6-) carboxyfluorescein is also treated under appropriate deprotection conditions (31, 32).

ACKNOWLEDGMENT

The authors thank Catherine Claparols and Suzy Richelme for ESI-MS data and fruitful discussions. I.D. is highly indebted to a grant of the joint program between the Academy of Sciences of Ukraine (Institute for Bioorganic Chemistry and Petrochemistry at Kiev) and the University Paul Sabatier organized by Dr. Justin Tessié (CNRS, Toulouse).

Bispecific Antibodies as Novel Bioconjugates

Y. Cao and M. R. Suresh*

Faculty of Pharmacy and Pharmaceutical Sciences, University of Alberta,
Edmonton, Alberta, Canada, T6G 2N8. Received April 30, 1998

Bispecific antibodies are unique macromolecular heterobifunctional cross-linkers with two different binding specificities within a single molecule. As ideal bioconjugates, they can specifically glue any two different molecules together without the need for chemical conjugation. With this unique feature, they have immense potential in biological and immunological fields. Their applications range from immunohistochemistry, immunoassays, radioimmunodiagnosis, radioimmunotherapy, and immunotherapy. Recently, a new second generation of bispecific molecules, bispecific single chain Fv and diabodies, has been produced by DNA recombinant technology. They can be considered as the ultimate magic bullets for in vivo applications. They may theoretically improve tumor or pathogen targeting and minimize side effects, eventually replacing the full-length bispecific antibodies. Emphasizing on developmental methodology and clinical applications of bispecific antibodies, this review gives a bird's-eye view of these unique bioconjugates.

INTRODUCTION

Monospecific antibodies exemplified by the naturally occurring major IgG class have two identical antigen-binding paratopes due to their makeup with two identical heavy and light chains. On the contrary, bispecific antibodies are artificially engineered immunoglobulins with two distinct binding specificities. They were first generated 37 years ago by chemical methods (Nisonoff and Rivers, 1961). In the past two decades, hybridoma technology established itself as one of the cornerstones of modern biotechnology (Kohler and Milstein, 1975), and bispecific monoclonal antibody (bsMAb) represents second generation monoclonals developed for a variety of in vivo and in vitro uses.

A number of applications using monoclonal antibody (MAb) involve chemical manipulation of the antibody to create covalent immunoconjugates with radioisotopes, enzymes, toxins, drugs, and a variety of other haptens. Early chemical conjugation methods using homobifunctional cross-linkers generated complex aggregates of the two entities. Refinement in chemical conjugation methods, employing heterobifunctional cross-linkers, has mitigated the problems but not entirely eliminated them (Hermanson, 1996). BsMAb with intrinsic binding sites to any two antigens has the capability to form uniform, homogeneous, and reproducible immunoconjugates with one or two entities in a predetermined order (Suresh et al., 1986a). Since such binding is noncovalent and dependent on the affinity of the epitope-paratope interaction, bsMAb has a singular advantage to cross-link two cells for targeting in vivo (Staerz and Bevan, 1989). The

latter feature has not been described to date using chemical conjugation for *in vivo* applications.

Current applications of bsMAb range from immuno-histochemistry (Milstein and Cuello, 1983), immunoassays (Kreutz and Suresh, 1995, 1997; Suresh et al., 1986a; Cao et al., 1998), complement-mediated cytotoxicity (Wong and Colvin, 1987), and *in vivo* retargeting (Fanger et al., 1995; Demanet et al., 1996; Somasundaram et al., 1996). BsMAb has great potential in a wide variety of research and eventually, clinical uses. Some of these exciting explorations include redirecting cytotoxicity to tumor cells, HIV virus, and infectious agents, targeting enzyme and site-specific activation of anticancer prodrugs and localizing fibrinogen activator to dissolve fibrin clots.

PRODUCTION OF BISPECIFIC ANTIBODIES

Many different types of bsMAb have been made (Figure 1) by one of the three general methods: (1) chemically cross-linking two antibody molecules or antibody fragments, (2) fusion of two different cell lines to form a quadroma or trioma, (3) recombinant DNA based approaches.

1. Chemically Coupling. More than 30 years ago, the first bispecific polyclonal antibodies were produced by chemically coupling two different polyclonal antibodies (Nisonoff and Rivers, 1961). This chemical manipulation involved the dissociation of the two different antibodies and reassociation of the two-half molecules. A portion of the reassembled antibodies was shown to be bispecific in nature by immunohistochemistry. With the advent of MAb and improvements in the chemistry of preferential formation of heteroconjugates, developing bispecific monoclonals became a reality eliminating the heterogeneous polyclonal reagents.

To prepare bsMAb, a large number of bifunctional reagents reactive with ϵ -amino groups or hinge region thiol groups have been used. These cross-linkers can be classified into two categories, homo- and heterobifunc-

tional reagents. Homobifunctional reagents react with the free thiols generated upon reduction of inter heavy chain disulfide bonds. 5,5'-Dithiobis(2-nitrobenzoic acid) (DTNB) or *o*-phenylenedimaleimide (O-PDM) can activate thiol groups on Fab' fragments of MAb (Brenner et al., 1985; Glennie et al., 1987; Shalaby et al., 1992). DTNB acts to regenerate disulfide bonds between the two Fabs, whereas O-PDM acts to form a thioether bond between the two Fab'. Generally, the thioether bond of O-PDM could be more stable than the disulfide bond regenerated by DTNB (Glennie et al., 1987). In addition to dimeric bsMAbs, trimeric and tetrameric antibodies with two or three specificities have been constructed using O-PDM and shown to have more potent redirecting effector cell tumor cytotoxicity than corresponding dimeric antibodies (Tutt et al., 1991a,b).

Heterobifunctional reagents can introduce a reactive group onto a protein that will enable it to react with a second protein. *N*-Succinimidyl-3-(2-pyridyldithio) propionate (SPDP) has been used to react with primary amino groups to introduce free thiol groups (Segal et al., 1988; Jung et al., 1991). SPDP can combine any two proteins that have exposed amino groups including antibodies and Fab' fragments, regardless of class or isotype (Van Dijk et al., 1989). Unfortunately, this approach causes random cross-linking of the molecules and hence exhibits batch to batch variations.

The improvements in cross-linking technology has led at least one biotechnology company (Medarex Inc., NJ) to develop bispecific (Fab')₂ antibodies and evaluate their utility in FDA-approved human clinical trials. Chemical linking that has been highly refined is more straightforward and faster, produces higher yields, and the products are comparatively easier to purify (Glennie et al., 1987). However, denaturation of either protein or loss of antibody activity are concerns during these types of chemical reactions.

2. Somatic Hybridization. Somatic hybridization for generating bispecific antibodies first appeared in 1973

Figure 2. Production of quadromas. A HAT sensitive (HAT^s) clone is isolated from one parental hybridoma by culturing in 8-azaguanine. This clone is subsequently made resistant to ouabain (Oua^r) by mutant selection. After fusion with a wild-type hybridoma that produces a different antibody, quadromas are selected by culturing the cells in HAT medium supplemented with ouabain. The unfused parental cells will die due to sensitivity to HAT and lack of resistance to ouabain, respectively.

(Cotton and Milstein, 1973), although the term and concept of bispecific antibodies were not appreciated. Basically, somatic hybridization included fusion of two hybridomas and purification of the bsMAB secreted by the resulting quadromas. Two different methods have been described: (1) fusion of two established hybridomas generates a quadroma (Milstein and Cuellar, 1983; Suresh et al., 1986b), and (2) fusion of one established hybridoma with lymphocytes derived from a mouse immunized with a second antigen generates trioma (Nolan and Kennedy, 1990).

Somatic hybridization for development of bsMAB involves methods similar to those for preparing hybridomas (Kohler and Milstein, 1975). It has been greatly facilitated by the use of drug resistance markers introduced into cell lines by conventional and molecular genetic techniques. First, each hybridoma cell line is made resistant to a specific drug-resistant marker. Quadroma cells are then selected after fusion using a culture medium containing both drugs which can kill both parental cells allowing only hybrid-hybridoma to survive (De Lau et al., 1989; Bos and Nieuwenhuizen, 1992). Alternatively, a universal fusion partner could be developed by sequentially culturing in 8-azaguanine and ouabain to generate a HAT sensitive and ouabain resistant cell line (Figure 2). After it is fused with a second normal hybridoma, which is HAT resistant and ouabain sensitive, only the fused quadromas survive in the combined HAT and ouabain medium. The advantage of using drug resistance markers is that the selected fused cells are functionally stable synkarions (fused nuclei).

Somatic hybrids can also be selected by sorting out the heterofluorescent cells without relying on drug selection (Karawajew et al., 1987, 1988). Hybridomas were pre-labeled with either fluorescein isothiocyanate (FITC) or tetramethylrhodamine isothiocyanate (TRITC) via the cell membrane marker octadecylamine. Differentially labeled hybridomas are fused, and the cells staining for both fluorochromes are isolated using a fluorescence-activated cell sorter (FACS). Electrofusion technique was developed as an alternative to conventional PEG fusion as it is innocuous and easy to perform and produces high yield (Chang, 1989). We have developed microelectrofusion and electrofusion plus FACS selection methodology to generate the desired hybrid-hybridoma with no laborious drug selection procedures (Cao et al., 1995; Kreutz et al., 1998b). Such protocols could also be predictably adopted to generate human hybridomas with few B cells isolated from peripheral blood lymphocytes enriched by antigen specific panning or affinity microelectrofusion.

The activity of bsMAB secreted by quadroma clones should be tested as quickly as possible. A bridge ELISA is a general way to screen bsMAB (Suresh et al., 1986a; Koolwijk et al., 1988; De Lau et al., 1989). Double antigen ELISA may be employed if sufficient quantities of the respective antigens are available. When two different H chain isotypes are present in the bsMAB, isotype specific reagents could be used for detection of hybrid molecules. Last, the supernatants of clones putatively containing bsMAB to redirect T cell cytotoxicity could be tested utilizing cytotoxic T cell clones and target cell lines (Haagen et al., 1992). Biologically produced bsMAB is synthesized, assembled and secreted by the same process as native immunoglobulins, and thus they have similar characteristics in terms of stability and pharmacokinetics (Songsivilai and Lachmann, 1990). Since individual light chains and heavy chains are transcribed separately and assembled randomly, the desired bsMAB produced by the quadroma could range 10–50% (Suresh et al., 1986a). Hence, purification of this bsMAB is essential and has been achieved by hydroxylapatite chromatography (Karawajew et al., 1987; De Lau et al., 1992), ion-exchange chromatography (Suresh et al., 1986b; Auriol et al., 1994) double affinity chromatography (Sahin et al., 1990; Smith et al., 1992), mimetic affinity methods (Xu et al., 1998), and gradient thiophilic T-gel chromatography (Kreutz et al., 1998b).

3. Genetic Engineering. Chemical conjugation or cell fusion generates a heterogeneous mixture, requiring labor-intensive methods to purify the bispecific form from the other homo and hetero aggregated species. Many of the limitations of generating bsMAB through these traditional methods may be potentially overcome by genetic engineering techniques (Pluckthun and Pack, 1997). This new technique was first described by Songsivilai and colleagues to generate transfectants for secreting humanized bsMAB (Songsivilai et al., 1989). Generally, the antibody or its fragment of different specificities was expressed as distinct polypeptides from the same transcript or from separate plasmid constructs, followed by combining different antibody fragments through binding motif (Shalaby et al., 1992). Recently, bsMAB molecules have been made as a single covalent structure by combining two single chain Fv (scFv) fragments using polypeptide linker (Winter and Milstein, 1991; Holliger et al., 1993; Kranz et al., 1995; Schmidt et al., 1996; Thirion et al., 1996). Different spacers have been tried to increase the bispecific yield (Gruber et al., 1994; Mallender et al., 1994). It is essential in this strategy to ensure that the two single-chain antibodies exhibit affinities similar to the parental MABs.

Ridgway and associates reported a novel “knobs into holes” method of making bsMAB (Ridgway et al., 1996). In this method, the knobs were created by replacing small amino acid side chains at the interface between C_H3 domains with larger ones, whereas the holes were generated by replacing large side chains with smaller ones. This engineering of the C_H3 domains of heavy chains resulted in the formation of heterodimers (Ab1-knob-hole-Ab2) more favorably than homodimerization (Ab1-Ab1 and Ab2-Ab2). This elegant strategy has been extended to make full-length bispecific human IgG, which could be used in immunotherapeutic strategies (Merchant et al., 1998).

Leucine zipper-based dimerization of MAB fragments has also been introduced (Kostelny et al., 1992). The leucine zippers are sequences derived from regions of the transcription factors *fos* and *jun*. A murine anti-CD3 Fab'-*fos* and anti-Tac Fab'-*jun* were individually ex-

pressed as homodimers in SP2/0 cells. When they were reduced, mixed, and reoxidized, the formation of *fos* and *jun* leucine zipper resulted in the generation of bsMAB fragment Fab' (anti-CD3 x anti-Tac). De Kruif and Logtenberg also described the fusion of *fos* or *jun* leucine zipper and a truncated mouse IgG3 hinge region to scFv proteins (De Kruif and Logtenberg, 1996). In their method, two cysteine residues were engineered into the zipper domains to produce disulfide-stabilized homodimers. Using scFv isolated from a phage display library and these modified zipper cassettes, they have produced functional stable secreted homodimers in *Escherichia coli*. After reduction, mixing, and reoxidation of the homodimers, functional bispecific scFv molecules were developed. Rheinhecker also utilized a similar approach to create scFv dimers by fusion of an artificial helix-turn-helix dimerization domain of p53 to a long IgG3 hinge-scFv construct (Rheinhecker et al., 1996).

Holliger and colleagues developed a diabody method to generate bsMAB fragments (Holliger et al., 1993). In the diabody method, constructing scFv with short linkers can prevent intrachain pairing but allow interchain pairing to form bivalent fragments. The scFv containing V_L and V_H with two different paratopes was assembled with the reciprocal scFv pair to form bsMAB fragments. Recently, a phage display diabody approach was developed to generate and screen bispecific scFv (McGuinness et al., 1996). Although the diabody approach appears promising with previously cloned scFv molecules, construction of diabody libraries from large Ab repertoires requires several cloning steps and the stability of the library in bacteria has not yet been extensively evaluated (Hayden et al., 1997).

Among a plethora of approaches to genetically engineer bsMAB, the most promising approaches appear to be bispecific scFv and bispecific diabodies. This is due to their small size and hence is more attractive for in vivo applications exhibiting faster clearance, better tissue penetration, and decreased immunogenicities.

APPLICATIONS OF BISPECIFIC ANTIBODIES

1. Immunohistochemistry and Enzyme Immunoassays. The advent of MAb technology was instrumental in the development and refinement of immunoassays using chemically linked radioisotopes, enzymes, fluorochromes, or others detection moieties. Despite the surge in these new applications, chemical cross-linking has many disadvantages: (1) chemical cross-linking is random generally resulting in batch to batch variations in reagent quality; (2) the size of conjugates or complexes obtained are not uniform thus influencing their penetration in immunohistochemical applications; (3) active site or binding site inactivation of markers and/or immunoglobulins may be encountered; (4) mostly irreversible covalent linkages are formed which are advantageous for in vitro applications but are less suitable for in vivo therapeutic studies. These drawbacks of covalent cross-linking of antibodies to enzyme or radioactive markers often influence the linearity and reproducibility of the assay method. On the contrary, bsMAB designed to specifically cross-link the antigen with a signal generating marker such as an enzyme eliminates the need for chemical conjugation, generating a greater degree of linearity, sensitivity, and reproducibility (Suresh, 1991).

Milstein and Cuello first (Milstein and Cuello, 1983) developed a bsMAB (anti-somatostatin x anti-peroxidase) used in immunohistochemistry. Suresh and co-workers (Suresh et al., 1986a) established a hybridoma-

secreting anti-peroxidase x anti-substance P, which simplified the immunohistochemical procedures and giving a better sensitivity. A bsMAB reacting with both horseradish peroxidase (HRPO) and fluorescein isothiocyanate (FITC) was used to label different MABs in enzyme immunoassay systems (Karawajew et al., 1988). Many investigators have developed bsMABs directed against enzyme (e.g., HRPO, alkaline phosphatase, and β -galactosidase) and a second antigen (e.g., tumor specific antigen, peptide, or hormone) for use in enzyme immunoassay or immunohistochemistry (Takahashi and Fuller, 1988; Wognum et al., 1989; Tada et al., 1989; Ribeiro-da-Silva et al., 1991; Allard et al., 1992; Kontseikova et al., 1992; Jantscheff et al., 1993; Piran et al., 1993; Auriol et al., 1994; Liu et al., 1995; Kreutz and Suresh, 1995, 1997; Berkova et al., 1996; Cao et al., 1998). Rylatt developed a homogeneous immunoassay system to detect circulating antigens in whole blood. The bsMAB used here cross-linked specific antigen of interest and red blood cells, causing agglutination of a patient's own blood sample (Rylatt et al., 1990).

2. Radioimaging and Radioimmunotherapy. Conventional radioimmunoimaging and, in particular, radioimmunotherapy with MAB conjugates is severely limited by radiation toxicity to normal organs, especially blood, liver, kidney, and bone marrow. This is largely due to the high radiation dose from prolonged circulating radiolabeled antibody to these organs, from normal tissue accumulation of the antibody, or from free radionuclide deposited in the organs. Pretargeted imaging and radioimmunotherapy with bsMAB is a two or three step strategy for delivering radioisotope (^{99m}Tc, ⁹⁰Y, ⁶⁷Ga, and ¹¹¹In) to a tumor quickly and specifically with minimal radiation exposure and hence lowered dosimetry to normal organs (Chetanneau et al., 1994; Chatal et al., 1995; Dillehay et al., 1995; Kranenborg et al., 1995; Schuhmacher et al., 1995).

Pretargeting involves administration of a bsMAB with high affinity for a small rapidly excreted effector molecule, which is given as a second step after the bsMAB has concentrated in the target tumor. Removal of the excess bsMABs from the circulation with a clearing agent is an optional step before giving the effector molecule for greatly improved target-to-blood ratio. Soon after the clearing agent, the effector molecule is given, and the maximum tumor concentration and tumor-to-normal tissue ratio is achieved in 1–3 h. Unbound radiolabel is rapidly excreted via the kidney, by glomerular filtration mechanism, leading to greatly decreased radiation exposure to normal tissue. Several different targeting macromolecule and effector small molecule pairs have been proposed in the literature (Goodwin, 1987; Goodwin et al., 1994).

Pretargeting combines the pharmacokinetics of long circulating MAB with rapidly excreted small effector molecules to give both high tumor concentration and high tumor-to-normal tissue ratios. The two or three step methods eliminate radiation exposure during the MAB localizing phase, which can take up to several days. Nonspecific localization at this stage in liver, spleen, and bone marrow does not contribute to normal tissue radiation since the radioactive hapten is only injected later. The total radiation dose to normal tissue is greatly reduced in the pretargeting method by two mechanisms: (1) absence of radiation during the localization phase, since the bsMAB is not radioactive at this time; (2) rapid renal excretion of excess radiolabeled hapten that is not bound to the bsMAB in the tumor. An obvious limitation of this two or three step pretargeting strategy

Figure 3. Schematic representation of different applications of bsMab in therapeutics.

is that bsMAbs directed to rapidly internalizing antigens would fail to capture and localize the radiolabeled hapten. Hence, poorly internalized bsMab is most useful in this strategy. An additional limitation of this strategy is that its practice requires several steps. From the perspective of drug development, this places an additional manufacturing burden and significantly complicates the design of clinical trials.

One bifunctional antibody currently under clinical evaluation was made by the chemical coupling of two Fab' fragments of anti-carcinoembryonic antigen (CEA) antibody and anti-DTPA-indium antibody. In patients with colorectal or medullary thyroid cancer, clinical studies were performed with this anti-CEA/anti-DTPA-indium bifunctional antibody and an indium-111-labeled bis-DTPA bivalent hapten. The results showed that tumor uptake was not altered compared to the results for F(ab')₂ fragments of the same anti-CEA antibody directly labeled with indium-111, whereas the radioactivity of normal tissues was significantly reduced (3–6-fold). The fast tumor uptake kinetics and high tumor-to-normal tissue ratios obtained with bifunctional antibody techniques exhibit parameters favorable for efficient radioimmunotherapy (Chatal et al., 1995).

Pretargeting methods have also incorporated the use of biotin or avidin labeled monospecific antibody followed by radiolabeled avidin or biotin respectively (Van Osdol et al., 1993). In this approach, however, the immunogenicity of the hen egg avidin or streptavidin could be a potential limitation.

3. Immunotherapy. BsMab is capable of activating and targeting the cellular immune defense system to kill tumor cells or other pathogens (Figure 3). Many groups have already demonstrated lysis of target cells by T effector cells using bsMab in a non-MHC restricted fashion. (Canevari et al., 1988; Roosnek and Lanzavecchia, 1989; Roosnek et al., 1990). The primary cytotoxic trigger complex on T cells is the TcR complex, which consists of a noncovalent association of Ti heterodimers with the CD3 molecular complex. The TcR complex is normally antigen specific, and major histocompatibility complex (MHC) restricted. However, a bsMab can react with this complex and initiate targeted cytotoxicity by activating and targeting the T-cell in a non-MHC restricted manner. Many efforts have been made to target bsMab to surface molecules such as TcR heterodimer (Staerz and Bevan, 1985), CD3 complex (Liu et al., 1985;

Rammensee et al., 1987) and CD2 molecule (Bolhuis et al., 1991; Tutt et al., 1991b). Cytotoxicity is not due to bystander lysis, since direct contact between effector and target cells is required (Barr et al., 1987; Lanzavecchia and Scheidegger, 1987). This in vivo cross-linking of specific targets with components of the cell-mediated immune response such as T-cells, natural killer cells, macrophages, and large granular lymphocytes is a unique feature outside the realms of chemical cross-linking methods.

Cancer immunotherapeutic strategies involving bsMab-mediated killing have been explored by several groups including anti-epidermal growth factor receptor for breast cancer (Knuth et al., 1994), anti-sialyl Lewis^x for colon cancer (Ohta et al., 1995), anti-ovarian cancer (Bolhuis et al., 1992; Canevari et al., 1995), anti-renal cell carcinoma (Van Dijk et al., 1991), anti small cell lung carcinomas (Azuma et al., 1992), anti-CD19 for B lymphoma (Anderson et al., 1992; De Gast et al., 1995), anti-CD13 for acute myeloid leukemia (Kaneko et al., 1993), and anti-tenascin for gliomas (Davico Bonino et al., 1995). The therapeutic success was mainly based on the retargeting of the relative small cytotoxic T cell pools which already exist and are further augmented by anti-CD28 costimulation (Demanet et al., 1996). Other types of effector molecules which have been used are FcγRIII receptor (CD16) (Hsieh-Ma et al., 1992; Weiner et al., 1995), complement receptor CR3 of macrophage (Somasundaram et al., 1996), Fc receptor (FcγRI) (Deramoudt et al., 1992), and anti-gamma/delta T cell receptor (Ferrini, 1989).

The exciting preclinical studies have prompted several clinical studies using bsMAbs. The toxicities associated with this immunotherapeutic approach appears to be minimal, and early results show promising clinical benefit as well. Guyre and Franger have developed a bsMab, MDX-210, which recognizes FcγR1 on monocytes and macrophages and the cell surface product of the HER-2/neu oncogene overexpressed on some breast and ovarian cancers. Clinical trials have demonstrated that treatment with MDX-210 is well tolerated and MDX-210 is both immunologically and clinically active. Optimization of the dose and schedule of MDX-210 and development of combination treatments with cytokines that modulate immune effector cells will greatly enhance the efficacy of this novel bsMab for treatment of tumors that overexpress HER-2/neu (Valone, 1995). Another bsMab

2B1 with specificity for the c-erbB-2 and Fc γ RIII extracellular domains has also been tested in humans. This bsMAB promotes the targeted lysis of malignant cells overexpressing the c-erbB-2 gene product of the HER2/neu proto-oncogene by human natural killer cells and mononuclear phagocytes expressing the Fc γ RIII A isoform. In a phase I clinical trial, the 2B1 treatment induced more than 100-fold increases in circulating levels of tumor necrosis factor- α , interleukin 6, and interleukin 8 and lesser rises in granulocyte-monocyte colony-stimulating factor and IFN- γ (Weiner, 1995).

BsMAB has also been tested for its immunotherapeutic applications in viral infections (Berg et al., 1991). Chamow and associates have developed a humanized bsMAB, comprised of CD4-IgG and humanized anti-CD3-IgG, to target and kill HIV-infected cells. First, the bsMAB can target to HIV-infected cells by the natural affinity of CD4 for gp120. Second, it recruits and activates, through its anti-CD3 moiety, cytotoxic T lymphocytes (CTL) to lyse target cells in a non-MHC restricted manner. They demonstrated that bsMAB could specifically lyse HIV-infected target cells using purified CTL and whole peripheral blood lymphocyte (PBL). In contrast, a human anti-gp120 monospecific antibody can lyse HIV-infected target cells only with PBL fractions and not with purified CTL. Moreover, the lytic activity of anti-gp120 antibody was completely blocked by the human serum (which competes for Fc gamma receptor binding with abundant human IgG), whereas bsMAB-mediated lysis of target cells was not affected. This has reflected a potential advantage of bsMAB over monospecific antibodies for HIV-directed therapy (Chamow et al., 1994, 1995).

4. Drug Delivery. BsMAB could be used as an effective drug delivery system for cancer treatment. BsMABs have been made with one binding site to methotrexate (Affleck and Embleton, 1992), saporin (Bonardi et al., 1992 and 1993; French et al., 1995), doxorubicin (Reddy and Ford, 1993), or vinca alkaloids (Corvalan et al., 1987). Clinical studies have been described using a combination of two bsMABs to deliver the ribosome-inactivating protein, saporin, in the treatment of low-grade, end-stage B-cell lymphoma. Both bsMABs have one arm directed at saporin and one at the CD22 on target B cells. However, the two bsMABs recognized different, nonoverlapping epitopes on each molecule, a strategy which allowed high-avidity double attachment of saporin to the target. Five patients were treated, mostly with weekly doses of between 2 and 4 mg of saporin for a period of up to 6 weeks. Toxicity was minimal and all patients showed a rapid and beneficial response to treatment (French et al., 1996).

The advantage of using bsMAB to deliver high molecular weight toxins or drugs to tumors, comparing to conjugating such moieties to MAb, is that chemical conjugations are totally avoided. This provides a more uniform cross-linking between the target and the effector molecule. However, if the toxin or drug is a low molecular weight effector molecule, the advantage is outweighed by the dose limitation of this approach. To circumvent this limitation, a strategy combining drug attached to polymeric biodegradable carriers or encapsulated in liposomes with bsMAB may be adopted.

BsMAB can also be used to activate a prodrug in vivo to cause localized targeted cytotoxicity. In this approach, a bsMAB has been made against a tumor marker human placental alkaline phosphatase and *E.coli* β -lactamase as the prodrug activating group. Activation of cephalosporin-based anti-cancer prodrugs at the tumor site can be achieved with this bsMAB (De Sutter and Fiers, 1994).

Another bsMAB against CD30 antigen and alkaline phosphatase was also used to activate the relatively nontoxic prodrug, mitomycin phosphate, to mitomycin alcohol, which is 100-fold more toxic (Sahin et al., 1990). Alternative strategies to antibody directed enzyme prodrug therapy (ADEPT) include the development of bifunctional antibody-enzyme fusion proteins. The advantage of bsMAB plus enzyme and prodrug approach over fusion protein is that the pharmacokinetics and targeting site accumulation of each component could be controlled separately. In addition, PEG-enzyme could be used for reduced immunogenicities. However, the limitation of this approach is the requirement of multistep injection.

5. Other Applications. Tissue plasminogen activator (TPA) triggers the conversion of plasminogen to the fibrinolytic enzyme plasmin, which causes dissolution of thrombi. BsMAB can be used to improve fibrinolytic efficacy of TPA by binding simultaneously to human fibrin and TPA in thrombosis therapy (Kurokawa et al., 1991). One study has shown that, in the presence of TPA, bsMAB caused a 10-fold more fibrinolysis in vitro than with TPA alone (Branscomb et al., 1990). Some researchers have also tried to use bsMAB to target urokinase-type plasminogen activator (UPA) to fibrin-containing clots (Charpie et al., 1990). It caused 13-fold more fibrinolysis in vitro than urokinase alone and 6-fold more clot lysis in vivo. In another study using baboon bearing ^{125} I-fibrin clots in femoral vein, continuous intravenous infusion of a bsMAB resulted in a 5-fold enhanced thrombolytic potency of UPA over that of unconjugated UPA (Imura et al., 1992).

BsMAB could be generated to improve the binding specificity and avidity by recognizing two different adjacent epitopes in the same antigen. This type of bsMAB has been made against two different subunits of the hormones such as human chorionic gonadotropin hormone (HCG), creatine kinase (CKMB), and adrenocorticotrophic hormone (ACTH) (Cheong et al., 1990; Cook and Wood, 1994). A bsMAB against polyhedral boron anion and a tumor associated antigen has been made to deliver a large amount of boron atoms to tumor cells for a novel radiotherapeutic application. The alpha particles can be released to destroy tumors locally when boron-10, a stable isotope, is irradiated with low-energy thermal neutrons (Pak et al., 1995; Liu et al., 1995).

The plethora of applications of bsMAB as unique macromolecular heterobifunctional cross-linkers is expanding with promising prospects for clinical uses as well. The sophistication of producing bsMAB will grow hand in hand with the increased utility of these molecules as tools for research and as therapeutic agents. Recent advances in molecular biology and cancer research have added new dimensions to our investigations and understanding of how the bsMAB works and the novel applications where it has been employed.

Addendum. Two recent reports have appeared adding to the spectrum of novel genetically engineered bispecific constructs. In the first strategy, the light chain constant domain is fused to one scFv and the first heavy chain constant domain fused to a second scFv of different specificity to form bispecific miniantibodies. This novel approach exploits the natural heterodimerization of the two constant domains. In another report, the same group link two different scFv's by a helical dimerization domain to express dimeric bispecific miniantibodies. This unique construct has not only two specificities but also incorporates bivalency to preserve avidity naturally found in immunoglobulins [Muller, K. M., Arndt, K. M., Stritt-

matter, W. and Pluckthun, A. (1998) The first constant domain(CH1 and CL) of an antibody used as heterodimerization domain for bispecific miniantibodies. *FEBS Lett.* 422, 259–264; Muller, K. M., Arndt, K. M. and Pluckthun, A. (1998) A dimeric bispecific miniantibody combines two specificities with avidity. *FEBS Lett.* 432, 45–49].

ACKNOWLEDGMENT

M.R.S. thanks MRC and Biomira for chair support and NSERC for grant funding. This review is dedicated to Dr. Cesar Milstein on the occasion of his retirement from the MRC Laboratory of Molecular Biology, Cambridge, U.K., in whose laboratory MRS was trained in the field of bispecific monoclonals. Thanks are also due to Dr. J. Kriangkum for help in preparing the cover figure.

ARTICLES

Synthesis of Water-Soluble, Nonimmunogenic Polyamide Cross-Linking Agents[†]

Ton That Hai, David E. Pereira,* and Deanna J. Nelson

Hemoglobin Therapeutics Division, Baxter Healthcare Corp., 25212 West State Route 120, Round Lake, Illinois 60073. Received November 17, 1997; Revised Manuscript Received August 15, 1998

Novel polyamides were developed that can be used as cross-linking agents for proteins such as hemoglobin. Water-soluble, nonimmunogenic polyamides containing oxygen and sulfur atoms in the backbone were prepared by the polycondensation of the diacids bis(carboxymethoxyacetyl)-1,4-diaminobutane (**1a**) or 3,3'-thiodipropionic acid (**1b**) with diethylene glycol bis(3-aminopropyl) ether (**2**). The resulting α,ω -diacids were converted to the corresponding activated esters using any of a variety of carboxylic acid activating reagents including the novel reagent diphenyl(1-methylimidazol-2-thiyl)phosphonate (**9**). The resulting polyamides could be activated with a broad spectrum of groups that allow for the cross-linking and surface modification of proteins.

INTRODUCTION

Cross-linking reagents that react with the amino or sulfhydryl groups of proteins have a broad range of applications (1–3). While some applications, such as the identification of binding sites (receptors) for ligands, the introduction of fluorescent or spin labels, or intramolecular cross-linking of neighboring functional groups, have few associated spatial requirements, many other applications require that the cross-linking agent have substantial length to prevent steric hindrance to cross-linking.

To reduce the resulting heterogeneity of the cross-linked proteins and to maximize the cross-linking efficiency, it is important that the size of the cross-linking agent be defined and restricted to as narrow a range as can be achieved. Concomitantly, it is important the size of the cross-linker be controlled and limited, so that water solubility of the product is maintained. Similarly, the ability to activate the termini of the cross-linker using a spectrum of approaches is an important feature of useful cross-linking agents, since there may be some variability from a general pattern in the effectiveness of modification of a specific protein.

One important application of cross-linking agents is to decrease immunogenicity and to increase the lifetime of the cross-linked product in the blood stream. Therefore, it is key that the cross-linker be nontoxic and nonimmunogenic.

Finally, most protein modification reactions are completed in aqueous media. Thus, it is key that the cross-linking agent be water soluble. Likewise, to reduce the opportunistic denaturation of the protein during reaction, it is desirable that the cross-linking agent not behave like a detergent or chaotropic agent.

The purpose of our current work was to synthesize novel polyamides that could act as cross-linking agents for hemoglobin in particular and proteins in general. The resulting modified hemoglobins or proteins could be candidates as blood substitutes or therapeutic agents, respectively. In addition to meeting the requirements defined above, we anticipated that cross-linking agents having molecular masses in the range 1000–7600 Da would provide the most useful tether length while minimizing undesirable and unnecessary additions to overall molecular mass or viscosity of the resulting cross-linked products.

EXPERIMENTAL PROCEDURES

General. NMR spectra were recorded on a Bruker 270 MHz or a Bruker 300 MHz spectrometer. ¹H and ¹³C chemical shifts were measured relative to partially deuterated solvent peaks but are reported relative to tetramethylsilane. ³¹P chemical shifts are reported relative to H₃PO₄ (85%). (NMR chemical shifts for the compounds and polymers described herein are included in the Supporting Information to this paper.) Thin-layer chromatography (TLC) of the polyamides was completed using Whatman 250 μ m silica gel TLC plates and 2-propanol/NH₄OH/water, 10:1:2, by volume, as the eluent. Melting points were determined on a Fisher-Johns melting point apparatus and are uncorrected. Elemental analyses were performed by Oneida Research Services, Whitesboro, NY, or Quantitative Technologies, Inc., Whitehouse, NJ.

Nomenclature. For simplicity, the following acronyms are employed as designating nomenclature. The acronym descriptions are presented in Table 1. The term polyamide is abbreviated "PA" (or "PAT" if one component of the polyamide is 3,3'-thiodipropionate). If each end of the polyamide terminates in a succinate residue, the letter "S" is added to the acronym. Finally, if the activating group is N-oxysuccinimide, a second letter "S"

Table 1. Polyamide Acronym Definitions and Potential Reactivity With Proteins

acronym	acronym definition	reactivity with proteins
PA	polyamide	not activated
PAT	polyamide containing 3,3'-thiodipropionate residues	not activated
PAS	functional end group is a succinate residue	not activated
PATS		
PAD	functional end group is an amine residue	not activated
PATD		
PASS	polyamide activated as bis(<i>N</i> -oxysuccinimidyl ester)	cross-linking achieved by reaction with amines to form amides
PATSS		
PADSC	polyamide activated as bis(<i>N</i> -oxysuccinimidyl urethane)	cross-linking achieved by reaction with amines to form ureas
PATDSC		
PADMP	polyamide activated as bis(maleimide)	cross-linking achieved by reaction with amines and/or thiols
PATDMP		
PADA	polyamide activated as bis(aldehyde)	cross-linking achieved by reaction with amines and reduction of the imine intermediates
PATDA		

is added. The approximate molecular mass of the polyamide follows a hyphen. Thus, the acronym PASS-7600 describes the bis(*N*-oxysuccinimidyl) activated ester of a polyamide having a molecular mass of about 7600 Da.

If the polyamide end groups are amino groups, these are designated by the acronym PAD (or PATD for thioether-containing analogues). The polyamide bis-(amines) were converted to reactive urethane, maleimide, or aldehyde end groups. The acronyms for urethane, maleimide, or aldehyde end groups are SC, MP, or A, respectively. Thus, the acronym PATDSC-5700 denotes a urethane-activated, thiodipropionate-containing polyamide having a molecular mass of about 5700 Da.

Size-Exclusion Chromatography (SEC). Analytes were eluted from a Superose-12 column (Pharmacia) with 50 mM phosphate buffer, pH 6.5, delivered at a flow rate of 0.4 mL/min, with analyte detection at 220 nm.

***M_r* Determination of PAS Polymers by ¹H NMR.**

An interval of approximately 6.3 s between excitation pulses was used; this interval was sufficient to realize a complete return of the spin system to the equilibrium magnetization state. The average number of repeating units per molecule of polymer was determined by comparing the area of the resonances attributable to protons attached to the repeating unit with the area of the resonances attributable to the protons attached to the succinic acid terminal group. The areas were normalized, as appropriate, for the relative number of equivalent protons generating each resonance. A total of six resonances attributable to the repeating unit was resolved and identified. Hence, it was possible to make six estimates of the number of repeating units per polymer molecule. It should be stressed that the six estimates were not completely independent: all were derived from a single estimate of the area of the resonance of the protons attached to the terminal unit. The *n* value was obtained from the average of the six estimates of the number of repeating units per polymer molecule. This method was used to determine the average *M_r* of PAS-7600, PAS-5600, PAS-4000, and PAS-2800 (Supporting Information, Table S-2).

***M_r* Determination of PATS Polymers by ¹³C NMR.**

Composite-pulse (WALTZ-16) decoupling was employed. Artificial enhancements of resonance areas due to the nuclear Overhauser mechanism were suppressed by the use of an inverse gating technique. An interval of approximately 22 s between excitation pulses was used; this interval was sufficient to realize a complete return of the spin system to the equilibrium magnetization state. The average number of repeating units per molecule of polymer was determined by comparing the area of the resonances attributable to carbons attached to the repeating unit with the area of the resonances attributable

to the carbons attached to the terminal units. The observed resonance areas were normalized, as appropriate, for the relative number of equivalent carbons generating each resonance. A total of three resonances attributable to eight carbon atoms on the terminal units were resolved. Because only one of the three resonances could be identified unambiguously, the total area for these eight carbon atoms was obtained by summation and treated as a single area measurement. A total of seven resonances attributable to the repeating unit were resolved. Three resonances attributable to carbon atoms adjacent to oxygen in the repeating unit of **2** were resolved but not individually identified. In addition, baseline resolution of these three resonances was not achieved. Because of these two factors, the total area for the three resonances was obtained by summation and treated as a single area. Hence, it was possible to make five estimates of the number of repeating units per polymer molecule. It should be stressed that the five estimates were not completely independent: all were derived from a single estimate of the area of the resonance of the carbons attached to the terminal unit. The average of the five estimates of the number of repeating units per polymer molecule gave the degree of polymerization *n*. This method was used to determine the average *M_r* of PATSS-5700, PATSS-5200, and PATSS-2800 (Supporting Information, Table S-5).

Bis(carboxymethoxyacetyl)-1,4-diaminobutane (1a). Diglycolic anhydride (1524 g, 13 mol) was dissolved in 3 L of *N,N*-dimethylformamide (DMF). The solution was heated to 60 °C, and the heating mantle was replaced with an ice bath. A solution of 1,4-diaminobutane (529 g, 6 mol) in 1.2 L of DMF was added at such a rate that the temperature was kept between 70 and 75 °C. After all of the 1,4-diaminobutane had been added, an additional 100 g of the anhydride was added to the reaction solution. The mixture was then cooled in an ice bath for 1.5 h, and a solid was formed. The DMF solution was decanted from the solid, and the solution volume was reduced to about 500 mL. The residue was combined with the solid, and 3 L of chloroform (CHCl₃) was added to the ice-bath-cooled mixture. The mixture was stirred, and the solid was collected by filtration, washed with 1 L of CHCl₃, and dried under vacuum to give 1882 g of **1a** (98%). Mp: 168–169 °C. Anal. (C₁₂H₂₀N₂O₈) C, H, N.

***N,N'*-Bis(methoxycarbonylmethoxyacetyl)-1,4-diaminobutane (10a).** Compound **1a** (250 g, 0.8 mol) was combined with methanol (1 L) and 50 mL of 4.0 M HCl in 1,4-dioxane. The mixture was stirred overnight. The solvent was removed by rotary evaporation under high vacuum to give a solid. The solid was dried over NaOH under high vacuum. The solid was dissolved in

500 mL of warm acetone (dried over anhyd K_2CO_3) and filtered. Ethyl ether was slowly added to the filtrate, and an oil separated. Stirring with a glass rod caused the oil to solidify. The solid was collected under a flow of nitrogen. The solid was dried under a vacuum over NaOH to give 248 g (88%) of **10a**. Mp: 76–77 °C. Anal. ($C_{14}H_{24}N_2O_8 \cdot 0.5H_2O$) C, H, N.

***N,N'*-Bis(carboxymethoxyacetyl)-1,4-diaminobutane Bis(*p*-nitrophenyl ester) (10b).** *p*-Nitrophenyl trifluoroacetate (2491 g, 10.6 mol) was combined with a solution of DMF (2 L) and 2,6-lutidine (4 L). Compound **1a** (1411 g, 4.4 mol) was added as a solid in one portion to the solution of *p*-nitrophenyl trifluoroacetate. After 2 h, an additional 1 L of DMF was added to the resulting mixture. After stirring an additional hour, 2 L of ethyl ether was added. The mixture was stirred for 30 min, and the solid was collected. The solid was then combined with 4 L of ethyl ether with mixing. The solid was collected and air-dried. The ethyl ether washing was repeated to give 1997 g (80%) of **10b**. Mp: 141–142 °C. Anal. ($C_{24}H_{26}N_4O_{12}$) C, H, N.

***N,N'*-Bis[(2,3-dihydro-2-thioxo-3-benzoxazolyl)-carbonylmethoxyacetyl]-1,4-diaminobutane (10d).** Compound **8** (12.7 g, 33 mmol) was added to a stirred suspension of **1a** (4.8 g, 15 mmol) and 2,6-lutidine (4 mL, 34 mmol) in DMF (25 mL). The resulting solution was stirred for 2 h. The precipitate was collected and washed with ethyl ether to give 6.30 g of **10d**. The filtrate was evaporated to dryness, and the residue was triturated with methanol to precipitate 0.53 g of additional product for a total yield of 6.83 g (78%) of **10d**. Mp: 140–141 °C. Anal. ($C_{26}H_{26}N_4O_8S_2 \cdot 2H_2O$) C, H, N, S.

***N,N'*-(3,3'-Thiodipropionyl)bis(benzoxazoline-2-thione) (14b).** Compound **8** (843 g, 2.2 mol) was added as a solid in one portion to a stirred solution of 3,3'-thiodipropionic acid (178 g, 1.0 mol) and triethylamine (224 g, 2.2 mol) in 3.4 L of $CHCl_3$. After 1.5 h, methanol (3 L) was added, and the mixture was cooled in an ice bath. After 10 min, the solid was collected and washed with ethyl ether (1 L). The solid was dried under house vacuum to give 356 g (80% yield) of **14b**. Mp: 168–170 °C. Anal. ($C_{20}H_{16}N_2O_4S_3 \cdot 0.25H_2O$) C, H, N, S.

Diphenyl(1-methylimidazol-2-thiyl)phosphonate (9). A solution of diphenyl chlorophosphate (**11**; 76.6 g, 0.285 mol) in $CHCl_3$ (100 mL) was added in one portion to a solution of 2-mercapto-1-methylimidazole (**12**; 22.0 g, 0.19 mol) and triethylamine (29.1 g, 0.285 mol) in $CHCl_3$ (200 mL). The solution was heated at reflux overnight. The solvent was evaporated, and the residue was dissolved in toluene (250 mL). The insoluble material was removed by filtration. The filtrate was passed through a pad of silica gel. The product was eluted with a solution of chloroform:acetone (5:1, v/v) (2×250 mL). The eluent was evaporated to an oil. Hexane (150 mL) was added to the oil, and a solid was obtained. The solid was collected, washed with hexane (50 mL), and dried to give 48.2 g (68%) of **9**. Mp: 113–114 °C. Anal. ($C_{16}H_{15}N_2O_3SP$) C, H, N, S.

***S,S'*-Bis(1-methyl-2-imidazolyl)-3-thiapentane-1,5-dithiocarboxylate (14c).** Compound **9** (8.00 g, 22.0 mmol) was added to a solution of 3,3'-thiodipropionic acid (1.77 g, 10.0 mmol) and triethylamine (3.1 mL, 22.0 mmol) in $CHCl_3$ (50 mL). The solution was heated at reflux overnight. The solution was cooled to ambient temperature (RT) and passed through a pad of silica gel. The silica gel was washed with a solution of chloroform:acetone (5:1, v/v) (100 mL). The filtrate was evaporated to a yellow solid. The solid was dissolved in acetone (10 mL), and ethyl ether (15 mL) was added to precipitate

^a Effects of reactant molar ratio and solvent. ^b Molecular mass was determined by ^{13}C - and ^1H -NMR. ^c SEC was performed using a Superose-12 column (Pharmacia). Polyamide was eluted with 50 mM phosphate buffer, pH 6.5, delivered at 0.4 mL/min; analytes were detected at 220 nm. SEC profiles were broad for PA obtained from DMF and narrow for PA obtained from chloroform. ^d The product distribution was estimated from the thin layer chromatographic response after silica gel plates were eluted with 2-propanol/ NH_4OH/H_2O (10:1:2, volume ratio) and stained with iodine or ninhydrin.

the product. The solid was collected to give 2.3 g (68%) of **14c**. Mp: 159–161 °C. Anal. ($C_{14}H_{18}N_4O_2S_3$) C, H, N, S.

***N* Anal. ($C_{14}H_{24}N_2O_8 \cdot 0.5H_2$) C, H, N. -(2,2-Dimethoxyethyl)succinamic Acid (18).** A solution of aminoacetaldehyde dimethylacetal (5.3 g, 50.4 mmol) in 20 mL of $CHCl_3$ was added dropwise to a solution of succinic anhydride (5.1 g, 51.0 mmol) in 50 mL of $CHCl_3$. The mixture was stirred for 1 h at RT. An additional 0.2 g of succinic anhydride was added to consume all of the amine. The mixture was filtered, and the filtrate was evaporated to provide 10.1 g (98%) of **18** as an oil. The oil was used without further purification. Anal ($C_8H_{15}NO_5$) Calcd: C, 46.82; H, 7.37; N, 6.83. Found: C, 44.85; H, 6.96; N, 6.33.

***N*-(2,2-Dimethoxyethyl)succinamic Acid Succinimide Ester (17).** 1,3-Dicyclohexylcarbodiimide (12.5 g, 61.0 mmol) in 25 mL of chloroform was added to a solution of **18** (11.4 g, 56 mmol) and *N*-hydroxysuccinimide (7.0 g, 61 mmol) in 90 mL of chloroform and 10 mL of DMF. The solution was stirred for 2 h and then filtered. The filtrate was evaporated to an oil. Due to its instability, the compound was used without further purification. (Analytical data are included in the Supporting Information.)

Synthesis of Polyamides. The following procedures serve as representative preparations of the described polyamides. The molar ratios, solvents, bases (if needed), and temperatures to prepare a certain M_r range of a polyamide are listed in Tables 2–5. Tabulated ^1H -NMR and ^{13}C -NMR data can be found in the Supporting Information.

Synthesis of Polyamide Bis(amine) (PAD-5600). Compound **10b** (102.6 g, 0.18 mol) was suspended in 330 mL of chloroform. The resulting slurry was cooled in an

ice bath to 5 °C and stirred at 131 rpm. A solution of 2,6-lutidine (42 mL, 0.36 mole) and diethylene glycol bis-(3-aminopropyl)ether (2) (47.6 g, 0.22 mol) in 85 mL of CHCl₃ was added to the stirred solution. After 15 min of stirring, the solvent was removed by rotary evaporation. The resulting oil was dissolved in 100 mL DMF, and ethyl acetate (600 mL) was added to precipitate the polymer as a yellow solid. The solid was washed with ethyl acetate (3 × 100 mL) and dried under vacuum to give 81.3 g of the polymer as the *p*-nitrophenol salt.

Synthesis of PADMP-5600. *N*-Succinimidyl 3-maleimidopropionate (16) (6.0 g, 24 mmol) was dissolved in 500 mL of CHCl₃. PAD-5600 (20.1 g, 4 mmol) and triethylamine (1.6 g) in 300 mL of CHCl₃ were slowly

added dropwise to the solution of 16. The addition was complete in 6 h. The solvent was removed to give an oil. The oil was dissolved in a solution of DMF (40 mL) and CHCl₃ (40 mL). Acetone was added to precipitate the product. The mixture was allowed to stand for 3 h, and the product was collected by filtration. The product was reprecipitated from chloroform:DMF one additional time. The precipitate was collected and dried to give 15.8 g of PADMP-5600.

Synthesis of PADSC-3000. To a stirred suspension of *N,N'*-disuccinimidyl carbonate (15) (5.86 g, 22.86 mmol) in a mixture of DMF (60 mL) and CHCl₃ (60 mL) was added dropwise a solution of PAD-2800 (8.00 g, 2.86 mmol) in CHCl₃ (65 mL) containing triethylamine (3.19 mL, 22.86 mmol) over 60 min. The mixture was stirred until all solid had dissolved (~2 h), and then stirring was continued for a further 1 h. The reaction mixture was evaporated to dryness; the residue was dissolved in DMF (50 mL), and the stirred solution was slowly diluted with acetone (400 mL) to precipitate the product, which was collected by filtration, washed with acetone and dried to provide 5.9 g of PADSC-3000 (74%).

Bis[*N*-(2,2-dimethoxyethyl)succinamyl]polyamide: PADA-2800 Bis(acetal). A solution of 10a (9.75 g, 28 mmol) and 2 (8.02 g, 36.4 mmol) in methanol (25 mL) was heated at reflux for 24 h to give crude PAD having a *M_r* of about 2800. Methanol was completely removed by evaporation, and the residue was dissolved in CHCl₃ (35 mL). To this solution was added a solution of *N*-(2-dimethoxyethyl)succinamic acid *N*-oxysuccinimide ester (17; 7.55 g, 25 mmol) and triethylamine (3.48 g, 25 mmol) in CHCl₃ (50 mL). The mixture was stirred until it became negative to ninhydrin (2 h). The solvent was removed by evaporation, and the residue was dissolved in methanol (100 mL). AG50-8X resin (Bio-Rad; 20 mL) was added until the solution pH reached 3.0. The mixture was filtered, and AG1-X8 resin (Bio-Rad; 40 mL) was gradually added to remove *N*-hydroxysuccinimide. The mixture was filtered and evaporated to dryness. The residue was triturated with acetone to precipitate bis-[*N*-(2-dimethoxyethyl)succinamyl]polyamide PADA-2800 bis(acetal) in a yield of 14.1 g after drying.

Bis[*N*-(2-formylethyl)succinamyl]polyamide: PA-DA-2800. PADA-2800 bis(acetal) (3.0 g) was dissolved in water (20 mL), and the solution was cooled in an ice-water bath. Trifluoroacetic acid (20 mL) was added gradually. After the addition was completed, the bath was removed, and the reaction mixture was stirred at room temperature for 2 h. The reaction mixture was evaporated under reduced pressure, and the residue was successively evaporated with water (50 mL) followed by acetone (3 × 50 mL). The residue was dried under high vacuum and then triturated with acetone to precipitate 2.25 g of PADA-2800 as a mixture of the aldehyde and hydrated aldehyde.

Synthesis of PAS-4200 Using 10a. Compound 10a (247 g, 0.7 mol) was dissolved in 400 mL of methanol. A solution of 2 (200 g, 0.9 mol) was added in one portion to the methanol solution. The resulting solution was heated at reflux for 24 h. The solvent was evaporated to give an oil (447 g, 0.12 mol). The oil was dissolved in CHCl₃ (1.5 L) and was added dropwise to a mixture of succinic anhydride (48.3 g, 0.48 mol) in CHCl₃ (500 mL). The mixture was stirred overnight. An additional portion of succinic anhydride (10 g) was added to the solution. The solution was stirred for 2 h, and the CHCl₃ was removed by rotary evaporation. The mixture was dissolved in water (1 L), and the mixture was placed on a rotary evaporator to remove residual chloroform. The aqueous

solution was treated with 500 g of AG50-8X resin (the resin was pretreated with 1.0 N HCl). The resin was collected and washed with 1.0 N NaOH, water, and then 1.0 N HCl. The aqueous solution was treated again with the resin. This was repeated one additional time. The filtered aqueous solution was evaporated to an oil. The oil was combined with DMF (200 mL), and the solution was evaporated to an oil. This was repeated to remove residual water. The resulting oil was dissolved in 400 mL of DMF, and acetone was slowly added to cause precipitation. A total of 4.5 L of acetone was used. By stirring the mixture with a glass rod, a solid was obtained. The solid was collected and dried under high vacuum to give 244 g of PAS-4200.

Synthesis of PAS-5600. Compound **10b** (912 g, 1.6 mol) was suspended in 3 L of CHCl_3 and cooled to 5 °C. A solution of **2** (429 g, 2.0 mol) and 2,6-lutidine (375 mL, 3.2 mol) in CHCl_3 (300 mL) was added in one portion to the suspension. The suspension was stirred at 131 rpm. After 15 min, the ice bath was removed, and succinic anhydride (26 g, 0.25 mol) was added. After 1 h, an additional 5 g of succinic anhydride was added. The solution was stirred for 45 min, and the solvents were removed by rotary evaporation. One-half of the resulting oil was dissolved in 800 mL of DMF. Acetone (5–6 L) was added to the solution to cause precipitation of the product. This was repeated with the other half of the oil. The precipitated solid was dissolved in 1.6 L of CHCl_3 , and acetone (5 L) was added to cause precipitation of the product. The solid was collected and washed with 500 mL of acetone to give 686 g of PAS-5600.

Synthesis of PAS Using 7. *N*-Methylmorpholine (726 μL , 6.6 mmol) was added to a stirred suspension of **1a** (0.961 g, 3 mmol) in CHCl_3 (15 mL). The mixture was stirred at room temperature for 10 min and then cooled to 0 °C. Compound **7** (1.155 g, 6.6 mmol) was added, and the mixture was stirred at 0 °C for 2.5 h. The cooling bath was removed, and the reaction was allowed to warm to room temperature for 1 h. A solution of **2** (0.529 g, 2.4 mmol) in CHCl_3 (2 mL) was added, and the solution was stirred overnight. The mixture was filtered, and to the filtrate was added succinic anhydride (0.140 g, 1.4 mmol) in DMF (2 mL). After 2 h, the solution was evaporated to dryness. The residue was dissolved in DMF (15 mL) and allowed to stand at room temperature for 30 min. The mixture was filtered, and the filtrate was slowly diluted with ethyl acetate (50 mL) to precipitate 1.14 g of PAS (SEC retention time, 37.5 min).

Synthesis of PAS-5600 Using 9. A solution of **2** (0.440 g, 2 mmol) in DMF (3 mL) was added to a stirred of **1a** (0.641 g, 2.4 mmol) and **9** (1.528 g, 4.4 mol) in DMF (10 mL). The solution became turbid. The solution was heated at 70 °C for 3 h and then at 50 °C overnight. The solution was evaporated to dryness. The residue was dissolved in DMF (5 mL), and the solution was slowly diluted with ethyl acetate (70 mL) to precipitate the polymer. The solid was collected, washed with acetone, and dried to give 0.680 g of PAD-5600.

Synthesis of PASS-5600. Polyamide PAS-5600 (1063 g, 0.2 mol) was dissolved in a solution of CHCl_3 (2 L) and DMF (700 mL). *N*-Hydroxysuccinimide (130 g, 1.1 mol) was added as a solid. 1,3-Dicyclohexylcarbodiimide (233 g, 1.12 mol) in DMF (500 mL) was then added. After stirring for 3 h, the mixture was filtered, and the filtrate was reduced in volume to about 2 L by rotary evaporation. The product was precipitated by the addition of acetone (8 L) while stirring. The solid was dissolved in CHCl_3 (3 L), and the product was precipitated by the

addition of acetone (6 L). The solid was collected and dried to provide 926 g of PASS-5600.

Synthesis of PATS-5200. Compound **14b** (193.0 g, 0.43 mol) was suspended in 1.6 L of CHCl_3 . A solution of **2** (99.1 g, 0.45 mol, 1.05 equiv) in 300 mL of CHCl_3 was added in one portion to the suspension. The resulting solution was stirred at room temperature overnight. Succinic anhydride (10.1 g) in 100 mL of DMF was added to the warmed reaction solution. After stirring for 2 h at room temperature, the solvent was removed. DMF (200 mL) was added, and the solvent was evaporated. DMF (350 mL) was added to the residue, followed by 2 L of ethyl acetate. The mixture was allowed to stand for 2 h, and the solid was collected by filtration. The solid was washed with acetone and dried under vacuum to give 73.2 g of PATS-5200.

Synthesis of PATSS-5200. PATS-5200 (100.0 g, 19 mmol) was dissolved in 1.8 L of CHCl_3 with warming. After cooling, triethylamine (22 mL, 155 mmol) was added followed by 300 mL of DMF. *N,N*-Disuccinimidyl carbonate (39.8 g, 155 mmol) was added as a solid. After stirring for 2 h, the solution was filtered, and the filtrate was reduced to a semisolid. The solid was dissolved in 500 mL of DMF with warming. Ethyl acetate was added in 500 mL portions with mixing. A total of 1.5 L of ethyl acetate was used. The resulting mixture was allowed to stand at room temperature for 1 h, and then the solid was collected, washed with ethyl acetate, and dried to give 79.3 g of PATS-5200.

Synthesis of PATS Using 7. A solution of 3,3'-thiodipropionic acid (0.535 g, 3 mmol) and *N*-methylmorpholine (0.726 mL, 6.6 mmol) in CHCl_3 (10 mL) was cooled to 0 °C in an ice bath. To this solution was added **7** (1.115 g, 6.6 mmol). The mixture was stirred at 0 °C. After 2 h, the temperature was allowed to warm to room temperature over 1 h. Compound **2** (0.595 g, 2.7 mmol) in CHCl_3 (2 mL) was added, and the reaction mixture was stirred at room temperature. The reaction mixture was filtered to remove the precipitate. The filtrate was treated with succinic anhydride (0.140 g) in DMF (2 mL). The solution was stirred at room temperature for 30 min and evaporated to dryness. The residue was evaporated with DMF to remove residual chloroform. The residue was dissolved in DMF (15 mL) and left at room temperature for 30 min. The mixture was filtered, and the filtrate was slowly diluted with ethyl acetate (50 mL) to precipitate PATS. The product was collected, washed with acetone, and dried to give 0.850 g of PATS having an SEC retention time of 37.9 min.

RESULTS AND DISCUSSION

General Synthetic Strategies. Incorporating oxygen atoms into the polymer backbone was deemed essential to achieve water solubility and practical non-toxicity and nonimmunogenicity in the polyamide polymers. This was accomplished by choosing ether-containing diacids and diamines as the monomers for polymerization.

Similarly, it was hypothesized that incorporation of sulfur atoms into the polymer backbone would enhance the antioxidant activity of the polyamides. Sulfur was conveniently incorporated as a thioether moiety in a diacid monomer.

It was also recognized that the number of heteroatoms in the backbone influences the water solubility and the melting point of the resulting polymers. For instance, a large number of oxygen atoms in the backbone would produce a very water-soluble but waxy polyamide that

Scheme 1

would be very difficult to purify. Conversely, the presence of few heteroatoms would give crystalline polyamides that would be much less soluble in water but easier to purify by recrystallization.

To achieve a balance between water solubility and crystallinity, both the effective length and heteroatom content of both the diacid and the diamine were critical. Altering the properties of the diacid was the strategy most frequently used in this work to achieve this balance. For example, the short diacid diglycolic acid yielded relatively low molecular mass, waxy polymers. Therefore, instead of using diglycolic acid as the diacid monomer, it was converted to the longer diamide bis(carboxymethoxyacetyl)-1,4-diaminobutane (**1a**) through the reaction of 1,4-butanediamine with diglycolic anhydride (see Scheme 1). Similarly, to obtain sulfur-containing polyamides, the sulfur was incorporated into the polymer backbone by using 3,3'-thiodipropionic acid (**1b**) as the diacid monomer. To further increase the oxygen content of the polymer backbone, the diamine diethylene glycol bis(3-aminopropyl) ether (**2**) was chosen as the diamine monomer for the polycondensation reactions.

Polycondensations of diacids and diamines can be performed at moderate temperatures if the diacids are activated (4). The general synthetic route that we chose to prepare the desired polyamides is summarized in Scheme 1. The first step in the polymerization is the conversion of a diacid **1** to an activated diacid **4** by employing an activating reagent **3**. Next, the activated diacid **4** is condensed with diamine **2** to give polyamides comprising bis(amine) end groups **5a**, monocarboxy

Figure 1. Carboxylic acid activating reagents.

monoamino polyamides **5b**, and polyamides with bis-(carboxy) end groups **5c**, together with the byproduct of polycondensation, HX (see Scheme 1).

The criteria that were used for selecting the diacid activating reagents were as follows: (a) the conversion of the diacid to the activated diacid **4** must be quantitative if the activated acid could not be isolated; (b) the byproduct HX must be eliminated from the product either by evaporation or through a simple recrystallization of the product mixture from an organic solvent system. The ease of removal of the byproduct HX was crucial for the purification of the polyamides.

Both traditional and novel reagents were studied for the successful activation of the diacids for polycondensation. The traditional activating agents that were studied included methanol (5), *p*-nitrophenyl trifluoroacetate (**6**), 2-chloro-4,6-dimethoxy-1,3,5-triazine (**7**), and diphenyl(2,3-dihydro-2-thioxo-3-benzoxazolyl)-phosphonate (**8**). We also studied the utility of a novel activating agent, diphenyl(1-methylimidazol-2-ylthio)-phosphonate (**9**) (see Figure 1).

In general, polycondensation conditions were varied in an attempt to optimize the yield of a single type of polyamide (**5a** or **5c**, preferentially, or **5b**) having a narrow range of molecular masses centered on a desirable value. If bis(carboxy-terminated) polyamides **5c** were obtained, these could be converted to any of a broad spectrum of activated esters. If bis(amine-terminated) polyamides **5a** were obtained, these could be activated directly to aldehyde, urethane, or maleimide derivatives or allowed to react with succinic anhydride to convert them to bis(carboxy-terminated) polyamides.

Analytical Methods. The polyamide condensation products were characterized by three methods. Size-exclusion chromatographic (SEC) analyses were performed using a Superose-12 column and 50 mM phosphate buffer, pH 6.5, as the mobile phase. SEC confirmed that polymerized products were formed and permitted the approximation of the molecular mass range of the polyamide product.

Thin-layer chromatographic (TLC) analysis was used to separate the polyamides and characterize the end-group functionality. The end-group functionality of each component was assigned on the basis of its relative migration (R_f) and reactivity toward ninhydrin spray reagent. Under the TLC conditions, polyamides with dicarboxy end groups have the largest R_f value. The polyamides with a monocarboxy and a monoamine end group have an intermediate R_f value, and the polyamides with diamine end groups have the smallest R_f value.

Finally, the molecular mass of the polyamide was determined by ^1H -NMR and ^{13}C -NMR analysis. Theoretical molecular masses were calculated by the comparison of the end group resonances to the polymer backbone resonances.

Figure 2. Activated esters of 1a.

Polyamides with Oxygen-Containing backbones.

The activated diester bis(methoxycarbonylmethoxyacetyl)-1,4-diaminobutane (**10a**) was selected initially as the diacid component for the synthesis of polyamides by a method described by Ogata et al. (5a) and Sato et al. (5b) (See Figure 2). Methanol, the byproduct of polycondensation, could easily be removed. However, we found that polycondensation with **10a** yielded a polyamide having a maximum molecular mass of about 4200 Da (by SEC retention volume). The conditions required for polycondensation were too strenuous and did not permit the production of polyamides having a range of molecular masses. Thus, methanol was not a sufficiently strong activating group to be the activating reagent of choice.

Treatment of diacid **1a** with *p*-nitrophenyl trifluoroacetate (**6**) quantitatively converted the diacid to the activated diester, **10b**. Polycondensation of PNP-activated diesters with diamines yields *p*-nitrophenol as the byproduct. This phenol is fairly soluble in organic solvents, and we anticipated that the resulting polyamides could be purified by simple recrystallization. This expectation was realized.

Compound **10b** condensed smoothly with the diamine **2** to give polyamides having molecular masses greater than 4000 Da, as indicated by SEC analysis. Under the reaction conditions employed in these studies, condensation of **2** and **10b** gave mixtures of three types of polyamide product: a polyamide bis(amine) **5a**; an α -carboxy- ω -aminopolyamide **5b**; and a polyamide bis(carboxylic acid) **5c**. The distribution and molecular masses of these polymers were found to be greatly affected by (a) the mixing rate; (b) the reaction temperature; (c) the base employed; (d) the molar ratio of **2** to **10b** employed; and (e) the solvent employed for the condensation. These parameters were studied, and the experimental results are summarized in Table 2.

The data indicate that under the same set of polycondensation conditions, chloroform was a superior solvent to *N,N*-dimethylformamide (DMF). Condensations that were performed in chloroform with various molar ratios of **10b** to **2** yielded polyamides having four different molecular masses ranging from 2.8 to 7.6 kDa and containing only the polyamide bis(amine) **5a**. In contrast,

polycondensation in DMF provided polyamides having only two different molecular masses (5.6 and 7.6 kDa). In addition, the latter polyamides were mixtures of **5a** and **5b**, and their SEC profiles were broad. With respect to the other parameters, we found the most useful polymerization conditions were a mixing rate of 130–135 rpm, 2,6-lutidine as the base, chloroform as the solvent, and -50°C as the reaction temperature.

Although *p*-nitrophenyl trifluoroacetate (**6**) was a very useful activating group, the synthesis of *p*-nitrophenyl trifluoroacetate is tedious and uses a large amount of trifluoroacetic anhydride. Furthermore, *p*-nitrophenol, the byproduct of the polycondensation, has a poor safety profile. For these reasons, we wanted to assess the utility of other activating groups.

Peptide synthesis using the coupling reagent 2-chloro-4,6-dimethoxy-1,3,5-triazine (**7**) was first proposed by Kaminski (**7**) in 1987. We reasoned that **7** might be a useful activating reagent for the polycondensation reaction, since the byproduct of the polycondensation reaction would be 2-hydroxy-4,6-dimethoxy-1,3,5-triazine, a reagent that is quite soluble in DMF and other organic solvents. This suggested that the desired polyamide could be purified easily by recrystallization of the product mixture from organic solvents.

The activation of **1a** was achieved by adding **7** to a mixture of the diacid **1a** and *N*-methylmorpholine (NMM) in chloroform at 0°C . However, the activated acid **10c** could not be isolated. Alternatively, polycondensation of **1a** and **2** could be achieved by the in situ activation of the diacid **1a** with **7**. Thus, the diamine **2** was added to a solution of the diacid **1a**, **7**, and NMM at 25°C , and the reaction was allowed to proceed overnight to produce a polyamide bis(amine) (PAD derivative).

We found that the choice of solvents and bases was critical for the polycondensation of **1a** and **2** with **7** to be successful. The combination of chloroform and NMM was found to be the best solvent and base pair for the polycondensation of **1a** with **2**. Employing chloroform as the solvent and triethylamine as the base did not produce a polyamide. The substitution of DMF for chloroform as the solvent and NMM as the base gave polyamides with much lower molecular masses.

The effect of the molar ratio of **2:1a** was also studied and was found to have little effect on the molecular mass and yield of the polyamide. For example, activation of **1a** with **7** followed by polycondensation with **2** under conditions where the molar ratio of **2:1a** was in the range 0.8–1.0 gave a high yield (80%) of polyamides having a molecular mass of approximately 2800 Da (estimated by SEC retention volume).

There were three major drawbacks to the use of **7** as the activation reagent. (1) The selection of solvents and bases for the activation step apparently is limited. In our hands, only chloroform and NMM may be used for this purpose. (2) Isolation and purification of the dimethoxytriazine-activated diester (**10c**) prior to addition of the diamine was prohibitively difficult. (3) The observation that polyamides cannot be prepared in a wide range of molecular masses argued against the use of this activating agent.

Diphenyl(2,3-dihydro-2-thioxo-3-benzoxazolyl)phosphonate (**8**) (**8**) was selected as an activating agent for evaluation for the following reasons. (1) This reagent is expected to have a better safety profile than *p*-nitrophenyl trifluoroacetate or PNP-esters. (2) The reagent is easily synthesized at large scales. (3) The leaving group, 2-mercaptobenzoxazole, is very soluble in organic

**Figure 3.** Activated esters of **1b**.

solvents; thus, polyamide products could be purified by simple recrystallization.

Treatment of **1a** with **8** provided the activated acid **10d** as an isolatable solid. However, polycondensation of **10d** with **2** met with only moderate success. The best results were obtained in DMF as the solvent and without the addition of a base. A polyamide of the PAS type with a molecular mass of about 4 kDa was obtained. Changes in the ratio of **10d**:**2** or the addition of a base did not change the outcome of the reaction. The use of chloroform as the solvent provided only very low molecular mass polymers under all reaction conditions tested.

Since the synthesis of PAS-type polyamides was not efficient with **10d**, a new activating reagent was designed. We used the strategy of substituting the benzoxazolin-2-thione group in **8** with 2-mercapto-1-methylimidazole (methimazole) (**9**). Preparation of the new activating reagent diphenyl(1-methylimidazol-2-thiyl)-phosphonate (**9**) is summarized in Scheme 2. The synthesis is based on the literature preparation of **8** (**8**). 2-Mercapto-1-methylimidazole (**12**) was treated with diphenyl chlorophosphate (**11**) in the presence of triethylamine. In theory, the product could be either the S-phosphoryl or the N-phosphoryl derivative (**9** or **13**, respectively), due to the tautomerization of 2-mercapto-1-methylimidazole. Both the ^{13}C -NMR and IR spectra of the isolated product established that it was the S-phosphoryl product **9**. The ^{13}C -NMR spectrum had a doublet, due to coupling with phosphorus, at 166.5 ppm that is representative of a carbon of the C=N bond type. Absent was a resonance in the region 180–200 ppm that would correspond to a carbon of the C=S bond type. The IR spectrum had an absorption at 1298 cm^{-1} of the P=O bond and no strong absorption in the 1340 cm^{-1} region indicative of a C=S bond (**10**).

Attempts to activate **1a** by heating at reflux with **9** in the presence of triethylamine in chloroform failed to give the desired activated diester **10e**. However, when **9** was added to a solution of **2**, **1a**, and triethylamine in DMF at 60–70 °C, a good yield (65%) of PAS that has an SEC profile similar to that of PAS-5600, was obtained. In contrast, one-step polycondensation of **2** and **1a** in the presence of **9** using triethylamine in chloroform at reflux gave only low molecular mass PAS.

Thio-Containing Polyamides. Sulfur-containing polyamides were obtained by the activation of 3,3'-thiodipropionic acid (**1b**) and subsequent treatment with **2** (see Figure 3). Compound **7** was the first activating reagent that was used in the preparation of thio-contain-

**Figure 4.** Polyamide activating reagents.**Scheme 2**

ing polyamides. As was seen with **1a**, the activated acid **14a** of **1b**, could not be isolated. Therefore, **2** was added to a solution of **7**, **1b**, and *N*-methylmorpholine at 25 °C. The reaction was allowed to proceed overnight to provide an amino-terminated, thio-containing polyamide (PATD). Variation of **2**:**1b** molar ratios from 0.8 to 1.1 gave only PATS having a molecular mass of 4000–5000 Da in good yields (73–88%). The PATS obtained using **7** has a narrow molecular mass distribution as indicated by SEC and contains only 3.5% of a lower molecular mass byproduct. The solvent of choice for the polymerization was chloroform, and the most suitable base was *N*-methylmorpholine.

Greater success was obtained with activation of 3,3'-thiodipropionic acid with **8**. Activation of **1b** with **8** was accomplished in chloroform in the presence of triethylamine to give a 76% yield of *N,N'*-(3,3'-thiodipropionyl) bis(benzoxazolin-2-thione) (**14b**). Polycondensation of **14b** and **2** to obtain polyamides having the desired molecular masses and end groups was found to depend on five experimental parameters: (a) the molar ratio of **14b** and **2**; (b) the solvent (CHCl_3 or DMF); (c) the temperature, (d) the base (triethylamine or 2,6-lutidine); and (e) the mixing rate. For all the following experiments, the mixing rate was maintained at a moderate rate to simplify the studies.

The data indicate the following. (a) Polycondensation in chloroform in the presence of triethylamine did not give reproducible results (Table 3). Employing the same molar ratio of **2** and **14b** did not yield polyamides of similar molecular mass. Usually, high molecular mass polyamides having a retention time of 31–32 min by SEC were obtained. This suggests that triethylamine was too strong of a base. (b) Polycondensation in chloroform in the absence of base or in the presence of a weak base such as 2,6-lutidine produced polyamides in a predictable manner (Table 4). For instance, a decrease in the **2**:**14b** molar ratio gave polyamides having higher molecular masses. Thus, using molar ratio of **2**:**14b** of 1.2:1 at 0 °C or 1.3:1 at 25 °C in the absence of base during the polycondensation furnished a polyamide having a molecular mass of about 2800 Da (a retention time of 38.7 min by SEC). (c) Polycondensation in DMF in the presence or in the absence of a weak base such as 2,6-lutidine gave polyamides of similar molecular mass. Polycondensation at 0 °C gave a polyamide with a very broad molecular mass distribution, as indicated by multiple peaks in the SEC profile of the product. Em-

Scheme 3

Scheme 4

employing **2** and **14b** in a molar ratio of 1.3:1 at 25 °C in the absence of base gave two distinct polyamides: one having molecular mass of 5700 Da that is insoluble in DMF and a second having molecular mass of 2800 Da that is soluble in DMF. It was found that simple filtration could be used to separate these two polyamides. (d) Polycondensation of **2** and **14b** in chloroform using a molar ratio of 1.2:1 at 0 °C or 1.3:1 at 25 °C yielded exclusively polyamide bis(amine) having a molecular mass of 2800 Da, whereas employing a molar ratio of 1.3:1 in DMF at 25 °C gave mostly polyamide monocarboxy monoamine having a molecular mass of 5700 Da.

Synthesis of PAT polyamides was also achieved using **9**. Synthesis of PAT derivatives using **9** was carried out in two steps. In the first step, activation of **1b** was achieved by reaction of **1b** with **9** in chloroform containing triethylamine. The reaction was sluggish at 25 °C; however, heating the reaction under reflux gave the activated acid **14c** in good yield (70%). On the basis of its ¹³C-NMR and IR spectra, the activated diester **14c** was assigned the structure of an S-acyl derivative. In the second step, polycondensation was achieved by simply mixing **2** and **14c** in a suitable solvent to give a PATD.

The effects of variation in solvent, reaction temperature and **2**:**14c** molar ratio on the polycondensation are summarized in Table 5. In general, polycondensations in DMF gave a higher yield (50–76%) and cleaner PAT than those in chloroform (30–46%). In addition, increasing the **2**:**14c** molar ratio decreased the yield and the molecular mass of PAT. Finally, polymerization in DMF at 0 and 25 °C gave PAT having a broad molecular mass distribution by SEC analysis, but at –50 °C, a narrow molecular mass distribution PAT was obtained. PAT

having a molecular mass range 2800–5000 Da may be obtained in 57–76% yield by polycondensation of **2** and **14c** at –50 °C in DMF.

Activation of the Polyamide End Groups. The polyamides obtained by the synthetic methods described above contain either bis(amine) **5a**, α-carboxy-ω-amino **5b**, or bis(carboxylic acid) **5c** end groups. Each of these polyamides could be activated for reaction with proteins using various strategies (Scheme 3). For example, both a bis(amine) polyamide **5a** and a α-carboxy-ω-amino polyamide **5b** were converted to bis(carboxylic acid) end-capped polyamides (PAS or PATS derivatives) by treatment with succinic anhydride. The resulting PAS and PATS polyamide dicarboxylic acids were efficiently converted to the corresponding activated bis(N-oxy succinimide) diesters (PASS and PATSS derivatives, respectively) using *N,N*-disuccinimidyl carbonate (**15**) (11).

Similarly, the PAD or PATD bis(amines) **5a** were activated in three ways. First, the amine end groups were converted to maleimide end groups (PADMP and PATDMP derivatives, respectively) by treatment of the bis(amines) **5a** with *N*-oxy succinimidyl 2-maleimidopropionate (**16**) (12). Alternatively, the PAD or PATD bis(amines) **5a** were activated with **15** to yield the corresponding urethane-terminated polyamides PADSC and PATDSC that contain succinimidyl oxycarbonyl end groups. Finally, the bis(amines) were activated with *N*-(2,2-diethyloxyethyl)succinamic acid *N*-oxy succinimide ester (**17**) to furnish the polyamide bis(aldehydes) PADA and PADTA, respectively. The synthesis of **17** is described in Scheme 4.

Conclusions. Water-soluble polyamides having well-defined molecular masses and end groups have been

synthesized. Acute toxicity screening of these polyamides in rodents suggests that these materials are neither toxic nor immunogenic (13). Both the carboxyl and amino end groups of the various polyamides can be converted to several types of activated end groups. This provides a spectrum of activated polyamides that can be useful in the cross-linking or modification of proteins such as hemoglobin. The polyamides described herein have been used for the synthesis of polymerized DCLHb (14) (DCLHb, α,α -cross-linked hemoglobin) (15); this reactivity will be the subject of a subsequent paper.

ACKNOWLEDGMENT

We thank Dr. Walter Smith for his help with the MW determination by NMR of the polyamides and Ms. Ana Srnak for performing the SEC analyses.

Supporting Information Available: Tables S1–S7 provide the ^1H - and ^{13}C -NMR data for the polyamides (9 pages). Ordering information is given on any current masthead page.

Covalent Immobilization of Proteins onto (Maleic Anhydride-*alt*-methyl Vinyl Ether) Copolymers: Enhanced Immobilization of Recombinant Proteins

Catherine Ladavière,[†] Thierry Delair,^{*,†} Alain Domard,[‡] Armelle Novelli-Rousseau,[†] Bernard Mandrand,[†] and François Mallet[†]

Unité Mixte UMR-103, CNRS-bioMérieux, ENS-Lyon, 46, allée d'Italie, 69364 Lyon, France, and Unité Mixte CNRS-Université Claude Bernard, UMR-5627, LEMPB, Université Claude Bernard, 43, Bd. du 11 Novembre 1918, 69612 Villeurbanne, France. Received November 28, 1997; Revised Manuscript Received August 1, 1998

Two genetically modified HIV-1 capsid p24 proteins, RH24 and RH24K, were covalently bound to maleic anhydride-*alt*-methyl vinyl ether (MAMVE) copolymer, under aqueous conditions. We demonstrated that the addition of a six lysine unit tag at the COOH-terminus of RH24K greatly improved the grafting reaction which could take place under many different experimental conditions. The course of the reaction was controlled by electrostatic attractive forces between the protein and the negatively charged polymer, as the chemical binding was more efficient at low ionic strength. The maximum loading capacity of the polymer depended on whether the protein bore the lysine tag (RH24K) or not (RH24). Twenty-four molecules of RH24 could be immobilized per polymer chain and 49 for RH24K. Such a difference could be explained by a difference of orientation of the protein on the polymer, side-on for RH24 and end-on for RH24K to account for the observed high packing density.

INTRODUCTION

Molecular recognition is a fundamental means of conveying information in living organisms. For applications such as in diagnostics, it may be required to immobilize proteins onto polymers, via the formation of covalent bonds, with ideally no loss of biological properties. To attain this goal, one strategy consists of directing the chemical reaction involved in the grafting, toward a specific site of the protein that is not essential for the molecular recognition process of interest. For instance, Rodwell et al. (1), used the carbohydrate moieties located at the hinge region of the immunoglobulin to target a chemical modification.

Protein modifications can be used to introduce a functional group on a specific site of the macromolecule. Enzymatic digestion of antibodies with subsequent reduction of disulfide bonds leads to the formation of thio groups exactly on the opposite end of the recognition site of the immunoglobulin (2). Genetic engineering allows the introduction or the substitution, at a well-defined position on the protein, of amino acids that bear the ad hoc functional group for further chemical modification, such as coupling. Chilkoti et al. (3), for instance, incorporated a unique cysteine residue in mutant cytochrome *b*₅ for conjugation to maleimide-terminated oligo(*N*-isopropylacrylamide). A closely related approach consists of introducing an oligo(amino acid) sequence, tags, at a defined position on the protein. For instance, oligo-(histidine) tags were introduced in recombinant HIV-1 p24 capsid protein, to allow its purification via coordination interactions between histidines and metal ion immobilized on a solid phase (4, 5). An oligo(arginine) tag

was reported (6) for solid-phase immobilization of the protein via electrostatic interactions with a negatively charged surface.

In the lab, we used a strategy related to the second approach described above. A six lysine residue tag was added at the COOH position of a recombinant p24 HIV-1 capsid protein. The rationale was that an increase of the density of amine groups at a particular position of the protein molecule, should enhance the efficiency of the immobilization reaction, as a whole, and would direct the grafting to the lysine-enriched site of the biological molecule. In the absence of the tag, the grafting onto the polymer would take place at random, on any of the 10 lysine residues available on the macromolecule. The great advantage in using amide bond formation to tether biomolecules to carriers is that the chemistry is simple to run, reproducible, and can sustain a diversity of experimental conditions which is a prerequisite for the development of a generic grafting method. Thiol chemistry, though very chemiospecific and regiospecific, suffers from the dimerization of the reactants by disulfide bond formation which easily occurs. To suppress this side reaction, strict experimental conditions have to be used (absence of traces of oxygen and divalent cations and no basic pH), which on an every day basis make this chemistry less attractive.

The p24 protein, and its recombinant equivalents, are commonly used in diagnostics tests for the detection of HIV antibodies in sera. On the basis of results obtained for the hepatitis B virus (HBV) DNA detection (7), the use of polymeric p24 in diagnostics tests should allow us to increase the sensitivity of the kits, for a still more reliable investigation of HIV infected patients.

We wish to report here on the comparative results obtained in the immobilization of two recombinant proteins: one with a six lysine residue tag and the other deprived of lysine tag.

EXPERIMENTAL PROCEDURES

Materials. Recombinant proteins were obtained in *Escherichia coli* from a procedure derived from ref 5. These proteins were termed RH24 and RH24K for, respectively, recombinant p24 with a six histidine residue tag (H) for metal chelate purification and recombinant p24 with a histidine (H) tag and the six lysine (K) residue tag. For both proteins, the histidine tags were at the NH₂ termini. For RH24K, the lysine tag was at the COOH-terminus. The amino acid sequence for each protein is reported as follows:

The lysine groups are randomly dispersed along the protein macromolecules. NMR (8) and crystal structure data (9, 10) demonstrated that, in the 3D structure of the protein, the 10 lysine groups were accessible for grafting. Theoretical molecular weights and isoelectric points were determined with the MacVector software (version 6.01).

The maleic anhydride-*alt*-methyl vinyl ether copolymer [P(MAMVE): M_n = 67 000 g/mol] was from Poly-science Inc. and used as received. Other chemicals were from Aldrich and used as received. Milli-Q grade (Millipore SA, France) deionized water was used for all buffers.

Coupling of Proteins to Copolymers. The appropriate amounts of polymers were dissolved in anhydrous dimethyl sulfoxide (DMSO) at 37 °C. To a protein buffer solution at the appropriate concentrations was added the required volume of polymer solution in DMSO. The reaction mixture was stirred for 3 h at 37 °C. The pH of the buffers was measured and monitored using an Ingold HA405-DXK-58/120 electrode and a Minis 8000 pH-meter (Taccussel-Radiometer, France). As stated by the supplier, the electrode was Tris compatible.

Kinetics of the Coupling Reaction. To monitor the course of the coupling of proteins onto polymers, 20 μ L of the reaction mixture was pipetted off and the reaction was quenched by addition of 5 μ L of 15% ammonium hydroxide solution.

Protein Interaction with the Hydrolyzed Copolymer. The copolymer sample was hydrolyzed at the same concentration as for coupling (stock concentration, 1 g/L), during 2 h at 67 °C, then 48 h at 37 °C in various buffers (pH 4.0, 6.8, 7.8, 8.2, 9.2, and 10.7). Then, the coupling reaction was performed as described above.

Stability of Proteins and Conjugates. This study was carried out for the proteins RH24 and RH24K and for the conjugates in the coupling medium (DMSO/ Tris buffer, pH 7, 5/95, [protein] = 0.95 g/L, [P(MAMVE)] = 0.048 g/L) at 37 °C, for 7 days. Prior to use, the buffer was filtered on a 0.22 μ m membrane and pipet tips and Eppendorf tubes were autoclaved (3 h at 120 °C).

Analyses of the Coupling Reactions. The crude coupling mixture was analyzed by size-exclusion chro-

matography (SEC) using a Shodex Protein KW-803 (Waters) or a Protein-Pak 125 (Waters), a Kontron HPLC 422 pump, a Kontron HPLC autosampler 465, and a Kontron UV diode array detector. Purifications were run in a 0.1 M phosphate buffer, pH 6.8, containing 0.5% (w/v) of sodium dodecyl sulfate (SDS) with a flow rate of 0.5 mL/min. Detection was achieved by measuring the absorbance at 280 nm corresponding to the proteins (at the concentrations used, the polymer had no absorption). The ratio of the peak area corresponding to the polymer-bound RH24(K) versus the sum of the two peaks corresponding to the unbound and to the bound RH24(K) (i.e., the total amount of protein involved in the reaction) gave the coupling yield (Y). The extinction coefficients of the bound and unbound proteins were checked by measuring the OD at 280 nm of crude conjugates obtained in a carbonate buffer compared to the reference-free protein in the same mixture. The OD data were found identical in a 10% range. Furthermore, for each HPLC analysis, the sum of the areas of the bound and unbound proteins was routinely compared to that of a reference sample recorded in the absence of polymer. To assess the average amount of protein molecules per polymer chain, $\bar{N} = nY/n'$ where n and n' , respectively, correspond to the number of protein molecules and the number of polymer chains in the reaction mixture; as a first approximation, we assumed, that each polymer chain reacted according to the same pattern [which is the case for oligonucleotide immobilization (7)]. Trying to assess the molecular weight of the conjugates by acrylamide gel electrophoresis was a failure probably because of polymer-gel interactions. Using viscometry on-line with SEC, was not possible due to the presence of SDS in the mobile phase (unstable signals were obtained). To calculate $\bar{N}$, which gives access to the level of loading of the polymer, we assumed that no cross-linking had occurred. This assumption seems realistic given that the protein to polymer molar ratio is 50:1.

Dynamic Light-Scattering Experiments. These experiments were performed on-line using a Protein-Pak 200 SW column (Waters) and a Waters 510 high-performance liquid chromatography pump, running in a 0.1 M phosphate buffer, pH 6.8, containing 0.5 M NaCl with a flow rate of 0.5 mL/min. The refractive index increment of proteins is ca. 0.19 mL/g (11). For the detection part, a Waters 484 absorbance detector, a Waters 410 differential refractometer, and a three angles Mini Dawn F detector (WYATT Technology) at 690 nm were used on-line.

Mass Spectrometry (LC-ESI-MS). Analyses were performed with a single quadrupole API 100 mass spectrometer, 140 B pumps, and a 785 A detector (Perkin-Elmer). Reversed-phase liquid chromatography was performed on a C18 column (Vydac, 5 μ m particle size). Solvent A was 0.1% (v/v) trifluoroacetic acid in water and solvent B was 0.1% (v/v) trifluoroacetic acid in a water/acetonitrile mixture (20:80 v/v). A gradient from 45 to 70% of B was used.

Circular Dichroism (CD). Analyses were performed in a 0.05 M Tris-HCl buffer, pH 7, with a protein concentration between 30 and 50 mM. CD measurements were performed with a Jobin-Yvon model CD6 spectrophotometer at 25 °C and with a Hellma cuvette; path length-0.2 cm. To eliminate the DMSO used for the coupling (high absorption of solvent), the conjugates were analyzed after dialysis on a polycarbonate membrane with a cutoff of 3000 g/mol (AMICON). This study was carried out with a conjugate of RH24K because the

coupling yield is high (~88%) and as a consequence the unbound protein does not perturb the analysis.

RESULTS AND DISCUSSION

Protein Characterizations. The molecular weight of each protein was determined by size-exclusion chromatography-multiangle laser light scattering (SEC-MALLS) and reversed-phase liquid chromatography coupled with electrospray ionization mass spectrometry (LC-ESI-MS).

Data depicted in Table 1 show a good correlation between the two techniques and the theoretical value deduced from the amino acid composition. In comparison to RH24 and RH24K proteins, data concerning R24 that bear no tag are shown as well.

CD spectra of RH24 and RH24K exhibited the same pattern as for the R24 protein reported in the literature (12), and the conformation corresponded to 43% α -helices and 17% β -sheets. This is an important result which demonstrated that no major conformational modification was induced by the addition of one or two tags.

Characterization of the Protein/Polymer Conjugates. Conjugates were analyzed and purified by size-exclusion HPLC. As shown in Figure 1, the polymer protein conjugates were recovered in the first elution peak and the unbound proteins in the second. We noticed a tendency of the protein to stick to many solid phases. That can probably be explained considering the role of a p24 protein, which is to protect the genetic code of the virus by aggregating to form a capsid. To overcome this autoassociation problem, whose dissociation constant of corresponding dimer, measured by Rosé et al. (13), was $(3-4) \times 10^{-5}$ M at pH 7, we added 0.5% (w/v) of sodium dodecyl sulfate in the HPLC mobile phase.

Determination of the Coupling Conditions. On the basis of results obtained in a preliminary study on bovine serum albumin, the grafting of recombinant proteins onto MAMVE copolymer was tested in aqueous buffers containing 5% (v/v) of DMSO (14). The results obtained, depicted in Figure 2, show that, in most cases, the grafting of the lysine-tagged protein, RH24K, was more efficient than the immobilization of the RH24 HIV-1 capsid protein. In the latter case, the coupling yields were higher at pHs close to neutrality and fell with increasing pH as the hydrolysis rate increased (15). The lysine-tagged protein reacted with the anhydride moieties of the MAMVE copolymer over a wide range of experimental conditions, demonstrating the enhancing effect of the tag on the course of the reaction. Coupling yields were over 50% except for extreme conditions, i.e., low (pH 5) or high (pH 11) pHs. The Tris buffer proved the most efficient medium for the covalent grafting of both proteins, demonstrating the poor reactivity of the amine of the Tris buffer toward acylation. It is worth noting that, in the phosphate buffer, pH 5, the conjugates precipitated but the proteins did not. The effect of the lysine tag on the course of the coupling reaction was drastically marked at pHs over 7. Above pH 7, the immobilization yields of RH24 leveled off at ca. 10%, whereas 60–88% yields were obtained for RH24K.

To explain the difference in behavior between both proteins, one can consider two factors: (i) different conformations, one of which would favor the coupling reaction via steric effects, and (ii) difference in reactivities due to the presence of the lysine tag in RH24K. CD spectra of RH24 and RH24K were identical, proving that the introduction of the lysine tag entailed no modification of the secondary structure of the protein. Therefore, conformational factors cannot be regarded responsible for the difference in behavior between the two proteins. Hence, reactivity factor must be evoked to account for such a large variation in behavior. The immobilization reaction onto the MAMVE copolymer occurs by nucleophilic attack of the reactive anhydride moieties by the primary amine groups of the proteins, as depicted in Figure 3. Since the reaction takes place in a mostly aqueous medium, the hydrolysis of the anhydride functions is very likely to occur. Therefore, the grafting pathway of the protein onto the polymer has to compete the hydrolysis reaction. The kinetics data reported in

Figure 4 were obtained in a 50 mM Tris buffer, pH 7, at 37 °C, and the coupling yields were measured after quenching the reaction with excess ammonia. The presence of ammonia did not alter the stability of the amide bond formed during acylation with the polymer as the amount of bound protein did not decrease over the analysis period (illustrated by the presence of plateaus in Figure 4). Furthermore, the plateau values of the coupling yields obtained in the presence of ammonia perfectly matched the coupling yields obtained without ammonia as seen in Table 4, run 5, and Table 5, run 5. After 10 min of reaction, the coupling yields did not evolve any more, meaning that the reaction had reached a plateau and that all reactive groups on the polymer were consumed, either to form an amide bond with the protein or by hydrolysis by water molecules. For both proteins, the reaction did not proceed any further after 10 min. Nevertheless, for the same time period, more RH24K molecules were bound to the polymer than RH24.

It was checked that no coupling between the polymer and RH24 occurred when all the anhydride groups of the

polymer were hydrolyzed (at different pHs: 4.0, 6.8, 8.2, and 10.6). Actually, the mixture of hydrolyzed polymer and RH24K always led to a precipitate (used buffers pHs: 4.0, 6.8, 7.8, 8.2, 9.2, and 10.7). This precipitate could be explained by electrostatic interactions between the negative charges of polymer chains and the cationic sites

of the protein molecules, leading to highly cross-linked polyelectrolyte complexes insoluble in water. When the ratio polymer/protein was increased, no precipitation was observed as more polymer was available. Under these conditions, no conjugation occurred as observed by HPLC.

The reproducibility of the grafting experiments is quite good, based on the following results obtained on different days. The immobilization yields of RH24K were 82, 80, and 88% for experiments described respectively in Figure 4, Table 5 (run 5), and Table 4 (run 4). For the same series of experiments, coupling yields of RH24 were 48, 46, and 47%.

Role of the Ionic Strength. With the lysine-tagged protein, a series of experiments was run in a carbonate buffer in which the immobilization yield was only 53% and the coupling yield was measured as the buffer ionic strength was lowered. The results reported in Table 2 show a drastic increase in coupling yields when lowering the ionic strength and clearly emphasize the major role played by electrostatic interactions in the immobilization process of RH24K. It is worth noting that, for a 20 mM carbonate buffer, the pH of the coupling mixture only decreased 0.15 pH unit in 53 min, proving that the buffer was not exhausted by the hydrolysis of the anhydride groups of the polymer.

Though at pH 8.2 the protein net charge is negative, some protonated amine groups remain. Since negative charges are formed on the polymer, either from the hydrolysis of the anhydride moieties or from the coupling reaction, attractive electrostatic forces can arise by interaction with the positive charges borne by the protein. These forces allow the macromolecular counterparts to get in contact for the chemical reaction to take place. Finally, the results obtained in Table 2 point out a fundamental difference in behavior of the two proteins. Lowering the ionic strength had a slight effect on the coupling yield for RH24, whereas a drastic increase in coupling yields was observed with RH24K. To observe any ionic strength effect with RH24, sodium chloride was added to a Tris buffer, pH 7. No data were available for the RH24K protein because, in this experiment, precipitation was observed on adding sodium chloride (the protein alone precipitated too). From the results shown in Table 3, an increase of ionic strength by adding sodium chloride resulted in a decrease of the grafting efficiency. A slight precipitation was observed in the Tris buffer at sodium chloride concentrations higher than 0.5 M. In another set of experiments, the ionic strength of the Tris buffer, pH 7, was reduced. No improvement of the immobilization yields was obtained, neither for the lysine-tagged protein, which was not surprising since the coupling yields were already as high as 80%, nor for the RH24 sample for which the maximum coupling yield was limited to ca. 40% (data not shown). This behavior was not expected on account of results obtained with BSA, for which coupling efficiency was improved by reduction of the buffer ionic strength (14).

From these results, one may conclude that the covalent immobilization of RH24K is mostly governed by electrostatic interactions. These interactions are attractive forces between the negatively charged polymer and the positive charges on the protein. The role of these forces is to bring together the macromolecular reactants in order to allow the chemical reaction to take place. For RH24, the coupling process is controlled by a diffusional process as well as by the differences in reactivities between the amino groups of the protein and the water molecules of the reaction mixture that hydrolyze the reactive groups on the polymer.

Figure 5. Number of protein molecules bound per polymer chain (N) for RH24 (○) and RH24K (●) as a function of protein concentration during coupling. Buffer: 0.05 M Tris, pH 7. Reaction time and temperature 3 h, 37 °C.

Figure 6. Representation of end-on (a) and side-on (b) orientations.

Role of the Reactant Concentration. The relative concentrations of both reactants are factors that can have an effect on the course of the binding reaction.

The increase of the protein concentration in the reaction mixture resulted in a more marked decrease of the immobilization yields of RH24 than of RH24K as seen in Table 4. More striking is the effect on the average amount of protein loaded per polymer chain, as represented by N in Figure 5. The amount of bound RH24 per polymer chain leveled off at 24 protein molecules, whereas no plateau value was reached yet for RH24K, though coupling yields started to significantly decrease at a concentration of 0.95 g/L (Table 4). The plateau value, obtained on increasing RH24 concentrations, suggests that the grafting reaction is controlled by a steric effect: the polymer chain is covered with proteins which adopted some sort of side-on orientation. For the same polymer chain, more than 49 molecules of RH24K can be tethered, which must have adopted an end-on type orientation. Due to the presence of positive charges on the six lysine residue terminus of RH24K, the tag favors the approach of a protein molecule toward a negatively charged P(MAMVE) chain, in some sort of an oriented manner. In other words, the tag acts as a leash to bind the protein to the polymer. The amino groups of the lysine tag are the first to get in contact, and react, with some anhydride moieties of the polymer which ensures an oriented immobilization of RH24K. When the concentration of RH24K is high, many proteic species can be grafted onto one polymer chain, preventing, thus, the protein to adopt a side-on orientation (Figure 6).

The next factor to be investigated was the polymer concentration in the coupling medium. This factor was investigated in a carbonate buffer for RH24K, in which RH24 very poorly binds (Table 2), which makes this buffer more selective toward the orientation of the grafting of the lysine-tagged protein. For RH24, a Tris buffer was selected which afforded a high grafting efficiency, whose variations should be quite significant. The coupling yields increased with the polymer concentrations, as reported in Table 5, and concomitant decrease

Figure 7. Amount of RH24(K) molecules bound per polymer chain ($\bar{N}$) in a 0.05 M Tris buffer, pH 7, for RH24 (○) and in a 0.02 M carbonate buffer pH 8.2 for RH24K (●) as a function of the polymer concentration. [protein] = 0.95 g/L.

of $\bar{N}$ was observed for both proteins as shown in Figure 7. It is worth noting that the maximum amount of RH24(K) bound to the polymer (i.e., at the lowest polymer concentration, run 1 in Table 5) was similar in both cases. The maximum loading capacity of ca. 58 protein molecules chain (Figure 7) could be reached when the reaction was run with a large excess of proteins (protein to polymer molar ratio of 500:1, run 1 in Table 5). At first, this result could challenge the side-on/end-on hypothesis postulated in the preceding paragraph. But one has to take into account that in run 1, Table 5, the protein to polymer molar ratio was 5-fold higher than in run 6, Table 4. Thus, under an extremely high concentration in protein (run 1, Table 5), RH24 was forced to adopt an end-on orientation during coupling. When the immobilization conditions were less drastic (run 6, Table 4, protein to polymer molar ratio of 100:1), the high level of loading of RH24K onto the polymer (49 proteins/chain) can only be explained if the protein binds in an end-on orientation. This orientation arises from attractive electrostatic forces generated by the interaction of the lysine tag and the polymer. This result clearly demonstrates that orientation of RH24K on binding to the polymer is achieved via electrostatic factors, and that the coupling reaction is indeed governed by these factors. In other words, binding of RH24 in an end-on orientation is under kinetic control, when a very large excess of proteins is used, the side-on orientation being obtained when the reaction is under thermodynamic control, i.e., at the lowest protein concentration.

When the polymer concentration in the reaction mixture was increased, more polymer chains were available for the same initial amount of protein and we observed a decrease in $\bar{N}$ as already observed with BSA (14). But the decrease in the case of RH24K is slower than for RH24. This difference in behavior could be explained by the already suspected higher reactivity of RH24K compared to the non-lysine-tagged protein. An increase in the polymer concentration of the reaction mixture results in an increase of the hydrolysis rate of the reactive groups (15) of the polymer. RH24 does not compete with hydrolysis as well as RH24K. When the polymer concentration was high, in large excess to the protein, the immobilization yields were maximum, and once again, higher for RH24K. It is worth mentioning that with RH24K three buffers were investigated in this series of experiments: 0.02 M carbonate buffer, pH 8.2, 0.05 M Tris buffer, pH 7, and 0.1 M borate buffer, pH 9.2. At low polymer concentrations in the Tris and borate buffers, an insoluble precipitate was formed. When enough polymer was present (0.024 g/L in Tris buffer, 0.038 g/L

in the borate buffer), no insoluble precipitate was formed, and the amounts of bound proteins in the three buffers were closely related.

Stability of Proteins and Conjugates. When RH24 and RH24K were incubated at 37 °C in the coupling medium (DMSO/Tris buffer, pH 7, 5/95), new peaks at higher elution times appeared, corresponding to degradation fragments of the proteins. The degradation yield increased with time at 37 °C, to reach 16% for RH24 and 20% for RH24K after 7 days.

The protein/polymer conjugates remained stable at 37 °C over the same time period. In the meantime, the unbound protein contained in the crude conjugate underwent degradation. So the conjugation of the proteins to the polymer was a means of stabilizing them and protecting them from degradation.

CONCLUSION

This work demonstrated that the introduction of a six lysine residue tag into a recombinant protein drastically modified the immobilization conditions onto a (maleic anhydride-*alt*-methyl vinyl ether) copolymer, though it only corresponded to ca. 3% of the global amino acid composition.

The nontagged protein (RH24) was immobilized at buffer pHs close to neutrality in order to disfavor the competing hydrolysis of the polymer reactive groups. For the lysine-tagged protein (RH24K), the hydrolysis reaction had less impact, and the protein could be tethered under a wide variety of experimental conditions, including high pH values. For a sufficient polymer concentration, the presence of the polylysine end allowed the immobilization of up to 50 protein molecules per polymer chain. When densely packed, the protein has probably adopted an end-on orientation. The maximal density of polymer-bound nontagged protein was shown to be lower than for its tagged counterpart. This upper limit was due to steric effects as an increase of the protein concentration in the coupling medium did not allow it to bind more RH24. Taking this last result into account, one may think that the orientation of the nontagged protein on the polymer is more of a side-on type. For a weak polymer concentration (protein-to-polymer ratio of 500:1), the maximal amount of polymer-bound protein was independent of the protein nature and attained 58 protein molecules/polymer chain. So when proteins are in large excess, they are forced to bind in an end-on orientation, affording the high loading value of 58 proteins per polymer chain. When coupling conditions were less drastic (protein to polymer molar ratio of 100:1), discrimination between the nature of the two proteins can occur. Thus, RH24K only, can bind in an end-on orientation, as shown by the high loading value of 49 proteins/chain, because of the orientation effect due to interaction of the tag with the copolymer. In the absence of these interactions, as in the case of RH24, the proteins bind according to a random orientation, which corresponds to a side-on orientation as shown by the reduced loading value of RH24 molecules.

The study on the stability of protein/polymer conjugates at 37 °C showed that the polymer-bound proteins were more stable than the unbound ones.

Finally, on a conformational standpoint, CD spectra of the conjugates with RH24K were identical to those of the unbound proteins, so the conjugation process occurred with no modification of the secondary structure of the bioactive species. Therefore, the evaluations of the

biological properties of the conjugates could take place and will be reported in due course.

ACKNOWLEDGMENT

The authors are grateful to Dr. L. Ladavière for CD measurements, Dr. G. Gervasi for analyses of proteins by mass spectrometry, and C. Hebrard for the preparation of proteins. C.L. is thankful to Fondation Mérieux for financial support.

Received December 31, 1997; Revised Manuscript Received June 5, 1998

The persistent localization of radioactivity in the kidney after administration of ^{111}In -DTPA-D-Phe¹-octreotide impairs the diagnostic accuracy of this radiopharmaceutical. To better understand the mechanisms responsible for the renal radioactivity levels of ^{111}In -DTPA-D-Phe¹-octreotide, the renal metabolism of this compound was compared with ^{111}In -DTPA-L-Phe¹-octreotide, where the N-terminal D-phenylalanine was replaced with L-phenylalanine to facilitate metabolism. DTPA-D-Phe¹-octreotide and DTPA-L-Phe¹-octreotide were synthesized by solid-phase methods. Both ^{111}In -DTPA-conjugated octreotide analogues were prepared with radiochemical yields of over 96%, and both remained stable after a 3 h incubation in murine serum at 37 °C. When injected into mice, the two ^{111}In -DTPA-conjugated octreotide analogues showed similar radioactivity elimination rates from the blood and accumulation in the kidney with about 60% injected radioactivity being excreted in the urine by 24 h postinjection. Over 85% of the radioactivity in the urine existed as intact peptides for both analogues. Despite the similar renal radioactivity levels, significant differences were observed in the radiolabeled species remaining in the kidney between the two; while ^{111}In -DTPA-L-Phe¹-octreotide was rapidly metabolized to the final radiometabolite, ^{111}In -DTPA-L-Phe, the metabolic rate of ^{111}In -DTPA-D-Phe¹-octreotide was so slow that various intermediate radiolabeled species were observed. However, both ^{111}In -DTPA-D-Phe and ^{111}In -DTPA-L-Phe remained in the lysosomal compartment of the renal cells as the final radiometabolites for long periods. These findings indicated that although the metabolic stability of ^{111}In -DTPA-D-Phe¹-octreotide in the renal cells may be partially involved, the slow elimination rate of the radiometabolite derived from ^{111}In -DTPA-D-Phe¹-octreotide from the lysosomal compartment of renal cells would be predominantly attributable to the persistent renal radioactivity levels of ^{111}In -DTPA-D-Phe¹-octreotide.

INTRODUCTION

Oncophilic low molecular weight peptides and polypeptides have attracted attention as new vehicles to deliver radioactivity to target tissues within a short postinjection period. In particular, the ^{111}In -labeled synthetic somatostatin analogue, ^{111}In -DTPA-D-Phe¹-octreotide (Figure 1), has been used clinically for imaging somatostatin receptor-positive tumors such as gastrointestinal pancreatic tumors, neuroblastoma, pheochromocytoma, breast cancer, Hodgkin's lymphoma, and small cell lung cancer (1). Besides being prepared by a simple kit formulation with specific activities and radiochemical purities sufficient for clinical applications, ^{111}In -DTPA-D-Phe¹-octreotide reduces upper abdominal radioactivity levels that are observed with a radioiodinated octreotide analogue (2). After administration, the ^{111}In -labeled peptide was cleared from the body predominantly by the kidney, 50% within the first 4.5 h; however, by 4 h postinjection, about 7% of the injected radioactivity was taken up into the renal parenchyma, and about 5% remained at 48 h, which eventually reduced the sensitivity of detection for small

tumors located in the perirenal region in the abdomen (2). Since reduction of the renal radioactivity levels of ^{111}In -DTPA-D-Phe¹-octreotide would markedly improve diagnostic accuracy, further clarification of the mechanisms responsible for the persistent renal localization of the radioactivity of this compound is warranted.

Recent studies indicated that the renal radioactivity levels of ^{111}In -DTPA-D-Phe¹-octreotide can be reduced by infusion of basic amino acids such as L-lysine (3, 4). A previous study of ^{111}In -DTPA-D-Phe¹-octreotide in rats indicated that the radioactivity is localized in the lysosomal compartments in the pancreas, tumor, and kidney

Reagents: (a) dicyclohexylcarbodiimide, *N*-hydroxysuccinimide; (b) H_2 gas, 10 % palladium on carbon; (c) trifluoroacetic acid, anisole; (d) dicyclohexylcarbodiimide, *N*-hydroxysuccinimide; (e) trifluoroacetic acid, anisole

even early postinjection (5). These findings suggested that ^{111}In -DTPA-D-Phe¹-octreotide would be reabsorbed at the renal tubules after glomerular filtration, followed by transfer to the lysosomal compartment, as has been documented with many polypeptides metabolized in the kidney (6, 7).

