however, gave an absorption spectrum with two similar absorption maxima at ~600 nm and at ~650 nm (dashed trace in Figure 7A), and the same profile was obtained after 10-fold dilution with buffer (dashed trace in Figure 7B). The anomalous effect was largely reversed when SDS was added at a final concentration of 1% (dotted trace in Figure 7A), i.e., when the protein was partially unfolded. This process took several minutes at RT and it did not occur in 0.1% SDS.

Further characterization of Cy5-labeled IgG and of avidin-bound *biotin-4-Cy5* gave the following results (see Supporting Information). (i) The spectra in Figure 7 were linear composites of a single absorption peak at 600 nm plus the normal spectrum of Cy5 (λ_{max} = 650 nm). (ii) The 600 nm absorption peak corresponded to a completely nonfluorescent state of protein-bound Cy5 residues. (iii) The nonfluorescent state was caused by intramolecular Cy5−Cy5 label interactions only and not by Cy5−protein interaction.

Upon the basis of these findings, it was possible to assess the relative contribution of the nonfluorescent state to fluorescence reduction at high Cy5/protein ratios. Figure 7A shows that the normal absorption peak at 650 nm was increased by a factor of 1.4 when IgG with 6 Cy5 labels (dashed trace) was treated with 1% SDS (dotted trace). This means that ~30% of all Cy5 labels had been in the nonfluorescent state before the addition of SDS, while 70% of all IgG-bound Cy5 labels had been in their normal condition, i.e., in a potentially fluorescent state. Nevertheless the actual extent of Cy5 quenching was as high as 97% (open circle at 6 Cy5/IgG in Figure 1B). From this follows that quenching of Cy5 fluorescence in highly Cy5-labeled proteins is mostly due to resonance energy transfer, while only a minor fraction of bound Cy5 labels adopts a nonfluorescent state, causing some additional reduction in fluorescence yield.

DISCUSSION

The present study provides a critical examination of protein labeling with Cy dyes. The results showed an astounding discrepancy between Cy3 and Cy3.5 on one hand and Cy5 and Cy7 on the other: Cy3- and Cy3.5-labeled antibodies fluoresced very well, even at high fluorophore/protein ratios (see Figures 1C, 2B, and 3B), whereas Cy5- and Cy7-labeled antibodies showed weak fluorescence, with a critical "optimum" at 2−3 labels/protein (see Figures 1C and 2B).

The exceptional fluorescence of Cy3- and Cy3.5-labeled antibodies and the noncritical role of fluorophore/protein ratio derived from fortunate coincidence of two effects: (i) covalent attachment of Cy3 or Cy3.5 labels to antibodies generally resulted in nearly 3-fold fluorescence enhancement (extrapolation of the solid lines in Figures 1A, 2A, and 3A to low fluorophore/protein ratio) which did not occur with the other Cy dyes, and (ii) mutual intramolecular quenching between Cy3 (or Cy3.5) labels by resonance energy transfer was much weaker than between the other Cy dyes (see Figure 1B, 2B, and 3B).

Fortunately the anomalous increase in Cy3 fluorescence was also observed when a very short biotin−Cy3 conjugate was noncovalently bound to (strept)avidin (see Figure 5A) and high fluorescence was still observed when up to four biotin-4-Cy3 were bound per (strept)avidin tetramer (see Figure 6A). Thus, biotin-4-Cy3 was discovered to be the first *small* fluorescent biotin derivative with strong fluorescence in the (strept)avidin-bound state. All other previously tested fluorescent biotin derivatives had suffered from strong quenching in the bound state unless the fluorophores were linked to biotin via long PEG spacers (Gruber et al., 1997, 1998; Marek et al., 1997; Kada et al., 1999). In conclusion, biotin-4-Cy3 appears well suited for specific and intense postlabeling of immobile (strept)avidin molecules and subsequent fluorescence detection.

The findings of the present study are particularly relevant to SMFM where detection of single probe molecules depends on fluorophores with high fluorescence yield, high photostability, and long excitation wavelength. Cy5, Cy5.5, and Cy7 can be excited at >600 nm where the autofluorescence background of live cells is lower by orders of magnitude as compared to the excitation range of TMR, Cy3, and Cy3.5 (Aubin, 1979; Benson et al., 1979; Marelius, 1995; Wolfbeis and Leiner, 1985). In fact, a Cy5-labeled phospholipid (Cy5-PE; Schütz et al., 1999; Schütz et al., 2000a) and a 1:1 conjugate of Cy5 and hongotoxin (Gruber et al., 2000; Schütz et al., 2000b) were the first single molecules visualized by far-field microscopy in live cells. Nevertheless Cy3-labeled antibodies are also expected to be useful for SMFM on live cells because (i) the cumulative signal from 5 to 6 Cy3 labels/protein is very high (see Figures 1C and 2B), (ii) the fluorescence signal (counts/ms) of a single Cy3 (Cy3-PE in a lipid membrane; G. Harms, unpublished results) is about 5-fold stronger than that of TMR−PE or Cy5-PE, and (iii) Cy3-PE proved to be 2−3-fold more stable to photobleaching than TMR−PE or Cy5-PE (G. Harms, unpublished results). Meanwhile single copies of a 1:1 EGF−Cy3 conjugate have also been observed on living cells (Sako et al., 2000), thus antibodies labeled with 6 Cy3 residues should be even easier to resolve despite the autofluorescence background.

The anomalous fluorescence enhancement of protein-bound Cy3 labels can tentatively be explained by simple assumptions. The fluorescence quantum yield of Cy3 is known to depend on solvent polarity and especially on viscosity; in ethanol Cy3 is ~2 and in glycerol ~10 times more fluorescent than it is in water (Mujumdar et al., 1993). If we assume that proteins contain surface patches with moderate Cy3-affinity then we expect two consequences: (i) intact Cy3 succinimidyl ester should preadsorb toward these sites and subsequently the activated hexanoic acid side chain of Cy3 should couple to some lysine residue that is within reach, and (ii) the so-coupled Cy3 residue will further stay adsorbed to the same patch most of the time, and the fluorescence of Cy3 will be enhanced by the low polarity of the site (as seen in ethanol), as well as by the reduction in conformational mobility of Cy3 (as observed in glycerol). The same concept also accounts for the enhancement of biotin-4-Cy3 fluorescence upon binding to avidin (see Figure 5A, solid circles). Obviously, the $-NH-CH_2-CH_2-NH-CO-(CH_2)_5-$ spacer (see Scheme 1) between the avidin-bound biotin residue and the chromophore of Cy3 allows the latter to reach a "Cy3-philic" patch on avidin. Streptavidin does not have such a site within reach of a bound biotin-4-Cy3 (see Figure 5A, open circles). Yet streptavidin can also enhance Cy3 fluorescence when a biotin-PEG_{800}−Cy3 conjugate is bound (Figure 5C, dotted line), i.e., the "Cy3-philic" patches on streptavidin are far away from the biotin-binding sites and only the PEG_{800} spacer gives the Cy3 label sufficient tether to reach it.

When a large protein is labeled with Cy3 succinimidyl ester the abundance of lysine residues provides for a high probability that Cy3 gets coupled to a surface patch which enhances Cy3 fluorescence. In contrast, there should be little chance for favorable Cy3-protein interaction if a small protein/peptide with a single free cysteine residue

is labeled with a thiol-reactive Cy3 derivative. To check this point we actually labeled a cysteine mutant of hongotoxin (HgTx-A19C; Schütz et al., 2000a) with a maleimide derivative of Cy3 (prepared as described for Cy5, Gruber et al., 2000). At 50 nM concentration this Cy3-HgTx conjugate showed only 55% of the fluorescence of 50 nM Cy3 succinimidyl ester or of 50 nM Cy3-maleimide derivative (data not shown). This finding, and the results for streptavidin-bound biotin-4-Cy3 (Figure 5A, open circles) proved that the anomalous enhancement of Cy3 fluorescence indeed depends on protein surface patches with *particular* properties and is not a general consequence whenever Cy3 is linked to the surface of a protein.

In contrast to Cy3, the fluorescence of Cy5 labels was neither enhanced nor much reduced when linked to a protein with a 1:1 stoichiometry. This was deduced from the relative fluorescence yield at low Cy5/antibody ratios (circles in Figures 1A and 2A) and from the observation that the 1:1 conjugate of HgTx-A19C with Cy5 showed the same fluorescence yield as free Cy5 succinimidyl ester (Gruber et al., 2000). On the other hand, the linking of ≥2 Cy5 labels to a single protein molecule was found to cause severe "quenching" (see circles in Figures 1A, 2A, and 5B).

The minor reason for low fluorescence at high Cy5/antibody ratio was appearance of a nonfluorescent state of Cy5 which showed a unique absorption spectrum, with a single absorption peak at 600 nm (see dashed lines in Figure 7). Interestingly, the fraction of Cy5 labels in the nonfluorescent state was linearly dependent on Cy5/antibody ratio, ranging from exactly 0% at the extrapolated number of 0.0 Cy5/antibody to 30% at 6 Cy5 labels/antibody molecule (see Figure 10A in the Supporting Information). From this dependence on Cy5/protein ratio, we conclude that (i) the nonfluorescent state can only be caused by a second Cy5 label which is located on the same protein molecule and (ii) the spatial distribution of Cy5 labels over the antibody surface must be far from random. In case of random distribution there would be no chance for Cy5−Cy5 interaction at very low Cy5/antibody ratios (e.g., at 0.1 or 0.2 Cy5/protein): even in the rare case of an antibody molecule with two Cy5 labels the average Cy5−Cy5 distance would be too large for direct Cy5−Cy5 contact and too large also for dipole−dipole interaction through space (dependent on r^{-6}). We therefore propose that the nonfluorescent state of protein-bound Cy5 derives from a Cy5 dimer, the two hexanoic acid side chains being covalently linked to properly spaced lysine residues on the protein. In aqueous solution Cy5 analogues lacking the sulfonate residues are well-known for dimer formation (Mujumdar et al., 1993), thus if positively charged side chains on the protein happen to compensate for the negative charges of the sulfonate groups (see Scheme 1), such a Cy5 dimer may well be stabilized to the extent that even in 1% SDS it takes minutes to break the Cy5−Cy5 and the Cy5−protein interactions (see Figure 7A). We suspect that the first Cy5 preadsorbs to such a positively charged site on the protein, covalently binds to a lysine, subsequently attracts a second Cy5 succinimidyl ester, and the latter also gets anchored to another lysine the position of which permits to retain the tight dimer geometry. If such an optimally positioned second lysine residue is not within reach, then the adsorbed second Cy5 succinimidyl ester molecule would still have a high chance for covalent reaction with some nearby lysine residue; the strict dimer could no longer persist but, due to the short Cy5−Cy5 distance, there should be strong resonance energy transfer between the two neighboring Cy5 residues, resulting in strong fluorescence quenching. In other words, the anomalously strong fluorescence quenching at high Cy5/antibody ratios (see circles in Figures 1A and 2A) seems to derive from "catalysis" of Cy5 attachment by already protein-bound Cy5 labels, leading to clusters of Cy5 even at rather low Cy5/protein ratios. As expected, this problem was much reduced in case of Cy5.5 the chromophore of which carries four, rather than two sulfonate groups; in comparison to Cy5, less quenching (solid circle in Figure 3A) and higher cumulative fluorescence (solid circle in Figure 3B) was seen at five Cy5.5 labels/antibody.

We are aware that the above presented hypotheses for anomalous enhancement of Cy3 fluorescence and anomalous quenching of Cy5 fluorescence are not yet proven by the available data but the concepts provide a first basis for discussion and for further strategies to get more fluorescence yield from Cy dye-labeled probes, needed to simplify single molecule studies in living cells and other systems.

ACKNOWLEDGMENT

We are indebted to Prof. Wolfgang Buchberger, Prof. Heinz Falk, and Prof. Norbert Müller for use of HPLC and spectrometer facilities. Helpful suggestions by one of the reviewers and advice by Prof. Karl Grubmayr is gratefully acknowledged. Abbreviations of Cy dyes. Cy3-monofunctional dye (= Cy3-mono-O-Su), sodium 1-[5-(*N*-succinimidyloxycarbonyl)-pent-1-yl]-2-[3-(3,3-dimethyl-1-ethyl-5-sulfonato-indolin-2-ylidene)-1-propen-1-yl]-3,3-dimethyl-3*H*-indolium-5-sulfonate; Cy3.5-monofunctional dye (= Cy3.5-mono-O-Su), trisodium 1-[5-(*N*-succinimidyloxycarbonyl)-pent-1-yl]-2-[3-(3,3-dimethyl-1-ethyl-5,7-disulfonato-benzo[e]indolin-2-ylidene)-1-propen-1-yl]-3,3-dimethyl-5-sulfonato-3*H*-benzo[e]indolium-7-sulfonate; Cy5-monofunctional dye (= Cy5-mono-O-Su), sodium 1-[5-(*N*-succinimidyloxycarbonyl)-pent-1-yl]-2-[5-(3,3-dimethyl-1-ethyl-5-sulfonato-indolin-2-ylidene)-1,3-pentadien-1-yl]-3,3-dimethyl-3*H*-indolium-5-sulfonate; Cy5.5-monofunctional dye (= Cy5.5-mono-O-Su), sodium 1-[5-(*N*-succinimidyloxycarbonyl)-pent-1-yl]-2-[5-(3,3-dimethyl-1-ethyl-5,7-disulfonato-benzo[e]indolin-2-ylidene)-1,3-pentadien-1-yl]-3,3-dimethyl-5-sulfonato-3*H*-benzo[e]indolium-7-sulfonate; Cy7-bifunctional dye, sodium 1-[5-(*N*-succinimidyloxycarbonyl)-pent-1-yl]-2-[7-(3,3-dimethyl-1-ethyl-5-sulfonato-indolin-2-ylidene)-1,3,5-heptatrien-1-yl]-3,3-dimethyl-3*H*-indolium-5-sulfonate;

Characterization of Protein-Bound Cy5 Labels by UV-vis Absorption and Fluorescence Spectroscopy. As shown in Figure 7 (see main article), simultaneous attachment of 6 Cy5 labels per IgG molecule led to appearance of a new absorption peak (λ_{max} ~ 600 nm) in addition to the normal absorption maximum of Cy5 (λ_{max} ~ 650 nm). For quantitative analysis, the normalized absorption spectra of IgG with different ratios of Cy5 label/protein were summarized in Figure 8A, and the dose-response function (peak ratio *versus* degree of Cy5 labeling) is shown in Figure 10A. Comparison of the absorption spectra (Figure 8A) with fluorescence excitation spectra (Figure 8B) revealed that the new absorption peak at ~600 nm did not contribute to Cy5 fluorescence as detected at 665 nm. The same observations were made with avidin and *biotin-4-Cy5* at various molar ratios (compare Figures 9A and 9B). To further exclude the possibility that the 600 nm peak gave any fluorescence at all, the excitation wavelength was also fixed to 600 nm and the emission was examined between 600 nm and 800

nm. However, both IgG with 6 Cy5 labels and avidin with 4 *biotin-4-Cy5* ligands gave only the normal emission spectrum of Cy5 (data not shown), with the low intensity as expected from excitation of Cy5 at 600 nm instead of at 630 nm (see Figures 8B and 9B). From the above data it was unequivocally concluded that the new absorption peak at ~600 nm seen in highly Cy5-labeled proteins derived from some "new state" of Cy5 which did not fluoresce at all.

Figures 10A and 10B finally demonstrate that the anomalous appearance of the 600 nm absorption peak solely derived from mutual interaction of Cy5 labels bound to the identical protein molecule. As argued in context with Figures 1B, 2B, 3B, and 5AB (see main article), extrapolation of the plotted function to 0 fluorophores per protein molecule gave the peak ratio (A_{600}/A_{650}) that would be observed from a homogeneous population of protein molecules carrying no more than one Cy5 label. Surprisingly, this extrapolated value for exactly mono-labeled IgG (solid line in Figure 10A) was identical with the peak ratio observed from free Cy5 dye (solid circle in Figure 10A). By analogy, the extrapolated peak ratio for a single *biotin-4-Cy5* ligand on an avidin molecule (solid line in Figure 10B) was identical to the peak ratio of free *biotin-4-Cy5* (solid circle in Figure 10B). In other words: the anomalous appearance of additional absorption at ~600 nm had nothing to do with the fact that some Cy5 dye was linked to the surface of a protein and was solely due to Cy5-Cy5 interaction because it only occurred when more than one Cy5 label was bound per protein.

It should be mentioned that some indication of the analogous phenomenon (additional absorption at ~500 nm at expense of the regular ~550 nm absorption maximum) was also seen with protein-bound Cy3 (and Cy5.5) labels and with avidin-bound biotin-4-Cy3 ligands at high Cy3/protein ratios - but the extent was by no means comparable to the effects on Cy5 labels.

A Comment on the Measurement of Protein-Bound Cy5 Labels. Admittedly the anomalous decrease of 650 nm absorption was ignored when quantifying the number of Cy5 labels per Ig(G). In this way only those Cy5 labels were counted which had retained their

fluorescence (see above). In 1 % SDS the *total* number of Cy5 labels per Ig(G) would have been measured. From a comparison of the dashed with the dotted trace in Figure 7A we can estimate that the total number of Cy5 labels per IgG would have been 8.3 when measured in 1 % SDS, rather than 6.0. Consequently we would have diluted with more buffer to arrive at a nominal concentration of 50 nM Cy5 label before measuring fluorescence yield in Figure 1A. The net effect would have been a 40 % higher abscissa value and a 40 % lower ordinate value of the solid circle in Figure 1A, and similar but smaller shifts would have occured with all open circles in Figure 1A. From the linear dependence of A_{600}/A_{650} on the number of Cy5/IgG (Figure 10A) we predicted the positions of the circles in Figure 1A as they would have been obtained by the "SDS method" (data not shown). The result: in spite of different locations these corrected data were positioned on the same fit line (dashed curve in Figure 1A) as the presently shown open and closed circles. In other words: the same dependence of fluorescence yield per Cy5 label (dashed line in Figure 1A) and of cumulative fluorescence yield (dashed line in Figure 1C) on the number of Cy5/IgG was obtained whether the fraction of non-fluorescent Cy5 labels was ignored (measurement of A_{600}/A_{650} in absence of SDS) or included (measurement of A_{600}/A_{650} in presence of 1 % SDS).

Synthesis of Biotin-NH-CH_2-CH_2-NH_3^+ Cl^-. Biotin-NH-CH_2-CH_2-NH_3^+ Cl^- was synthesized as described (Garlick and Giese, 1988). The product was pure by TLC. ^{1}H-NMR (D_2O, 500 MHz) δ: 4.64 (1H, m, position 6a in biotin) 4.46 (1H, m, position 3a in biotin) 3.53 (2H, t, J = 5.9 Hz, CH_2-NH_3^+) 3.38 (1H, m, position 4 in biotin) 3.17 (2H, t, J = 5.9 Hz, CO-NH-CH_2-CH_2-NH_3^+) 3.03 (1H, dd, J_{vic} = 5.0 Hz, J_{gem} = 13.1 Hz, position 6_I in biotin) 2.82 (1H, d, J = 13.1 Hz, position 6_{II} in biotin) 2.33 (2H, t, J = 7.3 Hz, CH_2-CH_2-CH_2-CH_2-CO-NH in biotin side chain) 1.53-1.83 (4H, m, CH_2-CH_2-CH_2-CH_2-CO-NH in biotin side chain) 1.32-1.53 (2H, m, CH_2-CH_2-CH_2-CH_2-CO-NH in biotin side chain).

TLC. Merck plastic sheets (silica gel 60) without fluorescent indicator were used. Eluents I, II, and III contained 70 parts of chloroform, 30 parts of methanol, and 4 parts of conc. ammonia, or water, or acetic acid, respectively. Cy dyes were visible without staining, other components were stained with iodine vapor.

Tentative Assignment of the proton NMR Signals in Position 6 of Biotin. The molecular structure of biotin is shown in Figure 14A. We believe that the NMR signals of proton $H6_I$ and $H6_{II}$ (at 3.03 and 2.82 ppm in the above spectrum) can be assigned to the absolute positions as indicated in Figure 14A. This conclusion is drawn from AM1 calculations using the MOPAC package (MOPAC 6.0 DEC-3100 Edition 1990, FJ Seiler Res. Lab., US Air Force Academy CO80840; Dewar et al., 1985), where coordinates derived from a force field calculation served as an input. The ring fragment of the so-obtained geometry is shown in Figure 14B. The most important feature is the close similarity between the dihedral angle of H3a and H4 (19°) and between the dihedral angle of H6a and the *cis*-H6 (20°). Consequently we would expect similar vicinal coupling constants in the NMR spectrum. The multiplet of H4 at 3.38 ppm contains a vicinal coupling constant of 4.6 Hz; the doublet of a doublet of the *cis*-H6 at 3.03 ppm ($H6_I$ in Figure 14A) shows very similar vicinal coupling (5.0 Hz) besides strong geminal coupling (13.1 Hz). The doublet at 2.82 ppm, on the other hand, must be attributed to the *trans*-H6 ($H6_{II}$ in Figure 14A) which only couples to its geminal, but not to its vicinal neighbour. This behaviour can be explained by the dihedral angle between H6a and the *trans*-H6 (141°). As the Karplus relation is known to be different for five- as compared to six-membered rings, it is likely that the minimum occurs at 141° and therefore the coupling between these two protons would become too small for being observed.

Synthesis of Biotin-4-Cy3 (see Scheme 1). Cy3-monofunctional dye (1.4 µmol) was dissolved in 1 mL of DMF containing 8.4 mg SbTMU (20.4 µmol, Bannwarth and Knorr, 1991), and 5 µL neat DIEA (57 µmol) was added. After 40 min of stirring at RT this mixture

was added to dry biotin-NH-CH_2-CH_2-NH_3^+ Cl^- (see above), another 20 µL neat DIEA (228 µmol) was added and stirring was continued under argon for 1 h at RT. The solvent was removed and the dry residue was dissolved in 5 mL 2 mM Na_2HPO_4 (pH 6.5 adjusted with NaOH). This solution was loaded on a QAE Sephadex A-25 column (1.5 x 8.5 cm, Cl^- form, prewashed in distilled water, see Gruber et al., 1997) at a flow rate of 1 mL/min. After washing with 10 mL portions of water, 40, 80, 160, 320, and 640 mM NaCl (without phosphate) the colored product was eluted with 1280 mM NaCl. The product fraction was adjusted to 2.5 % solvent B (100 % solvent B was a 5/2 mixture of ethanol and n-propanol [Feldhoff, 1991]; 100 % solvent A was 0.1 % acetic acid in water) and loaded on a LiChroprep column (1.5 x 3.5 cm, prewashed in 5 % solvent B, see Gruber et al., 2000) at a flow rate of 2 mL/min. After washing with 12 mL portions of 5, 10, 15, 20, and 25 % of solvent B the product was eluted with 30 % solvent B. After removal of solvent the dry residue was redissolved in methanol and dried down in a smaller flask.

Biotin-4-Cy3 (1.0 µmol out of the 1.2 µmol obtained from the LiChroprep column) was further purified by preparative HPLC on a Vydac C-18 column (# 218TP510, 250 x 10 mm, 2 mL/min, 0.1 % acetic acid instead of trifluoroacetic acid in all eluents). When applying a 30 min gradient from 5 to 50 % acetonitrile pure biotin-4-Cy3 (0.7 µmol according to Cy3 absorbance) was eluted at 16.5-17 min after the start of the gradient. The solvent was removed and the structure of biotin-4-Cy3 was confirmed by ^{1}H-NMR (see below). In parallel, a small aliquot was purified on an analytical Vydac C-18 column (# 218TP54, 250 x 4 mm, 1 mL/min), using the same elution protocol as above. Pure biotin-4-Cy3 was eluted 13 min after the start of the gradient, as detected by UV-vis absorption and by direct analysis of the eluent with electrospray MS. Only two m/e peaks were detected which exactly met expectation for the monoanion (897) and dianion (448) of biotin-4-Cy3.

^{1}H-NMR (D_2O, 500 MHz) δ: 8.59 (1H, t, J = 13.5 Hz, β proton of the methin bridge) 7.83-7.97 (4H, m, positions 4 and 6 of the indolin residues) 7.44 (2H, t, $J_{ortho} = J_{para}$ = 7.6 Hz, position 7 of the indolin residue) 6.43 (2H, m, α and α' protons of the methin bridge) 4.53 (1H, m, position 6a in biotin) 4.34 (1H, m, position 3a in biotin) 4.1-4.23 (4H, m, CH_2 of the *N*-ethyl group and N-CH_2-CH_2-CH_2-CH_2-CH_2-CO in Cy3 side chain) 3.21 (5H, s, CO-NH-CH_2-CH_2-NH-CO and position 4 in biotin) 2.86 (1H, m, position 6_I in biotin) 2.61 (1H, d, J = 12.8 Hz, position 6_{II} in biotin) 2.24 (2H, m, CH_2-CH_2-CH_2-CH_2-CO-NH in biotin side chain) 2.15 (2H, m, N-CH_2-CH_2-CH_2-CH_2-CH_2-CO in Cy3 side chain) 2.07 (~4H, s, acetic acid from reversed phase chromatography) 1.89 (2H, m, N-CH_2-CH_2-CH_2-CH_2-CH_2-CO in Cy3 side chain) 1.79 (12 H, s, four methyl groups of Cy3 residue) 1.44-1.70 (6H, m, CH_2-CH_2-CH_2-CH_2-CO-NH in biotin side chain, N-CH_2-CH_2-CH_2-CH_2-CH_2-CO in Cy3 side chain) 1.22-1.44 (7H, m, CH_2-CH_2-CH_2-CH_2-CO-NH in biotin side chain, N-CH_2-CH_2-CH_2-CH_2-CH_2-CO in Cy3 side chain, and CH_3 of the N-ethyl group).

Synthesis of *Biotin-4-Cy5*. The procedure was the same as described for biotin-4-Cy3, except that 1.0 µmol Cy5-monofunctional dye were used in place of Cy3-monofunctional dye (see above). LiChroprep chromatography gave 0.84 µmol of partially pure product according to Cy5 absorbance. 0.65 µmol were subjected to preparative HPLC, yielding 0.33 µmol of pure product. Only two m/e peaks were detected in electrospray MS which exactly met expectation for the monoanion (924) and dianion (461) of *biotin-4-Cy5*.

^{1}H-NMR (D_2O, 500 MHz) δ: 8.05-8.18 (2H, m, β and β' protons of the methin bridge) 7.80-7.94 (4H, m, positions 4 and 6 of the indolin residues) 7.39 (2H, t, $J_{ortho} = J_{para}$ = 9.7 Hz, position 7 of the indolin residue) 6.66 (2H, m, γ and γ' protons of the methin bridge) 6.37 (2H, m, α and α' protons of the methin bridge) 4.53 (1H, m, position 6a in biotin) 4.32 (1H, m, position 3a in biotin) 4.09-4.20 (4H, m, CH_2 of the *N*-ethyl group and N-CH_2-CH_2-CH_2-CH_2-CH_2-CO in Cy5 side chain) 3.21 (4H, s, CO-NH-CH_2-CH_2-NH-CO) 3.18 (1H, m,

position 4 in biotin) 2.86 (1H, m, position 6_I in biotin) 2.62 (1H, d, J = 12.7 Hz, position 6_{II} in biotin) 2.24 (2H, t, J = 6.5 Hz, CH_2-CH_2-CH_2-CH_2-CO-NH in biotin side chain) 2.15 (2H, t, J = 7.0 Hz, N-CH_2-CH_2-CH_2-CH_2-CH_2-CO in Cy3 side chain) 2.06 (~2H, s, acetic acid from reversed phase chromatography) 1.87 (2H, m, N-CH_2-CH_2-CH_2-CH_2-CH_2-CO in Cy3 side chain) 1.74 (12 H, s, four methyl groups of Cy3 residue) 1.44-1.70 (6H, m, CH_2-CH_2-CH_2-CH_2-CO-NH in biotin side chain, N-CH_2-CH_2-CH_2-CH_2-CH_2-CO in Cy3 side chain) 1.22-1.44 (7H, m, CH_2-CH_2-CH_2-CH_2-CO-NH in biotin side chain, N-CH_2-CH_2-CH_2-CH_2-CH_2-CO in Cy3 side chain, and CH_3 of the N-ethyl group).

Test for Specific Binding of Biotin-4-Cy3 and *Biotin-4-Cy5* towards Avidin. Specific binding towards avidin was demonstrated by incubation of biotin-4-Cy3 or *biotin-4-Cy5* with excess of avidin and subsequent gel filtration. In particular, avidin (~6 nmol according to ε_{282} = 96500 M^{-1} cm^{-1}; Green, 1990) and fluorescent biotin derivative (2.4 nmol biotin-4-Cy3 or 1.7 nmol *biotin-4-Cy5*, estimated from absorbance at 550 nm or 647 nm) were incubated in 0.2 mL buffer A for 30 min at RT, diluted with 0.3 mL of buffer A and loaded on a PD-10 column (~10 mL bed of Sephadex G-25M) which had been pre-equilibrated in buffer B (the high salt concentration in buffer B minimized binding of the positively charged avidin molecules to Sephadex G-25 which contains some residual COOH groups). The column was washed with buffer B (2 x 1 mL), and the eluent was discarded. Avidin was completely eluted by adding 2 mL of water on top of the column. Free ligand was eluted with another 10 mL of water. In the control run avidin (~6 nmol) was pre-blocked with *d*-biotin (270 nmol, 5 min incubation) before the fluorescent biotin derivative (~2 nmol) was added. Measured absorbance values at 282 nm were corrected for the small absorbances of Cy3 or Cy5 (as described for IgG in the main article) before calculating the avidin concentrations in the column fractions.

The results are shown in Table 1. In the absence of *d*-biotin all fluorescent ligands were bound to avidin (void peaks in Table 1). The incomplete recovery of biotin-4-Cy3 and *biotin-4-Cy5* from the PD-10 column (75-90 %) did not derive from incomplete binding to avidin but from adsorption to the Sephadex gel since neither biotin-4-Cy3 nor *biotin-4-Cy5* was observed in the "salt peak" when avidin was not blocked by *d*-biotin (see Table 1). The data were, therefore, consistent with 100 % bindability of biotin-4-Cy3 and *biotin-4-Cy5* towards avidin. Absence of non-specific binding was demonstrated by complete block of ligand binding in the presence of a large excess of *d*-biotin. In this case no fluorescent ligand co-migrated with avidin, and all nonadsorbed ligands were recovered in the "salt peak" (see Table 1).

Measurement of Biotin-Binding Sites in Stock Solutions of Avidin and Streptavidin. The primary standard was a 16 mM *d*-biotin stock solution prepared by dissolving 99 % pure *d*-biotin in DMSO. Aliquots were stored at -25 °C. The 16 µM *d*-biotin working solution was prepared by accurate dilution with buffer A.

Avidin and streptavidin were dissolved in buffer A (at ~2 to 3 µM *nominal* concentration by weight) and stored at 4 °C for up to one week, or at -25 °C for up to one month without refreezing. The concentration of *functional* avidin or streptavidin (= biotin binding sites/4) was determined by titration with *d*-biotin while monitoring the tryptophane fluorescence of (strept)avidin (Lin and Kirsch, 1979; Gruber et al., 1998). Buffer A (1920 µL) was mixed with 80 µL ~2 µM avidin stock solution and 5 µL aliquots of 16 µM *d*-biotin standard were successively added from a Hamilton syringe (see Figure 11A). The nearly linear decrease in tryptophane fluorescence mirrored progressive binding of *d*-biotin to avidin and the break-point at 34.9 µL *d*-biotin (558 pmol) indicated stoichiometric binding of 4 biotin molecules per avidin tetramers. Consequently the amount of avidin in the cuvette was calculated to be 140 pmol and the *functional* concentration of avidin in the *nominally* ~2 µM stock solution was determined as 140 pmol / 80 µL = 1.75 µM. Triplicate experiments gave a *functional*

concentration of 1.75 ± 0.03 μM in the avidin stock solution and 3.01 ± 0.03 μM in the streptavidin stock solution (not shown).

Measurement of Biotin Groups in the Stock Solutions of Biotin-4-Cy3 and *Biotin-4-Cy5*. Fortunately tryptophane quenching in avidin could also be used to monitor stoichiometric binding of the new fluorescent ligands biotin-4-Cy3 and *biotin-4-Cy5* towards avidin (in contrast to biotin-PEG-Cy dye conjugates; Gruber et al., 1997; Kaiser et al., 1997), as is demonstrated in Figure 11B. Buffer A (1954 μL) and 46 μL of 1.75 μM avidin stock solution (80 pmol avidin = 320 pmol of biotin-binding sites) were mixed and stirred in the cuvette, and 2 μL aliquots of a *nominally* 16 μM stock solution (according to UV-vis absorbance) of biotin-4-Cy3 (circles in Figure 11B) or *biotin-4-Cy5* (triangles in Figure 11B) were successively added from a Hamilton syringe at 3 min intervals (necessary for completion of ligand binding after each addition) while monitoring tryptophane quenching in avidin. Saturation of the 320 pmol of biotin-binding sites was achieved with 19.1 μL of *nominally* 16 μM *biotin-4-Cy5* (see triangles in Figure 11B), thus the *functional* concentration of *biotin-4-Cy5* in the stock solution was 320 pmol / 19.1 μL = 16.7 μM. This result agreed well with the *nominal* concentration of 16 μM that had been estimated from absorbance at 647 nm, assuming the same molar extinction coefficient as published for free Cy5-monofunctional dye.

A much larger discrepancy between *nominal* and *functional* concentration was observed with biotin-4-Cy3. 26.0 μL of *nominally* 16 μM biotin-4-Cy3 was necessary to saturate 320 pmol of biotin-binding sites (see circles in Figure 11B), corresponding to a *functional* concentration of 320 pmol / 26.0 μL = 12.3 μM in the stock solution of biotin-4-Cy3. In principle, the 12.3 μM biotin group content in the *nominally* 16 μM stock solution of biotin-4-Cy3 could have resulted from one or both of the following reasons: (i) The molar extinction coefficient (ε_{550}) of biotin-4-Cy3 may be much higher than 150000 M^{-1} cm^{-1} which is the known value for underivatized Cy3-monofunctional dye; or (ii) the stock solution of biotin-4-

Cy3 could have contained additional Cy3 chromophores that were not linked to biotin residues. The latter possibility, however, was excluded by TLC, HPLC, electrospray MS, and by the observed 100 % bindability of all Cy3 chromophores in biotin-4-Cy3 towards avidin (see Table 1 and corresponding text in these Supplements). It is, therefore, concluded that the molar extinction coefficients of biotin-4-Cy3 is ~195000 M^{-1} cm^{-1} and that both the biotin group content and the Cy3 chromophore content in the stock solution of biotin-4-Cy3 was 12.3 µM. Similar unpredictable shifts in the molar extinction coefficient of fluorophores have been observed with many other biotin-fluorophore conjugates (Gruber et al., 1997; Gruber et al., 1998; Kada et al., 1999).

Dissociation Kinetics of *Biotin-4-Cy5* from Avidin. As shown in Figure 7C (see original article) and Figure 9A, progressive binding of *biotin-4-Cy5* to avidin tetramers was accompanied by a steady increase in the 600 nm absorption peak, at the expense of the normal absorption maximum at 650 nm. Figure 10B depicts the nonlinear relationship between the ratio of the two absorption maxima ($r = A_{600}/A_{650}$) and the average number of ligands (n) that are bound per avidin tetramer. The data were fitted by the expression

$$r = 0.33 + 0.985 / (1 + 0.79 / n) \qquad (1)$$

(see solid line in Figure 10B). Inversion gave an expression which allowed to calculate the average number of bound ligands (n) in other experiments where only the ratio r of the absorption maxima is known:

$$n = 0.79 / [0.985 / (r - 0.33) - 1] \qquad (2)$$

This empirical expression provided for explicit monitoring of the dissociation kinetics of *biotin-4-Cy5* from an initial complex of avidin with 4 bound *biotin-4-Cy5* molecules (Figure 12). Irreversible dissociation of *biotin-4-Cy5* was caused by addition of a 100-fold excess of *d*-biotin which irreversibly occupied each biotin-binding site on avidin when a fluorescent *biotin-*

4-Cy5 molecule had dissociated spontaneously. As expected, the dissociation of *biotin-4-Cy5* molecules was accompanied by a decrease in the anomalous 600 nm absorption maximum (squares in Figure 12A) and concomitant revovery of the normal 650 nm absorption maximum of Cy5 chromophores (circles in Figure 12A). The ratio $r = A_{600}/A_{650}$ (Figure 12B) was then converted into the average number (n) of *biotin-4-Cy5* molecules that were still bound per avidin tetramer (Figure 12C) by means of equation (2). The time course of *biotin-4-Cy5* dissociation could be fitted to a bi-exponential decay: 2.8 ligands per avidin tetramer appeared to dissociate with a faster time constant (0.31 h) and the remaining 1.2 ligands per avidin tetramer appeared to dissociate with a roughly 10-fold longer time constant (4.7 h).

When viewed in a semiquantitative way the observed bi-exponential dissociation kinetics was quite informative. For proper interpretation it was necessary to explain why equation (2) yielded a rather imperfect conversion of the A_{600}/A_{650} values in Figure 12B into ligand numbers per avidin tetramer (Figure 12C). Equation (2) is the inversion of equation (1) which has been derived from stepwise titration of avidin tetramers with increasing amounts of *biotin-4-Cy5* (Figures 9A and 10B). The manual mixing process after each addition of *biotin-4-Cy5* (see Figures 9A and 10B) was certainly slower than the association kinetics of the ligands. Thus after each addition of *biotin-4-Cy5* some local excess of ligands over binding sites must have occured for a certain time in the vicinity of the pipette tip, giving rise to formation of higher fractions of avidin tetramers with 2, 3, and 4 bound ligands than would have occurred in the case of very fast mixing. During the 10 min intervals only a fraction of the non-equilibrium distribution could relax, as is obvious from Figure 12C; full relaxation would have required titration intervals of several days! Consequently the forward titration shown in Figure 10B gave an imperfect relationship between A_{600}/A_{650} and the average number of *biotin-4-Cy5* molecules bound per avidin tetramer.

For the above reasons it is justified to understand Figure 12C in the sense that two out of four bound *biotin-4-Cy5* molecules dissociated with a faster time constant (~0.5 h) while the remaining two ligands on the avidin tetramer dissociated with ~10-fold slower kinetics. Such biphasic dissociation has been observed with most biotin derivatives (Finn et al., 1980; Finn et al., 1984; Finn and Hofmann, 1985; Gruber et al., 1997; Gruber et al., 1998; Hofmann et al., 1983; Lavielle et al., 1983; Romovacek et al., 1983) and it is known to derive from the pairwise arrangements of biotin-binding sites in avidin (and streptavidin) tetramers (Green et al., 1971; Green, 1990; Hendrickson et al., 1989; Livnah et al., 1993; Pugliese et al., 1993). The linear distance between the carboxyls of two adjacently bound biotin residues is 20 Å (see Figure 13). Figure 13 also shows the dimensions of two adjacently bound *biotin-4-Cy5* molecules drawn on proper scale. From this sketch it is obvious that there is much steric interaction between neighbouring Cy5 residues. Binding of one *biotin-4-Cy5* molecule will, therefore, hamper the association of another *biotin-4-Cy5* to the neighbouring binding site. For the same reason, one out of two adjacently bound ligands will dissociate much faster than the single remaining ligand in the same pair of binding sites.

The whole avidin tetramer contains *two pairs* of biotin-binding sites (not shown in Figure 13). The distance between non-neighbouring sites is known to be 30 Å and the shortest connection of two non-neighbouring sites over the protein's surface would be even much larger (Hendrickson et al., 1989; Livnah et al., 1993, Pugliese et al., 1993). Under such geometric conditions absolutely no steric interaction between *biotin-4-Cy5* molecules is possible which are bound to non-neighbouring sites on avidin. Based on these geometric considerations, two out of four bound *biotin-4-Cy5* molecules are expected to dissociate more rapidly while the remaining two ligands stay bound on a longer time scale. As argued above, the time course shown in Fig. 13C is fully compatible with such biphasic dissociation kinetics within the inherent uncertainties of the experiment.

Table 1: Specificity of ligand binding towards avidin. Avidin (~6 nmol according to A_{282}) was incubated with fluorescent ligand (~2 nmol according to absorption at λ_{max}) and gel filtered on a PD-10 column. In the control runs, avidin had been pre-blocked with 270 nmol of *d*-biotin before fluorescent ligand was added.

PD-10 column:	**void peak**	**"salt peak"**
biotin-4-Cy3	5.9 nmol avidin	0.0 nmol avidin
	1.8 nmol biotin-4-Cy3 *a)*	0.0 nmol biotin-4-Cy3
d-biotin + biotin-4-Cy3	6.0 nmol avidin	0.0 nmol avidin
	0.0 nmol biotin-4-Cy3	1.9 nmol biotin-4-Cy3 *a)*
biotin-4-Cy5	5.8 nmol avidin	0.0 nmol avidin
	1.5 nmol *biotin-4-Cy5* *a)*	0.0 nmol *biotin-4-Cy5*
d-biotin + biotin-4-Cy5	6.2 nmol avidin	0.0 nmol avidin
	0.0 nmol *biotin-4-Cy5*	1.5 nmol *biotin-4-Cy5* *a)*

a) Free biotin-4-Cy3 and free *biotin-4-Cy5* showed the expected absorption maxima at 550 nm and at 647 nm, while the λ_{max} values in the avidin-bound state were 552 nm and 652 nm, respectively.

Figure 8: Comparison between absorption and excitation spectra of Cy5-labeled IgG. (A) Normalized absorption spectra of free Cy5-monofunctional dye (solid line) and of goat IgG with 0.5 (dashed line), 4.6 (dotted line) and 6.0 (dash-dot line) bound Cy5 labels per protein. (B) Fluorescence excitation spectra of free Cy5-monofunctional dye (solid line) and of goat IgG with 0.5 (dashed line), 0.9 (dotted line), 1.7 (dash-dot line), 3.2 (dash-dot-dot line), 4.6 (short dash line), and 6.0 (short dot line) bound Cy5 labels per protein. Emission was detected at 665 nm and the narrow scattering peaks around 665 nm were removed from all spectra for the sake of clarity.

Figure 9: Comparison between absorption and excitation spectra of avidin-bound *biotin-4-Cy5* at various protein/ligand ratios. (A) Normalized absorption spectra of free *biotin-4-Cy5* (thick solid line) and of avidin tetramers with 0.1 (thin solid line), 1 (dashed line), 2 (dotted line), 3 (dash-dot line), and 4 (dash-dot-dot line) bound *biotin-4-Cy5* molecules. 1.2 mL of buffer A containing 600 pmol *functional* avidin was mixed with increasing amounts of 14.5 µM *biotin-4-Cy5* (10 min intervals) to give the desired ligand/protein ratios and each spectrum was recorded at the end of a 10 min interval. (B) Fluorescence excitation spectra of free *biotin-4-Cy5* (solid line, 40 nM free ligand) and of avidin tetramers (40 nM) with an average of 1 (dashed line), 2 (dotted line), 3 (dash-dot line), and 4 (dash-dot-dot line) bound *biotin-4-Cy5* molecules. Emission was detected at 665 nm and the narrow scattering peaks around 665 nm were removed from all spectra for the sake of clarity.

Figure 10: Dependence of anomalous Cy5 absorption at 600 nm on the number of Cy5 labels per protein. (A) Peak ratios A_{600}/A_{650} of goat IgG with various numbers of bound Cy5 labels per protein (open circles, same samples as in Figures 1 and 8). Free Cy5-monofunctional

dye is shown for comparison (solid circle). (B) Peak ratios A_{600}/A_{650} of avidin tetramers with various numbers of bound *biotin-4-Cy5* molecules (open circles, same samples as in Figure 9). Free *biotin-4-Cy5* is shown for comparison (solid circle).

Figure 11: Titration of the biotin-binding sites in avidin with *d*-biotin or biotin-4-Cy3 or *biotin-4-Cy5*. (A) Avidin (2 mL, ~80 nM *nominal* concentration by weight) was titrated with a 16 µM *d*-biotin standard by cumulative additions at 40 sec intervals. The tryptophans in avidin were excited at 290 nm and fluorescence was monitored at 340 nm. From the breakpoint at 34.9 µL a *functional* avidin concentration of 70 nM was calculated. (B) Avidin (2 mL, 40 nM *functional* concentration) was titrated with a 16 µM stock solution (*nominal* concentration by absorbance) of biotin-4-Cy3 (circles, excitation at 530 nm, emission at 570 nm) or *biotin-4-Cy5* (triangles, excitation at 630 nm, emission at 665 nm). From the breakpoints at 26.1 µL and 19.1 µL the *functional* concentrations of the biotin-4-Cy3 and *biotin-4-Cy5* stock solutions were calculated to be 12.3 µM and 16.7 µM, respectively.

Figure 12: Displacement of *biotin-4-Cy5* from avidin tetramers. (A) 1.2 mL 0.5 µM avidin (0.6 nmol tetramers) was mixed with 166 µL 14.5 µM *biotin-4-Cy5* (2.4 nmol ligands) and equilibrated for 10 min at 25 °C. At t = 0 h 15 µL 16 mM *d*-biotin was added and absorbance at 600 nm (squares) and 650 nm (circles) was monitored for 22 h. (B) The ratio A_{600}/A_{650} was calculated from panel (A). (C) The number of bound *biotin-4-Cy5* molecules per avidin tetramer was calculated from A_{600}/A_{650} as described in the text.

Figure 13: Schematic representation of one pair of biotin-binding sites in an avidin tetramer. In reality the relative orientation of two neighbouring binding pockets is not parallel but this aspect is irrelevant for the purpose of this drawing. What counts for the interaction of two adjacently bound *biotin-4-Cy5* molecules (shown in proper scaling) is the linear distance between the two biotin carboxyls (20 Å, see dashed line) and the fact that the carboxylic groups of two adjacently bound biotins can be physically connected by a 22-atom spacer (Green, 1990).

Figure 14: Molecular structure of *d*-biotin. (A) Stereochemical structure and atomic numbering of biotin. (B) Prediction of ring fragment conformation from semi-empirical calculations (see text).

Synthetic methodology was developed for the preparation of chondrotin-4-sulfate reagents that could be specifically attached to the surface of diaspirin cross-linked hemoglobin (DCLHb), a chemically stabilized human hemoglobin. The surface-modified hemoglobin solutions had a significantly higher colloidal osmotic pressures (COP) than DCLHb. The P_{50} of the modified DCLHb was dependent upon the reactive end group of the chondrotin-4-sulfate reagents that was used for the protein modification. Modification of DCLHb with the chondroitin-4-sulfate derivatives containing the maleimide end group **23** provided a hemoglobin with a P_{50} value of 23 mmHg, while the P_{50} of hemoglobins prepared from chondroitin-4-sulfate derivatives containing the aldehyde end group **13** and **18** remained unchanged from that of DCLHb.

INTRODUCTION

Extracellular human hemoglobin is a protein composed of four polypeptide subunits, two α chains and two β chains, each with one heme associated with it. In the hemoglobin tetramer, each α chain is associated with a β chain to form two stable α-β dimers, which in turn associate to form the tetramer with a molecular weight of about 64 500. The subunits are noncovalently associated through van der Waals forces, hydrogen bonds and salt bridges.

Human hemoglobin is not suitable for use as an oxygen delivering therapeutic agent for several reasons. First, the oxygen affinity of extracellular human hemoglobin is too high and, therefore, does not effectively deliver oxygen to tissues. Second, in the circulation, extracellular hemoglobin dissociates into α-β dimers. High concentrations of these dimers overwhelm the haptoglobin scavenging system and accumulate in the tubules of the kidney, where they are nephrotoxic. These shortcomings may be overcome by the stabilization of the tetrameric hemoglobin through intramolecular cross-linking between the dimeric subunits of the native hemoglobin. One such chemically modified hemoglobin is diaspirin cross-linked hemoglobin (DCLHb), which is intramolecularly cross-linked between the α chains (lysine $99_{\alpha1}$−lysine $99_{\alpha2}$) by a fumarate bridge (*1*, *2*). Although stabilization of the tetrameric hemoglobin molecule by chemical modification was successful in addressing the above shortcomings, the full potential of extracellular hemoglobin solutions as an oxygen delivering therapeutic agent could not be met by tetrameric hemoglobin solutions.

A primary drawback of chemically modified tetrameric hemoglobins, such as DCLHb, was the limited duration of the hemoglobin in the circulatory system. A hemoglobin of this size, approximately 64 500, is able to traverse cellular pores in the membrane of the circulatory system and enter interstitial spaces between endothelial cells lining the lumen of the circulatory system. As a result, tetrameric hemoglobin can leave the intravascular space at a rate that is greater than that which is desired for optimal therapeutic utility. DCLHb has an elimination half-life of 2.5 h for a 25- and 50 mg/kg dose and an elimination half-life of 3.3 h for a 100-mg/kg dose in man (*3*).

Therefore, further modifications to the hemoglobin that have the effect of increasing the molecular size of the resulting hemoglobin composition have been developed to extend the circulatory duration of the hemoglobin molecules. These additional modifications can be divided into two groups: polymerization and surface modification. DCLHb has been polymerized with PEG and polyamide cross-linking agents in this laboratory (*4*, *5*) and human hemoglobin has been polymerized with other reagents, such as, glutaraldehyde and an *o*-raffinose derived dialdehyde (*6*).

Less investigated is the surface modification of hemoglobin. Surface modification of hemoglobin is accomplished with monofunctional derivatization reagents that react with either the 44 available lysine ϵ-amino groups and terminal amino groups or the two thiol groups of the cysteines at position 93 of the β-chains (β-93-Cys). Both human and bovine hemoglobin have been surface modified with monofunctional poly(ethylene glycol) derivatives (*7*). This modification is reported to extend the circulating half-life of the modified hemoglobin molecules. An area of hemoglobin surface modification that has not been extensively explored is the use of hydrophilic, anionic reagents. Hemoglobin molecules surface modified with a reagent that could impart a global negative surface charge to the molecule would be expected to be repulsed from the surface of the endothelial cells lining the lumen of the circulatory system. It has been reported in the literature that macromolecules with an anionic molecular charge have a decrease rate of vascular endothelial and glomerular permeability (*8*−*11*). Thus, a surface-modified hemoglobin with a global negative charge may be less likely to cross through capillary junctions or glomerular pores, thereby, extending the circulatory half-life of the hemoglobin composition (*12*).

Figure 1.

For these reasons, we chose to modify the surface of DCLHb with an anionic polysaccharide that would not only increase the size of the hemoglobin but also impart a global negative charge to the protein. In addition to imparting a negative charge, the polysaccharide needs to be nonimmunogenic and biocompatible. A polysaccharide that met these criteria was chondroitin-4-sulfate, one of the most abundant mucopolysacharides in the human body (*13*). Chondroitin-4-sulfate (C4S) is a long, unbranched polysaccharide chain composed of a repeating disaccharide structure containing uronic acid and hexosamine moieties. Chondroitin-4-sulfate molecules are strongly polyanionic due to the carboxylic acid and sulfate groups that are regularly spaced along the polymer backbone. The structure of chondroitin-4-sulfate (**1**) is shown in Figure 1.

EXPERIMENTAL PROCEDURES

General. Diaspirin cross-linked hemoglobin (DCLHb), Plasma Lyte A, and Lactated Ringer's irrigation solution were obtained from Baxter Healthcare Corporation, Deerfield, IL. Chondroitin-4-sulfate (injection grade, average MW of 50 000) was purchased from Maruha Corporation, Japan. All other commercial reagents were of the highest purity available. All solvents used were of HPLC grade. NMR spectrometry was performed on either a Bruker 270 MHz or a 300 MHz spectrometer.

Analytical Methods. Thin-layer chromatography (TLC) was performed with Whatman MK6F silica gel 60 Å TLC plates. The products were eluted with 2-propanol: ammonium hydroxide: water (6:1:3, v/v/v). The plates were analyzed with UV light or stained with either ninhydrin or 2,3,5-triphenylphenyltetrazolium chloride (TTC) (*25*). The TTC spray solution was freshly prepared before use by combining one part 4% methanolic TTC solution with 1 part 1 N NaOH solution. The sprayed plate was heated for 5−10 min at 100 °C. Reducing sugars produce a red color upon development.

Analytical RP-HPLC was performed on a Vydac Protein C_4 column (5 μm, 4.6 × 250 mm). The mobile phase was delivered at 1 mL/min. as a linear gradient of B (CH_3CN:H_2O:TFA, 60:40:0.1, by volume) in A (CH_3CN:H_2O:TFA, 20:80:0.1, by volume) as follows: (1) 50% B to 55% B over 20 min, (2) 55% B to 75% B over 10 min; and (3) 75% B to 85% B over 10 min. Analytes were detected by measuring the absorbance at 220 nm.

Size exclusion chromatography (SEC) was performed with a Superdex 200 (Pharmacia Biotech) SEC Column. A mobile phase of 50 mM phosphate buffer pH 7.0 containing 0.15 M NaCl at delivered a flow rate of 0.7 mL/min was used. SEC was also performed with a TSK G4000SW and G3000 SW columns (7.5 × 300 mm, Toso Haas) connected in series. Analytes were eluted with a binary mobile phase (50 mM phosphate, pH 6.5/2-propanol, 9:1 by volume) delivered at a flow rate of 1 mL/min. In both cases, analytes were detected by measuring the absorbance at 220 nm for chodroitin-4-sulfate and at 280 nm for hemoglobin products.

Sample preparation for chondroitin sulfate analysis: a 5 mg of the C4S sample was dissolved in 0.5 mL of Nanopure water, and the solution was filtered through a 0.2 μm filter. A 20 μL aliquot of the solution was loaded on the column. Sample preparation for hemoglobin analysis: a 7 μL aliquot of the hemoglobin solution was added to 0.5 mL of Nanopure water and the solution was filtered through a 0.2 μm filter. A 20 μL aliquot of the solution was loaded on the column.

Oxygen equilibrium curves were recorded by reoxygenation of nitrogen equilibrated deoxyhemoglobin in 0.1 M Bis-Tris buffer (pH 7.4 at 37 °C) in the spectral cuvette of a Hemox Analyzer (TCS Medical Products Co., Huntington Valley, PA). The oxygen pressure at which hemoglobin is half saturated (P_{50}) and the subunit cooperativity (n_{40-60}) were calculated from the oxygen equilibrium curves. The concentrations of oxy-, deoxy-, and methemoglobin were calculated from their absorbance at three wavelengths (630, 576, and 560 nm) using the reported molar extinction coefficients (*14*). Total hemoglobin concentration was calculated by summation of the concentrations of these components, and percent methemoglobin (MetHb) was calculated as its portion of the total hemoglobin concentration. The number of reactive thiols on the polyDCLHb molecules was determined by the method of Neis et al. (*15*).

Red Cell Aggregation Testing. A simple in vivo test in which red cell aggregation was monitored was used for assessing the biocompatibilty with blood of the chemically modified DCLHb. In this test, human blood was diluted with physiological electrolyte solution (negative control) or chemically modified DCLHb solution (test solution) and then incubated. Solutions containing 10, 30, and 50% (by volume) of the chemically modified DCLHb solution were prepared and tested in this way. If there was no interaction between the test solution and the red cells or platelets, the red cells were dispersed randomly through the sample and a score of "none" was recorded. However, if there were interactions between the test sample and red cells platelets, aggregates and/or platelet "clumps" were observed. A score of "very few", "few", "1", and "2" served to define increasing degrees of red cell aggregation of the chemically modified DCLHb solution.

Chondroitin-4-sulfate-4K (2). Chondroitin-4-sulfate (400.8 g) was dissolved in 5 L of 0.5 N HCl. The solution was heated at 65 °C for about 24 h. The solution was cooled in an ice bath to RT. The pH was adjusted to 7.6 with 5 N NaOH. To the solution was added 12 L of ethanol. The mixture was stirred for 3 h under ice bath cooling. The solvent was decanted and 4 L of ethanol was added. The mixture was stirred to obtain a solid. The solid was collected and washed with ethanol (2 × 500 mL) followed by ethyl ether (1 × 500 mL). The solid was vacuum-dried to give 343.5 g of product having MW of 4000 (*16*). The compound had a SEC a retention time of 26.3 min obtained on a Superdex 200 (Pharmacia Biotech) SEC column.

Diethylene Glycol Bis(3-aminopropyl)ether Mono-*tert*-butyl Carbonate (4). Diethylene glycol bis(3-aminopropyl)ether (**3**) (528.0 g, 2.4 mol) was dissolved in 2 L of dichloromethane. A solution of di-*tert*-butyl dicar-

bonate (261.4 g, 1.2 mol) in 1 L of dichloromethane was added dropwise over 4.5 h. The solution was stirred for 1 h and then extracted with 1 L of water. The organic phase was evaporated to an oil. The oil was dissolved in 2 L of water and the pH was adjusted to 5 with 5 and 1 N HCl. The solution was extracted with 1 L of dichloromethane. The pH of the aqueous phase was adjusted to 13 with 1 N NaOH. The solution was extracted with dichloromethane (4 × 750 mL). The extracts were combined and dried with $MgSO_4$. The solution was evaporated to give 241.3 g (31%) of viscous oil product.

^{1}H NMR ($CDCl_3$): δ 1.39 (s, 9-H); 1.67 (m, 4-H); 2.75 (t, 2-H, J = 6.75 Hz); 3.17 (q, 2-H, J = 6.2 Hz); 3.51 (m, 14-H) 5.19 (s, 1-H). ^{13}C NMR ($CDCl_3$): δ 28.3; 33.2; 39.5; 69.3; 69.5; 70.1; 70.4; 70.5; 78.7; 156.0; impurity resonances at 29.5; 38.4; 70.0. Anal. calcd for $C_{15}H_{32}N_2O_5$: C, 56.23; H, 10.07; N, 8.74. Found: C, 56.87; H, 9.86; N, 8.36.

Chondroitin-4-sulfate Derivative 5. Compound **2** (222.0 g, 55.0 mmol) and **4** (150.1 g, 470.5 mmol) were dissolved in 1.2 L of sterile water for irrigation, USP, and the solution pH was adjusted to 8.3 with 1 N HCl. Ethanol (600 mL) was added to the solution followed by borane−pyridine complex (57 mL). The solution was heated at 40 °C for 4 days. The solution was cooled to RT and the pH was adjusted to 10 using 5 N NaOH followed by 1 N NaOH. Ethanol (12 L) was added to solution with stirring. After stirring 3 h, the mixture was allowed to stand for 1 h. The solvent was decanted and the solid was collected and washed with ethanol (2 × 500 mL) followed by ethyl ether (1 × 500 mL). The solid was vacuum-dried to give 210.7 g (89%) of product.

^{1}H NMR (D_2O): δ 1.38 (s); 1.70 (t, J = 6.48 Hz); 1.98 (s); 3.09 (t, J = 6.48 Hz); 3.29−3.75 (m); 3.95 (m); 4.04 (m); 4.12 (m); 4.17 (m); 4.45 (m). ^{13}C NMR (D_2O): δ 25.4; 30.6; 31.6; 39.9; 53.6; 53.8; 54.4; 63.8; 70.3; 70.5; 71.2; 71.1; 72.4; 74.6; 75.3; 75.4; 75.5; 76.5; 77.4; 77.8; 77.9; 78.1; 78.4; 79.0; 79.2; 82.5; 82.8; 83.1; 83.7; 103.6; 104.2; 106.3; 106.6; 106.9; 107.1; 161.1; 177.2; 177.4; 177.5; 177.8; 178.8; 178.9.

Chondroitin-4-sulfate Derivative 6. Compound **5** (184.2 g) was dissolved in 750 mL of water and 750 mL of 1 N HCl. The pH of the solution was adjusted to 0.85 with 1 N HCl. The solution was stirred at RT for 24 h. The solution was evaporated from about 1.8 L to a volume of about 1 L. The solution was diluted with ethanol (8 L) and the mixture was stirred for 2 h. The precipitate was collected and washed with ethanol (250 mL) and then with ethyl ether (250 mL). The solid was vacuum-dried to give 143.9 g (79%) of **6**.

^{1}H NMR (D_2O): δ 1.89 (m); 3.09 (t, J = 6.48 Hz); 3.29−3.75 (m); 3.93 (m); 4.06 (m); 4.14 (m); 4.51 (m); 4.69 (m). ^{13}C NMR (D_2O): δ 23.1; 23.5; 26.4; 27.6; 38.7; 47.4; 48.4; 52.0; 52.2; 52.7; 62.0; 63.7; 68.5; 68.7; 69.4; 70.5; 70.6; 72.3; 72.4; 73.1; 73.3; 73.5; 73.7; 74.5; 74.8; 75.5; 75.6; 76.0; 76.1; 81.0; 99.2; 102.4; 104.8; 105.0; 105.3; 105.4; 172.4; 172.6; 173.6; 173.8; 173.7; 176.0; 176.2.

Methyl 4-Thia-7-diethoxy-heptanoate (10). Methyl 3-mercaptopropionate (**8**) (120.0 g, 1.0 mol) was added to a mixture of potassium carbonate (250.0 g, 1.8 mol) in 1 L of DMF. 3-Chloropropionaldehyde diethyl acetal (**9**) (194.6 g, 1.17 mol) was added to the mixture. The mixture was heated to 85 °C for 5 h. An additional 10.0 g portion of the acetal and 10.1 g of potassium carbonate was added. The mixture was heated for an additional 1.5 h at 85 °C. The mixture was cooled to about 20 °C and ethyl ether (1 L) was added to the mixture. Water (1 L) was added to the mixture while the mixture was well stirred. The phases were separated and the aqueous phase was extracted with ethyl ether (1 × 1 L; 1 × 500 mL). The combined extracts were extracted with a 5% potassium carbonate solution (800 mL). The organic phase was dried with $MgSO_4$ and filtered, and the filtrate was evaporated to an liquid. The product was collected by distillation from 115 to 120 °C at 0.2 mm Hg to give 186.1 g (74%) of product.

^{1}H NMR ($CHCl_3$): δ 1.19 (t, J = 7.1 Hz, 6-H); 1.86 (q, J = 7.7 Hz, 2-H); 2.59 (m, 4-H), 2.76 (m, 2-H); 3.45 (m, 2-H); 3.64 (m, 5-H); 4.57 (t, J = 5.6 Hz, 1-H). ^{13}C NMR ($CHCl_3$): δ 14.7; 26.3; 26.5; 33.0; 33.9; 51.0; 60.8; 100.9; 171.5. Anal. calcd for $C_{11}H_{22}O_4S$: C, 52.77; H, 8.86; S, 12.81. Found: C, 52.37; H, 8.66; S,12.71.

4-Thia-7-diethoxy-heptanoic Acid (11). Methyl 4-thia-7-diethoxy-heptanoate (**10**) (250.3 g, 1.0 mol) was dissolved in ethanol (600 mL). Potassium hydroxide (61.8 g, 1.1 mol) in water (200 mL) was added in one portion. After stirring for 45 min, the solvent was evaporated to two-thirds of the starting volume. To the remaining solution was added 500 mL of water. The solution was extracted with ethyl ether (2 × 300 mL). The aqueous phase was collected, and ethyl ether (500 mL) was added. The mixture was stirred vigorously as 5 N HCl (182 mL) was slowly added. The phases were separated and the aqueous phase was extracted with ethyl ether (2 × 300 mL). The extracts were combined and extracted with 1.00 N NaOH (1 × 72 mL) to remove impurities. The organic phase was dried with $MgSO_4$ and evaporated to provide 183.6 g (78%) of **11** as viscous oil.

^{1}H NMR ($CDCl_3$): δ 1.15 (t, J = 7.0 Hz, 6-H); 1.86 (q, J = 6.8 Hz, 2-H); 2.54 (t, J = 7.5 Hz, 2-H); 2.60 (t, J = 6.8 Hz, 2-H); 2.73 (q, J = 7.0 Hz, 2-H); 3.48 (m, 2-H); 3.61 (m, 2-H); 4.57 (t, J = 5.6 Hz, 1-H). ^{13}C NMR ($CDCl_3$): δ 15.3; 25.5; 26.3; 27.3; 31.8; 33.5; 61.6; 101.4; 167.1; 168.9. Anal. calcd for $C_{10}H_{20}O_4S$: C, 50.77; H, 8.30; S, 13.57; Found: C, 50.89; H, 8.30; S, 13.41.

N−Succinimidyl 4-Thia-7-diethoxy-heptanoate (12). 4-Thia-7-diethoxy-heptanoic acid (**11**) (153.9 g, 0.65 mol) and triethylamine (72.9 g, 0.72 mol) were combined in 1 L of acetonitrile. *N*,*N*′-Disuccinimidyl carbonate (184.6 g, 0.72 mol) was added as a solid in portions. The resulting solution was stirred at RT overnight. The solution was evaporated to an oil, and the oil was dissolved in 1 L of chloroform. The solution was extracted with 5% $NaHCO_3$ (2 × 500 mL). The organic phase was treated with activated carbon, and the mixture was dried with $MgSO_4$. The mixture was filtered through a pad of $MgSO_4$, and the filtrate was evaporated to give 186.5 g (95%) of **12** as an oil. The oil was used without further purification.

^{1}H NMR ($CDCl_3$): δ 1.19 (t, J = 7.0 Hz, 6-H); 1.89 (q, J = 6.7 Hz, 2-H); 2.60 (t, J = 7.5 Hz, 2-H); 2.85 (m, 12-H); 3.49 (m, 2-H); 3.62 (m, 2-H); 4.58 (t, J = 5.6 Hz, 1-H). ^{13}C NMR ($CDCl_3$): δ 15.2; 25.5; 26.2; 27.3; 31.8; 33.5; 61.5; 101.4; 167.1; 168.9. Anal. calcd for $C_{14}H_{23}NO_6S$: C, 50.43; H, 6.95; N, 4.20. Found: C,49.89; H, 6.61; N, 3.77.

Chondroitin-4-sulfate Derivative 7. Compound **6** (140.0 g, 35.0 mmol) was dissolved in 1.2 L of water. The pH of the solution was adjusted to 9 with 5 N NaOH. *N*-Succimidyl 4-thia-7-diethoxy-heptanoate **12** (58.8 g, 170.0 mmol) in 500 mL of DMF was added dropwise. After the addition was complete, the solution was stirred 4 h at RT. The solution was concentrated to 500 mL. Ethanol (4 L) was added to the solution. The solvent was decanted from the resulting oil. Ethanol (4 L) was added to the oil and the mixture was kept at 5 °C. The solvent was decanted. The remaining mixture was centrifuged to give a gellike pellet. The pellet was diluted with acetone and evaporated to a semisolid. Ethyl ether was

added, and the mixture was allowed to stand for 1 h. The mixture was filtered, and the gellike solid was dried under vacuum at room temperature. The solid was collected to give 104.7 g (71%) of **7**.