Although these findings portray *in vivo* behaviors of ^{111}In -DTPA-D-Phe¹-octreotide, further studies are required to determine what happens to the radiolabel after incorporation of this compound in the renal cells. In addition, since the parent peptide, octreotide, is originally designed to possess high metabolic stability against *in vivo* degradation, the metabolic stability of octreotide may also be responsible for the persistent radioactivity levels in the kidney. The answers to these questions would provide an insight for better understanding of the persistent renal radioactivity levels of ^{111}In -DTPA-D-Phe¹-

octreotide and would also contribute to the design of radiolabeled somatostatin analogues more suitable for diagnosis and applicable to therapy.

In the present study, ^{111}In -DTPA-D-Phe¹-octreotide was administered to mice, and the radiolabeled species remaining in the kidney and excreted in the urine were analyzed. To investigate the role played by the metabolic stability of the parent peptide, octreotide, in renal radioactivity levels, the ^{111}In -labeled octreotide analogue, ^{111}In -DTPA-L-Phe¹-octreotide, where the N-terminal D-phenylalanine (D-Phe) of DTPA-D-Phe¹-octreotide was replaced with L-phenylalanine (L-Phe) (Figure 1), was synthesized to facilitate metabolic rate. The biodistribution of the radioactivity and the radiolabeled species remaining in the kidney and excreted in the urine after administration of ^{111}In -DTPA-L-Phe¹-octreotide were analyzed and compared with those of ^{111}In -DTPA-D-Phe¹-

octreotide. The subcellular localization of the radioactivity after administration of each of the two ^{111}In -labeled octreotide analogues was also determined.

MATERIALS AND METHODS

Reagents and Chemicals. $^{111}\text{InCl}_3$ (2.5–129.5 MBq/mL in 0.02 N HCl) was kindly supplied by Nihon-Medical Physics (Tokyo, Japan). Nonradioactive indium chloride was purchased from Nacalai Tesque as $\text{InCl}_3 \cdot 4\text{H}_2\text{O}$ (Kyoto, Japan). Reversed-phase high-performance liquid chromatography (RP-HPLC) was performed with a Cosmosil 5C₁₈-MS column (4.6 $\times$ 150 mm, Nacalai Tesque, Kyoto). ^{111}In -DTPA-D-Phe¹-octreotide was eluted with 5% methanol in 0.05 M acetate buffer (pH 5.5) for the first 15 min, followed by a linear gradient of 5 to 55% methanol in 0.05 M acetate buffer (pH 5.5) in 10 min. The final solvent composition was maintained for a further 25 min. ^{111}In -DTPA-L-Phe¹-octreotide was eluted with 5% methanol in 0.05 M acetate buffer (pH 5.5) for the first 15 min, followed by a linear gradient of 5 to 60% methanol in 0.05 M acetate buffer (pH 5.5) in 10 min. The final solvent composition was maintained for a further 25 min. Cellulose acetate electrophoresis (CAE; Joko Co. Ltd., Tokyo) was run at an electrostatic field of 0.8 mA/cm for 40 min in veronal buffer ($I = 0.06$, pH 8.6; Nacalai Tesque). 1-*tert*-Butyl hydrogen 3,6,9-tris(*tert*-butoxycarbonyl)methyl-3,6,9-triazaundecanedioic acid (mDTPA) was synthesized as reported previously (8). Proton nuclear magnetic resonance (^1H NMR) spectra were recorded on a Bruker AC-200 spectrometer, and the chemical shifts are reported in parts per million downfield from an internal tetramethylsilane standard. Fast-atom bombardment mass spectra (FABMS) were obtained with a JMS-HX/HX110 A model (JEOL Ltd., Tokyo). Other reagents were of reagent grade and used as received. To facilitate collection of urine and feces by 24 h postinjection of ^{111}In -labeled peptides, mice were housed in metabolic cages (Metabolica, MM type; Sugiyama-Gen Iriki Co. Ltd., Tokyo).

DTPA-D-Phe. To a solution of mDTPA (536 mg, 0.868 mmol) and *N*-hydroxysuccinimide (109.84 mg, 0.954 mmol) in 0.5 mL of dimethylformamide (DMF) was added a solution of dicyclohexylcarbodiimide (196.2 mg, 0.954 mmol) in 0.5 mL of DMF at 0 °C, and the reaction mixture was stirred for 4 h at room temperature. After cooling to 0 °C again, a mixed solution of *D*-phenylalanine benzyl ester *p*-toluenesulfonate (370.93 mg, 0.868 mmol) and *N,N*-diisopropylethylamine (112.25 mg, 0.868 mmol) in 0.5 mL of DMF was then added slowly to maintain the temperature. The resulting reaction mixture was warmed to room temperature, and stirring was continued for 18 h. After filtration of the precipitate, the filtrate was extracted with 200 mL of ethyl acetate, and the organic layer was washed with a saturated aqueous solution of NaHCO_3 (150 mL $\times$ 3). After drying over anhydrous calcium sulfate, the solvent was removed in vacuo. The residue was chromatographed on silica gel using a mixture of chloroform-methanol (25:1) as an eluent to yield DTPA-D-Phe with the four carboxylates of DTPA protected with *tert*-butyl groups, while the carboxylate of *D*-Phe was protected with a benzyl group as a pale yellow oil (411.4 mg; 55.5%).

A mixture of the intermediate compound and 10% palladium on carbon (0.14 g) in ethyl acetate (4 mL) was hydrogenated at room temperature for 60 h. The catalyst was removed by filtration, and the filtrate was evaporated in vacuo to provide DTPA-D-Phe with the four carboxylates of DTPA protected with *tert*-butyl groups, as a pale yellow oil (166.8 mg, 45.3%).

A mixture of anisole (51 μL , 0.471 mmol) and trifluoroacetic acid (TFA, 1.5 mL) was added to the final intermediate at 0 °C. The reaction mixture was stirred for 5 min at 0 °C and then warmed to room temperature, and stirring was continued for further 7 h. After removing TFA in vacuo, ether (5 mL) was added to the residue to precipitate DTPA-D-Phe as a colorless solid (43.0 mg, 90.4%). ^1H NMR (DMSO-*d*₆): 2.84–3.20 (10H, m, $\text{CH}_2\text{CH}_2\text{-CH}_2\text{C}_6\text{H}_5$), 3.30 (2H, s, NCH_2CO), 3.31 (2H, s, NCH_2CO), 3.49 (4H, s, NCH_2CO), 3.96 (2H, s, NCH_2CO), 4.42–4.51 (1H, m, NHCH), 7.16–7.31 (5H, m, aromatic), 8.28 (1H, d, CONH). FABMS for $\text{C}_{22}\text{H}_{31}\text{N}_4\text{O}_9$ (MH^+): m/z calcd, 541; found, 541. Anal. Calcd. for $\text{C}_{22}\text{H}_{30}\text{N}_4\text{O}_9 \cdot 3/2\text{H}_2\text{O} \cdot 2/5\text{CF}_3\text{COOH} \cdot 1/5\text{C}_2\text{H}_5\text{OC}_2\text{H}_5$: C, 47.05; H, 6.00; N, 8.92; F, 3.63. Found: C, 47.09; H, 5.85; N, 8.70; F, 3.42.

DTPA-L-Phe. *L*-Phenylalanine *tert*-butyl ester hydrochloride (199.2 mg, 0.818 mmol) and the mDTPA (252.5 mg, 0.409 mmol) were condensed according to the procedure similar to those described above using acetonitrile as a solvent. The reaction gave DTPA-L-Phe with all the carboxylates being protected with *tert*-butyl groups, as a pale yellow oil (97.7 mg, 29.1%). The oily product was treated with TFA-anisole according to the procedure described above, and DTPA-L-Phe was obtained as a colorless solid (41.8 mg, 81.3%). ^1H NMR (DMSO-*d*₆): 2.84–3.17 (10H, m, $\text{CH}_2\text{CH}_2\text{-CH}_2\text{C}_6\text{H}_5$), 3.26 (2H, s, NCH_2CO), 3.29 (2H, s, NCH_2CO), 3.47 (4H, s, NCH_2CO), 3.77 (2H, s, NCH_2CO), 4.41–4.50 (1H, m, NHCH), 7.16–7.30 (5H, m, aromatic), 8.24 (1H, d, CONH). FABMS for $\text{C}_{22}\text{H}_{31}\text{N}_4\text{O}_9$ (MH^+): m/z calcd, 541; found, 541. Anal. Calcd. for $\text{C}_{22}\text{H}_{30}\text{N}_4\text{O}_9 \cdot \text{H}_2\text{O} \cdot 3/10\text{CF}_3\text{COOH} \cdot 1/4\text{C}_2\text{H}_5\text{O-C}_2\text{H}_5$: C, 48.17; H, 6.04; N, 9.11; F, 3.09. Found: C, 48.19; H, 6.01; N, 9.20; F, 2.91.

DTPA-D-Phe¹-Octreotide and DTPA-L-Phe¹-Octreotide. DTPA-D-Phe¹-octreotide was synthesized using mDTPA, as described previously (9). DTPA-L-Phe¹-octreotide was synthesized according to the procedures similar to those used for DTPA-D-Phe¹-octreotide except for the use of *N*^α-Fmoc-L-Phe in place of *N*^α-Fmoc-D-Phe (where Fmoc is 9-fluorenylmethoxycarbonyl). The amino acid ratios after 6 N HCl hydrolysis of DTPA-L-Phe¹-octreotide were as follows: Thr $\times$ 1, 1.03; Phe $\times$ 2, 2.00; Lys $\times$ 1, 1.10. The matrix-assisted laser-desorption/ionization time-of-flight mass spectra (Voyager-DE RP; PerSeptive Biosystems, Tokyo) for $\text{C}_{63}\text{H}_{88}\text{N}_{13}\text{O}_{19}\text{S}_2$ (MH^+): m/z calcd, 1394.57; found, 1394.94.

Radiolabeling of DTPA-D-Phe¹-Octreotide and DTPA-L-Phe¹-Octreotide. Two lyophilized kits (one containing DTPA-D-Phe¹-octreotide, 10 μg , and the other containing DTPA-L-Phe¹-octreotide, 10 μg), with trisodium citrate (4.91 mg), citric acid (0.37 mg), inositol (10.0 mg), and gentisic acid (2.0 mg) were prepared using ultrapure water (Milli Q, Millipore Japan, Tokyo). The ^{111}In radiolabeling of DTPA-conjugated octreotide analogues was performed by addition of 1 mL solution of $^{111}\text{InCl}_3$ (2.5–129.5 MBq) to each kit. After standing at room temperature for 1 h, ^{111}In -DTPA-D-Phe¹-octreotide and ^{111}In -DTPA-L-Phe¹-octreotide were each subjected to RP-HPLC purification to exclude non-peptide-bound ^{111}In species and unchelated peptides. An appropriate amount of DTPA-D-Phe¹-octreotide or DTPA-L-Phe¹-octreotide was then added to fractions containing the respective ^{111}In -labeled peptide, and the solvent was removed in vacuo. A HEPES [2-[4-(2-hydroxyethyl)-1-piperazinyl]ethanesulfonic acid]-buffered solution containing 0.1% human serum albumin (HSA) was added to the residue to prepare ^{111}In -labeled octreotide analogues each containing 0.1 μg of the DTPA-peptide in 100 μL for biodistribution studies and 150 μL for metabolic

Figure 2. Radioactivity profiles of ^{111}In -DTPA-D-Phe¹-octreotide and ^{111}In -DTPA-L-Phe¹-octreotide by (A) RP-HPLC and (B) CAE.

studies. The radiochemical purities of ^{111}In -DTPA-D-Phe¹-octreotide and ^{111}In -DTPA-L-Phe¹-octreotide exceeded 96% as determined by RP-HPLC and CAE analyses. Under the analytical conditions, both ^{111}In -DTPA-D-Phe¹-octreotide and ^{111}In -DTPA-L-Phe¹-octreotide showed two radioactivity peaks on the RP-HPLC (Figure 2), as reported previously (10).

Preparation of ^{111}In -DTPA-D-Phe, ^{111}In -DTPA-L-Phe, and ^{111}In -DTPA. The ^{111}In radiolabeling of DTPA-D-Phe, DTPA-L-Phe, and DTPA was performed according to the procedure described previously (8). Briefly, a solution of sodium acetate (1 M, 10 μL) was mixed with 40 μL of a diluted solution of $^{111}\text{InCl}_3$ (0.37–0.74 MBq/mL) in 0.02 N HCl. After the mixture was allowed to stand for 5 min, a 10 μL aliquot of DTPA-D-Phe, DTPA-L-Phe, or DTPA (20 μM) in 20 mM MES [2-(*N*-morpholino)ethanesulfonic acid]-buffered saline (pH 6.0) was added, and the reaction mixture was incubated at room temperature for 1 h. ^{111}In -DTPA-D-Phe, ^{111}In -DTPA-L-Phe, and ^{111}In -DTPA were obtained with radiochemical yields of over 97% by RP-HPLC and CAE analyses and used without further purification. ^{111}In -DTPA-D-Phe gave two peaks at retention times of 5 and 10 min on RP-HPLC, whereas ^{111}In -DTPA-L-Phe gave two peaks at retention times of 6 and 11 min. On the other hand, both ^{111}In -DTPA-D-Phe and ^{111}In -DTPA-L-Phe gave a single peak at a migration distance of 2 cm to the anode by CAE analysis. ^{111}In -DTPA had a retention time of 2 min on the RP-HPLC and showed a single peak at a migration distance of 2.5 cm to the anode by CAE analysis.

To further characterize the standards, nonradioactive indium was reacted with DTPA-D-Phe or DTPA-L-Phe as follows: a solution of $\text{InCl}_3 \cdot 4\text{H}_2\text{O}$ (3.4 mg/100 μL) in 0.05 M acetic acid was added to a solution of DTPA-D-Phe or DTPA-L-Phe (6.2 mg/100 μL) in 0.05 M acetic acid. After incubation for 30 min at room temperature, the reaction mixture was analyzed by FABMAS and RP-HPLC under the conditions described above. FABMAS of both In -DTPA-D-Phe and In -DTPA-L-Phe showed a peak at m/z 653 in the positive ion mode and 651 in the negative ion mode, respectively. The RP-HPLC trace (254 nm) of In -

DTPA-L-Phe showed two peaks at retention times of 6 and 11 min, while that of In -DTPA-D-Phe showed two peaks at retention times of 5 and 10 min. RP-HPLC analysis of one component (5 min) of In -DTPA-D-Phe showed two peaks at retention times of 5 and 10 min, indicating that In -DTPA-D-Phe eluted as well-separated isomers under the analytical conditions. Similar findings were obtained with another component of In -DTPA-D-Phe and with each component of In -DTPA-L-Phe.

Serum Stability of ^{111}In -DTPA-D-Phe¹-Octreotide and ^{111}In -DTPA-L-Phe¹-Octreotide. Aliquots of 1.5 μL solutions of ^{111}In -DTPA-D-Phe¹-octreotide or ^{111}In -DTPA-L-Phe¹-octreotide (1 ng, 71.7 kBq) were added to freshly prepared murine serum (400 μL), and the mixtures were incubated at 37 $^\circ\text{C}$. After incubation for 1 and 3 h, 50 μL aliquots of the samples were drawn, and the radioactivity was analyzed by CAE. The radioactivity in the serum was also analyzed by RP-HPLC after filtering through a 10 kDa cutoff ultrafiltration membrane (Microcon-10, Amicon Inc., Beverly, MA).

In Vivo Studies. Biodistributions of radioactivity after intravenous administration of ^{111}In -DTPA-D-Phe¹-octreotide or ^{111}In -DTPA-L-Phe¹-octreotide into 6-week-old male ddY normal mice (11) weighing 28–30 g were monitored at 10 and 30 min and 1, 3, 6, and 24 h postinjection. Groups of five mice which received 0.1 μg of radiolabeled peptide were used for the experiments. The organs of interest were removed and weighed, and the radioactivity was determined with a well counter (Aloka ARC 2000, Tokyo).

To determine the amounts and routes of the radioactivity excreted from the body, mice were housed in metabolic cages for 24 h after administration of the respective preparations, and urine and feces were collected and the radioactivity was determined.

The radiolabeled species remaining in the kidney at 1, 3, and 24 h postinjection and excreted in the urine by 24 h postinjection were analyzed according to the procedure described previously (12). Briefly, each ^{111}In -labeled octreotide analogue (0.1 μg , 37–45 MBq) was administered intravenously into 6-week-old male ddY mice. At 1, 3, and 24 h postinjection, both kidneys were perfused in situ with cold 0.1 M Tris-citrate buffer (pH 6.5) containing 0.15 M NaCl, 0.02% sodium azide, 1 TIU/mL aprotinin, 2 mM benzamidine-HCl, 2 mM iodoacetamide, 1 mM phenylmethanesulfonyl fluoride, and 5 mM diisopropyl fluorophosphate before being removed. Each tissue sample was placed in a test tube and subjected to three cycles of freezing (dry ice–acetone bath) and thawing. After addition of 5 vol of the same buffer containing an additional 35 mM β -octyl-glucoside, the sample was homogenized with a Polytron homogenizer (PT10-35, Kinematica GmgH Littau, Switzerland) at full speed with three consecutive 30 s bursts on ice before centrifugation at 48000g for 20 min at 4 $^\circ\text{C}$ (Himac CS-120 Centrifuge, Hitachi Co., Tokyo). The supernatant was separated from the pellet, and the radioactivity was counted. The kidney supernatant and the urine samples were analyzed immediately by CAE after filtration through a polycarbonate membrane with a pore diameter of 0.45 μm (Myrex, Millipore). The samples were also analyzed immediately by RP-HPLC after filtering through a 10 kDa cutoff ultrafiltration membrane (Microcon-10, Amicon). Each analysis was also performed by co-chromatography with ^{111}In -DTPA-D-Phe, ^{111}In -DTPA-L-Phe, or ^{111}In -DTPA.

The subcellular distribution of radioactivity in murine kidney after administration of ^{111}In -DTPA-D-Phe¹-octreotide or ^{111}In -DTPA-L-Phe¹-octreotide was determined

by perfusing the organ in situ with cold 0.25 M sucrose buffered with 10 mM phosphate buffer (pH 7.4) at 1 and 24 h postinjection. The kidney was treated according to the procedure described previously (13). Briefly, the kidney was suspended in 4 vol of 0.25 M sucrose buffered with 10 mM phosphate buffer (pH 7.4) and homogenized with a Dounce homogenizer by hand (20 strokes), followed by two final strokes in an ice-cooled Potter-Elvehjem homogenizer at 800 rpm. The 20% homogenate was centrifuged twice for 5 min each time at 340g for 4 °C. The isolated supernatant (0.45 mL) was layered onto iso-osmotic (0.25 M sucrose) 37.5% Percoll (9 mL, Pharmacia Biotech Co., Tokyo) at a density of 1.08 g/mL. After centrifugation at 20000g (RP 30 Rotar; Hitachi Co., Tokyo) for 90 min at 4 °C, the gradient (1.02 to 1.16 g/mL) was collected in 14 fractions before analyses of β -galactosidase (14), alkaline phosphodiesterase I activities (15), density, and the radioactivity of each fraction.

Statistical Analyses. Data are expressed as means (standard deviation) where appropriate. The results were analyzed using the unpaired Mann-Whitney test. Differences between $^{111}\text{In-DTPA-L-Phe}^1\text{-octreotide}$ and $^{111}\text{In-DTPA-D-Phe}^1\text{-octreotide}$ results were considered significant when the *p* value was less than 0.05.

RESULTS

Serum Stability. When incubated in freshly prepared murine serum at 37 °C for 3 h, 95.5 and 96.5% of the initial radioactivity were detected by RP-HPLC as the intact form for $^{111}\text{In-DTPA-D-Phe}^1\text{-octreotide}$ and $^{111}\text{In-DTPA-L-Phe}^1\text{-octreotide}$, respectively. No significant differences were observed in the serum stability between the two $^{111}\text{In-DTPA}$ -conjugated octreotide analogues. Similar results were obtained with CAE analyses.

In Vivo Studies. The biodistributions of radioactivity after administrations of $^{111}\text{In-DTPA-D-Phe}^1\text{-octreotide}$ and $^{111}\text{In-DTPA-L-Phe}^1\text{-octreotide}$ are shown in Table 1. Both $^{111}\text{In-DTPA}$ -conjugated peptides displayed rapid clearance of the radioactivity from the blood with similar elimination rates. The two peptides also showed similar tissue distributions of the radioactivity from 10 min to 6 h postinjection, although slight differences were observed in some tissues. At 24 h postinjection, no significant differences were observed in the radioactivity levels remaining in the tissues and excreted from the body between the two peptides.

The supernatant of kidney homogenate was extracted with efficiencies of over 90% for both $^{111}\text{In-DTPA-D-Phe}^1\text{-octreotide}$ and $^{111}\text{In-DTPA-L-Phe}^1\text{-octreotide}$ at all postinjection times. The RP-HPLC radioactivity profiles of the kidney supernatants at 1, 3, and 24 h postinjection and those of the urine by 24 h postinjection of the two $^{111}\text{In-DTPA}$ -peptides are shown in Figure 3. In the kidney, $^{111}\text{In-DTPA-D-Phe}^1\text{-octreotide}$ was gradually metabolized to the final radiometabolite via various intermediate species. At 24 h postinjection, the major radioactivity in the kidney had retention times identical to those of $^{111}\text{In-DTPA-D-Phe}$, which was confirmed by co-chromatographic analysis using $^{111}\text{In-DTPA-D-Phe}$ as a standard. Even at this postinjection time point, the intermediate radiolabeled species were still observed in the kidney. RP-HPLC analysis of the urine by 24 h postinjection of $^{111}\text{In-DTPA-D-Phe}^1\text{-octreotide}$ showed that the major radioactivity was observed with retention times identical to those of the intact $^{111}\text{In-DTPA-D-Phe}^1\text{-octreotide}$. Similar results were obtained by CAE analyses of the kidney homogenates. The radiolabeled species in the kidney and

urine determined by RP-HPLC are summarized in Table 2, where the radiolabeled species are classified into four groups; intact $^{111}\text{In-DTPA-D-Phe}^1\text{-octreotide}$, intermediate species eluted at the retention times between the intact peptide and the final radiometabolite, final radiometabolite (coeluted with $^{111}\text{In-DTPA-D-Phe}$), and others that represented radiolabeled species eluted earlier than the final radiometabolite (e.g., $^{111}\text{In-DTPA}$). At 3 h postinjection, the intermediate radiolabeled species represented about 60% of the radioactivity in the kidney. At 24 h postinjection, about 77% of the radioactivity in the kidney was present as the final radiometabolite. In the urine, over 85% and about 10% of the radioactivity was associated with the intact peptide and the intermediate species, respectively, whereas the final radiometabolite represented only about 3% of the radioactivity.

The radiolabeled species found in the kidney at 1, 3, and 24 h postinjection of $^{111}\text{In-DTPA-L-Phe}^1\text{-octreotide}$ are illustrated in Figure 3. The radioactivity profiles for the kidney supernatants showed much less radiolabeled species when compared with those of $^{111}\text{In-DTPA-D-Phe}^1\text{-octreotide}$. At 3 h postinjection, most of the radioactivity was detected at retention times identical to those of $^{111}\text{In-DTPA-L-Phe}$, which was confirmed by the co-

^a Radiolabeled species in each fraction determined by RP-HPLC analyses. Mean (sd) of three experiments. ^b Radiolabeled species eluted earlier times than ^{111}In -DTPA-D-Phe (e.g. ^{111}In -DTPA).

Figure 3. RP-HPLC radioactivity profiles of kidney homogenates at 1 (A), 3 (B), and 24 h (C) and urine samples by 24 h (D) postinjection of ^{111}In -DTPA-D-Phe¹-octreotide and ^{111}In -DTPA-L-Phe¹-octreotide. The kidney homogenates at 24 h (C) were eluted in the absence (●) or in the presence (○) of ^{111}In -DTPA-D-Phe or ^{111}In -DTPA-L-Phe for ^{111}In -DTPA-D-Phe¹-octreotide or ^{111}In -DTPA-L-Phe¹-octreotide, respectively.

chromatographic analysis using ^{111}In -DTPA-L-Phe as a standard. At 24 h, the radioactivity profiles of the kidney were almost identical to those at 3 h except that the radioactivity peak at around 32 min disappeared and a new small peak was observed at a retention time of 2 min. The analysis of urine by 24 h postinjection of ^{111}In -DTPA-L-Phe¹-octreotide showed that the major radioactivity was observed at retention times identical to those of the intact ^{111}In -DTPA-L-Phe¹-octreotide, and small radioactivity peaks corresponding to the final radiometabolites were also detected. Similar results were obtained by CAE analyses of the kidney homogenates. The radiolabeled species in the kidney and the urine determined by RP-HPLC are summarized in Table 3. The final radiometabolite represented over 57 and 93% of the radioactivity in the kidney at 1 and 3 h

Figure 4. CAE radioactivity profiles of kidney homogenates at 24 h (A) and urine samples by 24 h (B) postinjection of ^{111}In -DTPA-D-Phe¹-octreotide and ^{111}In -DTPA-L-Phe¹-octreotide. The kidney homogenates were co-analyzed in the absence (●) or in the presence (○) of ^{111}In -DTPA-D-Phe or ^{111}In -DTPA-L-Phe for ^{111}In -DTPA-D-Phe¹-octreotide or ^{111}In -DTPA-L-Phe¹-octreotide, respectively.

postinjection, respectively. At 24 h postinjection, the final radiometabolite represented over 96% of the radioactivity in the kidney. However, the intact peptide was the predominant radiolabeled species in the urine where the final radiometabolite represented less than 10% of the radioactivity.

Figure 4 illustrates the CAE radioactivity profiles of the kidney supernatant obtained at 24 h postinjection and the urine samples collected by 24 h postinjection of ^{111}In -DTPA-D-Phe¹-octreotide and ^{111}In -DTPA-L-Phe¹-octreotide, respectively. In the kidney supernatant, two radioactivity peaks were observed and the majority of the radioactivity was detected at a position similar to that of ^{111}In -DTPA-D-Phe or ^{111}In -DTPA-L-Phe. Analyses of urine samples indicated one major and one minor radioactivity peak with the majority of the radioactivity being detected at positions similar to those of the intact ^{111}In -labeled peptides.

The Percoll density gradient centrifugation profiles of the radioactivity in the kidney at 1 and 24 h postinjection of ^{111}In -DTPA-D-Phe¹-octreotide and ^{111}In -DTPA-L-Phe¹-octreotide are illustrated in Figure 5. Each kidney homogenate indicated a similar radioactivity profile with a major radioactivity peak being observed at a density of about 1.10 g/mL, which correlated well with the β -galactosidase activity profiles.

Table 3. Radiolabeled Species in the Kidney and Urine after Administration of ^{111}In -DTPA-L-Phe¹-Octreotide in Mice

^a Radiolabeled species in each fraction determined by RP-HPLC analyses. Mean (sd) of three experiments. ^b Radiolabeled species eluted earlier times than ^{111}In -DTPA-L-Phe (e.g., ^{111}In -DTPA).

Figure 5. Subcellular fractionation of the kidney at 1 (A) and 24 h (B) postinjection of ^{111}In -DTPA-D-Phe¹-octreotide and 1 (C) and 24 h (D) postinjection of ^{111}In -DTPA-L-Phe¹-octreotide in mice. Fractions were collected from the top of the gradient and assayed for radioactivity (●); lysosomal enzyme, β -galactosidase (Δ); plasma membrane enzyme, alkaline phosphodiesterase I ($\square$); density ($\circ$).

DISCUSSION

To identify the fate of the radiolabel after incorporation of ^{111}In -DTPA-D-Phe¹-octreotide in the renal cells, radiolabeled species remaining in the kidney and excreted in the urine were investigated after administration of ^{111}In -DTPA-D-Phe¹-octreotide and ^{111}In -DTPA-L-Phe¹-octreotide in experimental animals. After radiolabeling with ^{111}In , free DTPA-peptides were separated by RP-HPLC to prepare ^{111}In -DTPA-D-Phe¹-octreotide and ^{111}In -DTPA-L-Phe¹-octreotide with similar specific activity and radiochemical purity for subsequent studies.

The unchanged radioactivity profiles of ^{111}In -DTPA-D-

Phe¹-octreotide and ^{111}In -DTPA-L-Phe¹-octreotide after incubation in freshly prepared murine serum indicated that both ^{111}In -DTPA-conjugated octreotide analogues remained stable against transchelation with serum proteins. These findings also demonstrated that the replacement of the N-terminal D-Phe of ^{111}In -DTPA-D-Phe¹-octreotide with L-Phe did not result in any proteolytic degradation by serum enzymes.

In mouse biodistribution studies, both ^{111}In -DTPA-D-Phe¹-octreotide and ^{111}In -DTPA-L-Phe¹-octreotide showed rapid clearance of the radioactivity from the blood at similar rates (Table 1). In light of the high serum

stability and rapid blood clearance of the two ^{111}In -labeled peptides (Table 1), both ^{111}In -DTPA-D-Phe¹-octreotide and ^{111}In -DTPA-L-Phe¹-octreotide appeared to accumulate in the kidney and other tissues as their intact structures. Thus, the replacement of the N-terminal D-Phe of ^{111}In -DTPA-D-Phe¹-octreotide with L-Phe induced little changes in the *in vivo* behavior. This was supported by the similar amounts and routes of the radioactivity excreted from the body by 24 h postinjection of the ^{111}In -DTPA-peptides. In addition, ^{111}In -DTPA-D-Phe¹-octreotide and ^{111}In -DTPA-L-Phe¹-octreotide demonstrated similar subcellular localization patterns of the radioactivity at 1 and 24 h postinjection (Figure 5). The major radioactivity peak was observed in the lysosomal compartment, reinforcing that ^{111}In -DTPA-D-Phe¹-octreotide is rapidly delivered to the lysosomal compartment after incorporation into renal cells (5).

However, marked differences were observed between the two ^{111}In -labeled peptides when the radiolabeled species remaining in the kidney were compared. While ^{111}In -DTPA-D-Phe¹-octreotide and ^{111}In -DTPA-L-Phe¹-octreotide generated ^{111}In -DTPA-D-Phe and ^{111}In -DTPA-L-Phe, respectively, as the final radiometabolite in the kidney (Figures 3 and 4), different metabolic rates of the two ^{111}In -labeled peptides were observed in the kidney (Tables 2 and 3). ^{111}In -DTPA-D-Phe¹-octreotide was degraded to ^{111}In -DTPA-D-Phe via various intermediate species that represented over 57% of the radioactivity in the kidney even at 3 h postinjection. In contrast, the metabolic rate of ^{111}In -DTPA-L-Phe¹-octreotide was so rapid that over 93% of the radioactivity in the kidney was in the form of the final radiometabolite at the same postinjection timepoint. In addition, ^{111}In -DTPA-L-Phe¹-octreotide generated much fewer intermediate radiometabolites in the kidney. Thus, while replacement of the N-terminal D-Phe of ^{111}In -DTPA-D-Phe¹-octreotide with L-Phe preserved the metabolic stability in serum, this modification markedly impaired the metabolic stability of the resulting peptide in the lysosomes. The presence of the D-Phe-L-Cys sequence in ^{111}In -DTPA-D-Phe¹-octreotide was probably resistant to lysosomal proteolysis, which would have produced multiple intermediate radiometabolites along with the slow generation rate of the final radiometabolite. This was supported by recent findings of Bass et al. who demonstrated that the major intermediate species of ^{111}In -DTPA-D-Phe¹-octreotide in the rat kidney was ^{111}In -DTPA-D-Phe-Cys (16). When the N-terminal D-Phe was replaced with L-Phe, lysosomal proteolysis of ^{111}In -DTPA-L-Phe¹-octreotide proceeded much more rapidly, although ^{111}In -DTPA chelate was attached to the N-terminal L-Phe. These findings suggested that replacement of the N-terminal D-amino acid with the L-form would facilitate lysosomal proteolysis without impairing serum stability when ^{111}In -DTPA chelate is attached to the α -amino group of the N-terminal amino acid of peptides.

Despite the significant differences in the metabolic rates between the two ^{111}In -labeled peptides, only a slight difference was observed in the radioactivity levels between ^{111}In -DTPA-D-Phe¹-octreotide and ^{111}In -DTPA-L-Phe¹-octreotide in the kidney (Table 1). In addition, similar amounts of radioactivity were retained in the kidney at 24 h and excreted in the urine by 24 h postinjection of the respective ^{111}In -labeled peptide. The intact ^{111}In -labeled peptide represented as much as 85% of the radiolabeled species in both urine samples (Tables 2 and 3). Thus, while replacement of the N-terminal D-Phe with L-Phe accelerated the metabolic rate of ^{111}In -labeled octreotide analogues in the lysosomes, little

improvement was achieved in the renal radioactivity levels by this modification, due to the slow elimination rate of the final radiometabolite, ^{111}In -DTPA-L-Phe, from the renal cells.

Recent metabolic studies of ^{111}In -DTPA-labeled polypeptides in the liver indicated that the final radiometabolites of the polypeptides were observed as the ^{111}In -DTPA-adduct of L-lysine, and that the radiometabolite is retained in the lysosomal compartment of the tissues for a long time postinjection (17–19). A previous study by Rogers et al. also suggested that even when ^{111}In -DTPA was attached to an α amino group of the N-terminal aspartic acid of an antibody, ^{111}In -DTPA-aspartic acid was generated as the final radiometabolite and the radiometabolite showed persistent localization within the tissues (20). In the present study, ^{111}In -DTPA-D-Phe and ^{111}In -DTPA-L-Phe were generated as the final radiometabolites after administration of ^{111}In -DTPA-D-Phe¹-octreotide and ^{111}In -DTPA-L-Phe¹-octreotide, respectively, and both radiometabolites remained in the kidney for long periods postinjection. Thus, although the slow metabolic rate of ^{111}In -DTPA-D-Phe¹-octreotide may be partially involved, the generation of the ^{111}In -DTPA-adduct of an amino acid as the final radiometabolite would be predominantly responsible for the prolonged retention of the radioactivity in the kidney. Since both ^{111}In -DTPA-L-Phe and ^{111}In -DTPA-D-Phe were retained in the kidney, the generation of D-amino acid adduct of ^{111}In -DTPA would have little effect on the radioactivity levels in the kidney. These findings suggested that the ^{111}In -DTPA-adduct of acidic, basic, and aromatic amino acid would be barely excreted extracellularly. However, a recent study by Wu et al. indicated that when a ^{67}Ga -labeled antibody fragment using 2-(*p*-isothiocyanatobenzyl)-1,4,7-triazacyclononane-1,4,7-triacetic acid (SCN-Bz-NOTA) as the bifunctional chelating agent was administered, methionine-SCN-Bz-NOTA- ^{67}Ga and lysine-SCN-Bz-NOTA- ^{67}Ga were generated as radiometabolites in the kidney and the former had significantly shorter residence time than the latter in mouse renal cells (21). Thus, further studies are warranted to elucidate whether the long residence times of ^{111}In -DTPA-adduct of amino acids are attributable to inherent characteristics of ^{111}In -DTPA chelate or to the biological characteristics of amino acids conjugated with ^{111}In -DTPA chelate. Such studies would provide an insight for design of ^{111}In -labeled peptides and polypeptides using DTPA as the chelating agent.

In conclusion, the present findings combined with those of previous studies (3–5, 16) indicated the following *in vivo* behavior of ^{111}In -DTPA-D-Phe¹-octreotide: after administration, the majority of ^{111}In -DTPA-D-Phe¹-octreotide is excreted into urine as the intact structure following glomerular filtration. However, some of the glomerularly filtered ^{111}In -DTPA-D-Phe¹-octreotide is reabsorbed into the renal parenchyma and transported to the lysosomal compartment. Although the transportation of ^{111}In -DTPA-D-Phe¹-octreotide to the lysosomal compartment proceeds rapidly, the ^{111}In -labeled peptide is degraded to the final radiometabolite, ^{111}In -DTPA-D-Phe, slowly, presumably due to the presence of the D-Phe-L-Cys sequence in the molecule. The final radiometabolite is excreted from the lysosomal compartment of the renal cells at a slow rate. The latter process would be predominantly responsible for the persistent localization of the radioactivity in the kidney, considering the rapid generation of the radiometabolite from ^{111}In -DTPA-L-Phe¹-octreotide and the slow elimination rate of ^{111}In -DTPA-L-Phe from the renal cells. The present findings

also indicated that while replacement of the N-terminal D-Phe of ^{111}In -DTPA-D-Phe¹-octreotide with L-Phe facilitated metabolic rate in the lysosomes, little improvement was achieved in the renal radioactivity levels. Since ^{111}In -DTPA-D-Phe¹-octreotide is incorporated into tumor tissue (5, 22), ^{111}In -DTPA-D-Phe may also be generated as the final radiometabolite in the tumors. This may account for the prolonged radioactivity levels observed in the tumor tissue. A recent study of radiolabeled antibody fragments suggested that the renal radioactivity levels of radiolabeled polypeptides and peptides may be reduced by releasing radiolabeled compound of urinary excretion by the action of brush border enzymes before they are incorporated into the renal cells (23). Thus, the findings of the present study would facilitate the design of radiolabeled somatostatin analogues with lower renal radioactivity levels without impairment of the tumor radioactivity level.

Molecular Hybridization Probes Prepared with 4-Aminooxybutylamine

Vyacheslav A. Adarichev, Sergey M. Kalachikov, Anna V. Kiseliyova, and Grigory M. Dymshits*

Institute of Cytology and Genetics SD RAS, 10 Lavrentyeva Avenue, Novosibirsk 630090, Russia.
Received January 14, 1998; Revised Manuscript Received September 15, 1998

A versatile method is described for preparing nonradioactive DNA probes for molecular hybridization. The method is based on the transamination reaction of double-stranded DNA with 4-aminooxybutylamine (ABA). To optimize the procedure for obtaining stable and sensitive hybridization probes, time of modification, pH, and reaction temperature were varied. The optimal reaction conditions allowed the preparation of nonradioactive-labeled DNA probes that met demands for optimal length, modification degree, stability, and sensitivity. The use of 4-aminooxybutylamine as a bifunctional reagent for DNA modification allowed the possibility of choosing an appropriate reporter group: biotin or one of the fluorochromes. For probes carrying biotin, a high specificity and high sensitivity detection limit of 1 pg of target DNA were demonstrated. In addition, the applicability of probes carrying fluorochromes for multicolor direct fluorescence in situ hybridization was described.

INTRODUCTION

Nucleophilic reagents are broadly used to introduce nonradioactive labels into polynucleotides: bisulfite (Lebacqz et al., 1988), aliphatic amines (Turchinskii et al., 1988), hydrazides (Reisfeld et al., 1987; Turchinskii et al., 1989; Karpyshev et al., 1990), and substituted hydroxylamines (Adarichev et al., 1987; Brosalina et al., 1987). Within this range of chemicals, hydroxylamine and its derivatives display the highest rate of nucleophilic substitution and best stability (Kochetkov et al., 1971, 1972). Therefore, we tested 4-aminooxybutylamine (ABA)¹ as a carrier of nonradioactive labels. This bifunctional agent carries an aminooxy group on one end and an amino group on the other. On the first step of DNA modification (Scheme 1), the aminooxy group reacts selectively with cytosine, and the amino group allows a variety of reporter compounds such as biotin and different fluorochromes to be attached on the second step. We reported earlier that ABA can be used for introduction of amino groups into extended double-stranded polynucleotides (Adarichev et al., 1987). The aim of the present work was to determine the optimal conditions for the reaction of DNA with ABA in order to obtain highly sensitive nonradioactive probes. The probes were characterized for their application in molecular hybridization.

EXPERIMENTAL PROCEDURES

ABA was synthesized by Vector Inc., Koltsovo, Russia. Streptavidin-alkaline phosphatase conjugate was purchased from Boehringer Mannheim, Switzerland; agarose, *n*-nitrotetrasolium blue (NBT), 5-bromo-4-chloro-3-indolyl phosphate toluidine salt (BCIP), *N*-hydroxysuccinic ether *D*-biotinylaminocaproate, DMSO, and salmon sperm DNA were from Sigma and SDS, RNase, tetramethyl-

¹ Abbreviations: 1×SSC, 0.15 M NaCl, 0.015 M sodium citrate, pH 7.0; ABA, 4-aminooxybutylamine; SDS, Na dodecyl sulfate; kb, kilobases.

Modification of Polynucleotides. Step 1. Reaction of DNA with ABA. Chemical modification of polynucleotides was performed with 20 μL of 1 $\mu\text{g}/\mu\text{L}$ plasmid DNA and 10 μL of 1.0 M ABA at pH 3.6. The final volume was adjusted with water to 40 μL ; the mixture was incubated for 1–40 min at 65, 80, or 100 $^{\circ}\text{C}$. Acidity of ABA solution was adjusted to the required pH value by titration at 65 or 80 $^{\circ}\text{C}$. Reaction pH at 100 $^{\circ}\text{C}$ was calculated based on pH at 65 $^{\circ}\text{C}$ and dependency of the ABA ionization constant with temperature. The value $\Delta K_a/\Delta\text{C}$ was -0.03 deg^{-1} for 1.0 M ABA solution and was not affected by temperature over the range 30–80 $^{\circ}\text{C}$. Removal of an uncoupled reagent was performed on Sephadex G-25 gel filtration by elution with 20 mM NaHCO_3 . DNA solution was concentrated by successive extractions with *n*-butanol and diethyl ether. Ether was removed by vacuum. Modified DNA was stored at $-20\text{ }^{\circ}\text{C}$.

Step 2. Attachment of reporter compounds to modified polynucleotides was done as described earlier (Frumgarts et al., 1986). The reaction mixture consisted of 10 mM of *N*-hydroxysuccinic ether *D*-biotinylaminocaproate, tetramethylrhodamine isothiocyanate, or fluorescein isothiocyanate and 0.1 M NaHCO_3 , 0.2 $\mu\text{g}/\mu\text{L}$ ABA-DNA, and 10% DMSO. After incubation for 2 h at 37 $^{\circ}\text{C}$, the mixture was loaded onto Sephadex G-25 gel and eluted with 20 mM NaHCO_3 to remove uncoupled reagents. DNA samples labeled with fluorescein were characterized by absorption at 260 and 490 nm to calculate the ratio of bases carrying fluorochrome. Labeled DNA was stored at $-20\text{ }^{\circ}\text{C}$.

To evaluate the percentage of nucleotide bases of DNA carrying ABA or biotin (degree of modification), an aliquot of ABA-DNA after first step of modification was labeled with fluorescein. The degree of modification for fluorescein-labeled DNA was determined as a percentage of labeled bases over all bases using the 490/260 nm absorption ratio. The extinction coefficient of fluorescein in 20 mM NaHCO_3 was $42\,000\text{ M}^{-1}\text{ cm}^{-1}$ at 490 nm and $14\,400\text{ M}^{-1}\text{ cm}^{-1}$ at 260 nm, and the extinction coefficient of DNA was $6500\text{ M}^{-1}\text{ cm}^{-1}$ at 260 nm.

The sensitivity of biotin-labeled DNA probes was estimated by homologous dot-blot hybridization. Decreasing amounts of target DNA were immobilized onto nylon membrane, and DNA probe was labeled in a two-step procedure prior to hybridization with DNA on membrane. The probe sensitivity (in picograms) was defined as a lowest detectable amount of target DNA.

Distribution of labeled DNA fragments was confirmed by agarose gel electrophoresis in 30 mM NaOH . Fluorescein-labeled DNA in agarose gel was photographed under ultraviolet illumination using "Photodyne" camera with a green filter. Biotin-labeled DNA was transferred from agarose gels under vacuum onto nylon membranes and immobilized by ultraviolet illumination (Kalachikov et al., 1992). Biotin was detected with streptavidin-alkaline phosphatase conjugate as described earlier (Langer et al., 1981).

Chromosome In Situ Hybridization Using Fluorochrome-Labeled Probes. Slides with chromosomes of mink, mouse, and vole *Microtus arvalis* were kindly provided by Dr. S. M. Zakian and Dr. O. L. Serov (Institute of Cytology and Genetics, Novosibirsk, Russia). Slides were denatured with 70% formamide in $2\times\text{SSC}$ at 70 $^{\circ}\text{C}$ for 2 min and immediately transferred into 70, 80, and 96% ethanol series for 5 min each at 2 $^{\circ}\text{C}$, and slides were then air-dried. Fluorochrome-labeled probe (1 μg) was combined with 2 μg of sheared salmon sperm DNA and 20 μg of sheared *Escherichia coli* DNA in 40

μL of hybridization buffer containing 50% formamide and 10% dextran sulfate in $2\times\text{SSC}$. The mixture was denatured at 90 $^{\circ}\text{C}$ for 3 min, immediately chilled on ice for 5 min, and then added to the slides. Hybridization was carried out overnight in a moist chamber at 37 $^{\circ}\text{C}$. Slides were washed twice in 50% formamide in $2\times\text{SSC}$, twice in $2\times\text{SSC}$ at 42 $^{\circ}\text{C}$, stained with propidium iodide, and mounted in 5 mM *p*-phenylenediamine, 70% glycerol, and $2\times\text{SSC}$. Fluorescent signal was detected with luminescent microscope "Lumam I-3" (LOMO, Russia).

RESULTS AND DISCUSSION

Specifying the Reaction Conditions. Hydroxylamine and its derivatives possess a high specificity for single-stranded nucleic acids. Phage M13 single-stranded DNA can be modified by 10% for 20 h in 1.0 M ABA, pH 4.5, at 37 $^{\circ}\text{C}$. No breaks in DNA were detected in the course of modification, and the corresponding biotin probes displayed a high sensitivity upon homologous dot-blot hybridization. Under identical conditions, double-stranded DNA can be modified by less than 1% (data not shown). To denature DNA and promote transamination, the temperature was raised. The rate of ABA incorporation was sharply increased with the reaction temperature, and DNA probes obtained at 100 $^{\circ}\text{C}$ demonstrated a higher degree of modification with ABA/biotin compared with probes obtained at 80 and 65 $^{\circ}\text{C}$ (Figure 1). Nevertheless, despite the significantly higher quantity of biotin moieties, the probes produced at 100 $^{\circ}\text{C}$ demonstrated the least sensitivity among all tested samples. Thus, 80 $^{\circ}\text{C}$ was the optimal temperature for the first step of DNA modification due to the combination of high rate of ABA incorporation and high sensitivity of probes in homologous dot-blot hybridization.

DNA modification with ABA at 80 $^{\circ}\text{C}$ (Figure 2) showed a steady increase in ABA incorporation with time. However, the results from homologous dot-blot hybridization of corresponding biotinylated DNA probes, produced under these conditions, demonstrated that sensitivity was maximal for probes incubated for 5–10 min with ABA, and longer incubation decreased the hybridization signal. In addition, the portion of the probe bound nonspecifically to the membrane increased under extended incubation. The level of DNA probe sensitivity achieved after 5–10 min of modification was greater than 1 pg. This level of sensitivity was comparable to that of DNA probes prepared by other nonradioactive-labeling methods, both chemical and enzymatic (Langer et al., 1981; Reisfeld et al., 1987; Lebacqz et al., 1988; Turchinskii et al., 1989; Karpyshev et al., 1990).

Characterization of the Probes Produced by DNA Transamination. It was shown that *O*-alkylhydroxylamines demonstrate high specificity to cytosine, does not react with guanine and thymidine, and reacts minimally with adenine nucleus (Budowsky et al., 1971a,b; Budowsky et al., 1972; Kochetkov et al., 1971, 1972). Despite ABA belonging to *O*-alkylhydroxylamines, its reactive specificity may differ under particular conditions we used for modification. To determine the reactivity of ABA to different DNA bases, we incubate the reagent with single-stranded homopolynucleotides under conditions optimal for DNA modification (0.25 M ABA pH 3.6, 80 $^{\circ}\text{C}$, 10 min). Indeed, ABA showed reactivity for each of the DNA bases. The portion of modified cytosine among all the four bases was about 70%, but ABA reacted also with guanine (16%), adenine (10%), and thymidine (4%). The resulting ratio of rates ($G > A > T$) was identical for DNA depurination upon heating in acidic

Figure 1. Time course of the ABA incorporation into double-stranded DNA at different temperatures: (A) 100 °C; (B) 80 °C; (C) 65 °C, on left. Homologous dot-blot hybridization of the probes modified for 10 min, on right.

conditions (Kochetkov et al., 1971, 1972). Obviously, detachment of DNA bases followed by coupling the ABA with C1-deoxyribose aldehydes groups might explain homopolynucleotides reactivity.

Depurination at the C1 atom can lead to disintegration of polynucleotides and subsequent changes in the hybridization properties of the probe. For that reason, DNA probes obtained in the two-step labeling procedure were tested by gel electrophoresis under alkali conditions, which allowed us to detect all anucleated sites. Plasmid DNA was incubated with ABA and modified with biotin. DNA sample was fractionated on alkaline agarose gel and transferred onto nylon membrane. Following these procedures, the 6.0 kb plasmid DNA demonstrated some degree of degradation (Figure 3). Nevertheless, a final length of 1–5 kb remained optimal for hybridization. A similar size distribution pattern was also obtained for the fluorescein-labeled DNA.

The optimal degree for DNA probe labeling was studied by homologous dot-blot hybridization using plasmid DNAs carrying 0.2–8% biotin. Target DNA was spotted onto nylon membrane in decreasing amounts, and each biotinylated DNA sample was hybridized with target under standard conditions. Dependence of sensitivity at

Figure 3. Size distribution for DNA probes labeled with ABA and biotin after gel electrophoresis in alkaline conditions.

Figure 4. Sensitivity of biotinylated DNA probes with different degree of modification in homologous dot-blot hybridization.

Figure 5. ABA-modified DNA probes in fluorescent in situ hybridization with chromosomes of the vole *Microtus arvalis*. Transaminated and labeled with fluorescein plasmid carrying species-specific repeated sequences was used as a probe. Hybridization signal was detected by fluorescent microscopy (green-yellow). Chromosomes were contrasted with propidium iodide staining (red).

degree of modification demonstrated plateau started from 1.5% biotinylated bases (Figure 4). Biotinylated DNA probes that carried 1.5–8% biotin demonstrated equal sensitivity, which dropped abruptly if DNA probes carried less than 1% biotin. Thus, the maximum probe sensitivity for biotin-ABA label was at 1.5% of modified DNA bases. Higher degree of modification resulted in higher density of biotin labels on the DNA strand, and obviously, steric problems arose when the sizable streptavidin-alkaline phosphatase conjugate interacted with the biotin residues hindering increased sensitivity. In the case of fluorochrome-labeled probes, the dependence was also asymptotic, but maximal sensitivity was reached at 4% modified DNA bases. In the latter case, the mechanism of quenching of fluorescent signal was responsible for sensitivity hindering (Frumgarts et al., 1986).

The application of ABA-modified DNA probes was demonstrated for in situ hybridization. Plasmid DNA carrying species-specific sequences were modified with ABA, and either biotin or fluorescein was attached. The

Figure 6. Direct multicolor fluorescent in situ hybridization with a mixture of mink and mouse cell nuclei. The probe for mink carried tetramethylrhodamine (orange), the probe for mice carried fluorescein (green).

species-specific repeat was localized in the heterochromatin arm of the sex chromosomes of the vole *Microtus arvalis* by direct signal detection from fluorescein-labeled DNA probes (Figure 5). Nonradioactive hybridization of the biotinylated plasmid demonstrated identical chromosomal localization (data not shown).

The described two-step labeling procedure with ABA as the first modifying agent allows the choice of the most suitable label for the task. In the frame of one method, different fluorochromes can be attached to DNA probes opening the possibility of simultaneous hybridization of several probes carrying fluorochromes with different emission spectra. Figure 6 presents the results of multicolor fluorescent hybridization with a mixture of mink and mouse cells. Total mink DNA, as a first DNA probe, was labeled with ABA and tetramethylrhodamine (orange-yellow nuclei), and total mouse DNA, as a second probe, carried ABA-fluorescein label (green nuclei).

The described procedure for the preparation of molecular hybridization probes does not require enzymes or unstable compounds. In one round of two-step modification, a large quantity up to hundred microgram of fluorochrome- or biotin-labeled probe can be produced starting from double-stranded plasmid DNA. These probes can be used in all fields of molecular hybridization.

ACKNOWLEDGMENT

The authors acknowledge the helpful comments of Drs. E. I. Budowsky and B. P. Ulanov as well as collaboration of Drs. A. S. Grafodatsky, S. M. Zakian, G. A. Zayniyev, L. P. Zakharenko, L. P. Sadovaya, 1, bd.4, 113787 Moscow, Russia. Received January 15, 1998; Revised Manuscript Received May 7, 1998

A new family of bouquet-like molecules based on cyclodextrins is described. These compounds were obtained by polymerization of ethylene oxide. This reaction was initiated by primary and secondary hydroxyl groups of cyclodextrins, which constitute an organizing core. Analysis of structure and composition of conjugates based on α -CD and β -CD was performed using the data of MALDI-MS, GC-MS, and ¹³C-NMR spectra. Glass transition behavior of the conjugates shows that the above compounds are amorphous. Complexation properties of the conjugates are described with respect to sodium 4-nitrophenolate and calcium acetylhomotaurinate, which are used as guest molecules. Binding interaction between cyclodextrins or their conjugates and sodium 4-nitrophenolate was studied using differential absorption spectra. Association constants K_a between CD hosts and calcium acetylhomotaurinate composed of two equal anionic moieties were studied using ¹H-NMR spectroscopy. The values of binding constant for β -CD were found to increase by more than 2 orders of magnitude than that of the corresponding system based on α -CD. α -CD was shown to form the inclusion complex with one anionic moiety, whereas β -CD produces a ternary complex with two anionic moieties of CAHT. For PEO derivatives of CDs, K_a decreases as compared with that of parent CD for both guests. These conjugates may be used as potent drug-delivery systems.

INTRODUCTION

Cyclodextrins (CD)¹ have been extensively studied because of a unique ability of these cyclic starches to produce dynamic molecular inclusion complexes with various compounds including pharmaceuticals. The ability of CD for molecular recognition is controlled by hydrophobicity of a guest and fitness between the shape of guest species and a CD cavity (1). To change the molecular recognition ability of CDs, many derivatives of CDs containing various groups on both sides of CD have been investigated (1, 2). In this respect CDs, modified with water-soluble polymers, are of a great interest. At the present time, these investigations are

in their infancy. The advantages of polymer derivatives of CD were demonstrated for CDs modified with poly(*N*-isopropylacrylamide) chains (3). In these systems, polymer chains experience the coil-globule transition upon heating, and the inclusion of a guest molecule is controlled by temperature. Therefore, polymer chains are sensitive to the external action. More interesting polymer derivatives of CD are the conjugates of CD with poly(ethylene oxide), which may be presented as a microcapsule consisting of a CD core with short poly(ethylene oxide) chains attached to primary and secondary hydroxyl groups of CD (bouquet-shaped structures) (4). Even though modification of CD by PEO chains decreases the size of CD cavity and binding constant, one may anticipate that this modification would give rise to new properties such as amphiphilic character of CD derivatives (5) and the adaptation of guest accommodation due to the additional noncovalent fixation of the ligands in polymer surroundings.

In this work, the synthesis of the above compounds are described, and effect of polymer on the complexation with two guests, sodium 4-nitrophenolate (SN) and calcium acetylhomotaurinate (CAHT) was examined.

EXPERIMENTAL PROCEDURES

Chemicals. In this work, we used α - and β -cyclodextrins (Cyclolab, Hungary) and 2,5-dihydroxybenzoic acid (Aldrich); SN and CAHT² were analytically grade reagents.

¹ Abbreviations: CD, cyclodextrin; CI, chemical ionization; EI, electron impact; EO, ethylene oxide; GC-MS, gas chromatography-mass spectrometry; *M*, molecular mass; *M_w*, weight average molecular mass; *M_n*, number average molecular mass; MMD, molecular mass distribution; MALDI-MS, matrix-assisted laser desorption ionization-mass spectrometry; MS, molar degree of substitution; PEO, poly(ethylene oxide); NP, natrium 4-nitrophenolate; CAHT, calcium acetylhomotaurinate; PEO- α -CD, conjugate of PEO and α -CD; PEO- β -CD, conjugate of PEO and β -CD; *T_g*, temperature of glass transition.

Methods. Gas chromatography (GC) was performed with a Carlo Erba GC 6000 Vega Series 2 equipped with CPSi18 CB (Chrompack) and retention gap, on-column injector, and a flame ionization detector. Hydrogen was used as a carrier gas.

GC-MS. Mass spectra were recorded with a Hewlett-Packard 5840 A-5985A instrument (CI, ammonia, and EI) and VG/70-250S GC-MS-system (VG analytical).

MALDI-mass spectra were recorded using the TOF laser Kratos Compact MALDI III mass spectrometer (Kratos, Shimadzu, U.K.) in a reflection mode. Samples were prepared by casting the matrix compound (2,5-dihydroxybenzoic acid, 10 mg/mL in ethanol/water, 1:1, v/v) onto the slide. After evaporation of the solvent, the solution of conjugate (in methanol or for permethylated samples methanol-dichloromethane, 2:1, v/v, 1 mg/mL) was deposited on the matrix. The solvent was evaporated. Ions were produced by laser ionization/desorption at 337 nm (3 ns pulse width). Ionization was accelerated with 20 kV in the positive ion mode.

Differential absorption spectra were measured by a Hitachi 557 model UV spectrophotometer. ^1H -NMR spectra were recorded on a CXP-200 Bruker spectrometer. ^{13}C -NMR spectra were recorded on AM-300 Bruker spectrometer. Chemical shifts are given in parts per million. Sodium (4,4'-dimethyl-4-)-silapentane sulfonate and dimethylsulphoxide are used as internal references.

Glass transition temperatures were measured with a Mettler TA 400 thermal analyzer using a DSC-30 unit. Scanning rate was 20 K/min.

Synthesis. β -CD (3.5 g, 0.003 mol) in 50 mL of 0.9% NaCl solution (pH 11.2) was placed in the reaction stainless vessel. Ethylene oxide (EO) was added at 80 °C under a pressure of 0.145–0.196 MPa. After stirring for 4–10 h, the reaction mixture was cooled down to 40 °C and unloaded. The product was dissolved in water. The content of insoluble product was estimated to be ~5%. This product was separated by filtration. The dialysis of the solution was carried out using Seamless tubing (Sigma). The completion of dialysis was controlled using thin layer chromatography on Silufol plates in $\text{CHCl}_3:\text{C}_2\text{H}_5\text{OH}:\text{H}_2\text{O}$ (36:12:1). The spots were revealed by iodine. The solution was filtered through a glass fiber filter (Sigma) and lyophilized. A repeated drying of the conjugates was carried out by heating in vacuum in the presence of phosphorous pentoxide at 95–100 °C for 1 h. Water content in the lyophilized samples of the conjugates was estimated to be 10–13%. For the PEO- β -CD conjugate, calcd: C, 45.7%; H, 8.7%. Found: C, 45.8%; H, 8.5%.

Chemical Modification of PEO-CD Conjugates. PEO-CD conjugates were permethylated using powdered sodium hydroxide and methyl iodide (6). The permethylated products were extracted with dichloromethane. Hydrolysis of the conjugates was carried out in 2 N trifluoroacetic acid in a screw cap vial at 120 °C for 2 h. The solvent was evaporated under nitrogen flow. The traces of acid were removed by codistillation with toluene. Remethylation of glucose derivatives of PEO (hydrolysates) was performed using $\text{CD}_3\text{I}/\text{NaOH}$ in DMSO according to ref 6.

Complexation Properties. Complexation between SN and CD or their conjugates was studied by the measurements of differential absorption spectra in 0.05 M phosphate buffer (pH 9.5). Equilibrium constants of complexation between CD or their conjugates with CAHT

Figure 1. Analysis of the PEO-CD conjugates and their degradation products.

were estimated from ^1H -NMR spectra. The analysis of binding curves was carried out using computer program Microcal Origin 3.5. Thus, values δ_1 (the limiting value of chemical shift of methyl protons of CAHT in the presence of CD derivatives) were calculated. Correlation between chemical shifts of methyl protons of CAHT and concentration of CDs or their derivatives was described by the following equation:

$$\delta_{\text{obs}} = \delta_1 + \frac{\delta_0 - \delta_1}{1 + K_a} [\text{B}] \quad (1)$$

where δ_{obs} stands for the chemical shift of methyl protons of CAHT; δ_1 is the limiting value of chemical shift; δ_0 is the value of the chemical shift of the initial CAHT; [B] is the concentration of CDs or their derivatives; K_a is the microscopic binding constant of CDs or their derivatives with one binding center (anionic moiety of CAHT). This equation holds when both anionic moieties of CAHT (centers) are equivalent and do not interact with each other and $[\text{B}] \gg [\text{CAHT}]$.

RESULTS AND DISCUSSION

Synthesis of Conjugates. PEO-CD conjugates were synthesized in one-pot manner by polymerization of EO. The reaction was initiated by hydroxyl groups of multifunctional core of CD. This method was developed for the synthesis of graft copolymers of EO on starch (7). PEO, the main byproduct of this reaction, was produced by the polymerization of ethylene oxide initiated by hydroxide ions (8).

Characteristics of Conjugates. Characteristics of the conjugates (molecular mass, molecular mass distribution, M_w/M_n , molar degree of substitution, MS, and mode of substitution) were obtained through the procedure of successive permethylation, hydrolysis, and perdeutero-methylation (6). The consequence of the reactions and the methods of investigation are presented in Figure 1.

² CAHT was kindly presented by Dr. R. N. Alyautdin (Moscow Sechenov Medical Academy).

Figure 2. MALDI-mass spectra of PEO- β -CD (1) and its permethylated derivative (2). Sodium adducts are detected (Minor series of homologous present sodium adducts).

Table 1. Characteristics of PEO-CD Conjugates

CD	$\bar{M}_w$		$\bar{M}_w/\bar{M}_n$		MS-range/ CD	MS _{av}
	con- jugate	hydrol- ysate	con- jugate	hydrol- ysate		
α	3025	608	1.004	1.04	35–60	8
β	3540	778	1.005	1.09	40–70	8

Mass Spectrometry. Three parameters of the conjugates, molecular mass, $\bar{M}_w/\bar{M}_n$, and MS were determined by MALDI-MS method (Table 1). The MALDI-mass spectrum of the conjugates exhibit the distribution of weight molecular mass M_w . Using graphical method (9) values of average weight and number molecular masses, M_w and M_n , were calculated. Note that the MALDI-mass spectra are characterized by a narrow and symmetrical distribution of the components (Figure 2) with $\bar{M}_w/\bar{M}_n$ close to unity. This is characteristic of anionic polymerization. Mass distribution of the permethylated PEG-CD conjugates agrees with that of the original samples, $\Delta M = n42$ (42 is 3×14 for three methyl groups per glucose unit) where n is a number of glucose units per CD (Figure 2). To estimate molecular mass and $\bar{M}_w/\bar{M}_n$ of PEO substituents, the permethylated conjugates were hydrolyzed. The MALDI-mass spectra of the resultant PEO-containing glucose derivatives are presented in Figure 3. As it is seen, these products are characterized by a narrow interval of $\bar{M}_w/\bar{M}_n$ values (1.04–1.09). These values are slightly higher than those of the initial conjugates but MMD is still narrow. This evidence suggests that the degree of polymerization of PEO substituents attached to different positions of glucose units of CD does not differ substantially. The total number of ethylene oxide units in the conjugates was obtained from molecular mass of the conjugate minus molecular mass of the initial CD divided by 44 (molecular mass ethylene oxide unit) (Table 1). An average numbers of monomer units in each PEO substituent (MS_{av})

presented in Table 1 were calculated using the following formula:

$$\text{MS}_{\text{av}} = (M_{w,\text{hyd}} - 245)/44$$

where 245 is the total mass of all non-PEO fragments of oligomer (180 for glucose fragment, 42 for 3 methyl groups, and 23 for sodium).

Mode of Substitution. Additional information concerning the number of substituents in PEO-CD conjugates was obtained using GLC-MS method. This method allows one to estimate the number of substituents in a given compound (from the molecular mass of separate peaks). For example, using both EI and CI modes, it was shown that methyl glucosides with MS from 0 to 11 present in PEO- β -CD. This implies that, even at these high values of MS, unmodified groups in CD still exist. From the fragmentation patterns of the EI mass spectra, preferred 6-O-hydroxyethylation was demonstrated in the fraction with MS = 1 ($6 \gg 2$). For the fraction with MS = 2 the order was $66' \gg 22' > 26$. For methyl glucosides with MS = 3, the patterns $66'6''$, $266'$, $22'2''$, and $22'3$ are detected. At higher MS, the formation of oligoether at 2-OH dominates. However, it seems difficult to differentiate between longer PEO chains because the structure of isomers becomes very complex.

As known, the relative reactivities of hydroxyl groups of CD or starch during the kinetically controlled etherification are controlled by the concentration of base (10). Polymerization proceeds without any addition of base but due to nucleophilic opening of oxirane by chloride ion of NaCl pH of the reaction media achieves about 11. Under these conditions, the reaction at the most acidic 2-OH, supported by the axial glucoside oxygen, dominates. In general, a poor reactivity of secondary 3-OH in CDs prevents peretherification. Formation of oligoether in 2 and 6 positions is preferable and makes the sterically

Figure 3. MALDI-mass spectra of glucose derivatives of PEO (hydrolysates): (1) From PEO- α -CD; (2) from PEO- β -CD.

hindered 3-OH even less accessible. Therefore, for the various hydroxyl groups in the glucose unit of PEG-CDs, molar degree of substitution changes in the following order: $2 > 6 \gg 3$. Polymerization of ethylene oxide in the presence of CDs yields randomly distributed PEO chains attached to CD with $MS_{av} = 8-11$ per glucose unit. In this case, MMD is symmetrical and narrow, and M_w/M_n is close to unity.

NMR Spectra. PEO-CD conjugates were studied using ^1H - and ^{13}C -NMR spectra. In the ^1H -NMR spectra, the signals of protons of glucose rings were shielded by a strong signal from PEO protons. In the ^{13}C -NMR

spectra, one may distinguish well-defined signals corresponding to carbon atoms of polymer chains which are characterized by the following chemical shifts: 62.173, 71.315, and 73.477 ppm. Furthermore, the spectrum shows broad signals of carbon atoms corresponding to CD moiety (62, 71-75, 80-84, and 100-103 ppm). Our efforts to achieve a better resolution of spectral lines by heating the sample up to 90 °C failed. This is likely to be associated with the statistical character of substitution at different positions of hydroxyl groups and a crowding effect of PEO substituents.

Thus, the formula of conjugates may be presented as

Figure 4. Curves of DSC of glass transition of PEG 300 (1) and PEO- β -CD conjugate (preparation 4). (2) The rate of heating is 10 °C/min.

Figure 5. Binding curves for the systems based on SN and α -CD (■), PEO- β -CD (▲), PEO- α -CD (preparation 4) (●). Concentration of SN = 5×10^{-5} M; $T = 297$ K.

Additional information concerning the physical state of the conjugates was obtained studying of glass transition behavior and glass transition temperatures T_g (Figure 4). Figure 4 shows the DSC scan for PEG 300. Note that the parent β -CD is a crystalline compound with melting temperature of about -50 °C. As is seen, T_g of PEG 300 is close to T_g of PEO- β -CD conjugate and lies in the range from -75 to -70 °C. At the same time, the temperature interval of transition depending on the degree of cooperativity is much wider for bound polymer chains as compared with that of initial polymer. As follows from Figure 4, the DSC scans of PEG 300 are characterized by both picks of crystallization and melting, whereas the corresponding DSC scans of the conjugates show only the region of glass transition.

Complexation Properties of the Conjugates with Sodium 4-Nitrophenolate. The fundamental property of PEO-CD derivatives concerns their complexation ability. In this work, we used two organic compounds SN and CAHT as guest molecules. Upon the addition of α -CD, SN in aqueous solutions exhibits a spectral shift of about 15 nm (11). Figure 5 shows the binding curves for α -CD and for two conjugates with SN. As is seen, an

increase in the concentration of host molecule leads to an abrupt linear increase in the value of optical absorbance, then this value levels off when the guest:host ratio varies in the range from 1:1 to 1:2. One may conclude that (1) the affinity between the ligand and PEO-CD conjugates decreases as compared with that of the system based on parent α -CD; (2) the binding curve for PEO- α -CD conjugate shows an S-shaped profile which suggests a far more complex character of binding as compared with that of the native α -CD.

As compared to parent α -CD a decrease in the complexation ability of this conjugate is likely to be related to a decrease of the cavity size. The same effect was observed for other types of CD derivatives (12). As was shown in ref 13, the binding constant of β -CD with respect to SN is by 1 order of magnitude lower than that of the system based on α -CD. This is likely to be related to the fact that an increase in the size of β -CD cavity decreases the complex stability. The complexation between β -CD and SN was not identified by differential UV spectroscopy. At the same time, as follows from the binding curve presented in Figure 5, PEO- β -CD forms the complex with SN. For the systems based on PEO- β -CD and α -CD, the comparison between the slopes of linear portions of the corresponding binding curves shows that both hosts are characterized by similar binding constants. Therefore, flexible oligo(ethylene oxide) chains may facilitate the adaptation of guest accommodation because of the additional noncovalent fixation of guests by noncovalent forces.

As known, PEO forms inclusion compounds with α -CD (14). It seems important to understand whether self-inclusion of the grafted PEO chains in PEO- α -CD conjugates is possible. Our experiments within the framework of Stuart-Breigleb models show that oligo(oxyethylene) chains grafted to CD core are able to form complexes with one grafted oligo(oxyethylene) chain incorporated in the cavity of the same molecule (auto-complexes). Actually, these structures should show poor complexation properties in respect to the external guest. This conclusion is proved by a low value of the slope of the first portion of the binding curve (Figure 6). Probably, an increase in the affinity of components at a higher concentration of the conjugate is provided by the destruction of autocomplexes and formation of amphiphilic type associates (15).

Complexation Properties of the Conjugates with Calcium Acetylhomotaurinate. Taking into account the ability of PEO-CD conjugates for drug targeting (16), it seems interesting to study the complexation between these conjugates and biologically active ligands. As one of these substances, we have chosen CAHT [$\text{CH}_3\text{CONH}(\text{CH}_2)_3\text{SO}_3^-$] Ca^{2+} , which is used in the clinic to prevent relapses in weaned alcoholics (17). This ligand is also interesting as a guest molecule containing two anionic moieties in one molecule. Modeling of complexes based on CAHT and α -CD using Stuart-Breigleb models shows that the most stable structure is formed by the incorporation of hydrophobic fragment of CAHT to the cavity of CD, whereas the charged sulfonate groups stay outside of the cycle. For complexes based on β -CD, both of anionic moieties may be incorporated into the cavity. In both cases, the molar stoichiometry of complexes is 1:1.

The complexation of CAHT was studied by ^1H -NMR spectroscopy. When the guest molecule is accommodated in CD, hydrogen atoms of CAHT located in the channel of CD should be shifted upfield (18). Figure 6 presents ^1H -NMR spectra of free CAHT and its complex with α -CD. As follows from this figure, the character of

Figure 6. ^1H -NMR spectra of CAHT (1) and CAHT in the presence of α -CD. (2) Concentration of CAHT = 1.25×10^{-2} M, concentration of α -CD = 0.12 M.

Figure 7. Binding curves for the system based on CAHT and β -CD (■), and PEO- β -CD (preparation 4) (●). Concentration of CAHT is 1.25×10^{-2} M, $T = 303$ K.

changes in ^1H -chemical shifts of methylene and methyl group of CAHT suggests the formation of inclusion complexes. Note that, in the presence of α -CD, the value of ^1H -chemical shift of CH_3 proton is higher than that of methylene groups. These values were used to estimate of K_a . At the same time, as follows from the spectra of the conjugates, C3-H and C5-H of α -CD are also shifted upfield. However, these shifts cannot be used to estimate K_a of the conjugate because of the complex character of the corresponding ^1H -NMR spectrum of CD core. Binding constants K_a were determined from the binding curves (change of ^1H -chemical shifts of methyl protons of CAHT, D , as a function of concentration of CDs) by a curve-fitting analysis using eq 1 (Figure 7 and Table 2).

For complexes based on α - and β -CD, the comparison between K_a shows that K_a for β -CD-CAHT complex increases by more than 2 orders of magnitude as com-

Table 2. Binding Properties of System Based on CDs and Their PEO Derivatives Toward Calcium Acetylhomotaurinate

	CDs or their derivatives	temp K	$D = \delta_0 - \delta_1$	K_a , 1/mol
1	α -CD	313	0.0360	4.6 ± 0.4
		323	0.0335	3.0 ± 0.2
		333	0.0320	2.1 ± 0.2
2	PEO- α -CD	313	0.0360	2.1 ± 0.1
3	β -CD	303	0.0148	1800 ± 200
		323	0.0150	1060 ± 20
		343	0.0124	860 ± 40
4	PEO- β -CD	303	0.0195	320 ± 20
		323	0.0148	168 ± 10
		343	0.0179	63 ± 2

pared this the corresponding constant of α -CD-CAHT. This situation seems to be rather unusual for the complexation of the guests with CDs, which is characterized by a decrease in the K_a with the increase of the size of the cavity (1). This behavior may be explained as follows: β -CD forms a complex with two anionic moieties of CAHT in contrast to α -CD. Both types of PEO-CD conjugates were found to be less effective hosts with respect to CAHT as compared with parent CDs.

Upon binding of CAHT with conjugates, no self-inclusion phenomenon was observed. This is likely to be related to the fact that the interval of concentrations of the conjugate was by 2-3 orders of magnitude higher than that of the corresponding systems based on SN. Taking into account the fact that the formation of autocomplexes proceeds at low concentrations, it seems evident that their effect on binding properties of the conjugates is absent at high concentrations of host molecule. As follows from the Table 2, for all systems under study, the values of K_a decrease with increasing of temperature.

Therefore, a facile procedure for synthesis of new derivatives of CD modified with PEO chains was advanced. These compounds present randomly substituted CD molecules with PEO chains predominantly linked at 2 and 6 positions of glucoside units. Note, that PEO chains are characterized by a narrow MMD. Analysis of the binding properties of PEO-modified derivatives of CD reveals some characteristic features of these hosts. In addition, trivial steric effects associated with the decrease in the dimensions of the cavity of CD-PEO chains grafted to the CD were shown to assist the adaptation due to an additional noncovalent fixation of the ligands in polymer surrounding. The application of biologically active compound CAHT composed of two anionic moieties allows one to identify new types of topologic structures of inclusion complexes of CAHT with CD and PEO-CD conjugates. These investigations provide the basis for a new strategy of targeting of this neuroleptic to brain (16). The conjugates may be used as potent drug delivery systems.

ACKNOWLEDGMENT

We would like to thank Prof. A. S. Shashkov for his valuable assistance in recording and interpretation of NMR spectra, Dr. T. E. Grokhovskaya, F. A. Kalashnikov, and E. I. Popova for their assistance in experimental work and Prof. V. I. Sokolov and Prof. B. I. Kurganov for their interest and fruitful discussion. This work was supported by the Russian Foundation of Basic Research (Project 93-03-33519a) and International Science Foundation (MPE 300).

Self-Complementary Oligodeoxyribonucleotides Incorporating L-Related Isodeoxynucleosides: Synthesis, Physical Characterization, Enzymology, and CD Studies

Thomas Wenzel and Vasu Nair*

Department of Chemistry, The University of Iowa, Iowa City, Iowa 52242. Received January 15, 1998; Revised Manuscript Received May 22, 1998

The synthesis of self-complementary oligodeoxyribonucleotides (**14–16, 18**) incorporating the L-related isodeoxynucleotides, isodA (**1**) and/or isodT (**2**), is described. For this purpose, the fully protected phosphoramidite building blocks **10** and **12** were synthesized. The conceptually new oligomers exhibit high resistance towards exonucleases. Temperature- and concentration-dependent CD spectral data and accompanying thermodynamic parameters of the oligomers show that isodA-isodT or mixed dA-isodT/isodA-dT base pairs participate in duplex stabilization.

INTRODUCTION

Naturally occurring oligonucleotides are readily degraded by extra- and intracellular nucleases that limit their usefulness in vivo applications. A number of modifications are known that increase the enzymatic stability of oligonucleotides (*1–9*), and most of them are at the phosphate backbone or at the sugar moiety. Unfortunately, in many cases, the increase in stability toward nucleases is accompanied by a decrease in the binding affinity to the target. Hitherto, unknown are oligodeoxynucleotides which incorporate nucleoside components in which the nucleobase at the natural C-1' position is transposed to the isomeric 2'-position (also equivalent to transposition of oxygen), while maintaining the cis relationship of the base with the hydroxymethyl group (Scheme 1).

Recently, isomeric deoxy- and dideoxynucleosides including (S,S)-isodideoxyadenosine [(S,S)-isodda] were synthesized in our laboratory (*10–13*). [S,S]-Isodda exhibited very high resistance toward chemical and enzymatic degradation and was also endowed with significant antiviral activity against HIV-1, HIV-2, and HIV clinical isolates (*14*). Furthermore, (S,S)-isodda triphosphate was a potent inhibitor of HIV reverse transcriptase with K_i values in the nanomolar range (*14*). In order to gain a better understanding of the special characteristics that would be acquired by oligodeoxynucleotides incorporating isomeric nucleosides, including those isonucleosides that exhibit antiviral activity through viral DNA chain termination, we have investigated the synthesis, enzymology, and properties of such conceptually new, self-complementary oligodeoxynucleotides.

EXPERIMENTAL PROCEDURES

Materials. Melting points are uncorrected and were determined on a Thomas Hoover apparatus fitted with a microscope. ^1H - and ^{13}C -NMR spectra were recorded on a Bruker WM 360 in CDCl_3 or $\text{Me}_2\text{SO}-d_6$. Chemical shift values are reported in δ , parts per million, relative to the internal standard (TMS). UV spectra were recorded on a Varian Cary 3 spectrophotometer (Melbourne, Australia). CD spectra were measured on an AVIV Circular Dichroism Spectrometer, model 62DS (AVIV, Lakewood, NJ). Elemental analysis was per-

formed at NuMega Resonance Labs, Inc. (San Diego, CA). Thin-layer chromatography (TLC) was carried out on Polygram Sil G/UV₂₅₄ (0.25 mm, Machery-Nagel, Düren, Germany). TLC plates were visualized by ultraviolet absorbance or charring for several minutes after exposure to a 10% sulfuric acid/ethanol solution. Flash chromatography (FC) was carried out using glass columns packed with 230–400 mesh silica gel. Reversed-phase HPLC separations (4.6 $\times$ 250 mm, RP-18, 10 μm , Li-Chromosorb column, Merck, Darmstadt, Germany) were achieved using a Waters automated 600E system (Milford, MA) interfaced with a photodiode array detector (Waters 990) and a Satellite WISP (Waters 700) for automated sampling. The solid-phase synthesis of oligonucleotides was performed on an automated DNA-synthesizer (Applied Biosystems, Foster City, CA, model AB 391, PCR-MATE for phosphoramidite chemistry). The β -cyanoethyl phosphoramidites of regular 2'-deoxynucleosides and the Fractosil-linked 2'-deoxynucleosides were also products of Applied Biosystems. Snake-venom phosphodiesterase (EC 3.1.4.1., *Crotallus durissus*), calf-spleen phosphodiesterase (EC 3.1.16.1.), alkaline phosphatase (EC 3.1.3.1., *Escherichia coli*), and Eco R1 (*E. coli* BS 5) were purchased from Boehringer Mannheim (Mannheim, Germany).

Synthesis (Schemes 2 and 3). **4(R)-(6-Amino-9H-purin-9-yl)-2(R)-(hydroxymethyl)tetrahydrofuran-3(R)-ol (1).** To an ice-cold solution of **3** (4.00 g, 29.8 mmol) in anhydrous pyridine (80 mL) was added, under N_2 , *tert*-butyldiphenylsilyl chloride (7.8 mL, 29.8 mmol). The mixture was stirred for 3 h at 0 $^\circ\text{C}$, quenched with H_2O (10 mL), evaporated, and the oily residue applied on the top of a silica gel column (column, 25 $\times$ 5 cm; solvent, $\text{CHCl}_3/\text{MeOH}$ 95:5). Evaporation of the separated product yielded **4** (9.50 g, 86%) as a colorless solid. mp 75 $^\circ\text{C}$. TLC ($\text{CHCl}_3/\text{MeOH}$): R_f 0.3. ^1H -NMR (CDCl_3): δ 1.09 [s, 9H, $(\text{CH}_3)_3\text{C}$], 3.20 [s (br), 1H, OH-3], 3.39 [s (br), 1H, OH-4], 3.75–3.83 (m, 3H, H β -5/ CH_2), 3.86 (m, 1H, H-2), 4.15 (dd, 1H, J = 4.7, 9.1 Hz, H α -5), 4.20–4.26 (m, 2H, H-3/H-4), 7.34–7.42 (m, 6H, arom. H), 7.65–7.70 (m, 4H, arom. H). ^{13}C -NMR (CDCl_3): δ 19.4 [$(\text{CH}_3)_3\text{C}$], 27.0 [$(\text{CH}_3)_3\text{C}$], 64.5 (CH_2), 71.7 (C-3), 73.2 (C-4, C-5), 83.1 (C-2). A solution of **4** (5.00 g, 13.4 mmol) in dry CH_2Cl_2 (125 mL) was cooled down to 0 $^\circ\text{C}$. At this

Found: C, 63.63; H, 6.46; N, 7.45.

Solid-Phase Synthesis of the Oligonucleotides 13–18. Synthesis of the oligomers **13–18** was carried

out on a 1 μ mol scale using the 3'-cyanoethyl phosphoramidites of the following protected deoxynucleosides: [(MeO)₂Tr]dT, [(MeO)₂Tr]Bz⁴dC, [(MeO)₂Tr]Bz⁶dA, [(MeO)₂Tr]ib²dG, and compounds **1** and **2**. Deprotection of the oligonucleotides was performed in 25% aqueous NH₃ at 60 $^{\circ}$ C for 24 h. The 5'-[(MeO)₂Tr]-oligomers were purified, detritylated and desalted using OPC (ABI, Masterpiece). The oligonucleotides were lyophilized, dissolved in H₂O (200 μ L), and stored frozen at –20 $^{\circ}$ C.

Enzymatic Hydrolysis of the Oligomers. The self-complementary oligonucleotides **13–17** (0.2 A₂₆₀ units) were dissolved in 0.1 M Tris-HCl buffer (pH 8.3; 200 μ L) and treated with snake-venom phosphodiesterase (6 μ g) for 24 h at 37 $^{\circ}$ C followed by alkaline phosphatase (2 μ g) for 30 min at 37 $^{\circ}$ C. The mixture was analyzed using RP-18 HPLC (gradient II, followed by gradient I, see below). The quantification of the oligomers was made on the basis of the peak areas which were divided by the extinction coefficients of the nucleoside constituents.

Enzymatic Hypochromicity of the Oligonucleotides 13–17. The enzymatic hypochromicities were determined by enzymatic degradation of 0.2 A₂₆₀ units of the corresponding oligomer as described above.

Time Course of Phosphodiester Hydrolysis of the Oligomers 13–18. For these experiments, the corresponding oligonucleotide (2.25 A₂₆₀ units) was dissolved in 0.1 M Tris-HCl buffer (900 μ L, pH 8.3), and alkaline phosphatase (22.5 μ g) was added; two stock solutions were prepared. The reaction was started by addition of either snake-venom phosphodiesterase (67.5 μ g) or calf-spleen phosphodiesterase (135 μ g). From the stock solutions, samples (100 μ L) were taken after a certain interval of time. An aliquot (80 μ L) was examined by HPLC (gradient II, followed by I, see below). The UV absorbance was measured at 260 nm and quantification was made on the basis of peak areas and extinction coefficients.

HPLC Separation. The following solvent systems consisting of 0.1 M (Et₃NH)OAc (pH 7)/MeCN 95:5 (A) and MeCN (B) were used: gradient I, 20 min 0–30% B in A, 5 min 30% B in A, flow rate, 1 mL/min; gradient II, 30 min 100% A, flow rate, 0.6 mL/min.

CD Spectral Data. Temperature-dependent CD spectra were obtained under the conditions described in Figures 1 and 2.

RESULTS AND DISCUSSION

Synthesis of Monomers. While two methods are available for the synthesis of isomeric deoxyadenosine

Figure 2. (a) Normalized melting profiles of d(G-T-A-G-iA-iA-T-T-C-T-A-C) (**14**, □) and d(G-T-A-G-iA-iA-iT-T-C-T-A-C) (**15**, △); conditions, see Figure 1a; oligomer concentration 5 μ M. (b) $- \ln c$ vs $1/T_m$ plot, **14** (□) and **15** (△). (c) Normalized melting profiles of d(G-iT-iA-G-A-A-T-T-C-iT-iA-C) (**16**, □) and d(A-iT)₆-T (**18**, △); conditions, see Figure 1a. (**15**, **16**), these either give low yields of product or have been developed for very small scale synthesis. As the synthesis of oligodeoxyribonucleotides requires the availability of isodeoxyadenosine in gram quantities, we developed a synthesis strategy for isodA (**1**) starting from 1-deoxyribose (**3**) (**17**). This approach was based on previous work from our laboratory (**18**). Selective protection of the primary hydroxyl group by treatment of **3** with *tert*-butyldiphenylsilyl chloride (TBDPS-Cl) in anhydrous pyridine at 0 °C afforded **4** in 86% yield. Methanesulfonylation of **4** at 0 °C led to a mixture of mesylates from which **5** was isolated in 53% yield. The 3-mesylate was the minor product (21%). Following protection of the 3-hydroxyl group in **5** (78%), the resulting compound **6** was coupled with adenine in the presence of K₂CO₃ and 18-crown-6 in dry DMF. However, this alkylation step required drastic conditions (120 °C, 60 h) and compound **7a** and its partially deprotected derivative **7b** were obtained in only 49% yield. Deprotection of nucleosides **7a** and **7b** was carried out using 0.5 M methanolic NH₄F solution to furnish **1** in high yields.

The isomeric thymine analog, isodT, could not be prepared in good yields using the alkylation step described above because of complications associated with O-alkylation. However, this intermediate **2** was prepared using modification of a procedure developed previously in our laboratory recently (**18**).

Nucleosides **1** and **2** were converted into the β -cyanoethyl phosphoramidite building blocks **10** and **12**. As *N*⁶-benzoyldeoxyadenosine has a half-life of 71 min under mild alkaline conditions (25% aqueous NH₃ solution (**19**), we protected the exocyclic amino group of **1** with the benzoyl group. Reaction of **1** with benzoyl chloride, after temporary protection of the sugar hydroxyls with Me₃Si

residues (transient protection) (**20**), afforded compound **8** in 81% yield. Compounds **8** and **2** were converted into the 4,4'-dimethoxytrityl [(MeO)₂Tr] derivatives **9** and **11** under standard conditions (60–62%). Subsequent phosphorylation of **9** and **11** with chloro(diisopropylamino)- β -cyanoethoxyphosphine furnished the phosphoramidites **10** and **12** as diastereoisomeric mixtures in good yields. These new compounds were characterized by ¹H-, ¹³C-, and ³¹P-NMR spectral data (see Experimental Procedures). Assignment of the protons was made on the basis of COSY spectra, whereas the unequivocal assignment of the carbons was aided by [¹H,¹³C]-2D-correlation or [¹H,¹³C]-gated decoupled spectra. The anomeric configuration and the alkylation position of compound **1** were assigned by ¹H-NOE difference spectroscopy (see Experimental Procedures) (**21**).

Synthesis of Oligonucleotides. The β -cyanoethyl phosphoramidites **10** and **12** were used in automated solid-phase synthesis of oligonucleotides (**22**). However, the incorporation of the isomeric DNA building blocks **10** and **12** required 10 times longer coupling times than the corresponding 2'-deoxyribophosphoramidites. Furthermore, the coupling yields determined on the liberation of the 4,4'-dimethoxytrityl cation at 498 nm were significantly lower than those of the regular DNA-building blocks (**10**, 70%; **12**, 80%). After treatment with concentrated aqueous NH₃ solution (24 h at 60 °C), the 5'-(MeO)₂Tr-protected oligomers were purified, detritylated, and desalted on oligonucleotide-purification cartridges (Perkin Elmer, Applied Biosystem Division) to yield the oligomers **13–18** (Table 1). The content of the modified oligonucleotides was determined by tandem hydrolysis with snake-venom phosphodiesterase followed by alkaline phosphatase (Table 2).

Duplex Stability of Oligodeoxyribosides Incorporating L-Related Isodeoxynucleosides. Figure 1a displays the temperature-dependent CD spectra of d(G-T-A-G-iA-iA-iT-iT-C-T-A-C) (**15**) measured in 1 M NaCl. As can be seen, the change from the low- to the high-temperature profile led to significant decrease of the ellipticity of the CD minima and maxima, whereas increasing of the temperature did not alter the wavelength of the Cotton effects. Furthermore, the temperature-dependent CD profiles exhibit well-defined isodichroic points, an experimental finding which is in good agreement with our results on the dinucleotide, 2'-deoxyadenylyl-(3'→5')-isodideoxyadenosine (23). The CD spectra of the self-complementary alternating oligomers **17** and **18** were also measured (Figure 1b). While the unmodified oligomer **17** shows a B_{1u} transition at 246 nm with a negative sign and a B_{2u} transition at 268 nm with positive sign, the corresponding π - π^* transitions of oligonucleotide **18** exhibit similar Cotton effects but with a strong bathochromic shift of the B_{1u} and B_{2u} transitions (8 nm). Moreover, the ellipticity value of the B_{1u} transition is markedly reduced, whereas the intensity of the B_{2u} band is almost the same.

The structural stability of the modified oligonucleotides **14–16** and **18** using temperature-dependent CD spectroscopy was also investigated by measuring both π - π^* transitions (B_{1u}, B_{2u}) as a function of temperature (10 and 70 °C). In all cases, sigmoidal monophasic melting profiles were obtained (Figure 2, panels a and c). Furthermore, both π - π^* transitions exhibited almost the same *T_m* value. To discriminate between duplex and hairpin formation, the thermal denaturation curves of **14–16** and **18** as a function of oligomer concentration were determined (Figure 2, panels b and d). Reduction of the oligomer concentration from 10 to 2 μ mol led to a significant decrease of the *T_m* values by 4–6 °C. Therefore, in all cases, duplex melting was observed; the formation of hairpin structures could be excluded.

Surprisingly, the modified oligonucleotide d(A-iT)₆-T (**18**) showed exactly the same *T_m* value as determined for the regular counterpart **17**. Moreover, the oligomers **14–16** exhibited only a moderate decrease of the *T_m* values compared to the parent duplex **13**. These experimental findings encouraged us to study the thermodynamic parameters for the conceptually novel oligonucleotides. From the ln *c* vs 1/*T_m* plot (Figure 2, panels b and d), ΔH and ΔS of the melting process can be determined according to Borer et al. (Table 3) (24).

The experimentally determined ΔH values of the duplexes **15** and **16** were slightly reduced compared to the parent duplex **13**. Surprisingly, the incorporation of two isodA residues opposite of dT within the oligonucleotide **14** led to an increase of the enthalpy. The measured ΔH values of all self-complementary oligonucleotides (**13–16**) were in good agreement with calculated values ($\Delta H = -95$ kcal/mol for **13**) using published increments (25). These results indicate that incorporation of L-related isodeoxynucleosides does not disturb duplex formation to any significant extent; the isodA-dT base pair (oligomer **14**) is enthalpically favored but entropically unfavored. The incorporation of 4 isodA-isodT base pairs in the innermost part (**15**) or at the termini (**16**) of **13** led to stable duplex structures. However, the contribution of each isodA-isodT base pair to ΔH (−4.0 to −4.5 kcal/mol) is lower than that of the dA-dT base pair (−6 kcal/mol). Evaluations of the thermodynamics of duplex formation of the alternating self-complementary oligomers **17** and **18** exhibited a significant difference. While the enthalpy of duplex formation for d(A-iT)₆-T (**18**) is 16% lower than that of the regular counterpart, d(A-T)₆

Table 2. Composition of the Oligomers 14–16 and 18 Determined by Tandem-Hydrolysis with Snake-Venom Phosphodiesterase and Alkaline Phosphatase in 0.1 M Tris-HCl Buffer, pH 8.3

^a Measured in 1 M NaCl containing 100 mM MgCl₂ and 60 mM sodium-cacodylate (pH 7.0); single strand concentration 5 μ M. ^b Enzymatic hypochromicity (snake-venom phosphodiesterase). ^c No significant hydrolysis of the phosphodiester backbone.

Figure 3. Time course of phosphodiester hydrolysis of the oligonucleotides **13–16** in 0.1 M Tris-HCl buffer (pH 8.3) at 37 °C; (---) d(G-T-A-G-A-A-T-T-C-T-A-C) (**13**), (□) d(G-T-A-G-iA-iA-T-T-C-T-A-C) (**14**), (○) d(G-T-A-G-iA-iA-iT-iT-C-T-A-C) (**15**), (△) d(G-iT-iA-G-A-A-T-T-C-iT-iA-C) (**16**); (a) snake-venom phosphodiesterase (3',5'-exonuclease); (b) calf-spleen phosphodiesterase (5',3'-exonuclease), both followed by alkaline phosphatase treatment.

Figure 4. Time course of phosphodiester hydrolysis of d(A-iT)₆-T (**18**); conditions, see Figure 3; (a) snake-venom phosphodiesterase; (b) calf-spleen phosphodiesterase, both followed by alkaline phosphatase treatment.

(**17**), the entropical term is favored by about 18%. In that case, the contribution of each dA-isodT base pair to ΔH is still approximately -4.2 kcal/mol.

Finally, these studies show that the novel synthesized oligonucleotides **14–16** and **18** form stable Watson–Crick duplex structures in which formation of the hydrogen bonds between isodA-dT or isodA-isodT or dA-isodT is not disturbed.

Enzymology. Nuclease stability of the phosphodiester backbone is an important requirement for the development of therapeutic oligonucleotides. To test this behavior of the modified oligomers, **14–16** and **18**, we carried out enzymatic studies using snake-venom phosphodiesterase as well as calf-spleen phosphodiesterase. Figure 3 shows the rates of phosphodiester bond hydrolysis of the oligonucleotides **13–16** in the presence of the exonucleases. As can be seen, incorporation of L-related isodeoxynucleosides within the parent oligomer **13** led to significant resistance of the phosphodiester bonds towards exonucleases. Furthermore, the resistance increased with the number of isomeric nucleosides within the self-complementary oligonucleotides. Exchange of the innermost part of the oligomer by isomeric nucleosides (oligomer **15**) exhibited the highest stability toward exonucleases. The enzyme kinetics follows a two-step mechanism in which the unmodified nucleotides are hydrolyzed first with rates almost identical to the parent sequence, **13**. In the second step the modified inner part is hydrolyzed at a much lower rate.

Figure 4 shows the enzymatic degradation of the phosphodiester backbone of the alternating self-complementary d(A-iT)₆-T (**18**). The kinetic studies show that

oligomer **18** is very resistant toward enzymatic hydrolysis, toward either snake-venom or calf-spleen phosphodiesterase. Even after 100–120 h (Figure 4) only minimal amounts of oligonucleotide **18** had hydrolyzed.

Summary and Conclusion. In summary, the L-related isodeoxynucleosides **1** and **2** were successfully incorporated within self-complementary oligonucleotides, (**14–16**, **18**). These conceptually novel oligomers, and especially the alternating self-complementary oligonucleotide, d(A-iT)₆-T (**18**), exhibit high resistance toward nucleases. Comprehensive CD spectral studies and the resulting thermodynamic parameters indicate the participation of the isodA-isodT or mixed dA-isodT/isodA-dT base pairs in duplex stabilization.

ACKNOWLEDGMENT

We thank Dr. G. Pearson for technical assistance with several 2D-NMR spectra and Dr. R. Forsyth of the Protein Structure Facility for help with the operation of the CD spectrometer. This research work was supported by the National Institutes of Health (NIAID).

The pentadentate H₃bhci [1,3,5-trideoxy-1,3-bis((2-hydroxybenzyl)amino)-*cis*-inositol] and its bifunctionalized analogue H₃bhci-glu-H [1,3,5-trideoxy-1,3-bis((2-hydroxybenzyl)amino)-5-glutamido-*cis*-inositol] were synthesized, and their coordination chemistry was investigated with inactive rhenium, with no carrier added Re-188 and with carrier added Re-186. The neutral Re(V) complexes [ReO(bhci)] and [ReO(bhci-glu-H)] are formed in good yields starting from [ReOCl₃(P(C₆H₅)₃)₂] or in quantitative yield directly from [^{186/188}ReO₄][−] in aqueous solution by reduction with Sn(II) or Sn(0). The X-ray structures of [ReO(bhci)] and [ReO(bhci-glu-H)] were elucidated revealing pentadentate “side on” coordination of the ligands to the “Re=O” core. The basic cyclohexane frame adopts a chair form in the case of [ReO(bhci)] and a twisted boat form in the case of [ReO(bhci-glu-H)]. [ReO(bhci)] crystallizes in the monoclinic space group *C2/c* with *a* = 27.425(3), *b* = 14.185(1), *c* = 19.047(2) Å, and β = 103.64(2)° and [ReO(bhci-glu-H)] in the monoclinic space group *P2₁/c* with *a* = 13.056(3), *b* = 10.180(1), *c* = 22.378(5) Å, and β = 98.205(9)°. Both ¹⁸⁸Re complexes are stable in human serum for at least 3 days without decomposition. After injection into mice, [ReO(bhci-glu)][−] is readily excreted through the intestines, while [ReO(bhci)] is excreted by intestines, liver, and the kidneys. TLC investigations of the urine showed exclusively the complexes [ReO(bhci-glu-H)] and [ReO(bhci)], respectively, and no decomposition products. For derivatization of antibodies, the carboxylic group of [ReO(bhci-glu-H)] was activated with *N*-hydroxysuccinimide, which required unusually vigorous reaction conditions (heating). The anti colon cancer antibody mAb-35 [IgG and F(ab')₂ fragment] was labeled with [^{186/188}ReO(bhci-glu)] to a specific activity of up to 1.5 mCi/mg (55 MBq/mg) with full retention of immunoreactivity. Labeling yields followed pseudo-first-order kinetics in antibody concentration with the ratio of rates between aminolysis and hydrolysis being about 2. Biodistributions of ¹⁸⁶Re-labeled intact mAb-35 as well as of its F(ab')₂ fragment in tumor-bearing nude mice revealed good uptake by the tumor with only low accumulation of radioactivity in normal tissue.

INTRODUCTION

Labeling of tumor-seeking monoclonal antibodies with radioactive nuclides is an important method in nuclear medicine for the diagnosis of small cancer metastases or for therapy (1–6). One of the most widely applied isotopes for diagnosis is ^{99m}Tc due to its favorable γ -decay characteristics, its convenient availability, and its chemical properties. The β -emitting rhenium isotopes ¹⁸⁶Re and ¹⁸⁸Re are suited for therapeutic purposes. On the basis of the chemical relationship between rhenium and technetium, it has been proposed that the same ligands

and protocols that are used with ^{99m}Tc for diagnostic purposes should be applicable to ^{186/188}Re for therapy (7, 8). There is increasing evidence, however, that this strategy suffers from the observation that the thermodynamic, kinetic, and electrochemical properties of rhenium and technetium are more different than previously expected and, as a consequence, Re(V) complexes tend to be reoxidized to [ReO₄][−] much faster than Tc(V) complexes to [TcO₄][−] (9). The facile reduction of [^{99m}TcO₄][−] to lower oxidation states at ambient conditions, for instance with S₂O₄^{2−}, allows convenient postlabeling techniques, whereas under equivalent conditions, reduction and subsequent complex formation are barely possible with [^{186/188}ReO₄][−]. Therefore, the use of ^{186/188}Re requires the application of prelabeling techniques with the disadvantage of further purification steps (10). A widely applied ligand in tumor therapy with ^{186/188}Re is MAG3, a tetradentate N₃S ligand originally developed for renal function measurement with ^{99m}Tc. The ^{186/188}Re-MAG3 system was applied in phase I radioimmuno-therapy studies and showed very promising results (11–

Scheme 2. Prelabeling Protocol with H₃bhci-glu-H

generated (8 atm) for 2 days at ambient temperature in the presence of $\text{PtO}_2 \cdot \text{H}_2\text{O}$ (0.15 g) as catalyst. Methanol was added until the solution turned clear, and the solution was separated from the catalyst. The solvent was removed in vacuo, and the residue extracted twice with hot ethanol to remove impurities and byproducts. The remaining white powder was dried in vacuo to yield 1.50 g (35%) of analytically pure H_3bhci . IR (KBr, cm^{-1}):

3404 s, 3366 s, 3242 s, 2928 w, 1654 m, 1600 m, 1572 m, 1484 s, 1452 s, 1258 s, 1234 m, 1094 m, 1066 s, 980 m, 950 s, 880 m, 860 m, 826 m, 768 s. FAB-MS (m/z , M^+): 390.1 (calcd for $\text{C}_{20}\text{H}_{27}\text{N}_3\text{O}_5$ 389.46). Anal. Calcd for $\text{C}_{20}\text{H}_{27}\text{N}_3\text{O}_5$: C, 61.68; H, 6.99; N, 10.79. Found: C, 61.86; H, 6.94; N, 10.52. ^1H NMR (d^6 -DMSO) δ (ppm): 7.10–7.03 (m, 4H), 6.75–6.67 (m, 4H), 5.5–3.5 (br m, 9H), 4.03 (t, 1H), 3.95 (s, 4H), 3.80 (t, 2H), 2.42 (t, 3H). ^{13}C NMR (d^6 -DMSO) δ (ppm): 157.59, 128.43, 127.80, 123.83, 118.40, 115.38, 72.22, 68.24, 56.99, 52.74, 46.88.

1,3,5-Trideoxy-1,3-bis[(2-hydroxybenzyl)amino]-5-glutaramido-*cis*-inositol ($\text{H}_3\text{bhci-glu-H}$). Glutaric anhydride (0.495 g, 4.33 mmol) was added to a solution of taci (0.762 g, 4.3 mmol) in 300 mL of methanol. A white precipitate readily formed and the suspension was stirred for another 30 min at ambient temperature. Salicylaldehyde (1.138 g, 9.31 mmol) was added to this suspension, which resulted in an instantaneous color change to yellow, and the solid dissolved completely after brief heating. $\text{PtO}_2 \cdot \text{H}_2\text{O}$ (0.08 g, catalyst) was added and the mixture was hydrogenated (8 atm) for 2 days at ambient temperature. The grayish suspension was taken to dryness, 200 mL of hot water was added to dissolve the solid, and the catalyst was filtered off. The slightly yellowish solution was taken to dryness again and treated twice with boiling ethanol. After filtration, the white powder was dried in vacuo to yield 1.330 g (2.64 mmol, 61%) of analytically pure $\text{H}_3\text{bhci-glu-H}$. IR (KBr, cm^{-1}): 3326 s, 2964 s, 1636 vs, 1544 s, 1460 s, 1406 s, 1252 s, 1188 w, 1158 w, 1118 m, 1068 w, 1004 w, 916 w, 874 w, 758 m, 572 w. ES-MS (m/z , M^+): 504 (calcd for $\text{C}_{25}\text{H}_{33}\text{N}_3\text{O}_8$ 503.55). Anal. Calcd for $\text{C}_{25}\text{H}_{33}\text{N}_3\text{O}_8 \cdot 2\text{H}_2\text{O}$: C, 55.65; H, 6.61; N, 8.34. Found: C, 55.51; H, 7.19; N, 8.02. ^1H NMR (d^6 -DMSO) δ (ppm): 7.23–7.16 (m, 4H), 7.85–6.80 (m, 4H), 4.19 (br s, 1H), 4.04 (s, 4H), 4.01 (br s, 2H), 3.81 (br s, 1H), 2.71 (br s, 2H), 2.34–2.30 (m, 4H), 1.88–1.79 (q, 2H). ^{13}C NMR (d^6 -DMSO) δ (ppm): 175.06,

171.46, 157.64, 128.75, 128.07, 124.14, 118.68, 115.58, 69.80, 68.72, 56.87, 51.03, 46.75, 34.62, 33.72, 20.99

[$\text{ReO}(\text{bhci})$]. H_3bhci (0.134 g, 0.35 mmol) and 1.1 mL of a 1 M NaOH solution were added to a suspension of $[\text{ReOCl}_3(\text{P}(\text{C}_6\text{H}_5)_3)_2]$ (0.281 g, 0.34 mmol) in methanol. The mixture was refluxed for 30 min, and the violet precipitate was removed by filtration. The solid was washed first with methanol, then with ether, and dried in vacuo to yield 0.143 g (72%) of analytically pure $[\text{ReO}(\text{bhci})]$. IR (KBr, cm^{-1}): 3396 br, 2894 m, 1598 m, 1570 m, 1482 s, 1446 m, 1364 w, 1258 s, 1234 s, 1098 m, 1068 m, 1048 m, 948 m, 912 m, 880 m, 862 m, 774 s, 766 s, 722 s. FAB-MS (m/z , M^+): 589.0 (calcd for $\text{C}_{20}\text{H}_{24}\text{N}_3\text{O}_6\text{-Re}$ 588.63). Anal. Calcd for $\text{C}_{20}\text{H}_{24}\text{N}_3\text{O}_6\text{Re}$: C, 40.81; H, 4.11; N, 7.14. Found: C, 40.81; H, 4.05; N, 7.01. ^1H NMR (d^7 -DMF) δ (ppm): 9.08 (m, 2H), 7.20 (dd, 2H), 7.04 (d, 2H), 6.96 (d, 2H), 6.60 (dd, 2H), 6.10 (m, 2H), 5.33, (d, 2H), 4.70 (dd, 2H), 4.52 (t, 1H), 3.99 (t, 2H), 3.86 (t, 1H), 2.89 (t, 2H), 2.72 (m, 2H). ^{13}C NMR (d^7 -DMF) δ (ppm): 172.35, 133.14, 129.91, 122.97, 120.73, 118.33, 81.81, 66.04, 64.53, 64.30, 57.37.

[$\text{ReO}(\text{bhci-glu-H})$]. NEt_3 (249 μL , 0.181 g, 1.789 mmol), concentrated NH_3 (300 μL) and $[\text{ReOCl}_3(\text{P}(\text{C}_6\text{H}_5)_3)_2]$ (0.486 g, 0.583 mmol) were added to a solution of $\text{H}_3\text{bhci-glu-H}$ (0.300 g, 0.596 mmol) in 15 mL of MeOH and 1 mL of doubly distilled water. The suspension was refluxed for 30 min, giving a deep violet solution which was evaporated to dryness. The residue was washed three times with ether and CHCl_3 . The crude product (0.363 g) was dissolved in 10 mL of MeOH/ H_2O 2/1 (v/v) and allowed to stand for 2 weeks to evaporate the MeOH. The precipitated violet solid was removed by filtration and washed twice with 2 mL of water and THF. The crystals were dried in vacuo to yield 0.110 g (26%) of analytically pure $[\text{ReO}(\text{bhci-glu-H})]$. IR (KBr, cm^{-1}): 3396 br, 2894 m, 1598 m, 1570 m, 1482 s, 1446 m, 1364 w, 1258 s, 1234 s, 1098 m, 1068 m, 1048 m, 948 m, 912 m, 880 m, 862 m, 774 s, 766 s, 722 s. ES-MS (m/z , M^+): 702.0 (calcd for $\text{C}_{25}\text{H}_{30}\text{N}_3\text{O}_9\text{Re}$ 702.73). Anal. Calcd for $\text{C}_{25}\text{H}_{30}\text{N}_3\text{O}_9\text{Re} \cdot 3.25\text{H}_2\text{O}$: C, 39.44; H, 4.83; N, 5.52. Found: C, 39.55; H, 4.88; N, 5.46. ^1H NMR (d^6 -DMSO) δ (ppm): 7.61 (d, 1H), 7.33 (t, 2H), 7.29 (br., 1H), 7.21 (d, 2H), 6.94 (d, 2H), 6.77 (t, 2H), 6.08 (br., 1H), 4.92 (t, 1H), 4.58 (dd, 4H), 4.42 (dd, 2H), 3.76 (br s, 1H), 3.33 (dd, 2H), 2.35 (t, 4H), 1.86 (q, 2H). ^{13}C NMR (d^6 -DMSO)

δ (ppm): 174.54, 171.52, 131.97, 129.55, 123.46, 118.45, 118.16, 77.97, 65.47, 62.79, 61.64, 48.49, 34.58, 33.05, 20.74.

[$^{186/188}\text{ReO}(\text{bhci-glu-H})$] (A). NaCl solution (1 mL of 0.9%) containing [$^{186/188}\text{ReO}_4$] $^-$ [up to 4.3 mCi (160 MBq)] was added to a solution of $\text{H}_3\text{bhci-glu-H}$ (2 mg) and of $\text{Na}_3\text{citrate}$ (40 mg) in 1 mL of doubly distilled water. The solution was heated to 90 °C and SnCl_2 (12 mg) was added. After 30 min, the solution was cooled to ambient temperature. Monitoring the reaction by TLC [stationary phase, silica gel; mobile phase, $\text{CH}_3\text{CN}/\text{H}_2\text{O}$ 4/1 (v/v)] revealed that complex formation was complete to >98% ($R_f = 0.45$). The mixture was purified using a preconditioned reversed-phase Sep-Pak column, eluting inorganic residues with 25 mL of water, and the complex was finally eluted with 2 mL of $\text{CH}_3\text{CN}/\text{H}_2\text{O}$ 10/1 (v/v). TLC revealed radiochemical purity to be better than 99%.

[$^{186/188}\text{ReO}(\text{bhci-glu-H})$] (B). [$^{186/188}\text{ReO}_4$] $^-$ [up to 16.2 mCi (600 MBq)] in 0.5–1 mL 0.9% NaCl solution was added to a solution of $\text{H}_3\text{bhci-glu-H}$ (1.3 mg) in 1 mL of doubly distilled water. The solution was heated to 90 °C and small pieces of metallic Sn(0) (about 250 mg) were added. After 60 min ([$^{188}\text{ReO}_4$] $^-$) or 150 min ([$^{186}\text{ReO}_4$] $^-$), the solution was allowed to cool to ambient temperature. TLC (see above) showed that complex formation was >95%. HCl (0.1 M, 1 mL) was added, and the solution was purified using a column containing 0.75 g of cation-exchange resin (Dowex 50W, X8 50–100 mesh; ionic form, H^+) and a preconditioned reversed-phase Sep-Pak column. Inorganic and organic residues were eluted with 10 mL of 0.1 M HCl. After removal of the cation-exchange column, the Sep-Pak column was rinsed with 10 mL of doubly distilled water and subsequently dried using a N_2 -stream. A second preconditioned reversed-phase Sep-Pak column was attached to the one loaded with the radioactive complex, and the complex was eluted with 2 mL of $\text{CH}_3\text{CN}/\text{H}_2\text{O}$ 10/1 (v/v). TLC revealed radiochemical purity to be better than 99%.

[$^{186/188}\text{ReO}(\text{bhci-glu-NHS})$]. *N*-(3-Dimethylaminopropyl)-*N'*-ethylcarbodiimide hydrochloride (EDC, 8 mg) and *N*-hydroxysuccinimide (NHS, 6 mg) were dissolved in 0.5 mL of dry DMSO. The fraction from the Sep-Pak column containing the complex was dried under a stream of N_2 , and 0.2 mL of the EDC/NHS mixture was added. This solution was heated to 45–55 °C and the activation monitored by TLC (see above; R_f [$\text{ReO}(\text{bhci-glu-H})$] = 0.45 and R_f [$^{186/188}\text{ReO}(\text{bhci-glu-NHS})$] = 0.65). After 70–80 min, more than 80% of the complex was in its activated form. The solution containing [$^{186/188}\text{ReO}(\text{bhci-glu-NHS})$] was diluted with 5 mL of doubly distilled water and purified using a preconditioned reversed-phase Sep-Pak column, eluting EDC, NHS and nonactivated complex with 10 mL of doubly distilled water, 8 mL of a 1/9 (v/v) mixture of ethanol and 0.01 M phosphate buffer pH 7.0, and 10 mL of doubly distilled water. The Sep-Pak column was dried using a N_2 -stream and the [$^{186/188}\text{ReO}(\text{bhci-glu-NHS})$] was eluted with 1.3 mL of CH_3CN . TLC showed radiochemical purity to be better than 90%, the remainder being in its nonactivated form. Aliquots of this solution were used for the protein-labeling experiment.

Labeling Experiments. The solution containing [$^{186/188}\text{ReO}(\text{bhci-glu-NHS})$] was taken to dryness under a stream of N_2 . DMSO (50 μL) was added to dissolve the activated complex, then 0.25 mg of mAb-35 antibody [IgG or $\text{F}(\text{ab}')_2$ fragment] in 0.15 mL PBS 1 $\times$ pH 7.4 and 0.3 mL 0.9% NaCl solution were added ([mAb] = 0.5 mg/mL). After thorough mixing, the solution was allowed to stand at ambient temperature for 30 min, then diluted to 1 mL

with doubly distilled water and purified by gel filtration chromatography using a PD-10 column and by FPLC (Superose 12 column, Pharmacia) with PBS 1 $\times$ as mobile phase. Labeling yield was up to 15% (see Results and Discussion).

Serum Stability Studies. An aliquot (20 μL) of the radiolabeled conjugate containing approximately 2.7 μCi (0.1 MBq) of ^{188}Re was added to 1 mL of fresh human serum. The mixture was incubated at 37 °C for 3 days and then analyzed by TLC.

Tumor Cell Binding Assays. The immunoreactivity of the labeled antibody was determined following a procedure described by T. Lindmo et al. (28), using the CEA-expressing LoVo (human colon adeno carcinoma) cell line (American Type Culture Collection). Six serial dilutions (2×10^6 to 6.25×10^4 cells) of LoVo cells were dried onto a 24-well cell-culture plate. After presaturation of the cells with 0.5% HSA in PBS 1 $\times$, 10 ng of $^{186/188}\text{Re}$ -labeled mAb-35 [IgG or $\text{F}(\text{ab}')_2$ fragment] in 0.5 mL of 0.5% HSA in PBS 1 $\times$ was added to each well. Equivalent samples containing a 100-fold excess of unlabeled mAb-35 were assayed for each cell concentration to determine nonspecific binding. The plate was incubated for 16 h at 37 °C, wells were washed twice with ice-cold PBS 1 $\times$ and the cells were digested using 0.5 mL 0.1 M NaOH. Radioactivity bound to the LoVo cells was determined in a β -counter. Data were analyzed according to the method of Lindmo.

Biodistributions of [$^{188}\text{ReO}(\text{bhci})$] and [$^{188}\text{ReO}(\text{bhci-glu})$] in White Mice and of [$^{186}\text{ReO}(\text{bhci-glu})$]-Labeled mAb-35 [IgG and $\text{F}(\text{ab}')_2$ fragment] in Tumor-Bearing Nude Mice. The complexes [$^{188}\text{ReO}(\text{bhci})$] and [$^{188}\text{ReO}(\text{bhci-glu-H})$] and the radioimmunoconjugate [$^{186}\text{ReO}(\text{bhci-glu})$]-mAb-35 were synthesized and purified as described above. ^{188}Re complex [ca. 30 μCi (1.1 MBq)] in 100 μL of PBS 1 $\times$, pH = 7.4, and ca. 10 μCi (0.4 MBq) of [$^{186}\text{ReO}(\text{bhci-glu})$]-mAb-35 [intact antibody or $\text{F}(\text{ab}')_2$ fragment] in 150 μL of PBS 1 $\times$, pH 7.4, were injected in the tail venes of groups of three white mice or three nude mice bearing LoVo tumor-xenografts (mean tumor weights, 50–150 mg). The mice were sacrificed and dissected at the indicated time points, the organs were removed, and the activity was measured in a γ -counter using an energy window between 145 and 165 keV. Results are expressed as a percentage of injected dose per gram of tissue (% ID/g).

X-ray Crystallography. Structure Analysis of [$\text{ReO}(\text{bhci})$]. A violet crystal ($0.4 \times 0.4 \times 0.3$ mm) was mounted on an Enraf Nonius CAD4 diffractometer. Reflections were collected using graphite monochromated $\text{MoK}\alpha$ radiation ($\lambda = 0.71073$ Å) and operating in the ω scan mode. The unit cell was determined by the angular setting of 25 high angle reflections ($8.59 < \theta < 14.57$). Intensity data were collected in the range $6.12 < 2\theta < 50.0$. Every 300 reflections, three reflections were measured for decay control, with an observed decrease of intensity of 5.1%. A total of 6744 reflections were measured at $T = 208$ K from which 3746 were observed [$I \geq 2.0\sigma(I)$]. A Ψ -scan absorption correction was applied ($T_{\min} = 0.742$ and $T_{\max} = 0.955$), and the structure solved by direct methods. Subsequent refinements were performed by full-matrix least-squares calculations with SHELXL 97 (29). The maximum residual electron density ($1.20 \text{ e}^-/\text{\AA}^3$) was found close to the heavy-atom site. A ZORTEP representation of the complex is given in Figure 1, crystallographic data is summarized in Table 1, and important bond lengths and angles are presented in Table 2.

Figure 1. ORTEP presentation of [ReO(bhci)].

Structure Analysis of [ReO(bhci-glu-H)]. A violet crystal (0.2 × 0.1 × 0.1 mm) of [ReO(bhci-glu-H)] was obtained by slow evaporation of MeOH from a solution of the complex in MeOH/H₂O 2:1 (v/v). X-ray data were collected on a CAD4 diffractometer (Enraf Nonius) using graphite-monochromated MoKα radiation (λ = 0.710 73 Å) and operating in the ω — θ scan mode. Intensity data were collected at 293 K with ω-scans in the range 3.16 ≤ θ ≤ 49.96°. Of the 5378 measured reflections, 5171

were independent and 1879 had $I \geq 2\sigma(I)$. The unit cell parameters were obtained through a least-squares analysis of 25 reflections ($10^\circ < \theta < 14^\circ$). Data reduction and empirical absorption corrections were applied with the XTAL package (30) (Ψ -scans, $T_{\min} = 0.81$ and $T_{\max} = 1.00$). No corrections for decay were employed. The structure was solved by heavy atom methods with SHELXS 86 (31) and refined by full-matrix least-squares analysis with SHELXL 93 (32, 33). All non-H atoms were refined with anisotropic thermal parameters, whereas H-atoms were included at estimated positions. A ZORTEP representation of the complex is given in Figure 2, crystallographic data is summarized in Table 1, and important bond lengths and angles are presented in Table 3. Disorder of the carboxylic acid group over three sites was modeled by restraining the occupancies of three independent C-atoms: C(39A), C(39B), and C(39C). Only carboxyl O-atoms attached to C(39A) were modeled.

RESULTS AND DISCUSSION

The stable complexation of metal centers under in vivo conditions demands ligands providing high thermodynamic stability and kinetic inertness. It is well-known that, for a particular metal center, ligands of higher denticity usually give rise to complexes of higher stability. Therefore, ligands with high denticity should be of particular value for in vivo applications. In the case of rhenium and technetium, practically all the known complexes involve tetradentate open-chained ligand systems with nitrogen and/or sulfur as donor atoms. Most of these complexes have tetragonal pyramidal geometry with four ligand atoms in the basal plane and the terminal oxo in the apical position (34–38).

We recently described the preparation and structure of the complex [ReO(thci)] (Scheme 1), which demon-

Scheme 3. Two Synthetic Ways to H₃bhci-glu-H

strates this coordination mode (39). Although H₃bhci is potentially a hexadentate ligand, the Re=O moiety was maintained during coordination, leading to pentadentate coordination with one of the pendant arms remaining uncoordinated. This uncoordinated amine functionality of the taci framework is convenient for the attachment of linking groups of choice without influencing the coordinating properties of the metal-binding site. This expectation was confirmed by H₃bhci and in particular by H₃bhci-glu-H.

Ligand Synthesis. The ligand H₃bhci was synthesized by the condensation of 2 equiv of salicylaldehyde with taci and subsequent reduction of the imines to amines, which gives rise to a statistical mixture of 1:1, 1:2, and 1:3 products from which the 1:2 product was extracted (Scheme 3). Due to the various nucleophilic functionalities of H₃bhci, derivatization of H₃bhci with glutaric anhydride and subsequent chromatographic purification resulted in a very poor yield of the desired product. Therefore, to bifunctionalize H₃bhci by the introduction of a glutaric acid group as a linker to the protein at the underivatized amine function of H₃bhci, the derivatization of the taci framework with the linker was performed prior to the attachment of the two other pendant arms. In this case, the 1:1 product precipitated from solution and the formation of a mixture of the statistically distributed 1:1, 1:2, and 1:3 products is avoided. The subsequent addition of 2 equiv of salicylaldehyde and reduction of the imines was easily performed and good yields of the bifunctional ligand H₃bhci-glu-H were achieved (Scheme 3).

This procedure allows the introduction of linkers with varying chain lengths and other biological characteristics such as lipophilicity, charge, or cleavable groups.

Structure of [ReO(bhci)] and [ReO(bhci-glu-H)]. Complex formation on the nonradioactive level was achieved by reaction of [ReOCl₃(P(C₆H₅)₃)₂] with H₃bhci

or H₃bhci-glu-H in methanol and addition of base to neutralize the released protons.

The crystal structures of both [ReO(bhci)] and [ReO(bhci-glu-H)] were determined by X-ray diffraction (Figures 1 and 2). It can be seen that the primary amino group of [ReO(bhci)] and the carboxylic group of [ReO(bhci-glu-H)] do not participate in the Re(V) coordination. This is crucial for the linkage of the complex to the protein. Some structural parameters of [ReO(bhci)], [ReO(bhci-glu-H)], and of the previously reported [ReO(thci)] (39) are presented in Table 4. They all show the same "asymmetric" Re(V)—N₂O₃ coordination (40). The distances between Re and the donor atoms of the ligands fall in the expected ranges (41), and differences between the three complexes are generally not significant. In contrast to the well-known, symmetric M—N,N,N coordination of taci, the asymmetric Re—N,N,N,O coordination causes some characteristic distortion of the ligand backbone. This is evident when comparing interatomic, nonbonding distances between the substituents in the 1,2- and the diaxial 1,3-positions. The 1,2-interactions between the coordinated donor atoms of the Re complexes all lie between 2.50 and 2.62 Å. This is remarkably short when compared to the free ligand or to the symmetric hexamine [Co(taci)₂]³⁺ (27) and indicates the considerable strain inherent in this coordination mode.

Although the three rhenium complexes have related coordination spheres, it is noteworthy that a significantly different conformation is observed between the cyclohexane rings of [ReO(thci)] and [ReO(bhci)] on one hand and for [ReO(bhci-glu-H)] on the other. Inspection of the puckering parameters presented in Table 4 shows that a slightly flattened chair is present in [ReO(thci)] and [ReO(bhci)]. However, for [ReO(bhci-glu-H)] the puckering parameters correspond to an almost ideal twisted boat (42). In the chair arrangement of [ReO(thci)] and [ReO(bhci)], the N—H bonds of the coordinated amines are oriented directly toward the lone pair of the noncoordinating amine, and the structure is stabilized by N—H...N hydrogen bonding (43). In contrast, no such stabilization would be possible in the corresponding chair conformation of [ReO(bhci-glu-H)]. However, the observed twisted boat conformation in the latter complex allows hydrogen bonding between a coordinated N—H group and a noncoordinated hydroxy group. Hence, there is evidence that hydrogen bonding between the coordi-

Figure 3. Biodistribution studies of $[^{188}\text{ReO}(\text{bhci})]$ and $[^{188}\text{ReO}(\text{bhci-glu})]^-$ in white mice. Organ uptake was determined at 0.25, 0.5, 1, 2, and 4 h postinjection for $[\text{ReO}(\text{bhci})]$ (A) and at 0.5, 1, 2, 4, and 8 h postinjection for $[\text{ReO}(\text{bhci-glu})]^-$ (B).

nated amines and additional noncoordinating substituents is one of the key factors responsible for the observed differences in the conformation of these complexes.

Synthesis of $[^{186/188}\text{ReO}(\text{bhci})]$ and $[^{186/188}\text{ReO}(\text{bhci-glu-H})]$. For the preparation of the radioactive complexes, $[^{186/188}\text{ReO}_4]^-$ was reduced with Sn(II) in citrate buffer or with Sn(0) in water in the presence of small amounts of ligand to yield the analogous $^{186/188}\text{Re}$ complex in quantitative yield. TLC/HPLC were used to establish that the radioactive and nonradioactive products were equivalent.

Serum and in Vivo Stability of the Complexes. The complexes $[^{188}\text{ReO}(\text{bhci})]$ and $[^{188}\text{ReO}(\text{bhci-glu-H})]$ contain ligand groups in the coordination sphere which can easily be protonated since the corresponding pK_a values are rather high. This is in particular the case for the aliphatic alkoxo-group trans to the terminal oxo function.

To investigate the stability of the two complexes, the corresponding ^{188}Re compounds were dissolved in freshly prepared human serum at 37 °C, and the solution was checked by TLC over a 3 day period. Potential decomposition products such as $^{188}\text{ReO}_2$ or $[^{188}\text{ReO}_4]^-$ can easily be detected by this method. Decomposition amounting to less than 5% was found under these conditions, clearly demonstrating the excellent stability of both of these compounds.

Furthermore, the two complexes were injected intravenously into mice in order to check their in vivo stability and behavior. The results of the biodistribution experiments are shown in Figure 3.

It was found that the uncharged complex $[^{188}\text{ReO}(\text{bhci})]$ is excreted via the liver, the kidneys, and the intestines, while $[^{188}\text{ReO}(\text{bhci-glu})]^-$, which is anionic at physiological pH values, is mainly excreted via the intestines. As $[^{188}\text{ReO}_4]^-$ is excreted via kidneys into urine, the urine was checked for the presence of this potential decomposition product using TLC/HPLC. Essentially, the total activity in the urine samples was accounted for as $[^{188}\text{ReO}(\text{bhci-glu})]^-$ with less than 5% in the form of $[^{188}\text{ReO}_4]^-$. On the other hand, samples obtained at later times revealed the presence of another $[^{188}\text{Re}]$ complex with an R_f of 0.1, which was obviously neither $[^{188}\text{ReO}_4]^-$ nor ReO_2 . It is not possible to say whether the degradation process leading to this species was already occurring in the serum or only in the urine. However, since a similar compound was not detected during in vitro incubation, it seems to be more likely that transformation occurred only in the urine. Furthermore, the R_f value indicates a degradation at the backbone rather than at the complex itself. The study shows that there is no decomposition of the complexes and that the complexes were essentially excreted in the same form as injected. The high in vivo stability and rapid renal clearance of

Figure 4. Formation of the [ReO(bhci-glu)-NHS] active ester at 50 °C.

[ReO(bhci-glu)]⁻ indicate that this may be a suitable complex for use in antibody labeling and RIT applications.

Studies on Active Ester Formation. Activation of the carboxylic acid function by esterification with strongly acidic alcohols is a technique that is widely applied for the covalent attachment of molecules to proteins by amide formation with the ϵ -amino group of lysine. Optimal coupling conditions are particularly important if prelabeling studies are intended. The competition between aminolysis and hydrolysis often results in poor labeling yields on the *nca* level. Accurate quantification of coupling conditions is relatively rare in the literature since they vary considerably from system to system. The EDC/NHS approach with activation after complex formation was chosen mainly due to the enhanced reactivity of the NHS esters (e.g., compared to tetrafluorophenol) toward amines, and since activation prior to coordination would probably result in cross linking to secondary amine groups in the ligand itself. Although most of the activations with NHS described in the literature were carried out under ambient conditions, no activation could be observed under these conditions with the [ReO(bhci-glu-H)] complex. The formation of the NHS active ester could only be achieved by increasing the temperature (80% yield after 60 min at 50 °C). The progress of the activation process was monitored by TLC, where [¹⁸⁸ReO(bhci-glu-H)] and [¹⁸⁸ReO(bhci-glu-NHS)] could be readily distinguished. A typical profile for the formation of [¹⁸⁸ReO(bhci-glu-NHS)] as a function of time is given in Figure 4.

The profile shows first-order kinetic behavior which is reasonable considering the large excess of NHS and EDC over the rhenium complex. Thus, the concentrations of the former compounds can be considered to remain constant over the reaction period. Quantitative activation could not be achieved under any conditions, but this did not appear to be simply an analytical problem. Deactivation on the silica gel plates would result in significant tailing of the peaks, but these were in fact fully symmetrical.

Labeling Experiments. Aliquots of [¹⁸⁸ReO(bhci-glu-NHS)], prepared as described above, were used for the labeling of the intact antibody mAb-35 and its F(ab')₂ fragment. Prelabeling often gives poor yields, so efforts were made to optimize the reaction conditions by varying the pH, mAb concentration, and reaction volume. The progress of the labeling reaction was monitored by TLC. The labeled protein remained at the origin while the complexes had defined *R_f* values (see Experimental Procedures). The final labeling yield was determined after separation of protein from small molecular weight materials and aggregates by FPLC gel chromatography.

Figure 5. Labeling yield as a function of mAb concentration.

Figure 6. Protein concentration dependent ratio of hydrolysis of the active ester [ReO(bhci-glu)-NHS] (B) and binding of the complex to the antibody (C).

Labeled mAb appeared as a single peak in the same fractions as unlabeled IgG or F(ab')₂ fragment. A typical curve for the labeling yield as a function of protein concentration is depicted in Figure 5.

Yields ranged from about 7% at mAb concentrations of 0.2 mg/mL to 43% at 3.65 mg/mL. The latter value seems to represent a kinetic maximum since the curve approaches a horizontal line at this concentration. At even higher protein concentrations, there was no further increase in labeling yield, but there was a decrease in specific activity of the radioimmunoconjugate due to the larger amount of protein. Specific activities of up to 1.5 mCi/mg (55 MBq/mg) could be achieved.

The two main reactions are (a) hydrolysis of the activated metal complex [ReO(bhci-glu-NHS)] (A) with a first-order rate k_1 ($d[A]/dt = -k_1[A]$) to [ReO(bhci-glu)]⁻ (B) and (b) the effective labeling of the protein (mAb) with a rate constant k_2 . Assuming only [ReO(bhci-glu-NHS)] on the *nca* level and no free activated ligand, the rate law of the reaction b must be pseudo-first-order in protein concentration ($d[A]/dt = -k_2[A][mAb]$) since the available amine groups are in excess relative to [¹⁸⁸ReO(bhci-glu-NHS)] and can be considered as having a constant concentration. The yield of labeled protein (C) under this assumption would depend only on k_1 , k_2 , and [mAb], giving rise to the expression $[C]/[B] = k_2 [mAb]/k_1$. It is not possible to determine individual values for k_1 and k_2 , although graphical analysis of $[C]/[B]$ vs [mAb] showed that $k_2/k_1 \approx 2$ (44). The graphical representation is given in Figure 6. The linearity of the curve supports the formulated pseudo-first-order model, the invariance of protein concentration, and importantly, the absence of significant amounts of free, activated ligand. From this idealized model, it is to be expected that the labeling yield will not depend on the initial amount of metal complex, and this was indeed confirmed for the investi-

Figure 7. Biodistribution studies of [$^{186}\text{ReO}(\text{bhci-glu})$]-labeled mAb-35 in tumor-bearing nude mice. Organ and tumor uptake was determined at 4, 8, 12, 24, and 48 h postinjection for the labeled $\text{F}(\text{ab}')_2$ fragment (A) and at 24, 96, and 144 h postinjection for the labeled IgG (B).

gated range. However, when the concentration of the rhenium complex was increased by a factor of 10 or more, the yield decreased by a factor of 2 but the absolute specific activity of the radioimmunoconjugate increased by a factor of 5. It can be concluded from this observation that small amounts of free, activated ligands are nevertheless present, and these change the available amine concentration upon coupling to the protein. The pseudo-first-order kinetics are then transformed into true second-order kinetic behavior. This dependence clearly demonstrated the importance of purifying the complex prior to activation. This purification is not only essential to achieve good labeling yields and consequently high specific activities but also to maintain the immunoreactivity of the labeled mAb-35.

Samples of mAb-35 were labeled with [$^{186}\text{ReO}(\text{bhci-glu})$] as described above. The labeling yields with carrier added ^{186}Re (0.4% radioactive ^{186}Re , 99.6% "cold" Re) were ca. 30% lower than in case of *nca* ^{188}Re from the $^{188}\text{W}/^{188}\text{Re}$ generator. Calculations revealed that, at a specific activity of the radioimmunoconjugates of 1 mCi/mg (37 MBq/mg), the complex:antibody molar ratio is 1:1230 for *nca* ^{188}Re and about 1:1 for carrier added ^{186}Re .

Serum Stability and Immunoreactivity. The radioimmunoconjugate thus prepared with a specific activity of 1 mCi/mg (37 MBq/mg) was stable in serum over

at least 72 h (>95% ^{186}Re bound to the protein after 72 h in blood serum at 37 °C). Assessment by Lindmo assay (28) of the immunoreactivity of the ^{186}Re -labeled preparations of both intact and fragmented mAb-35 showed them to have an immunoreactivity of over 90%. Nonspecific binding was determined by competition with excess unlabeled mAb-35 and was less than 5% in all cases. These results are in good correlation with the results obtained in the literature using other methods for the labeling of mAb-35, such as ^{131}I -labeling (iodogen-method) or ^{67}Cu -labeling (21), where immunoreactivities of over 80% were determined.

Biodistribution of [$^{186}\text{ReO}(\text{bhci-glu})$]-Labeled mAb-35 [IgG and $\text{F}(\text{ab}')_2$] in Tumor-Bearing Nude Mice. Free [$^{186/188}\text{ReO}(\text{bhci})$] and [$^{186/188}\text{ReO}(\text{bhci-glu})$] $^-$, respectively, are rapidly cleared from the body with a maximum of 1.5% ID/g remaining in the intestines and the liver after 4 h (Figure 3). The ^{186}Re bound to intact mAb-35 is cleared much more slowly due to the pharmacokinetic behavior of the antibody. Biodistributions of ^{186}Re -mAb-35 (IgG) in tumor-bearing mice were measured over a period of 6 days. The results are shown in Figure 7B. It was found that tumor uptake reached a maximum after 4 days with 7% ID/g, and after 6 days still more than 5% ID/g was bound to the tumor. Clearance of radioactivity from all organs, with the exception of blood, was rapid.

Figure 8. Tumor-to-organ ratios of $[^{186}\text{Re}(\text{bhci-glu})]$ -labeled mAb-35 in tumor-bearing nude mice. The ratios were determined at 4, 8, 12, 24, and 48 h postinjection for the labeled $\text{F}(\text{ab}')_2$ fragment (A) and at 24, 96, and 144 h postinjection for the labeled IgG (B).

Tumor-to-organ ratios, which were achieved after 24, 96, and 144 h, are shown in Figure 8B. As negative control for the specific binding of ^{186}Re -labeled mAb-35, the non-CEA-specific antibody chCE7 (an internalizing, neuroblastoma-specific mAb) was labeled and purified in the same way as mAb-35, and consecutively injected in mice bearing LoVo-cell xenografts. After 4 days, tumor-to-organ ratios of the chCE7 antibody were generally three to four times lower than with mAb-35, demonstrating the specific binding of labeled mAb-35 to CEA antigen presented on LoVo cells. The labeled $\text{F}(\text{ab}')_2$ fragment showed much faster clearance from the body than the intact mAb-35 antibody. Biodistributions of ^{186}Re - $\text{F}(\text{ab}')_2$ in tumor-bearing mice were measured over a period of 2 days. The corresponding results are shown in Figure 7A. The maximum tumor uptake was reached after 12 h (9% ID/g), and after 48 h, the tumor accumulation was still 8% ID/g.

Tumor-to-organ ratios 24 h postinjection were better for ^{186}Re - $\text{F}(\text{ab}')_2$ than for intact mAb-35 (Figure 8A). MAb-35 has been evaluated in both radioiodinated (21, 25, 45) and radiocopper labeled (21) form in nude mice bearing LoVo cell xenografts. The ^{186}Re -labeled mAb-35 [IgG and $\text{F}(\text{ab}')_2$] shows similar results as its ^{131}I -labeled analogues in terms of tumor uptake and tumor/organ ratios. Biodistributions of ^{67}Cu -labeled mAb-35 are characterized by higher levels of radioactivity in tumors but also by considerably higher uptake of the label in liver and spleen. In the case of ^{67}Cu -labeled $\text{F}(\text{ab}')_2$, fragment accumulation of radioactivity in the kidneys is very prominent and the biodistributions of ^{186}Re - $\text{F}(\text{ab}')_2$ appear to be more favorable.

Samples of blood from the dissected mice were checked by TLC, revealing that 100% of radioactivity found in the

blood was still bound to the antibody. To determine in which form the radioactivity was excreted in the urine, samples were checked by TLC. After 1 day, the radioactivity consisted of 50% $[^{186}\text{ReO}(\text{bhci-glu})]^-$, 20% $[^{186}\text{ReO}_4]^-$, and 30% $[^{186}\text{ReO}(\text{bhci-glu})]$ bound to low molecular protein, while after 4 and 6 days, most of the ^{186}Re was excreted in the form of low molecular protein bound $[^{186}\text{ReO}(\text{bhci-glu})]$ with only roughly 5% $[^{186}\text{ReO}_4]^-$. Preliminary experiments to establish the composition of this low molecular protein bound $[^{186}\text{ReO}(\text{bhci-glu})]$ showed that on TLC it has the same R_f (0.15) as $[^{186}\text{ReO}(\text{bhci-glu-Lys})]$. The results show that these metabolites are characterized by rapid renal and hepatic clearance. In summary, our data show that the labeling of monoclonal antibodies with $[^{186/188}\text{ReO}(\text{bhci-glu})]$ leads to stable, fully immunoreactive mAb conjugates having favorable biodistributions in tumor-bearing mice, and may have potential for application in RIT.

CONCLUSION

The novel pentadentate ligands H_3bhci and $\text{H}_3\text{bhci-glu-H}$ have been prepared. These ligands form the very stable Re(V) complexes $[\text{ReO}(\text{bhci})]$, and $[\text{ReO}(\text{bhci-glu-H})]$ which showed no detectable decomposition under in vivo conditions. Ligands with a denticity greater than four provide significantly better stability than the more common tetradentate systems. Furthermore, the underivatized ligand H_3bhci offers the possibility of introducing various linking systems and allows the systematic study of the influence of this part of a protein label on tumor accumulation of radioimmunoconjugates. Activation of the carboxylic acid group in $[\text{ReO}(\text{bhci-glu-H})]$ with the widely applied EDC/NHS method was found to require increased temperature and time to achieve a

reasonable yield of the activated complex form. Labeling yields depended strongly on protein concentration, the latter influencing the rate in a pseudo-first-order kinetic fashion in the absence of excess ligand, otherwise the labeling yields are dramatically reduced. It was found that it is essential to purify the activated complex before the labeling of the antibody to retain full immunoreactivity of the immunoconjugate. Animal experiments showed promising results in terms of biodistribution and clearance from the body, especially of the labeled mAb-35 F(ab')₂ fragments. The results with the novel [ReO-(bhci-glu)] label indicate its potential for the ¹⁸⁶Re labeling of antitumor antibodies for the use in RIT.

ACKNOWLEDGMENT

Thanks to C. De Pasquale and C. Ruch for their help with the biodistribution studies and to P. Osvath for the correction of this publication.

Supporting Information Available: Tables giving details of data collection, atomic coordinates, bond distances and angles, anisotropic thermal parameters, and hydrogen atom positions for the complexes [ReO(bhci)] and [ReO(bhci-glu-H)] are available (14 pages). Ordering information is given on any current masthead page.

Table 1 : Crystal data and structure refinement for ReO(bhci).

Compound	ReO(bhci)
Empirical formula	C30 H46 N3 O11.50 Re S
Formula weight	850.96
Temperature	208(2) K
Wavelength / Radiation	0.71073 Å / MoK α
Crystal system / Spacegroup	Monoclinic/ C2/c
Unit cell dimensions	a = 27.425(3)Å alpha = 90 deg. b = 14.185(1)Å beta = 103.64(2) deg. c = 19.047(2)Å gamma = 90 deg.
Volume	7200.8(12) Å ³
Z	8
Density (calculated)	1.570 Mg/m ³
Absorption coefficient	3.493 mm ⁻¹
F(000)	3440
Crystal description	pale violet block
Crystal size	0.40 x 0.40 x 0.30 mm
No. of reflns. (lattice)	25
Theta range (lattice)	8.59 to 14.57 deg.
Theta range for data collection	3.06 to 25.00 deg.
Index ranges	-1<=h<=32, 0<=k<=16, -22<=l<=22
Reflections collected	6744
Independent reflections	6321 [R(int) = 0.0456]
Reflections observed	3746
Criterion for observation	>2sigma(I)
Absorption correction	Psi scans
Max. and min. transmission	0.9549 and 0.7422
Measurement method	omega scans
No. of standard reflections	3
Interval count/time	300/3600
Decay	5.1 %
Structure solution	SHELXS-97 (Sheldrick, 1990)
Structure refinement	
Molecular graphics	SCHAKAL (Keller,1995), ZORTEP(Zsolnai,1997)
Publication material	SHELXL-97 (Sheldrick, 1997)
Refinement method	Full-matrix least-squares on F ²
Weighting scheme	calc w=1/[\s ² (Fo ²)+(0.0632P) ² + 48.7902P] where P=(Fo ² +2Fc ²)/3
Solution primary	Patterson
Hydrogen treatment	mixed
Data / restraints / parameters	6321 / 0 / 434
Final R indices [I>2sigma(I)]	R1 = 0.0568, wR2 = 0.1284
Goodness-of-fit on F ²	1.063
Final R indices (all) R1 / wR2	0.1369 / 0.1558
Largest diff. peak and hole	1.200 and -0.673 e.Å ⁻³

Table 2: Atomic coordinates and equivalent isotropic displacement parameters ($\text{\AA}^2 \times 10^3$) for $\text{ReO}(\text{bhci})$. ($U(\text{eq})$ is defined as one third of the trace of the orthogonalized U_{ij} tensor).

ReO(bhci)

Table 1. Crystal data and structure refinement for ReO(bhci-glu).

Identification code	ReO(bhci-glu)
Empirical formula	C ₂₅ H ₃₀ N ₃ O ₉ Re
Formula weight	702.72
Temperature	293(2) K
Wavelength / Radiation	0.71073 Å / MoK α
Crystal system	P2 ₁ /c
Space group	monoclinic
Unit cell dimensions	a = 13.056(3) Å alpha = 90 deg. b = 10.180(1) Å beta = 98.205(9) deg. c = 22.378(5) Å gamma = 90 deg.
Volume	2943.8(10) Å ³
Z	4
Density (calculated)	1.586 Mg/m ³
Absorption coefficient	4.179 mm ⁻¹
F(000)	1392
Crystal size	0.2 x 0.1 x 0.1 mm
Theta range for data collection	1.58 to 24.98 deg.
Index ranges	-15 ≤ h ≤ 15, 0 ≤ k ≤ 12, 0 ≤ l ≤ 26
Reflections collected	5378
Independent reflections	5171 [R(int) = 0.0637]
Refinement method	Full-matrix least-squares on F ²
Data / restraints / parameters	5169 / 0 / 322
Goodness-of-fit on F ²	1.036
Final R indices [I > 2sigma(I)]	R ₁ = 0.0674, wR ₂ = 0.1772
R indices (all data)	R ₁ = 0.2326, wR ₂ = 0.2555
Largest diff. peak and hole	1.853 and -0.909 e.Å ⁻³

Table 2. Atomic coordinates ($\times 10^4$) and equivalent isotropic displacement parameters ($\text{\AA}^2 \times 10^3$) for $\text{ReO}(\text{bhci-glu})$. $U(\text{eq})$ is defined as one third of the trace of the orthogonalized U_{ij} tensor.

Conformational Transition of Restriction Endonuclease *MvaI*–Substrate Complex under the Influence of Mg^{2+} Probed by DNA–Protein Cross-Linking Studies

G. Y. Sheflyan,[†] E. A. Kubareva, E. S. Gromova, and Z. A. Shabarova*

A.N. Belozersky Institute of Physical and Chemical Biology, Department of Chemistry, M.V. Lomonosov Moscow State University, 119899 Moscow, Russia. Received February 10, 1998; Revised Manuscript Received May 22, 1998

The method of protein affinity modification by DNA analogues was used to study the characteristic features of restriction endonuclease *MvaI* interaction with DNA. Oligonucleotide duplexes containing a monosubstituted pyrophosphate internucleotide bond were used for cross-linking to the enzyme. The conditions of the reaction of *MvaI* endonuclease with these reagents were investigated. On the basis of data obtained, the model of successive inclusion of two Mg^{2+} ions into *MvaI* endonuclease–substrate complex was proposed and confirmed by the kinetic scheme of the process.

INTRODUCTION

Restriction endonuclease *MvaI* recognizes the DNA sequence

and cleaves it, as shown by the arrows, Mg^{2+} being the cofactor of this reaction. The interaction of this enzyme with DNA was probed via the use of modified DNA substrates (1). We use the method of DNA–protein cross-linking to reveal the characteristic features of substrate scission by R.*MvaI*.¹

In our laboratory, the novel method of affinity modification of proteins by modified DNA was developed (2). DNA analogues contain a monosubstituted pyrophosphate internucleotide bond in the definite position of sugar–phosphate backbone. This method was successfully applied for the cross-linking of restriction-modification enzymes *EcoRI* and *RsrI* (3) and restriction endonucleases *EcoRII* (4, 5), *MvaI* (5), and *SsoII* (6). Cross-linking follows the scheme:

¹ Abbreviations: R.*MvaI*, restriction endonuclease *MvaI*; NuH, nucleophilic agent; MeIm, *N*-methylimidazole; PAGE, polyacrylamide gel electrophoresis; SDS, sodium dodecyl sulfate; Tris, tris(hydroxymethyl)aminomethane.

The aim of this paper is to extend the application of this cross-linking technique toward the probing of conformational changes of enzyme in the enzyme–substrate complex on the example of restriction endonuclease *MvaI*.

MATERIALS AND METHODS

R.*MvaI* was purchased from NPO "Fermentas" (Lithuania). Its preparation had the specific activity of 250 units/ μL and concentration of 46 $\mu\text{g}/\text{mL}$. Oligodeoxyribonucleotides were synthesized by T. S. Oretskaya, E. M. Volkov, and E. A. Romanova as described in ref 7. DNA duplexes with a monosubstituted pyrophosphate internucleotide bond for cross-linking to R.*MvaI* were synthesized as described in ref 2. DNA duplexes were ^{32}P -labeled by T4 polynucleotide kinase. ^{32}P label was at the disubstituted phosphate group of the modified internucleotide linkage within the DNA duplexes I and II modified strands (see formulas) and at the 5'-end of the nonmodified duplex IV unless otherwise stated. Cross-linking of R.*MvaI* (138 ng, concentration per monomer 2.5×10^{-7} M) to ^{32}P -labeled DNAs (100 000 cpm, concentration per duplex, C_D , 1.8×10^{-7} M) in 20 μL of buffer X (10 mM Tris-HCl, pH 8.5, 150 mM NaCl, 1 mM dithiotreitol, and 0.1 mg/mL albumin) or buffer Y (10 mM MeIm-HCl, pH 8.5, 150 mM NaCl, 1 mM dithiotreitol, and 0.1 mg/mL albumin) was performed at 37 °C as described in ref 5. Concentrations of Mg^{2+} ions have been varied. Incubation time was 18 h. Cross-linking reaction was monitored by SDS–PAGE (5, 6). The enzymatic hydrolysis was performed under the same conditions except that radioactivity of DNA per reaction was 20 000 cpm, $C_D = 3.5 \times 10^{-7}$ M, incubation time varied from 1 to 18 h, and the reaction was followed by 20% PAGE containing 7 M urea.

RESULTS AND DISCUSSION

We used the following modified DNA duplexes as R.*MvaI* substrates or their analogues:

Duplex	#	Strand
5' ACCTACC- P -TGGTGGT 3'	I	Ia
3' TGGATGG---ACCACCA 5'		Ib
5' GTCACCT- P -CCTGGATCCG 3'	II	IIa
3' CAGTGA---GGACCTAGGCA 5'		IIb
5' GCCAACCTGGCTCT 3'	III	IIIa
3' CGGTTGGACCGAGA 3'		IIIb
5' ACCTACCTGGTGGT 3'	IV	IVa
3' TGGATGGACCA 5'		IVb

* - location of ^{32}P -label

In duplex I, the modified group was located in the middle of *R.MvaI* recognition site and coincided with the scissile bond. In duplex II, we probed protein contacts with sugar-phosphate backbone on the border between the flanking sequence and the recognition site (5). Nonmodified duplexes III and IV were used in control experiments.

The monosubstituted pyrophosphate internucleotide bond in DNA duplexes does not interfere with their binding to the enzyme (5). Previously, we demonstrated (5) that the cross-linking reaction of *R.MvaI* to duplex I required Mg^{2+} ions in the concentration of $37.5 \mu\text{M}$. At higher as well as lower concentrations of Mg^{2+} , modification of *R.MvaI* proceeded with low yield. The increase of nucleophilicity of reaction buffer replacing Tris-HCl (buffer X) by MeIm (buffer Y) did not result in the increase of a cross-linking product unlike the data previously observed for *R.EcoRII* (4). The cross-linking extent of duplex II to *R.MvaI* did not exceed 2% in the absence of Mg^{2+} ions nor in their presence till the Mg^{2+} concentration $150 \mu\text{M}$ (5).

The specificity of covalent attachment of duplex I to *R.MvaI* was established through the standard method of competitive inhibition of the affinity modification reaction by the increasing amounts of duplex III (Figure 1). This reaction proved to be specific. Therefore, it can reflect the structure of DNA-protein interface and its changes during the course of enzymatic hydrolysis.

To explain the results of *R.MvaI* affinity modification by duplexes I and II we checked (i) the ability of *R.MvaI* to hydrolyze duplex I and II in comparison with duplex IV; (ii) *R.MvaI* activity dependence on the Mg^{2+} concentration on the example of duplex IV; and (iii) *R.MvaI* activity dependence on the buffer nucleophilicity.

The results of hydrolysis of duplexes I, II and IV by *R.MvaI* are adduced in Table 1. Hydrolysis of duplex I in buffer containing 10 mM MgCl_2 results in the number of products corresponding to the weak enzymatic hydrolysis of intact strand Ib as well as the monosubstituted pyrophosphate bond degradation. Since the active group coincides with the *R.MvaI* scissile bond, it is difficult to explain the degradation of the modified strand Ia by either enzymatic or chemical cleavage. However, in ref 1, it was shown that *R.MvaI* cleaves only the intact strand of the DNA duplex containing a pyrophosphate group instead of the scissile phosphodiester bond. This allows us to suggest that the enzymatic hydrolysis of a

Figure 1. The dependence of relative cross-linking yields of *R.MvaI* to duplex I on the C_D ratio of duplexes I and III. C_D of duplex I is $1.8 \times 10^{-7} \text{ M}$. Cross-linking yield in the absence of duplex III was referred to as 100%.

	b	8
II	a	9; 51 ^b
	b	84
IV	a + b	88

^a Modified bond coincides with the scissile bond. ^b For 18 h.

Figure 2. The dependence of duplex IV hydrolysis by *R.MvaI* on Mg^{2+} concentration. C_D of duplex IV is $3.5 \times 10^{-7} \text{ M}$. The Mg^{2+} concentration is adduced in the logarithmic scale.

modified strand of duplex I does not occur. It was also demonstrated in ref 8 that *R.MvaI* is capable of cutting certain single-stranded oligodeoxyribonucleotides, for example, strand IVa, having the same sequence as Ia, but not strand IVb (Ib). This eliminates the possibility that the weak cleavage of strand Ib in duplex I is due to the formation of an incomplete duplex by strand Ib alone.

When monosubstituted pyrophosphate internucleotide bond is located on the border between the recognition site and the flanking nucleotide sequence (duplex II), the hydrolysis of modified strand IIa at the Mg^{2+} concentration equal to 10 mM occurs in a time-dependent manner. The intact strand IIb is efficiently cleaved by the enzyme (Table 1).

At low Mg^{2+} concentrations (till $7.5 \mu\text{M}$), *R.MvaI* practically does not cleave duplex IV (Figure 2). At Mg^{2+} concentration equal to $37.5 \mu\text{M}$, the hydrolysis extent of duplex IV is equal to 20%. The following addition of Mg^{2+} ions causes the fast growth of enzymatic activity. At the Mg^{2+} concentration $75 \mu\text{M}$, duplex IV is completely digested by *R.MvaI*. The efficiency of hydrolysis does not depend on incubation time (1 and 18 h, data not shown). We demonstrated that Tris-HCl replacement for MeIm-HCl in the reaction buffer did not decrease *R.MvaI* enzymatic activity in cleaving duplex IV (data not

shown). The weak enzymatic hydrolysis of only strand Ib in duplex I made it impossible to investigate the influence of Mg^{2+} on the enzymatic cleavage of this duplex by R.MvaI. All the reactions with duplex IV, having the identical sequence as duplex I, were performed under the same conditions as cross-linking experiments, with C_D of duplex IV being in the same range as the C_D of the cross-linking reagent (350 nM for duplex IV and 180 nM for duplex I).

The necessity of the presence of Mg^{2+} in low concentration for the R.MvaI covalent attachment to duplex I and the hydrolysis studies is believed to show the following features of DNA recognition by R.MvaI:

(1) In the absence of Mg^{2+} ions, there are no nucleophilic amino acid residues in the proximity to the scissile bond modified in duplex I.

(2) The introduction of Mg^{2+} in an enzyme–substrate complex results in a conformational change of the enzyme. As a consequence of this transition, a nucleophilic amino acid residue is moved toward the scissile bond. This is demonstrated by the increase of the cross-linking extent of the enzyme to duplex I in these conditions.

(3) The Mg^{2+} concentration equal to $37.5 \mu M$ is not sufficient for the effective substrate hydrolysis (Figure 2), though Mg^{2+} ion is already incorporated into the enzyme–substrate complex as revealed by cross-linking studies. Hence, more than one Mg^{2+} ion is necessary for the R.MvaI catalytic act.

(4) With the further increase of Mg^{2+} concentration, the catalytically active complex is formed and the substrate is cleaved. In the case where duplex I is the substrate, the covalent attachment is inhibited due to enzymatic hydrolysis. This explains the reduction in the cross-linking extent of duplex I to R.MvaI at Mg^{2+} concentrations above $150 \mu M$.

(5) The ability of duplex II to modify R.MvaI demonstrates the contact of a nucleophilic group with the phosphate group adjacent to 5'-terminus of recognition sequence. The absence of the dependence of the cross-linking yield of duplex II to R.MvaI on Mg^{2+} concentration $150 \mu M$ confirms that the enzyme conformational change has a local character and occurs only in the surroundings of the scissile bond.

Thus, R.MvaI requires more than one Mg^{2+} ion for catalysis. The same feature was supposed in ref 9 for EcoRV restriction endonuclease and confirmed in ref 10. One can conclude that these enzymes share the same mode of action. From the data obtained, as well as taking into account (10), we proposed the following scheme of the enzymatic reaction together with the parallel cross-linking process:

where E is the enzyme, S is the general substrate or duplex I in the case of covalent attachment, and $[E-S]_{CL}$ is the product of attachment of R.MvaI to duplex I.

On the basis of this scheme, we calculated the theoretical dependence of R.MvaI cross-linking to duplex I on Mg^{2+} concentration and compared it with the experimental data.

To simplify the calculation, we assumed that the formation of the complex with two Mg^{2+} ions is irreversible since it undergoes quick substrate hydrolysis and

dissociation into the enzyme and products. If only complex B with one Mg^{2+} ion can be transformed into the cross-linked product, the cross-linking yield is proportional to the complex B concentration in the reaction mixture. Complex C can also retain the conformation favorable for cross-linking, but the degradation of this complex through substrate cleavage proceeds faster than the affinity modification of the enzyme. Using the assumption of steady-state concentrations of intermediate compounds as well as material balance for enzyme concentration, we get the system of equations:

$$\frac{d[A]}{dt} = k_1[E][S] - k_2[A] - k_3[A][Mg^{2+}] + k_4[B] = 0$$

$$\frac{d[B]}{dt} = k_3[A][Mg^{2+}] - k_5[B][Mg^{2+}] - k_4[B] = 0$$

$$\frac{d[C]}{dt} = k_5[B][Mg^{2+}] - k_6[C] = 0$$

$$[E] = [E_0] - [A] - [B] - [C]$$

To calculate the concentration of B we use the following assumptions: (1) the consumption of the complex B in covalent attachment is too small to influence its concentration and (2) analysis of the Mg^{2+} binding was performed in terms of the concentration of free Mg^{2+} ions. The concentration of free Mg^{2+} ions was obtained by the subtraction of the phosphate group concentration from the initial concentration of Mg^{2+} . We used an assumption that one phosphate group binds one cofactor ion. The concentration of the phosphate groups in the cross-linking reactions was equal to $4.5 \mu M$.

Since the concentrations of E and S are fixed, the concentration of B is adduced as a function of Mg^{2+} concentration. The final equation is

$$[B] = \frac{l[Mg^{2+}]}{m[Mg^{2+}]^2 + n[Mg^{2+}] + p}$$

where

$$l = k_1 k_3 k_6 [S] [E_0]$$

$$m = k_1 k_3 k_5 [S] + k_3 k_5 k_6$$

$$n = k_1 k_5 k_6 [S] + k_1 k_3 k_6 [S] + k_2 k_5 k_6$$

$$p = k_1 k_4 k_6 + k_2 k_4 k_6$$

Since we suppose that γ (the extent of affinity modification) is proportional to a concentration of B with the coefficient q determining the probability of formation of covalent conjugate, we get

$$\gamma = q \frac{l[Mg^{2+}]}{m[Mg^{2+}]^2 + n[Mg^{2+}] + p}$$

We picked the coefficients via computer simulations. The function obtained is in a good agreement with the experimental data (Figure 3).

The requirement of two Mg^{2+} ions for successful cleavage of substrate demonstrates the similarity of mechanisms of R.MvaI and EcoRV restriction enzyme, the later being extensively studied by different methods including kinetics, X-ray structure analysis, and stop flow technique. As proposed in ref 11 on the basis of the

Figure 3. Theoretical dependence of covalent attachment of R.MvaI to duplex I on the Mg^{2+} concentration (solid line) in comparison with the experimental data (◆) (5).

kinetic order of enzymatic hydrolysis on Mg^{2+} concentration, R.EcoRV involves only one ion in catalysis. But as mentioned in ref 12, the kinetic equation for R.EcoRV would have the second order on Mg^{2+} concentration only in the case when both ions are attached with high cooperativity in one action. By kinetic means, it is possible to determine only the order of the slowest step of the process. One can conclude the possibility of successive binding of Mg^{2+} ions to sites with different affinity to cofactor.

In ref 12, on the basis of the previously obtained X-ray structure of the R.EcoRV complex with substrate, two Mg^{2+} -binding sites formed by carboxyl-groups of Asp90, Asp74, and Glu45 residues were proposed. Both Asp residues originate from consensus sequence common to a number of restriction endonucleases Pro-Asp...Asp-X-Lys, where X is the hydrophobic amino acid residue. Glu residue is in close contact with scissile phosphodiester bond only in the case of R.EcoRV compared to R.EcoRI, for which one Mg^{2+} ion was proved to be sufficient for DNA cleavage.

Modeling the crystal structure of R.EcoRV with substrate and one cofactor ion also allowed a confirmation of the binding site and the catalytic significance of the second Mg^{2+} ion (13).

Though the participation of two Mg^{2+} ions does not raise any doubts now, the location of the second cofactor binding site is still under discussion. EcoRV triple mutant Glu45Ala/Asp74Ala/Asp90Ala was obtained in ref 14, which retained the ability to discriminate cognate DNA only in the presence of Mg^{2+} being catalytically inactive. By cleavage experiments with phosphorothioate bond containing substrates as well as site-mutagenesis experiments, it was revealed that the second Mg^{2+} -binding site is probably formed by Tyr 129 residue and a phosphate group between dG and dA residues of the EcoRV recognition site (14). But Asp residues from the consensus sequence are still critical for cofactor and substrate binding.

In the R.MvaI amino acid sequence, the motif ⁴⁹Pro-⁵⁰Asp...¹¹⁷Asp-¹¹⁸Phe-¹¹⁹Lys exists, which can play an analogous role in Mg^{2+} binding.

Complex B can be a covalent one, being an intermediate compound during enzymatic hydrolysis. To test this possibility we used duplex IV containing the ^{32}P -label within the scissile bond. The mixtures of R.MvaI and duplex IV were incubated under various Mg^{2+} concentrations during 2.5 or 18 h and analyzed by SDS-PAGE.

No radioactive bands with mobility less than that of initial DNA were detected. So, we did not manage to reveal the covalent intermediate between R.MvaI and duplex IV in the course of enzymatic hydrolysis. The catalysis of phosphodiester bond hydrolysis possibly occurs without the formation of enzyme-DNA linkage, which is in accordance with the data of ref 15. As computer simulations showed, the appropriate coordination of cofactor ions could cause the catalysis of internucleotide bond cleavage (16).

The possibility of conformational changes for restriction endonucleases in the complexes with substrates is now discussed for a number of enzymes. By X-ray analysis, the existence of structural disturbances of substrate is revealed on the example of R.EcoRI and R.EcoRV complexes with DNA (17). The further conformational changes of these complexes are suggested under the influence of Mg^{2+} ions. It is particularly essential for R.EcoRV, since only in the presence of Mg^{2+} , the enzyme can distinguish its recognition site in DNAs (18). Analogous data were recently obtained for R.TaqI and R.PaeR7 (19). Retardation assays of R.EcoRV-substrate complexes demonstrated that Mg^{2+} ions introduced into these complexes form contacts with both protein and DNA. Changes in DNA-protein interface lead to close contact of active amino acid residue and the scissile bond (20). Mg^{2+} ions induce conformational changes not only in the enzyme but in DNA as well (21).

So, by means of covalent attachment of R.MvaI to activated substrate analogues, we established the conformational perturbation of the enzyme under the influence of a cofactor. At the first stage of the catalytic act the complex is formed with one Mg^{2+} ion, which is a structural precursor of the catalytic active complex. In this complex, the initial conformational changes occur, induced by the cofactor, and are completed by the subsequent addition of the second Mg^{2+} ion to form the full catalytic unit.

ACKNOWLEDGMENT

Lactose-Poly(ethylene Glycol)-Grafted Poly-L-Lysine as Hepatoma Cell-Targeted Gene Carrier

Young Hun Choi,[†] Feng Liu,[‡] Jong Sang Park,[†] and Sung Wan Kim^{*,‡}

Department of Chemistry, Seoul National University, Seoul, Korea, and Center for Controlled Chemical Delivery, Department of Pharmaceutics and Pharmaceutical Chemistry, University of Utah, Biomedical Polymers Research Building, Room 205, Salt Lake City, Utah 84112. Received February 10, 1998; Revised Manuscript Received August 17, 1998

To investigate the delivery of DNA into cells, lactose-poly(ethylene glycol)-grafted poly-L-lysine (Lac-PEG-PLL) polymers were synthesized as polymeric gene carriers. The new synthetic carriers, varying the substitution ratio of lactose-poly(ethylene glycol) (lactose-PEG), were characterized by NMR spectroscopy and size-exclusion chromatography. Electrophoretic mobility assay confirmed that the new gene carrier makes a complex with plasmid DNA. The attached poly(ethylene glycol) gives better solubility properties to gene/carrier complex. Transfection experiments showed that Lac-PEG-PLL efficiently delivers DNA to a hepatoma cell line *in vitro*; the best efficiency was achieved at a 1:3 weight ratio of DNA to carrier. As the lactose-PEG substitution content increased up to 30%, the transfection efficiency increased, which demonstrates that the lactose serves as a targeting moiety. No considerable cytotoxicity was observed due to Lac-PEG-PLL or its complex with DNA within the concentration range for this experiment. The use of chloroquine increased transfection efficiency that indicates the involvement of hydrolytic degradation of the system in lysosome. It is likely that plasmid DNA/Lac-PEG-PLL complexes enter the cells through a receptor-mediated endocytosis mechanism. These results show that Lac-PEG-PLL can form a complex with plasmid DNA and serve as an efficient gene delivery carrier with lower cytotoxicity compared to that of poly-L-lysine. Therefore, it is expected that our Lac-PEG-PLL carrier can be used as an *in vivo* gene delivery vector.

INTRODUCTION

Twenty-five years ago, Friedmann outlined prospects for human gene therapy (1). Since then, gene therapy has represented a new paradigm for therapy of human disease and for drug delivery (2). The implicit emphasis of the research so far has been on determining the safety of gene transfer procedures, sometimes with efficacy as a secondary goal (3). A major technical impediment to gene transfer is the lack of ideal gene delivery systems (3). If it were possible to deliver the gene to the appropriate specific cells in sufficient quantities, gene therapy would be efficacious. Currently, very few organs or cells can be specifically targeted for gene delivery. There are many established protocols for transferring genes into cells, including calcium phosphate precipitation, electroporation, particle bombardment, liposomal delivery, viral-vector delivery, and receptor-mediated gene delivery (4). Although all of these methods can be used for mammalian cultured cells, there are many difficulties in introducing genes into target cells *in vivo*.

Transfection methods using retroviral or adenoviral vectors (5) permit us to overcome some of these limitations. Retroviral vectors, in particular, have been used successfully for introducing exogenous genes into the genomes of actively dividing cells such that stable transformants are obtained (6). All the viral vectors use approaches that involve complementation of defective vectors by genes inserted into helper cell lines to generate

the transducing infectious agent. It is well-known that the host immune response to adenoviruses limits their use to a single administration. To address this limitation, fusion peptides of the influenza virus hemagglutinin have been employed to replace adenoviruses as endosomal lytic agents, but with limited success (7). However, despite their high transfection efficiency *in vitro*, inserting genes into the host cell's genome in this method depends on the viral infection pathway. Its application for human gene therapy introduces serious concerns about endogenous virus recombinations, oncogenic effects, and inflammatory or immunologic reactions (3, 8, 9). Such concerns have limited the use of viral vectors for human gene therapy (6).

On the other hand, nonviral gene delivery systems such as cationic liposomes (8) or synthetic gene carriers, such as poly-L-lysine (PLL) (10), are being widely sought as alternatives (11). There are several theoretical advantages of nonviral therapies including their relative safety and cost of manufacture (2). No significant toxicity has been encountered in preclinical toxicology studies using several cationic lipid:DNA complexes (12, 13) or in initial human studies (12, 14). Despite a theoretical concern about raising anti-DNA antibodies (15), there is no evidence for the formation of antibodies against DNA or antinuclear antibodies after administration of "naked DNA" or DNA formulated with lipids or proteins in clinical gene therapy studies (12, 14, 15). The major limitation of plasmid-based approaches has been that both the efficiency of gene delivery to several important somatic targets (*i.e.*, liver and lung) and *in vivo* gene expression level are lower using nonviral approaches than with viral vectors.

It has been shown previously that the presence of polycations in culture medium can increase in vitro cellular uptake of a variety of substances, for example, albumin (16) and nucleic acids (17). These effects were shown to be dependent on size and concentration (16, 17). The enhancement was found to be most effective with polyornithines, but PLLs also demonstrated considerable activity. Laemmli (18) characterized that PLL makes condensates with DNA. Since then, PLL, modified with various substances, was used as a part of gene carrier (4, 19–27).

Recently, poly(ethylene glycol) (PEG)-grafted PLL (PEG-g-PLL) was synthesized in this laboratory, based on the idea that PLL modified with PEG showed high solubility, low cytotoxicity, and enhanced cell permeability. The synthesized PEG-g-PLL was shown to make a complex with plasmid DNA and do so with lower cytotoxicity and improved transfection efficiency to that of over PLL (28). In addition, Kabanov et al. (29) and Wolfert et al. (11) have developed A–B type block polycations as carriers for oligonucleotide and gene delivery. For these carriers, one hydrophilic polymer region (PEG) combines with one polycationic polymer region (PLL). This block copolymer forms a complex with DNA, maintaining a low cytotoxicity comparable to the cation alone but with high solubility.

In this paper, the grafted polymers were synthesized by introducing lactose group to the end of PEG first and covalently attaching the carboxylic acid group of lactose-PEG to the ϵ -amino group of PLL. The purpose of using lactose is to target hepatoma cells for gene delivery. The ratio of lactose-PEG and PLL can be adjusted by changing reaction conditions. The synthesized carrier, named Lac-PEG-PLL, formed a complex with pSV- β -gal plasmid DNA. PEG, grafted to PLL, resulted in better solubility and reduced cytotoxicity of the plasmid DNA/carrier complex. The gene transfection efficiency and cytotoxicity of the Lac-PEG-PLL system were investigated and compared to those of DNA complexed with PLL alone. Hep G2 cells were transfected specifically with plasmid DNA/Lac-PEG-PLL complex, indicating that lactose serves as a targeting moiety for a hepatoma cell line.

MATERIALS AND METHODS

Materials. Isobutyl chloroformate (IBCF), *N,N'*-dimethylformamide (DMF), triethylamine (TEA), and dimethyl sulfoxide (DMSO) were purchased from Aldrich (St. Louis, MO). PLL-hydrobromide (120 repeating units; MW = 25 000), *p*-aminophenyl- α -D-lactopyranoside, Concanavalin A (Con A)-Sephacrose column, methyl- α -D-mannopyranoside, *N*-(2-hydroxyethyl)piperazine-*N'*-(2-ethanesulfonic acid) (HEPES), ethidium bromide, chloroquine, 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT), and *o*-nitrophenyl- β -D-galactopyranoside (ONPG) were purchased from Sigma (St. Louis, MO). PEG diacid (MW = 550) was bought from Fluka (Ronkonkoma, NY). Plasmid pSV- β -gal, 5X reporter Lysis buffer, and DNA size marker were purchased from Promega (Madison, WI). Hep G2 cells (a human liver carcinoma cell line, ATCC accession no. HB 8065), A7R5 cells (a rat smooth muscle cell line, ATCC accession no. CRL 1444), and NIH3T3 cells (a mouse embryonic cell line, ATCC accession no. CRL 1658) were purchased from ATCC (Rockville, MD). Fetal bovine serum (FBS), minimal essential medium (MEM), Dulbecco's minimal essential medium (DMEM), 0.25% trypsin, and 1 $\times$ phosphate-buffered saline (PBS) were purchased from Hyclone (Logan, UT). Lipofectin was purchased from GIBCO

BRL (Gaithersburg, MD). Bigger Prep DNA purification kit was purchased from 5'-3' Prime Inc. (Boulder, CO). Dialysis tubings (molecular weight cutoff of 1000 and 25 000) were purchased from Spectrum (Houston, TX).

Synthesis of Lac-PEG-PLL. The reaction scheme for synthesis of Lac-PEG-PLL is shown on Figure 1a. It consists of two reactions, synthesis of lactose-PEG diacid and grafting of lactose-PEG diacid to PLL. The lactose-PEG diacid is synthesized and purified according to a similar reported procedure (50). Six hundred milligrams (1.0 mmol) of PEG diacid (MW = 550) was dissolved in 1.5 mL of dried DMF containing 1.0 mmol of TEA in an ice–water bath under nitrogen. One millimole of IBCF dissolved in 1.0 mL of dried DMF was added dropwise, and the mixture was stirred for 15 min in an ice–water bath. IBCF served as the activator of carboxylic acid. Then *p*-aminophenyl- α -D-lactopyranoside (1.0 mmol) dissolved in 1.0 mL of DMF was added, and the mixture was stirred 30 min in an ice–water bath. It was stirred for additional 3 h at room temperature. The product was precipitated in an excess of dry ether (100 mL). Then the precipitate was dissolved in 20 mL of distilled water, dialyzed against distilled water (dialysis tubing with MWCO 1000), and freeze-dried. The product was purified by removing unreacted PEG diacid on a Con A-Sephacrose column. Forty milligrams of the lyophilized product was dissolved in 40 mL of 0.02 M Tris buffer (pH 7.4, 0.5 M NaCl, 3 mM CaCl₂, and 3 mM MnCl₂) and loaded on Con A-Sephacrose column at a flow rate of 0.10 mL/min. The column was eluted until absorbance at 280 nm dropped below 0.01, and then identical buffer containing 0.1 M methyl- α -D-mannopyranoside was applied. The specifically eluted peak of lactose-PEG and lactose-PEG-lactose mixture was detected by monitoring at 280 nm, collected, dialyzed against distilled water, and finally freeze-dried. The content of lactose was assayed by UV using *p*-aminophenyl- α -D-lactopyranoside as standard. The content of carboxylic acid was measured by titration. The mole ratio of lactose-PEG to lactose-PEG-lactose was about 2:1.

From the lactose-PEG and PLL, four different grafted copolymers Lac-PEG-PLLs with various mole ratios of lactose-PEG to ϵ -amino groups of PLL (mol/mol %) were further synthesized. As an example, the synthesis of Lac-PEG-PLL with 30% (mol/mol %) lactose-PEG is described. Lactose-PEG and lactose-PEG-lactose mixture (51.1 mg; containing 0.042 mmol of lactose-PEG) was dissolved in 0.5 mL of dried DMF under nitrogen in an ice–water bath. IBCF (0.036 mmol) dissolved in 0.5 mL of DMF was added to the above solution dropwise. The mixture was stirred 30 min in an ice–water bath, then added dropwise to 1 mL of dried DMSO containing 25 mg of PLL-HBr and 10 μ L of TEA which had been purged with nitrogen for 10 min in an ice–water bath, then stirred an additional 3 h at room temperature. The product was precipitated in 100 mL of dried ether, and the precipitate was dissolved in 10 mL of distilled water. It was dialyzed (dialysis tubing with MWCO 25 000) first against 0.01 M NaHCO₃ solution, second against 0.01 M HCl solution, and finally against distilled water. The dialyzed product was finally freeze-dried. The mole ratios of lactose-PEG to the amino group in PLL were calculated from ¹H NMR.

Size-Exclusion Chromatography Lac-PEG-PLL. The relative distribution of Lac-PEG covalently grafted to PLL was examined by size-exclusion chromatography (SEC) on a analytical Superose 12 column (10 mm $\times$ 30 cm) (Pharmacia AB) using FPLC. The column was eluted with 0.05 M PBS buffer (pH 7.3) containing 0.5 M NaCl at a flow rate 0.3 mL/min at 25 $^{\circ}$ C. A 200 μ L sample (2

Figure 1. (a) Synthesis scheme of Lac-PEG-PLL. The ratio of lactose-PEG-attached amine group to total amine group was calculated from the peak intensities in the ¹H-NMR spectrum. (b) ¹H-NMR analysis of Lac-PEG-PLL. The ¹H-NMR spectrum of 30 mol % Lac-PEG-PLL was obtained in H₂O. The peak at about 3.5 ppm designates the existence of PEG. (c) SEC of Lac-PEG-PLL on an analytical Superose 12 column. The 30 mol % Lac-PEG-PLL was used. The column was equilibrated with PBS buffer (0.05 M, pH 7.3) containing 0.5 M of NaCl at a flow rate 0.3 mL/min. Sample (200 μ L, 2 mg/mL) was injected.

mg of Lac-PEG-PLL/mL) was injected and the refractive index (RI) and A_{280} of the elute were continuously monitored.

Synthesis of PEG-g-PLL. The procedure for synthesis of PEG-g-PLL was previously described (28).

Preparation of pSV- β -gal Plasmid DNA. The plasmid pSV- β -gal was prepared as previously reported (28).

Band Retardation Assay. Various amounts of Lac-PEG-PLL, ranging from 0.1 to 10 μ g, were added to 1 μ g of plasmid DNA in HEPES buffer (20 mM, 0.15 M NaCl, pH 7.4) and incubated for 30 min at room temperature. Gel electrophoresis sample buffer was added to each sample, and it was electrophoresed on 1% (w/v) agarose gel for 90 min at 100 V using the Easy-Cast Electrophoresis System (Owl Scientific Inc., Woburn, MA). TBE (45 mM Tris-Borate and 1 mM EDTA, pH 8.0) buffer was used as electrophoresis buffer. The gel was stained with ethidium bromide (0.5 μ g/mL) for 30 min and illuminated with an UV illuminator to show the location of the DNA. Lambda DNA, which was digested by *Hind*III, was used as a DNA size marker.

Solubility Test. The solubility of the carrier/plasmid DNA complex was determined by a method which was originally developed by Wadhwa et al. (4) with a slight modification. pSV- β -gal plasmid DNA and carrier were mixed in 1 mL of HEPES buffer (20 mM and 0.15 M NaCl, pH 7.4) with final concentration of 50 μ g/mL in 1.5 mL centrifuge tubes. After incubation for 30 min at

room temperature, the tubes were centrifuged for 5 min at 10 000 rpm. The supernatant was taken, and its absorbance at 260 nm was measured for the determining of the DNA remaining in solution. A DNA sample without carrier was used as a standard.

Cell Culture. Hep G2 cells were maintained in MEM medium supplemented with 1 mM sodium pyruvate and 10% FBS at 37 °C in a 5% CO₂ Napco incubator (Precision Scientific Inc., Chicago, IL). A7R5 cells were similarly maintained in DMEM medium supplemented with 10% FBS. NIH3T3 cells were likewise maintained in DMEM medium supplemented with 4.5 g/L glucose and 10% FBS. Cells were normally grown in 25 cm² (for Hep G2 cells) or 75 cm² (for the A7R5 and NIH3T3 cells) polystyrene tissue culture flasks (Becton Dickinson, Franklin Lakes, NJ), until they became approximately 80% confluent as assessed by light microscopy.

Transfection. In vitro transfection was performed as follows. For the transfection and cytotoxicity studies, Hep G2 cells were seeded at a density of 2×10^4 cells/each well in 96-well flat-bottomed microassay plates (Becton Dickinson, Franklin Lakes, NJ). The cells were incubated for 24 h before the addition of either the plasmid DNA/carrier complex or the carrier only. For A7R5 and NIH3T3 cells, the seeding concentration was 5×10^3 cells/well and 2×10^4 cells/well, respectively.

All reagents used in the transfection experiments were sterilized by filtering through 0.22 μ m polycarbonate

membrane filters. Plasmid pSV- β -gal/Lac-PEG-PLL complexes were prepared by mixing 1 μ g of pSV- β -gal and various amounts of carrier in 100 μ L of FBS-free cell culture medium and incubated for 30 min at room temperature. FBS and chloroquine were added at a final concentration of 10% (v/v) and 100 μ M, respectively. Medium from each well of the 96-well plate was replaced with 100 μ L of transfection mixture. The cells were then incubated for 4 h at 37 °C in a 5% CO₂ incubator. After 4 h, the transfection mixtures were removed and 100 μ L of fresh medium containing 10% FBS was added to each well. Cells were incubated for an additional 48 h at 37 °C.

Assay for Expressed β -Galactosidase. The β -galactosidase activity in transfected cells was determined spectrophotometrically at 405 nm using ONPG with a slight modification (30). Briefly, the growth medium was removed from the cells in 96-well plates to be assayed, and the cells were washed twice with 1 $\times$ PBS carefully to prevent adherent cell detachment. Cells were lysed by adding 60 μ L of 1X reporter lysis buffer (Promega, Madison, WI) to the cells and incubating for 30 min at room temperature, rocking the plate halfway through the incubation period, followed by scraping the cells. Sixty microliters of ONPG (1.33 mg/mL) in 2 $\times$ assay buffer (Promega, Madison, WI) was added to the lysed cells, and the cells were incubated at 37 °C for 4 h. The reaction was terminated by adding 150 μ L of 1 M sodium carbonate solution to each well and the absorbance at 405 nm was read with a Bio-Tek EL-311, the microplate reader (Bio-Tek Instrument Co., Winooski, VT) for the β -galactosidase activity.

Cell Viability Assay. Evaluation of cytotoxicity was performed as previously reported (28).

RESULTS

Synthesis of Gene Carriers. The synthesis of Lac-PEG-PLL consists of two reactions, synthesis of lactose-PEG diacid and synthesis of comb-shaped polymer Lac-PEG-PLL from lactose-PEG diacid and PLL. In the first reaction, IBCF and a carboxylic acid in PEG diacid formed a mixed anhydride, and a molecule of hydrochloric acid was released. TEA had a role as a base to neutralize hydrochloric acid which is formed during this reaction. The amino group in *p*-aminophenyl- α -D-lactopyranoside reacted with the carbonyl atom carbon on PEG-side, and an amide bond was formed between the sugar and PEG. After a 3.5 h reaction, the products were precipitated in an excess of ether. The precipitates were dissolved in distilled water and dialyzed using a dialysis membrane, 1000 MWCO, to remove unreacted *p*-aminophenyl- α -D-lactopyranoside. Con A-Sepharose column was used to remove unreacted PEG. Then lactose-PEG diacid was dissociated from the Con A-Sepharose column when 0.1 M methyl- α -D-mannopyranoside-containing buffer was applied. In that fraction, lactose-PEG-lactose, which means both carboxylic acid sides of PEG diacid had been modified to lactose moiety, was also eluted with lactose-PEG diacid, but no further purification was required because lactose-PEG-lactose will not take part in the second reaction. The content of carboxylic acid is determined by titration (50). Also, the lactose-PEG-lactose (MW = about 1400) was removed completely during the dialysis in the second reaction. In the second reaction, the carboxylic acid was activated by IBCF to form a mixed anhydride then the anhydride reacted with amino group on PLL.

The ¹H-NMR spectrum of 30 mol % Lac-PEG-PLL is shown on Figure 1b. The content of PEG was calculated

from the NMR spectrum by relating the PEG ($-\text{CH}_2-\text{CH}_2-$, s, 3.4–3.7 ppm) peak and side chain of PLL ($-\text{CH}_2\text{CH}_2\text{CH}_2-$, m, 1.1–1.8 ppm) peak. From this method, the lactose-PEG content ratios of the four carriers were verified as follows: 6, 12, 20, and 30 mol %, respectively.

The size exclusion chromatography data of Lac-PEG-PLL is shown in Figure 1c. From the peak number and peak shape, we can see that grafted polymer Lac-PEG-PLL is chromatographically homogeneous and that the RI and A₂₈₀ signal ratio was practically constant, which indicated that Lac-PEG was evenly distributed (conjugated) to PLL, and the Lac-PEG-PLL has certain molecular weight. Because the Lac-PEG-PLL is a grafted polymer and it is difficult to find suitable standard molecules, the molecular weight of the Lac-PEG-PLL is not calculated.

Physicochemical Characterization. Experiments were performed to investigate whether the synthesized Lac-PEG-PLL forms complexes with pSV- β -gal plasmid DNA. Figure 2a shows the result from the band retardation assay using Lac-PEG-PLL carrier for condensation with pSV- β -gal. A fixed amount of pSV- β -gal plasmid was titrated with increasing amounts of Lac-PEG-PLL resulting in complexes. The movement of pSV- β -gal (bands on lane 2) was retarded as the amount of Lac-PEG-PLL in a complex increased, suggesting that Lac-PEG-PLL forms a complex with pSV- β -gal and the negative charges of DNA were neutralized by the positive charges of Lac-PEG-PLL (lane 3–9). The pSV- β -gal/Lac-PEG-PLL complexes in lanes 6–9 did not enter the gel and show much weaker band in fluorescence intensity. It is most likely due to exclusion of ethidium bromide following formation of complex. Complete retardation was achieved at and above a 1:1 weight ratio of pSV- β -gal:Lac-PEG-PLL.

Plasmid DNA/carrier complexes were defined as soluble if centrifugation under the conditions selected failed to remove DNA from the supernatant. Figure 2b shows that complexation between pSV- β -gal and PLL at a final DNA concentration of 50 μ g/mL led to the formation of a fine precipitate which sedimented upon centrifugation at 10 000 rpm for 5 min. However, when the PEG-modified PLL was used to make complex with pSV- β -gal, nearly 98% of the DNA remained in the supernatant after centrifugation. The modification of the end of the PEG group with lactose moiety did not give more than a 10% decrease when compared to that of pSV- β -gal/PEG-*g*-PLL complexes. So the attached PEG groups on PLL prevent the pSV- β -gal/carrier complexes from making fine precipitates and becoming insoluble.

Transfection and Cytotoxicity. The transfection efficiency of the synthesized Lac-PEG-PLL was evaluated using in vitro Hep G2 cell line. Hep G2 cell, a hepatoma cell line, has a specific lactose receptor on its surface. For the transfection experiments, various pSV- β -gal/Lac-PEG-PLL complexes were formulated with a fixed amount of pSV- β -gal (10 μ g/mL) and increasing amounts of Lac-PEG-PLL (1–100 μ g/mL). The cell culture media without FBS was used as a mixing medium.

The Lac-PEG-PLL showed transfection ability into Hep G2 cells (Figure 3). Below 1:1 weight ratio of pSV- β -gal/Lac-PEG-PLL (0.3 or 0.5 μ g carriers), very weak or no transfection efficiency was observed regardless of using any lactosylated carrier. At 1:2 and 1:3 weight DNA/carrier ratios, those carriers with higher lactose quantity showed higher efficiency. The 30 mol % Lac-PEG-PLL was the best carrier among four lactosylated carriers at both of these ratios. This may be due to the targeting

Figure 2. (a) Band retardation assay using Lac-PEG-PLL. Thirty mol % Lac-PEG-PLL was used. The band retardation showed that complete retardation was achieved at and above 1:1 weight ratio of plasmid DNA:Lac-PEG-PLL. The MWs of DNA size markers are 23 130, 9416, 6682, 4361, 2322, 2027, 564, and 265. Lanes 1 and 10: molecular weight marker. Lane 2: 1 μg of plasmid DNA. Lane 3: 1 μg of plasmid DNA + 0.1 μg of Lac-PEG-PLL. Lane 4: 1 μg of plasmid DNA + 0.3 μg of Lac-PEG-PLL. Lane 5: 1 μg of plasmid DNA + 0.5 μg of Lac-PEG-PLL. Lane 6: 1 μg of plasmid DNA + 1.0 μg of Lac-PEG-PLL. Lane 7: 1 μg of plasmid DNA + 3.0 μg of Lac-PEG-PLL. Lane 8: 1 μg of plasmid DNA + 5.0 μg of Lac-PEG-PLL. Lane 9: 1 μg of plasmid DNA + 10.0 μg of Lac-PEG-PLL. (b) Solubility test. Plasmid pSV-B-gal and carrier were mixed in 1 mL of HEPES buffer (20 mM, 0.15 M NaCl, pH 7.4) with final concentration of 50 μg/mL. After incubation for 30 min at room temperature, the tubes were centrifuged for 5 min at 10 000 rpm. The supernatant was taken and its absorbance at 260 nm was measured.

ability of lactose to Hep G2 cells, which reveals a rather different tendency from the case of PEG-*g*-PLL. As previously reported, 10 mol % PEG-*g*-PLL showed a higher efficiency than 25 mol % PEG-*g*-PLL (28). Using 30 mol % Lac-PEG-PLL carrier, the highest transfection efficiency was achieved at 1:3 weight ratio, but the 1:2 weight ratio revealed transfection of almost the same magnitude. It was shown that the higher the lactose-

Figure 3. Optimization of transfection using different lactose-PEG substitution degree of Lac-PEG-PLL. "6 mol %" means 6 mol % Lac-PEG-PLL. The amount of each Lac-PEG-PLL was varied from 0.3 to 3.0 μg with 1 μg of pSV-B-gal in the presence of 10% FBS and 100 μM chloroquine. After subsequent culture for 48 h, the cells were lysed and assayed for β-galactosidase activity.

Figure 4. Comparison of transfection efficiencies of different polymeric gene carriers in Hep G2 cells. The concentration of gene carrier (except for lipofectin) and pSV-β-gal were 3 μg and 1 μg/well of 96-well plate, respectively (30 μg/mL and 10 μg/mL). The concentration of lipofectin was 1 μg/mL. Error bar shows standard deviation from six experiments.

PEG substitution degree in the carrier, the greater the quantity of carrier required to reach the highest transfection efficiency. When we used 6 mol % Lac-PEG-PLL, a 1:1 ratio complex showed the highest efficiency. In the case of 30 mol % Lac-PEG-PLL, 1:3 ratio complex showed the highest efficiency. This may be explained by the ability of the gene carrier to make complexes with pSV-β-gal. Higher substituted Lac-PEG-PLL has less free amine to interact with negative charge on DNA. Therefore, more carrier is needed to make complex with DNA to the same extent.

Figure 4 summarizes the results for the transfection using PLL and modified PLL. Lipofectin was used for the comparison of transfection efficiency. Among the 3 kinds of carrier—PLL, PEG-*g*-PLL, and Lac-PEG-PLL—and lipofectin, Lac-PEG-PLL showed the best efficiency for Hep G2 cells.

Cytotoxicity of the synthesized carriers for Hep G2 cells is shown in Figure 5. Hep G2 cells were incubated in the presence of 30 μg/mL of gene carrier for 4 h. The 30

Figure 5. Comparison of cytotoxicity of various gene carriers in Hep G2 cells. The concentration of gene carrier was 3 μ g/well of 96-well plate (30 μ g/mL in cell culture medium). The gene carriers were incubated for 4 h with cells at 37 $^{\circ}$ C, then cell viability was determined using MTT assay method.

μ g/mL concentration was chosen because PEG-*g*-PLL and Lac-PEG-PLL showed the best transfection efficiency at that concentration. For Lac-PEG-PLL, no cytotoxicity was observed in Hep G2 cells, whereas PLL showed moderate to high cytotoxicity. The difference in lactose-PEG substitution ratio gave no significant change in cell viability. It was further supported by the phase contrast microscopic observation that the incubation of Lac-PEG-PLL with Hep G2 cells did not give any significant influence in cell viability. The incubation of PLL for 4 h with the cells transformed cell morphology, but PEG-*g*-PLL or Lac-PEG-PLL at the same concentration and incubation time did not significantly alter the morphology (data not shown).

To investigate the function of attached lactose moiety, the competition experiments with free sugars were performed. The pSV- β -gal/Lac-PEG-PLL complexes were formed and transfected into Hep G2 cells on the presence of free sugar for 4 h. After this, the transfection mixture including free sugar was removed and the cells were incubated for additional 48 h. Four sugars were used: galactose, glucose, lactose, and lactobionic acid. In the competition using free lactose, 0.5 mM lactose lowered the transfection efficiency up to 61.3% compared to that of no lactose (Figure 6a). Lactobionic acid was also used because of its greater solubility than lactose. Lactobionic acid showed a very close competition ability to that of lactose within the experimental range of lactose competition (0.01–0.05 mM). When the concentration of lactobionic acid was raised to 10 mM, the transfection was inhibited more than 80%. Over the concentration of 50 mM of lactobionic acid, almost no transfection activity was observed to Hep G2 cells, but the cell viability was also dramatically dropped. Below 10 mM concentration, free lactobionic acid did not give considerable cytotoxic effect to Hep G2 cells. Galactose and glucose also showed blockage of transfection derived from pSV- β -gal/Lac-PEG-PLL complex, though their blocking strengths were lower than that of lactose or lactobionic acid. It can be concluded from these observations that the pSV- β -gal/Lac-PEG-PLL complex is delivered to Hep G2 cells via a receptor-mediated endocytosis mechanism using lactose receptors existing on the cells.

We also tried to use Lac-PEG-PLL carrier as the gene delivery carrier to other cell lines. The cell lines that we used were A7R5 (a rat smooth muscle cell line) and

Figure 6. (a) Competition experiment with free sugar molecule. After making pSV- β -gal/Lac-PEG-PLL complex in medium, noted concentrations of each competitor were added, followed by incubation with Hep G2 cells for 4 h in the presence of 10% FBS and 100 μ M chloroquine. Error bar shows standard deviation from six experiments. (b) Comparison of transfection efficiency on various cell lines. ONPG β -galactosidase enzyme assay was used for expressed enzyme quantity. The amount of enzyme at 1:3 plasmid DNA/Lac-PEG-PLL ratio (w/w), on Hep G2 cells was regarded as 100%.

NIH3T3 (a mouse embryonic cell line). Neither cell line showed detectable or remarkable transfection results (Figure 6b), regardless of the degree of cytotoxic effect. This result suggests that the lactose serves as a targeting moiety for a specific gene delivery system.

Figure 7a shows the effect of chloroquine, an endosomal disrupting agent, to the transfection efficiency. In the absence of chloroquine, the transfection efficiency of pSV- β -gal/Lac-PEG-PLL complex on Hep G2 cells was as low as that obtained by PLL. As the concentration of chloroquine increased up to 100 μ M, the transfection efficiency from pSV- β -gal/Lac-PEG-PLL complex increased (Figure 7a). When 150 or 200 μ M chloroquine was used, the decrease in galactosidase activity was

Figure 7. (a) Influence of chloroquine on gene transfection. Thirty mol % Lac-PEG-PLL was used as a gene carrier. The chloroquine at noted concentrations was added to the transfection mixture for 4 h, in the presence of 10% FBS, and the cells were incubated further for 48 h prior to assay for β -galactosidase. (b) Influence of FBS on gene transfection. Either lipofectin or 30 mol % Lac-PEG-PLL was used as a gene carrier. The FBS at noted concentrations was added to the transfection mixture for 4 h, in the presence of 100 μM of chloroquine, and the cells were incubated further for 48 h prior to assay for β -galactosidase.

observed. It is probable because large amounts of chloroquine were toxic to the cells and a morphological study showed granulated cells. From the results, it is likely that pSV- β -gal/Lac-PEG-PLL complexes enter the cells through an endocytosis mechanism.

The influence of FBS on transfection efficiency was investigated. Figure 7b shows that the presence of FBS in the transfection mixture increased transfection efficiency. The pSV- β -gal/Lac-PEG-PLL system showed about a 1.7-fold increased transfection efficiency on Hep G2 cells in the presence of 10% FBS. The best efficiency was achieved when 15% of FBS was included during the incubation of the transfection mixture with Hep G2 cells. It is not fully understood yet why transfection efficiency is decreased a little when 20% of FBS was used. It is possibly due to binding of the serum components to polycations (31). Lipofectin did not show any dependence of transfection efficiency on the concentration of FBS.

We also investigated the influence of other factors of in vitro transfection such as quantity of pSV- β -gal, incubation time with pSV- β -gal/carrier complex, and the

Figure 8. Optimization of pSV- β -gal quantity on transfection. Thirty mol % Lac-PEG-PLL was used. The amount of pSV- β -gal was varied from 0.1 to 5 μg with the same 1:2 or 1:3 ratio of pSV- β -gal to Lac-PEG-PLL, in the presence of 10% FBS and 100 μM chloroquine. After subsequent culture for 48 h, the cells were lysed and assayed for β -galactosidase activity.

time course of protein expression. Figure 8 shows the influence of DNA quantity. One microgram of pSV- β -gal is typically used for the transfection into cells which were grown in a well of 96-well microplate. It was already shown that at 1:2 and 1:3 ratio of pSV- β -gal/Lac-PEG-PLL complex the best transfection efficiency was achieved using 1 μg of pSV- β -gal. Therefore, we tried to optimize the quantity of pSV- β -gal per well. The results showed that the 1 μg of pSV- β -gal DNA is the best dose for a well of 96-well microplate on Hep G2 cells. It is very interesting that the pSV- β -gal/Lac-PEG-PLL complex at 1:3 ratio showed better efficiency than one at 1:2 ratio below 1 μg of pSV- β -gal dose, while the latter proved to be better over 1 μg of pSV- β -gal dose.

The optimal incubation time of the complex with Hep G2 cells was also determined (Figure 9a). It was shown that 4 h of incubation achieved the best transfection efficiency. The expression of β -galactosidase along the time course after transfection was also monitored up to 96 h (Figure 9b). The result showed that the expression of β -galactosidase in Hep G2 cells, which were transfected with pSV- β -gal/Lac-PEG-PLL complex, was maintained up to 96 h as a linear fashion. The synthesized Lac-PEG-PLL has ability to make complexes with DNA and showed enhanced transfection efficiency into Hep G2 cells.

DISCUSSION

Receptor-mediated gene delivery has its advantages and limitations (32). Its advantages for use in gene therapy are as follows. First, the gene delivery carrier can be designed and customized for a specific target receptor. Second, the DNA does not have to integrate into the host cell genome to be expressed. Third, the delivery system is theoretically unlimited by the size of the transgene. Finally, the technique does not involve the use of potentially infectious agents. There are also disadvantages which must be overcome before this procedure can be routinely used for human gene therapy. For example, the transgene is not integrated into the host cell chromosomes so that its expression is transient. Therefore, it will most likely be necessary to subject patients to multiple injections of a gene of interest. The

Figure 9. (a) Influence of the time of transfection. Thirty mol % Lac-PEG-PLL was used. The amount of pSV- β -gal was 1 μ g with the 1:3 ratio of pSV- β -gal to Lac-PEG-PLL. The transfection time was examined from 0.5 to 6 h in the presence of 10% FBS and 100 μ M chloroquine. After each time, the Hep G2 cells were incubated for 48 h, followed by β -galactosidase assay using ONPG. (b) Influence of the time of gene expression. Thirty mol % Lac-PEG-PLL was used as a gene carrier. The amount of pSV- β -gal was 1 μ g with the 1:3 ratio of pSV- β -gal to Lac-PEG-PLL. After 4 h incubation of pSV- β -gal/Lac-PEG-PLL with Hep G2 cells, the transfection medium was removed and the cells were incubated. At the noted times, the cells were lysed and assayed for β -galactosidase activity.

DNA-ligand complexes are difficult to prepare and, until recently, little was known about their structure–function relationship. Also there is only a fragmentary understanding of the biological process involved in the transfer of the transgene into the cell and its subsequent expression. These and other features of this system for gene therapy have recently been reviewed in detail (33).

PLL itself can be used as a DNA condensate (18), but the use of PLL as a gene delivery carrier has several disadvantages. First, its transfection efficiency is very low because PLL has no functional group except the amine group used in charge neutralization. Also due to the negative charges of the DNA phosphate backbone, an increase in the degree of charge neutralization of the DNA often results in extensive condensation and the separation of the DNA phase in the form of insoluble compact structures (32, 34, 35).

Lac-PEG-PLL was synthesized to serve as a nonviral vector. It was used to deliver the pSV- β -gal reporter gene

into Hep G2 cells with enhanced transfection efficiency, compared to that of PLL alone. Plasmid pSV- β -gal, which is a modification of pRSV- β -galactosidase vector, is often used as a reporter gene for monitoring gene expression in mammalian cells (36). The SV40 early promoter and enhancer drive the transcription of the *lacZ* gene in mammalian cells. β -Galactosidase is an excellent reporter enzyme (37) which can be assayed quickly and directly in cell extracts using a spectrophotometric assay.

It was shown that lactose-PEG-modified PLL has the ability to make a complex with pSV- β -gal from band retardation assay (Figure 2a). The shift of the pSV- β -gal/Lac-PEG-PLL band during electrophoresis depends on the pSV- β -gal:Lac-PEG-PLL ratio that alters the complex net charge as well as its size and density (9). The decrease in the electrophoretic mobility of pSV- β -gal/Lac-PEG-PLL complex was accompanied by the increase in the content of Lac-PEG-PLL in the system, and it is due to neutralization of the DNA negative charge by the carrier positive charge. Formation of a DNA–carrier complex was also observed in the dye displacement assay (data not shown).

As discussed earlier, one of the problems of PLL as a gene carrier is that complexation between PLL and DNA frequently results in formation of fine precipitates, limiting the concentration that can be used (38). In our experiment, complexation of pSV- β -gal with PLL in 20 mM HEPES (pH 7.4) with 0.15 M NaCl resulted in precipitates at 50 μ g/mL of pSV- β -gal. On the other hand, PEG-*g*-PLL and Lac-PEG-PLL maintained the solubility of pSV- β -gal when they made complexes with DNA at this concentration. Therefore, it is apparent that the attached PEG moiety makes pSV- β -gal/gene carrier complexes substantially more soluble.

The gene delivery ability of our synthesized carriers and its specificity were investigated. Hep G2 cells were chosen for specificity test because they have specific lactose receptors on their surface. The recognition of lactose is mediated by the lactose receptors on liver cell (39). They are used for removal of glycoproteins from the blood. Many newly synthesized glycoproteins, such as immunoglobulins and peptide hormones, contain carbohydrate units with terminal sialic acid and galactose residues. During hours or days, depending on the particular protein, terminal sialic acid residues are removed by sialylases on the surface of blood vessels. The exposed galactose residues of these trimmed proteins are detected by the asialoglycoprotein receptors in the plasma membranes of liver cells. The complex of the asialoglycoprotein and its receptor is then internalized into the liver cell by endocytosis process to remove the trimmed glycoprotein from the blood. We predicted that the lactose moiety on the carrier could serve as a targeting material for the hepatoma cell line.

Lac-PEG-PLL showed improved transfection efficiency over PLL and PEG-*g*-PLL. Among Lac-PEG-PLLs with different modified ratios, 30 mol % Lac-PEG-PLL accomplished the highest efficiency at 1:3 weight ratio to pSV- β -gal. It demonstrates that the lactose moiety on the end of PEG renders cell targeting ability to pSV- β -gal/Lac-PEG-PLL complexes. In our opinion, the fusogenic ability of PEG may serve as another factor for increase of transfection efficiency. It is supported by the fact that PEG is known to associate with the phospholipid headgroup of cell membranes, assisting modified proteins to penetrate into cell membranes (40).

The free sugar competition experiment of transfection using Lac-PEG-PLL emphasizes the probability that pSV- β -gal/Lac-PEG-PLL complexes are delivered into

Hep G2 cells by a receptor-mediated endocytosis mechanism. The increasing concentrations of lactose or lactobionic acid added to the transfection medium decreased the expression of β -galactosidase. Lactose (0.5 mM) and lactobionic acid (1 mM) caused 39.0 and 55.3% inhibition in β -galactosidase activity, respectively. In the case of other sugars, the higher concentration of galactose (50 mM) or glucose (200 mM) is needed to achieve more than 50% inhibition (54.8 and 51.0%, respectively). So lactose has 50-fold more specificity into Hep G2 cells than galactose. Aring et al. (41) found that lactosylated human serum albumin (HSA) strongly bound to the hepatic lectins, in contrast to galactosylated and glucosylated HSA. Also, it was reported that mammalian hepatic Gal/GalNAc receptors show preference for three terminal galactose residues in the triantennary ligand (42). It means that the spatial arrangement of the Gal residues is very important for optimal binding. Our Lac-PEG-PLL carrier contains multiple lactose groups in it, and may bind to the receptor with greater affinity compared with the monomeric sugars.

It was further supported that the lactose on Lac-PEG-PLL was served as targeting moiety by using different cell lines in transfection. In the A7R5 and NIH3T3 cell line, which do not have lactose receptors on their surface, the transfection efficiencies were much lower than that in Hep G2 cells. Wu and Wu (20) used an asialoglycoprotein-PLL conjugate for gene delivery and reported that all receptor (–) cells tested, regardless of the tissue source (SK-hep-1, hepatoma; IMR-90, fibroblasts; uterine smooth muscle cells), failed to undergo gene transformation under the conditions identical to those which were successful for Hep G2 [receptor (+)] cells. Their results further support our concept in which the cell specificity of this new delivery system for gene transformation is based on the presence of unique receptors on the target cells.

That the attached sugar on PEG-g-PLL can serve as a targeting moiety onto specific cells can bring up the other possibility for gene delivery. Membrane lectins are present at the surface of many normal cells as well as on various tumor cells, and the sugar specificity is dependent on the cell types (24). For example, mannose is recognized by macrophages, liver nonparenchymal cells, and some B cells; mannose-6-phosphate by monocytes; galactose by melanoma cells; glucose by colon carcinoma cells; and *N*-acetyllactosamine by T cells. Many ligands that bind to the target receptor can be used as targeting moieties for gene delivery (for reviews, see ref 43). Folate is indispensable for health, and therefore, its receptor is expressed on many cell types (44). In addition, this receptor is highly expressed on ovarian cancer cells (45). Several kinds of cancer cells are known to express the receptors highly for epidermal growth factor (EGF), low-density lipoprotein (LDL), and/or transferrin. Brain capillary endothelial cells express at least three types of receptors, transferrin, insulin, and insulin-like growth factor receptors, implying that these may be a suitable target for delivering gene to the brain (46). Fc and polymeric immunoglobulin receptors (pIgR) can be used for targeting the lung. In the lung, the Fc receptor is expressed on macrophages, the pIgR on epithelial cells (47).

The efficiency of gene transfection via receptor-mediated endocytosis can be augmented by the use of pharmacologic agents that disrupt the endocytic trafficking of DNA–ligand complexes (33). Chloroquine is known to induce a partial neutralization of acidic cell compartments, to reduce the fusion between endosomes and

lysosomes, to decrease intracellular degradation of the internalized plasmid by lysosomal enzymes, and to cause an increase in the volume of endocytic vesicles. In the presence of chloroquine, the DNA carried by Lac-PEG-PLL conjugates could escape degradation by endosome and lysosome hydrolases, allowing a correlative large number of DNA molecules to reach the cytosol and/or the nucleus (24). Moreover, chloroquine, which binds to DNA might also protect DNA molecules from nuclease degradation (25, 48). One hundred micromolar concentration of chloroquine was found to be optimal in transfecting Hep G2 cells using pSV- β -gal/Lac-PEG-PLL complexes. At higher concentration (150 and 200 μ M), the efficiency was lower in relation to a higher toxicity. It has not been definitely solved how and where DNA gets rid of the carrier chains in cell. Kabanov suggested that negatively charged membranes and/or polynucleotides in a cell may serve as components reacting with DNA/carrier complex and providing for DNA release as a result of carrier substitution (9).

Other factors of the in vitro transfection experiment were also optimized. The expression of β -galactosidase along the time course after transfection was also monitored up to 96 h (Figure 9b). The expression was maintained until 96 h. The maintenance of gene expression up to 96 h is an advantage of these synthesized gene carriers for transfection in cultured cells to provide a window for manipulation of transfected cells. As an opposite case, the transfected luciferase activity in human macrophage with mannosylated PLL/DNA was maximal after 24 h, then rapidly diminished to only 2% after 72 h (49).

In conclusion, the Lac-PEG-PLL polymers, with four ratios of lactose-PEG substitution, namely 6, 12, 22, and 30 mol %, were synthesized as gene carriers. Our synthetic comb-shaped polymers could make a complex with pSV- β -gal. The attached PEG made the complex soluble, while the complex between pSV- β -gal and PLL alone formed fine precipitate. The Lac-PEG-PLL carrier/DNA complex had more than a 10-fold increase in transfection efficiency when compared to that of a PLL complex on Hep G2 cells. This increase may be due to the cell-targeting effect of lactose moiety and partially from the fusogenic effect of PEG. The attached PEG group also allowed the Lac-PEG-PLL and the pSV- β -gal/Lac-PEG-PLL complex to be less cytotoxic than PLL. The lactose moiety specifically served as a targeting moiety for the transfection into Hep G2 cells, a human hepatoma cell line. This was indicated by two pieces of evidence. First, free lactose inhibited transfection at millimolar concentration. Second, very low transfection efficiency was monitored when other lactose receptor-deficient cell lines were used for transfection. The existence of FBS and chloroquine improved transfection, showing us that the transfection occurred via an endocytosis mechanism. Therefore, the application of these new carriers to animal studies in vivo has been concluded to be promising.

Water-Soluble Conjugate of Double-Stranded DNA and Poly(*N*-isopropylacrylamide) for One-Pot Affinity Precipitation Separation of DNA-Binding Proteins

Daisuke Umeno, Masafumi Kawasaki, and Mizuo Maeda*

Department of Materials Physics and Chemistry, Graduate School of Engineering, Kyushu University, 6-10-1, Hakozaki, Higashi-ku, Fukuoka 812-8581, Japan. Received February 17, 1998;
Revised Manuscript Received June 4, 1998

Poly(*N*-isopropylacrylamide) having a terminal psoralen group was synthesized and covalently bound to plasmid pBR 322 DNA through a photochemical reaction. The resulting conjugate exhibited temperature-responsive precipitation due to the aggregation of poly(*N*-isopropylacrylamide) chains when heated above 31 °C. This system was used for the one-pot separation of restriction endonuclease *EcoRI*.

INTRODUCTION

Bioaffinity reactions using single- or double-stranded DNA have been widely used for the detection and purification of biomolecules. Double-stranded (ds) DNA is extensively employed as an affinity ligand (1, 2) for the separation and purification of DNA-binding proteins, such as transcription factors, and immobilized onto solid supports such as sepharose beads (3), synthetic polymer resins (4), and silica gels (5). These approaches, however, have fundamental disadvantages resulting from the insolubilization of DNA ligands. The vibrational and rotational motions of biomolecules immobilized on solid surfaces are restricted, and in most cases, these restrictions reduce the affinity of the ligands for the target molecules as compared with free DNA (6). In addition, solid–liquid heterogeneous reactions are generally slower than solution reactions due to restricted diffusion. Therefore, it is preferable that DNA ligands be immobilized on a water-soluble polymeric supports, enabling the homogeneous binding of the target molecules. However, there must exist a strategy for the collection of the molecules captured by the DNA ligands on the water-soluble carriers.

Poly(*N*-isopropylacrylamide) (polyNIPAAm) is one of the candidates which have both of the water solubility and collectable property: it has a phase transition between water-soluble and -insoluble forms in response to small temperature changes around 31 °C (7) and has recently been successfully utilized for the separation of biomolecules such as antibodies and enzymes (8, 9). In these systems, the binding of ligands and target molecules takes place in homogeneous solution (capturing mode) and the resulting complex is collected upon heat-induced precipitation (collection mode). This strategy is also applicable to the separation of DNA-binding proteins providing there exists a method for the conjugation of DNA with polyNIPAAm.

We have studied a method for the synthesis of soluble conjugates of ds DNA and synthetic polymers (10–12)

and recently found that psoralen derivatives are quite suitable for the stable conjugation between them (13). Psoralens are well-known DNA intercalators which cross-link double-stranded DNA when irradiated with a UV light (14). In previous work (15, 16), vinyl groups were introduced into dsDNA in two steps: a vinyl derivative of psoralen was photochemically bound to the ds DNA, then the resultant DNA-macromonomer was copolymerized with acrylamide in water. This resulted in the covalent grafting of polyacrylamide chains to ds DNA. The conjugate between calf thymus DNA and poly(*N*-isopropylacrylamide) was successfully applied to the separation of DNA-binding dyes (17). In the present study, we synthesized polyNIPAAm having a 4,5',8-trimethylpsoralen (trioxalen) moiety at its terminus. The psoralen-terminated polyNIPAAm was then photochemically bound to DNA. The resulting DNA–polyNIPAAm conjugate was applied to the one-pot affinity separation of restriction endonuclease *EcoRI*.

EXPERIMENTAL PROCEDURES

Materials. *N*-Isopropylacrylamide (NIPAAm) was obtained from Tokyo Kasei Kogyo and recrystallized from a mixture of benzene and hexane. *N,N'*-Azobisisobutyronitrile (AIBN) was purchased from Kishida Chemicals. Trioxalen (4,5',8-trimethylpsoralen) and 3-mercaptopropionic acid (MPA) were obtained from Aldrich. pBR322 DNA was purchased from Fermentas. *HindIII* and *EcoRI* were purchased from Boehringer Mannheim. Other reagents and solvents were obtained commercially and used without further purification.

Synthesis of Carboxyl-Terminated PolyNIPAAm (PolyNIPAAm-COOH). Semitelechelic polyNIPAAm possessing a carboxyl end group was synthesized by the method described by Takei et al. (18). Briefly, it was prepared by radical polymerization of NIPAAm in dimethylformamide (DMF) using AIBN as initiator and MPA as a chain-transfer agent. The polymer was purified by repeated reprecipitation from DMF-diethyl ether. The molecular weight of the resulting polymer was determined by acid–base titration of the terminal carboxyl group.

The phase-transition temperature (cloud point) of aqueous solutions of the polymer was monitored at 500

polyNIPAAm-COOH	5400 ^a	31.3
polyNIPAAm-COOSu	6700 ^b	
PsoPNIPAAm	6000 ^c	30.8

^a Calculated by NaOH titration of the terminal COOH group.^b Calculated from the UV absorption of the succinimidyl group at 260 nm ($\epsilon = 9700$). ^c Calculated by UV absorption of the psoralen moiety at 300 nm ($\epsilon = 11\,000$).

nm with temperature raised at the rate of 0.4 °C/min using a spectrophotometer (Hitachi, U-3210). The temperature at which the polymer solution exhibited 10% light transmittance was defined as the cloud point.

Activation of the Terminal Carboxyl Group of PolyNIPAAm. The carboxyl group at the polymer terminus was esterified using *N*-hydroxysuccinimide and dicyclohexylcarbodiimide (DCC) in a molar ratio of 1.0:1.2:1.2 in dry DMF at ca. 25 °C for 24 h. The reaction mixture was concentrated in vacuo and poured into diethyl ether to precipitate the product. The activated polymer (polyNIPAAm-COOSu) was purified by repeated reprecipitation from DMF-diethyl ether. Ester formation was confirmed by UV spectrometry (19).

Psoralen-Terminated PolyNIPAAm (PsoPNIPAAm). 4'-[[*N*-(2-Aminoethyl)amino]methyl]-4,5',8-trimethylpsoralen was synthesized according to a method described by Lee et al. (20). The amino derivative of psoralen (0.07 g, 235 μ mol) and the activated polyNIPAAm (polyNIPAAm-COOSu; 0.5 g, 94 μ mol) were dissolved in dry DMF (total volume, 10 mL). After stirring for 12 h at ca. 25 °C, the solution was concentrated in vacuo and poured into diethyl ether. The precipitate was collected

and washed with 100 mL of diethyl ether. The white powder was dried in vacuo. The polymer thus obtained was dissolved in pure water and its concentration was determined from the UV absorption due to the psoralen moiety (300 nm).

Photoimmobilization of PsoPNIPAAm on Plasmid pBR 322 DNA. Plasmid pBR322 DNA was linearized using *Hind*III and purified by phenol extraction and ethanol precipitation, then resuspended in TE buffer (10 mM Tris-HCl, 1 mM EDTA, pH 7.4).

To a solution of linearized pBR 322 (615 μ M in base pair, bp) in a micro test tube (Eppendorf, 1.5 mL) was added a TE solution of PsoPNIPAAm. The total volume was then adjusted to 30 μ L to give a final DNA concentration of 62 μ M bp. The concentration of PsoPNIPAAm was varied from 50 nM to 10 μ M (in strand). Each solution was cooled in an ice bath and irradiated for 10 min (ca. 30 mW/cm²) using a 500 W ultrahigh pressure Hg lamp equipped with a high-pass filter (Toshiba, UV-31) for 10 min.

To the resultant mixture was added 9 μ L of aqueous NaOH (1.2 M) in order to make the DNA denatured, and then was combined with 9 μ L of gel-loading solution (glycerin:water, 1:1, v/v), quickly loaded to a 1.0% agarose gel, and electrophoresis was performed at 7 V/cm for 1 h in TAE buffer (80 mM Tris-acetate, 1 mM EDTA, pH 7.6). Gel electrophoresis was performed at 10 °C since polyNIPAAm and its conjugates precipitate from aqueous glycerin (25 v/v %) at ambient temperature (12). After electrophoresis, DNA in the gel was stained by ethidium bromide (Figure 1).

Thermal Response of the DNA-PolyNIPAAm Conjugate. To a solution of λ DNA (48 502 bp) was added PsoPNIPAAm from the stock (100 μ M in strand) to give a final concentration of 58 μ M bp DNA. The concentration of PsoPNIPAAm was varied from 0 to 50

μM (in strand). Samples were irradiated with UV light as described above, and the thermally induced precipitation of the resulting conjugates between λDNA and polyNIPAAm was examined. To the conjugate solution (100 μL) was added 20 μL of aqueous solution of poly(*N*-isopropylacrylamide) (10 w/v%; 1.7 w/v % in total) and the mixture was then incubated at 40 $^{\circ}\text{C}$ for 3 min and centrifuged (15 000 rpm) at the temperature for 3 min to precipitate the DNA–polyNIPAAm conjugate. After centrifugation, the supernatant was collected and subjected to gel electrophoresis (0.7% agarose, at 7 V/cm for 2 h) in TBE (80 mM Tris-borate, 2.5 mM EDTA, pH 8.0) buffer. After the gel was stained with ethidium bromide, the band due to the conjugate was evaluated using scanning densitometry to estimate the amount of unprecipitated conjugate.

Precipitation Separation of *EcoRI*. DNA–polyNIPAAm conjugates were synthesized by the photochemical reaction between pBR 322 (linearized using *BsmI*, 60 μM bp) and PsoPNIPAAm (20, 40, and 60 μM) in micro test tubes (30 μL in total) as described above. As a reference sample, a mixture of pBR 322 (*BsmI* digest, 58 μM bp) and PsoPNIPAAm (60 μM), which had not been irradiated with UV light, was also prepared. To these samples were then added *EcoRI* (60 units) and polyNIPAAm (1.0 w/v %). The solutions (total volume, 60 μL) were incubated at ca. 25 $^{\circ}\text{C}$ for 1 h then heated up to 40 $^{\circ}\text{C}$ in a water bath and centrifuged for 1 min at 40 $^{\circ}\text{C}$ (15 000 rpm). The supernatant (30 μL) was taken from each sample and combined with DNA (pBR 322/*BsmI* digest, 0.6 μg). DNA was not added to the supernatant of the reference sample (the mixture of the native DNA and polyNIPAAm), because the DNA in this precedent mixture remained in solution even after the heat and precipitation procedure unless it was conjugated to polyNIPAAm. These solutions were mixed with buffer (total volume, 40 μL ; 5.0 mM Tris-HCl, 10 mM NaCl, 1.0 mM MgCl_2 , 0.1 mM dithioerythritol, pH 7.5), and after incubation for 30 min at 37 $^{\circ}\text{C}$, samples were subjected to gel electrophoresis (1.0% agarose, at 7 V/cm for 1 h) in TBE buffer (Figure 3).