^{1}H NMR (D_2O): δ 1.18 (m); 1.76 (m); 1.91 (m); 2.05 (s); 2.57 (m); 2.61 (m); 2.79 (m); 2.99 (s); 3.29−3.75 (m); 3.95 (m); 4.09(m); 4.15 (m); 4.21 (m); 4.49 (m); 7.91 (s). ^{13}C NMR (D_2O): δ 15.5; 17.9; 22.9; 23.1; 23.6; 26.2; 26.4; 27.3; 27.8; 29.3; 32.5; 34.2; 36.7; 37.4; 38.0; 51.9; 52.1; 52.6; 53.1; 58.5; 62.1; 63.9; 64.0; 68.6; 68.7; 69.4; 69.5; 70.4; 70.6; 72.9; 73.5; 73.6; 73.8; 74.6; 74.7; 75.7; 76.0; 76.3; 76.4; 77.2; 77.4; 77.7; 80.6; 81.1; 81.3; 82.2; 101.9; 102.4; 103.0; 104.3; 104.5; 104.8; 105.2; 105.3; 166.0; 175.4; 175.6; 175.7; 176.1; 176.3; 176.5; 176.9; 177.0; 178.0.

Chondroitin-4-sulfate Aldehyde 13. Compound **7** (104.3 g) was dissolved in a solution of 750 mL of sterile water and 750 mL of 1 N HCl. The pH of the solution was adjusted to 2 with 1 N HCl. The solution was stirred for 3.5 h. The reaction solution was concentrated to about 100 mL. Acetone (250 mL) was added to precipitate the product as an oil. The solvent was decanted and an additional 250 mL of acetone was added. The mixture was agitated, and the solvent was decanted. To the resulting semisolid was added an additional 250 mL of acetone. The mixture was allowed to stand for 1 h. The resulting solid was collected, washed with 100 mL of acetone, and dried under vacuum to give 113.6 g of **13**.

^{1}H NMR (D_2O): δ 1.75 (m); 2.02 (s); 2.51 (m); 2.58 (m); 2.79 (m); 3.29−3.75 (m); 3.95 (m); 4.04 (m); 4.12 (m); 4.17 (m); 4.54 (m); 5.08 (s); 9.64(s). ^{13}C NMR (D_2O): δ 22.9; 23.1; 23.5; 36.7; 37.4; 51.9; 52.1; 52.7; 62.0; 68.4; 68.68.7; 69.4; 70.4; 70.6; 72.3; 73.1; 73.3; 73.5; 74.7; 75.5; 75.7; 76.0; 76.8; 77.0; 77.2; 80.9; 81.1; 90.7; 102.3; 102.5; 104.4; 104.7; 104.9; 105.3; 172.6; 172.9; 173.8; 173.9; 174.0; 175.5; 175.7; 176.0; 176.2; 207.4. Compound exists in the aldehyde and hydrated form (90.8 and 207.4 resonances).

***N*-(4-Diethoxybutyryl)succinamic Acid (15).** 4-Aminobutyraldehyde diethylacetal (**14**) (5.3 g, 32.9 mmol) was dissolved in 10 mL of chloroform. A solution of succinic anhydride (3.3 g, 33.0 mmol) in 20 mL of chloroform was added dropwise. The oil was used without further purification. ^{1}H NMR ($CDCl_3$): δ 1.15 (m, 12-H); 2.00 (m, 8-H); 2.63 (m, 8-H); 3.45 (m, 2-H); 3.56 (m, 2-H); 3.69 (m, 4-H); 5.07 (d, J = 4.05 Hz, 1-H); 5.45 (d, J = 5.19 Hz, 1-H); 7.25 (s, 2-H). ^{13}C NMR ($CDCl_3$): δ 15.1; 15.2; 21.0; 22.8; 28.7; 28.8; 29.1; 29.3; 31.4; 31.6; 45.7; 46.0; 62.2; 64.3; 85.8; 87.6; 171.9; 172.0; 176.5. Impurity resonances: 176.4; 58.1; 28.6; 18.0.

***N*-Succinimidyl *N*-(4-Diethoxybutyryl)succinamate (16).** Disuccinimidyl carbonate (6.5 g, 25.3 mmol) was added as a solid to a solution of *N*-(4-diethoxy)butyrylsuccinamic acid (**15**) (6.0 g, 23.0 mmol) and triethylamine (2.6 g, 25.3 mmol) in acetonitrile. The solution was stirred overnight at room temperature. The solution was evaporated to an oil. The oil was dissolved in chloroform (75 mL) and extracted with water (2 × 25 mL). The organic phase was extracted with 5% $NaHCO_3$ (2 × 25 mL) and then dried over anhydrous $MgSO_4$. The mixture was filtered, and the filtrate was concentrated under vacuum to give **16** as an oil. The oil was used without further purification.

^{1}H NMR ($CDCl_3$): δ 1.11 (m, 6-H); 1.53 (m, 4-H); 2.62 (s, 4-H); 3.42 (m, 6-H); 3.56 (m, 2-H); 4.35 (dd, 1-H); 4.40 (t, 1-H). ^{13}C NMR ($CDCl_3$): δ 15.1; 22.9; 25.4; 27.9; 30.7; 61.4; 102.1; 168.7; 168.9; 177.1. Chondroitin-4-sulfate Derivative 17. Compound **6** (10.0 g, 2.5 mmol) was dissolved in 100 mL of water, and the solution pH was adjusted to 9.3 with 1 N NaOH. A solution of *N*-oxysuccinimidyl *N*-(4-diethoxy)butyrylsuccinamate (**16**) (4.5 g, 12.5 mmol) in 10 mL of DMF was added to the reaction solution. The solution was stirred for 3 h at room temperature. The solution was concentrated under vacuum to a volume of about 25 mL. To the solution was added 1 L of ethanol. The mixture was cooled to 5 °C and allowed to stand overnight. The solvent was decanted, and the solid was collected by filtration. The solid was washed with ethanol (25 mL) and then with ethyl ether (2 × 25 mL). The solid was dried under vacuum to give 6.8 g (64%) of **17**.

^{1}H NMR (D_2O): δ 1.24 (m); 1.76 (m); 2.06 (br. s); 2.49 (m); 2.72 (s); 3.2−4.20 (br. s); 4.49. ^{13}C NMR (D_2O): 14.3; 14.9; 15.4; 23.6; 26.2; 29.3; 31.0; 31.4; 32.5; 33.0; 37.4; 39.0; 52.0; 52.6; 62.1; 63.6; 64.1; 68.5; 68.8; 69.2; 69.4; 70.4; 70.6; 72.6; 72.9; 73.8; 74.7; 75.7; 76.0; 76.4; 76.6; 77.2; 77.4; 80.7; 81.0; 81.3; 101.9; 104.5; 104.8; 105.1; 105.3; 108.7; 175.3; 175.6; 175.7; 176.0; 177.0; 177.1; 178.7.

Chondroitin-4-sulfate Aldehyde 18. Compound **17** (5.5 g, 1.4 mmol) was dissolved in 25 mL of water, and the solution pH was adjusted to 1.5 with 1 N HCl. The solution was stirred at RT for 4 h. The solution was concentrated under vacuum to a volume of about 10 mL, and then acetone (50 mL) was added. The solvent was decanted, and an additional 50 mL of acetone was added. The solvent was again decanted, and 50 mL of acetone was added. The mixture was stirred and the solid was collected. The solid was dried under vacuum to give 5.0 g (83%) of **18**.

^{1}H NMR (D_2O): δ 1.14 (m); 1.74; (br. s); 1.80 (br. s); 2.47 (br. s); 2.61 (br. s); 2.75 (br. s); 3.20−4.16 (m); 4.56 (br. s); 5.63 (s). ^{13}C NMR (D_2O): δ 14.5; 15.0; 22.9; 23.1; 23.5; 26.3; 28.4; 31.4; 37.5; 46.8; 47.7; 52.2; 52.8; 62.0; 68.5; 68.7; 69.5; 69.9; 70.4; 70.7; 72.3; 73.5; 74.5; 74.6; 74.8; 75.4; 75.6; 75.7; 76.0; 76.1; 76.4; 77.0; 77.3; 80.4; 81.1; 8`.9; 82.7; 102.5; 104.5; 104.8; 105.0; 172.3; 172.5; 173.4; 173.6; 175.8; 176.0; 176.2; 183.0.

***N*-Succinimidyl 2-Formylphenoxyacetate (20).** 2-Formylphenoxyacetic acid (**19**) (18.0 g, 0.1 mol) and *N*-hydroxysuccinimide (13.0 g, 0.11 mol) were combined in 300 mL of acetonitrile. 1,3-Dicyclohexylcarbodiimide (24.1 g, 0.12 mol) in 100 mL of acetonitrile was added. The resulting mixture was stirred for 3 h and then filtered. The filtrate was concentrated to dryness under vacuum, and tetrahydrofuran (THF; 50 mL) was added. The solid was collected by filtration, and the filtrate was reduced in volume to about 15 mL. The precipitated solid was collected, combined with the first crop, and dried to give 22.8 g (82%) of **20**.

^{1}H NMR (DMSO-d_6): δ 2.82 (s, 4-h); 5.54 (s, 2-H); 7.16 (t, J = 7.43 Hz, 1-H); 7.25 (d, J = 8.42 Hz, 1-H); 7.71 (m, 2-H); 10.41 (s, 1-H). ^{13}C NMR (D_2O): δ 25.2, 63.7, 122.2, 124.8, 136.2, 159.3, 165.3, 169.9, 188.8. Surface Modification of DCLHb with Chondroitin-4-sulfate Containing Aldehyde End Groups. A solution of DCLHb in 0.1 M borate, pH 9.0, was deoxygenated by vacuum/nitrogen cycles for 1.5 h at room temperature. A solution of **13**, **18**, or **21** in water and borane−pyridine complex (borane-pyridine/**2** in a molar ratio of 5/1) were added so that the final concentration of DCLHb was 6 g/dL in borate buffer, pH 9.0. The reaction mixture was stirred at room temperature under nitrogen for 24 h and dialyzed against Plasma-Lyte A to give the final product. The results are summarized in Tables 2 and 3 and Figure 2.

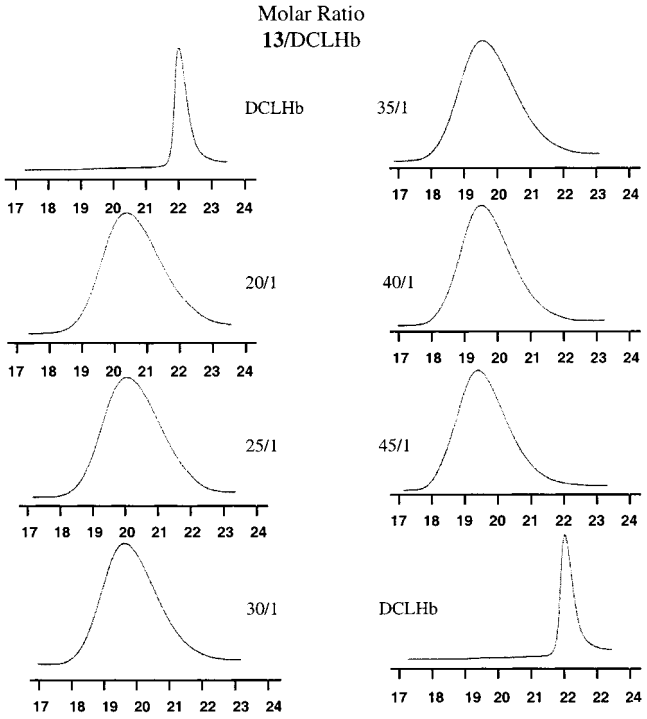

Figure 2.

temperature. A solution of **23** in water and borane−pyridine complex (borane−pyridine/**2** in a molar ratio of 5/1) were added so that the final concentration of DCLHb was 6 g/dL in 0.1 M HEPES, pH 8.0. The hemoglobin solution was stirred at room temperature under nitrogen, and the reaction was monitored by SEC (column: TSK G3000SW and TSK G4000SW in series). SEC indicated that the surface modification of DCLHb was completed within 6 h. The reaction mixture was dialyzed against Plasma Lyte A to give the final product. The results are summarized in Table 1.

RESULTS AND DISCUSSION

Synthesis of Monofunctional Chondroitin-4-sulfate Derivatives. Chondroitin-4-sulfate has a MW of 50 000. A solution of hemoglobin surface modified with chondroitin-4-sulfate molecules with this high of MW would result in a solution too viscous to be used as a therapeutic solution. Therefore, the MW of chondroitin-4-sulfate was reduced to 4000 via acid-catalyzed hydrolytic cleavage at 65 °C. The hydrolysis was stopped at the time the size exclusion chromatography (SEC) profile of the reaction product was comparable with the SEC profile of a chondroitin-4-sulfate standard with a MW of 4000 provided by Biorelease, Inc. (*16*). The hydrolysis method provided Chondroitin-4-sulfate (C4S) (**2**) with reproducible product distributions as determined by SEC and yields.

It has been reported in the literature that the reducing terminus of a disaccharide or polysaccharide can be directly derviatized with a primary amine by reductive amination under mild conditions (*17*−*19*). We took advantage of this chemistry to introduce a primary amine to the reducing terminus of chondroitin-4-sulfate. The reductive amination was achieved by treatment of chondroitin-4-sulfate (**2**) with the monoprotected diamine diethylene glycol bis(3-aminopropyl)ether mono-*tert*-butyl carbonate (**4**) in the present of a reducing agent depicted in Scheme 1. The choice of the reducing agent for this transformation was critical. Sodium cyanoborohydride has been successfully used for the reductive amination of carbohydrates (*17*−*21*). However, for large-scale syntheses the use of poisonous sodium cyanoborohydride is unattractive as is the workup, because care must be exercised with respect to the sodium cyanide and hydrogen cyanide byproducts. The use of sodium cyanoborohydride could be avoided by the use of borane-pyridine complex. Cabacungan et al. (*22*) found that borane−pyridine complex has a higher reducing capacity than sodium cyanoborohydride for the reductive methylation of N-α-acetyl-lysine with formaldehyde. In addition, borane−pyridine complex does not readily reduce aldehydes (*23*, *24*). Therefore, the reduction of the reducing terminus of chondroitin-4-sulfate during the reductive amination reaction could also be avoided by the use of borane-pyridine complex. The aminated product **5** was prepared by the treatment chondroitin-4-sulfate (**2**) with **4** in the present of borane-pyridine complex under alkaline conditions at 40 °C over four days. The reaction was terminated when the detection with 2,3,5-triphenyltetrazolium chloride (TTC) of the reducing terminus was negative (*25*). The diethylene glycol bis(3-aminopropyl)-ether (**3**) was monoprotected with a *tert*-butyl carbonate group using di-*tert*-butyl dicarbonate (Scheme 1). The BOC protecting group was removed by acid hydrolysis from **5** to give the deprotected product **6**.

The primary amine of **6** was coupled to both alkyl and aromatic aldehyde moieties via an amide linkage. 4-Thia-7-diethoxy-heptanoyl was covalently linked to **6** as outlined in Scheme 2. Treatment of **6** with *N*-succinimidyl 4-thia-7-diethoxy-heptanoate (**12**) gave **7** in moderate yields. *N*-Succinimidyl 4-thia-7-diethoxy-heptanoate (**12**) was synthesized by a three step method (Scheme 3). Methyl 3-mercaptopropionate (**8**) was allowed to react

with 3-chloropropionaldehyde diethyl acetal (**9**) in the presence of potassium carbonate to give methyl 4-thia-7-diethoxy-heptanoate (**10**). Methyl 4-thia-7-diethoxy-heptanoate (**10**) was hydrolyzed to the free acid (**11**) with potassium hydroxide in aqueous ethanol. Treatment of the free carboxylic acid with disuccinimidyl carbonate provided *N*-succinimidyl 4-thia-7-diethoxy-heptanoate (**12**) in good yields. The target compound **13** was prepared by the deprotection of the aldehyde group of **7** by acid hydrolysis.

The coupling of the aldehyde groups with amino groups on the surface of proteins is dependent upon the distance of the aldehyde to a heteroatom on the reagent chain as demonstrated by Harris and Sedaghat-Herati (*26*). They showed that PEG propionaldehyde (PEG-OCH_2CH_2CHO) was more reactive toward the protein amino groups than was PEG acetaldehyde (PEG-OCH_2CHO). To test the reactivity of a reagent with a greater distance between the aldehyde group and a heteroatom, a chondroitin-4-sulfate derivative containing a butyraldehyde end group (**18**) was prepared. The carboxylic acid of *N*-(4-ethoxybutyryl)-succinamic acid (**15**) was activated with *N*-hydroxysuccinimide to provide **16** that was readily coupled to the primary amino group of **6** to afford the target compound **17**. The ethoxy groups of **17** were removed under acidic conditions to provide **18** (Schemes 4 and 5).

In addition to alkyl aldehydes, we also wanted to investigate the utility of employing aromatic aldehydes and maleimide groups for the attachment of chondroitin-4-sulfate to DCLHb. The chondroitin-4-sulfate derivative **21**, terminating with an aromatic aldehyde, was prepared from *N*-sucinimidyl 2-formylphenaoxyacetic acid and **6** shown in Scheme 6. A maleimide moiety was conveniently coupled to **6** using *N*-succinimidyl maleimidopropionate (**22**) to provide **23** (Scheme 7).

Modification of DCLHb with Chondroitin-4-sulfate Derivatives. The typical surface modification of DCLHb with the maleimide derivative **23** was accomplished by the reaction of deoxyDCLHb in HEPES buffer, pH 8, with the chondrotin-4-sulfate derivative under a nitrogen atmosphere at room temperature over the course of 6 h. The results are summarized in Table 1. The data indicates that **23** surface-modified DCLHb provides a product that exhibited a single peak by SEC with a shorter retention time than that of DCLHb. The greater the **23**/DCLHb molar ratio, the more extensively surface modified the products are as detected by the decrease in the product SEC retention times. The P_{50} and n (cooperativity) values are in the range 21−23 mm Hg

Scheme 6[a]

and 1.9−2.1, respectively. The decrease in the P_{50} of the surface-modified DCLHb product solutions was expected and is due to the alkylation of β-cys93 residues by **23** (*27*, *28*). The maleimide group is known to alkylate both thiol and amino groups although the reagent will preferentially react with a thiol group and, indeed, this was the case. It was found that 30−35% of the added **23** would react with the surface of DCLHb as determined by NMR spectrometry (*29*). Since the *N*-acetyl groups of chondroitin-4-sulfate give an isolated and distinct resonance at 2 ppm in a ^{1}H NMR spectrum, this resonance was used to quantitate the number of chondroitin-4-sulfate moieties attached to the protein. The method involved generating a standard curve of integrals of the *N*-acetyl groups of **6** in a DCLHb solution. The degree of alkylation of DCLHb by **23** was determined by the measurement of the resonance at 2 ppm and relating that value to the standard curve.

It has been demonstrated that the reductive amination of a protein or peptide is most effective using cyanoborohydride or borane−pyridine under slightly alkaline conditions (pH 7−9) (*18*, *21*, *30*). Thus, the surface modification of DCLHb with aldehydes **13**, **18**, and **21** was performed under deoxy conditions in borate buffer, pH of 9, in the presence of borane−pyridine. The latter was selected to avoid the toxicity associated with sodium cyanoborohydride. Since borane−pyridine complex does not readily reduce aldehyde groups at neutral or alkaline pH (*24*), the reagent can be added along with the aldehyde allowing the Schiff bases that are formed to be reduced during the course of the reaction.

The data indicate that **13** and **18** effectively surface-modified DCLHb. The surface-modified DCLHb showed a single, broad peak by SEC with the retention time in the range 19−20 min as shown in Figure 2. The P_{50} and *n* values of the products are the range of 31−33 mm Hg and 2.2−2.6, respectively. These values indicate that the surface modification of DCLHb with **13** or **18** do not greatly perturb the conformation of the protein. The chondroitin-4-sulfate derivative that contains a butyraldehyde end group, **18**, is as active as the chondroitin-4-sulfate derivative with the propionaldehyde end group (**13**) toward the surface modification of DCLHb. The aromatic aldehyde containing derivative **21** also modified DCLHb; however, the modified product was rapidly oxidized to metHb during the reaction workup. The mechanism of this rapid oxidation is unknown.

The physical properties of DCLHb modified with **13** are presented in Table 3. The two most distinguishing features of the modified DCLHb are the colloidal osmotic pressure (COP) and red blood cell aggregation data. The COP of the **13**-DCLHb conjugates were 2−3-fold greater than that of DCLHb. The high COP can be attributed to the highly hydrated chondroitin-4-sulfate moieties attached to the protein surface.

Red blood cell aggregation was determined by mixing known concentrations of the modified hemoglobin products with red blood cells. Red cell aggregation (*31*) has been observed with some polyDCLHb solutions prepared by polymerization with bifunctional polyamide reagents (*5*). *In* vitro, RBCs are also known to form red cell aggregates when they are suspended in saline solution in the presence of a wide variety of macromolecules such as serum proteins (*32*), dextran (*33*−*38*), polylysine (*34*−*38*), poly(ethylene glycol) (*34*, *35*), poly(vinylpyrrolidone) (*37*), polysaccharides (*36*), and polyglutamic acid (*36*). Several mechanisms of red cell aggregate formation have been proposed (*33*, *35*−*44*), including size-dependent interaction of the macromolecule with the red cell membrane, changes in the surface charge or charge density of the red cell membrane induced by the adherent macromolecule, and the volume excluded effect of the polymer. Since DCLHb-chodroitin-4-sulfate conjugates do not cause red cell agregation even though the products' COP are high, the volume-excluded mechanism of cell aggregation cannot be invoked. The negatively charged surface of DCLHb-chodronitin-4-sulfate conjugates may prevent red cell aggregation.

In conclusion, chondrotin-4-sulfate reagents that could be readily attached to the surface of diaspirin cross-linked hemoglobin (DCLHb) were prepared. Synthetic methodology has been developed that allows for the modification of proteins, such as DCLHb, through alkylation of protein thiols or amino groups by the chondroitin-4-sulfate derivatives. The modification of proteins with chondroitin-4-sulfate would add an global negative charge that has the potential to alter the in vivo properties of the proteins and, possibly, increase their therapeutic utility.

Linker-Mediated Modulation of the Chemiluminescent Signal from N^{10}-(3-Sulfopropyl)-*N*-sulfonylacridinium-9-carboxamide Tracers

Maciej Adamczyk,* Yon-Yih Chen, Jeffrey R. Fishpaugh, Phillip G. Mattingly, You Pan, Kevin Shreder, and Zhiguang Yu

Abbott Laboratories, Diagnostics Division, Department of Chemistry D9NM, Building AP 20, 100 Abbott Park Road, Abbott Park, Illinois 60064-6016. Received March 20, 2000; Revised Manuscript Received May 1, 2000

Four chemiluminescent *N*-sulfonylacridinium-9-carboxamide active esters (**17**−2**0**) were prepared from the corresponding acids and coupled to both of the aminated phenobarbital (**13**) and *N*-(6-aminohexyl)-phenytoin (**16**) haptens. The level of signal produced by chemiluminescent *N*-sulfonylacridinium-9-carboxamide phenobarbital and phenytoin tracers in a solid-phase immunoassay format was found to be modulated by at least 20-fold by the judicious choice of the reactive acridinium-hapten linking group.

INTRODUCTION

The linker group used to connect a label to a small molecule hapten or a macromolecule can have a profound influence on the performance of the bioconjugate. Linkers can contribute to "bridge-binding" interactions (*1*−*11*) between tracers and antibodies when the same linker is used both in the immunogen and tracer. In this phenomenon, the antibody recognizes the commonly used linker in addition to or to the exclusion of the hapten. Frequently the length of the linker must be optimized to ensure accessibility of the bioconjugate for a binding interaction or to otherwise maximize the signal from the label (*8*, *9*, *12*−*20*). At others times, the linker must be modified to increase the solubility of the bioconjugate. In these cases, the linker group remains intact once the bioconjugate is formed, i.e., no covalent bonds are intentionally formed or broken. It is advantageous at other times to incorporate a linker that can be selectively cleaved, thus separating the label from the hapten or macromolecule (*21*−*24*).

We have recently reported on the synthesis and characterization of a new class of highly hydrophilic N^{10}-(3-sulfopropyl)-*N*-sulfonyl-acridinium-9-carboxamide chemiluminescent labels (*25*, *26*) (**1**, Figure 1). The linker groups used in bioconjugates with these labels are *not* chemically inert; in fact, they might be expected to exert a profound influence on the chemiluminescent reaction. As shown in the figure, on treatment with basic hydrogen peroxide, N^{10}-(3-sulfopropyl)-*N*-sulfonyl-acridinium-9-carboxamide labeled tracers or conjugates give rise to the light emitting N^{10}-(3-sulfopropyl)-9-acridone (**6**) with loss of the linking group (**5**) (*27*). Examination of unconjugated N^{10}-(3-sulfopropyl)-*N*-sulfonyl-acridinium-9-carboxamides showed that changing the R and R′ groups in the linker could result in a greater than 20-fold change in the chemiluminescence lifetime of the label, while the total light output remained essentially constant (*26*). If the linker-dependent variability displayed in solution by the unconjugated label were to be duplicated once the label was incorporated into an assay, two effects would be expected. Conjugates using the slower emitting labels would require longer read times to harvest the maximum amount of signal and therefore exhibit a negative impact on the throughput of the assay. Alternatively, signal could be sacrificed for shorter read times and higher throughput, but with the result of poorer sensitivity. For assays designed for analytes present in the microgram per millilter concentration range, however, less signal may be a beneficial characteristic. Many automated chemiluminescent detectors are tuned for maximum sensitivity and are likely to be overwhelmed by the signal generated in assays for high-concentration analytes.

To assess the magnitude of these effects, haptens for the high-concentration analytes phenobarbital (*28*) and phenytoin (*29*−*32*) were conjugated to N^{10}-(3-sulfopropyl)-*N*-sulfonyl-acridinium-9-carboxamides via representative linking groups from the previous model study (*26*). The effect of the linker on the observed signal using a short read time was evaluated in a microtiter plate chemiluminescent immunoassay format using the complementary sheep polyclonal antibodies specific for the respective tracers.

MATERIALS AND METHODS

Sheep polyclonal *anti*-phenobarbital and *anti*-phenytoin were obtained from the Abbott Laboratories antibody production facility (Abbott Laboratories, Abbott Park, IL). Phenobarbital and phenytoin calibrators were taken from the Abbott AxSYM assay kits for those analytes. Reagent-grade sheep polyclonal IgG[1] was purchased from Sigma Chemical Co. (St. Louis, MO.) The HiTrap protein G affinity column (5 mL) was purchased from Amersham Pharmacia (Piscataway, NJ). The FPLC system used consisted of a liquid chromatography controller (LCC-500, Pharmacia LKB) control unit (UV-1) and optical unit (LKB, UV-1). The MicroLumat Plus microplate lumi-

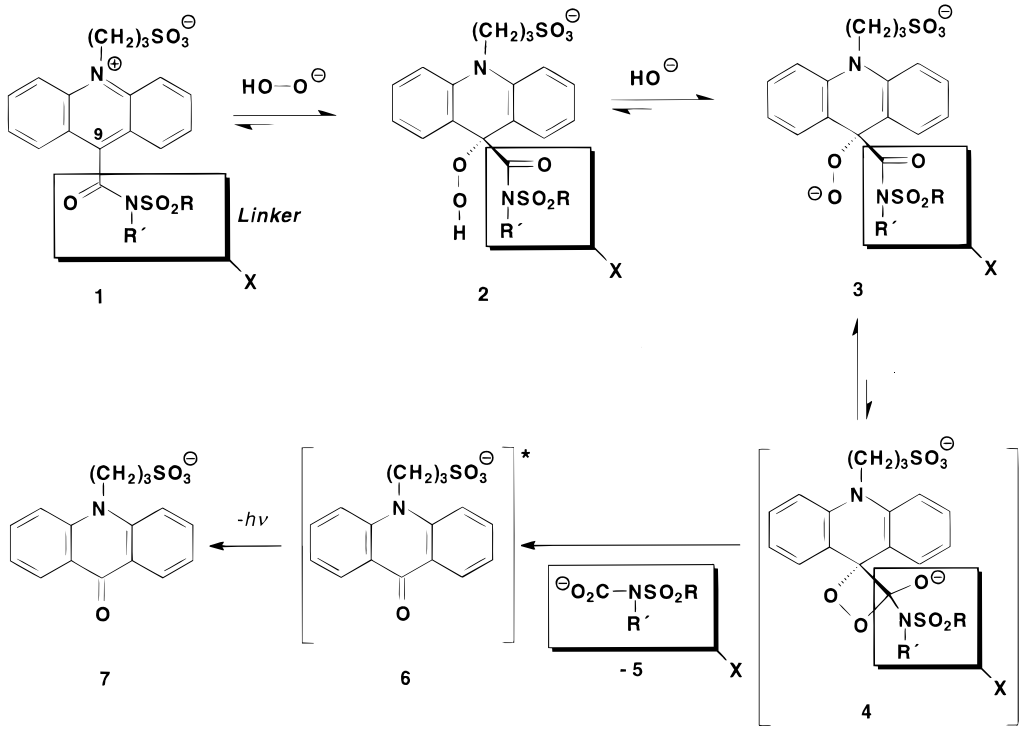

Figure 1. Reaction of N^{10}-(3-sulfopropyl)-*N*-sulfonyl-acridinium-9-carboxamides with basic hydrogen peroxide.

nometer LB 96V equipped with WinGlow software and the microtiter plates were obtained from EG&G Berthold (Gaithersburg, MD).

All reagents for synthesis were purchased from Aldrich Chemical Co. (Milwaukee, WI) or Sigma Chemical Co. and used without further purification, except where noted. All the solvents employed were of HPLC grade purchased from EM Science (Gibbstown, NJ) and used as received. ^{1}H NMR (300 MHz) and ^{13}C NMR (75 MHz) spectra were recorded on a Varian Gemini spectrometer in the solvent noted; chemical shifts (δ) are reported in parts per million relative to TMS; coupling constants (J) are reported in hertz. Mass spectra were obtained on a Perkin-Elmer Sciex API 100 electrospray mass spectrometer in the positive ion mode unless noted otherwise. Reversed-phase (RP) analytical HPLC was performed using a Waters μBondapak C_{18} 10 μm (8 mm × 100 mm) column eluting at 2 mL/min (elution solvent ratio v/v reported) with UV detection at 254 nm, unless otherwise stated. Preparative RP-HPLC was performed using a Waters μBondapak C_{18} 10 μm (40 mm × 100 mm) column eluting at 45 mL/min (elution solvent ratio v/v reported) with UV detection at 254 nm, unless otherwise stated. IUPAC names of new compounds were obtained using the ACD/ILab Web service version 3.5 at http://www.acdlabs.com/ilab.

Diethyl 2-Phenyl-2-[6-(tetrahydro-2H-pyran-2-yloxy)hexyl]malonate (9). To a suspension of KH (3.19 g, 35% w/w, 27.9 mmol) in THF (20 mL) was added diethyl phenylmalonate **8** (4.39 g, 18.60 mmol) in DMF (20 mL). After stirring for 1 h, 1-bromo-6-tetrahydropyranyloxyhexane (4.93 g, 18.6 mmol) in THF (8 mL) and DMF (8 mL) was added and the resulting mixture was heated to reflux for 14 h. The reaction solution was cooled, then poured into water (50 mL), and extracted with dichloromethane (3 × 50 mL). The extract was dried over anhydrous sodium sulfate, filtered, and evaporated in vacuo to give a brown oil which was purified by column chromatography (silica gel, 10−20% ethyl acetate in hexane). Fractions were pooled then evaporated in vacuo to afford **9** (3.78 g, 48%). ^{1}H NMR ($CDCl_3$): 7.43−7.28 (5 H, m), 4.55 (1 H, t, J = 3), 4.22 (4 H, m), 3.84 (1 H, m), 3.71 (1 H, m), 3.68 (1 H, m), 3.36 (1 H, m), 2.27 (1 H, m), 1.68 (1 H, m), 1.52 (7 H, m), 1.28 (7 H, m), 1.20 (6 H, m). ESI-MS: m/z 437 $(M + NH_4)^+$. Analytical HPLC (8 mm × 100 mm Nova-Pak HR C_{18}, 0.05% trifluoroacetic acid in acetonitrile/0.05% aqueous trifluoroacetic acid, 80:20): 3.91 min, >90%.

5-Phenyl-5-[6-(tetrahydro-2H-pyran-2-yloxy)hexyl]-2,4,6(1H,3H,5H)-pyrimidinetrione (10). Sodium (0.7 g, 30.5 mmol) was dissolved in ethanol (8 mL). Urea (0.602 g, 10.03 mmol) and **9** (3.66 g, 8.72 mmol) were then added. The resulting solution was heated to reflux for 14 h. Ice was added, and the solution was acidified with concentrated HCl to pH 1. The solution was extracted with dichloromethane (4 × 50 mL). The extract was dried over anhydrous sodium sulfate, filtered, and evaporated in vacuo to give a yellow oil which was purified by column chromatography (silica gel, 25−75% ethyl acetate in hexane). Fractions were pooled then evaporated in vacuo to afford **10** (1.21 g, 36%). ^{1}H NMR ($CDCl_3$): 7.35 (5 H, m), 4.56 (1 H, q, J = 3.5), 3.87 (1 H, m), 3.71 (1 H, m), 3.51 (1 H, m), 3.36 (1 H, m), 2.40 (1 H, m), 1.69 (2 H, m), 1.52 (8 H, m), 1.25 (9 H, m). ESI-MS: (negative ion) m/z 387 $(M - H)^-$. Analytical HPLC (8 mm × 100 mm Nova-Pak HR C_{18}, 0.05% trifluoroacetic acid in acetonitrile/0.05% aqueous trifluoroacetic acid, 45:55): 5.33 min, >90%.

5-(6-Hydroxyhexyl)-5-phenyl-2,4,6(1H,3H,5H)-pyrimidinetrione (11). A solution of **10** (1.21 g, 3.12 mmol) in THF (6 mL) and HCl (2 N, 6 mL) was stirred for 4 h. The reaction mixture was extracted with dichloromethane (40 mL × 5). The combined extracts were dried over anhydrous sodium sulfate, filtered, and evaporated in vacuo to give a light yellow oil which was purified by column chromatography (silica gel, 30−75% ethyl acetate in hexane). Fractions were pooled and then evaporated in vacuo to afford **11** (0.276 g, 30%). ^{1}H NMR (CD_3OD): 7.36 (5 H, m), 3.31 (2 H, m), 2.32 (2 H, m), 1.51 (2 H, m), 1.37 (6 H, m). ESI-MS: (negative ion) m/z 303 $(M - H)^-$.

Analytical HPLC (8 × 100 mm, Nova-Pak HR C_{18}, 0.05% trifluoroacetic acid in acetonitrile/0.05% aqueous trifluoroacetic acid, 30:70): 3.45 min, >99%.

6-(2,4,6-Trioxo-5-phenylhexahydro-5-pyrimidinyl)hexyl 2-[(*tert*-Butoxycarbonyl)amino]ethylcarbamate (12). To a solution of **11** (274 mg, 0.901 mmol) in THF (5 mL) was added phosgene in toluene (1.93 N, 10 mL, 19.3 mmol). After stirring for 3 h, the reaction mixture was evaporated in vacuo. The residue was redissolved in THF (10 mL) and cooled to 0 °C. *tert*-Butyl *N*-(2-aminoethyl)carbamate (624 mg, 3.9 mmol) was added and the solution was stirred for 2 h. After removing the solvent in vacuo, the residue was purified by column chromatography (silica gel, 60−75% ethyl acetate in hexane). Fractions were pooled then evaporated in vacuo to afford **12** (426 mg, 96%). ^{1}H NMR ($CDCl_3$): 9.49 (1 H, br), 7.36 (5 H, m), 5.39 (1 H, br), 5.02 (1 H, br), 4.02 (2 H, m), 3.25 (4 H, m), 2.40 (2 H, m), 1.53 (2 H, m), 1.42 (9 H, s), 1.25 (6 H, m). ESI-MS (negative ion): *m*/*z* 489 $(M - H)^-$. Analytical HPLC (8 × 100 mm Nova-Pak HR C_{18}, 0.05% trifluoroacetic acid in acetonitrile/0.05% aqueous trifluoroacetic acid, 40:60): 5.83 min, >99%.

6-(2,4,6-Trioxo-5-phenylhexahydro-5-pyrimidinyl)hexyl 2-Aminoethylcarbamate (13). To a solution of **12** (152 mg, 0.310 mmol) in dichloromethane (2 mL) was added trifluoroacetic acid (2 mL). After stirring for 15 min, the reaction mixture was evaporated in vacuo to afford **13**. ^{1}H NMR (CD_3OD): 7.38 (5H, s), 4.04 (2 H, t, J = 6), 3.36 (2 H, t, J = 6), 3.02 (2 H, t, J = 6), 2.34 (2 H, m), 1.61 (2 H, m), 1.39 (8 H, m). ESI-MS: *m*/*z* 391 $(M + H)^+$. Analytical HPLC (8 × 100 mm prep Nova-Pak HR C_{18}, 0.05% trifluoroacetic acid in acetonitrile/0.05% aqueous trifluoroacetic acid, 25:75): 3.52 min, >99%. The residue was dissolved in DMF (4 mL), and the solution (0.08 mmol/mL) was retained for use in later reactions.

3-(6-Bromohexyl)-5,5-diphenyl-2,4-imidazolidinedione (15) (*33*). Potassium hydroxide (628 mg, 10.0 mmol) was added to a suspension of 5,5-diphenylhydantoin (**14**, 2.52 g, 10.0 mmol) in absolute ethanol (50 mL). The reaction mixture was stirred for 2 h under a nitrogen atmosphere at ambient temperature. Removal of solvents in vacuo afforded the desired phenytoin potassium salt. The salt was added to a solution of 1,6-dibromohexane (24.4 g, 100 mmol) in acetonitrile (70 mL). The mixture was refluxed under a nitrogen atmosphere for 22 h, cooled, and poured into 1:1 ethyl acetate/water (150 mL). The two layers were separated. The aqueous layer was extracted with ethyl acetate (2 × 50 mL). The combined organic extracts were washed with brine (25 mL), dried over anhydrous sodium sulfate, and evaporated in vacuo to give an oily residue. The residue was purified by flash chromatography (silica gel, 20−50% ethyl acetate in hexanes) to afford the bromide **15** (2.03 g, 45%). ^{1}H NMR ($CDCl_3$): 7.41−7.34 (10 H, m), 6.55 (1 H, s), 3.58 (2 H, t, J = 7.3), 3.34 (2 H, t, J = 6.8), 1.77 (2 H, p, J = 7.1), 1.66 (2 H, p, J = 7.4), 1.44 (2 H, p, J = 7.4), 1.30 (2 H, p, J = 7.3). ESI-MS: *m*/*z* $(M + NH_4)^+$ 432, 434.

3-(6-Aminohexyl)-5,5-diphenyl-2,4-imidazolidinedione Trifluoroacetate Salt (16). Ammonium hydroxide (13 mL, 65 mmol) was added to a solution of 3-(6-bromohexyl)-5,5-diphenyl-2,4-imidazolidinedione (**15**) (415 mg, 1.00 mmol) in water (15 mL) and dioxane (30 mL). After stirring for 2 days at reflux, the solvents were removed in vacuo to give an oil. Purification by preparative reversed-phase HPLC (acetonitrile/0.03% aqueous trifluoroacetic acid, 30:70) afforded the desired amine TFA salt **16** (122 mg, 35%). ^{1}H NMR ($CDCl_3$): 7.94 (2 H, br s), 7.61 (1 H, s), 7.31 (10 H, s), 3.49 (2 H, t, J = 6.9), 2.84 (2 H, br s), 1.64−1.53 (4 H, m), 1.38−1.16 (4 H, m). ESI-MS: $(M + H)^+$ 352. Analytical HPLC (acetonitrile/0.03% aqueous trifluoroacetic acid, 30:70): 10.65 min, 99.8%.

Preparation of N^{10}-(3-Sulfopropyl)-*N*-sulfonylacridinium-9-carboxamide Active Esters. *3-[9-({{4-[(2,5-Dioxo-1-pyrrolidinyl)oxy]-4-oxobutyl}[(4-methylphenyl)-sulfonyl]amino}-carbonyl)-10-acridiniumyl]-1-propanesulfonate (**17**).* 9-[[(3-Carboxypropyl)[(4-methylphenyl)-sulfonyl]amino]-carbonyl]-10-(3-sulfopropyl)-acridinium inner salt (*25*) (8.00 g, 13.68 mmol) was suspended in DMF (80 mL) and pyridine (11 mL). A solution of *N*-trifluoroacetoxysuccinimide (*34*) (29 g, 137 mmol) in DMF (80 mL) was added. All the solids gradually dissolved after which a yellow precipitate formed. After stirring for 24 h in the dark, the precipitate was collected by filtration and washed sequentially with ethyl acetate (200 mL), cold ethanol (60 mL), and again with ethyl acetate (2 × 200 mL). Further drying in vacuo afforded the desired active ester **17** (9.5 g, 99%). ^{1}H NMR ($CDCl_3$): 9.00 (2 H, m), 8.44 (2 H, m), 8.19 (1 H, d, J = 8.4), 8.50−7.80 (4 H, m), 7.67 (1 H, d, J = 8.5), 7.17 (2 H, m), 5.63 (2 H, m), 4.30 (2 H, m), 3.01 (2 H, t, J = 7.0), 2.87 (4 H, s), 2.32 (3 H, s), 1.74 (2 H, m). Analytical RP-HPLC (4.6 × 300 mm μBondapak C_{18}, acetonitrile/0.1% aqueous formic acid, 30:70, 1 mL/min, 254 nm): 4.34 min, 97%. ESI-MS: *m*/*z* 683 $(M + H)^+$. Anal. calcd for $C_{32}H_{31}N_3O_{10}S_2$: C, 56.38; H, 4.58; N, 6.16; S, 9.41. Found: C, 56.15; H, 4.70; N, 6.24; S, 9.31.

*3-(9-{[Isopropyl({4-[4-oxo-4-(2,3,4,5,6-pentafluorophenoxy)butyl]phenyl}sulfonyl)amino] carbonyl}-10-acridiniumyl)-1-propanesulfonate (**18**).* 3-(9-{[{[4-(3-Carboxypropyl)phenyl]sulfonyl} (isopropyl)-amino]carbonyl}-10-acridiniumyl)-1-propanesulfonate inner salt (*26*) (100 mg, 0.16 mmol) and pentafluorophenyl trifluoroacetate (550 μL, 3.2 mmol) were dissolved in dimethylformamide (2 mL). Pyridine (260 μL, 3.2 mmol) was added, and the solution was stirred for 16 h. Afterward, the reaction mixture was evaporated in vacuo and the residue was triturated with diethyl ether (4 × 5 mL). The remaining solid was purified by preparative RP-HPLC (μ-Bondapak C_{18}, acetonitrile/0.05% aqueous TFA 45:55, λ = 254 nm, 70 mL/min) to afford the desired active ester **18** (52%). ^{1}H NMR ($CDCl_3$): 9.10−8.90 (2 H, m), 8.50−8.30 (2 H, m), 8.30−7.25 (8 H, m), 5.82 (2 H, m), 4.44 and 3.70 (1 H, m), 4.37 and 3.64 (2 H, m), 1.62 and 1.43 (6 H, d, J = 6.7), 3.0−1.20 (10 H, m). ^{13}C NMR ($CDCl_3$): δ 173.2, 168.9, 165.5, 164.1, 160.2, 159.7, 153.1, 150.7, 150.3, 149.6, 148.6, 142.8, 141.4, 141.2, 141.0, 140.3, 140.0, 139.5, 139.3, 137.8, 137.7, 136.7, 136.1, 133.9, 131.3, 129.8, 129.7, 129.4, 129.1, 129.0, 128.3, 127.4, 126.7, 124.9, 122.3, 122.1, 119.9, 119.6, 119.3, 117.7, 113.9, 57.0, 55.1, 50.8, 50.5, 47.8, 34.7, 34.5, 32.4, 32.3, 25.7, 25.6, 24.8, 21.7, 19.9, 19.4, 17.3. ESI-MS: *m*/*z* 779.4 $(M + H)^+$. Analytical HPLC (4.6 × 300 mm μBondapak C_{18}, acetonitrile/0.05% aqueous trifluoroacetic acid, 50:50, 1 mL/min): 14.58 min, >95%.

Antibody purification. Sheep serum proteins were precipitated by the slow, dropwise addition of saturated NH_4SO_4 until a final concentration of 50% saturated NH_4SO_4 was reached. The sample was then allowed to stand for 12 h at 4−8 °C. The precipitate was then pelleted using ultracentrifugation, the supernatant discarded, and the pellet taken up in PBS (10 mL, 100 mM sodium phosphate, 150 mM NaCl, pH 7.0). The mostly dissolved serum proteins were clarified by filtration (0.2 μm polyethersulfone syringe filter, Nalge Nunc International, Rochester, NY) and then dialyzed exhaustively against PBS. The resulting solution was loaded onto a HiTrap protein G column (0.5 mL/min) that had been equilibrated with sodium phosphate buffer (20 mM, pH 7.0). When the A_{280} of the eluant returned to background, the bound antibodies were eluted with aqueous glycine-HCl (100 mM, pH 2.7, 3 mL/min). Fractions with an A_{280} > 0.1 AU were pooled, immediately neutralized with Tris buffer (1 M, pH 9.0), and then dialyzed exhaustively against PBS. The antibody solutions were concentrated to 5−10 mg/mL using ultracentrifugation (Centriprep 30, Millipore, Bedford, MA) and stored at −78 °C prior to use. Concentration of the antibody stock solutions was determined using an extinction coefficient of 1.4 $(mg/mL)^{-1}\ cm^{-1}$ (*35*).

Chemiluminescence Evaluation of Phenobarbital (21−24) and Phenytoin (25−28) Tracers on Binding with Antibodies. *Immobilization of the Antibodies.* Each antibody (*anti*-phenobarbital, *anti*-phenytoin, and control sheep polyclonal serum) was diluted with sodium bicarbonate buffer (100 mM, pH 9.6) to afford the desired concentration stock solution (2.5 μg/mL). Each antibody solution was dispensed into the microtiter plate (200 μL/well) and incubated at ambient temperature (2 h) to allow for passive immobilization. After the antibody solution was aspirated, the each well was then treated with 2% nonfat dry milk dissolved in PBS buffer (pH 7.2, 200 μL/well) for 1 h.

Determining Microtiter Plate-Bound Antibody Binding Capacity. All tracers were first dissolved in absolute ethanol to afford the desired concentration stock solutions (0.5 mM). Each stock solution was serially diluted with 2% nonfat dry milk dissolved in PBS buffer to make tracer solutions ranging from 5.0 μM to 10 pM. Tracer solutions (150 μL/well) were added to each well of the corresponding immobilized antibody and incubated at

Table 1. Acridinium-Labeled Tracers

Hapten	N^{10}-(3-Sulfopropyl)-*N*-sulfonylacridinium-9-carboxamide active ester	Tracer Structure
Phenobarbital (**13**)	**17**	 **21**
	18	 **22**
	19	 **23**
	20	 **24**
Phenytoin (**16**)	**17**	 **25**
	18	 **26**
	19	 **27**
	20	 **28**

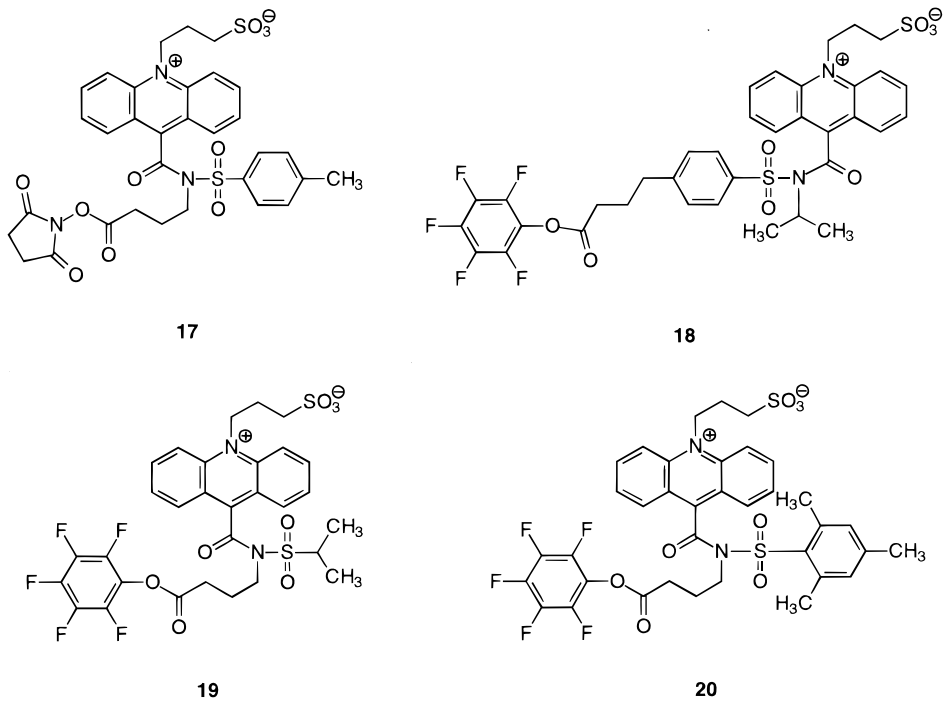

Figure 2. N^{10}-(3-Sulfopropyl)-*N*-sulfonylacridinium-9-carboxamide active esters.

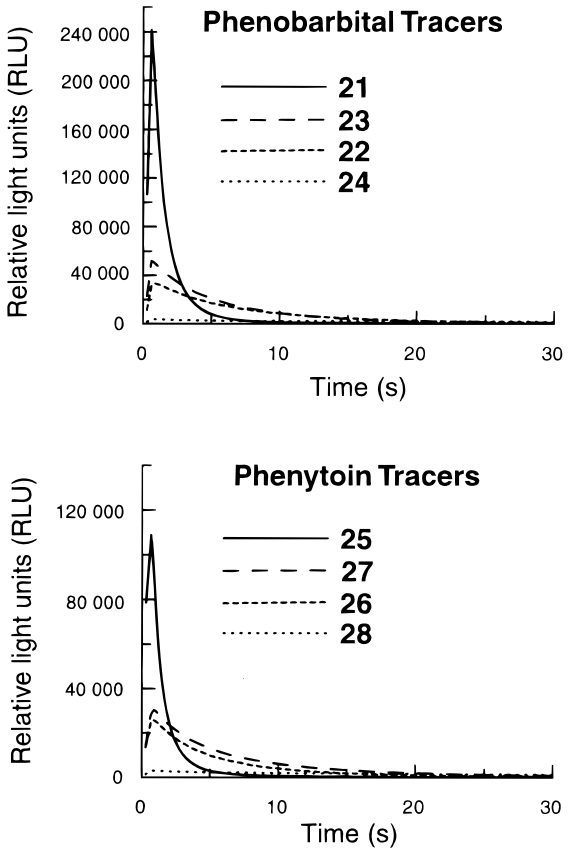

Figure 3. Typical chemiluminescent emission vs time profile for each linker modified tracer. Each microtiter well was coated with polyclonal *anti*-phenobarbital or *anti*-phenytoin antibody solution (2.5 μg/mL, 200 μL/well). Phenobarbital tracers (**21**−**24**, 250 nM, 150 μL/well) and phenytoin tracers (**25**−**28**, 100 nM, 150 μL/well) were incubated with the immobilized antibodies for 1 h. Chemiluminescence was recorded for 30 s.

ambient temperature for another 1 h. Afterward, the plate was thoroughly washed (PBS, 0.1% Tween-20, 6 × 1 min). The plate was transferred to the luminometer, and each well was sequentially triggered [200 μL, 1:1 solution A (0.35 M sodium hydroxide, 2% Triton X-100)/ solution B (0.008 N HNO_3, 1.32% H_2O_2, 0.09% DTPA)]. Chemiluminescence emission from each well was recorded for 30 s. A typical chemiluminescent emission vs time profile for each tracer (**21**−**24**, 250 nM; **25**−**28**, 100 nM) is shown in Figure 3. Plots of the total chemiluminescent emission (initial 3 s) first vs tracer concentration are shown in Figure 4. Nonspecific chemiluminescence background from control sheep polyclonal serum was subtracted to get the specific chemiluminescence signal for the *anti*-hapten antibody/tracer complex. Relative chemiluminescence output was calculated by comparing the saturated responses of each phenobarbital or phenytoin tracer to that of tracers **21** and **25**, respectively, and is reported in Table 2.

Assessing the Effect of Linker Chemistry on Antibody Affinity (IC_{50}). Solutions (150 μL), each containing a phenobarbital tracer (**21**−**24**) (1.0 μM) and phenobarbital (100 μM-10 nM), were dispensed into separate microtiter wells and incubated at ambient temperature for 1 h with the immobilized *anti*-phenobarbital antibody. The plate was thoroughly washed (PBS, 0.1% Tween-20, 6 × 1 min). Bound tracer was triggered, and chemiluminescence was measured for 30 s. The signal at each analyte concentration was normalized using the noninhibited chemiluminescence signal as the reference. The IC_{50} value for each tracer was determined from a plot (Figure 5) of normalized signal vs analyte concentration using this four parameter logistic (GraFit 3.0) (*36*):

$$Y = \frac{a}{1 + (x/\mathrm{IC}_{50})^{s}} + \text{background}$$

where *a* is the maximum *y* range, *s* is a slope factor, and *x* represents the concentration of analyte.

The experiment was repeated with phenytoin tracers **25**−**28**.

Effect of Signal Modulation on the Chemiluminescence Dose/Response Curve. Each phenobarbital acridinium tracer (**21**−**24**) was diluted into 2% nonfat dry milk in

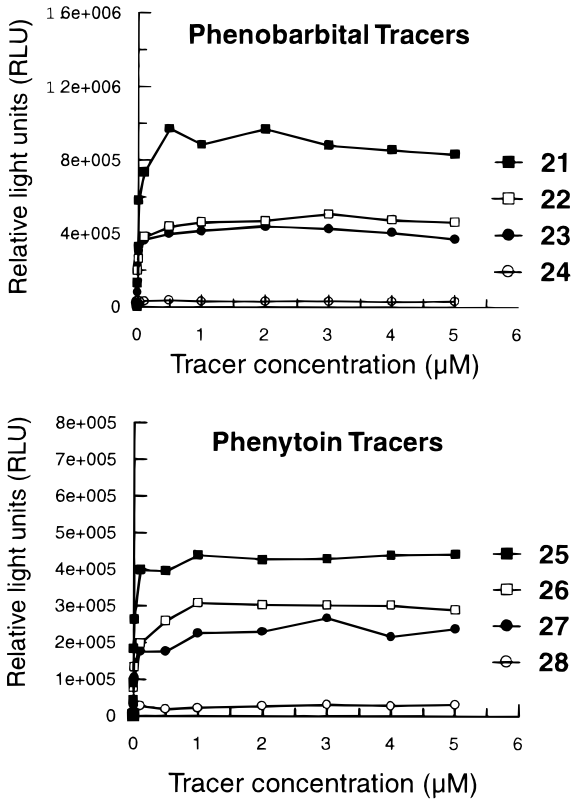

Figure 4. Total chemiluminescent emission vs tracer concentration. After polyclonal *anti*-phenobarbital or *anti*-phenytoin antibody was immobilized (2.5 μg/mL, 200 μL/well), each tracer solution with concentration ranging from 0.001, 0.01, 0.1, 1.0, 10, 100 nM, 1.0, 2.0, 3.0, 4.0, to 5.0 μM was incubated (150 μL/well). The saturated chemiluminescence response of each tracer was averaged and normalized to obtain the relative chemiluminescence output.

Table 2. Linker Affect on Chemiluminescent Signal and Antibody Affinity

compd	relative signal (3 s)	IC_{50} (μM)
phenobarbital tracers		
21	1.00	5.5
22	0.57 ± 0.14	1.8
23	0.49 ± 0.11	2.1
24	0.04 ± 0.01	2.3
phenytoin tracers		
25	1.00	14.0
26	0.65 ± 0.07	7.7
27	0.54 ± 0.07	9.2
28	0.06 ± 0.03	14.6

PBS buffer, pH 7.2, to obtain a stock solution (250 nM). To each well of the *anti*-phenobarbital coated plate were added a tracer (145 μL) and one of six phenobarbital calibrators (0, 5, 10, 20, 40, and 80 μg/mL, 5 μL). The plate was incubated for 1 h and washed, and the chemiluminescence was recorded for 3 s (Figure 6).

Evaluation of the phenytoin tracers **25**−**28** was conducted similarly. The concentration of each phenytoin tracer solution was 100 nM, and the concentration of the phenytoin calibrators were 0, 2.5, 5, 10, 20, and 40 μg/mL.

RESULTS

Preparation of Haptens and Chemiluminescent Tracers. Each hapten was prepared by standard protocols. Thus, phenobarbital hapten **13** was prepared in six steps from diethyl phenylmalonate **8** (Scheme 1), while

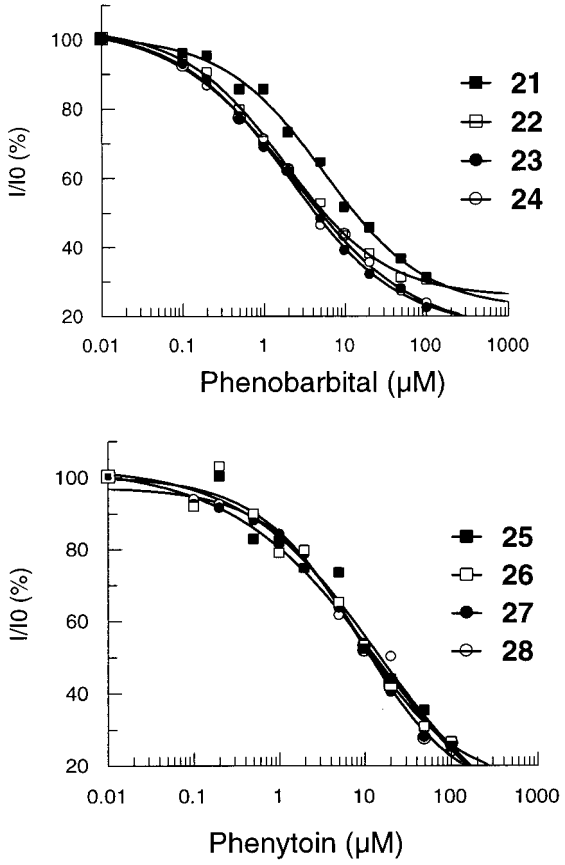

Figure 5. The effect of linker chemistry on antibody avidity (IC_{50}). The total concentration of each tracer was fixed at 1.0 μM. Phenobarbital or phenytoin was diluted into each tracer stock (1.0 μM) to get final phenobarbital or phenytoin concentration of 0.01, 0.1, 0.2, 0.5, 1.0, 2.0, 5.0, 10, 20, 50, and 100 μM. The normalized chemiluminescence count (I/I_0) was plotted against each inhibitor concentration.

diphenylhydantoin **14** afforded the desired phenytoin hapten **16** in two steps (Scheme 2).

The requisite active esters of the chemiluminescent acridinium salts **17**−**20** (Figure 2) were prepared from the corresponding free acids (*25*, *26*). *N*-Hydroxysuccinimide active ester **17** precipitated from the reaction of the free acid with *N*-trifluoroacetoxysuccinimide in nearly quantitative yield. Pentafluorophenyl active esters **18**-**20** were isolated in 52−88% yield as lyophilized powders after purification by preparative reversed-phase HPLC.

Reaction of the phenobarbital and phenytoin aminated haptens **13** and **16** with each of the chemiluminescent acridinium salt active esters **17**−**20** in buffered aqueous DMF afforded the chemiluminescent tracers **21**-**28** listed in Table 1 in 26−78% yield after preparative RP-HPLC.

Evaluation of Chemiluminescent Phenobarbital and Phenytoin Tracers with Polyclonal Antibodies. Purified sheep *anti*-phenobarbital, *anti*-phenytoin IgGs, and a control sheep antisera were dispensed into the wells of a white polystyrene microtiter plate (500 pg/well) and incubated for 2 h. Afterward, the plate was overcoated with a 2% solution of nonfat dry milk in PBS buffer to minimize nonspecific binding of the acridinium tracers. Solutions of the complementary chemiluminescent tracers were added to each well (150 μL, 10 pM to 5 μM, corresponding to 1.5 fmol to 750 pmol/well). After incubation and washing, the chemiluminescence was triggered and recorded for 30 s. From this experiment both the chemiluminescence profile of the tracers in the

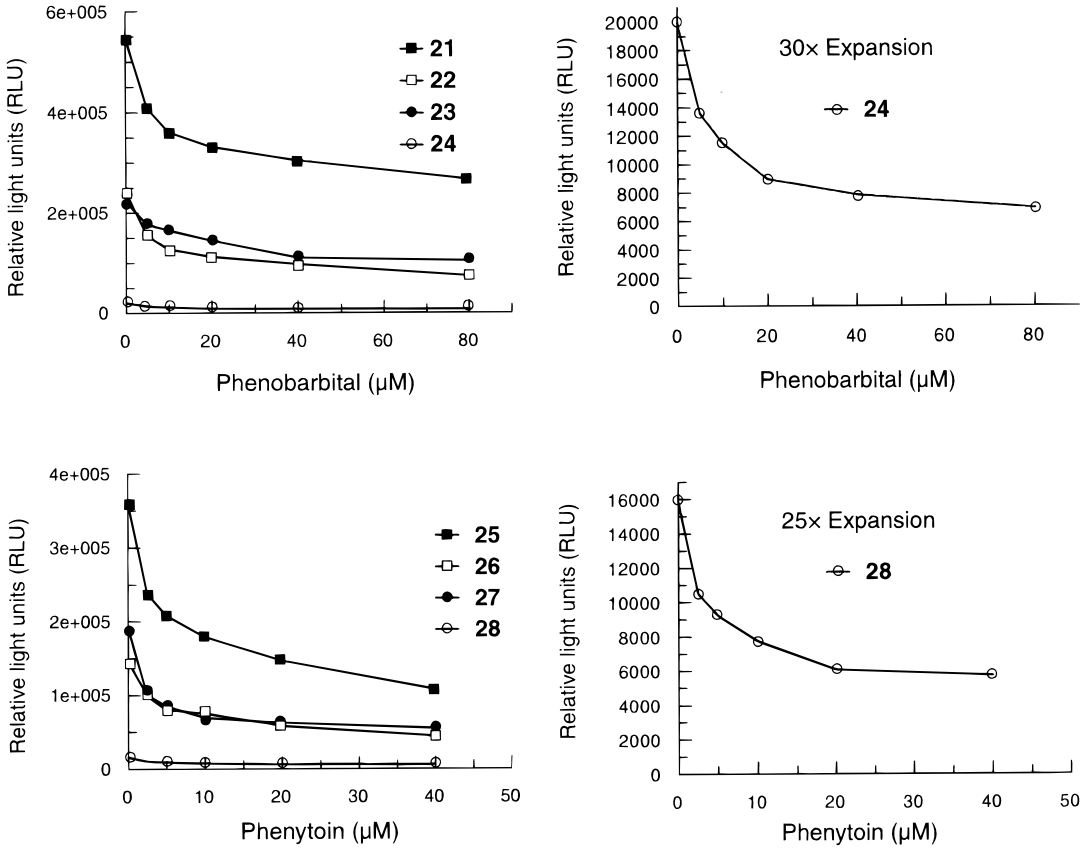

Figure 6. Linker-mediated signal modulation in a solid-phase chemiluminescence assay. Each tracer series, **21**−**24** (145 μL, 250 nM) and **25**−**28** (145 μL, 100 nM) was incubated with the complementary immobilized antibody and calibrators (5 μL of 0, 5, 10, 20, 40, and 80 μg/mL for phenobarbital; 0, 2.5, 5, 10, 20, and 40 μg/mL for phenytoin) for 1 h. Chemiluminescence was then triggered and recorded for 3 s.

presence of the corresponding antibodies and the binding capacity of the immobilized antibodies could be determined.

Thus, the change in the chemiluminescence signal from each tracer (**21**−**28**) over the observation period paralleled that which was recorded for the unconjugated *N*-sulfonylacridinium-9-carboxamide acids (*26*) in the absence of antibody. Figure 3 illustrates this point for a single concentration of the phenobarbital (**21**−**24**, 37.5 pmol) and phenytoin (**25**−**28**, 15 pmol) tracers, respectively. The chemiluminescence signal from phenobarbital tracer **21** and phenytoin tracer **25**, both derived from acridinium label **17**, peaked within 2 s and was essentially exhausted within 6 s. At the other extreme, tracers **24** and **28**, derived from active ester **20** had a nearly constant lower-level glow over the entire observation period. Even so, regardless of the linker used to attach the acridinium nucleus, the total harvested signal remained essentially constant (data not shown). Therefore, as a practical demonstration of the signal modulating effect of the linkers, subsequent experiments used only the signal recorded in the first three seconds of the chemiluminescent reaction.

Figure 4 shows that the immobilized antibodies were saturated once the concentration of chemiluminescent tracer reached about 1 μM. A comparison of the chemiluminescence signal at saturation also demonstrated the effect of the linker chemistry. The signals for the tracers in each series were normalized to the phenobarbital tracer **21** or phenytoin tracer **25**, respectively. As shown in Table 2, the signal of phenobarbital tracers **22** and **23**, which possessed the more sterically demanding isopropyl-substituted linkers, were reduced nearly 50%, while the light emission from **24** that carried the even more sterically hindered mesityl group, was decreased to only 4% of **21**. Phenytoin tracers demonstrated the same trend.

The linker chemistry had little effect on the binding interaction of the tracers with the antibodies, as evidenced by the slight differences in the observed inhibition constant (IC_{50}) in the presence of free phenobarbital or phenytoin. Solutions containing each tracer (1.0 μM) and fixed concentrations of the free analytes (0, 0.01, 0.1, 0.2, 0.5, 1.0, 2.0, 5.0, 10, 20, 50, and 100 μM) were allowed to compete for the available antibody binding sites on the microtiter plate, causing a decrease in the observed chemiluminescence signal. For each tracer, the chemiluminescence signal at each inhibitor concentration was normalized to the uninhibited chemiluminescence signal (Figure 5). IC_{50} values (Table 2) of three phenobarbital tracers **22**−**24** were very similar (1.8, 2.1, and 2.3 μM, respectively). Phenobarbital tracer **21** has an IC_{50} of 5.5 μM. The inhibition constants of phenytoin tracers **25**−**28** were also close to each other, ranging from 7.7 to 14.6 μM.

Modulating Effect of Acridinium Linker Chemistry in an Immunoassay Format. The polyclonal *anti*-phenobarbital and *anti*-phenytoin antibodies were immobilized on the microtiter plate as described above (500 pg/well). To generate calibration curves, each tracer series **21**−**24** (145 μL, 250 nM) and **25**−**28** (145 μL, 100 nM) was incubated with the complementary immobilized antibody and calibrators (5 μL of 0, 5, 10, 20, 40, and 80 μg/mL for phenobarbital; 0, 2.5, 5, 10, 20, and 40 μg/mL for phenytoin) for 1 h. Chemiluminescence was then triggered and recorded for 3 s. The integrated chemilumi-

nescence signals were plotted vs calibrator concentrations (Figure 6). Calibration curves from the four tracers in each series have similar shapes and are roughly parallel to each other. In both series, the *N*-sulfonylacridinium-9-carboxamide tracers bearing the mesityl-substituted linker showed the most pronounced attenuation of signal, while the isopropyl derivatives produced an intermediate signal.

DISCUSSION

It was previously demonstrated that chemiluminescent *N*-sulfonylacridinium-9-carboxamide labels all produce the same excited-state acridone (**6**, Figure 1**)** but have different light-generating profiles in solution that are governed by the steric and electronic properties of the linking group (*26*). In an immunoassay for low-molecular weight analytes, these labels must be conjugated to hapten molecules to form tracers that interact further with antibodies and the sample containing the analyte of interest. Commonly, these chemiluminescent immunoassays (CLIA) are heterogeneous, i.e., the antibody component is immobilized on a solid support such as a microtiter plate or microparticles. The noncovalent tracer/antibody complex may dissociate under the stringent conditions of the chemiluminescent reaction. If so, the chemiluminescence profile of the tracer in a heterogeneous immunoassay should parallel profile of the unconjugated label in solution; the signal generated would be affected by the linker substituents. In the absence of dissociation, the linking group may be sufficiently long to allow the triggering reagents access to the acridinium nucleus unhindered by the antibody. On the other hand, the tracer molecule may be deeply docked into the antigen-binding region of the antibody, making the tracer less accessible to the triggering reaction. The chemiluminescence profile of the tracer might then be different from that of the corresponding unconjugated acridinium label. Additionally, the interaction with the antibody could have a leveling effect, masking differences due to the chemical reactivity of the linking group.

In this study, the data support the first or second scenario. Four *N*-sulfonylacridinium-9-carboxamide labels, each having linking groups with distinctive steric and electronic properties, were chosen and conjugated to phenobarbital and phenytoin haptens. A chemiluminescence immunoassay was developed for characterizing their light-generating and binding properties. Both phenobarbital and phenytoin tracers showed the same trend seen in the unconjugated labels: the tracers with the least sterically hindered linker, phenobarbital **21** and phenytoin **25**, had the fastest light-emission therefore the most signal within the first three seconds. The tracers with the most sterically hindered linkers, phenobarbital **24** and phenytoin **28**, had dramatically attenuated chemiluminescence within the first three seconds. Their light outputs dropped to about 5% compared to the tracers **21** and **25**. There were no obvious changes in binding interaction between the tracers and antibodies that could be attributed changes in the linker chemistry, as indicated by the inhibition constants (IC_{50}). Even though the IC_{50} value of phenobarbital tracer **21** was about three times higher than the other three phenobarbital tracers, the thermodynamic difference is negligible.

CONCLUSION

Chemiluminescent labels were developed because they offered lower detection limits than fluorescent or enzymatic labels and were more convenient to use than radiolabels. While assays and instrumentation have been fine-tuned to maximize sensitivity, clinically relevant analytes such as phenobarbital and phenytoin are often present in high concentration. So high, that assays that employ high yield chemiluminescent labels often can produce too much signal, overwhelming the instrument detector. The present study indicates that the level of signal produced by *N*-sulfonylacridinium-9-carboxamide tracers in a solid-phase immunoassay format can be modulated by at least 20-fold by the judicious choice of the acridinium-hapten linking group.

Synthesis and Characterization of Novel Spin-Labeled Photoaffinity Nonnucleoside Analogues of ATP as Structural and EPR Probes for Myosin

Xiaoru Chen,[†] Jean Grammer,[†] Roger Cooke,[‡] Edward Pate,[§] and Ralph G. Yount*,[†]

School of Molecular Biosciences, Department of Pure and Applied Mathematics, Department of Chemistry,-Washington State University, Pullman, Washington 99164, and Department of Biochemistry and Biophysics & CVRI, University of California, San Francisco, California 94143. Received March 21, 2000

Two new spin-labeled photoreactive nonnucleoside ATP analogues, 1-(4-azido-2-nitrophenyl)amino-3-(1-oxyl-2,2,5,5-tetramethylpyrrolidinyl-3-carbamido)-2-propyl triphosphate (SL-NANTP) and 2-(4-azido-2-nitrophenyl)amino-2,2-(1-oxyl-2,2,6,6-tetramethyl-4-piperidylidene)di(oxymethylene) ethyl triphosphate (SSL-NANTP), were synthesized and characterized. This study aims to develop a second generation of NANTP-based analogues containing immobile spin labels that can be used to monitor conformational changes in myosin during the contractile cycle of muscle. Previous studies have shown that both a photoaffinity nonnucleoside ATP analogue, 2-[(4-azido-2-nitrophenyl)amino] ethyl triphosphate (NANTP) [Nakamaye et al. (1985) *Biochemistry 24*, 5226−5235], and a photoaffinity ATP analogue, 3′(2′)-*O*-4-[4-oxo-(4-amino-2,2,6,6-tetramethyl-piperidino-1-oxyl)-4-benzoyl] benzoyl adenosine 5′-triphosphate (SL-Bz_2ATP) [Wang et al. (1999) *J. Muscle Res. Cell Motil. 20*, 743−753], behave like ATP in their interactions with myosin. Remarkably, photolabeled myosin recovers all of its normal enzymatic properties after treatment with actin in the presence of MgATP [Luo et al. (1995) *Biochemistry 34*, 1978−1987]. For SL-NANTP, the spin label moiety is attached to NANTP via an aminomethyl side chain. In SSL-NANTP, attachment is via a restricted spiro ring. The two new probes interact with myosin subfragment-1 (S1) in a manner analogous to ATP, and after photoincorporation, labeled S1 recovers full activity after treatment with actin and MgATP. The electron paramagnetic resonance (EPR) spectrum resulting from S1 photolabeled with SL-NANTP shows a very high degree of probe mobility. However, the EPR spectrum of S1 photolabeled with SSL-NANTP shows that the probe is highly immobilized with respect to S1, constrained to move within a cone of angle 52° (full-width, half-max). Unlike the parent, NANTP, which photolabels on the 23 kDa tryptic fragment of S1, SSL-NANTP photolabels on the 20 kDa fragment. Its highly immobile nature means that it is potentially a useful reporter group to monitor cross-bridge motion in muscle fibers.

INTRODUCTION

Electron paramagnetic resonance (EPR)[1] has been a frequently employed method to monitor possible conformational changes of myosin and actin that may occur during active contraction of muscle (reviewed in refs *1* and *2*). The most commonly used target for EPR spin probes is the reactive thiol on the heavy chain of myosin termed SH1 (Cys-707 in rabbit skeletal myosin) (*3*−*7*). SH1 on skeletal myosin can be modified with *N*-(1-oxyl-2,2,6,6-tetramethyl-4-piperidinyl)iodoacetamide (IASL) to provide an immobile probe that can monitor changes in the orientation of myosin heads (*8*). A significant disadvantage to this approach is that chemical modification of SH1 changes the properties of myosin (*8*, *9*) and potentially affects the active tension of muscle fibers (*5*, *10*). Moreover, SH1 is known from the crystal structure of myosin subfragment 1 (S1) to lie in a region between the globular motor domain and the light chain binding domain (*11*). Recently, it was reported that a large and distinct rotation of the myosin light chain domain occurs upon muscle contraction when Cys-108 of the regulatory light chain (RLC) was labeled with a cysteine-specific spin probe, 3-(5-fluoro-2,4-dinitroanilino)-2,2,5,5-tetramethyl-1-pyrrolidinyloxy (*12*). This indicates that movement of the tail portion of myosin heads is important in force generation. Similar probes to monitor possible

movement of the motor domain have depended on spin-labeled ATP analogues (*13*−*15*). The disadvantage to this approach is that a large and sharp spectral signal arises from unbound ATP analogue and overlaps with the desired spectral components from the probe bound at the active site of myosin. This problem potentially can be overcome by use of spin-labeled ATP photoaffinity analogues. As reported previously, it is possible to specifically photolabel rabbit skeletal myosin at Ser-324 with a photoreactive ATP analogue, Bz_2ATP (*16*) and then reactivate the enzyme by treatment with actin and MgATP (*17*). This approach then when combined with a spin label attached to the photoreactive ATP analogue means it should be possible to introduce a site specific label at the active site. As a first step, we have synthesized and studied the spin-labeled photoaffinity ATP analogue, SL-Bz_2ATP (*18*). A photoreactive p,p′-dicarboxybenzophenone moiety is attached to the 2′(3′) hydroxyls of ATP via an ester linkage, and the spin label 4-amino-TEMPO is amidated to the second carboxyl group. SL-Bz_2ATP is a substrate for S1 and myosin in muscle fibers. It can be covalently incorporated at the active site with high specificity and yield, and the photolabeled myosin retains characteristic enzymatic properties. However, the EPR spectrum of SL-Bz_2ATP photolabeled muscle fibers showed that this probe is too mobile to provide orientational information about myosin heads during contraction (*18*).

A second synthetic approach utilizing the smaller nonnucleoside ATP analogue based on NANTP (*19*) was initiated. NANTP is a photoreactive ATP analogue, 2-[(4-azido-2-nitrophenyl)amino]ethyl triphosphate that is a substrate for myosin, Fl ATPase and kinesin (Pate et al., unpublished data). It behaves like ATP when it reacts with myosin (*19*) and supports active tension and shortening of muscle fibers (*20*). Interestingly, it specifically photolabels Trp-130 in the 23 kDa of rabbit skeletal S1 (*21*). After treatment, with actin to weaken analogue binding, NANDP-labeled S1 has normal ATPase activity in the presence of MgATP (*17*).

With these considerations in mind, we set out to design and synthesize new analogues of NANTP containing a nitroxide spin probe in addition to its nitrophenyl azide photoaffinity group. The synthesis and characterization of 1-(4-azido-2-nitrophenyl)amino-3-(1-oxyl-2, 2,5,5-tetramethylpyrrolidinyl-3-carbamido)-2-propyl triphosphate (SL-NANTP) and 2-(4-azido-2-nitrophenyl)amino-2,2-(1-oxyl-2,2,6,6-tetramethyl-4-piperidylidene)di(oxymethylene) ethyl triphosphate (SSL-NANTP) are described here. These two new nonnucleoside ATP analogues are substrates for myosin, and the respective NANDP products are stably trapped at the active site by the phosphate analogues AlF_4^- or vanadate. While the EPR spectrum of photoincorporated SL-NANDP showed the probe to be too mobile to act as a reporter group, comparable labeling of S1 with SSL-NANDP gives a highly immobile spectrum, suitable to monitor conformational changes in myosin heads. In addition, SSL-NANDP was found to photolabel the carboxyl terminal 20 kDa tryptic fragment of S1 rather than the 23 kDa amino terminal fragment labeled by NANDP (*21*), showing that both of these major tryptic fragments, 23 and 20 kDa, function to make up part of the nucleotide binding site of myosin. This use of photoreactive spin-labeled substrates then represents a second method to do site-specific spin labeling that potentially can be used to report myosin head movement even in complex systems such as glycerinated muscle fibers.

MATERIALS AND METHODS

Microanalyses were carried out by Desert Analytics (Tucson, AZ) with a Perkin-Elmer 240C Elemental Analyzer. UV spectra were recorded on a Varian 2200 spectrometer. ^1H NMR spectra were recorded on a Bruker AMX 300 and referenced to HOD (4.70 ppm) or TMS (0.0 ppm). ^{31}P NMR spectra were obtained on a Varian VXR-500 spectrometer by using 85% phosphoric acid as an external standard. EPR spectra of synthesized compounds were obtained on a Varian E-3 spectrometer using an ER 3200 cavity. Low-resolution mass spectra of the compounds without phosphate were recorded on a 7070 EHF VG analytical mass spectrometer. Low-resolution mass spectra of the compounds with phosphate were recorded on a matrix-assisted laser desorption/ionization mass spectrometer (MALDI) from PerSeptive Biosystems. High-resolution mass spectra of the final probes with phosphate were obtained at the Mass Spectrometry Center (University of Washington, Seattle, WA) on a PE Biosystems (Foster City, CA) Mariner electrospray-TOF run in negative ion mode with a mobile phase of 1:1 CH_3CN/H_2O. Thin-layer chromatographic analyses (TLC) were done on aluminum backed silica gel 60 F_{254} thin-layer chromatography plates (EM Industries, Inc.) using solvent A [isobutyric acid/H_2O/concentrated NH_4OH (66:33:1)] or as described. Analyses of total phosphate and acid-labile phosphate were done as described previously (*22*). Flash chromatography used TLC silica gel (Aldrich, average particle size = 2−25 gm) in a 4.2 (w) × 5.2 (h) cm sintered glass funnel.

HPLC analysis was performed on a Spherisorb C18 column (100 × 4.6 mm). Eluant A, 100 mM triethylammonium acetate, pH 6.2; eluant B, 100 mM triethylammonium acetate, pH 6.2, in 90% acetonitrile; gradient 0 to 50% over 50 min at a flow rate of 1 mL/min. Capillary electrophoresis (CE) was performed on a Pace 5500 (Beckman) using a 50 cm × 75 μm uncoated capillary. Buffer: 20 mM sodium phosphate, pH 7.5; 20 kV, normal polarity; 20 °C; 215 nm.

4-Oxo-TEMPO, chymotrypsin, and Li_3ADP were from Sigma Chemical Co.; 4-fluoro-3-nitrophenyl azide was synthesized from 4-fluoro-3-nitroaniline (Aldrich) as described by Guillory and Jeng (*23*). Other reagents not from Aldrich were BCA protein assay reagents (Pierce); sodium orthovanadate and Tris base (Fischer); Ultima-gold scintillation Fluid (Packard); [^{32}P]phosphoric acid (NEN). The boiling point of the petroleum ether used was 35−60 °C.

Bis(tri-*n*-butylammonium) pyrophosphate was prepared as described by Moffatt (*24*) as follows: the solution of tetrasodium pyrophosphate decahydrate (4.46 g, 10 mmol) in cold water (100 mL) was applied to Dowex 50WX8 in the H^+-form. This column was eluted with water at 4 °C. The fractions with pH below 5 (pH paper) were pooled (approximately 200 mL) and added into a vigorously stirred solution of tributylamine (3.70 g, 20 mmol) in ethanol (40 mL) in an ice bath. The solvents were removed by rotary evaporation and then coevaporated twice with ethanol (20−30 mL each time) at 30 °C. The last traces of water/ethanol were removed by coevaporating twice with anhydrous dimethylformamide (DMF) dried over molecular sieves. The residue was dissolved in DMF (20 mL) to form a light yellowish solution which was stored in a brown bottle under argon at −20 °C until used.

Myosin subfragment 1 (S1) (115 000 g/mol) was prepared by a modification of the method of Okamoto and Sekine (*25*) as previously described (*26*) and stored in 50

mM Tris, 100 mM KCI, pH 8.0, at 4 °C (S1 buffer). F-actin was purified from rabbit skeletal muscle as described (*27*).

Analytical Procedures. Protein concentrations were determined by the BCA protein assay or Coomassie Blue (Pierce) using unmodified S1 as the standard as previously described (*28*); $\epsilon_{280}^{1\%} = 7.5\ cm^{-1}$ (*29*). ATPase assays were performed as described previously (*30*), except that release of inorganic phosphate was measured at 2 and 8 min after the addition of S1 to the assay mixture.

1-Oxyl-2,2,5,5-tetramethylpyrrolidinyl-3-carboxylic acid N-hydroxysuccinimide ester (SL-ester). SL-ester was synthesized by the general procedures of Hoffman et al. (*31*). 1-Oxyl-2, 2,5,5-tetramethylpyrrolidinyl-3-carboxylic acid (3-carboxy-proxyl) (0.53 g, 2.85 mmol) and *N*-hydroxysuccinimide (0.331 g, 2.88 mmol) were dissolved in the mixed solvent of ethyl acetate (10 mL) and DMF (3 mL) and cooled in an ice bath. A solution of *N*,*N*′-dicyclohexylcarbodiimide (0.595 g, 2.89 mmol) in ethyl acetate (4 mL) was added dropwise with stirring. After 2 h, the reaction mixture was taken out of the ice bath and stirred overnight at room temperature. Solvents were removed by rotary evaporation at 30 °C and the residue was fractionated by reduced pressure flash column chromatography using the solvents ethyl acetate/petroleum ether (1:3, 1:2, and then 1:1, v/v) as eluents. A light yellowish solid (0.63 g) was obtained from the eluent of ethyl acetate/petroleum ether (1:1, v/v). TLC: one spot, $R_f = 0.42$ (ethyl acetate/petroleum ether, 1:1, v/v). Yield: 78%. Melting point (mp): 185−186 °C. Electron ionization mass spectroscopic (EI-MS) analysis *m/e* (M^+) found 283 (calcd, $C_{13}H_{19}O_5N_2$, 283). The EPR spectrum of the pure solid sample was recorded at 9.46 GHz and showed a typical nitroxyl radical spectrum with a singlet centered at 3381.0 G.

1-Amino-3-(4-azido-2-nitrophenyl)amino-2-propanol (1). 1,3-diamino-2-propanol (3.0 g, 33.34 mmol) was dissolved in 100 mL of 80% DMF/20% H_2O and cooled in an ice bath. A solution of 4-fluoro-3-nitrophenyl azide (1.82 g, 10 mmol) in DMF (25 mL) was added dropwise with stirring in a period of 20−30 min. A deep-red solid was precipitated from the solution. After 0.5 h, the reaction mixture was taken out of the ice bath and stirred overnight at room temperature. The deep-red solid was harvested by filtration and washed several times with methanol (10 mL each time). TLC of the solid product in solvent A showed one spot ($R_f = 0.58$). The filtrate was concentrated to dryness by rotary evaporation at 30 °C, and the residue recrystalized from methanol to produce the second portion of pure product **1**. Product: 2.02 g, mp 81−82 °C. Yield 80%. EI-MS *m/e* (M^+) found 252 (calcd, $C_9H_{12}O_3N_6$, 252). ^{1}H NMR (CD_3COCD_3): δ 1.17−1.27 (br, 2 H, NH_2), 2.74 (br s, 1 H, OH), 2.90−3.25 (m, 2 H, CH_2), 3.34−3.52 (m, 2 H, CH_2), 4.10−4.13 (m, 1 H, CH), 7.13−7.25 (m, 2 H, phenyl H), 7.70 (d, 1 H, phenyl H), 8.10 (br s, 1 H, NH). Anal. ($C_9H_{12}N_6O_3$) C, H, N.

1-(4-Azido-2-nitrophenyl)amino-3-(1-oxyl-2,2,5,5-tetramethylpyrrolidinyl-3-carbamido)-2-propanol (2). To a solution of 1-amino-3-(4-azido-2-nitrophenyl)-amino-2-propanol (0.504 g, 2 mmol) in DMF (20 mL) was added dropwise SL-ester (0.566 g, 2 mmol) dissolved in 10 mL of ethyl acetate through a dropping funnel with a pressure-equalization arm at room temperature. After stirring overnight, the solvents were removed by rotary evaporation at 30 °C, and the residue isolated by reduced pressure flash column chromatography using acetone/petroleum ether (1:3 and then 1:2, v/v) as eluents. Product: deep-red amorphous solid, 0.70 g, mp 137−138 °C. Yield: 83%. TLC: one spot, $R_f = 0.46$ (acetone/petroleum ether, 1:2, v/v). Chemical ionization mass spectroscopic analysis (CI-MS) *m/e* (M^+) found 420 (calcd, $C_{18}H_{26}O_5N_7$, 420). The EPR analysis of the pure solid sample was performed at a frequency of 9.46 GHz and showed a typical nitroxide spectrum with a singlet centered at 3381.0 G. The compound was further characterized by reduction to the hydroxylamine as described below. Anal. ($C_{18}H_{26}N_7O_5$) C, H, N.

To obtain ^{1}H NMR spectrum, the nitroxy group of compound 2 was reduced to the *N*-hydroxyl derivative as described (*32*). To a solution of compound **2** (0.1 g, 0.24 mmol) in chloroform (1 mL) 2 mL of 0.2 M phenylhydrazine in chloroform was added. This mixture was stirred for 1 h and then the solvent was removed. The residue was purified by flash chromatography using acetone/petroleum ether (1:3 and then 1:2, v/v) as eluents. Product: deep-red solid, 50 mg. TLC: one spot, $R_f = 0.46$. ^{1}H NMR ($CDCl_3$): δ 1.12 (s, 3 H, CH_3), 1.18 (s, 3 H, CH_3), 1.22 (s, 6 H, CH_3), 1.74−1.78 (d, 2H, CCH_2C), 2.01−2.08 (t, 1 H, CHCO), 2.70 (br s, 1 H, OH), 2.90−3.10 (m, 2 H, CH_2), 3.36−3.50 (m, 2 H, CH_2), 4.10−4.13 (m, 1 H, CH−O), 7.10−7.21 (m, 2 H, phenyl H), 7.65 (d, 1 H, phenyl H), 8.10 (br s, 1 H, NH). CI-MS *m/e* (M^+) found 421 (calcd, $C_{18}H_{27}O_5N_7$, 421).

1-(4-Azido-2-nitrophenyl)amino-3-(1-oxyl-2, 2, 5, 5-tetramethylpyrrolidinyl-3-carbamido)-2-propyl triphosphate (SL-NANTP). SL-NANTP was synthesized according to the procedures of Ludwig and Eckstein (*33*−*35*) by which nucleoside triphosphates were synthesized. Compound **2** (0.39 g, 0.93 mmol) was dissolved in anhydrous dioxane/pyridine (8 mL, 3/1, v/v) in a rubber septum capped vessel under argon and cooled in an ice bath. A freshly prepared solution of SPC (0.207 g, 1 mmol) in anhydrous dioxane (2 mL) was injected through the septum and the resulting solution vigorously stirred for 10 min in an ice bath and another 10 min at room temperature. A solution of 0.5 M tetra(tri-*n*-butylammonium) pyrophosphate in anhydrous DMF (4 mL, 2 mmol) was injected into the reaction system cooled in an ice bath. After stirring for 10 min, a solution of 1% iodine in pyridine/water (98/2, v/v) (20 mL, 1.6 mmol) was added to oxidize phosphite to phosphate. After stirring for an additional 10 min in an ice bath and then for 30 min at room temperature, the excess iodine was destroyed by addition of 6 mL of 5% aqueous solution of sodium bisulfite. The reaction mixture was concentrated to dryness by rotary evaporation at 30 °C. The residue was dissolved in H_2O (20 mL), and the solution cooled in an ice bath, and a concentrated ammonium hydroxide solution (40 mL) was added to hydrolyze the cyclic triphosphate. After 2 h, the reaction mixture was taken out of the ice bath and stored overnight at 4 °C. Argon was bubbled for 0.5 h to remove ammonia. The solution was evaporated to dryness by rotary evaporation at 30 °C, and the residue was dissolved in H_2O (30 mL) (pH 6.95). One-half of this solution was applied to DEAE Sephadex A-25 (Aldrich, 40−120 gm) in a column (3.2 × 50 cm) and eluted with a linear gradient of 0.3 to 0.6 M triethylammonium bicarbonate (TEAB) at 4 °C (flow rate = 3.5 mL/min, 4.8 min/fraction, total elution time = 24 h). Pyrophosphate was eluted in fractions 95−141, and the deep-red product in fractions 149−173. A total of two runs of the DEAE Sephadex A-25 column were performed, and the fractions containing product SL-NANTP as determined by TLC (solvent A) were pooled. Water and triethylammonium bicarbonate were removed by rotary evaporation at 30 °C. The product showed a single spot on TLC with solvent A ($R_f = 0.48$). HPLC analysis

(>97% pure): t_R = 27.8 min. CE analysis (>97% pure): t_R = 9.9 min. Yield: 0.20 mmol, 21.6% (based on its molar extinction coefficient of 4680 M^{-1} cm^{-1} at 473 nm).

Phosphate assays showed that the ratio of total phosphate to acid labile phosphate was 1.49; theory, 1.50. UV spectrum (water, pH 7.20): λ_{max} at 261 and 473 nm. Molar extinction coefficients calculated from total phosphate assays were 24 360 ± 440 M^{-1} cm^{-1} at 261 nm and 4680 ± 80 M^{-1} cm^{-1} at 473 nm. High-resolution negative electrospray MS *m/e* $(M - H)^-$ found 659.0911 (calcd, M − H, $C_{18}H_{28}O_{14}N_7P_3$, 659.0907). The EPR spectrum of the solution of SL-NANTP dissolved in methanol recorded at 9.46 GHz showed a typical nitroxide spectrum with a triplet centered at 3378.3 G and a hyperfine splitting of 17.5 G.

To obtain NMR spectra free of triethylamine, SL-NANTP was precipitated as the sodium salt by addition of NaI acetone solution (1 M) and washed several times with cold acetone as described previously (*21*). A portion of SL-NANTP (0.2 mL, 23 mM, and pH 7.0) was reduced to the hydroxyamine derivative by addition of 50 μL of 100 mM ascorbic acid (pH 7.0) (*13*). Negative MALDI-MS using α-cyano-4-hydroxy-cinnamic acid as matrix found *m/e* $(M - H)^-$ 660.09 (calcd, $C_{18}H_{29}O_{14}N_7P_3$, 660.10) (*36*). ^1H NMR (D_2O): δ 1.26 (s, 3 H, CH_3), 1.39 (s, 3 H, CH_3), 1.42 (s, 3 H, CH_3), 1.43 (s, 3 H, CH_3), 1.82−1.86 (d, 2 H, CCH_2C), 2.10−2.21 (m, 1 H, CHCO), 2.96−3.18 (m, 2 H, CH_2), 3.59−3.72 (m, 2 H, CH_2), 4.53−4.57 (m, 1 H, CH−O), 7.20−7.30 (m, 2 H, phenyl H), 7.82 (d, 1 H, phenyl H). ^{31}P NMR (D_2O): −9.70 (d, γ−P), −11.25 (d, α−P) and − 22.34 (t, β−P).

2-(Hydroxymethyl)-2-(4-azido-2-nitrophenyl)amino-1,3-propanediol (3). To a solution of 4-fluoro-3-nitrophenyl azide (7.50 g, 41.0 mmol) dissolved in 26 mL of 80% DMF/20% H_2O, 2-amino-2-(hydroxymethyl)-1,3-propanediol (Tris base) (4.84 g, 20.0 mmol) was added. After stirring for 8 days, the solvents were removed with rotary evaporation at room temperature. The residue was isolated by flash chromatography using acetone/petroleum ether (1:2 and then 1:1). Product: 0.75 g, orange solid, mp 153−154 °C. Yield 26.5%. TLC showed one spot, R_f = 0.32 (acetone/petroleum ether, 1:1). ^1H NMR ($CDCl_3$): δ 1.48 (br s, 3 H, OH), 3.86 (s, 6 H, CH_2), 6.90−7.28 (m, 2 H, phenyl), 7.70 (d, 1 H, phenyl H), 8.30(s, 1 H, NH). EI-MS *m/e* (M^+) found 283 (calcd, $C_{10}H_{13}O_5N_5$, 283). Anal. ($C_{10}H_{13}N_5O_5$) C, H, N.

2-(4-Azido-2-nitrophenyl)amino-2,2-(1-acetoxy-2,2,6,6-tetramethyl-4-piperidylidene)di(oxymethylene) ethanol (5). 1-Acetoxy-4-methoxy-2,2,6,6-tetramethyl-1,2,5,6-tetrahydropyridine **(4)** was prepared according to the method of Alessi et al. (*32*). A total of 2.6 g (11.45 mmol) of compound **4** was added into a solution of compound **3** (0.3 g, 1.06 mmol) in tetrahydrofuran (THF) (5 mL), followed by a catalytic amount of *p*-toluenesulfonic acid monohydrate. After the reaction solution was stirred for 6 days, THF was removed by rotary evaporation at room temperature. The residue was isolated by flash chromatography using ethyl acetate/petroleum ether (1:3, 1:2, and then 1:1) as eluents. Product: 0.16 g, orange solid, mp 135−136 °C. Yield 31.6%. TLC: one spot at R_f = 0.37 (ethyl acetate/petroleum ether, 1:1). ^1H NMR ($CDC1_3$): δ 1.01 (s, 6 H, CH_3), 1.19 (s, 3 H, CH_3), 1.21 (s, 3 H, CH_3), 1.50 (br s, 1 H, OH), 1.77−1.86 (t, 2 H, CH_2), 1.98−2.06 (m, 5 H, CH_2 and CH_3CO), 3.76 (m, 6 H, CH_2), 7.0−7.39 (m, 2 H, phenyl H), 7.79 (d, 1 H, phenyl H), 8.34 (s, 1 H, NH). CI-MS *m/e* $(M + 1)^+$ found 479 (calcd, $C_{21}H_{30}O_7N_6$, 478). Anal. ($C_{21}H_{30}N_7O_6$) C, H, N.

2-(4-Azido-2-nitrophenyl)amino-2,2-(1-acetoxy-2,2,6,6-tetramethyl-4-piperidylidene)di(oxymethylene) Ethyl Triphosphate (AcSSL-NANTP). The phosphorylation of the spiroketal intermediate **5** and the subsequent displacement reaction were done as described previously (*19*, *20*). Phosphorus oxychloride (0.15 mL, 1.6 mmol) was pipetted into a solution of N-acetoxy spiro ketal **5** (0.19 g, 0.4 mmol) in trimethyl phosphate (3 mL) in a glovebag under argon at room temperature. The reaction flask was sealed with a septum, an argon balloon was connected to the reaction flask to exclude moisture, and the reaction flask was immersed in an ice-bath immediately. After 8 h with stirring, the reaction solution was injected into a solution of bis(tri-*n*-butylammonium) pyrophosphate in DMF (6.4 mL, 3.2 mmol) and tri-*n*-butylamine (1.52 mL, 6.4 mmol) under argon and precooled in an ice bath. After 10 min, 1 M TEAB (25 mL) was added, and this mixture was left overnight at 4 °C. The solvents were removed with rotary evaporation at 30 °C. TEAB was removed by coevaporating with methanol. The residue was dissolved in water (30 mL), and this solution applied to DEAE Sephadex A-25 (Aldrich, 40−120 gm) column (3.2 cm × 50 cm). The product was eluted with a linear gradient of 0.3 to 0.6 M TEAB (5 L total volume, pH 7.60) at 4 °C with a flow rate of 3.5 mL/min, and 16.8 mL fractions were collected. The major peak, AcSSL-NANTP, was eluted at 0.46 M TEAB buffer. The product fractions were pooled and taken to dryness by rotary evaporation at 30 °C. The residue was coevaporated three times with methanol to remove TEAB. Product: deep red solid, 0.2 mmol (based on the molar extinction coefficient ϵ_M of 4100 M^{-1} cm^{-1} at 464 nm). Yield: 50.0%. TLC: one spot at R_f = 0.32 (solvent A). HPLC analysis (>97% pure): t_R = 31.6 min. CE analysis (>97% pure): t_R = 8.4 min. Mass spectroscopic analysis (negative MALDI) found *m/e* $(M - H)^-$ 717.42 (calcd, $C_{2l}H_{32}O_{16}N_6P_3$, 717.43) (*36*). ^1H NMR(D_2O): δ 1.21 (s, 6 H, CH_3), 1.26 (s, 3 H, CH_3), 1.39 (s, 3 H, CH_3), 1.66−1.72 (t, 2 H, CH_2), 2.01−2.12 (m, 5 H, CH_2 and CH_3CO), 3.64 (m, 6 H, CH_2), 7.02−7.30 (m, 2 H, phenyl H), 7.80 (d, 1 H, phenyl H). ^{31}P NMR (D_2O): −10.20 (d, γ−p), −11.10 (d, α-p), −22.81 (t, β-p).

2-(4-Azido-2-nitrophenyl)amino-2,2-(1-oxyl-2,2,6,6-tetramethyl-4-piperidylidene)di(oxymethylene) ethyl triphosphate (SSL-NANTP). SSL-NANTP was prepared from AcSSL-NANTP by a method modified from Alessi et al. (*14*). A solution of potassium hydroxide (0.55 g) in methanol (10 mL) was added into a reaction flask containing AcSSL-NANTP (164 μmol), methanol (15 mL), and water (15 mL). After the reaction mixture was saturated with oxygen, it was connected to an oxygen balloon and vigorously stirred for 8 days. A few drops of glacial acetic acid were added to bring the pH to 7.0. This solution was applied to a DEAE Sephadex, A-25 (Aldrich, 40−120 μM) column (3.2 cm × 50 cm) and eluted with a linear gradient of 0.3 to 0.6 M TEAB (5 L total volume, pH 7.60) at 4 °C and a flow rate of 3.5 mL/min. The red fractions containing the product were pooled and concentrated to dryness with rotary evaporation at 30 °C. The last traces of TEAB were removed by coevaporating three times with methanol (50 mL each). The yield was 156 μmol (95%) (based on ϵ_M 4100 M^{-1} cm^{-1} at 464 nm). TLC showed one spot at R_f = 0.32 (solvent A). HPLC analysis (>97% pure): t_R = 32.3 min. CE analysis (>97% pure): t_R = 10.6 min.

High-resolution mass spectroscopy (negative electrospray) *m/e* $(M - H)^-$ found 674.0911 (calcd, $C_{19}H_{29}O_{15}N_6P_3$, 674.0904). Phosphate assays showed that the ratio of total phosphate to acid labile phosphate was 1.47; theory, 1.50. UV (water, pH 7.0): λ_{max} at 464 and 262 nm. Molar

extinction coefficients calculated from the total phosphate assay were 4100 ± 30 M^{-1} cm^{-1} at 464 nm and 25 480 ± 360 M^{-1} cm^{-1} at 262 nm. The EPR analysis of the solution of the product in methanol recorded at 9.45 GHz showed a typical nitroxide spectrum with a triplet centered at 3375 G and a hyperfine splitting of 16.0 G.

To obtain NMR spectra free of triethylamine, SSL-NANTP was converted to the sodium salt as described (*22*). A small portion of the solution of the product in water (2.3 μmol, pH 7.0) was reduced with a solution of sodium ascorbate in water (2.3 μmol, pH 7.30) and then dried with a speed vacuum. The residue was dissolved in D_2O for running ^{31}P NMR which showed three sets of peaks: −8.70 (d, γ−p), −10.80 (d, α−p), −22.24 (t, β−p). ^1H NMR (D_2O): δ 1.20 (s, 6 H, CH_3), 1.24 (s, 3 H, CH_3), 1.38 (s, 3 H, CH_3), 1.70−1.78 (t, 2 H, CH_2), 2.03−2.15 (m, 2 H, CH_2), 3.68 (m, 6 H, CH_2), 7.01−7.22 (m, 2 H, phenyl H), 7.82 (d, 1 H, phenyl H). Negative MALDI mass spectroscopic analysis found $(M - H)^-$ 675.12 (calcd, $C_{19}H_{30}O_{15}N_6P_3$, 675.10) (*36*).

Synthesis of 2-(4-Azido-2-nitrophenyl)amino-2,2-(1-oxyl-2,2,6,6-tetramethyl-4-piperidylidene)di(oxymethylene) ethyl [β-^{32}P]diphosphate ([^{32}P]SSL-NANDP). [^{32}P]SSL-NANDP was prepared by coupling of [^{32}P]phosphate to 2-(4-azido-2-nitrophenyl)amino-2,2-(1-oxyl-2,2,6,6-tetramethyl-4-piperidylidene)di(oxymethylene) ethyl monophosphate (SSL-NANMP) as described (*19*, *21*). Yield 76% (based on the molar extinction coefficient of 4100 M^{-1} cm^{-1} at 464 nm). Specific activity 63 000 cpm/nmol. After 5 months, a small amount of [^{32}P]-SSL-NANDP was reduced by sodium ascorbate to obtain NMR spectra. ^1H NMR (D_2O) δ 1.10 (s, 6 H, CH_3), 1.24 (s, 3 H, CH_3), 1.37(s, 3 H, CH_3), 1.69−1.75 (t, 2 H, CH_2), 2.04−2.12 (m, 2 H, CH_2), 3.68 (m, 6 H, CH_2), 7.02−7.20 (m, 2 H, phenyl H), 7.81 (d, 1 H, phenyl H). ^{31}P NMR (D_2O): −9.62 (d, β−P), −12.20 (d, α−P). Negative MALDI mass spectroscopic analysis found $(M - H)^-$ 594.10 (calcd, $C_{19}H_{28}O_{12}N_6P_2$, 594.12). SSL-NANMP was prepared by a similar method as for synthesis of SSL-NANTP, except that 1 N NaOH was added to pH 7.30 to hydrolyze the dichlorophospate to the monophosphate instead of addition of pyrophosphate. NMR analysis of SSL-NANMP reduced by sodium ascorbate: ^1H NMR (D_2O) δ 1.11 (s, 6 H, CH_3), 1.21 (s, 3 H, CH_3), 1.36(s, 3 H, CH_3), 1.68−1.76 (t, 2 H, CH_2), 2.01−2.12 (m, 2 H, CH_2), 3.67 (m, 6 H, CH_2), 7.03−7.23 (m, 2 H, phenyl H), 7.80 (d, 1 H, phenyl H). ^{31}P NMR (D_2O): 0.387 (s). Negative MALDI mass spectroscopic analysis found $(M - H)^-$ 514.12 (calcd, $C_{19}H_{27}O_9N_6P$, 514.16).

Vanadate Trapping and Photoincorporation of SSL-NANDP and SL-NANDP onto Rabbit Skeletal Myosin S1. For SSL-NANTP trapping, S1 (26.1 μM) was incubated with 2 mM $NiC1_2$, 0.1 mM [^{32}P]SSL-NANDP, and 1 mM sodium orthovanadate or an equivalent volume of S1 buffer (control) at 25 °C. After 40 min, EDTA (pH 8.0) and ATP were added to 20 and 5 mM, respectively, and the samples purified by Sephadex G-50 spin columns in S1 buffer (50 mM Tris, 100 mM KCI, pH 8.0 at 4 °C). The purified S1·Ni·[^{32}P]SSL-NANDP·Vi complex was irradiated at 0 °C for 16 min using a Hanovia 450 W medium-pressure Hg lamp. To avoid photodamage and nonspecific labeling, a Pyrex filter and a Schott 408 filter were used to remove most of the radiation below 400 nm. To determine the amount of trapping, samples of the complex and the control before irradiation were counted by liquid scintillation and the protein concentrations were measured by use of Coomassie blue. To determine the amount of covalent incorporation, known samples of the complex after irradiation were precipitated by addition of perchloric acid to 5%, centrifuged and the pellets were analyzed for radioactivity.

For SL-NANTP trapping, S1 (34 μM) was incubated with 2 mM $MgCl_2$ and 0.2 mM SL-NANTP in S1 buffer for 10 min at 25 °C followed by addition of 5 mM NaF and 1 mM $AlCl_3$ or an equivalent volume of S1 buffer (control). After 40 min at 25 °C, EDTA and pyrophosphate were added to 20 and 1.8 mM, respectively, and the samples purified by Sephadex G-50 spin columns in S1 buffer (for ATPase assays) or S1 buffer with NaCl replacing the KCl. The purified S1·MgSL·NANDP·AlF_4 complex in NaCl−S1 buffer was irradiated at 0 °C for 4 min using a Hanovia 450 W medium-pressure Hg lamp. To determine the amount of trapping and covalent incorporation, samples of the complex before and after irradiation were precipitated by addition of cold perchloric acid to 5% and microcentrifuged, and the OD_{261} of the neutralized supernatent was measured. The extinction coefficient at 261 nm for the photolyzed SL-NANDP was determined by measuring the OD_{261} of a sample of SL-NANDP followed by irradiation of the sample and remeasuring the OD_{261} and was determined to be 11 880 M^{-1} cm^{-1}.

SDS−PAGE Analysis. Myosin S1 samples were analyzed by SDS−PAGE on 18 × 20 cm 12% gels according to the procedure of Laemmli (*37*). Protein bands were visualized by staining with a solution of Coomassie blue (1.61 g of Coomassie blue in 1 L of methanol, 1 L of water, and 200 mL of glacial acetic acid). Gel strips containing the bands of interest were excised and placed in 20 mL glass vials. Ultimagold (Packard) (10 mL) was added, and the radioactivity was determined.

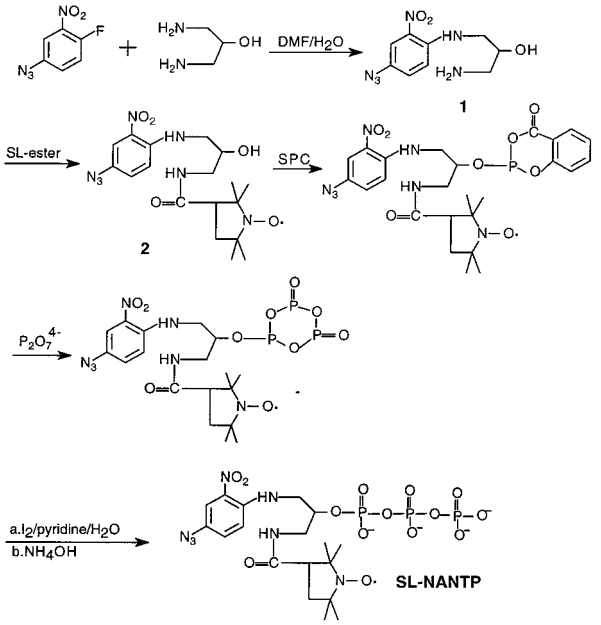
EPR Spectroscopy. After irradiation in the presence of SL-NANTP or SSL-NANTP and Pi analogue, the S1 solution is a mixture of covalently photolabeled S1, unmodified S1, and trapped but unmodified S1. The spectrum of covalently bound diphosphate analogue is desired. Irradiated samples were treated with actin at low ionic strength to release trapped Pi analogue and noncovalently bound SSL-NANDP or SL-NANDP before adding excess ATP to dissociate S1 and photolabeled S1 from the actin as previously described by Luo et al. (*17*). The samples were then centrifuged, and the supernatant was purified by gel filtration (*17*). The protein solution was dialyzed into a buffer containing 0.12 M KOAc, 5 mM $Mg(OAc)_2$, 40 mM MOPS, 1 mM EGTA, pH 7.0, and then concentrated to 65 μM S1-SL-NANDP or S1-SSL-NANDP by centrifugation through a semipermeable membrane (Centricon, 30 kDa cutoff). A sample in a 50 μL glass capillary was placed in the center of a TE_{011} cavity.

Experiments were done at room temperature, 21−23 °C. EPR measurements were performed with an ER/200D EPR spectrometer from IBM Instruments, Inc. (Danbury, CT). First derivative, X-band spectra were recorded using 50 s, 125 G wide sweeps with the following instrument settings: microwave power, 25 mW; gain, 1.0×10^5−1.0×10^6; center field, 3478−3480 G; time constant, 200 ms; frequency, 9.3 GHz; modulation, 1 gauss at a frequency of 100 kHz. Each spectrum is the average of 25 distinct sweeps from an individual experimental preparation.

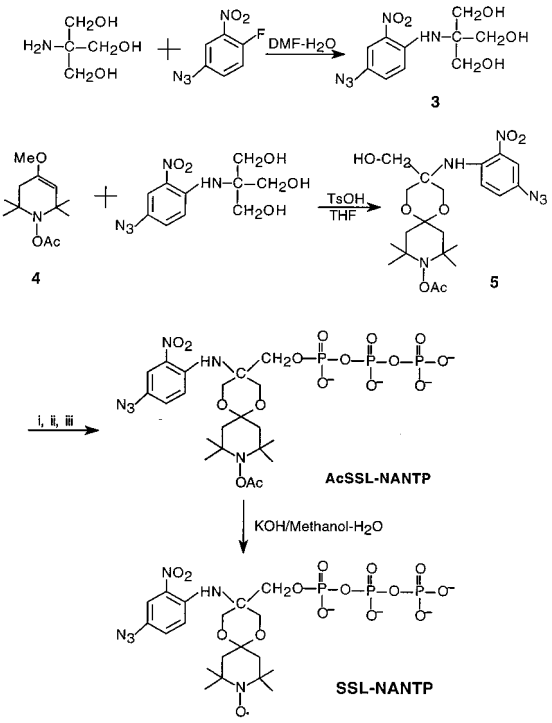
RESULTS AND DISCUSSION

Synthesis of SL-NANTP. The purpose of this study is to develop a series of second generation spin-labeled photoaffinity nonnucleoside ATP analogues based on NANTP. The plan is to photolabel the residues of myosin

Scheme 1: Synthesis of SL-NANTP



Scheme 2: Synthesis of SSL-NANTP



specifically near the active site so that motion of the head (or part of the head) can be monitored spectroscopically during the contraction process. The key step in the synthesis of SL-NANTP was phosphorylation of intermediate **2**. Phosphorus oxychloride has been used in the past as a phosphorylating reagent for primary alcohols to synthesize ATP analogues (*19*, *20*). Initially, we tried to use phosphorus oxychloride to phosphorylate the secondary alcohol of intermediate **2** without success, possibly because of steric hindrance. Salicylphosphorochloridite (SPC) has been previously employed as a phosphorylating reagent for the preparation of ATP analogues (*33*−*35*). This reagent is capable of undergoing three nucleophilic displacement reactions. We have exploited this multifunctionality in the synthesis of SL-NANTP. The sequence of the synthetic reactions is shown in Scheme 1. The synthesis proceeds via the phosphorylation of intermediate **2** by SPC. This is followed by displacement of the leaving group with pyrophosphate, oxidation of phosphite by iodine, and hydrolysis of the cyclic meta-triphosphate by concentrated ammonium hydroxide. The total yield from phosphorylation of intermediate **2** to the final product SL-NANTP was around 22%, which compares favorably with other syntheses that used phosphorus oxychloride.

The ^{31}P NMR and ^{1}H NMR spectra of SL-NANTP are very broad because of the presence of the nitroxide spin label. Reduction of the nitroxide of SL-NANTP with ascorbic acid yields the hydroxyamine derivative whose ^{31}P NMR and ^{1}H NMR spectra confirmed the predicted structure.

Synthesis of SSL-NANTP. The route used to synthesize SSL-NANTP, in which the free radical is attached to NANTP via a spiro ketal group, is shown in Scheme 2. The most important steps in the synthesis of SSL-NANTP were the syntheses of the triol intermediate **3** and *N*-acetoxy spiroketal intermediate **5**. Because Tris base is only soluble in water whereas 4-fluoro-3-nitrophenyl azide is not, a mixture of 80% DMF and 20% water was chosen as the reaction solvent. Tris base was still not completely soluble, which resulted in long reaction times (8 days) and relatively low yields (26%). Nevertheless, Tris base was chosen for several reasons. First, Tris base contains three hydroxyl groups and an amino group which are necessary to attach the spin label to NANTP via a spiroketal ring. Second, Tris base is the simplest compound suitable for our design, which makes the synthesized probe SSL-NANTP more likely to be a substrate for myosin. And third, Tris base is a convenient and cheap reagent. The *N*-acetoxy spiroketal intermediate **5** was synthesized by the reaction of the triol intermediate **3** and the enol ether spin label precursor **4** in the presence of the catalyst, *p*-toluenesulfonic acid monohydrate, by a procedure similar to that of Alessi et al. (*14*, *32*). Because the steric hindrance to the reaction of the two hydroxyl groups of the intermediate **3** with enol ether **4** is large, the reaction proceeded slowly. However, using the chemistry we have described, intermediate **5** could be prepared smoothly. The *N*-acetoxy triphosphate derivative, AcSSL-NANTP, was prepared by phosphorylation of the intermediate **5** with $POCl_3$ followed by the addition of tributylammonium pyrophosphate (*19*) or tributylammonium phosphate (*38*) to form the tri- and diphosphate products, respectively. In our experiments, the yield from the tributylammonium pyrophosphate reaction was much higher (50%) than that from tributylammonium phosphate (10%). To oxidize AcSSL-NANTP to the free radical probe SSL-NANTP, it was helpful to saturate the reaction solution with oxygen and to keep it in an oxygen atmosphere to accelerate the reaction. Alternatively, the final product SSL-NANTP was also prepared by oxidation of the intermediate **5** to the free radical nitroxide followed by phosphorylation with $POCl_3$ and reaction with tributylammonium pyrophosphate, but the yield was lower (36%).

SSL-NANTP and SL-NANTP Are Substrates for Myosin. It was first important to verify that SSL-NANTP and SL-NANTP bound to myosin in a manner similar to ATP. The hydrolysis studies of SSL-NANTP, SL-NANTP, and ATP by S1 are summarized in Table 1. S1 cleaved SSL-NANTP in the presence of Ca^{2+} and K^{+}/EDTA at the rate of 208% and 16% of that with ATP, respectively. The hydrolysis rates for SL-NANTP in the presence of Ca^{2+} and K^{+}/EDTA were 76% and 1.5% of that with ATP, respectively. In the presence of actin, V_{max}

Table 1. Reaction Rates for SSL-NANTP and SL-NANTP as substrates for S1[a]

assay conditions	ATP (μmol of Pi/ mg/min)	SSL-NANTP (μmol of Pi/ mg/min)	SL-NANTP (μmol of Pi/ mg/min)
K^+	5.39 ± 0.20	0.89 ± 0.13	0.08 ± 0.01
Ca^{2+}	1.18 ± 0.04	2.45 ± 0.07	0.90 ± 0.10
Mg^{2+}/actin	5.68 ± 0.14	2.83 ± 0.02	not determined

[a] S1 and actin-activated ATPase activities were determined from liberated Pi assayed using the methods of Wells and Yount (*42*) and White (*43*). Assays were measured at 25 °C with the following conditions. Ca^{2+}ATPase: 152 mM KC1, 15.2 mM $CaCl_2$, 152 mM Tris, 7.6 mM SSL-NANTP or SL-NANTP or ATP, 0.35 μM S1, pH 7.70. K^+/EDTA ATPase: 50 mM Tris, 5 mM EDTA, 0.6 M KC1, 5 mM SSL-NANTP or ATP, 0.35 μM S1, pH 7.50. Actin-activated Mg^{2+}ATPase: 10 mM Tris, 3 mM $MgCl_2$, 3 mM SSL-NANTP or SL-NANTP or ATP, 5.6 μM S1, pH 7.90, with 4.0−119 μM actin.

Table 2. Trapping and Incorporation of SSL-NANDP in S1

sample[a]	% ATPase[b]	% trapped SSL-NANDP/S1	% covalent SSL-NANDP/S1
control	98.0	2.5	
Vi/Ni^{2+} trapped	31.0	66.0	13.5

[a] The S1·Ni^{2+}·SSL-NANDP·Vi complex was prepared and irradiated as described as under Materials and Methods. [b] The NH_4^+-EDTA ATPase activity of the purified S1·Ni.SSL-NANDP·Vi complex and control sample were determined as previously described (*42*), except that the release of inorganic phosphate was measured after 2 and 8 min. These were then compared to standard S1.

Table 3. Trapping and Incorporation of SL-NANDP in S1

sample[a]	% ATPase[b]	% trapped SL-NANDP/S1	% covalent SL-NANDP/S1
control	101.0	4.4	
AlF_4 trapped	22.4	89.7	38.5

[a] The S1·Mg^{2+}·SL-NANDP·AlF_4 complex was prepared and irradiated as described as under Materials and Methods. [b] The NH_4^+-EDTA ATPase activity of the purified S1·Mg^{2+}·SL-NANDP·A1F_4 complex and control sample were determined as described in Table 2 and were then compared to standard S1.

for the MgSSL-NANTPase was 50% of MgATPase. These results show that both SSL-NANTP and SL-NANTP are substrates for S1 with properties similar to ATP.

Trapping and Covalent Photoincorporation of SSL-NANDP and SL-NANDP into S1. The specificity of labeling is an important consideration in the photoincorporation of ATP analogues in myosin. It has been shown that trapping of nucleotide analogues prior to irradiation is essential to obtain specific photolabeling of the active site of myosin (*25*, *26*, *19*). S1 was incubated with [^{32}P]SSL-NANDP and Vi as described in Methods and Materials, and untrapped SSL-NANDP and Vi were then removed by gel centrifugation columns. It was found that 66% of the sites were occupied. After photoirradiation and removal of unbound SSL-NANDP by actin treatment, S1 was covalently labeled at 13.5% of the sites (see Table 2). Here the Ni^{2+} acts to prevent vanadate-promoted photooxidation of myosin that occurs in the presence of Mg^{2+} (*26*). If S1 was treated with SL-NANTP, $MgCl_2$ and AlF_4^-, almost 90% of the active sites were trapped, and 38% of the active sites were subsequently photolabeled (See Table 3).

EPR Spectroscopy of Photoincorporated SL-NANTP and SSL-NANTP. Figure 1 shows EPR spectra obtained from S1 photolabeled with SL-NANDP (dashed line) and SSL-NANDP (solid line). The three sharp peaks (P2, P3, and the central large peak) in the SL-NANDP spectrum are indicative of a probe that is covalently attached to the protein. However, the probe is highly mobile with respect to the protein, undergoing rapid, nanosecond rotation. The low-field shoulder at P1 in the SL-NANDP spectrum does indicate a very small, more highly immobilized population of probes. This component is too small to be of use in orientational studies, however.

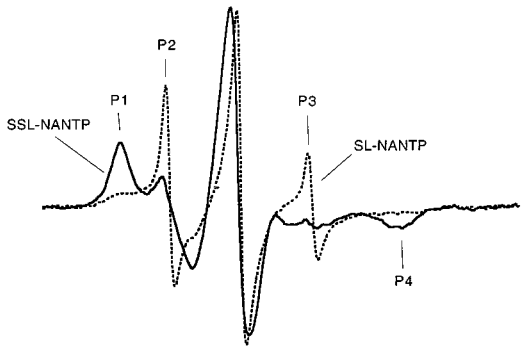


Figure 1. EPR spectra of SL-NANDP (dashed line) and SSL-NANDP (solid line) covalently attached to S1 in solution. The spectra are the average of 25 distinct, 125 mT wide sweeps.

The solid line in Figure 1 is the EPR spectrum obtained from S1-SSL-NANDP. The splitting between the low field peak, P1, and the high field dip, P4, is 65.5 ± 0.5 G (mean ± SEM, 4 obs) indicating a covalently attached probe that is highly immobilized with respect to S1. The analysis of Griffith and Jost (*39*) indicates the probe constrained to move within a cone of angle approximately 52° (full-width, half-max). The small superimposed peaks at P2 and P3 show an additional, small (<5%) highly mobile component. This probably is the result of a small degree of nonspecific labeling.

Our goal is to develop EPR photoaffinity probes for use in orientational studies of myosin. The high degree of mobility seen in the spectrum of S1-SL-NANDP makes this probe unusable for this purpose, and further characterization was not done. However, due to the high degree of immobilization of the S1-SSL-NANDP spectrum, it was of interest to localize SSL-NANDP on S1.

Localization of [^{32}P]SSL-NANDP on Myosin S1. The heavy chain of S1 can be partially digested with trypsin into three characteristic fragments, the NH_2-terminal 23-kDa fragment, the central 50-kDa fragment and the COOH-terminal 20-KDa fragment (*40*). Previously, Trp-130 on 23-kDa fragment of rabbit skeletal muscle myosin (*26*) and its equivalent amino acid, Arg-128 of scallop myosin, have been shown to be specifically photolabeled by NANDP (*41*). Our initial hypothesis was that SSL-NANDP would also specifically label Trp-130. As seen in Figure 2, all of the label, prior to trypsinization, was in the parent heavy-chain fragment 95-kDa and none in the light chains (Figure 2A). Surprisingly, after trypsinization for 15 min, the label was found to be essentially all in the COOH-terminal 20-kDa fragment. The 23- and 50-kDa fragments were not labeled (Figure 2B). These results demonstrated that a residue(s) in the 20-kDa fragment were the major site of photolabeling, and that elements of this fragment, like those of the 23 kDa and 50 kDa fragments, are close to the active site.

CONCLUSION

Two new spin-labeled photoaffinity, nonnucleoside ATP analogues have been synthesized and characterized. Both are based upon a previously characterized, photoaffinity probe, NANTP. For SL-NANTP, the spin label moiety is

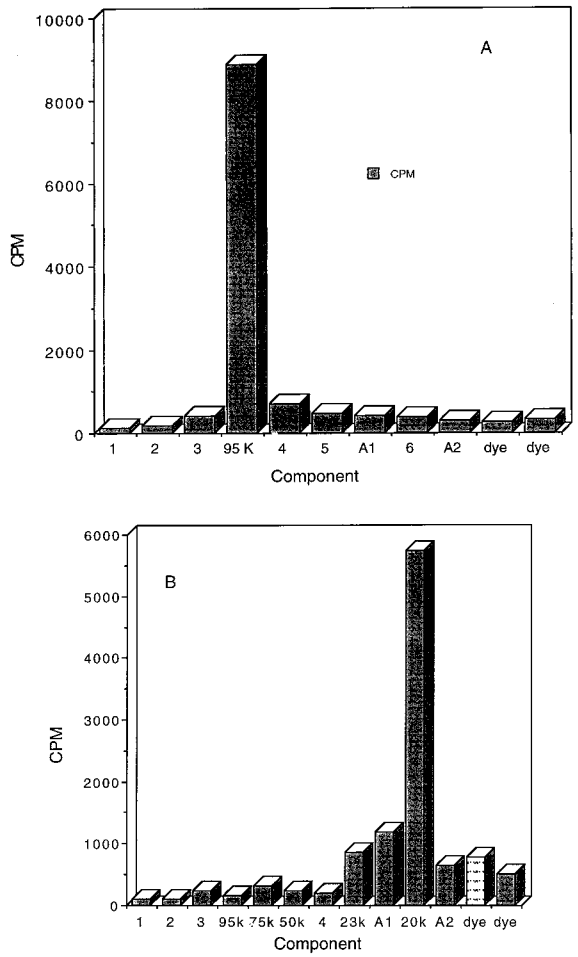

Figure 2. SSL-NANDP specifically labeled 20 kDa of myosin. S1 was trapped and photolabeled with [^{32}P]SSL-NANDP as described under Materials and Methods. The photolabeled S1 was analyzed by gel electrophoresis using a 12% SDS polyacrylamide gel before (panel A) and after (panel B) partially digestion with trypsin (1:100 w:w of trypsin to S1). The gels were stained with Coomassie Blue and sliced into fragments. The fragments were analyzed for radioactivity by scintillation counting.

attached to NANTP via an aminomethyl side chain. In SSL-NANTP, the attachment is via a restricted spiro ring. These two new probes are substrates for S1 and can be trapped at the active site of S1 with phosphate analogues. Both photolabeled S1 with good yields. Attachment of the spin probe moiety using an aminomethyl side chain resulted in a probe that was too mobile after photoincorporation to be of significant use in orientational studies. The more restrictive spiro ring in SSL-NANTP resulted in a highly immobilized probe once attached covalently to S1. Its degree of immobilization is comparable to that observed for EPR probes covalently attached at SH1 (Cys-707) that have been used to monitor myosin head motion (*2*−*10*). Surprisingly, SSL-NANTP specifically labeled the 20 kDa fragment of rabbit skeletal myosin S1, instead of 23 kDa, where NANTP photolabels. However, unlike the SH1-modified myosin, photolabeled S1 appears to retain its normal enzymatic properties. SSL-NANTP offers the possibility of a benign, site-specific probe that can report changes in motor domain orientation within an intact muscle fiber.

ACKNOWLEDGMENT

This project was supported by NIH Grants DK 05195 (R.G.Y.), AR39643 (E.P.), and AR42895 (R.C.). We are grateful to G. Reid Asbury, Drs. William Siems and Qing Wu (Washington State University) for their help in low-resolution mass spectroscopic analyses, and Dr. Ross Lawrence (University of Washington) for high-resolution mass spectroscopic determinations.

Responsive Hybrid Hydrogels with Volume Transitions Modulated by a Titin Immunoglobulin Module

Li Chen,[†] Jindřich Kopeček,[‡] and Russell J. Stewart*,[†]

Department of Bioengineering and Department of Pharmaceutics and Pharmaceutical Chemistry, 20 South 2030 East, Room 506, University of Utah, Salt Lake City, Utah 84112. Received May 3, 2000; Revised Manuscript Received July 11, 2000

The I28 immunoglobulin (Ig)-like module of human cardiac titin, an elastic muscle protein, was used to cross-link acrylamide (AAm) copolymers into hybrid hydrogels. Cross-linking was accomplished through metal coordination bonding between terminal histidine tags (His tags) of the I28 module and metal-chelating nitrilotriacetic acid (NTA)-containing side chains on the copolymer. In solution, the β-sheet structure of the I28 module unfolded with a transition midpoint of about 58 °C as the temperature was elevated. Hydrogels cross-linked with the I28 module demonstrated positive temperature responsiveness; they swelled to 3 times their initial volume at temperatures above the melting temperature of the cross-links. Positive temperature responsiveness is unusual for synthetic hydrogels. The I28 hybrid hydrogels demonstrate that cross-linking synthetic polymers with natural, well-characterized protein modules is a practical strategy for creating new materials with unique environmental responsiveness predictably determined by the mechanical properties of the protein cross-links. These new materials may be useful for controlled chemical delivery.

INTRODUCTION

Stimuli-responsive hydrogels undergo volume transitions in response to physical or chemical changes in their environment. A remarkable number of hydrogels have been developed that are responsive to changes in pH, ionic strength, biochemicals, solvent, temperature, electric and magnetic fields, and light (*1*). The extensive interest in responsive hydrogels stems in large part from the broad range of their potential applications. Responsive hydrogels have been used as selective absorbents (*2*), as matrixes for immobilization of enzymes (*3*), as reservoirs for controlled release of chemicals and drugs (*4*), and as microactuators (*5*). The majority of responsive hydrogels have been created using conventional methods of chemical and physical cross-linking of a relatively small number of synthetic polymers, especially (methyl)-acrylates and their copolymers.

As an alternative approach to synthesizing stimuli-responsive hydrogels, we are interested in cross-linking synthetic water-soluble polymers with recombinant protein modules to create hybrid hydrogels with environmental responsiveness that has not been observed in purely synthetic hydrogels. The rationale behind this approach is that the unique properties of the protein module cross-links, like well-defined structures, consistent mechanical properties, and cooperative folding and unfolding, may allow hydrogels to be designed with new, more pronounced, or uniquely controlled responses to environmental stimuli. The defined structures and properties of the cross-links will allow the hydrogel response to be directly related to the structure of the cross-links. Via adjustment of the amino acid sequence of the cross-links, it should be possible to fine-tune the responsiveness of the hybrid hydrogel for a specific application, perhaps much more precisely than previously possible through conventional polymer synthesis. As an example of a hybrid hydrogel, we recently reported a thermally responsive hybrid hydrogel that was assembled by cross-linking a copolymer of *N*-(2-hydroxypropyl)methacrylamide (HPMA) with synthetic and natural coiled-coil domains (*6*). These hydrogels collapsed sharply to about 10% of their equilibrium volume at a temperature that corresponded to a temperature-induced conformational transition in the coiled-coil cross-links. Responsive hydrogels have also been cross-linked with intact antibody molecules (*7*).

In this paper, we describe a new hybrid hydrogel assembled by cross-linking an acrylamide copolymer with a single immunoglobulin (Ig)-like domain from the elastic muscle protein, titin. Titin is a gigantic, modular protein consisting of more than 200 Ig and fibronectin type III domains. Structurally, the repeating titin Ig domain is a sandwich of two antiparallel β-sheets held together by hydrophobic interactions between the β-sheets in the core of the domain and by hydrogen bonds between the β-strands forming the β-sheets (*8*). Lately, a number of research groups have used optical tweezers (*9*, *10*) or AFMs (*11*−*13*) to stretch individual molecules of native titin, or recombinant segments of titin containing defined numbers of titin Ig domains, to investigate the molecular basis of titin's elasticity. The most prominent feature of the force-extension profiles generated in these experiments was a sawtooth pattern of exponential increases in force, followed by stress relaxation at a force threshold of about 200 pN. The number of events in the pattern corresponded to the number of Ig domains and the approximately 30 nm periodicity corresponded to the length of a stretched-out Ig domain, providing evidence that the events were due to the sequential stress denaturation of individual Ig domains. Steered molecular

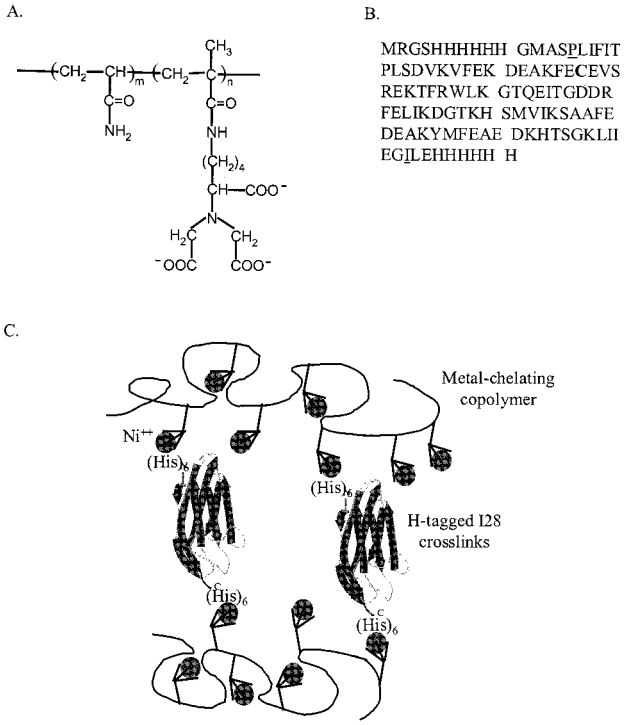

Figure 1. Assembly of the I28 cross-linked hydrogel. (A) Chemical structure of metal-chelating copolymer poly(AAm-*co*-MABNTA). The polymer was prepared by copolymerizing AAm with the metal-chelating comonomer MABNTA in Tris buffer (pH 8.9) under nitrogen, using ammonium persulfate and *N*,*N*,*N*′,*N*′-tetramethylenediamine as the redox initiator. (B) Protein sequence of the recombinant titin I28 cross-linker H-I28-H. The protein contains His tags at both ends. Single-letter abbreviations for amino acids are used: M, methionine; R, arginine; G, glysine; S, serine; H, histidine; A, alanine; P, proline; L, leucine; I, isoleucine; F, phenylalanine; T, threonine; D, aspartic acid; V, valine; K, lysine; E, glutamic acid; C, cysteine; W, tryptophan; Q, glutamine; Y, tyrosine. The underlined amino acid residues mark the start or end of the human cardiac titin I28 segment. The recombinant protein module contains 111 amino acids with a predicted molecular mass of 12.2 kDa. (C) Structure of the hybrid hydrogel. The hydrogel was formed through metal complex formation by the pendant metal-chelating ligand, NTA-Ni^{2+}, on the polymer and the terminal His tags of the protein.

dynamic simulations suggested that a folded Ig domain when pulled from its ends resists stretching until hydrogen bonds between β-strands begin rupturing near a threshold force, which is followed by a sudden drop in force and complete unraveling of the domain structure (*14*).