Sequence-Dependent Affinity Separation of *EcoRI*. DNA conjugates with and without *EcoRI* binding site were prepared. The former was synthesized by the photoreaction between PsoPNIPAAm (60 μL) and pBR 322 (61 μM bp) which had been linearized using *StyI*, while the latter was synthesized by the photoreaction between PsoPNIPAAm (60 μM) and pBR 322 (61 μM bp) linearized using *EcoRI*. A mixture of PsoPNIPAAm (60 μM) and pBR 322 (61 μM bp, linearized using *StyI*) was also prepared. Each sample was mixed with *EcoRI* (60 units) and polyNIPAAm (1.0 w/v %) and incubated for 2 h at 4 $^{\circ}\text{C}$, followed by the heating and precipitation procedure. Thirty microliters of each supernatant was collected, mixed with DNA (0.6 μg of pBR 322 linearized using *StyI*), and endonuclease reaction was allowed to proceed for 1 h upon the addition of Mg^{2+} (1 mM). The resultant solution was subjected to gel electrophoresis (1.0 % agarose, at 7 V/cm for 1 h) in TBE buffer (Figure 4).

RESULTS AND DISCUSSION

Psoralen-Terminated PolyNIPAAm. The synthesis of psoralen-terminated poly(*N*-isopropylacrylamide) (PsoPNIPAAm) is shown in Scheme 1. The number-averaged molecular weight of polyNIPAAm was determined by NaOH titration of terminal carboxyl group and the calculated value for the polyNIPAAm-COOH was about

Figure 1. Gel electrophoresis (1.0 % agarose) of linear pBR 322 (62 μM in bp) which was irradiated with UV light in the presence or absence of PsoPNIPAAm. Samples from lane 2 to 10 were treated with NaOH (0.3 M) before loading. All samples were loaded on a nondenaturing gel. Lanes 1 and 2, control DNA; lane 3, [PsoPNIPAAm] = 0; lane 4 [PsoPNIPAAm] = 50 nM; lane 5 [PsoPNIPAAm] = 100 nM; lane 6 [PsoPNIPAAm] = 500 nM; lane 7 [PsoPNIPAAm] = 1 μM ; lane 8 [PsoPNIPAAm] = 5 μM ; lane 9 [PsoPNIPAAm] = 10 μM ; lane 10, [PsoPNIPAAm] = 10 μM , but no UV irradiation.

5400 (ca. 50 mer), which is in good agreement with the previous report (4500) (18). In each step of the synthesis, the nature of end groups was determined and the apparent molecular weights were estimated (Table 1). No significant differences were observed among the three molecular weights. Slight difference should be ascribed to the different methods of evaluation and to the fact that each reaction involved a reprecipitation which could change the molecular weight distribution.

PolyNIPAAm is a well known polymer which exhibits a phase transition (7): when an aqueous solution of polyNIPAAm is gradually heated, it abruptly precipitates at 31 $^{\circ}\text{C}$. The transition temperatures of the polymers prepared in this study were found to be all about 31 $^{\circ}\text{C}$ and the transition between soluble and insoluble form was fully reversible.

Photo-Induced Conjugation of PsoPNIPAAm to pBR 322. Psoralens are known to intercalate into DNA double strands in dark and form covalent bonds at their 3,4 and 4',5' double bonds with pyrimidines upon near-UV (~ 365 nm) irradiation (14). If both sites of the psoralen are reacted, an interstrand DNA cross-linking takes place to make both strands connected to each other.

Photoreactivity of the psoralen moiety which had been introduced to the terminus of polyNIPAAm was examined for pBR 322 plasmid DNA according to the literature (21). Figure 1 shows the electrophoretic migration profiles of linearized pBR 322 (*EcoRI* digest) after the photoreaction with PsoPNIPAAm and further treatment with 0.3 M NaOH. The alkali treatment denatures double-stranded DNA to give single strands, which are characterized by faster electrophoretic migration and the weaker band intensity (lane 2). The alkali denaturation also yielded the single strands from DNA which was irradiated with UV light (lane 3). On the contrary, there was observed significant amount of DNA which ran as ds form even after the alkali-treatment for DNAs which were mixed with PsoPNIPAAm and irradiated with UV light (lanes 4–9). Increasing amount of PsoPNIPAAm fed at the photoreaction resulted in increasing ratio of ds form DNA. When a certain amount of PsoPNIPAAm (1 μM for the 60 μM bp DNA) was used, 100% of DNA behaved as dsDNA (lanes 7–9), while even the highest concentration of PsoPNIPAAm produced no crosslinking in the absence of UV light (lane 10). This is because DNA double strands were cross-linked by the psoralen moiety of PsoPNIPAAm when irradiated with UV light, so that they were not separate to single strands even upon alkali treatment. Therefore, the cross-linked DNA quickly

Figure 2. Gel electrophoresis (0.7 % agarose) of DNA-polyNIPAAm conjugates before (a) and after (b) centrifugation at 40 °C. The conjugate of polyNIPAAm and λ DNA (58 μ M bp) was heated and centrifuged in the presence of 1.7 wt% of NIPAAm homopolymer. Lane 1, DNA alone (control); lane 2, [PsoPNIPAAm] = 0 μ M; lane 3, [PsoPNIPAAm] = 2 μ M; lane 4, [PsoPNIPAAm] = 5 μ M; lane 5, [PsoPNIPAAm] = 10 μ M; lane 6, [PsoPNIPAAm] = 20 μ M.

renatured to the ds form in the buffer (pH 7.6) used for gel electrophoresis and ran as the ds form, while non-cross-linked DNA remained single strands and ran with greater mobility. Thus, it was clearly shown that polyNIPAAm was successfully immobilized on the DNA strands with the aid of the terminal psoralen group when irradiated by UV light.

There was observed significant retardation in bands corresponding to the ds DNA which was reacted with PsoPNIPAAm, depending on the amount of PsoPNIPAAm used in the photochemical reaction (lanes 5–9). This result should reconfirm the modification of DNA with PsoPNIPAAm, since the conjugation should make the whole molecular size larger.

The gradual retardation dependently on the amount of PsoPNIPAAm (lanes 5–9) indicates that one can regulate the degree of modification with polyNIPAAm just by changing the amount of PsoPNIPAAm used in the photoreaction. We also found that the degree of modification can be regulated by changing reaction period, i.e., time period of UV irradiation (data not shown).

Temperature-Responsive Precipitation of the Conjugates. In order to take advantage of it for the precipitation separation, the concentration of polyNIPAAm was adjusted to 1.7 wt % by adding NIPAAm homopolymer because we found that a certain concentration of ca. 1.0 wt % is required to ensure reproducible precipitation. The conjugate solution was heated to 40 °C and centrifuged (15 000 rpm) at that temperature to give a white precipitate. The supernatant was carefully collected and subjected to gel electrophoresis. Figure 2 shows the electrophoretic profiles of the conjugate solution (upper lanes) and those of the supernatant after centrifugation at 40 °C (lower lanes). At the upper lanes of 3–6 are observed bands of DNA conjugates with less mobility than the control DNA (lane 1). Similarly to Figure 1, the degree of retardation increased with the amount of

Scheme 2. Affinity Precipitation Separation of DNA-Binding Substances

PsoPNIPAAm used in the photoinduced conjugation reaction. After heating and centrifugation, these profiles changed dramatically (lower lanes). The bands due to the DNA conjugate dramatically faded as the amount of polyNIPAAm used in the photochemical reaction was increased. At a certain level (lanes 5 and 6), almost 100% of the conjugate disappeared in the supernatant, due to precipitation. In contrast, the unirradiated mixture of DNA and PsoPNIPAAm did not show any change (lane 2). Samples containing relatively small amounts of PsoPNIPAAm did not show such diminution (lanes 3 and 4). These results indicate that the DNA conjugates acquired thermo-sensitivity derived from the polyNIPAAm chains. We assumed that the polyNIPAAm chains attached to DNA turned to be insoluble above 32 °C and the side chains and polyNIPAAm in bulk condensed via hydrophobic interaction to form a new phase separated from aqueous system, resulting in the distribution (extraction) of DNA conjugated with polyNIPAAm into the newly emerged phase.

Affinity Precipitation Separation of *Eco*RI. The conjugate was applied to the precipitation separation of a DNA-binding protein (Scheme 2). The restriction endonuclease *Eco*RI recognizes the 5'-GAATTC-3' unique sequence in pBR 322 (linearized using *B*smI; 4363 bp) to give two fragments of 3008 and 1355 bp.

The protocol is summarized in Scheme 3. The conjugate between pBR322 and PsoPNIPAAm was added to a buffer solution containing *Eco*RI. It should be noted that the *Eco*RI solution was free from magnesium ion in this stage so that DNA scission should not take place (22). It is reported that *Eco*RI bind tightly ($K_d \approx 10^{10}$) to its recognition site even in the absence of magnesium ion (23). The mixture was then centrifuged (15 000 rpm) at 4 °C to give a white precipitate. The supernatant was carefully collected and the endonuclease activity of any remaining *Eco*RI was evaluated. The results are shown in Figure 3. As seen in lane 1, the supernatant retained its *Eco*RI activity after the centrifugation (at 40 °C) in the presence of DNA and PsoPNIPAAm (no UV irradiation). In contrast, the *Eco*RI activity in the supernatant dramatically decreased after centrifugation when the pBR 322-polyNIPAAm conjugate was present (lanes

Scheme 3. Procedure for the precipitation separation of *Eco*RI and for the evaluation of precipitation/separation efficiency^a

^a DNA-polyNIPAAm conjugates were added to *Eco*RI (60 units) and the concentration of polyNIPAAm was adjusted to 1 wt %. The mixtures were heated at 40 °C and centrifuged to yield a white precipitate. The amount of *Eco*RI remaining in the supernatant was evaluated by its endonuclease activity.

2–4). The conjugate thus seems to be responsible for the decrease in the amount of *Eco*RI in the supernatant. These decrease in activity is proportional to the concentration of PsoPNIPAAm used in the modification of the DNA, reflecting the difference in the efficiency of precipitation of the conjugates. These results strongly corroborate the affinity separation system illustrated in Scheme 2.

To ascertain that the DNA conjugate functions as a sequence-dependent affinity separator for *Eco*RI, two types of conjugates were prepared and used for the precipitation separation of *Eco*RI: a conjugate between PsoPNIPAAm and pBR 322 digested with *Sty*I and a conjugate between PsoPNIPAAm and pBR 322 digested with *Eco*RI. The conjugates differ only in that the former has an *Eco*RI-binding site on its strand, while the latter does not. An aqueous solution of restriction endonuclease *Eco*RI (60 units), conjugate, and NIPAAm homopolymer (1.0 w/v % in total) were incubated, and then the mixture was heated to 40 °C and centrifuged at that temperature. The supernatant was collected and its *Eco*RI activity was determined.

The result is shown in Figure 4. Supernatant retained a certain level of *Eco*RI activity to give two fragments (1371 and 2992 bp) when the DNA-polyNIPAAm conjugate without the *Eco*RI-binding site was used as a separation agent (lane 4). The enzymatic activity was almost the same as that for the simple mixture of DNA and PsoPNIPAAm (no UV irradiation, lane 2) in the supernatant after the heating and precipitation. This indicates that the DNA-polyNIPAAm conjugate without an *Eco*RI binding site failed to complex with *Eco*RI. On the other hand, there was no sign of *Eco*RI activity in the supernatant when the DNA-polyNIPAAm conjugate having an *Eco*RI site was used (lane 3). These results indicate that ds DNA bearing a recognition site for *Eco*RI acts as an affinity ligand for *Eco*RI and that the presence of this site is exclusively responsible for the separation of *Eco*RI.

It has been clearly demonstrated that *Eco*RI was captured by the conjugate bearing its recognition site and

Figure 3. Precipitation separation of *Eco*RI using DNA-polyNIPAAm conjugates. *Eco*RI solution (60 units) and DNA-polyNIPAAm conjugates were mixed and the concentration of polyNIPAAm was adjusted to 1.0 w/v %. The mixtures were then heated at 40 °C and centrifuged. To a fixed volume of the supernatant, substrate DNA (pBR 322/*Bsm*I digest) and the reaction buffer were added, followed by incubation for 30 min at 37 °C. The solution was then subjected to gel electrophoresis. Lane 1, mixture of DNA (61 μM) and PsoPNIPAAm (60 μM); lanes 2–4, conjugates between DNA (61 μM) and polyNIPAAm (lane 2, 20 μM; lane 3, 40 μM; lane 4, 60 μM). Lane 5 is a control (*Bsm*I digest of pBR 322).

precipitated from aqueous solution as illustrated in Scheme 2. We have observed endonuclease activity in the precipitated fractions, but the quantitative evaluation of the recovery was not performed. The separation capacity of this system also remains to be clarified. Such information could be obtained if this system were used on a larger scale and could be much refined if the DNA sequence of the conjugate were properly designed. At present, plasmid DNA with a tandem array of *Eco*RI sites is being developed for further investigations of this separation system.

There remains an important question before applying this system to the practical uses: how could we recover the proteins isolated by this system? We assumed that it would be possible if the precipitation fraction was dissolved in fresh water and a certain concentration of salt was added. According to the literature (23), the interaction between *Eco*RI and its recognition sequence becomes drastically weak by increasing NaCl concentration, and *Eco*RI bound to the sepharose column carrying its recognition sequence could be easily eluted by adding ca. 0.3 M of KCl (24) or by adding 1.5 M of NaCl (25) to mobile phase. On the other hand, the transition temperature of polyNIPAAm is known to decrease with increasing salt concentration (7). According to our observation, it becomes as low as 15 °C at the NaCl concentration of 1.5 M and becomes insoluble at room temperature. Taking advantages of these two facts, *Eco*RI collected by our system would be separated from DNA-polyNIPAAm conjugate upon addition of NaCl (1.5 M) and isolated as supernatant fraction at room temperature. At present, however, we have no data supporting this conjecture.

We have demonstrated the affinity precipitation separation of DNA-binding molecules using a DNA-polyNIPAAm conjugate. This conjugate may provide a rapid and widely applicable separation technique, since the complexation with the target takes place under homogeneous conditions and the separation is accomplished

Figure 4. Sequence-dependent affinity separation of *EcoRI*. *EcoRI* (60 units), polyNIPAAm (1.0 w/v %), and conjugates were mixed and incubated for 2 h at 4 °C, then subjected to the heat and precipitation procedure. Supernatant was collected from each sample and the enzymatic activity of any residual *EcoRI* was evaluated. To a substrate DNA (0.6 μg of pBR 322 linearized using *StyI*) was added 30 μL of the supernatant, and the endonuclease reaction was performed for an hour upon adding Mg^{2+} (1.0 mM). The resultant solution was subjected to gel electrophoresis. Lanes 1 and 5, control DNA (pBR 322); Lane 2, the mixture of pBR 322 (62 μM) digested using *StyI* and PsoPNIPAAm (60 μM); lane 3, the conjugate between PsoPNIPAAm (60 μM) and pBR 322 digested using *StyI*; lane 4, conjugate between PsoPNIPAAm (60 μM) and pBR 322 digested using *EcoRI*.

in a single reaction vessel. The present method allows us to use double-stranded DNA as an affinity ligand, so that one may collect any ions, molecules, or macromolecules which bind to the DNA.

ACKNOWLEDGMENT

We thank Dr. Scott J. McNiven (Research Center for Advanced Science and Technology, the University of Tokyo) for helpful discussion. This work was supported in part by a Grant-in-Aid for Scientific Research from Ministry of Education, Science, Sports and Culture of Japan. Financial support by the General Sekiyu Research and Development Encouragement and Assistance Foundation is also acknowledged.

We describe the site-specific enzymatic biotinylation of recombinant anti-estradiol Fab fragments through a 13 amino acid acceptor peptide translationally fused to the C-terminus of the Fd chain. The Fab-peptide fusion proteins were secreted to the periplasm of *Escherichia coli*, purified, and biotinylated in vitro using biotin ligase, biotin, and ATP. The *E. coli* biotin ligase (the BirA protein) was produced as a novel N-terminal fusion protein with glutathione S-transferase (GST) and purified in one step from bacterial cell lysate using a Glutathione Sepharose affinity column. The purified fusion protein worked as such (without cleavage of the GST part) for the in vitro biotinylation of the Fab fragments. After the removal of nonbiotinylated Fab fragments by monomeric avidin chromatography, the overall yield of biotinylated Fab was 40%. The site-specifically biotinylated Fab fragments (BioFab) were tested in streptavidin-coated microtitration wells, to which they were shown to bind linearly with respect to the amount of BioFab added, specifically as indicated by biotin inhibition, and tightly with a half-life of several days. Moreover, the enzymatic BioFab exhibited uniform antigen binding affinity unlike the same recombinant Fab fragments biotinylated through random chemical conjugation to surface lysines. Finally, the BioFab demonstrated its potential as a well-behaving immunoassay reagent in a model competitive assay for estradiol.

INTRODUCTION

The biotin–avidin/streptavidin system is used in a variety of biotechnological and diagnostic applications owing to the exceptionally high affinity of this noncovalent interaction between a protein and a small organic molecule (Wilchek and Bayer, 1990a). In in vitro diagnostics, streptavidin-coated tubes, microtitration wells, or spherical particles are used as universal surfaces for the capture of biotinylated antibodies in immunoassays of various formats (Diamandis and Christopoulos, 1991). The biotinylation of antibodies can be done by several well-established chemical methods in which an activated biotin derivative is conjugated to the protein surface residues (most often lysine) to the hinge region cysteines or to a carbohydrate moiety (Bayer and Wilchek, 1990; Diamandis and Christopoulos, 1991; Hermanson, 1996). The most widely used biotin derivative, biotinyl-*N*-hydroxysuccinimide ester (BNHS),¹ reacts mainly with the ϵ -amino groups of surface lysines and, under optimal conditions, generally causes no serious damage to the antigen binding activity (Bayer and Wilchek, 1990). Mikkala et al. (1993) synthesized an isothiocyanate derivative of biotin (BITC), which is, like BNHS, prima-

rily reactive with amino groups. The BITC reagent has since been used in our laboratory for the biotinylation of a number of different purified mAbs and has proven to be a viable complement to BNHS and other commercially available biotin reagents.

The recent advances in antibody engineering (for a review, see Hayden et al., 1997) and the availability of bacterially produced recombinant Fab fragments has led to a situation in which increasingly more antibodies will be biotinylated in the Fab form. As the Fab fragment is only one-third of the size of the whole immunoglobulin, the chemical biotinylation at surface residues even at low degrees of conjugation will more often result in the destruction or modification of the antigen-binding site. The recombinant Fab fragments come with an advantage that they can be modified by protein engineering. For example, new functionalities useful in specific applications can be added to the carboxyl ends of the constant domains while leaving the variable regions intact (Rappley, 1995). Therefore, we sought for a protein engineering solution to aid in the safe biotinylation of recombinant Fab fragments.

In the living cells, a few proteins (depending on the organism) are naturally biotinylated through the covalent linkage of biotin to a unique lysine residue (Wood, 1977). This posttranslational modification is catalyzed by a biotin ligase and involves the formation of an amide bond between the carboxyl group of biotin and the ϵ -amino group of the lysine residue (Figure 4A; Shenoy and Wood, 1988). In *Escherichia coli*, the only biotinylated protein is the biotin carboxyl carrier protein (BCCP), a subunit of the acetyl-CoA carboxylase. The C-terminal 84–88 amino acids of BCCP form an independent domain that can be fused to recombinant proteins and biotinylated in vivo by the *E. coli* endogenous biotin ligase (Cronan, 1990; Li and Cronan, 1992). Although the biotinylation

¹ Abbreviations: apo-Fab, nonbiotinylated form of the Fab-biotin acceptor peptide fusion protein; BioFab, Fab fragment that is biotinylated through the 13 amino acid peptide tail; BITC, biotin isothiocyanate; BirA, the bifunctional biotin-holocarboxylase synthetase/biotin operon repressor protein of *Escherichia coli*; BNHS, biotinyl-*N*-hydroxysuccinimide ester; BSA, bovine serum albumin; dNTP, deoxynucleoside triphosphate; GST, glutathione S-transferase of *Schistosoma japonicum*; IPTG, isopropyl β -D-thiogalactopyranoside; OD₆₀₀, optical density at the wavelength of 600 nm.

takes place in the cytoplasm, also fusions of the biotinyl domain with periplasmic proteins such as alkaline phosphatase and β -lactamase can be biotinylated to some extent (Reed and Cronan, 1991). The biotinylation of secreted fusion proteins can be enhanced by slowing down the secretory process (using *sec⁻* strains) so as to win extra time for the action of the biotin ligase and/or by coexpressing the biotin ligase so as to increase the biotinylation rate. (Reed and Cronan, 1991; Jander et al., 1996). However, we did not want to compromise the secretion of the Fab fragments and, therefore, considered an alternative approach to achieve higher biotinylation yields. We chose to perform enzymatic biotinylation *in vitro* after the production of the recombinant Fab fusion protein, which enabled us to control the biotinylation conditions independently of the various cellular factors. Furthermore, to possibly improve the secretion and periplasmic stability of the fusion protein, we aimed at minimizing the size of the fusion partner. Schatz (1993) used an elegant selection strategy to find novel peptide substrates for the biotin ligase from plasmid-encoded random peptide libraries. He defined a consensus sequence of 13 amino acids, containing an internal lysine residue, sufficient for *in vivo* biotinylation in *E. coli*. We here describe the construction of a Fab fusion vector in which the coding sequence for such a biotin acceptor peptide is inserted at the C-terminus of the Fd chain.

The biotin ligase (biotin holoenzyme synthetase) of *E. coli* is a bifunctional protein coded by the *birA* gene (Barker and Campbell, 1981). In addition to being biotin ligase, the BirA protein acts as the repressor of the *bio* operon responsible for biotin biosynthesis (Cronan, 1989). The BirA protein can be overexpressed in *E. coli* up to 1000-fold with apparently no toxic effects (Buonocristiani and Otsuka, 1988) thus facilitating the production of large amounts of biotin ligase for *in vitro* studies. To simplify the enzyme purification, we constructed a fusion protein between BirA and the glutathione S-transferase (GST) of *Schistosoma japonicum* (Smith and Johnson, 1988), which allowed us to use Glutathione-Sepharose for the one step purification of the enzyme from crude cell lysate. In this study, we show that the purified fusion protein is capable of *in vitro* biotinylation of the 13 amino acid peptide tail in the presence of the substrates biotin and ATP.

Recently, we cloned and expressed in *E. coli* the recombinant Fab fragment of the monoclonal anti-estradiol antibody 57-2 (Pajunen et al., 1997). In this paper, we describe the construction of the biotin acceptor peptide fusion protein of Fab 57-2 as well as the *in vitro* biotinylation of the apo-Fab using the GST-BirA fusion protein. The immunochemical properties of the enzymatically biotinylated Fab fragment relevant to immunoassay applications will be characterized and discussed. Finally, the functionality of the novel biotinylated Fab fragment is demonstrated by setting up a competitive estradiol immunoassay.

MATERIALS AND METHODS

Strains and Plasmids. *E. coli* MC1061 [cI⁺, Δ (*ara*, *leu*)7697, Δ *lacX*74, *galU*⁻, *galK*⁻, *hsr*⁻, *hsm*⁺, *strA*, *araD*139; Casadaban and Cohen, 1980] was used for DNA cloning and for the overproduction of the GST-BirA fusion protein. The strain XL-1 Blue [*recA*1, *endA*1, *gyrA*96, *thi*-1, *hsdR*17, *supE*44, *relA*1, *lac* (F' *proAB*, *lacI*^q Δ M15, Tn10 (tet^r)), Stratagene] was used for Fab expression. The plasmid pJMR1 containing the *birA* gene from the *E. coli* biotin biosynthetic operon was kindly provided by

Dr. Anthony J. Otsuka. The plasmid pGEX-1 λ T with the glutathione S-transferase gene of *Schistosoma japonicum* was purchased from Pharmacia Biotech (Uppsala, Sweden).

Construction of Biotin Acceptor Peptide:Fab Genetic Fusion. The plasmid p57-2 (Pajunen et al., 1997) was used as the vector for the insertion of the biotin acceptor peptide coding sequence. The vector was digested with the restriction enzymes *Spe*I and *Nhe*I and dephosphorylated with calf intestinal phosphatase (Pharmacia) followed by agarose gel purification of the 4.6 kb fragment. The insert was prepared from two partially complementary (15 nucleotide overlap at the 3'-ends) synthetic oligonucleotides: the forward 43-mer 5'-GTAC ACT AGT GG C GGT GGC CCA GGT GGC CTG GTT TCT ATC TT-3' and the reverse 53-mer 5'-CTAG GCT AGC TTA GTG CCA TTC GAT TTT CTG AGC TTC GAA GAT AGA AAC CAG-3'. The forward and reverse oligonucleotides (50 pmol each) were annealed together by heating to 90 °C for 5 min and slowly cooling to room temperature. The single-stranded ends were filled in with the Klenow fragment of DNA polymerase I (Boehringer Mannheim) for 15 min at room temperature in the presence of 1 mM dNTPs. The double-stranded 80-mer was digested with *Spe*I and *Nhe*I (the recognition sites are underlined in the oligonucleotide sequences above) followed by agarose gel purification with the Glass Milk procedure (Bio101). The purified fragment was ligated to the vector with T4 DNA ligase and electroporated into *E. coli* MC1061 cells. The presence of the insert was tested from plasmid minipreps by digestion with *Sfi*I, and the correct coding sequence was verified by nucleotide sequencing over the whole insert region. The plasmid construct (p572Bio) was later transferred to the strain XL-1 Blue for Fab production. An otherwise identical construct but lacking the biotin tail was produced for the chemical biotinylation experiments (see below) by self-ligating the compatible cohesive ends of the *Spe*I-*Nhe*I digested vector (the open reading frame ends right after the *Nhe*I site at the tandem stop codons TAG TAA).

Construction of the GST-BirA Genetic Fusion. The plasmid pGEX-1 λ T was used as the vector for the construction of the GST-BirA genetic fusion. The vector was linearized by digestion with *Eco*RI followed by filling in the cohesive ends with the Klenow fragment of DNA polymerase I for 15 min in the presence of 1 mM dNTPs. The *birA* gene was cut from the plasmid pJMR1 by double digestion with *Bsp*HI and *Xba*I and was made blunt ended similarly as the vector. The insert and the vector were gel purified, blunt ligated with T4 DNA ligase, and electroporated into MC1061 cells. The orientation of the insert as well as the integrity of the joints in the resulting plasmid were checked by test digestions with the appropriate restriction enzymes (in the correct construct all the restriction sites were regenerated as a result of the ligation of the blunt-ended fragments).

Overproduction and Purification of the GST-BirA Fusion Protein. *E. coli* MC1061 strain containing the plasmid pGEX-BirA was inoculated in two 1-L shake flasks each containing 250 mL of 2 $\times$ YT (16 g/L Bacto tryptone, 10 g/L Yeast extract, and 5 g/L NaCl) supplemented with 0.2% glucose and 100 mg/mL ampicillin. The cells were grown at 30 °C at 240 rpm until the OD₆₀₀ of 1 was reached. The fusion protein expression was induced by the addition of 0.1 mM IPTG, after which the cells were grown for an additional 6 h and harvested by centrifugation. The cell pellet was resuspended in 15 mL of PBS buffer (140 mM NaCl, 2.7 mM KCl, 10 mM Na₂-

HPO₄, and 1.8 mM KH₂PO₄, pH 7.4) containing 5% glycerol, 0.1 mM DTT, and 10 mM MgCl₂. The cells were disrupted with the French press (Aminco Corp.) after which DNaseI was added into the lysate (final concentration 1 µg/mL) and the cell debris was removed by centrifugation. Triton X-100 was added to a final concentration of 1% (v/v), and the extract was filtered with a 0.45 µm filter.

GST-BirA fusion protein was purified from the cell extract by affinity chromatography through Glutathione Sepharose 4B (Pharmacia Biotech). The column (bed volume 5 mL) was equilibrated with PBS buffer containing 5% glycerol, 0.1 mM DTT, 10 mM MgCl₂, and 1% Triton X-100. The sample (15 mL) was loaded on the column at a flow rate of 0.5 mL/min, followed by washing with 10 vol of the equilibration buffer except that the concentration of Triton X-100 was reduced to 0.01%. The purified product was eluted with 10 mM reduced glutathione in 50 mM Tris-HCl, pH 8.0, containing 5% glycerol and 10 mM MgCl₂. The pooled fractions were concentrated, and the protein concentration was determined by Bradford's protein determination assay (Bradford, 1976) using BSA as a standard. The purified GST-BirA protein was divided into aliquots and stored at -20 °C in a buffer containing 52% glycerol, 50 mM NaCl, 24 mM Tris-HCl, pH 8.0, 4.7 mM reduced glutathione, and 4.7 mM MgCl₂.

Fab Production and Purification. A fresh colony of *E. coli* XL-1 Blue cells containing the plasmid p572Bio was inoculated in 5 mL of SB medium (30 g/L tryptone, 20 g/L Yeast extract, and 10 g/L MOPS, pH 7.0) supplemented with glucose (0.2%), ampicillin (100 µg/mL) and tetracycline (10 µg/mL) and grown at 300 rpm, 37 °C until the OD₆₀₀ of approximately 0.5 was reached. One milliliter of the preculture was inoculated in 50 mL of SB medium supplemented with 0.05% glucose, 50 µg/mL ampicillin, 5 µg/mL tetracycline, and 100 µM IPTG and shaken at 240 rpm and 30 °C for 14 h. The cells were collected by centrifugation, resuspended in 10 mL of TBS buffer (50 mM Tris-HCl, pH 7.5, and 150 mM NaCl), and disrupted by sonication (model Labsonic U fitted with the needle probe 40T, B. Braun, Germany). The lysate was clarified by centrifugation (20000g, 4 °C, 15 min), the supernatant was recovered and stored frozen (-20 °C) until the purification. The Fab was purified from the clarified lysate with a prepacked 1 mL HiTrap Protein G column (Pharmacia Biotech) according to the manufacturer's instructions. Briefly, the thawed lysate was filtered through a 0.22 µm filter and loaded on the column which was preequilibrated with TBS buffer. After washing with 5 column volumes of TBS, the Fab was eluted with 100 mM glycine-HCl buffer, pH 2.5, containing 0.01% Tween20, at a flow rate of 0.5 mL/min. Fractions (1 mL) were collected in Eppendorf tubes that contained 30 µL of neutralization buffer (2 M Tris, pH 9.0, and 0.33% BSA). After the determination of the immunoreactive Fab concentrations, the peak fractions were pooled and stored at +4 °C.

Immunoassay Reagents and Equipment. All immunochemical measurements were performed using the DELFIA technology (Wallac, Finland), which is based on the time-resolved measurement of fluorescent lanthanide chelates formed in the enhancement solution after the lanthanide ion has been dissociated from the original, nonfluorescent chelate conjugated to the biomolecule. The following DELFIA assay reagents and equipment were used: (rabbit) anti-mouse IgG-coated microtitration strips, streptavidin-coated microtitration strips, europium-labeled streptavidin, Assay buffer, Washing solution,

Enhancement solution, and Plate Fluorometer (model 1232). Two europium-labeled estradiol derivatives, conjugated either from C4 or C6 of the steroid skeleton, were used as immunoassay tracers. The position 6 conjugate (estradiol-6-carboxymethyl oxime conjugated to an europium chelate; Pajunen et al., 1997) was kindly provided by H. Mikola while the position 4 conjugate (unpublished material) was obtained from N. Meltola.

Determination of Immunoreactive and Biotinylated Fab Fragments. Immunoreactive Fab concentrations were determined with a microtitration plate assay using europium-labeled estradiol (C4 conjugate) as the detection marker. Purified, nontailed recombinant Fab 57-2 (Pajunen et al., 1997) was used as the calibration standard. All dilutions were made in the Assay buffer. Samples and standards (200 µL) were added to pre-washed anti-mouse IgG-coated microtitration strips, shaken for 60 min at room temperature, followed by four washes after which 200 µL of europium-labeled estradiol (2 nM) was added to each well. The incubation was continued for 60 min, after which the strips were washed four times and Enhancement solution (200 µL) was added. The time-resolved fluorescence signal was measured with the Plate Fluorometer, controlled by the MultiCalc immunoassay program (1224-310) running on a personal computer. The program automatically produced a spline-fitted standard curve and calculated the unknown Fab concentrations.

The detection of biotinylated Fab fragments was performed as above, except that Eu-labeled streptavidin at 100 ng/mL instead of Eu-labeled estradiol was used. The degree of biotinylation was estimated by comparing the signals obtained from the same sample detected with either Eu-labeled estradiol or Eu-labeled streptavidin.

Enzymatic Biotinylation. The Fab sample (3 mL) was changed into the biotinylation buffer (100 mM potassium phosphate, 12 mM MgCl₂, and 0.06% Tween20) using a Centricon-30 concentrator (Amicon) with two cycles of concentration and dilution. Buffer-exchanged Fab (50 µg) was used for a 500 µL biotinylation reaction which contained 10 mM ATP, 100 µM D-biotin, 1 µg/mL pyrophosphatase, and 100 µg/mL of the GST-BirA fusion protein in the biotinylation buffer. The reaction was kept at 37 °C for 4 h, after which the unreacted biotin was removed by gel filtration using a prepacked Sephadex G-25 column (NAP-5, Pharmacia Biotech). The biotinylated and unbiotinylated Fab fragments were separated using monomeric avidin agarose (the Softlink resin, Promega) according to the manufacturer's instructions. Briefly, 1 mL of the Softlink resin was packed into a disposable minicolumn, regenerated with 10% acetic acid and equilibrated with TBS-Tween (TBS, pH 7.5, containing 0.05% Tween20). The Fab sample was passed through the column at a flow rate of 0.5 mL/min, followed by washing with 5 mL of TBS-Tween, after which the biotinylated Fab was eluted with 5 mM D-biotin in TBS-Tween supplemented with 0.01% BSA. Fractions (0.5–1.0 mL) were collected and analyzed for the immunoreactive Fab concentrations. The peak fractions eluted with biotin were pooled, and the free biotin was removed by repeated concentration with Centricon-30 followed by dilution with TBS-Tween. After seven cycles of concentration/dilution, the final volume was 0.3 mL and the estimated residual free biotin concentration was 0.3 µM.

Chemical Biotinylation with Biotin Isothiocyanate. Biotin isothiocyanate (BITC) was obtained as a gift from V.-M. Mikkala. BITC is reactive mainly with the primary amino groups in the proteins (Mikkala et al., 1993) and is used the same way as the commonly used

N-hydroxysuccinimide derivatives of biotin. The chemistry of the biotinylation reaction is described in Figure 4B. The recombinant Fab 57-2 fragments used for the chemical biotinylation were produced using an expression vector that did not contain the biotin acceptor tail at the end of the Fd chain. Purified Fab, originally stored in 10 mM MES, pH 6.0, was buffer exchanged into 0.9% NaCl using a NAP5 column (Pharmacia Biotech). The biotinylation was performed in a reaction volume of 100 μ L containing 100 μ g (2 nmol) of Fab, either 30 or 50 nmol of freshly dissolved BITC, and 50 mM sodium carbonate buffer (pH 9.8). The BITC reagent was used in either 15- or 25-fold molar excess, known from previous experience to be near optimal for Fab fragments. For a number of reasons, the conditions used do not lead to the stoichiometric conjugation of biotin and therefore we prefer to state the molar reagent concentrations (300 and 500 μ M) instead of the reagent excess per se. The biotinylation reaction was incubated at room temperature for 4 h after which the unreacted BITC was separated by passage through two buffer exchange columns (NAP5, followed by NAP10, Pharmacia Biotech), equilibrated with TSA (50 mM Tris-HCl, pH 7.75, 150 mM NaCl, and 0.02% NaN_3). After the buffer exchange, BSA (0.1%) and NaN_3 (0.05%) were added and the sample was filtered through a 0.22 μ m filter. The biotinylated fraction (>90%) was purified using the monomeric avidin resin similarly as described for the purification of the enzymatically biotinylated Fab.

Immunochemical Characterization of Biotinylated Fab Fragments. The biotinylated Fab fragments were tested in streptavidin-coated microtitration strips for binding capacity, biotin inhibition, binding stability, and antigen affinity constant. All incubations were done at room temperature, the strips covered with an adhesive tape. All dilutions were made in the Assay buffer.

To determine the *binding capacity* of the streptavidin-coated wells for BioFab, a series of BioFab samples (0.03–60 ng/200 μ L) was added to the wells and shaken for 60 min at room temperature, followed by four washes. The bound BioFab was then detected with europium-labeled estradiol (10 nM C6 conjugate/200 μ L) which was shaken for 30 min, followed by four washes. Finally, the europium content in the wells was determined by adding 200 μ L of Enhancement solution, shaking for 30 min to develop the fluorescent chelates, and measuring the europium signals with the Plate Fluorometer.

In the *biotin inhibition* test, the samples (200 μ L) contained fixed amounts of Fab (5.4 ng) and europium-labeled estradiol (2 nM C6 conjugate), while each sample contained a different concentration of biotin (0–10 μ M). The premixed samples were added to the streptavidin-coated wells, shaken for 60 min, and washed four times. Since the europium-labeled estradiol was already present from the beginning, there was no need for a separate tracer incubation for the detection of the bound BioFab. The europium signals were measured as above.

The *binding stability* test was started by preattaching BioFab to the streptavidin-coated microtitration wells (5.4 ng/200 μ L, 120 min), after which further binding and rebinding was stopped by the addition of 20 μ L of 33 μ M biotin (final concentration 3 μ M). The incubation was continued for varying times (15 min–24 h), followed by the removal of unbound/dissociated BioFab with four washes. The bound BioFab was detected with europium-labeled estradiol (2 nM C6 conjugate, 30 min, four washes); the europium signals were measured as described above.

In the *affinity constant* determination, the BioFab samples (2 ng/200 μ L) were preattached to the streptavidin-coated wells for 120 min, followed by four washes. Europium-labeled estradiol (200 μ L) (C4 tracer) was added at varying concentrations (0.08–8 nM) to each well and incubated for 2 h, followed by the removal of the unbound tracer with four washes. Finally, the bound tracer concentrations were determined by the measurement of the europium signals as before.

Calculation of Affinities. The affinities (K_d constants) were calculated with the KELL RADLIG program version 5.0.2 (Biosoft, Cambridge, U.K.). The analysis was performed with the hot saturation mode; binding data were input as molar concentrations; free ligand was calculated from specific bound. The multisite saturation models (1, 2, or 3 binding sites) were fitted with the $1/Y^2$ weighting; the fits were statistically compared using a built-in approximate F test included in the RADLIG program. In essence, the test determined whether there was a significant decrease in the weighted sum of squared deviations, given the increase in the model parameters when assuming more binding sites.

Competitive Immunoassay for Estradiol. BioFab (2 ng in 200 μ L of assay buffer) was preattached to streptavidin-coated microtitration wells for 60 min followed by four washes. Estradiol standards (0–100 nM) were prepared directly in the tracer solution (0.2 nM C6 conjugate in assay buffer). Each standard (200 μ L) (i.e., mixture of estradiol and tracer) was added to three replicate wells, incubated for 60 min, and washed four times, after which the measurement of the bound tracer was performed as above. The MultiCalc immunoassay program was used for the data management and the following calculations. A four-parameter logistic fitting algorithm was used to produce the standard curve and the associated parameters: ED_{50} , i.e., the concentration corresponding to the half-maximal signal and the slope factor, i.e., the measure of the steepness of the sigmoidal curve. The estradiol concentrations in the individual wells were back-calculated from the fitted standard curve using the measured signals, after which the coefficient of variation (CV%) was calculated for each set of triplicate wells.

RESULTS

Design of the Fab-Biotin Acceptor Peptide Fusion Protein. To produce the Fab-biotin acceptor peptide fusion protein, we constructed the plasmid p572Bio (Figure 1). The Fd and light chain genes of the original anti-estradiol mAb 57-2 (Pajunen et al., 1997) were previously cloned into the phage display vector pComb3 (Barbas et al., 1991), where the Fd chain was fused to the carboxyl-terminal domain of the gene III protein of the filamentous phage M13. We excised the gene III fragment using the unique flanking restriction sites *SpeI* and *NheI* and replaced it by a synthetic DNA cassette containing the coding sequence for a 13 amino acid biotinylation signal, adapted from Schatz (1993). To increase the availability of the biotin acceptor peptide for the BirA protein, we inserted a flexible linker of eight amino acids between the peptide and the carboxyl end of the Fd chain. The cassette was constructed from two overlapping synthetic oligonucleotides which also included the restriction sites *SpeI* and *NheI* for cloning into the pComb3 vector and an internal unique *SfiI* site for the checking of the presence of the insert. The nucleotide sequence of the cassette is shown in the upper part of Figure 1.

Figure 1. Map of the plasmid p572Bio. The expression of the heavy (Fd) and the light chains is controlled by the *lac* promoter-operator (*lacPO*) in front of each gene. *pelB* signal sequences, fused to the amino termini of each chain, direct the synthesized polypeptides to the periplasmic space. The biotin acceptor peptide coding region is cloned in-frame to the carboxyl terminus of the Fd chain which ends right before the *SpeI* site. The nucleotide sequence between the *SpeI* and *NheI* sites as well the translated amino acid sequence are shown above the plasmid map. The biotinylated lysine residue is indicated by a circle. Labels: ColE1 ori, the region containing the plasmid origin of replication; f1 ori, the region containing a filamentous phage origin of replication; ApR, ampicillin resistance (beta-lactamase) gene.

Construction, Expression and Purification of the GST-BirA Fusion Protein. The translational fusion between the GST and the BirA protein was carried out by cloning the *birA* gene of *E. coli* to the GST gene fusion vector pGEX-1 λ T containing the gene for the glutathione S-transferase of *S. japonicum* (Smith and Johnson, 1988). In the resulting plasmid pGEX-BirA, the GST coding region, followed by a thrombin cleavage site, is fused in-frame to the first methionine codon of the full-length *birA* gene (Figure 2). The overexpression of the fusion protein was achieved by IPTG induction of the strong *tac* promoter, resulting in the accumulation of approximately 10 mg/L of the fusion protein in the cells. Comparison of the SDS-PAGE samples of the whole cell lysate before and after centrifugation suggests that the fraction of insoluble protein was less than 30% of the total recombinant protein produced (Figure 3, lanes 2–3).

The GST-BirA protein was purified from the clarified cell lysate by one-step affinity chromatography using a glutathione Sepharose 4B column. The purification procedure was highly efficient as judged by the SDS-PAGE of the samples taken before the column, from the flow-through fraction and from the eluted material (Figure 3, lanes 3–5). The eluted fusion protein (lane 5) appeared to be over 90% pure, migrated roughly according to the expected size (62 kDa), and showed no signs of proteolytic degradation into truncated fragments such as the mere GST part (~26 kDa). The final yield of the purified GST-BirA from the 500 mL shake flask culture was 3.5 mg.

Purification and Biotinylation of apo-Fab 57-2. The total production level of apo-Fab in a shake flask

Figure 2. Map of the plasmid pGEX-BirA. A *BspHI*-*XbaI* fragment containing the *birA* gene was excised from the plasmid pJMR1 (a gift from A. Otsuka) and cloned into the *EcoRI* site of the vector pGEX-1 λ T. The cohesive ends of the insert and the linearized vector were filled in with the Klenow fragment of DNA polymerase I and ligated as blunt-ended fragments. The ligation of the insert in the correct orientation resulted in the regeneration of all the original restriction sites. The GST-BirA fusion gene is controlled by the strong *tac* promoter (*tacP*) which is in turn repressed by the plasmid-encoded *lac* repressor (*lacIq*). Fusion protein expression is induced by IPTG which derepresses the *tac* promoter. The joining region from the end of the glutathione S-transferase gene to the start of the *birA* gene is shown above the plasmid map. The thrombin site is indicated above the amino acid translation. For other labels, see legend to Figure 1.

Figure 3. SDS-PAGE analysis of the purification of the GST-BirA fusion protein. Samples were diluted in PBS, mixed with equal volume of 2 $\times$ reducing sample buffer and heated to 95 $^{\circ}$ C for 5 min. After a brief centrifugation, 1 μ L of each sample was loaded on a PhastGel 8–25% polyacrylamide gel which was run with SDS buffer strips using the PhastSystem electrophoresis apparatus (Pharmacia Biotech). Samples: molecular weight markers (1); cell lysate before (2) and after (3) the removal of insoluble material by centrifugation; flow through fraction (4) and eluate (5) of the glutathione Sepharose 4B chromatography.

culture after overnight induction at 30 $^{\circ}$ C was 800 μ g/L, of which 80% remained in the periplasm. The cells were disrupted by sonication after which the apo-Fab was purified from the total cell lysate by protein G chromatography. This simple miniscale purification procedure

Figure 4. Protein biotinylation via the ϵ -amino group of a lysyl residue. A three-residue fragment of a larger polypeptide chain is shown with the lysyl residue in the middle. R_{-1} and R_{+1} denote the side chains of the residues preceding and following the lysyl residue. (A) The enzymatic biotinylation reaction catalyzed by the biotin ligase. The reaction proceeds through a biotinyl-AMP intermediate from which the biotinyl moiety is transferred to the acceptor protein. (B) The chemical biotinylation reaction using BITC. The nucleophilic amine of the lysyl residue attacks the central, electrophilic carbon of the isothiocyanate group. An electron shift and a proton loss create a stable thiourea bond.

Table 1. Purification and Biotinylation of the apo-Fab

procedural step	volume (mL)	Fab concn ($\mu\text{g/mL}$)	Fab mass (μg)	yield (%) ^a step-wise	overall
initial purification					
clarified lysate	10	21	207	100	100
after freeze and thaw	10	16	160	77	77
protein G pool	3	26	79	50	38
biotinylation ^b					
reaction mixture	0.5	100	50	100	100
after buffer exchange	1.1	48	53	106	106
monomeric avidin column ^c					
flow-through + washes	5.5	5.3	29	55	58
eluted fractions (pool)	2.5	6.2	16	29	31
total out			45	85	90
concentrated pool	0.3	64	19	123	38

^a Percentage of Fab remaining after each step, expressed with respect to the preceding step (stepwise yield) as well as with respect to the starting point of the procedure (overall yield). ^b The complete biotinylation procedure consisted of the enzymatic reaction, buffer exchange with NAP5 column, and separation of biotinylated and nonbiotinylated Fab with monomeric avidin column and the final concentration of the pooled fractions with a Centricon 30 concentrator. ^c All the buffer-exchanged material (1.1 mL) was loaded on the monomeric avidin column.

gave a relatively low overall yield (38%), since there were losses both in the intermediate frozen storage of the clarified lysate as well as in the protein G chromatography (Table 1). No optimization of the purification method was attempted.

GST-BirA fusion protein was used to biotinylate 50 μg of the purified apo-Fab. After the biotinylation reaction and a buffer change to remove free biotin, the biotinylated and nonbiotinylated Fab fragments were separated with monomeric avidin chromatography (SoftLink resin); the bound Fab fragments were eluted from the column with 5 mM free biotin. All fractions (flow-through, wash as well as elution) were recovered and subjected for the determination of immunoreactive Fab concentrations (Table 1). The total sum of the collected fractions was 85% of the input, consisting of 55% in the flow-through

and wash fractions (representing the apparently nonbiotinylated Fab fragments) and 29% in those fractions eluted with biotin (representing the biotinylated Fab fragments). Thus, the degree of biotinylation could be estimated to be about $29/85 \approx 34\%$. The fact that apparently 15% of the input Fab was not recovered at all may be partly explained by minor underestimation of the individual fraction volumes. After the pooling and final concentration steps, we had 19 μg of purified BioFab, which constituted 38% of the initial 50 μg used for the biotinylation procedure. Thus the net efficiency of the whole procedure was estimated to be 38% (bottom line of Table 1).

The degree of biotinylation was also estimated by another method in which the Fab samples were first immobilized on secondary antibody-coated wells and then detected either with europium-labeled streptavidin or with europium-labeled estradiol. For each sample, the ratio of the signals obtained with europium-labeled streptavidin versus europium-labeled estradiol was taken as an indicator of the degree of biotinylation. The analysis of the Fab samples before and after the enzymatic reaction as well as after the final purification is described in Table 2. Assuming that the signal ratio of the purified BioFab (4.68) represents a fully biotinylated population, the efficiency of the biotinylation reaction was calculated to be 42%, agreeing well with the previous estimate based on the separation of the biotinylated and nonbiotinylated forms with the monomeric avidin resin (above). The degree of biotinylation in vivo (i.e., before the enzymatic in vitro reaction) was approximately 2%.

Binding of BioFab to Streptavidin-Coated Wells.

The interaction of the enzymatically biotinylated Fab 57-2 with coated streptavidin was characterized in terms of the binding capacity, specificity, and stability. To study the binding capacity, varying amounts of BioFab (0.003–160 ng) were incubated in the streptavidin-coated wells. After washes, the bound BioFab was detected using europium-labeled estradiol as the tracer. The

Table 2. Degree of Biotinylation^a

process stage	streptavidin signal (CPS)	estradiol signal (CPS)	ratio ^b	proportion ^c biotinylated
purified apo-Fab	5460	54 398	0.10	2%
after enzyme reaction	129 680	65 403	1.98	42%
purified BioFab	422 192	90 294	4.68	100%

^a Fab samples were captured to anti-mouse IgG coated microtitration strips and detected with either europium-labeled streptavidin or europium-labeled estradiol. The streptavidin signal is proportional to the amount of biotinylated fragments in the sample while the estradiol signal is proportional to the amount of Fab fragments containing intact binding sites. ^b The ratio of the signals obtained with labeled streptavidin and estradiol. ^c The extent of biotinylation was estimated by comparing the streptavidin/estradiol signal ratio at each stage with that of the purified BioFab. It was assumed that the BioFab fragments purified with the monomeric avidin resin were completely biotinylated.

dependence of the measured europium signals on the amount of BioFab added is shown in Figure 5A. The response stays virtually linear for almost 5 orders of magnitude, indicating that the binding of the BioFab is not dependent on its own concentration. No saturation of the streptavidin surface could be demonstrated within the range of BioFab concentrations tested; therefore, the binding capacity is at least 160 ng/well.

As a control for the specificity of the attachment of BioFab to the streptavidin-coated wells, we tested whether the binding could be inhibited by free biotin. Figure 5B shows how the BioFab binding decreased rapidly as the free biotin concentration went from 40 to 100 nM, indicating that BioFab and biotin competed for the same binding sites. Consequently, the observed binding of the BioFab to the surface was not caused by general non-specific forces such as the stickiness of the protein. The inhibition experiment also revealed that 3 μ M biotin concentration blocked practically all BioFab binding. Consequently, this concentration was used in the stability test (below) to prevent rebinding of dissociated BioFab fragments.

The stability of the complex between BioFab and the coated streptavidin in the microtitration well was studied by incubating the preformed complexes in 3 μ M biotin solution for varying times, followed by washes and detection of the bound BioFab with labeled antigen. Although 3 μ M biotin effectively blocked the binding of BioFab when added simultaneously (Figure 5B), it could not displace BioFab already bound to streptavidin (Figure 5C). In the time period of 24 h, less than 10% of the bound BioFab dissociated from streptavidin, indicating that the half-life of the complex must be several days.

Affinity Comparison of Enzymatically and Chemically Biotinylated Fab Fragments. To study whether the enzymatic and chemical biotinylation methods differed in their effects on the antigen-binding affinity, we made a binding site titration using labeled antigen. Biotinylated Fab fragments were immobilized on streptavidin-coated wells, after which varying concentrations of europium-labeled estradiol (C4 conjugate) were added and allowed to equilibrate between the bound and free states. Figure 6A shows that the binding sites were efficiently titrated as the signal levels of the bound labeled antigen were approaching saturation at the higher total concentrations. To determine the affinity constants, the data were initially plotted as bound/free vs bound (the Scatchard's plot) so as to calculate the K_d s from the slopes of the plots by linear regression (Figure 6B). However, the plots for the chemically biotinylated Fab fragments were clearly curved, suggesting the pres-

Figure 5. Testing the binding of BioFab to streptavidin-coated microtitration wells. The amount of BioFab bound to the wells was detected with europium-labeled antigen (C6 conjugate of estradiol). Each symbol in the plots represents the average of two replicate wells. (A) Capacity. The signal of the bound labeled antigen is linearly dependent on the amount of BioFab added throughout the tested range. (B) Specificity. BioFab binding is inhibited by increasing concentrations of free biotin. (C) Stability. The dissociation of bound BioFab from the coated streptavidin was monitored for 24 h. Excess free biotin was used to block the rebinding of dissociated BioFab.

ence of two or more subpopulations of binders with different affinity constants. Therefore, the binding data were nonlinearly fitted to different models involving one

Figure 6. Affinity determination of the enzymatically and chemically biotinylated Fab fragments. Biotinylated Fab fragments were immobilized on streptavidin-coated wells, after which the binding sites were titrated with europium-labeled estradiol (C4 conjugate). (A) The bound concentration (pM) is plotted against the total added concentration of europium-labeled estradiol. The replicates (two parallel wells) are plotted separately. (B) Scatchard plot presentation of the same data. As an exception to the conventional presentation (bound/free vs bound), the x values were normalized to the form $B/B_{\max}$. This way, all the curves cross the x-axis at the same point and can be more readily compared. (The absolute $B_{\max}$ values are shown in Table 3). The curves drawn through the data points were fitted according to the model involving two binding sites.

ligand and either one, two, or three binders. Statistical comparison between the fits (performed by the RADLIG fitting program) supported the model involving two classes of binders in each case, although the exact nature of the minor classes could not be accurately defined. Realizing that the two-binder model only gave the statistically most plausible fit for the available binding data, we concentrate on the comparison of the major binder classes within that model (Table 3). While the major class always represented more than 90% of the total binding site population, it can be seen that the enzymatically biotinylated Fab fragments were the most uniform (98.6% major binder). The dissociation constants (K_d) of the chemically biotinylated Fab fragments were 2.6–3.6-fold higher than that of the enzymatically biotinylated Fab (Table 3), suggesting that the random attachment of biotin lead in most cases to the decrease of antigen-binding affinity.

Competitive Immunoassay for Estradiol. To demonstrate the usage of the BioFab as an immunoassay reagent, we set up a competitive estradiol immunoassay in streptavidin-coated microtitration strips, using europium-labeled estradiol (C6 conjugate) as the tracer. The B_0 signal (corresponding to zero estradiol concentration) was approximately 51 000 cps whereas the signals obtained with estradiol standards between 1 and 100 nM decreased from 44 800 down to 4300, covering practically the whole measurable concentration range (Figure 7).

Table 3. Affinities for Europium-Labeled Estradiol^a

biotinylation method ^b	percentage of major binder ^c	$B_{\max}$ (pM $\pm$ SD)	K_d (nM $\pm$ SD)
enzymatic	98.6%	66.0 $\pm$ 1.5	1.57 $\pm$ 0.16
BITC 300 μ M	94.5%	78.2 $\pm$ 9.5	4.11 $\pm$ 1.34
BITC 500 μ M	93.5%	74.2 $\pm$ 9.4	5.70 $\pm$ 1.62

^a The affinities (K_d constants) of the biotinylated Fab fragments for europium-labeled estradiol were calculated from the data obtained in the hot saturation experiment shown in Figure 6. ^b The Fab fragments were biotinylated either enzymatically (using the GST-BirA fusion protein as the biotin ligase) or chemically (using either 300 or 500 μ M BITC reagent). ^c The binding data were initially fitted into models involving either one, two or three binding site subpopulations. The two site model was the statistically most plausible one in each case, even when the second sites were present at very low proportions. However, the binding parameters of the minor sites could not be accurately defined and were omitted from the table.

Figure 7. Competitive immunoassay for estradiol. The assay was performed in streptavidin-coated microtitration plates to which purified, enzymatically biotinylated anti-estradiol Fab fragments (BioFab) were precaptured in a separate incubation. The assay incubations (60 min) contained a fixed concentration of tracer (0.2 nM europium-labeled C6 conjugate of estradiol) and a varying concentration (0–100 nM) of estradiol; the x-axis refers to the final estradiol concentrations in the wells. After washes, the bound tracer was measured with time-resolved fluorescence as described in materials and methods. Filled circles indicate the average signal (CPS, left y-axis) obtained from the measurement of three replicate wells for each estradiol concentration. The MultiCalc program was used for curve fitting as well as for the reverse calculation of estradiol concentrations from the measured signals for the individual wells. The coefficient of variation (CV%, right y-axis) of the calculated estradiol concentrations for each set of triplicate wells is indicated by open triangles.

The europium signals were fitted with a sigmoidal dose–response curve model (the four-parameter logistic equation) producing a standard curve with an ED_{50} of 6.7 nM and a slope factor of -0.94 . When the estradiol concentrations of the standards were reverse calculated from the fitted curve using the measured signals, the coefficient of variation (CV%) of the concentrations remained less than 10% throughout the range (Figure 7), indicating that the assay is technically reliable and could be applied to the measurement unknown estradiol concentrations.

DISCUSSION

We describe the site-specific enzymatic biotinylation of recombinant anti-estradiol Fab fragments through a 13 amino acid acceptor peptide translationally fused at the C-terminus of the Fd chain. To our knowledge, this is the first report on the in vitro application of the biotin ligase to biotinylate antibodies. Moreover, we describe the usage of a novel fusion protein (GST-BirA) as the biotinylating enzyme.

The production of correctly folded recombinant Fab fragments in *E. coli* requires that they be secreted to the periplasm where the oxidative conditions allow for the formation of the necessary disulfide bridges (Plückthun and Skerra, 1989). Because efficient secretion is not ideally compatible with in vivo biotinylation (Reed and Cronan, 1991; Jander et al., 1996), we decided not to try to optimize the intracellular conditions but rather perform the biotinylation in vitro. Nevertheless, we observed a low (2%) basal level of biotinylation in the protein G purified apo-Fab fragments (Table 2). A similar figure was reported by Weiss et al. (1994) in a study of secreted recombinant Fab fragments to which a 101 amino acid C-terminal fragment of the *E. coli* BCCP was fused at the C-terminus of the Fd chain. Relying on the activity of the endogenous biotin ligase, they initially achieved an in vivo biotinylation level of 3%, although they reported a 5-fold enhancement of the basic level on the addition of biotin to the growth medium. The basal biotinylation level observed by us and by Weiss et al. (1994) may represent the fraction of fusion proteins that are biotinylated in the cytoplasm before they are secreted (Reed and Cronan, 1991); possibly some biotinylation occurs also when cytoplasmic biotin ligase enters the periplasm as a result of partial cell lysis typical of recombinant Fab expression. Furthermore, here we used a shortcut (sonication) instead of osmotic shock for the extraction of the periplasmic Fab fragments and, thus in effect, mixed the cytoplasm and periplasm for a while before the protein G purification. The biotinylation in the cell lysate could indeed be an effective alternative to in vivo biotinylation, as shown by Chapman-Smith et al. (1994). They achieved only limited biotinylation of the overexpressed BCCP biotin acceptor domain in vivo despite the coexpression of the biotin ligase. However, the biotinylation was taken to completion in the cell lysate on addition of ATP and biotin.

The minimum size for the C-terminal fragment of BCCP that can be biotinylated as a fusion protein is about 84 residues (Li and Cronan, 1992). Compared to this, the 13 residue peptides described by Schatz (1993) seem to bring a definite advantage for recombinant fusion protein applications at least when the size of the tail is critical. Other parameters important for the general utility of these fusion tails include their efficiency as biotin ligase substrates, compatibility with secretion, and possible susceptibility to proteolysis. The biotinylated lysine of BCCP is located in a highly conserved hairpin β -turn (Athappilly and Hendrickson, 1995), and the cloned acceptor proteins from various bacterial as well as eucaryotic sources act as substrates for *E. coli* biotin ligase (Cronan, 1990). However, the consensus sequence of the 13 amino acid peptides differs considerably from the natural acceptors, indicating that different constraints and perhaps a different mechanism of recognition apply to the small acceptor peptides (Schatz, 1993). Despite this, the peptides have been shown to be quantitatively biotinylated in vivo, both as N- and C-terminal fusions, provided that biotin ligase is coexpressed (Tsao et al., 1996). The periplasmic secretion of the 13 amino acid biotin acceptor peptides as fusion proteins has not been attempted before. Our results indicate that the peptides fused at the C-terminus of the Fd chain are compatible with membrane translocation which is a prerequisite for the assembly of functional Fab fragments. We have constructed several similar Fab-acceptor peptide fusion proteins, and the production levels vary between 30 and 100% of that of the nonfusion versions, depending on the particular Fab fragment (M. Vehni-

äinen, unpublished data). There are large inherent differences in the folding and stability of different recombinant Fab fragments in the bacterial periplasm (Knappik and Plückthun, 1995), which may be reflected in the differing effects of the fusion tail on the production levels. The fact that more than half of the purified apo-Fab 57-2 could not be biotinylated suggests that the tail was not always accessible for the biotin ligase or it was proteolytically degraded. The biotinylation degree did not improve with the use of more enzyme or prolonging the incubation time, nor in attempts to rebiotinylate the nonbiotinylated fraction (data not shown). Further studies will be needed to clarify whether the incomplete biotinylation was caused by proteolytic cleavage of the tail or by some conformation-dependent mechanism.

To facilitate the purification of the biotin ligase, we cloned the *birA* gene into the GST fusion vector pGEX-1 λ T (Smith and Johnson, 1988). The fusion of glutathione S-transferase to the amino terminus of BirA was considered a minor risk, especially because there was an option to remove the fusion partner by thrombin cleavage at a site in the joining linker (Figure 2). On the basis of genetic data as well as sequence comparisons, Buoncrisiani et al. (1986) suggested that the N-terminal part of the BirA protein contains a helix-turn-helix motif responsible for DNA binding, while the central part contains the catalytic activities. In the crystal structure of BirA (Wilson et al., 1992), there is only a loose connection between the N-terminal domain (residues 1–60) and the central domain (residues 68–269), suggesting that the fusion of GST to the amino-terminus of BirA would not affect the catalytic activity. However, the catalytic and repressor functions are actually intimately connected. The biotin ligase activity consists of two steps: the formation of biotinyl-5'-AMP from biotin and ATP and the transfer of the activated biotin moiety to the acceptor protein (BCCP). If all acceptor proteins are already biotinylated, the biotinyl-5'-AMP remains bound to BirA and acts as the corepressor of biotin biosynthesis (Cronan, 1989). Not only is biotinyl-5'-AMP required for the binding of BirA to the *bio* operator but, in turn, also the presence of the DNA-binding domain is important for the binding of biotinyl-5'-AMP to the catalytic domain. In a study of a truncation mutant of BirA lacking the N-terminal DNA-binding domain, Xu and Beckett (1996) found that the affinities for biotin and biotinyl-5'-AMP were 100- and 1000-fold decreased, respectively, although the maximal catalytic rates for the formation of biotinyl-5'-AMP and the transfer of biotin to BCCP were unchanged. These results implied that the N-terminal fusion of GST to BirA could, in an unfortunate case, affect the enzymatic activity. However, the fusion protein worked reasonably well for our purposes, so we did not attempt removing the GST part by taking advantage of the thrombin cleavage site. Biochemical studies are needed in the future to assess the possible effect of the GST fusion as well as to determine the catalytic parameters of the BirA biotin ligase for the peptide substrates.

The enzymatically biotinylated Fab fragments were characterized for their interaction with surface-bound streptavidin in order to assess their potential usefulness as immunoassay reagents. First, the binding of BioFab to streptavidin-coated wells was found to be linear in a wide concentration range (almost 5 decades), indicating that the Fab fragments bind independently of each other. The binding was also specific as demonstrated by the blocking of binding by submicromolar concentrations of biotin. The stability of the complex between BioFab and the coated streptavidin was a concern as it is known that

some biotinylated macromolecules show considerably weaker binding to streptavidin than does biotin (Vincent and Samuel, 1993). We tested the binding stability by measuring the time-dependent dissociation of Bio-Fab from streptavidin in the presence of a vast excess of free biotin to block the rebinding. The dissociation rate was extremely low, less than 10% in 24 h, which should be adequate for most immunoassay applications. Moreover, typical assay conditions would allow the rebinding of dissociated BioFab and thus would show even higher apparent binding stability. In conclusion, the above results indicate that the fusion peptide tail presents the biotin moiety in a favorable position for streptavidin binding.

The determination of the antigen-binding affinities of one enzymatically biotinylated and two chemically biotinylated Fab fragments indicated that the enzymatic biotinylation results in a more uniform binder population. Moreover, comparison of the major binders shows that the dissociation constants (K_d) of the chemically biotinylated Fabs are 2.6–3.6 times higher than that of the enzymatically biotinylated one (Table 3). These differences may be explained by the location of the biotin moiety on the surface of the Fab fragment. In the chemical procedure, in principle all surface lysines are targets for conjugation, although some may be preferred over the others. The outcome of the chemical biotinylation is therefore dependent on the content and distribution of surface lysines. The conjugation of a lysine residue at or near the antigen binding site can have an effect on the affinity either directly by interfering with the antibody–antigen interaction or indirectly by steering the immobilization of the Fab in an unfavorable orientation. The disadvantages of the chemical conjugation process can often be reduced by careful optimization of the conditions, aiming at one biotin per Fab. Even then, it depends on the primary structure of the Fab whether the single biotinylated lysine is preferentially found in the antigen binding site, elsewhere in the variable domains or in the constant domains. Ultimately, it is possible to engineer the primary structure of the binding site in order to decrease its sensitivity to chemical labeling, as shown in a recent study in which two lysine residues in the CDR loops of a recombinant immunotoxin were changed into arginines (Benhar et al., 1994). As this technique is by no means trivial or universally applicable, there will remain an increasing number of recombinant Fab (as well as single chain Fv) fragments that cannot be labeled with amine-reactive chemistries. Our results show that the enzymatic biotinylation through a peptide acceptor tail can produce a homogeneous, well-behaving binder population when the chemical biotinylation through amino groups fails to do so.

Finally, we demonstrated that the enzymatically biotinylated Fab fragments work as reagents in a competitive estradiol immunoassay. The standard curve (Figure 7) followed nicely the four-parameter logistic model and had a slope factor close to -1 which again indicated that the antigen and the tracer reacted with a single binder population. Although the assay is technically reliable (CV% was less than 10% throughout the measuring range), it is not yet useful for the measurement of clinical samples because the affinity of the antibody 57-2 for estradiol is not high enough. However, we are currently modifying its binding properties by random mutagenesis and phage display (Saviranta et al., 1998) and expect to use the mutated version for the assay of clinical samples. Furthermore, the site-specifically biotinylated Fab fragments should be ideal for the novel miniaturized assay

formats, such as single microparticle-based assays (Lövgren et al., 1997) where maximally efficient usage of the coated surface is required.

ACKNOWLEDGMENT

The financial support from State Technology Development Centre of Finland (TEKES) is gratefully acknowledged. We thank H. Mikola and N. Meltola for delivering the europium-labeled estradiol conjugates. M. Pajunen, M. Vehniäinen, and P. Nurmikko are thanked for help in DNA cloning, protein purification, and chemical biotinylation, respectively.

Comparison of Recombinant Immunotoxins against Le^Y Antigen Expressing Tumor Cells: Influence of Affinity, Size, and Stability

Tapan K. Bera and Ira Pastan*

Laboratory of Molecular Biology, DBS, National Cancer Institute, National Institutes of Health, Building 37, Room 4E16, 37 Convent Drive MSC 4255, Bethesda, Maryland 20892-4255. Received March 6, 1998; Revised Manuscript Received August 11, 1998

Monoclonal antibody B3 (MAb B3) reacts with many epithelial cancers. It recognizes a carbohydrate antigen (Le^y) which is expressed in a variety of solid tumors including breast and colon. We have used the Fab portion of MAb B3 and a portion of the constant domain of human IgG1 to make recombinant immunotoxins of different compositions. The toxin component employed is a truncated form of *Pseudomonas* exotoxin (PE38). The light chain or Fd of the antibody was cloned from hybridoma RNA and fused to PE38. Immunotoxin (IT) was then expressed in *Escherichia coli* as a fusion protein and refolded with either the Fd or the light chain. We have also made B3(Fab) immunotoxins of different sizes ranging 85–140 kDa, by introducing different portions of the constant domain of human IgG1 at the junction of Fd and PE38 fusion site. We compared the properties of the resulting immunotoxins with existing anti-Le^y immunotoxins side by side. All recombinant Fab-immunotoxins made in this study were cytotoxic to antigen-positive cancer cell lines. However, in contrast to the B3(scFv) immunotoxin, the B3(Fab) immunotoxins are very stable, retaining 90% of their activity after 24 h of incubation in human serum albumin at 37 °C. A pharmacokinetics study with these immunotoxin molecules showed a longer survival in the circulation of mice compared to the smaller Fv immunotoxins. The smaller size of the Fab immunotoxins compared to B3Lys-PE38 and the increased $T_{1/2}$ value compared to B3(scFv)-PE38 and B3(dsFv)-PE38 make these recombinant immunotoxins alternative therapeutic agents to treat Le^y antigen positive cancers.

INTRODUCTION

Monoclonal antibodies (MAb) which recognize antigens on cancer cells are now being used for targeted therapy for the delivery of toxins, radioisotopes or drugs (Vitetta et al., 1987; Mulshine et al., 1991; Pastan et al., 1995; Brinkmann and Pastan, 1995). To produce an immunotoxin, the antibody is linked to a toxin made by bacteria or plants. Immunotoxins of this type are being developed for the treatment of cancer and other diseases including acquired immune deficiency syndrome (AIDS) and immunological disorders (Vitetta, 1990). In our laboratory we have used mutant forms of *Pseudomonas* exotoxin A (PE) to produce immunotoxins (Pastan and Fitzgerald, 1991). PE is a three domain protein, each with a different function. Domain I is responsible for cell binding, domain II for the translocation across the cell membrane, and domain III for the ADP-ribosylation activity of the toxin (Hwang et al., 1987). Using recombinant DNA technology, we have deleted domain I of PE to make a 38 kDa fragment (PE38) that retains the full ADP-ribosylation activity of the toxin (Brinkmann et al., 1991; Pai et al., 1991).

Immunotoxin B3Lys-PE38 (LMB1) is composed of MAb B3 chemically linked to PE38 (Pai et al., 1991). Single-chain Fv immunotoxins are recombinant fusion proteins composed of a cell-targeting moiety and the cytotoxic domain of the toxin molecule (Chaudhary et al., 1989). In B3(Fv)-PE38, the Fv portions of the monoclonal antibody B3 were cloned from the B3 hybridoma, fused to PE38 and expressed as a single molecule in *Escheri-*

chia coli (Brinkmann et al., 1991). Using this approach, a variety of other recombinant single-chain immunotoxins have been made. B3(Fv)-PE38 and B3Lys-PE38 are currently being examined for the treatment of Le^y-positive solid tumors. A phase I study was conducted with B3Lys-PE38 immunotoxin for 38 patients with solid tumors who failed conventional therapy and whose tumors expressed the Le^y antigen. Objective antitumor activity was observed in 5 patients, 18 had stable disease, and 15 progressed. A complete remission was observed in a patient with metastatic breast cancer to supraclavicular nodes. A greater than 75% tumor reduction and resolution of all clinical symptoms lasting for more than 6 months were observed in a colon cancer patient with extensive retroperitoneal and cervical metastasis (Pai et al., 1996). Anti-Tac(Fv)-PE38 is currently being evaluated for the treatment of leukemia (Kreitman et al., 1992). Although single-chain immunotoxins are relatively easy to make, they have some limitations. One is that frequently these molecules are unstable, probably due to the fact that the hydrophobic residues in the Fv fragments which are covered by the constant region of the whole antibody get exposed, and as a result, they have a tendency to aggregate. This problem has been solved by generating an Fv molecule in which the V_H and V_L fragments are connected by a disulfide bond (Brinkmann et al., 1993; Reiter et al., 1994a–c). The disulfide-stabilized Fv (dsFv) containing immunotoxins is very stable at 37 °C, effectively killing target cells and promoting tumor regressions. Depending on the antibody, the relative affinity of the dsFv molecule for antigen can be increased, unchanged, or reduced compared with the single chain Fv (Reiter et al., 1994a–c). Another

limitation for both scFv and dsFv-containing immunotoxins is that their half-lives in the circulation of mice and monkeys are short with a $T_{1/2}$ ranging 20–60 min (Reiter et al., 1994c). In contrast, the half-life of the chemical conjugate of whole antibody is about 10 h in mice (Pai et al., 1991) and 9 h in humans (Pai et al., 1996). The plasma half-life of the immunotoxins constructed from the chemical conjugation between whole antibody and the toxin is mainly contributed by the antibody because the half-life of the toxin molecule is very short (Brinkmann and Pastan, 1995).

The Fab fragments of antibodies composed of Fd and light chain linked by a disulfide bond are very stable. These have been used to make chemical conjugates with several different toxins and also recombinant immunotoxins (Reiter et al., 1997; Kreitman et al., 1994). In this study, we have made an Fab immunotoxin with MAb B3 and combined it with different portions of the constant domain of human IgG1 and PE38. Our goal was to determine if we could make immunotoxin molecules of different sizes containing one or two PE38 domains and to study the properties of these molecules.

MATERIALS AND METHODS

Cloning of Fd and Light Chain of MAb B3. The Fd and light chain of MAb B3 were PCR-amplified from reverse transcribed hybridoma mRNA using primers designed from the published B3(Fv) sequences and from the sequences of the constant region of heavy and light chain. PCR primers used in this study are

T30	CAT ATG GAG GTG AAG CTG GTG GAA TCT
T31	TGA AGC TTC ACC ACA ATC CCT GGG CAC
T32	GG AAT TCA TTA ACA ATC CCT GGG CAC
T38	CAT ATG GAT GTT CTG ATG ACT CAA
T34	TGA AGC TTC ACA CTC ATT CCT GTT GAA GCT
T35	GG AAT TCA TTA ACA CTC ATT CCT GTT GAA GCT
T47	AGC CTC CAC CAA GGG CCC ATC G
T48	TCA TTT ACC CGG AGA CAG GGA G
T49	TCC ATC TCT TAA GCT TCA CCT GAG CTC CTG GGG GGA CCG
T50	CCC ACG GGT CCA AGC TTT GGC TTT GGA GAT GGT TTT CTC G
T51	AAC CTC TGT AAA GCT TCG CAG CCC CGA GAA CCA CAG
T52	CGG CCG TCG CAA AGC TTT ACC CGG AGA CAG GGA GAG

The 5' primers (T30 and T38) used to amplify Fd or light-chain fragments were designed from B3(Fv) sequence. The 3' primers (T31 and T32) for Fd fragment were designed from the nucleotide sequence of the constant region of heavy-chain subgroup III(A) to which B3 IgG belongs. Similarly, the 3' primers (T34 and T35) for light chain were designed from the sequence of the constant region of κ chain. *NdeI*–*HindIII* or *NdeI*–*EcoRI* sites were introduced to clone the fragment into the expression vector to express either antibody-immunotoxin

fusion protein (pTKB1.5.1 and pTKB3.1.1) or antibody fragment alone (pTKB2.1.1 and pTKB4.1.7), respectively.

Isolation of Constant Region of Human IgG1 from Spleen cDNA. Polymerase-chain-reaction (PCR)-ready human spleen cDNA was purchased from Clontech (Palo Alto, CA), and the constant region of human IgG1 was isolated by PCR. Primers T47 and T48 were designed from the published sequences (Ellison, 1982) and were used to amplify the constant region of human IgG1. The amplified fragment was cloned into TA vector (Invitrogen, Carlsbad, CA), the sequence verified by DNA sequencing. The cDNA clone was then used as a template to amplify CH2, CH3, or CH2–CH3 region by primer pairs T49/T50, T51/T52 or T49/T52, respectively.

Cloning of Various Constant Regions of Human IgG1 into Expression Vector pTKB1.5.1. Restriction site *HindIII* was generated by PCR on both sides of the fragment to be inserted between the Fd and the PE38 portions of plasmid pTKB1.5.1. To construct the plasmids expressing either CH2, CH3, or both CH2 and CH3 fragment, pTKB1.5.1 plasmid was linearized with *HindIII* and then ligated with *HindIII* restricted DNA fragments that contain either CH2, CH3, or both. The correct inframe insertion of the fragments in the resulting plasmids pTKB12.1.7, pTKB13.1.4, and pTKB15.1.3 were checked first by DNA sequencing and finally by determining the sizes of the fusion protein expressed in *E. coli*.

Protein Expression and Purification. *E. coli* BL21 (λ DE3) was transformed with different plasmids and the protein production was induced by adding 10 mM IPTG as described earlier (Brinkmann et al., 1991). All of the fusion proteins were accumulated as insoluble inclusion bodies (IBs) in *E. coli*. IBs were solubilized and refolded by the procedure described earlier (Buchner et al., 1992). Briefly, the purified IBs were dissolved in solubilization buffer (6 M guanidine-HCl, 0.1 M Tris-HCl, and 2 mM EDTA). After the protein concentration was determined, equimolar amounts of Fd or light chains and their PE38 fusion proteins were reduced by the addition of 0.3 M dithioerythritol (DTT) for 4 h at room temperature and then refolded for 48 h at 10 °C in a refolding buffer described earlier (Buchner et al., 1992). Properly folded protein was then chromatographically purified using first ion exchange (Q-Sepharose and MonoQ; Pharmacia) and finally size-exclusion chromatography (TSK G3000 SW, Toso HAAS) using the procedure described earlier (Buchner et al., 1992).

Cytotoxicity Assay. The cytotoxicity of different immunotoxins was determined by measuring the inhibition of protein synthesis in different antigen-positive and -negative cancer cell lines by using a method described earlier (Chaudhary et al., 1989; Batra et al., 1990). All assays were performed in 96 well plates, each well containing 1.6×10^4 cells in 200 μ L of RPMI medium containing either 10% (A431, LnCap, CRL1739, and Hut102) or 5% (MCF7) fetal bovine serum. Cytotoxicity assays were performed with different immunotoxins for 2 h, and then fresh medium was added to each well after removing the toxin. The incubation continued for 16 h before [³H]leucine was added.

Assay of Blood Levels of B3(Fab)-PE38 Immunotoxin in Mice. Female BALB/c mice were injected in the tail vein with 10 μ g of immunotoxin. Blood samples were drawn at various time intervals and the level of the active immunotoxin was measured by the cytotoxicity assay using A431 cells. The A431 cells were incubated with the diluted serum samples and their ability to inhibit protein synthesis was measured. A standard curve was made with each pure immunotoxin. The data

were analyzed by an exponential curve fitting program RSTRIP (Version 5, MicroMath Scientific Software, Salt Lake City, UT).

Stability Assay. The stability of B3(Fab)-PE38-1 and B3(Fab)-PE38-2 immunotoxin was determined by incubating the proteins at 10 μ g/mL at 37 °C in human serum albumin. Active immunotoxin remaining at different times was determined by a cytotoxicity assay on A431 cells.

Binding Assay. B3-antigen-positive A431 cells were used for a binding competition assay. B3 antibody, radioiodinated with Bolton–Hunter reagent (New England Nuclear, Boston, MA), was used as a tracer in the competition binding assay. Equal counts (50 000 cpm) of labeled B3 antibody with increasing amounts of competitors (cold B3 antibody or immunotoxin) were combined in RPMI, 1% BSA, 50 mM BES, pH 7, and 0.04% NaN_3 and added to the cells after nonspecific sites on the cells were blocked. After 2 h of incubation with gentle rocking at 4 °C, unbound counts were washed off and the cells were lysed with 0.5% SDS. The bound radioactivity was assessed in a Beckman 5500B γ counter (Beckman Instruments, Fullerton, CA).

RESULTS

The primary goal of this study was to make recombinant immunotoxins of different sizes and compositions using the Fab fragment of MAb B3 and different portions of the human IgG1 constant region and to compare their cytotoxicity, pharmacokinetics, and binding affinity with the chemical conjugate B3-LysPE38 ($M_r \approx 195$ kDa) and two other recombinant immunotoxins B3(Fv)-PE38 (M_r 63 kDa) and B3(dsFv)-PE38 (M_r 63 kDa) in which the Fv portion was fused to PE38.

Plasmid Construction and Production of Recombinant Immunotoxin. The cDNA fragments encoding Fd and light chain of monoclonal antibody B3 were obtained by reverse transcriptase reaction of the mRNA from the B3 hybridoma cell line (Pastan et al., 1991), using the PCR primer pair as described in Materials and Methods. PCR-ready human spleen cDNA was purchased from Clontech and used to isolate the constant region of human IgG1 using the primer pairs described in Materials and Methods. The CH2 and CH3 regions of the IgG1 were then isolated separately from the constant region using the specific primer pairs as described in Materials and Methods.

Plasmid Construction. To produce the recombinant B3(Fab)-PE38 molecule, we constructed four expression plasmids, pTKB2.1.1, pTKB4.1.7, pTKB1.5.1, and pTKB3.1.1. (Figure 1). The first two plasmids were constructed to produce the Fd and light chain of MAb B3, respectively. The third and fourth plasmids were constructed to generate the Fd-PE38 and LC-PE38 fusion proteins. A polypeptide connector (C3, ASGGPE) was inserted between the antibody molecule and the toxin (Brinkmann et al., 1991).

To produce recombinant immunotoxins of different sizes, we constructed three plasmids by introducing CH2, CH3, and CH2-CH3 fragments of human IgG1 into the plasmid pTKB1.5.1. Schematic pictures of the plasmids used in this study are shown in Figure 1.

Protein Expression, Refolding, and Purification of Immunotoxins. Plasmids encoding different components of B3(Fab)-PE38 immunotoxins were expressed separately in *E. coli* BL21 (λ DE3) cultures as described previously (Buchner et al., 1992). All recombinant proteins accumulated in large amounts as insoluble

Figure 1. Plasmids for expression of the components of B3 Fab immunotoxin. The plasmid pTKB2.1.1 and pTKB4.1.7 code for the Fd and light chain of the MAb B3, respectively. The expression plasmid pTKB1.5.1 encodes Fd-PE38 fusion protein and plasmid pTKB3.1.1 codes for the fusion protein of B3 light chain and PE38. The plasmids pTKB12.1.7, pTKB13.1.4, and pTKB15.1.3 were generated from the parental plasmid pTKB1.5.1 by introducing CH2, CH3, and CH2-CH3 fragment of human IgG1 between the Fd and PE38 and encode Fd-CH2-PE38, Fd-CH3-PE38 and Fd-CH2-CH3-PE38 fusion protein, respectively.

intracellular inclusion bodies (IBs). IBs containing different components were used to produce different immunotoxins. Soluble recombinant immunotoxins were recovered using a purification scheme that included ion exchange and size-exclusion chromatography previously established for purification of single-chain immunotoxins (Buchner et al., 1992).

The scheme we used to make different immunotoxin molecules is shown in Figure 2, with the summary of the expected molecular mass and the yield of each purified protein. B3(Fab)-PE38-1 was made by refolding Fd-PE38 and light chain. B3(Fab)-PE38-2 was made by refolding light chain-PE38 and B3 Fd. Both B3(Fab)-PE38-1 and B3(Fab)-PE38-2 could be produced as monomers with final yields from purification of about 2.5%. The purity of those molecules after purification is shown in Figure 3. B3(Fab)-PE38-3 did not refold into a soluble monomeric protein, perhaps because of the inhibition of the disulfide bond formation between Fd and light chain by the PE38 portion of each component.

B3(Fab)-PE38-4 and B3(Fab)-PE38-6 also could be produced as pure proteins with final yields of about 2.5%. The purity of those molecules after refolding and subsequent purification is shown in Figure 3. B3(Fab)-PE38-5 and B3(Fab)-PE38-7 immunotoxins refolded very poorly. After size exclusion chromatography, the final yield for B3(Fab)-PE38-5 and B3(Fab)-PE38-7 was only about 0.1%.

Specific Cytotoxicity of B3(Fab)-PE38 Recombinant Immunotoxin. PE38 is a truncated form of *Pseudomonas* exotoxin, and the fusion proteins of antibody fragments with PE38 are cytotoxic to cells that specifically bind and internalize the fusion protein. Since the degree of cytotoxicity to a given antigen depends primarily on binding affinity, cytotoxicity assays of immunotoxin fusion proteins can thus serve as an accurate test system for specificity as well as for the relative affinity of engineered antibody fragments (Brinkmann and Pastan, 1995). To test whether all of the six immunotoxins made retain not only the affinity but also specificity, we analyzed the activity of these recombinant immunotoxins using several B3 antigen-positive and

The calculated molecular mass and the corresponding % yield of each immunotoxin is indicated.

-negative cancer cell lines. For convenience, protein synthesis inhibition was measured. This assay has shown a strong correlation with cell death (Brinkmann et al., 1991). The antigen-positive cell lines used for protein synthesis inhibition assays were A431, MCF-7, LnCAP, and CRL1739. All of the immunotoxins generated were very cytotoxic to B3 antigen positive cell lines but were nontoxic for the antigen negative HUT102 cell line. The IC₅₀ values of individual immunotoxin molecules toward different cell lines are shown in Table 1. In 20 h cytotoxicity assays, both B3(Fab)-PE38-1 and B3(Fab)-PE38-2 were very cytotoxic for A431 cells (IC₅₀, 0.6 ng/mL), CRL 1739 cells (IC₅₀, 0.4 ng/mL), and MCF-7 cells (IC₅₀, 1.0 ng/mL). All of the three cancer cell lines express large amounts of B3 antigen on the surface. The prostate cancer cell line LnCAP, which expresses a moderate amount of the B3 antigen, was also sensitive to these immunotoxin molecules with an IC₅₀ of about 10 ng/mL. Except for B3(Fab)-PE38-5, the other three immunotoxins showed more or less similar IC₅₀ values

ranging 1–3 ng/mL for the A431 and MCF cell lines (Table 1). B3(Fab)-PE38-5 was about 10-fold more cytotoxic to all of the B3 antigen positive cell lines tested, compared to B3(Fab)-PE38-4, B3(Fab)-PE38-6, and B3(Fab)-PE38-7 molecules. The adult T-cell leukemia cell line HUT102, which does not express B3 antigen, was not sensitive to any of the above immunotoxin molecules but very sensitive to anti-Tac(scFv)-PE38 immunotoxin directed to IL2 receptor (Chaudhary et al., 1989).

B3(Fv)-PE38 immunotoxin is very unstable at 37 °C, however, the molecule is very cytotoxic to B3 antigen-positive cancer cell line. B3(Fv)-PE38 loses much of its activity after 2 h at 37 °C (Reiter et al., 1994c), even so its IC₅₀ value is similar to the IC₅₀ value of B3(dsFv)-PE38 in a 20 h cytotoxicity assay. This is because B3(Fv)-PE38 has a higher affinity for the Le^y antigen than B3(dsFv)-PE38 (Reiter et al., 1994c). In this study, we determined the cytotoxicity of B3 (Fab) immunotoxin at 37 °C for 2 h and compared the values with B3(Fv)-PE38 and B3(dsFv)-PE38.

Figure 3. SDS-PAGE analysis of purified recombinant B3 Fab-PE38 immunotoxin. Coomassie blue stained SDS PAGE of (A) reduced, and (B) nonreduced samples of B3(Fab)-PE38 immunotoxin; lane 1, B3(Fab)-PE38-6; lane 2, B3(Fab)-PE38-4; lane 3, B3(Fab)-PE38-2; lane 4, B3(Fab)-PE38-1.

In 2 h cytotoxicity assays, the immunotoxins were washed away after 2 h of incubation, the cells were incubated for additional 16 h, and protein synthesis inhibition was measured after 18 h as described in Materials and Methods. The IC_{50} values of individual immunotoxin molecules for different cell lines in 2 h cytotoxicity assays are summarized in Table 2. Both B3(Fab)-PE38-1 and B3(Fab)-PE38-2 molecules were cytotoxic to all B3 antigen-positive cell lines tested. They were less active than B3(Fv)-PE38 but more active than B3(dsFv)-PE38. This difference in activity can be explained by the fact that the affinity of the B3(Fab)-PE38 immunotoxin is higher than the B3(dsFv)-PE38 but lower than B3(Fv)-PE38, and therefore in 2 h, the binding of the B3(Fab)-PE38 immunotoxin to the target cells was

higher than the B3(dsFv)-PE38 and lower than the B3(Fv)-PE38 (Reiter et al., 1994c).

Stability of B3(Fab)-PE38 Immunotoxin. The recombinant Fv or Fab fragments of antibody are widely used in diagnosis and therapy of cancer in the form of radiolabeled or toxin fusion protein. For such applications, it is important that these therapeutic molecules are stable at 37 °C in human circulation so they will retain activity for a long time after injection into patients. Therefore, we examined the stability of B3(Fab)-PE38-1, B3(Fab)-PE38-2, B3(Fab)-PE38-4, and B3(Fab)-PE38-6 by incubating the purified proteins at 37 °C. The immunotoxins, at a concentration of 10 μ g/mL, were incubated at 37 °C for different periods of time in phosphate-buffered saline containing 0.2% human serum albumin. The remaining activity of the incubated immunotoxins was determined by protein synthesis inhibition assays using B3 antigen positive A431 cell lines. The data in Table 3 shows that all of the molecules were very stable at 37 °C retaining 80–90% of initial activity for at least 24 h when incubated in human serum albumin.

Pharmacokinetics of B3(Fab)-PE38 Recombinant Immunotoxin. We next determined the pharmacokinetics of B3(Fab)-PE38-1 and B3(Fab)-PE38-4 immunotoxin in mice. Each immunotoxin was injected i.v. with

Figure 4. Blood levels of B3(Fab)-PE38 immunotoxin in mice. Female BALB/c mice were injected i.v. with 10 µg of B3(Fab)-PE38-1 or B3(Fab)-PE38-4. The level of immunotoxin in blood samples drawn at different times was measured by protein synthesis inhibition assay on A431 cells as described in Materials and Methods. Results are average of three animals for each time point. Open circle, blood levels of B3(Fab)-PE38-1; Close circle, blood levels of B3(Fab)-PE38-4.

Table 4. Relative Binding Affinity (IC₅₀) of B3 (Fab)-Immunotoxins^a

analyte	tracer	IC ₅₀ (nM)	cell line
B3 IgG	B3 IgG	85	A431
B3-Lys-PE38	B3 IgG	2500	A431
B3 Fab-PE38-1	B3 IgG	3000	A431
B3 Fab-PE38-2	B3 IgG	3500	A431

^a The affinities of different immunotoxins were determined by competition binding analyses to cells expressing B3 (Le^y) antigen. The antigen positive cell line used was A431. The relative binding affinities were calculated from the concentration of competitor which caused 50% inhibition of the binding of ¹²⁵I-B3 IgG to the Le^y-expressing cell line.

a single dose of 10 µg administered to a series of mice. Blood was drawn at different time points after the injection and assayed for immunotoxin activity by measuring its ability to inhibit protein synthesis on A431 cells as described in Materials and Methods. In Figure 4 the plasma clearance curve of B3(Fab)-PE38-1 and B3(Fab)-PE38-4 immunotoxin was shown. The *T*_{1/2} for B3(Fab)-PE38-1 and B3(Fab)-PE38-4 molecules was found to be 104 and 121 min, respectively.

Relative Binding of B3(Fab)-PE38 Immunotoxin.

The relative binding affinities of B3(Fab)-PE38-1 and B3(Fab)-PE38-2 immunotoxins were determined by competition binding assay on B3 antigen expressing A431 cells. Various amounts of B3(Fab)-PE38-1, B3(Fab)-PE38-2, B3Lys-PE38, or B3 IgG were used to compete for the binding of radiolabeled B3 IgG to the B3 antigen positive A431 cells. Table 4 summarizes the relative binding of B3(Fab)-PE38 immunotoxins. B3(Fab)-PE38-1, B3(Fab)-PE38-2, and B3Lys-PE38 are equipotent competitors with ¹²⁵I-labeled B3 IgG for antigen sites on cultured A431 cells. The IC₅₀ was between 2 and 5 µM. Both B3(Fab)-PE38-1 and B3(Fab)-PE38-2 competed approximately 30-fold less well than the whole B3 IgG antibody (IC₅₀ ≈ 85 nM). Since B3(Fab)-PE38-1 and B3(Fab)-PE38-2 are both monovalent, a decrease in apparent binding affinity is to be expected.

DISCUSSION

In this study, we have made recombinant immunotoxins of different sizes and compositions using the Fab fragment of the B3 antibody, a truncated version of *Pseudomonas* exotoxin (PE38), and different portions of the human IgG1 constant region. We have successfully made recombinant immunotoxins with molecular masses of 86 000, 96 000, and 134 000 kDa.

B3(Fab)-PE38-1 and B3(Fab)-PE38-2, both have molecular masses of 86 000 kDa. In the case of B3(Fab)-PE38-1, the Fd fragment of monoclonal antibody B3 was fused to PE38 and disulfide bonded with B3 light chain. The Fd fragment of B3 antibody, in B3(Fab)-PE38-2, was linked with light chain-PE38 fusion molecules by a disulfide bond. Both recombinant immunotoxin molecules refolded well and could be purified as active monomers. There is no difference between B3(Fab)-PE38-1 and B3(Fab)-PE38-2 molecules with regard to cytotoxicity toward antigen positive cancer cell lines, stability of the molecule, and total yield after refolding and subsequent purification steps.

In a previous report (Choe et al., 1994), the B3(Fab) was made from the fusion of the Fv fragment of MAb B3 and the constant region of Fd and the V_L of MAb MAK33 (Buckel et al., 1987). To make the immunotoxin, the resulting Fd or V_L chain was fused to PE38^M and then refolded with the corresponding V_L or Fd chain. In PE38^M, two of the lysine residues in domain III were mutated to glutamine and lysine 613 was deleted (Choe et al., 1994). In this study, we have used the natural constant region of the Fd and the V_L of MAb B3 to make the Fab. These fragments were isolated using mRNA from the B3 hybridoma. Although the C_κ chain sequence for antibody MAK33 is identical to that of B3 antibody, there is an alanine (Kabat position 113) instead of serine at the FR4 region of the V_H domain of the B3 antibody. Interestingly, the immunotoxins made using the natural B3 Fab fragment were about 4–5-fold more active than the previously made Fab immunotoxin on B3 antigen-positive cell line. At the same time, the final yield of the properly folded immunotoxin was severalfold less than the previous report. Whether the mutations in the PE38^M domain and the serine to alanine substitution at the FR4 region of the heavy chain have any effect on the yield and the activity of the immunotoxin molecules are not clear.

The components used to prepare B3(Fab)-PE38-3 were B3(Fd)-PE38 and the light-chain PE38 fusion protein. This molecule aggregated during the refolding procedure and purified monomer could not be produced. Western blot analysis of the material obtained after the ion-exchange chromatography purification step indicated the presence of nondisulfide bonded individual components in the mixture (data not shown). It is possible that the two PE38 portions interacted and prevented association of Fd with V_L. It is possible that the C3 linker used to fuse Fd or light chain to the PE38 molecule, which is only six amino acids long, is too short and caused the PE38 domains to interact and prevent folding and disulfide bond formation between Fd and the light chain. This view is supported by the fact that the monomeric form of B3(Fab)-PE38-6 could be produced with a yield of 2.5%. In B3(Fab)-PE38-6, the CH2 fragment of the human IgG1 was introduced between the Fd and PE38 and probably served as a flexible linker and thus prevented destructive interaction of the PE38 portions of the Fd and light chain.

For B3(Fab)-PE38-5 and B3(Fab)-PE38-7, we were not able to make highly purified monomeric molecules and the final yield was very low (0.1%). Both molecules contain the CH3 domain of human IgG1. In B3(Fab)-PE38-5, the CH3 domain was inserted between Fd and PE38. The B3(Fab)-PE38-7 molecule has the CH2 and CH3 domains of human IgG1. The CH3 portion of the IgG1 has a tendency to form a homodimer (Ridgway et al., 1996), and probably, that region is responsible for making noncovalent dimer with those immunotoxin molecules. B3(Fab)-PE38-4, which contained a CH2

Table 5. Summary of the Properties of Recombinant Immunotoxins against Le^y Antigen

instead of a CH3 domain and is the same size as B3-(Fab)-PE38-5, can be prepared on good yield as a monomer. These data support our interpretation that CH3 causes dimerization.

Cytotoxicity of B3(Fab)-PE38 Recombinant Immunotoxins. All of the six B3(Fab)-PE38 immunotoxins were tested for their cytotoxicity on several B3 antigen-positive cell lines and one negative cancer cell line. The molecules were very cytotoxic to B3 antigen-positive cell lines and nontoxic to the antigen-negative cell line. In 20 h cytotoxicity assays, both B3(Fab)-PE38-1 and B3-(Fab)-PE38-2 gave IC₅₀ values very similar to B3(Fv)-PE38, which were lower than the values for B3Lys-PE38 and B3(dsFv)-PE38 for most of the B3 antigen-positive cell lines tested (Table 1). But in 2 h cytotoxicity assays, the IC₅₀ values for B3(Fab)-PE38-1 and B3(Fab)-PE38-2 were closer to B3Lys-PE38, which were higher than the values for B3(Fv)-PE38 (Table 2). The IC₅₀ values for B3(dsFv)-PE38 in 2 h cytotoxicity assays were much higher than the values for B3(Fab)-PE38-1 and B3(Fab)-PE38-2 molecules for all of the B3 antigen-positive cell lines. The cytotoxicity data for the B3(Fab)-PE38 immunotoxins in 2 and 20 h assays are directly correlated with their relative binding affinity to B3 antigen and also the stability of the molecule at 37 °C. B3(Fv)-PE38 is very unstable and loses much of its activity by 2 h. Nevertheless, it has a very low IC₅₀ as the result of its higher affinity to B3 antigen and there is no difference in IC₅₀ values between 2 and 20 h assay. B3(dsFv)-PE38, on the other hand, had very poor IC₅₀ in a 2 h assay because of its poor binding to B3 antigen; but due to its extreme stability at 37 °C, it can kill the B3 antigen-positive cells as efficiently as B3(Fv)-PE38 in 20 h assays. B3(Fab) immunotoxins are also very stable at 37 °C, and their binding affinity is much better than B3(dsFv)-PE38. As a result, B3(Fab) immunotoxins had the same IC₅₀ values as B3(Fv)-PE38 in 20 h cytotoxicity assays and much better IC₅₀ than B3(dsFv)-PE38 in 2 h assays.

Except B3(Fab)-PE38-5, the other three immunotoxins had similar IC₅₀ values which are closer to the values of B3Lys-PE38. B3(Fab)-PE38-5 was about 10-fold more cytotoxic to all B3 antigen-positive cell lines tested, compared to B3(Fab)-PE38-4, B3(Fab)-PE38-6, and B3-(Fab)-PE38-7. Increased cytotoxicity of B3(Fab)-PE38-5 immunotoxin to the B3 antigen-positive cells could be due to its dimer formation and activity as a bivalent molecule. Surprisingly, B3(Fab)-PE38-6 which contains two PE38 molecules did not show increased cytotoxic activity to B3 antigen-positive cells.

Stability Compensates for Loss of Affinity. The stability of immunotoxin, as for all other therapeutic drugs, is an important factor. B3(Fv)-PE38 is very unstable when incubated at 37 °C and loses most of its activity within 2 h. We determined the stability of B3-(Fab)-PE38 immunotoxins by incubating the molecules at 37 °C. All molecules are very stable at least up to 24 h at 37 °C as are B3(dsFv)-PE38 molecules reported

earlier (Reiter et al., 1994c). The relative binding affinity of B3(Fab)-PE38 molecule was determined by radioactive binding and competition assay. Both B3(Fab)-PE38-1 and B3(Fab)-PE38-4 immunotoxins competed approximately 30-fold less than the whole B3 IgG antibody (IC₅₀ ≈ 85 nM). The lower affinity of these molecules toward B3 antigen compared to B3(Fv)-PE38 is compensated by the fact that all B3(Fab)-immunotoxins are very stable at 37 °C. As a result, the cytotoxic effect of those molecules is very similar to B3(Fv)-PE38 immunotoxin.

Increased Half-Life of B3(Fab)-PE38 Immunotoxin. Both B3(Fv)-PE38 and B3(dsFv)-PE38 have very short half-lives in mouse serum. The rate of elimination of these molecules from the mouse blood is very similar, with a T_{1/2} of 20–23 min (Reiter et al., 1994c). On the other hand, the chemical conjugate of the B3 antibody with PE38 (LMB-1) has a longer survival time in mouse blood with a T_{1/2} of about 10 h (Pai et al., 1991). We determined the pharmacokinetics of B3(Fab)-PE38-1 and B3(Fab)-PE38-4 immunotoxins in mice. The T_{1/2} for B3-(Fab)-PE38-1 and B3(Fab)-PE38-4 molecules was found to be 104 and 121 min, respectively, which are much higher than B3(Fv)-PE38 and B3(dsFv)-PE38 (Reiter et al., 1994c) but lower than B3Lys-PE38 (Pai et al., 1991). The increased T_{1/2} values of B3(Fab)-PE38-1 and B3(Fab)-PE38-4 immunotoxin molecules compared to B3-(Fv)-PE38 and B3(dsFv)-PE38 could be due to their increased size or to the CH1 and CL portion of the molecules or both. The CH2 domain insertion in B3-(Fab)-PE38-4 molecule does not have any significant effect on T_{1/2} value of the molecule in mouse blood.

Conclusion. We have made B3 immunotoxins of different compositions and compare their properties with other existing anti Le^y immunotoxins. The side by side comparison of the properties of these molecules is summarized in Table 5. We have successfully made recombinant immunotoxin molecules of sizes 86 000, 96 000, and 134 000 kDa. All molecules are very cytotoxic to B3 antigen-positive cancer cell lines. We are able to increase the retention time of the immunotoxin molecule in mouse blood by introducing the constant region of human IgG1. We believe that the increased T_{1/2} value compared to B3-(Fv)-PE38 and smaller size compared to B3 lys-PE38 will make these immunotoxin molecules potential alternative therapeutic agents to treat cancer patients with Le^y antigen positive cancer soon.

Cross-Linking of Protein Subunits by 1,3,5-Triacryloyl-hexahydro-s-triazine

Gervydas Dienys,[‡] Jolanta Sereikaitė,^{*,§} Gintaras Gavėnas,^{§,||} Rimantas Kvederas,[§] and Vladas-Algirdas Bumelis[§]

Faculty of Chemistry, Vilnius University, Lithuania, and Institute of Biotechnology, Graičiūno 8, Vilnius 2028, Lithuania. Received March 18, 1998; Revised Manuscript Received July 2, 1998

Six difunctional and trifunctional derivatives of acrylamide were synthesized and investigated as potential protein lysine residue cross-linking agents. 1,3,5-Triacryloyl-hexahydro-s-triazine (TAT) was considered the best. The rate constants for the reactions of TAT with model nucleophiles in water solution at 25 °C were with the glycine anion amino group, $7.69 \times 10^{-3} \text{ M}^{-1} \text{ s}^{-1}$; with the anionic form of the *N*-acetyl-L-cysteine thiol group, $5.54 \text{ M}^{-1} \text{ s}^{-1}$; and with the *N*α-acetyl-L-histidine imidazole ring, $1.19 \times 10^{-5} \text{ M}^{-1} \text{ s}^{-1}$ (at pH 9.0). The kinetics of modification of amino groups by TAT were studied for several proteins: α₁-casein, bovine serum albumin, recombinant human growth hormone, recombinant human interferons-α2b, and -γ. The results indicate that if proteins are associated into oligomeric structures in water, their subunits are effectively cross-linked by TAT.

Activated ethylenes of the general formula $\text{CH}_2=\text{CH}-\text{X}$ (X = CN, COOR, CONH₂, COR, NO₂, SO₂R, etc.) can be used in the chemical modification of protein nucleophilic functional groups. Acrylonitrile ($\text{CH}_2=\text{CH}-\text{CN}$) is considered the principal representative of the group (1, 2). Systematic investigation of interactions between acrylonitrile and amino acids and peptides or model compounds have previously been reported by Friedman and his collaborators (2–7), who demonstrated that of the nucleophilic groups of proteins thiol groups are modified most readily. Amino groups are less reactive by 2–3 orders of magnitude, and the imidazole groups of histidine are still less reactive (8). Other functional groups of proteins are not modified.

In addition, thiol groups (7, 9, 10) and amino groups (11) of proteins have been demonstrated to be successfully modified by acrylamide ($\text{CH}_2=\text{CH}-\text{CONH}_2$), though the reaction is slower (approximately by a factor of 10) than that with acrylonitrile. As a result, β-carbamidoethyl groups ($\text{CH}_2\text{CH}_2\text{CONH}_2$) are introduced into the protein molecule. These groups closely resemble glutamine residues. Neither protein electric charge nor pI is altered, nor is solubility decreased, a common result after modification by acrylonitrile or alkylating agents (11). Acrylamide therefore is seen as an agent for the “delicate” modification of proteins. Finally, there are also publications on the modification of proteins by several other activated ethylenes: methylacrylate (2, 7), 4-vinylpyridine (2, 12), and alkylvinylsulphones (2, 13, 14).

A large variety of *N*-substituted acrylamides can be synthesized easily (15). Reactivity of their ethylenic bonds in nucleophile-driven addition reactions varies considerably depending on the nature of *N*-substituents (16). We therefore investigated several bifunctional and

trifunctional derivatives of acrylamide as potential cross-linking agents for protein lysine residues. 1,3,5-Triacryloyl-hexahydro-s-triazine (TAT)¹ was found to be a very promising agent because of its high activity and stability in water solutions.

MATERIALS AND METHODS

Chemicals. Human serum albumin from Calbiochem, bovine serum albumin, myoglobin, acrylamide, *N,N'*-diacryloyl-diaminomethane, *N*-acetyl-L-cysteine, dithiothreitol, and 2,4,6-trinitrobenzene sulfonic acid from Serva, α₁-casein from Sigma, and *N*α-acetyl-L-histidine from Reachim (Russia) were used. Recombinant human interferon-α2b (IFN-α2b), recombinant human interferon-γ (IFN-γ), recombinant tumor necrosis factor α (TNFα), and recombinant human growth hormone (hGH) were products of Biofa AB (Lithuania). Protein markers for sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS–PAGE) from Sigma, Pharmacia, and Bio-Rad were used.

¹H-NMR Analysis. ¹H-NMR spectra were recorded on a Hitachi 22 spectrometer, operating at 90 MHz, using tetramethylsilane as the internal standard.

Synthesis of Cross-Linking Agents. *N,N'*-Diacryloyl-diamines (Table 1, nos. 3–5). Acryloylchloride (8 mL, 0.10 mol) was slowly added with stirring to a mixture of diamine (0.05 mol), anhydrous sodium acetate (9 g, 0.11 mol), chloroform (50 mL), and hydroquinone (0.05 g) at 10 °C. The reaction mixture was stirred for 2 h at room temperature and then was filtered. The filtrate was left overnight at 4 °C. A white precipitate was collected and recrystallized from chloroform or hexane.

***N,N'*-Diacryloyl-piperazine.** Yield, 6.3 g (65%); mp, 91–92 °C [lit. (18) mp, 98 °C]. ¹H-NMR (CD₃SOCD₃): δ 3.76 (s, 8H, piperazine ring), 5.91 (q), 6.31 (q), 7.04 (q, 6H, $CH=CH_2$).

1,3,5-Triacryloyl-hexahydro-s-triazine (TAT, Table 1, no. 6). TAT was prepared as described by T. L. Gresham and T. R. Steadman (19) and recrystallized from water. TAT polymerized when heated and no definite melting point could be identified. ¹H-NMR (CDCl₃): δ 5.39 (s, 6H, CH_2), 5.80 (q), 6.32 (q), 6.78 (q, 9H, $CH=CH_2$).

Diacrylimide (Table 1, no. 7). Diacrylimide was prepared as previously described (20). The product was purified by column chromatography on silica gel using ethyl acetate/chloroform (1/1, v/v) as the eluent. Diacrylimide was crystallized from water: mp, 179 °C [lit. (20) mp, 180 °C]. ¹H-NMR (CDCl₃): δ 5.82 (q), 6.42 (q), 6.81 (q, 6H, $CH=CH_2$).