Our objective was to create a hydrogel in which the chemical potential of the hydrogel polymer matrix generates the driving force stretching titin Ig modules from their ends. The titin Ig module, in turn, would control the swelling of the polymer matrix. The cooperative unfolding of the Ig module cross-links would lead to a unique hydrogel swelling profile in response to environmental conditions. Our strategy for assembling an Ig module cross-linked hydrogel is diagrammed in Figure 1. Cross-linking is through noncovalent, metal coordination bonds between pendant metal-chelating nitrilotriacetic acid (NTA) groups on the polymer side chain and terminal histidine residues (His tag) of the titin Ig module. This convenient protein binding scheme has been applied extensively in recombinant protein purification (*15*), in protein immobilization at interfaces (*16*, *17*), and recently in hybrid hydrogel assembly (*6*).

EXPERIMENTAL PROCEDURES

Construction of the pET24a-I28 Expression Plasmid. A segment of DNA encoding the I28 Ig domain of human cardiac titin was PCR amplified from a plasmid kindly provided by A. Pastore. The I28 PCR product was digested with *Nhe*I and *Xho*I (Promega) and ligated into a pET21a *Escherichia coli* expression vector (Novagen) that had been previously modified to add histidine tags at both the amino and carboxyl ends of the expressed protein. The construct was verified by restriction enzyme digestion analysis and DNA sequencing (Figure 1B). The double-His-tagged I28 insert was transferred to the kanamycin resistant pET24a plasmid.

Expression and Purification of I28. For expression, the pET24a-I28 plasmid was transformed into *E. coli* strain BL21(DE3) (Novagen, Inc.). Single colonies were selected and grown overnight at 37 °C in LB medium (5 mL) containing 50 μg/mL kanamycin. LB cultures (500 mL) with 50 μg/mL kanamycin were then inoculated with the overnight cultures and grown at 37 °C until the A_{600} reached approximately 0.8 (about 2 h). Expression was induced with 0.1 mM isopropyl β-D-thiogalactopyranoside (IPTG) for 4 h at 37 °C or for 6 h at 30 °C. The induced cells were pelleted (Beckman JA 10 rotor, 4500 rpm, 30 min) and stored at −70 °C.

To purify the double-His-tagged I28 (H-I28-H), the cell pellets were resuspended in binding buffer [10 mM Tris and 200 mM sodium chloride (pH 7.4)] containing 20 μg/mL lysozyme, 1 mM phenylmethanesulfonyl fluoride (PMSF), and 0.1% Triton X-100. The cell suspension was sonicated on ice four times for 10 s using an ultrasonic demembranator (Fisher Scientific) to lyse the cells. After centrifugation at 4 °C, the clarified lysate was loaded onto a Ni-NTA (Qiagen, Inc.) column pre-equilibrated with binding buffer. The column was washed with binding buffer with 60 mM imidazole. H-I28-H was eluted with binding buffer with 300 mM imidazole. The H-I28-H fractions were combined and exchanged into 20 mM HEPES buffer with 150 mM NaCl (pH 7.4). The protein was concentrated, frozen in liquid nitrogen, and stored at −70 °C.

Sedimentation Equilibrium. H-I28-H samples were dialyzed into PBS buffer (pH 7.4) with 5 mM dithiothreitol (DTT). Three H-I28-H solutions with A_{280} values of 0.70, 0.35, and 0.18 were analyzed simultaneously in a Beckman Optima XL-A analytical ultracentrifuge with an An-60 Ti rotor. Centrifugation was carried out at 20 °C at three speeds, 25K, 32K, and 38K rpm. Protein sedimentation was assessed at 280 nm. Data analysis was performed using the nonlinear regression program NONLIN (*23*).

Circular Dichroism Spectroscopy. H-I28-H CD spectra were generated using a quartz rectangular cuvette with a path length of 0.1 cm and a volume of 300 μL in an Aviv 62DS CD spectrometer equipped with a thermoelectric temperature control system. Data were collected using the program Star3.0. Wavelength scans were performed at 25 °C, in 0.5 nm steps, and 5 s data averaging at each step. Scans for each sample were repeated at least five times and averaged. In the thermal stability experiments, the CD signal at 215 nm was monitored as the temperature was ramped from 30 to 90 °C in 1 °C increments. The sample was equilibrated for 2 min at each temperature, and the signal was averaged for 1.5 min.

Fluorescence Spectrometry. The fluorescence of the single tryptophan residue in H-I28-H was investigated using an ISS Grey multifrequency fluorometer with an

excitation wavelength of 293 nm. The fluorescence spectra of H-I28-H were determined under native conditions in PBS buffer [20 mM $NaPO_4$, 150 mM NaCl, and 5 mM DTT (pH 7.4)] and under denaturing conditions in PBS buffer with 5 M urea. For the denaturation experiment, spectra were recorded after 20 h at room temperature. The fluorescence spectra of H-I28-H cross-links in a hydrogel were collected at room temperature in PBS buffer and after heating the cuvette at 85 °C overnight.

Synthesis of a Metal-Chelating Acrylamide Copolymer [Poly(AAm-*co*-MABNTA)]. The metal-chelating monomer 2-methacrylamidobutyl nitrilotriacetic acid (MABNTA) was synthesized as described previously (*24*). The final product had a melting point of 104−107 °C, and a molecular mass of 329.7 Da determined by electrospray ionization mass spectrometry. ^{1}H NMR analysis (DMSO-d_6, 200 MHz): δ 1.33−1.59 [m, 6.9H, $CH_2(C\underline{H}_2)_3$], 1.82 (s, 3H, $C\underline{H}_3$), 3.05 (t, 1.7H, CO-NH-$C\underline{H}_2$), 3.40 [t, 1H, CH_2-$C\underline{H}$(COOH)-N], 3.53 [3.3H, N-($C\underline{H}_2$-$C\underline{O}O)_2$], 5.28, 5.60 (s, s, 2H, $C\underline{H}_2$=), 7.87 (1H, CO-N$\underline{H}$), 12.40 [s, 3H, (COO$\underline{H}$)$_3$].

Copolymerization (total monomer, 2.6 wt %) of acrylamide (AAm, Polysciences, Inc., chemzymes ultrapure, 86.5 mol %) and MABNTA (13.5 mol %) was carried out in Tris buffer (pH 8.9) at room temperature, under nitrogen for 24 h, using ammonium persulfate (Fisher Scientific, electrophoresis grade, 7 wt %) and *N*,*N*,*N*′,*N*′-tetramethylenediamine (Bio-Rad, electrophoresis grade) as the redox initiator. The copolymer was dialyzed against water and lyophilized. Weight and number-average molecular masses were measured by size exclusion chromatography on a fast protein liquid chromatography system equipped with a Superose 6 (10/30) column (Pharmacia, Piscataway, NJ) and a light-scattering detector (MiniDawn, Wyatt). The column was calibrated using poly(HPMA) standards with narrow polydispersity. The percentage of NTA side chains in the copolymer was determined by proton NMR (500 MHz) and by acid−base titration using a 10 mL ABU80 autoburet and a PHM84 research pH meter.

Assembly of I28 Cross-Linked Hydrogels. The metal-chelating acrylamide copolymer was charged with nickel by mixing the copolymer and nickel sulfate in 20 mM HEPES buffer (pH 7.4) and 150 mM NaCl at a 1:1 molar ratio of Ni^{2+} to NTA side chains. A gel formed initially before the mixture was thoroughly mixed, likely because of cross-linking between NTA side chains. With continued mixing, the gel completely dissolved. The pH of the solution was adjusted to 7.8 with NaOH. To assemble the hybrid hydrogels, the H-I28-H protein from a 110 mg/mL stock solution was mixed with the Ni-charged copolymer solution to give approximately 2 mol % protein cross-linking. As a control, the same amount of H-I28-H was mixed with the chelating copolymer in the absence of Ni^{2+}. A chemically cross-linked control was prepared by copolymerizing the same ratio of acrylamide and MABNTA comonomers with 2.5 mol % *N*,*N*′-methylenebisacrylamide (Polysciences, Inc., chemzymes ultrapure) under the same conditions used for preparing the titin cross-linked copolymer.

Temperature Responsiveness of I28 Cross-Linked Hydrogels. Small pieces of the hydrogels were immersed in PBS buffer [20 mM $NaPO_4$ and 150 mM NaCl (pH 7.4)] in a quartz cuvette with a jacket connected to a water bath to control the temperature. The gels were observed by brightfield microscopy (Nikon Eclipse E800) and recorded on videotape. The dimensions of the gel were measured from digitized images using Scion Image (Scion Corp.) software. The average rate of temperature increase was 2 °C/min, with the equilibration time being about 1 h at each recorded temperature. The temperature of the water bath was calibrated by measuring the temperature inside the cuvette with a thermocouple. The volume swelling ratio is the ratio of the hydrogel volume at an elevated temperature to the volume at 29 °C. Three samples were measured at each time.

RESULTS

Characterization of the H-I28-H Protein Module. The I28 Ig module from human cardiac titin was chosen because it was previously cloned, biochemically characterized, and had a reasonable melting temperature, 58 °C (*18*). During the subcloning process, His tags were added to both the carboxyl and amino termini of the I28 Ig module, which we term H-I28-H. The His-tagged Ig module was expressed efficiently in *E. coli* and was purified by metal affinity chromatography from *E. coli* lysates. By SDS−PAGE (Figure 2), the molecular mass of the Ig module was estimated to be about 12 kDa, in good agreement with the calculated molecular mass of 12.2 kDa based on the sequence. The native mass of H-I28-H was analyzed by sedimentation equilibrium in PBS buffer [20 mM phosphate, 150 mM NaCl, and 5 mM DTT (pH 7.4)]. The sedimentation data (not shown) were well-fit by an equation for a single ideal species with a molecular mass of 11.4 kDa. Comparison of the native molecular mass to the calculated molecular mass of 12.2 kDa suggested that H-I28-H was a stable, nonaggregating monomer in physiological conditions we used in our experiments.

The secondary structure and thermal stability of H-I28-H were investigated by CD spectroscopy. The CD spectrum of H-I28-H had a negative peak at about 213 nm (Figure 3A) characteristic of β-sheet structure (*19*), suggesting that the recombinant His-tagged I28 module was in its native conformation, which is comprised primarily of β-sheet. Thermal stability was investigated by monitoring the CD signal at 215 nm as the temperature was raised from 30 to 90 °C. In agreement with previously published stability studies of the I28 module (*18*), the H-I28-H module underwent thermal denaturation with a transition midpoint of about 58 °C (Figure 3B).

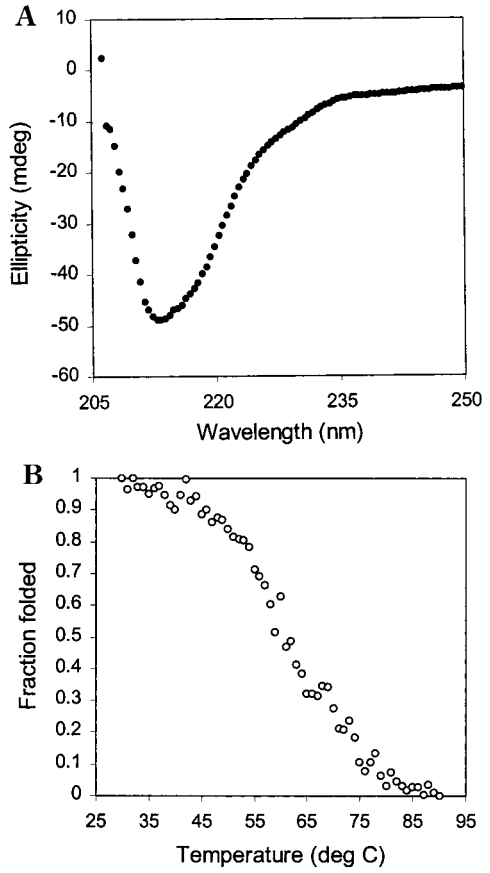

Figure 3. (A) CD spectra of H-I28-H at 25 °C in phosphate-buffered saline (pH 7.2). (B) Thermal denaturation of H-I28-H monitored by ellipticity at 215 nm.

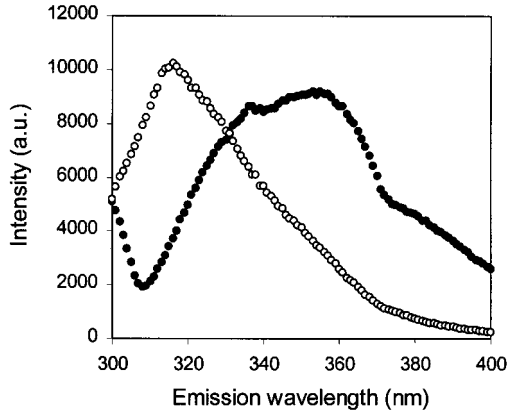

Figure 4. Intrinsic fluorescence of the single tryptophan residue of H-I28-H determined in the native state in phosphate-buffered saline (○) and after denaturation in phosphate-buffered saline and 5 M urea (●). The excitation wavelength was 293 nm.

The I28 module contains a single tryptophan (W) residue that is highly conserved in titin's Ig domains. From the structure of the titin Ig domains (*8*), the single W residue is known to be buried in the hydrophobic core between the two β-sheets of the Ig fold. Tryptophan residues that are fully exposed to water fluoresce maximally at about 350 nm, whereas Ws buried in a hydrophobic environment fluoresce at about 330 nm (*20*). Fluorescence spectrometry in the presence and absence of denaturant (Figure 4) confirmed that the W residue of H-I28-H was buried; in 5 M urea, the peak emission was at 350 nm, compared to peak emission at 317 nm in PBS.

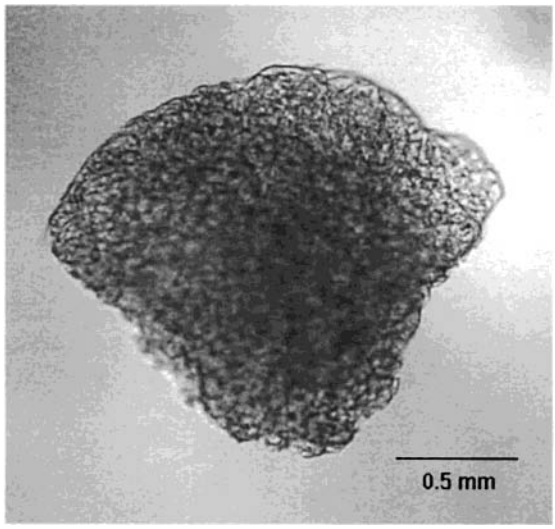

Figure 5. Photograph of a titin I28 cross-linked hydrogel. The thickness of the gel was less than 1 mm.

Characterization of the Metal-Chelating Acrylamide Copolymer [Poly(AAm-*co*-MABNTA)]. The chemical structure of the chelating MABNTA monomer was confirmed by ^{1}H NMR spectroscopy. After copolymerization with acrylamide, the copolymer number and weight-average molecular mass were 11 and 14 kDa, respectively. The percent of chelating monomers in the copolymer was determined by ^{1}H NMR and acid−base titration of the three COOH groups of the MABNTA units. During titration, a single neutral point was observed (not shown). If it is assumed that all three COOH groups in the MABNTA side chains were neutralized, the copolymer contained 10.0 mol % MABNTA. The same mol % of MABNTA was obtained by ^{1}H NMR.

Assembly of I28 Hybrid Hydrogels. When poly(AAm-*co*-MABNTA) chelated with a stoichiometric amount of Ni^{2+} was mixed with an H-I28-H solution at a cross-linking ratio of about 2 mol %, gels formed immediately. The I28 cross-linked hydrogels were translucent, macroscopically homogeneous, and relatively rigid (Figure 5). The gels remained intact for more than 30 days submerged in PBS buffer. In control experiments in which poly(AAm-*co*-MABNTA) was mixed with I28 in the absence of Ni^{2+}, no gels formed, confirming that gel formation occurred through metal coordination bonds. Additional control experiments were carried out in the absence of I28 and with substoichiometric amounts of Ni^{2+} to investigate gel formation by cross-linking between NTA side chains. When poly(AAm-*co*-MABNTA) chelated with a stoichiometric amount of Ni^{2+} was mixed with unchelated poly(AAm-*co*-MABNTA) at final NTA to Ni^{2+} ratios of 1.7:1 and 2.5:1, soft gels formed. However, these soft gels dissolved in excess PBS buffer, or when Ni^{2+} was added to raise the NTA to Ni^{2+} ratio toward 1:1. The control experiments suggest that the stable gel formation that we observed with Ni^{2+}-chelated poly(AAm-*co*-MABNTA) and H-I28-H was predominantly due to specific cross-linking between the His tags of H-I28-H and the NTA side chains of the copolymer.

Temperature Response of the Hybrid Hydrogels. The dimensions of the I28 cross-linked hydrogels were recorded as the hydrogels were heated under a video microscope. Via measurement of the distance between three triangular points on the gel, it appeared that the gel swelled isotropically (not shown). Therefore, the

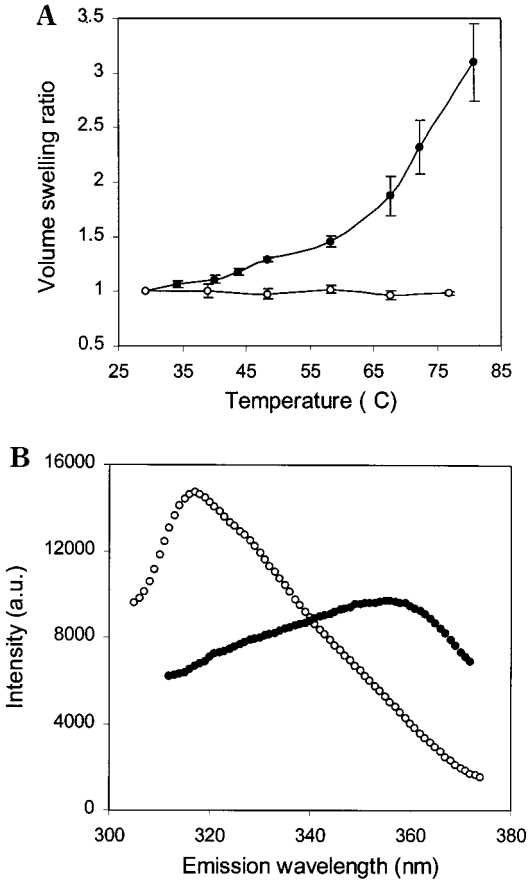

Figure 6. (A) Temperature responses of hydrogels in phosphate-buffered saline (pH 7.2). The volume swelling ratio is the ratio of hydrogel volume at an elevated temperature to the volume at 29 °C: (●) titin I28 cross-linked hydrogel (10 mol % NTA comonomer and 2 mol % protein cross-link) and (○) chemically cross-linked hydrogel (10 mol % NTA comonomer and 2.5 mol % BisAAm). The gels were heated in a jacketed quartz cuvette connected to a water bath. The average rate of temperature increase was 2 °C/min, with an equilibration time of about 1 h. The temperature of the water bath was calibrated by measuring the temperature inside the cuvette with a thermocouple. The dimensions of the gel were measured from digitized video images using Scion Image (Scion Corp.) software. (B) Intrinsic fluorescence of the H-I28-H cross-linked hydrogel at room temperature (○) and after heating the gel at 85 °C (●). The excitation wavelength was 293 nm.

volume swelling ratio,

$$Q = (L/L_0)^3 \quad (1)$$

, was calculated as where L/L_0 is the ratio of the length to the initial length. As the temperature was increased from 30 to 80 °C, the hybrid hydrogel swelled to about 3 times its initial equilibrium volume (Figure 6A). In contrast, a chemically cross-linked control gel, prepared with the same level of MABNTA (10 mol %) and a similar amount of cross-linking agent (2.5 mol %) as the hybrid gels, did not change in volume over the same temperature range. The temperature transition was not reversible since 12 h after returning the gel to room temperature the volume of the temperature-swelled hydrid hydrogel did not change.

The structure of the H-I28-H cross-links inside the hydrogel was investigated using the fluorescence of the I28 W residue as a reporter. At room temperature, the fluorescence maximum of the I28 cross-linked hydrogel was 317 nm (Figure 6B), corresponding to the fluorescence maximum of the protein in PBS buffer without denaturant (Figure 4), which suggested that the I28 cross-links were in their native structure. After the gel was heated at 85 °C, the fluorescence maximum shifted to 360 nm, corresponding to the denatured state of I28, providing evidence that gel swelling occurred due to the denaturation of the I28 cross-links.

DISCUSSION

The titin protein has unique viscoelastic properties that arise from the highly ordered molecular structure of the modules of which it is comprised. Our goal was to take advantage of the consistent structure and predictable mechanical properties of one of titin's well-characterized structural modules, an Ig module, to create a hydrogel with unique environmental responsiveness. We constructed a double-His-tagged single I28 Ig domain, which we produced in *E. coli*. The recombinant I28 domain was correctly folded into its native structure as judged by its molecular mass in solution, its secondary structure, its thermal stability, and intrinsic fluorescence spectra.

Hydrogels readily formed when the H-I28-H protein was mixed with the Ni^{2+}-chelated acrylamide copolymer. The metal coordination cross-linking strategy provides a convenient and effective method for assembling hybrid hydrogels. One of the major advantages of this strategy is that hydrogels are formed in aqueous buffer, at neutral pH, at ambient temperature, and in the absence of redox initiators (radicals) that can damage proteins. The metal coordination linkage between His tags and NTA is quite robust; the H-I28-H cross-linked gels were stable submerged in buffer for more than 30 days. One concern about the strategy could be the potential for Ni^{2+} cross-linking between NTA side chains. In control experiments, in which Ni^{2+} was added to the chelating copolymer with a substoichiometric ratio of Ni^{2+} to NTA side chains, soft gels formed at high polymer concentrations. These gels dissolved in excess buffer or as nickel sulfate was added. After the chelating polymer had been preloaded with a stoichiometric amount of Ni^{2+}, the NTA−NTA cross-links were minimized during hydrogel assembly and cross-linking most likely occurred predominantly through metal coordination between His tags and NTA.

The H-I28-H cross-linked gel responded to rising temperature by swelling isotropically more than 3-fold over the temperature range of 30−80 °C (Figure 6). The equilibrium volume increased significantly above 58 °C, the melting temperature of the H-I28-H protein determined by CD spectroscopy (Figure 3B), suggesting that the swelling was due to the thermally induced unfolding of the H-I28-H cross-links. The fluorescence maximum at 350 nm from the heated gel confirmed that the H-I28-H domain was unfolded in the temperature-swollen gels (Figure 6B). A chemically cross-linked gel of the chelating acrylamide copolymer did not change in volume over the same temperature range (Figure 6A). Swelling due to disruption of the metal coordination bonds at elevated temperatures can be ruled out by previously reported hybrid hydrogels that were cross-linked by metal coordination with a His-tagged coiled coil that had a melting temperature of >100 °C. These gels did not change in volume over the temperature range of 25−90 °C (*6*).

The positive temperature response of the I28 hybrid hydrogel is unusual. Most temperature-responsive hydrogels demonstrate negative thermal responses; they shrink at elevated temperatures. A common example is chemically cross-linked poly(*N*-isopropylacrylamide)

[p(NIPAAm)] which shrinks near the LCST of pNIPAAm due to hydrophobic interactions among its side chains that become stronger as the temperature increases. Hydrogels of chemically cross-linked polymers and copolymers of other *N*,*N*′-alkyl-substituted acrylamides, such as *N*-ethylacrylamide or *N*,*N*′-dimethylacrylamide, also have similar but less sharp negative thermosensitivity (*21*). An exception is poly(acrylic acid)-containing hydrogels, which swell with elevated temperature at low pH due to disruption of hydrogen bonding between acrylic acid and acrylamide side chains (*22*). The poly(acrylic acid) hydrogels are not temperature-responsive at pHs significantly greater than the pK_a of the carboxylic acid side chains, i.e., neutral pH. Therefore, the I28 cross-linked hydrogels may be unique in demonstrating a substantial positive temperature response at neutral pH.

In the single titin molecule stretching experiments, some Ig modules were observed to consistently unfold at lower forces than others (*11*). Likewise, biochemical stability studies with isolated titin Ig modules demonstrated that there can be dramatic variations in stability between modules (*18*). For example, the melting temperature of the I27 module was 72.6 °C, compared to 35.3 °C for the I11 module. The variable stability of homologous titin Ig modules suggests that small changes in amino acid sequence can have pronounced effects on module stability. It may be possible, therefore, to select natural Ig modules as cross-links to create hydrogels for a particular application that respond at a specified temperature. The temperature response could be adjusted over a wide range of temperatures. Furthermore, since the Ig module structure is known (*8*), it is likely that the thermal stability of the Ig modules can be adjusted in a predictable manner by altering a few key amino acids within the domain. By using multiple-Ig module cross-links, it may be possible to assemble hydrogels that undergo volume transitions at multiple temperatures.

In addition to its temperature response, we expect that the I28 cross-linked hybrid hydrogel may respond to other stimuli as well, like ionic strength. As the ionic strength is lowered, the osmotic pressure inside the polyanionic acrylamide copolymer gel will exert increasing force on the I28 cross-links. At a critical ionic strength, the swelling force exerted by the polymer matrix may exceed the threshold force needed to rupture the I28 structure, leading to the cooperative unraveling of the I28 modules. The sudden expansion of the hydrogel cross-links from 4 to ∼30 nm, as seen in the titin stretching experiments (*11*), could result in a pronounced step in the volume transition. The novel swelling profile in response to changes in temperature, and potentially other environmental conditions, along with the potential for adjusting the response over a wide range of environmental conditions, suggests that the I28 cross-linked hybrid hydrogels may have applications in controlled chemical delivery. The gels may be particularly useful for controlled delivery of biologically active proteins because of the mild hydrogel assembly conditions.

The Ig cross-linked hybrid hydrogels demonstrate that well-defined protein modules can be used to mechanically modulate the intrinsic response of a synthetic copolymer matrix in a predictable manner. Biology is a vast resource of predesigned, prefolded protein modules, with well-characterized structures and properties, which can be recombined and modified using the tools of molecular biology. Cross-linking synthetic water-soluble copolymers with recombinant protein modules offers a new approach and a new inventory of molecular materials with which to design responsive hydrogels for a wide variety of applications.

Transition Metal Derivatives of Peptide Nucleic Acid (PNA) Oligomers—Synthesis, Characterization, and DNA Binding

Jeroen C. Verheijen,[‡] Gijs A. van der Marel,[‡] Jacques H. van Boom,*[,‡] and Nils Metzler-Nolte*[,§]

Leiden Institute of Chemistry, P.O. Box 9502, 2300 RA Leiden, The Netherlands, and Max-Planck-Institut für Strahlenchemie, Stiftstrasse 34-36, Mülheim/Ruhr, Germany. Received June 28, 2000

This work describes the first automated solid-phase synthesis of metal derivatives of peptide nucleic acid (PNA) oligomers and their interaction with DNA and PNA. PNA constitutes a relatively young and very promising class of DNA analogues with excellent DNA and RNA binding properties. However, PNA lacks a suitable handle that would permit its sensitive detection on its own as well as when hybridized with complementary oligonucleotides. Metal complexes, on the other hand, offer high potential as markers for biomolecules. In this paper, we describe the synthesis of PNA heptamers (tggatcg-gly, where gly is a C-terminal glycine carboxylic acid amide) with two covalently attached metal complexes at the PNA N-terminus, namely a ferrocene carboxylic acid derivative and a tris-(bipyridine)ruthenium(II) derivative. We show how all synthesis steps may be carried out with high yield on a DNA synthesizer, including attachment of the metal complexes. The conjugates were characterized by HPLC (>90% purity) and ESI-MS. Binding studies of the purified Ru-PNA heptamer to complementary DNA and PNA and comparison to the isosequential metal-free acetyl PNA heptamer proves that the attached metal complex has an influence on the stability (UV-T_m) and structure (CD spectroscopy) of the conjugates, possibly by disruption of the nearby A:T base pair.

Many human diseases can nowadays be traced to genetic dispositions such as mutations of a single base in the DNA, deletions or translations of a whole sequence, or even multiple genetic disorders. Consequently, genetic diagnostics are becoming increasingly important and common (*1*). Technically, the presence of a certain DNA sequence is detected by hybridization with a complementary DNA sequence which carries a radioactive or fluorescence marker that will permit the detection of the hybridization event. Though commonly employed, this scheme is far from ideal in a number of aspects. Stability and sequence specificity, as well as binding affinity of natural DNA, are often worse than desired. The use of radioactive markers is undesirable for obvious reasons. In addition, the signal from fluorescence markers is sometimes difficult to quantify, and indeed fluorescence may be quenched all together under unfavorable circumstances.

Much effort has been directed to the development of DNA analogues with improved properties. A promising DNA analogue, dubbed PNA (peptide nucleic acid), was published by Nielsen et al. in 1991 (*2*). PNA strands bind complementary RNA and ss-DNA stronger than homologous DNA with likewise increased mismatch discrimina-

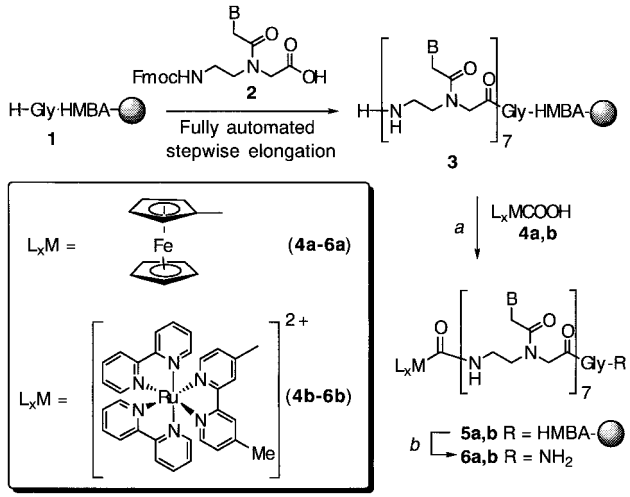
Table 1. Binding Properties of Ru-PNA 6b with Complementary PNA or DNA[a]

entry	duplex	type	T_m (°C) (melting)	T_m (°C) (annealing)
1	Ac-tggatcg-gly (**9**) gly-acctagc-Ac (**8**)	PNA·PNA	61.4	61.4
2	Ru-tggatcg-gly (**6b**) gly-acctagc-Ac (**8**)	Ru-PNA·PNA	59.7 ($\Delta T_m = -1.7$ °C)	59.4 ($\Delta T_m = -2.0$ °C)
3	Ac-tggatcg-gly (**9**) 3′-ACCTAGC-5′ (**7**)	PNA·DNA	41.3	40.3
4	Ru-tggatcg-gly (**6b**) 3′-ACCTAGC-5′ (**7**)	Ru-PNA·DNA	39.0 ($\Delta T_m = -2.3$ °C)	36.0 ($\Delta T_m = -4.3$ °C)

[a] All temperatures were determined by UV spectroscopy (UV-T_m). Hybridization studies were performed in a phosphate buffered solution at pH 7, with a NaCl concentration of 100 mM. Heating and cooling rate was 0.5 °C/min after equilibration at the starting temperature (20 and 90 °C). Gly denotes a C-terminal glycine carboxamide, capital and small letters stand for DNA and PNA, respectively.

Scheme 1. Synthesis of Metal-PNA Oligomers[a]



[a] (a) 2-(7-Azabenzotriazol-1-yl)-1,1,3,3-tetramethyluronium Hexa-fluorophosphate (HATU), *N*,*N*-di-*iso*-Propylethylamine (DiPEA), 30 min. (b) NH_3/MeOH, 50 °C, 16 h.

tion (*3*−*5*). Transition-metal complexes, on the other hand, hold great promise for sensitive detection by improved fluorescent properties or in electrochemical assays (*6*−*12*). We have recently published the first transition-metal derivatives of PNA monomers (*13*). In the following, we describe the automated solid-phase synthesis of transition-metal derivatives of PNA oligomers as well as their characterization and interaction with complementary DNA and PNA. To the best of our knowledge, apart from a single cationic manganese porphyrin PNA conjugate that was shown to effect sequence-specific oxidative DNA cleavage upon addition of $KHSO_5$ by Nielsen and Meunier (*14*), no systematic studies on PNA oligomers with covalently bound transition-metal complexes have been reported up to the present date.

Two metal complexes were selected for attachment to immobilized PNA oligomers, namely ferrocene derivative **4a** and tris(bipyridine)ruthenium(II) complex **4b**. Both complexes are very stable, undergo reversible one-electron oxidation, and exhibit characteristic UV−vis absorptions that will facilitate their detection for instance during HPLC purification. In addition, Ru complexes have become important tools for the study of electron transport in DNA (*15*, *16*). It should be noted that the octahedral ruthenium complex **4b** exists as a racemic mixture of topological stereoisomers (Λ and Δ). The synthesis of the metal−PNA conjugates (M-PNAs) **6a**,**b** is depicted in Scheme 1 and starts with the assembly of a PNA heptamer according to a well-established solid-phase synthesis protocol (*17*) using Fmoc/*N*-acyl protected PNA monomers **2** [*B* = A(Bz), C(Bz), G(^{i}Bu), T] (*18*). The metal complex **4** was coupled to the terminal amino group of PNA heptamer **3**. To this end, a standard PNA coupling cycle was slightly adapted by increasing the coupling time to 30 min and omitting the capping step. Subjection of the resulting immobilized M-PNA **5** to methanolic ammonia resulted in cleavage from the resin with simultaneous deprotection of the exocyclic amines. The crude mixtures were filtered, concentrated and analyzed by HPLC-MS. In both cases, the HPLC diagram of the crude mixture showed one major product **6** with the correct mass (>90% by HPLC, see Supporting Information). In case of the Ru-PNA complex **6b**, HPLC detection was performed using dual wavelength monitoring (254 and 370 nm). Only the Ru complex has an appreciable absorption at the latter wavelength and it is of interest to note that only one HPLC peak was observed at both wavelengths simultaneously which corresponded to the desired product.

Purification by RP-HPLC furnished the homogeneous complexes. Unfortunately, the solubility of the uncharged, lipophilic ferrocene conjugate **6a** in neutral aqueous buffer was rather low, precluding further studies. Since we have a special interest in conjugates of PNA with bulky chiral metal complexes, Ru-PNA **6b** was selected for further characterization. The UV−vis spectrum of **6b** was essentially the sum of the UV−vis spectrum of metal complex **4b** (with characteristic MLCT bands around 454 nm) and the known spectrum of mixed-sequence PNA oligomers. The duplex stability with complementary DNA (**7**) and PNA (**8**) was determined by monitoring the UV absorption upon heating or cooling of equimolar mixtures in phosphate buffered solutions at pH 7 (UV-T_m). Comparison to isosequential native PNA (**9**) reveals that the presence of the bulky ruthenium complex is fully compatible with duplex formation (Table 1). Thus, the melting temperature (T_m) of the Ru−PNA·PNA duplex (entry 2) was only 1.7 °C lower than that of the corresponding PNA·PNA duplex (entry 1), whereas the drop in T_m was 2.3 °C with complementary DNA (compare entries 3 and 4). This drop in T_m is about the value generally accepted for one A:T base pair. Furthermore, in the latter case a small but significant T_m-hysteresis is observed (3 °C, entry 4). A similar phenomenon was described earlier for the melting behavior of various PNA analogues (*19*, *20*). Clearly, the forward kinetics of duplex formation and the duplex stability are diminished by the bulky Ru complex, possibly by disrupting the hydrogen bonding of the N-terminal A:T base pair.

An appreciable effect of the bulky Ru complex on the secondary structure of the duplex was observed by CD spectroscopy. A positive Cotton effect with maximum at 266 nm is observed for the PNA·DNA system (Figure 1), corresponding to the expected B-DNA like helix (*21*). When the acetyl group is replaced by a Ru-complex (as

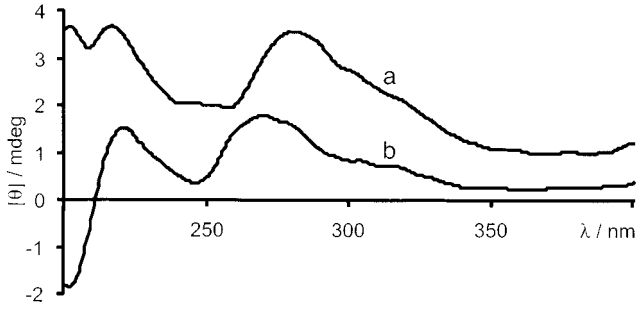


Figure 1. CD spectra of **6b**·DNA (a) and Ac-PNA·DNA (b).

in **6b**), the maximum at 266 nm shifts to 280 nm. In addition, the observed Cotton effect is rather weak, which may be ascribed to the following two reasons. A full helical turn in a PNA·DNA duplex takes 13 base pairs (*22*). Since in this study only heptamers are used, the secondary structure may not be fully developed. More interestingly, it should be remembered that a racemic mixture of both topological isomers of Ru−PNA **6b** is used. Therefore, duplexation with DNA gives an equimolar mixture of diastereoisomers, each giving rise to their own CD signals. Giese and co-workers have recently described the synthesis of diastereomerically pure DNA conjugates of tris(phenanthroline)ruthenium complexes (*23*). There is an ongoing debate as to which way optically pure Ru complexes of this type interact with DNA (*15*, *24*). Investigations into the preparation and hybridization properties of chirally pure Ru-PNA complexes are currently in progress.

In conclusion, we have demonstrated that the synthesis of metal PNA conjugates with high yield and purity is feasible by standard solid support peptide synthesis methods. The stability of a ruthenium-PNA conjugate binding to complementary DNA is only slightly less than for a nonmetalated PNA strand, allowing the metal complex to act as a marker for PNA·DNA binding. Studies on the synthesis and behavior of enantiomerically pure metal−PNA conjugates are underway and will be reported in due course.

ACKNOWLEDGMENT

This work was supported by the Council for Chemical Sciences of The Netherlands Organization for Scientific Research (CW-NWO) and the Fond der Chemischen Industrie. We thank Hans van den Elst for recording the HPLC-MS spectra. N.M.N. is grateful to Prof. K. Wieghardt for generous support of this work.

Supporting Information Available: Experimental details and HPLC chromatograms of **6a** and **6b**. This material is available free of charge via the Internet at http://pubs.acs.org.

Transition Metal Derivatives of Peptide Nucleic Acid (PNA) Oligomers - Synthesis, Characterization and DNA Binding

Jeroen C. Verheijen, Gijs A. van der Marel, and Jacques H. van Boom, and Nils Metzler-Nolte*

Experimental section

*Solid-phase synthesis of M-PNA adducts **6a,b**:* All solvents (Biosolve, DNA synthesis grade) were used as received. Ferrocene carboxylic acid was purchased from Aldrich, the Ru complex **4b** was prepared following published procedures (Peek et al., *Int. J. Pept. Prot. Res.*, 38, **1991**, 114 - 123). Solid phase synthesis was performed on a Pharmacia Gene Assembler using highly cross-linked polystyrene beads as the solid support (loading: 26-28 μmol/g) on a 1 μmol scale. The support was functionalized with a glycine moiety via a *p*-hydroxymethylbenzoic acid linker. Assembly of the PNA part was established using solutions of 0.3 M of monomers **2** or **4a,b** in dimethylformamide, 0.3 M D*i*PEA in acetonitrile/dimethylformamide (1/1, v/v) and 0.3 M HATU in acetonitrile/dimethylformamide (1/1, v/v). Prior to coupling, the monomers were pre-activated for 1 min by mixing equal amounts of the PNA monomer (15 equiv per μmol support), HATU and D*i*PEA solutions. The protocol for one PNA chain extension cycle consisted of (1) wash: acetonitrile/dimethylformamide (1/1, v/v), 2.5 mL; (2) coupling: PNA + HATU + DiPEA in acetonitrile/dimethylformamide (1/1, v/v), 15 min; (3) wash: acetonitrile/dimethylformamide (1/1, v/v), 2.5 mL (4) capping: Ac_2O/lutidine/*N*-methylimidazole/tetrahydrofuran (1/1/1/7, v/v/v/v), 2.0 mL; (5) wash: acetonitrile/dimethylformamide (1/1, v/v), 2.5 mL; (6) Fmoc deprotection: 20% piperidine in

acetonitrile/dimethylformamide (1/1, v/v), 3 min; (7) wash: acetonitrile/dimethylformamide (1/1, v/v), 2.5 mL. For metal complexes **4a,b** the coupling time in step 2 was increased to 30 min and step 4 (capping) was omitted. After the last elongation step, the oligomers were cleaved from the support with concomitant deprotection of the exocyclic amino groups by treatment with methanolic ammonia (1.5 mL) at 50 °C for 16 h. HPLC-MS analysis was carried out on a Jasco LCMS system equipped with an Altima C-18 column (4.6 x 150 mm) with mass detection on a Perkin Elmer Sciex API 165 equipped with an Electrospray Interface (ESI). RP-HPLC purification of **6a,b** was performed on a Jasco HPLC system equipped with a LiChrospher 100 RP-18 endcapped column (4.0 x 250 mm). In all cases, gradient elution was performed by building up a gradient starting with buffer A (0.1% TFA in water) and applying buffer B (0.1% TFA in acetonitrile/water, 9/1, v/v) with a flow rate of 1.0 mL/min.

Thermal melting studies: Melting temperatures (T_m) were determined with equimolar mixtures of PNA **9** or Ru-PNA **6b** and complementary DNA **7** or PNA **8** at a concentration of 3 μM, in a 10 mM phosphate buffer, pH=7.0, containing NaCl (100 mM) and EDTA (0.1 mM). Prior to recording the melting profile, the solutions were heated at 90 °C for several minutes and then cooled to 20 °C over 2.0 h. The mixtures were kept at 20 °C for 1 h and heated to 80 °C at a rate of 0.5 °C per minute while the A_{260} was recorded against temperature. Prior to recording the annealing profile, the mixtures were heated at 90 °C for several minutes. The mixtures were cooled to 20 °C at a rate of 0.5 °C per minute while the A_{260} was recorded againts temperature. The T_m values were determined as the maxima of the first-derivative plots of absorbance versus temperature.

CD measurements: CD spectra were recorded on a JASCO J715 instrument at room temperature and calibrated against a standard camphor sulphate solution, using equimolar mixtures of PNA **9** or Ru-PNA **6b** and complementary DNA **7** or PNA **8** at a concentration of 3 μM, in a 10 mM phosphate buffer, pH=7.0, containing NaCl (100 mM) and EDTA (0.1 mM).

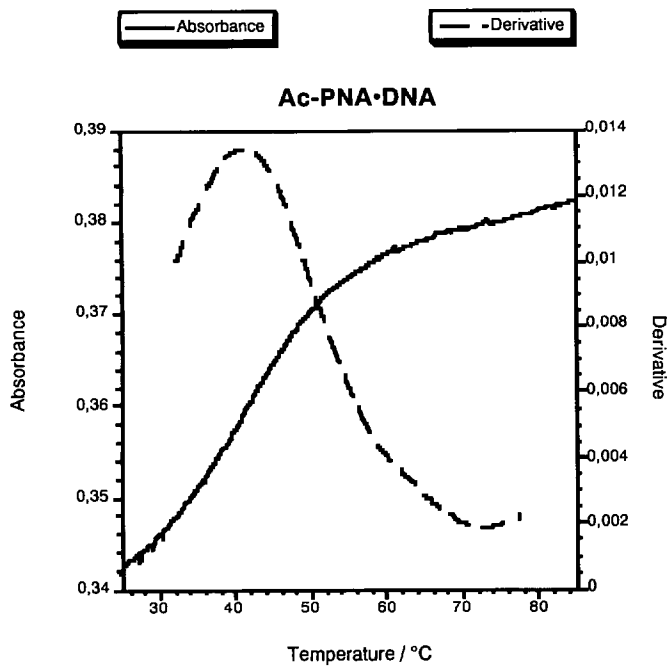
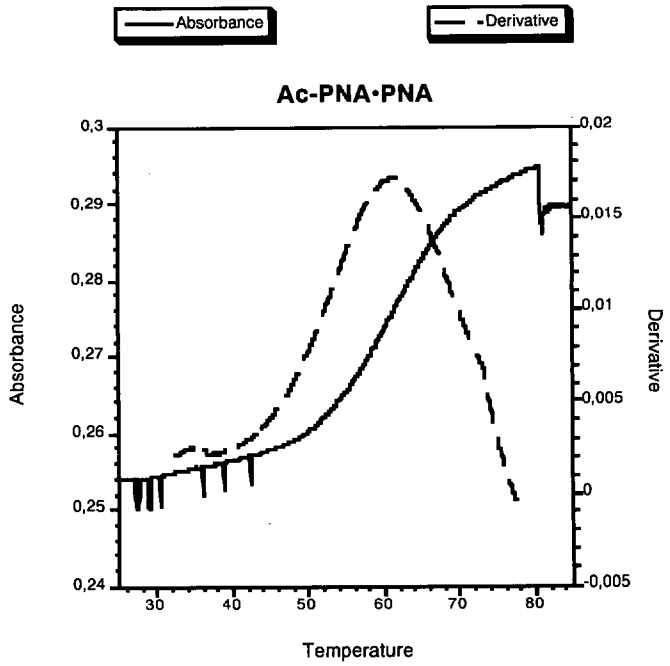
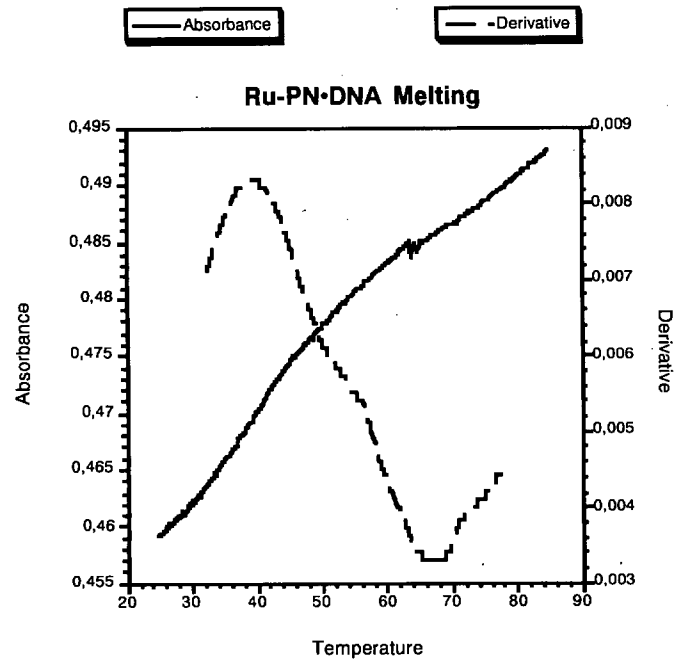
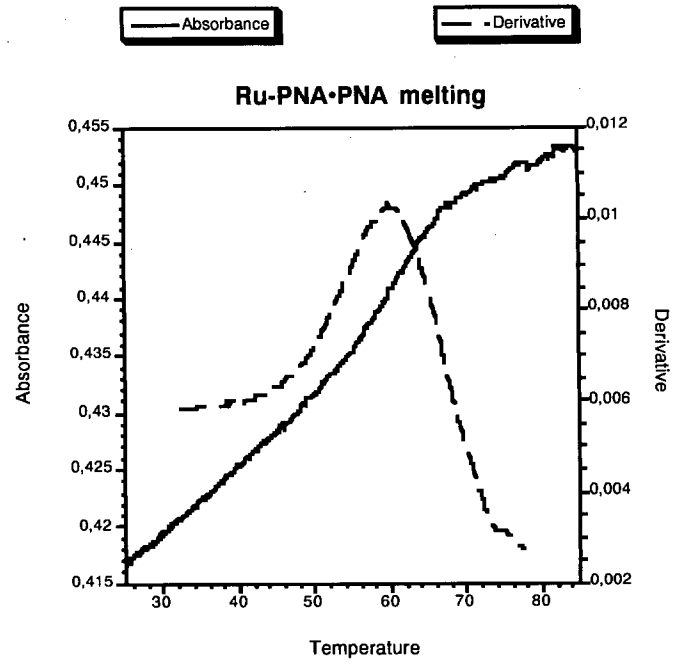
Melting Curves









Example melting curves are shown for each type of conjugate together with the first derivative. For determination of Tm, an average of at least two measurements was taken. No annealing data are shown in this material but the overall appearance of the annealing curves is very similar to the melting curves. See experimental section and table 1 for details.

Transition Metal Derivatives of Peptide Nucleic Acid (PNA) Oligomers—Synthesis, Characterization, and DNA Binding

Jeroen C. Verheijen,[‡] Gijs A. van der Marel,[‡] Jacques H. van Boom,*[,‡] and Nils Metzler-Nolte*[,§]

Leiden Institute of Chemistry, P.O. Box 9502, 2300 RA Leiden, The Netherlands, and Max-Planck-Institut für Strahlenchemie, Stiftstrasse 34-36, Mülheim/Ruhr, Germany. Received June 28, 2000

This work describes the first automated solid-phase synthesis of metal derivatives of peptide nucleic acid (PNA) oligomers and their interaction with DNA and PNA. PNA constitutes a relatively young and very promising class of DNA analogues with excellent DNA and RNA binding properties. However, PNA lacks a suitable handle that would permit its sensitive detection on its own as well as when hybridized with complementary oligonucleotides. Metal complexes, on the other hand, offer high potential as markers for biomolecules. In this paper, we describe the synthesis of PNA heptamers (tggatcg-gly, where gly is a C-terminal glycine carboxylic acid amide) with two covalently attached metal complexes at the PNA N-terminus, namely a ferrocene carboxylic acid derivative and a tris-(bipyridine)ruthenium(II) derivative. We show how all synthesis steps may be carried out with high yield on a DNA synthesizer, including attachment of the metal complexes. The conjugates were characterized by HPLC (>90% purity) and ESI-MS. Binding studies of the purified Ru-PNA heptamer to complementary DNA and PNA and comparison to the isosequential metal-free acetyl PNA heptamer proves that the attached metal complex has an influence on the stability (UV-T_m) and structure (CD spectroscopy) of the conjugates, possibly by disruption of the nearby A:T base pair.

Many human diseases can nowadays be traced to genetic dispositions such as mutations of a single base in the DNA, deletions or translations of a whole sequence, or even multiple genetic disorders. Consequently, genetic diagnostics are becoming increasingly important and common (*1*). Technically, the presence of a certain DNA sequence is detected by hybridization with a complementary DNA sequence which carries a radioactive or fluorescence marker that will permit the detection of the hybridization event. Though commonly employed, this scheme is far from ideal in a number of aspects. Stability and sequence specificity, as well as binding affinity of natural DNA, are often worse than desired. The use of radioactive markers is undesirable for obvious reasons. In addition, the signal from fluorescence markers is sometimes difficult to quantify, and indeed fluorescence may be quenched all together under unfavorable circumstances.

Much effort has been directed to the development of DNA analogues with improved properties. A promising DNA analogue, dubbed PNA (peptide nucleic acid), was published by Nielsen et al. in 1991 (*2*). PNA strands bind complementary RNA and ss-DNA stronger than homologous DNA with likewise increased mismatch discrimina-

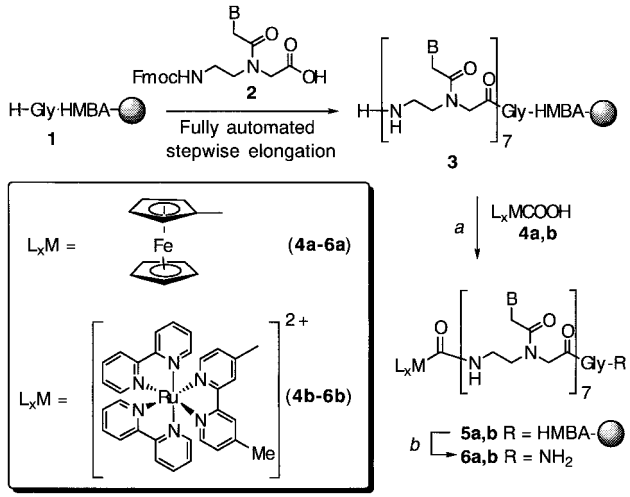
Table 1. Binding Properties of Ru-PNA 6b with Complementary PNA or DNA[a]

entry	duplex	type	T_m (°C) (melting)	T_m (°C) (annealing)
1	Ac-tggatcg-gly (**9**) gly-acctagc-Ac (**8**)	PNA·PNA	61.4	61.4
2	Ru-tggatcg-gly (**6b**) gly-acctagc-Ac (**8**)	Ru-PNA·PNA	59.7 ($\Delta T_m = -1.7$ °C)	59.4 ($\Delta T_m = -2.0$ °C)
3	Ac-tggatcg-gly (**9**) 3′-ACCTAGC-5′ (**7**)	PNA·DNA	41.3	40.3
4	Ru-tggatcg-gly (**6b**) 3′-ACCTAGC-5′ (**7**)	Ru-PNA·DNA	39.0 ($\Delta T_m = -2.3$ °C)	36.0 ($\Delta T_m = -4.3$ °C)

[a] All temperatures were determined by UV spectroscopy (UV-T_m). Hybridization studies were performed in a phosphate buffered solution at pH 7, with a NaCl concentration of 100 mM. Heating and cooling rate was 0.5 °C/min after equilibration at the starting temperature (20 and 90 °C). Gly denotes a C-terminal glycine carboxamide, capital and small letters stand for DNA and PNA, respectively.

Scheme 1. Synthesis of Metal-PNA Oligomers[a]



[a] (a) 2-(7-Azabenzotriazol-1-yl)-1,1,3,3-tetramethyluronium Hexa-fluorophosphate (HATU), *N*,*N*-di-*iso*-Propylethylamine (DiPEA), 30 min. (b) NH_3/MeOH, 50 °C, 16 h.

tion (*3*−*5*). Transition-metal complexes, on the other hand, hold great promise for sensitive detection by improved fluorescent properties or in electrochemical assays (*6*−*12*). We have recently published the first transition-metal derivatives of PNA monomers (*13*). In the following, we describe the automated solid-phase synthesis of transition-metal derivatives of PNA oligomers as well as their characterization and interaction with complementary DNA and PNA. To the best of our knowledge, apart from a single cationic manganese porphyrin PNA conjugate that was shown to effect sequence-specific oxidative DNA cleavage upon addition of $KHSO_5$ by Nielsen and Meunier (*14*), no systematic studies on PNA oligomers with covalently bound transition-metal complexes have been reported up to the present date.

Two metal complexes were selected for attachment to immobilized PNA oligomers, namely ferrocene derivative **4a** and tris(bipyridine)ruthenium(II) complex **4b**. Both complexes are very stable, undergo reversible one-electron oxidation, and exhibit characteristic UV−vis absorptions that will facilitate their detection for instance during HPLC purification. In addition, Ru complexes have become important tools for the study of electron transport in DNA (*15*, *16*). It should be noted that the octahedral ruthenium complex **4b** exists as a racemic mixture of topological stereoisomers (Λ and Δ). The synthesis of the metal−PNA conjugates (M-PNAs) **6a**,**b** is depicted in Scheme 1 and starts with the assembly of a PNA heptamer according to a well-established solid-phase synthesis protocol (*17*) using Fmoc/*N*-acyl protected PNA monomers **2** [*B* = A(Bz), C(Bz), G(^{i}Bu), T] (*18*). The metal complex **4** was coupled to the terminal amino group of PNA heptamer **3**. To this end, a standard PNA coupling cycle was slightly adapted by increasing the coupling time to 30 min and omitting the capping step. Subjection of the resulting immobilized M-PNA **5** to methanolic ammonia resulted in cleavage from the resin with simultaneous deprotection of the exocyclic amines. The crude mixtures were filtered, concentrated and analyzed by HPLC-MS. In both cases, the HPLC diagram of the crude mixture showed one major product **6** with the correct mass (>90% by HPLC, see Supporting Information). In case of the Ru-PNA complex **6b**, HPLC detection was performed using dual wavelength monitoring (254 and 370 nm). Only the Ru complex has an appreciable absorption at the latter wavelength and it is of interest to note that only one HPLC peak was observed at both wavelengths simultaneously which corresponded to the desired product.

Purification by RP-HPLC furnished the homogeneous complexes. Unfortunately, the solubility of the uncharged, lipophilic ferrocene conjugate **6a** in neutral aqueous buffer was rather low, precluding further studies. Since we have a special interest in conjugates of PNA with bulky chiral metal complexes, Ru-PNA **6b** was selected for further characterization. The UV−vis spectrum of **6b** was essentially the sum of the UV−vis spectrum of metal complex **4b** (with characteristic MLCT bands around 454 nm) and the known spectrum of mixed-sequence PNA oligomers. The duplex stability with complementary DNA (**7**) and PNA (**8**) was determined by monitoring the UV absorption upon heating or cooling of equimolar mixtures in phosphate buffered solutions at pH 7 (UV-T_m). Comparison to isosequential native PNA (**9**) reveals that the presence of the bulky ruthenium complex is fully compatible with duplex formation (Table 1). Thus, the melting temperature (T_m) of the Ru−PNA·PNA duplex (entry 2) was only 1.7 °C lower than that of the corresponding PNA·PNA duplex (entry 1), whereas the drop in T_m was 2.3 °C with complementary DNA (compare entries 3 and 4). This drop in T_m is about the value generally accepted for one A:T base pair. Furthermore, in the latter case a small but significant T_m-hysteresis is observed (3 °C, entry 4). A similar phenomenon was described earlier for the melting behavior of various PNA analogues (*19*, *20*). Clearly, the forward kinetics of duplex formation and the duplex stability are diminished by the bulky Ru complex, possibly by disrupting the hydrogen bonding of the N-terminal A:T base pair.

An appreciable effect of the bulky Ru complex on the secondary structure of the duplex was observed by CD spectroscopy. A positive Cotton effect with maximum at 266 nm is observed for the PNA·DNA system (Figure 1), corresponding to the expected B-DNA like helix (*21*). When the acetyl group is replaced by a Ru-complex (as

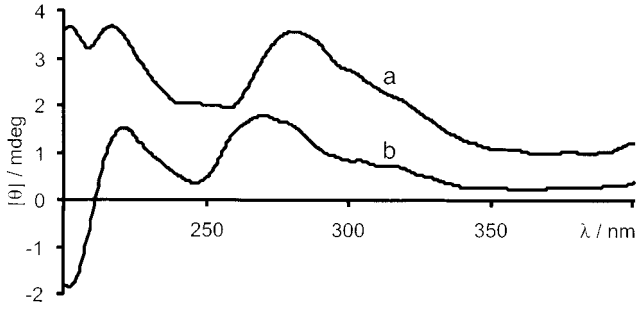


Figure 1. CD spectra of **6b**·DNA (a) and Ac-PNA·DNA (b).

in **6b**), the maximum at 266 nm shifts to 280 nm. In addition, the observed Cotton effect is rather weak, which may be ascribed to the following two reasons. A full helical turn in a PNA·DNA duplex takes 13 base pairs (*22*). Since in this study only heptamers are used, the secondary structure may not be fully developed. More interestingly, it should be remembered that a racemic mixture of both topological isomers of Ru−PNA **6b** is used. Therefore, duplexation with DNA gives an equimolar mixture of diastereoisomers, each giving rise to their own CD signals. Giese and co-workers have recently described the synthesis of diastereomerically pure DNA conjugates of tris(phenanthroline)ruthenium complexes (*23*). There is an ongoing debate as to which way optically pure Ru complexes of this type interact with DNA (*15*, *24*). Investigations into the preparation and hybridization properties of chirally pure Ru-PNA complexes are currently in progress.

In conclusion, we have demonstrated that the synthesis of metal PNA conjugates with high yield and purity is feasible by standard solid support peptide synthesis methods. The stability of a ruthenium-PNA conjugate binding to complementary DNA is only slightly less than for a nonmetalated PNA strand, allowing the metal complex to act as a marker for PNA·DNA binding. Studies on the synthesis and behavior of enantiomerically pure metal−PNA conjugates are underway and will be reported in due course.

ACKNOWLEDGMENT

This work was supported by the Council for Chemical Sciences of The Netherlands Organization for Scientific Research (CW-NWO) and the Fond der Chemischen Industrie. We thank Hans van den Elst for recording the HPLC-MS spectra. N.M.N. is grateful to Prof. K. Wieghardt for generous support of this work.

Synthesis of a Stable and Specific Surface Plasmon Resonance Biosensor Surface Employing Covalently Immobilized Peptide Nucleic Acids

Martin Burgener,* Michael Sänger, and Urs Candrian

R+D Unit and Section for Vaccines, Division of Biologicals, Swiss Federal Office of Public Health, P.O. Box, CH-3003 Berne, Switzerland . Received January 18, 2000; Revised Manuscript Received July 5, 2000

Biosensors allow the real-time and label-free observation of biochemical reactions between various ligands including antigen−antibody reactions and nucleic acids hybridizations. In our studies, we used a surface plasmon resonance biosensor to elucidate the hybridization characteristics of a peptide nucleic acid (PNA) ligand immobilized on sensor surfaces either through covalent or streptavidin−biotin coupling. A biotin-labeled PNA was employed in the latter approach whereas the covalent immobilization included the following steps: A maleimide group was attached to the N-terminal of the PNA using *N*-succinimidyl 4-(*N*-maleimidomethyl)-cyclohexane-1-carboxylate (SMCC). To generate free thiol groups for coupling, a carboxylated dextran matrix of the sensor surface was activated with *N*-hydroxysuccinimide (NHS) and *N*-ethyl-*N*′-(dimethylaminopropyl)-carbodiimide (EDC) and thiolated by addition of cystamine dihydrochloride followed by reduction with 1,4-dithioerythrite (DTE). Finally, the modified PNA was coupled to the sulfhydryl groups of the activated dextran matrix. Repetitive hybridizations of a single-stranded synthetic DNA oligomer to the PNAs demonstrated the superior stability of covalent immobilization compared to noncovalent immobilization. Differentiation of point mutations in the analyte molecule was accomplished at 40 °C using guanidine thiocyanate concentrations of 1.5−1.7 M. In further experiments, we showed that a perfectly matched PNA allows the detection of a single-stranded DNA at a sensitivity of less than 1% in a background of single-stranded DNA having a single C to T point mutation in the region complementary to the PNA. Consequently, covalently bound PNAs provide a stable and reproducible environment for the development of mutation-specific DNA analysis assays.

INTRODUCTION

Detection and characterization of nucleic acids allow the identification of biological samples and are of central interest in many fields of molecular biology. The analysis relies on the sensitive and specific hybridization of oligonucleotide probes to nucleic acid target molecules. The hybridization of a primer to a template molecule is the central step in all amplification reactions such as polymerase chain reaction (PCR), reactions based on reverse transcription as well as DNA sequencing reactions. Southern blotting and DNA-based ELISAs rely also on the hybridization of a probe to a target sequence. In all those techniques, the final nucleic acid duplex is detected but the actual hybridization process is not monitored. The end-point determination requires direct labeling of the probe with radioactive isotopes, chemiluminescent, or fluorescent molecules. Alternatively, indirect detection is achieved by introducing marker molecules like biotin or antigenic sites that can be recognized with streptavidin and antibodies which are modified to allow color reactions (*1*). Only recently, instruments such as Taq-Man from Perkin-Elmer and the Lightcycler from Roche that allow real time monitoring of PCR have been introduced (*2*, *3*). But in most formats performed with these instruments, labeling of hybridization oligonucleotides is still required.

One area, in which nucleic acid analysis will become important in the future is the quality assurance of vaccines, e.g., live attenuated poliovirus vaccines. These vaccines were developed decades ago by Sabin and are known to be capable of reversion to neurovirulence (*4*). Therefore, each vaccine production lot is tested for neurovirulence by direct inoculation of poliovirus into the central nervous system of susceptible primates (*4*). The molecular basis for neurovirulence of poliovirus vaccine strains is the reversion of attenuating point mutations such as the backmutation from T to C at nucleotide position 472 of the Sabin poliovirus serotype 3. Assays based on PCR and restriction enzyme digestion of amplification products have been developed to detect this backmutation. One such test to assess the consistency of production at a molecular level is the so-called MAPREC (mutant analysis by polymerase chain reaction and restriction enzyme cleavage) in vitro assay. A disadvantage of the MAPREC assay, which is time and labor consuming and uses radiolabeled oligonucleotides, is the fact that it depends on the nucleotide sequence around the mutation (*4*). An adaptation of the assay to other mutations may therefore be difficult or even impossible.

In the past years, biosensor technology has been developed rapidly and it is now possible to elucidate nucleic acids interactions (*5*). Kinetic properties of hybridizations can be determined due to the ability to observe the interaction of ligand and analyte in real time, providing important knowledge for all hybridization based investigations (*6*). Applications of biosensor technology in the field of nucleic acids analysis include the detection of point mutations (*7*), the simultaneous screening of nucleic acid samples on high-density DNA arrays

(*8*), and the detection of products of the PCR employing DNA−DNA hybridization (*9*, *10*).