Kinetic Measurements. The kinetics of reactions shown in Scheme 1 were followed spectrophotometrically in thermostated cell at 255 nm for unsaturated amides no. 1–5 and 7 (Table 1) and at 260 nm for TAT (no. 6). The extinction coefficients of amides no. 1–5 and 7 at 255 nm were 134, 1260, 1680, 1470, 8340, and 2530 M⁻¹ cm⁻¹, respectively, and that of TAT at 260 nm was 3120 M⁻¹ cm⁻¹. The optical density of the piperidine and glycine

at 255 and 260 nm was negligible. The extinction coefficient of piperidine at 255 nm was 1.46 M⁻¹ cm⁻¹. UV-absorption spectra of addition products were shifted toward the short-wave side with respect to the spectra of initial unsaturated amides. From 6 to 10 kinetic runs were carried out for each reaction. Molar concentration of the product at the time $t(x)$ was calculated by the equation

$$x = a(A_0 - A/A_0 - A_{inf})$$

where A is the absorbance at the time t , A_0 is the initial absorbance and A_{inf} is the final absorbance, when the reaction is completed, a is the initial concentration of N-substituted acrylamide.

The kinetics of the reactions shown in Scheme 1B were studied in alkaline solutions at several pH values and rate constants were calculated for anion $NH_2CH_2COO^-$ as the nucleophile. The kinetics of alkaline hydrolysis of diacrylimide were also investigated spectrophotometrically at pH values between 10.05 and 13.6.

The kinetics of modification of protein amino groups (Scheme 3, Table 2) were followed by measuring the concentration of free amino groups in aliquots of the reaction mixture every 30 min over a period of 3–4 h, using the 2,4,6-trinitrobenzene sulfonic acid method (21) as described by Jonušienė et al. (22). Three kinetic runs were carried out for each reaction. Second-order rate constants were calculated from the reaction rate values obtained by the method of cubic smoothing splines (23) at the initial moment and after modification of 50% of the amino groups.

The kinetics of the reaction of TAT with *N*-acetyl-L-cysteine thiol groups were followed spectrophotometri-

cally in a thermostated cell, at 275 nm. Six kinetic runs were carried out for each experiment. The second-order rate constants for the *N*-acetyl-L-cysteine dianionic form were calculated from initial rate values at 6.5, 10.5, and 14.5 °C: $2.67 \pm 0.08 \text{ M}^{-1} \text{ s}^{-1}$, $3.26 \pm 0.22 \text{ M}^{-1} \text{ s}^{-1}$ and $3.69 \pm 0.51 \text{ M}^{-1} \text{ s}^{-1}$, respectively. The rate constant at 25 °C was calculated using an Arrhenius plot, $5.54 \text{ M}^{-1} \text{ s}^{-1}$.

The kinetics of the reaction of TAT with the imidazole ring of *N*-acetyl-L-histidine at pH 9.0 was also followed spectrophotometrically in a thermostated cell at 275 nm, under pseudo-first-order conditions (150-fold excess of *N*-acetyl-L-histidine). Three kinetic runs were carried out for each experiment. The second-order rate constants calculated at 60, 70, and 80 °C were $(2.32 \pm 0.39) \times 10^{-4} \text{ M}^{-1} \text{ s}^{-1}$, $(3.98 \pm 0.56) \times 10^{-4} \text{ M}^{-1} \text{ s}^{-1}$, and $(9.31 \pm 0.33) \times 10^{-4} \text{ M}^{-1} \text{ s}^{-1}$, respectively. The rate constant at 25 °C was calculated using an Arrhenius plot, $1.19 \times 10^{-5} \text{ M}^{-1} \text{ s}^{-1}$.

Cross-Linking of Oligomeric Proteins by TAT.

Protein solutions were prepared in 0.05 M borate buffer, pH 9.2, such that the initial concentration of amino groups was between 0.06 and 0.59 mM. TAT was added in 4.5–67-fold molar excess with respect to the concentration of amino groups in the protein solution. The reaction mixture was incubated at 30 °C. Aliquots were withdrawn over the course of the reaction, and the reaction was stopped by the addition of excess cysteine or dithiothreitol. Samples of the reaction mixture were dialyzed and analyzed by SDS–PAGE for identification of cross-linked protein forms.

SDS–PAGE. SDS–PAGE was carried out on the Mighty Small electrophoresis unit (Hoefer Scientific Instruments) according to the method of Laemmli (24). The acrylamide concentrations used in the gel were 12.5% (for hGH, TNF α), 15% (for INF- γ , myoglobin), and 7.5% (for human serum albumin). Proteins were stained with Coomassie Brilliant Blue R-250 and the gels were scanned at 633 nm using the Dual-Wavelength TLC scanner (CS 930, Shimadzu).

RESULTS AND DISCUSSION

Investigation of Cross-Linking Agents. Six difunctional and trifunctional derivatives of acrylamide were synthesized. Their activity in nucleophilic addition reactions was evaluated by measuring the kinetics of the

reactions with low molecular weight model N-nucleophiles—piperidine and the anion of glycine (Scheme 1). The rate constants measured are given in Table 1. For comparison, acrylamide is included together with its polifunctional derivatives.

N,N'-Diacryloyl-diaminoalkanes (Table 1, nos. 2–4) were found to be less reactive than acrylamide. They are of little interest as cross-linking agents, however, because their rate of modification is too low for practical purposes. The half-life of the most reactive protein amino groups at 25 °C is over 6 h if a concentration of acrylamide of 0.1 M is used (11).

Diacrylimide was the most active of the tested compounds (Table 1, no. 7). It is not, however, stable in alkaline solutions. It is hydrolyzed to form acrylamide and acrylate (25). Diacrylimide is a weak acid, and in alkaline solution it ionizes partly to form the anion (CH₂=CHCO)₂N⁻; a process which needs to be taken into account when the kinetics of its hydrolysis and nucleophilic addition of amines are studied. We measured the diacrylimide ionization constant ($pK_a = 10.9$) using the spectrophotometric method (26) and investigated the kinetics of its alkaline hydrolysis. The kinetic data are consistent with the mechanism including, as the slow step, the attack of diacrylimide unionized molecule by an hydroxide anion (Scheme 2). The rate constant of the reaction described under Scheme 2 at 25 °C in water solution was $4.35 \text{ M}^{-1} \text{ s}^{-1}$, a value similar to or slightly higher than those for the hydrolysis of saturated imides: diacetimide ($k = 0.88 \text{ M}^{-1} \text{ s}^{-1}$), succinimide ($k = 3.14 \text{ M}^{-1} \text{ s}^{-1}$) (25). At pH 9.2, the half-life of diacrylimide is approximately 3 h, at pH 10, approximately 30 min. Diacrylimide may therefore be of interest, under conditions where temporary cross-linking is required.

We found that the best cross-linking agent from the compounds listed in Table 1 was TAT. Its activity was conveniently high and its stability in water was remarkable. No change was identified after storing TAT in buffer, pH 9.2, over the course of 1 week at room temperature. Its three active groups make it an especially effective cross-linking agent.

In order to characterize the reactivity of TAT, the kinetics of its reactions with two other model nucleophiles *N*-acetyl-L-cysteine and *N*-acetyl-L-histidine were investigated. The rate constant of the anionic form of *N*-acetyl-L-cysteine (a model of thiol groups of proteins) was $5.54 \text{ M}^{-1} \text{ s}^{-1}$ at 25 °C in water, a value which exceeded, by nearly three orders of magnitude, the rate constant of the glycine anion amino group (Table 1). Such an activity ratio is supported by the literature (4). The histidine residue imidazole ring is not as active a nucleophile as the amino group. The rate constant of the reaction between *N*-acetyl-L-histidine and TAT at 25 °C and pH 9.0 was $1.19 \times 10^{-5} \text{ M}^{-1} \text{ s}^{-1}$. Consequently, it is clear that, if there are no free thiol groups, TAT is quite a specific modifying agent for protein amino groups.

Modification and Cross-Linking of Proteins. The first step in the interaction between TAT and a protein molecule is generally the addition of an amino group to one of the acryloyl groups (Scheme 3). If free thiol groups

Figure 1. (Top) SDS-PAGE (15%) of IFN- γ samples. Lane 1, protein markers; lane 2, unmodified IFN- γ ; lanes 3-5, samples taken at 15, 30, and 60 min. Concentration of IFN- γ , 0.16 mg/mL; initial concentration of amino groups, 0.18 mM; concentration of TAT, 1.0 mM. (Bottom) SDS-PAGE (12.5%) of hGH samples modified in the absence of Zn^{2+} . Lane 1, unmodified hGH; lanes 2 and 3, samples taken at 60 and 120 min; lane 4, protein markers. Concentration of hGH, 0.75 mg/mL; initial concentration of amino groups, 0.39 mM; concentration of TAT, 4.5 mM. (Middle) SDS-PAGE (12.5%) of hGH samples modified in the presence of Zn^{2+} . Lane 1, unmodified hGH; lanes 2 and 3, samples taken at 60 and 120 min; lane 4, protein markers. Concentrations of hGH, amino groups and of TAT were the same as those in the bottom panel. Molar ratio of Zn^{2+} to hGH in the reaction mixture was 2:1.

are present, though, their reaction precedes that of the amino groups. Intra- and intersubunit cross-linking of amino groups then follows.

We therefore studied the kinetics of the TAT-induced modification of the amino groups of several proteins (Table 2). It was found that the rate constants decreased during the addition reaction. Solubility of TAT in water is limited (approximately 40 mM at room temperature). Half of the amino groups are modified in less than 15 min in the presence of such a concentration of TAT at 30 °C and pH 9.2. We therefore used mixed solvents water-methanol and water-ethanol to promote the modification rate in some cases (27).

Cross-linking investigations were carried out with several proteins, both monomeric and oligomeric forms. The course of cross-linking was followed by SDS-

Figure 2. Kinetics of hGH cross-linking by TAT (0.05 M borate buffer, pH 9.2, 30 °C; initial concentrations: hGH, 0.3 mg/mL, 14 μM ; TAT, 1.8 mM). Experiment A (Δ), Zn^{2+} (28 μM) was added together with TAT; experiment B ($\circ$), Zn^{2+} (28 μM) was added after 25% of amino groups were modified by TAT.

electrophoresis of samples of reaction mixtures. Most experiments were performed at pH 9.2 and 30 °C using a 4.5–14-fold excess of TAT compared with the concentration of amino groups present. At pH 8.0, though, using the maximum possible concentration of TAT (approx. 40 mM) and leaving the reaction mixture overnight at 30 °C practically complete cross-linking could also be achieved.

At the protein concentrations used (0.5–2.0 mg/mL), no cross-linking was registered for proteins which were monomeric in water (see, for example, Figure 1, bottom). But after modification by TAT, electrophoretic bands of proteins were slightly displaced and became broader. The change was greatest for the proteins having the greater number of Lys residues (human serum albumin, myoglobin). Proteins, that are dimeric in water [for example, IFN- γ (28)], were transformed by TAT into covalently bonded dimers, which were not separated during SDS-electrophoresis (Figure 1, top).

It is known that Zn^{2+} ions induce the dimerization of hGH (29), an observation confirmed by our measurements of the action of TAT. In the presence of Zn^{2+} , cross-linked dimers were formed (Figure 1, middle), but no dimers were detected in the absence of Zn^{2+} (Figure 1, bottom). The kinetics of hGH cross-linking are shown in Figure 2. If Zn^{2+} ions were added after amino groups had been already partly modified by TAT (Figure 2, experiment B), formation of cross-linked dimers occurred more rapidly, where Zn^{2+} and TAT were added together (Figure 2, experiment A). Apparently, the cross-linking step is faster than the addition of amino groups to TAT. If experiments were continued for long enough (24 h), the yield of dimer in both cases approached 100%.

TNF α is known as a trimeric protein in water (30). The time course of its cross-linking by TAT was also investigated (Figure 3). Polymerization was evident after 30 min, when the dimeric form was clear, its presence was maximal after 90 min, but at longer time intervals the trimeric form developed to become predominant, though two bands of molecular weight higher than the dimeric form were identifiable. Most likely, both repre-

Figure 3. SDS-PAGE (12.5%) of TNF α samples. Lane 1, unmodified TNF α ; lane 2–12, samples taken at 15, 30, 45, 60, 90, 120, 180, 240, 480 min, 24, and 48 h; lane 13, protein markers. Concentration of TNF α , 0.15 mg/mL; initial concentration of amino groups, 0.06 mM; concentration of TAT, 4 mM.

sent cross-linked trimers (31). A very weak band of a molecular weight corresponding to that of a hexamer appeared also at long time intervals. X-ray studies indicate the assembly of two trimers of TNF α to make a hexameric unit in the crystal form (32). Dimerization of trimers may also occur to some extent in solution.

Cross-linking of protein amino groups by TAT is a very simple and rapid way to establish whether protein oligomers are formed in solution. The high stability of TAT in water promotes its utility. It would be very difficult to conduct experiments similar to those shown in Figures 2 and 3 with any unstable cross-linking agent, for example, dimethyl suberimide.

ACKNOWLEDGMENT

We thank Biofa AB for the gift of hGH, INF- α 2b, INF- γ , and TNF α .

Delivery of Antisense Oligonucleotides Using HPMA Polymer: Synthesis of A Thiol Polymer and Its Conjugation to Water-Soluble Molecules

Laixin Wang, Jakob Kristensen, and Duane E. Ruffner*

University of Utah Department of Pharmaceutics and Pharmaceutical Chemistry 421 Wakara Way, Suite 318 Salt Lake City, Utah 84108. Received March 19, 1998; Revised Manuscript Received July 21, 1998

Here, we report the synthesis and characterization of an HPMA-based polymer for use as a carrier for the delivery of water soluble drugs. The polymer contains active-sulfhydryl groups for coupling of ligands through a disulfide linkage. The polymer can also be prepared containing pendant amino groups in addition to the active-sulfhydryl moiety. This allows the use of different chemistries to conjugate a variety of ligands to the polymer. We demonstrate that a sulfhydryl-terminated antisense oligonucleotide can be efficiently and rapidly conjugated to the polymer. The polymer–oligonucleotide conjugate is efficiently taken up by cultured cells.

INTRODUCTION

Antisense oligonucleotides have shown great potential as therapeutic agents in several areas including anti-cancer and antiviral chemotherapy (1). One limitation to their successful development as therapeutics is their poor uptake by mammalian cells. Many approaches to increase uptake efficiency have been examined, but none have achieved wide scale acceptance (see ref 2 for review). Development of a better delivery system is still being explored worldwide to take antisense to clinical usage.

Water-soluble macromolecular carrier systems have shown great potential in drug delivery due to their diversity in physicochemical and biological properties which can improve the chemical stability and pharmacokinetics of the conjugated drug (see ref 3 for review). One promising macromolecular carrier is the synthetic *N*-(2-hydroxypropyl)methacrylamide (HPMA) polymer. The polymer alone exhibits little or no binding to cell surfaces in a number of test systems [rat visceral yolk sacs (4) and hepatocytes (5)], exhibits little immunogenicity (6, 7), and is captured by cells at a rate consistent with fluid-phase pinocytosis. The pinocytotic uptake of soluble HPMA copolymers by cultured cells was dependent on the molecular mass (M_r) of polymers. Usually, the higher the M_r , the lower the rate of cell capture (8). But some cultured cells, such as rat intestinal sacs, showed an increased rate of pinocytic capture with increasing polymer M_r , which is proposed to be due to adsorptive-pinocytosis (8).

The M_r of HPMA copolymers also influences in vivo behavior, such as the rate of excretion and pharmacological activity (9). The blood-clearance of HPMA homopolymer preparations ($M_r = 28$ –91 kDa) has been studied following intravenous administration to rabbits. It was shown that polymers of higher M_r had a slower rate of clearance from the blood stream, and the limiting molecular-mass threshold for glomerular filtration was determined to be 45 kDa (9). Therefore, the size alone

of the HPMA carrier can provide a variable element to optimize the drug delivery system for a specific therapeutic purpose.

N-(2-Hydroxypropyl)methacrylamide polymer (HPMA) has shown great potential as a carrier for targeted delivery and controlled release of small molecule pharmaceuticals (10–15). Successful targeted delivery has been achieved using a variety of targeting moieties, including carbohydrate residues [galactosamine (16) and fucosylamine (11)], proteins [hormones or transferrin (12)], and antibodies (12, 17, 18). For controlled release, the drug molecules have been conjugated to HPMA polymer through peptide bonds using a reactive *p*-nitrophenyl ester comonomer. Since *p*-nitrophenyl ester is relatively unstable in aqueous solutions (19), this reaction usually needs to be performed in organic solvents in order to obtain high yields. In aqueous solution, hydrolysis of the active ester is expected to compete for the desired aminolysis, especially when the amino groups are carried by large molecules, such as peptides, antisense oligonucleotides, and proteins. Therefore, coupling efficiency in aqueous solution is expected to be low for these molecules. Additionally, coupling through a peptide linkage requires proteolytic degradation for release of the drug. This requires a lysosomal route of uptake which can place biopharmaceuticals such as peptides and nucleic acids in the presence of degradative enzymes.

Here, we describe the synthesis and characterization of an active thiol-containing HPMA copolymer. Coupling to the polymer of water-soluble molecules, such as an antisense oligodeoxynucleotide, occurs rapidly and in high yield. Since the drug and polymer are conjugated through a disulfide bond, the conjugate is expected to be stable in the bloodstream but cleaved intracellularly by thiols such as glutathione and/or redox enzymes. In preliminary experiments, we find that an antisense-oligonucleotide–polymer conjugate is efficiently internalized by cultured cells.

amide (APMA) hydrochloride, 2,2'-azo-bis(isobutyronitrile) (AIBN), and methacryloyl chloride were purchased from Polyscience Inc. 2-Aldrithiol (DPDS) was from Aldrich, and cysteamine and Dulbecco's modified eagle's medium (DMEM) nutrient mixture were purchased from Sigma. HeLa S3 cells (human epithelial carcinoma cells) were from American Type Culture Collection. Other chemicals or reagents were from Aldrich or Sigma. NMR spectra were recorded on a Bruker AC200 NMR spectrometer. Mass spectra were obtained on a Thermabeam Mass detector. UV spectroscopy was performed using a Varian Cary 3E spectrophotometer. Buffer A (McIlvaine's citric acid-phosphate buffer, pH 3.0–8.0) was prepared by combining 0.5 M citric acid and 0.5 M disodium phosphate in a suitable ratio to give the desired pH. Buffer B (Sorensen's glycine II buffer, pH 9.0–13.0) was prepared by combining suitable volumes of 0.5 M glycine in 0.5 M NaCl with 0.5 M NaOH.

Sulfhydryl peptide (Figure 5, pAntp-SH) and disulfide modified oligonucleotide (Figure 5, RSS-OSH) were synthesized by the University of Utah DNA/Peptide core facility. Peptide was purified by HPLC and stored at -70°C in the elution buffer containing approximately 1% TFA. The oligodeoxynucleotide phosphorothioate was synthesized on an Applied Biosystems 394 automated DNA synthesizer on a 1.0 μmol scale using standard

Figure 2. FPLC chromatogram of copolymer A eluted from a gel permeation column. UV absorbance was measured at 280 nm (solid line). The refractive index is indicated by the dotted line. Column: Pharmacia HR10/30. Buffer: pH 7.3, PBS. Flow rate: 0.4 mL/min. Chart speed: 0.5 cm/min.

Figure 3. UV spectrum of copolymer A in 0.1 M, pH 7.0, phosphate buffer and 2-thiopyridone in 0.1 M buffer B at pH 9, 10, or 11, as indicated.

Figure 4. Kinetics of the hydrolysis of copolymer A at pH 8–13 as monitored by the absorbance at 320 or 341 nm.

phosphoramidite chemistry, except that 3H-1,2-benzodithiol-3-one 1,1-dioxide replaced aqueous iodine in the oxidation step (20). For the oligodeoxynucleotide synthesis, most reagents were from Applied Biosystems Inc. except Spacer 9, thiol-modifier C6 SS, and fluorescein phosphoramidite, which were from Glen Research. The oligonucleotides were purified using 20% PAGE and recovered by electroelution followed by ethanol precipitation.

Synthesis of *N*-[2-(2-Pyridyldithio)ethyl] Methacrylamide (PDTEMA). DPDS (5.135 g, 23 mmol) was dissolved in 60.0 mL of 95% EtOH in a 250 mL round-bottom flask. A solution of 1.223 g of cysteamine (16 mmol) in 60.0 mL of deionized water (pH approximately 8.5) was added dropwise over 10 min to the DPDS

Cys-Arg-Gln-Ile-Lys-Ile-Trp-Phe-Gln-Asn-Arg-Arg-Met-Lys-Trp-Lys-Lys

Figure 5. Chemical structure of sulfhydryl pAntp peptide (pAntp-SH) and fluorescein labeled oligonucleotide (RSS-OSH). The underlined portion of RSS-OSH indicates the sequence of the oligonucleotide which contains phosphorothioate linkages.

solution with stirring at room temperature. After incubation for 1.5 h at room temperature, the solvent was removed by rotary evaporation at 35 °C. The product was obtained as a syrup which was dried by coevaporation 3 times with 6 mL of anhydrous pyridine.

The dried crude product was dissolved in a mixture of 25.0 mL of anhydrous DMF and 50 mL of anhydrous pyridine. N₂ was bubbled through for 5 min to remove oxygen. A magnetic stirrer was added, and the bottle was sealed tightly with a rubber stopper. Methacryloyl chloride (3.10 mL, 32 mmol) was added slowly over 5 min using a syringe. After stirring the solution for 2 h at room temperature, the reaction was quenched by adding 400 mL of saturated NaHCO₃ and extracted twice with 400 mL of ethyl acetate. The combined organic phase was washed with 2 × 100 mL of deionized water and dried using anhydrous MgSO₄. The clear solution was evaporated to dryness at 35 °C by rotary evaporation. The crude product was dissolved in CHCl₃ and absorbed to about 10 mL of silica gel, which was then applied to a short silica gel column (12.5 × 5.5 cm, packed with hexane). The column was eluted with a hexane:EtOAc concentration gradient (5 to 40% ethyl acetate). The fractions were monitored by TLC, and the fractions containing the main product were combined and dried by rotary evaporation. The product was confirmed by ¹H NMR and mass spectral analysis. The yield was 2.9 g or 70% for the two steps. ¹H NMR (CDCl₃, 200 MHz): δ (ppm) 7.0–8.6 (m, 5H, Ar-H and -NH), 5.809 (s, 1H, one of =CH₂), 5.361 (s, 1H, one of =CH₂), 3.603 (m, 2H, -CH₂-NR), 2.960 (t, 2H, -S-CH₂-), 2.002 (d, 3H, -CH₃, the split of this peak is due to the tautomerization of the adjacent double bond). MS (FAB), *m/e* 255 (M + 1).

Synthesis of Pyridine Disulfide Modified HPMA Copolymer. HPMA, PDTEMA, and AIBA were dissolved in acetone (12.5 wt % monomers, 0.6 wt % AIBN). Insoluble impurities were removed by filtration or centrifugation. The solution was bubbled with N₂ for 5 min to remove the dissolved oxygen and the reaction vessel was closed tightly. The reaction was placed in a 50–55 °C water bath for 24 h. The white precipitate formed was recovered by filtration and was dried in a vacuum desiccator. The crude product was dissolved in a small

volume of MeOH (approximately 1 g of polymer in 4 mL of MeOH), then precipitated by slowly adding excess acetone. The MeOH/acetone precipitation was performed twice. After the last precipitation, the polymer was dried in a desiccator until the weight was constant, and the polymer was then stored at –20 °C. The mole percentage of pyridine ring in each polymer was quantified by the UV absorption at 281 nm using an extinction coefficient of 4900 in pH 7.0 aqueous solution (21–23).

Synthesis of Amino and Pyridine Disulfide Modified HPMA Copolymer. HPMA, PDTEMA, APMA, and AIBN were dissolved in methanol (12.5 wt % monomers, 0.6 wt % AIBN). The solution was bubbled with N₂ for 5 min, and the reaction vessel was sealed. The tube was placed in a 50–55 °C water bath for 24 h. Insoluble impurities were removed by filtration or centrifugation. Excess acetone was added to the clear solution to precipitate the copolymer product. The white product was purified by reprecipitation and stored as described above.

Hydrolysis of Pyridyl Disulfide Modified HPMA Copolymer. The kinetics of hydrolysis were measured using a dual beam spectrophotometer. Sample and blank cuvettes contained 0.1 M buffer A or B, depending on the desired pH. To the sample cuvette was added polymer A to a final concentration of 0.23 mg/mL. After addition, the absorbance at 320 nm (pH equal to or greater than 11) or 341 nm (pH equal to or less than 10) was measured at 2 min intervals for 14 h at room temperature.

Kinetics of the Reaction between Polymer A and Sulfhydryl Peptide. A sample and blank cuvette were filled with 0.1 M buffer A, and polymer A was added to the sample cuvette to a final concentration of 0.23 mg/mL. pAntp-SH (in 0.1% TFA) was added to both cuvettes to a final concentration of 0.50 mM, and the absorbance was measured at 341 nm every 0.5 min for 50 min. The free sulfhydryl in pAntp-SH was quantified using Ellman's reagent (24).

Kinetics of the Conjugation between the HPMA Copolymer and Oligonucleotides. Ten nanomoles of disulfide modified oligonucleotide (RSS-OSH) was treated with 0.2 M DTT in 100 μL of 0.1 M pH 9.0 buffer B for 2 h. Excess DTT was removed by ethyl acetate extraction (3 × 100 μL). The oligonucleotide was precipitated by

adjusting the solution to 0.3 M NaOAc and adding 2.6 vol of ethanol. The mixture was placed at -20°C for 1 h and centrifuged for 25 min at 13000*g*. The oligonucleotide pellet was dissolved in 80 μL of deionized water, and 10 μL of 1.0 M buffer and 20 nmol (in pyridine ring) of copolymer A were added. The reaction was incubated at room temperature. Ten microliters of the reaction mixture was removed at different times, stopped, and immediately loaded into a running 20% PAGE. The gel was illuminated with UV light for fluorescence visualization. To confirm that oligonucleotide was covalently conjugated to HPMA polymer in the reaction product, 10 μL of the 30 min reaction mixtures was treated with 0.1 M DTT for 30 min at room temperature and loaded on the gel together with the 60 min reaction sample.

Preparation of Oligonucleotide–Polymer Conjugate. One hundred nanomoles of disulfide modified oligonucleotide (RSS-OSH) was treated with 0.2 M DTT in 300 μL of 0.1 M, pH 9.0, buffer B for 2 h. Excess DTT was removed by ethyl acetate extraction ($3 \times 300 \mu\text{L}$), and the oligonucleotide was precipitated by adjusting the solution to 0.3 M NaOAc and adding 2.6 vol of ethanol. The mixture was placed at -20°C for 1 h and centrifuged for 25 min at 13000*g*. The oligonucleotide pellet was dissolved in 100 μL of deionized water, and 200 nmol (in pyridine ring) of active HPMA copolymer and 30 μL of, pH 9.0, buffer B were added. The mixture was brought to a final volume of 300 μL with deionized water and incubated at room temperature for 2 h. The pH of the reaction mixture was adjusted to about 7 using 1.0 M HCl to inhibit disulfide exchange. L-Cysteine was added to the reaction mixture to a final concentration of 1.0 mM and incubated at room temperature for 10 min to destroy the excess pyridyl disulfide bonds in the copolymer. At pH 7, L-cysteine reacts rapidly and completely with all unreacted pyridyl disulfide linkages (data not shown). The product was purified by passing the reaction mixture through a short G-50 column. The reactions were characterized using 20% PAGE. Eighty percent of the oligonucleotide was conjugated to the HPMA polymer as indicated by its inability to enter the gel. The conjugation product was concentrated to a small volume using a Microcon-30 filter.

Preparation of Oligonucleotide–Peptide–Polymer Conjugate. The oligonucleotide–peptide–polymer conjugate was prepared as for the oligonucleotide–polymer conjugate, except that 200 nmol (in pyridine ring) of HPMA copolymer was first reacted for 10 min at room temperature with 20 nmol of pAntp-SH peptide in 0.1 M, pH 9.0, buffer B. Subsequently, the oligonucle-

otide was added. The product was worked up as described above.

RESULTS AND DISCUSSION

Synthesis of Pyridyl Disulfide Modified HPMA Copolymers. *N*-[2-(2-Pyridyldithio)ethyl methacrylamide (PDTEMA) was synthesized through a two step, one-pot reaction, as illustrated in Figure 1. Cysteamine reacted completely with DPDS in an ethanol/water mixture at room temperature in less than 1 h. Although 2-(2-pyridyldithio)ethylamine (PDTEA) has reportedly been crystallized from benzene (25), we used the dried crude product directly in the second step. Subsequently, PDTEMA was purified by silica gel chromatography in an overall yield of greater than 70%. The structure was confirmed by UV, ^1H NMR, and MS.

PDTEMA comonomer was incorporated into HPMA polymer by precipitation radical polymerization with HPMA monomer in acetone at $50\text{--}55^{\circ}\text{C}$ (26, 27). Copolymers varying in the percentage of active pyridyl disulfide groups were synthesized. The mole percent of pyridine ring in each polymer was quantified by the UV absorption at 281 nm using a molar extinction coefficient of 4900 at pH 7.0 in aqueous solution (21–23). The percent conversion of PDTEMA in all the syntheses was similar (Table 1), indicating that the pyridyl group of PDTEMA does not significantly affect its incorporation into the HPMA copolymer. This also suggests that there was no significant degradation of the active pyridyl disulfide moiety during the polymerization reactions. Since the structure of the comonomers is very similar, in terms of the active double bond, the pyridyl disulfide moieties are expected to be distributed homogeneously in the polymer molecules. This is confirmed by the overlapping UV detection and fraction index detection curves in the chromatogram of the gel permeation chromatography of the polymer (Figure 2). This indicates that the percentage of pyridyl groups is similar throughout the full size range of molecules within the same polymer batch.

Amine/pyridyl disulfide containing polymers could also be synthesized by the inclusion of APMA in the polymerization reaction (Table 2). Since APMA is supplied as a hydrochloride salt, and is insoluble in acetone, APMA-containing reactions were performed in methanol solutions. The ability to incorporate both groups into the polymer allows conjugation of different moieties to the polymer using different chemistries.

Aqueous Stability and Reactivity of Pyridyl Disulfide Side Chains in the Copolymer. The UV

absorbance spectra of the 2-pyridyl disulfide containing HPMA polymer and the PDTEMA monomer are similar to that for 2,2'-dipyridyl disulfide (DPDS) (21). DPDS has a maximum absorption at 284 nm, which is substantially different from the UV spectrum of 2-thiopyridone under the same conditions (Figure 3). 2-Thiopyridone has a maximum absorption at 341 nm, and this is relatively constant below a pH of 8 (21). Between pH 9 and 11 the spectrum changes drastically (Figure 3). This is likely the result of the ionization of the nitrogen proton which has a pK_a of approximately 10 and the presence of the 2-pyridine-thiolate ion at pH higher than 10. Since the absorbance at 320 nm is relatively high and constant for 2-thiopyridone and at a minimum for the pyridyl disulfide group, the absorbance at 320 nm was used to monitor release of 2-thiopyridone from the polymer at pH greater than 10. For pH equal to or less than 10 the absorption maximum at 341 nm was used to monitor the release of 2-thiopyridone from the copolymer.

The pyridyl disulfide bond is very stable in deionized water (pH 6.5), and there is no detectable release of 2-thiopyridone after storage for 2 months at -20°C in a 20 mM (in pyridine ring) polymer stock solution. The kinetics of hydrolysis/aminolysis were analyzed at room temperature using 0.1 M glycine/NaOH buffers over a wide range of pH values (Figure 4). The stability of the pyridine disulfide bond in the copolymer decreases with increasing pH in aqueous solution. There was no detectable degradation of the active disulfide bond within 14 h in 0.1 M, pH 8.0, citric acid/NaOH buffer. Incubation for the same time at pH 9.0 and 10.0, in 0.1 M glycine/NaOH buffered solution, released approximately 11 and 17% of the active pyridine group, respectively. Above a pH of 10 the degradation increased significantly with a half-life of hydrolysis and/or aminolysis of approximately 25 min in pH 13 glycine buffer. These results indicate that pyridyl disulfide modified HPMA copolymer can be safely stored and/or further derivatized in aqueous solutions of pH equal to or less than 8. If necessary, the excess active pyridyl disulfide bond can be quickly destroyed by increasing the pH to 13 or higher.

The reactivity of the pyridyl disulfide activated HPMA copolymers with thiol groups was first examined using the model compounds L-cysteine and 2-mercaptoethanol. Similar to DPDS, SPDP, and other small molecule active pyridyl disulfide compounds, the active pyridyl group in HPMA copolymer can be replaced by L-cysteine or 2-mercaptoethanol in aqueous solutions in a wide range of pH values (data not shown). At neutral pH, the reaction is rapid and complete, and disulfide exchange is suppressed.

Characterization of the Conjugation Reaction of HPMA Copolymer with Peptide and/or Oligonucleotide. To examine the reactivity of the activated polymer with larger bioactive molecules, a moderate sized peptide (pAntp-SH, FW = 2407) was first examined (Figure 5). pAntp-SH is 16 amino acids long and possesses a cysteine residue at its amino terminus. pAntp-SH is derived from the homeodomain of Antennapedia. pAntp was chosen since it has been shown to translocate across biological membranes in an energy independent and nonendocytotic manner (28). When conjugated to a bioactive peptide or antisense oligonucleotide, pAntp has been demonstrated to enhance uptake and activity of these molecules (28, 29). Similar to cysteine and 2-mercaptoethanol, pAntp-SH can readily react with pyridyl disulfide HPMA copolymer in aqueous solutions. As seen in Figure 6, the reaction goes to completion within minutes in a mildly basic solution. The rate of reaction decreases with

Figure 6. Kinetics of the conjugation reaction between pAntp-SH and copolymer A at pH 3–8 as monitored by the absorbance at 341 nm.

decreasing pH, but even in acidic solution the rate of reaction is relatively high. The half-life of reaction is less than 50 min at pH 3.

It is believed that the protonation of the pyridine ring nitrogen makes the pyridyl group a good leaving group in pyridyl disulfide mediated thiol-disulfide exchange reactions. This is in contrast to thiol-disulfide exchange reactions between aliphatic thiols and aliphatic disulfides, where the thiolate ion, rather than the thiol, is the reactive species in the nucleophilic displacement reaction. Since the pK_a of most aliphatic thiols is between 7 and 9, little or no reaction occurs in acidic solutions, owing to the low thiolate ion concentration.

An oligonucleotide targeted to the 3' splice junction of the second intron of the HIV tat gene was selected for examination of the conjugation of an antisense oligonucleotide to the polymer (Figure 5, RSS-OSH, FW = 7130). This oligonucleotide was chosen since, in an examination of 20 different targets on HIV, this target was one of the more effective ones at inhibiting viral replication (30). To increase the resistance of the oligonucleotide to nucleolytic degradation, all phosphodiester linkages were substituted with phosphorothioates, and a 3'-3' inverted cap was added to the 3'-end during chemical synthesis (31, 32). A fluorescein group was added to the 5'-end, followed by a linker and a disulfide group.

The disulfide group on the oligonucleotide was reduced to produce a free thiol using DTT. Subsequently, the oligonucleotide was allowed to react with the pyridyl disulfide modified copolymer. Since the oligonucleotide has a strong UV absorbance between 200 and 300 nm, UV absorbance could not be used to monitor the course of the reaction. Instead gel electrophoresis was used. We examined the kinetics of conjugation of RSS-OSH with the 2-pyridyl disulfide modified polymer at pH 7.0–10 (Figure 7). The reaction was allowed to proceed for up to 20 h, and aliquots were removed at various times, combined with an equal volume of gel loading dye, and immediately loaded onto a denaturing 20% polyacrylamide gel. Since the polymer is a large neutral molecule, the polymer-oligonucleotide conjugate barely migrates into the gel, while the mobility of the free oligonucleotide is very fast. The different apparent mobility of the free oligonucleotide, at various times, is due to the different times in which each sample was loaded on the gel. As seen in Figure 7, the conjugation was inefficient until the pH of the solution reached 8.0. When the pH was 7.0, less than half of the oligonucleotide coupled to the

Figure 7. Kinetics of the conjugation of oligonucleotide to polymer C at different pHs as indicated. Aliquots of the reaction mixtures were removed and run into denaturing 20% polyacrylamide gels immediately at the times indicated. For the pH 7.0 and 8.0 reactions, 20 h samples are also shown. The control reactions were treated with 0.1 mM DTT for 30 min.

polymer after incubation for 20 h (Figure 7). However, the half-life of the conjugation was reduced to about 10 and 5 min, respectively, when the reaction was performed at pH 8.0 or 9.0. The reaction was 50% complete in minutes when performed at pH 10.0.

Preparative Conjugation of HPMA Copolymer with Peptide and/or Oligonucleotide. All preparative conjugation reactions were conducted in pH 9.0 buffer in the presence of excess pyridyl disulfide groups of the HPMA copolymer. For peptide–oligonucleotide conjugates, the peptide was conjugated first followed by the oligonucleotide. After completion of the conjugation, the pH of the reaction mixture was adjusted to about 7, and excess pyridyl disulfide groups were inactivated by addition of L-cysteine to a final concentration of 1.0 mM. The conjugation products could be easily separated from the free oligonucleotide and peptide as a result of the increased size of the polymer conjugate. The conjugate was characterized by PAGE, and conjugation was confirmed by release of the oligonucleotide after treatment with DTT (data not shown). The UV spectrum of the oligonucleotide–HPMA polymer is exactly the same as the free oligonucleotide, while there was a small change in the shape of the spectrum for the pAntp peptide–oligonucleotide conjugate (Figure 8). The ratio of the optical densities at 260 and 280 nm was significantly higher for the oligonucleotide–peptide–HPMA conjugate (1.77) than for the oligonucleotide–HPMA conjugate (1.51), indicating the presence of peptide in the former terplex conjugate. The structure of the oligonucleotide–peptide–HPMA terplex conjugate was further confirmed by DTT reduction. An orange precipitate formed after the addition of 0.2 M DTT in pH 9.0 buffer to the terplex conjugate. The precipitate is likely a polyelectrolyte complex between oligonucleotide and peptide resulting from electrostatic interaction of the 21 negative charges on the oligonucleotide and the 7–10 positive charges on the peptide (4 from lysines, $pK_a = 10.69$; and 3–6 from arginines, $pK_{a1} = 12.48$ and $pK_{a2} = 8.99$). This was confirmed by the immediate formation of an orange precipitate on combining equal amounts of free oligonucleotide and peptide in pH 9.0 buffer.

Cell Uptake of the HPMA–Oligonucleotide Conjugate. The uptake, by mammalian cells, of the oligonucleotide–HPMA conjugate was examined using the HeLa S3 cell line. Cells were precultured in DMEM medium containing 10% fetal bovine serum on sterilized

Figure 8. UV spectrum of oligonucleotide–HPMA conjugate (solid line), oligonucleotide–peptide–HPMA conjugate (dotted line), and HPMA copolymer (dashed line). The HPMA copolymer sample was prepared from the same pyridyl disulfide modified HPMA copolymer but was treated with 1.0 mM L-cysteine to release the active pyridyl groups. The polymer was purified away from the released thiopyridone by G-50 chromatography.

cover slips. The cells were plated to give approximately 10% coverage in 2–3 days. The media was removed, and the cells were washed with fresh media. The media was replaced and the free oligonucleotide or the oligonucleotide polymer conjugate was added to a final oligonucleotide concentration of 5 μ M in oligonucleotide. After incubation for 5 h, the cells were rinsed with PBS three times, fixed using acetone, and analyzed by confocal microscopy.

Uptake of the polymer–oligonucleotide conjugate is mildly enhanced relative to the free oligonucleotide (Figure 9). Most of the fluorescence of the oligonucleotide is present in endosomes as is typically observed for endocytotic uptake of antisense oligonucleotides (33) or HPMA polymers (8). To confirm an endocytotic mode of uptake, the experiments were repeated, except that incubation in the presence of oligonucleotide or oligonucleotide–polymer conjugate was performed at 4 $^{\circ}$ C. In this case, little or no internalized fluorescence was observed, indicative of a lack of significant uptake.

Since the oligonucleotide has a 3' inverted cap and is composed of phosphorothioate linkages, it is expected to be stable toward nuclease degradation. In fact, for the free oligonucleotide, it remained 90% intact after 24 h

Figure 9. Cell uptake as determined by confocal microscopy. HeLa S3 cells were pre-cultured in DMEM medium containing 10% fetal bovine serum on 1.5 cm diameter cover slips for 2–3 days, such that about 10% of the cover slip was covered by cells. The media was replaced and the free oligonucleotide OSH (left panel) or the oligonucleotide-HPMA conjugate (right panel) was added to a final oligonucleotide concentration of 5 μ M. After 5 h incubation in a CO₂ incubator, the cells were rinsed with PBS three times and fixed using acetone. The coverslips were fixed to slides using nail polish and observed through a 100 $\times$ oil immersion objective on a Nikon Diaphot 200 confocal microscope equipped with an OmNichrome argon laser 150. Pictures were taken with a digital camera attached to the microscope and integrated five times.

at 37 °C in 50% calf serum (data not shown). Stability should be further enhanced for the conjugated oligonucleotide as its 5' end is blocked by coupling to the polymer. It is therefore likely that the internalized oligonucleotide remains primarily intact.

These results provide preliminary evidence to support the value of this novel polymer for delivery of antisense oligonucleotides. The effectiveness of this delivery system can be further enhanced in a variety of ways. First, in the uptake studies, the polymer was only loaded at a low level, approximately one oligonucleotide per molecule. Since the polymer contains 6–20 active thiols, depending on the mole % of PDTEMA in the polymer feed, higher loading will likely lead to further enhancement of uptake. Second, release of the oligonucleotide from endosomal compartments would certainly improve antisense efficacy. The coupling of a lysogenic agent, such as a fusogenic peptide, to the polymer could aid in this regard (34–36). A fusogenic peptide could be coupled to the polymer using the activated sulfhydryl. Alternatively, the use of our APMA/PDTEMA copolymer could allow different chemistries to be used for the oligonucleotide and lysogenic agent. Finally, targeted delivery would also enhance efficacy. This could be accomplished by coupling a targeting moiety through the activated thiol, or alternatively, in the case of our APMA/PDTEMA copolymer, through the amino groups. The use of both a targeting moiety and a lysogenic agent would likely further enhance efficacy.

Activity could likely also be enhanced by internalization of the conjugate by nonendocytotic means. This would prevent exposure of the oligonucleotide to the degradative enzymes of the lysosome. Additionally, direct cytoplasmic uptake would likely lead to rapid nuclear accumulation of the oligonucleotide (37, 38). It has been shown that a short peptide (pAntp) from the Antennapedia homeodomain protein can translocate across biological membranes in an energy-independent, nonendocytotic manner. Uptake of peptides and oligonucleotides has been reported to be increased greater than 100-fold when coupled to pAntp (29). In our hands,

this has proven ineffective for oligonucleotides. When we coupled our anti-HIV oligonucleotide directly to pAntp, we produced a conjugate that was only soluble at pH 13 and greater. We believe that this is due to the formation of an intramolecular polyelectrolyte complex. This could result from interaction of the approximately 10 positive charges on pAntp and the 20 negative charges on the oligonucleotide at neutral pH, as discussed above. To solve the solubility problem, we coupled pAntp to our polymer and subsequently conjugated the oligonucleotide. While this solved the solubility problem, we saw no alteration in the amount of uptake or the intracellular distribution of the oligonucleotide–pAntp–polymer conjugate. Again, this is likely the result of electrostatic association of peptide and oligonucleotide. This could prevent electrostatic interaction of the peptide with the cell membrane, which may be essential to its correct functioning. Additionally, this would likely prevent proper folding of the peptide into a structure necessary for translocation. It therefore seems unlikely that pAntp can be used successfully for translocation of negatively charged oligonucleotides, unless a delivery system can be developed that allows the peptide and oligonucleotide to be physically separated.

2-Pyridyl disulfide homogeneously modified HPMA copolymer was synthesized by copolymerization of PDTEMA and HPMA. To our knowledge, this is the easiest and probably the only way, to date, to synthesize homogeneous thiol or active thiol polymers. Most of the available thiol-polymers have been synthesized by derivatizing pendant hydroxyl or other functional groups on various hydrophilic polymers (20, 39–41).

The pyridyl disulfide activated copolymer is stable in aqueous solutions of pH lower than 8.0 and can readily react with thiol containing molecules in aqueous solutions of a wide range of pH. Consequently, it provides a very mild and efficient way to conjugate water-soluble molecules to HPMA polymer. Coupling of a drug through a disulfide linkages provides other advantages as well. Disulfide linkages have been shown to be stable in the blood stream so the drug will remain with its carrier until

it reaches its site of action (42–44). Subsequently, the drug can be released by disulfide exchange with intracellular thiols such as glutathione, or alternatively by the action of redox enzymes. Since drug release is not dependent on any enzymatic activity, the route of uptake, endocytotic or nonendocytotic, should have little effect on release. This can be very important since enzyme-dependent release likely requires endocytotic uptake and lysosomal targeting. This places the drug, an oligonucleotide in our case, in contact with degradative enzymes. The use of a fusogenic peptide on the drug carrier could limit lysosomal degradation. However, for other delivery systems that require enzymatic release of the drug, inclusion of a fusogenic peptide could also prevent drug release.

Our PDTEMA/HPMA copolymer has many attributes that make it a valuable alternative for delivery of water-soluble drugs such as antisense oligonucleotides. The utility of this polymer is further enhanced by the ability to incorporate pendant amino groups as well. It is also possible that *p*-nitrophenol or *N*-succinimidyl active ester groups could also be introduced during polymerization. This allows great flexibility in the design of an effective drug delivery system. The drug, a targeting moiety, a fusogenic peptide, and any other desirable functionality can be coupled using a variety of chemistries. For the PDTEMA/HPMA copolymer alone, there are different chemistries that can be employed. Aside from the obvious coupling of thiol-containing molecules through the activated pyridyl disulfide, one can reduce the pyridyl disulfide linkage (22) and couple directly through the free sulfhydryl group. In this way nondegradable linkages can be produced by reaction with maleimido (45, 46) or iodoacetal derivatized ligands.

ACKNOWLEDGMENT

We are greatly indebted to Pavla Kopeckova and Jindrich Kopecek of the CCCD at the University of Utah for their general help in synthesis and characterization of HPMA copolymers, and for suggestions on this manuscript. We thank Michael Pierce and Peter Mayer for technical assistance. We appreciate Dr. Robert Schackmann of the University of Utah DNA/Peptide core facility for synthesis of oligonucleotide and peptide. The core facility is supported by a grant from the NCI, CA42014. This work was supported by an NIH grant to D.E.R., 5R29AI34278.

Iodopyridine-for-Iodobenzene Substitution for Use with Low Molecular Weight Radiopharmaceuticals: Application to *m*-Iodobenzylguanidine

Ganesan Vaidyanathan,* Michael R. Zalutsky, and Timothy R. DeGrado

Department of Radiology, Duke University Medical Center, P.O. Box 3808, Durham, North Carolina 27710.
Received March 19, 1998; Revised Manuscript Received August 14, 1998

Substituting a pyridine ring for a benzene ring in the acylation agent *N*-succinimidyl 3-iodobenzoate has resulted in a useful approach for the radiohalogenation of monoclonal antibodies, peptides, and labeled biotin conjugates. It was hypothesized that such a substitution in *m*-iodobenzylguanidine (MIBG), a radiotracer used in the detection and treatment of neuroendocrine tumors, might result in an analogue with more rapid normal tissue clearance, thereby facilitating its use for tumor therapy. For the preparation of this analogue, 3-guanidinomethyl-5-iodopyridine (GMIP; **9b**), the silicon precursor **4** was synthesized starting from 5-bromonicotinic acid. Attempts to convert **4** to **9b** under various conditions were not successful. Radioiodinated **9b** could be prepared by the iododestannylation of the tin precursor **8** in 65–70% radiochemical yield. A number of in vitro, in vivo, and ex vivo studies showed that pyridine-for-benzene substitution in MIBG yielded a compound that no longer was taken up by the uptake-1 pathway.

INTRODUCTION

An important consideration in the design of radiopharmaceuticals for oncology is the achievement of maximum tumor-to-normal tissue ratios in a time frame compatible with the physical half-life of the radionuclide. One way of accomplishing this is to reduce the background activity in normal tissues. In many cases, normal tissue clearance is governed in large part by the lipophilicity of the radiolabeled agent.

Reducing the lipophilicity of a tracer generally accelerates its clearance from normal tissues. This fact has been made use of in the development of acylation agents for the radioiodination of mAbs (Garg et al., 1991). Using *N*-succinimidyl 5-iodopyridine-3-carboxylate (SIPC),¹ instead of the prototypical acylation agent *N*-succinimidyl 3-iodobenzoate (SIB), mAbs could be radioiodinated without any change in their stability, immunoreactivity, and affinity (Garg et al., 1993; Reist et al., 1996). Moreover, from a comparative biodistribution of the potential catabolites in normal mice, it was found that iodonicotinic acid cleared generally faster than iodobenzoic acid from most organs. Similarly, preliminary results have suggested that peptides labeled with SIPC are less lipophilic than those labeled using SIB (Garg et al., 1992). The utility of SIPC for the synthesis of radioiodinated biotin conjugates has been recently demonstrated (Foulon et al., 1997). A faster clearance of

activity from normal tissues was seen with the biotin conjugate radioiodinated with SIPC in comparison to that radioiodinated with SIB. In all of the above cases, an agent containing a pyridine backbone was appended to proteins or peptides or coupled at a site known to be of little importance to biological activity of the final tracer. Encouraged by the fact that substitution of pyridine moiety for that of benzene in the above cases resulted in faster tissue clearance with no other adverse effects, we wished to determine the effect of such a substitution in a low molecular weight molecule.

The radiopharmaceutical MIBG was chosen for these studies. Originally, MIBG was pursued based on an extensive structure–activity study of a series of ring and side-chain-modified arylalkyl guanidines (Wieland, 1986). Although a contrary view exists (Jaques et al., 1987; Smets et al., 1990), it has been suggested that the guanidino moiety (not the aromatic ring) is more important for the biological activity of MIBG (Smets et al., 1988; 1990). However, an MIBG analogue with a fluorine substituent in its aromatic ring (FIBG) actually had a higher uptake and retention than MIBG in SK–N–SH human neuroblastoma cells in vitro (Vaidyanathan et al., 1997). FIBG also had a higher resistance, compared to MIBG, toward in vivo deiodination.

In the structure–activity study mentioned above, no compound was evaluated in which the radioiodine-containing benzene ring was replaced with a heterocyclic ring. Heterocyclic phenylpiperazine derivatives as potential alternatives to MIBG for adrenomedullary and myocardial imaging have been reported (Hanson, 1982, 1983), and recently, some of these agents were evaluated in SK–N–SH and SK–N–BE(2c) human neuroblastoma cells in vitro (Babich et al., 1996). A preliminary evaluation of iodonicotinic acid as a brain and/or adrenomedullary imaging agent has also been reported (Chan et al., 1983).

We hypothesize that by replacing the benzene ring of MIBG with a pyridine, its lipophilicity will be reduced, thereby resulting in faster clearance from normal tissues.

¹ Abbreviations: ADV, apparent distribution volume; CPP, 1-carboxamdino(4-iodophenyl)piperazine; DEAD, diethyl azodicarboxylate; FIBG, 4-fluoro-3-iodobenzylguanidine; GMIP, 3-guanidinomethyl-5-iodopyridine; IPP, 4-(3-iodophenyl)piperazine; MIBG, *m*-iodobenzylguanidine; NCS, *N*-chlorosuccinimide; NE, norepinephrine; SIB, *N*-succinimidyl 3-iodobenzoate; SIPC, *N*-succinimidyl 5-iodopyridine-3-carboxylate; TBHP, *tert*-butylhydroperoxide; TFA, trifluoroacetic acid.

If this structural change does not affect the compound's tumor uptake, tumor-to-normal tissue ratios higher than that for the parent compound might be obtained. To investigate this possibility, the pyridine analogue 3-guanidinomethyl-5-iodopyridine (GMIP) was prepared and evaluated by *in vitro*, *in vivo*, and *ex vivo* methods. Unfortunately, the results indicated that this small structural change yielded a compound with poor specificity for the norepinephrine transporter for which MIBG is a substrate.

MATERIALS AND METHODS

General. All chemicals were purchased from Aldrich unless otherwise noted. Sodium [^{125} I]iodide and sodium [^{131} I]iodide with specific activities of 2200 and 1200 Ci/mmol, respectively, were obtained from DuPont-New England Nuclear. Unlabeled MIBG and radioiodinated MIBG (no-carrier-added) were prepared as reported (Vaidyanathan et al., 1993).

Melting points were determined on a Fisher-Johns or on a Haake Buchler melting point apparatus and were uncorrected. NMR spectra were obtained with a General Electric Midfield GN-300 spectrometer. Mass spectra were obtained on a Hewlett-Packard GC/MS/DS model HP-5988A instrument or on JEOL SX-102 high-resolution mass spectrometer. High-performance liquid chromatography was conducted using one of the following systems: (1) a Beckman System (System Gold) equipped with a model 126 programmable solvent module, a model 168 diode array detector, and a model 170 radioisotope detector which was interfaced using a model 406 analog interface module; (2) two LKB model 2150 pumps, an LKB model 2152 control system, an LKB model 2138 fixed-wavelength UV-detector, and a Beckman model 170 radioisotope detector. Peak analysis in the latter was performed using a Nelson Analytical software package on an IBM computer. For reversed-phase HPLC, a Waters 3.9 $\times$ 300 mm μ -Bondapak C18 (10 μ) column or a 3.9 $\times$ 300 mm Bondclone 10 (10 μ) C-18 column (Phenomenex, Torrance, CA) was eluted with 98:2 $\text{NH}_4\text{H}_2\text{PO}_4$ (0.2M):THF. For normal-phase HPLC, an Alltech Partisil 10 μ column (250 $\times$ 4.6 mm) was eluted with a mixture of acetic acid, ethyl acetate, and hexane of varying compositions. Analytical TLC was performed on aluminum-backed sheets (Silica gel 60 F₂₅₄), and normal-phase column chromatography was performed using Silica gel 60, both obtained from EM Science (Gibbstown, NJ). For column chromatography, factors such as silica gel amount and column diameter were kept in accordance with literature protocols (Still et al., 1978). In most cases, quartz columns were used facilitating visualization of the bands. In these cases, the silica gel was mixed with zinc silicate phosphor (Sigma) at a ratio of 99:1 (w/w). Fractions were collected using a Gilson model 203 micro fraction collector (Middleton, WI) or an ISCO Foxy 200 fraction collector (Lincoln, NE) and identified by TLC. In some cases, an ISCO UA-6 UV-vis detector was placed between the column outlet and the fraction collector to identify fractions. Preparative thick layer chromatography was performed using 20 $\times$ 20 cm, 1000 μ plates (Whatman, Clifton, NJ). Before applying the sample, the plates were run in ethyl acetate to clean the plates of any adsorbed impurities.

Cells and Culture Conditions. The human neuroblastoma cell line SK-N-SH (uptake-1 positive; Biedler et al., 1973) was purchased from American Type Culture Collection (Rockville, MD). The incubation medium (JRH Biosciences, Lenexa, KS) was made by mixing 440 mL

of RPMI 1640, 50 mL of Serum Plus, 5 mL of penicillin-G/streptomycin (5000 units of penicillin and 5000 μ g of streptomycin in 1 mL of 0.85% saline) and 5 mL of glutamine (200 mM in saline). The cells were grown at 37 $^\circ\text{C}$ in a humidified incubator containing 5% CO_2 . Cell viability was evaluated prior to each binding experiment by trypan blue dye (Kaltenbach et al., 1958) and was 95–98% for all studies.

5-(Trimethylsilyl)nicotinic Acid (2). A solution of 5-bromonicotinic acid (**1**; 2.02 g; 10 mmol) in 60–70 mL of freshly distilled THF under argon was cooled to -78°C in a dry ice/acetone bath. To this, butyllithium in hexanes (13–14 mL of 1.6 M; 22 mmol) was added dropwise via a syringe over a period of 20–25 min. After stirring the mixture at -78°C for 30 min under argon, chlorotrimethylsilane (3.2 mL; 25 mmol) was added via a syringe over a period of 10–15 min. The reaction mixture was allowed to warm gradually to room temperature and left stirring at room-temperature overnight. The THF was removed from the reaction mixture by rotary evaporation, and the residual oil was partitioned between water (50 mL) and ethyl acetate (50 mL). The aqueous layer was extracted with 3 $\times$ 50 mL of ethyl acetate and the pooled ethyl acetate layer was washed with brine (25 mL), dried with anhydrous sodium sulfate, and evaporated. Silica gel chromatography of this crude product using 1:4 ethanol:chloroform yielded 335 mg (17%) of **2** as an oil. An analytical sample was obtained by preparative TLC using 3:7 ethanol:chloroform and subsequent recrystallization from 4:1 chloroform:hexane mixture: mp 175 $^\circ\text{C}$. TLC: R_f (3:7 ethanol:chloroform) = 0.47. HPLC: μ -Bondapak C18 column; flow rate 1.5 mL/min; t_R = 22 min (see Supporting Information for the chromatogram). ^1H NMR (CDCl_3): δ 0.37 (s, 9H), 8.59 (s, 1H), 8.89 (s, 1H), 9.32 (s, 1H). ^{13}C NMR (CDCl_3): δ -1.4, 127.1, 136.3, 144.0, 149.6, 155.0, 168.3. MS (CI): m/z 196, 178, 152. HRMS (EI^+) calcd for $\text{C}_9\text{H}_{13}\text{NO}_2\text{Si}$ (M^+): 195.0716. Found: 195.0715. Anal. Calcd for $\text{C}_9\text{H}_{13}\text{NO}_2\text{Si} \cdot \frac{1}{2}\text{H}_2\text{O}$: C, 52.86; H, 6.85; N, 6.85. Found: C, 53.28; H, 6.59; N, 6.97.

3-Hydroxymethyl-5-(trimethylsilyl)pyridine (3). To a mixture of **2** (1.91 g; 9.8 mmol) and trimethyl borate (6.7 mL; 59 mmol) in 15 mL of dry THF under argon was added dropwise borane methyl sulfide (2.2 mL; 23 mmol) via a syringe. The mixture was stirred at room temperature for 3–4 h, and at the end of this period, methanol (3 mL) was added. After evaporating the THF and methanol, the residual oil was partitioned between water (50 mL) and ethyl acetate (50 mL). The aqueous layer was further extracted with 3 $\times$ 50 mL of ethyl acetate. The pooled ethyl acetate layer was washed with 1 N NaOH (10 mL) and brine (25 mL) in that order, and then dried with anhydrous sodium sulfate. Silica gel chromatography of the residual oil using 1:1 ethyl acetate:hexane yielded 258 mg (15%) of a crystalline solid (**3**). An analytical sample was obtained by two consecutive preparative TLCs using the solvent systems used for analytical TLC (see below): mp 117–119 $^\circ\text{C}$. TLC: R_f (2:3 ethyl acetate:hexane) = 0.25; (1:19 ethyl acetate:chloroform) = 0.15. Normal-phase HPLC: 0.2:35:65 acetic acid:ethyl acetate:hexane; flow rate 1 mL/min; t_R = 10.7 min (see Supporting Information for the chromatogram). ^1H NMR (CDCl_3): δ 0.34 (s, 9H), 4.80 (s, 2H), 7.98 (s, 1H), 8.52 (s, 1H), 8.55 (s, 1H). ^{13}C NMR (CDCl_3): δ -1.6, 61.7, 137.8, 138.3, 142.2, 145.7, 149.9. MS (CI): m/z 182, 164. HRMS (FAB^+) calcd for $\text{C}_9\text{H}_{16}\text{NOSi}$ (MH^+): 182.1001. Found: 182.0997. Anal. Calcd for $\text{C}_9\text{H}_{15}\text{NOSi} \cdot \text{H}_2\text{O}$: C, 54.19; H, 8.59; N, 7.03. Found: C, 54.65; H, 9.31; N, 7.01.

3-[*N*¹,*N*²-Bis(*tert*-butyloxycarbonyl)guanidinomethyl]-5-(trimethylsilyl)pyridine (4**).** Compound **3** (258 mg; 1.4 mmol), 700 mg (2.7 mmol) of triphenylphosphine, and 735 mg (2.84 mmol) of [*N*¹,*N*²-bis(*tert*-butyloxycarbonyl)guanidine (**5**; prepared according to Dodd and Kozikowski, 1994)] were dissolved in 10 mL of dry THF in an argon-purged and dried flask. Diisopropyl azodicarboxylate (0.43 mL; 3 mmol) was added via a syringe over a period of 25 min to this stirred solution at room temperature. The reaction mixture was stirred at room temperature for another 3–4 h. Evaporation of THF from the reaction mixture resulted in a highly viscous oil. This oil was redissolved in 50 mL of ethyl acetate, and 10 g of silica gel was added to it. Evaporation of ethyl acetate allowed uniform adsorption of the oil onto the silica gel which was then packed on the top of a silica gel column. Chromatography using 1:9 ethyl acetate:hexane yielded 141 mg (24%) of **4** as a white crystalline solid: mp 140–142 °C. TLC: R_f (1:4 ethyl acetate:hexane) = 0.31. Normal-phase HPLC: 0.2:20:80 acetic acid:ethyl acetate:hexane, flow rate 1 mL/min, t_R = 6.9 min (see Supporting Information for the chromatogram). ¹H NMR (CDCl₃): δ 0.33 (s, 9H), 1.50 (s, 9H), 1.54 (s, 9H), 5.12 (s, 2H), 8.33 (s, 1H), 8.46 (s, 1H), 8.62 (s, 1H), 9.20 (br s, 2H). ¹³C NMR (CDCl₃): −1.5, 28.1, 28.2, 44.6, 79.2, 85.6, 135.3, 137.9, 145.2, 147.7, 149.8, 154.2, 160.1, 163.2 (for ¹³C NMR of similar compounds see Yong et al., 1997). HRMS (FAB⁺) calcd for C₂₀H₃₅N₄O₄Si (MH⁺): 423.2428. Found: 423.2423. Anal. Calcd for C₂₀H₃₄N₄O₄·Si·1/2H₂O: C, 55.61; N, 8.11; O, 12.97. Found: C, 55.66; H, 8.17; N, 12.98.

3-Bromo-5-hydroxymethylpyridine (6**).** This compound was prepared from **1** (10 g; 50 mmol) using a procedure similar to that used for the preparation of **3** to yield 2.63 g (28%) of an oil. TLC: R_f (1:4 ethyl acetate:hexane) = 0.32. ¹H NMR (CDCl₃): δ 2.60 (br s, 1H), 4.74 (s, 2H), 7.90 (s, 1H), 8.47 (s, 1H), 8.58 (s, 1H). MS (CI): m/z 188 and 190. Anal. Calcd for C₆H₆BrNO: C, 38.33; H, 3.22; N, 7.45. Found: C, 38.16; H, 3.35; N, 7.31.

3-Bromo-5-[*N*¹,*N*²-bis(*tert*-butyloxycarbonyl)guanidinomethyl]pyridine (7**).** This compound was prepared using the same procedure described for the preparation of **4**. Briefly, to a solution of **6** (300 mg; 1.6 mmol), triphenylphosphine (615 mg; 2.34 mmol) and **5** (646 mg; 2.50 mmol) in 10 mL of dry THF was added dropwise 0.3 mL (1.92 mmol) of DEAD. An equivalent amount of diisopropyl azodicarboxylate can be substituted for DEAD. After stirring for 3–4 h at room temperature, the THF was evaporated and the residual oil was adsorbed onto silica gel as described before. Chromatography using 3:17 ethyl acetate:hexane yielded 680 mg (100%) of **7** as a waxy solid: mp 94–97 °C. TLC: R_f (1:3 ethyl acetate:hexane) = 0.25. ¹H NMR (CDCl₃) δ 1.44 (s, 9H), 1.53 (s, 9H), 5.13 (s, 2H), 7.93 (s, 1H), 8.51 (s, 1H), 8.56 (s, 1H), 9.35 (br s, 2H). MS (FAB⁺): m/z 429 and 431, 373 and 375, 317 and 319, 229 and 231. Anal. calcd for C₁₇H₂₅BrN₄O₄: C, 47.56; H, 5.87; N, 13.05. Found: C, 47.87; H, 6.28; N, 13.22.

3-[*N*¹,*N*²-Bis(*tert*-butyloxycarbonyl)guanidinomethyl]-5-(trimethylstannyl)pyridine (8**).** A mixture of **7** (940 mg; 2.5 mmol), hexamethylditin (3.5 g; 11 mmol), and bis(triphenylphosphine)palladium dichloride (355 mg; 0.5 mmol) in 45 mL of dioxane was refluxed for 2 h under argon. The dioxane was removed from the dark reaction mixture by rotary evaporation and the residue (oil plus black particles) was taken up in ethyl acetate (50 mL). This mixture was filtered through silica gel (20 g) using a frit funnel. The silica gel was washed with liberal amounts of ethyl acetate and the ethyl acetate was

evaporated off from the filtrate. The yellow oily residue was subjected to silica gel chromatography. The column was packed and eluted initially with chloroform. After the excess tin reagent was eluted off, the solvent was gradually changed to 10% ethyl acetate in chloroform. Evaporation of solvents from pooled fractions yielded 500 mg (40%) of **8** as an oil. An analytical sample was obtained as a white crystalline solid by preparative TLC using 1:3 ethyl acetate:hexane. mp 103–104 °C. TLC: R_f (7:13 ethyl acetate:hexane) = 0.28. ¹H NMR (CDCl₃): δ 0.34 (s, 9H), 1.43 (s, 9H), 1.50 (s, 9H), 5.12 (s, 2H), 7.90 (s, 1H), 8.53 (m, 2H), 9.30 (br s, 1H), 9.43 (br s, 1H). MS (FAB⁺): m/z cluster peaks at 515, 459, 415, 315. HRMS- (FAB⁺) calcd for C₂₀H₃₅N₄O₄Sn (MH⁺) 513.1680. Found 513.1689. Anal. Calcd for C₂₀H₃₄N₄O₄Sn: C, 46.81; H, 6.68; N, 10.92. Found: C, 46.74; H, 6.61; N, 10.77.

3-Guanidinomethyl-5-iodopyridine (9b**).** A mixture of **8** (392 mg; 0.8 mmol) and iodine (520 mg; 2 mmol) in 15 mL of acetic acid was heated at 70 °C for 15–20 min in a closed flask. At the end of this period, 20 mL of trifluoroacetic acid was added and heated for another 5–10 min. The solvents and excess iodine were removed at 35–40 °C using a rotary evaporator under aspirator vacuum. The dark residual solid was dissolved in 5 mL of water and a solution of saturated sodium bisulfite (0.3 mL) was added. This solution was extracted with 3 × 5 mL of ethyl acetate to remove nonpolar impurities. The aqueous layer was evaporated, and the residual solid was taken up in 25 mL of warm methanol. The undissolved inorganic material was filtered, and ether (50 mL) was added with stirring to the filtrate. The resultant granular precipitate was filtered and washed with ether to yield 80 mg (25%) of **9b**. An analytical sample was obtained by recrystallization from water: mp 248–250 °C (decomposing). TLC (NaBr impregnated plate; Bluhm and Li, 1998): R_f (1:4 methanol:dichloromethane) = 0.34. HPLC: μ -Bondapak C18 column; flow rate 1.0 mL/min; t_R = 13.6 min (see Supporting Information for the chromatogram). ¹H NMR (CD₃OD): δ 4.42 (s, 2H), 8.18 (s, 1H), 8.48 (s, 1H), 8.76 (s, 1H). ¹³C NMR (CD₃-SOCD₃): 41.1, 94.3, 135.2, 143.0, 147.3, 154.3, 156.7. MS (FAB⁺): m/z 277, 260, 235. HRMS (FAB⁺) calcd for C₇H₁₀IN₄ (MH⁺): 276.9950. Found: 276.9945. Anal. Calcd for C₇H₉IN₄·HI: C, 20.84; H, 2.50; N, 13.90. Found: C, 20.83; H, 2.96; N, 14.04.

Radioiodination of **8.** A solution of **8** (0.5 μ mol in 5 μ L) in chloroform was taken in a 1/2-dram vial and the chloroform was evaporated with an argon stream. Iodine-125 or ¹³¹I (0.2–2 mCi) in 1–2 μ L of 0.1 N NaOH was added to the vial followed by NCS in acetic acid (0.4 mg in 20 μ L). The mixture was heated at 70 °C for 10–12 min in an oil bath. Trifluoroacetic acid (20 μ L) was added and the mixture was heated again for 5 min. Most of the solvent was removed by evaporation with a stream of argon, and the residue was redissolved in 40 μ L of methanol. The product was isolated by reversed-phase HPLC. For HPLC, a 3.9 × 300 mm Bondclone 10 (10 μ) C-18 (Phenomenex, Torrance, CA) column was eluted with 98:2 ammonium dihydrogen phosphate (0.2 M):THF at a flow rate of 1 mL/min. Under these conditions, the product (**9b**) had a retention time of 17–18 min. The radiochemical yield was in the range 65–70%. No coeluting mass peak was detected by HPLC. The activity from HPLC fractions was concentrated using a C18 solid-phase cartridge as described for MIBG and other benzylguanidine derivatives (Vaidyanathan and Zalutsky, 1993; Vaidyanathan et al., 1997).

Lipophilicity Measurements. Octanol/buffer partition coefficients of MIBG and GMIP were determined in a paired-label format at two different pH values. This was performed following a reported method (Vaidyanathan et al., 1994) except that phosphate buffers of pH 7.4 and 4.7 (measured using a pH meter) were used instead of water. Lipophilicity was also determined by calculating the log k' values from HPLC data. For this a Waters μ Bondapak C18 column was eluted with 80:20 ammonium dihydrogen phosphate (0.2 M):THF at a flow rate of 1 mL/min.

In Vitro Assessment of 9b. SK-N-SH cells were plated in 6-well plates at an initial density of 5×10^5 cells/well in 3 mL of medium and incubated for 24 h. The medium was removed by aspiration, and 100 nCi each of [^{131} I]MIBG and [^{125} I]GMIP in 3 mL of medium was added to each well and incubated for 2 h at 37 °C. To determine the effect of DMI and ouabain, the initial medium was removed and the cells were incubated with 3 mL each of 1.5 μ M DMI and 1 mM ouabain, respectively, for 30 min. The medium was removed, and tracers were added as above and incubated for 2 h at 37 °C. To determine the effect of temperature, the original medium was removed, and fresh medium precooled to 4 °C was added followed by tracers (100 nCi each) in 10 μ L of the medium and then incubated for 2 h at 4 °C. Finally, the effects of norepinephrine and MIBG were ascertained by removing the original medium and coincubating the cells with the tracers (100 nCi in 10 μ L each) and 3 mL each of 50 μ M NE and 10 μ M MIBG, respectively, at 37 °C for 2 h.

At the end of 2 h incubation period, cells were solubilized by incubation with 500 μ L of 0.5 N NaOH for 30 min at room temperature and then removed with cotton swabs. The cell-bound activity was counted along with input standards using a dual-channel γ counter. Each set of experiments was performed in six replicates. The entire experiment was conducted twice.

Paired-Label Biodistribution of [^{131} I]MIBG and [^{125} I]GMIP in Normal Mice. Male BALB/c mice weighing about 25 g were utilized. Tissue uptake of [^{125} I]GMIP was compared with that of [^{131} I]MIBG at 1, 4, and 24 h postinjection by administering via the tail vein 6 μ Ci of the former and 4 μ Ci of the latter in 100 μ L of phosphate-buffered saline. Groups of five mice were used for each time point. The mice were killed by an overdose of halothane. Tissues of interest were isolated, washed, blot-dried, and counted for ^{131} I and ^{125} I using a dual-label program in a γ counter. A 5 or 10% aliquot of the injected activity was also counted so that the percentage of injected dose per organ or per gram of tissue could be computed.

Isolated Rat Heart Studies. Perfusion of isolated working rat hearts was performed as described previously (DeGrado et al., 1995). The perfusion protocol consisted of a 15 min stabilization period, a 4 min radiotracer wash-in (pulse) period and a 56 min wash-out period in succession. Before each perfusion, the radiotracer perfusion circuit was filled with approximately 500 mL of perfusion medium containing 30–40 μ Ci/L [^{131} I]GMIP. Specific extraneuronal uptake (uptake-2) into myocytes was pharmacologically blocked in a group of hearts with 0.8 μ M *N*-(9-fluorenyl)-*N*-methyl- β -chloroethylamine hydrochloride (SKF550, SmithKline-Beecham, King of Prussia, PA; Iversen et al., 1972).

At the end of perfusion, radioactivity in the heart was measured and normalized to the radioactivity concentration of the wash-in medium and heart mass to obtain myocardial retention in units of apparent distribution

Scheme 1

volume [ADV (mL/g)] as previously described (DeGrado et al., 1995). Iodine-131 radioactivity in the rat heart was externally monitored using two lead-collimated 5×5 cm NaI(Tl) scintillation probes. Counts were sampled every second and stored on an IBM PC/AT computer. The total count rate in the heart [Y_i (counts/s)] was calculated as the sum of the count rates for the two detectors corrected for background and radioactive decay. The resultant time-activity curve was normalized by the concentration of radioactivity in the wash-in perfusate and the mass of the heart to give ADV (mL/g) at each sample point. This was accomplished by multiplication of each Y_i by a calibration factor (f_c):

$$ADV_i \text{ (mL/g)} = Y_i f_c \quad (1)$$

where f_c is given by

$$f_c \left(\frac{\text{mL/g}}{\text{counts/s}} \right) = \frac{ADV_e}{Y_e} \quad (2)$$

ADV_e is the apparent distribution volume measured at the end of perfusion and Y_e is the average total count rate over the last 10 s of the experiment.

Indices of cellular accumulation and clearance of [^{131} I]-GMIP were derived from each of the myocardial uptake curves. The uptake rate, K_i (mL/min/g), was estimated from the linear portion of the curve over the interval of 2–3 min. In this isolated heart preparation, coronary flow is supraphysiologic (typically 11–12 mL/g/min), allowing rapid equilibration of tracer in extracellular spaces within 2 min (DeGrado et al., 1995). Therefore, K_i indicates the accumulation rate of [^{131} I]GMIP in cellular spaces. The clearance kinetics were described by the multiexponential model: $y = A_1 \exp[-E_1(t - t')]$ + $A_2 \exp[-E_2(t - t')]$, where t' = time of commencement of washout period. Estimates of the constants A_1 , A_2 , E_1 , and E_2 were obtained by a weighted nonlinear least-squares fitting procedure. Data are expressed as means $\pm$ standard error. The t -test (two-tailed) for unpaired samples was used to compare means.

RESULTS AND DISCUSSION

Due to the highly basic nature of guanidine functionality, it was anticipated that strong acidic conditions would be necessary to perform the halodemetalation reaction. Since a tin derivative may undergo proteodestannylation under strong acidic conditions, initial attempts were made to prepare a silicon precursor. The compound targeted was 3-[N^1, N^2 -bis(*tert*-butyloxycarbonyl)guani-

dinomethyl]-5-(trimethylsilyl)pyridine (**4**). A number of approaches were made for the synthesis of this compound; the successful one is depicted in Scheme 1. Butyllithium-mediated silylation of 5-bromonicotinic acid gave **2**, which was reduced with borane methyl sulfide (Lane et al., 1974) to **3**. Treatment of this alcohol with *N*¹,*N*²-bis(*tert*-butoxycarbonyl)guanidine (**5**) under Mitsunobu conditions (Dodd and Kozikowski, 1994) gave the target silicon precursor. A number of attempts to iododesilylate **4** using various oxidizing agents (NCS, TBHP, etc.) and media (TFA, concentrated HCl, methanol, and combinations thereof) were unsuccessful even at 100 °C; 3-guanidinomethyl-5-trimethylsilylpyridine was isolated in almost quantitative yields. Attempts to convert **7** to **9** by copper-mediated exchange (Moerlin, 1990) also were unsuccessful.

Having failed to prepare GMIP by these two routes, a tin precursor was sought. The synthetic method used to prepare this compound, 3-[*N*¹,*N*²-bis(*tert*-butoxycarbonyl)guanidinomethyl]-5-(trimethylstannyl)pyridine (**8**) is shown in Scheme 2. First, 5-bromonicotinic acid was reduced with borane methyl sulfide to the corresponding alcohol **6**. This alcohol was converted to the guanidine derivative **7** by treatment with **5** under Mitsunobu conditions. Finally, **7** was converted to **8** by palladium catalyst-mediated coupling with hexamethylditin. Treatment of **8** with iodine in acetic acid at 70 °C did yield **9b**. The precursor **8** could also be radioiodinated using NCS in acetic acid to give [¹²⁵I]GMIP in about 70% radiochemical yield.

The octanol/buffer partition coefficient of GMIP, determined from a paired-label experiment, was more than 10-fold lower than that of MIBG. For example, the values using phosphate buffer of pH 7.4 were 0.17 ± 0.01

Scheme 3

and 2.83 ± 0.35, respectively. The log *k'* values calculated for MIBG and GMIP were 0.30 and -0.40, respectively. These results indicate that GMIP, as expected, has much lower lipophilicity than MIBG.

Results from a paired-label tissue distribution of [¹²⁵I]-GMIP and [¹³¹I]MIBG in normal mice are shown in Table 1. As expected, GMIP cleared much faster than MIBG from all tissues. Interestingly, [¹²⁵I]GMIP was less susceptible to *in vivo* deiodination because its thyroid uptake, especially at 24 h, was much lower than that for [¹³¹I]MIBG. This may reflect a greater difference in the chemical structure of GMIP, compared to MIBG, to that of monoiodotyrosine, one of the natural substrates for deiodinases. Heart (9.41 ± 1.99 vs 19.82 ± 2.38% ID/g) and adrenal (10.17 ± 4.32 vs 19.32 ± 6.98% ID/g) uptake of [¹²⁵I]GMIP at 1 h was about 50% lower than [¹³¹I]-MIBG, and at later time points, the difference in uptake of [¹²⁵I]GMIP and [¹³¹I]MIBG was even more apparent. The piperazine derivative, 1-carboxamidino(4-[¹²⁵I]iodophenyl)piperazine ([¹²⁵I]CPP) has myocardial and adrenal uptake similar to that for MIBG (Hanson, 1982). Another heterocycle-containing compound, 4-(3-[¹²⁵I]iodophenyl)piperazine ([¹²⁵I]IPP), had myocardial uptake 50% or lower than that for MIBG (Babich et al., 1996). The latter piperazine compound, however, was shown to have high affinity for the norepinephrine transporter in SK-N-SH and SK-N-BE(2c) cells *in vitro*. Provided GMIP is sequestered specifically in neuroendocrine tumors, its lower normal tissue uptake may result in tumor-to-normal tissue ratios higher than that of MIBG.

To investigate this possibility, [¹²⁵I]GMIP was evaluated *in vitro*, along with [¹³¹I]MIBG, using SK-N-SH human neuroblastoma cells which take up MIBG specif-

Figure 1. Paired-label uptake of [¹²⁵I]GMIP (□) and [¹³¹I]MIBG (■) by SK-N-SH human neuroblastoma cells in vitro: Influence of various blocking agents and conditions.

Figure 2. Representative time-activity curves of GMIP in control (solid) and uptake-2 blocked (dashed) perfused rat hearts. Uptake-2 blocked condition used 0.8 μM SKF550 in the perfusion medium. The uptake and clearance patterns were nearly identical in both conditions, showing negligible sensitivity of the kinetics to inhibition of the uptake-2 (extraneuronal) catecholamine transporter.

ically via the uptake-1 mechanism (Buck et al., 1985; Smets et al., 1989; Vaidyanathan et al., 1997). The results from this experiment showed that MIBG was taken up specifically by these cells. About 40% of input [¹³¹I]MIBG was incorporated into the cells, and this uptake could be effectively impeded by various agents and conditions that block the uptake-1 mechanism (Figure 1). In contrast, less than 1% of the input activity of [¹²⁵I]GMIP was cell-bound even in the absence of uptake-1 inhibitors. This suggests that the benzene ring of MIBG is a *sine qua non* for its recognition by the norepinephrine uptake-1 transporter, which also probably accounts for the lower uptake of GMIP in mouse heart and adrenals. To explore the possibility that GMIP could be useful as a tracer of specific extraneuronal transport of catecholamines (uptake-2; Iversen et al., 1972), experiments were carried out in an isolated rat heart model. Figure 2 shows representative time-activity curves for GMIP in isolated rat hearts perfused in control conditions and with uptake-2 blockade by 0.8 μM SKF550. The uptake and clearance parameters for GMIP in control and uptake-2 blocked conditions are shown in

Table 2. The uptake rate of GMIP was 0.43 ± 0.03 mL/g/min in control conditions and was not significantly different in uptake-2 blocked hearts. Clearance was biphasic. In control hearts, roughly one-half of the radioactivity cleared with a clearance half-time of 5 min. The other half showed a clearance half-life of 24 min. Thus, after 60 min, approximately 90% of the radioactivity had cleared from the heart. No significant differences were observed in the clearance kinetic parameters in uptake-2 blocked hearts versus control (Table 2). These results indicate minimal retention of GMIP in myocardial tissue, consistent with the lack of specific cellular uptake of the tracer. Indeed, the kinetic properties of GMIP are very similar to those previously observed for MIBG in the same isolated rat heart model with blockade of both neuronal (uptake-1) and extraneuronal (uptake-2) transporters (DeGrado et al., 1995).

In conclusion, a synthetic method was developed for the preparation of GMIP, a pyridine analogue of MIBG. In vitro, in vivo, and ex vivo experiments demonstrated that substitution of the benzene ring in MIBG with a pyridine ring resulted in its total loss of specificity for norepinephrine transporter. This may not be entirely due to the more polar nature of GMIP over MIBG as derivatives of MIBG with polar substituents such as -OH and -NH₂ on its benzene ring exhibited similar biological properties as MIBG itself (Wieland, 1986). Thus, although antibodies, peptides, and biotin iodopyridine conjugates can be synthesized with excellent biological properties, iodopyridine-for-iodobenzene substitution was not successful in MIBG.

Protein and Peptide Labeling with (Cyclopentadienyl)tricarbonyl Rhenium and Technetium

Todd W. Spradau and John A. Katzenellenbogen*

Department of Chemistry, University of Illinois, 461 Roger Adams Laboratory, Box 37-5, 600 South Mathews Avenue, Urbana, Illinois 61801. Received April 13, 1998; Revised Manuscript Received July 24, 1998

A method for labeling proteins and peptides with (methoxycarbonyl cyclopentadienyl)tricarbonyl rhenium and technetium is described. The precursors used for this labeling are conveniently produced from perrhenate and pertechnetate, respectively, using a double ligand transfer reaction. For labeling the lysine residues of the model protein bovine serum albumin, the technetium methyl ester was saponified and then transformed into its N-hydroxysuccinimidyl ester. For the labeling of the model peptides leucine enkephalin, substance P, oxytocin, and the tumor imaging/therapy candidate octreotide, the rhenium methyl ester was saponified and activated using either 1-hydroxybenzotriazole or 1-hydroxy-7-azabenzotriazole. The activation and peptide-coupling reactions were followed using reversed-phase (C_{18}) HPLC and yields averaged approximately 70%.

INTRODUCTION

We recently reported a novel double ligand transfer (DLT) reaction that permits the rapid synthesis of substituted (cyclopentadienyl)tricarbonylrhenium (CpTR) complex **1** from $KReO_4$ (Scheme 1) (1). The chemical stability and the ease of Cp-ring derivatization of these compounds make them attractive candidates for the preparation of technetium and rhenium-based radiopharmaceuticals, agents that are widely used in diagnostic imaging (^{99m}Tc) and radiotherapy (^{186}Re , ^{188}Re) (2–5). Complexes derived from **1** have not as yet been exploited for such applications, however, because they are difficult to prepare from ReO_4^- , the only available chemical form of ^{186}Re and ^{188}Re (6–8). ^{99m}Tc is also available only as $^{99m}TcO_4^-$, and as a result, most rhenium and technetium radiopharmaceuticals are inorganic complexes with the metals in a +5 oxidation state. If the scope of the DLT reaction could be extended to include the synthesis of the technetium analogues of the rhenium complex **1** [i.e., (cyclopentadienyl)tricarbonyl technetium (CpTT) complexes], a variety of new organometallic radiopharmaceuticals could be developed.

One simple method which has been widely used for the creation of new radiopharmaceuticals involves the attachment of the radioisotope to a protein (antibody) or peptide that is known to localize in a desired region of the body (9, 10). The resulting adducts can then be used for imaging and/or therapy of that region if their biodistribution characteristics remain favorable. The goal of this study was to apply the DLT reaction to prepare precursors suitable for attaching CpTR and CpTT complexes to proteins and peptides.

The many procedures that have been developed for incorporating technetium and rhenium into proteins and peptides can be grouped into three categories: (a) direct labeling, (b) indirect labeling, and (c) the preformed chelate approach. Each method has been used successfully in a variety of applications, but each has drawbacks and limitations (11).

Scheme 1. Double Ligand Transfer (DLT) Reaction

In the direct-labeling approach, which is the simplest of the three, the sulfhydryl groups of the protein itself are exploited as chelation sites for the metal, and labeling is accomplished simply by incubation of the protein with ReO_4^- or TcO_4^- and a reducing agent (usually stannous ion) or by transchelation of the prereduced metal onto the protein from a donor ligand (12). The stability and incorporation level of the label can sometimes be enhanced by increasing the number of free thiols of the native protein by reducing disulfide bonds or by adding exogenous sulfhydryl groups by prior derivatization of the protein (13). Such procedures, however, can alter the structure and, consequently, the biological properties of the protein or peptide (14). Furthermore, the direct-labeling approach is often plagued by ambiguities regarding the sites of attachment and oxidation states of the bound metals, as well as by instability of the label (13–17).

Indirect labeling involves the attachment of strong chelators to the protein or peptide prior to direct labeling. A wide variety of tightly binding chelates have also been attached to proteins and peptides and labeled successfully [e.g., hydrazino nicotinamide (HYNIC) (18, 19), diaminodithiol (DADT) (20), bis(aminoethanethiol) (BAT) (21), and short peptide sequences (22–24)]. However, even though these strategies often result in increased complexation yields and label stability, the shortcomings of the direct-labeling strategies (site of attachment and oxidation state ambiguity, label instability) still remain.

The preformed chelate approach seeks to eliminate the drawbacks associated with direct and indirect labeling. By this approach, the radiometal is first securely bound inside a chelate system, and then, in a subsequent step, the derivatized metal is firmly attached to the protein or peptide. The resulting product possesses a label that

Figure 1. Reagents used to couple CpTR to proteins.

Scheme 2. General Strategy for Protein or Peptide Labeling with the Cyclopentadienyl Tricarbonyl Technetium (CpTT) Unit

is chemically well-defined and stable, but this approach comes at the cost of additional synthetic steps. Some "bifunctional" chelates that have been successfully employed in this strategy include tetradentate N_2S_2 (25, 26) and N_3S (27, 28) system, and boronic acid adducts of technetium dioximes (BATOs) (29).

The labeling strategy we have pursued is outlined in Scheme 2. The key step is the formation of methyl ester **2** from pertechnetate via the double ligand transfer (DLT) reaction. The subsequent steps involve simple modifications of the Cp ring side chain to make it suitable for coupling to the amino groups of proteins and peptides. Thus, this method can be classified as a preformed chelate approach, with active ester **4** being an organometallic analogue of the inorganic bifunctional chelates mentioned above.

Most proteins and peptides labeled with technetium or rhenium contain *inorganic* derivatives of the metals, but a few examples of *organometallic* variations exist. Alberto and co-workers reported the conjugation of the $Re(CO)_3$ fragment to proteins in a direct-labeling approach using $[Re(OH_2)_3(CO)_3]^+$ as the donor molecule (30), and, in an investigation similar to our own, Jaouen and co-workers described the coupling of CpTR to proteins using a preformed chelate approach with the active esters **5** and **6** (Figure 1) (31). In a subsequent study, pyridium salt **7** was used as well (32). Our study expands upon this earlier work.

RESULTS

Protein Labeling. The first step in the execution of our approach was to demonstrate that the DLT reaction could be extended from perrhenate to pertechnetate. Table 1 shows that the transformation did in fact work just as well with technetium as it did with rhenium. Notably, the desired methyl ester **2** could be prepared in very high yield.

As shown in Scheme 3, the methyl ester of **2** could be rapidly and quantitatively saponified in a mixture of 1:1 NaOH (2M):dioxane to provide carboxylic acid **3**. When cosolvents other than dioxane (e.g., THF, acetonitrile, and methanol) were tried, longer times (15–120 min) were

Figure 2. Incorporation of $[^{99m}Tc]CpTT$ into bovine serum albumin (BSA). Sephadex G-25 size exclusion chromatographic analysis of the labeling process. $[^{99m}Tc]CpTT$ -labeled BSA elutes in the void volume (fraction 1). Unreacted active ester **8** or hydrolysis product **3** elutes in fractions 4–8. Further details are given in the Experimental Section.

CO_2CH_3	CO_2CH_3	89

Scheme 3. Demonstration of Protein Labeling with $[^{99m}Tc]CpTT$, Using Bovine Serum Albumin

required for the reaction to go to completion. The acid was then treated with a uronium salt described by Knorr and co-workers to provide the N-hydroxysuccinimide (NHS) ester **8** (33). We chose N-hydroxysuccinimide as the activating group for our protein coupling experiments because of the stability of the resultant ester in aqueous solution and its high reactivity toward the ϵ -amino groups of lysine residues (34).

Coupling experiments were performed with the model protein bovine serum albumin (BSA), which contains 59 lysine residues and one N-terminal amino group for a total of 60 possible covalent attachment sites. The reactions were found to be rapid (complete in less than 5 min), with yields that varied depending on the relative amount of BSA to active ester **8** that was used. Figure 2 is a graphical representation of the elution profiles obtained upon size-exclusion column chromatographic separation (Sephadex G-25) of the products from three reactions with varying ratios of BSA to **8**. The void volume of the column, which contained the labeled and unlabeled proteins, comprised the first 20–25 drops

Scheme 4. Labeling of Leucine Enkephalin with CpTT Using an NHS Ester**Scheme 5. Peptide Labeling with CpTT Using Esters Activated by HOBt or HABt**

collected from the 5 cm column, while the small molecules included within the pores of the gel [i.e., unreacted **8** and **3** (from ester hydrolysis)], began to elute at approximately 40–45 drops. As the amount of BSA was increased from 0.01 to 1.0 equiv of active ester (**8**), the incorporation yields increased from 5% to greater than 70%. Since radiolabeling experiments using ^{99m}Tc, ¹⁸⁶Re, and ¹⁸⁸Re are typically done in the presence of a large excess of protein, the potential for the tracer-level labeling of proteins by this approach appears to be great.

Peptide Labeling. The strategy outlined in Scheme 2 was also adopted for the labeling of selected peptides, with two changes from the protein-labeling protocol. First, rhenium was used instead of technetium, and second, activating groups other than NHS were employed. Scheme 4 shows that the conjugation of the CpTR NHS ester **5** to the model peptide leucine enkephalin was much slower than the corresponding reaction of the corresponding CpTT NHS ester **8** with BSA, most likely because of a relative increase in steric hindrance near the N-terminal amino group of the peptide compared to that of the numerous and more accessible ϵ -amino groups of the lysine residues of the protein.

Reaction sequences with short-lived radioisotopes need to be as rapid as possible to maximize the specific activities of the final products. For this reason, we investigated alternative activating agents, bases, and solvents for the coupling reactions of rhenium carboxylate **10** (Scheme 5) with the model peptides leucine enkephalin (Tyr-Gly-Gly-Phe-Leu), substance P (Arg-Pro-Lys-Pro-

Figure 3. HPLC traces of the reaction of carboxylic acid **10** with HOBt (panel A) and HABt (panel B). The structures of compounds **10**, **11a**, **11b**, and **12** are given in Scheme 5. The vertical arrow indicates the time of injection. HPLC conditions are given in the Experimental Section.

Figure 4. Structures of HABt and HOBt.

Gln-Gln-Phe-Phe-Gly-Leu-Met-NH₂), and oxytocin (Cys-Tyr-Ile-Gln-Asn-Cys-Pro-Leu-Gly-NH₂, disulfide bridge: 1–6). Leucine enkephalin was included because of its simple structure and affordability, substance P because it possesses a lysine residue and thus two potential sites for labeling, and oxytocin because of its intramolecular disulfide bond. The disulfide bond was important to us because the fourth peptide we chose for this study, octreotide, also contains a cystine bridge and is, moreover, an attractive candidate for radiolabeling with Tc-99m (35, 36).

Leucine Enkephalin, Oxytocin, and Substance P.

We found that the related reagents 1-hydroxybenzotriazole (HOBt) and 1-hydroxy-7-azabenzotriazole (HABt) could both be used to provide intermediates that were capable of coupling with the model peptides (Scheme 5). The activation/coupling sequences were complete in less than 20 min for each of the peptides studied, and both steps could be followed using reversed-phase (C₁₈) HPLC.

Interestingly, the reaction of acid **10** with HOBt in the presence of DCC produced three distinct intermediates that were visible by HPLC analysis, each of which disappeared upon addition of peptide, whereas DCC/HABt produced two intermediates (Figure 3). The product that was produced by both reagents, which eluted at 12.6 min under these conditions (Figure 3), was tentatively assigned structure **12**, a reactive anhydride dimer of the starting carboxylic acid **10**. The compound that eluted at 10 min in the DCC/HABt reaction was most likely the HABt adduct **11b** (panel A), while that at 10.7 min in the DCC/HOBt reaction is probably its slightly more hydrophobic analogue **11a** (panel B). The polar compound at 7.2 min may be a condensation product of acid **10** with DCC (or its urea), and its absence from the HABt reaction can be explained by the higher reactivity (nucleophilicity) of HABt vs HOBt toward this compound, due to its zwitterionic tautomer (Figure 4). The activation reactions were complete within 1 min in CH₂Cl₂, and the active intermediates produced were stable for at least 24 h in that solvent. When the same reactions were performed in DMF, no intermediates could be detected by HPLC, and starting acid **10** was the only peak observed (8.4 min; see a trace of **10** in Figure 3, panel B).

Representative traces of the reactions of the active intermediates (Figure 3) with each of the three model peptides are shown in Figure 5. The peptides themselves eluted at approximately 5.9 min in the solvent gradient

Figure 5. HPLC traces of the reactions of CpTR with leucine enkephalin (panel A), oxytocin (panel B), and substance P (panel C). The structures of compounds **10** and **13a–c** are shown in Scheme 5. The vertical arrow indicates the time of injection. HPLC conditions are given in the Experimental Section.

used, and varying amounts of the unreacted peptides can be seen in each trace. Yields averaged 70% for each reaction, based upon integration of the peaks corresponding to the coupled products **13a**, **13b**, and **13c** (Scheme 5), which appeared at 9.0 and 7.3 min in the leucine enkephalin and oxytocin reactions, respectively (Figure 5, panels A and B), and at 7.8 and 9.4 min for the two conjugates obtained in the reaction with substance P (Figure 5, panel C). The CpTR derivative of leucine enkephalin (**13a**) was isolated and characterized by ^1H NMR and FAB mass spectrometry.

A peak at 8.4 min corresponding to starting acid **10** was a prominent feature in all of the HPLC traces (Figure 5) and indicates that there is a competition between amide bond formation with the peptide and hydrolysis of the activated intermediates in the coupling reactions. Although the intermediates were stable in pure CH_2Cl_2 , their hydrolysis was found to be catalyzed by the base used in the reaction, with the rate of hydrolysis increasing in the order diisopropylethylamine < triethylamine << (dimethylamino)pyridine (DMAP). The yields of the labeled peptides produced in the presence of those bases decreased in the same order, and diisopropylethylamine, the most sterically hindered base that engendered the highest yields, was thereafter used in all of the reactions. Solvents other than methylene chloride, such as acetonitrile and DMF, were unsuitable for the preparation of the active esters; we found that if the active esters were first prepared in CH_2Cl_2 , then DMF could subsequently be added to form a mixed solvent system in which the active intermediates were moderately stable. The addition of DMF was important for the coupling reactions with all of the peptides except leucine enkephalin, because while the latter reacted rapidly in CH_2Cl_2 , the others were insoluble, and therefore unreactive, in that solvent.

Octreotide Labeling. Octreotide (**13a**, Figure 6) interested us because of its known affinity for a wide range of somatostatin receptor-containing neuroendocrine tumors, including those of the lung, pancreas, pituitary, breast, and prostate (37). If labeled with

Figure 6. Structures of unprotected and Boc protected octreotide (**14a** and **14b**) and their CpTR and CpTT labeled derivatives **15a, b** and **16a, b**.

Figure 7. HPLC traces of reaction for the formation of Boc-protected CpTR-labeled octreotide **15a** (panel A) and from CpTR-labeled octreotide **15b** (panel B). The structures of compounds **10**, **11b**, **15a**, and **15b** are shown in Scheme 5 and Figure 6. The vertical arrow indicates the time of injection. HPLC conditions are given in the Experimental Section.

Tc-99m or Re-186/Re-188, it could potentially be used to detect and/or treat cancer in those tissues. Furthermore, it is an exceptionally challenging target for Tc/Re labeling, since its essential disulfide linkage is sensitive to the reducing conditions generally employed in labeling with those metals (38).

Like oxytocin and substance P, octreotide was insoluble in CH_2Cl_2 , and DMF was therefore required to promote its conjugation reactions. These reactions were typically performed by adding a methylene chloride solution of the freshly prepared active ester **11b** to a vial containing solid, Boc-protected octreotide (**14b**). After removal of the CH_2Cl_2 under a nitrogen stream, DMF and diisopropylethylamine were added to initiate the coupling. Again, all attempts to do this sequence from start to finish in DMF were unsuccessful.

Figure 7 shows representative reversed-phase (C_{18}) HPLC traces for the formation of the CpTR-N-terminally labeled Boc-octreotide **15a** (panel A) and its deprotection to CpTR-octreotide **15b** (panel B). Starting acid **10** and its active ester **11b** were visible at 4.6 and 8.1 min, respectively, in this gradient (panel A), while the Boc-octreotide (**14b**), which eluted at 6.2 min, had already been completely consumed. The coupled product (**15a**, 14.7 min) was isolated and characterized by its MALDI and FAB mass spectra, and its yield typically ranged 70–80%. The final, deprotected product (**15b**, 6.1 min) (panel B) was generated in 95% trifluoroacetic acid, and it also was isolated and identified by its MALDI, FAB (Figure 8), and high-resolution FAB mass spectra.

The same reaction sequence was finally repeated with technetium-99g-labeled acid **3** to provide the corresponding Boc-protected (**16a**) and deprotected (**16b**) [$^{99\text{Tc}}$]-CpTT-octreotide conjugates, which also were characterized by their FAB mass spectra. To our knowledge, these syntheses represent the first successful preparations of Re and Tc-99g-labeled octreotide, although Tc-99m-labeled octreotide derivatives have been reported (38–

Figure 8. FAB mass spectrum of the CpTR-octreotide conjugate **15b**. The peaks at m/z 1401.8 and 1403.7 correspond to the $(M + Na)^+$ ion with ^{185}Re and ^{187}Re , respectively.

40). The *in vivo* properties of those compounds were not ideal, however. The results of our own Tc-99m labeling of octreotide using the chemistry described in this report and the tissue distribution of this radiopharmaceutical will be reported elsewhere (41).

CONCLUSION

A double ligand transfer reaction that was previously developed for the rapid synthesis of substituted (cyclopentadienyl)tricarbonylrhenium complexes from KReO_4 was found to be effective for the preparation of the corresponding technetium compounds from $\text{NH}_4^{99g}\text{TcO}_4$ as well. One of the products of this reaction, namely the methyl ester substituted derivative **2**, was found to be a useful precursor for the ^{99g}Tc labeling of protein lysine residues. The protocol included transformation of methyl ester **2** into NHS ester **8**, and then treatment with the model protein bovine serum albumin in pH 9 buffer. These reactions were complete in less than 5 min, and incorporation yields varied depending upon the relative amounts of BSA to active ester used, but exceeded 70% in the reactions performed with 1 equiv of each coupling partner.

In like manner, the model peptides leucine enkephalin, substance P, and oxytocin were labeled using the HOBt and/or HABt active ester derivatives of rhenium acid **10**. The activation and peptide-coupling reactions were followed using reversed-phase (C_{18}) HPLC, and it was found that although DMF was required as a solvent in the couplings of two of the three peptides, it was an unsuitable medium for the activation step, which worked best in CH_2Cl_2 .

Finally, the octapeptide octreotide, which is an attractive candidate for radiolabeling with ^{99m}Tc , ^{186}Re , and/or ^{188}Re , was labeled for the first time with nonradioactive rhenium and Tc-99g, using the reaction protocol optimized for the model peptides. It is hoped that the chemistry described in this paper will prove useful for the preparation of a variety of ^{99m}Tc , ^{186}Re , and ^{188}Re -labeled proteins and peptides, including octreotide.

EXPERIMENTAL SECTION

General Comments. The following reagents were purchased from the commercial sources indicated and used as received: acetylferrocene, 1,1'-diacetylferrocene, *O*-(*N*-succinimidyl)-*N,N,N',N'*-tetramethyluronium tetrafluoroborate, 1-hydroxybenzotriazole, 1-hydroxy-7-azabenzotriazole, dicyclohexylcarbodiimide, pH 9 buffer (Hydriion), from Aldrich; chromium hexacarbonyl from Alfa; chromium(III) chloride from Strem; ammonium pertechnetate from Alan Davison, MIT; and bovine serum albumin, leucine enkephalin, substance P, oxytocin, and

Sephadex G-25 superfine gel from Sigma. Diisopropylethylamine and dimethylformamide were purchased from Aldrich and distilled from CaH_2 and MgSO_4 , respectively. Boc-protected octreotide was provided by M. J. Welch, Washington University. 1,1'-Bis(carbomethoxy)ferrocene was prepared as described elsewhere (1).

General Procedure for Double Ligand Transfer

Reactions. Cautionary Note. Pressure tubes were placed within a specially made solid aluminum block containing holes drilled deep enough to admit the tubes to about three-fourths of their height and wide enough to allow room for the addition of some mineral oil to ensure good thermal contact. The tubes and aluminum base were covered with a matching hollow aluminum screw cap, equipped with a small hole aligned with one drilled in the base (to the same depth as those for the pressure tubes) to hold a metal thermometer. This containment device minimized the potential danger of explosions during heating, allowed for the efficient stirring of the reactions, and enabled the reaction temperature to be monitored readily. All manipulation of sealed reaction tubes during and after the reactions were done with suitable protective equipment: blast shield, full-face visor, heavy gloves. Details of the procedure are described elsewhere (1). Briefly, $\text{NH}_4^{99g}\text{TcO}_4$ (0.0106 g, 0.0586 mmol), 1,1'-bis(methoxycarbonyl)ferrocene (0.1034 g, 0.342 mmol), $\text{Cr}(\text{CO})_6$ (0.0923 g, 0.419 mmol), and CrCl_3 (0.0249 g, 0.157 mmol) were combined in a 4 mL pressure tube containing a magnetic stir bar. Dry methanol (1 mL) was added, and the tube was sealed, heated to 165 °C over the course of an hour, and then cooled to -78 °C. The reaction mixture was transferred to a 15 mL disposable vial with CH_2Cl_2 and the solvent was evaporated under a stream of N_2 at 30 °C. The mixture was redissolved in a minimum of CH_2Cl_2 and purified by flash column chromatography (1:1 hexane:benzene) to give 0.0159 g (89%) of tricarbonyl(methoxycarbonylcyclopentadienyl)technetium (**2**). ^1H NMR (200 MHz, CDCl_3) δ ppm: 5.96 [t, J = 2.38 Hz, 2H, -CO-Cp- $\text{H}_2(\alpha)$], 5.27 [t, J = 2.16 Hz, 2H, -CO-Cp- $\text{H}_2(\beta)$], 3.79 (s, 3H, CpCOOCH_3). MS (EI): m/z 306 (M^+). Anal. Calcd for $\text{C}_{10}\text{H}_7\text{O}_5\text{Tc}$: C, 39.23; H, 2.30. Found: C, 39.35; H, 2.27.

Tricarbonyl(acetylcyclopentadienyl)technetium. The reactions were performed according to the general procedure and purified by flash column chromatography (4:1 hexane:ethyl acetate) to give 0.040 g (81%) of tricarbonyl(acetylcyclopentadienyl)technetium from diacetylferrocene, and 0.033 g (73%) from acetylferrocene. ^1H NMR (500 MHz, CDCl_3) δ ppm: 5.94 [t, J = 2.31 Hz, 2H, -CO-Cp- $\text{H}_2(\alpha)$], 5.31 [t, J = 2.30 Hz, 2H, -CO-Cp- $\text{H}_2(\beta)$], 2.33 (s, 3H, CpCOCH_3). ^{13}C NMR (125 MHz, CDCl_3) δ ppm: 193.36 (COCH_3), 90.50, 87.12 (C_5H_4), 90.31 (C ipso), 29.68 ($\text{Tc}(\text{CO})_3$), 26.53 (COCH_3). MS (EI): m/z 290 (M^+).

General Procedure for the Labeling of Bovine Serum Albumin

Serum Albumin. To a stirred solution of tricarbonyl(methoxycarbonylcyclopentadienyl)technetium (**2**) (1.4 mg, 0.0046 mmol) in dioxane (0.5 mL) was added an aqueous solution of NaOH (2 M, 0.5 mL). After 5 min, concentrated HCl was added dropwise until the reaction was acidic to litmus paper. The solvent was evaporated at 40 °C under a gentle stream of nitrogen, and the solid residue was redissolved in DMF (400 μL). Triethylamine (2 μL , 0.014 mmol) and *O*-(*N*-succinimidyl)-*N,N,N',N'*-tetramethyluronium tetrafluoroborate (5 mg, 0.017 mmol) were added, and the solution was stirred for 5 min. The reaction mixture, containing NHS active ester **8**, was then added to a solution of bovine serum albumin (38

mg, 0.000 55 mmol) in pH 9 buffer (6 mL), and the reaction vial was further rinsed with DMF (200 μ L) and pH 9 buffer (1.4 mL) to provide a final solution of 7.5% DMF in the pH 9 buffer. After stirring for 10 min, 10 μ L of the reaction mixture was purified by passing it through 5 cm of Sephadex G-25 Superfine gel in a disposable Pasteur pipet and eluting with pH 9 buffer. Sixty drops of eluent was collected in 10-drop fractions, with the first two fractions (20 drops) roughly corresponding to the column void volume as determined by the elution profile of Blue Dextran. The amount of radioactivity in each fraction was determined by scintillation counting of the fractions in solutions of Aquasol (12 mL) scintillation fluid. An incorporation yield of at least 50% was determined by comparing the total activity in all fractions to the activity in the first three fractions.

Reactions performed according to the above procedure showed an incorporation yield of 5% from 1.34 mg (0.004 38 mmol) tricarbonyl(methoxycarbonylcyclopentadienyl)technetium and 3.81 mg (0.0552 μ mol) BSA and at least 70% from 1.16 mg (0.0038 mmol) tricarbonyl(methoxycarbonyl cyclopentadienyl)technetium and 309 mg (0.00447 mmol) BSA. A graphical representation of the elution profiles is shown in Figure 2.

Analytical Methods. Reversed-phase (C_{18}) HPLC analyses were performed using a Vydac C_{18} column (4.6 mm $\times$ 25 cm) at a flow rate of 1.5 mL/min. Gradients were performed with mobile phases A (0.1% TFA in H_2O) and B [0.1% TFA in acetonitrile/0.1% TFA in H_2O (10:1)] under conditions described in the individual reactions below. UV detection was performed at either 254 or 280 nm.

General Peptide Labeling Procedure. To a stirred solution of tricarbonyl(methoxycarbonyl cyclopentadienyl)rhenium (0.25 mg, 0.06 μ mol) in dioxane (0.5 mL) was added an aqueous solution of NaOH (2 M, 0.5 mL). After 5 min, concentrated HCl was added dropwise until the reaction was acidic to litmus paper. The solvent was evaporated at 40 $^{\circ}$ C under a gentle stream of nitrogen, and the solid residue was redissolved in CH_2Cl_2 (300 μ L). 1,3-Dicyclohexylcarbodiimide (0.5 mg, 2.4 μ mol) and 1-hydroxybenzotriazole (0.9 mg, 6.7 μ mol) were added, and the solution was stirred for 5 min. Reversed-phase (C_{18}) HPLC analyses were performed using the following gradient: 20% B for 1 min, 20% B to 30% B in 1 min, 30% B for 1 min, 30% B to 50% B in 2 min, and 50% B to 60% B in 10 min, which showed that the activation step to form the HOBt ester **11a** was complete [see Figure 3 (panel A)]. Leucine enkephalin (0.7 mg, 1.1 μ mol) and diisopropylethylamine (1 μ L) were added, and the reaction was stirred for 20 min, at which time RP-HPLC indicated the formation of CpTR/leucine enkephalin coupled product (rt = 9.0 min) in a yield of 70% [Figure 5 (panel A)]. The peak at 9.0 min, corresponding to the CpTR-labeled leucine enkephalin **13a**, was collected and concentrated in vacuo. Comparison of the ^1H NMR (300 MHz, $CDCl_3$) of the isolated product with leucine enkephalin revealed the following new peaks (δ ppm): 6.26 and 6.11 [d, J = 1.58 Hz, 2H, $-CO-Cp-H_2(\alpha)$], 5.54 and 5.51 [d, J = 1.95 Hz, 2H, $-CO-Cp-H_2(\beta)$]. MS (FAB): m/z 940 ($M + Na$) $^+$, 962 ($M + 2Na$) $^+$.

CpTR Labeling of Oxytocin. The reaction was performed according to the general procedure, with two changes: (a) 1-hydroxy-7-azabenzotriazole (1 mg, 7.4 μ mol) was used instead of 1-hydroxybenzotriazole (HOBt) (see Figure 3, Panel B for an HPLC trace of the HABT active ester **11b**), and (b) DMF (50 μ L) was added to the activated ester at the same time as the diisopropylethylamine (1 μ L) and oxytocin (0.5 mL, 0.47 μ mol). The

reaction was analyzed by RP-HPLC with the gradient of the general procedure, which revealed a new peak attributed to N-terminally CpTR-labeled oxytocin **13b** [70%, Figure 5 (panel B)] from tricarbonyl(methoxycarbonylcyclopentadienyl)rhenium (0.25 mg, 0.66 μ mol).

CpTR Labeling of Substance P. The reaction was performed according to the general procedure, with one change: DMF (50 μ L) was added to the activated ester at the same time as the diisopropylethylamine (1 μ L) and substance P (0.6 mg, 0.4 μ mol). The reaction was analyzed by RP-HPLC using the gradient of the general procedure, which revealed two new peaks of equal intensity attributed to N-terminally and lysine CpTR-labeled substance P **13c** [75%, Figure 5 (panel C)] from tricarbonyl(methoxycarbonylcyclopentadienyl)rhenium (0.25 mg, 0.66 μ mol).

CpTR Labeling of Boc-Octreotide. The reaction was performed according to the general procedure, with the following changes: (a) 1-hydroxy-7-azabenzotriazole (1 mg, 7.4 μ mol) was used instead of 1-hydroxybenzotriazole (HOBt), and (b) a methylene chloride solution of the newly formed active ester **11b** was added to a vial containing solid Boc-octreotide **14b** (150 μ g, 0.1 μ mol), and the solvent was evaporated at 40 $^{\circ}$ C under a gentle stream of nitrogen. DMF (100 μ L) and diisopropylethylamine (1 μ L) were added, and the reaction was stirred for 20 min. The reaction was analyzed by RP-HPLC using a gradient of 50% B to 70% B over 20 min. A new peak attributed to N-terminally CpTR-labeled Boc-octreotide **15a** [80%, Figure 7 (panel A)] was obtained from the original tricarbonyl(methoxycarbonylcyclopentadienyl)rhenium (0.125 mg, 0.33 μ mol). The peak was collected and concentrated in vacuo. MS (MALDI): m/z 1503 ($M + Na$) $^+$.

Deprotection of CpTR-Boc-Octreotide. CpTR-Boc-octreotide **15a** ($\leq$ 150 μ g, 0.1 μ mol) was dissolved in a 95% solution of trifluoroacetic acid in H_2O (100 μ L) and stirred for 2 min. The reaction was then quenched with water (100 μ L) and analyzed by RP-HPLC, again using a gradient of 50% B to 70% B in 20 min. A new peak attributed to N-terminally CpTR-labeled octreotide **15b** [90%, Figure 7 (panel B)] was collected and concentrated in vacuo. HR-FAB-MS m/z calcd for $C_{58}H_{69}N_{10}O_{14}S_2NaRe$: 1403.389151. Found: 1403.391400 [Δ -1.6 ppm, ($M + Na$) $^+$].

CpTT Labeling of Boc-Octreotide. The reaction was performed according to the general procedure, with the following changes: (a) tricarbonyl(methoxycarbonylcyclopentadienyl)technetium (15 μ g, 0.05 μ mol) was used instead of tricarbonyl(methoxycarbonylcyclopentadienyl)rhenium as the starting material; (b) 1-hydroxy-7-azabenzotriazole (0.1 mg, 0.7 μ mol) was used instead of 1-hydroxybenzotriazole (HOBt); and (c) a methylene chloride solution of the newly formed active ester **11b** was added to a vial containing solid Boc-octreotide **14b** (50 μ g, 0.03 μ mol), and the solvent was evaporated at 40 $^{\circ}$ C under a gentle stream of nitrogen. DMF (100 μ L) and diisopropylethylamine (1 μ L) were added, and the reaction was stirred for 30 min. The reaction was analyzed by RP-HPLC using a gradient of 45% B to 65% B in 20 min. A new peak attributed to N-terminally CpTT-labeled Boc-octreotide **16a** (80%, 14.6 min) was collected and concentrated in vacuo. MS (FAB): m/z 1414 ($M + Na$) $^+$, 1431 ($M + K$) $^+$.

Deprotection of CpTT-Boc-Octreotide. CpTT-Boc-octreotide **16a** ($\leq$ 50 μ g, 0.03 μ mol) was dissolved in a 95% solution of trifluoroacetic acid in H_2O (100 μ L) and stirred for 2 min. The reaction was then quenched with water (100 μ L) and analyzed by RP-HPLC, again using

a gradient of 45% B to 65% B in 20 min. A new peak attributed to N-terminally CpTT-labeled octreotide **16b** (90%, 10.0 min) was collected and concentrated in vacuo. MS (MALDI): m/z 1294 ($M + H$)⁺.

ACKNOWLEDGMENT

We are grateful for the support of this research through grants from the National Institutes of Health (PHS 5R01 CA25836) and the Department of Energy (DE FG02 86ER60401). We are grateful to A. Davison and M. J. Welch for providing us with research materials and to C. J. Anderson and M. Lanahan for providing Boc-octreotide.

⁹⁰Yttrium-Labeled Complementarity-Determining-Region-Grafted Monoclonal Antibodies for Radioimmunotherapy: Radiolabeling and Animal Biodistribution Studies[†]

Serengulam V. Govindan,[‡] Lisa B. Shih,[‡] David M. Goldenberg,[§] Robert M. Sharkey,[§] Habibe Karacay,[‡] Joseph E. Donnelly,[‡] Michele J. Losman,[‡] Hans J. Hansen,[‡] and Gary L. Griffiths^{*,‡}

Immunomedics, Inc., 300 American Road, Morris Plains, New Jersey 07950, and Garden State Cancer Center, Belleville, New Jersey 07109. Received April 21, 1998; Revised Manuscript Received July 21, 1998

⁹⁰Yttrium-labeled monoclonal antibodies (mAbs) are likely to be important to radioimmunotherapy (RAIT) of a variety of cancers. The goal of this study was to select and evaluate a form of [⁹⁰Y]mAb suitable for RAIT and determine conditions for high-yield, reproducible radiolabelings. ⁹⁰Y-Labelings, at 2–40 mCi levels, of cdr-grafted versions of anti-B-cell lymphoma (hLL2) and anti-CEA (hIMMU-14) mAbs were optimized to >90% incorporations using the macrocyclic chelator DOTA as the metal carrier. In vitro challenge assays, the stability of mAbs labeled with [⁹⁰Y]DOTA was better than that of the corresponding [⁹⁰Y]benzyl-DTPA conjugates. The retention of [⁹⁰Y]DOTA-hLL2 on Raji tumor cells in vitro was similar to that of the same mAb labeled with [⁹⁰Y]benzyl-DTPA and was about twice as much as with [¹²⁵I]hLL2, indicating residualization of metalated mAb. Both [⁹⁰Y]-hLL2 conjugates, prepared using DOTA and Bz-DTPA, had similar maximum tolerated doses of 125 μ Ci in BALB/c mice and showed no discernible chelator-induced immune responses. Animal biodistribution studies in nude mice bearing Ramos human B-cell lymphoma xenografts revealed similar tumor and tissue uptake over a 10 day period, with the exception of bone uptake which was up to 50% lower for [⁸⁸Y]DOTA-hLL2 compared to [⁸⁸Y]Bz-DTPA-hLL2 at time points beyond 24 h. With [⁹⁰Y]DOTA-hLL2 fragments, in vivo animal tumor dosimetries were inferior to those for the IgG, and kidney uptake was relatively high even with D-lysine administration. The ability of [¹¹¹In]-DOTA-hLL2 to accurately predict [⁹⁰Y]DOTA-hLL2 biodistribution was established. These preclinical findings demonstrate that [⁹⁰Y]DOTA-(CDR-grafted) mAbs are suitable for examination in clinical RAIT.

INTRODUCTION

RAIT¹ using radiolabeled mAbs has shown considerable promise against radiosensitive cancers such as NHL (1–6). Its role as a treatment against solid tumors has

yet to be clearly defined, but clinical and preclinical results obtained using unlabeled mAbs (7), radiolabeled mAbs alone (8), and radiolabeled mAbs along with chemotherapy (9) suggest that useful roles will also be identified in the treatment of at least some solid tumors. For adequate testing of RAIT and RAIT-related treatment modalities, high-quality radiolabeled mAbs must be made available.

As far as the antibody part of any radioimmunoconjugate is concerned, because of the induction of human anti-mouse antibody (HAMA), particularly in patients treated with multiple doses of murine antibodies (10), CDR-grafted (humanized) mAbs (hmAbs), comprising over 90% human sequence homology, are preferred over murine or chimerized versions of mAbs. Two such hmAbs were prepared in our laboratories using the same human framework, and each was described in detail with regard to its binding properties compared to the original murine versions. They are hIMMU-14 (anti-carcinoembryonic antigen mAb, anti-CEA) (11) and hLL2 (anti-lymphoma mAb, anti-CD22) (12).

¹³¹Iodine has been the most widely used nuclide for RAIT studies, but its principal 364 keV, 81% abundant, γ emission and 8 day half-life will engender substantial levels of nonspecific toxic radioactivity being received by the recipient. Indeed, it has been estimated that up to one-half to two-thirds of the energy deposited from ¹³¹I-labeled antibodies is due to penetrating γ emissions (13). The use of fragments (14) and antibody constructs (15) have been proposed to improve the therapeutic ratios

obtained with ^{131}I -based RAIT, although both approaches involve the adoption of radioimmunoconjugates with somewhat reduced tumor uptake, even when such fragments are chemically cross-linked to enhance stability (16). Another aspect to consider is the fact that certain mAbs are internalized, and when radioiodinated versions of these mAbs are used, radioiodine is not retained substantially in tumor after intracellular metabolism (17, 18).

Of the available nuclides that can be reasonably considered as alternatives to ^{131}I for RAIT, the pure β -particle-emitting ^{90}Y is one of the most promising. Its lack of γ emissions will be advantageous in terms of target-localized radiation as well as general radiation safety. Its half-life could be suited for use with a $\text{F}(\text{ab}')_2$ fragment, but like all radiometals used with antibody fragments, ^{90}Y tends to accumulate in kidney postinjection (19). Pretreatment with basic amino acids (20, 21) will reduce renal accretion substantially in animals and to some degree in humans, but there is still a significant portion of the injected fragment-associated-radioactivity retained.

Among the bifunctional chelates useful for ^{90}Y labeling of proteins, those based on the macrocycle DOTA produce the most stable complexes (22). However, a number of articles have pointed out the difficulties of obtaining reproducibly high yields of ^{90}Y -DOTA-mAb conjugates (22–24), and for this reason, bifunctional chelates based on Bz-DTPA and its derivatives are still in widespread use (25). In addition, there have been reports of immune responses to both types of chelate in previously published works (26, 27), although use of a syngeneic mAb with either chelate has been predicted to be minimally immunogenic (28).

The goal of this work was to choose a ^{90}Y chelator and a form of CDR-grafted mAb (intact or fragment) in ^{90}Y -mAb for eventual clinical application. For mAb labelings with radioyttrium, we set out to choose between DOTA and Bz-DTPA as preferred metal chelator on the basis of comparative *in vitro* and *in vivo* behavior of ^{90}Y -DOTA-mAb and the corresponding ^{90}Y -Bz-DTPA-mAb conjugates. The optimal conditions for the preparation and radiometal labelings of mAb-Bz-DTPA conjugates were already established (29). Optimization of mAb-DOTA conjugate preparation and radiolabeling was examined in this study. DOTA conjugation and ^{90}Y radiolabelings of two CDR-grafted mAbs were examined, and their *in vitro* stabilities and tumor cell bindings were compared with those of the corresponding ^{90}Y -Bz-DTPA-mAb conjugates. The ^{88}Y -labeled DOTA and Bz-DTPA conjugates of a CDR-grafted mAb, hLL2, were also compared in *in vivo* animal studies, in terms of biodistribution in tumor-bearing mice, immune responses to chelates, and maximum tolerated dose in normal mice. Finally, we determined whether an ^{111}In -mAb agent was predictive of the corresponding ^{90}Y -mAb biodistribution (30) and whether ^{90}Y -labeled fragments, used with D-lysine administration, might be superior to a comparably labeled IgG, using a humanized mAb.

EXPERIMENTAL PROCEDURES

General Procedures. Intact and fragment forms of mAbs used in this study were obtained from Immunomedics' antibody production laboratories. DOTA was purchased from Parish Chemical Co. (Orem, UT). All other chemicals, of high-purity grades, were obtained from commercial sources and used without further purification. Yttrium-90 chloride was purchased from

Pacific Northwest National Laboratory (Richland, WA) and, during the initial phase of the work, from NEN Life Science Products (Boston, MA). Indium-111 chloride was from NEN, while yttrium-88 chloride was from Los Alamos National Laboratory (Los Alamos, NM). HPLC analyses were performed on a Bio-Sil SEC-250 analytical column connected to a guard column (Bio-Rad Laboratories, Hercules, CA) and fitted with in-line UV and radiomatic detectors using 0.2 M sodium phosphate buffer, pH 6.8, as mobile phase at a flow rate of 1 mL/min. Cell lines were obtained from the American Type Culture Collection (Rockville, MD), and were routinely tested for mycoplasma by the Mycotect assay (Life Technologies, Gaithersburg, MD).

Preparation of DOTA Conjugates. A procedure based on the work of Lewis et al. (23) was adopted and modified. Briefly, antibodies were rendered metal-free, and exchanged with conjugation buffer in a sequence of dialyses or diafiltrations with 20 mM DTPA/0.25 M ammonium acetate, pH 7.0, 0.25 M ammonium acetate, pH 7.0, and 0.1 M potassium phosphate-0.1 M sodium bicarbonate, pH 8.5 buffers. Activated DOTA was prepared (4 °C, 45 min) using DOTA, sodium bicarbonate, sulfo-NHS, and EDC at 10:30:10:1 molar ratios. Conjugation was carried out by adding a 90-fold molar excess of activated DOTA to IgG, or a 30–50-fold molar excess to mAb fragments, adjusting pH to be in the 8.1–8.3 range, and incubating for 18 h at 4 °C. Purification was achieved by a series of dialyses or diafiltrations with 20 mM DTPA/0.25 M ammonium acetate, pH 7.0, and then with 0.25 M ammonium acetate, pH 5.4. The final conjugates, suitably concentrated, were filtered through 0.22 μm filters and stored under sterile conditions. A published procedure (31) involving conjugate labeling with a known excess of indium acetate, spiked with ^{111}In , was used to determine DOTA MSRs. Variations in conjugation chemistry examined included coupling pH (7.5, 8.0, and 8.5) and molar excess of activated DOTA to mAb used (40, 100, or 500). Preparation of Bz-DTPA-hLL2 conjugate was based on the procedure described previously (29).

Comparison of Affinities of DOTA-Conjugated and Unmodified mAbs. Competitive binding assays were carried out using Raji cells (a human Burkitt lymphoma cell line) and CEA as the source of antigens for hLL2 and hIMMU-14, respectively. For hLL2, a 96-well filtration plate fitted with a microporous (0.45 μm pore) hydrophilic membrane assembly (Millipore, Milford, MA) was used to incubate a 0.1 mL suspension of Raji cells (~200 000) with a fixed concentration of ^{125}I murine LL2 (~500 000 cpm) and varying concentrations (0.1–100 $\mu\text{g}/\text{mL}$) of competitors (murine LL2 control or DOTA conjugate of hLL2). After gently shaking the assembly for 2.5 h at ambient temperature, the well contents were drained by vacuum, and the wells were washed three times with 0.2 mL of 10 mM PBS, pH 7.4, and 1%BSA. Membrane-bound residual ^{125}I activity was determined in a γ counter, and the readings were corrected for nonspecific membrane binding. The latter was determined using a control consisting of ^{125}I mLL2 in the same final volume but without the antigen. Duplicate measurements were made, and the average residual bindings were plotted as a function of competitor concentrations. For hIMMU-14 substrates, an IMMU-14 blocking assay was performed as follows. ELISA plates were coated with CEA (Calbiochem, San Diego, CA) at a concentration of 2.5 $\mu\text{g}/\text{mL}$ and incubated for 1 h at 20 °C. HRP-conjugated murine IMMU-14, at a concentration of 200 ng/mL, was mixed with varying concentrations

of murine IMMU-14 (control) or hIMMU-14-DOTA conjugate, added to CEA-coated ELISA plates, and incubated for 1 h at 20 °C. CEA binding of HRP-conjugated IMMU-14 was determined with a substrate solution containing 0.0125% of H₂O₂ and 0.004 M *O*-phenylenediamine dihydrochloride. Each measurement was the mean of duplicate experiments.

Radiolabelings. In optimizing [⁹⁰Y]mAb yields, the DOTA MSR, pH (5–6 range), incubation time (up to 2.5 h), use of ascorbic acid as a radioprotectant, and the effect of trace metal contaminants in commercial ⁹⁰Y were examined. In an optimized radiolabeling, the DOTA conjugate, at a concentration of 3–10 mg/mL, was added to yttrium-90 acetate (obtained by buffering yttrium-90 chloride with 0.25 M ammonium acetate pH 5.4), so as to achieve a specific activity in the range 1–5 mCi/mg. Freshly prepared aq ascorbic acid (0.25 g of ascorbic acid dissolved in 1 mL of water) was added to the labeling mixture at 27 μL/mL of the labeling volume and heated at 45 °C (bath) for 2 h. The final ascorbic acid concentration was ~6 mg/mL. The solution was made 10 mM in DTPA using aq 0.1 M DTPA (pH 6–7), and heated for 20–30 min at the same temperature. The radiolabeled mAb was diluted to ~1 mCi/mL using ABS buffer. ¹¹¹In and ⁸⁸Y radiolabelings were carried out in a similar fashion, except the specific activities of [⁸⁸Y]mAbs were ~0.1 mCi/mg. Radiolabel incorporations in the latter categories were usually 90% or greater, but yields of less than 90% were observed in some ⁸⁸Y labelings. For this reason, the radiolabeled mAbs for *in vivo* studies were routinely purified by centrifuged-size-exclusion column purification using Sephadex G50/80 equilibrated in 0.1 M sodium acetate, pH 6.5. These conjugates were at least 95% pure by ITLC and HPLC; the remainder was present as EDTA- or DTPA-bound isotope.

In Vitro Stability. Purified [⁹⁰Y]DOTA-mAb (~16–25 μCi, in ~4–6 μL) was added to 0.55 mL of fresh human serum, which was made 0.02% in sodium azide, and incubated at 37 °C. The substrate concentration was 170 nM for hLL2 and 143 nM for hIMMU-14. In a similar fashion, radiolabeled preparations (~14–18 μCi, in ~3–6 μL) were added to 0.55 mL of 1 mM DTPA/1% HSA in 25 mM ammonium acetate/150 mM saline, pH 6.4, and incubated at 37 °C. The DTPA in the latter medium was in 10325-fold and 6244-fold molar excess with respect to hLL2 and hIMMU-14, respectively. Aliquots of serum and DTPA incubates were analyzed, on size-exclusion analytical HPLC, over a 10 day period. Serum aliquots were briefly challenged with DTPA (1 mM) prior to HPLC analyses. Analyses consisted of determining the percent of radioactivity associated with the antibody. This was accomplished by complexing the antibody with a 100-fold molar excess of either an anti-idiotopic antibody, WN (32), for hLL2, or CEA (for hIMMU-14), either of which converted radiolabeled antibody to a higher MW component (hLL2:WN complex or hIMMU-14:CEA complex), appearing as an earlier eluting peak on SE-HPLC. This method separated, by HPLC retention time, [⁹⁰Y]DOTA-mAb from serum proteins such as albumin and transferrin. Loss of label to serum proteins, as well as loss of label as free metal ion (analyzed as [⁹⁰Y]DTPA), were then determined from integrations of all HPLC peaks. In a separate experiment, [⁹⁰Y]DOTA-hLL2 was compared with [⁹⁰Y]Bz-DTPA-hLL2 for stability in serum and 1 mM DTPA, over an 11 day period at 37 °C, using 5–7 μg of radiolabeled conjugate and 0.55 mL of serum or DTPA, as described above.

In Vitro Retention of [⁹⁰Y]hLL2 on Lymphoma Cells. For these studies, a DOTA conjugate, as well as a Bz-DTPA conjugate derived from ITC-Bz-DTPA, of hLL2-IgG were radiolabeled at over 90% incorporation. The radiolabeled conjugates were made 10 mM in DTPA (for DOTA conjugate) or EDTA (for Bz-DTPA conjugate) to chelate unbound radiometal. ¹²⁵I-Labeled hLL2 (or [¹²⁵I]mLL2) was prepared using a chloramine-T procedure (33). Raji cells (American Type Culture collection, Rockville, MD) were cultured in Dulbecco's Eagle Medium (Life Technologies, Grand Island, NY) supplemented with 10% fetal bovine serum, 5% horse serum, and 1% pyruvate, penicillin/streptomycin and glutamine, in a 5% CO₂ atmosphere. Cells were allowed to grow to confluence. For binding studies, cells (5 × 10⁵ to 1 × 10⁷) in cell culture media were treated with ~10–50 μCi of [⁹⁰Y]mAb conjugate (5–25 μg) and incubated at 37 °C for 2 h. The cells were separated from supernatant by centrifugation at 1500 rpm for 6 min, washed three times with cold media, resuspended in media, and incubated at 37 °C. At periodic intervals over 40 h, aliquots were withdrawn, centrifuged to separate cells from the supernatant, and the radioactivity associated with each was counted using appropriate windows set for ⁹⁰Y and ¹²⁵I. The percent of cell-associated radioactivity was thus calculated for each time point. In general, measurements reflect the mean of triplicate samples. To determine the percent of cell-associated radioactivity internalized into tumor cells, aliquots of cell suspension at various time points (as described in the above experiment) were first chilled at 4 °C and then centrifuged. The cell pellet was then treated with 0.1 M sodium acetate/0.1 M glycine at pH 3 for 30 min at 40 °C, then spun down and separated prior to counting. In these experiments, [¹²⁵I]hLL2 was used as a comparative substrate and [⁹⁰Y]IMMU-14 was used as nonspecific control.

Animal Experiments. All animal experiments were carried out under approved IACUC protocols. For hLL2 conjugates, 3–4 week old nude mice (Taconic, Germantown, NY) were quarantined for 2 weeks, and then injected s.c. with 5 × 10⁶ Ramos tumor cells grown in tissue culture. Tumor growth was visible after a further 2 week period, and animal experiments were started immediately thereafter. For biodistribution studies, 1–2 μCi of [⁸⁸Y]mAb or 10–20 μCi of [¹¹¹In]mAb was used for each tumor-bearing mouse. One experiment involved comparing [⁸⁸Y]DOTA-hLL2-IgG (SA, 0.06 μCi/μg; 2.3% aggregation; protein dose per animal, 17.4 μg) with [⁸⁸Y]-Bz-DTPA-hLL2-IgG (SA, 0.08 μCi/μg; 0% aggregation; protein dose per animal, 14.2 μg). A second experiment was a paired-label experiment involving targeting of [⁸⁸Y]DOTA-hLL2 (SA, 0.08 μCi/μg; 1.19 μCi/animal) and [¹¹¹In]DOTA-hLL2 (SA, 1.1 μCi/μg, 16.4 μCi/animal), with a total protein dose of 15 μg/animal. Corrections for the backscatter of ⁸⁸Y into the ¹¹¹In window were made in determining ¹¹¹In biodistributions. A third experiment consisted of two groups of animals administered with [⁸⁸Y]DOTA-hLL2 F(ab')₂ or [⁸⁸Y]DOTA-hLL2 Fab', with D-lysine administration (40 mg/mouse) given intraperitoneally 15 min before and 1, 2, and 3 h after the i.v. injection of radiolabeled conjugates. Each animal in this experiment received a protein dose of 21.3 μg [F(ab')₂ fragment] or 20.7 μg [Fab' fragment] and 1.0 μCi of ⁸⁸Y activity. A fourth experiment was the repetition of radiolabeled fragment biodistributions, as before, but without D-lysine administration. Necropsy was performed at 1, 3, 5, 7, and 10 days after radiolabeled IgG injection or at 4, 24, and 48 h after radiolabeled fragment

injection. At the indicated times, animals were anesthetized with sodium pentobarbital, bled by cardiac puncture, and then sacrificed. Tissues were weighed and the radioactivity was determined in a γ counter using appropriate windows. In each instance, counting standards were included for the determination of total injected radioactivity. The data were then calculated as a percentage per gram of the total injected activity.

For MTD experiments, 11 mg each of hLL2-DOTA-IgG and hLL2-Bz-DTPA-IgG were radiolabeled with 30 mCi of ^{90}Y activity. The radiochemical purity was 94% for the DOTA conjugate and 99% for the Bz-DTPA conjugate. Unbound ^{90}Y was present as [^{90}Y]DTPA in the DOTA conjugate and as [^{90}Y]EDTA in the Bz-DTPA conjugate. In each case, the radiolabeled mAb was diluted serially with ABS buffer to obtain the desired microcurie amount in a final volume of 0.15 mL. Radioactivity contained in the injectate volume in each case was determined by counting suitably diluted samples in a β -counter. Eighty-four normal BALB/c mice were sorted into six groups of seven animals, with animals in each group given 125, 150, 175, 200, 225, or 250 μCi of [^{90}Y]DOTA-hLL2 or [^{90}Y]Bz-DTPA-hLL2. Animal weights and mortality, postinjection of radiolabeled conjugates, were recorded over time.

To examine the immunogenicity of DOTA and Bz-DTPA, forty-eight normal BALB/c mice were divided into four groups of 12 animals each. Animals in each group received either murine LL2-IgG or LL2 F(ab')₂ conjugates of DOTA (containing 3–4 chelates/mAb) or Bz-DTPA (containing 1–2 chelates/mAb), administered i.v. at 33 $\mu\text{g}/\text{mouse}$. After 3 weeks, four mice in each group were anesthetized, bled by cardiac puncture, and sacrificed by cervical dislocation. Serum samples were collected and stored frozen for subsequent analyses. The remaining mice in each group were readministered the respective substrates at the same dose of 33 $\mu\text{g}/\text{mouse}$. After a further 3 week period, again, four mice from each group were taken and serum samples collected and stored, while remaining mice in each group received a third dose of the conjugates. These mice were taken in turn after an additional 3 week period. Serum samples (50 μL) from individual mice were incubated with 100 ng (10 μL) of [^{125}I]mLL2-Bz-DTPA and [^{125}I]mLL2-DOTA, in a total volume made up to 100 μL with 5% HSA, at 37 $^{\circ}\text{C}$ for 1 h. The samples were then analyzed, by SE-HPLC, for their ability to form immune complexes with added radiolabeled conjugates.

RESULTS AND DISCUSSION

Development of suitable bifunctional chelating agents for ^{90}Y has evolved from using DTPA cyclic anhydride (34), to backbone-substituted bifunctional DTPAs (Bz-DTPA, MX-DTPA, and cyclohexyl-DTPA) (35, 36) and to chelates based on the macrocyclic chelating agent DOTA (37). The exceptional kinetic inertness of DOTA-type chelates has been documented (38). Such stability portends well for RAIT applications, as any dissociation of ^{90}Y from mAb-chelate conjugates can result in a portion of this radioactivity being bound in cortical bone, which could increase the level of myelotoxicity associated with these agents. The routine use of DOTA-mAb conjugates has been hampered by required lengthy syntheses of DOTA bifunctional chelates and subsequent difficulties in ^{90}Y radiolabeling of DOTA-mAb conjugates. Lewis et al. (23) addressed these problems by using in situ-generated monoactivated DOTA for mAb conjugation, which obviated a long synthesis, and by employing a

Figure 1. Comparisons of immunoreactivities of hLL2-DOTA conjugates with that of unmodified antibody, determined in competitive binding assays using Raji cells as the source of antigen. The competitive binding of hLL2 conjugate with a DOTA MSR of 3.7 ($\blacktriangle$) is similar to that of unmodified hLL2 ($\square$). The conjugate with a DOTA MSR of 6.7 ($\circ$) exhibits a somewhat reduced competitive binding.

higher temperature ^{90}Y -labeling of a mAb-DOTA conjugate. By conducting the radiolabelings at 43 $^{\circ}\text{C}$, a 59% ^{90}Y incorporation was obtained for a cT84.66-DOTA mAb conjugate.

We have optimized this methodology for our own humanized DOTA-mAbs, using a 90–100-fold molar excess of activated DOTA for IgGs and a 40–50-fold molar excess of activated DOTA for F(ab')₂ and Fab' fragments. The DOTA:mAb MSRs for our conjugates were determined by the method of Meares et al. (31) using ^{111}In -spiked indium. At a given molar excess of DOTA-NHS used in conjugations, variations of pH in the 7.5–8.5 range did not affect the final DOTA MSR. The MSR was influenced by the molar excess of activated DOTA used in conjugations. At pH 8.0–8.3, a 100-fold molar excess of DOTA gave a substitution ratio of 3.7–3.9 for hLL2, while a 500-fold excess of DOTA gave a MSR of 9.0. With hIMMU-14, typically 4–5 DOTAs were introduced under the same conditions, using 100-fold excess of monoactivated DOTA. For hLL2-F(ab')₂ and hLL2 Fab', DOTA substitutions of 3.6 and 1.5, respectively, were obtained using a 40–50-fold molar excess of activated DOTA. By comparison, the average number of Bz-DTPA groups on hLL2, in the hLL2-Bz-DTPA conjugate, was 1.5.

Competitive Binding Assays. The effect of MSR on immunoreactivity was examined for conjugates of hLL2 and hIMMU-14 by competitive binding assays on Raji cells and CEA, respectively. Figure 1 shows competitive binding to Raji cells of hLL2 (control) and two hLL2-DOTA conjugates differing in the DOTA MSR. Figure 2 shows results from an ELISA assay involving residual binding, to CEA, of HRP-conjugated IMMU-14 as a function of competitor concentration against either hIMMU-14-DOTA substituted at a 4.4:1 ratio or murine IMMU-14 as control. For the hLL2 conjugate, the binding profiles for a conjugate with 3.7 DOTA is similar to that of unmodified hLL2, whereas a DOTA substitution of 6.7 leads to a somewhat reduced competitive inhibition (Figure 1). The CEA-blocking experiment (Figure 2) showed that a hIMMU-14-IgG-DOTA conjugate, with a DOTA MSR of 4.4, had a target binding profile identical to that of control IMMU-14. For a murine IMMU-14-DOTA conjugate containing 6.8 DOTAs, competitive binding to CEA was similar to that of unsubstituted IMMU-14 (not shown). While the limit of DOTA substitution beyond which a reduction in immunoreactivity is observed is seen to be antibody dependent,

Figure 2. Comparison of immunoreactivity of hIMMU-14-DOTA conjugate with DOTA MSR of 4.4 (▲) with that of unmodified IMMU-14 (○), determined in a CEA-blocking assay. The competitive binding profiles of the two are very similar.

Table 1. Representative Incorporations of ⁹⁰Y into IgG-DOTA Conjugates

conjugate	mCi	specific activity (mCi/mg)	incorporation (%) by HPLC	
			IgG	aggregate
hIMMU-14-IgG	2.3 ^a	4.6	94.7	5.0
	2.8 ^a	2.8	93.6	5.2
	4.0 ^a	4.7	93.2	3.6
	4.9 ^a	3.3	91.3	6.5
	13.0 ^b	3.4	94.3 ^c	0.7
	22.0 ^b	2.2	99.5 ^d	0

	30.0 ^b	2.7	94.4 ^e	1.6
	32.2 ^b	2.9	99.4 ^f	0
	45.0 ^b	4.1	98.6 ^g	0

^a Ascorbic acid was not used. ^b Ascorbic acid was used at a concentration of ~6 mg/mL, in these labelings. ^c ITLC incorporations of 96.3% were observed in these findings. ^d ITLC incorporations of 97.0% were observed in these findings. ^e ITLC incorporations of 94.5% were observed in these findings. ^f ITLC incorporations of 97.9% were observed in these findings. ^g ITLC incorporations of 97.6% were observed in these findings.

apparently even in mAbs having the same human framework, we conclude that DOTA substitution in the 3–5 range would generally be well tolerated.

⁹⁰Y Radiolabelings. Maximizing the DOTA:mAb substitution ratios, consistent with the preservation of tumor targeting properties, provided the best opportunity for near-quantitative ⁹⁰Y incorporations under optimized labeling conditions. Optimal radiolabeling conditions involved adding the desired radioactivity of yttrium-90 chloride buffered with 0.25 M ammonium acetate, pH 5.4) to the conjugate containing aq ascorbic acid (~6 mg/mL) and incubating at 45 °C for 2 h. The final conjugate concentration was 3–12 mg/mL (the range of concentrations examined), and the pH was approximately in the 5.0–5.4 range. Table 1 shows typical yields for ⁹⁰Y labelings of hIMMU-14- and hLL2-DOTA, using 2.3–45 mCi of ⁹⁰Y. Initially, ascorbic acid was not used during radiolabeling, but we found that addition of ascorbic acid during labeling significantly reduced aggregation (Table 1). During the course of our work, Chakrabarti et al. (39) reported on the use of ascorbic acid as a radioprotectant during ⁹⁰Y labelings. These workers found that the immunoreactivity of a 100 μg sample of a ¹²⁵I-labeled murine mAb was reduced by about 65–90% in the presence of 320–640 Gy doses of [⁹⁰Y]DTPA (1.1–2.2 mCi), but the immunoreactivity was completely restored when the same experiment was conducted in the presence of ~0.2–11 mg/mL concentration of ascorbic acid.

Incorporation of ⁹⁰Y into DOTA-mAb conjugates was

Figure 3. In vitro stabilities of [⁹⁰Y]DOTA-hIMMU-14 in serum (□) and in 1 mM DTPA/1% HSA (Δ) and of [⁹⁰Y]DOTA-hLL2 in serum (▲) and in 1 mM DTPA/1% HSA (○). The y-axis scale is displayed in a narrow range of 95–101%.

found to be affected by trace metal contaminants in the yttrium-90 chloride used. Stimmel et al. (24) have studied the role of ferrous, zinc, and calcium ions on the efficiency of ⁹⁰Y incorporation into free macrocyclic and acyclic ⁹⁰Y chelators. Their quantitative analyses showed that ⁹⁰Y chelation is most sensitive to the presence of trace levels of zinc and, to a lesser extent, ferrous and calcium ions. We found the same connection between ⁹⁰Y yields into DOTA-mAb conjugates and trace metal contaminants in ⁹⁰Y shipments, with >10–50 ppm levels of contaminating trace metals, particularly zinc, being detrimental.

In Vitro Stability of [⁹⁰Y]hLL2-DOTA and hIMMU-14-DOTA. The stability of radiolabeled conjugates to serum and to DTPA challenge was examined using substrate concentrations of 140–170 nM in serum and DTPA/conjugate molar ratios of ~6000–10000:1. Incubations were kept at 37 °C for 10 days. At regular intervals, aliquots were analyzed by SE-HPLC. To separate radiolabeled IgG from other serum proteins, as well as from HSA in DTPA-challenge assays, aliquots of challenged material were complexed with CEA (in the case of hIMMU-14) or WN (anti-id mAb to hLL2; ref 32) prior to HPLC analyses. As seen from Figure 3, the percentage of ⁹⁰Y associated with antibody was >98% over this time period, which affirmed the kinetic stability of these [⁹⁰Y]DOTA-mAb conjugates. In a separate experiment, 0, 0, and 0.4% of the radioactivity (analyzed as the [⁹⁰Y]DTPA by HPLC) were found to be dissociated from the [⁹⁰Y]DOTA-hLL2 conjugate when incubated in serum at 37 °C and analyzed after 18 h, 5 d, and 11 d, respectively. Under the same conditions, 3.0, 3.6, and 10.7% of the radioactivity (analyzed as the [⁹⁰Y]EDTA by HPLC) were found dissociated from the [⁹⁰Y]Bz-DTPA-hLL2 conjugate after serum challenge. When incubated in 1 mM DTPA under the same conditions and analyzed over the same period of time, 0, 1, and 0.3% of the radioactivity of the DOTA conjugate and 1.6, 5.2, and 8.7% of the radioactivity of the Bz-DTPA conjugate of hLL2, respectively, were found unbound.

In Vitro Binding Studies of Radiolabeled hLL2 Conjugates. In vitro binding studies were carried out using ⁹⁰Y-labeled murine and humanized LL2 mAbs, along with the respective mAbs radioiodinated by the chloramine-T method (33), to compare binding, retention, turnover, and metabolism by Raji tumor cells (40). At time points out to 40 h, a higher percentage of the [⁹⁰Y]-hLL2 (12–70% higher, increasing with time), compared to radioiodinated hLL2, remained associated with the cells (Figure 4A). A small reduction in the percentage of retained activity was observed for [⁹⁰Y]DOTA versus [⁹⁰Y]Bz-DTPA conjugates of hLL2 (Figure 4A) in some

Figure 4. In vitro cell bindings of ^{90}Y -[Bz-DTPA]-hLL2 (■), ^{90}Y -DOTA-hLL2 (Δ) and ^{125}I -hLL2 (○) on Raji cells. (A) Percent of initially bound radioactivity still retained on cells at various times, and (B) percent of cell-bound radioactivity internalized into tumor cells at various times.

earlier experiments, but this difference was not noticed subsequently when the radiolabeling procedure included the use of ascorbic acid as radioprotectant (not shown). Percent of cell-bound mAb internalized at various times is shown in Figure 4B. At later time points, cells treated with ^{90}Y -DOTA-hLL2 and ^{90}Y -Bz-DTPA-hLL2 had between 50 and 60% of nonremovable cell-bound radioactivity, while those treated with ^{125}I -hLL2 had between 30 and 40% nonremovable activity. In a cell-binding experiment using ^{90}Y -Bz-DTPA-hLL2, the SE-HPLC of cell-culture supernatant showed a peak eluting with a retention time of 13.4 min, indicating that ^{90}Y was released from cells in a low MW form. This retention time was similar to that of ^{90}Y -DTPA, although the SE-HPLC would not distinguish it from ^{90}Y -DTPA-lysine adduct. Lysine adducts of metal chelates had been inferred to be the end products of antibody-chelate catabolism in the lysosomes (41). The bindings of ^{90}Y -

DOTA-hLL2 and ^{90}Y -Bz-DTPA-hLL2 were similar when continuously exposed to Raji, Daudi, or Ramos cell lines, as were the bindings observed for each of these conjugates, in the Raji cell line, using ~30 mCi level radiolabeling preparations (not shown). These findings implied that higher temperature DOTA conjugate labeling with high-energy ^{90}Y did not impair its cell-binding ability. Other experiments involving divalent fragments of murine and humanized LL2 showed similar trends of higher binding for ^{90}Y versus ^{125}I -labeled conjugates, while nonspecific controls (^{90}Y -Bz-DTPA-murIMMU-14 and other IMMU-14 derivatives) did not bind to Raji cells (not shown). This is the first extensive study involving radiolabeled conjugates of intact and fragment forms of hmAb, including comparisons with the murine counterparts and using three different cell lines (40). The results obtained are similar to in vitro tumor cell binding data reported for murine LL2 labeled with either a residualizing form of radioiodine or ^{111}In (42). Internalizations observed in Raji cell binding of ^{90}Y -hLL2 conjugates suggest that they should be preferred agents compared to iodinated hLL2 in targeting B-cell lymphoma.

In Vivo Experiments. For biodistributions involving radioyttrium, conjugates labeled with γ -emitting ^{88}Y were used to render determination of tissue-bound radioactivity more accurate. Tumor targeting and biodistribution of ^{88}Y -DOTA-hLL2 and ^{88}Y -Bz-DTPA-hLL2 were compared in s.c. Ramos tumor xenograft-bearing nude mice. Table 2 shows comparative biodistribution out to 10 days, which is 3.75 times ^{90}Y physical half-life. ^{88}Y -DOTA-hLL2 had 2.4, 1.8, 1.6, 1.4, and 1.0% injected dose/g (% ID/g) uptake in bone at 1, 3, 5, 7, and 10 days postinjection and the ^{88}Y -Bz-DTPA-hLL2 conjugate had 2.8, 3.4, 3.4, 2.7, and 3.6% ID/g in bone at the same times. As discussed by DeNardo et al. (43), these differences may be particularly significant when one considers clinical RAIT since human marrow volume is much larger than that of mouse, and the differences seen in these animals may be reflective of a larger toxicity difference in a clinical situation. Dosimetrically (44), per millicurie numbers derived from these data were 10 564, 8274, 6866, and 23 921 for ^{90}Y -DOTA-hLL2-IgG and 9901, 9579, 7403, and 27 124 for ^{90}Y -Bz-DTPA-hLL2 for blood, liver, bone, and Ramos tumor, respectively.

A second experiment compared biodistribution of ^{111}In -DOTA-hLL2 to ^{88}Y -DOTA-hLL2 (Table 3). This was a paired-label experiment which maintained identi-

cal animal and tumor weight conditions for both the labels. The ¹¹¹In radioconjugate very accurately predicted the blood clearance of the ⁸⁸Y conjugate with 11.3, 8.9, 4.9, 5.6, and 3.0% ID/g and 11.7, 9.3, 5.0, 5.7 and 3.2% ID/g at 1, 3, 5, 7, and 10 days postinjection, for the ¹¹¹In and ⁸⁸Y conjugates, respectively. As can be seen, the percent injected dose per gram and standard deviations for all other organs, particularly bone, at all time points were also remarkably similar. This finding is important in that at least one other study, with other mAb conjugates, has suggested that ¹¹¹In is not predictive of ⁹⁰Y biodistribution (45).

Tables 4 and 5 show animal data for [⁸⁸Y]DOTA-hLL2-F(ab')₂ and [⁸⁸Y]DOTA-hLL2-Fab', respectively, and in each case, biodistributions were determined with and without D-lysine administration. With radiometalated fragments, kidney uptake of the radiometal is a serious problem, and Behr et al. (20) and others (21) have shown that kidney radioactivity levels can be reduced by administering basic amino acids, such as lysine, with D-lysine recommended (20). Lysine dose selection and timing are in themselves problematic, as discussed by DePalatis et al. (21), in that timing of the lysine admin-

istration for Fab' and F(ab')₂ species is expected to be different. In our work, kidney levels decreased up to 5-fold in the case of the [⁸⁸Y]Fab' and somewhat less in the case of F(ab')₂, although kidney percent injected dose per gram then rose sharply between 4 and 24 h time points, from 19.89 to 29.11% ID/g for the Fab' and 19.93 to 39.31% ID/g for the F(ab')₂. The tendency to increased kidney percent injected dose per gram seems indicative of a need to continuously administer D-lysine beyond 3 h postinjection of the labels. For clinical applications, these D-lysine levels appear impractical. Even with lysine administration, dosimetry numbers remained adverse for both fragments at 1200, 5443, 17 129, and 1162 rads/mCi for [⁹⁰Y]DOTA-F(ab')₂ and 1536, 1497, 10 959, and 350 rads/mCi for [⁹⁰Y]DOTA-Fab' for Ramos tumor, liver, kidney and blood, respectively.

A MTD study was performed with ⁹⁰Y-labeled DOTA- and Bz-DTPA-IgG conjugates in normal BALB/c mice, using six increasing doses in the range 125–250 μ Ci. The MTD for both reagents was identical since all animals survived at a dose of 125 μ Ci, while with each reagent, three of seven died at the 150 μ Ci dose level. Two points are of significance here. First, these data differ from that

of DeNardo et al. (43) using radiolabeled Lym-1 antibody in that they found a significantly higher toxicity for their mAb when labeled with DTPA versus DOTA chelates. Second, the microcurie MTD amount of [^{90}Y]mAb using hLL2 in nude mice is much less than reported with other mAbs, which are usually in the 250 $\mu\text{Ci}/\text{animal}$ range (43).

The occurrence of immune response to DOTA chelate was first noticed (26) in the form of serum sickness in some patients in a phase I/II trial of i.p. therapy of ovarian cancer using a [^{90}Y]DOTA conjugate of murine mAb HMFG1 [[^{90}Y]2-IT-(s)-BAD-HMFG1]. In a detailed study of this phenomenon, Watanabe et al. (28) found that the carrier protein of the immunoconjugate played a significant role in eliciting anti-chelate responses. They found that when a rabbit IgG conjugate of the same bifunctional DOTA, in the form of ^{111}In -labeled conjugate, was injected into rabbits, no hapten immunogenicity was observed even when using a protein dose equivalent of 233 mg in 70 kg patient and a chelate/protein substitution ratio of 4.5:1. However, their study found the corresponding mouse IgG conjugate to be immunogenic when administered in rabbits. Watanabe et al. (28) concluded that the induction of chelate immunogenicity is observed when a conjugate of a foreign protein is administered, but not when the conjugate of same species mAb is used, and they further predicted that conjugates of humanized antibodies would be considerably less antigenic in humans than the murine forms.

In an experiment designed to test whether DOTA and/or Bz-DTPA chelators are immunogenic, we repeatedly (up to three times) injected BALB/c mice with conjugates using the respective murine LL2-IgG and murine-LL2 F(ab')₂ and tested serum for the presence of anti-chelate mAbs. There was no evidence of immune complex formation by HPLC after the addition of serum from these mice to trace amounts of radiolabeled mAbs. In terms of sensitivity, 100 ng of iodinated probe would be sufficient to form a 1:1 immune complex with anti-chelate-mAb entity, if present. We concluded that no immune responses were found, in mice, to murine mAb conjugate of either chelate, given three times over 9 weeks at protein doses equivalent to 100 mg/70 kg in humans. This finding supports the contention of Watanabe et al. (28) that chelates are substantially more immunogenic when attached to foreign antibodies compared to syngeneic immunoglobulins. It is encouraging that no immune response is seen in mice with murine mAb substituted with as much as four DOTA chelates per IgG.

CONCLUSIONS

We have optimized a procedure for simple DOTA conjugation of CDR-grafted monoclonal antibodies, leading to consistently >90% ^{90}Y incorporation in conjugate radiolabelings. Factors governing DOTA molar substitution ratios and optimized labelings were addressed. [^{88}Y]DOTA-hLL2 was more stable to challenge and had substantially lower bone uptake in Ramos lymphoma-bearing animals than [^{88}Y]Bz-DTPA-hLL2. In other properties such as cell binding and retention, MTD, and induction of anti-chelate response in animals, the reagents appeared to be similar. Whether DOTA conjugates will prove more useful than Bz-DTPA conjugates for ^{90}Y RAIT in humans can only be answered by a direct comparison of both in patients with similar disease burdens. It is our intention to develop [^{90}Y]DOTA-hLL2

and [^{90}Y]DOTA-hIMMU-14 for clinical RAIT applications against NHL and CEA-expressing solid tumors, respectively, due to their better stabilities, evidenced by lower bone uptake, in these preclinical studies.

ACKNOWLEDGMENT

We are grateful to Ms. Rosarito Aninipot for expert technical assistance. This work was supported in part by U.S. Public Health Service (PHS) Outstanding Investigator Grant CA 39841 from the National Institutes of Health (D.M.G.) and Grant CA 66348 under the SBIR program of the NIH (G.L.G.).

Cholesterol Phosphate Derivatives: Synthesis and Incorporation into a Phosphatase and Calcium-Sensitive Triggered Release Liposome

S. C. Davis and F. C. Szoka Jr.*

Department of Biopharmaceutical Sciences and Pharmaceutical Chemistry, School of Pharmacy, University of California, San Francisco, California 94143-0446. Received May 6, 1998;
Revised Manuscript Received August 27, 1998

A series of cholesterol derivatives that position a phosphate monoester at increasing distance from the sterol ring system was synthesized, and their utility as a triggered release liposome tested. Stable anionic liposomes consisting of the novel cholesterol phosphate derivatives and dioleoylphosphatidylethanolamine (DOPE) can be induced to collapse upon phosphatase-catalyzed removal of the phosphate group. Control liposomes containing DOPE and cholesterol phosphate or phosphatidic acid, which are not phosphatase substrates, do not undergo phosphatase-mediated collapse. The phosphatase-sensitive liposomes also collapse in the presence of calcium. The precise concentration of calcium that induces the collapse is controlled by the structure of the cholesterol phosphate derivative. Plasmid DNA encoding luciferase, encapsulated in the cholesterol derivative/DOPE liposomes, transfected cells in vitro. The level of transfection is dependent upon the cholesterol derivative and is mediated by both a calcium-independent and a calcium-dependent pathway; however, the involvement of phosphatase in the latter mechanism is not yet resolved. The transfection efficiency is between 10^6 and 10^7 of luciferase activity in relative light units per milligram of protein, which is similar to transfection values reported using other triggered release liposomes.

INTRODUCTION

One approach to the delivery of drugs and DNA to the cytoplasm of cells is to use triggered release liposomes (1, 2). Such liposomes are stable under normal physiological conditions but release their contents upon receipt of a defined stimulus (1). This allows the controlled delivery of the liposome contents to the site of the stimulus, either intracellularly or at defined sites in the body.

Triggered release liposomes rely on the ability of lipids to interconvert among different phases in aqueous media. The two phases most commonly utilized in triggered release liposomes are the lamellar and the inverted hexagonal phase. When the lipids prefer the lamellar phase, liposomes are formed which are capable of encapsulating exogenous material. When the lipids form an inverted hexagonal phase, no vesicle structure is possible.

A commonly employed lipid for triggered release compositions is dioleoylphosphatidylethanolamine (DOPE)¹ which prefers the inverted hexagonal phase under physiological conditions (3) but can be stabilized in the lamellar phase by the addition of at least 25 mole percent of a charged colipid. Removal of the charge from

the colipid is sufficient to induce the phase change. Several different strategies have been used for the controlled removal of charge from the surface of a phosphatidylethanolamine/colipid bilayer, including pH change [e.g., cholesterol hemisuccinate, CHEMS (4) and oleic acid (5)], enzyme catalysis [e.g., phospholipase C or acetylcholine esterase (6)], and light [cleavage of plasmalogen vinyl ethers (7)].

We hypothesized that lipids with a doubly negatively charged phosphate monoester headgroup (similar to phosphatidic acids) would stabilize phosphatidylethanolamine bilayers. Two mechanisms for the triggered release of the liposomes could then be envisaged, enzymatic and ionic. Phosphatase enzymes which catalyze the hydrolysis of phosphate monoesters could remove the phosphate and its corresponding charge from the bilayer surface, thus allowing collapse to the hexagonal phase and release of the liposome contents. Two examples of this class of enzymes are alkaline phosphatase (8, 9), which is a widely specific, highly active enzyme found in serum and on the cell membrane, and acid phosphatase, which is found intracellularly in endosomes and lysosomes (10). Alkaline phosphatase has long been utilized in the area of pro-drugs to convert inactive phosphate derivatives into the active compounds (11). Recently, this enzyme has been shown to inactivate endotoxin by removing the phosphate from this lipopolysaccharide (12). This suggested that alkaline phosphatase would be capable of hydrolyzing phosphate from a lipid derivative. Second, divalent cations such as calcium are well-known to cause aggregation and fusion (13) of anionic liposomes, and in this phosphate containing system, the calcium effect may trigger the collapse to the hexagonal phase (14).

¹ Abbreviations: DOPE, dioleoylphosphatidylethanolamine; PE, phosphatidylethanolamine; HEPES, (hydroxyethyl)piperazine-*N'*-2-ethanesulfonic acid; HBS, HEPES buffered saline; ANTS, 8-aminonaphthalene-1,2,3-trisulfonic acid; DPX, *p*-xylenebis(pyridinium)bromide; CHEMS, cholesterol hemisuccinate; REV, reversed-phase evaporation vesicles; RLU, relative light units; I. U., international unit; sat, saturated aqueous solution; POPG, palmitoyl-*sn*-3-phosphatidylglycerol.

We show here that novel cholesterol phosphate derivatives can be incorporated into PE liposomes, confer calcium and phosphatase sensitivity, and can be used to trigger the release of liposome contents.

EXPERIMENTAL SECTION

General. All purchased chemicals were of ACS grade or better and were used without further purification. Solvents for HPLC analysis were obtained as HPLC grade and were filtered (0.2 μ M) and degassed before use. NMR spectra were recorded on a GE 300 MHz instrument and chemical shifts are expressed as parts per million using as internal standard, tetramethylsilane (δ = 0.0 ppm) for ^1H NMR and CDCl_3 (δ = 77.0 ppm) for ^{13}C NMR. Optical rotation measurements were taken on a Perkin-Elmer 241 Polarimeter using the sodium line. IR measurements were taken on a Nicolet Impact 400 as a film on a 3M Type 62 disposable IR card. Calf intestinal alkaline phosphatase and DNase 1 were purchased from Boehringer Mannheim. Acid phosphatase (Sweet potato) was purchased from Sigma (St. Louis, MO).

Cholest-5-en-3 β -tosylate (1). To a solution of cholesterol (5 g, 12.9 mmol) in anhydrous pyridine (70 mL) was added *p*-toluenesulfonyl chloride (5 g, 26 mmol), and the mixture was stirred for 16 h under an inert atmosphere at room temperature. The solvent was filtered off, and the white mass washed with pyridine (50 mL) and water (100 mL). Recrystallization from chloroform/methanol gave the product as white crystals (6.5 g, 12 mmol, 93%). R_f = 0.8 (CHCl_3). ^1H (300 MHz, CDCl_3): δ 0.65 (3H, s); 0.85–1.57 (33H, m); 1.78–2.01 (6H, m); 2.23–2.29 (2H, m); 2.44 (3H, s); 4.28–4.33 (1H, m); 5.29 (1H, d, J = 4.5 Hz); 7.32 (2H, d, J = 8 Hz); 7.79 (2H, d, J = 8 Hz). ^{13}C (75 MHz, CDCl_3): δ 11.77, 18.66, 19.11, 21.59, 22.52, 22.78, 23.77, 24.20, 27.96, 28.16, 28.58, 31.70, 31.81, 35.71, 36.12, 36.30, 36.83, 38.84, 39.46, 39.61, 42.25, 49.86, 56.05, 56.59, 82.15, 123.68, 127.58, 129.69, 134.65, 138.79, 144.34. LSIMS: m/z 369 ($\text{M} - \text{tosylate}$, 100%).

Cholest-5-en-3 β -oxyethan-2-ol (2a). To a suspension of cholest-5-en-3 β -tosylate (**1**) (500 mg, 0.9 mmol) in anhydrous dioxane (9 mL) was added ethylene glycol (1 g, 23.4 mmol), and the mixture was stirred under reflux for 4 h in an inert atmosphere. The solution was cooled, and the solvent removed in vacuo. The white residue was partitioned between diethyl ether (20 mL) and water (20 mL), and the organic layer was washed sequentially with sat NaHCO_3 (2 $\times$ 10 mL), water (10 mL) and sat brine (10 mL). The solution was dried over magnesium sulfate, and the solvent removed in vacuo. Recrystallization of the residue from chloroform/methanol gave the product as white crystals (350 mg, 0.81 mmol, 88%). Cholest-5-en-3 β -oxyethane-2-phosphate (3a). To a stirred solution of cholest-5-en-3 β -oxyethan-2-ol (**2a**) (86 mg, 0.2 mmol) in anhydrous chloroform (0.5 mL) was added a solution of tetra-*n*-butylammonium phosphate (340 mg, 1 mmol) in chloroform (0.5 mL) immediately followed by addition of trichloroacetonitrile (120 μL , 1.2 mmol). The solution was stirred under an inert atmosphere for 15 min and the solvent was removed in vacuo. The residue was dissolved in water saturated *n*-butanol (5 mL), and the solution washed sequentially with *n*-butanol-saturated water (2 $\times$ 2 mL), *n*-butanol-saturated 1 M HCl (2 $\times$ 2 mL), and sat brine (2 mL). The organic phase was dried over magnesium sulfate and filtered, and the solvent removed in vacuo. The residue was dissolved in chloroform (2 mL), and sodium iodide (150 mg, 1 mmol) in acetone (2 mL) was added. After 15 min, the precipitate was separated by centrifugation, the solvent decanted, and the precipitate washed with chloroform (2 $\times$ 2 mL) to yield the product as the sodium

salt (80 mg, 0.14 mmol, 72%). (Cholesterol C₂ phosphate) $R_f = 0.35$ (CHCl₃/MeOH/H₂O 65/25/4). IR (film): 2924 (st, C-H), 2844 (st, C-H), 2365 (st, PO-H), 2340 (st, PO-H), 1650 (m), 1457 (m, C=C). ¹H (300 MHz, CDCl₃/MeOD/*d*₅-pyridine/DCI 10/2/1/1): (16): δ 0.70 (3H, s), 0.83–1.60 (33H, m); 1.83–2.05 (6H, m); 2.16–2.18 (1H, m); 2.33–2.38 (1H, m); 3.20–3.33 (1H, m); 3.74 (2H, t, $J = 4.5$ Hz); 4.17 (2H, t, $J = 4.5$ Hz), 5.36–5.38 (1H, m). ¹³C (75 MHz, CDCl₃/MeOD/*d*₅-pyridine/DCI 10/2/1/1): δ 11.17, 18.03, 18.61, 20.46, 21.80, 22.04, 23.19, 23.65, 27.35, 27.59, 31.31, 35.16, 35.58, 36.18, 36.51, 38.26, 38.90, 39.19, 41.74, 49.62, 55.60, 56.18, 65.81, 66.52, 79.19, 121.39, 139.77. ⁻LSIMS: m/z 509 (M - H⁻, 100%).

Cholest-5-en-3 β -oxyhexane-6-phosphate (3b). This compound was prepared similarly to cholest-5-en-3 β -oxyethane-2-phosphate (3a) to yield a white powder (75 mg, 0.13 mmol, 66%). $R_f = 0.35$ (CHCl₃/MeOH/H₂O 65/25/4). IR (film): 2930 (st, C-H), 2856 (st, C-H), 2359 (st, PO-H), 2327 (st, PO-H), 1656 (m), 1451 (m, C=C). ¹H (300 MHz, CDCl₃/MeOD/*d*₅-pyridine/DCI 10/2/1/1): δ 0.72 (3H, s), 0.78–1.69 (33H, m); 1.84–2.07 (6H, m); 2.19–2.24 (1H, m); 2.34–2.37 (1H, m); 3.17–3.19 (1H, m); 3.46–3.52 (2H, m); 3.99–4.09 (2H, m), 5.38 (1H, d, $J = 4$ Hz). ¹³C (75 MHz, CDCl₃/MeOD/*d*₅-pyridine/DCI 10/2/1/1): δ 10.77, 17.66, 18.25, 20.01, 21.41, 21.67, 22.66, 23.21, 23.90, 24.29, 24.70, 26.85, 27.14, 30.86, 34.66, 35.08, 35.78, 36.18, 38.08, 38.40, 38.72, 41.26, 49.14, 55.08, 55.70, 66.90, 78.05, 120.57. ⁻ESI: m/z 565 (M - H⁻, 26%).

Cholest-5-en-3 β -oxypent-3-oxa-ane-5-phosphate (3c). This compound was prepared similarly to cholest-5-en-3 β -oxyethane-2-phosphate (3a) to yield a white powder (55 mg, 0.14 mmol, 50%). $R_f = 0.35$ (CHCl₃/MeOH/H₂O 65/25/4). IR (film): 2929 (st, C-H), 2856 (st, C-H), 2359 (st, PO-H), 2342 (st, PO-H), 1662 (m), 1463 (m, C=C). ¹H (300 MHz, CDCl₃/MeOD/*d*₅-pyridine/DCI 10/2/1/1): δ 0.68 (3H, s); 0.68–1.57 (33H, m); 1.77–2.06 (6H, m); 2.16–2.24 (1H, m); 2.31–2.37 (1H, m); 3.16–3.20 (1H, m); 3.64–3.71 (8H, m); 4.08–4.12 (2H, m); 5.33 (1H, d, $J = 4$ Hz). ¹³C (75 MHz, CDCl₃/MeOD/*d*₅-pyridine/DCI 10/2/1/1): δ 11.43, 18.29, 18.41, 18.89, 20.64, 22.09, 22.33, 23.40, 23.85, 27.54, 27.79, 31.48, 35.25, 35.76, 36.38, 36.72, 38.24, 38.52, 39.07, 41.90, 49.56, 49.75, 55.76, 56.33, 64.60, 66.64, 70.16, 79.21, 121.43, 140.11. ⁻LSIMS: m/z 554 (M - H⁻, 28%).

Cholest-5-en-3 β -oxy-oct-3,6-oxa-ane-8-phosphate (3d). This compound was prepared similarly to cholest-5-en-3 β -oxyethane-2-phosphate (3a) to yield a white powder (65 mg, 0.11 mmol, 55%). Cholesterol triethylene phosphase $R_f = 0.35$ (CHCl₃/MeOH/H₂O 65/25/4). IR (film): 2932 (st, C-H), 2861 (st, C-H), 2361 (st, PO-H), 2338 (st, PO-H), 1647 (m), 1456 (m, C=C). ¹H (300 MHz, CDCl₃/MeOD/*d*₅-pyridine/DCI 10/2/1/1): δ 0.68 (3H, s), 0.86–1.60 (33H, m); 1.77–2.04 (6H, m); 2.12–2.19 (1H, m); 2.31–2.36 (1H, m); 3.14–3.19 (1H, m); 3.61–3.70 (12H, m); 4.12–4.15 (2H, m), 5.33 (1H, d, $J = 5$ Hz). ¹³C (75 MHz, CDCl₃/MeOD/*d*₅-pyridine/DCI 10/2/1/1): δ 11.48, 18.33, 18.96, 20.68, 22.17, 22.43, 23.45, 23.91, 27.63, 27.86, 31.50, 35.41, 35.81, 36.44, 36.75, 38.56, 39.13, 39.37, 41.93, 49.33, 49.77, 55.77, 56.36, 65.35, 66.67, 69.35, 70.27, 76.22, 79.02, 79.44, 121.39. ⁻LSIMS: m/z 597 (M - H⁻, 38%).

Leakage Studies. A premixed solution of cholesterol and DOPE (5/4 molar ratio) was evaporated to a lipid film, and the film was exposed to high vacuum (<150 mTorr) for at least 2 h before use. The lipids were hydrated in 20 mM HEPES, 12.5 mM ANTS, and 45 mM DPX at pH 7.0 with vortexing and brief sonication (17). The liposomes thus formed were then extruded through

a hand held extrusion device (Avestin, Ottawa, Canada) with a 0.2 μ m polycarbonate membrane (Nucleopore Corp., Pleasanton, CA). The liposomes were applied to a Sephadex G50 gel filtration column (1 $\times$ 20 cm) to remove any unencapsulated dye. The liposome concentration was quantified using the phosphorus assay of Bartlett (18). The dequenching of ANTS upon liposome leakage was measured according to Ellens et al. (17). The fluorescence arising from excitation at 360 nm was measured through a Schott GG 435 nm cutoff filter (50% transmittance at 435 nm). Leakage experiments were performed at room temperature in triplicate for each condition, and each cuvette (Polymethacrylate Fluorimeter cuvette, Sigma, St. Louis, MO) was stirred and analyzed separately. The initial fluorescence of the intact liposomes at time 0 was measured and set as F_0 , or 0% leakage. The fluorescence for each cuvette was measured at the times indicated after addition of the enzyme. At the end of the time course F_{100} , 100% leakage was defined by the fluorescence arising from addition of the detergent, dodecyl octaethylene glycol monoether (C12E8) (Calbiochem, La Jolla, CA). The percent leakage at time t was determined for each cuvette using the formula $(F_t - F_0 / F_{100} - F_0)100$, and then the results were combined. Leakage experiments with calcium were performed sequentially with timepoints measured every second, and the percentage of F_{100} observed at the plateau point was calculated using the same formula as before. Lipid-mixing experiments were performed according to the method of Struck et al. (19). NBD-PE (0.5 mol %) and 0.5 mol % Rhodamine-PE were incorporated into cholesterol C2 phosphate (3a)/DOPE liposomes, and these were mixed with unlabeled liposomes (9-fold excess). Lipid mixing was followed using the increase of fluorescence at 535 nm upon addition of calcium. Values in the figures are the mean $\pm$ standard deviation from three determinations.

Identification of the Products of Reaction. One micromole of cholesterol C2 phosphate (3a)/DOPE (4/5) liposomes in HEPES buffered saline (10 mM HEPES and 150 mM NaCl, pH 7.4) (10 mL) was incubated with 0, 20, and 100 I. U. of alkaline phosphatase in triplicate. The samples were placed in sealed tubes and mixed by slow rotation ($\sim$ 50 rpm) for 24 h at room temperature and the incubation stopped by freezing and lyophilization. The residue was redissolved in water (1 mL), and the lipids were extracted using the Bligh and Dyer protocol (20) and dried down separately for HPLC analysis. The aqueous phase was lyophilized, taken up in water (300 μ L) and the phosphate concentration measured using a modification of the method of Drueckes et al. (21). Thirty microliters of this solution was mixed with the assay mixture (125 μ L) and incubated at 30 $^{\circ}$ C for 10 min, and the absorbance measured at 630 nm. To form the assay mixture, ammonium molybdate (10 mM final) was dissolved in a solution of zinc acetate (15 mM) at pH 5.0. This was mixed with a 10% ascorbate solution, pH 5.0, and a solution of sodium dodecyl sulfate (200 mg/mL) in a 40:10:1 ratio. The assay mixture was used immediately.

The lipids isolated in the Bligh and Dyer extraction were dissolved in chloroform/methanol (2/1, 200 μ L) and separated on a Hewlett-Packard 1090 HPLC system with a Partisil ODS3 column (5 μ m, 4.5 mm $\times$ 250 mm) using methanol (1 mL/min) as the mobile phase and UV detection at 215 nm. The cholesterol C2 alcohol (2a) was identified by coinjection with synthetic material and quantified via a standard curve of 2a.

Encapsulation of Plasmid DNA in Liposomes. A cholesterol phosphate derivative/DOPE (4/5) lipid film (20 μmol) was dissolved in a mixture of diethyl ether and 1,1,2-trichloro-2,2,1-trifluoroethane (57:43, 3 mL), and 10 mM HEPES, 5% glucose buffer at pH 7.4 (0.5 mL) was added. The mixture was vigorously sonicated to form an emulsion to which plasmid DNA (375 μg) (pLC0785.112, a generous gift of GeneMedicine Inc.) in 10 mM HEPES and 5% glucose, pH 7.4 (0.5 mL), was added followed by further brief sonication. The emulsion was then dried down to the gel phase, which was broken under reduced pressure to yield liposomes, of 300 nm z-average diameter as determined by dynamic light scattering (Coulter Electronics Inc., Hialeah, FL). Using the multimodel algorithms, these liposomes were purified on a discontinuous Ficoll gradient to remove excess DNA (22). DNA encapsulation efficiency was measured after determining the amount of lipid phosphate and DNA in the fraction containing the liposomes. The DNA concentration was measured using the Hoescht dye 33258 (Polysciences, Inc., Warrington, PA) and a DNA fluorometer (TKO100, Hoefer Scientific Instruments, San Francisco, CA). The liposomal phosphate was quantified using the assay of Bartlett (18) for the total phosphate and subtracting the amount of phosphate contributed by the associated DNA.

DNase Protection Assay. Plasmid DNA (1 μg), either encapsulated in liposomes or free, was dissolved in HBS (10 μL) and DNase was added and the mixture incubated at room temperature for 16 h. The samples were then purified by a Bligh and Dyer extraction and the DNA separated by electrophoresis on a 0.8% agarose gel with ethidium bromide staining.

Transfection of Monkey Kidney Fibroblast Cells. CV-1 cells were plated in a 96 well plate at 2×10^4 cells/well in 100 μL of growth medium consisting of DME-H21 with 10% fetal calf serum and antibiotics (100 units/mL penicillin and 100 $\mu\text{g}/\text{mL}$ streptomycin). The cells were incubated for 19 h at 37 $^{\circ}\text{C}$ in a 95% air, 5% CO_2 atmosphere. The growth medium was then removed, the cells were washed with serum free medium, and serum free medium was added (150 μL). The transfection system was then added in 50 μL of 10 mM HEPES and 5% glucose, pH 7.4, buffer, and the cells were incubated in this medium for 3 h. Subsequently, the medium was replaced with complete growth medium, and the cells were incubated for a further 36 h. The medium was removed, and the cells were washed with phosphate-buffered saline and assayed for luciferase activity and total cell protein (Bio-Rad BCA protein assay). For the phosphatase inhibitor experiments, inorganic phosphate (10 mM final) and L-*p*-bromotetramisole (1 mM final) (Sigma, St. Louis, MO) were added to the serum-free medium before addition of the transfection system. Nonencapsulated DNA/liposomes were prepared by mixing 100 nmol of cholesterol phosphate derivative/DOPE (4/5) liposomes with 1 μg of pLC 0785.112 (GeneMedicine Inc.) in 50 μL of buffer before addition to the cells.

Transfections in low-calcium media were performed utilizing calcium/magnesium-free Hanks-buffered salt solution, supplemented with nonessential amino acids, antibiotics, and glutamine (2 mM) in place of serum free media. The calcium concentration noted was added to the media from a stock solution of CaCl_2 immediately before use. Where noted, the salt wash was performed, immediately after aspiration of the transfection medium, with 1 M NaCl and 20 mM HEPES buffer, pH 7.4, followed by a media wash and incubation in growth medium for a further 36 h.

RESULTS

Synthesis. Our approach to the synthesis of a phosphatase-sensitive lipid employed cholesterol as the lipophilic anchor due to the ability of cholesterol to promote the lamellar to hexagonal transition in PE membranes (23) and for synthetic ease. Since the structural requirements of phosphatase enzymes using lipids as substrates are not known, we sought a versatile synthesis amenable to the production of a series of lipids (Scheme 1). $\text{S}_{\text{N}}1$ displacement of tosylate from the 3- β position of cholesterol with ethylene glycol had been shown to be an efficient method for derivatizing cholesterol (15), and this displacement proceeds smoothly for a wide variety of diols. Phosphorylation of the prepared diols was performed via the method of Danilov et al. (24) and the tetra-*n*-butylammonium salt was smoothly transformed into the sodium salt with sodium iodide.

Liposome Formation. To determine which lipids would be most appropriate to use in a triggered release system a variety of cholesterol alcohol derivatives (eight in all) (25) were synthesized. These were then tested for the ability to stabilize a DOPE bilayer. At pH 7.4, none of the derivatives formed liposomes with DOPE in a 4/5 cholesterol alcohol/DOPE ratio. At pH 9.0, DOPE is sufficiently charged to support a bilayer in the presence of cholesterol. Inclusion of the cholesterol alcohol derivatives in place of cholesterol showed that only those lipids with hydrophilic linkers or hydrophobic linkers of six carbons or less formed liposomes with DOPE. All the formulations collapsed upon reduction of the pH to 7.4, after protonation of the DOPE (25). This suggested that phosphatase-mediated removal of the phosphate groups from the cholesterol phosphate derivative/DOPE liposomes would initiate collapse of the liposomes with concomitant release of the contents. This initial screen of linker structure against liposome stability allowed us to identify a number of lipids to study in greater detail. The selected lipids were structurally distinguished by a short linker (3a), the longest stable hydrophobic linker (3b), a hydrophilic linker (3c), and the longest linker tested (3d), respectively (Scheme 1).

Sensitivity to Phosphatase. Liposomes were formed from mixtures of PE with three cholesterol phosphate derivatives (3a, b, d). The sensitivity of the phosphate derivatives to alkaline phosphatase was first measured by the leakage of encapsulated ANTS/DPX (17). Exposure of the liposomes to alkaline phosphatase resulted in the leakage of contents from all three compositions

Figure 1. Effect of alkaline phosphatase upon the stability of liposomes encapsulating ANTS/DPX. (□) Cholesterol triethylene phosphate (3d)/DOPE in HBS (cholesterol C2 phosphate (3a)/DOPE and cholesterol C6 phosphate (3b)/DOPE showed the same leakage profile); (▽) cholesterol C2 phosphate (3a)/DOPE with 10 I. U. alkaline phosphatase; (○) cholesterol C6 phosphate (3b)/DOPE with 10 I. U. alkaline phosphatase; (△) cholesterol triethylene phosphate (3d)/DOPE with 10 I. U. alkaline phosphatase.

Figure 2. Dose response of cholesterol C2 phosphate (3a)/DOPE liposomes to alkaline phosphatase. (□) Cholesterol C2 phosphate (3a)/DOPE in HBS; (△) cholesterol C2 phosphate (3a)/DOPE with 1 I. U. alkaline phosphatase; (○) cholesterol C2 phosphate (3a)/DOPE with 20 I. U. alkaline phosphatase.

(Figure 1). In contrast, liposomes formulated with cholesterol phosphate or egg phosphatidate with DOPE showed no leakage under these conditions, showing that they were not phosphatase sensitive. The cholesterol C2 phosphate (3a)/DOPE liposomes were most sensitive to alkaline phosphatase, and further experiments were performed with this system.

The leakage of dye from the liposomes in the presence of alkaline phosphatase exhibited two phases, a lag phase followed by a more rapid phase. Exposure of cholesterol C2 phosphate (3a)/DOPE liposomes to increasing amounts of enzyme lead to an increased rate of release from the liposome (Figure 2). The lag phase before liposome leakage was also observed to be sensitive to the amount of enzyme activity present in the assay. Inactivation of the enzyme by heat treatment completely blocked the enzyme-mediated leakage of dye from the liposome (Figure 3). The leakage of dye from the liposomes was

Figure 3. Effect of heat inactivation upon the alkaline phosphatase mediated leakage. (□) Cholesterol C2 phosphate (3a)/DOPE in HBS; (△) cholesterol C2 phosphate (3a)/DOPE with 10 I. U. alkaline phosphatase; (○) cholesterol C2 phosphate (3a)/DOPE with heat inactivated alkaline phosphatase.

Table 1. Stoichiometry of Alkaline Phosphatase Catalyzed Liposome Destruction

incubation conditions	cholesterol C2 alcohol (nmol)	inorganic phosphate (nmol)
no alkaline phosphatase	not detected	30 ± 15
20 units of alkaline phosphatase	190 ± 10	190 ± 40
100 units of alkaline phosphatase	180 ± 15	160 ± 30

thus shown to be dependent upon and sensitive to the presence of active alkaline phosphatase.

The expected products of the reaction of a phosphatase with cholesterol C2 phosphate (3a) are the cholesterol C2 alcohol (2a) and inorganic phosphate. To detect the products of any reaction between the liposomes and alkaline phosphatase, a large scale (1 μmol) incubation of the cholesterol C2 phosphate (3a)/DOPE liposomes with the enzyme was performed. Due to problems with product inhibition of the enzyme, it was necessary to perform the incubation at the same concentration as the leakage experiments (0.1 mM). After 24 h, the reaction was frozen and the mixture lyophilized. The residue was rehydrated in a small volume of water, and the lipids were separated by a Bligh and Dyer extraction (20).

HPLC separation of the lipids isolated in the extraction allowed identification and quantification of the lipids formed in the reaction. The lipids were isolated utilizing the method described by New (26) for the quantification of α-tocopherol with cholesterol as a standard. Under these conditions, cholesterol C2 alcohol (2a) eluted at 15 min, 2 min after cholesterol eluted. Analysis of the lipids isolated from the extraction showed the presence of a peak eluting at 15 min only in the reactions containing alkaline phosphatase. Coinjection of the reaction products with cholesterol C2 alcohol (2a) resulted in enhancement of this peak. To determine the amount of cholesterol C2 alcohol (2a) produced, a standard curve of 2a was set up and a linear relationship between the area under the peak and the amount of material injected was shown. From this curve, 190 ± 10 nmol of 2a was formed in the reaction with alkaline phosphatase (Table 1).

Identification and quantification of inorganic phosphate in the aqueous phase was performed at pH 5.0 to avoid any contamination from lipids that remained in the aqueous phase. The presence of zinc in the assay mixture

Figure 4. Effect of acid phosphatase upon cholesterol C2 phosphate (**3a**)/DOPE liposomes. (□) Cholesterol C2 phosphate (**3a**)/DOPE in acetate buffered saline, pH 5.0; (Δ) cholesterol C2 phosphate (**3a**)/DOPE with 2 I. U. acid phosphatase.

allows the formation of the reduced phosphomolybdate complex under mild conditions (21). Inorganic phosphate formation was shown to be dependent upon the presence of alkaline phosphatase. In the presence of alkaline phosphatase, 190 ± 40 nmol of inorganic phosphate are formed after 24 h (Table 1). In the absence of enzyme only, background levels of phosphate were detected in the assay. Under these conditions, only 40% of the initial cholesterol C2 phosphate (**3a**) was hydrolyzed by the enzyme. This was ascribed to product inhibition by inorganic phosphate, which at $20 \mu\text{M}$ concentration was severalfold higher than its K_i for the enzyme.

To test the general nature of the reaction observed with alkaline phosphatase, a second physiologically relevant isozyme, an acid phosphatase (10), was tested. Incubation of the cholesterol C2 phosphate (**3a**)/DOPE liposomes at pH 5, the optimal pH for this enzyme, highlighted the stability of this liposome composition. In the presence of acid phosphatase, the leakage of dye from the liposomes exhibited two phases, a lag phase followed by a more rapid phase (Figure 4). The extent of leakage observed for this isozyme was significantly higher than that observed with the alkaline phosphatase.

Sensitivity to Calcium. The second mechanism for triggering a phase change in an anionic liposome is the use of divalent cations. Addition of 0.4 mM calcium to cholesterol C2 phosphate (**3a**)/DOPE liposomes causes complete leakage of the liposome contents and the formation of large flocculate aggregates. The lipid mixing assay of Struck et al. (19) gave a transition threshold for this effect of $150 \mu\text{M}$ calcium (data not shown).

The ability of calcium to aggregate and fuse liposomes is thought to be mediated by the dehydration of the bilayer surface (27). Accordingly, a number of cholesterol phosphate derivatives (**3b–d**) in which the linker moiety was longer and more hydrophilic than the cholesterol C2 phosphate (**3a**) was formed into liposomes with DOPE and tested for their calcium sensitivity. The sensitivity to Ca^{2+} was reduced by increasing the hydrophilicity and length of the linker between the cholesterol moiety and the phosphate group (Table 2). The triethylene glycol phosphate (**3d**) is stable up to 1 mM Ca^{2+} , which is greater than physiological levels in some tissues in vivo (28). Intriguingly, the cholesterol C2 phosphate (**3a**)/DOPE liposomes are much more sensitive than the parent molecule in the series, cholesterol phosphate, and then the diacyl glycerol lipid, egg phosphatidate.

Table 2. Effect of Calcium upon the Stability of Cholesterol Phosphate Derivative/DOPE Liposomes

liposome formulation	200 μM Ca^{2+}	500 μM Ca^{2+}	1 mM Ca^{2+}	2 mM Ca^{2+}
cholesterol C2 phosphate (3a)/DOPE	+	++	++	++
cholesterol C6 phosphate (3b)/DOPE	—	+	++	++
cholesterol diethylene phosphate (3c)/DOPE	—	—	+	++
cholesterol triethylene phosphate (3d)/DOPE	—	—	+	++
cholesterol phosphate/DOPE	—	+	++	++
egg phosphatidate/DOPE	—	—	—	+

^a The liposomes were exposed to the indicated calcium concentration and the rate of dye leakage and increase of turbidity was measured. (—) No detectable effect. (+) Leakage of $<20\%$. (++) leakage and aggregation of $>60\%$.

Encapsulation of DNA. Encapsulation of DNA in such negatively charged liposomes was potentially a problem but was readily achieved utilizing a modification of the REV methodology (29). The liposomes were purified on a discontinuous Ficoll gradient to remove excess DNA. In a typical procedure, the final liposome concentration was 18 nmol of lipid and $0.2 \mu\text{g}$ of DNA/ μL of solution. This corresponds to a 29% encapsulation efficiency for DNA.

The DNA was shown to be intact and encapsulated within the liposomes using a DNase protection assay. Liposomes encapsulating DNA were exposed to DNase for 16 h at room temperature and the lipids were then extracted. Plasmid DNA was completely degraded under these conditions (lane 7), whereas the encapsulated DNA was not degraded (lane 2) even in the presence of 10% serum (lane 4, the material at the wells for lanes 3 and 4 is serum derived) (Figure 5). The DNA also gave the same mobility profile as the initial plasmid DNA, indicating that it had not been sheared in the encapsulation process. Indeed, the encapsulated DNA can be extracted via the Bligh and Dyer protocol (20) and complexed with the heat-activated dendrimer (30). This complex is completely transfection competent (data not shown), confirming the agarose gel data that the DNA structure was not damaged in the encapsulation protocol.

Transfection Studies. The ability of the cholesterol C2 phosphate (**3a**)/DOPE liposomes to transfect CV-1 cells in vitro is shown in Figure 6. The transfection efficiency observed was intermediate in level between the degraded cationic polyamidamine dendrimer (29), which was used as a positive control, and naked DNA as shown.

Transfection experiments in the presence of phosphatase inhibitors such as inorganic phosphate (31) and *L-p*-bromotetramisole (32) showed that the ability of the liposome system to transfect CV-1 cells was not affected by inhibition of phosphatase. At the levels of inhibitor included in the transfection experiments, no phosphatase activity was observed. At 1 mM , *L-p*-bromotetramisole mediated some cellular toxicity which reduced the transfection levels for all transfecting agents. The relative transfection levels were unaffected by the treatments, however, indicating that another mechanism is at work (Figure 6).

The ability of the liposomes to mediate transfection in the absence of encapsulation is shown in Figure 7. The cells were exposed to DNA and cholesterol C2 phosphate (**3a**)/DOPE liposomes with the DNA either inside or outside of the liposome. The transfection efficiency was the same in both cases, whereas naked DNA did not transfect in the absence of lipid. The flocculate lipid/DNA aggregate formed upon exposure to the calcium in the

Condition D; 10 mM inorganic phosphate added to medium.

culture medium must therefore mediate the transfection. DNA encapsulated by the more calcium stable cholesterol triethylene phosphate (**3d**)/DOPE liposomes caused efficient transfection, whereas the mixed liposome/DNA suspension resulted in significantly reduced levels of transfection. These liposomes do not flocculate on addition to media but are active in transfection, indicating that a different mechanism of transfection is occurring

Figure 7. Effect of encapsulation of the plasmid on transfection efficiency. Transfection with liposomes premixed with plasmid DNA (1 μ g of DNA/well) (dotted bars). in this case, from that observed with the cholesterol C2 phosphate (**3a**)/DOPE system. We have tested anionic liposome formulations prepared from naturally occurring lipids, such as POPG/DOPE, cholesterol phosphate/DOPE or egg phosphatidate/DOPE, and these *do not* transfect when they are simply mixed with DNA.

Transfection of cells in vitro with reduced levels of calcium in the media was performed using calcium/magnesium-free Hanks-buffered salt solutions supplemented with an energy source (glutamine) and the required level of calcium. Cell viability was unaffected by this treatment in untransfected controls. The cholesterol C2 phosphate (**3a**)/DOPE liposomes were shown to be sensitive to the calcium concentration (Figure 8), showing only background levels of transfection in the absence of added calcium. Cholesterol triethylene phosphate (**3d**)/DOPE liposomes were less affected by the calcium concentration and were still active in transfection in the absence of any

added divalent cations. The cationic dendrimer was unaffected by the calcium concentration unless the surface-bound polyplex was removed by salt wash before addition of calcium-containing media.

DISCUSSION

Nonviral gene therapy remains a relatively inefficient process that could benefit from improved approaches for gene delivery. We hypothesized that a phosphatase-triggered release lipid composition could sequester DNA to prevent degradation until the target site is reached. The DNA would be released when triggered by the relatively high concentration of phosphatase isozymes associated with the cell surface and lysozymes (8, 28). A triggered release liposome sensitive to this activity may therefore provide an efficient method for the transfection of cells or delivery of drugs.

To test this hypothesis, we synthesized a series of novel phosphate monoester derivatives of cholesterol. The synthesis allowed a large number of different lipids to be constructed from cholesterol tosylate (Scheme 1), a stable crystalline solid which has been used for over 60 years as an intermediate for the derivatization of cholesterol at the 3- β position (33). The stereochemistry of the incoming nucleophile is defined by the cholesterol geometry, and in the absence of ionic promoters, the 3- β isomer is formed exclusively. Phosphorylation of the alcohol and counterion exchange provided the desired cholesterol phosphate derivatives. The cholesterol phosphate derivatives (**3a–d**) support a bilayer with DOPE at neutral pH whereas the expected products of phosphatase action, the cholesterol alcohol derivatives (**2a–d**), do not (25).

Alkaline phosphatase, a triggering enzyme, is associated with the extracellular matrix of cells and is known to be elevated in many disease states such as cancer (8). This enzyme has a pH optimum *in vitro* of 10.5, but acts upon polyanionic substrates at physiological pH (12). Moreover, the enzyme dephosphorylates and inactivates lipopolysaccharide (bacterial endotoxin) at the lipid–water interface of the micelle surface and should be capable of hydrolyzing the appropriate cholesterol phosphate derivatives in a bilayer. Liposomes encapsulating a fluorophore were prepared from a number of cholesterol phosphate derivatives formulated with DOPE and used to examine liposome leakage in the presence of the triggering enzyme. Exposure of these liposomes to physiologically relevant levels (28) of alkaline phosphatase led to a time-dependent leakage of the aqueous contents (Figure 1). Importantly, the naturally occurring lipids, cholesterol phosphate, and egg phosphatidate, were resistant to phosphatase-mediated leakage under these conditions. As the cholesterol C2 phosphate (**3a**)/DOPE system was significantly more sensitive to the presence of the enzyme than the other cholesterol derivatives, it was decided to test the activity of alkaline phosphatase more rigorously upon this system.

The proposed catalytic route of liposome destruction is based on the sequential removal of phosphate from individual lipid molecules. Little dye release is expected until a critical point of cholesterol hydrolysis is reached. Once there is insufficient cholesterol phosphate remaining in the bilayer to stabilize the lamellar phase, the liposomes will collapse to form the hexagonal phase with concomitant release of their contents. This observed lag phase is also sensitive to the enzyme concentration (Figure 2)—the greater the enzyme concentration the shorter the lag phase. Inactivation of the enzyme by heat

treatment (Figure 3) clearly indicates that an active enzyme, rather than a nonspecific protein–liposome interaction, must catalyze the transformation. This release profile may provide an advantage for *in vivo* delivery applications; the slow release of the lag phase might counteract the fast release observed in the burst phase with most controlled release systems (34).

The catalytic destruction of the liposomes is dependent upon the hydrolysis of the cholesterol C2 phosphate (**3a**) to the cholesterol C2 alcohol (**2a**) and inorganic phosphate. The expected products were isolated, identified, and quantified; inorganic phosphate and cholesterol C2 alcohol are produced in a 1:1 molar ratio (Table 1). This is consistent with the stoichiometry of the reaction of alkaline phosphatase with its substrate. Acid phosphatase also mediated the leakage contents from the cholesterol C2 phosphate (**3a**)/DOPE liposomes at pH 5.0 and was significantly more effective than alkaline phosphatase. The leakage profile induced by acid phosphatase was very similar to that observed with alkaline phosphatase supporting a catalytic mechanism of liposome collapse.

Divalent cations have been extensively used to trigger a phase change in anionic liposomes. Calcium, and to a lesser extent, magnesium and zinc are known to interact with anionic lipids such as phosphatidic acid (35), phosphatidylserine (36), and CHEMS (14), leading to phase separation and aggregation of liposomes. Depending upon the lipid composition, the calcium concentrations found in cell culture and *in vivo* are sufficient to mediate this transition.

Calcium is a very efficient trigger for the cholesterol C2 phosphate (**3a**)/DOPE liposomes and caused complete leakage of liposome contents at the comparatively low concentration of 0.4 mM. The threshold value at which calcium begins to show effects is 150 μ M for this liposome composition. *In vivo* administration would expose the liposomes to higher calcium concentrations, so we examined if calcium sensitivity was dependent upon the cholesterol phosphate derivative (**3a–d**). The structure of the linker has a pronounced effect upon the calcium sensitivity as shown in Table 2. Adding a linker initially slightly increases the sensitivity of DOPE liposomes to the effects of calcium [compare cholesterol phosphate to cholesterol C2 phosphate (**3a**)] then decreases the sensitivity, presumably because the phosphate group is positioned further from the bilayer surface. Incorporation of oxygens into the linker region improves the calcium stability still further, most likely because the linker is more hydrophilic. Liposomes formulated with the most hydrophilic derivative (**3d**) were largely unperturbed by physiological levels of calcium (28). Thus, the cholesterol phosphate derivative/DOPE liposomes form a triggered release system which is sensitive to two separate triggering mechanisms: phosphatase isozymes and calcium.

The utility of this system for delivery purposes was evaluated using gene transfer. Transfection with DNA encapsulated in the cholesterol C2 phosphate (**3a**)/DOPE liposome was tested using kidney fibroblast cells (CV-1) and the luciferase reporter gene. The levels of luciferase activity detected after transfection compare favorably with the CHEMS/DOPE pH-triggered release system (22) at 10⁷ RLU/mg of protein. This is 3–4 orders of magnitude above background, although lower than the cationic heat activated dendrimer (30).

To test whether the transfection was entirely or partially mediated by phosphatase activity, transfections were performed in the presence of known phosphatase

inhibitors. Inorganic phosphate competitively inhibits phosphatase isozymes with a micromolar K_i (31). With 10 mM phosphate in the transfection medium, no phosphatase activity was observed with the cells using *p*-nitrophenyl phosphate as the marker. The second inhibitor *L*-*p*-bromotetramisole (32) is a specific inhibitor of alkaline phosphatases, and complete inhibition of phosphatase activity is observed at the concentration used. The ability of the C2 system to transfect in the absence of alkaline phosphatase activity means that this isozyme is not the dominant mechanism in the transfection process but does not rule out the involvement of acid phosphatase.

Calcium was known (*vide supra*) to cause the aggregation of the liposomes at the concentration found in cell culture media (1.36 mM), and flocculate particles were observed in the transfection medium. The interaction of calcium with the negatively charged liposomes, causing aggregation and fusion of the liposomes, could mediate the transfection. Moreover, calcium phosphate precipitation is a widely used method for the transfection of cells in culture, though at much higher concentrations of calcium and phosphate (37). Addition of the same amount of inorganic phosphate as was found in the liposome experiments (50 nmol of P_i) to naked DNA or to the cholesterol C2 phosphate (**3a**)/DOPE liposomes had no effect upon the transfection efficiency (Figure 6). Therefore, a direct effect of released phosphate via a DNA/calcium phosphate precipitation does not mediate the transfection. However, the liposomes may provide a multivalent surface that could form a coprecipitate with DNA in the presence of calcium to mediate the transfection. Formation of this coprecipitate would not require the DNA to be encapsulated in the liposome before addition of the calcium as long as it could be recruited into the aggregate. Indeed, if cholesterol C2 phosphate (**3a**)/DOPE liposomes are mixed with DNA at the same concentrations used in the encapsulated transfection experiments, the transfection efficiency is identical.

The ability of anionic liposomes to form cochleates in the presence of divalent cations has long been recognized (38). More recently, this has been used to encapsulate macromolecules such as proteins and DNA inside the cochleate (39). These cochleates have been proposed for use as an oral DNA vaccine which is absorbed by the lower intestine before slowly releasing the trapped immunogen, thus, initiating a strong immune response (40). The cholesterol C2 phosphate (**3a**)/DOPE liposomes readily formed cochleate-like structures upon the addition of calcium to the suspension. Fluorescent DNA was incorporated into the precipitate even without preencapsulation, and addition of EDTA lead to partial release and partial encapsulation of the DNA in giant liposomes (data not shown). In the case of the cholesterol C2 phosphate (**3a**)/DOPE system, the coprecipitate appears to mediate the transfection of cells in culture.

The more calcium stable cholesterol triethylene phosphate (**3d**)/DOPE liposomes do not form flocculates in the culture medium. DNA encapsulated in the liposomes, however, is capable of transfecting cells in culture (Figure 7) which implies that the formation of visible aggregates is not essential for transfection with this liposome composition. Plasmid DNA mixed with empty liposomes of this composition is incapable of transfection. Indeed, only the cholesterol C2 phosphate (**3a**)/DOPE liposomes have shown this remarkable activity to date.

Removal of calcium from the transfection medium prevents endocytosis and will stop the calcium-mediated transfection of cells observed with CV-1 cells. The ability

of cholesterol C2 phosphate (**3a**)/DOPE liposomes to mediate transfection is dependent upon the presence of calcium in the medium (Figure 8). In the absence of the calcium required to form the flocculate, the cholesterol C2 phosphate (**3a**)/DOPE liposome did not transfer DNA into cells. The cationic dendrimer-mediated transfection is also unaffected by the calcium concentration in the culture medium. The cationic polyplex, as opposed to the anionic liposomes, would be expected to bind to the cell surface electrostatically and undergo endocytosis once calcium was returned to the system. Removal of surface-bound polyplex with a salt wash prior to the readministration of calcium containing media significantly reduced transfection.

Transfection mediated by the cholesterol triethylene phosphate (**3d**)/DOPE liposomes are less affected by the absence of calcium in the media. Thus, the phosphatase-sensitive cholesterol triethylene phosphate (**3d**)/DOPE liposomes do not mediate transfection exclusively through a calcium mediated mechanism.

The ability to modulate the calcium sensitivity of the triggered release liposomes and to utilize other release mechanisms should allow liposome formulations to be designed for specific tasks based upon the site of action and desired route of administration. For example, the extremely high levels (~50 units/mL) of acid phosphatase present in the prostate gland (28) suggests that this system may be an efficient agent for disease states of this gland. Alternatively, by utilizing the antibody-directed enzyme prodrug therapy (ADEPT) approach (41), very high concentrations of the activating enzyme, such as alkaline phosphatase (42), can be directed to tumors. The passively circulating cholesterol phosphate derivative/DOPE liposomes would then be specifically degraded at the site of the tumor, targeting the transfection or drug delivery to the desired site of action.

CONCLUSION

We have proposed and synthesized a novel class of triggered release liposomes. These conditionally stable liposomes collapse in the presence of phosphatase isozymes or calcium which results in the release of the liposome contents. The sensitivity of the liposomes to each triggering mechanism can be modulated by changing the structure of the cholesterol phosphate derivative. This allows the triggered release liposome to be tailored to give the desired balance of sensitivity for a particular purpose and site of action. DNA encapsulated in these liposomes is capable of transfecting CV-1 cells *in vitro* at levels competitive with other triggered release systems. The transfection is mediated by calcium for certain formulations, but other transfection mechanisms start to play a role in the less calcium-sensitive cholesterol triethylene phosphate (**3d**)/DOPE formulations.

Functionalized Semitelechelic Poly[*N*-(2-hydroxypropyl)methacrylamide] for Protein Modification

Zheng-Rong Lu,[†] Pavla Kopečková,^{†,‡} Zhuchun Wu,[§] and Jindřich Kopeček^{*,†,‡}

Departments of Pharmaceutics and Pharmaceutical Chemistry/CCCD and of Bioengineering, Mass Spectrometry Facility, University of Utah, Salt Lake City, Utah 84112. Received May 12, 1998; Revised Manuscript Received July 17, 1998

Semitelechelic poly[*N*-(2-hydroxypropyl)methacrylamide]s (ST-PHPMA) with different functional end groups, namely carboxyl, methyl ester, hydrazide, and amino groups, were prepared by chain transfer free-radical polymerization. 2,2'-Azobisisobutyronitrile (AIBN) was used as an initiator and 3-mercaptopropionic acid, methyl 3-mercaptopropionate, 3-mercaptopropionic hydrazide, and 2-mercaptoethylamine were used as chain-transfer agents. The semitelechelic polymers have been characterized by end-group analysis, size-exclusion chromatography (SEC), and matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS). The effects of the concentrations of the mercaptans and the initiator on the molecular weight of the polymers have been investigated. The higher the concentration of mercaptan, the lower the molecular weight of ST-PHPMA. The concentration of initiator did not have a significant effect on the molecular weight of the semitelechelic polymers. The end groups of the ST polymers can be readily transformed by polymeranalogous reactions. A model protein, α -chymotrypsin, has been modified with ST-PHPMA-CONHNH₂ and ST-PHPMA-COOSu and the conjugates characterized by MALDI-TOF MS. The activity of modified chymotrypsins toward a high molecular weight substrate, P-Gly-Leu-Phe-Nap (where P is the HPMA copolymer backbone, and Nap is *p*-nitroanilide), was slightly lower than the activity of the native enzyme. The cleavage of a low molecular weight substrate, Z-Gly-Leu-Phe-Nap, by modified chymotrypsins was dependent on their structure. Whereas the activity of the amino group modified chymotrypsins was higher than that of the native enzyme, the activity of carboxyl-modified chymotrypsins was lower than that of the native enzyme. In summary, the data seem to indicate that ST-PHPMA is an effective protein-modifying agent.

INTRODUCTION

Semitelechelic (ST)¹ polymers are linear macromolecules containing a functional group at one end of the polymer chain. The functional group can be used for conjugating or grafting the polymer chains to other molecular species or surfaces without causing cross-

linking. For example, the covalent attachment of methoxy poly(ethylene glycol) (mPEG) to therapeutic proteins increases their resistance to proteolysis, reduces their antigenicity, and prolongs their intravascular half-life (1–3). The attachment of PEG to biomaterial surfaces results in protein repulsion as a result of PEG's low interfacial free energy with water, hydrophilicity, high surface mobility, and steric stabilization effects (4). Covalent conjugation of PEG with hydrophobic anticancer drugs results in more soluble and more easily formulated and delivered drugs (5).

Numerous ST polymers of different structures have been evaluated and many possess effects similar to PEG when conjugated to proteins. Structural characteristics of ST polymers, such as the molecular weight (6), linearity, or branching (7), chemical structure (8–15), and degree of substitution (16) are decisive for the properties of the conjugates. A suitable route for the synthesis of ST polymers is radical polymerization in the presence of chain-transfer agents. Okano et al. have shown that mercaptans are effective at introducing functional groups to the ends of macromolecules and regulating the molecular weight via chain-transfer reactions (12, 17).

N-(2-Hydroxypropyl)methacrylamide (HPMA) copolymers are water-soluble biocompatible polymers used in anticancer drug delivery (reviewed in ref 18). HPMA copolymers containing reactive groups at side-chain termini were used for the modification of trypsin (19), chymotrypsin (19, 20), and acetylcholinesterase (21). The attachment via side-chain termini most probably resulted

in multiple point attachment of the macromolecules to the protein. Nevertheless, a dramatic increase in the acetylcholinesterase survival in the blood stream of mice (21) and in the thermostability of modified enzymes (19, 21) was observed when compared to the native proteins.

The multipoint attachment of the polymers to protein has the disadvantage that it may cause unexpected cross-linking. The synthesis of semitelechelic poly[*N*-(2-hydroxypropyl)methacrylamide] (ST-PHPMA) permits one-point attachment of HPMA macromolecules to surfaces and proteins, and avoids the possible cross-linking caused by multipoint attachment. Its covalent attachment to nanospheres resulted in surfaces with decreased biorecognizability (10). It appears that ST-PHPMA has potential as a protein or biomaterial surface-modifying agent. Consequently, this study is devoted to the synthesis of ST-PHPMA containing different functional groups, namely amino, carboxyl, *N*-hydroxysuccinimide ester, methyl ester, and hydrazide groups. These groups were introduced at one end of the polymer chains using functionalized mercaptans as chain-transfer agents or by polymeranalogous reactions of semitelechelic intermediates. The functionality and the molecular weight of ST-PHPMA were characterized by end-group determination and size exclusion chromatography (SEC).

Carboxyl and amino group directed modifications of a model protein, α -chymotrypsin, with ST-PHPMA were performed. The impact of chemical modification on the enzymatic activity of ST-PHPMA-substituted chymotrypsins was determined using low and high molecular weight substrates. The macromolecules and conjugates have been characterized by classical methods (SEC, UV, protein content, and functional group determination) and by matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS) (22).

EXPERIMENTAL PROCEDURES

Chemicals. Phe and Leu were of L-configuration. HPMA (23) and the substrates Z-Gly-Leu-Phe-Nap (16) and HPMA copolymer attached Gly-Leu-Phe-Nap, P-Gly-Leu-Phe-Nap (16) were prepared as described. α -Chymotrypsin from bovine pancreas was from Sigma, St. Louis, MO. 2,2'-Azobisisobutyronitrile (AIBN) was purified by recrystallization from ethanol. Methyl 3-mercaptopropionate, 3-mercaptopropionic acid, and 2-mercaptoethylamine (Aldrich, Milwaukee, WI) were used without further purification. Solvents and all other reagents were of reagent grade or better.

Synthesis of 3-Mercaptopropionic Hydrazide. Methyl 3-mercaptopropionate (10 g, 83 mmol) was added dropwise to an excess of hydrazine monohydrate (10 g, 200 mmol) dissolved in 30 mL of methanol, and the reaction mixture was stirred at rt for 72 h. Methanol was removed under vacuum and the product separated by chromatography on a silica gel column eluted with methanol/diethyl ether (1:4). The fraction containing the product was collected and the solvent removed by rotoevaporation. The oily product, 3-mercaptopropionic hydrazide, was dried under vacuum; yield 8.3 g, (83%); R_f = 0.62 (methanol/acetonitrile, 1:4). ^1H NMR (CDCl_3 , ppm): 1.57 (t, 1H, SH), 2.43 (t, 2H, COCH_2), 2.76 (m, 2H, CH_2SH), 3.96 (sh, 2H, NH_2), 7.55 (sh, 1H, NH). MS (scan ES^+ , m/z): 121.6 ($\text{M}^+ + 1$).

Synthesis of Semitelechelic Polymers. Semitelechelic HPMA polymers were prepared by free-radical solution polymerization in methanol using functionalized mercaptans as chain-transfer agents (17) and AIBN as the initiator. A typical synthesis is described below using

Table 1. Synthesis and Characterization of ST-PHPMA-COOSu^a Polymers

as an example the synthesis of a ST-PHPMA-COOH polymer. All polymers were isolated by precipitation as described below, except the ST-PHPMA-CONHNH₂ polymers which were dialyzed against water using a membrane with molecular weight cut off (MWCO) 500 and isolated by freeze-drying.

Synthesis of ST-PHPMA-COOH. HPMA (1.0 g, 7.0 mmol), 3-mercaptopropionic acid (22 mg, 0.21 mmol), and AIBN (50 mg, 0.3 mmol) were dissolved in 10 mL of methanol. The solution was bubbled with nitrogen and sealed in an ampule. The reaction mixture was stirred at 50 °C for 24 h. After polymerization, the volume of the reaction mixture was reduced, the polymer was isolated by precipitation into diethyl ether, filtered, and washed with diethyl ether. The product was purified by reprecipitation three times. The weight-average (M_w) and number-average (M_n) molecular weights and polydispersity were determined by size-exclusion chromatography (SEC) on a Superdex 75 HR 10/30 column calibrated with ST-PHPMA samples of narrow polydispersity ($M_w/M_n < 1.1$; molecular weight of calibration samples were determined by MALDI-TOF MS) using a Pharmacia FPLC system (PBS buffer, pH 7.3); $M_n = 5410$, $M_w = 7530$, $M_w/M_n = 1.4$. The content of end groups determined by titration was 0.181 mmol/g. The number-average molecular weight [$M_{n(\text{end})}$] calculated from the content of end groups was 5510; the ratio of molecular weights obtained from SEC and end group determination, $M_n/M_{n(\text{end})} = 0.98$.

Fractionation of ST-PHPMA Polymers. The fractionation of ST-PHPMA polymers was performed by SEC on a Superdex 75 HR 16/60 column (PBS buffer, pH 7.3). For example, ST-PHPMA-NH₂ in PBS buffer was applied on the column, and the polymer fractions were collected at different elution time intervals. The polymer fractions were desalted by dialysis, lyophilized, and characterized by MALDI-TOF MS and SEC on a Superdex 75 HR 10/30 column (PBS buffer, pH 7.3) using a Pharmacia FPLC system equipped with a refractive index detector.

Polymeranalogous Transformations. *Synthesis of ST-PHPMA-COOSu.* ST-PHPMA-COOSu polymers were synthesized by the reaction of ST-PHPMA-COOH and *N*-hydroxysuccinimide in the presence of dicyclohexylcarbodiimide (DCC) in anhydrous DMF. Polymers with different properties were obtained under different synthetic conditions, and the yield and degree of the modification are reported in Table 1. The procedure will be demonstrated by the synthesis of polymer 3. ST-PHPMA-COOH [$M_{n(\text{end})} = 3800$; 280 mg, 0.073 mmol] and *N*-hydroxysuccinimide (120 mg, 1.0 mmol) were dissolved

in 5 mL of anhydrous DMF and cooled in an ice–water bath. DCC (200 mg, 1.0 mmol) in 3 mL of DMF was added dropwise with stirring. The mixture was kept at 4 °C for 48 h, and at rt for an additional 12 h. The volume of the reaction mixture was reduced under vacuum, dicyclohexyl urea (DCU) was removed by filtration, and the polymer solution was precipitated by dropping it into an excess of diethyl ether. The product (**3**) was purified by reprecipitation three times (methanol solution to diethyl ether) and dried under vacuum. Yield: 150 mg, 54%. The amount of active ester groups was determined by detecting the released *N*-hydroxy-succinimide anion after addition of an excess of 1-amino-2-propanol; $\epsilon_{260\text{ nm}} = 8500\text{ M}^{-1}\text{ cm}^{-1}$ (24). The yield of active ester formation was 80%, based on the COOH content determined by titration.

Synthesis of ST-PPHMA-CONHNH₂ by Hydrazinolysis of ST-PPHMA-COOCH₃. An alternate route of ST-PPHMA-CONHNH₂ synthesis was the hydrazinolysis of ST-PPHMA-COOCH₃. The ST-PPHMA-COOCH₃ polymers used for hydrazinolysis, the yield and properties of ST-PPHMA-CONHNH₂ are reported in Table 2. The synthesis of polymer **8** (Table 2) is shown as an example. ST-PPHMA-COOCH₃ (0.7 g, 0.2 mmol) was dissolved in 5 mL of methanol and added dropwise to a 20 mL methanol solution of hydrazine monohydrate (0.75 g, 15 mmol) with stirring. The reaction mixture was refluxed for 5 h and concentrated by rotoevaporation. The product was isolated by precipitation into an excess of diethyl ether, dialyzed against deionized water (tubing, MWCO 500), and lyophilized; yield 0.41 g, 58%. The weight-average (M_w), number-average (M_n) molecular weights, and polydispersity were determined by SEC on a Superdex 75 column calibrated with fractions of PPHMA (PBS buffer, pH 7.3) using a Pharmacia FPLC system, $M_n = 4830$, $M_w = 7930$, $M_w/M_n = 1.64$. The content of hydrazide end groups was determined by the modified TNBS assay (0.300 mmol/g) (25). The number-average molecular weight [$M_{n(\text{end})}$] based on the content of end groups was 3330, $M_n/M_{n(\text{end})} = 1.45$.