In our studies, we used a Biacore biosensor, based on surface plasmon resonance (SPR), to investigate as a model the mutation specific hybridization of poliovirus nucleic acids. SPR measurements are rapid and can be performed within minutes without the need for specific labels. The detection system relies on the measurement of changes in the refractive index, which is proportional to the mass of the bound analyte. With the Biacore instrument, premanufactured streptavidin-coated matrix surfaces are often used (*11*, *12*). Such surfaces allow the coupling of biotinylated DNA ligands. However, it was found that this approach does not produce stable ligand−surfaces complexes (*12*), a result that has been reproduced in our laboratory (not published). Since a high reproducibility of results is of central interest in kinetic evaluation as well as in concentration measurements, manufacture of stable sensor surfaces containing nucleic acid probes is indispensable.

We therefore replaced the insufficiently stable streptavidin−biotin-mediated attachment of nucleic acid ligands to the biosensor surface by direct covalent coupling of the ligand to the dextran surface. In addition, instead of the conventional oligonucleotide ligand, a peptide nucleic acid (PNA) was used (*13*, *14*). Due to it's unique chemical properties, application of PNAs in molecular biology has proven to be a very attractive approach for different assays (*15*−*17*): PNAs are not cleaved by common nucleases and restriction enzymes and are therefore more stable than oligonucleotides, have a higher affinity for nucleic acids than DNA, can invade DNA duplexes under low salt concentrations and build very stable triplexes with DNA (*14*, *18*). As a consequence of these properties, PNAs are more specific in the detection of point mutations, which has been shown by Wang et al. employing an electrochemical biosensor (*19*). Our work demonstrates that it is feasible to synthesize a stable, covalently linked PNA sensor surface complex able to detect point mutations in analyte oligonucleotides thus combining the advantages of real time label-free analysis with superior specificity and reproducibility.

EXPERIMENTAL PROCEDURES

Materials. All ligand and analyte oligonucleotides, except Oligo neg, were designed to cover position 472 in the domain V of the 5′ untranslated region (UTR) of Poliovirus Serotype 3, Sabin Strain. This position (boldface in the sequences below), is responsible for the attenuated phenotype, as well as reversion to neurovirulence. Oligo T and Oligo C correspond to the cDNA sequence of vaccine and revertant strain, respectively. Oligo neg was designed not to match any other sequence neither ligand, nor analyte. Oligo T, 5′-GGG TTG CAG CTG CCT GCT CCA TGG TTA G**A**A TTA GCC GCA TTC AGG-3′; Oligo C, 5′-GGG TTG CAG CTG CCT GCT CCA TGG TTA G**G**A TTA GCC GCA TTC AGG-3′; Oligo neg, 5′-ATG GCA CGC ACG ATA AAC TAG ACG CAC GAG TGA AAG ATA AAT GGC-3′.

All DNA-oligonucleotides were used as analytes and were synthesized by Microsynth, Balgach, Switzerland. Polio-PNA-SMCC, SMCC-OO-GGC TAA T**C**C TAA CCA-O-Lys-NH_2 (Figure 1), and Polio-PNA-Biotin, Bio-OO-GGC TAA T**C**C TAA CCA-Lys-NH_2, were used as Ligands (O = linker unit) and were synthesized by PE Biosystems (Framingham, MA).

All experiments were performed on a Biacore X biosensor, from Biacore, Uppsula, Sweden. Carboxymethylated-sensor chips (CM chips), streptavidin-sensor chips (SA chips), *N*-hydroxysuccinimide (NHS), *N*-ethyl-*N*′-(dimethylaminopropyl)-carbodiimide (EDC), ethanolamine and HBS buffer (10 mM HEPES, pH 7.4, 150 mM NaCl, 3.4 mM EDTA, 0.005% (v/v) surfactant P20) were purchased from Biacore.

Cystamine dihydrochloride, *N*-ethylmaleimide (NEM), guanidine thiocyanate (GuSCN), and 1,4-dithioerythritol (DTE) were from Merck, Darmstadt, Germany.

Experimental data were evaluated with Biaevolution 3.0.2, Biacore, and Gauss 3.2.38, Aptech Systems, Maple Valley, WA.

Immobilization of Biotinylated PNAs (SA-PNA Chip). All solutions are in water, expect otherwise stated. All immobilizations were carried out in HBS buffer, 25 °C, and at a flow rate of 5 μL/min. The SA chip was twice exposed to 20 μL of 50 mM sodium hydroxide to precondition the surface. Polio-PNA-Biotin (0.1 μM in 20 mM sodium phosphate buffer, pH 7.0) was immobilized to a level of about 600 RU. Not bound ligand was removed by washing with 20 μL of 50 mM NaOH.

Standard Procedure for Covalent Immobilization of PNAs (CM-PNA Chip). A total of 15μL of 50 mM NHS and 200 mM EDC was injected to yield a NHS-activated CM-Matrix. By injecting 15 μL of a 40 mM cystamine dihydrochloride, cystamine dihydrochloride was covalently bound via amine coupling (Figure 1). Surplus-active groups were deactivated using 20 μL of 1 M ethanolamine. Bound cystamine was reduced by injecting 15 μL of 100 mM DTE. Polio-PNA-SMCC (5 μM in 20 mM sodium phosphate buffer, pH 7.0) was immobilized to a level of about 600 RU. Free sulhydryl groups were deactivated by injecting 20 μL of 20 mM NEM, 1 M NaCl, 20 mM sodium phosphate buffer, pH 7.0. Not bound ligand was removed by washing with 20 μL of 50 mM NaOH.

Stability of Specific Sensor Surfaces. All hybridization experiments were carried out in 1.6 M GuSCN, 0.1 M sodium phosphate buffer, pH 7.0, 0.15 M NaCl (GuSCN buffer) as running buffer, at 40 °C and a flow rate of 10 μL/min. The regeneration solution was 50 mM of NaOH. Oligo C was dissolved in running buffer to obtain serial dilutions ranging from 39 nM to 20 μM. A total of 30 μL of each dilution was injected. Each dilution series was repeated four times on each sensor surface (SA-PNA and CM-PNA chip).

A calibration curve employing Oligo C (40 nM to 40 μM) in GuSCN buffer was established for both sensor surfaces (SA-PNA and CM-PNA chip). The curves were fitted to the equation $f(R) = R_{Hi} - [(R_{Hi} - R_{Lo})/(1 - (x/A_2)^{A_1})]$ as used in the Biaevaluation 3.0.2 software. Eighteen consecutive injections of 30 μL of 5 μM Oligo C in GuSCN buffer were performed on the SA-PNA chip. Using the first derivation of $f(R)$, $f'(R) = R_{Hi} - R_{Lo})A_2x^{(A_2-1)}/(1 + (\frac{x}{A_1})^{A_2})^2 \cdot A_1{}^{A_2}$, the concentration with the same slope as the 5 μM oligo C based on the SA calibration curve was determined for the CM-PNA calibration curve (3.8 μM). Eighteen consecutive injections of 30 μL of 3.8 μM oligo C in GuSCN buffer were performed on the CM-PNA chip.

Specificity of PNA−DNA Hybridization. A total of 30 μL of 2 μM Oligo C, Oligo T, and Oligo neg was separately injected in 0.1 M sodium phosphate buffer, pH 7.0, 0.15 M NaCl with increasing GuSCN concentrations (from 0 to 2.4 M in 0.3 M steps). Running buffer was HBS. The regeneration solution was 50 mM NaOH.

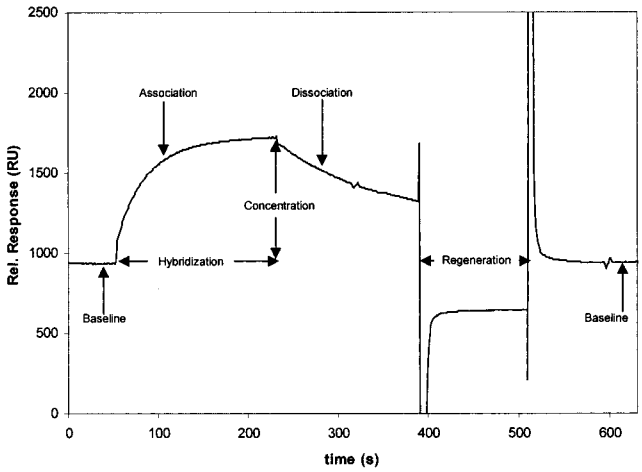

Figure 2. SPR response from a single measurement-cycle. The plot represents the difference between the analytical cell compared to the reference cell. The concentration corresponds to the maximal response signal. For experimental details see the Experimental Procedures.

Mixtures of Oligo C, Oligo T, and Oligo neg were produced to measure the specific detection of Oligo C. The amount of Oligo C compared to Oligo T was 100, 50, 10, 5, 2.5, 1, and 0.75%. The concentration of Oligo C was kept at 0.2 μM and Oligo neg was used to adjust the total amount of DNA to 26.6 μM. As controls served 100% Oligo T (40 μM) and 100% Oligo neg (40 μM). All oligos were dissolved in GuSCN buffer. A total of 30 μL of each DNA mixture was injected and the measurement cycle including hybridization, and regeneration (Figure 2) was repeated several times.

RESULTS

Synthesis of PNA Chips. As described in the Experimental Procedures, a PNA−oligonucleotide specific for the 5′ UTR of the poliovirus serotype 3 revertant, which contains a T to C mutation at nucleotide position 472, was used as a probe. The PNA was coupled to the sensor surface as follows. In one method, the PNA labeled with biotin was immobilized on a sensor chip precoated with streptavidin as previously published by Sawata et al. (*9*) (SA-PNA chip). In an alternative approach, we developed a standard procedure for the covalent binding of the PNA, modified at its N-terminal with a maleimide group, to a carboxylated dextran matrix of a sensor surface (CM-PNA chip) (Figure 1). As shown in Figure 3, this synthesis, encompassing several steps, was performed and monitored directly on the Biacore X biosensor. Six immobilizations followed by hybridization with Oligo C at an analyte concentration of 20 μM demonstrated the reproducibility of the standard immobilization procedure (2072 RU, se=23.2; excluding an extreme value of 1606 RU). Increase of NHS/EDC concentration or injection volume yielded higher PNA binding capacity, whereas increasing concentration or injection volume of cystamine dihydrocloride did not influence the binding capacity (data not shown).

Stability of PNA Sensor Chips. The stability of both types of PNA sensor chips was evaluated by hybridizing the complementary Oligo C to the immobilized PNA. For each type of PNA sensor chip, the hybridization of increasing concentrations of target DNA was measured and the dilution series was repeated four times. The resulting hybridization curves are shown in Figure 4. Clearly, each series of measurements with the SA-PNA chip yielded curves with decreased signal intensities

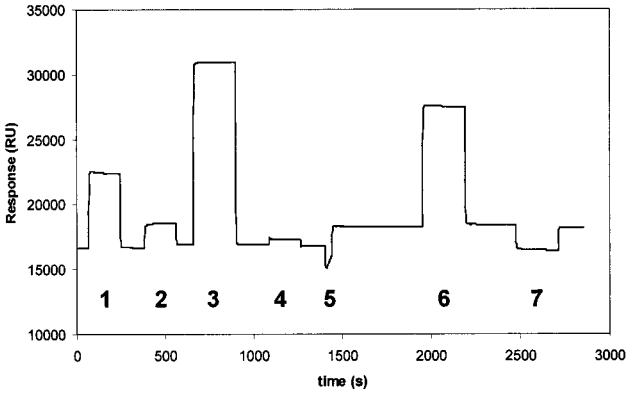

Figure 3. SPR sensogram of covalent immobilization of PNA to a CM surface. NHS activated CM Matrix (1), amine coupling of cystamine (2), deactivation of surplus NHS groups (3), reduction of cystamine to yield free sulfhydryl groups (4), covalent immobilization of Polio-PNA-SMCC (5), deactivation of free sulfhydryl groups using NEM (6), removal not bound PNA with NaOH Injection (7).

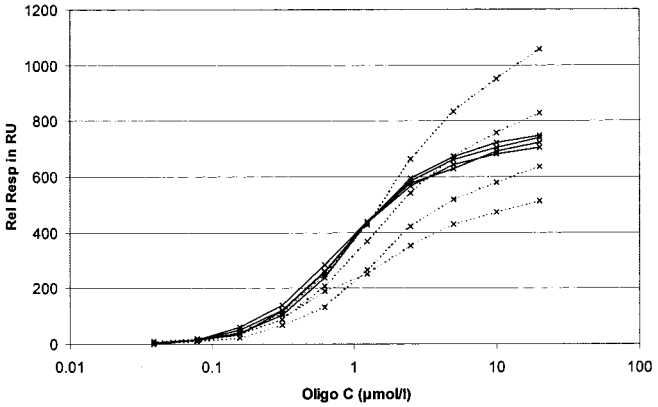

Figure 4. Overlay of concentration curves (SPR response) from four consecutive experiments with hybridization of increasing amounts of Oligo C to both, the CM-PNA chip (dashed line) and the SA-PNA chip (solid line) in GuSCN buffer. The Oligo C concentration was ranging from 39nM to 20μM.

indicating a progressive loss of hybridization capacity. At the highest target DNA concentration, the signal intensity obtained during the fourth measurement was only 48% of the one observed during the first measurement. In contrast, the chip with the covalently bound PNA gave quite consistent results through all four measurement series (94%). This result was confirmed by hybridizing constant concentrations to both types of PNA chips (Figure 5). The concentration of Oligo C was adjusted to 5 μM and 3.8 μM for the SA-PNA chip and the CM-PNA chip, respectively, to correspond to the same calibration curve slope. The chosen concentrations deliver Response signals at about 75% of the maximal saturation. The mean signal loss from one hybridization experiment to another was 2.2% for the SA-CM chip, whereas for the CM-PNA chip only 0.2%. For the 18 experiments, the last measurement reached 96 and 68% of the first for the CM-PNA chip and the SA-PNA chip, respectively.

Specificity of PNA−DNA Hybridization.. In these experiments, the CM-PNA chip was exclusively used because of its superior stability. When perfectly matched target molecules (Oligo C) as well as species with a single mismatch (Oligo T) at the 472 position were hybridized in standard salt buffer (0.1 M sodium phosphate, 0.15 M sodium chloride) to the PNA, the ligand was not specific for the analyte. Addition of the chaotropic salt guanidin thiocyanate improved the specificity of the hybridization

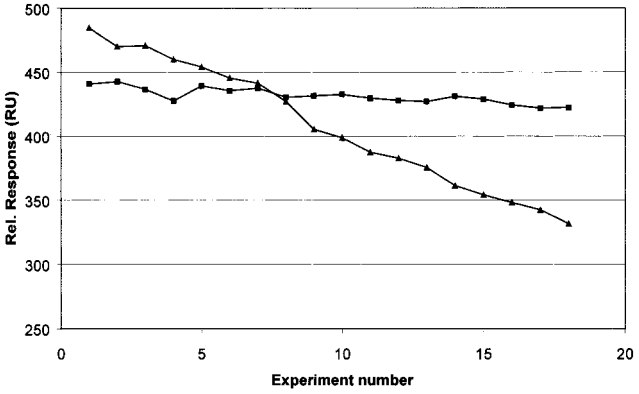

Figure 5. SPR response from 18 hybridization experiments with Oligo C for both, the CM-PNA chip (■) and the SA-PNA chip (▲). The concentration of Oligo C was 5 μM for the SA-PNA chip hybridization and 3.8 μM for the CM-PNA chip, respectively.

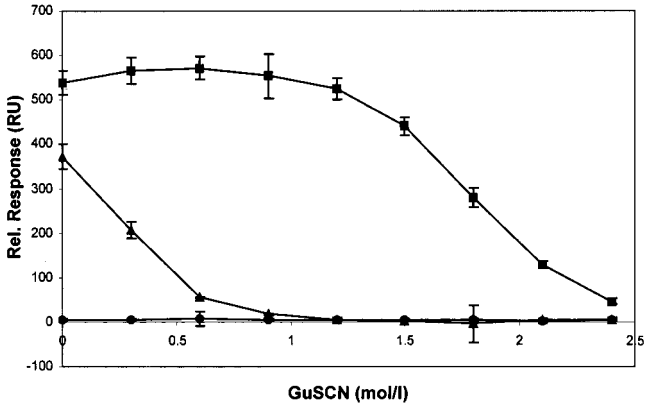

Figure 6. Determination of GuSCN concentration for specific detection of perfect match hybridization (SPR response on the CM-PNA chip). Concentration for all oligos was adjusted to 2 μM. GuSCN concentration was ranging from 0 to 2.4 M. Oligo C (■), Oligo T (▲), and Oligo neg (●). Bars indicate the confidence interval (significance level $\alpha = 0.05$).

substantially (Figure 6). At a concentration of 1.6 M GuSCN, the signal obtained with the mismatched oligonucleotide did not exceed the background signal (Oligo neg) whereas the hybridization of the perfectly matched oligonucleotide was only slightly weaker than in the buffer without GuSCN.

Sensitivity of PNA−DNA Hybridization. Again, the CM-PNA chip was used for these experiments. All hybridizations were performed in buffer containing the 1.6 M GuSCN buffer to ensure high specificity. Under these conditions, the detection of complementary Oligo C at a concentration of 0.2 μM was demonstrated with increasing amounts of the mismatched Oligo T. During the hybridization, the DNA concentration was kept constant at 26.6 μM using Oligo neg of completely unrelated sequence. As shown in Table 1, the increasing amounts of Oligo T (one mismatch) did not increase the background, and Oligo C could still be detected in the 0.75% assay, indicating that the hybridization of Oligo C was not disturbed by high background. Paradoxically, a slight increase in signal intensity was noticed with increasing amounts of mismatched oligonucleotide in mixture, although both controls, 100% oligo T and 100% Oligo neg, respectively, produced no detectable signals.

DISCUSSION

In our work we evaluated the potential of a SPR biosensor for the mutation specific characterization of

poliovirus nucleic acids. The suitability of SPR for the analysis and characterization of nucleic acids has been shown before (*8*, *9*). However, these authors failed to demonstrate the stability and the specificity at the level of point mutations of their approach based on ligand bound by the biotin−streptavidin interaction to the sensor surface. In our work, we could prove that such a surface does not give reproducible results due to loss of binding capacity of the sensor surface. There are three possible explanations for this effect: (a) loss of ligand, (b) inactivation of ligand, or (c) incomplete regeneration of the surface. In additional experiments (data not published), we could demonstrate that the reduced capacity could almost completely be replenished by immobilizing new ligand, favoring the loss of ligand explanation (while the other effects may play a minor role). Since the biotin−streptavidin binding is not a covalent one, its kinetics will depend on the conditions of the reaction; harsh conditions (e.g., regeneration of sensor surface with NaOH) may lead to a decreased association constant, therefore, destabilizing the streptavidin−biotin complex and leading to loss of ligand. This will finally lead to an decreased capacity of the sensor surface for the ligand and a lower resonance signal. We could solve this problem by attaching the PNA ligand covalently to the sensor surface. For this purpose, we developed a chemical synthesis consisting of several standardized reaction steps that could be performed within minutes and monitored online on the SPR apparatus. Increased PNA immobilization could be achieved altering NHS/EDC concentrations or injection volume, but this did not result in increased sensitivity.

In our experiments, we showed that the use of a PNA as ligand and a hybridization buffer containing a high concentration of the chaotropic salt guanidine thiocyanate results in a highly sequence specific system. We envision that adoption of our approach to other sequences requires the optimization of the GuSCN concentration only. To achieve this, experiments as shown in Figure 6, which can be completed within hours, have to be done. However, this remains to be proven even if the poliovirus sequence used in this study as a model contains internal complementary structures that make hybridization assays more difficult to perform. Furthermore, our approach is not sufficiently sensitive at this time. Target nucleic acid concentrations in the sensitivity experiment (Table 1) were 0.2 μM with a total DNA concentration of 40 μM. Compared to this, a typical PCR may contain amplified DNA at a concentration of 0.1 μM. Would one attempt to detect a mutated fragment at a level of less than 1%, the biosensor approach described in this paper would have to be 400 times more sensitive. The data presented in Table 1 may point to a solution of this problem, showing that 0.2 μM complementary Oligo C alone gave a lower signal compared to the measurement when the same concentration was mixed with 26.6 μM Oligo T with a single mismatch. Binding of this oligonucleotide to the PNA ligand can be excluded since we showed that high concentration does not yield signals even slightly above background. Thus, this observation is not due to unspecific target DNA adsorption to the sensor surface because the total DNA concentration was kept constant during the experiment and control probes produced no signal. Since our oligonucleotides, the perfectly matched as the one with a point mutation contain internal complementary sequences, we propose at this time the following hypothesis: we have proven that perfectly matched target molecules only bind to the PNA ligand. Since these molecules are substantially longer than the ligand, parts of their sequences, with internal complementarily, remain exposed and available for hybridization with free analyte in the solution. The molecules with a single mismatch in the part of the sequence complementary to the PNA ligand are able to hybridize to exposed sequences to which they are perfectly complementary. This increases the mass of the molecule bound to the PNA ligand and results according to the principals of SPR in a stronger signal. We currently investigate this phenomena and evaluate its potential to be used to obtain improved sensitivity.

ACKNOWLEDGMENT

We thank Prof. Dr. Th. Seebeck for his interest in this work and helpful discussions. This work was supported by a grant from the Swiss Defence Procurement Agency (Grant 321.001.96.53.06.03).

Photopatterning of Antibodies on Biosensors

Xiao-hui Liu, Hsu-kun Wang,† James N. Herron,† and Glenn D. Prestwich*

Department of Medicinal Chemistry and Department of Pharmaceutics and Pharmaceutical Chemistry, 30 South 2000 East, Room 201, The University of Utah, Salt Lake City, Utah 84112-5820. Received January 27, 2000; Revised Manuscript Received May 5, 2000

The immobilization of biomolecules on surfaces in defined micropatterns has become increasingly important for the development of new diagnostic devices and high-throughput genetic and drug screening protocols. We describe the synthesis and testing of thiol-reactive, photoactivatable linkers that will permit laser micropatterning or photolithographic patterning of surfaces. In these linkers, a benzophenone photophore is tethered through a variable-length poly(ethylene glycol) hydrophilic spacer to a maleimide group. Spacers containing one to five ethylene glycol units were examined. Antibodies were photoimmobilized on polystyrene waveguides and the resulting biosensors were used for fluorescence immunoassays. The spacer with five ethylene glycol units optimally decreased the steric interactions among large molecules (antibodies and antigens) and increased binding capacity and response rate of the biosensor. Two different sandwich assay protocols were examined. In the first, the antigen and fluorescently labeled second antibody were added sequentially to the biosensor ("stepwise"). In the second, the antigen and antibody were premixed before injection into the biosensor ("premixed"). The stepwise protocol gave a significantly higher response than that of the premixed protocol. Although the premixed protocol is more convenient, the stepwise protocol provides enhanced sensitivity.

INTRODUCTION

Micropatterning of surfaces with biomolecules has become important in applications that include medical diagnostic assays, high-throughput screens for drug discovery, drug toxicity screening, and genetic screening. In each application, a surface is patterned with a two-dimensional array of chemically distinct molecules. Two general approaches have emerged for patterning surfaces: (i) direct dispensing (or "spotting") of the different biomolecules on their appropriate positions in the array using a microfluidic system, and (ii) photopatterning of biomolecules on the surface using either photoactivatable cross-linkers or photodeprotection of masked or "caged" reactive functional groups (*1*). In many respects, the spotting approach is easier and faster than photopatterning. However, it is susceptible to both reduced biological activity (of the immobilized ligands) and nonspecific binding resulting from unoriented immobilization of the biomolecules by physical adsorption. Also, spotting limits the diversity of molecules that can be immobilized by photopatterning. In contrast, the heterobifunctional reagents employed in photopatterning permit site-directed coupling of biomolecules to the surfaces to provide optimal orientation for maximal bioactivity (*2*, *3*). In addition, cross-linkers can be used to covalently attach biomolecules to surfaces that are coated with thin films of hydrophilic polymers, e.g., poly(ethylene glycol) (PEG)[1] or triblock copolymers such as the Pluronic family (*4*, *5*). These site-specific cross-linking strategies can reduce nonspecific binding to proteins and other blood components.

Numerous heterobifunctional, photoactivatable cross-linking agents for protein conjugation have been reported (*6*, *7*) and many are commercially available. Most of these compounds contain aryl azides as the photophore. Benzophenone (BP)-containing reagents, however, have also been developed and used for photoimmobilization (*8*−*10*). BPs can be manipulated in ambient light and can be activated at wavelengths that cause little damage to proteins. Importantly, BPs also cross-link with higher efficiency than other photoreactive functionalities (*11*, *12*). 4-Maleimidobenzophenone (BPMI) is a commercially available thio-reactive, photoactivatable linker that is potentially useful for photoimmobilization of biopolymers on surfaces (*13*, *14*). However, this reagent is not optimal for tethering macromolecules to surfaces because the two functional groups are rigidly held within less than 8 Å of each other. We reasoned that introduction of a hydrophilic spacer would allow generation of fluorescence biosensors in which increased accessibility of the immobilized antibody to soluble antigens improved sensitivity. PEG was selected for the spacer because of its high water solubility, conformational flexibility, and biocompatibility. We report herein the preparation of a series of four BP-oligo(ethylene glycol)-maleimides (BP-EG*n*-MI, $n = 1, 2, 3, 5$) and their use to photopattern surfaces with antibodies in a site-specific manner. Sensors that were the most responsive were obtained when the BP-EG*n*-MI was first coupled to the biomolecule and the bioconjugate was subsequently photoimmobilized on the waveguide surface.

EXPERIMENTAL PROCEDURES

General. Tetrahydrofuran (THF) was distilled from sodium/benzophenone immediately prior to use. All reactions were conducted in oven-dried glassware. Column chromatography was performed using silica gel (60 Å, 240−400 mesh ASTM) from Whatman Co. (Hillsboro, OR). BPMI (Molecular Probes, Inc., Eugene, OR) and FluoroLink Cy5 (Amersham Life Science, Inc., Arlington Heights, IL) were used as supplied. All other organic reagents were obtained from Aldrich Chemical Co. (Milwaukee, WI).

Antibodies. Antibodies of several different specificities were employed in these studies: anti-bovine serum albumin (anti-BSA), anti-human chorionic gonadotrophin (anti-hCG), and anti-fluorescein (anti-FL). Anti-BSA was a murine monoclonal antibody (mAb) obtained from Sigma Chemical Co. (Milwaukee, WI). It was labeled with FluoroLink Cy5 (*13*). Two different anti-hCG antibodies (anti-hCGA and anti-hCGB) were used; each reacts with a different epitope on hCG, and thus the two antibodies can be employed in a sandwich immunoassay. Both anti-hCG antibodies were a generous gift of Akzo-Nobel Chemicals, Inc. (Dobbs Ferry, NY). Anti-hCGA was cleaved into monovalent half molecules using 2-mercaptoethylamine (*15*). This procedure produces several reactive thiol groups in the hinge region that were used for site-specific immobilization. Anti-hCGB was labeled with FluoroLink Cy5 to give the second antibody for the sandwich immunoassays.

The anti-fluorescein antibody (anti-FL 9-40) belongs to the $IgG_1(\kappa)$ subclass and exhibits an affinity of about 1×10^7 M^{-1} at 25 °C (*16*). The hybridoma cell-line that secretes this antibody was obtained from Professor Edward W. Voss, Jr. (University of Illinois at Urbana−Champaign). Anti-FL 9-40 was produced in murine ascites fluid and purified (*13*). Purified anti-FL 9-40 was then digested with pepsin to produce $(Fab')_2$ fragments, which were then reduced to Fab′ fragments using dithiothreitol (DTT) (*13*). The Fab′ fragments contain thiol groups at the C-terminal end that were used for site-specific immobilization.

Antigens. BSA was labeled with both fluorescein isothiocyanate (FITC) and FluoroLink Cy5. The labeling was carried out as follows: BSA (2 mg) was reacted with FITC (20-fold molar excess) in sodium carbonate buffer, pH 8.0, at room temperature for 2 h and the BSA-FL was separated by a PD-10 column with phosphate-buffered saline (PBS) as eluent. Then the BSA-FL was allowed to react with Cy5 dye in sodium carbonate buffer, pH 9.3, at room temperature for 30 min; the product, Cy5-BSA-FL, was purified again by a PD-10 column using PBS buffer as eluent. UV−vis: $\lambda_{max} = 278$, 496, and 652 nm; calculation based on extinction coefficients indicated a BSA:FL:Cy5 ratio of 1:0.7:0.7. BSA and hCG were obtained from Sigma.

Synthetic Methods. 2-(2-Fluorenylmethoxycarbonyl-aminoethoxy)-ethanol (1) (*17*). A solution of 9-fluorenylmethyl chloroformate (1.00 g, 3.86 mmol) in 30 mL of dry THF was cooled in an ice bath. 2-(2-Aminoethoxy)-ethanol (810 mg, 7.70 mmol, dissolved in 20 mL of dry THF) was added slowly. The mixture was stirred in the ice bath for 20 min and at room temperature for 20 min. After filtration to remove the amine salt, the solution was condensed to give 1.26 g (100%) of the carbamate **1** as white semisolid. ^{1}H NMR ($CDCl_3$, 200 MHz) δ 3.40 (m, 2H, CH_2N), 3.56 (m, 4H, 2-CH_2O−), 3.70 (m, 2H, −OCH_2−), 4.22 (t, $J = 7$ Hz, 1H, −CH−), 4.40 (d, $J = 7$ Hz, 2H, −CH_2OCO), 7.29 (m, 4H, 4H−Ar), 7.57 (d, $J = 7.6$ Hz, 2H, 2H−Ar), 7.75 (d, $J = 7.6$ Hz, 2H, 2H−Ar). ^{13}C NMR ($CDCl_3$, 200 MHz) δ 195.9, 156.5, 143.9, 141.3, 127.6, 127.0, 124.9, 120, 72.2, 70.0, 66.5, 61.6, 47.2, 40.8. EI-MS *m/z* 327(M^+, 0.19), 196 (0.2), 180 (2.0), 179 (21.9), 178 (100), 165 (7.2). HRMS (EI) (*m/z*) calcd for $C_{19}H_{21}NO_4$ (M^+) 327.1470; found 327.1456.

4-(2-(2-Fluorenylmethoxycarbonyl-aminoethoxy)-ethoxy)-benzophenone (2). 4-Hydroxybenzophenone (624 mg, 3.15 mmol), 2-(2-fluorenylmethoxycarbonyl-aminoethoxy)-ethanol (**1**, 1.00 g, 3.05 mmol), and Ph_3P (948 mg, 3.6 mmol) were dissolved in 24 mL of dry THF and cooled to 0 °C under N_2. Diethyl azodicarboxylate (DEAD) (0.6 mL, 3.79 mmol) was added slowly. The mixture was stirred for 3 h then stored at room temperature overnight. After concentration in vacuo, the residue was purified on SiO_2 (ethyl acetate−hexanes 1:3 to 1:1) to give 1.21 g (78%) of compound **2** as a pale yellow oil. ^{1}H NMR ($CDCl_3$, 200 MHz) δ 3.46 (m, 2H, CH_2N), 3.64 (m, 2H, −OCH_2−), 3.85 (m, 2H, −CH_2O−), 4.20 (m, 3H, −OCH_2-, −CH−), 4.36 (d, $J = 6.6$ Hz, −CH_2CO−), 6.98 (m, 2H, Ar), 7.2−7.8 (15H, Ar). ^{13}C NMR ($CDCl_3$, 200 MHz) δ 195.5, 162, 156.2, 143.9, 141.0, 138.0, 132.5, 131.9, 129.7, 128.2, 127.6, 127.0, 125.0, 120.0, 114.0, 70, 69.3, 67.5, 68.9, 62.5, 47.2, 41.0. EI-MS *m/z* 508 ($M^+ + 1$, 0.02) 463 (0.05), 311 (7.5) 256 (14.8) 198 (28.8), 178 (100). CI-MS: *m/z* 508 ($M^+ + 1$, 1.04), 314 (15.9), 286 (95), 199 (44.5) 179 (100), 105 (20). HRMS (EI) (*m/z*) calcd for $C_{32}H_{30}NO_5$ ($M^+ + 1$) 508.2124; found 508.2136.

4-(2-(2-Aminoethoxy)ethoxy)-benzophenone (3) (*17*). Compound **2** (872 mg, 1.72-mmol) was dissolved in 5 mL of piperidine and stirred for 40 min at room temperature. Then the solution was concentrated in vacuo, and the residue was dissolved in dichloromethane and washed with water (20 mL × 2). The organic layer was dried over $MgSO_4$, concentrated, and purified on SiO_2 (ethyl acetate:methanol:ammonium hydroxide 100:2:1) to give 400 mg (81.6%) of **3** as a pale yellow oil. ^{1}H NMR ($CDCl_3$, 200 MHz) δ 2.99 (t, $J = 5.3$ Hz, 2H, CH_2N), 3.58 (t, $J = 5.3$ Hz, 2H, −OCH_2−), 3.85 (t, $J = 5.0$ Hz, 2H, −CH_2O−), 4.20 (t, $J = 5.0$ Hz, 2H, −OCH_2−), 6.99 (m, 2H, Ar), 7.50 (m, 3H, Ar), 7.75 (m, 4H, Ar). ^{13}C NMR ($CDCl_3$, 200 MHz) δ 195.5, 162.4, 138.0, 132.5, 131.6, 130.2, 129.7, 128.1, 114.0, 73.6, 69.2, 67.5, 41.7. EI−MS: *m/z* 285 (M^+, 2.29), 256 (50.7), 198 (100), 121 (19.2), 105 (24.4), 98 (15.4). HRMS (EI) (*m/z*) calcd for $C_{17}H_{19}NO_3$ (M^+) 285.1365; found 285.1358.

N-Substituted Maleamic Acid (4) (*18*). A reaction mixture containing compound **3** (100 mg, 0.35 mmol), and maleic anhydride (35 mg, 0.35 mmol) in 0.7 mL of glacial acetic acid was stirred for 20 h. The mixture was purified on SiO_2 (ethyl acetate:acetic acid, 100:3) to afford 110 mg (82%) of **4** as a colorless oil. ^{1}H NMR ($CDCl_3$, 200 MHz) δ 3.65 (t, $J = 5.4$ Hz, 2H, −CH_2N), 3.72 (t, $J = 5.4$ Hz, 2H, −OCH_2−), 3.92 (t, $J = 4.4$ Hz, 2H, −CH_2O−), 4.20 (t, $J = 4.4$ Hz, 2H, −OCH_2−), 6.10 (d, $J = 14.8$ Hz, 1H, CH =), 6.35 (d, $J = 14.8$ Hz, 1H, =CH), 6.98 (m, 2H, Ar), 7.50(m, 3H, Ar), 7.80 (m, 4H, Ar). EI-MS *m/z* 383-(M^+, 4.32), 365 (19.5), 312 (9.3), 256 (29.2), 242 (48.5), 198 (93), 165 (23), 121 (100), 105 (56.8). HRMS (EI) (*m/z*) calcd for $C_{21}H_{21}NO_6$ (M^+) 383.1369; found 383.1374.

BP-EG2-MI (5). A reaction mixture containing maleamic acid **4** (85 mg, 0.22 mmol) in 0.3 mL of acetic anhydride and sodium acetate (25 mg, 3 mmol) was heated at 90 °C for 2 h. It was cooled to room temperature and quenched with 10 mL of water. The aqueous solution was extracted with ethyl acetate (10 mL × 2). The combined organic extracts were dried (Na_2SO_4) and concentrated in vacuo. The residue was purified on SiO_2 (ethyl acetate:hexane 3:1) to give 67 mg (83%) of the pure product **5** as

a colorless oil. ^{1}H NMR ($CDCl_3$, 200 MHz) δ 3.72 (m, 4H, $-OCH_2CH_2N=$), 3.82 (m, 2H, $-CH_2O-$), 4.13 (t, J = 4.4 Hz, 2H, $-OCH_2-$), 6.64 (s, 2H, CH=CH), 6.93 (m, 2H, Ar), 7.50 (m, 3H, Ar), 7.75 (m, 4H, Ar). ^{13}C NMR ($CDCl_3$, 200 MHz) δ 195.4, 170.5, 162.3, 139.1, 134.0, 132.4, 131.6, 130.2, 129.6, 129.1, 114.0, 68.8, 68.0, 67.5, 67.3, 67.0, 38.0, 36.9, 20.4. EI-MS *m/z* 365 (M^+, 68.4), 288 (4.26), 224 (21.7), 198 (32.5), 124 (100), 105 (32). HRMS (EI) (*m/z*) calcd for $C_{21}H_{19}NO_5$ (M^+) 365.1263; found 365.1247.

4-Hydroxyethoxybenzophenone (6). 4-Hydroxybenzophenone (300 mg, 1.513 mmol), ethylene glycol (281 mg, 4.54 mmol), and Ph_3P (595 mg, 2.27 mmol) were dissolved in 20 mL of dry THF and cooled to 0 °C under N_2. Diisopropyl azodicarboxylate (DIAD) (0.34 mL, 2.27 mmol) was added slowly. The mixture was stirred at 0 °C for 3 h then stored at room temperature for 24 h. After concentration in vacuo, the residue was purified on SiO_2 (ethyl acetate:hexane 1:1) to afford 201 mg (55%) of compound **6** as a colorless oil. ^{1}H NMR ($CDCl_3$, 200 MHz) δ 4.0 (t, J = 4.6 Hz, 2H, $-CH_2O-$), 4.16 (t, J = 4.6 Hz, 2H, $-OCH_2-$), 6.96 (d, J = 8.8 Hz, 2H, Ar), 7.24−7.56 (m, 3H, Ar), 7.71−7.84 (m, 4H, Ar). ^{13}C NMR ($CDCl_3$, 200 MHz) δ 195.6, 162.3, 138.0, 132.5, 131.9, 130.3, 129.7, 128.2, 114.0, 69.4, 61.1. EI-MS *m/z* 242.1 (M^+, 63.9), 165.1 (35.4), 121.0 (100), 105.0 (34.4), 77 (22.9). HRMS (EI) (*m/z*) calcd for $C_{15}H_{14}O_3$ (M^+) 242.0943, found 242.0930.

BP-EG1-MI (7) (*19*, *20*). DIAD (0.056 mL, 0.371 mmol) was added to a solution containing 4-hydroxyethoxybenzophenone (**3**, 60 mg, 0.248 mmol), maleimide (96 mg, 0.99 mmol), and Ph_3P (97 mg, 0.371 mmol) in 3 mL of dry THF precooled to 0 °C. The mixture was stirred at 0 °C for 3 h, then allowed to stand at room temperature for 24 h. After concentration in vacuo, the residue was purified on SiO_2 (ethyl acetate:hexane 1:2) to afford 51 mg (32%) of BP-EG1-MI **7** as pale yellow oil. ^{1}H NMR ($CDCl_3$, 200 MHz) δ 3.96 (t, J = 5.5 Hz, 2H, CH_2), 4.20 (t, J = 5.5 Hz, 2H, CH_2), 6.73 (s, 2H, CH=CH), 6.90 (d, J = 8.8 Hz, 2H, Ar), 7.24−7.55 (m, 3H, Ar), 7.69−7.80 (m, 4H, Ar). ^{13}C NMR ($CDCl_3$, 200 MHz) 195.6, 170.4, 161.7, 138.1, 135.0, 134.2, 132.5, 131.9, 130.5, 129.7, 128.2, 114.1, 70.0, 64.7, 37.0, 21.9. EI-MS *m/z* 321.3 (14.4), 211.2 (5.82), 124.1 (100), 105.1 (8.4). HRMS (EI) (*m/z*) calcd for $C_{19}H_{15}NO_4$ (M^+) 321.1001, found 321.1007.

4-Tri(ethylene glycol) Benzophenone (8). 4-Hydroxybenzophenone (500 mg, 2.52 mmol), tri(ethylene glycol) (378 mg, 2.52 mmol), and Ph_3P (758 mg, 2.88 mmol) were dissolved in 24 mL of dry THF and cooled to 0 °C under N_2. DEAD (0.48 mL, 3.03 mmol) was added slowly. The mixture was stirred at 0 °C for 3 h, then allowed to stand at room temperature overnight. After condensation, the residue was purified on SiO_2 (ethyl acetate-petroleum ether) to afford 327 mg (58%) of compound **8** as a colorless oil. ^{1}H NMR ($CDCl_3$, 200 MHz) δ 3.61 (t, J = 3.35 Hz, 2H, CH_2OH), 3.72 (m, 6H, 3-CH_2-), 3.89 (t, J = 4.9 Hz, 2H, $-CH_2O-$), 4.20 (t, J = 4.9 Hz, 2H, $-OCH_2-$), 6.96 (d, J = 8.9 Hz, 2H, Ar), 7.44−7.55 (m, 3H, Ar), 7.70−7.62 (m, 4H, Ar). ^{13}C NMR ($CDCl_3$, 200 MHz) δ 195.5, 162.2, 138.1, 132.5, 132.1, 131.7, 130.2, 129.7, 128.6, 128.3, 128.1, 114.0, 72.4, 70.8, 70.2, 69.4, 67.5, 61.6. EI-MS *m/z* 331.1 (0.14), 277 (74.0), 198 (26.7), 183 (9.16), 121 (16.3), 105 (50.4), 77 (24.7), 45 (100). HRMS (EI) (*m/z*) calcd for $C_{19}H_{22}O_5$ (M^+) 330.1467; found 330.1473.

BP-EG3-MI (9). DEAD (0.05 mL, 0.309 mmol) was added to a solution containing 4-tri(ethylene glycol) BP (**8**, 100 mg, 0.303 mmol), maleimide (30 mg, 0.309 mmol), and Ph_3P (81 mg, 0.309 mmol) in 2 mL of dry THF that was precooled to 0 °C. The reaction was performed and worked up as described for compound **7** to afford 32 mg (27%) of BP-EG3-MI **9** as a colorless oil. ^{1}H NMR ($CDCl_3$, 200 MHz) δ 3.62−3.72 (m, 8H), 3.64 (t, J = 4.5 Hz, 2H, CH_2), 4.18 (t, J = 5 Hz, 2H, CH_2), 6.66 (s, 2H, CH=CH), 6.95 (d, J = 8.88 Hz, 2H, Ar), 7.45−7.49 (m, 3H, Ar), 7.71−7.82 (m, 4H, Ar). ^{13}C NMR ($CDCl_3$, 200 MHz) δ 195.0, 171.5, 162.4, 134.1, 132.5, 131.9, 129.7, 128.1, 114.1, 106.5, 103.5, 102.5, 70.8, 70.0, 69.5, 67.9, 67.6, 37.1, 13.0. EI-MS *m/z* 409.4 (10.3), 224.2 (11.6), 168.2 (4.5), 124.1 (100), 105.1 (31.06). HRMS (EI) (*m/z*) calcd for $C_{10}H_{23}NO_6$ (M^+) 409.1525; found 409.1523.

4-Penta(ethylene glycol) Benzophenone (10). 4-Hydroxybenzophenone (250 mg, 1.26 mmol), penta(ethylene glycol) (734 mg, 3.78 mmol), and Ph_3P (331 mg, 1.26 mmol) were dissolved in 8 mL of dry THF and cooled to 0 °C under N_2. DEAD (0.2 mL, 1.26 mmol) was added slowly and stirred at 0 °C for 3 h, then continuous stirring at room temperature for 2 days. After concentration in vacuo, the residue was purified on SiO_2 (ethyl acetate: hexane 1:1 to ethyl acetate:methanol 20:1) to afford 163 mg (34%) of compound **10** as a colorless oil. ^{1}H NMR ($CDCl_3$, 200 MHz) δ 3.57−3.76 (m, 16H, 8CH_2), 3.85 (t, J = 5 Hz, 2H, $-CH_2-$), 4.20 (t, J = 4.6 Hz, 2H, $-CH_2-$), 6.96 (d, J = 8.8 Hz, 2H, Ar), 7.45−7.52 (m, 3H, Ar), 7.71−7.82(m, 4H, Ar). ^{13}C NMR ($CDCl_3$, 200 MHz) δ 195.5, 162.4, 138.2, 132.4, 131.6, 130.2, 129.6, 128.1, 114.1, 72.5, 70.8, 70.5, 70.2, 69.4, 67.5, 61.6. EI-MS *m/z* 388.2 (1.85), 300.2 (7.93), 286.1 (10.4), 224.0 (22.6), 198.1 (21.9), 147.0 (6.9), 121.0 (15.8), 105.0 (60.6), 45.0 (100).

BP-EG5-MI (11). DIAD (0.043 mL, 0.286 mmol) was added into a solution containing 4-penta(ethylene glycol) BP (**1**, 80 mg, 0.191 mmol), maleimide (74 mg, 0.764 mmol), and Ph_3P (75 mg, 0.286 mmol) in 3 mL of dry THF that was precooled to 0 °C. The reaction was performed and worked up as described above to afford 36 mg (38%) of BP-EG5-MI **11** as a pale yellow oil. ^{1}H NMR ($CDCl_3$, 200 MHz) δ 3.58−3.74 (m, 16H), 3.87 (t, J = 5.2 Hz, 2H, CH_2), 4.20 (t, J = 4.4 Hz, 2H, CH_2), 6.67 (s, 2H, CH=CH), 6.95 (d, J = 8.8 Hz, 2H, Ar), 7.24−7.55 (m, 3H, Ar), 7.71−7.62 (m, 4H, Ar). ^{13}C NMR ($CDCl_3$, 200 MHz) 195.5, 170.6, 162.4, 138.2, 134.1, 132.5, 131.9, 130.2, 129.7, 128.1, 114.1, 70.8, 70.6, 70.5, 70.0, 69.5, 67.7, 67.6, 37.1. EI-MS *m/z* 472.2 (0.64), 30.1 (6.56), 286.1 (10.6), 268.1 (4.98), 224.0 (19.6), 198.1 (7.58), 124.0 (100), 105.0 (41.2). HRMS (EI) (*m/z*) calcd for $C_{27}H_{31}NO_8$ (M^+) 497.2050; found 497.2027.

Photoimmobilization of Antibodies on Biosensor Waveguides. Photoimmobilization of BP-EG*n*-MI (*n* = 0, 1, 2, 3, 5) and Antibody Immobilization. The biosensor waveguide is a 2.54 × 2.54 cm clear polystyrene (PS) slide with a molded lens for the coupling of excitation light (*13*, *14*, *21*). The surfaces were tested either on clean PS or PS-coated (adsorbed) with Pluronic P105. The waveguides were mounted on metallic coating trays. Stock solutions of linkers (10 μM) were prepared in DMF and diluted into buffer. An aliquot (1 mL) of a given BP-EG*n*-MI cross-linker (150 nM in 0.1 M $NaPO_4$, pH 6.0) was applied to cover the surface of each tray. The trays were then irradiated (360 nm, 1.9 mW/cm^2) at 4 °C for 45 min. After the photochemical reaction, the surfaces were washed three times with 0.1 M NaH_2PO_4 buffer, pH 6.0 containing 5 mM EDTA.

Freshly prepared anti-FL Fab′ (1 mL, 3 mM in 0.1 M $NaPO_4$ buffer, pH 6.0, with 5 mM EDTA) was applied onto each of the freshly washed surfaces, and the reaction between the free thiol group and the maleimide double bond was allowed to proceed at 4 °C overnight. After the reaction the surfaces were postcoated with a solution of 0.5 BSA and 0.1% trehalose in PBS buffer at room temperature for 30 min and dried in vacuo.

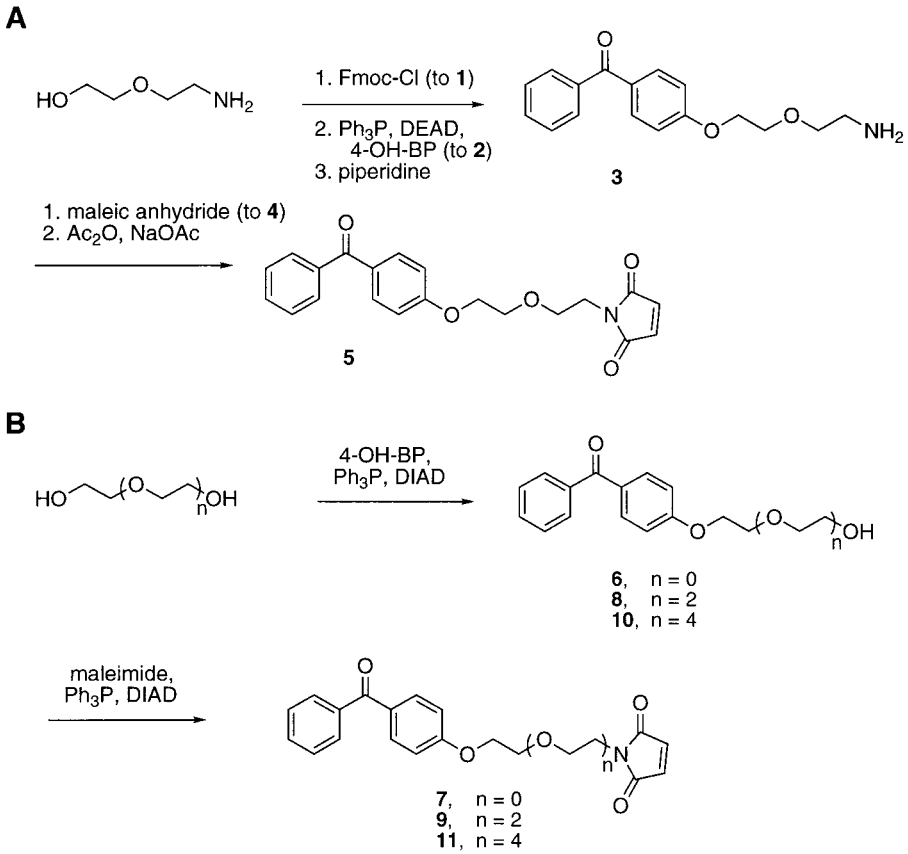

Figure 1. Synthesis of BP-EG*n*-MI (n = 0, 1, 2, 3, 5).

In other experiments (routes 3 and 4), the order of addition was reversed. Thus, PB-EG*n*-MI reagents were first coupled to a half-molecule of anti-hCG-A and the BP-containing bioconjugates were subsequently photoimmobilized on the PS surfaces.

Biosensor Assays. Both direct antigen binding assays (for FL-BSA-Cy5) and sandwich assays (for both FL-BSA and hCG) were employed. For the direct antigen binding assay, FL-BSA-Cy5 acted as both antigen and tracer. A waveguide surface coated with anti-FL Fab′ was assembled into the flow cell, and the flow cell was mounted into the instrument. A solution of FL-BSA-Cy5 at a given concentration was pumped into the flow cell and the binding of FL-BSA-Cy5 was recorded over time with a CCD camera. Cy5 fluorescence was excited at 635 nm using a red semiconductor laser. Fluorescence emission was detected at 670 nm using an interference filter (Omega). For sandwich assays having FL-BSA as the antigen, FL-BSA was allowed to react with the sensor surface for 5 min, and then the surface was flushed with PBS buffer to remove the unbound antigen. Tracer solution (anti-BSA-Cy5) was then injected, and the sandwich formation was monitored using the CCD camera. Alternatively, the antigen and the tracer solutions could be premixed and injected. For the hCG assays, waveguides coated with the half-molecule of anti-hCG-A antibody were allowed to react with hCG for 5 min, tracer-antibody (anti-hCG-B−Cy5) was injected into the flow cell, and sandwich formation was monitored with a CCD camera. In some cases, hCG and tracer antibody (anti-hCG-B−Cy5) were premixed before injection into the flow cell. Details of the assay technique have been previously described (*13, 14, 21*).

Photopatterning of a Waveguide Surface. A clean waveguide surface was covered by a gasket in the shape of the letter "U", and the photolinker-antibody solution-BP-EG5-MI-1/2 anti-hCG-A (150 nM in PBS) was added to the "U". The entire unit was irradiated (360 nm, 1.9 mW/cm^2) at 4 °C for 45 min. The surface was then washed with 10 mM phosphate buffer, pH 7.4, and the entire surface was postcoated with 10% StabilCoat (BSI Corporation, Eden Prairie, MN). The surface was incubated with hCG (3.5 nM) for 30 min at room temperature and binding of anti-hCG-B-Cy5 (1 nM) for another 30 min at room temperature. The surface was washed with deionized water and air-dried. A fluorescence image of the "U" was obtained using CCDOPS 1.061(SBIG, Santa Barbara, CA).

RESULTS AND DISCUSSION

Four new BP-EG*n*-MI (n = 1, 2, 3, 5) cross-linkers were synthesized using two different routes (*17*−*20*). BP-EG2-MI (Figure 1A) was prepared in five steps from 2-(2-aminoethoxy)ethanol. After protection as the Fmoc derivative **1**, the BP ether **2** was formed by Mitsunobu coupling with 4-hydroxybenzophenone. Deprotection with piperidine gave free amine **3**, and the maleimide moiety was introduced by acylation with maleic anhydride followed by cyclization of maleamic acid **4** to the final product **5**. A more efficient route was subsequently developed for the remaining heterobifunctional reagents, BP-EG*n*-MI (n = 1, 3, 5). Using sequential Mitsunobu reactions (Figure 1B), first the 4-hydroxybenzophenone and then maleimide moieties were sequentially coupled to the ends of any given PEG. Although the yield of the first coupling is complicated by the production of a bis-BP ether byproduct, this was removed by chromatography and gave a net overall increase in synthetic yield in fewer steps. Each compound was characterized by ^{1}H and ^{13}C NMR. The final compounds, BP-EG*n*-MI, were not soluble in water but were prepared as 10 μM DMF

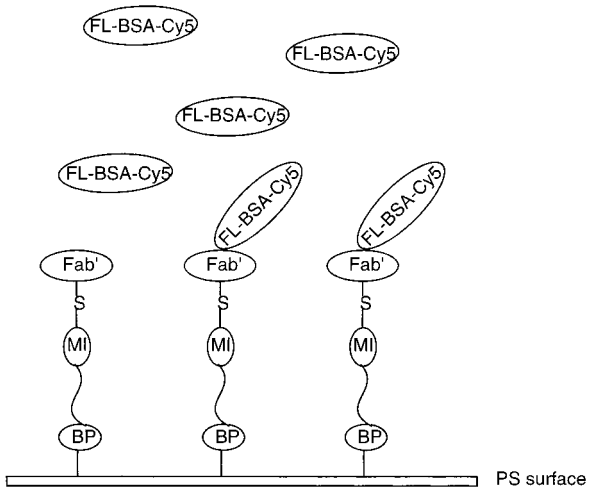

Figure 2. Schematic diagram of photoimmobilization and biosensor assays. BP-EG*n*-MI reagents were first coupled to anti-FL Fab′, then the BP-containing bioconjugates were photoimmobilized on PS or Pluronic P105-coated PS surfaces. In the direct antigen binding assay, FL-BSA-Cy5 acted as both antigen and tracer. In the sandwich assay (not shown), FL-BSA (used as antigen) was injected into the flow cell and allowed to react with the immobilized antibodies for 5 min. A solution containing anti-BSA-Cy5 was then injected into the flow cell, and binding to the immobilized antigen−antibody complex was monitored with a CCD camera.

solutions, then diluted to 150 nM in 0.1 M NaH_2PO_4 (pH 6.0) buffer for subsequent photoimmobilization experiments.

Uncoated (clean) and P105-coated PS surfaces reacted differently with BP-EG*n*-MIs. The cross-linker-antibody conjugates covalently coupled to the uncoated PS surface to give an essentially homogeneous monolayer. In contrast, the P105-coated PS had many PEG chains that could either react with or prevent hydrophobic adsorption of the bioconjugates. As a result, attachment of the antibody was reduced, and antigen-containing sites appeared unavailable for binding. The poor reproducibility of biosensor response for antibodies photoimmobilized onto P105-coated PS (data not shown) led us to abandon this approach. Several different approaches were thus compared to obtain the analytical system illustrated diagrammatically in Figure 2.

In Figure 3, route 1 involves initially photoimmobilizing the BP-EG*n*-MI (n = 0, 1, 2, 3, 5) onto PS surfaces and subsequent incubation with anti-FL Fab′ fragment at 4 °C overnight to produce a monolayer of BP-EG*n*-MI−Fab′ conjugates (see Figure 2). After postcoating with BSA to block regions of unmodified PS, a FL-BSA-Cy5 solution was passed over the surface in the flow cell, and fluorescence emission was recorded. The results are shown in Figure 4. Among the five BP-EG*n*-MIs, BP-EG5-MI and BPMI gave the best binding rates and highest capacities, while BP-EG1-MI, BP-EG2-MI, and BP-EG3-MI gave essentially identical specific binding properties. Specific binding is a function of antibody orientation and density. At present, the particular steric and orientational factors that cause high specific binding by the EG0 and EG5 ligands and the reduced binding of the EG1, EG2, and EG3 ligands remain unclear.

The effectiveness of the different BP-EG*n*-MIs at reducing nonspecific binding was evaluated (route 2, Figure 3). Figure 5 shows that with no coating on the PS surface, FL-BSA-Cy5 absorbed rapidly and gave a strong increase in fluorescence. In contrast, after the photoimmobilization of BP-EG*n*-MI onto the PS, the

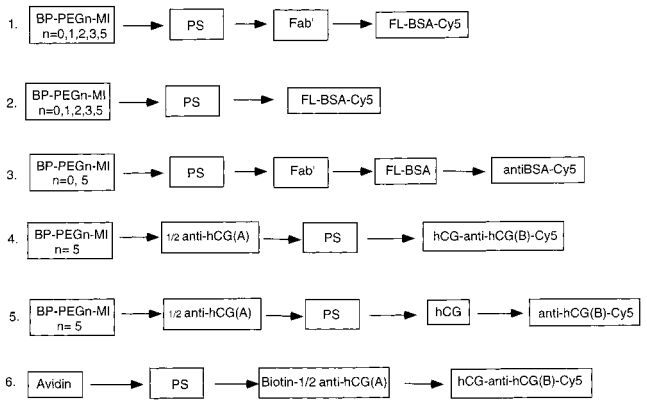

Figure 3. Protocols used for photoimmobilization and biosensor assays on PS surfaces. In route 1, each of the BP-EG*n*-MI cross-linkers was photoimmobilized on a waveguide surface, followed by reaction with anti-FL Fab′. The ability of the immobilized Fab′ fragment to bind antigen (FL-BSA-Cy5) was then tested. Routes 1 and 2 are direct antigen binding assays; routes 3−6 are sandwich assays.

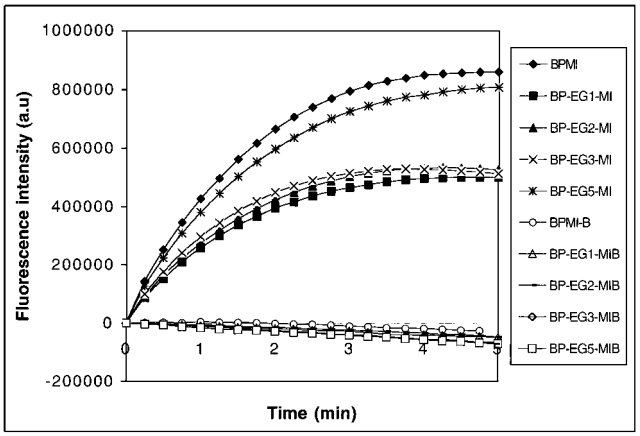

Figure 4. Effect of ethylene glycol spacer length on the antigen-binding activity of Fab′ fragment immobilized with the BP-EG*n*-MI cross-linkers. The immunoassay was performed as in route 1 (Figure 3). In the control experiments (labeled BP-EG*n*-MIB), the different BP-EG*n*-MI cross-linkers were photoimmobilized, followed directly by postcoating BSA; however, no Fab′ fragment was immobilized. Nonspecific binding was examined by injecting various concentrations of FL-BSA-Cy5 into the flow cell. Each data point is the mean of six independent determinations. Error bars are displayed but not readily visible since their size is comparable to the plot symbols. The time courses for the controls ("MIB") are overlapped at the baseline.

nonspecific binding of FL-BSA-Cy5 decreased significantly with an increasing number of ethylene glycol units. However, if the surface was further treated with BSA (without Fab′), the binding of FL-BSA-Cy5 was negligible (BP-EG*n*-MIB). Therefore, the nonspecific binding of FL-BSA-Cy5 on BP-EG5-MI-coated surfaces was higher than desired and postcoating the surface with BSA was still necessary prior to performing the biosensor assay.

Since comparable results were observed for BP-EG5-MI and BPMI in Figure 4, we examined a third protocol (route 3, Figure 3) using a sandwich immunoassay. Following photoimmobilization and chemical linking of the anti-FL Fab′, FL-BSA and anti-BSA-Cy5 solutions were allowed to react with the PS waveguide sequentially at 5 min intervals. Two different concentrations (1 and 10 nM) of anti-BSA were examined. In the case of stepwise immunoassay, the rate of binding to the BP-EG5-MI surface was four times faster than for the BPMI surface (Figure 6). This demonstrates that the penta-(ethylene glycol) unit spacer can decrease the steric

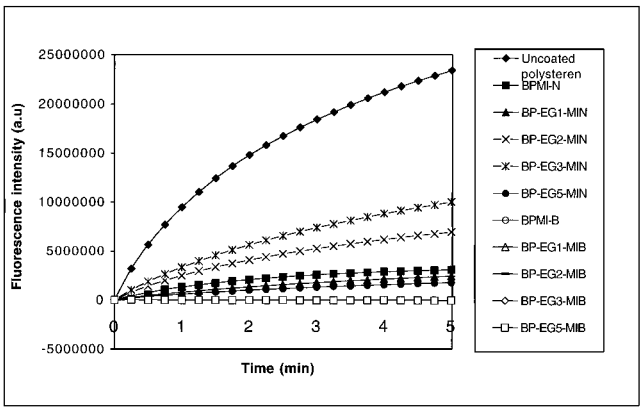

Figure 5. Effects of ethylene glycol spacer and post-coating on the nonspecific adsorption of BSA to PS surfaces. The binding sequence on the waveguide is shown in route 2 (Figure 3). The time courses for the controls are overlapped at the baseline. See text for experimental details and Figure 4 legend for details of data presentation.

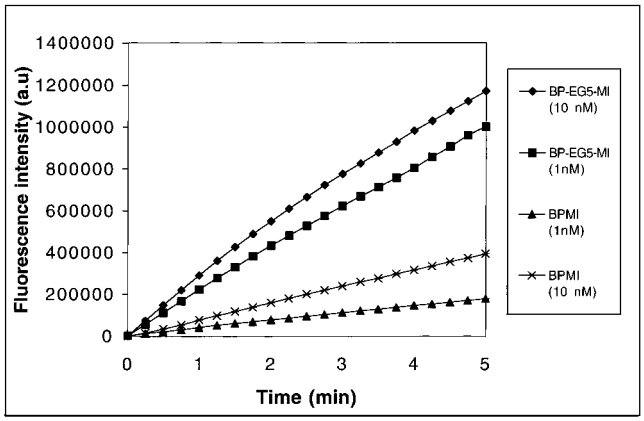

Figure 6. Effect of ethylene glycol spacer length on the antigen-binding capacity of anti-FL antibodies immobilized with BP-EG5-MI and BPMI. The binding sequence used in this experiment is shown in route 3 (Figure 3). Two different concentrations of anti-BSA (1 and 10 nM) were employed. See text and Figure 4 legend for details.

hindrance for the antigen to approach the antibody epitopes, and thereby enhance the antigen-binding capacity and resultant sensitivity of a biosensor.

To evaluate the feasibility and generality of BP-EG5-MI use in fluorescence biosensors, we examined routes 4, 5, and 6 (Figure 3) using a fluorescence immunoassay for hCG. In routes 4 and 5, BP-EG5-MI was allowed to react with the monovalent half-molecule of anti-hCG-A. Then, these half-antibody conjugates were photoimmobilized on a PS waveguide for subsequent immunoassays. The photoimmobilization strategy was compared to the classic avidin−biotin coupling chemistry in route 6.

In addition, two different assay protocols were compared. In the first protocol (stepwise), hCG was allowed to react with immobilized antibodies for 5 min, and then a Cy5-labeled second antibody (also reactive with hCG) was added. Its binding to the immobilized antigen−antibody complex was monitored using the biosensor. In the second protocol (premixed), hCG and the Cy5-labeled second antibody were premixed and then the binding rate of the complex was monitored with the biosensor. Figure 7 shows that the stepwise assay gave a 2-fold increase in binding rate relative to the premixed assay. This phenomenon may be due to the ease of binding of smaller molecules (antigen) to give high density on the surface. For the binding of hCG/anti-hCG-B-Cy5 onto BP-EG5-

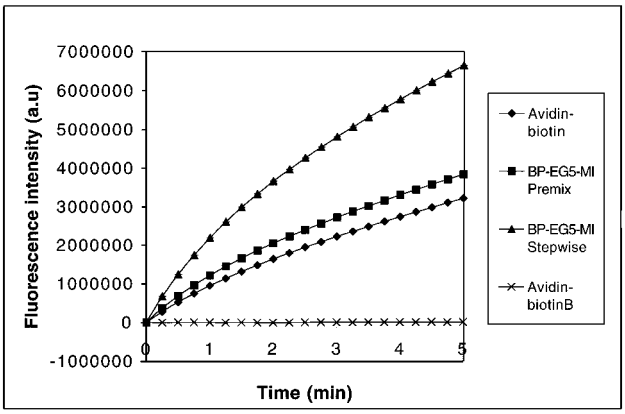

Figure 7. Comparison of photoimmobilization and avidin/biotin immobilization. The binding sequences on the waveguide are shown in routes 4, 5, and 6 (Figure 3). See text and Figure 4 legend for details.