Methods for End Group Determination. *Determination of COOH Groups.* ST-PPHMA-COOH samples were titrated with sodium hydroxide standard solution using an ABU80 autoburet and PHM84 research pH meter as monitor.

Determination of COOCH₃ Groups by Hydrolysis. ST-PPHMA-COOCH₃ samples (<50 mg) were dissolved in standard KOH solution (excess). The solution was kept at 50 °C for 2 h to hydrolyze all COOCH₃ groups, followed by back-titration of residual KOH by HCl.

Determination of COOCH₃ Groups by ¹H NMR. The proton NMR spectra were recorded on a Bruker NR200 FTNMR spectrometer using D₂O as the solvent. The integration of the peaks of the protons of the methyl ester group ($\delta = 3.58\text{ ppm}$) and the proton on C-2 ($\delta = 3.8\text{ ppm}$) of the 1-amino-2-propanol residue were used to estimate the content of methyl ester and the number average molecular weight, $M_{n(\text{end})}$.

Determination of Hydrazide Groups by TNBS Assay. ST-PPHMA-NHNH₂ was dissolved in 0.1 M sodium tetraborate, pH 9.3. The polymer solution (1.0–2.0 mg; 1.0 mL) was mixed with 25 μL of 0.03 M TNBS aqueous solution in a cuvette, vortexed, and kept at room temperature for 30 min. Absorbance was read at 500 nm (25). NH₂NHCOOC₂H₅ was used as a calibration standard.

*Determination of COOSu Groups by Polymeranalogous Reaction with Glycine *p*-Nitroanilide.* Example: ST-PPHMA-COOSu (**2**, Table 1; 5.31 mg, $1.0 \times 10^{-3}\text{ mmol}$) and (excess) glycine *p*-nitroanilide (5.0 mg, 0.026 mmol) were dissolved in 0.5 mL of DMF and kept at rt for 1 h and the polymer purified on a Sephadex G-25 column (PD-10, Pharmacia). The content of polymer bound *p*-nitroanilide was determined by UV spectrophotometry at 315 nm ($\epsilon = 1.3 \times 10^4\text{ M}^{-1}\text{ cm}^{-1}$ in water). The content of COOSu end groups was 77% of theory.

Determination of Amino Groups. The amino groups were determined by ninhydrin assay. Glycine was used for the calibration.

Modification of Chymotrypsin with ST-PPHMA. Nine conjugates of chymotrypsin with ST-PPHMA were synthesized. Conjugates **I–IV** were synthesized by amino group directed modification whereas conjugates **V to IX** were synthesized by carboxyl-directed modification. The synthesis and characterization of the conjugates are described below.

Amino Group-Directed Modification of Chymotrypsin with ST-PPHMA-COOSu. *Conjugate I.* ST-PPHMA-COOSu (**2**, Table 1) [200 mg, 0.036 mmol, based on $M_{n(\text{end})}$] and α -chymotrypsin (30 mg; $1.2 \times 10^{-3}\text{ mmol}$) were dissolved in 6 mL of 20 mM CaCl₂ aqueous solution [molar ratio of chymotrypsin to polymer, based on $M_{n(\text{end})}$ was 1:30]. The pH of the reaction mixture was maintained at 7.0–7.5 for 1 h at 4 °C by adding dilute NaOH solution, raised to 8.0 and maintained for 30 min. The pH was then adjusted with dilute HCl to 3.0 for storage. The unbound polymer was removed by ultrafiltration with a Centricon-30 concentrator (membrane MWCO = 30 000). The ultrafiltration was repeated 5 times by adding fresh 20 mM CaCl₂ solution (pH 3.0) each time. The degree of conjugation was 22% as determined by the TNBS assay (26) calibrated with chymotrypsin. The conjugate was characterized with MALDI-TOF MS, and the M_n and M_w of the conjugate were 44 900 and 46 600 Da, respectively. The molecular weights of the conjugate ($M_n = 46\text{ 300}$; $M_w = 54\text{ 000}$) were also determined by SEC on a Superose 6 HR 10/30 column with a light-scattering detector (MiniDawn, Wyatt) after the conjugate was desalted and lyophilized. The conjugate contained three to four ST-PPHMA chains per protein molecule.

Conjugate II. The reaction of ST-PPHMA-COOSu (**4**; Table 1) with chymotrypsin was performed as described for conjugate **I** with the exception that the molar ratio of chymotrypsin to the polymer was 1:40 and pH of the reaction mixture was maintained at 8.5. The degree of the conjugation was 43% as determined by the TNBS

Figure 1. The MALDI-TOF mass spectrum of amino group modified chymotrypsin conjugate (**III**). ST-PHPMA-COOSu (**5**; Table 1) prepared from ST-PHPMA-COOH (**11**, Table 5, Figure 6) was used for the conjugation. The M_n and M_w of the fraction calculated from the MS were 40 860 and 41 690, respectively. Average six polymer chains were attached to each enzyme molecule.

assay. The M_n and M_w of the conjugate as determined by MALDI-TOF MS were 49 400 and 51 000 Da, respectively. The conjugate contained six to seven ST-PHPMA chains per protein molecule.

Conjugate III. The reaction of ST-PHPMA-COOSu (**5**; Table 1) with chymotrypsin was performed as described for conjugate **I**. The degree of conjugation was 34% as determined by the TNBS assay. The M_n and M_w of the conjugate from MALDI-TOF MS (Figure 1) were 40 900 and 41 700 Da, respectively. The conjugate contained six ST-PHPMA chains per protein molecule.

Conjugate IV. The reaction of ST-PHPMA-COOSu (**5**; Table 1) with chymotrypsin was performed as described for conjugate **III** with the exception that the molar ratio of α -chymotrypsin and polymer was 1:17 based on $M_{n(\text{end})}$. The degree of conjugation was 25% as determined by the TNBS assay. The M_n and M_w of the conjugate from MALDI-TOF MS were 36 100 and 37 800 Da, respectively. The conjugate contained four ST-PHPMA chains per protein molecule.

Carboxyl-Directed Modification of Chymotrypsin with ST-PHPMA-CONHNH₂. **Conjugate V.** ST-PHPMA-CONHNH₂ [$M_{n(\text{end})}$ = 2490; M_n = 3380, M_w = 4750] [300 mg, 0.12 mmol based on $M_{n(\text{end})}$] and α -chymotrypsin (25 mg, 1.0×10^{-3} mmol) were dissolved in 5 mL of 20 mM CaCl₂ aqueous solution, pH 5.0. 1-Ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride (38 mg, 0.2 mmol) was added to the solution, and the reaction mixture stirred at 4 °C for 12 h. The pH of the reaction mixture was maintained at 4.5–5.0 by adjusting with diluted HCl. After the reaction was completed, the pH of the reaction mixture was adjusted to 3.0 with diluted HCl and the unbound polymer removed by ultrafiltration with a Centricon-30 concentrator (membrane MWCO = 30 000). The ultrafiltration was repeated 5 times after adding fresh 20 mM CaCl₂ solution (pH 3.0) each time. The enzyme conjugate was characterized by SEC on a Superdex 75 HR 10/30 column (PBS buffer, pH 7.3) using a Pharmacia FPLC system. The result indicated that almost all free polymer was removed. In addition, the conjugate was characterized with MALDI-TOF MS (Figure 2); the M_n and M_w of the conjugate were 46 600 and 47 800 Da, respectively. The conjugate contained eight to nine ST-PHPMA chains per protein molecule.

Conjugate VI. The conjugate was synthesized by the reaction of α -chymotrypsin with a narrow fraction of ST-PHPMA-CONHNH₂. The ST-PHPMA-CONHNH₂ fraction collected from SEC on a Superdex 75 HR16/60 column was lyophilized. The salts were removed by

Figure 2. The MALDI-TOF mass spectrum of carboxyl group modified chymotrypsin conjugate (**V**). ST-PHPMA-CONHNH₂ [$M_{n(\text{end})}$ = 2490; M_n = 3380, M_w = 4750] was used for the conjugation. The peak around m/z = 45 000 is the single charged conjugate, the small peak around m/z = 22 000 is the double charged conjugate. The M_n and M_w of the conjugate calculated from the MALDI-TOF MS were 46 600 and 47 800 Da, respectively. There are eight to nine polymer chains attached to each enzyme molecule.

extracting the polymer with ethanol. The content of hydrazide groups was determined by TNBS assay, which was used for calculating the stoichiometry of the conjugation reaction. The ST-PHPMA-CONHNH₂ fraction (M_n = 1300, M_w = 1400; 22 μ mol), α -chymotrypsin (10 mg, 0.4 μ mol), and 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride (40 mg, 0.2 mmol) were dissolved in 2.0 mL of pH 4.5 water. The reaction mixture was stirred at 4 °C for 12 h and the pH of the reaction mixture maintained at 4.5–5.0. The conjugate was separated from the free polymer by SEC on a Superose 6 HR 10/30 column, concentrated and desalted by centrifuge ultrafiltration with a Centricon-10 concentrator (MWCO = 10 000). The conjugate was characterized by MALDI-TOF MS (Figure 3), and the average M_n and M_w of the conjugate as calculated from the MS were 36 650 and 36 800, respectively. Approximately nine ST-PHPMA chains were attached to one protein molecule.

The conjugates **VII**, **VIII**, and **IX** were prepared by the conjugation of chymotrypsin with ST-PHPMA-CONHNH₂ polymer fractions with different molecular weight. The conjugation reactions were carried out according to the procedure for preparation of conjugate **VI**. All of the conjugates were characterized by MALDI-TOF MS. The molarity of different reactants, the molecular weights of the fractions and the molecular weights of the conjugates calculated from the MALDI-TOF MS are reported in Table 3.

Chymotryptic Activity. α -Chymotrypsin contained 65% of active protein as determined by titration of active sites with Z-Tyr-ONp (27). The stock solutions of native and modified α -chymotrypsins were prepared in 1 mM HCl containing 20 mM CaCl₂, pH 3.0. Their concentrations were determined spectrophotometrically at 280 nm using ϵ = 5.2×10^4 M⁻¹ cm⁻¹. A low molecular weight substrate, Z-Gly-Leu-Phe-NAP and a high molecular weight substrate, P-Gly-Leu-Phe-NAP (HPMA copolymer containing 3.4 mol % of -Gly-Leu-Phe-NAP side chains) were used for the evaluation of enzyme activities. The stock solution of Z-Gly-Leu-Phe-NAP was prepared by dissolving it in the smallest amount of DMSO possible and then diluting with Tris/CaCl₂ buffer (80 mM Tris + 20 mM CaCl₂, pH 8.0). The final concentration of DMSO in the reaction mixture was less than 5% (v/v). The stock solution of P-Gly-Leu-Phe-NAP was prepared directly in the Tris/CaCl₂ buffer. The concentration of NAP in the

Table 3. Characterization of Carboxyl Group Modified Chymotrypsin Conjugates with ST-PHPMA-CONHNH₂ Polymer Fractions

Figure 3. (A) The MALDI-TOF mass spectrum of ST-PHPMA-CONHNH₂ with narrow distribution of molecular weights obtained by SEC fractionation. Peak series **a** represent the peaks of polymer chains with initiator end groups; peak series **b** represent the peaks of semitelechelic polymer chains with hydrazide end groups; peak series **c** represent the peaks of polymer chains with unknown structure, probably formed by the side reaction during the polymerization. Peaks **x** are peaks related to the matrix used for analysis. The M_n and M_w of the ST-PHPMA-CONHNH₂ fraction calculated from the MS were 1300 and 1400, respectively. (B) The MALDI-TOF mass spectrum of the chymotrypsin conjugate (**VI**) with the ST-PHPMA-CONHNH₂ fraction shown above. The peak around $m/z = 35\,000$ is the single charged conjugate, and the small peak around $m/z = 17\,500$ is the double charged conjugate. The M_n and M_w of the conjugate were 36 650 and 36 800, respectively. Average nine (8.8) polymer chains were attached to each enzyme molecule.

stock solutions was determined by UV spectrophotometry (315 nm, $\epsilon = 13\,000\text{ M}^{-1}\text{ cm}^{-1}$).

Cleavage of *p*-Nitroanilide Substrates. The kinetics of enzymatic cleavage of the substrates was performed at 37 °C and the *p*-nitroanilide release monitored at 410 nm using a Lambda 9 Perkin-Elmer spectrophotometer. The concentration of enzyme was $2.16 \times 10^{-7}\text{ M}$; the concentration of substrates was (8.0×10^{-6}) – $(9.0 \times 10^{-5})\text{ M}$ for Z-Gly-Leu-Phe-NAP, and (8×10^{-5}) – $(1 \times 10^{-3})\text{ M}$ for P-Gly-Leu-Phe-NAP. Each set of kinetic measurements was performed with eight different substrate concentra-

tions. The initial rates were calculated using $\epsilon = 8800\text{ M}^{-1}\text{ cm}^{-1}$. The kinetic parameters were calculated from Lineweaver–Burk plots of the initial rates of release of *p*-nitroaniline.

MALDI-TOF Mass Spectrometric Analysis. All ST-PHPMA polymers and α -chymotrypsin polymer conjugates were dissolved in 50% aqueous acetonitrile solution. 2-(4-Hydroxyphenylazo)benzoic acid (HABA) was used as the matrix for polymer samples, while sinapinic acid [SA; *trans*-3-(4-hydroxy-3,5-dimethoxyphenyl)acrylic acid] was used for the α -chymotrypsin polymer conjugates. The cationizing reagent, sodium chloride, was added to the matrixes to facilitate the ionization process in the analysis of polymers. All spectra were collected on a MALDI-TOF mass spectrometer (Voyager-DE STR Biospectrometry Workstation, PerSeptive Biosystems, Inc., Framingham, MA). The mass spectrometer is equipped with a nitrogen laser with a wavelength of 337 nm. The instrument was operated at a 20 kV accelerating voltage with the use of delayed extraction and the low-mass gate. The low-mass gate was set to cut out the matrix ions. The delayed time was varied to achieve the highest mass resolution. All spectra were obtained in linear mode with the instrument calibrated externally using peptides or proteins, such as angiotensin, insulin, and myoglobin, in the same solution and matrixes as used for sample analysis.

RESULTS AND DISCUSSION

Synthesis of ST-PHPMA Polymers. ST-PHPMA polymers with amino, carboxy, hydrazo, and methyl ester groups were synthesized by free radical chain-transfer polymerization using alkyl mercaptans, 2-mercaptoethylamine, 3-mercaptopropionic acid, 3-mercaptopropionic hydrazide, and methyl 3-mercaptopropionate as chain transfer agents, respectively (Scheme 1). The polymerization was carried out in methanol with AIBN as an initiator in the presence of alkyl mercaptans. The course of the polymerization was investigated systematically by variation of the concentration of mercaptans with constant concentrations of HPMA and AIBN or by variation of the concentration of AIBN with constant concentrations of HPMA and mercaptan. The change of the molar ratio of AIBN to HPMA did not have a significant effect on the chain length of the polymers when polymerization proceeded in the presence of chain-transfer agents (data not shown). However, the molecular weights of the semitelechelic polymers were strongly affected by the molar ratio of the chain-transfer agent and HPMA. The molecular weight decreased with increasing concentration ratio of the chain transfer agent and HPMA, Figure 4.

The reciprocal of the number average polymerization degree $[1/DP_{n(\text{end})}]$, determined by end group assays, was plotted against the molar ratio of chain transfer agent and HPMA ($[S]/[M]$). The linear relation of $1/DP_{n(\text{end})}$ and $[S]/[M]$ observed for all four chain-transfer agents used

Scheme 1. Synthetic Pathways for the Preparation of Semitelechelic PolyHPMA

Figure 4. The effect of molar ratio of chain transfer agents [2-mercaptoethylamine (Δ), methyl 3-mercaptopropionate ($\square$), 3-mercaptopropionic acid ($\diamond$) and 3-mercaptopropionic hydrazide ($\circ$)] to HPMA ($[S]/[HPMA]$) on the molecular weight of functionalized ST-PHPMA. The weight average molecular weights of the polymers, determined by SEC on a Superdex 75 HR10/30 column are shown here.

Table 4. Chain Transfer Constants (C_s) of Mercaptans Used for the Synthesis of ST-PHPMA Polymers

mercaptan	C_s
$HSCH_2CH_2NH_2$	0.08
$HSCH_2CH_2COOCH_3$	0.32
$HSCH_2CH_2COOH$	0.38
$HSCH_2CH_2CONHNH_2$	0.8

fits well with the Mayo equation (28):

$$1/DP_{n(end)} = 1/DP_{n,0} + C_s[S]/[M]$$

where $DP_{n(end)}$ and $DP_{n,0}$ are the number-average degrees of the polymerization in the presence and in the absence of the chain-transfer agent S; C_s is the chain-transfer constant, and $C_s = k_{tr}/k_p$, where k_{tr} is the rate constant for chain transfer and k_p is the rate constant for propagation. The chain-transfer constants of 2-mercaptoethylamine, 3-mercaptopropionic acid, methyl 3-mercaptopropionate and 3-mercaptopropionic hydrazide are listed in Table 4. 3-Mercaptopropionic hydrazide has the highest C_s , and was the most efficient chain-transfer agent among the four mercaptans, while 2-mercaptoethylamine has

the lowest C_s and was the least efficient chain-transfer agent. This is reflected in the molecular weights obtained; the lower the C_s , the higher the molecular weight of the ST-PHPMA at a constant ratio $[S]/[HPMA]$ (Figure 4).

Polymeranalogous Transformations. Semitelechelic polymers with active ester groups ST-PHPMA-COOSu were synthesized by the functional transformation reaction of ST-PHPMA-COOH with a large excess of *N*-hydroxysuccinimide and DCC (Scheme 1). This reaction is also called polymeranalogous transformation, because the main structure of the polymer is not changed. The results of the conversion of COOH into COOSu groups are summarized in Table 1. The ST-PHPMA-COOSu reacted quantitatively with an excess of glycine-*p*-nitroanilide, which was used for the determination of the content of the active ester end groups. The molecular weight of ST-PHPMA after polymeranalogous esterification did not change, confirming our assumption that secondary OH groups of HPMA monomer units were not reactive under the experimental conditions used. ST-PHPMA-CONHNH₂ was synthesized by the reaction of ST-PHPMA-COOCH₃ with an excess of hydrazine in high conversion of the functional groups (Table 2). The molecular weight of the ST-PHPMA-CONHNH₂ was higher than that of the polymer precursor, most probably due to the loss of low molecular weight polymer fractions during the dialysis used for purification. The proton NMR of the products showed that all methyl ester groups were converted to hydrazide groups. ST-PHPMA-CONHNH₂ can readily react with acetone to form ST-PHPMA with a hydrazone end group, which was used to distinguish ST-PHPMA-CONHNH₂ from ST-PHPMA-COOCH₃ in the MALDI-TOF mass spectroscopy, because both end groups have almost the same mass.

Characterization of the ST-PHPMA Polymers. The molecular weights of the semitelechelic polymers were estimated by SEC. The average molecular weights of the narrow ST-PHPMA fractions ($M_w/M_n < 1.1$) calculated from MALDI-TOF mass spectra have been used for the calibration of the SEC column. The end-group content of ST-PHPMA was determined by different chemical assays. The amino groups in ST-PHPMA-NH₂ were determined by ninhydrin and TNBS assays. The carboxyl groups of ST-PHPMA-COOH were determined by titration. The methyl ester groups in ST-PHPMA-COOCH₃ were determined by proton NMR and by hydrolysis with excess KOH followed by titration of the remaining KOH with HCl. The hydrazide end groups in ST-PHPMA-CONHNH₂ were determined by TNBS assay, or by the spectrophotometric measurement of

^a **A** and **B** are fractions of polymer **13** prepared by size-exclusion chromatography on a preparative Superdex 75 column. ^b Determined by SEC on a Superose 6 HR 10/30 column with MiniDawn light scattering detector; the molecular weights of all other polymers were determined on a Superdex 75 HR 10/30 column calibrated with fractions of PHPMA of narrow polydispersity.

p-nitrobenzaldehyde hydrazone after reacting the polymer with *p*-nitrobenzaldehyde. The functionalities of the polymers determined by different assays used for the same functional group were in good agreement. The number-average molecular weight $M_{n(\text{end})}$ of the polymers was also calculated from the content of the functional end groups. However, it has been noticed that the $M_{n(\text{end})}$ of the ST polymers prepared with a low molar ratio of mercaptan to HPMA (used to prepared high molecular ST polymers) was higher than the M_n determined by SEC, because more polymer chains with initiator end groups were produced when the concentration of chain-transfer agent was lower.

The ST-PHPMA polymers were also characterized by MALDI-TOF mass spectrometry. MALDI-TOF MS is an important new tool for the characterization of proteins and synthetic polymers. It can accurately determine the molecular weight of a protein and a polymer chain. The precise measurement of the molecular weights of polymer chains by MALDI-TOF MS enables the determination of repeating units and end-group compositions (29, 30). The classic SEC can only provide the molecular weight distribution, which requires calibration with standard materials of similar structure to calculate the molecular weight, and the effect of column broadening in the SEC contributes to an increased value of the M_w/M_n observed (31). However, for synthetic polymers with a broad molecular weight distribution, MALDI-TOF MS could not provide the accurate molecular weight distribution, and the peaks corresponding to higher masses are underestimated in the spectra (32, 33). Published data on polymers of different structures indicate that MALDI-TOF MS analysis results in lower values of molecular weights for the polymers with high polydispersity ($PD > 1.1$) when compared to SEC. There were attempts to improve the analysis of MALDI-TOF MS spectra of polydisperse samples (32); however, the best agreement between data from MALDI-TOF MS and traditional methods was obtained for polymer samples with a narrow polydispersity (31, 34). The analyses of ST-PHPMA polymers here also show that there is a good agreement of the average molecular weights between MALDI-TOF MS and SEC for polymers with a narrow polydispersity ($PD < 1.1$), and the average molecular weight of the polymers with high polydispersity ($PD > 1.2$) determined by the MS was lower than those determined by SEC.

Table 5 lists the average molecular weights determined by SEC, MALDI-TOF MS for ST-PHPMA polymer fractions **A** and **B**, polymer–chymotrypsin conjugate (**III**), and some ST-PHPMA polymers. For polymer fractions (**A** and **B**) with a narrow polydispersity ($M_w/M_n < 1.1$), which were fractionated by SEC from polymer **13** (Table 5), both the number-average and weight-average molecular weights from the MS were only slightly lower than those from SEC, and the difference between two methods

was less than 7%. The molecular weights of the chymotrypsin–polymer conjugates determined by MALDI-TOF MS also agreed well with those determined by SEC equipped with an on-line light-scattering detector (MiniDawn, Wyatt). The difference between the number-average molecular weights (3%) was smaller than the difference between the weight-average molecular weights (14%). However, for polymers **10–13** with higher polydispersity ($PD > 1.2$), the molecular weights from MALDI-TOF MS were considerably lower than those obtained from SEC (using a column calibrated with fractions), because MALDI-TOF MS underestimated the contribution from higher molecular weight polymer chains (32). The difference between the molecular weights obtained from the two methods increased with increasing polydispersity.

Although MALDI-TOF MS could not give the true shape of the molecular weight distribution for ST-PHPMA polymers with high polydispersity (33), the accurate determination of the molecular weight of individual polymer chains may provide very important information on the chemical structure of the end groups and the composition of the individual macromolecules of semitelechelic polymers (29, 30).

Figure 5 shows the MALDI-TOF mass spectrum of ST-PHPMA-CONHNH₂ (**10**; Table 5). The mass spectrum clearly showed the presence of HPMA polymer chains with different end groups in the polymer mixture. The peak-to-peak increment for the polymer chains with identical end groups was 143.2, the molar mass of HPMA. The peak series **a** at $m/z = (n \times 143.2) + 23.0$ (Na^+) + 68.1 + 1.0 (n is the number of repeat units; mass of initiator residue $\text{Me}_2[\text{CN}]\text{C} = 68.1$) corresponds to the polymer chains initiated by isobutyronitrile (IBN) radicals and then terminated by a proton from the chain transfer agent. The sodium ion was used to cationize the polymer chains. The peak series **b** at $m/z = (n \times 143.2) + 23.0$ (Na^+) + 120.2 (molar mass of 3-mercaptopropionic hydrazide = 120.2 Da) represents the semitelechelic polymer chains $\text{H}-(\text{HPMA})_n\text{-SCH}_2\text{CH}_2\text{CONHNH}_2$. There was an unknown series **c** at $m/z = (n \times 143.2) + 23.0$ (Na^+) + 146.0 in the spectrum of ST-PHPMA-CONHNH₂, whose origin is not known. One might suspect that these macromolecules are products of side reactions during polymerization.

Figure 6 shows the MALDI-TOF mass spectrum of ST-PHPMA-COOH (**11**; Table 5) which was used, after esterification to ST-PHPMA-COOSu, for the synthesis of conjugate **III**. The spectrum contains the peak series **a** which corresponds to the polymer chains initiated by IBN radicals and then terminated by a proton from the chain-transfer agent (similar to that shown in the spectrum in Figure 5). The peak series **d** at $m/z = (n \times 143.2) + 23.0$ (Na^+) + 106.1 (molar mass of mercaptopropionic acid = 106.1) and **e** at $m/z = (n \times 143.2) + 23.0$ (Na^+) + 128.1

Figure 5. The MALDI-TOF mass spectrum (A) of ST-PHPMA-CONHNH₂ (**10**; Table 5) and its expanded spectrum (B) in the region of 1300–1800 Da. IBN is the isobutyronitrile radical, formed by decomposition of AIBN; Hyz is the hydrazide end group; X is an unknown end group.

(molar mass of sodium mercaptopropionate = 128.1) represents the peaks of the semitelechelic polymer chains of H-(HPMA)_n-SCH₂CH₂COOH and H-(HPMA)_n-SCH₂-CH₂COONa, respectively. The latter peak series is due to the replacement of the proton in the carboxyl group by Na⁺ during the analysis by MALDI-TOF MS.

It appears that the polymerization of HPMA in the presence of potent chain-transfer agents permits the synthesis of semitelechelic macromolecules. The polymerization method is based on the assumption that the reaction of the chain-transfer agent occurs with primary radicals formed by the decomposition of AIBN. However, this takes place only when a high excess of the chain-transfer agent is present. The participation of the chain-transfer reaction with growing polymer chains results in macromolecules containing the initiator residues at one end of the macromolecule and a saturated chain end, formed by hydrogen atom transfer, at the other (see peak series **a** in Figures 5 and 6). Moreover, for a given

composition of the polymerization mixture, the probability of the reaction of chain-transfer agent with primary radicals will decrease with time (conversion). It is important to note, that from the point of view of protein modification, macromolecules having the structure **a** are nonreactive, inert components of ST-PHPMA.

Modification of Chymotrypsin with ST-PHPMA Polymers. Both carboxyl and amino groups can be used for the modification of proteins with semitelechelic polymers. The selection of the modification mode may be important for the biological activity of the protein-polymer conjugate. For example, Sakam and Pardridge (35) have shown that carboxyl-directed pegylation of brain-derived neurotrophic factor preserved the biological activity of the conjugate, whereas the amino group directed modification did not. Pettit et al. (36) have shown that amino group directed pegylation of interleukin-15 alters the biological activity of the conjugate.

There are 17 carboxyl groups and 17 amino groups in

Figure 6. The MALDI-TOF mass spectrum (A) of ST-PHPMA-COOH (**11**; Table 5) and its expanded spectrum (B) in the region of 1500–1900. IBN is the isobutyronitrile radical, formed by decomposition of AIBN.

α -chymotrypsin. ST-PHPMA-CONHNH₂ and ST-PHPMA-COOSu were used for the carboxyl and amino group directed modification of chymotrypsin, respectively. The amino-directed modification of proteins with polymers containing active ester groups is the most frequently used method. The carboxyl group directed modification with polymers containing hydrazo groups is a new method, which was first introduced by Zalipsky (3, 25, 37). The difference of the pK_a of hydrazide ($pK_a \approx 3.0$) and the amino groups of proteins ($pK_a = 6.8$ – 8.0 for α -amino, 10.4–11.1 for ϵ -amino of lysine) makes it possible to react the hydrazo groups with the carboxyl groups of proteins in the presence of water soluble carbodiimide at mildly acidic pH, while the amino groups on the same proteins remain deactivated due to protonation.

Conjugates **I**, **II**, **III**, and **IV** have been prepared by the reaction of the amino groups on α -chymotrypsin with ST-PHPMA-COOSu nos. **2**, **4**, **5**, and **5** listed in Table 2,

respectively. This is a relatively easy reaction. To achieve a high yield of conjugation, a proper pH of the reaction mixture has to be chosen based on the pH dependence of the rate constants of hydrolysis and aminolysis. All the conjugates were characterized by MALDI-TOF MS, and Figure 1 shows the MALDI-TOF mass spectrum of conjugate **III**. The average molecular weights of the conjugates calculated from the MS are listed in Table 6.

Conjugate **V** has been prepared by the reaction of chymotrypsin with a large excess of ST-PHPMA-CONHNH₂; the molar ratio of chymotrypsin to polymer was about 1:120. The conjugation reaction was carried out at pH 4.5–5.0 in the presence of 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride (EDC), and the polymer chains were attached to carboxyl groups of chymotrypsin via hydrazide bonds. Since carboxyl groups were consumed by conjugation, dilute HCl was added to

^a Number average molecular weight determined by end group analysis. ^b Determined by MALDI-TOF MS. ^c The conjugation degree was calculated from M_n of the conjugate and the $M_{n(\text{end})}$ of the polymers; the data in the parentheses were obtained from TNBS assay. ^d P represents polymer, and E the enzyme.

maintain the pH at 4.5–5.0. The MALDI-TOF mass spectrum of conjugate **V** (Figure 2) showed a broad peak of the conjugate because of the random conjugation of macromolecules with different molecular weights to the enzyme. The main peak around $m/z = 45\,000$ reflects the single charged conjugate, whereas the small peak around $m/z = 22\,000$ corresponds to the double charged conjugate. The average molecular weights calculated from the MS are listed in Table 6.

Chymotrypsin was also modified with narrow fractions of ST-PHPMA-CONHNH₂, and conjugates **VI**, **VII**, **VIII**, and **IX** were prepared by conjugation with the polymer fractions (Table 3). In the preparation of conjugates **VI** and **IX**, the polymer enzyme molar ratio used was lower than that used in the preparation of conjugates **V**, **VII**, and **VIII**, and a larger excess of the coupling agent EDC was used to achieve a high conjugation degree. The results indicated that the larger excess of EDC was helpful when the polymer enzyme molar ratio was lower. The molar ratio in the preparation of conjugate **IX** was only 23:1, but the conjugation degree obtained was the same as that of conjugate **VIII**, which was prepared with the molar ratio of 100:1. All the conjugates prepared with the polymer fractions were characterized by SEC and MALDI-TOF MS, and the mass spectrum of conjugate **VI** is shown in Figure 3. The calculated average molecular weights of the conjugates and the average number of polymer chains attached to each chymotrypsin molecule were calculated from the MS and reported in Table 3. As expected, conjugates prepared from the polymer fractions possessed a more uniform structure than those prepared from unfractionated semitelechelic macromolecules. The MALDI-TOF MS of the conjugates also indicated that there was no cross-linking of proteins under the mildly acidic reaction conditions used, and no peak of protein–protein conjugate was found in the spectrum (see Figure 3 as an example). The molecular mass of the protein–protein conjugate would be about 50 000 Da (molar mass of α -chymotrypsin is 25 240 Da) if there was cross-linking between protein molecules. The molecular mass of most of the conjugates is well below 50 000 Da. Even when a larger excess of EDC and a lower polymer enzyme molar ratio was used, no evidence of protein–protein cross-linking was shown in the SEC and MALDI-TOF MS of the conjugate **IX**. The number

average and weight average molecular weights of the conjugate were 45 600 and 46 200, lower than the molecular weight of a possible protein–protein conjugate.

It seems that about 10 is the maximum number of ST-PHPMA polymer chains which can be attached to one chymotrypsin molecule. It appeared, however, that the molecular weight of the ST-PHPMA played a role. The results in Table 3 indicated that the molecular weight of the polymer fractions affected the conjugation degree of the conjugates. Lower molecular weight polymer fractions produced conjugates with a higher conjugation degree, because the smaller spherical size of the lower molecular weight fraction possessed a lower sterical exclusion effect. The influence of the properties of the ST-PHPMA on the distribution of molecular weights of the α -chymotrypsin conjugates was demonstrated by MALDI-TOF mass spectra (compare Figure 3A with Figures 5 and 6).

The conjugation degree of all conjugates was calculated from the M_n of the conjugates and the $M_{n(\text{end})}$ of the polymers (Table 6). The conjugation degrees of the amino group directed conjugates were also determined by the TNBS assay. The conjugation degrees obtained from both methods were in good agreement. Depending on the conjugation conditions and on the structure of the ST-PHPMA, there were about 3–9 polymer chains attached to each enzyme molecule. The number of chains attached depended on the ratio of the enzyme to the polymer in the reaction mixture as well as on the molecular weight of the ST-PHPMA used. A higher concentration ratio of polymer to enzyme gave conjugates with a higher conjugation degree; see, for example, conjugates **III** and **IV**. For conjugates **I** and **III**, the same reaction conditions and the same molar ratios were used; ST-PHPMA **5**, with a lower molecular weight, gave a higher conjugation degree in the conjugate **III** when compared to ST-PHPMA **2** and conjugate **I**. In conjugates **VI** and **VII**, the relatively high conjugation degree (~50%) was achieved when a high molar ratio of polymer to enzyme, and a low molecular weight narrow fraction of ST-PHPMA-CONHNH₂ was used in the conjugation. When the polymer enzyme molar ratio was low in the carboxyl directed modification, a much larger excess of coupling agent was necessary to achieve a relatively high conjugation degree.

The conjugation degree of ST-PHPMA with chymotrypsin was lower (about 9 vs 14 chains) than that of the chymotrypsin conjugates with PEG-SC (16). This might be attributed to the solution structure difference between the two polymers. PHPMA has a random coil structure in aqueous solution, while PEG possesses a more extended one. The coiled PHPMA may cover more surface of the enzyme, and the steric effect may prevent more PHPMA macromolecules from attaching to the enzyme. One may hypothesize that PHPMA may cover a larger area of the protein than the extended macromolecules per modifying chain of a particular molecular weight. The impact of different shapes of macromolecules on the protein repulsion characteristics of a modified biomolecule or biomaterial surface needs careful evaluation.

Activity of ST-PHPMA-Chymotrypsin Conjugates. The activity of ST-PHPMA-chymotrypsin conjugates for enzymatically catalyzed hydrolysis of peptide substrates was investigated. Native α -chymotrypsin was used as control; Z-Gly-Leu-Phe-NAP and P-Gly-Leu-Phe-NAP were the substrates. The Michealis-Menten kinetic constants of the enzymatic cleavage reaction of the substrates were calculated from Lineweaver-Burk plots of the initial rates of the release of *p*-nitroaniline and are listed in Table 6. Both the chymotrypsin conjugates and the native chymotrypsin were active for the cleavage of the substrates. All conjugates and the native enzyme exhibited a high activity for Z-Gly-Leu-Phe-NAP and a lower activity for P-Gly-Leu-Phe-NAP. The steric hindrance of the polymer chain of P-Gly-Leu-Phe-NAP renders the formation of the enzyme-polymer substrate complex more difficult, resulting in lower turnover rates, in agreement with previously published data (20).

For the cleavage of Z-Gly-Leu-Phe-NAP, amino group modified conjugates **I**, **II**, **III**, and **IV** showed higher reactivities than the native enzyme, similar to literature data (11, 16). Carboxyl group modified conjugate **V** showed a lower activity toward Z-Gly-Leu-Phe-NAP than the native enzyme. This indicated that the type of bond between the enzyme and the polymers affects the activity of the conjugates, at least for the low molecular weight substrate, as observed by modification of other proteins (35, 36). It is known that a carboxyl group of an aspartic acid was involved in the active site of chymotrypsin (38). In addition, the conjugation of a carboxyl group in the vicinity of the enzyme active site might cause the decrease of the activity of the carboxyl group-modified chymotrypsin conjugates. The activity of chymotrypsin-ST-PHPMA conjugates to catalyze the hydrolysis of the polymer-bound substrate, P-Gly-Leu-Phe-NAP, was similar and lower than the native enzyme with small variations. Conjugate **II** possessed a slightly higher activity than the average for all the conjugates. It appears that the conjugation degree and the molecular weight of the polymers did not have a pronounced effect on the activity of chymotrypsin-ST-PHPMA conjugates toward P-Gly-Leu-Phe-NAP. These data seem to indicate that the sterical hindrance that occurs upon the formation of the enzyme-polymer substrate complex is the leading cause of the decreased potential for enzyme-substrate formation.

Self-Assembly of Polyamine–Poly(ethylene glycol) Copolymers with Phosphorothioate Oligonucleotides

Serguei V. Vinogradov, Tatiana K. Bronich, and Alexander V. Kabanov*

Department of Pharmaceutical Sciences, University of Nebraska Medical Center, 600 South 42nd Street, Omaha, Nebraska 68198. Received May 21, 1998; Revised Manuscript Received August 7, 1998

The cationic copolymers for DNA delivery were synthesized by conjugating poly(ethylene glycol) (PEG) and polyamines: polyspermine (PSP) and polyethyleneimine (PEI). These molecules spontaneously form electrostatic complexes with a model 24-mer phosphorothioate oligonucleotide, T₂₄ (PS-ODN). The copolymer complexes are water soluble. This is a marked contrast with the complexes formed by nonmodified PSP and PEI, which immediately precipitate out of solution. The potentiometric titration study suggests that the amino groups of the copolymers form a cooperative system of salt bonds with the thiophosphate groups of the PS-ODN. The PEG-PEI complexes are stable at physiological pH and ionic strengths. The PEG-PSP complexes are less stable in the presence of the low molecular mass electrolytes compared to the PEG-PEI complexes. The dynamic light scattering and transmission electron microscopy demonstrate that the complex particles are small—ca. 12 nm for PEG-PSP and ca. 32 nm for PEG-PEI. They can be lyophilized and redissolved or stored in solution for up to several months without changing size. The study suggests that as a result of formulation with the PEG-PEI the interactions of PS-ODNs with serum proteins (using the example of bovine serum albumin) are decreased and PS-ODN is protected against nuclease degradation. The simplicity of preparation and long shelf life make these systems attractive as potential pharmaceutical formulations for oligonucleotides.

INTRODUCTION

Chemically modified oligonucleotides (ODNs), such as antisense phosphorothioates (PS-ODNs), are promising candidates for clinical use (1, 2). These compounds show much higher resistance to exonucleases than unmodified phosphodiester ODNs (PO-ODNs). However, there is a growing body of evidence suggesting that nonspecific interactions with plasma proteins, liver and renal uptake, and degradation can significantly decrease the performance of PS-ODNs after systemic administration (3–5).

In efforts to improve the efficacy of gene therapies a number of delivery systems have been investigated (see, for review, ref 6). The most sustaining and promising attempts in this area were made with cationic lipids and polycations (7–10). These types of cationic carriers all bind spontaneously with negatively charged ODN molecules. In a number of cases, these carriers were shown to enhance stability of ODNs and their uptake into the cells in vitro. However, in vivo performance of these systems with ODNs appears to be much more problematic (11). A major problem with most cationic carriers is that their complexes with polynucleotides are often poorly soluble and tend to aggregate in aqueous solutions (8, 12).

A promising approach for overcoming the solubility problem has recently been proposed (13–17). It is based on the use of a new type of cationic carrier that has block (or graft) copolymer architecture and contains polycation and water-soluble nonionic segments. The complexes formed between polynucleotides and these carriers remain in solution due to the effect of the nonionic chains

that are soluble in water. Several systems have been recently described including poly(ethylene glycol)–polyspermine (PEG-PSP) (13), poly(ethylene glycol)–polylysine (PEG-PLL) (14, 15), dextran–PLL (16), poly-*N*-(2-hydroxypropyl)methacrylamide–poly(trimethylammonioethyl methacrylate chloride) (14), and some other copolymers (17). The use of PEG-PSP with modified PO-ODNs increased antiviral activity of antisense ODNs in vitro (13). It was also used successfully with PO-ODNs to transfect primary neurons (18) and with PS-ODNs to modulate gene expression in the rat retina in vivo (19).

Despite the recent use of the cationic copolymers for ODN delivery, little information is presently available about self-assembly and structural characterization of the copolymer and ODN species. Several papers have recently described the complexes of the double-stranded DNA with polycations (8, 13, 20–22). Short single-stranded ODNs represent one of the most difficult polynucleotide types for complexation and delivering with polycations. Indeed, the lengths of antisense ODNs lie in the range of ca. 6–30 bases, which limits the number of the negatively charged groups available for the cooperative binding with the polycation. Further, the effects of the single-stranded DNA vs double-stranded DNA as well as the effects of the backbone modification in PS-ODNs can significantly contribute to the binding with polycations. These problems have a general character, probably, contributing to relatively low success in using the cationic systems “tailored” for gene transfer for the ODN delivery (11). This work investigates complexes of PS-ODNs with PEG-PSP and PEG-polyethyleneimine (PEG-PEI) copolymers. It reports physicochemical characterization, solution behavior, and stability of these complexes and characterizes the effects of cationic co-

polymers on the binding of PS-ODNs with serum proteins and nuclease resistance of PS-ODNs.

MATERIALS AND METHODS

Polycations. PEI (MW 2000) was purchased from Sigma-Aldrich (St. Louis, MO). PSP (MW 500) was synthesized by polycondensation of *N*-(3-aminopropyl)-1,3-propanediamine and 1,4-dibromobutane using the previously described procedure (13).

Synthesis of Activated PEG. PEG (MW 8000) obtained from Aldrich (St. Louis, MO) was modified by one terminal hydroxyl group using with 4,4'-dimethoxytrityl (DMT) chloride (Sigma, St. Louis, MO). Briefly, 16 g (2 mmol) of PEG was dried by coevaporation in vacuo with anhydrous pyridine (3×50 mL) and dissolved in 100 mL of the solvent. After that, 0.34 g (1 mmol) of 4,4'-dimethoxytrityl chloride in 10 mL of anhydrous pyridine was added to this solution dropwise for 30 min and the mixture was left under stirring overnight at 25 °C. Monotritylated polymers were separated from fast-moving bis-substituted byproducts and nonreacted initial compounds by preparative column chromatography on Silicagel (Selecto Scientific, Norcross, GA), particle size 32–63 μ m, using a stepwise elution by methanol in dichloromethane. Fractions containing mono DMT-substituted PEG (DMT-PEG) were collected and solvents were removed in vacuo. DMT-PEG was obtained with 40% yield.

On the second stage, the free terminal hydroxy group of the DMT-PEG was activated for subsequent conjugation with polycations. 4 g (0.5 mmol) of the DMT-PEG were dried by coevaporation with anhydrous acetonitrile (3×20 mL) and then reacted with 0.51 g (3 mmol) of 1,1'-carbonyldiimidazole (Aldrich, St. Louis, MO) in 20 mL of anhydrous acetonitrile. The reaction mixture was agitated for 3 h at 40 °C and then diluted with water (25 mL). The solution obtained was dialyzed twice against 50% ethanol using Membra-Cel MD-25-03.5 (Applied Technologies Group, Chicago, IL), and the solvent was then removed in vacuo. The activated DMT-PEG (slightly yellow solid) was obtained with ca. 95% yield.

Conjugation of Activated PEG with PSP. Activated DMT-PEG (2.5 g, 0.3 mmol) was reacted with 1 g (1.4 mmol) of PSP in 20 mL of acetonitrile for 24 h at 25 °C. The reaction mixture was twice dialyzed against 50% ethanol, and the solvent was removed in vacuo. The DMT groups at the end of PEG chains were removed by treating the conjugates with 80% acetic acid (40 min at 25 °C). After solvent removing in vacuo, the remaining oily products were dissolved in 10 mL of methanol and precipitated into the cold ethyl ether (250 mL). The precipitates were washed twice with ether and dried in vacuo. The yield of the product was 1.9 g.

Conjugation of Activated PEG with PEI. Activated PEG (10 g, 1.2 mmol) was reacted with 7.2 g (3.6 mmol) of PEI in 80 mL of methanol for 24 h at 25 °C. The reaction mixture was twice dialyzed against 50% ethanol, and the DMT groups were removed by treating the conjugates with 80% acetic acid as described above. The remaining products were dissolved in 40 mL of methanol and precipitated into the cold ethyl ether (1000 mL). The precipitates were washed twice with ether and dried in vacuo. The yield of the product was 8.1 g.

Characterization of the Cationic Copolymers. The molecular masses of the synthesized copolymers were determined by static light scattering. The ratio of PEG and polyamine segments in the copolymers was deter-

mined from $^1\text{H-NMR}$ spectra using integral values obtained for the $-\text{CH}_2\text{CH}_2\text{O}-$ protons of PEG and $-\text{CH}_2\text{NH}-$ protons of polyamines. The total content of the nitrogen is 0.48 $\mu\text{mol/mg}$ for PEG-PSP and 2.2 $\mu\text{mol/mg}$ for PEG-PEI as determined by elemental microanalysis. The ratio of primary, secondary, and tertiary amino groups was determined from $^1\text{H-NMR}$ spectra. The concentration of the free primary amino groups was measured also by fluorescamine titration (23) using 1,6-diaminohexane (Sigma, St. Louis, MO) as a standard. The amount of ionizable groups in polycations and the degrees of ionization at a given pH were determined by potentiometric titration.

ODNs. 24-mer PS-ODNs (T_{24}) were synthesized on a 381 Applied Biosystems DNA synthesizer at a 10 μmol scale using the standard phosphoramidite chemistry and manufacturer's protocols. For fluorescent labeling, the 5'-Aminomodifier C6 (Glen Research, Sterling, VA) was introduced in PS-ODNs and the amino group containing PS-ODNs were then modified by FITC (Sigma, St. Louis, MO) using a standard protocol. The FITC-PS-ODNs were purified by reversed-phase HPLC using preparative Vydac C18, 10 μm column (9×250 mm) (Sigma, St. Louis, MO) and gradient elution with acetonitrile-triethylammonium acetate buffer, pH 7.5.

Formation of the Complexes and Their HPLC Analysis. The complexes were formed by simple mixing of the 0.1–0.5 mM solutions of PS-ODN and cationic copolymers and allowed to equilibrate for 60 min at 37 °C. After that, the solutions were filtered through 0.22 μm filter and analyzed by gel permeation chromatography (GPC) at 37 °C using Shimadzu LC-10AT system and SigmaChrom GFC-100 column (30 cm $\times$ 7.5 mm; 0.5 mL/min flow rate).

Static Light Scattering. Light-scattering experiments were performed using DAWN multiangle laser photometer (Wyatt Technology, Santa Barbara, CA) equipped with He-Ne laser (632.8 nm) and operating at 15 angles (26–137°). Minimum of four concentrations of polymers or complexes in 0.05 M NaCl were used for weight average molecular weight determination. The specific refractive index increments (dn/dc) were measured using Wyatt/Optilab 903 interferometric refractometer at 632.8 nm. Prior to the dn/dc measurements, the samples were dialyzed for at least 1 day against in 0.05 M NaCl using the membrane with the 3500 Da cutoff.

ζ -Potential and Sizing Measurements. ζ -Potential measurements were performed at 25 °C using "ZetaPlus" Zeta Potential Analyzer (Brookhaven Instrument Co.) equipped with a 15 mV solid-state laser operated at a wavelength of 635 nm. Effective hydrodynamic diameter was measured by photon correlation spectroscopy using the same instrument equipped with the Multi Angle option. The sizing measurements were performed at 25 °C at the angle of 90°.

Fluorescence Studies. Fluorescence measurements were carried out with the complexes containing 5 μM FITC-PS-ODN using Shimadzu P5000 spectrofluorophotometer ($\lambda_{\text{ex}} = 488$ nm, $\lambda_{\text{em}} = 520$ nm).

Electron Microscopy. The samples for the transmission electron microscopy (TEM) studies were prepared using negative staining with 1% uranyl acetate. Briefly, a drop of the sample solution was allowed to settle on a Formvar precoated grid for 1 min, the excess sample was wicked away with filter paper and a drop of staining solution was allowed to contact the sample for 1 min. The samples were analyzed using a Hitachi H-7000 electron microscope.

b. PEG-PEI

Figure 1. Cationic copolymers: (a) PEG–PSP and (b) PEG–PEI.

Protein-Binding and Nuclease Resistance Studies

For protein-binding study, 20–400 μM PS–ODN or their complexes were mixed with 2.5% BSA (Sigma, St. Louis, MO) in PBS, pH 7.4. The mixtures were incubated for either 2 or 16 h at 25 $^{\circ}\text{C}$ and then analyzed by GPC using Progel-TSK G3000 SW_{XL} column (7.8 mm $\times$ 30 cm) and sizing measurements as described above. For nuclease resistance studies, 100 μL samples of 25 μM free PS–ODNs or their complexes were treated with 20 μL (0.024 units) of snake venom phosphodiesterase (phosphodiesterase I from *Crotalus adamanteus*) (Sigma, St. Louis, MO) at 37 $^{\circ}\text{C}$. The samples were collected at 2, 6, and 18 h, and the reaction mixtures were analyzed by GPC as described above.

RESULTS AND DISCUSSION

Cationic Copolymers. Cationic copolymers were synthesized by conjugating PSP and PEI with PEG (Figure 1). According to NMR data, PEG–PSP and PEG–PEI contained an average of 1.4 and 1.7 PEG segments/polycation chain, respectively. This is in a reasonable agreement with the molecular weights of these copolymers determined by light scattering: 8900 for PEG–PSP and 16 600 for PEG–PEI.

The polyamine fragments of the synthesized copolymers are randomly branched, i.e., contain primary, secondary, and tertiary amino groups. The ratio of these groups determined by NMR is 1:1.7:1 for PEG–PSP and 1.3:1.2:1 for PEG–PEI. The basic properties of the PEG–PSP and PEG–PEI copolymers were characterized by potentiometric titration. As it is seen in the Figure 2, the potentiometric titration curves for each copolymer can be divided into two distinct regions corresponding to two different types of amino groups. The ratio of these groups determined from the titration curves is 1:1.8 for PEG–PSP and 1.5:1.3 for PEG–PEI. This is in a good agreement with the NMR data for the ratio between primary and secondary amino groups. Furthermore, the concentrations of the amino groups corresponding to the first regions of the potentiometric titration curves (Figure 2) equal the concentration of the primary amino groups determined by fluorescamine titration (data not shown). Therefore, potentiometric titration data reveal the primary and secondary amino groups. The amount of titrated groups of both types is less than the total amount of amino groups determined by the elemental analysis,

Figure 2. Potentiometric titration curves for the cationic copolymers titrated by HCl in 0.1 M NaCl: (a) PEG–PSP, polymer concentration 1 mg/mL, 0.002 M HCl; (b) PEG–PEI, polymer concentration 0.58 mg/mL, and 0.01 M HCl. Two regions corresponding to two different types of titrated amino groups are shown by dashed lines.

i.e., part of amino groups does not protonate. This part is ca. 27% for PEG–PSP and 32% for PEG–PEI, which is consistent with the content of the tertiary amino groups in these copolymers as determined by NMR. Therefore, it appears that the tertiary amino groups do not participate in the ion-exchange reactions under the conditions studied.

Polyion Coupling Reaction. The formation and solution behavior of the polyelectrolyte complexes of the nucleic acids are very similar to those of complexes formed by synthetic polyions (24, 25). These complexes are spontaneously produced as a result of the polyion coupling reaction after mixing of nucleic acid and polycation solutions (8). The stability of such system critically depends on the number of the salt bonds between interacting polyions. Normally, it takes at least 6–10 salt bonds to form a cooperative system (25). With a fixed polyion length, a charge density is a parameter determining possible number of electrostatic bonds in the complex. Therefore, with weak polybases, such as PSP and PEI, the polyion coupling reactions strongly depend on pH.

The polyion coupling reaction involving a weak polybase represents the ion-exchange process as shown by the following scheme:

Figure 3. (a) Potentiometric titration curves for PEG-PEI (1, $\circ$) and for the mixture of PEG-PEI with PS-ODN (2, $\bullet$). The value reported on the x-axis is the number of moles of the added HCl. The concentration of copolymer is 0.6 mg/mL. (b) pH dependencies of the degree of conversion (θ) in the polyion coupling reactions ($\bullet$, $\blacksquare$) and degree of ionization (α) of polybase samples ($\circ$, $\square$) for the following systems: PEG-PEI (curve 1, $\circ$); PEG-PEI and PS-ODN (curve 2, $\bullet$); PEG-PSP (curve 3, $\square$); PEG-PSP and PS-ODN (curve 4, $\blacksquare$). The pH-shift, ΔpH , between the θ -pH and α -pH dependencies is shown for the PEG-PEI and PS-ODN complex as an example.

where B is a functional group of the weak polybase and A^- is the charged group of the polyacid. The formation of the complex is accompanied by the release of the hydroxyl ions, which can be determined by the potentiometric titration. For example, Figure 3a presents the potentiometric titration curves for PEG-PEI alone (curve 1) and in the presence of PS-ODN (curve 2). Curve 2 is shifted toward higher pH compared to curve 1. This shift is a result of the hydroxyl ion release and indicates the formation of the complex between the polycation and PS-ODN.

Degree of conversion, θ , in the reaction between polycation chains and PS-ODN can be defined as the ratio of the current number of salt bonds formed by the polyions to their maximal number. This parameter can be determined from the titration curves assuming that all acid is consumed for ionization of the amino groups of the copolymer, which then form ionic pairs with the PS-ODN. It was previously demonstrated that, in the presence of a strong polyacid, practically all ionized units of the weak polybase participate in the formation of ionic pairs and therefore θ is approximated as follows (24):

$$\theta = (m_a/V + [\text{OH}^-] - \sqrt{K_b C_0})/C_0 \quad (1)$$

where m_a is the number of moles of the added acid, V is the current volume of the reaction system, K_b is the characteristic ionization constant of the polybase, and C_0 is the base-molar concentration of the polybase.

Figure 4. Chromatography profiles of the (1) free PS-ODN and (2) its complex with PEG-PEI ($Z = 1$). Conditions: SigmaChrom GFC-100 column (7.5 mm $\times$ 30 cm), flow rate 0.5 mL/min; temperature 37 $^\circ\text{C}$; mobile phase PBS, pH 7.4, PS-ODN concentration in samples is 10 μM .

Figure 3b presents the θ -pH dependencies for mixtures of PS-ODN with PEG-PSP and PEG-PEI (filled symbols). (To ensure that all amino groups of the copolymers form ionic pairs with the oligonucleotide units, the titration experiment was conducted at the PS-ODN excess.) Also the copolymers were titrated in the absence of PS-ODN to determine the degrees of ionization, α . The corresponding α -pH curves are presented in Figure 3a for comparison (empty symbols).

As it is seen in the Figure 3b, θ increases sharply in a narrow range of pH. It is noteworthy that for both copolymers the θ -pH curves are shifted in the alkaline area compared to the respective α -pH curves in the absence of PS-ODN. These shifts are indicative of the cooperative electrostatic interaction between the polyamine chains and PS-ODN that results in stabilization of the ionized form of the polyamines. The pH difference, ΔpH , between θ -pH and α -pH curves at each $\theta = \alpha$ is a differential measure of free energy of cooperative stabilization of the polyelectrolyte complexes (see Appendix). Overall, these studies suggest that PEG-PSP and PEG-PEI form stable polyelectrolyte complexes with PS-ODN in a wide range of pH.

Composition of the Mixture. At a given pH, the number of the salt bonds formed between the polyions depends on the ratio of the concentrations of the ionic groups of these polyions. This ratio is termed "the composition of the mixture", or "charge ratio", Z . In this work, Z is determined as the ratio of the concentration of ionizable amino groups of the copolymer and the concentration of the thiophosphate groups of PS-ODN. As a result of induced ionization of PSP and PEI fragments of the copolymers in the presence of PS-ODN, practically all ionizable amino groups participate in the formation of the salt bonds at pH 7.4.

Formation of the Soluble Complexes and Their Characterization by GPC. Simple mixing of the solutions of cationic copolymers and PS-ODN forms the complexes. Immediately after mixing, these systems are optically transparent. This is a marked contrast with the complexes formed by nonmodified PSP and PEI, which immediately precipitate out of solution. PEG-PSP- and PEG-PEI-based complexes did not precipitate and were optically transparent during the observation times (up to months).

The soluble complexes were further characterized by GPC. Typical chromatographic profiles are shown in Figure 4. The PS-ODN alone is eluted as a single peak. In the presence of the PEG-PEI, a peak with a lower retention time compared to the free PS-ODN is observed, which evidently corresponds to the complex. The portion of PS-ODN incorporated into the complex depends on

Figure 5. ζ -Potential of the complexes of PS-ODN with (●) PEG-PSP and (○) PEG-PEI, and (*) normalized fluorescence intensity, $(I_{\max} - I)/(I_{\max} - I_{\min})$, of FITC-PS-ODN complex with PEG-PEI as a function of the composition of the mixture. Phosphate buffer, 10 mM, pH 7.4, 22.5 °C.

the concentration of the cationic copolymer (data not shown). Complete incorporation of PS-ODN in the complex is observed at the charge equivalency, i.e., $Z = 1$. Similar behavior was also observed for PEG-PSP and PS-ODN mixtures in 20 mM phosphate buffer (data not shown). In this case, however, the retention time for the PEG-PSP complex was closer to the free PS-ODN retention time, so that the peaks for the complex and free oligonucleotide overlapped.

The chromatography analysis was used to evaluate the stability of the complexes at various ionic strengths. These studies suggest that PEG-PSP complexes are the least stable in the phosphate buffered saline (PBS), pH 7.4. These complexes are observed in PBS only at relatively high concentrations—above 100 μ M/PS-ODN chain in the injected samples. (Dilution of the samples during chromatography is ca. 100–200-fold.) At lower concentrations (e.g., 10 μ M in the injected sample), the complexes dissociate. However, in the phosphate buffer at lower ionic strengths (less than 0.1 M NaCl), the PEG-PSP and PS-ODN complexes are formed at all concentrations examined (minimal sample concentration was 10 μ M).

ζ -Potential Measurements. Soluble complexes from cationic copolymers and PS-ODNs are characterized using the laser microelectrophoresis technique. Figure 5 presents the ζ -potential of the PEG-PSP- and PEG-PEI-based complexes as a function of Z . At $0 < Z < 0.5$, the ζ -potential sharply increases with elevating the copolymer concentration. With the compositions approximating Z values of 0.7–1 the ζ -potential is leveled off at small negative values, ca. –2 mV for PEG-PSP and –4 to –2 mV for PEG-PEI, indicating that the particles are practically electroneutral. Since no changes in ζ -potential are observed at $Z > 1$ (at least up to $Z = 3$), the polycation excess does not incorporate into the complex.

Fluorescence Detection of the Complex Formation. Figure 5 also presents the results of the fluorescence measurements with FITC-PS-ODN in the presence of PEG-PEI. Addition of the copolymer results in the shift of the maximum of the UV absorption of fluorescent tag in FITC-PS-ODN from 494 to 503 nm. Simultaneously, the fluorescence emission at 520 nm (excitation 488 nm) is decreased. The results of the fluorescence measurements are presented as a function of normalized fluorescence, $(I_{\max} - I)/(I_{\max} - I_{\min})$, on Z (Figure 5). The trend of this curve is similar to that of the corresponding ζ -potential curve. The saturation is observed at ca. $Z = 0.7$ –1. It appears that all FITC-

PS-ODN molecules bind to the copolymer at these compositions.

Size and Molecular Mass Determination. Table 1 presents the effective diameters of the complexes formed by PS-ODN and cationic copolymers measured at various time intervals after preparation of these systems. PEG-PSP and PEG-PEI complexes have average diameters of 12 and 32 nm, respectively. As it is seen from Figure 6, the particles are characterized by the relatively narrow distribution of the size. No size changes are observed after storing these systems in solution for very long periods (at least three months in the case of PEG-PEI complex) (Table 1). Further, sizes did not change after lyophilizing these complexes, storing them for several months, and then redissolving in buffer (data not shown).

Figure 7 presents typical microphotographs obtained for PS-ODN and PEG-PEI complexes with the cationic

Figure 8. Interaction of PS-ODN/PEG-PEI complex ($Z = 1$) with BSA. The chromatography profiles are shown for (1) 2.5% solution of BSA in PBS, (2) complex in PBS, (3) complex in 2.5% BSA after 2 h incubation, and (4) complex in 2.5% BSA after 16 h incubation. Conditions: Progel-TSK G3000 SW_{XL} column (7.8 mm $\times$ 30 cm), flow rate 0.5 mL/min; temperature 37 $^{\circ}$ C; mobile phase PBS, pH 7.4, PS-ODN concentration in samples is 10 μ M.

copolymers. They reveal spherical particles with narrow size distributions. Similar type particles with the diameters ca. 3 times smaller are formed by the PEG-PSP complexes (data not shown).

The molecular weight of particles formed by PS-ODN and PEG-PEI at $Z = 1$ is ca. 590 000 as determined by static light scattering. These particles contain an average of 24 PS-ODN and 23 PEG-PEI molecules as was estimated assuming that the complex was electroneutral. The "driving forces" for self-assembly of such structures are hydrophobic interactions of the neutralized polyion chains, which form a core of a micelle-like particle. The particle hydrophilic shell is evidently formed by the PEO chains, which stabilize the particles in the aqueous media.

Interactions with Serum Proteins and Resistance to Nuclease Degradation. Addition of 0.5% bovine serum albumin (BSA) does not change the size of the PEG-PEI and PS-ODN complex ($Z = 1$) for several days at 37 $^{\circ}$ C, PBS, pH 7.4. In contrast, large aggregates (113 nm) are rapidly formed (within minutes) when BSA is added to the free copolymer. This result suggests that while BSA binds to the cationic copolymer alone, it does not readily substitute the PS-ODN in the complex. The BSA effects are further characterized in the GPC experiment. The retention time and amounts of the PEG-PEI and PS-ODN complex do not change in the presence of 2.5% BSA for 2 h (Figure 8). Also, BSA elution profiles are not affected in the presence of the complex during this time. However, after longer time intervals (16 h), the destruction of the complex is observed as determined from the changes in the chromatography profiles (Figure 8). This experiment suggests that the interactions of PS-ODN with serum proteins are decreased as a result of oligonucleotide formulation with the PEG-PEI.

Figure 9 shows the results of the study of nuclease degradation of free PS-ODN and its complex with PEG-PEI by phosphodiesterase I from *Crotalus adamanteus*. Following an 18 h incubation with the enzyme, the free PS-ODN was degraded by over 80%. In contrast, over 70% of PS-ODN incorporated in the complex with PEG-PEI remained undegraded at this time point. Therefore, incorporation of the PS-ODN into the complex with

Figure 9. Degradation of ($\diamond$) free PS-ODN and ($\bullet$) PS-ODN in the complex with PEG-PEI, $Z = 1$ in the presence of phosphodiesterase I from *Crotalus adamanteus*. (0.1 mg of phosphodiesterase in 30 μ L of PBS, pH 7.4, 37 $^{\circ}$ C).

cationic copolymer stabilizes the oligonucleotide against nuclease degradation. The stabilization against the nuclease evidently results from masking the PS-ODN chain by the polycation fragments in the core of the complex particles. Similar effect was previously reported for the plasmid DNA bound to poly(4-vinylpyridinium) salts (26). In the previous report (26), the complete stabilization of the plasmid against enzymatic digestion was observed at $Z = 1$. However, the electroneutral complexes of the DNA with poly(4-vinylpyridinium) salts were aggregated. In contrast, the systems described in this work remain both stable to nuclease degradation and soluble due to the effect of the PEG segments.

Core-Shell Model for the Complexes of Polyamine-PEG Copolymers with PS-ODNs. The studies on the solution behavior and transfection activity of the polyelectrolyte complexes formed between polycations and plasmid DNA were reviewed recently in ref 27. It was shown that under certain conditions these systems produce small (under 100 nm) "core-shell" particles with the insoluble core from neutralized polyions and shell from positively charged polycation chains stabilizing these particles in aqueous solution. Incidentally, formation of the core-shell particles coincided with the conditions for the maximal transfection activity in vitro, suggesting that these particles represent the transfecting

species formed in the DNA and polycation mixtures (27). Among other factors necessary for the formation of such particles, the polycation excess is needed to produce soluble cationic corona. Also, the increased length of the polycation favors the formation of the corona at the polycation excess.

In contrast to plasmid and other high molecular mass DNA, antisense oligonucleotides represent one of the most difficult polynucleotide types for complexation and delivering with polycations. Indeed, the lengths of antisense oligonucleotides lie in the range 6–30 bases approximately (28). Hence, with short oligonucleotides, the number of phosphate charges may be insufficient to provide for cooperative binding to polycation. Due to the same reason, the polycation chain cannot be shorter than that of oligonucleotide. Thus, soluble polyelectrolyte complexes using polycation homopolymers can be produced only with sufficiently long polycations, and these complexes are always positively charged. Indeed, some earlier work on PEI and oligonucleotide transfection (29–31) used the polycation excess and high molecular mass PEI (50–800 kDa). Although these studies did not specifically characterize solution stability of the complexes, these systems may be soluble due to the lyophilizing effects of the charged sites in the PEI chain that are not neutralized by the oligonucleotide. The use of cationic copolymers instead of the homopolymer polycations offers different possibility for preparing soluble “core-shell” complexes of oligonucleotides. In the systems reported in refs 13–19 and in this study, the hydrophobic core is formed by the neutralized polyions while nonionic water-soluble chains such as PEG form hydrophilic shell. As a result, soluble uncharged complexes can be produced which are stabilized in solution by PEG corona. Such systems may have advantage compared to cationic core-shell structure for certain *in vivo* applications due to potentially lower toxicity (19) and decreased interactions with serum proteins (27). Also, the use of the inert hydrophilic corona may provide for better control of pharmacokinetics and biodistribution parameters compared to cationic particles. Indeed, PEG-modified polymeric micelles are currently developed for drug delivery having prolonged half-life in blood and decreased interactions with reticuloendothelial system (32, 33). Furthermore, the PEG corona can be modified with vector molecules, such as antibodies, to enable addressed delivery of the polymer micelle in the body (34).

CONCLUSION

This paper reports the studies on a new family of cationic carriers for ODNs. These carriers include conjugates of PEG with polycation segments: PSP and PEI. Aqueous solubility of the complexes formed by PEG–PSP and PEG–PEI copolymers is an apparent advantage compared to the complexes of homopolymer polycations (8) and cationic lipids (12) with PS–ODN that aggregate. The neutralized polyamine segments and PS–ODN chains self-assemble into a hydrophobic core surrounded by the PEG segments, determining the aqueous solubility of these systems. The complexes are small – ca. 12 nm for PEG–PSP and ca. 32 nm PEG–PEI and have relatively narrow size distribution. Small size of the DNA complexes (below 100 nm) and their aggregation stability were shown to be essential for high transfection efficacy with the polycations (8, 20). The small size and stability of the systems described in this work probably contributed to the efficient ODN delivery with PEG–PSP reported *in vitro* (13, 18) and *in vivo* (19).

PEG–PSP complexes appear to be less stable in the presence of the low molecular mass electrolytes when compared to PEG–PEI complexes. This probably results from lower charge density of PSP segments compared to PEI segments and/or some differences in their structure conformity with respect to PS–ODN chains. On the basis of high stability of PEG–PEI complexes in physiological conditions, we further focus on PEG–PEI as potential PS–ODN delivery systems. The simplicity of preparation and long shelf life makes these systems very attractive pharmaceutical formulations for PS–ODNs. Decreased interactions of PS–ODNs with serum proteins (using the example of BSA) and protection of PS–ODNs against nuclease degradation are further evidence of the potential benefits of these systems in delivery of PS–ODNs.

ACKNOWLEDGMENT

The National Science Foundation (BES-9712657) and Nebraska Research Initiative supported this work. Supratek Pharma Inc. sponsored the synthesis and characterization of the cationic copolymers. Dr. Kabanov has a financial interest in and serves as a consultant to this company. M-H-W Laboratories (Phoenix, AZ) did elemental analysis. TEM studies were performed at the Central Microscopy Research Facility, University of Iowa (Iowa City, IA). Core laboratories at the University of Nebraska Medical Center (Omaha, NE) carried out the NMR measurements and PS–ODN synthesis.

APPENDIX

The dependence of ionization equilibrium of the weak polybase in the absence of the PS–ODN is described by the following equation:

$$\frac{[\text{OH}^-]'\alpha}{1-\alpha} = K_b'(\alpha) = e^{-\Delta G'(\alpha)} \quad (2)$$

and in the presence of PS–ODN by the following equation:

$$\frac{[\text{OH}^-]''\alpha}{1-\alpha} = K_b''(\alpha) = e^{-\Delta G''(\alpha)/RT} \quad (3)$$

where α is the ionization degree, $K_b'(\alpha)$ and $K_b''(\alpha)$ are the apparent ionization constants, and $\Delta G'(\alpha)$ and $\Delta G''(\alpha)$ are the free energies of the ionization in the absence and presence of PS–ODN, respectively. Dividing eq 2 by eq 3 and then taking the logarithm of the resultant equation yields the following:

$$-\Delta\text{pH}(\alpha) = \frac{\Delta\Delta G_{st}(\alpha)}{2.303RT} \quad (4)$$

where $\Delta\text{pH}(\alpha)$ is the pH difference between θ –pH curve of the complexes and α –pH curves at each $\theta = \alpha$, and $\Delta\Delta G_{st}(\alpha)$ is the difference of free energies of ionization of polybase in the presence and absence of the DNA: $\Delta\Delta G_{st}(\alpha) = \Delta G''(\alpha) - \Delta G'(\alpha)$, R is the universal gas constant, and T is the absolute temperature. The $\Delta\Delta G_{st}(\alpha)$ value is a *differential* characteristic of the impact of DNA in ionization of polybase.

Biotin Reagents for Antibody Pretargeting. 3. Synthesis, Radioiodination, and Evaluation of Biotinylated Starburst Dendrimers

D. Scott Wilbur,^{*,†} Pradip M. Pathare,[†] Donald K. Hamlin,[†] Kent R. Buhler,[‡] and Robert L. Vessella[‡]

Departments of Radiation Oncology, 2121 North 35th Street, and Urology, University of Washington, Seattle, Washington 98195. Received May 26, 1998; Revised Manuscript Received September 10, 1998

We are investigating the hypothesis that biotin multimers can be used with streptavidin and monoclonal antibody conjugates in cancer pretargeting protocols to provide a method of increasing the amount of radioactivity bound on cancer cells in patients. As part of that investigation, a series of biotinylated Starburst dendrimers (BSBDs) have been prepared and evaluated in vitro and in vivo. In this study, a new biotinidase-stabilized, water-solubilizing biotinylation reagent was prepared and reacted with Starburst (PAMAM) dendrimers, generations 0, 1, 2, 3, and 4. The reaction conditions employed resulted in perbiotinylation of generation 0 (four biotin moieties conjugated), generation 1 (eight biotin moieties conjugated), generation 2 (16 biotin moieties conjugated), and generation 3 (32 biotin moieties conjugated). With generation 4, incomplete biotinylation was achieved resulting in the largest portion of that BSBD having 51 biotin moieties (of 64 possible) conjugated. The ability of each BSBD to cross-link streptavidin (SAv) was examined in an in vitro assay. In that assay, an assessment was made of the quantity of [¹²⁵I]SAv bound with polystyrene-bound SAv after treatment with the synthesized BSBDs. All BSBDs cross-linked the polystyrene-bound SAv with [¹²⁵I]SAv; however, the amount of [¹²⁵I]SAv bound varied with the different BSBDs. Roughly 1 equiv of [¹²⁵I]-SAv was bound when Starburst dendrimers containing three or four biotin moieties (generation 0) were used. Two equivalents were bound with BSBD generation 1, and 4 equiv were bound with BSBDs generations 2, 3, and 4. To assess the distribution of BSBDs generations 0, 1, and 2 in mice (at 4 h postinjection), a method was developed for radioiodinating them using the NHS ester of *p*-[¹²⁵I]-iodobenzoate ([¹²⁵I]PIB). It was found that the radioiodinated BSBDs had low blood concentrations (i.e., 0.13–0.20% ID/g) at the 4 h time point. In fact, most tissues examined had low concentrations of biotinylated dendrimers, except kidney and liver. Kidney had the highest concentration of [¹²⁵I]-labeled BSBDs, and its concentration increased with increasing size and charge of dendrimer (e.g., 8–48% ID/g). On the basis of the increased radioactivity observed in the in vitro assay and the rapid clearance from blood in mice, additional in vivo studies with perbiotinylated Starburst dendrimer, generation 2, are planned.

INTRODUCTION

Reagents containing biotin, avidin, or streptavidin and tumor-specific monoclonal antibodies (mAbs),¹ in combination with a variety of radionuclides, are under investigation in an approach to cancer therapy that is termed "pretargeting" (1–3). The pretargeting approach is being investigated as a means of circumventing some of the inherent problems associated with directly radiolabeled

mAbs in therapy protocols (4–6). Importantly, in the pretargeting approach, the tumor selective targeting of mAbs is retained, but the delivery of the radionuclide is relegated to another molecule, which in many investigations is either a radiolabeled biotin derivative or a radiolabeled avidin or streptavidin molecule (7–17). The selection of these reagents for the pretargeting approach has been made because of the very high binding avidity of biotin with avidin (18, 19) and streptavidin (20). Tumor localization of the radiolabeled biotin or (strept)avidin is achieved by binding with an antibody conjugate that has been previously localized on tumor cells. Because avidin and streptavidin are composed of four identical subunits, four biotin molecules can bind each protein molecule. This tetrameric binding nature of avidin and streptavidin permits their use in various combinations of mAbs/biotin/(strept)avidin, which are administered in "2-step" or "3-step" pretargeting protocols (6, 21). The introduction of multiple "steps" in tumor targeting provides additional variables for optimizing the pharmacokinetics and distributions of the therapeutic radionuclide not previously obtainable with directly labeled mAbs (5).

In addition to improving the pharmacokinetics and distribution of the therapeutic radionuclide, the use of

I: Biotin Trimer or Tetramer

II: Biotin Multimer - Starburst Dendrimer Based

Figure 1. Schematic representation of biotin multimers cross-linking (strept)avidin with mAb-(S)Av conjugates bound to cancer cell antigens. Amplification (doubling) of the number of binding sites is provided in reaction sequence I by cross-linking tumor bound (strept)avidin with a biotin trimer (B) or biotin tetramer. In reaction I, either the biotin trimer or (strept)avidin molecule can be used as a carrier of the radionuclide. With Starburst dendrimer based biotin multimers (E) more than one (strept)avidin molecule (C) may be added in a single administration as depicted in reaction sequence II. In reaction II, amplification is obtained by having the radiolabel on the (strept)avidin molecule.

biotin/(strept)avidin-based reagents in pretargeting may provide a method for increasing the amount of radionuclide bound to cancer cells *in vivo* (3, 7, 15). If the number of binding sites for either radiolabeled biotin or radiolabeled (strept)avidin is increased, then it may be possible for more radioactivity to be bound to each cancer cell. One possible method for increasing the biotin/(strept)avidin-binding sites on cancer cells is to cross-link (strept)avidin with molecules that contain more than two biotin moieties as depicted in Figure 1. For example, a radiolabeled biotin trimer (B in Figure 1) could be used in a multistep protocol that alternates administration of that reagent with (strept)avidin (C in Figure 1) (22). In such a protocol, it might be possible to regenerate an equivalent number of new binding sites (biotin moieties) as there are bound mAbs with each administration cycle. If this occurred, the repetitive cycles could provide a doubling, tripling, and quadrupling of the total amount of radioactivity on the cancer cells in sequential steps. Such a protocol is under investigation in our research group, but it is not an ideal protocol for clinical adaptation as it involves multiple administrations of biotin/(strept)avidin reagents [and blood clearing agents/methods (23–28)].

Our desire to maximize the amount of radioactivity deposited on tumor cells in as few steps as possible led to consideration of molecules that contain multiple biotin moieties for cross-linking of streptavidin. Unlike biotin trimers, the use of molecules which contain multiple (i.e., more than four) biotin moieties could lead to the addition of two or more streptavidin molecules in a single step. Although there are many polymeric molecules that could be used as carriers of multiple biotin moieties,² poly-amidoamines (PAMAM) Starburst dendrimers (29–31) were particularly attractive candidates as they are small

spherical compounds, and a variety of sizes (generations)³ is available from commercial sources. We hypothesized that the number of streptavidin molecules bound to an mAb-streptavidin conjugate (F in Figure 1) might be significantly increased in a single step using the biotinylated Starburst dendrimers (E in Figure 1). As an initial evaluation of that hypothesis, an investigation of the synthesis, radioiodination, *in vitro* binding, and *in vivo* distribution of biotinylated Starburst dendrimers (BSBDs) has been conducted. In the investigation, a new biotinylation reagent was prepared in which the linking moiety provides increased water solubility and also provides resistance to degradation by the enzyme biotinidase (32–34). Biotinylation of five Starburst dendrimers (SBDs) containing a large variation in the number of biotin moieties per molecule was synthesized. Subsequently, the number of streptavidin (Sav) molecules that can bind with the biotinylated dendrimers was determined by an *in vitro* assay using streptavidin-coated wells. On the basis of the results of the *in vitro* studies, three radioiodinated biotinylated dendrimers were prepared. The radiolabeled biotinylated Starburst dendrimers were administered to athymic mice, and their distributions *in vivo* were determined at 4 h postinjection. The results of our investigation are described herein.

² For example, polybiotinylated aminodextrans are commercially available from Molecular Probes (Eugene, OR).

³ Starburst Dendrimers of increasing sizes are given the terminology of “generations” as they are built up from “shells”. The generations (abbreviated G) used are 0 (G = 0; four terminal amines); 1 (G = 1; eight terminal amines); 2 (G = 2; 16 terminal amines); 3 (G = 3; 32 terminal amines); and 4 (G = 4; 64 terminal amines). Information on the Starburst dendrimers used in this study is provided in Table 1. SBD nomenclature and chemistry are provided in reviews by Tomalia (29–31).

EXPERIMENTAL PROCEDURES

General. Chemicals purchased from commercial sources were of analytical grade or better and were used without further purification. Solvents for HPLC analysis were obtained as HPLC grade and were filtered (0.2 μ m) prior to use. Starburst Dendrimers, d-Biotin; triethylene glycol, **1**; *tert*-butyl acrylate, **2**; methylamine, 2,3,5,6-tetrafluorophenol; chloramine-T; and most other chemicals were purchased from Aldrich Chemical Co. (Milwaukee, WI). Recombinant streptavidin (r-SAv) was obtained as previously described (35). BSA was Fraction V (catalog no. 160069) obtained from ICN (Costa Mesa, CA).⁴ Silica gel chromatography was conducted with 70–230 mesh 60 Å silica gel (Aldrich Chemical Co.). Sephadex G-25 (NAP-10) columns were obtained from Pharmacia Biotech AB (Uppsala, Sweden). Avidin and Reacti-Bind streptavidin-coated polystyrene 96 well plates were obtained from Pierce (Rockford, IL). Melting points were obtained in open capillary tubes on a Mel-Temp II apparatus with a Fluke 51 K/J electronic thermometer and are uncorrected. ¹H-NMR data, MS data, and HPLC chromatography were used to assess compound identity and purity (data provided in the Supporting Information).

Spectral Analyses. ¹H NMR spectra were obtained on either a Bruker AC-200 (200 MHz) or a Bruker AC-500 (500 MHz) instrument. Proton chemical shifts are expressed as parts per million using tetramethylsilane as the internal standard (δ = 0.0 ppm). IR data were obtained on a Perkin-Elmer 1420 infrared spectrophotometer. Mass spectral data for the compounds of low molecular weight (i.e., <1000) were obtained on a VG Analytical (Manchester, England) VG-70SEQ mass spectrometer with associated 11250J Data System using fast atom bombardment (FAB⁺) at 8 keV in a matrix of MeOH/DMIX (Thioglycerol/DMSO/TFAA, 90/9/1) or 3NBA (3-nitrobenzyl alcohol). Mass spectral data for the high molecular weight biotinylated Starburst dendrimers were obtained with MALDI-TOF mass spectrometry conducted on a PerSeptive Biosystems Voyager-Elite EL time-of-flight mass spectrometer. In-source metastable ion decay MALDI-TOF mass spectra were produced using DE linear TOF-MS at an ion source bias potential of 25 kV and a 200 ns pulsed ion extraction delay time.

Chromatography. HPLC separations of biotin dendrimers were obtained on a Hewlett-Packard quaternary 1050 gradient pumping system with a variable wavelength UV detector (254 nm) and a Vares ELSD MKIII evaporative light-scattering detector. Analysis of the HPLC data were conducted on a Hewlett-Packard HPLC ChemStation software. All reactions were monitored by HPLC. Reversed-phase HPLC chromatography was carried out using an Alltech Altima C-18 column (5 μ m, 250 mm $\times$ 4.6 mm) with a gradient solvent system at a flow rate of 1 mL/min. The gradient mixture was composed of MeOH (solvent A) and 1% aqueous HOAc (solvent B). Starting with 40% MeOH, the initial solvent mixture was held for 2 min, increased to 100% MeOH over the next 10 min, then held at 100% MeOH for 5 min. Retention times (t_R) under these conditions for biotin conjugates

were (**3**) 10.3 min; (**4**) 13.3 min; (**5**) 5.2 min; (**7**) 11.6 min; (**8**) 8.1 min; (**9**) 12.4 min; (**11**) 8.6 min; (**13**) 7.5 min; (**15**) 7.1 min; (**17**) 7.6 min; (**19**) 7.6 min; (**21a**) 13.5 min; (**21b**) 9.8 min.

HPLC separations of radioiodinated biotin derivatives were conducted using a gradient system which consisted of two Beckman model 110B pumps, a Beckman 420 controller, a Beckman model 153 UV detector (254 nm), and a Beckman model 170 radioisotope detector. The separations were obtained using HPLC conditions described above, except water was used in the place of 1% aqueous HOAc. Retention times under these conditions were ([¹²⁵I]**21b**) 12.1 min; ([¹²⁵I]**22**) 11.4 min; ([¹²⁵I]**23**) 10.2 min.

Radioactive Materials. Na[¹²⁵I]I was purchased from NEN/Dupont (Billerica, MA) as high pH, high concentration solutions in 0.1 N NaOH. *N*-Succinimidyl *p*-[¹²⁵I]iodobenzoate ([¹²⁵I]PIB) was prepared as previously described (36). Measurement of ¹²⁵I was accomplished on the Capintec CRC-15R or a Capintec CRC-6A Radioisotope Calibrator. Radioactive samples were counted in a LOGIC Model 111B Gamma Counter (Abbott Laboratories, Chicago, IL).

12-Hydroxy-4,7,10-trioxadodecanoic Acid *tert*-Butyl Ester, 3. This compound was prepared from triethyleneglycol, **1**, and *tert*-butyl acrylate, **2**, as previously described (37).

13-O-*p*-Tosyl-4,7,10,13-tetraoxadodecanoic Acid *tert*-Butyl Ester, 4. To a solution of **3** (15 g, 54 mmol) in 100 mL pyridine at 0 °C was added *p*-toluenesulfonyl chloride (20.6 g, 108 mmol). The reaction mixture was stirred at 0 °C for 4 h, poured into ice–H₂O, and the aqueous layer was extracted with CH₂Cl₂ (3 $\times$ 125 mL). The combined organic layers were washed with 2% HOAc and H₂O, and then dried over anhydrous Na₂SO₄. The solvent was removed under vacuum to yield a colorless oil. The oil was dried under vacuum to give 22 g (96%) of **4**. ¹H NMR (CDCl₃): δ 1.42 (s, 9H), 2.48 (s, 3H), 2.5 (t, 2H), 3.5–3.8 (m, 13H), 4.2 (m, 2H), 7.3 (d, 2H), 7.8 (d, 2H). IR (Nujol, cm^{−1}): 3420, 1720, 1630, 1590, 1450, 1360, 1250, 920. HRMS calcd for C₂₀H₃₂O₈SnA (M + Na): 455.1716. Found: 455.1707.

12-N-Methylamino-4,7,10-trioxadodecanoic Acid *tert*-Butyl Ester, 5. To a solution of **4** (11 g, 25.3 mmol) in THF (10 mL) was added a 2 M solution of methylamine in THF (176 mL, 352 mmol). The reaction was stirred at room temperature for 40 h. The solvent was removed under vacuum. The residue was extracted with chloroform (3 $\times$ 100 mL). The combined chloroform extracts were washed with (2 $\times$ 50 mL) H₂O and dried over anhydrous Na₂SO₄, and the CHCl₃ was removed under vacuum. The product was loaded on a silica column. The column was first eluted with ethyl acetate and then with varying percentages of ethyl acetate:methanol until 100% MeOH was eluted. The fractions containing product were reduced in volume, and the isolated product was dried under vacuum to yield 3 g (40%) of **5** as an oil. ¹H NMR (CDCl₃): δ 1.4 (s, 9H), 2.38 (s, 3H), 2.42 (t, 2H), 2.7 (m, 2H), 3.5–3.8 (m, 13H). IR (Nujol, cm^{−1}): 3320, 1720, 1550, 1450, 1360, 1250, 1100, 940. HRMS calcd for C₁₄H₃₀NO₅ (M + H)⁺: 292.2124. Found: 292.2116.

Biotin Tetrafluorophenyl Ester, 6. This compound was prepared by reaction of biotin with 2,3,5,6-tetrafluorophenyl trifluoroacetate as previously described (15).

12-N-Biotinyl-(*N*-methyl)amino-4,7,10-trioxadodecanoic Acid *tert*-Butyl Ester, 7. To a solution of **5** (0.12 g, 0.412 mmol) in 25 mL of DMF was added Et₃N (60 μ L, 0.412 mmol), followed by **6** (0.161 g, 0.412 mmol).

⁴ The BSA used in these experiments is stated to be "more highly purified than our traditional True Cohn Fraction V powder" by its manufacturer, ICN. It has been noted by manufacturers of in vitro assay kits using biotin/streptavidin that cell culture media such as BSA often contain free biotin. Although we did not measure the quantity of biotin in the BSA used, its concentration must be very low because the results obtained in the in vitro binding assay were very nearly the same with or without its use (unreported results).

Table 1. Generalized Reaction for Perbiotinylation of Starburst Dendrimers (SBD) Using Biotinylation Reagent 9

starting dendrimer A	MW (amu)	SBD core ^a	biotin moieties ^b <i>N</i>	product B	MW (amu)	yield (%)	distance ^c (Å)

^a The starburst dendrimer core for each generation (*G*) is composed of the previous generation, except the terminal primary amines are substituted with two of the groups shown in parentheses in structure **A**. ^b This is the maximum number that can be attached under normal conjugation conditions. ^c The distances cited are those between two biotin carboxylate carbon atoms that are the farthest apart when fully linearized. For binding purposes, this distance can be considered the diameter of the biotinylated SBD as the biotin moieties are buried within pockets on the (strept)avidin molecule. ^d R is shown in parentheses for generalized structure **A** above. ^e See discussion on product characterization of this dendrimer in the Results. The perbiotinylation product was not obtained under the reaction conditions employed in this study.

The reaction was stirred at room temperature for 4 h, and the solvent was removed under vacuum. The residue was extracted with CHCl₃ (300 mL). The CHCl₃ solution was washed with saturated aqueous NaHCO₃ (3 × 25 mL), then H₂O (2 × 25 mL), and was dried over anhydrous Na₂SO₄. The CHCl₃ was removed under vacuum to yield 0.21 g (98%) of **7** as an oil. ¹H NMR (CDCl₃): δ 1.4 (s, 10H), 1.6–1.8 (m, 4H), 2.3 (t, *J* = 4.25 Hz, 3.9 Hz, 1H), 2.4 (t, *J* = 3.75 Hz, 3.6 Hz, 1H), 2.5 (t, *J* = 3.5 Hz, 3.4 Hz, 2H), 2.8 (d, *J* = 6.75 Hz, 1H), 2.9–3.0 (m, 4H), 3.1 (s, 2H), 3.2 (bs, 1H), 3.45–3.7 (m, 13H), 4.35 (s, 1H), 4.55 (s, 1H), 5.7 (d, *J* = 7.5 Hz, 1H), 6.1 (d, *J* = 10.5 Hz, 1H). IR (Nujol, cm⁻¹): 3260, 3060, 1780, 1690, 1520, 1480, 1260, 1080, 930. HRMS calcd for C₂₄H₄₄N₃O₇S (M + H)⁺: 518.2900. Found: 518.2923.

12-*N*-Biotinyl-(*N*-methyl)amino-4,7,10-trioxadodecanoic Acid Tetrafluorophenyl Ester, **9.** To a solution of **7** (0.21 g, 0.406 mmol) in 10 mL CH₂Cl₂ was added CF₃CO₂H (1 mL). This mixture was stirred at room temperature for 5 h. The mixture was reduced in volume under vacuum, and the residue, **8**, was dissolved in 20 mL of CH₃CN. Tetrafluorophenol (0.083 g, 0.5 mmol) was added, followed by EDC (0.096 g, 0.5 mmol). The reaction mixture was stirred at room temperature for 16 h, and the solvent was removed under vacuum. The residue was extracted with CHCl₃ (300 mL), washed with saturated aqueous NaHCO₃ (3 × 25 mL), then H₂O (2 × 25 mL), and dried over anhydrous Na₂SO₄. The solvent was removed under vacuum to yield 0.23 g (93%) of **9** as an oil. ¹H NMR (CDCl₃): δ 1.4 (s, 2H), 1.5–1.7 (m, 4H), 2.3 (m, 2H), 2.65 (d, *J* = 6.25 Hz, 1H), 2.8–2.9 (m, 4H), 3.0 (s, 2H), 3.1 (s, 1H), 3.4–3.6 (m, 13H), 3.8 (s, 2H), 4.35 (s, 1H), 4.45 (s, 1H), 6.0 (d, *J* = 8.25 Hz, 1H), 6.3 (d, *J* = 6.75 Hz, 1H), 6.95 (m, 1H). IR (Nujol, cm⁻¹): 3260, 3060, 1780, 1690, 1520, 1480, 1260, 1080, 930. HRMS calcd for C₂₆H₃₅N₃O₇F₄S (M + H)⁺: 610.2210. Found: 610.2216.

Biotinylation of Starburst Dendrimers Generation 0, **11.** A 20% MeOH solution of Starburst dendrimer, generation 0, **10** (0.54 mmol, 1.64 mL), was reduced in volume and then dried under vacuum (50 micron) for 2 h. The resulting residue was dissolved in 10 mL of DMF, and Et₃N (0.378 mmol, 55 μL) was added. To that solution was added a solution of **9** (0.378 mmol, 0.230 g) in DMF (10 mL). The reaction mixture was stirred at room temperature for 48 h, and the DMF was removed under vacuum. The residue was dissolved in

water (100 mL) and was washed with chloroform (2 × 25 mL). The aqueous layer was lyophilized to yield 0.084 g (49%) of tetrabiotin derivative, **11**, as a tacky white solid. ¹H NMR (MeOH): δ 1.65 (m, 10H), 1.7–2.0 (m, 19H), 2.5–2.65 (m, 25H), 2.85–3.0 (m, 14H), 3.1 (s, 10H), 3.3 (s, 7H), 3.4–3.5 (m, 21H), 3.7–3.95 (m, 66H), 4.5 (m, 4H), 4.7 (m, 4H). IR (Nujol, cm⁻¹): 3160, 2720, 1450, 1370, 1250, 1160, 960. Mass calcd for C₁₀₂H₁₈₀N₂₂O₂₈S₄: 2290.91. Found: 2290.89.

Biotinylation of Starburst Dendrimers, Generations 1, 2, 3, and 4. The solvent was removed from the Starburst Dendrimer (generation 1, **12**, 0.14 mmol; generation 2, **14**, 0.075 mmol; generation 3, **16**, 0.035 mmol; generation 4, **18**, 0.018 mmol), and the residue was dried under vacuum for 2 h, then it was dissolved in 10 mL of DMF. To this solution was added Et₃N (0.12 mmol, 157 μL), followed by the biotinylation reagent, **9** (1.12 mmol, 0.682 g). The reaction mixture was stirred at room temperature for 5 days. The DMF was removed under vacuum and the residue was dissolved in H₂O (100 mL). The aqueous solution was washed with CHCl₃ (2 × 25 mL), and then lyophilized to give the crude product. The crude product was purified by silica column chromatography, first eluting with MeOH, then with a MeOH/CHCl₃/H₂O mixture. Yields and information on the products are provided below and in Table 1.

Generation 1, **13.** A (5/5/1) MeOH/CHCl₃/H₂O elution mixture was used to obtain 0.4 g (57%) of product as a tacky white solid. ¹H NMR (MeOH): δ 1.4–1.8 (m, 48H), 2.3–2.6 (m, 68H), 2.7–2.85 (m, 32H), 2.95 (m, 20H), 3.1 (s, 12H), 3.15–3.3 (m, 76H), 3.5–3.8 (m, 120H), 4.3 (m, 8H), 4.5 (m, 8H). MS (MALDI-TOF): *m/e* 4975.

Generation 2, **15.** A (14/14/1) MeOH/CHCl₃/H₂O elution mixture was used to obtain 0.95 g (48%) of a tacky white solid. ¹H NMR (MeOH): δ 1.4–1.8 (m, 96H), 2.3–2.5 (m, 120H), 2.52–2.85 (m, 108H), 2.95 (m, 40H), 3.1 (s, 24H), 3.15–3.3 (m, 150H), 3.5–3.8 (m, 246H), 4.3 (m, 16H), 4.5 (m, 16H). MS (MALDI-TOF): *m/e* 10 353.

Generation 3, **17.** A (30/60/5/1) MeOH/CHCl₃/H₂O/Et₃N elution mixture was used to obtain 0.6 g (81%) of a tacky white solid. ¹H NMR (MeOH): δ 1.4–1.8 (m, 200H), 2.3–2.95 (m, 586H), 3.1 (s, 48H), 3.15–3.3 (m, 262H), 3.5–3.8 (m, 504H), 4.3 (m, 32H), 4.5 (m, 32H). MS (MALDI-TOF): *m/e* 21 110.

Generation 4, **19.** A (30/60/5/1) MeOH/CHCl₃/H₂O/Et₃N elution mixture was used to obtain 0.56 g (74%) of

Table 2. Generalized Reaction of Starburst Dendrimers (SBD) with [¹²⁵I]PIB NHS Ester and Biotinylation Reagent 9

starting dendrimer ^a A	MW (amu)	reaction time (days)	biotin moieties ^b <i>N</i>	product B	MW ^c (amu)	radiochemical yield (%)

^a The starburst dendrimer core for each generation (*G*) is composed of the previous generation, except the terminal primary amines are substituted with two of the groups shown in parentheses in structure **A**. ^b This is the maximum number that can be attached under normal conjugation reaction conditions. ^c The molecular weight has been calculated with the predominant iodine nuclide, iodine-127.

a tacky white solid. ¹H NMR (MeOH): δ 1.4–1.8 (m, 426H), 2.3–2.95 (m, 1148H), 3.1 (s, 104H), 3.15–3.3 (m, 502H), 3.5–3.8 (m, 1052H), 4.3 (m, 64H), 4.5 (m, 64H). MS (MALDI-TOF): *m/e* 36887.

***p*-Tri-*n*-butylstannylbenzoate Tetrafluorophenyl Ester, 20a, and *p*-Iodobenzoate Tetrafluorophenyl Ester, 20b.** These compounds were prepared as previously described (32).

***p*-Iodobenzoyl-Biotin Trimer, 21b.** A 20% MeOH solution of Starburst dendrimer, generation 0, **10** (0.54 mmol, 1.64 mL) was reduced in volume under vacuum. The resulting residue was dissolved in 10 mL of DMF, and Et₃N (0.378 mmol, 55 mL) was added. To that solution, **20b** (0.5 mmol, 0.198 g) in 30 mL of DMF was added dropwise over a period of 4 h. Then, a solution of **9** (2.16 mmol, 1.33 g) in DMF was added (10 mL). The reaction was stirred at room temperature for 16 h, and the solvent was removed under vacuum. The residue was extracted with CHCl₃ (300 mL) and washed with saturated aqueous NaHCO₃ (3 × 25 mL) and then H₂O (2 × 25 mL). The CHCl₃ solution was dried over anhydrous Na₂SO₄. The CHCl₃ was reduced in volume, silica gel (0.5–1 g) was added, and the remaining CHCl₃ was evaporated. The residue was placed on a silica column. Column elution began with EtOAc/1% Et₃N. Subsequent elution used increasing quantities of MeOH in a EtOAc/MeOH/1% Et₃N mixture until 100% MeOH was eluted. The fractions containing desired product were reduced in volume under vacuum to yield 0.15 g (14%) of **21b** as an oil. ¹H NMR (MeOH): δ 1.4–1.9 (m, 20H), 2.3–3.9 (m, 120H), 4.35 (s, 3H), 4.5 (s, 3H), 7.6 (s, 2H), 7.9 (s, 2H). IR (Nujol, cm⁻¹): 3180, 2720, 1450, 1370, 1300, 1140, 960. Mass calcd for C₈₉H₁₅₀N₁₉O₂₃S₃I: 2076. Found: 2096 (M + Na).

***p*-Tributylstannylbenzoyl-Biotin Trimer, 21a.** This compound was prepared as described for **21b**, except **20a** was used and the reaction was allowed to proceed for 48 h at room temperature. A yield of 0.26 g (22%) of **21a** (an oil) was obtained. ¹H NMR (MeOH): δ 0.8–1.8 (m, 47H), 2.3–3.8 (m, 120H), 4.3 (m, 3H), 4.5 (m, 3H), 7.6 (m, 2H), 7.8 (m, 2H). IR (Nujol, cm⁻¹): 3180, 2720, 1450, 1370, 1300, 1140, 960. Mass calcd for C₁₀₁H₁₇₇N₁₉O₂₃S₃-Sn: 2239. Found: 2260 (M + Na).

Preparation of [¹²⁵I]21b from 21a. To 100 μL of a 1 mg/mL solution of **21a** in 5% HOAc was added a mixture containing 2–3 μCi Na[¹²⁵I] and 0.2–0.8 equiv of NaI in H₂O (1 mg/mL solution). To this mixture was added 10 μL of a 2 mg/mL solution of *N*-chlorosuccinimide in MeOH. After 5 min at room temperature, 10 μL of a sodium metabisulfite solution (2 mg/mL in H₂O) was added to quench the reaction. Radiochemical yields were determined by HPLC to be 32–56%.

General Procedure for Radioiodination of Biotinylated Starburst Dendrimers using [¹²⁵I]PIB to prepare [¹²⁵I]21b, [¹²⁵I]22, and [¹²⁵I]23. An aliquot (3.2–4.1 μL) of the SBD (*G* = 0, 1, or 2) in MeOH that contained the desired quantity (0.5–0.6 mg) was evaporated and dried under vacuum for 2 h. The residue was placed under Ar atmosphere and dissolved in 25 μL of anhydrous DMF. To this solution was added 0.2 equiv (18–87 μg, 1 mg/mL solution) of [¹²⁵I]PIB reagent in DMF, then 5 μL of TEA was added. The reaction was allowed to proceed for 1 h at room temperature before 5.5 (*G* = 0), 9.5 (*G* = 1), or 17.5 (*G* = 2) equiv of a 100 mg/mL solution of **9** in DMF was added. The reaction mixture was then stirred at room temperature for 3 days, and the radiolabeled BSBDs were purified by HPLC. Radiochemical yields are provided in Table 2.

Radioiodination of r-SAv. Radioiodination of r-SAv was conducted using chloramine-T and Na[¹²⁵I] as reported previously [15,38]. The radioiodinated r-SAv was purified on a NAP-10 column, eluting with PBS to give a radiochemical yield of 76% and a specific activity of 0.39 μCi/μg.

r-[¹²⁵I]SAv Binding in SAv-Coated Wells. A Reacti-Bind Streptavidin Coated Polystyrene Strip Plate was washed 2 times with 100 mM PBS/0.1% BSA⁴ (100 μL/well) prior to use. To lane one (12 wells) was added 100 pmol of biotin in 100 μL of PBS. To lanes 2–8 was added 100 pmol of biotin trimers (**29** and **21b**) or perbiotinylated Starburst dendrimers (*G* = 0, **11**; *G* = 1, **13**; *G* = 2, **15**; *G* = 3, **17**; *G* = 4, **19**) to be tested in 100 μL of PBS. The plate was then incubated at room temperature for 15 min. All the wells were emptied and rinsed with 100 μL of PBS/0.1% BSA. The PBS was removed and 25 pmol of r-[¹²⁵I]SAv (specific activity of 0.39 μCi/μg) was added

Figure 2. Graph of data obtained for cross-linking of polystyrene bound SAV and r-[¹²⁵I]SAV with biotinylated dendrimers and biotin trimer at room temperature for 15 min. Data were obtained from triplicate runs and are plotted as average $\pm$ standard deviation. The experiment was conducted as follows. An excess of biotin derivative was added, rinsed with PBS containing 1% BSA, then an excess of [¹²⁵I]SAV was added, incubated for 15 min, and rinsed with PBS containing 1% BSA. This procedure was repeated four times, with the only change being the number of additions of the biotin derivative (i.e., all wells received four additions of [¹²⁵I]SAV). When 1, 2, or 3 additions of biotin derivative were made, 100 μ L of PBS was added in the place of biotin derivative to keep the number of additions/rinses constant. All additions and rinses were made in a volume of 100 μ L. Determining the quantity of radioactivity in each well and the specific activity of the [¹²⁵I]SAV permitted calculation of the picomoles bound.

to each well in 100 μ L of PBS. The plate was incubated at room temperature for 15 min. The nonbound r-[¹²⁵I]-SAV was removed, and all wells were washed with 100 μ L of PBS/0.1% BSA. After removal of the wash PBS solution, the first three wells of each lane were again filled with 100 μ L of PBS/0.1% BSA. The remaining wells were filled with 100 μ L of their respective biotin trimer or biotinylated Starburst dendrimer (as in the first step). The plate was incubated for 15 min at room temperature, and all wells were rinsed with PBS/0.1% BSA as before. Another 100 μ L of the r-[¹²⁵I]SAV was added to all wells and incubated for 15 min at room temperature. After removal of the unbound r-SAV by rinsing the wells, 100 μ L of PBS was added to the first six wells of each lane. The remaining six wells in each lane were filled with 100 μ L of their respective biotin compound and again incubated for 15 min at room temperature. After removing the liquid in the wells and washing with PBS, 100 μ L of the r-[¹²⁵I]SAV was again added to each well followed by 15 min of incubation. The [¹²⁵I]SAV was removed, and the wells were washed with PBS/0.1% BSA. The first nine wells in each lane were then filled with 100 μ L of PBS, and the remaining three wells in each lane were filled with 100 μ L of their respective biotin compound. After incubating and washing, 100 μ L of r-[¹²⁵I]SAV was again added to each well. After incubating for 15 min at room temperature, each well was washed with 100 μ L of PBS/0.1% BSA and all liquid was removed. The wells were then separated and each well placed in a γ counter and counted. Results of the r-[¹²⁵I]SAV binding are shown in Figure 2.

Biodistributions of Radioiodinated Starburst Dendrimers Generations 0, [¹²⁵I]21b; 1, [¹²⁵I]22; and 2, [¹²⁵I]23. Animal care and handling was as previously described (15). Radiolabeled BSBDs ([¹²⁵I]21b, [¹²⁵I]22,

Figure 3. Structure of biotin trimer, **29**, used as control in the *in vitro* assay. Its synthesis and evaluation of binding in the same binding assay have been previously described (22).

and [¹²⁵I]23) were administered to mice in a total volume of approximately 100 μ L via the lateral tail vein. The actual amount of injectate administered to each animal was determined by weighing the administering syringe pre- and postinjection. The animals were sacrificed at 4 h postinjection, and muscle, lung, kidney, spleen, liver, intestine, neck (including thyroid), and stomach were excised. Blood samples were obtained by cardiac puncture immediately before sacrifice. Urine samples were obtained by syringe bladder tap at the time the tissues were excised. Excised tissues were blotted free of blood, weighed, and counted. Calculation of the percent injected dose (%ID) and percent injected dose per gram (% ID/g) in the tissues was based on internal standards containing 1 μ L of the injected dose. Total blood volume was estimated to be 8% of body weight for the calculations

Figure 4. Amine reactive biotinylation reagents.

^a Values shown are average % injected dose/gram $\pm$ standard deviation; sacrifice was 4 h postinjection; data were obtained for $n = 5$ mice per group; average animal weight, 24.61 $\pm$ 2.28 g; all injections were made in approximately 100 μ L of 0.9% sterile saline. ^b Injectate for each animal had 10 μ Ci/284 μ g of [^{125} I]**21b**. ^c Injectate for each animal had 10 μ Ci/70 μ g of [^{125} I]**22**. ^d Injectate for each animal had 10 μ Ci/59 μ g of [^{125} I]**23**. ^e Urine was collected by syringe bladder tap after sacrifice.

(39). A spreadsheet program in Excel (Microsoft Corp., Redmond, WA) was used to perform the calculations. Data on the average animal weight per group, specific activity of each preparation, and quantities of [^{125} I]-labeled BSBDs administered are provided in the caption below the biodistribution data in Table 3.

RESULTS

Preparation of the Biotinylation Reagent, 9. The synthetic approach to obtain **9** is shown in Scheme 1. A key step in the synthesis, the preparation of 12-hydroxy-4,7,10-trioxadecanoic acid *tert*-butyl ester, **3**, was previously described by Seitz and Kuntz (37). Tosylation of **3** provided **4** in high yield, but the displacement of the tosylate group with methylamine was problematic, resulting in low (e.g., 40%) isolated yields of **5**. However, conjugation of **5** with biotin TFP ester, **6**, was facile, as was the carboxylate deprotection and reesterification steps. Since most reaction steps are high yielding, an overall yield of 30% was obtained for the biotinylation reagent, **9**, from triethylene glycol.

Preparation and Characterization of Biotinylated Starburst Dendrimers. Five Starburst dendrimers (SBDs) were biotinylated with **9**. The SBDs, **10** ($G = 0$),³ **12** ($G = 1$), **14** ($G = 2$), **16** ($G = 3$), and **18** ($G = 4$) were obtained as 10–20% (by wt) solutions in MeOH. After removing the MeOH under vacuum, the SBDs were reacted with an excess of the biotinylation reagent **9** in DMF at room temperature to prepare the perbiotinylated dendrimers **11**, **13**, **15**, **17**, and **19**, respectively. Biotinylation of SBDs **10** and **12** are shown in Schemes 2 and 3, and a generalized scheme depicting biotinylation of all

of the dendrimers studied is shown in Table 1. The crude products were purified by silica gel column chromatography. Reversed-phase HPLC chromatograms of the purified biotinylated dendrimers are provided in the Supporting Information. Proton NMR gave additional proof of the purity of the biotinylated dendrimers through integration of the biotin ring juncture protons ($\delta = 4.3$ and 4.5 ppm) relative to the integration of other proton peaks. Mass spectra data confirmed the identity of the compounds prepared. All of the SBDs, except SBD **18** ($G = 4$; 64 terminal amines), were perbiotinylated under the reaction conditions studied. The expected mass for perbiotinylated **18** is 42 602 whereas the MALDI-TOF mass spectra indicated that the mass of highest abundance was 36 887. Since the mass of the acylation portion of the biotinylation reagent **9** is 445, it appears that the largest portion of **19** has added 51 biotin moieties, not 64. It is likely that longer reaction times and/or elevated reaction temperatures could provide more biotin moieties attached to **19**. However, the results obtained in our studies suggest that perbiotinylation would not make a difference in the number of streptavidin molecules it could bind.

Preparation and Characterization of Radioiodinated Biotinylated Starburst Dendrimers. Radioiodinated derivatives of the BSBDs were prepared to evaluate their in vivo distribution. Our radioiodination studies began by preparing the *p*-tri-*n*-butylstannylbenzoate derivative of the smallest SBD ($G = 0$). Syntheses of the tris-biotinylated stannylbenzoyl-SBD, **21a**, and the corresponding iodinated derivative, **21b**, were accomplished as shown in Scheme 4. Synthesis of **21a** was accomplished by reaction of 1 equiv of the tetrafluorophenyl ester of *p*-tri-*n*-butylstannylbenzoate, **20a**, with Starburst dendrimer **10**, followed by reaction with an excess (4 equiv) of the biotinylation reagent **9**. The iodinated derivative, **21b**, was prepared in a similar manner. Difficulties in purification of **21a** and **21b** from the mixture of compounds produced resulted in low isolated yields of pure compounds. Radioiodination of purified **21a** was conducted in MeOH/5% HOAc at room temperature using *N*-chlorosuccinimide (NCS) as the oxidant. The radioiodination yields were also low, being only 32–56% by HPLC analysis (not isolated). The low yields obtained prompted us to investigate another method for radioiodination of the BSBDs.

As an alternative method of radioiodination, the NHS ester of *p*-[^{125} I]iodobenzoate ([^{125} I]PIB) (**36**) was reacted with SBDs **10**, **12**, and **14**. To ensure that most SBDs only reacted with one molecule of [^{125} I]PIB, the reactions were conducted with 0.2 equiv. The conjugation of [^{125} I]-PIB was conducted in DMF/Et₃N for 1 h at room temperature, then an excess of the biotinylation reagent

9 was added and allowed to react for an additional 3 days at room temperature. A general scheme for the radioiodinations and the radiochemical yields obtained is shown in Table 2. The radioiodinated products were isolated from the HPLC effluent and reduced in volume to provide an aqueous solution that was used directly in the *in vivo* distribution studies.

Biotinylated Dendrimer Cross-Linking of r-SAV with Immobilized SAV. The quantity (pmol) of [¹²⁵I]-SAV that binds with immobilized BSBD was determined in an *in vitro* binding assay. The assay involved binding the BSBD to streptavidin that is immobilized in polystyrene wells (in a "strip" plate), followed by binding r-[¹²⁵I]SAV to the resulting exposed biotin moieties. Four cycles of reagent additions were used to determine the increase of r-[¹²⁵I]SAV obtained after each addition. Excess reagents were used in each addition to saturate the binding capacity. The excess BSBD or [¹²⁵I]SAV was removed by rinsing the wells with PBS containing 0.1% BSA. Nonspecific binding of r-[¹²⁵I]SAV was minimized by addition of 0.1% BSA.⁴ Only one rinse was used after each addition due to concerns about removing polystyrene

bound SAV with multiple rinses. All wells received four additions of [¹²⁵I]SAV, but the number of additions of the biotin reagent to each well varied from 1 to 4. To ensure consistency, the wells that did not receive the biotin reagent got an equal volume of PBS added in its place. The incubation conditions for binding BSBDs and [¹²⁵I]-SAV were limited to 15 min at room temperature. These conditions were chosen as no difference in the quantity bound was noted when the incubations were conducted at 37 °C or when they were conducted over a 30 min period (unreported studies). Triplicate wells were used for each reagent so the variance in wells could be averaged. The quantity of r-[¹²⁵I]SAV which bound with immobilized BSBDs (**11**, **13**, **15**, **17**, **19**), biotin trimers (**21b**, **29**), and biotin (control) is shown in Figure 2. It is interesting to note that the quantity of [¹²⁵I]SAV bound for BSBD **13** is double (7.9 ± 0.2 pmol) that of the smaller BSBD **11** (3.6 ± 0.2 pmol) and is one-half of the larger BSBD **15** (16.0 ± 0.2 pmol). Another interesting observation is that the amount of [¹²⁵I]SAV bound is higher for the biotin trimers, **21b** and **29**, than it is for the biotin tetramer, **11**. It is tempting to believe that this difference

is due to branching as previously proposed (22), but that has not been proven in these studies. Perhaps the most interesting, and surprising, data was that no additional binding of [¹²⁵I]SAv, over that observed for BSBD **15** (16 biotin moieties), was obtained when BSBD **17** (32 biotin moieties) and BSBD **19** (up to 64 biotin moieties) were evaluated.

In Vivo Distribution of Radioiodinated Dendrimers. Biodistributions of radioiodinated BSBDs, [¹²⁵I]**21b** (three biotins), [¹²⁵I]**22** (seven biotins), and [¹²⁵I]**23** (15 biotins) were evaluated in athymic mice at 4 h postinjection. The biodistributions of the larger BSBDs, *G* = 3 and 4, were not evaluated because no increase in *r*-[¹²⁵I]-SAv binding had been noted over the smaller BSBDs in the *in vitro* study. For the comparative evaluation, a minimum number of mice (5 per compound tested) were used. The data obtained is provided in Table 3. The radioiodinated tribiotin compound, [¹²⁵I]**21b**, appears to be rapidly cleared from the blood via both renal and

hepato-biliary excretion. Similar tissue distributions were found for the larger biotinylated dendrimers, [¹²⁵I]**22** and [¹²⁵I]**23**. The most striking difference observed in the biodistributions of the three biotinylated dendrimers was that the kidney concentration (or retention) was increased significantly with increasing size and positive charge.

DISCUSSION

A focus of our tumor pretargeting studies has been to develop biotinylated reagents that will increase the amount of radioactivity associated with mAb targeted cancer cells in patients (15, 22). We hypothesized that it may be possible to increase the quantity of radiolabeled molecules attached to cancer cells by using the tetrameric biotin-binding nature of avidin or streptavidin to provide additional binding sites through cross-linking on targeted cells. This concept is depicted in Figure 1. Our initial evaluation of the concept was directed at biotin dimers

and trimers (22). The reason for choosing those compounds was that we believe that when they are used to carry the radionuclide, it will be important to keep the molecular weight low to obtain good tumor penetration and rapid blood clearance, preferably by renal excretion. Although those studies are still ongoing, we have expanded our investigation to include larger biotinylated molecules as well. This expansion in the scope of our studies has been undertaken as concerns have been raised about the multiple injections envisioned in therapeutic protocols with biotin trimers. Thus, optimization of the amount of radioactivity bound to cancer cells may have to be conducted in a single injection. A further consideration in the inclusion of biotinylated dendrimers in our studies came from the fact that the use of SAV as a carrier of the radionuclide is now practical due to our finding that kidney localization of SAV may be significantly decreased (e.g., from 29 to 2% injected dose/gram) by lowering its pI to below 4 (35). This latter point is important as compounds containing multiple biotin moieties could provide an increased number of binding sites for radiolabeled avidin or SAV.

In this investigation, we set out to synthesize a series of polybiotin compounds, determine the number of streptavidin molecules each could bind to a surface, and gain some information on biodistributions of the polybiotinylated compounds. Our initial task was to prepare the targeted polybiotin molecules. After evaluating the many possible approaches to making polybiotin compounds, we were attracted to amine containing Starburst dendrimers as core molecules for the targeted compounds. The SBDs were attractive as they are compact spherical molecules and a variety of sizes are commercially available. It seemed that the spherical shape of the SBDs might accommodate binding of a number of SAV molecules in a compact structure. A schematic representation of biotinylated SBDs is shown in Figure 1, panel II.

A key consideration in the development of biotinylated SBDs was the biotinylation reagent to be used. Although there are several amine reactive biotinylation reagents available from commercial sources, a new biotinylation reagent was designed and synthesized for biotinylation of SBDs. One reason for synthesizing the new biotinylation reagent was that commercially available biotinylation reagents, such as the *N*-hydroxysuccinimidyl (NHS) ester of biotin, **26** (Table 4) (40), or the NHS ester of aminocaproate linked biotin, **27** (41), could be degraded by the action of the serum enzyme biotinidase (42–45). Another consideration was the fact that most commercially available biotinylation reagents have low water solubility,⁵ making their use questionable for the preparation of compounds containing multiple biotin moieties. Although we have previously prepared another water solubilized, biotinidase stabilized amine reactive biotinylation reagent, **28** (46), its molecular weight (i.e., 617 g/mol for each conjugated moiety) made it unattractive for preparation of molecules that contain multiple biotin moieties. The new biotinylation reagent, **9**, has a lower mass (i.e., 445 g/mol for the conjugated moiety) than the previously prepared reagent, **28**, but it is similar in structure as it contains water solubilizing ether functionalities and a *N*-methyl functionality for stabilization toward biotinidase cleavage (32, 34). Synthesis of the new biotinylation reagent was readily accomplished and

biotinylation of the SBDs was facile. Low yields were obtained for the polybiotin compounds as only the fractions that contained relatively narrow peaks on reversed-phase HPLC were retained after purification by column chromatography. We felt that this would provide the most homogeneous biotinylated compounds for study. A method of radioiodinating the BSBDs was also developed so that their *in vivo* distribution could be evaluated. Radioiodination was accomplished by reacting substoichiometric quantities of the amine reactive *p*-[¹²⁵I]-iodobenzoate NHS ester ([¹²⁵I]PIB) prior to reaction with the biotinylation reagent, **9**. The low stoichiometric quantity of [¹²⁵I]PIB was used to ensure that only one iodobenzoate was incorporated in the radiolabeled polybiotin compounds.

Once the BSBDs had been prepared, an assessment of the number of [¹²⁵I]SAV molecules that bound each of the BSBDs was made. To accomplish this, we used an assay in which unlabeled BSBDs were bound with immobilized SAV in polystyrene wells, then radioiodinated SAV was bound to the exposed biotin moieties. In the studies, the picomole quantity of [¹²⁵I]SAV bound after saturating the biotin-binding sites with unlabeled BSBDs was measured. Those values, shown graphically in Figure 2, were obtained directly from the radioactivity measurements and the specific activity of the added [¹²⁵I]-SAV. However, to obtain an estimate of the average number of [¹²⁵I]SAV molecules bound with each BSBD (after one addition), an assumption had to be made. That assumption was that the picomole quantities required for 1 equiv of [¹²⁵I]SAV binding was equal to the amount of [¹²⁵I]SAV bound with the biotin tetramer, **11**. Our rationale for using this assumption was that the value obtained (3.6 ± 0.2 pmol) was very close to that previously obtained for biotin trimers (22) in the same assay system, and it seems most likely that **11** would bind with 1 molecule of r-[¹²⁵I]SAV after binding with immobilized SAV. If one uses the 3.6 pmol value for each equivalent of r-[¹²⁵I]SAV bound, the number of equivalents of [¹²⁵I]-SAV bound with the BSBDs can be readily estimated. By definition, BSBD **11** ($G = 0$), which has four biotin moieties, bound with 1 equiv of r-[¹²⁵I]SAV and 1 equiv of polymer bound SAV. In the BSBD **13** ($G = 1$), the number of biotin moieties is 8. If two of the biotin moieties on **13** are bound to the immobilized SAV, it might be estimated that three additional r-[¹²⁵I]SAV molecules could bind (assuming two biotin moieties bound each SAV molecule). Instead, a doubling was seen, binding 2 equiv of [¹²⁵I]SAV. Similarly, with the BSBD **15**, which has 16 total biotin moieties, 4 equiv of [¹²⁵I]SAV bound in addition to binding with SAV on the plate. No additional increase in the number of [¹²⁵I]SAV molecules bound was found with BSBD **17** (32 biotin moieties) or BSBD **19** (up to 64 biotin moieties when perbiotinylation).

The smaller number of r-[¹²⁵I]SAV molecules bound to the SAV-coated plates than had been predicted, based on the number of biotin moieties (pairs) available, might be a result of steric hindrance to addition of more SAV molecules about the SAV-coated BSBDs. This same explanation may account for the lack of increased binding observed for **17** and **19** over that observed for the smaller BSBDs. However, one cannot rule out the possibility that, as the BSBD molecules get larger, fewer of them bind with the immobilized SAV. Fewer molecules of the larger BSBDs might bind if (1) more than one immobilized SAV bound with each BSBD molecule and/or (2) if steric hindrance from the bound BSBD molecules precluded binding of more [¹²⁵I]SAV molecules. Another consideration is that after reaching a certain size, more

⁵ Sulfo-*N*-hydroxysuccinimidyl esters are sometimes used to provide water soluble biotinylation reagents, but after loss of sulfosuccinimide in the conjugation reaction, the biotin moiety has a high lipophilicity.

than two biotin moieties might bind with each SAV molecule. Through computer modeling,⁶ we have estimated that it would take a linker of >60 Å length (biotin carbonyl carbon to second biotin carbonyl carbon) to bind at opposite faces of SAV. The estimated through bond distances between any two biotin moieties in the SBDs $G = 1-4$ (Table 1) appear to be adequate for more than two biotin moieties to bind with a single SAV molecule. Irrespective of the explanation for the results obtained, there appears to be no advantages for our application to use BSBDs larger than generation 2.

Even though a smaller number of SAV molecules were attached to the immobilized BSBDs than might be predicted, substantial amplification of the amount of radioactivity bound to the SAV-coated plates was obtained. We have previously shown that in a single addition, cross-linking with biotin trimers in the same assay system resulted in 4–6 pmol of [¹²⁵I]SAV bound/well. Further, it was demonstrated that a doubling of that quantity (10–12 pmol) of [¹²⁵I]SAV was obtained in four alternating cycles of reagent additions (22). Those results were reproduced in this study with biotin trimer **29** and iodobenzoyl-biotin trimer **21b** (Figure 2). However, much larger quantities (16–30 pmol) of [¹²⁵I]SAV were bound when biotinylated SBDs **15**, **17**, and **19** were used. Indeed, with one addition of the biotin multimers **15**, **17**, or **19**, there was a 300% increase of [¹²⁵I]SAV bound over that of a single addition of the biotin trimers **29** or **21b**, and a 40+% greater quantity bound than obtained previously with four alternating administrations of the biotin trimers. The *in vitro* results support the potential for amplification of tumor targeting of radioactivity using the biotin multimers and radiolabeled SAV.

As our ultimate goal is to use the BSBDs for *in vivo* application to tumor pretargeting of radionuclides for cancer therapy, it is important to evaluate the *in vivo* distribution and pharmacokinetics of the BSBDs. We have previously shown that a variety of biotin trimers cross-linked SAV in the coated wells (22), but we had not conducted *in vivo* distribution studies with the biotin trimers. As we are interested in the development of radiolabeled biotin trimers as carriers of radionuclides, [¹²⁵I]**21b** was included in the *in vivo* evaluation. The BSBD [¹²⁵I]**23**, which has 15 biotin moieties, appeared to be the best candidate for *in vivo* amplification of binding sites, but the intermediate size of BSBD [¹²⁵I]**22** made its *in vivo* distribution of interest as well. Although it is envisioned that the perbiotinylated SBDs $G = 1$ or 2 will not be radiolabeled for *in vivo* use, it was necessary to radiolabel them to assess their biodistribution. To utilize the data obtained, it must be assumed that the radioiodinated versions of the biotinylated dendrimers, [¹²⁵I]**22** and [¹²⁵I]**23**, will have distribution similar to the perbiotinylated SBDs **13** and **15** (respectively).

In this preliminary investigation, we felt that it would be adequate to obtain comparative information about the tissue distribution of the three BSBDs ([¹²⁵I]**21b**, [¹²⁵I]**22**, and [¹²⁵I]**23**) in athymic mice⁷ at one time point (i.e., 4 h postinjection). The limited biodistribution study was designed to determine if additional, more detailed dis-

tributions were warranted. The results of the investigation are shown in Table 3. Interestingly, the concentrations of radiolabeled BSBDs in blood at 4 h postinjection are nearly the same. Differences in distribution between radiolabeled BSBDs are minor except for the kidney and liver concentrations. In previous distributions of radioiodinated biotin monomers in mice, blood clearance was similar at 4 h to that found for [¹²⁵I]**21b**, but quite high intestine concentrations were observed (unreported results). In this investigation, intestinal concentration of radioactivity was not particularly high for the biotin trimer [¹²⁵I]**21b**, but the kidney concentration is troubling. The high kidney concentration is problematic for a carrier of radioactivity, so chemical modification of the biotin trimer is being investigated to make it pass through the kidney more rapidly. Contrary to the biotin trimer, the high concentrations of [¹²⁵I]**22** and [¹²⁵I]**23** in the kidney and liver at 4 h postinjection may not present a problem for application to cross-linking SAV on cancer cells, as they will not be used as carriers of radionuclides.

In Summary. In this study, Starburst dendrimers, **10** ($G = 0$; four amines), **12** ($G = 1$; 8 amines), **14** ($G = 2$; 16 amines), **16** ($G = 3$; 32 amines), and **18** ($G = 4$; 64 amines), were reacted with a new water solubilized, biotinidase stabilized biotinylation reagent, **9**, to prepare polybiotinylated dendrimers for *in vivo* application. Data from an *in vitro* binding assay indicates that the biotinylated Starburst dendrimer **11**, which has four biotin moieties, binds one ¹²⁵I-labeled SAV molecule in addition to a SAV molecule bound to the polystyrene well. Biotinylated Starburst dendrimer **13**, which has eight biotin moieties, binds two additional [¹²⁵I]SAV molecules, and **15**, which has 16 biotin moieties, binds four additional [¹²⁵I]SAV molecules. Larger biotinylated Starburst dendrimers **17** and **19** were similar to **15** in that they only bound four additional SAV molecules. Biodistributions of radioiodinated polybiotin dendrimers in mice indicated that they were cleared from blood by 4 h, but that relatively high kidney and liver concentrations were noted at that time. A substantial increase in kidney localization or retention was noted as the polybiotin compounds increased in size and charge. The results presented herein suggest that further investigation of the concept of amplifying the amount of radiolabeled SAV that will bind to a tumor through the use of BSBDs is warranted. Animal studies to investigate this are planned.

ACKNOWLEDGMENT

We thank Dr. Ross Lawrence (Department of Medicinal Chemistry, University of Washington) and Santosh Kumar (Department of Biochemistry, University of Washington) for efforts in obtaining mass spectral data. We thank Dr. Patrick Stayton and Dr. Richard To for providing r-SAV used in the studies, and for their helpful comments on the manuscript. We are grateful for the financial support provided by the Department of Energy, Medical Applications and Biophysical Research Division, Office of Health and Environmental Research under Grant DE-FG06-95ER62029, and the Richard M. Lucas Foundation.

Supporting Information Available: Complete structures for the biotinylated dendrimers are provided along with HPLC chromatograms, NMR spectra, and mass spectra of all new compounds (**4**, **5**, **7**, **9**, **11**, **13**, **15**, **17**, **19**, **21a**, and **21b**). An HPLC chromatogram of biotin derivative **8**, which was not isolated, is also included (41

⁶ Measurements of distances in biotin derivatives were obtained from the computer program ChemDraw3D (Cambridge-Soft Corporation, Cambridge, MA) after structural and energy minimization of fully extended, planar conformations of the compounds.

⁷ Athymic mice (BALB/c nu/nu) were used in this investigation so that the results can be compared with planned studies involving human tumor xenografts in athymic mice.

Tailored Hydrophobic Cavities in Oligonucleotide–Steroid Conjugates

Robert L. Letsinger* and Surendrakumar Chaturvedi†

Department of Chemistry and Department of Biochemistry, Molecular Biology, and Cell Biology, Northwestern University, Evanston, Illinois 60208. Received June 5, 1998; Revised Manuscript Received August 11, 1998

Hydrophobic pockets can be generated readily in aqueous solution by hybridization of oligonucleotide conjugates containing one or two androstane units inserted into each strand by short phosphoryl linkers. Both double- and triple-stranded complexes formed by the conjugates are stabilized by adding to the solution a water-soluble hydrophobic substrate, 3,17-diaminoandrostane dihydrochloride, that can bind in the pocket. This substrate has no effect on the dissociation of unmodified oligonucleotides, and 1,10-diaminodecane dihydrochloride has no effect on dissociation of complexes of these steroid conjugates under the same conditions. This system provides a new means for selectively modulating and triggering hybridization of oligonucleotide conjugates. Cetyltrimethylammonium bromide strongly enhances the stability of complexes of the steroid conjugates; however, it also leads to precipitation of complexes of unmodified oligonucleotides.

INTRODUCTION

Hydrophobic cavities play an important role in binding substrates to enzymes and receptor proteins in an aqueous environment. Technique for generating such cavities synthetically can be useful in creating new catalysts and assembly systems. However, the construction of hydrophobic-binding cavities, even for small molecules, can be challenging since it entails creation of a relatively large, defined structure that is soluble in water yet possesses hydrophobic surfaces suitably positioned in space to envelop the substrate. One approach to synthesizing enzymes mimics has been to append catalytically active functional groups to natural cyclodextrins that serve as binding sites for aromatic esters (1, 2). Cavities have also been created de novo by assembling appropriate peptides into four-helix bundles (3). We show here that complexes derived from appropriately designed oligonucleotide–steroid conjugates can function as entities with hydrophobic pockets that interact selectively with a small molecule substrate in aqueous solution. Distinctive features of the system are the simplicity of synthesis and the fact that the hydrophobic pockets that are generated also provide a new means for selectively modulating and triggering hybridization of oligonucleotide derivatives, namely, by addition of a low concentration of a hydrophobic binding agent targeted to the pocket.

RESULTS AND DISCUSSION

Duplex Assembly. Initial experiments were carried out with **1a** + **2a**, a duplex comprising two oligonucleotide conjugates with androstane units inserted into the chains via phosphoryl groups (Scheme 1). This system was selected since molecular models indicated that hybridization of the oligonucleotide segments would bring the steroid groups into proximity but at a distance

unfavorable for direct hydrophobic interaction. Oligomers **1a** and **2a** and the related conjugates indicated in Scheme 1 were synthesized by conventional solid support methodology using nucleoside phosphoramidite reagents along with intermediate **5** to introduce the androstane units. Compound **5** was prepared from epiandrosterone by successive treatment with dimethoxytrityl chloride, reduction of the 17-ketone function to the alcohol, and phosphitylation with 2-cyanoethyl *N,N*-diisopropylchlorophosphoramidite.

Thermal dissociation data for the duplex formed from **1a** + **2a** in fact support the view that contact between the two steroid units in the fully hybridized double stranded complex is minimal at best. The dissociation temperature (T_m) of the complex is only 17 °C (Figure 1), a value near that expected for independent dissociation of the 5-bp arms. This value contrasts markedly with data for systems in which organic groups on separate strands of a duplex are aligned by linkers that enable the organic groups to come into contact. Thus, the T_m for duplex **1b** + **2b** is 39 °C (4, 5) and unusually high dissociation temperatures have been observed for oligonucleotides conjugated to cholesterol groups than overlap in a duplex (6, 7). Melting curves exhibiting a hyperchromic change at 330 nm for the stilbenedicarboxamide band that parallels the change at 260 nm for dissociation of the oligonucleotide strands provided direct evidence that the stilbenedicarboxamide units were in contact in **1b** + **2b** (4, 5).

If the aligned androstane groups in **1a** + **2a** indeed form a hydrophobic pocket in the aqueous solution, one might expect that filling the pocket with a hydrophobic substrate would stabilize the duplex. As a test of this idea, we examined the effect of 3,17-diaminoandrostane dihydrochloride, **6**, on the dissociation of complex **1a** + **2a**. Compound **6** has a well-defined, large hydrophobic surface and contains two well separated cationic sites that confer water solubility, disfavor formation of micelles, and facilitate binding to the anionic oligonucleotide complex. Melting curves for duplex **1a** + **2a** carried out in the absence and in the presence of low concentrations

1. 5' d-GCTCA-X-AGTCT 3. 5' d-TTTTTTTTTT-X-TTTTTTTTTT
 2. 5' d-AGACT-X-TGAGC 4. 5' d-AAAAAAAAAA-X-AAAAAAAAAA

Figure 1. Thermal dissociation curves for complexes formed from **1a** + **2a** ($5 \mu M$ each) in 0.1 M NaCl, 10 mM Tris·HCl, pH 7.0, in the presence of A, no additive; B, compound **6** (1×10^{-4} M); and C, compound **6** (5×10^{-4} M).

of **6** are given in Figure 1. The results demonstrate that **6** does interact with and stabilize duplex **1a** + **2a**. For a solution 5×10^{-4} M in **6**, the increase in T_m is $\sim 10^\circ C$.

Control experiments carried out under comparable conditions showed that 1,10-diaminodecane dihydrochloride, a dicationic species with a relatively small hydrophobic surface, has no detectable effect on the dissociation of **1a** + **2a** and that substrate **6** has no detectable effect on dissociation of either **1b** + **2b** or 5' d-GCTGAAGTCT/3' d-CGACTTCAGA, duplexes which lack a hydrophobic pocket. We therefore conclude that the enhancement in thermal stability depends on both a hydrophobic pocket in the duplex and a water soluble substrate possessing a large hydrophobic surface.

A striking effect was observed when cetyltrimethylammonium bromide (CTAB) was added to the solution containing **1a** + **2a**. At a concentration of 5×10^{-4} M,

which is above the critical micelle concentration, it increased the T_m value for dissociation of the duplex by $34^\circ C$ (from 17 to $51^\circ C$). Below the critical micelle concentration, it was ineffective. These results suggest that the aligned steroid units in the duplex interact with the surfactant molecules to form micellar type structures in which the hydrophobic cavities are filled with hydrocarbon tails of the surfactant. A noteworthy feature is that the duplex formed by the conjugates did not precipitate in the presence of the CTAB micelles, even at $0^\circ C$. As previously reported, CTAB readily precipitates DNA and RNA from solution (8, 9). Also, we found that the oligonucleotides 5' d-GCTGAAGTCT/3' d-CGACTTCAGA precipitate when CTAB is added under the conditions used in the experiment with **1a** + **2a**. The cationic surfactant CTAB, therefore, is particularly effective as an additive for stabilizing the duplex formed by hybridization of the steroid-oligonucleotide conjugates; however, applications involving homogeneous systems containing unmodified oligonucleotides in addition to the modified oligonucleotides can be limited by the insolubility of the unmodified oligonucleotide-surfactant complexes.

Triplex Assembly. We then ask whether compound **6** might be exploited in enhancing stability or triggering formation of triple-stranded complexes possessing hydrophobic pockets. This question was examined with oligothymidylate and oligodeoxyadenylate conjugates **3a** and **4a**. Dissociation curves for complexes obtained using 1/1 and 2/1 dT/dA ratios in the presence and in the absence of substrate **6** are presented in Figure 2. It may be noted that the pattern for the duplex (curves C and D) is similar to that obtained for **1a** + **2a**, i.e., addition of **6** leads to an increase in T_m of several degrees. The melting curve for the mixture with a 2:1 dT/dA ratio in absence of **6** (curve A) exhibits a single break, corresponding to dissociation of the duplex, and significantly reduced normalized hyperchromicity, indicating that the second equivalent of the oligothymidylate conjugate is not bound to the duplex under the conditions of the

Figure 2. Dissociation curves for complexes of oligothymidylate conjugate **3a** + oligodeoxyadenylate conjugate **4a** in 0.1 M NaCl and 10 mM Tris·HCl, pH 7.0: A, **3a** (10 μ M) + **4a** (5 μ M); B, **3a** (10 μ M) + **4a** (5 μ M) + **6** (1×10^{-4} M); C, **3a** (5 μ M) + **4a** (5 μ M); D, **3a** (5 μ M) + **4a** (5 μ M) + **6** (1×10^{-4} M).

Figure 3. Dissociation curves for complexes of dT₂₀ + dA₂₀ in 0.1 M NaCl, 10 mM Tris·HCl, pH 7.0: circles, dT₂₀ (10 μ M) + dA₂₀ (5 μ M); stars, dT₂₀ (10 μ M) + dA₂₀ (5 μ M) + **6** (1×10^{-4} M); squares, dT₂₀ (5 μ M) + dA₂₀ (5 μ M).

experiment (0.1 M NaCl). In contrast, the 2:1 dT/dA mixture in the presence of **6** (1×10^{-4} M) exhibits not only an enhanced T_m for dissociation of the double-stranded complex but also a break in the curve at a lower temperature corresponding to dissociation of a third strand from a triple-stranded complex. As shown in Figure 3, **6** has no effect on complexes of comparable oligonucleotides lacking the hydrophobic sites. We conclude that **6** both interacts with the hydrophobic cavity in the double-stranded **3a** + **4a** complex and stimulates formation of a triple stranded complex in which the three androstane units linked within the conjugates are aligned in a structure stabilized by an interaction with **6**.

Double Pockets. Oligonucleotide conjugates containing multiple, contiguous phosphoryl–steroid bridges can be readily generated by repetitive condensations of phosphoramidite **5** at the proper stage in the oligomer synthesis. As representatives of this class of compounds, we prepared and examined the hybridization properties of conjugates **1c**, **2c**, **3c**, and **4c**. Interestingly, introduction of the second phosphoryl–androstane group leads to significant stabilization of the duplexes. For the mixed

Figure 4. Dissociation curves for complexes of **3c** + **4c** in 0.1 M NaCl, Tris·HCl, pH 7.0: A, **3c** (10 μ M) + **4c** (5 μ M); B, **3c** (10 μ M) + **4c** (5 μ M) + **6** (1×10^{-4} M); C, **3a** (5 μ M) + **4c** (5 μ M).

base oligomers, **1c** + **2c**, the enhancement in T_m relative to that for **1a** + **2a** is 13 $^{\circ}$ C (T_m values, 30 and 17 $^{\circ}$ C for the **c** and **a** duplexes, respectively) and for the dT/dA compounds, **3c** + **4c**, the enhancement relative to **3a** + **3b** is 5 $^{\circ}$ C (T_m values, 41 and 36 $^{\circ}$ C, respectively). Addition of substrate **6** (1×10^{-4} M) further increases the stability of these duplexes (enhancement in T_m for **1c** + **2c**, 10 $^{\circ}$ C; for **3c** + **4c**, 6 $^{\circ}$ C). Our interpretation is that alignment of contiguous phosphoryl–androstane bridges in this system permits some, but not complete, contact between the hydrophobic units. This interaction stabilizes the duplex relative to that containing the single pocket (series **a**) even though the nonnucleotide bridge is longer and contains additional flexible linkages. Interaction with compound **6** then leads to additional hydrophobic contacts that further stabilize the complex.

The pattern for the melting curves for the double pocket 2dT/dA system (Figure 4) is similar to that for the single pocket 2dT/dA system (Figure 2) except that the complexes formed by the double pocket oligomers are somewhat more stable. A break at 10 $^{\circ}$ C in curve A (Figure 4) demonstrates that some triple-stranded complex forms below 10 $^{\circ}$ C even in absence of **6**; the break at 26 $^{\circ}$ C in curve B shows that addition of **6** further stabilizes the triple stranded complex, and the low absorbance at 0 $^{\circ}$ C in B indicates that formation of the triple stranded complex is essentially complete at 0 $^{\circ}$ C when **6** is present.

SUMMARY

These oligonucleotide–androstane derivatives may be considered prototypes for a family of conjugates that self-assemble in aqueous media to form hydrophobic cavities that can be used to take up appropriate substrates from solution. Two motifs were investigated. In one, a single androstane unit was inserted into the backbone of each member of a pair of complementary oligonucleotides such that hybridization would align the hydrophobic groups in proximity but at a distance unfavorable for direct hydrophobic interaction. Thermal dissociation experiments showed that the steroid inserts in these conjugates strongly destabilized the oligonucleotide duplex, as expected for a structure in which hydrophobic interaction between the bridging elements was weak and that addition of 3,17-diaminoandrostane dihydrochloride, a

water-soluble steroid derivative that could fit into the cavity formed by the androstane units, stabilized the duplex structure. In the second motif, a pair of androstane units linked by a phosphoryl group served as the insert. Complexes formed by these conjugates were somewhat more stable than those of the first type, yet the tandem bridges in the complexes still functioned as pockets that interacted with 3,17-diaminoandrostane dihydrochloride in solution. This additive was also effective in inducing formation of triple-stranded complexes in which three inserts of each type were aligned. The hydrophobic groups in these complexes may function both as a binding sites for appropriate substrates and as a control site for triggering selective enhancement in stability of a given segment of an oligonucleotide assembly. An attractive extension of the chemistry would be to utilize two conjugate strands to generate a binding site for a substrate together with a third strand that would bind to the duplex and align a functional group in position to catalyze a reaction of the bound substrate.

EXPERIMENTAL PROCEDURES

General Methods. Reagent grade chemicals were used throughout. Pyridine, 4-(dimethylamino)pyridine, and CH₃CN were dried over CaH₂. THF was freshly distilled over sodium and benzophenone prior to use. 3, 17-Diaminoandrostane was prepared as described (10) and was characterized by NMR, IR, and FAB MS. FAB mass spectra were obtained on a VG-70-250 SE mass spectrometer. ¹H and ³¹P NMR spectra were recorded on a Varian XL-300 MHz spectrometer using CDCl₃ as solvent. Chemical shifts are reported relative to TMS and 85% H₃PO₄ in parts per million. Elemental analyses were carried out by the Searle Laboratory and Oneida Research Services, Inc.

Melting curves were determined using a Perkin-Elmer Lambda 2 UV spectrometer equipped with a Peltier 2 temperature programmer for automatically increasing the temperature at the rate of 1 °C/min. The solutions were 5 μM in each oligonucleotide, 0.10 M in NaCl, and 10 mM in Tris·HCl (pH 7.0). Experiments with the hydrophobic additives (**6** and CTAB) were carried out by mixing the additive with the oligonucleotide complexes at room temperature, cooling slowly to 0 °C (~15 min), then monitoring the absorbance at 260 nm as the temperature was increased at the rate of 1 °C/min.

3β-(4,4'-Dimethoxytrityloxy)-5-α-androstan-17-one. 5-α-Androstan-3β-ol-17-one (2.9 g, 0.5 mmol) and 4-(dimethylamino)pyridine (61 mg, 0.5 mmol) were stirred with Et₃N (126 mL) for 15 min; then, dimethoxytrityl chloride (5.08 g, 15 mmol) was added, and the mixture was stirred at room temperature for 1.5 h. TLC indicated that the reaction of the steroid was complete. The mixture was poured into CH₂Cl₂ (100 mL), washed with 5% aqueous NaHCO₃, dried over Na₂SO₄, and evaporated under reduced pressure. Purification by column chromatography on silica gel with CH₂Cl₂/Et₃N/MeOH (98/1/1, v/v/v) then afforded 4.6 g (76%) of the title compound. ¹H NMR (CDCl₃): δ 0.79 (s, 3H, -CH₃), 0.82 (s, 3H, -CH₃), 0.5–2.5 (m, 20H), 3.35 (s, 1H, -C₃H), 3.8 (s, 6H, -OCH₃), 6.8–7.5 (m, 13 H, DMT). FAB MS: calcd M, 592.8; found, 593.3. Analysis calcd for C₄₀H₄₈O₄: C, 81.04; H, 8.16. Found: C, 80.71; H, 8.69.

3β-(4,4'-Dimethoxytrityloxy)-5-α-androstan-17-ol. NaBH₄ (5.2 g) was added with stirring to 3β-(4,4'-dimethoxytrityloxy)-5-α-androstan-17-one (4 g) in 150 mL of 1:1 THF/MeOH over a period of 45 min while maintaining the temperature <20 °C. After stirring for 14 h,

the mixture was poured into CH₂Cl₂, washed repeatedly with water, dried over Na₂SO₄, and evaporated. Column chromatography on silica gel using CH₂Cl₂/Et₃N/MeOH (98/1/1, v/v/v) afforded 3.5 g (88% yield) of the title compound. ¹H NMR (CDCl₃): 0.7 (s, 3H, -CH₃), 0.8 (s, 3H, -CH₃), 0.5–2.1 (m, 20H), 3.35 (s, 1H, -C₃H), 3.6 (m, 1H, -C₁₇H), 3.8 (s, 6H, -OCH₃), 5.8–7.5 (m, 13 H, DMT). FAB MS: calcd M, 594.8; found 594.4. Analysis calcd for C₄₀H₅₀O₄: C, 80.77; H, 8.47. Found: C, 80.28; H, 8.10.

2-Cyanoethyl N,N-Diisopropylphosphoramidite Derivative of 3β-(4,4'-Dimethoxytrityloxy)-5-α-androstan-17-ol (5). 2-Cyanoethyl N,N-diisopropylchlorophosphoramidite (0.42 mmol) was added with stirring under a nitrogen atmosphere to 3β-(4,4'-dimethoxytrityloxy)-5-α-androstan-17-ol (0.34 mmol) and diisopropylethylamine (1.00 mmol) in CH₂Cl₂ (3 mL). After 1 h, the reaction of the alcohol was complete as indicated by TLC. The mixture was diluted with CH₂Cl₂, washed twice with brine (50 mL each), dried (Na₂SO₄), and concentrated. Chromatography on a 250 mm silica gel plate (10 × 25 cm) using EtOAc:hexane:Et₃N (10/10/3 by volume) gave the desired product, **5** (0.26 g, 95%), as a white solid ³¹P NMR: 147.47 and 148.39 ppm.

Oligonucleotide Conjugates. These compounds were synthesized on an Expedite DNA Synthesizer using commercial phosphoramidite reagents and intermediate **5**. Couplings with **5** proceeded smoothly in >95% yield as judged by the dimethoxytrityl assay. The DMT-protected oligomers were isolated by reversed-phase (RP) HPLC on a Hypersil ODS column (4.6 × 200 mm, 5 μ particle size) with a 1%/min gradient of CH₃CN in Et₃NH⁺OAc⁻ buffer, pH 7.0. The products were lyophilized, detritylated (80% aqueous acetic acid, 30 min, followed by washing with ether and lyophilization), and purified by RP-HPLC. The elution times for **1a**, **2a**, **3a**, **4a**, **1c**, **2c**, **3c**, and **4c** were 20.5, 20.7, 21.2, 21.7, 26.5, 27.0, 26.9, and 27.5 min, respectively. These times are somewhat longer than those for the corresponding underivatized oligonucleotides (18.9, 19.1, 19.5, and 19.7 min for d-GCTCAAGTCT, d-AGACTTCAGC, dT₂₀, and dA₂₀, respectively), reflecting the presence of the hydrophobic inserts. The conjugates were also characterized by polyacrylamide gel electrophoresis carried out with nondenaturing cross-linked polyacrylamide gel (15% bisacrylamide) purchased from ICN, CA. The migration distances relative to bromophenol blue for oligomers **1a**, **2a**, **3a**, **4a**, **1c**, **2c**, **3c**, and **4c** were 1.03, 1.13, 0.65, 0.70, 0.83, 0.94, 0.58, and 0.65, respectively. For comparison, the relative migration distances for d-GCTCAAGTCT, d-AGACTTCAGC, dT₂₀, and dA₂₀ were 1.06, 1.17, 0.78, and 0.91, respectively.

ACKNOWLEDGMENT

This research was supported by a grant from the National Institute of General Medical Sciences (GM 10265). Conjugates **1b** and **2b** were provided by Dr. T. Wu.

Synthesis of Oligodeoxynucleotides Containing N^4 -Mercaptoethylcytosine and Their Use in the Preparation of Oligonucleotide–Peptide Conjugates Carrying *c-myc* Tag-Sequence

Dirk Gottschling, Hartmut Seliger,[†] Gema Tarrasón,[‡] Jaume Piulats,[‡] and Ramon Eritja*

European Molecular Biology Laboratory, Meyerhofstrasse 1, D-69117 Heidelberg, Germany, Universität Ulm, Sektion Polymere, Albert-Einstein-Allee 11, D-89081 Ulm, Germany, and Merck Farma-Química, Laboratori de BioInvestigació, C/Casp 108, 08010 Barcelona, Spain. Received June 26, 1998; Revised Manuscript Received August 17, 1998

The preparation and properties of oligodeoxynucleotides containing mercaptoethyl groups at position N-4 of cytosine are described. The resulting thiol-oligodeoxynucleotides were reacted with a maleimido-peptide carrying the *c-myc* tag-sequence. The peptide-oligonucleotide conjugate is specifically recognized by an anti *c-myc* monoclonal antibody, thus constituting a labeling system with sensitivity similar to other existing methods of nonradioactive labeling.

INTRODUCTION

Oligonucleotides carrying thiol groups are useful intermediates for different applications including (a) introduction of biotin, fluorescent compounds, and other nonradioactive labels (Beaucage and Iyer, 1993; Connolly, 1985); (b) preparation of conformationally restricted oligonucleotides (Ferentz et al., 1993; Glick, 1991; Osborne, 1997); (c) immobilization of oligonucleotides to solid supports such as affinity columns (Blanks and McLaughlin, 1988) and gold particles (Elghanian et al., 1997; Mirkin et al., 1996); and (d) preparation of oligonucleotide-peptide conjugates (Corey, 1995; Eritja, 1991; Zuckermann and Schultz, 1988).

In most of the cases, the thiol groups are introduced at the 5'- and 3'-ends in order to maintain the hybridization properties of oligonucleotides (Beaucage and Iyer, 1993; Connolly, 1985). But also thiol groups have been introduced at the phosphate bond (Fidanza and McLaughlin, 1992), at the 2'-position (Gundlach et al., 1997), and at the nucleobases (Goodwin and Glick, 1993; Osborne, 1997). We are interested in introducing peptide sequences in oligonucleotides as a nonradioactive labeling system. The great diversity of antibodies raised against peptide sequences and the many possibilities with regard to the labeling of such antibodies, leads us to consider oligo-tag-peptide conjugates as alternative labeling systems with great potential. Not only can such conjugates be used in hybridization assays but also different tag sequences can be introduced in the four nucleobases, which can be recognized by differently labeled antibodies, and used as sequencing tools. To test these possibilities, oligonucleotides carrying the *c-myc* tag-sequence have been prepared (Figure 1). For the preparation of the oligonucleotide-peptide conjugates, the protocol based on the reactivity of the thiol group was used (Eritja et al., 1991). In this method, a thiol group is introduced on the

oligonucleotide that will react with a maleimido-peptide carrying the *c-myc* tag-epitope. For this purpose, a derivative of 2'-deoxycytidine carrying the mercaptoethyl group at position N-4 has been developed (Figures 1 and 2). The synthesis of oligonucleotides carrying N^4 -mercaptoethyl-dC have been previously described (MacMillan and Verdine, 1991; Wolfe and Verdine, 1993) using a 2'-deoxyuridine derivative with the 2,4,6-trimethylphenyl group at position 4, which is reacted with cystamine at the end of the synthesis. This method needs postsynthetic steps and could produce some unwanted side reactions (MacMillan and Verdine, 1991). In the present article, a protected derivative of N^4 -mercaptoethyl-2'-deoxycytidine is described. This derivative is compatible with the standard phosphoramidite methodology and yields oligonucleotides carrying mercaptoethylcytosine residues using standard deprotection conditions. These oligonucleotides have been used for the preparation of an oligonucleotide-peptide conjugate carrying the *c-myc* tag-sequence. The conjugate is recognized by an anti-*c-myc* monoclonal antibody, and detection is achieved through interaction with a peroxidase conjugated antibody and a chemiluminiscent substrate.

EXPERIMENTAL SECTION

Materials and Methods. All ^1H -, ^{31}P -NMR, and ^{13}C -NMR spectra were recorded on a Bruker AM 250 spectrometer. Chemical shifts are reported in parts per million (δ) relative to an internal standard. High-performance liquid chromatography (HPLC) was performed either on a Waters chromatograph (Millipore) or on a BioCAD Sprint chromatograph (PerSeptive Biosystems). The products were purified by using one of the following columns: Nucleosil 120 C18 (250 $\times$ 4 mm) or PRP-1 (Hamilton, 305 $\times$ 7 mm). Buffer A was 5% acetonitrile in 0.1 M aqueous triethylammonium acetate (TEAA) (pH = 6.5). Buffer B was 70% acetonitrile in 0.1 M aqueous TEAA (pH = 6.5). A 30 min gradient from 0 to 60% B was used. Column chromatography was performed on Kieselgel (35–70 μm) (SDS) using solvent systems indicated in the text. Analytical thin-layer chromatography (TLC) was performed on aluminum foil supported silica gel 60 F₂₅₄ (Merck). For immunodetec-

Figure 2. Synthesis of the N^4 -(*tert*-butylthioethyl)-dC phosphoramidite derivative. (a) Hexamethyldisilazane followed by mesitylenesulfonyl chloride, Et_3N , DMAP and *p*-nitrophenol. (b) 2-Aminoethyl-*tert*-butyl disulfide. (c) Dimethoxytrityl chloride, pyridine. (d) 2-Cyanoethoxy-*N,N*-diisopropylamino chlorophosphine.

tion of oligonucleotide-peptide conjugate, samples were blotted with a dot-blot manifold (GIBCO, BRL) on a nitrocellulose membrane 0.2 μm (Bio-Rad). Immunodetection was carried out with supernatant from a murine hybridoma anti-*c-myc* (clone 9E10, 24.6 $\mu\text{g/mL}$; Evan, 1985) and a Goat anti-mouse peroxidase-conjugated secondary antibody (IgG + IgM, Jackson Immunoresearch Laboratories), and finally developed with ECL (Amersham). Washes of the membrane between antibody incubations were performed in a phosphate-buffered saline containing high-salt concentration (0.69 g of $\text{NaH}_2\text{PO}_4 \cdot \text{H}_2\text{O}$, 1.98 g of Na_2HPO_4 , 58.44 g of NaCl) and 0.1% Tween-20 (Merck).

Chemicals. Nucleosides were purchased from Pharma Waldhof GmbH (Germany). All chemicals for the synthesis of the modified nucleosides were obtained from Aldrich, Fluka (Switzerland), Merck (Germany), and Sigma. Anhydrous solvents were obtained from Merck (Germany), SDS (France), PerSeptive Biosystems, and Romil (U.K.). All chemicals for the peptide synthesis were purchased from Novabiochem (Switzerland) except 3-maleimidobenzoic acid *N*-hydroxysuccinimide ester

(Bachem), 1-hydroxybenzotriazole (HOBt), trifluoroacetic acid (TFA), and piperidine that were purchased from Aldrich. All chemicals for the oligonucleotide synthesis were purchased either from Perkin-Elmer-Applied Biosystems or PerSeptive Biosystems. Phosphoramidites protected with more labile *tert*-butylphenoxyacetyl groups (PerSeptive Biosystems) were used. Phosphodiesterase (from *Crotalus durissus*) and alkaline phosphatase were obtained from Boehringer Mannheim (Germany).

2-Aminoethyl-*tert*-butyl Disulfide. Di-*tert*-butyl 1-(*tert*-butylthio)-1,2-hydrazinedicarboxylate (Wünsch et al., 1982) (25 g, 78 mmol) and triethylamine (5.4 mL, 39 mmol) were dissolved in anhydrous dimethylformamide (DMF) (70 mL) under argon. A solution of cysteamine hydrochloride (4.43 g, 39 mmol) and dry DMF (150 mL) was added dropwise to the stirred solution. After stirring 24 h at room temperature, a white solid was precipitating. Dry DMF (200 mL) was added to obtain a nearly clear solution. Triethylamine was added until a white solid was precipitating again. The reaction mixture was stirred at room temperature for several hours. The solution was filtered and evaporated under reduced pressure. Wet diethyl ether (20 mL) was added to the residue and filtered. The white solid was collected and dried in a desiccator. Afterward, this white solid was dissolved five times in wet diethyl ether (5×10 mL), stirred for several minutes, and filtered. The desired product (3.0 g, 46%) was obtained as a white solid. TLC (methanol/dichloromethane 10:90) $R_f = 0.17$; ^1H NMR, δ_{H} (CDCl_3): 1.36 (s, 9H), 3.07 (t, 2H), 3.40 (t, 2H), 8.30 (s, 2H). ^{13}C NMR, δ_{C} (CDCl_3): 30.03, 35.91, 38.86, 48.42; FAB⁺MS 166 $[\text{M} + \text{H}]^+$ ($\text{M} = 165.1$ g/mol calculated for $\text{C}_6\text{H}_{15}\text{NS}_2$). Anal calcd for $\text{C}_6\text{H}_{15}\text{NS}_2$: C, 43.59; H, 9.15; N, 8.47; S 38.79. Found: C, 43.26; H, 9.11; N, 8.32; S, 38.65.

4-(*p*-Nitrophenoxy)-1-(β -D-2-deoxyribofuranosyl)-pyrimidin-2(1H)-one (3). 2'-Deoxyuridine (7.3 g, 32 mmol) was dried by evaporation of anhydrous DMF under reduced pressure, and the residue was dissolved in anhydrous DMF (150 mL) under argon. Hexamethyldisilazane (13.8 mL, 64 mmol) was added with a syringe to the stirred solution with exclusion of moisture. After 30 min of magnetic stirring at room temperature, the solution was evaporated under reduced pressure. The residue was dissolved three times in toluene (3×10 mL) and concentrated to dryness. The residue was dissolved in a small amount of dichloromethane. Triethylamine (24.1 mL, 172.2 mmol) and 4-(dimethylamino)pyridine (DMAP) (0.94 mg, 7.7 mmol) were added. A solution of mesitylenesulfonyl chloride (10.1 g, 46.4 mmol) in dichloromethane (20 mL) was added dropwise with exclusion

of moisture. After 30 min of magnetic stirring at room temperature 1,4-diazabicyclo[2.2.2]octane (0.69 g, 6.1 mmol) and a solution of 4-nitrophenol (8.6 mg, 62.3 mmol) in tetrahydrofuran (20 mL) was added to the red reaction mixture. The reaction mixture was stirred overnight at room temperature. After removing the solvent under reduced pressure, the residue was dissolved in dichloromethane (150 mL), washed with 5% aqueous sodium hydrogen carbonate (150 mL), and washed with saturated NaCl (150 mL), and the organic phase was dried with sodium sulfate. The solvent was removed under reduced pressure. Acetic acid:methanol (1:4 v/v, 96 mL) was added to the residue, and the resulting solution was stirred for 10 h at room temperature. The white solid was collected. To increase the yield, the solution was reduced to 25 mL, and diethyl ether (45 mL) was added dropwise. After 3 h of stirring, the white solid was collected. The solids were combined and washed three times with dichloromethane (20 mL). The desired product (5.2 g, 47%) was obtained as a white solid. TLC (10% methanol in dichloromethane) $R_f = 0.4$; physical and spectroscopic data were in agreement with previously published data (Miah et al., 1997). FAB-MS 349 $[M]^-$ ($M = 349.3$ g/mol calculated for $C_{15}H_{15}N_3O_7$).

2'-Deoxy-N⁴-(tert-butylthioethyl)cytidine (4). 2-Aminoethyl-tert-butyl disulfide (2.95 g, 18 mmol) was dissolved in a 40 °C warm solution of dry DMF (150 mL) and triethylamine (2.5 mL, 18 mmol). After addition of compound **3** (2.5 g, 7.16 mmol), the mixture was stirred for 14 h at 50 °C. The solvent was removed under reduced pressure, and the residue was dissolved two times in toluene (2×30 mL) and concentrated to dryness. The residue was dissolved in a small amount of dichloromethane and purified by chromatography on silica gel. The product was eluted with a gradient of methanol from 0 to 15% in dichloromethane. ¹H-NMR spectroscopy showed that the product was contaminated with 2-aminoethyl-tert-butyl disulfide. To purify the product a column with a 10-fold excess (by mass) of Dowex-50WX4 resin was used. First, the resin was washed with methanol until the solvent was colorless. After, the residue was dissolved in a small amount of methanol and the solution was applied on the column. The Dowex (50WX4) resin was washed several times with methanol. The product was eluted with a 5% triethylamine solution in methanol. The pure compound was obtained as white, oily foam (1.48 g, 54%). TLC (10% methanol in dichloromethane) $R_f = 0.18$. ¹H NMR, δ_H (CD_3OD): 1.32 (d, 9H), 2.15 (m, 1H), 2.32 (m, 1H), 2.91 (t, 2H), 3.65 (t, 2H), 3.74 (m, 2H), 3.91 (m, 1H), 4.34 (m, 1H), 5.84 (d, 1H), 6.25 (t, 1H), 7.89 (d, 1H). ¹³C NMR, δ_C (CD_3OD): 30.29, 39.93, 40.88, 42.03, 49, 62.86, 72.10, 87.56, 88.83, 97.04, 141.32, 158.65, 165.62. FAB-MS 376 $[M + H]^+$ ($M = 375.3$ g/mol calculated for $C_{15}H_{25}N_3O_4S_2$). Anal calcd for $C_{15}H_{25}N_3O_4S_2$: C, 47.98; H, 6.71; N, 11.19; S, 17.08. Found: C, 47.67; H, 6.52; N, 11.32; S, 17.13.

The silica gel purification step can be avoided. In this case, after Dowex purification, ¹H NMR of the product shows a very small amount of impurities in the final product which are not present when the silica gel purification is performed.

4-(p-Nitrophenoxy)-1-[5-O-(4,4'-dimethoxytriphenylmethyl)- β -D-2-deoxyribofuranosyl]pyrimidin-2(1H)-one (5). Compound **3** (2.25 g, 6.44 mmol) was dried by evaporation of anhydrous pyridine in vacuo and then dissolved in dry pyridine (26 mL) under argon. Triethylamine (2.13 mL, 15.3 mmol) and 4,4'-dimethoxytriphenylmethyl chloride (2.62 g, 7.74 mmol) were added with exclusion of moisture. The reaction mixture was

stirred overnight at room temperature. At this time, the reaction was not complete as judged by TLC. As a consequence more 4,4'-dimethoxytriphenylmethyl chloride was added (2×0.44 g, 2×1.3 mmol). After each addition the reaction mixture was allowed to stir at room temperature for 2 h. Afterward the reaction was quenched with methanol (1 mL). The solvent was removed in vacuo at room temperature, and the residue was dissolved in chloroform (100 mL). The solution was washed with 5% aqueous sodium hydrogen carbonate (100 mL) and with saturated aqueous sodium chloride (100 mL). After drying the organic phase with sodium sulfate, the solvent was evaporated under reduced pressure at room temperature. The residue was dissolved two times in toluene (2×10 mL) and evaporated to dryness. The residue was dissolved in a small amount of dichloromethane and purified by chromatography on silica gel. The column was packed with silica gel using a 1% triethylamine solution in dichloromethane. The product was eluted with a gradient of methanol from 0 to 2% in dichloromethane. The pure compound was obtained as yellow foam (2.76 g, 65.8%). TLC (5% methanol in dichloromethane) $R_f = 0.72$ (TLC plates were preincubated with triethylamine). ¹H NMR, δ_H ($CDCl_3$): 2.26 (m, 1H), 2.61 (m, 1H), 3.44 (dq, 2H), 3.80 (s, 6H), 4.08 (m, 1H), 4.52 (m, 1H), 5.82 (d, 1H), 6.21 (t, 1H), 6.82–7.41 (m, 15H), 8.23 (m, 2H), 8.34 (d, 1H). ¹³C NMR, δ_C ($CDCl_3$): 41.99, 55.29, 62.51, 70.67, 86.34, 87.06, 87.16, 94.75, 113.35, 122.74, 125.36, 127.18, 128.05, 128.17, 130.12, 135.29, 135.41, 144.34, 145.27, 145.27, 155.01, 156.38, 158.76, 170.48. FAB-MS 650 $[M - H]^-$ ($M = 651.6$ g/mol calculated for $C_{36}H_{33}O_9N_3$). Anal calcd for $C_{36}H_{33}O_9N_3$: C, 66.35; H, 5.10; N, 6.45. Found: C, 66.12; H, 5.25; N 6.27.

2'-Deoxy-5'-O-(4,4'-dimethoxytriphenylmethyl)-N⁴-(tert-butylthioethyl)-cytidine (6). **Starting from Compound 5.** 2-Aminoethyl-tert-butyl disulfide (0.51 g, 3.08 mmol) was dissolved in a 40 °C warm solution of dry DMF (26 mL) and triethylamine (0.43 mL, 3.08 mmol) under argon. Compound **5** (1 g, 1.53 mmol) was added with exclusion of moisture. The reaction mixture was stirred for 22 h at 45 °C. After this time, TLC (2% methanol in dichloromethane, TLC plates were preincubated with 1% triethylamine) showed no complete reaction. As a consequence, more 2-aminoethyl-tert-butyl disulfide (0.14 g, 0.85 mmol) was added and the solution was stirred for 7 h at 45 °C. After removing the solvent under reduced pressure, the residue was dissolved two times in toluene (2×10 mL) and concentrated to dryness. The residue was dissolved in chloroform (70 mL), washed with 5% aqueous sodium hydrogen carbonate (70 mL) and washed two times with saturated NaCl (70 mL). The organic phase was dried with sodium sulfate, filtered, and concentrated to dryness. The residue was dissolved in a small amount of dichloromethane and purified by chromatography on silica gel. The column was packed with silica gel using a 1% solution of triethylamine in dichloromethane. The product was eluted by a gradient of methanol from 0 to 2% in dichloromethane. The pure product was a colorless oil (0.55 g, 53%): TLC (5% methanol in dichloromethane) $R_f = 0.57$ (TLC plates were preincubated with triethylamine). ¹H NMR, δ_H ($CDCl_3$): 1.32 (s, 9H), 2.22 and 2.59 (m, 2H), 2.87 (m, 2H), 3.39 (m, 2H), 3.79 (m, 8H), 4.07 (m, 1H), 4.51 (m, 1H), 5.35 (d, 1H), 5.44 (s, 1H), 6.34 (t, 1H), 6.81–7.41 (m, 13 H), 7.81 (d, 1H). ¹³C NMR, δ_C ($CDCl_3$): 29.93, 39.07, 39.07, 41.99, 48.22, 55.26, 63.05, 71.32, 85.76,

86.11, 86.73, 94.78, 113.24, 126.97, 127.93, 128.17, 130.10, 135.54, 135.62, 140.24, 144.53, 156.16, 158.59, 163.58.

Starting from Compound 4. 2'-Deoxy-N⁴-(*tert*-butyldithioethyl)cytidine (**4**) (0.58 g, 1.54 mmol) was reacted with 4,4'-dimethoxytriphenylmethyl chloride (0.66 g, 1.95 mmol) in dry pyridine (2.5 mL) under argon. After 4 h of stirring at room temperature, the reaction mixture was quenched with methanol (1 mL), and the mixture was treated as described for compound **5** giving the desired product as colorless oil (0.6 g, 57%). The purified product has the same chromatographic and spectroscopic properties as the product described above. In this route, it is possible to observe the formation of a small percentage of a compound with two DMT groups: one at the 5'-OH and the other at position N⁴. This side product is easily separated during silica gel purification.

2'-Deoxy-5'-O-(4,4'-dimethoxytriphenylmethyl)-N⁴-(*tert*-butyldithioethyl)cytidine-3'-O-(2-cyanoethyl N,N-diisopropylphosphoramidite) (7). Compound **6** (0.32 g, 0.47 mmol) was dried by evaporation of anhydrous acetonitrile in vacuo, and the residue was dissolved in dry acetonitrile (10 mL) under argon. N,N-Diisopropylethylamine (0.17 mL, 0.95 mmol) was added with exclusion of moisture. The solution was cooled on ice and 2-cyanoethoxy N,N-diisopropylaminochlorophosphine (0.16 mL, 0.72 mmol) was added dropwise with a syringe over a period of 2 min. Afterward, the solution was stirred at 0 °C for 5 min and at room temperature for 1 h. After this time, TLC (ethyl acetate/hexane 1/1 with 5% triethylamine, TLC plates were preincubated with triethylamine) showed complete reaction. The solvent was removed in vacuo and the residue was dissolved in dichloromethane (20 mL). The solution was washed with 1 M aqueous sodium hydrogen carbonate (50 mL) and afterward with saturated NaCl (50 mL). After drying the organic phase with sodium sulfate, the solvent was removed in vacuo. The residue was dissolved in a solution (1 mL) of ethyl acetate/hexane (2/1) with 5% triethylamine and purified by chromatography on silica gel. The product was eluted with ethyl acetate/hexane (2/1) with 5% triethylamine. The pure product was obtained as white foam (0.23 g, 57%); TLC (ethyl acetate/hexane 2/1 with 5% triethylamine) *R_f* = 0.49 and 0.36 (TLC plates were preincubated with triethylamine). ¹H NMR, δ_{H} (CDCl₃): 1.0–1.7 (3 d, 12H), 1.32 (s, 9H), 2.20 (m, 1H), 2.40 and 2.60 (2 t, 2H, two diastereoisomers), 2.62 (m, 1H), 2.88 (t, 2H), 3.40 and 3.48 (m, 2H), 3.6–3.8 (m, 9H), 4.09 (m, 1H), 4.60 (m, 1H), 5.30 (m, 2H), 6.32 (m, 1H), 6.81–7.41 (m, 13H), 7.80 and 7.90 (2d, 1H, two diastereoisomers). ³¹P NMR, δ_{P} (CH₂Cl₂; concentric external D₂O lock): 145.62 ppm. Anal. Calcd for C₄₅H₆₀N₅O₇S₂P: C, 61.55; H, 6.89; N, 7.98; S, 7.30. Found: C, 61.16; H, 6.95; N, 7.58; S, 6.94.

Synthesis of the Peptide Containing the c-myc Tag Sequence. The peptide *m*-maleimido-benzoyl-Ala-Glu-Gln-Lys-Leu-Ile-Ser-Glu-Glu-Asp-Leu-Asn was synthesized manually by using a Rink-Amide support (0.4 g, functionalization 0.56 mmol/g) and Fmoc strategy on a 0.2 mmol scale. The Fmoc protecting group was removed by treating the resin with a 1/1 solution of piperidine/DMF for 2 and 8 min with a solution of 20% piperidine in DMF. Afterward, the resin was washed four times with DMF. A mixture of 4 equiv of Fmoc-protected amino acid (0.9 mmol), 4 equiv of N-hydroxybenzotriazole (0.121 g, 0.9 mmol), 4 equiv of 2-(1H-benzotriazol-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HBTU) (0.34 μ L, 0.9 mmol), 8 equiv of N-ethyl-diisopropylamine (312 μ L, 1.8 mmol), and a small

amount of DMF was preactivated for 5 min and afterward added to the resin. Fmoc-Asn, Fmoc-Asp(*t*Bu) and Fmoc-Gln were used as pentafluorophenyl esters. In this case, 6 equiv of activated ester (1.34 mmol) and 6 equiv of HOBT (0.182 g, 1.34 mmol) were dissolved in a small amount of DMF and added directly to the resin. After 25 min, the completion of the coupling reaction was checked with the ninhydrin test (Sarin et al., 1981). If the ninhydrin test was positive, the reaction mixture was incubated for further 30 min. If the ninhydrin test was still positive after this time, the coupling reaction was repeated. To block unreacted amino groups, a mixture of acetic anhydride (1 mL), diisopropylethylamine (1.7 mL) and DMF (15.3 mL) was added for 15 min.

If the reaction was complete, the resin was washed three times with DMF, and the next cycle of deprotection and addition followed. At the last step, 6 equiv of 3-maleimidobenzoic acid N-hydroxysuccinimide ester (MBS) and 6 equiv of HOBT in a small amount of DMF were added. The maleimido-peptide was deprotected and released from the resin by treatment with TFA containing 5% of water for 4 h at room temperature. The resin was filtered and washed several times with water. The combined solutions were evaporated under reduced pressure. The residue was treated three times in diethyl ether and concentrated to dryness to eliminate the excess of TFA. MS (MALDI-TOF): 1587.2 [M + H]⁺ (M = 1585.5 g/mol calculated for C₆₉H₁₀₄N₁₈O₂₅).

Synthesis and Purification of Oligonucleotides.

The oligonucleotides were synthesized either on an ABI 394 DNA-synthesizer or on a PerSeptive Expedite 8900 synthesizer using the protocols recommended by the supplier. The standard β -cyanoethyl-protected phosphoramidite method was used. Phosphoramidites protected with *tert*-butylphenoxyacetyl groups (PerSeptive Biosystems) were used. The coupling efficiency of the modified phosphoramidite (**7**) was 98.2–99.8% (as measured by the absorbance of the DMT group). The oligonucleotides were removed from the solid support by treatment with concentrated ammonia for 6 h at 55 °C. Under these conditions, all base protecting groups were also cleaved. The crude oligonucleotides were purified with OPC cartridges (Cruachem, Glasgow, Great Britain). The following oligonucleotide sequences (Fàbrega, 1995) were synthesized on a 1 μ mol scale using the DMTr-on method: (O1) 5'-d(TAG AGG 1TC CAT TGC)-3', MS (MALDI-TOF) [M] = 4716.1 (M = 4715.5 g/mol calculated for C₁₅₂H₁₉₇N₅₅O₈₉P₁₄S₂); (O2) 5'-d(TAG AGG 1TC 1AT TGC)-3', MS (MALDI-TOF) [M] = 4864.6 (M = 4863.6 g/mol calculated for C₁₅₈H₂₀₉N₅₅O₈₉P₁₄S₄); (O3) 5'-d(TAG AGG CT1 1AT TGC)-3', MS (MALDI-TOF) 4868.1 [M + H]⁺ (M = 4863.6 g/mol calculated for C₁₅₈H₂₀₉N₅₅O₈₉-P₁₄S₄).

All oligonucleotides were characterized by mass spectrometry and enzymatic digestion.

Synthesis and Purification of the Oligonucleotide–Peptide Conjugate. To prevent side reactions, the oligonucleotide and the maleimido-peptide were cleaved from the solid support just before use. For the same reason, the maleimido-peptide was used without further purification. For the preparation of the oligonucleotide–peptide conjugate, an oligonucleotide (24 OD units at 260 nm) with the sequence 5'-d(TAG AGG 1TC CAT TGC)-3' was used. After purification with OPC cartridges, the oligonucleotide was treated with a solution (1 mL) of 0.1 M dithiothreitol (DTT) in concentrated ammonia at 55 °C overnight. Under these conditions, the *tert*-butylthiol protecting group was removed. The solution was concentrated to dryness. The residue was

dissolved in sterile water. DTT was removed by using a NAP-10 column (Pharmacia). The oligonucleotide was eluted with 1.5 mL of sterile water. This solution was collected directly in buffer A (500 mL), which contained a 10-fold excess of the maleimido-peptide. To adjust the solution to pH = 6.5, some drops of 1 M aqueous TEAA solution (pH = 6.5) were added. After 10 h at room temperature, the reaction mixture was concentrated to dryness, dissolved in sterile water, and purified with HPLC. Yield: 3 OD units at 260 nm (12%). MS (MALDI-TOF): 6214 [M + H]⁺ (M = 6213.0 g/mol calculated for C₂₁₇H₂₉₃N₇₃O₁₁₄P₁₄S). The oligonucleotide-peptide conjugate was also characterized by enzymatic digestion.

Melting Studies. Melting studies were performed in an aqueous solution (1 mL) of 0.15 M NaCl, 50 mM Tris-HCl, pH 7.5. Pentadecamer duplexes were made by mixing equimolar amounts (0.5 OD units at 260 nm) of two complementary pentadecamer strands. Duplexes were annealed by slow cooling from 80 °C to room temperature. UV-absorption and melting curves of the oligonucleotides were measured at 260 nm in 1 cm path-length cells on a Varian Cary 13 UV spectrometer.

Enzymatic Digestion. All oligonucleotides and oligonucleotide-peptide conjugates were subjected to enzymatic digestion. Pure product (0.5 OD) was incubated with 92 μ L of H₂O, 5 μ L of 1 M aqueous Tris-HCl solution (pH 8.0), 1 μ L of 1 M MgCl₂ solution, 1 μ L of phosphodiesterase solution, and 1 μ L of alkaline phosphatase solution for 8 h at 37 °C. Afterward, 15 μ L of this reaction mixture were analyzed with HPLC. All peaks in the HPLC diagram were automatically integrated. The retention time of 2'-deoxy-N⁴-(tert-butylthioethyl)cytidine was about 28.2 min. The retention time of the peptide containing nucleoside was about 18.7 min (see HPLC conditions in material and methods).

Immunodetection of the Oligonucleotide-Peptide Conjugate. Serial dilutions (from 5 μ g) of the oligonucleotide-peptide conjugate dissolved in water, were applied to a nylon or a nitrocellulose membrane (0.2 mm, Bio-Rad) using a manifold attached to a suction device. After drying at 70 °C for 30 min, the membrane was UV cross-linked for 2.5 min. The membrane was blocked with PBS containing 1% of Tween-20 for 1 h at room temperature, and incubated with culture supernatant from anti-*c-myc* murine hybridoma clone 9E10 (24.6 mg/mL) (Evans, 1985) for 1 h at room temperature. After washing twice with PBS containing 0.1% of Tween-20 for 5 min, the membrane was incubated with a horseradish peroxidase-conjugated goat anti-mouse antibody (Jackson, 0.9 mg/mL) at a 1:20000 dilution for 1 h. Finally, after several washes with PBS containing Tween-20, the membrane was developed in ECL and exposed to X-ray film.

RESULTS AND DISCUSSION

Synthesis of Monomers for Oligonucleotide Synthesis. The synthesis of the protected phosphoramidite derivative of N⁴-mercaptoethyl-2'-deoxycytidine is illustrated in Figure 2. The preparation of compound **3** was previously described (Miah et al., 1997), but in our hands, the desired product was difficult to isolate from the large excess of *p*-nitrophenol used in the reaction. For this reason, the following changes were introduced: transient protection of alcohol functions was performed with hexamethyldisilazane. Activation of position 4 of dU was done with mesitylenesulfonyl chloride, DMAP, triethylamine instead of phosphoryl chloride, and 1,2,4-

triazole. Further a smaller excess of *p*-nitrophenol was used. The desired product (**3**) was isolated pure without silica gel purification in a 47% yield. Displacement of the *p*-nitrophenyl group with protected 2-mercaptoethylamine gave protected N⁴-mercaptoethyl-dC (compound **4**). The *S*-tert-butylthio group (Goodwin and Glick, 1993; Gundlach et al., 1997; Osborne, 1997; Wünsch et al., 1982) was selected for the protection of the thiol group of mercaptoethylcytosine. Other groups such as the *S*-trityl (Connolly, 1985; Sproat et al., 1987), acetyl (Kuijpers and van Boeckel, 1993), benzoyl (Glick, 1991), and *S*-2,4-dinitrophenylethyl (de la Torre et al., 1993) have previously been used for the synthesis of oligonucleotides containing thiol groups. The *S*-tert-butylthio group is stable to oligonucleotide synthesis conditions and easily removed during or after standard synthesis conditions (Goodwin and Glick, 1993; Gundlach et al., 1997; Osborne, 1997) and for these reasons was selected. Protection of the 5'-OH of compound **2** with the dimethoxytrityl (DMT) group was accompanied with a small percentage of reaction at position N⁴, but the desired DMT-derivative (**6**) was isolated in good yields (57%). Alternatively, compound **3** was protected with the DMT group (66% yield) followed by displacement of the *p*-nitrophenyl group with *tert*-butylthio-2-mercaptoethylamine (53% yield) giving compound **6** in slightly better yields. Phosphitylation of compound **6** gave the desired phosphoramidite **7** (47% yield).

Preparation of Oligonucleotide-Peptide Conjugates. Pentadecamer sequences (O1) 5'-d(TAGAGG1TCCATTGC)-3', (O2) 5'-d(TAGAGG1TC1ATTGC)-3', and (O3) 5'-d(TAG AGG CT11AT TGC)-3' were prepared using phosphoramidite **7** and the phosphoramidites of the natural bases protected with *tert*-butylphenoxyacetyl groups. Coupling efficiencies of the modified phosphoramidite were of the same order as commercially available phosphoramidites (98–99%). Standard ammonia deprotection conditions (concentrated ammonia for 6 h at 55 °C) gave *tert*-butylthio protected oligonucleotides that were purified using standard protocols. Purified oligonucleotides were characterized by mass spectrometry and by enzymatic digestion followed by HPLC analysis of the nucleosides (see Figure 3). Removal of the *tert*-butylthio group was performed with dithiothreitol (DTT). Several conditions were tested including aqueous solutions at different pH and DTT concentrations. In general, at neutral pH, the removal of the protecting group was slow, but in alkaline solutions the removal was faster. For this reason, a 0.1 M DTT solution in concentrated ammonia was used. The reaction was always complete after an overnight treatment at 55 °C. These are the same conditions that were used for the removal of the protecting groups after oligonucleotide synthesis. Although the removal of the *tert*-butylthio group could be performed at the same time as the removal of the other protecting groups by adding DTT to the ammonia solution, we preferred to perform both reactions separately. In this way, oligonucleotides containing protected mercaptoethyl groups can be purified, characterized, and stored without inter- and intramolecular disulfide formation. Before use, the *tert*-butylthio protected oligonucleotide was deprotected with DTT, and the excess of DTT was eliminated by a Sephadex column (NAP 10). Thus, a solution of oligonucleotide with the free thiol group was obtained.

The peptide sequence maleimido-Ala-Glu-Gln-Lys-Leu-Ile-Ser-Glu-Glu-Asp-Leu-Asn carrying the *c-myc* tag-sequence, an extra alanine residue, and a maleimido group at the N-terminus was assembled on a Rink amide

Figure 3. Enzyme digestion of (a) purified 15-mer $5'$ TAG AGG 1TC CAT TGC $3'$ and (b) purified oligonucleotide-peptide conjugate.

polystyrene support (Rink, 1987) using Fmoc-chemistry as described (Eritja et al., 1991). To prevent side reactions between amino acids lateral chains and the maleimido group (Eritja et al., 1991), the maleimido peptide was cleaved from the support just before use. An aliquot of peptide support was deprotected with trifluoroacetic acid (TFA) containing 5% of water as scavenger and the product was analyzed by HPLC. A major peak was obtained which had the expected molecular mass.

Conjugation of maleimido-peptide with thiol containing oligonucleotide was performed at pH 6.5, overnight at room temperature with 10-times excess of freshly deprotected maleimido-peptide over free thiol oligonucleotide O1 (Eritja et al., 1991). The slightly acidic pH was selected in order to protonate amino groups of the peptide and avoid possible side reactions with the maleimido group. One major oligonucleotide product was obtained that was isolated by reversed-phase HPLC. The oligonucleotide-peptide conjugate was characterized by mass spectrometry and enzymatic digestion.

Properties of Oligonucleotide-Peptide Conjugate. Hybridization of oligonucleotides carrying N^4 -tert-butylthioethyl-dC and oligonucleotide-peptide conjugate to their complementary DNA sequence was evaluated spectrophotometrically. The melting temperatures (T_m)

Table 1. Melting Temperatures^a (°C) of Duplexes Containing N^4 -(tert-Butylthioethyl)-dC (1) and Peptide-Oligonucleotide Conjugate (2)

Figure 4. Dot-Blot analysis of oligonucleotide-peptide conjugate. Serial dilutions (from 5 μ g) of the oligonucleotide-peptide conjugate and an oligonucleotide control (without peptide) were applied on a nitrocellulose membrane, incubated with anti-c-myc murine hybridoma clone 9E10 followed by a horseradish peroxidase-conjugated goat anti-mouse antibody and developed with ECL system (Amersham) as described in the Experimental Section. First line: 1/2 dilutions from 5000 ng; 5000, 2500, 1250, 600, 300, 150, and 75 ng of oligonucleotide. Second line: 1/2 dilutions from 500 ng; 500, 250, 125, 60, 30, 15, and 7 ng of oligonucleotide.

for the various duplexes are shown in Table 1. These data show a decrease for the modified oligonucleotides on the ability to form duplexes. One protected mercaptoethyl-dC residue introduces on average a destabilization of 6–7 °C/residue and the c-myc sequence a destabilization of approximately 10 °C. The decrease on melting temperatures is assigned to the utilization of one of the hydrogen bonding amino groups of cytosine (N^4) for connecting to the peptide sequence. A similar destabilization has been described for oligonucleotides carrying a N^4 -cystamine-C derivative (MacMillan and Verdine, 1991). The destabilization effect of the peptide on the oligonucleotide is judged as relatively weak, taking into account the small size of the oligonucleotide (15 bases), the small size of the mercaptoethyl linker between oligonucleotide and peptide, and the high carboxylic acid (4 out of 13 residues) content of the c-myc sequence. These results indicate that oligonucleotides conjugated to peptide sequences may be used as specific hybridization probes.

Nonradioactive detection of oligonucleotide-peptide conjugate was assayed through immobilization on a dot-blot. Serial dilutions of the oligonucleotide-peptide conjugate (from 5 μ g) were applied to a membrane, either nylon or nitrocellulose using a manifold attached to a suction device. After immobilization of the oligonucleotides, the samples were incubated with an anti-c-myc monoclonal antibody (Evan, 1985), followed by incubation with a secondary antibody conjugated to horseradish

peroxidase, and developed with a chemiluminescent substrate (ECL, Amersham). Figure 4 shows the autoradiography of the detection, of both an oligonucleotide carrying the c-myc tag peptide and a control oligonucleotide without peptide. Positive dots were obtained for the oligonucleotide-peptide conjugate, the sensitivity of the detection being approximately 50 ng (8 pmol), while no signal was obtained for control oligonucleotide.

In conclusion, we have shown that oligonucleotides carrying mercaptoethyl-dC residues were easily prepared using phosphoramidite 7. These oligonucleotides are useful intermediates to obtain oligonucleotide-peptide conjugates such as oligonucleotides carrying peptide-tag-sequences that can be immunoreactive. Oligonucleotide-peptide conjugates carrying the c-myc tag-sequence are able to hybridize with their complementary sequences, maintaining their immunoreactivity. The possibility of using the large diversity of available antibodies and their many different labeling possibilities makes oligonucleotide-tag-peptide conjugates a valuable tool in multiple hybridization experiments.

ACKNOWLEDGMENT

We thank M. Wiersma for valuable suggestions and Dr. O. Massó for his generous gift of culture supernatants of anti-c-myc murine hybridoma clone 9E10. We also thank Dr. M. Mann and his group for mass spectroscopic measurements.

TECHNICAL NOTES

Acid-Polyacrylamide Gel Electrophoresis of Lysozyme–Estrone Glucuronide Conjugates

C. Mark Smales, David F. Elgar, Christopher H. Moore, and Leonard F. Blackwell*

Department of Chemistry, Massey University, Private Bag 11 222, Palmerston North, New Zealand.

Received October 25, 1997; Revised Manuscript Received February 26, 1998

Acid-polyacrylamide gel electrophoresis (acid-PAGE) was used for analysis of lysozyme–estrone glucuronide conjugates. The resolution of the system allowed the identification of individual conjugate families which differed only in the position of acylation or in the number of estrone glucuronide units. Acid-PAGE was a good alternative to denaturing cation-exchange chromatography for the analysis, separation, and small-scale purification of lysozyme–estrone glucuronide conjugates. It revealed the true order of the relative degree of positive charge on the lysozyme–estrone glucuronide conjugates.

INTRODUCTION

The Ovarian Monitor home assay system (1–3) for the definition of the fertile period of the menstrual cycle utilizes a homogeneous enzyme immunoassay (4) to measure urinary levels of estrone glucuronide (E1G) and pregnanediol glucuronide (PdG). These urinary metabolites of ovarian estradiol and progesterone are reliable markers for the beginning (5) and end (6) of ovarian activity and, hence, are closely related to the length of the fertile period (2). The success of a homogeneous enzyme immunoassay for this purpose depends on the ability to separate lysozyme–steroid glucuronide conjugates from unreacted lysozyme and the availability of an analytical method to monitor the purity of the conjugate products. We have previously published such an analytical method involving the use of Mono-S cation-exchange chromatography in 7 M urea (7), which successfully separates lysozyme–estrone glucuronide (E1G) conjugates on the basis of their relative degrees of positive charge. This analytical procedure can also be used preparatively; however, it involves the denaturation of the enzyme in 7 M urea solutions. The urea is also damaging to the FPLC system used for the analysis, hence it is desirable to develop an alternative analytical system which gives the same resolution of the individual lysozyme–steroid glucuronide conjugate families but which utilizes nondenaturing conditions. Such an analytical system also may be used to check on the overall structural integrity of the conjugates following urea denaturation.

Use of the active ester coupling procedure gave rise to six distinct conjugate families and an unreacted lysozyme peak (8). The six conjugate families were labeled E1–E6 based on their order of elution from the Mono S cation-exchange column (7). Fraction E6 eluted first and E1 eluted next to lysozyme. The other fractions, E2–E5,

eluted in the order of their overall degrees of positive charge. It would be expected on this basis that the electrophoretic mobilities would also differ for the different conjugate families. Both pH 8.9 polyacrylamide gel electrophoresis (PAGE) (9, 10) and acid-polyacrylamide gel electrophoresis (acid-PAGE) (11) have been used for the analysis of modified lysozymes and native lysozyme, respectively. Both of these methods have the potential to separate the different conjugate families on the basis of their charge differences. So far however, no studies with lysozyme–steroid glucuronide conjugates have been reported. Thus, we have examined the electrophoretic separation of the lysozyme–estrone glucuronide families under acidic, nondenaturing conditions.

EXPERIMENTAL PROCEDURES

All reagents were of analytical grade or better. Cytochrome *c* (from bovine heart) was purchased from Sigma Chemical Co. (St. Louis, MO). Minigels were run on a Mini-Protean II dual slab system while larger gels were run on a Protean II xi system, both from Bio-Rad laboratories (Richmond, CA). The synthesis of 17- α -oestra-1,3,5- β -yl-D-glucopyranosiduronic acid (E1G) was essentially according to Conrow and Bernstein (12) as previously reported (7). Conjugation of lysozyme with E1G by the active ester coupling method (8) and analysis of the resulting E1G–lysozyme conjugates by Mono-S cation-exchange chromatography in 7 M urea at pH 6.0 were undertaken as described previously (7). All urea was of analytical grade, and solutions were prepared immediately prior to use and stored at 4 °C. Analysis of the E1G–lysozyme conjugates by SDS–PAGE was undertaken at pH 8.30 using standard electrophoresis procedures (13). High pH nondenaturing PAGE was undertaken at pH 8.9 using the system of Habeeb and Atassi (9, 10).

E1G–lysozyme conjugates were also analyzed by acid-PAGE at room temperature on continuous acrylamide slab gels at pH 4.08 with reverse polarity (lower chamber cathode). The reservoir buffer in both upper and lower chambers consisted of glycine (28.1 g), glacial acetic acid

(3.06 mL), and Milli-Q water as required to adjust the volume to 1 L at pH 4.08 as described by Hrkal (14). This buffer was freshly prepared before use.

Both minigels and larger gels were prepared and run. Minigels were prepared using commercially available Bio-Rad 40% acrylamide solution as follows: acrylamide (3.75 mL) to give a 15% final solution was mixed with pH 4.08 reservoir buffer (6.25 mL). After degassing, *N,N,N',N'*-tetramethylethylenediamine (15 μ L) and ammonium persulfate (100 μ L of a freshly prepared 50 mg/mL solution) were added and mixed before the gel was poured. For larger gels (160 $\times$ 200 mm), a 40% acrylamide solution was prepared and the gels were mixed in the same ratio's as for the minigels. Mini gels were prerun at 200 V for 1.5 h or until a constant current was obtained, while the larger gels were prerun for 3.5 h. Following prerunning, both the upper and lower chambers were refilled with fresh reservoir buffer. The conjugate samples were then loaded in reservoir buffer which contained 20% glycerol. The gel was run with one lane containing cytochrome *c* so that its bright orange color could be used as a tracking agent. Electrophoresis was undertaken at constant voltage (200 V) with the usual current reversed so that the polarity was from the anode (upper chamber) to the cathode (lower chamber) until the cytochrome *c* marker reached the bottom of the gel. All gels were stained with a 0.1% Coomassie Blue solution.

RESULTS AND DISCUSSION

SDS-PAGE analysis of the E1G-lysozyme conjugates showed no evidence of resolution between the conjugate families and lysozyme, hence there were no significant size differences between the different conjugate families and lysozyme. A nondenaturing system was therefore investigated for the separation of the E1G-lysozyme conjugates as it has previously been shown that nonurea, high pH PAGE (pH 8.9, 0.043 M Tris, and 0.046 M glycine) can be used to give distinct bands when analyzing lysozyme derivatives, with good results (9, 10). However, when the E1G-lysozyme conjugates were analyzed by this system, distinct bands were not observed and there was little visible separation between the collection of individual conjugate families and lysozyme. Habeeb and Atassi (10) have suggested that the laddering effect they reported when analyzing lysozyme derivatives (acetylated, succinylated, maleylated, and guanidinated lysozyme derivatives) was due to esterification of lysozyme and not to amino group modification. This could explain why the E1G-lysozyme conjugates did not exhibit the laddering effect since the stable conjugate derivatives are modified at lysine residues only. A similar system was therefore used but at low pH (pH 4.08) where most of the ionizable groups in the protein molecule would be protonated, and hence the more positively charged derivatives would migrate down the gel toward the negative electrode.

Under these conditions (pH 4.08), nondenaturing acid-PAGE analysis of the estrone glucuronide-lysozyme conjugates prepared by the active ester method (7) gave seven distinct conjugate populations (Figure 1) as expected from the results obtained previously with the Mono-S cation-exchange column in the presence of denaturing 7 M urea solutions (Figure 2) (7). Positive identification of the acid-PAGE bands with those from the 7 M urea cation-exchange column (7) was achieved by diffusing each one from the gel and running it through the Mono-S 7 M urea system. The presence of estrone

Figure 1. Analysis of E1G-lysozyme active ester conjugates by acid-PAGE as described in the text. Cytochrome *c* was run as a marker protein (lane 1) while the E1G-lysozyme active ester conjugation reaction mixture was run in lanes 2, 5, and 11. The individual conjugate peaks, as collected off the Mono-S column (Figure 2) were also analyzed by acid-PAGE and can be seen in lanes 4 (E1), 6 (E2), 7 (E3), 8 (E4), 9 (E5), 10 (E6), and 12 (lysozyme).

Figure 2. E1G-lysozyme active ester conjugation reaction mixture in 7 M urea on a Mono-S cation-exchange HR 5/5 column. Conditions as described in ref 7.

glucuronide in all of these bands, apart from the fastest moving (unmodified lysozyme) which was free of estrone glucuronide, was confirmed by homogeneous immunoassay using an Ovarian Monitor (1-3) as previously described (7). Alternatively, each conjugate fraction and unreacted lysozyme was collected from the Mono-S 7 M urea column and run on the acid-PAGE system (Figure 1) for positive identification. The distance each conjugate travels on the acid-PAGE system should decrease in the order $L(0) > E1(1) > E2(1-1.5) > E3(1) > E4(2) > E5(2) > E6(3)$, this being the order of decreasing positive charge as deduced from the relative elution positions on the Mono-S 7 M urea column (Figure 2) and the increasing degree of acylation (shown by the numbers in

brackets) as determined by the trinitrobenzenesulfonic acid method (7). However, despite the fact that the same number of conjugate bands was observed, their order of separation by acid-PAGE was not a simple correspondence between the degree of lysine substitution and the distance traveled toward the negative electrode. Experimentally, unmodified lysozyme being the most positively charged moved furthest down the gel as expected while the triacylated conjugate E6 (7) moved the shortest distance (Figure 1) being the least positively charged, also as expected. Native, unmodified lysozyme was shown to run in the same position as the experimentally unmodified lysozyme (data not shown). Conjugate E1 ran next to lysozyme (L) but moved as two bands, one migrating to the expected position (the furthest of any conjugate) and one which did not migrate as far (Figure 1), consistent with the presence of two closely related conjugates within this conjugate family. Supporting evidence that this is so can be seen also in the Mono-S 7 M urea analysis where a slight shoulder is observed on the trailing edge of the E1 peak (Figure 2).

However, the order of migration of the remaining conjugates (E2–E5) by acid-PAGE analysis was unexpected being $E3 > E5 > E2 > E4$; that is, conjugates E3 and E5 both had a higher degree of positive charge than indicated from their chromatographic behavior. This difference in apparent charge is unlikely to be due to denaturation or conformational changes in the presence of the concentrated urea solutions used during cation-exchange chromatography as lysozyme crystals grown in the presence of high urea concentrations (up to 9 M) are essentially isomorphous with the structure of native crystals (15). Also, in the presence of urea, the crystal structure of hen egg white lysozyme shows no evidence of carbamylation of the free amino groups (15) ruling out this possibility as a variable affecting the separation of the conjugates. Although there may be an increased hydrophobic interaction between the conjugates and the polyacrylamide matrix compared with the unmodified lysozyme, this factor alone cannot account for the observed separation and resolution of the estrone glucuronide–lysozyme conjugates by acid-PAGE. If hydrophobic interactions between the E1G moieties and the polyacrylamide were the sole determining factor, then those conjugates with the same level of acylation would be expected to run in the same position. This is obviously not the case as conjugates E1–E3 (all with E1G substitution levels of 1–1.5) are clearly separated from each other as are conjugates E4–E5 (both with E1G substitution levels of 2).

Urea does have a pronounced effect on the high-performance cation-exchange chromatography behavior of hen egg white lysozyme, significantly reducing its retention time over that observed in the absence of urea (16). Although this result is expected on the basis of the increase in solvent dielectric constant, it is also possible that it may be due, in part, to the specific binding of a urea molecule. For example, it has been reported that a urea molecule hydrogen bonds to lysine residue 116 of the hen egg white lysozyme structure (15), and this would be expected to reduce the apparent positive charge on the enzyme under these conditions. Thus, in the urea cation-exchange system, the contribution of lysine residue 116 to the overall positive electrostatic field of lysozyme may be underestimated for some conjugates.

The difference in the observed migration orders between the two analytical procedures can therefore be explained if it is assumed that conjugate families E2 and E4 are acylated with estrone glucuronide at lysine

residue 116 but conjugate families E3 and E5 are not. Hence, conjugate families E3 and E5 will elute from a cation-exchange column in the presence of 7 M urea earlier than expected on the basis of their true formal charges due to the masking effect of a urea molecule hydrogen binding to lysine residue 116. On the other hand, the elution positions of conjugate families E2 and E4 would not be effected by urea if lysine residue 116 is acylated. When the urea effect is absent as for the nondenaturing acid-PAGE system, lysine residue 116 can now exert its full effect on the positive field of these two conjugates (E3 and E5) and both migrate further than their counterparts E2 and E4. On this explanation, conjugates E1 and E6 must also be acylated at lysine residue 116. The true order of the overall positive charge for the lysozyme conjugates is, therefore, $L > E1 > E3 > E5 > E2 > E4 > E6$.

Whatever the correct explanation of the elution behavior, nondenaturing acid-PAGE can be used to assess, analyze, and purify small amounts of individual lysozyme–estrone glucuronide conjugates. The advantage of the system is that it is rapid, simple to perform, gives excellent resolution between the different E1G–lysozyme conjugate families, and avoids the use of urea. A major hurdle in analyzing protein conjugates is that often there is very little chemical, or size, difference between the unconjugated and conjugated protein products. It may therefore be possible to use the acid-PAGE system presented here for use with other conjugate systems which utilize proteins with high isoelectric points ($I.E.P > 6.0$), and for other modification studies (chemical and site directed mutagenesis) whereby lysozyme is used as a model protein.

Convenient Polymer-Supported Synthetic Route to Heterobifunctional Polyethylene Glycols

Thierry Bettinger, Jean-Serge Remy, Patrick Erbacher, and Jean-Paul Behr*

Laboratoire de Chimie Génétique associé CNRS/Université Louis Pasteur de Strasbourg, UMR 7514, Faculté de Pharmacie, BP 24, 67401 Illkirch Cedex, France. Received April 12, 1998; Revised Manuscript Received June 22, 1998

Conventional synthesis of heterobifunctional poly(ethylene glycol) derivatives, especially of medium size, is a rather tedious task. A straightforward solid-phase methodology has been developed that is illustrated here by the synthesis of α -pyridyldithio- ω -hydroxy-poly(ethylene glycol)₆₀₀. This derivative was prepared from resin-bound PEG₆₀₀ with a global yield of 65% for 6 individual steps, i.e., with an average yield of 93%/step. Intermediate purification steps simply consisted of resin washing. Progress of each reaction toward completion could conveniently be monitored by ¹³C NMR of the resin-bound PEG derivatives. This example highlights both the versatility and efficiency of combining polymer-supported synthesis with direct ¹³C-NMR characterization of the intermediate compounds.

INTRODUCTION

Poly(ethylene glycol) (PEG)¹ conjugation chemistry has been developed recently as a consequence of the potential therapeutic interest of pegylated drugs (Herman et al., 1995; Zalipsky, 1995). Indeed it is now demonstrated that PEG-modified biological molecules can benefit from extended plasma lifetimes, from reduced uptake by the reticuloendothelial system (Allen, 1994; Papahadjopoulos et al., 1991; Woodle and Lasic, 1992) and more generally from a decrease of the undesired consequences of electrostatic and van der Waals interactions. Following the synthesis of PEG–protein conjugates, new developments have emerged such as nonimmunogenic drugs and nucleic acid vectors. One of the future directions toward nonviral gene therapy is the use of PEG-grafted synthetic vectors as long circulating carriers for receptor-mediated gene delivery (Blume et al., 1993; Maruyama et al., 1995). In this context, heterobifunctional poly(ethylene glycol) linkers are required that allow attachment of ligands to one extremity of PEG-grafted synthetic vectors.

Protein modification with PEG does not require true heterobifunctional PEG derivatives. Methoxy-PEG (mPEG), carrying an inert ether end group, was used to make the chemical processing easier (Greenwald et al., 1996; Herman et al., 1995; Zalipsky, 1995). The chemistry of heterobifunctional PEG derivatives is not well developed, reaction yields are far from being quantitative, hence, cumbersome polymer purification techniques have to be used (Zalipsky, 1993). Most published procedures use classical derivatization chemistry in homogeneous

solution (sometimes even in potentially reactive aqueous medium), and often the functionalized PEG cannot be fully separated from the starting polymer (Zalipsky et al., 1994). Another possibility is to choose suitable initiator and/or terminator reagents for the polymerization of ethylene oxide (Yokoyama et al., 1992). However, recent work showed that such strategies may be obscured by diol impurities (Nagasaki et al., 1997), and the polymerization process still remains difficult to control (ethylene oxide is toxic and explosive).

In another register, poly(ethylene glycol) is also being widely used in solid-phase synthesis (Bayer, 1991). Indeed, improvement of polymeric supports for peptide synthesis has led to using PEG as a good solvent-swelling linker between the inert resin and the solid-supported reaction center. The PEG linker mobility is high (Bayer, 1990) and peptide yields are good, showing it to be possible to combine the advantages of a solid support with those of the liquid-phase methodology.

According to this background, we decided to develop a new strategy for heterobifunctionalization of poly(ethylene glycol) based on solid-phase chemistry. A major aspect of PEG functionalization lies in the proper characterization of intermediate and final products. We used gel-phase ¹³C NMR which allows convenient and nondestructive monitoring of reaction progress directly on the resin (Bayer, 1990). This is possible because of the rather long ¹³C relaxation times which are a consequence of the high mobility of the fully solvated PEG (Bayer, 1990). The method is sensitive and allows us to accurately determine the end point of each reaction step (among others, the terminal carbons of PEG usually exhibit characteristic chemical shifts).

To demonstrate the interest of this strategy, we have prepared a low molecular weight PEG derivative (MW 600), which is known to be difficult to purify by size exclusion chromatography or diethyl ether precipitation. Such small PEGs can act as very effective molecular scale filters for preventing binding to underlying liposome or particle surfaces (Needham et al., 1997). PEG was functionalized with a 2-pyridyldithio residue which is widely used for specific coupling with thiol groups (Carlsson et al., 1978; Woghiren et al., 1993) since coupling

Table 1. ^{13}C -Nuclear Magnetic Resonance Peaks of Polymer-Grafted Poly(ethylene Glycol) Derivatives

structure	(δ) ^a (ppm)
resin-PEG-O-CH ₂ CH ₂ -OTos	69.3, 68.7, 145, 129.7, 128.1, 130.1, 21.8
resin-PEG-O-CH ₂ CH ₂ -S(C=S)O-CH ₂ CH ₃ ^b	69.8, 35.2, nd, 68.7, 13.7
resin-PEG-O-CH ₂ CH ₂ -SH	72.6, 24
resin-PEG-O-CH ₂ CH ₂ -S-Pyridine ^c	68.7, 38.2, nd, 119.4, 136.9, 120.4, 149.2

^a The polymer-bound derivative (150 mg) was added to CDCl₃ (0.5 mL). Chemical shifts were normalized relative to CDCl₃ = 77.0 ppm. The large poly(ethylene glycol) backbone peak was at 70.3 ± 0.3 ppm. Chemical shifts are listed according to the structures shown in Figure 1. ^b The SC=S resonance was not observed. ^c The SCNCH resonance was not observed.

releases a chromophore which allows straightforward reaction monitoring. We further activated the HO-PEG₆₀₀-SSPy as the *N*-hydroxysuccinimide carbonate derivative (Zalipsky et al., 1992); coupling of this compound with an amine to give a carbamate led to higher yields than classical amide bond formation.

EXPERIMENTAL PROCEDURES

General. Aminomethylated polystyrene-1% divinylbenzene was purchased from Novabiochem (Meudon, France). Toluene-4-sulfonyl-chloride (TsCl), potassium *O*-ethyl dithiocarbonate, propylamine, and poly(ethylene glycol) (MW 600) were from Fluka (St Quentin Fallavier, France). 2,2'-Dipyridyl disulfide was obtained from Lancaster (Strasbourg, France). Thin layer chromatography (TLC) was performed on Kieselgel 60 F₂₅₄ plates (Merck). Preparative chromatography was carried out on Chromatotron 8924 (Harrison Research). PEG was revealed by TLC by the Dragendorff assay (Thoma et al., 1964). The Kaiser qualitative ninhydrin test was carried out specifically as described elsewhere (Sarin et al., 1981). As a reaction vessel, we used a glass column ended with a join connection and a glass frit (porosity n°2) on the upper and lower end, respectively. This allowed us to stir the resin on a rotary evaporator and to wash the resin after each reaction step. Solid-phase reactions were carried out at room temperature. After each step, the resin was stirred (20 min) and rinsed successively with CH₂Cl₂ (5 × 50 mL) and CH₃OH (5 × 50 mL). The resin was dried in vacuo to allow analytical analysis (5 mg was taken for IR analysis and 150 mg for ^{13}C NMR). ^1H - and ^{13}C -NMR spectra were recorded on a Bruker DPX300 Avance instrument at 300 MHz (scan number = 1000 with classical acquisition parameters). Infrared spectra (IR, KBr pellet) were recorded on a spectrophotometer FT-IR 1600 (Perkin-Elmer).

Synthesis of Crude α -Hydroxy- ω -Carboxy Poly(ethylene Glycol) (HO-PEG₆₀₀-COOH) (1). Poly(ethylene glycol) (28 g, 46.7 mmol, 600 g/mol) was dissolved in 40 mL of dry CH₂Cl₂. To this solution was added 10 mL of dry THF containing diglycolic anhydride (1.02 g, 8.8 mmol) and pyridine (720 μL , 9 mmol). After stirring overnight under argon at room temperature, the reaction was completed as indicated by TLC (CH₂Cl₂/MeOH/Et₃N 90:10:1) (no anhydride left and detection of a single polar PEG-compound). The monoacid derivative of poly(ethylene glycol)₆₀₀ was used without purification.

PEG₆₀₀ Grafting to the Resin via Amide Bond Formation (2). The above HO-PEG₆₀₀-COOH solution (ca. 8.8 mmol) was activated with 1.2 molar equivalent of *N*-hydroxysuccinimide (1.22 g, 10.6 mmol) and *N,N'*-dicyclohexylcarbodiimide (2.19 g, 10.6 mmol). The solution was stirred for 2 h at room temperature under argon. The dicyclohexylurea (DCU) suspension was filtered off. Aminomethylated poly(styrene-co-1% divinylbenzene) resin (1.1 g, 1.2 mmol of amino group) was poured into the glass column (see General) with the activated carboxylic acid solution. The column was connected to a rotary

evaporator and stirred for 2 days at room temperature. The solvent was then filtered off and the resin beads were washed as described above. Two additional washes with DMF/CH₃OH (10/3) were necessary to remove the remaining DCU as checked by IR. Complete amino group capping was indicated by a negative Kaiser test. The resin was dried in vacuo for IR and ^{13}C -NMR characterization. At this stage, the resin did not stick anymore to the glass wall. IR spectrum of the resin showed the characteristic absorption band of PEG ether backbone (1100 cm⁻¹) and absorption bands at 1750 and 1680 cm⁻¹ for the ester and amide bond, respectively (C=O sym stretch).

Reaction of Polymer-Bound α -Hydroxy-Poly(ethylene Glycol)₆₀₀ with Tosyl Chloride (3). Twenty-fold molar excess of toluene-4-sulfonyl chloride (4.6 g, 24 mmol) and 3.34 mL of Et₃N (24 mmol) in 15 mL of CH₂Cl₂ were added slowly to the resin suspended in 30 mL of CH₂Cl₂. The mixture was stirred overnight at room temperature while the resin turned brown-yellow. The solvent was filtered off and the resin was washed as described above. The resin became white again after these washes. The IR spectrum showed the characteristic sulfonyl group absorption at 1177 cm⁻¹ (SO₂, sym stretch) and did not show any residual hydroxyl absorption (3200–3600 cm⁻¹) of the starting polymer. See ^{13}C -NMR data in Table 1.

Reaction of the Polymer-Bound α -Tosyl-*O*-Poly(ethylene glycol)₆₀₀ with Potassium *O*-Ethyl Dithiocarbonate (4). Potassium *O*-ethyl dithiocarbonate (212 mg, 1.32 mmol) in 25 mL of THF/DMF (50/1) was added to the polymer. The mixture was stirred for 4 h at room temperature. The solvent was filtered off, and the resin was washed. IR spectrum of the resin confirmed the disappearance of the tosyl group (1177 cm⁻¹). See ^{13}C -NMR data in Table 1.

Synthesis of Polymer-Bound α -Thiol-poly(ethylene Glycol)₆₀₀ (5). Thirty-fold molar excess of propylamine (3 mL, 36 mmol) in 25 mL of CH₂Cl₂ was added to the column and stirred for 1 h. The solvent was filtered off and the resin was washed as above. ^{13}C NMR confirmed that no disulfide bond formation (PEG-S-S-PEG) had occurred. See ^{13}C -NMR data in Table 1.

Activation of Polymer-Bound α -Thiol-poly(ethylene Glycol)₆₀₀ with 2,2'-Dipyridyl Disulfide (6). Five fold molar excess of 2,2'-dipyridyl-disulfide (1.32 g, 6 mmol) in 30 mL of CH₂Cl₂ was added to the column and stirred overnight at room temperature. The resin turned yellow. The solvent was filtered off, and the resin was washed while turning white. Again, no disulfide bond formation had occurred as indicated by ^{13}C NMR. See ^{13}C -NMR data in Table 1.

Cleavage of α -Pyridyldithio- ω -hydroxy-poly(ethylene Glycol)₆₀₀ from the Solid Support (7). A mixture of 30 mL of THF/CH₃OH/Et₃N (1/1/1) was added to the resin and stirred for 3 days at room temperature. The solution was filtered and the resin was washed as usual. The combined organic fractions were concentrated

Scheme 1

in vacuo, and Et₃N was removed by rough chromatography on SiO₂ with CH₂Cl₂/CH₃OH (20/1) as eluent. A brown oil was recovered (550 mg, 0.78 mmol), which was identified by TLC and characterized by ¹H- and ¹³C-NMR spectroscopy. The global yield was 65% as determined by quantitative released of 2-thiopyridone upon reduction with DTT (Carlsson et al., 1978).

$R_f = 0.45$ (CH₂Cl₂/CH₃OH 10/1). ¹H NMR (CDCl₃): δ 3.01 (t, SSCH₂CH₂O, 2H), 3.54 (s, PEG, 48H), 3.66 (t, SSCH₂CH₂O, 2H), 7.17 (m, SCCHCH, 1H), 7.75 (m, SCCHCHCH, 2H), 8.46 (m, SCNCH, 1H). ¹³C NMR (CDCl₃): δ 38.4 (SSCH₂CH₂), 61.7 (OCH₂CH₂OH), 68.9 (SSCH₂CH₂), 70.5 (CH₂CH₂O of PEG backbone), 72.5 (OCH₂CH₂OH), 119.6 (SCCHCH), 120.6 (SCCHCHCH), 137.1 (SCCHCH) 149.5 (SCNCH).

RESULTS AND DISCUSSION

Stepwise conversion of PEG₆₀₀ to the thiol-activated HO-PEG₆₀₀-SSPy (7) was carried out according to Scheme 1. To avoid a tedious PEG monofunctionalization/isolation procedure, diglycolic anhydride was reacted with a

large excess of PEG. In such conditions, the only carboxylic acid formed should be the compound of interest. This compound can be selectively activated and grafted to the resin via amide bond formation. Resin washing should remove all other compounds. In practice, HO-PEG₆₀₀-COOH (1) was activated with *N*-hydroxysuccinimide (NHS) and *N,N'*-dicyclohexylcarbodiimide (DCC). The reaction mixture was filtered in order to remove most of the dicyclohexylurea (DCU) formed. After PEG grafting onto the resin, IR spectroscopy revealed some residual DCU sticking to the resin (broad absorption band at 1800–1600 cm⁻¹). The solid support was therefore further washed with DMF/CH₃OH (7/3). An extended reaction time was required for PEG grafting to the resin, which could be explained by the waxy constitution of PEG solution at this concentration (1 M). Complete reaction was confirmed by a negative Kaiser test. IR spectroscopy revealed the characteristic absorption bands for PEG (CH₂-O-CH₂, ether 1100 cm⁻¹) as well as for the connecting ester and amide functions (1750 and 1680 cm⁻¹, respectively, C=O sym stretch).

The glycolic ester bond being labile, thiol group formation with strong nucleophiles such as alcoholates (Woghiren et al., 1993) had to be avoided. Thiol derivatization was achieved by a modification of the protocol reported by Zalipsky (Zalipsky et al., 1987) which used milder conditions compatible with an ester linkage. The primary hydroxyl group of PEG was activated with tosyl chloride in standard conditions, and the tosylated resin (3) showed an IR spectrum with the expected strong absorption at 1177 cm⁻¹ (SO₂). The ¹³C-NMR spectrum contained the characteristic tosyl group resonances at 21.8 ppm and between 128 and 145 ppm, which correspond to the methyl and aromatic ring carbon atoms, respectively (Figure 1). The broad signals around 130 and 40 ppm were due to the phenyl and aminoethyl groups of the solid support. At this stage, the activated resin-grafted PEG is easy to handle as solid beads and is stable upon long-term storage (at least 4 months at -20 °C). It may be regarded as a convenient starting material for the preparation of a variety of PEGs. Tosyl-PEG₆₀₀ was reacted with a stoichiometric amount of potassium *O*-ethyl dithiocarbonate to give the diester 4. Preliminary experiments using excess reagent were shown by ¹³C NMR and IR to lead to complete cleavage of the PEG from the resin. Compound 4 could not be characterized by IR spectroscopy. However, ¹³C-NMR spectrum confirmed complete removal of tosyl group (21.8 ppm and 128–145 ppm) and the appearance of two new resonances at 13.7 ppm (O-CH₂-CH₃) and 35.2 ppm (O-CH₂-CH₂-S) (Figure 1).

The thiocarbonate was aminolyzed, but instead of glycine, we used propylamine to remain in organic solution and avoid disulfide bond formation. Several attempts to cleave the thiocarbonate in mild basic solution (<0.1 M propylamine, 1 h) led to uncomplete aminolysis as revealed by ¹³C NMR (4 peaks at 72.6, 35.2, 24, and 13.7 ppm). Complete conversion into the thiol-PEG derivative 5 required a high concentration of propylamine (1.2 M). Strictly anhydrous condition (CH₂Cl₂) prevented cleavage of the functionalized PEG from the resin. ¹³C NMR showed clean conversion to the thiol 5 (24 and 72.6 ppm) without oxidation into the disulfide (no resonance at ca. 36 ppm) (Figure 1). The thiol group was activated as the 2-pyridyldithio derivative 6. The conversion was complete as again indicated by ¹³C NMR (Figure 1).

Finally, the functionalized PEG₆₀₀ was cleaved off from the resin with a mildly basic polar solvent (THF/CH₃-

Figure 1. ^{13}C -NMR spectrum (300 MHz) of polymer-bound PEGs in CDCl_3 . Inset for **4** is an enlargement of the major peak.

$\text{OH}/\text{Et}_3\text{N}$). Acidic conditions ($\text{TFA}/\text{CH}_2\text{Cl}_2$) were avoided because a protonated pyridine residue would be a good leaving group, too. Examination of the remaining resin by IR and ^{13}C -NMR spectroscopy indicated that all material had been cleaved off. The global yield for the conversion of resin-bound poly(ethylene glycol) $_{600}$ -OH to α -pyridyldithio- ω -hydroxy-poly(ethylene glycol) $_{600}$ **7** was 65% (i.e., 93% per step) as determined by quantitative release of 2-thiopyridone upon reduction with excess 1-4-dithio-L-threitol (Carlsson et al., 1978).

In summary, we describe here a new, fast, and efficient route to heterobifunctionalized poly(ethylene glycol) derivatives using a solid-phase methodology and employing readily available and inexpensive PEG-diol of any length

as a starting material. Chemistry was combined with solid-phase ^{13}C NMR to optimize and determine the end point of each step. The multistep synthesis described here outlines a general approach valid for any functionalized poly(ethylene glycol) derivative.

ACKNOWLEDGMENT

We warmly thank Dr. Alain Wagner for advice concerning NMR of resin-bound molecules.