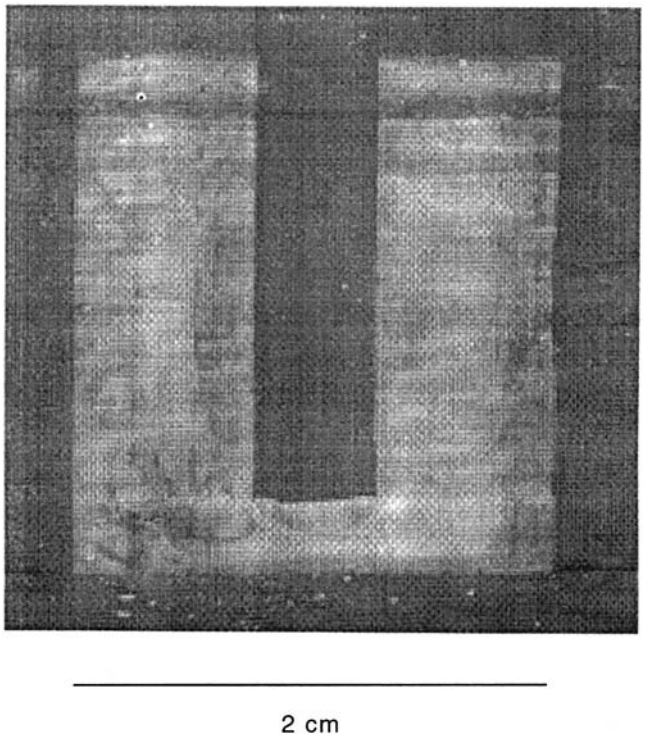

Figure 8. Photopatterning of a planar waveguide biosensor. See text for details.

MI-1/2 anti-hCG-A coated PS surfaces, the rate was slightly higher than that of a parallel reaction using avidin−biotin-1/2 anti-hCG-A-coated surfaces. This demonstrated that BP-EG5-MI was the photo-cross-linker with strongest potential for practical applications.

Immunosensors used in clinical diagnostic assays generally require no surface regeneration as they are being developed as "single-use" devices for point-of-care applications. However, regeneration of the immunologically active surface may be desirable for biosensors used in remote and/or continuous sensing applications (e.g., food process monitoring, environmental testing, biological warfare detection). Previously, we studied the reversibility of antigen binding to antibodies and Fab′ fragments immobilized to silica surfaces coated with PEG (*22*). These studies showed that there was an inverse correlation between reversibility and the surface density of immobilized antibody and/or Fab′ fragment. Thus, for

reusable sensors, it may be advantageous to control the surface density by using the BP-EG5-MI photo-cross-linker.

Finally, we demonstrated that it was possible to use BP-EG*n*-MI for photopatterning. Figure 8 shows the image of a "U" created on a PS surface by irradiation of a template-confined solution of BP-EG5-MI coupled to a half-antibody of hCG-A.

In summary, the biosensor assays described above demonstrated that BP-EG5-MI was an excellent heterobifunctional cross-linker for the photopatterning of biomolecules onto PS surfaces. The optimal conditions for the photoimmobilization and the biosensor assays included the following steps. First, the half-molecule of anti-hCG-A antibody was coupled to the maleimide moiety of BP-EG5-MI. Second, the conjugated antibody is photoimmobilized onto PS via the BP moiety, and the surface was postcoated with BSA. Third, antigen was incubated on the surface for 5−10 min. Fourth, the tracer solution was allowed to flow over the surface in a flow cell, and laser excitation resulted in emission of a detectable signal. Biosensors, with photopatterned antibodies prepared in this way, have important applications for continuous sensing of analytes and in clinical diagnostic assays.

Novel Tat-Peptide Chelates for Direct Transduction of Technetium-99m and Rhenium into Human Cells for Imaging and Radiotherapy

Valery Polyakov, Vijay Sharma, Julie L. Dahlheimer, Christina M. Pica, Gary D. Luker, and David Piwnica-Worms*

Laboratory of Molecular Radiopharmacology, Department of Radiology and Department of Molecular Biology and Pharmacology, Washington University Medical School, St. Louis, Missouri 63110. Received January 28, 2000; Revised Manuscript Received July 10, 2000

Rapid and efficient delivery of radioactive metal complexes to the cell interior would enable novel applications in medical imaging and radiotherapy. Membrane permeant peptide conjugates incorporating HIV-1 Tat transactivation protein sequences (GRKKRRQRRR) and an appropriate peptide-based motif (ϵ-KGC) that provides an N_3S donor core for chelating technetium and rhenium were synthesized. Oxotechnetium(V) and oxorhenium(V) Tat−peptide complexes were prepared by facile transchelation reactions with permetalates, tin(II) chloride and sodium glucoheptonate. RP-HPLC showed two major [^{99m}Tc]Tat−peptide species (**4**) that differed in retention time by ∼2 min corresponding to two [Re]-Tat−peptide species (**7**) shown to have identical mass, consistent with formation of two isomers, likely the oxo-metal diastereomers. [^{99m}Tc]Tat−peptides were stable to transchelation in vitro. In human Jurkat cells, [^{99m}Tc]Tat−peptide **4** showed concentrative cell accumulation (30-fold greater than extracellular concentration) and rapid uptake kinetics ($t_{1/2}$ < 2 min) in a diastereomeric-comparable manner. Paradoxically, uptake was enhanced in 4 °C buffer compared to 37 °C, while depolarization of membrane potential as well as inhibition of microtubule function and vesicular trafficking showed no inhibitory effect. Cells preloaded with **4** showed rapid washout kinetics into peptide-free solution. Modification of [^{99m}Tc]Tat−peptide by deletion of the N-terminus Gly with or without biotinylation minimally impacted net cell uptake. In addition, the C-terminus thiol of the prototypic Tat−peptide was labeled with fluorescein-5-maleimide to yield conjugate **8**. Fluorescence microscopy directly localized conjugate **8** to the cytosol and nuclei (possibly nucleolus) of human Jurkat, KB 3-1 and KB 8-5 tumor cells. Preliminary imaging studies in mice following intravenous administration of prototypic [^{99m}Tc]Tat−peptide **4** showed an initial whole body distribution and rapid clearance by both renal and hepatobiliary excretion. Analysis of murine blood in vivo and human serum ex vivo revealed >95% intact complex, while murine urine in vivo showed 65% parent complex. Thus, these novel Tat−peptide chelate conjugates, capable of forming stable [Tc/Re(V)]complexes, rapidly translocate across cell membranes into intracellular compartments and can be readily derivatized for further targeted applications in molecular imaging and radiotherapy.

INTRODUCTION

Peptide-based imaging and radiotherapeutic agents offer high molecular target specificity and a great degree of flexibility in their design (*1*−*4*). Peptide-based imaging agents, exemplified by the commercially available agents Octreoscan and Acutech (*5*−*7*), often are composed of a domain for targeting cell-surface receptors and a moiety for stable chelation of desired radiometals (*1*, *2*). Among these, technetium-99m (^{99m}Tc) is the most commonly used isotope in medical imaging (*3*). Readily available through ^{99}Mo/^{99m}Tc generator systems, ^{99m}Tc has an ideal photon energy for imaging applications and possesses a short half-life (6 h) compatible with the pharmacokinetics in vivo of many biological and clinical applications (*1*, *3*, *8*, *9*). In addition, chelation chemistry for ^{99m}Tc has received much attention because these donor cores also enable radiotherapy using the chemically analogous ^{186}Re/^{188}Re species (*10*). Targeting of peptide-based imaging agents largely has been limited to extracellular or externally oriented membrane receptors because charge, size, and pharmacokinetic considerations of conventional peptide constructs do not enable translocation across cellular membranes (*2*). The dielectric constant of the lipid bilayer of the plasma membrane poses a formidable barrier to the entry of charged compounds into cells (*11*). Because targeted delivery of peptide agents to intracellular compartments would enable a broad range of novel applications in medical imaging and radiotherapy, a peptide conjugate capable of incorporating medically relevant metals while permeating the plasma membrane is highly desired.

Several transduction sequences capable of permeating the plasma membrane of cells and thereby enabling delivery of biomolecules and various “cargos” have been reported recently. These include the third helix of the homeodomain of Antennapedia (*12*), a peptide derived from the heavy chain variable region of an anti-DNA monoclonal antibody (*13*), and several viral proteins including Herpes simplex virus VP22 (*14*), HIV-1 Rev protein and HTLV-1 Rex protein basic domains (*15*), and HIV-1 Tat protein basic domain (*16*, *17*). Although the exact mechanisms of membrane transduction are not well

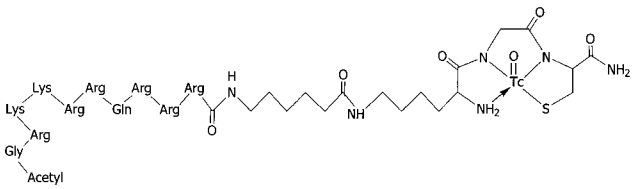

Figure 1. Structure of a [^{99m}Tc]Tat−peptide complex.

characterized, they generally have been described as achiral and independent of a receptor (*12*, *18*). Membrane transduction peptides have been shown to deliver into cells a variety of polypeptides (*14*, *17*, *19*), immunoreactive epitopes (*20*), fluorescent probes (*21*), and derivatized superparamagnetic iron oxide nanoparticles (*22*).

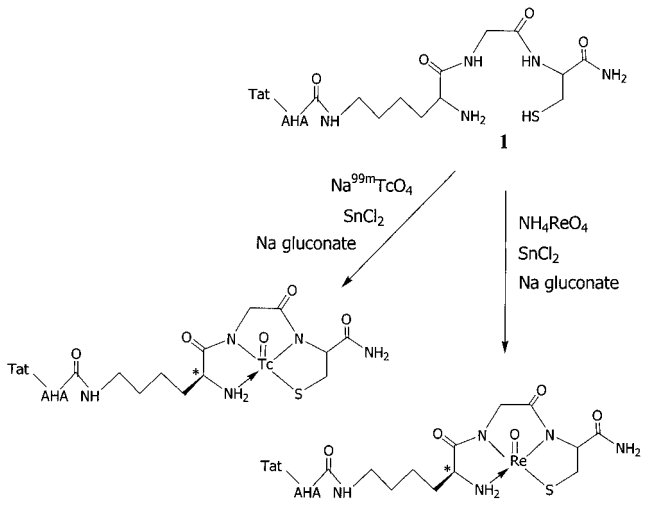
Herein we report a Tat−peptide basic motif for transduction of peptide chelates across plasma membranes as a delivery vehicle for imaging and radiotherapeutic isotopes. We designed prototypic peptides that constituted in their simplest form two functional domains, a membrane permeant peptide sequence derived from HIV-1 Tat protein residues 48−57 (GRKKRRQRRR) and a peptide-based chelator able to coordinate isotopes of metals useful in medical imaging and therapy (Figure 1). Novel radiolabeled Tat−peptide chelates are shown to rapidly and quantitatively concentrate by over 30-fold within the cytoplasm and nucleus of living human cells.

EXPERIMENTAL PROCEDURES

Peptide Synthesis. Peptide conjugate **1** (Gly-Arg-Lys-Lys-Arg-Arg-Gln-Arg-Arg-Arg-AHA-ϵ-Lys-Gly-Cys) was prepared by solid-phase peptide synthesis using all L *N*-α-FMOC-protected amino acids and standard BOP/HOBt coupling chemistry, except for the ϵ-Lys residue which used an *N*-α-tBOC, *N*-ϵ-FMOC-Lys to direct peptide coupling to the ϵ-amine. AHA represents 6-aminohexanoic acid as an aliphatic linker between the Tat 48−57 residues and the peptide chelating moiety. For peptides **2** and **3**, the N-terminus Gly was omitted. Peptides were either N-terminus acetylated (**1** and **2**) or biotinylated (**3**), C-terminus amidated (**1**, **2**, and **3**), and deprotected by standard methods. Peptides were purified (>94%) by preparative C_{18} reversed-phase HPLC using as eluent 0.1% trifluoroacetic acid in water (0.1% TFA/H_2O) modified with 0.1% trifluoroacetic acid in 90% acetonitrile/10% water [0.1% TFA/(90% CH_3CN/H_2O)] by a linear gradient (5−40% over 40 min) flowing at 1.0 mL/min. A single HPLC peak was observed for each peptide conjugate. The identity of peptide conjugates **1**−**3** was confirmed by amino acid analysis [**1**, 14 amino acids (Gln 1; Gly 2; Cys 1; Lys 3, Arg 6, AHA 1); **2** and **3**, 13 amino acids (Gln 1; Gly 1; Cys 1; Lys 3; Arg 6, AHA 1] and electrospray mass spectrometry (**1**, *m*/*z* 1839.0, calcd $C_{74}H_{143}N_{37}O_{16}S_1$, 1839.3; **2**, *m*/*z* 1782.8, calcd $C_{72}H_{140}N_{36}O_{15}S_1$, 1782.2; **3**, *m*/*z* 1965.6, calcd $C_{80}H_{151}N_{38}O_{16}S_2$, 1965.5).

Preparation of Radiolabeled [^{99m}Tc^{V}O]Tat−Peptide. Tat−peptide conjugates were labeled with ^{99m}Tc by ligand exchange using [^{99m}Tc]glucoheptonate as the ligand exchange reagent (Scheme 1) (*7*). A commercially available stannous glucoheptonate radiopharmaceutical kit [Sn(II)Cl_2·2H_2O, 0.14 mg; sodium glucoheptonate, 200 mg; Glucoscan, DuPont Pharma, Billerica, MA] was reconstituted with 1.0 mL of [^{99m}Tc]Na(TcO_4) (50 mCi) in isotonic saline obtained by eluting a commercial radionuclide ^{99}Mo/^{99m}Tc generator and allowed to stand for 15 min at room temperature. In a small glass vial, to a 10 μL aliquot of Tat−peptide conjugate stock solution

Scheme 1



(10 mg dissolved in 1 mL of 0.9% saline or water), [^{99m}Tc]-glucoheptonate solution (15−50 μL), and sufficient water to generate a final volume of 100 μL were added, and the reaction was allowed to proceed at room temperature for 15 min. Radiochemical yields (>95%) of oxotechnetium [^{99m}Tc]Tat−peptide complexes were determined by TLC using silica gel developed with either 15% TFA or H_2O as indicated and scanning radiometric detection (Bioscan, Inc., Washington DC). By TLC with TFA, [^{99m}Tc]Tat complexes **4**, **5**, and **6** from peptides **1**, **2**, and **3**, respectively, each showed an $R_f \approx 0.45$, readily distinguished from [^{99m}Tc]glucoheptonate ($R_f = 0.95$) and [^{99m}Tc]TcO_4^- ($R_f = 0.95$). By TLC with H_2O, [^{99m}Tc]Tat complexes remained at the origin while [^{99m}Tc]glucoheptonate and [^{99m}Tc]TcO_4^- moved with the solvent front. Radiochemical purity (>90%) was determined by radiometric RP-HPLC using the solvent gradient system described above as well as a linear gradient (0−60% over 60 min) also flowing at 1.0 mL/min. Specific activity was estimated to be 2×10^8 mCi/mol.

Preparation of [Re^{V}O]Tat−Peptide. [Re]Tat−peptide conjugates also were obtained through ligand exchange using [Re]glucoheptonate as the ligand exchange reagent (7). To 0.1 mL of a freshly prepared stock solution [sodium α-D-glucoheptonate, 200 mg, 0.81 mmol and tin(II)chloride dihydrate, 18.4 mg, 0.082 mmol in 1 mL of distilled water] was added 0.1 mL of a stock solution (ammonium perrhenate, 14.9 mg, 0.055 mmol in 1 mL of water), and the mixture allowed to stand for 15 min at room temp. To the mixture was added the appropriate Tat−peptide conjugate (1 mg, ~0.4 μmol) in water, and the reaction allowed to proceed at room temperature for 30 min. RP-HPLC analysis was performed using the solvent gradient system described above and the desired fractions collected. Identity of isolated [Re]Tat−peptide complexes was confirmed by electrospray mass spectrometry (acetyl-Gly-Arg-Lys-Lys-Arg-Arg-Gln-Arg-Arg-Arg-AHA-ϵ-Lys-Gly-Cys[Re] (**7**), *m*/*z* 2039.0, calcd $C_{74}H_{140}N_{37}O_{17}Re_1S_1$, 2038.4).

Preparation of Tat−Peptide-Fluorescein. Tat−peptide conjugates were labeled on the C-terminal thiol with fluorescein maleimide (FM) as described previously (*21*). Briefly, in a small glass vial, Tat−peptide conjugate (1 mg) was dissolved in phosphate buffered saline (PBS, pH 7.4) and reacted with 1.2 eq of fluorescein maleimide dissolved in dimethylformamide for 2 h in the dark at room temperature. Fluorescent peptide was purified by RP-HPLC (single peak; purity >97%) using the above

gradient conditions and lyophilized in the dark. Identity of the desired fluorescein tagged Tat−peptide was confirmed by electrospray mass spectrometry (acetyl-Gly-Arg-Lys-Lys-Arg-Arg-Gln-Arg-Arg-Arg-AHA-ϵ-Lys-Gly-Cys-FM (**8**), *m/z* 2266.0, calcd $C_{98}H_{156}N_{38}O_{23}S_1$, 2266.6; acetyl-Arg-Lys-Lys-Arg-Arg-Gln-Arg-Arg-Arg-AHA-ϵ-Lys-Gly-Cys-FM (**9**), *m/z* 2210.0, calcd $C_{96}H_{153}N_{37}O_{22}S_1$, 2209.6).

Cell Culture. Monolayers of human epidermoid carcinoma KB 3-1 cells and the colchicine-selected KB 8-5 derivative cell lines were grown at 37 °C in an atmosphere of 5% CO_2 as previously described (*23*, *24*). For experiments, cells were plated in 100-mm Petri dishes containing seven 25-mm glass coverslips on the bottom and grown to subconfluence in DMEM (GIBCO, Grand Island, NY) supplemented with L-glutamine (1%), penicillin/streptomycin (0.1%), and heat-inactivated fetal calf serum (10%) in the absence or presence of 10 ng/mL colchicine, respectively.

Human Jurkat leukemia cells were maintained in RPMI also supplemented with L-glutamine, penicillin/streptomycin, and 10% fetal calf serum at 37 °C in an atmosphere of 5% CO_2 (*25*).

Cellular Uptake and Washout Studies of [^{99m}Tc]-Tat−Peptide Conjugates. Control solution for tracer uptake experiments was a modified Earle's balanced salt solution (MEBSS) containing (mM): 145 Na^+, 5.4 K^+, 1.2 Ca^{2+}, 0.8 Mg^{2+}, 152 Cl^-, 0.8 $H_2PO_4^-$, 0.8 SO_4^{2-}, 5.6 dextrose, 4.0 HEPES, and 1% bovine calf serum (vol/vol), pH 7.4 ± 0.05. A 130 mM K^+/20 mM Cl^- solution was made by equimolar substitution of potassium methanesulfonate for NaCl as described (*26*).

Kinetic experiments of [^{99m}Tc]Tat−peptide complexes were performed in Jurkat leukemia cells suspended in MEBSS with minor modifications of methods described in the literature (*27*). Transport experiments were performed in siliconized microfuge tubes and initiated by addition of 732.5 μL cells at 5×10^6 cells/ml to 10 μL of MEBSS containing [^{99m}Tc]Tat−peptide complex and 7.5 μL of vehicle alone or of any added drug in vehicle at 100-fold the desired concentration. Unless stated otherwise, [^{99m}Tc]Tat−peptide complex was added to MEBSS accompanied by molar excess unlabeled Tat−peptide as obtained directly from the labeling procedure; final total peptide concentration was typically 0.5−1 μM (50 nmol/mCi; 10 μCi/mL). Tubes were incubated in a 37 °C water bath with occasional mixing. The reaction was terminated by spinning 250 μL aliquots from the reaction for 10 s through 800 μL of a 75:25 mixture of silicon oil (density = 1.050; Aldrich) and mineral oil (density = 0.875; Acros). An aliquot of the aqueous phase was obtained to normalize extracellular concentration of the Tc-peptide to cell-associated activity, then the oil and aqueous phases were aspirated and the cell pellet extracted in 0.5 mL of 1% SDS, 10 mM sodium borate. For peptide washout experiments, cells were first incubated to plateau uptake (10 min) in MEBSS loading buffer (37 °C), collected by rapid centrifugation and the pellet resuspended in 750 μL peptide-free MEBSS (4 °C) to clear extracellular tracer. Following another rapid spin, the cell pellet was resuspended in peptide-free MEBSS (37, 25, or 4 °C) for various times and the experiment terminated as above. All cell extracts were assayed for protein by BCA analysis (Pierce Chemical Co.) using bovine serum albumin as the protein standard. Cell extracts, stock solutions, and extracellular buffer samples were assayed for gamma activity in a well-type sodium iodide gamma counter (Cobra II, Beckman; 130−165 keV window). Absolute concentration of total [Tc]Tat−peptide complex in solution was determined from the specific activity of Tc, based on equations of Mo/Tc generator equilibrium (28). Transport data are reported as pmol of peptide_i (mg protein)$^{-1}$ (μM_o)$^{-1}$, wherein peptide_i represents total peptide within the cells and (μM_o)$^{-1}$ represents concentration of total peptide in the extracellular buffer (*29*). Data are generally reported as mean ± SEM.

Fluorescence Microscopy. Exponentially growing Jurkat cells were incubated in fresh media or MEBSS containing the fluorescein labeled Tat−peptide conjugate (0.5−1 μM) at 37 or 4 °C for 10−20 min. Cells were then cytospun onto glass slides, fixed at room temperature or on ice by direct addition of 4% (v/v) paraformaldehyde in PBS to the adherent cells for 10 min and then rinsed three times with PBS (1 min each). Similarly, human KB 3-1 and KB 8-5 epidermoid carcinoma cells growing on coverslips or chamber slides were incubated in MEBSS containing the fluorescein labeled Tat−peptide conjugate at 37 °C for 10 min, then fixed in 4% paraformaldehyde at room temperature and rinsed three times with PBS. Cells were then mounted with anti-fading mounting medium following the recommended procedures of the manufacturer (Vector). Distribution of fluorescein conjugates was analyzed on a Zeiss epifluorescence microscope or laser-scanning confocal fluorescence imaging system coupled to a Nikon microscope equipped with a CCD interfaced to a PC (*30*).

Stability of Radiolabeled Peptide in Vitro and in Vivo. The stability in vitro of [^{99m}Tc]Tat−peptide **4** in aqueous buffers between pH 4 and 9 was evaluated by incubation of radiolabeled peptide (10 mg/mL) for 1 h at RT in HEPES (10 mM) or Tris base (50 mM) buffer pH adjusted with HCl or NaOH, followed by TLC and scanning radiometric analysis. Additional effects of reduced glutathione (2.5 mM), cysteine (10 μM and 2.5 mM) or EDTA (2.5 mM) on radiolabeled Tat−peptide stability was performed by addition of competing chelator to buffers at each pH. Stability in vitro was further assessed by radio-TLC after incubation of [^{99m}Tc]Tat−peptide for 1 h at 37 °C in human serum, bovine calf serum, murine urine, culture media containing 10% fetal calf serum as well as MEBSS transport buffer.

In addition, human Jurkat cells were incubated with [^{99m}Tc]Tat−peptide **4** in MEBSS transport buffer for 1 h at 37 °C, centrifuged, and the cell pellet lysed in modified mammalian lysis buffer {100 mM NaCl; 50 mM Tris base (pH 8); 2 mM dithiothreitol; 0.5% NP-40; 1 mM phenylmethylsulfonylfluoride; 10 μg/mL leupeptin; 10 μg/mL aprotinin}. Radio-TLC analysis of both extracellular buffer and cell lysate was performed. Furthermore, stability in vivo of radiolabeled Tat−peptide was characterized by radio-TLC analysis of serum and urine samples 30 min after intravenous administration of 270 μCi of [^{99m}Tc]Tat−peptide **4** to FVB mice.

Biodistribution and Imaging Studies. Vertebral animal procedures were approved by the appropriate institutional review committee. Distribution of [^{99m}Tc]-Tat−peptide complex **4** in tissues of Balb/c mice was determined as previously described (*31*, *32*). Mice were anesthetized by metofane inhalation and injected with **4** (2 μCi in 50 μL saline) via bolus injection through a tail vein. Animals were sacrificed by cervical dislocation at 5, 30, 60, and 120 min postinjection ($n = 3$ each). Blood samples were obtained by cardiac puncture and tissues harvested rapidly. Gamma activity in organ samples was counted for 1 min, or until two standard deviations of sampling were below 0.5%. Data are expressed as percent of injected dose (% id) per organ [(organ μCi) (injected μCi)$^{-1}$ × 100] or % id per gram of tissue [(tissue μCi) (injected μCi)$^{-1}$ (g tissue)$^{-1}$ × 100].

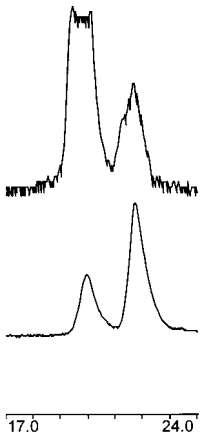


Figure 2. Radiometric (top) and UV (bottom) RP-HPLC chromatograms of [^{99m}Tc]Tat−peptide complex **4** and [Re]Tat−peptide complex **7**, respectively. Isolation and mass spectrometry of each Re species revealed identical masses (*m*/*z* 2039.0) consistent with formation of syn and anti isomers upon chelation of the metal.

For imaging studies, Balb/c mice also were lightly anesthetized with metofane inhalation. [^{99m}Tc]Tat−peptide complex **4** (200 μCi in 50 μL saline) was injected via a tail vein into mice positioned under a gamma scintillation camera (Siemens Basicam, Siemens Medical Systems, Iselin, NJ; 5 mm pinhole collimator; 20% energy window centered over 140 keV photopeak of Tc-99m). Sequential posterior images of mice were collected for 3 min each at 1, 30, and 60 min postinjection of the radiotracer with the mouse recovering and being reanesthetized just prior to each timepoint. A 256 × 256 image matrix with correction for radioactive decay was used on a PC platform and standard image analysis software. No corrections were made for scatter or attenuation. Whole body distribution of the complexes are presented with gray scale images.

RESULTS

Chemistry. Tat−peptide conjugates were synthesized by standard solid-phase methods and their corresponding ^{99m}Tc- and Re-complexes were obtained by ligand exchange using [^{99m}Tc]glucoheptonate or [Re]glucoheptonate, respectively (Scheme 1). Incorporation of a metal into the N_3S donor core has been shown to result in the formation of three five-membered rings and create a chiral center (*33*). Such structures typically resemble a square pyramid with the nitrogens at the base and the oxygen in the apical position (*33*) and are known to be stable (*34*). Radiochemical yield (>95%) and purity (>90%) of the oxotechnetium complexes were determined by TLC using silica gel with scanning radiometric detection and by radiometric RP-HPLC, respectively. By TLC, [^{99m}Tc]Tat peptide complexes were readily distinguished from [^{99m}Tc]glucoheptonate and [^{99m}Tc]TcO_4^- which moved at or near the solvent front. RP-HPLC analysis and radiometric detection of [^{99m}Tc]Tat−peptide **4** revealed two closely eluting peaks (Figure 2). Similarly, RP-HPLC analysis and UV detection of [Re]Tat−peptide **7** also revealed two eluting peaks with retention times differing by ∼2 min (Figure 2), close to the radiometric peaks observed with the ^{99m}Tc-labeled species. Furthermore, a second gradient system revealed similar results. Each Re peak was isolated and the identity of the oxorhenium Tat−peptide complex confirmed by mass spectrometry. Because both peaks had identical mass (*m*/*z* 2039.0 each; calcd 2038.4), we concluded that each represented an

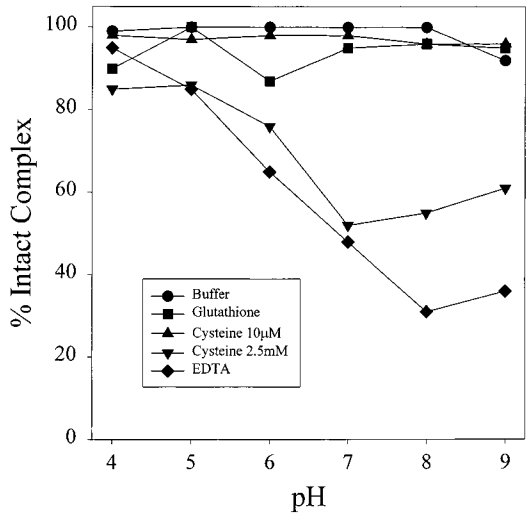

Figure 3. Effect of pH and competing chelation compounds on stability of radiolabeled Tat−peptide. Following incubation of [^{99m}Tc]Tat−peptide complex **4** for 1 h at RT in HEPES or Tris buffer adjusted to the indicated pH in the absence (●) or presence of reduced glutathione [2.5 mM (■)], cysteine [10 μM (▲)], cysteine [2.5 mM (▼)], or EDTA [2.5 mM (♦)], percent intact complex was determined by radio-TLC.

isomer of the N_3S chelation moiety in relation to the metal−oxygen bond due to participation of the chiral α-C atom of lysine in the chelation ring (*2*, *33*, *35*). The data were consistent with formation of the two anticipated diastereoisomers, the apical oxygen being syn and anti relative to the side chain of the Lys residue (see the asterisk in Scheme 1), as validated with analogous N_3S structures.

Separation of the isomers of Re−Tat−peptide complex **7** was accomplished by RP-HPLC and the kinetics of interconversion studied in aqueous solution at RT. For analysis, an HPLC fraction (assigned to isomer a) was collected, lyophilized, resuspended in water or PBS and monitored over 48 h. Interconversion of isomer a was not observed in deionized water. However, in PBS (pH 7.4), the emergence of isomer b was evident after 1 h at RT and a peak ratio of ∼2:1 (isomer a:isomer b) was observed at 2 h. After 48 h, the ratio remained ∼2:1, the inverse of the original mixture of **7** (see Figure 2). Thus, while PBS facilitated interconversion of the chelate, equilibrium was not observed with the peptide conjugate over this time interval. A proposed mechanism for interconversion of an analogous isolated N_3S chelate involves the coordination of a water molecule in the sixth position on the metal, trans to the metal−oxo bond (*33*).

To study the stability of the Tat−peptide chelate conjugates in vitro, radio-TLC analysis of [^{99m}Tc]Tat−peptide **4** was examined after incubation of peptide in buffered solution ranging in pH from 4 to 9 (Figure 3). As shown, [^{99m}Tc]Tat−peptide **4** was very stable to transchelation between pH 4−9, a physiologically relevant range of pH values likely to be encountered in vivo. Percent intact complex remained >97% over 1 h. The presence of reduced glutathione (2.5 mM; ∼100000-fold molar excess over labeled peptide complex), a competing physiologic chelator with modest binding affinity, showed no effect. Furthermore, [^{99m}Tc]Tat−peptide **4** remained >96% intact in the presence of physiological concentrations of the strong chelator cysteine (10 μM; ∼1000-fold molar excess), even under alkaline conditions. However, under extreme conditions of highly concentrated cysteine (2.5 mM) or EDTA (2.5 mM), evidence of over 50% transchelation was observed at pH ≥7. Additionally,

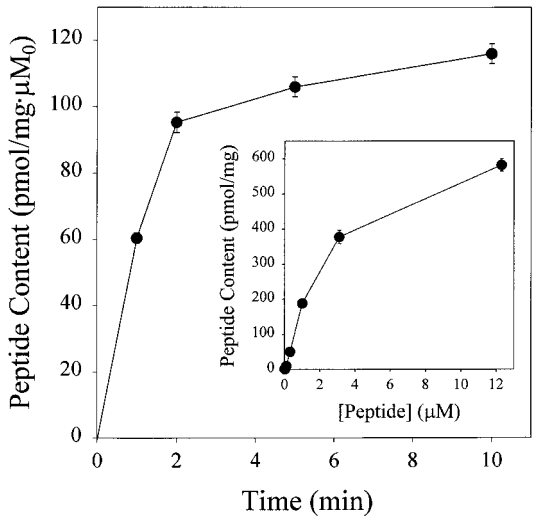

Figure 4. Kinetics of [^{99m}Tc]Tat−peptide complex **4** accumulation into human Jurkat cells. Cells were incubated in MEBSS loading buffer for the indicated times, washed, and cell-associated activity determined. Each point represents the mean of three to four determinations; bars represent ± SEM when larger than the symbol. Plot is representative of four independent experiments. (Inset) Concentration dependence of plateau accumulation of **4**. Twenty minute net uptake values at the indicated extracellular concentrations of **4** are plotted.

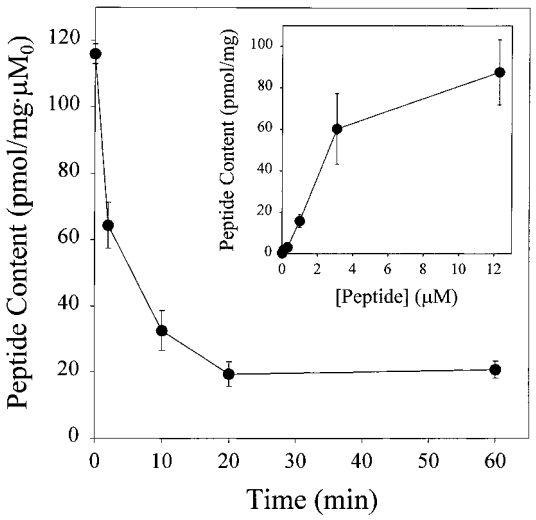

Figure 5. Washout kinetics of [^{99m}Tc]Tat−peptide complex **4** from human Jurkat cells at 37 °C. Cells were incubated (10 min) in MEBSS loading buffer (37 °C), washed, and then incubated in peptide-free MEBSS (37 °C). Cell-associated activity as a function of time in washout buffer is shown. Each point represents the mean of three to four determinations; bars represent ± SEM when larger than the symbol. Plot is representative of three independent experiments. (Inset) Concentration dependence of cellular residual activity of **4**. Sixty minute washout residual values after cell loading at the indicated extracellular concentrations of **4** are plotted.

incubation of [^{99m}Tc]Tat−peptide in human serum, bovine serum, cell culture media or MEBSS transport buffer for 1 h at 37 °C showed no evidence of metabolites or transchelation reactions by TLC (H_2O) (data not shown), further suggesting that the [^{99m}Tc]Tat−peptide was resistant to the action of serum proteases and natural chelators.

Cellular Transport Kinetics of [^{99m}Tc]Tat−Peptides. We first examined the overall uptake kinetics of [^{99m}Tc]Tat−peptide **4** in human Jurkat leukemia cells. Jurkat cells rapidly accumulated **4**, approaching a plateau in less than 5 min (Figure 4). This exceeded by an order of magnitude the uptake kinetics previously reported for an organometallic hydrophobic cation, [^{99m}Tc]-Sestamibi, which also is known to localize intracellularly (*29*, *36*). Steady-state values for the [^{99m}Tc]Tat−peptide complex were 116 ± 3 pmol (mg protein)$^{-1}$ (μM_o)$^{-1}$ (n = 4). Given a typical cell water space of 4 μL (mg protein)$^{-1}$ (*23*), this would indicate an intracellular/extracellular ratio for complex **4** of ∼30, consistent with the complex being rapidly concentrated within cells. Furthermore, TLC analysis of cell lysates showed >95% intact complex (data not shown).

To further characterize transport of the complex, plateau accumulation of [^{99m}Tc]Tat−peptide **4** in Jurkat cells (10 min incubation) was determined as a function of extracellular concentration of the agent by addition of increasing amounts of radiolabeled peptide to the buffer (at a fixed specific activity). While readily detectable at concentrations as low as 7 nM, cell content of **4** rose in proportion to the extracellular concentration of the complex. There was evidence of concentration saturation as extracellular concentrations rose into the 8 μM range (Figure 4, inset). The shape of the concentration-dependence curve implied the existence of a diffusive component and a saturable binding component to the overall uptake mechanism (*31*). Curve fitting of the data (*37*) suggested a half-maximal value of 2 μM for the saturable component.

Washout of [^{99m}Tc]Tat−peptide complex **4** also showed very rapid kinetics. Washout was ∼90% complete within 20 min (Figure 5). This may have favorable impact on signal-to-noise for nontarget tissues regarding use of this general class of agents in vivo. However, a residual compartment of slowly exchanging or retained activity was observable for longer time points. This residual was a function of extracellular peptide concentration (Figure 5, inset). Because the Arg-rich Tat protein basic domain is known to bind to viral RNA, this residual compartment may represent binding to analogous nuclear components in human cells, but this remains to be ascertained.

The radiosynthetic reaction for the Tat−peptide complexes inherently yields a mixture of isomeric [^{99m}Tc]Tat−peptide complexes (as described above) as well as ∼10000-fold molar excess unlabeled Tat−peptide conjugate. The latter arises as a consequence of the extremely high specific activity of the radiolabeling isotope ^{99m}Tc (*3*). To determine whether human cells could distinguish between putative syn and anti isomers of purified Tat−peptide complexes, fractions containing pure isomers of [^{99m}Tc]Tat−peptide complex **4** were isolated by RP-HPLC, lyophilized and each added to MEBSS buffer for accumulation experiments into Jurkat cells (10 min incubation, a short time compared to the solution interconversion times shown above). In Jurkat cells, the 10-min uptake of purified [^{99m}Tc]Tat−peptide isomer b was ∼60% of the uptake of isomer a (Table 1). However, in the same cells, when 20000-fold molar excess unlabeled Tat−peptide conjugate was added to purified [^{99m}Tc]Tat−peptide isomers in buffer, thereby simulating standard peptide mixtures, 10-min uptake of isomer b was now ∼80% of the uptake of isomer a. In addition, no consistent stereospecific trend was observed for the washout residual (Table 1). Thus, while net accumulation of putative syn and anti isomers of [^{99m}Tc]Tat−peptide complex **4** were not exactly equal, conformation per se produced only modest effects on the net cell uptake and washout of these [^{99m}Tc]Tat−peptide complexes. Furthermore, the 3−4-fold enhancement of cellular accumulation of purified isomers of [^{99m}Tc]Tat−peptide in the presence of

Table 1. Uptake and Washout of Isomers of [^{99m}Tc]Tat−peptide 4 in Human Jurkat Cells[a]

peptide	isomer a	isomer b
10-min net uptake [pmol (mg protein)$^{-1}$ (μM$_o$)$^{-1}$]		
purified [^{99m}Tc]Tat-peptide	62.8 ± 4.1	36.6 ± 5.2
added unlabeled peptide	185.9 ± 10.9	149.2 ± 4.5
30-min washout residual [pmol (mg protein)$^{-1}$ (μM$_o$)$^{-1}$]		
purified [^{99m}Tc]Tat-peptide	10.8 ± 1.1	7.9 ± 1.4
added unlabeled peptide	11.2 ± 0.8	23.8 ± 4.8

[a] Cells were incubated in MEBSS loading buffer (10 min; 37 °C) containing HPLC-purified isomers of **4** in the absence or presence of ~20000-fold molar excess unlabeled peptide, and then analyzed, or washed and then incubated in peptide-free MEBSS (30 min; 37 °C) prior to analysis. Cellular content of **4** is expressed as [pmol (mg protein)$^{-1}$ (μM$_o$)$^{-1}$]. Values represent the mean ± SEM of three to four determinations each.

Table 2. Effect of Various Drugs on Net Uptake of [^{99m}Tc]Tat−peptide 4 in Human Jurkat Cells

drug	10-min net uptake [pmol (mg protein)$^{-1}$ (μM$_o$)$^{-1}$]
control MEBSS	79.1 ± 2.0
0.1% DMSO vehicle	94.4 ± 20.2
Colchicine (100 ng/mL)	96.5 ± 11.8
Taxol (1 μM)	72.0 ± 4.3
Nocodozole (5 μg/mL)	66.8 ± 1.7
Cytochalasin D (1 μM)	76.2 ± 1.9
Brefeldin A (2.5 μg/mL)	79.4 ± 9.8
Wortmannin (100 nM)	82.9 ± 10.0

[a] Cells were incubated in MEBSS loading buffer (10 min; 37 °C) containing **4** and the indicated drugs prior to analysis. See the legend of Table 1 for details.

20000-fold molar excess unlabeled peptide (Table 1) obviates a simple receptor−ligand interaction for the net cell uptake process on one hand and simple diffusion on the other hand. These data provide evidence for a translocation mechanism with overall high capacity and a modest degree of positive cooperativity.

Because several membrane permeant peptides have been reported to accumulate within cells by mechanisms related to cytoskeletal function (*14*), several inhibitors known to impact microtubules, actin filaments, and various cytoskeletal-mediated vesicular transport pathways were tested. In Jurkat cells, neither the microtubule-disrupting agents colchicine (100 ng/mL), taxol (1 μM), nocodozole (5 μg/mL), the filament-disrupting agent cytochalasin D (1 μM), the trans-Golgi transport inhibitor brefeldin A (2.5 μg/mL), nor the phosphatidylinositol-3 kinase inhibitor wortmannin (100 nM) had any significant effect on net cell uptake of [^{99m}Tc]Tat−peptide **4** (Table 2). Thus, the pathway for accumulation of [^{99m}Tc]-Tat−peptide was unlikely to be mediated by a microtubulin or cytoskeletal-mediated transport mechanism. Furthermore, ice-cold buffer (4 °C) not only failed to inhibit uptake, but modestly enhanced net accumulation of the complex over time (Figure 6). In addition, after loading in 37 °C buffer, washout into ice-cold buffer was only modestly inhibitory (Figure 7). These data point to an unique cell membrane translocation pathway not highly dependent on endocytosis, vesicular trafficking or cellular metabolism.

To further examine potential mechanisms of localization, Jurkat cells were incubated with standard [^{99m}Tc]-Tat−peptide **4** in control MEBSS or buffer comprised of 130 mM K^+/20 mM Cl^- plus valinomycin (1 μg/mL), a potassium ionophore (*29*). When cells are incubated in this high K^+ buffer, electrical potentials of the mitochondrial membrane ($\Delta\Psi$), and plasma membrane (E_m) are depolarized toward zero, eliminating the inward driving force for uptake of cationic molecules (*38*). While Tat−peptide has amphiphilic cationic properties (*21*), net uptake of [^{99m}Tc]Tat−peptide complex **4** under isoelectric conditions was actually 42 ± 3% greater than control (data not shown), rather than decreased, indicating that the mechanism of Tat−peptide accumulation was independent of membrane potential.

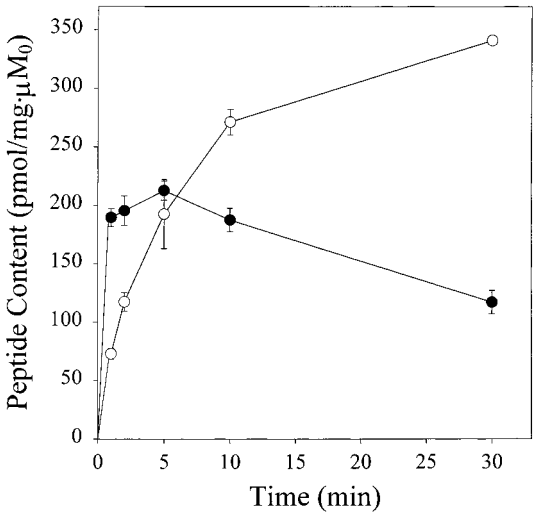

Figure 6. Effect of temperature on accumulation of [^{99m}Tc]-Tat−peptide complex **4** into human Jurkat cells. Cells were incubated in MEBSS loading buffer at 37 °C (●) or 4 °C (○) for the indicated times, washed, and cell-associated activity determined. Each point represents the mean of four determinations, except the 30 min point at 4 °C (n = 1); bars represent ± SEM when larger than the symbol. Plot is representative of two independent experiments.

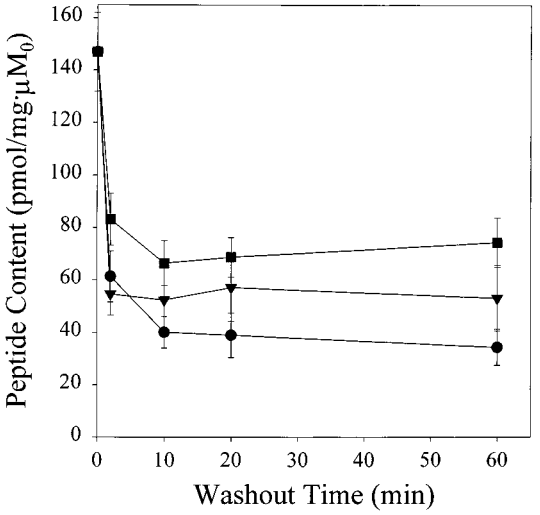

Figure 7. Effect of temperature on washout of [^{99m}Tc]Tat−peptide complex **4** from Jurkat cells. Cells were incubated (10 min) in MEBSS loading buffer (37 °C), washed, and then incubated in peptide-free MEBSS at 37 °C (●), 25 °C (▼), or 4 °C (■). Cell-associated activity as a function of time in washout buffer is shown. Each point represents the mean of three to four determinations; bars represent ± SEM when larger than the symbol.

The effect of N-terminus modifications on cellular uptake of the [^{99m}Tc]Tat−peptide conjugates was also explored. Deletion of the N-terminus Gly as in [^{99m}Tc]-Tat−peptide **5** modestly reduced both Tat−peptide net uptake and the washout residual in Jurkat cells (Table 3), but resulted in an increased net uptake/washout ratio.

Table 3. Effect of N-Terminus Modification on Net Uptake and Washout of [^{99m}Tc]Tat−peptides in Human Jurkat Cells

	[pmol (mg protein)$^{-1}$ (μM$_0$)$^{-1}$]	
peptide	20-min net uptake	30-min washout residual
[^{99m}Tc]Tat-peptide **4**	77.9 ± 3.5	24.3 ± 7.6
[^{99m}Tc]Tat-peptide **5**	61.7 ± 6.1	11.0 ± 1.8
[^{99m}Tc]Tat-peptide **6**	42.7 ± 3.2	24.3 ± 6.3

[a] Cells were incubated in MEBSS loading buffer (20 min; 37 °C) containing **4**, **5,** or **6**, and then analyzed, or washed and then incubated in peptide-free MEBSS (30 min; 37 °C). Cell content of peptide was determined as indicated. See the legend of Table 1 for details.

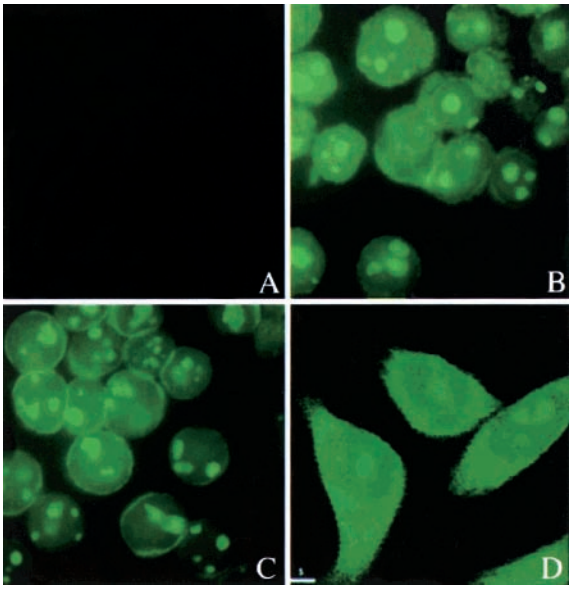

Figure 8. Cellular accumulation of fluorescein labeled Tat−peptide conjugate (**8**) in human Jurkat and KB-3-1 tumor cells. Cells were incubated with substrate for 10−20 min at 37 or 4 °C as indicated followed by fixation. Panels show fluorescence micrographs of Jurkat cells incubated at 37 °C in buffer containing fluorescein maleimide (1 μM) alone (A), at 37 °C in buffer containing **8** (B), and at 4 °C in buffer containing **8** (C) as well as a confocal micrograph of KB-3-1 cells incubated at 37 °C in buffer containing **8** (D). Note green fluorescence from labeled peptide residing in both cytosolic and nuclear (putative nucleolar) components. The cytosolic compartment containing fluorescent peptide, while more obvious in KB-3-1 tumors cells, appears as a rim surrounding the Jurkat cell nuclei, typical of lymphocytic cell types. Panel D, bar = 5 μm; panels A−C, magnified ~2× panel D.

However, N-terminus biotinylation of the shortened peptide (**6**) decreased net uptake while increasing the washout residual resulting in a lower uptake/washout ratio (Table 3).

Fluorescence Microscopy. While the tracer experiments advantageously determined cell-associated radioactivity in a quantitative manner, the exact subcellular location of [^{99m}Tc]Tat−peptides cannot be evaluated by population-based γ-counting techniques. To directly localize and thereby prove intracellular distribution of the Tat−peptide chelate construct, uptake experiments were performed with a fluorescein derivatized Tat−peptide conjugate (**8**) using suspension cultures of human Jurkat cells. As expected, cells did not show internalization of fluorescein maleimide when the nonconjugated fluorophore was added to the media or MEBSS alone (Figure 8A). However, fluorescence microscopy revealed diffuse cytoplasmic and focal nuclear accumulation of the fluorescein derivatized Tat−peptide in all Jurkat cells (Figure 8B). Overall, the multifocal nuclear staining pattern was suggestive of nucleolar localization of the conjugate. Interestingly, the same uptake and localization pattern was observed at 4 °C (Figure 8C). In both KB 3-1 epidermoid carcinoma cells (Figure 8D) and *MDR1* P-glycoprotein-expressing multidrug resistant KB 8-5 cells (data not shown), a cytoplasmic and focal nuclear accumulation pattern also was observed, providing evidence for the ubiquitous nature of tumor cell uptake for this Tat−peptide conjugate. The results in KB 8-5 cells also suggested that P-glycoprotein, an efflux pump of many hydrophobic cationic compounds (*39*), was not involved in the cell permeation pathway of Tat−peptides. Peptide **9** also showed a similar subcellular localization pattern (data not shown). Overall, the fluorescence staining pattern provided direct evidence for the intracellular localization of these novel Tat−peptide chelate based imaging and radiotherapeutic agents.

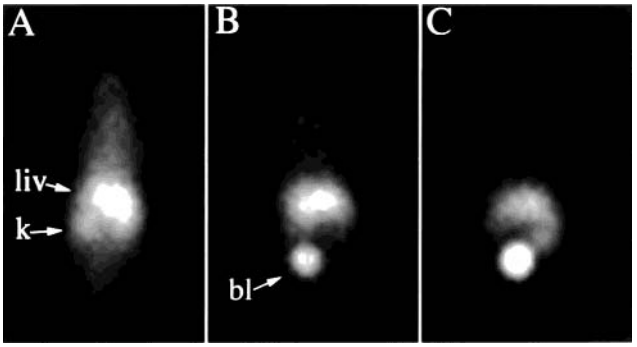

Figure 9. Scintigraphic gray scale images of [^{99m}Tc]Tat−peptide complex **4** in a Balb/c mouse. Following bolus intravenous injection of **4**, posterior images of the mouse were obtained with a gamma scintillation camera. Representative planar images obtained 3 min (A), 30 min (B), and 60 min (C) postinjection are shown. Rapid whole body distribution is followed by predominantly renal clearance of the [^{99m}Tc]Tat−peptide complex and appearance in the urinary bladder. Arrows demarcate liver (liv), kidneys (k), and bladder (bl).

Whole Body Imaging and Biodistribution Analysis. Exploiting the 140 keV emission photon of ^{99m}Tc, preliminary imaging of Balb/c mice was performed by gamma scintigraphy following tail vein bolus injection of [^{99m}Tc]Tat−peptide complex **4** (200 μCi). The complex was observed to rapidly distribute throughout the body, in a pattern initially consistent with organ perfusion (Figure 9). Of note, dynamic analysis of serial images as well as biodistribution data (Table 4) revealed that the complex reached peak organ levels within the first few minutes after injection and displayed modestly rapid blood clearance, favorable pharmacokinetic properties for potential uses of these complexes as imaging agents. Over the subsequent 2 h, [^{99m}Tc]Tat−peptide complex **4** was cleared by both renal and hepatobiliary excretion with activity appearing in the urinary bladder and bowel (Figure 9 and Table 4).

Analysis of [^{99m}Tc]Tat−peptide stability in vivo also was performed. In FVB mice, radio-TLC analysis of serum and urine samples 30 min after intravenous injection of [^{99m}Tc]Tat−peptide **4** revealed >95% intact complex in serum, but only 65% intact complex in the urine. However, direct addition of [^{99m}Tc]Tat−peptide **4** to murine urine samples ex vivo for 1 h at 37 °C showed no evidence of transchelation, thus localizing the observed transmetalation/metabolic reactions to the renal parenchyma in situ.

DISCUSSION

Design of Membrane Permeant Imaging and Radiotherapeutic Peptides. HIV-1 Tat transactivation protein is a potent viral transcriptional regulator capable of rapid translocation through the cell membrane (*21*, *40*). Tat is efficiently taken up by cells and interacts with trans-activation responsive region (TAR) RNA, a stem-loop structure located at the 5′-end of nascent HIV-1 transcripts (*41*). A small region of the HIV-1 Tat protein centered on a cluster of basic amino acids (residues 47−58) suffices to confer this permeation property (*21*). Given the many constraints that large molecular weight compounds may impose on pharmacokinetics and tissue penetration in vivo (*42*), we were attracted to this domain as a small candidate permeation motif likely to confer favorable translocation properties to imaging and radiotherapeutic peptide chelates.

Prototypic all L-peptides were synthesized containing two functional domains, a membrane permeant peptide sequence derived from Tat protein and a peptide-based chelator able to coordinate the desired imaging and therapeutic radionuclides. Among several choices available for the chelator moiety (*2*), a convenient starting point for these prototypic peptides was the ϵ-Lys-Gly-Cys sequence which generates an amino diamido thiol (N_3S) chelating core for an incoming TcO^{3+} or ReO^{3+} metallic species (*6*, *33*). Advantages of this sequence include (a) an appropriate ϵ-Lys residue which is readily available as a protected precursor for solid-phase peptide synthesis, (b) amino acid chain extension off the ϵ-amine of Lys confers rotational freedom between the membrane permeation and chelating domains of the peptide conjugate, (c) the chelation moiety is readily radiolabeled at room temperature using a facile transchelation reaction, and significantly, (d) this chelation moiety has proven favorable pharmacokinetic and metabolic properties in the clinical development of other targeted peptide agents (*6*, *43*). In this regard, cysteine, a naturally occurring and strong chelating compound for technetium, is a commonly used competitive compound for in vitro stability studies of ^{99m}Tc labeled compounds (*44*). In the present study, while 100000-fold molar excess cysteine produced 50% transchelation, the more physiologic challenge of 1000-fold molar excess cysteine (10 μM) showed little evidence of transchelation. These results are comparable to a recent stability report of an analogous N_3S chelating moiety (*34*), wherein 1000-fold molar excess cysteine for 24 h at room temperature (phosphate buffer, pH 7.4) resulted in no detectable transchelation of the ^{99m}Tc labeled conjugate. Other natural chelators also were without effect and, thus, we conclude that the ϵKGC chelation moiety, in accordance with published data in vitro and in vivo (*7*), is sufficiently stable to warrant further exploration for labeling [^{99m}Tc]Tat−peptides. Future studies will explore additional combinations of Tat peptide with interesting chelation moieties (*2*), including histidine (*45*), which readily coordinates Tc/Re(I)-carbonyl compounds.

Tissue penetration is a significant factor limiting efficacy of large macromolecules in vivo (*46*). Significantly, the data in this report now reduce by one amino acid the minimum Tat peptide basic motif sufficient for membrane transduction of a conjugated cargo. For example, previous studies have utilized HIV-1 Tat protein amino acid residues 48−60 (*21*), 48−59 (*47*), residues 47−57 (*19*), and residues 48−57 (*22*). Deletion of the N-terminus Gly as in [^{99m}Tc]Tat−peptide complex **5** (representing Tat protein amino acid residue 48) only minimally impacted net cell uptake compared to **4**. Thus, Tat protein amino acid residues 49−57 appear sufficient to impart the desired membrane translocation properties. However, further analysis of the minimally required motif would be of great interest as the smallest possible permeation sequence likely would show favorable pharmacokinetics in vivo.

In Vivo Imaging with Peptide Complexes. Low molecular weight peptides and antibody fragments provide rapid tumor targeting and uniform distribution in

tumor tissues (*48*). While such characteristics render low molecular weight peptides attractive vehicles for the delivery of radioactivity to tumor tissues and organs for both targeted imaging and radiotherapy, problems have been encountered. High and persistent localization of radioactivity is often observed in the kidneys, which compromises tumor visualization in the kidney region and limits therapeutic potential (*49*, *50*). As discussed by Arano et al. (*51*), radiolabeled low molecular weight peptides and antibody fragments would become much more useful for targeted imaging and therapy if the renal radioactivity levels could be reduced without impairing those in the target tissue. Previous studies have indicated that after glomerular filtration radiolabeled low molecular weight peptides and antibody fragments are likely resorbed by proximal tubules via luminal endocytosis (*52*, *53*). The long residence times of nontransported radiometabolites generated after lysosomal proteolysis of the radiolabeled fragments in renal cells also were reported to be responsible for the persistent renal radioactivity levels (*49*, *53*). The rapid renal clearance observed for the [^{99m}Tc]Tat−peptide complexes suggests that lysosomal proteolysis is not relevant to the overall excretion pathway of [^{99m}Tc]Tat−peptides in vivo and may favorably impact whole body imaging and therapeutic applications with these complexes.

Given the nuclear localization and RNA binding properties of Tat (*41*, *54*), an appealing potential use of our novel [^{99m}Tc]Tat−peptide complexes would entail chelation of ^{186}Re or^{188}Re for delivery of therapeutic radiopharmaceuticals directly to the cell nucleus. Combined with appropriate targeting constructs, this might enable efficient delivery of gamma irradiation doses directly to RNA/DNA pools within tumors. It should also be possible to synthesize alternative Tat−peptide conjugates using DTPA or DOTA, chelates suitable for other incoming radiotherapeutic and relaxivity metals, for applications in radiotherapy and magnetic resonance imaging.

CONCLUSION

In summary, a new class of peptide-based membrane permeant radiopharmaceuticals incorporating Tat−peptide basic sequences and a convenient peptide motif for chelation of metal isotopes was designed and synthesized. These potential imaging and radiotherapeutic agents are capable of rapid transduction through the plasma membrane of a variety of human cells and are shown to accumulate in a highly concentrative manner. Fluorescence microscopy of fluorescein-tagged Tat−peptide conjugates directly verified the cytosolic and focal nuclear localization of these agents. These prototypic [^{99m}Tc]Tat−peptide complexes can be easily derivatized for further targeted applications.

Kinetics of CO and O_2 Binding to Human Serum Albumin-Heme Hybrid

Teruyuki Komatsu, Yasuko Matsukawa, and Eishun Tsuchida*

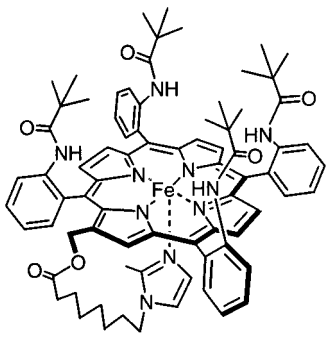
Department of Polymer Chemistry, Advanced Research Institute for Science & Engineering, Waseda University, Tokyo 169-8555, Japan. Received February 14, 2000; Revised Manuscript Received April 21, 2000

The kinetics of the CO and O_2 binding to the synthetic hemoprotein, recombinant human serum albumin (rHSA) incorporating *eight* 2-[8-{*N*-(2-methylimidazolyl)}octanoyloxymethyl]-5,10,15,20-tetrakis(*o*-pivalamido)phenylporphinatoiron(II)s (FePs) [rHSA-FeP(8)] have been investigated by laser flash photolysis. Time dependence of the absorption change accompanied the CO rebinding to rHSA-FeP(8) was composed of three phases. The fastest component was the axial base elimination, and the long-lived biphasic decay corresponds to the direct recombination of CO to the five-N-coordinated FePs in rHSA. The rate constants of the fast and slow phases of the CO association [k_{on}^{CO}(fast), k_{on}^{CO}(slow)] were determined to be 4.9×10^6 M^{-1} s^{-1} and 6.7×10^5 M^{-1} s^{-1}, respectively. The initial amplitude after the laser pulse gave the concentration ratio of the fast and slow phases ($n = 3$); (i) two of the eight FePs exhibited the slow rate constants and (ii) they are presumably accommodated in the second and fifth binding sites of FeP in the albumin structure. The absorption decay following the O_2 photodissociation of rHSA-FeP(8) also showed the same behavior. Thermodynamically, the large $\Delta G^{\ddagger}$ of the slow phase of the CO rebinding, which mainly comes from the enthalpic factor, suggests the appearance of additional steric hindrance on the central metal iron of FeP. Furthermore, orientation of the porphyrin plane in rHSA was predicted by molecular simulation, which supports the experimental data from the kinetic observations.

INTRODUCTION

The binding kinetics of small gaseous ligands (CO, O_2, or NO) to hemoproteins, e.g., myoglobin (Mb) and hemoglobin (Hb), have been widely studied for many years and it is still of current interest for the development of their mutant derivatives (Gibson 1970; Olson et al., 1971, 1988; Sawicki et al., 1977; Sharma et al., 1976; Steinmeier et al., 1975). For instance, the main features of the binding processes of Mb can be described as a scheme including two intermediate states in which the ligand molecule is inside the protein, but has not yet bound to the iron center of the heme. Much research has been carried out to interpret these transient states in terms of the stereochemistry of the Mb molecule (Ansari et al., 1985; Austin et al., 1975; Jongeward et al., 1988; Sato et al., 1990). A variety of theoretical simulations have also been undertaken to study the response of the ligand and protein structure to the photodissoiation (Case et al., 1979; Kottalam et al., 1988).

We have recently found that the recombinant human serum albumin (rHSA) incorporating the tetraphenylporphinatoiron(II) derivative linked a covalently bound axial base, 2-[8-{*N*-(2-methylimidazolyl)}octanoyloxymethyl]-5,10,15,20-tetrakis(α,α,α,α-*o*-pivalamido)phenylporphinatoiron(II) (FeP) (rHSA-FeP) can reversibly bind and release O_2 under physiological conditions (in aqueous media, pH 7.3, 37 °C) like Hb and Mb (Komatsu et al., 1999; Tsuchida et al., 1997, 1999). It is noteworthy that the obtained rHSA-FeP hybrid shows a good compatibility with the human whole blood and can quantitatively transport O_2 in vivo (Tsuchida et al., 2000). That is, rHSA-FeP is now one of the most promising materials as a totally synthetic red cell substitute. Interestingly, laser flash photolysis to the dioxygenated rHSA-FeP leads to nonexponential relaxation of the O_2-photodissociated products on a microsecond time scale (Tsuchida et al., 1999). This paper describes the rebinding kinetics of CO and O_2 to this synthetic hemoprotein and its thermodynamic properties. Furthermore, molecular simulation allows us to predict the orientation of the porphyrin plane in the albumin structure, which supports the kinetic observations.



FeP

EXPERIMENTAL PROCEDURES

Materials and Prepration. The synthetic heme, 2-[8-{*N*-(2-methylimidazolyl)}octanoyloxymethyl]-5,10,15,20-tetrakis(*o*-pivalamido)phenylporphinatoiron(II) (FeP) was prepared according to our previously reported procedures (Tsuchida et al., 1995). A recombinant human serum albumin (rHSA; 25 wt %) was obtained from WelFide Corporation (Sumi et al., 1993). The rHSA-FeP solution

Published on Web 09/30/2000

was prepared by the following procedure. Aqueous ascorbic acid (120 mM, 10 μL) was added to an ethanol solution of Fe(III)P (60 μM, 20 mL) under a CO atmosphere to reduce the central ferric ion of FeP. The obtained six-coordinate carbonyl Fe(II)P in ethanol was slowly added to the phosphate buffer solution (30 mM, pH 7.3) of rHSA (3.75 μM, pH 7.3, 40 mL) through the wall of the round flask. The mixture was then dialyzed with a cellulose membrane against phosphate buffer (pH 7.3) for 2 h and another 16 h at 4 °C. The ethanol content was finally reduced to less than 95 ppm, affording an aqueous solution of rHSA-FeP(8) [[FeP]: 20 μM, FeP/rHSA = 8 (mol/mol)].

Laser Flash Photolysis. CO and O_2 bindings to FeP were expressed by

$$\mathrm{FeP} + \mathrm{L} \underset{k^{\mathrm{L}}_{\mathrm{off}}}{\overset{k^{\mathrm{L}}_{\mathrm{on}}}{\rightleftharpoons}} \mathrm{FeP\text{-}L} \qquad (1)$$

$$[K^{\mathrm{L}} = k^{\mathrm{L}}_{\mathrm{on}}/k^{\mathrm{L}}_{\mathrm{off}}]$$

where L is CO or O_2. The association rate constants of these gaseous ligands ($k^{\mathrm{L}}_{\mathrm{on}}$) were obtained from the rebinding kinetics following photodissociation of CO or O_2 by laser flash photolysis [Continium Surelight I-10 (Nd:YAG laser SHG: 532 nm, 6 ns pulse width)]. In particular, a CO/O_2 competitive binding technique was employed for the determination of $k^{\mathrm{O_2}}_{\mathrm{on}}$ (Tsuchida et al., 1993; Collman et al., 1983; Traylor et al., 1985). The Xenon lamp (150 W) was used as the monitor light source. The time dependence of the absorption changes that accompanied the CO or O_2 recombination were detected by a Hamamatsu Photonics R636 photomultiplier, and the relaxation curves were fitted to triple-exponentials. A KOFLOC Gas Blender GB-3C prepared the mixture gas with the desired partial pressure. For the solubility of CO and O_2 in water at 25 °C, we used the values of 0.94 and 1.25 mM, respectively. Gas concentrations were always at least 10 times that of the FeP concentration, therefore, the pseudo-first-order approximation could be applied throughout. The cuvette of the sample ([FeP]: 20 μM) was fixed into a thermostated holder and the temperature was mainteined from 10 to 35 °C for the Arrhenius equation in order to obtain the activation energy parameters.

Binding Equilibria. The gaseous-binding affinity (partial pressure at half binding for FeP, $P^{\mathrm{L}}_{1/2} = 1/[K^{\mathrm{L}}]$) was determined by spectral changes at various partial pressures of CO or O_2 as in previous reports (Tsuchida et al., 1993; Collman et al., 1983). The FeP concentrations of 20 μM were normally used for the UV−vis absorption spectroscopy. The UV−vis absorption measurements were performed using a Shimadzu V-570 spectrometer within the range of 350−700 nm.

Molecular Simulations. The orientation of FeP in the hydrophobic cavity of rHSA was predicted by the ESFF force field simulation using an Insight II system (Molecular Simulations Inc.) on a Silicon Graphics O_2 computer. First, the domain for FeP was preliminarily predicted using the domain analysis program. The initial structure in which FeP was placed in the crevice between IB and IIA, namely the hemin site, was proposed. The potential energy was obtained after the energy minimization with 100 steps of the conjugate gradient method assuming a dielectric constant of 1.0. Random numbers automatically produced the degrees of freedom of FeP and the residues within the length of 12 Å from the porphyrin center were permitted to move.

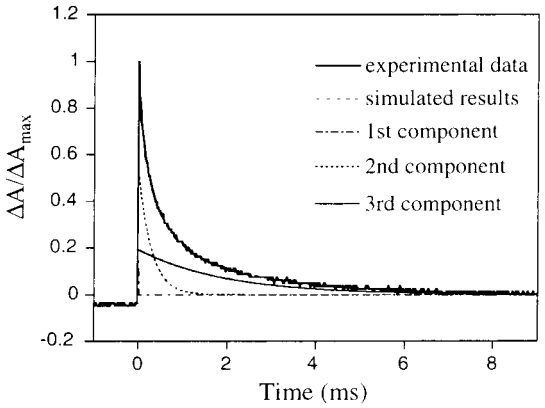

Figure 1. Absorption decay of CO rebinding to rHSA-FeP(8) after the laser flash photolysis at 25 °C. The kinetics was composed of three phases and the relaxation curve was fitted by triple-exponentials.

RESULTS AND DISCUSSION

CO-Binding Kinetics. We have shown earlier that a maximum of *eight* FeP molecules are incorporated into certain domains of human serum albumin with binding constants from a K_1 of 1.2×10^6 to a K_8 of 1.3×10^4 M^{-1} (Tsuchida et al., 1997, 1999). Three of the eight sites were estimated to be subdomains IB−IIA (hemin site), IIA (bilirbin site), and IIIA (typical palmitic acid site), respectively. For convenience, the eight binding sites of FeP are now named the *first site* to the *eighth site* in order of their magnitudes of the binding constants (K_1−K_8). As a matter of course, the microenvironment around the each FeP in albumin should not be identical. Therefore, one can expect the multiple binding processes of CO and O_2 with this synthetic hemoprotein. Flash photolysis experiments were then carried out to characterize the CO- and O_2-binidng behavior of rHSA-FeP in detail. First, an aqueous solution of rHSA incorporating eight carbonyl-FePs [rHSA-FeP(8)], which displayed absorption maxima at 427 and 539 nm, was irradiated. The time dependence of the absorption change [ΔA(t)] at 443 nm after the laser flash photolysis showed nonexponential kinetics (Figure 1), which was independent of the monitoring wavelength and the laser pulse intensity. On the basis of the careful inspection of the relaxation curve, it could be fitted to triple-exponentials using eq 2,

$$\Delta A(t) = C_1 \exp(-k_1 t) + C_2 \exp(-k_2 t) + C_3 \exp(-k_3 t) \quad (2)$$

where k_1, k_2, and k_3 are apparent rate constants for the each reaction. The fastest component with a k_1 of 2.4×10^5 s^{-1} was relatively minor (C_1: 0.16) and found to be independent of the CO concentration. This kinetics should be related to an axial base elimination (Geibel et al., 1978), so that the latter biphasic decay corresponds to the direct rebinding process of CO to the five-N-coordinated FeP in rHSA (deoxy form). The k_2 and k_3 values yield the association rate constants for the fast and slow phases [$k^{\mathrm{CO}}_{\mathrm{on}}$(fast), $k^{\mathrm{CO}}_{\mathrm{on}}$(slow)] (Table 1); the $k^{\mathrm{CO}}_{\mathrm{on}}$(slow) ($6.7 \times 10^5$ M^{-1} s^{-1}) became one-seventh of $k^{\mathrm{CO}}_{\mathrm{on}}$(fast) ($4.9 \times 10^6$ M^{-1} s^{-1}). Interestingly, the absorption decay during the CO recombination of rHSA-FeP(1) was almost monophasic ($k_{\mathrm{on}} = 4.7 \times 10^6$ M^{-1} s^{-1}). Therefore, it can be supposed that the CO-association rate of FeP is largely affected by the protein environments surrounding the metal center of FeP, e.g., steric hindrance of the amino acid residues and difference in polarity.

Table 1. Association and Dissociation Rate Constants of CO and O_2 to rHSA-FeP in Phosphate Buffer (pH 7.3) at 25 °C

	CO		O_2			
	10^{-6} k_{on}(fast) (M^{-1} s^{-1})	10^{-6} k_{on}(slow) (M^{-1} s^{-1})	10^{-7} k_{on}(fast) (M^{-1} s^{-1})	10^{-7} k_{on}(slow) (M^{-1} s^{-1})	10^{-2} k_{off}(fast) (s^{-1})	10^{-2} k_{off}(slow) (s^{-1})
rHSA-FeP(2)	4.5 [69]	0.65 [31]	3.4 [67]	0.94 [33]	7.4	2.0
rHSA-FeP(4)	4.7 [65]	0.66 [35]	3.2 [63]	1.0 [37]	7.2	2.2
rHSA-FeP(8)	4.9 [73]	0.67 [27]	3.4 [73]	0.95 [27]	7.5	2.0
Hb(T-state)α[a]	0.22		0.29		1.8	

[a] In brackets (%); the percentage of the fast and slow components in CO- or O_2-rebinding to the five-N-coordinated FeP in rHSA, which is estimated from the amplitude of $\Delta A(t=0)$. [b] pH 7, 20 °C (Sawicki et al., 1977; Steinmeier et al., 1975).

Table 2. Free-Energy Changes and Activation Parameters of the CO Association to rHSA-FeP(8) in Phosphate Buffer (pH 7.3) at 25 °C

	phase	10^{-6} k_{on}^{CO} (M^{-1} s^{-1})	$\Delta G^{\ddagger}$ (kJ mol^{-1})	$\Delta H^{\ddagger}$ (kJ mol^{-1})	$\Delta S^{\ddagger}$ (J mol^{-1} K^{-1})
rHSA-FeP(8)	fast	4.9	43	19	−80
	slow	0.67	49	23	−83
FeP (in toluene)		6.9	44 (:$\Delta G_I^{\ddagger}$)	13	−104

We then calculated the concentration ratio of the fast and slow phases (n) from the initial amplitude after the laser pulse [$\Delta A(t=0)$]. For the rHSA-FeP(8), the n value was approximately three, indicating two of the eight FePs exhibited the slow rate constants [k_{on}^{CO}(slow)]. The absorption decays of rHSA-FeP(2) and rHSA-FeP(4) also obeyed the triple-exponentials in which the second and third components again showed the clear CO-concentration dependence. The determined k_{on}^{CO}(fast) and k_{on}^{CO}(slow) were all the same as those of rHSA-FeP(8). On the basis of the n values of rHSA-FeP with different numbers of FeP/rHSA [1, 2, 4, 8 (mol/mol)], it takes into account that two of the eight FePs with the slow rate constant reside in the second and fifth binding sites of the FePs in the albumin structure, i.e., "slow site". Of course, since the numbers of FePs bound represent average numbers, we made two assumptions; (1) the binding numbers of FeP in an rHSA are identical to the mixture ratio, and (2) in the case of rHSA-FeP(4), for example, the two states (I, II) exist in the solution; I state in which FePs occupy the first to the fourth binding sites (66%), and II state in which FePs occupy the first to the third binding sites and the fifth site (34%).

To interpret the reaction profile, the activation parameters and free energy changes ($\Delta G^{\ddagger}$) of the CO rebinding to rHSA-FeP(8) were measured (Table 2). The Arrhenius plots of each relaxation component showed a straight line in the temperature range of 15−35 °C. $\Delta G^{\ddagger}$ of the slow phase (49 kJ mol^{-1}) was significantly higher than that of the fast phase (43 kJ mol^{-1}), and its enthalpy term mainly contributes to the destabilization of the transition state. This result suggests that an additional steric hindrance opposes the binding of CO. In a protein, the multiple free energy barriers generally regulate the entering or leaving of the gaseous ligand. We then proposed a double-barrier model in which CO encounters two barriers on its way from water to the binding site of FeP (Figure 2). **A** is the FeP−CO bound state, **S** is the dissociated state and **B**, is an intermediate state that is only transiently populated. The external barrier II is attributed to the matrix disturbance of the free diffusion of CO from the outer aqueous phase. Once within the pocket of the serum albumin, CO has to overcome energy barrier I for the bond formation. In general, the association rate constants of CO with synthetic hemes and hemoproteins are low compared with those of O_2 or NO and far below the diffusion limit at room temperature (Austin et al., 1975; Sharma et al., 1976; Tetreau et al., 1990). Therefore, the overall reaction rates of CO with rHSA-FeP should be governed by the height of barrier I. The $\Delta G^{\ddagger}$ of the CO binding to FeP in homogeneous toluene solution was determined to be 44 kJ mol^{-1}, which is identical to that of the fast component of rHSA-FeP(8) [$\Delta G^{\ddagger}$(fast): 43 kJ mol^{-1}]. At the "fast sites", the rHSA structure does not interfere with the CO recombination. In contrast, the height of the barrier increased at the slow site and the CO rebinding could be opposed by the steric hindrance of the bulky amino acid residues located over the porphyrin plane.

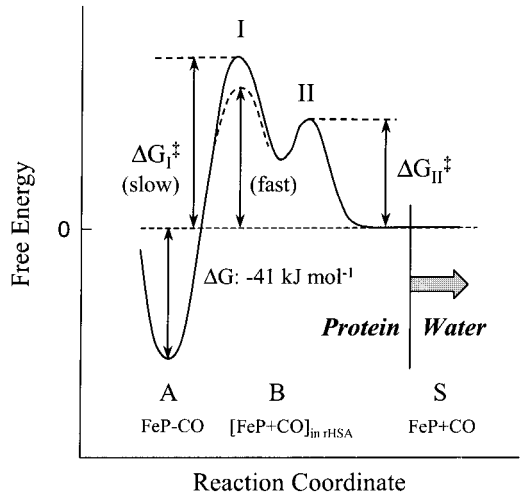

Figure 2. Double-barrier model for CO rebinding to rHSA-FeP. $\Delta G_I^{\ddagger}$ and $\Delta G_{II}^{\ddagger}$ refer to the top of barriers I and II relative to the reactants. The overall reaction rate is determined by $\Delta G_I^{\ddagger}$.

O_2-Binding Kinetics. The O_2-binding kinetics of rHSA-FeP showed exactly the same trend observed in the CO recombination. The absorption decay [$\Delta A(t)$] of rHSA-FeP(8) following the O_2 photodissociation was again fitted by triple-exponentials. The fastest relaxation with the apparent rate constant of k_1 (less than 10%) was independent of the O_2 concentration. This reaction is considered to be the unfavorable base elimination (Geibel et al., 1978). The slopes of the linear plots of k_2 and k_3 versus [O_2] yield two association rate constants for the fast and slow phases [$k_{on}^{O_2}$(fast), $k_{on}^{O_2}$(slow)] (Table 1). The differences in the $k_{on}^{O_2}$(fast) and $k_{on}^{O_2}$(slow) values are significantly smaller than that observed in CO. As predicted, the O_2-binding kinetics of rHSA-FeP(1) obeyed a single-exponential (k_{on} = 3.2 × 10^7 $M^{-1}s^{-1}$). The n values for rHSA-FeP [FeP/rHSA = 2, 4, 8 (mol/mol)] were the same as those of the CO recombination. Conse-

Table 3. CO- and O_2-Binding Affinities of rHSA-FeP in Phosphate Buffer (pH 7.3) at 25 °C

	CO		O_2	
	10^{-1} $P_{1/2}$(fast) (Torr)	10^{-1} $P_{1/2}$(slow) (Torr)	$P_{1/2}$(fast) (Torr)	$P_{1/2}$(slow) (Torr)
rHSA-FeP(4)	1.1	1.1	13	13
rHSA-FeP(8)	1.2	1.2	14	13

quently, the second and the fifth binding sites of FeP are again assigned to the *slow sites* for O_2 binding.

CO- and O_2−Binding Affinities. The CO- and O_2-binding affinities ($P_{1/2}$ is the gaseous pressure at half ligand-binding for FeP) of rHSA-FeP were determined based on the UV−vis absorption spectral changes by the CO and O_2 titrations. According to the results of the kinetics experiments, the $P_{1/2}$ values were divided by two components using eq 3,

$$Y = A(K(\text{fast})[\text{L}]/(1 + K(\text{fast})[\text{L}])) + B(K(\text{slow})[\text{L}]/(1 + K(\text{slow})[\text{L}])) \quad (3)$$

where Y is total CO and O_2 saturation of FeP in rHSA, $K(\text{fast}) = [P_{1/2}(\text{fast})]^{-1}$, $K(\text{slow}) = [P_{1/2}(\text{slow})]^{-1}$, and $A/B = n$. The obtained $P_{1/2}$(fast) and $P_{1/2}$(slow) of the CO and O_2 bindings to rHSA-FeP(4) and rHSA-FeP(8) did not show any significant difference (Table 3). Furthermore, the O_2 dissociation rate constants in the slow sites [k_{off}(slow)] became smaller than those of the fast sites (Table 1). Since the O_2-binding affinities were constant, the dissociation of O_2 from the dioxygenated FeP is also retarded in the slow sites.

Molecular Simulations. The three-dimensional structure of these synthetic hemoproteins has not yet been solved, although we have attempted to prepare its single crystal. Molecular simulation, however, allows us to predict the orientation of the guest molecule in rHSA. If the CO- and O_2-binding plane of FeP, i.e., the four-pivalamido substituted face of the porphyrin, looks toward the albumin surface and there is no steric hindrance of the protein matrix above, the association rates should not be disturbed. This is actually observed in the *fast site*. The most stable structure of rHSA-FeP, in which FeP was placed in the subdomains IB−IIA (hemin site), has been simulated by the ESFF force field. The first position of FeP was preliminary predicted using the domain analysis program (see experimental). In the converged state with the lowest potential energy, the four-pivalamido face turns to the outside (Figure 3). In addition, there seems to be a pathway for the small gaseous ligands from the bulk water to the porphyrin plane. This site could be the *fast site* for the CO and O_2 bindings to FeP. These simulation results preliminary support the experimental data based on the kinetic observations.

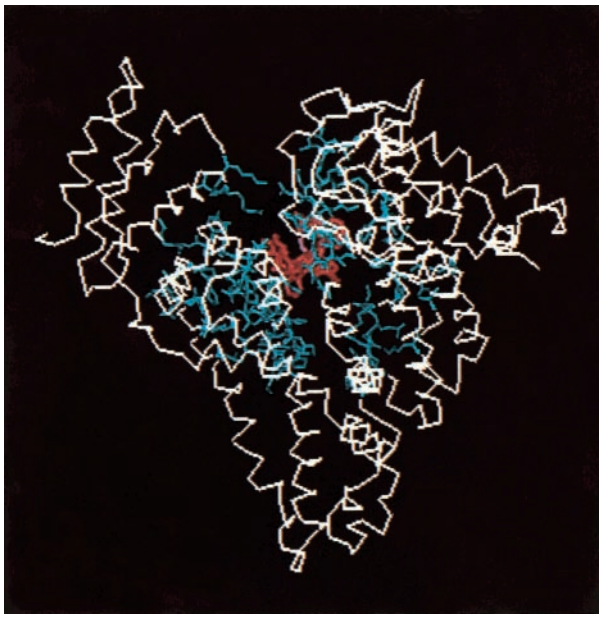

Figure 3. Molecular simulation image of the most stable conformation of dioxygenated rHSA-FeP(1) in which FeP is placed into the well-known hemin site. The backbones and amino acid residues within the length of 12 Å from the porphyrin center are permitted to move and colored blue. The four-pivalamido groups on the porphyrin ring plane obviously face the outside bulk water.

In conclusion, the CO- and O_2-binding kinetics of the recombinant human serum albumin incorporating *eight* tetraphenylporphinatoiron(II) derivatives are composed of three phases, in which the long-lived biphasic decay corresponds to the direct recombination of CO and O_2 to the five-N-coordinated FePs in rHSA. Two of the eight sites of FeP (the second and fifth binding sites) are estimated to be the *slow sites* for the CO and O_2 associations. A thermodynamic study revealed that the large $\Delta G^{\ddagger}$ of the slow phase in the CO recombination is brought about by the enthalpic factor. The association of the gaseous ligands to the porphyrin in the slow site is probably interfered by the steric hindrance of the amino acid residues of the protein interior. Furthermore, the predicted structure of the rHSA-FeP hybrid by molecular simulation supports the experimental results from the kinetic observations. This procedure can presumably be useful for understanding the CO- and O_2-binding behaviors on a shorter time scale.

Design and Synthesis of Novel Glycopolythiophene Assemblies for Colorimetric Detection of Influenza Virus and *E. coli*

Myung-Gi Baek,* Raymond C. Stevens, and Deborah H. Charych†

Lawrence Berkeley National Laboratory, Materials Sciences Division, Berkeley, California 94720

A novel family of glycopolythiophenes containing sialic acid or mannose ligands were prepared and evaluated for their ability to bind lectins, virus, and bacteria. For the set of glycopolythiophenes studied, the spacer-length between the polymer backbone and the ligand was varied to optimize binding interactions. The glycopolymers were blue-shifted (absorbance of ca. 400 nm) relative to the corresponding homo-polythiophenes (absorbance ca. 440 nm), suggesting a twisted conformation for the glycopolymers. The altered conformation is likely due to electrostatic or H-bonding interactions between the polymer chains, arising from the carbohydrate ligand. Further conformational changes in the polythiophene backbone were detected by the binding of specific receptors; lectins (wheat germ agglutinin, concanavalin A), Influenza virus, and *Escherichia coli*. The binding interactions result in an unusual red-shift in the visible absorption of the polymer backbone, suggesting a lengthening of the effective conjugated length upon interaction of the ligand with its congnate receptor. These conjugated glycopolymeric systems offer a potentially new platform for the detection of molecular binding interactions.

INTRODUCTION

In the past few decades, new types of organic polymers such as polyacetylene, polydiacetylene, polypyrrole, polyaniline, and polyphenylene have received increased attention due to the high demand for materials capable of performing various optical and electronic functions. Important properties of these materials include electroconductivity, liquid crystallinity, nonlinear optical effects, and novel chromatic properties (*1*−*4*). These conjugated polymers exhibit high electrical conductivity with good thermal stability. For their preparation, synthetic efforts were geared toward minimizing structural defects (e.g., broad molecular weight distribution, branching, crosslinking, etc.). Polythiophene is an important member of this class of π-conjugated polymers. Due to a planar−nonplanar conformational transition of the π-conjugated system, these materials exhibit a variety of optical transitions upon external stimuli such as heat (*5*−*8*), light (*9*), metals (*10*, *11*), chemicals (*12*), and proteins (*13*, *14*). These effects have been termed thermochromism, photochromism, ionochromism, or biochromism, respectively. Another important polymer of this class is polydiacetylene. Ligand-derivatized versions of self-assembling polydiacetylenes have been studied extensively for their biochromic properties (*15*, *37*, *38*−*43*). For example, sialic-acid-derivatized polydiacetylenes detect influenza virus hemagglutinin by a color change from blue to red (*15*, *42*). Other derivatives have been shown to detect toxin (*37*, *43*). The chromic transitions of both polydiacetylene and polythiophene can be strongly correlated with the electronic structure and the conformation of the polymer backbone. Indeed, theoretical studies have shown that a high degree of planarity along the polymer chains leads to better electrical properties (*16*). However, the rearrangement of the polymer backbone also strongly depends on the conformational state of the side chains (*17*, *18*). In addition, aggregation of polythiophene chains induces the formation of π-stacks in the macromolecular assembly and generates enhanced electronic and photonic properties (*9*, *18*, *19*). Therefore, the degree of π-conjugation of the polymer chains and their susceptibility to external stimuli are critical if the material is to be used as a sensory device (*20*).

Applications of polythiophene-based biosensors require that the material must be tailored to biological environments. This requires the incorporation of biologically active species, such as proteins, peptides, lipids, or carbohydrates in the polymeric system. In particular, carbohydrates are attractive because they are relatively small when compared to proteins and are expressed externally from the cell surface as a component of glycoproteins, glycolipids, and capsular polysaccharides (*21*). Carbohydrates are involved in key recognition events (*22*−*24*) with a variety of receptor proteins such as hormones, enzymes, toxins, lectins, antibodies, viruses, and bacteria. Carbohydrates are also involved in numerous biological processes (*25*) such as cell growth, recognition and differentiation, cancer metastasis, inflammation, and pathogen-entry. Finally, the hydrophilicity of the carbohydrate moieties facilitates water solubility of the polymeric material. Thus, the carbohydrate moieties are excellent candidates for creating new types of biochromic polythiophene materials. For example, an analogue of sialic acid is the receptor-specific carbohydrate for the influenza virus hamagglutinin (*22*, *26*−*29*). In addition, certain mannose residues recognize some bacterial species, such as *Escherichia coli* and *Salmonella* (*30*−*35*). In particular, Type I piliated *E. coli* is a pathogen responsible for many urinary tract infections and is a mannose-specific bacteria (*31*−*33*, *35*). Considering the interactions of sialic acid and mannose toward these specific pathogen proteins, we designed and synthesized

a series of new thiophene-carbohydrate monomers with well-defined spacer-lengths (side chains) to optimize protein binding. Subsequent copolymerization of the thiophene-carbohydrate monomer with methyl (3-thienyl) acetate (**7**) as a comonomer gave a series of novel glycopolythiophenes (glyco-PTs) (Figure 1). In addition, the multivalent display of carbohydrates on the glyco-PTs overcomes the characteristic low binding affinity of the individual carbohydrates to their receptor proteins. The glyco-PTs were tested for their ability to undergo absorption shifts after the addition of proteins. The mannose-glyco-PTs were studied with *Concanavalin A* (Con A), biotin-labeled Con A, and *E. coli* (HB101 strain), whereas the sialic acid-glyco-PTs were investigated with *Triticum Vulgaris* (Wheat germ) and Influenza virus (A/B).

EXPERIMENTAL PROCEDURES

General Procedures. Air- and moisture-sensitive reactions were carried out in dried glasswares under nitrogen atmosphere. Chloroform was distilled from phosphorus pentoxide. Methanol was degassed under high vacuum until no gas bubbles were observed and handled under nitrogen prior to use. Sialic acid and *p*-nitrophenyl mannopyranoside were obtained from Rose Scientific Ltd. 3-Thiopheneacetic acid was obtained from Acros. *Triticum Vulgaris* (Wheat germ), *Concanavalin* A (Con A), biotin-labeled Con A (Sigma), and streptavidin (Pierce) were used as received. Influenza virus was obtained from Department of Health Service, Public Health Laboratory, San Diego. *E. coli* (HB101) was obtained from department of Plant and Microbial Biology, UC−Berkeley. All other reagents were used as received from Aldrich. NMR spectra were recorded with a Bruker AMX-300 (300 MHz), VBAM-400 (400 MHz), or AMX-500 (500 MHz) spectrometer. Optical rotations were recorded with Perkin-Elmer Polarimeter (model 241). UV−vis absorption spectroscopy was performed on Shimadzu Spectrophotometer (model UV-1601).

Succinimidyl (3-Thienyl)acetate (9). To a solution of 3-thiopheneacetic acid (1 g, 7.8 mmol) in $CHCl_3$ (25 mL) was slowly added thionyl chloride (0.6 mL, 1 equiv) at room temperature. The resulting solution was refluxed for 1 h. After cooled to 0 °C, the mixture of *N*-hydroxysuccinimide (0.9 g, 1 equiv) and DIPEA (2.8 mL, 1 equiv) in $CHCl_3$ (20 mL) was slowly added and the reaction was continued another 2 h. The solution was diluted with $CHCl_3$ (20 mL), washed with water, then, dried over Na_2SO_4. After solvent was removed by rotary evaporator, the residue was purified by silica gel column chromatography ($CHCl_3$/MeOH, 40/1) or recrystallized ($CHCl_3$/hexane, 1/1) to afford yellowish powder in 71% yield (1.32 g, 5.5 mmol). MS (EI) 240.0 (MH^+); ^{1}H NMR ($CDCl_3$) δ 7.30 (dd, 1H, ^4J = 3.0 Hz, ^4J = 4.90 Hz, thiophene), 7.26 (m, 1H, thiophene), 7.06 (dd, 1H, J = 1.3 Hz, ^4J = 4.9 Hz, thiophene), 3.94 (s, 2H, CH_2), 2.76 (s, 4H, $2CH_2$); ^{13}C NMR ($CDCl_3$) δ 169.5, 166.7, 131.1, 128.5, 126.6, 124.2, 32.7, 25.9.

4-[(3-Thienyl)acetamido]butanoic acid (12). To a solution of thiophene active ester (**9**) (1.1 g, 4.6 mmol) and 4-aminobutanoic acid (**10**) (0.48 g, 4.6 mmol) in $CHCl_3$ (50 mL) was added couple of drops of DIPEA, and the resulting solution was stirred overnight at room temperature. A white precipitate was filtered off, and the filtrate was condensed under reduced pressure. Without further workup, the residue was purified by silica gel column chromatography ($CHCl_3$/MeOH, 10/1) to give a white solid in 67% yield (0.7 g, 3.1 mmol). MS (EI) 228.0 (MH^+); mp 77.3−77.6 °C; ^{1}H NMR (CD_3OD) δ 7.27 (dd, 1H, J = 3.0 Hz, ^4J = 4.7 Hz, thiophene), 7.11 (m, 1H, thiophene), 6.95 (dd, 1H, J = 1.1 Hz, ^4J = 4.8 Hz, thiophene), 3.44 (s, 2H, thiophene-CH_2), 3.14 (t, 2H, J = 6.9 Hz, amide-CH_2), 2.22 (t, 2H, J = 7.4 Hz, CH_2-acid), 1.70 (m, 2H, CH_2); ^{13}C NMR (CD_3OD) δ 178.2, 174.0, 136.8, 129.4, 126.9, 123.6, 40.1, 38.6, 32.3, 25.9.

6-[(3-Thienyl)acetamido]caproic acid (13). Thiophene active ester (**9**) (1 g, 4.2 mmol) and 6-aminocaproic acid (**11**) (0.55 g, 4.2 mmol) were coupled as described above to give white solid in 90% yield (0.97 g, 3.8 mmol). MS (EI) 255.0 (M^+); mp 78.6−79.5 °C; ^{1}H NMR (CD_3OD) δ 7.33 (1H, dd, thiophene), 7.17 (1H, m, thiophene), 7.01 (1H, dd, thiophene), 3.49 (s, 2H, thiophene-CH_2), 3.16 (t,

2H, $J = 6.9$ Hz, amide-CH_2), 2.25 (t, 2H, $J = 7.4$ Hz, CH_2-acid) 1.63−1.42 (m, 4H, $2CH_2$), 1.36−1.28 (m, 2H, CH_2); ^{13}C NMR (CD_3OD) δ 177.6, 173.8, 136.9, 129.5, 126.9, 123.6, 40.5, 38.7, 35.0, 30.2, 27.6, 25.9.

2-[(3-Thienyl)acetamido]-1-aminoethane (16). To a solution of ethylenediamine (356 μL, 5.3 mmol) in $CHCl_3$ (200 mL) was added thiophene active ester (**9**) (1.0 g, 4.4 mmol) in $CHCl_3$ (30 mL) by dropwise fashion for 2 h period at room temperature. The mixture was stirred overnight at the same condition. A precipitate was filtered off and the filtrate was extracted with 1 M HCl-(aq) (30 mL × 5). The aqueous layer was combined and evaporated under reduced pressure. The residue was purified by silica gel column chromatography ($CHCl_3$/MeOH/2-propanol, 5/3/2) to give white hygroscopic solid in 83% yield (3.7 g, 20 mmol). MS (EI) 184 (M^+); mp 89.7−92.1 °C; ^{1}H NMR (CD_3OD) δ 7.34 (dd, 1H, thiophene), 7.20 (m, 1H, thiophene), 7.04 (dd, 1H, thiophene), 3.54 (s, 2H, CH_2), 3.25 (t, 2H, $J = 6.3$ Hz, CH_2), 2.73 (t, 2H, $J = 6.3$ Hz, CH_2); ^{13}C NMR (CD_3OD) δ 174.3, 136.8, 129.5, 126.9, 123.7, 42.9, 42.0, 38.6.

8-[(3-Thienyl)acetamido]-1-octylamine (17). 1,8-Octanediamine (0.78 g, 5.4 mnol) and **9** (1.2 g, 1 equiv) were coupled as described above to give yellowish resin in 96% yield (1.4 g, 5.2 mmol). MS (EI) 268 (M^+); ^{1}H NMR (CD_3OD) δ 7.31 (dd, 1H, thiophene), 7.13 (broad s, 1H, thiophene), 6.98 (dd, 1H, thiophene), 3.45 (s, 2H, thiophene-CH_2), 3.11 (m, 2H, amide-CH_2), 2.82 (m, 2H, CH_2-amine), 1.43 (m, 8H, $4CH_2$); ^{13}C NMR (CD_3OD) δ 173, 137.0, 129.4, 126.8, 123.6, 40.9, 40.6, 38.7, 30.4, 30.2, 30.1, 28.6, 27.8, 27.5.

8-[(3-Thienyl)acrylamido]-1-octylamine (20). To a solution of **18** (1.1 g, 4.4 mmol) and **19** (0.7 g, 1 equiv) in $CHCl_3$ (30 mL) was added HOBt (0.7 g, 1.2 equiv) at ice water temperature. The solution was stirred for 15 min, then DIPEA (pH 9) and EDC (1 g, 1.2 equiv) were added. The reaction was continued for 6 h at room temperature. The reaction mixture was diluted with $CHCl_3$ (30 mL), washed successively with saturated $NaHCO_3$(aq) and water, then dried over Na_2SO_4. The solution was briefly condensed and the residue was purified by silica gel column chromatography (EtOAc/hexane, 4/1) to give yellowish solid. Subsequently, the solid was treated with TFA (30% in CH_2Cl_2) for 3 h at room temperature to give light yellow solid in overall 87% yield (1.07 g, 3.8 mmol). mp 147.2−147.9 °C; ^{1}H NMR ($CDCl_3$) δ 7.58 (broad s, thiophene), 7.50 [d, 1H, $J_{trans} = 15.5$ Hz, =CH−C(O)NH], 7.42 (m, 1H, $J = 2.9$ Hz, $^4J = 5.0$ Hz, thiophene), 7.33 (broad d, 1H, thiophene), 6.42 (d, 1H, thiophene-CH=), 3.26 (t, 2H, $J = 7.2$ Hz, CH_2), 2.88 (t, 2H, $J = 7.7$ Hz, CH_2), 1.62 (m, 2H, CH_2), 1.53 (m, 2H, CH_2), 1.35 (m, 6H, 3 CH_2); ^{13}C NMR ($CDCl_3$) δ 183.3, 167.5, 137.9, 126.9, 126.6, 124.7, 133.9, 120.1, 39.3, 39.1, 29.0, 28.7, 27.1, 26.5, 25.9.

***p*-[(3-Thienyl)acetamido]phenyl Methyl (5-Acetamido-4,7,8,9-tetra-*O*-acetyl-3,5-dideoxy-D-glycero-α-D-galacto-2-nonulopyranosid)onate (21).** To a solution of **1** (0.4 g, 0.7 mmol) and thiopheneacetic acid (90 mg, 1 equiv) in CH_2Cl_2 (5 mL) was added DIPEA (pH 9) and TBTU (0.27 g, 1.2 equiv). The resulting solution was stirred for 5 h at an ambient temperature. The solution was diluted with CH_2Cl_2 (10 mL) and washed successively with saturated $NaHCO_3$, water, and dried over Na_2SO_4. Solvent was eliminated by rotary evaporator, and the residue was purified by silica gel column chromatography ($CHCl_3$/MeOH, 10/1) to give ivory foam solid in 90% yield (0.43 g, 0.62 mmol). MS (positive FAB) 707.3 (MH^+); mp 58.5−60.7 °C; ^{1}H NMR ($CDCl_3$) δ 8.33 (s, 1H, NH), 7.33 (d, 2H, $J_{om} = 8.6$ Hz, Ar-ortho), 7.23 (dd, 1H, $J = 2.8$ Hz, $^4J = 4.9$ Hz, thiophene), 7.12 (broad s, 1H, thiophene), 6.98 (dd, 1H, $J = 1.2$ Hz, $^4J = 4.9$ Hz, thiophene), 6.91 (d, 2H, Ar-meta), 6.41 (d, 1H, $J_{N5} = 9.8$ Hz, NH), 5.31 (m, 2H, H-7, H-8), 4.85 (ddd, 1H, $J_{45} = 10.2$ Hz, $J_{43e} = 4.7$ Hz, $J_{43a} = 11.7$ Hz, H-4), 4.31 (dd, 1H, $J_{56} = 10.7$ Hz, H-6), 4.21 (dd, 1H, $J_{9a9b} = 10.3$ Hz, H-9a), 4.06 (m, 2H, H-5, H-9b), 3.63 [s, 3H, C(O)O−CH_3], 3.51 (s, 2H, CH_2-thiophene), 2.64 (dd, $J_{3e4} = 4.4$ Hz, $J_{3e3a} = 12.9$ Hz, H-3e), 2.10 (dd, 1H, $J_{3a4} = 11.2$ Hz, H-3a), 2.02, 2.01, 1.93, 1.92, 1.79 (5 s, 15H, 5 AcO); ^{13}C NMR ($CDCl_3$) δ 171.0, 170.9, 170.4, 170.3, 169.3, 168.2, 150.2, 135.0, 134.7, 128.8, 126.7, 123.5, 121.2, 120.9, 100.5, 73.5, 69.4, 69.3, 67.6, 62.3, 53.1, 49.2, 39.1, 38.8, 23.3, 21.2, 21.0.

Compound 22. 22 was prepared from **1** and **12** using the peptide coupling protocol. Yield 75%; FAB (+)−MS 791.3 (MH^+); ^{1}H NMR ($CDCl_3$) 6.28 (t, 1H, $J_{NCH2} = 5.6$ Hz, NH), 5.85 (d, 1H, $J_{N5} = 9.9$ Hz, NH), 3.28 [m, 2H, CH_2−HNC(O)], 2.29 [t, 2H, $J = 6.0$ Hz, HNC(O)-CH_2], 1.78 (m, 2H, CH_2); ^{13}C NMR ($CDCl_3$) 39.3, 38.3, 34.9, 28.9. Compound 25. 25 was prepared from **1** and **19** using the peptide coupling protocol. Yield 82%; MS (positive FAB) 719.2 (MH^+); mp 79.3−81.1 °C; ^{1}H NMR ($CDCl_3$) δ 7.62 [d, 1H, $J_{trans} = 15.5$ Hz, HNC(O)CH=], 6.51 (m, 2H, =CH-thiophene, NH), 5.34 (m, 2H, H-7, H-8), 4.88 (ddd, 1H, $J_{45} = 10.2$ Hz, $J_{3e4} = 4.7$ Hz, $J_{3a4} = 11.7$ Hz, H-4), 4.34 (dd, 1H, $J_{6ab} = 10.5$ Hz, H-6), 4.24 (dd, 1H, $J_{9ab} = 12.4$ Hz, H-9a), 4.06 (m, 2H, H-9b, H-5), 3.51 (s, 3H, CO_2-CH_3), 2.50 (hidden, 1H, H-3e), 2.13 (hidden, 1H, H-3a), (5 s, 15H, AcO); ^{13}C NMR ($CDCl_3$) δ 171.1, 170.9, 170.4, 170.3, 168.2, 166.0, 151.2, 138.2, 135.5, 127.7, 127.1, 125.5, 121.0, 100.6, 73.5, 69.4, 67.7, 62.3, 53.1, 49.2, 38.3, 23.2, 21.2, 21.1. Other chemical shifts are same as **24**.

***p*-[(3-Thienyl)acetamido]phenyl-α-D-2,3,4,6-tetra-*O*-acetyl mannopyranoside (26).** To a solution of 4-aminophenyl-α-D-mannopyranoside (**4**) (2.0 g, 4.6 mmol) and thiopheneacetic acid (**6**) (0.6 g, 4.6 mmol) in CH_2Cl_2 (50 mL) were added DIPEA (0.8 mL) and TBTU (1.8 g, 5.5 mmol). The resulting solution was stirred for 4 h at room temperature. The solution was diluted with CH_2-

Cl_2 (20 mL) and washed successively with saturated $NaHCO_3$(aq) and water and then dried over Na_2SO_4. The solution was condensed under reduced pressure, and the residue was purified by silica gel column chromatography (EtOAc/hexane, 2/1) to give light yellowish amorphous solid in 83% yield (2.1 g, 3.8 mmol). MS (positive FAB) 564 (MH^+), 586.3 (MNa^+); mp 62.5−64.0 °C; ^{1}H NMR ($CDCl_3$) δ 7.35 (m, 3H, Ar-ortho, thiophene), 7.19 (m, 1H, thiophene), 7.03 (d, 1H, J = 4.9 Hz, thiophene), 6.98 (d, 2H, J_{om} = 9.0 Hz, Ar-meta), 5.50 (dd, 1H, J_{23} = 3.4 Hz, J_{34} = 10.0 Hz, H-3), 5.41 (d, 1H, J_{12} = 1.9 Hz, H-1), 5.39 (dd, 1H, J_{23} = 3.3 Hz, H-2), 5.34 (dd, 1H, J_{34} = 10.0 Hz, $J_{45} \leq$ 1 Hz, H-4), 4.24 (dd, 1H, J_{56a} = 5.4 Hz, J_{6ab} = 12.4 Hz, H-6a), 4.04 (m, 2H, H-5, H-6b), 3.71 (s, 2H, CH_2), 2.16, 2.02, 2.01, 2.00 (4 s, 4 AcO); ^{13}C NMR ($CDCl_3$) δ 176.0, 170.6, 170.0, 169.7, 168.7, 156.0, 134.4, 133.0, 128.4, 127.0, 123.7, 121.5, 117.0, 96.1, 69.3, 69.1, 68.9, 65.9, 62.1, 38.9, 20.9, 20.8, 20.7.

Compound 27. 27 was prepared from **4** and **12** using the peptide coupling protocol. Yield (quantitative); MS (positive FAB) 649 (NH^+); ^{1}H NMR ($CDCl_3$) δ 9.04 (broad s, 1H, NH), 7.50 (d, 2H, J_{om} = 9.1 Hz, Ar-ortho), 7.28 (dd, 1H, J = 3.0 Hz, ^4J = 4.9 Hz, thiophene), 7.09 (broad s, 1H, thiophene), 6.96 (m, 3H, Ar-meta, thiophene), 6.25 (broad t, 1H, NH), 5.51 (dd, 1H, J_{23} = 8.4 Hz, J_{34} = 10.0 Hz, H-3), 5.43 (d, 1H, J_{12} = 1.9 Hz, H-1), 5.40 (dd, 1H, J_{23} = 3.5 Hz, H-2), 5.32 (dd, 1H, J_{34} = 10.0 Hz, $J_{45} \leq$ 1 Hz, H-4), 4.24 (dd, 1H, J_{56a} = 5.0 Hz, J_{6ab} = 12.1 Hz, H-6a), 4.08−4.00 (m, 2H, H-5, H-6b), 3.56 (s, 2H, thiophene-CH_2), 3.28 (m, 2H, CH_2-amide), 2.28 (m, 2H, carbonyl-CH_2), 2.16, 2.01, 2.00, 1.99 (4 AcO), 1.79 (m, 2H, CH_2); ^{13}C NMR ($CDCl_3$) δ 171.9, 171.1, 170.6, 170.0, 169.9, 169.7, 156.0, 134.6, 133.9, 128.4, 126.7, 123.5, 121.2, 116.9, 96.1, 69.4, 69.1, 68.9, 65.9, 62.1, 38.9, 38.6, 38.1 34.5, 26.2, 20.9, 20.7.

Compound 28. 28 was prepared from **4** and **13** using the peptide coupling protocol. Yield quantitative; MS (positive FAB) 677 (MH^+); ^{1}H NMR ($CDCl_3$) δ 7.95 (broad s, 1H, NH), 5.78 (broad t, 1H, NH), 5.51 (dd, 1H, J_{23} = 3.4 Hz, J_{34} = 10.0 Hz, H-3), 5.40 (m, 2H, H-1, H-2), 5.33 (dd, 1H, J_{34} = 10.0 Hz, $J_{45} \leq$ 1, H-4), 4.24 (dd, 1H, J_{56a} = 4.8 Hz, J_{6ab} = 11.9 Hz, H-6a), 4.05 (m, 2H, H-5, H-6b), 3.54 (s, 2H, thiophene-CH_2), 3.18 (m, 2H, CH_2-amide), 2.26 [m, 2H, C(O)-CH_2], 2.16, 2.02, 2.01, 2.00 (4 AcO), 1.66 (m, 2H, CH_2), 1.45 (m, 2H, CH_2), 1.28 (m, 2H, CH_2); ^{13}C NMR ($CDCl_3$) δ 171.7, 171.3, 170.8, 170.6, 170.0, 169.7, 156.0, 134.9, 133.6, 128.4, 126.7, 123.4, 121.3, 116.9, 96.1, 69.4, 69.1, 68.9, 65.9, 62.1, 38.9, 38.6, 38.1, 26.2, 20.9, 20.7. Other chemical shifts are same as **26**.

Compound 29. 29 was prepared from **4** and **19** using the peptide coupling protocol. Yield 70%; MS (positive FAB) 576 (MH^+); mp 63.1−63.8 °C; ^{1}H NMR ($CDCl_3$) δ 7.89 (broad s, 1H, NH), 7.68 [d, 1H, J_{trans} = 15.4 Hz, C(O)-NH−CH=], 7.55 (d, 2H, J_{om} = 8.3 Hz, Ar-ortho), 7.40 (dd, 1H, J = 3.0 Hz, ^4J = 4.9 Hz, thiophene), 7.28 (broad s, 1H, thiophene), 7.20 (broad d, 1H, thoiophene), 7.00 (d, 2H, Ar-meta), 6.40 (1H, d, =CH-thiophene), 5.53 (dd, 1H, J_{23} = 3.5 Hz, J_{34} = 10.0 Hz, H-3), 5.41 (m, 2H, H-1, H-2), 5.34 (dd, 1H, J_{34} = 9.9 Hz, $J_{45} \leq$ 1, H-4), 4.25 (dd, 1H, J_{56a} = 5.1 Hz, J_{6ab} = 12.0 Hz, H-6a), 4.09−4.02 (m, 2H, H-5, H-6b), 2.17, 2.03, 2.02, 2.01 (4 AcO); ^{13}C NMR ($CDCl_3$) δ 175.1, 173.0, 170.6, 170.0, 169.8, 156.0, 137.7, 133.6, 135.7, 127.6, 126.9, 125.0, 121.4, 120.5, 117.1, 96.1, 69.4, 69.1, 68.9, 66.0, 62.1, 26.2, 20.9, 20.7. Other chemical shifts are same as **26**.

Compound 32. To a solution of 3-thiophenehydrazide (**30**) (0.2 g, 1.42 mmol) and 2-iminothiolane hydrochloride (**31**) (0.2 g, 1 equiv) in degassed MeOH (5 mL) was saturated with N_2 gas and added couple of drops of DIPEA. The resulting solution was stirred for 3 h at room temperature. *p*-Acrylamidophenyl methyl (5-acetamido-4,7,8,9-tetra-*O*-acetyl-3,5-dideoxy-D-glycero-α-D-galacto-2-nonulopyranoside) onate (**2**) (0.45 g, 0.7 mmol) in degassed $CHCl_3$ (5 mL) was injected slowly and continued the reaction overnight at the same condition. Solvent was briefly evaporated and the residue was dissolved in $CHCl_3$ (20 mL), washed with saturated $NaHCO_3$ and water and then dried over Na_2SO_4. The solution was condensed and the residue was purified by silica gel column chromatography ($CHCl_3$/MeOH, 10/1) to give a dark violet solid in 51% yield (0.33 g, 0.36 mmol). MS (positive FAB) 880.2 $(M\text{-}Cl)^+$; mp 103.5−104.7 °C; ^{1}H NMR ($CDCl_3$) δ 2.82 [broad t, 2H, HNC(O)-CH_2], 2.67 (broad t, 2H, CH_2−S), 2.53 [m, 4H, S−CH_2, CH_2−C(NH)], 1.85 (m, 2H, CH_2); ^{13}C NMR ($CDCl_3$) δ 49.2, 36.5, 35.3, 30.5, 27.6. Other chemical shifts are same as **21**.

Compound 33. 33 was prepared from **2** and **16** with 2-iminothiolane hydrochloride (**31**) using successive the ring opening and the peptide coupling protocol. Yield 44%; MS (positive FAB) 922.3 $(M - Cl)^+$; mp 115.2−116.7 °C; ^{1}H NMR ($CDCl_3$) δ 3.57 (s, 2H, CH_2-thiophene), 3.35 [broad s, 4H, HN−CH_2CH_2−HNC(O)], 2.74 [NHC(O)-CH_2], 2.67 (broad s, 2H, CH_2−S), 2.52 (broad s, 2H, S−CH_2), 2.48 [broad s, 2H, CH_2−C(NH)], 1.84 (m, 2H, CH_2); ^{13}C NMR ($CDCl_3$) δ 42.7, 37.4, 37.1, 32.0, 31.4, 27.8, 27.1, 26.5. Other chemical shifts are same as **21**.

Compound 34. 34 was prepared from **2** and **17** with iminothiolane hydrochloride (**31**) using successive the ring opening and the peptide coupling protocol. Yield 78%; MS (positive FAB) 1006.5 $(M - Cl)^+$; mp 69.3−71.2 °C; ^{1}H NMR ($CDCl_3$) δ 3.39−3.35 [m, 7H, CH_2-thiophene, CH_2−HNC(O), C(O)O−CH_3], 3.09 [m, 2H, C(NH)NH−CH_2], 2.86 [m, 6H, HNC(O)-$CH_2CH_2SCH_2$], 2.49 [m, 3H, H-3e, CH_2−C(NH)NH], 1.99 (m, 1H, H-3a), 1.86 (m, 2H, CH_2), 1.50 (m, 2H, CH_2), 1.34 (m, 2H, CH_2), 1.10 (m, 8H, $4CH_2$); ^{13}C NMR ($CDCl_3$) δ 50.6, 42.5, 39.6, 37.9, 37.3, 30.7, 29.2, 28.8, 27.7, 27.5, 26.4. Other chemical shifts are same as **21**.

Compound 35. 35 was prepared from **5** and 3-thiophenehydrazide (**30**) with iminothiolane hydrochloride (**31**) using successive the ring opening and the peptide coupling protocol. Yield 41%; MS (positive FAB) 737.0 $(M - Cl)^+$; mp 69.7−70.4 °C; ^{1}H NMR ($CDCl_3$) δ 2.72 [broad t, 2H, HNC(O)-CH_2], 2.57 (broad t, 2H, CH_2−S), 2.43 [m, 4H, S−CH_2, CH_2−C(NH)], 1.80 (m, 2H, CH_2); ^{13}C NMR ($CDCl_3$) δ 44.3, 37.1, 30.5, 27.4, 26.5. Other chemical shifts are same as **36**.

Compound 36. 36 was prepared from **5** and **16** with iminothiolane hydrochloride (**31**) using successive the ring opening and the peptide coupling protocol. Yield 53%; MS (positive FAB) 779.4 $(M - Cl)^+$; mp 86.3−87.8 °C; ^{1}H NMR ($CDCl_3$) δ 9.50 (s, 1H, NH), 8.99 (s, 1H, NH), 8.75 (s, 1H, NH), 7.95 (s, 1H, NH), 7.53 (d, 2H, J = 8.9 Hz, Ar-ortho), 7.20 (broad d, 1H, thiophene), 7.07 (broad d, 1H, thiophene), 6.95 6.92 (m, 3H, thiophene, Ar-meta), 5.48 (dd, 1H, J_{23} = 3.3 Hz, J_{34} = 10.1 Hz, H-3), 5.42 (d, 1H, J_{12} = 1.8 Hz, H-1), 5.39 (dd, 1H, H-2), 5.33 (dd, J_{34} = 10.1 Hz, $J_{45} \leq$ 1, H-4), 4.22 (dd, 1H, J_{56a} = 4.7 Hz, J_{6ab} = 12.3 Hz, H-6a), 4.02 (m, 2H, H-5, H-6b), 3.51 (s, 2H, CH_2-thiophene), 3.38 [broad s, 4H, HN−CH_2CH_2−HNC-(O)], 2.76 [NHC(O)-CH_2], 2.64 (broad s, 2H, CH_2−S), 2.53 (broad s, 2H, S−CH_2), 2.44 [broad s, 2H, CH_2−C(NH)], 2.16, 2.02, 2.00, 1.99 (4 s, 12H, 4 AcO), 1.86 (m, 2H, CH_2); ^{13}C NMR ($CDCl_3$) δ 175.6, 171.8, 170.7, 170.5, 170.1, 169.7, 168.0, 152.0, 134.5, 133.7, 128.5, 126.2, 123.3, 121.6, 116.9, 96.1, 69.3, 69.1, 68.9, 65.9, 62.1, 42.8, 37.5, 37.3, 32.1, 31.4, 27.6, 27.1, 26.2, 20.9, 20.7.

Compound 37. 37 was prepared from **5** and **17** with iminothiolane hydrochloride (**31**) using successive the ring opening and the peptide coupling protocol. Yield 43%; MS (positive FAB) 863.5 $(M - Cl)^+$; mp 69.3−71.2 °C; ^{1}H NMR ($CDCl_3$) δ 3.19 [m, 2H, CH_2−HNC(O)], 3.07 [m, 2H, C(NH)NH−CH_2], 2.12, 1.98, 1.96 (3 s, 12H, AcO), 1.84 (m, 2H, CH_2), 1.50 (m, 2H, CH_2), 1.34 (m, 2H, CH_2), 1.15 (m, 8H, 4 CH_2); ^{13}C NMR ($CDCl_3$) δ 50.6, 42.9, 39.6, 37.8, 37.3, 30.7, 29.2, 28.7, 27.6, 27.5, 26.4. Other chemical shifts are same as **36**.

Compound 38. 38 was prepared from **5** and **20** with iminothiolane hydrochloride (**31**) using successive the ring opening and the peptide coupling protocol. Yield 35%; MS (positive FAB) 875.5 $(M - Cl)^+$; mp 88.7−90.0 °C; ^{1}H NMR ($CDCl_3$) δ 7.45 [d, 1H, J_{trans} = 15.4 Hz, HNC-(O)-CH=], 6.48 (d, 1H, =CH-thiophene), 3.25 [m, 4H, CH_2−HNC(O)], 3.07 [m, 2H, C(NH)NH−CH_2], 2.15, 2.01, 2.00, 1.99 (4 s, 12H, AcO), 1.85 (m, 2H, CH_2), 1.54 (m, 2H, CH_2), 1.42 (m, 2H, CH_2), 1.23−1.14 (m, 8H, 4 CH_2); ^{13}C NMR ($CDCl_3$) δ 137.8, 121.6, 50.6 42.9, 39.8, 37.3, 37.3, 30.7, 29.2, 28.8, 27.6, 27.5, 26.4. Other chemical shifts are same as **36**.

Polymerization. *Oxidative Polymerization by $FeCl_3$.* To a suspension of $FeCl_3$ (4 equiv) in dry $CHCl_3$ was saturated with N_2 and slowly added a solution of carbohydrate-thiophene monomer and methyl (3-thienyl)-acetate (**7**) (mole ratio, 1/5) in dry $CHCl_3$ over 2−3 h period. The resulting emulsion was stirred for 3 days at room temperature under N_2. The solution was then poured into MeOH (20 mL), and the brownish solid was filtered, then briefly washed with MeOH. Polymer obtained was washed thoroughly by Soxhlet extraction using MeOH. The residue was dried under reduced pressure to give red-brownish solid. [for sialic acid glycopolymers; 31−50% (w/w), for mannose glycopolymers; 28−46% (w/w)].

Poly[methyl (3-thienyl)acetate] (39). To a solution of $FeCl_3$ (22.4 g, 0.1 mol) in dry $CHCl_3$ (50 mL) was saturated with N_2 and slowly added **7** (4.9 g, 34.4 mmol) in dry $CHCl_3$ (20 mL) over 5 h period. The resulting emulsion was stirred for 3 days at room temperature under N_2. MeOH (50 mL) was directly added, and the solution was stirred another couple of hours. A dark brown solid was filtered and briefly washed with MeOH. Polymer was then thoroughly washed by Soxhlet extraction using MeOH. The residue was dried under reduced pressure to give dark brownish solid (3.3 g) in 67% (w/w) yield. ^{1}H NMR ($CDCl_3$) δ 7.20 (broad t, 1H, thiophene), 3.75−3.61 (m, 5H, CH_2, CH_3).

Poly(thiopheneacetic acid) (40). To a solution of **39** (0.3 g) in MeOH (20 mL) was added NaOH (85 mg, 1.2 equiv), and the mixture was refluxed overnight. The dark red homogeneous solution was cooled to ice water temperature and acidified by concentrated HCl. The precipitate was filtered, thoroughly washed with water, and then dried under high vacuum to give light brown solid (0.27 g) in 90% (w/w) yield.

Deprotection of Glycopolymers. The glycopolythiophene-*co*-methyl ester (0.2 g) was suspended in $CHCl_3$ (10 mL), and $CH_3O^-Na^+$/MeOH (25 wt %) was added to adjust pH ∼9. The solution was stirred for 7 h at room temperature. The solution was briefly dried under reduced pressure, then treated with 0.3 M aqueous NaOH solution (7 mL) for another 5−10 h at room temperature. The insoluble portion was filtered off through Celite pad and the filtrate was dialyzed (12 000 MW cutoff) against distilled water (2 L) for 3 days. This solution was employed for the assays without further purification.

Bioassays of Glyco-PTs with Proteins. Biochromic capability of glyco-PTs were evaluated with various proteins such as lectins, virus, and bacteria depending on carbohydrate ligands. It was found that 15−20 μL of protein stock solution was optimal, producing a detectable color change within 4−5 h. To maximize color change, incubation time was given up to 12 h. However, longer incubation times resulted in precipitation of the glyco-PT-protein complexes.

Precipitation Assays with Lectins (ConA and WGA). A glycopolymer stock solution was diluted 1:4−5 in 0.01 M phosphate buffer (pH 7.3), and 300 μL of the solution was transferred to a 500 μL eppendorf tube. A total of 20 μL of stock solution prepared from lectin (1 mg/mL, 0.01 M PBS) was mixed and incubated at room temperature for 12 h. Visible absorption spectra were recorded and compared with the same concentration of the mother solution as a negative control. Each test was performed in duplicate.

Precipitation Assays with *Concanavalin* A-Biotin-Streptavidin. A glycopolymer stock solution was diluted 1:4−5 in 0.01 M phosphate buffer (pH 7.3), and 300 μL of the solution was transferred to two of the 500 μL eppendorf tubes. A total of 20 μL of stock solution prepared from biotin-labeled Con A (1 mg/mL, 0.01 M PBS) was mixed and preincubated at room temperature for 1 h. Subsequently, 20 μL of Streptavidin (1 mg/mL, 0.01 M PBS) was added, and the resulting solution was incubated at room temperature for 10−12 h. Visible absorption spectra were recorded and compared with the same concentration of the mother solution as a negative control. A slight precipitate was detected visually within 24 h after addition of streptavidin. Each test was performed in duplicate.

Colorimetric Assay with *Esherichia coli*, strain HB101. *E. coli* HB101 (pSH2) were grown for 24 h in static LB broth, and the solution was gently centrifuged and collected a clear supernatant before use. A glycopolymer stock solution was diluted 1:4−5 in 0.01 M phosphate buffer (pH 7.3), and 300 μL of the solution was transferred to a 500 μL eppendorf tube. After centrifugation of the stock solution, 20 μL of supernatant *E. coli* HB101 was mixed and incubated at room temperature for 12 h. The visible absorption spectra were recorded and compared with the same concentration of the mother solution as a negative control. The darker red color of *E. coli*-treated mannose-PTs was verified visually with the brownish colored mother solution. Each test was performed in duplicate.

Colorimetric Assays with Influenza Virus A/B. A glycopolymer stock solution was diluted 1:4−5 in 0.01 M phosphate buffer (pH 7.3), and 300 μL of the solution was transferred to a 500 μL eppendorf tube. A total of 20 μL of the stock solution of Influenza Virus A or B was mixed and incubated at 4 °C for 2−6 h. The visible absorption spectrum was recorded and compared with the same concentration of the mother solution as a negative control. The darker red color of Influenza-virus-treated sialic acid-PTs was verified visually with the brownish colored mother solution. Each test was performed in duplicate.

RESULTS AND DISCUSSION

General Procedures for Synthesis of Carbohydrate Monomers. Suitably functionalized sialic acid and mannose moieties at the O-linked aromatic aglycon (**1**, **2**, **3**, **4**, and **5**) were prepared according to literature procedures (*26*, *36*) (Figure 2). Aromatic aglycon was used

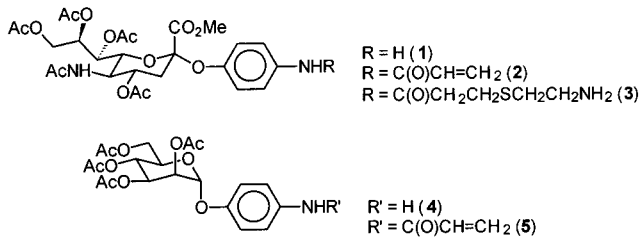

Figure 2. Structure of carbohydrate ligands bearing aromatic aglycon.

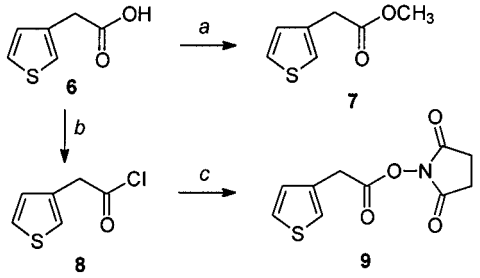
Scheme 1. Synthesis of Thiophene Esters



[a] $SOCl_2$/MeOH, 0 °C → r.t., 3 h, 88%. [b] $SOCl_2$/dioxane, r.t. [c] NHS, DIPEA/$CHCl_3$, 0 °C, 75%.

as the mannose ligand since a hydrophobic pocket mainly composed of tyrosine (Tyr) residues in the mannose specific protein stabilizes the carbohydrate by $\pi-\pi$ interactions with the hydrophobic substituent of the aglycon (*60*). For sialic acid, the aromatic aglycon enhances the binding of sialoside ligand to hemagglutinin and prevents the neuraminidase of the influenza virus, from cleaving the O-linked glycosidic bond (*26*, *27*, *29*). On the basis of the fixed carbohydrate structures, two series of thiophene-carbohydrate monomers were synthesized, derived from the thiophene esters shown in Scheme 1.

In the first set of experiments, amine and carboxylic acid terminated thiophene intermediates were prepared (Scheme 2) and subsequently coupled with carbohydrate moieties. In the second set, the distance between thiophene and carbohydrate was extended by iminothiolane hydrochloride (**30**) and a thiol was generated after extension. These thiols were prepared in situ and coupled with **2** or **5** by Michael-type addition to give another set of thiophene−carbohydrate monomers. The two types of carbohydrate moieties are summarized in Tables 1 and 2. Commercially available 3-thiopheneacetic acid (**6**, Acros, Organics, Fisher Scientific) was converted into the corresponding methyl ester (**7**) in 88% yield by thionyl chloride in methanol. Thiopheneacetyl chloride (**8**) was prepared in situ, by thionyl chloride in dioxane. Direct addition of *N*-hydroxysuccinimide (NHS) in the presence of diisopropylethylamine (DIPEA) at 0 °C afforded thiophene active ester (**9**) in 75% overall yield. Product **9** was stable under the dry condition and could be prepared in bulk quantities.

Carboxylic acid functionalized thiophenes, **12** and **13** with the hydrocarbon spacers, were prepared by nucleophilic addition of bifunctionalized **10** and **11** to **9** in 95% yields (Scheme 2). In a similar manner, **9** was reacted with diamines **14** and **15**, under highly dilute conditions. Dimerized byproduct was removed by silica gel chromatography to give the amines **16** and **17** in 83 and 96% yields, respectively. Product **17** was also obtained from **6** and mono-Boc protected **18** by peptide coupling and subsequent deprotection by 30% trifluoroacetic acid (TFA) in CH_2Cl_2. To extend the π-conjugation in the polymer

to the spacer, 3-(3-thienyl)acrylic acid (**19**) was used, followed by treatment with TFA to afford the thiophene free amine (**20**), in 93% yield. No polymerization of the acrylic functional group was detected during synthesis and the results were confirmed by NMR. Carboxylic acid functionalized thiophenes, **6**, **12**, **13**, and **19**, were coupled with carbohydrate moieties, **1**, **3** or **4** by *O*-benzotriazol-

Scheme 3. Oxidative Polymerization with $FeCl_3$

1-yl-*N*,*N*,*N*′,*N*′-tetramethyluronium tetrafluoroborate (TBTU) strategy to afford the series of thiophene-spacer (side chain)-carbohydrates, **21**, **22**, **23**, **24**, **25** for sialic acid and **26**, **27**, **28**, and **29** for mannose. The yields were 60−90% for the sialic acid residue and 70% quantitative for the mannose residue, respectively (Table 1).

For a mimic of the lipid−carbohydrate monomer used in previous studies of biochromism (*15*, *37*, *41*, *42*), more elongated spacers were designed and synthesized using the iminothiolane hydrochloride (**31**) strategy (Table 2). Ring opening nucleophilic addition of **31** was initiated by the free amine bearing thiopene derivatives, **16**, **17**, **20**, and **30** in the presence of diisopropylethylamine (DIPEA) and degassed methanol to generate a series of mercapto-thiophene intermediates. Subsequent addition of **2** or **5** derived Michael-type addition of a thiol to the acrylamido functional group to afford the second set of thiophene-spacer-carbohydrate species, **32**, **33**, **34** for sialic acid and **35**, **36**, **37**, and **38** for mannose in 51−78% and 35−53% yields, respectively. All structures were confirmed by NMR (^1H, ^{13}C) and mass spectra.

General Procedures for Polymer Formation. The formation of carbohydrate-modified polythiophene was carried out primarily by (co-) polymerization of the thiophene−carbohydrate monomers, and the thiophene methyl ester (**7**), using $FeCl_3$ as a promoter (Scheme 3).

The homopolymer, poly(methyl 3-thiopheneacetate), **39** (Scheme, 3), was prepared from chemical oxidative polymerization of **7** in $CHCl_3$ (*13*, *49*). **39** was purified by Soxhlet extraction with methanol for 3 days to eliminate the low molecular weight portion and any residual promoter to afford 67% (w/w) yield. Subsequently, **39** was further refluxed in the presence of NaOH in methanol for 5 h and acidified with concentrated HCl at 0 °C to give **40** in 90% (w/w) yield.

A series of thiophene−carbohydrate monomers was copolymerized with **7** by $FeCl_3$ in dry $CHCl_3$ followed by Soxhlet extraction with methanol to afford the corresponding glycopolythiophene derivatives in 50−76% (w/w) yields. The ratio of **7** to thiophene−carbohydrate applied was 5/1. The structural regularity of some glycopolythiophenes having reasonable solubility in organic solvent were determined by ^1H NMR spectral data. Mostly, they possessed a randomly distributed chain structure and presented a broad distribution of signals over the whole range of the spectra (*44*−*46*).

Conversion of these glycopolythiophenes into the corresponding deprotected analogues was accomplished as follows. Fully protected glycopolythiophenes were treated with MeO^-Na^+ in MeOH/$CHCl_3$ mixture for 7−9 h, and subsequently, an excess of aqueous NaOH was reacted for 5−10 h at room temperature depending on the polymers. The heterogeneous solution turned into a homogeneous red-brown solution when deesterification was complete. The solution was dialyzed (molecular weight 12 000 cutoff) against water to eliminate excess NaOH and low molecular weight portion and lyophilized to afford brownish solid, **41**, **42**, **43**, **44**, **45**, **46**, **47**, and **48** for sialic acid-PTs in 31−50% (w/w) yields and **49**, **50**, **51**, **52**, **53**, **54**, **55**, and **56** for mannose-PTs in 28−48% (w/w) yields, respectively (Table 3). However, these dried polymers were poorly soluble in aqueous solution again and NaOH was required to induce solubility.

Biochromic Effects. As recently reported (*13*), polythiophene derivatives that display biotin were synthesized and shown to undergo colorimetric transitions in response to binding of streptavidin. The degree of conjugation in the polythiophene backbone is influenced by external stimuli (*5*−*14*, *47*−*51*) and usually involves planar−nonplanar transitions. Another important driving force for the conformational change of the polymer backbone is electrostatic interactions, leading to aggregation, gelation, or even crystallization (*12*, *52*, *53*). As reported by McCullough et al. (*12*), regioregular polythiophenes having carboxylic acid side chains on an ethylene spacer showed significant H-bonding that contributes to extended π-orbital overlap along the main

[a] Not available. [b] Weight percent yields of polymers.

chain. In that particular work, the absorption maximum of the polymer was 560 nm.

In the polymers described herein, the nonregioregular polythiophene homopolymer derivative (**40**), containing a methylene spacer between the backbone and the acid group, showed a maximum absorption at 440 nm. This comparison suggests that regioregularity and the nature of the functionalized side chain are important factors in determining the conformation of the polymer backbone (*10*, *11*, *17*, *18*, *47*−*49*).

Concanavalin A (Con A) is a lectin that binds terminal α-D-mannosyl residues (*54*, *60*) and has been previously used as a model for the study of mannose-lectin interactions. Similarly, *Triticum Vulgaris* (wheat germ agglutinin) is a sialic-acid (NeuAc)-binding lectin (*55*). On the basis of these binding specificities, the series of glycopolythiophenes were examined for their ability to bind and detect these lectins. All of the glycopolythiophene derivatives produced a main absorption peak around 400−430 nm indicating that the degree of conjugation of the polymer backbone is reduced relative to the parent homopolymer (**40**). The blue-shift of the glycopolymer absorption suggests a more nonplanar conformation of the backbone. These relative absorption shifts compared to **40** strongly depend on the nature of the substituent in the polymer side chain. This agrees well with previous results that demonstrate the effect of side-chain bulk on polymer backbone planarity (*11*, *17*, *18*).

To demonstrate the biochromic capability of these glycopolythiophenes, several bioassays were performed. We hypothesized, based on previous studies (*7*, *10*−*15*, *17*, *53*), that the degree of planarity in the polymer backbone could depend on electrostatic, H-bonding, steric, or van der Waals interactions within or between polymer. These interactions are expected to be disrupted or altered upon receptor binding.

The steric effects produced by bulky carbohydrates in the glyco-PTs should also be considered (*18*, *56*, *57*). These possible interactions can amplify or reduce the sensing capability of the polymers by planar-nonplanar transitions. Therefore, we tested sialic acid-PTs (series I) and mannose-PTs (series II) to determine the ability of these materials to interact with WGA and Con A,

respectively (Tables 4 and 5). In the case of series I (Table 4), compounds **42**, **43**, and **48** exhibit a distinct blue-shift of the maximum absorption wavelength upon addition of WGA. The other polymers in this series remain unchanged. This indicates that the carbohydrate−protein interaction occurs, but there is a relatively small change in the conformation of the polymers upon protein addition. Increasing the lectin concentration does not affect the absorption shift. Eventually, the solution precipitates after a few hours. We expected polymer **47** would be more sensitive than the others due to the extension of the polymer π-conjugation system to the side chain. However, it showed no absorption shift upon addition of WGA.

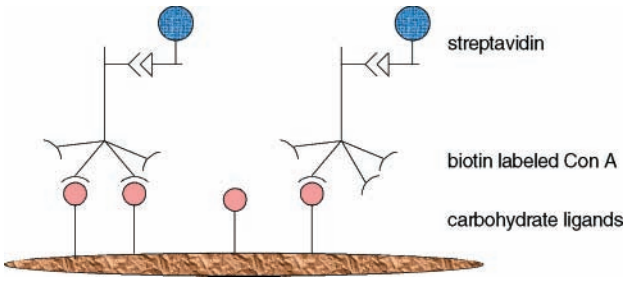

Figure 3. Schematic representation of the double sandwiched biochromic sensory device based on mannose-PT.

Similarly, the glyco-PTs of series II were also examined with Con A (Table 5). All polymers formed a red-brown precipitate regardless of the concentration of the polymer solution. Indeed, these precipitates were the complexes of mannose-polythiophene and Con A (*58*), and precipitation seems to have occurred before the absorption change. This may be due to the higher density of the binding site in Con A (4 subunits/molecule) and also higher its molecular weight (102 000 kDa) than that of WGA (2 subunits/molecule, 36 000 kDa). The Con A effectively cross-links the mannose-PTs before the observation of an absorption shift.

To minimize the problem of precipitation, we used a biotinylated Con A, complexed to streptavidin. This complex, when bound to the mannose-PT helps stabilize the polymer−protein complex, presumably by inhibiting cross-linking.

Using this motif, a small but significant biochromic response was observed upon the addition of streptavidin (Figure 3). A red-shift of up to 8 nm was observed upon the addition of the protein complex (Table 5). The result suggests that the binding of biotin-labeled Con A/streptavidin increases the π-conjugated system of polymer backbone. This result agrees qualitatively with a similar report by Leclerc et al. (*13*) where biotin-containing polythiophene was incubated directly with avidin to generate a biochromic response. However, in that report, the protein binding produced a blue-shift of the polymer backbone absorption.

We were interested in determining whether the size and valency of the binding receptor has any influence on the optical shifts observed with these glyco-PTs. To that end, we investigated the interactions of influenza virus A and B and *E. coli* (HB101 strain) with the sialic acid-PTs and mannose-PTs, respectively. The interaction of these agents with these sugars are well-documented in the literature (*22*, *26*, *27*, *29*, *31*, *33*−*35*). Interestingly, all assays indicated an absorption maximum wavelength shift that was substantially higher than that of the lectins. This wavelength shift was to the red, and in the range of 0 to +27 nm for Influenza virus A, 0 to +32 nm for Influenza virus B, and +8 to +32 nm for *E. coli*. For the sialic acid-PTs, polymer **45** showed the largest wavelength shift upon addition of both influenza A and B (+27 and +32 nm, respectively) (Figure 4). For the mannose-PTs, polymer **56** showed the largest wavelength shift (+32 nm) after *E. coli* binding (Figure 5). The wavelength shift was observed with the naked eye, as a color change to dark red. The direction of the wavelength shift is contradictory to those previously reported (*12*, *13*, *15*, *37*). In the case of the sialic acid-PT series, **41**, **42**, and **47**, having a relatively short side chain showed the weakest wavelength shifts. Morever, **47** exhibited the weakest degree of transition (+4 nm for influenza A, 0 nm for influenza B), most likely because of the inability of the virus to access the carbohydrate on the short

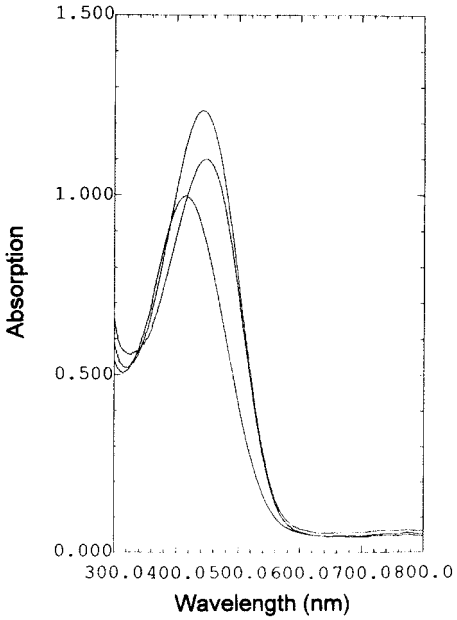

Figure 4. UV−vis spectra of sialic acid-PT (**45**) before and after addition of Influenza virus. Influenza virus A (top), Influenza virus B (middle), and no virus (bottom).

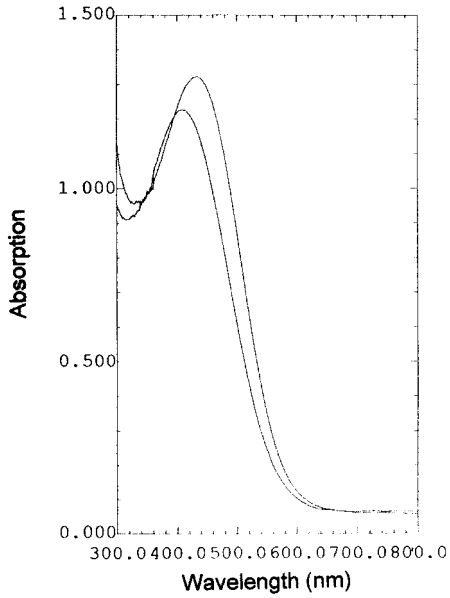

Figure 5. UV−vis spectra of mannose-PT (**56**) before and after addition of *E. coli*. with *E. coli* (top) and without *E. coli* (bottom).

linker. The other polymers, **44**, **45**, and **48** having longer side chains, exhibited $\Delta\lambda_{max}$ values up to 27 nm for influenza A and 32 nm for influenza B, with an observed color change to dark red (Figure 6). Polymer **43**, which has an intermediate side chain length indicated a wavelength shift of 10 nm.

A similar trend was observed for the mannose-PTs where the absorption maximum shifts were, in general, more significant than the sialic acid-PTs. Interestingly, **55** showed a strong absorption maximum shift to the red by 25 nm. Similar side-chain lengths of **49** and **50** showed somewhat smaller $\Delta\lambda_{max}$ values, +16 and +8 nm, respectively. These results suggest that, upon highly cooperative interactions between the carbohydrate and receptor protein, the degree of conjugation of the glycopolythiophene backbone is increased and the chain is rearranged to a more extended π-conjugated system. In general, the polymers with the longer side chains exhibit greater shift,

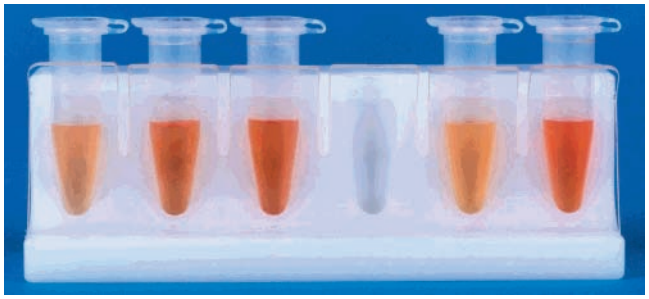

Figure 6. Color Change of Polythiophenes by addition of the receptor protein. From the left side, Sialic aicd-PT (**45**), **45** with Influenza virus A, **45** with Influenza virus B, blank, Mannose-PT (**56**), and **56** with *E. coli*.

again suggesting a higher degree of transition to the more planar conformer (see for example, **52**−**56**).

The unusual red-shift of these polymers upon interaction with protein, virus, or bacteria may be explained in a simple sense, by a nonplanar to planar transition of the polymer backbone. Because these polymers are soluble polymers in free solution [unlike previous biochromic studies with polydiacetyle ne where ordered assemblies such as vesicles or LB films were used (*15*, *38*−*41*)], it is likely that numerous intermolecular interactions can occur. The acidic groups in the polymer backbone and carbohydrate side chains can easily engage in electrostatic or H-bonding interactions. The favorable energetics of these interactions could exceed that of efficient π-orbital overlap of the backbone. Therefore, twisting of the polymer backbone is favored under these conditions. Indeed, these types of interactions are supported by the fact that the homopolymer **40**, already has an absorption maximum that is significantly more in the red compared all of the carbohydrate-modified polymers (**41**−**56**). This is not completely unexpected given the high propensity of carbohydrates to engage in H-bonding interactions. However, upon binding of the cognate receptor, such as lectin, virus, or *E. coli*, the intermolecular interactions between the carbohydrate side chains are disrupted. This would be reasonable since the binding interaction has a higher affinity than the simple intermolecular forces occurring between carbohydrates. Once the intermolecular interactions are disrupted, the polymer assumes a more extended conformation, with decreased twisting of the polymer backbone. The increased π-orbital overlap of this extended conformation results in the observed red-shift. In addition, the multivalent nature of the influenza virus and *E. coli* receptors can bind multiple sites on the polymer, further amplifying the changed conformation. This agrees with the greater shifts observed for these particles, in comparison to that of the simple lectins.

CONCLUSIONS

Water-soluble glycopolythiophenes containing sialic acid or mannose ligands have been synthesized by oxidative copolymerization of methyl (3-thienyl)acetate (**7**) and thiophene-carbohydrate monomers. The ability of these materials to detect lectins, influenza virus, and *E. coli* was evaluated by visible absorption spectrometry. The biochromic properties were dependent on the structure of polymers and the nature of the binding receptors (e.g., divalent versus multivalent). Due to the presence of the carbohydrate ligands on the polymer backbone, each chain has lower degree of π-conjugation than the corresponding homopolythiophene. These intermolecular interactions play a critical role in the unusual red shifts observed upon interaction with the cognate receptors. Once the virus or bacterium binds, the intermolecular interactions that produce a twisted polymer backbone are disrupted, and a more planar polymer backbone results. In general, the longer the side chain between the carbohydrate and the polymer backbone, the greater the absorption maximum shift. This may be related to optimized fit of the ligand to the receptor pocket. It is possible that these effects could be amplified by the preparation of more regioregular species, or thiophenes oligomers (*59*). Further optimization of these systems may result in enhanced detection of biological macromolecules.

ACKNOWLEDGMENT

This research was supported by the Director, Office of Energy Research, Office of Basic Energy Sciences and Division of Materials Sciences. We thank Dr. Y. H. Choi and K. H. Kim for their generous gift of *E. coli* HB101 (pSH2). We also would like to thank Dr. M. Alper, Director of the Biomolecular Materials Program for his support.

A unique antibody-binding protein, (E12B2)n, was genetically synthesized, which was characterized by a hydrophobic peptide, E12, at one terminus and an antibody-binding peptide, B2, at the other. It was clarified by atomic force microscopy (AFM) imaging that this protein was efficiently self-assembled on a hydrophobic solid surface. (E12B2)n self-assembled on a microplate exhibited an excellent performance of antibody-binding affinity. The proposed design of antibody-binding protein seems promising in immobilizing antibody molecules on hydrophobic solid surfaces.

INTRODUCTION

Immobilization of antibody molecules on a solid surface is a widely used technique in various fields such as immunoassays, immunosensors, and affinity chromatography (*1*−*3*). In these systems, it is essential to assemble antibody molecules stably on a solid surface in a highly oriented manner with retaining their antigen-binding affinity.

Antibody molecules may be stably immobilized by covalent bonding to the solid surface. However, it often results in a loss of their antigen-binding affinity. Although simple adsorption offers an easy method for immobilization, it results in partial or complete denaturation of adsorbed molecules (*4*−*10*).

One of the methods is to immobilize antibody molecules indirectly on the solid surface via antibody-binding proteins, including staphylococcal protein A (SpA) and protein G (*11*−*18*), which specifically recognize and bind the Fc region of numerous mammalian immunoglobulin G (IgG) with leaving the Fab regions available for antigen binding. In this method, direct damage of antibody molecules due to immobilization may be avoided, and the orientation of Fab regions can be controlled. However, immobilization of such antibody-binding proteins on the solid surface should suffer from the inactivation of their antibody-binding abilities.

To overcome these disadvantages, a novel antibody-binding protein has been designed in such a manner as a hydrophobic peptide unit in sequence may surround the surface loop of the antibody-binding domain to be self-assembled on the hydrophobic solid surface. The B domain of SpA (*19*−*21*) and elastin-based polyhexapeptide repeat (Ala-Pro-Gly-Val-Gly-Val), E (*22*−*24*), were sequenced to construct the designed protein. The structural gene for 2-repeat of the B domain (B2) was ligated to the gene for 12-repeat of elastin-based poly-hexapeptide (E12) in frame. The 2-repeat of the B domain has been confirmed to exhibit enough binding affinity to stably immobilize the Fc region of IgG, while the 12-repeat of E is expected to provide the protein with hydrophobicity strong enough to be self-assembled on a hydrophobic solid surface. The synthesized gene was expressed in *Escherichia coli* and purified with affinity chromatography. The structure of resulting protein was designated E12B2. Two-repeat and four-repeat of E12B2, designated $(E12B2)_2$ and $(E12B2)_4$, respectively, were also constructed. The self-assembled protein molecules on a hydrophobic solid surface were individually visualized and evaluated by atomic force microscopy (AFM) imaging, which could reveal the rationality of our designing the antibody-binding protein. Furthermore, antibody-binding ability of (E12B2)n assembled on a hydrophobic plastic surface was investigated.

EXPERIMENTAL PROCEDURES

Materials. Plasmid pET-32 (c), *E. coli* BL21 (DE3) competent cells, enterokinase, and EKapture Agarose were purchased from Novagen (Madison, W1). Ni-NTA agar was purchased from Qiagen (Hilden, Germany). Nontreatment-type 96-wells microtiter plate (FALCON 1172) was obtained from Becton Dickinson Labware (Franklin Lakes, NJ). Block Ace was purchased from Snow brand milk products Co., Ltd. (Sapporo, Japan). Bovine serum albumin (BSA) was obtained from Sigma Chemical Co. (St. Louis, MO). Rabbit anti-BSA antibody was purchased from Intercell Technologies Inc. (Hopewell, NJ). Peroxidase conjugated protein A (SpA-POD) was obtained from Wako Pure Chemicals Industries, Ltd. (Osaka, Japan), peroxidase was purchased from Toyobo (Osaka, Japan), and rabbit anti-peroxidase (horseradish) antibody was purchased from Rockland (Gilbertsville, PA).

Plasmid Construction. In the previous study, we constructed the plasmid designated pKK−B2 (*25*), which was inserted a 2-repeat of the gene encoding the B domain of SpA. This inserted fragment (B2) was amplified with polymerase chain reaction (PCR) by using the synthesized DNA primer containing *Bam*HI site and the reverse primer containing *Bgl*II and *Eco*RI sites. This amplified fragment (B2) was digested with *Bam*HI and *Eco*RI and inserted into the *Bgl*II−*Eco*RI site of pGEX-E12 (*26*), which was encoding GST and the 12-repeat of the APGVGV sequence. The resulting plasmid was designated pGEX-E12B2. A *Bam*HI−*Eco*RI fragment of

the pGEX-E12B2 was inserted at *Bgl*II−*Eco*RI site of the same plasmid, and pGEX-$(E12B2)_2$ was constructed. This procedure was repeated for pGEX-$(E12B2)_2$, and pGEX-$(E12B2)_4$ encoding a 4-repeat of $(APGVGV)_{12}$-$(B\ domain)_2$ sequence was constructed. Finally, each fragment of *Bam*HI−*Eco*RI from pGEX-E12B2, pGEX-$(E12B2)_2$, and pGEX-$(E12B2)_4$ was inserted into the pET-32 (c) at the same site as a fusion with the gene of thioredoxin in frame. The resulting plasmids were designated pET-E12B2, pET-$(E12B2)_2$, and pET-$(E12B2)_4$, respectively.

Expression and Purification of Proteins. *E. coli* BL21 (DE3) cells were transformed with the plasmids pET-E12B2, pET-$(E12B2)_2$, and pET-$(E12B2)_4$ and they were grown in LB medium supplemented with 50 μg/mL ampicillin to $OD_{660} = 0.5$ at 37 °C. After induction with 1 mM isoproplylthio-β-galactoside (IPTG), cells were cultured for another 4 h at 20 °C. They were harvested by centrifugation, washed with lysis buffer (10 mM imidazole, 300 mM NaCl, and 50 mM phosphate, pH 8.0) and disrupted by sonication. After centrifugation, the supernatant was applied to the Ni-NTA Agar to purify the fusion protein with thioredoxin by using the affinity of histidine-tag at N-terminus. The purified fusion protein was cleaved site-specifically with enterokinase to cut off the thioredoxin moiety for 16 h at 21 °C. After cleavage reaction, thioredoxin and enterokinase were removed by applying Ni-NTA Agar and EKapture Agarose. The resulting proteins possessing reciprocally 1, 2, and 4-repeated sequences were designated E12B2, $(E12B2)_2$, and $(E12B2)_4$, respectively. These proteins were dialyzed with phosphate-buffered saline (PBS). Purified samples of E12B2, $(E12B2)_2$, and $(E12B2)_4$ were analyzed by SDS−PAGE and Western blotting.

AFM Imaging of Self-Assembled (E12B2)n on HOPG or Mica Surface. Purified (E12B2)n protein was dissolved in PBS to a final concentration of 100 nM in PBS. Twenty microliters of the solution containing (E12B2)n protein was incubated on a freshly cleaved highly oriented pyrolytic graphite (HOPG) or mica for 1 h at 37 °C, which was washed with 1 mL of distilled water and dried shortly in a stream of compressed and filtered air. All samples were further dried in a 2 L glass desiccator in the presence of P_2O_5 for 10 min.

The samples were imaged with an AFM of NanoScope III MultiMode system (Digital Instruments, Santa Barbara, CA) in the tapping mode in air. The tip of the cantilever is modulated sinusoidally to touch briefly the surface as it scans the surface of the sample. Standard silicon cantilevers of 125 μm in length were used. Cantilever oscillation frequency was tuned to the resonance frequency of the cantilever (280−350 kHz). The 512 × 512 pixel images were captured with a scan size between 1.0 and 2.0 μm at a scan rate of 1−2 scan lines/s. The area of (E12B2)n self-assembled on substrates was determined with the NanoScope image analysis package.

Competitive ELISA. One hundred microliters of rabbit anti BSA antibody (10 μg/mL) was added to the wells of microplate coated with BSA and incubated for 1 h at 37 °C. After these wells were washed several times with phosphate-buffered saline including 0.1% Tween 20 (PBS-T), 100 μL of 0.25% Block Ace in PBS-T was added to the wells and they were incubated for 1 h at 37 °C. These wells were washed several times with PBS-T. Thus, antibody molecules were coated on the surface with orientation as displaying their Fc region to liquid phase.

The various concentrations of (E12B2)n solution including 0.25 μg/mL SpA-POD were reacted on the microplate coated with rabbit IgG for 1 h at 37 °C. After these wells were washed several times with PBS-T, 50 μL of 0.5 mg/mL *o*-phenylene diamine in 50 mM acetate buffer (pH 5.0) and 50 μL of 0.06% hydrogen peroxide were added to the wells. This enzyme reaction was stopped with 50 μL of 4 M H_2SO_4. The absorbance of the reaction mixture at 490 nm was measured with a microplate-reader (Bio-Rad, Hercules, CA).

Antibody Binding Assay on Each Protein-Coated Microplate. One hundred microliters of solution of each SpA, E12B2, $(E12B2)_2$, and $(E12B2)_4$ was added to the individual well of a 96-well nontreatment-type microtiter plate (Falcon 1172) in various concentrations, and they were incubated for 1 h at 37 °C. After these wells were washed several times with PBS-T, 100 μL of 0.25% Block Ace in PBS-T was added to the wells, and they were incubated for 1 h at 37 °C. These wells were washed several times with PBS-T. Thus, these protein-coated microplates were designated SpA-plate, E12B2-plate, $(E12B2)_2$-plate, and $(E12B2)_4$-plate.

One hundred microliters of 10 μg/mL rabbit anti-peroxidase antibody solution was reacted to SpA-plate, E12B2-plate, $(E12B2)_2$-plate, and $(E12B2)_4$-plate, and they were incubated for 1 h at 37 °C. All wells were washed several times with PBS-T, then 100 μL of 10 μg/mL peroxidase was added to the wells and incubated for 1 h at 37 °C. After these wells were washed several times with PBS-T, peroxidase enzyme reaction was done according to the previous procedure.

Antibody Assembling Ability on $(E12B2)_4$-Coated and Noncoated Plate. One hundred microliters of rabbit anti-peroxidase antibody solution was added to the $(E12B2)_4$-coated microplate and noncoated microplate in various concentrations, and they were incubated for 1 h at 37 °C. All wells were washed several times with PBS-T and then blocked with 0.25% Block Ace. One hundred microliters of 10 μg/mL peroxidase was added to the wells, and they were incubated for 1 h at 37 °C. After these wells were washed several times with PBS-T, peroxidase enzyme reaction was done according to the previous procedure.

RESULTS

Plasmid Construction and Protein Purification. Designed antibody-binding proteins, E12B2, $(E12B2)_2$, and $(E12B2)_4$, were produced in *E. coli* by using the GST-fusion system. However, no desired proteins were produced in both soluble and insoluble fractions of *E. coli* (data not shown). Then the fusion partner was changed from GST to thioredoxin. Through the use of this system, E12B2, $(E12B2)_2$, and $(E12B2)_4$ were produced in larger amounts in the soluble fraction than the insoluble fraction. SDS−PAGE analysis of these purified samples revealed the single band in the predicted molecular mass, approximately 21, 42, and 84 kDa, respectively (Figure 1A). Western blotting analysis revealed the same pattern of protein band as SDS−PAGE analysis (Figure 1B).

AFM Imaging of Self-Assembled (E12B2)n on HOPG or Mica Surface. Each solution of (E12B2)n was assembled on HOPG and mica plates as hydrophobic and hydrophilic surfaces, respectively, and they were observed by AFM (Figure 2). From these images, the ratio of covered area with (E12B2)n was calculated (Table 1). Assembling amounts of proteins on the HOPG surface increased with an increase of E12B2 unit (Figure 2, panels A−C). In the case of $(E12B2)_4$, almost the whole surface (87.88%) of the HOPG was covered with the proteins (Figure 2C). In contrast, the protein was scarcely assembled on the mica surface (Figure 2, panels D−F). The $(E12B2)_4$ was assembled on hydrophobic HOPG

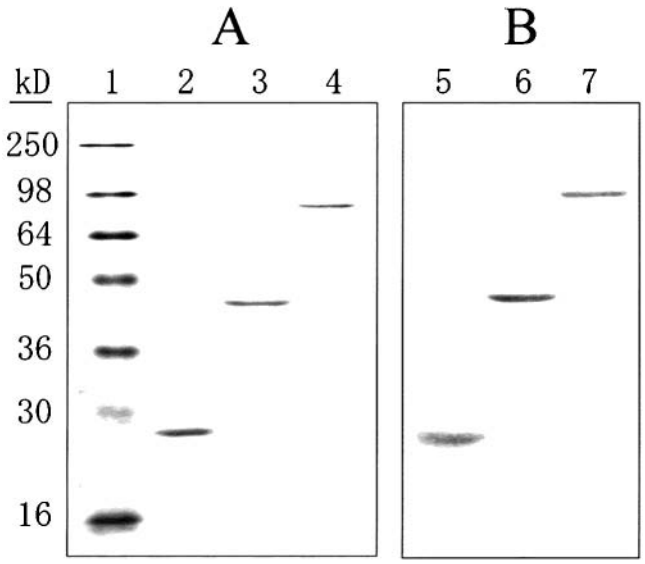

Figure 1. (A) SDS−PAGE analysis of purified E12B2, $(E12B2)_2$, and $(E12B2)_4$. Purified proteins were separated by electrophoresis in 12% SDS−polyacrylamide gel. The gel was stained with coomassie brilliant blue. (1) molecular weight marker, (2) E12B2, (3) $(E12B2)_2$, (4) $(E12B2)_4$, (B) Western blotting of E12B2, $(E12B2)_2$, and $(E12B2)_4$. surface about 200 times more than hydrophilic mica surface (Figure 2, panels C and F).

Competitive ELISA. The antibody-binding ability of (E12B2)n in liquid phase was investigated by comparing with SpA. The various concentrations of (E12B2)n or SpA solution including SpA-POD (0.25 μg/mL) were reacted to rabbit IgG immobilized microplate. The amount of reacted SpA-POD to immobilized IgG was estimated by peroxidase activity. They are plotted against protein concentrations as shown in Figure 3. The antibody-binding ability of E12B2 was lower than that of SpA. However, that of $(E12B2)_2$ was slightly higher than that of SpA. Furthermore, $(E12B2)_4$ gave an excellent antibody-binding ability, which was about 10 times higher than that of SpA.

Antibody Binding Assay on Each Protein-Coated Microplate. The antibody-binding ability of (E12B2)n on a solid phase was investigated by enzyme immunoassay. At first, (E12B2)n were coated on the microplate surface in various concentrations. A constant amount of rabbit anti-peroxidase antibody was reacted to each protein-coated microplate and then peroxidase was added. Amount of immobilized peroxidase was estimated by peroxidase activity, which reflected the amount of assembled (E12B2)n retained antibody binding ability on the microplate surface. They are plotted against protein concentrations as shown in Figure 4. A large amount of E12B2 over 100 nM was required for saturated assembling on the microplate surface. However, the required amount of (E12B2)n for assembling was dramatically reduced by repeating E12B2 sequence. In the case of $(E12B2)_4$, less than 10 nM of protein concentration was sufficient for saturated assembling. To compare with the other IgG-binding protein, the same experimental procedure was done in the case of SpA. The antibody binding ability of SpA in solid phase was slightly lower than that of $(E12B2)_2$. In the following study, the sufficient amount of $(E12B2)_4$ was coated on a microplate for immobilizing antibody.

Antibody Assembling Ability on $(E12B2)_4$-Coated and Noncoated Plate. The antibody assembling ability of the $(E12B2)_4$-coated plate was investigated by comparing with that of the noncoated plate. Rabbit anti-peroxidase antibody was reacted to $(E12B2)_4$-coated and noncoated microplate in various concentrations, then peroxidase was added. Amount of immobilized peroxidase was estimated by peroxidase activity, which reflected the amount of immobilized antibody molecule on the microplate. The results for $(E12B2)_4$ are shown in Figure 5. Antibody could be assembled on microplate surface by physical adsorption. However, the antibody-assembling ability on $(E12B2)_4$-coated microplate was more efficiently by than noncoated one.

DISCUSSION

In this study, we have designed and constructed a unique antibody-binding protein, (E12B2)n, which was characterized by a hydrophobic peptide unit.These proteins tried to be produced in *E. coli* by using the GST-fusion system. However, no desired proteins were produced in both soluble and insoluble fractions of *E. coli* (data not shown). Then the fusion partner was changed from GST to thioredoxin which could increase drastically the solubility of heterologous proteins synthesized in the *E. coli* cytoplasm and result in an increased accumulation of the fusion protein to higher levels. Furthermore, since the host *E. coli* BL21 (DE3) has a gene for T7 RNA polymerase under the control of tac promoter in their chromosomal DNA, production of T7 RNA polymerase is induced with IPTG. As the result, an enhanced expression of the gene under T7 promoter is induced by adding IPTG (*27*). Through the use of this system, E12B2, $(E12B2)_2$, and $(E12B2)_4$ were produced in larger amounts in the soluble fraction than in the insoluble fraction. These proteins were purified by Ni-NTA affinity chromatography from the soluble fraction, and thioredoxin was removed by cleavage reaction with enterokinase. Purified samples were dialyzed with PBS.

Simple adsorption of protein molecules on solid surface is mostly dependent on the hydrophobic interaction between protein molecule and solid surface. Since (E12B2)n has the hydrophobic peptide, E12, in their structure, they should be efficiently self-assembled on the hydrophobic solid surface by hydrophobic interaction. To investigate the assembling efficiency of (E12B2)n onto the hydrophobic and hydrophilic surfaces, each protein was assembled on HOPG and mica plates as the hydrophobic and hydrophilic surfaces, respectively, and was visualized by AFM (Figure 2). (E12B2)n was assembled preferably on the HOPG hydrophobic surface. And more, assembling amounts of proteins on the HOPG surface increased with an increase of E12B2 unit (Table 1). In contrast, the protein was scarcely assembled on the mica surface. These results suggest that (E12B2)n are self-assembled on the HOPG surface through strong hydrophobic interaction between the E12 sequence and the hydrophobic solid surface. Generally, the interaction between molecule and surface of HOPG are very weak (*28*). Therefore, Droz et al. modified the surface of HOPG by glow discharge to assemble IgG (*29*). However, E12B2 was assembled homogeneously without any modification of HOPG surface. It is a distinctive feature of this protein.

The antibody-binding ability of (E12B2)n was compared with that of SpA. Competitive ELISA and antibody binding assay revealed that the 4-repeat of E12B2 sequence, $(E12B2)_4$, was superior in antibody binding to SpA in both liquid and solid phases, although $(E12B2)_2$ was comparable with SpA. In the following study, $(E12B2)_4$ was coated as an antibody-binding matrix on a hydrophobic solid surface.

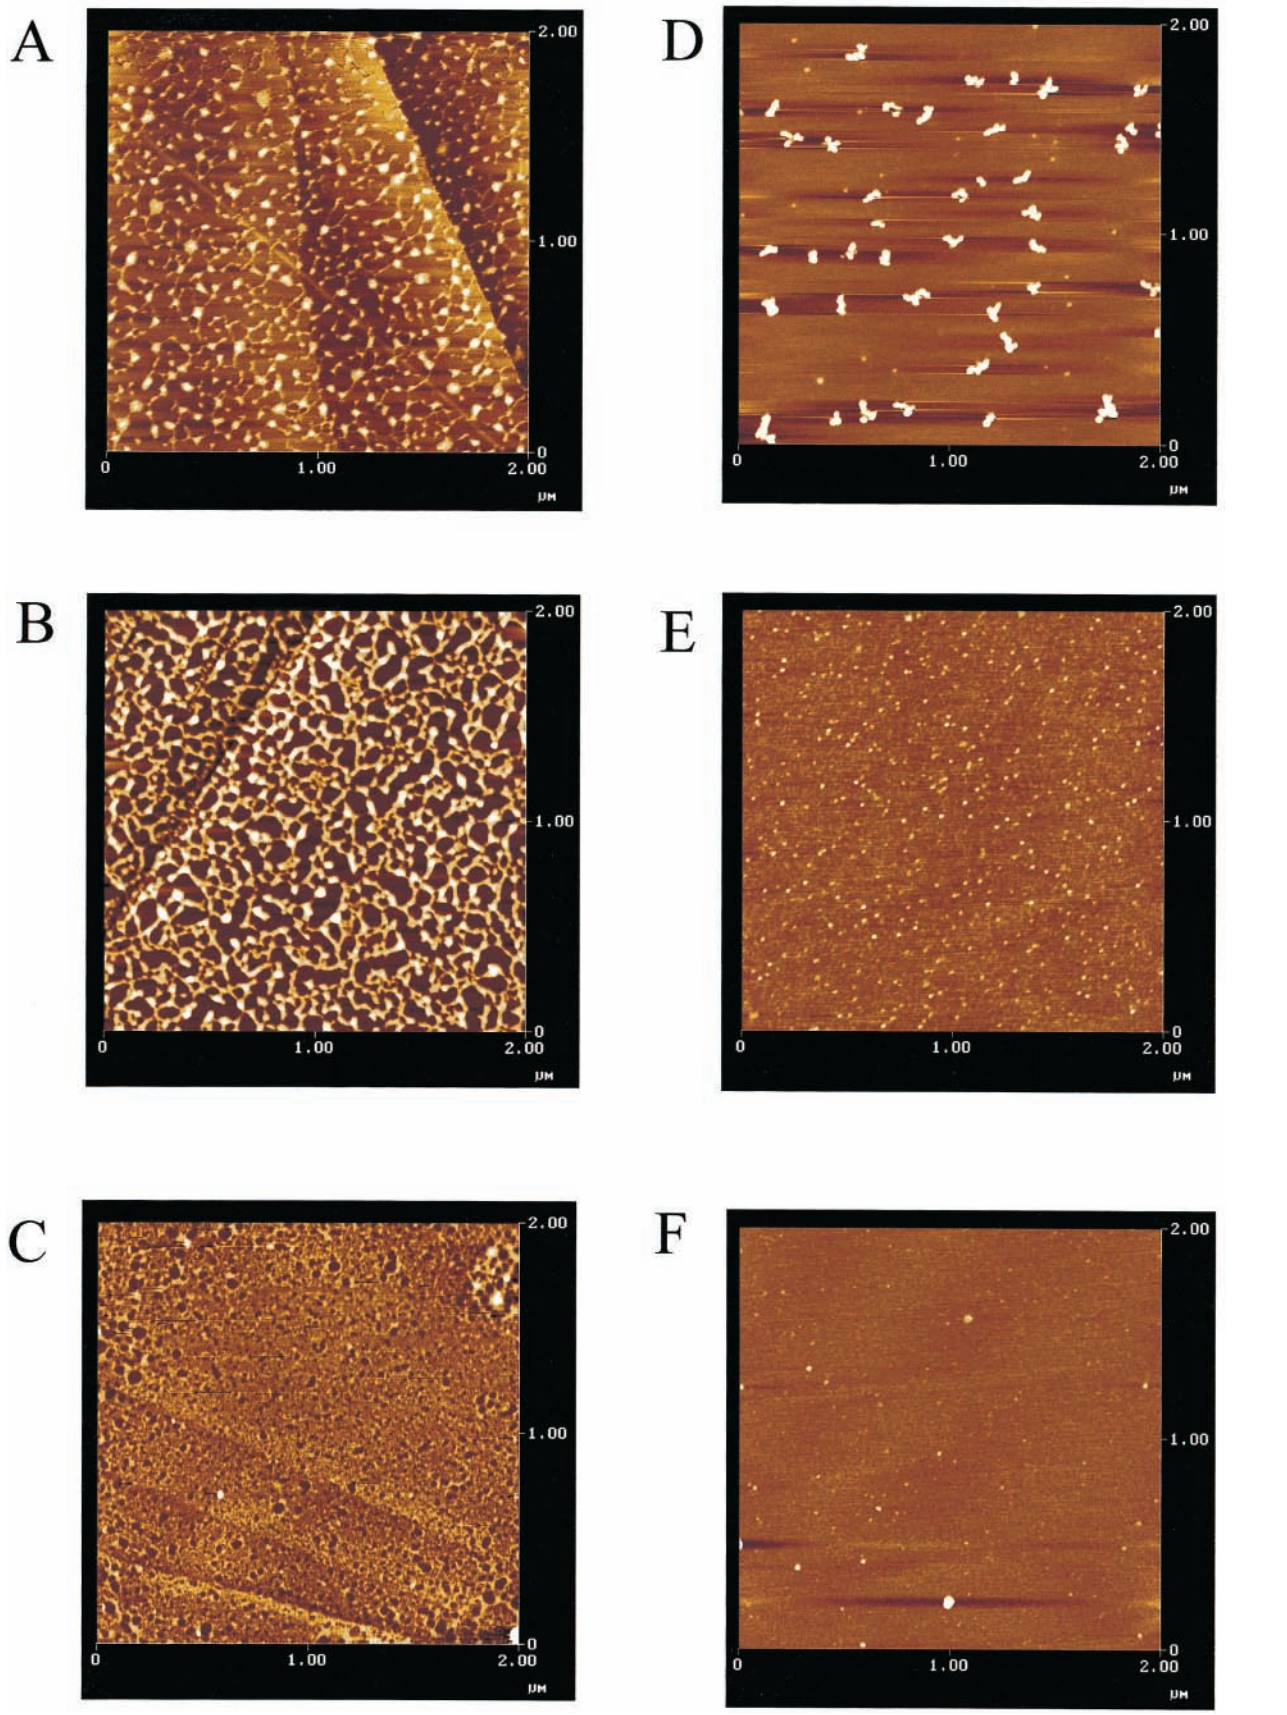

Figure 2. AFM imaging of assembling (E12B2)n on HOPG or mica surface. When adding 100 nM of (E12B2)n solution, assembled (E12B2)n was imaging by atomic force microscopy. (A) E12B2 on HOPG, (B) $(E12B2)_2$ on HOPG, (C) $(E12B2)_4$ on HOPG, (D) E12B2 on Mica, (E) $(E12B2)_2$ on Mica, (F) $(E12B2)_4$ on Mica.

In general immunoassy methods, antibody was assembled on a microplate surface by simple adsorption. Therefore, the antibody-assembling ability of the $(E12B2)_4$-coated plates was investigated by comparing with that of the noncoated plate. As shown in Figure 5, antibody molecule was more effectively immobilized on the

Table 1. Ratio of Covered Areas by (E12B2)n on HOPG or Mica Surface[a]

	HOPG (%)	mica (%)

$(E12B2)_2$	50.18	3.60
$(E12B2)_4$	87.88	0.45

[a] The area of (E12B2)n self-assembled on structure was determined with bearing of the NanoScope image analysis package.

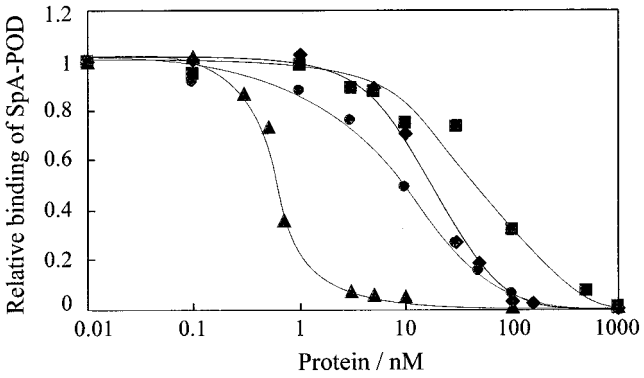

Figure 3. Antibody-binding activity of E12B2, $(E12B2)_2$, $(E12B2)_4$, and SpA. The binding of SpA-POD with each protein to rabbit IgG adsorbed on microplate surface was measured in the presence of competing protein. The absorbance at 490 nm at each concentration of competing protein was divided by the absorbance without the protein, and the value was plotted against the logarithmic of molar concentration of each protein. Values are the mean ± SD from four independent assays. E12B2 (■), $(E12B2)_2$ (●), $(E12B2)_4$ (▲), and SpA (◆).

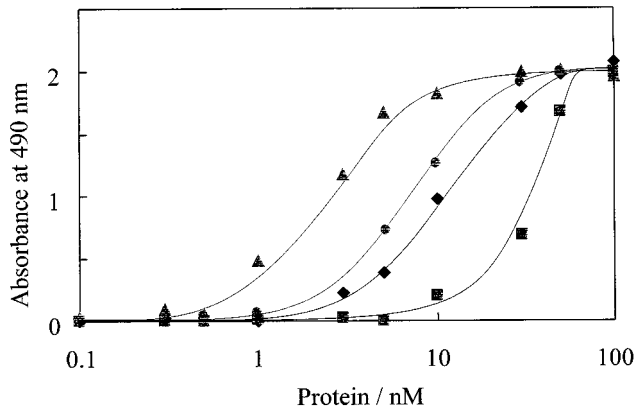

Figure 4. The absorbances by peroxidase reaction were plotted against the adding protein concentrations. These curves reflected the amount of assembled protein molecules on microplate surface. E12B2 (■), $(E12B2)_2$ (●), $(E12B2)_4$ (▲), and SpA (◆).

$(E12B2)_4$-coated microplate than noncoated microplate. In the model case of immunoassay, we tried the sandwich ELISA for targeting mouse IgM on $(E12B2)_4$-coated or noncoated microplate. The required amount of primary antibody for assembling on microplate surface is reduced with $(E12B2)_4$ coating (data not shown). These results suggest that (E12B2)n, especially $(E12B2)_4$, is a good material for assembling antibody on a hydrophobic matrix.

CONCLUSION

Genetically synthesized protein, (E12B2)n, showed an excellent performance of antibody binding on the hydrophobic solid surface. The antibody immobilization is simply carried out by coating the hydrophobic solid surface with (E12B2)n, which is followed by affinity binding of antibodies. (E12B2)n will find a wide application in immunoassays, immunosensors, and affinity chromatography.

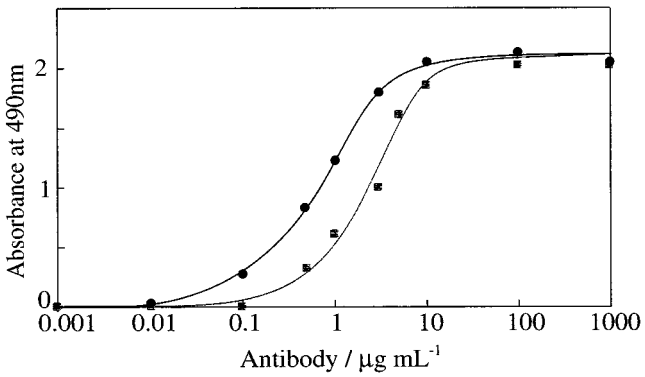

Figure 5. The absorbances by peroxidase reaction were plotted against the adding antibody concentration. These curves were reflected the amount of assembled antibody molecules on $(E12B2)_4$-coated (●) or noncoated microplate (■).

Oligonucleotide–Polymer Conjugates: Effect of the Method of Synthesis on Their Structure and Performance in Diagnostic Assays

Claire Minard-Basquin, Carole Chaix,* Christian Pichot, and Bernard Mandrand

UMR 2142 CNRS/bioMérieux, ENS Lyon, 46 allée d'Italie, 69364 Lyon Cedex 7, France.
Received January 31, 2000; Revised Manuscript Received June 25, 2000

Oligonucleotide–polymer conjugates have been described to improve the sensitivity of an enzyme-linked oligosorbent assay diagnostic test. To understand the influence of their structure and conformation in solution on the efficiency of the test during the capture step, two different ways of synthesizing these conjugates were compared. The first consisted of coupling 5′ amino modified oligonucleotides to poly(maleic anhydride-*alt*-methylvinyl ether) and poly(maleic anhydride-*alt*-ethylene). The second resulted from direct synthesis of oligonucleotides from poly(maleic anhydride-*alt*-ethylene) previously grafted onto a controlled pore glass support. The different conjugates were analyzed by size-exclusion chromatography and viscometry. The former method for conjugate synthesis produced aggregates, which was not the case for the latter. These conjugates were then used in the capture phase of a hybridization assay using a HBV DNA target, on a bioMérieux VIDAS instrument. Different parameters were studied, such as the purity of the conjugate solution and the number of oligonucleotides per polymer chain. The amount of conjugate coated on the solid-phase receptacle surface at the time of the capture phase was evaluated by radioactive labeling. Finally, it was demonstrated that conjugates produced an amplification factor of 50 versus the capture oligonucleotide probe used as the reference. The detection limit reached 10^8 copies/mL.

INTRODUCTION

Hepatitis B virus (HBV) disease is a major worldwide health problem, affecting millions of people. The diagnosis of the infection traditionally depends on various serologic HBV markers. However, the quantitation of HBV DNA in serum by molecular hybridization represents the most informative method for determining viral replication and serum infectivity (*1*). In the past, different hybridization assays for HBV DNA measurement have been developed. Dot blot (*2*) and liquid hybridization (*3*) were first employed, but were found to lack sensitivity. Later on, the polymerase chain reaction (PCR) efficiently improved the limits of HBV DNA detection. However, this very sensitive method often lacked reproducibility and stringent conditions were also required to avoid contamination (*4*). In this context, new signal amplification strategies were investigated as an alternative to target enzymatic amplification. These methods enabled direct measurement of HBV DNA in serum, allowing its quantitation. First of all, it was envisioned to develop modified oligonucleotides used as probes carrying multiple nonradioactive labels, e.g., fluorophore (*5*) or biotin (*6*), with the purpose of increasing sensitivity. Furthermore, to reduce nonspecific binding, another hybridization assay was developed that used branched DNA (bDNA) (*7*–*9*). More recently, oligonucleotide dendrimers were described to amplify radioactive or fluorescent signals in hybridization tests (*10*).

In this context, our laboratory focused early on the detection of viral nucleic acid material using the ELOSA technique (enzyme-linked oligosorbent assay) (Figure 1) (*11*). The principle of this test is (i) to isolate the DNA target using a capture oligonucleotide (ON) probe immobilized on a solid support and (ii) to detect and quantify the DNA target using a detection probe labeled by an enzyme. With this strategy, oligonucleotide-polymer conjugates used as probes for both capture and detection of the nucleic acid target (*12*, *13*) have been described to improve the sensitivity of the test on a bioMérieux VIDAS immunoanalysis instrument (Figure 2). In the capture step, oligonucleotide–polymer conjugates were used to increase the coating of the probe on the solid support. Likewise, in the detection step, oligonucleotide–polymer conjugates have been described to improve detection signal due to an increase in the enzyme concentration. These conjugates were previously obtained by the coupling of 5′ amino modified oligonucleotides onto polymer reactive functions. Several polymers have been investigated such as poly(*N*-vinylpyrrolidone-*N*-acryloxysuccinimide) (P[NVPNAS]) (*14*), maleic anhydride copolymers (*15*), *N*-(2,2-dimethoxyethyl)-*N*-methacrylamide (*16*) and 6-deoxy-6-methacryloylamido-D-glucopyranose (*17*). It has been demonstrated that conjugates obtained

with the poly(maleic anhydride-*alt*-methylvinyl ether) (P[MAMVE]) copolymer increased the sensitivity of an ELOSA diagnostic test in the capture phase (*18*) and that the P[NVPNAS] conjugate copolymer used in the detection step also enhanced detection signal (*18*). However, the coupling method has shown some drawbacks. Indeed, the coupling reaction led to the formation of aggregates that entrapped ONs and hindered their accessibility. Several hypotheses were put forward to explain such aggregate formation: (i) cross-linking of several polymer chains (*19*) and/or (ii) coupling side reactions induced by exocyclic amine functions of the nucleic bases (*18*, *20*). To avoid the aggregation process observed during the coupling reaction and to control biomolecule orientation onto the polymer chain, a new method of conjugate synthesis has been recently described (*21*). Direct synthesis of oligonucleotides has been performed on the poly(maleic anhydride-*alt*-ethylene)(P[MAE]) and the P[MAMVE] (Figure 3) previously grafted on a solid support (controlled pore glass). P[MAE] was preferred to P[MAMVE] because of its good stability under ammonia treatment used for nucleic base deprotection. To compare the two families of conjugates, both synthesis methods were carried out (Figure 4). Conjugates were analyzed by SEC and SEC-MALLS−viscometry with the aim of evaluating their structure in solution. They were then tested in the capture phase of the HBV DNA sandwich hybridization diagnostic assay. The correlation between their structure and their ability to amplify the DNA detection signal is discussed in this work. Different parameters were examined, such as the influence of the free ON part and the number of ONs per copolymer chain. Finally, conjugates were compared by running an ELOSA sandwich test with a range of concentrations of the HBV DNA target. This experiment allowed us to estimate the real influence of conjugates on the sensitivity limits of the test. Moreover, the amount of conjugate coated on the SPR surface during the capture phase was evaluated by radioactive labeling.

EXPERIMENTAL SECTIONPROCEDURES

Materials. P[MAE] was obtained from Aldrich. P[MAMVE] was obtained from PolyScience Inc. Their number average molecular weight ($\overline{M}$n) of 27 000 and 67 000 g/mol, respectively, was determined by size-exclusion chromatography (SEC) in organic solvent (DMSO) using poly(ethylene oxide) standards. P[NVPNAS] (*22*) was obtained by free radical polymerization in *N*,*N*-dimethylformamide (DMF). The copolymer was characterized by UV spectroscopy and by ^{13}C nuclear resonance spectroscopy to determine respectively its composition and the monomer sequence distribution. The apparent number average molecular weight ($\overline{M}$n$_{,app}$) of 35 000 g/mol was determined by SEC coupled to a multiangle laser light scattering detector (conditions described below) with a d*n*/d*c* of 0.2 mL/g.

Anhydrous dimethyl sulfoxide (DMSO) and DMF were purchased from Aldrich. Oligonucleotide syntheses were carried out on an Expedite System Instrument (Millipore). SEC analyses were performed using a Waters UltraHydrogel 500 column or a Waters UltraHydrogel 500 column and a Waters UltraHydrogel 2000 column on line, a Kontron HPLC 420 pump running in a 0.1 M phosphate buffer, pH 6.8, and a Kontron 430 UV detector. Detection was achieved by absorbance at 260 nm which corresponded to the λ_{max} adsorption of the oligonucleotide. Viscometry analyses were performed using SEC coupled to a multiangle laser light scattering detector and coupled to an on line viscometer in a triple detector configuration (SEC-MALLS−viscometry). Two associated columns (Waters UltraHydrogel 500 and 2000) were connected to a Spectra-physics isochrome pump running in a 0.1M phosphate buffer/20 mM NaCl, pH 6.6. For the detection part, a seventeen angle DAWN DSP (WYATT Technology) operating at 690 nm, a viscometer H502 (Viscotek) and a Waters 510 differential refractometer were used on line.

(α-^{32}P)ddATP was obtained from Amersham and (γ-^{32}P)ATP from NEN. Terminal transferase was purchased from Boehringer Mannheim and T4 polynucleotide kinase from Ozyme. Radioactivity was counted with a Liquid Scintillation Analyzer 1900 TR (Packard).

Conjugates Obtained by ON Coupling. Conjugates were obtained according to the protocol described by Ladavière et al. (*15*). Oligonucleotides (ONs) used in this part (ON1, Table 1), were synthesized by standard DNA cyanoethyl *N*,*N*-diisopropylamino phosphoramidite chemistry. ONs were modified at their 5′ position by an

aminohexyl arm for coupling to the copolymer. The appropriate amount of polymer (P[MAMVE]) or (P[MAE]) was first dissolved in 1 mL of DMSO at 37 °C. Dried ON1 was dissolved in 7 μL of 0.1M sodium borate/0.5 M sodium chloride buffer pH 9.3. Then, 10 μL of the polymer solution and 143 μL of DMSO were added. The reaction was carried out for 3 h at 37 °C. Before use, the solvents were removed under vacuum, and the conjugates resuspended in water. Coupling conditions were described in Table 2.

For P[NVPNAS], the coupling protocol differed (*23*). Dried 5′ amino modified ON2 (15 nmol) was dissolved in 10 μL of 0.1M sodium borate buffer, pH 9.3. Then 21 μL of polymer solution at 1 mg/mL in DMF and 70 μL of DMF were added. The reaction was carried out for 2 h at 50 °C. After drying, conjugates were resuspended in water and purified by SEC.

Conjugates Obtained by Direct ON Synthesis on CPG Support. Conjugates were synthesized according to the protocol described by Chaix et al. (*21*). The P[MAE] used in this strategy was first functionalized with different amounts of the nucleotide initiator of ON synthesis (Figure 4). In a second step, the resulting polymer was grafted onto a hydroxylated CPG support. The amount

of starter nucleotide bound to CPG via the polymer was established by trityl cation measurement (*21*). It was estimated to be from 1.49 to 4.25 μmol/gram of support, according to the quantities of nucleotide introduced in the mixture. ON1b (Table 1) was synthesized from this functionalized CPG by standard DNA cyanoethyl *N*,*N*-diisopropylamino phosphoramidite chemistry on an Expedite Nucleic Acid Synthesis Instrument (Millipore). Conjugates were recovered in solution after ammonia treatment (NH_4OH 30%, 16 h at 60 °C). Before use, conjugates were dried under vacuum, resuspended in water and purified by filtration on Centricon (cutoff 100 000 g/mol). The structure and purity of the conjugates used are summarized in Table 3.

Detection of HBV DNA by ELOSA Test. *Molecular Tools To Run Sandwich Test.* The capture probe consisted of an ON−polymer conjugate carrying an oligonucleotide sequence complementary to HBV DNA from position 2430 to 2454 (ON1, Table 1). The conjugate was diluted at 150 nM in 4× phosphate buffer saline (PBS) (10× PBS is 1.37 M NaCl, 27 mM KCl, 43 mM Na_2HPO_4, and 14 mM KH_2PO_4).

The target used was a PCR product of HBV DNA (double-stranded 2339 bp) cloned in pBR 322 and purified by agarose gel electrophoresis as previously described by Erout et al. (*23*). The PCR target was diluted in PEG buffer (0.1 M sodium phosphate pH 7, 0.5 M NaCl, 0.65% Tween, 0.14 mg/mL DNA salmon sperm, 2% PEG 4000). Before use, the target was denatured in 1.4 N NaOH (5 min at room temperature) and neutralized by 1.4 N acetic acid.

The intermediate ONs (mix) contained 17 ONs complementary to 17 highly conserved regions of HBV sequence. These 17 ONs have an identical non-HBV sequence of 20 nucleotides in length in their 3′ position (ON3, Table 1). The mix was diluted at 26.85 nM, for each ON, in PEG buffer.

The detection phase used a conjugate ON2−P[NVPNAS], complementary to the non-HBV common sequence of the mix (ON3), and complementary to a probe covalently linked to an enzyme (alkaline phosphatase) (ON3-AP). The conjugate ON2−P[NVPNAS] and the ON3-AP were diluted at 15 nM in PEG buffer.

The enzyme detection substrate used was 4-methylumbelliferyl phosphate (4-MUP). The washing buffer used was PBS-Tween (1X PBS with 0.5% Tween).

HBV DNA Test on VIDAS. Detection was performed using a bioMérieux VIDAS immunoanalysis instrument. The test was based on sandwich hybridization (*24*, *25*) using specific probes complementary to highly conserved regions of the HBV DNA sequence. For the capture phase, the conjugate ON1(1b)−copolymer was coated on the inside of a disposable conical VIDAS solid-phase receptacle (SPR) by passive adsorption (*23*). After 1 h of coating at 37 °C, the SPRs were washed with PBS-Tween to remove the uncoated conjugates. The hybridization test was performed for 3h at 37 °C during which the following steps occurred: capture of the target by ON1(1b)−copolymer conjugate, washing, incubation with the mix, washing, incubation with ON2−P[NVPNAS] conjugate, washing, incubation with ON3-AP and AP substrate. The enzymatic reaction converted the substrate into a detectable fluorescent signal expressed in Relative Fluorescent Units (RFU) by the VIDAS detector.

Quantitation of the ON Number Adsorbed onto the VIDAS Solid-Phase Receptacle (SPR). *^{32}P Labeling.* The conjugates obtained by the coupling reaction and the 5′ amino modified oligonucleotide (ON1, Table 1) were labeled in their 3′ position as follows: 30 pmol of conjugate (concentration of nucleic acid part measured at 260 nm) or ON were mixed with 4 μL of 5× reaction buffer (5× reaction buffer is comprised of 1 M potassium cacodylate, 1.25 mM Tris-HCl, bovine serum albumin, 1.25 mg/mL, pH 6.6 at 25 °C), 2 μL of 25 mM cobalt chloride solution, 1 μL of terminal transferase (25 units), and 3 μL of (α-^{32}P)ddATP (30 μCi). The final volume was adjusted to 20 μL with water. The reaction was left for 1 h at 37 °C. The enzyme was then inactivated at 70 °C for 10 min. The conjugate was purified by two filtrations with 500 μL of water on Centricon (cutoff, 100 000 g/mol). The 5′ amino modified ON1 was purified using a G25 column.

The conjugates obtained by ON direct synthesis were labeled in their 5′ position. 30 pmol of the conjugate nucleic acid material were mixed with 2 μL of 10× T4 polynucleotide kinase buffer (1× final concentration is 70 mM Tris-HCl, 10 mM $MgCl_2$, 5 mM DTT, pH 7.6 at 25 °C), 1 μL of T4 polynucleotide kinase (10 units), 3 μL (γ-^{32}P)ATP (15μCi). The final volume was adjusted to 20 μL with water. The reaction was left for 1 h at 37 °C. The enzyme was inactivated at 70 °C for 10 min. The conjugates were purified by two filtrations with 500 μL of water on Centricon (cutoff, 100 000 g/mol).

After purification, the specific activity of each product was measured.

Coating. To a conjugate or ON solution at 150 nM (concentration of nucleic acid part measured at 260 nm) in PBS 4×, 300 000 counts/minute (cpm) of labeled conjugates or ON were introduced, respectively (total volume of the reaction = 600 μL). A total of 300 μL of solution was introduced into the VIDAS conical SPRs sealed at the narrow extremity. SPRs were made of Polystyrene−polybutadiene plastic. The coating was realized by aspirating and dispensing the liquid in the SPR (35 times) for 50 min with a pipetman. SPRs were then washed twice with 300 μL of PBS-Tween, and counted in a liquid scintillation analyzer. Data are summarized in Figure 12.

RESULTS AND DISCUSSION

Conjugates Obtained by the ON Coupling Reaction. Conjugates were produced by coupling ON1 on P[MAMVE] or P[MAE]. Different amounts of ON or polymer were introduced to obtain conjugates with various ON/polymer ratios and purity levels. The reaction was controlled by SEC analysis. Experimental conditions and the corresponding coupling yields are summarized in Table 2.

Figure 5 shows an example of SEC analysis for the coupling of ON1 to P[MAMVE] copolymer, in which three different populations were separated by chromatography. The first population (peak 1) was eluted as an excluded

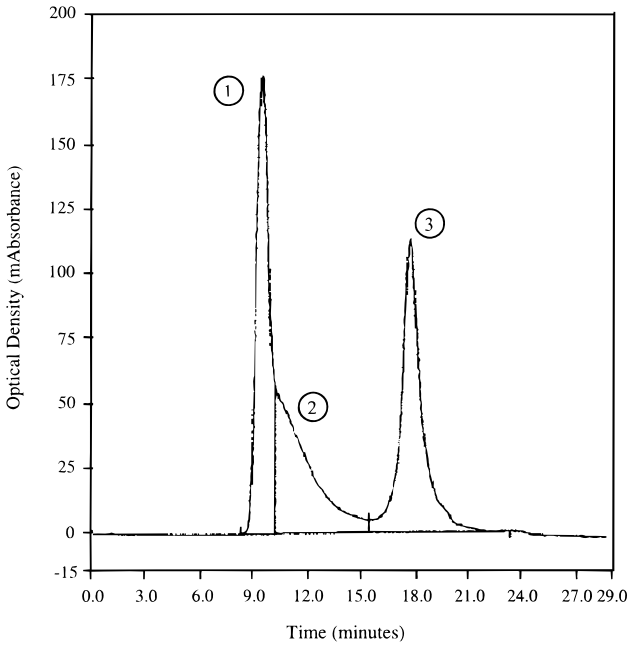

Figure 5. SEC analysis of ON1−PMAMVE conjugate (conjugate [1]) using Waters UltraHydrogel 500 column in 0.1M phosphate buffer pH 6.8. (Flow = 0.5 mL/min) Three populations appeared: (1) excluded peak, (2) lower molecular weight conjugate, (3) free oligonucleotide.

peak corresponding to high molecular weight conjugates. As demonstrated by Ladavière et al. (*15*), this population showed a very high molecular weight (more than 2 000 000 g/mol) when analyzed by SEC coupled to a multiangle laser light scattering detector (SEC-MALLS). The second population eluted (peak 2) corresponded to conjugate with lower molecular weight and the last population (16 min. to 22 min) to residual ONs (peak 3). From that analysis, the coupling yield (*R*) has been defined as the ratio of ON−copolymer versus the total amount of ON introduced in the reaction mixture:

$$R = \frac{\text{area(ON/polymer)}}{\text{area(ON/polymer)} + \text{area(freeON)}} = \frac{\text{area(peak1} + \text{peak2)}}{\text{area (peak1} + \text{peak2)} + \text{area(peak3)}} \quad (1)$$

This calculation takes into account that at 260 nm, the molar extinction coefficient of the ON bound to conjugate is the same as for free ON (*15*). The ratio *R* enables determination of the average number *N* of ONs per copolymer chain according to:

$$N = \frac{n\text{ON}}{n\text{copolymer}} \times R \quad (2)$$

where n_{ON} and $n_{copolymer}$ are the amount in moles of the ON and copolymer introduced in solution, respectively.

Conjugates Obtained by ON Direct Synthesis. Before running ON synthesis on an Expedite DNA synthesis instrument, polymer functionalized CPG was performed as follows: First, the nucleotide **1** coupling yield on polymer was optimized at 90% in a 4 h reaction in DMSO (*21*). Second, hydroxyl-CPG was added to the solution and grafting of the nucleotide activated polymer was performed for 24 h (Figure 4).

According to the amount of nucleotide initially introduced into the reaction mixture, different functionalized CPGs were obtained, from 1.49 to 4.25 μmol of 1 per gram of support. ON1b were then synthesized from these functionalized supports with a sequence differing from ON1 by a supplement of five thymidine in the 3′ position. Indeed, in direct synthesis, ONs were developed from 3′ to 5′. So, this short oligothymidine spacer was necessary to distance the ON1 sequence from the polymer chain, thereby avoiding steric hindrance phenomena. Conjugates were recovered in solution by ammonia treatment, and analyzed by SEC. Results are summarized in Table 3.

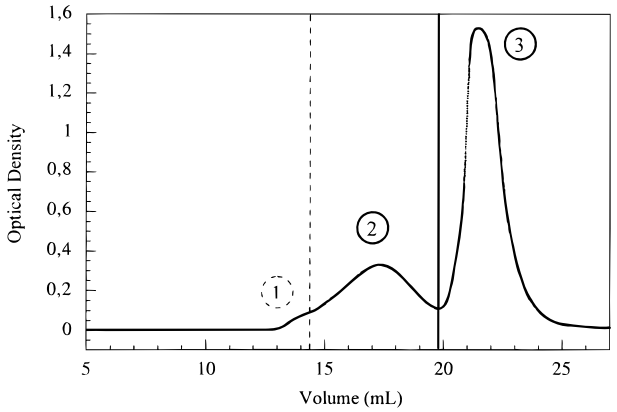

Figure 6. SEC analysis of ON1b-PMAE conjugate (conjugate [15]) using Waters UltraHydrogel 500 and 2000 columns on line in 0.1M phosphate buffer pH 6.8. (Flow = 0.5 mL/min) Two main populations were observed: (2) conjugate, (3) parasite population.

Figure 6 shows an example of SEC analysis of a ON1b−P[MAE] conjugate. As we can see, three kinds of peaks are also observed. The first population of conjugates formed a weak shoulder at the excluded volume (14 min in the chromatographic conditions). But the main population of conjugates was under peak 2 and corresponded to lower masses. Finally, a third population (peak 3) was identified as free ON by ^{32}P labeling (*26*). This latter result was unexpected and was attributed to the following phenomena. (i) An adsorption of both nucleotide **1** and phosphoramidite monomers on the support initiated uncontrolled DNA synthesis. Nucleotide **1** was adsorbed on the CPG surface during the preparation of functionalized support and phosphoramidite monomers during the first cycle of ON synthesis (*26*). (ii) Some starter nucleotide (**1**) was coupled to the polymer by its nucleic base exocyclic amine function. Indeed, by capillary electrophoresis, it appeared that almost 10% of the nucleotide **1** was bound via this more labile link and was cleaved under ammonia treatment (unpublished results). (iii) It was also demonstrated that about 20% of the amide bond between polymer and starter was broken during ammonia treatment (*27*). Consequently, to approximate the real number *N* of ONs per copolymer chain, the initial equivalent number of nucleotides incorporated on P[MAE] (considering the coupling reaction yield) was reduced to 30% (step one, Figure 4). The estimations of the number of ONs per polymer chain are summarized in Table 3.

Conjugate Structure. From SEC analyses in 0.1 M phosphate buffer, pH 6.8, it can be observed that conjugates obtained using the two different methods of synthesis exhibit different structures. Indeed, it was shown that conjugates obtained by the coupling reaction mainly produced aggregates of high molecular weight. For instance, the percentage of aggregates was close to 100% in the case of the P[NVPNAS] coupling reaction with ONs (results not shown). In contrast, no excluded peak was observed for conjugates obtained by direct synthesis, which tends to prove that no aggregated structure was formed.

Table 4. Conjugate Structure

conjugate	*a* parameter	$R_{g,app}$ (nm)	% of conjugate population[a]

[15] (peak 2)	0.73	47	73

[a] UV detection.

Conjugates were also analyzed by SEC coupled to a multiangle laser light scattering detector and a viscometer on line. This analytical system enabled the estimation of the *a* parameter from the Mark−Houwink−Sakurada relationship: $[\eta] = KM^a$ (*28*) and measurement of the radius of gyration, for populations of conjugates separated by chromatography (two columns, UltraHydrogel 500 and 2000). These data provide information concerning the structure of conjugates in 0.1 M phosphate buffer/20 mM NaCl, pH 6.6. For those obtained by the ON coupling reaction strategy, two populations were previously identified (Figure 5). SEC-MALLS−viscometry analyses revealed some differences in their conformation, as reported in Table 4. Whereas the aggregates (peak 1) had an apparent radius of approximately 78 nm for conjugate [2] and 81 nm for conjugate [5] with a compact random coil form ($a \approx 0.3$), the lower molecular weight conjugate population eluted from 10 to 16 min (peak 2) had a smaller apparent radius of gyration of approximately 38 nm with a more expanded random coil form ($a \approx 0.8$). As the proportion of aggregates was predominant (>50%), the conjugates were considered to be essentially in a random coil form in solution with a relatively compact structure. On the other hand, SEC analyses of conjugates obtained by ON direct synthesis (Figure 6) and data obtained by SEC-MALLS−viscometry system (Table 4) showed the presence of a small amount of aggregates which eluted close to the excluded volume of 14 min in the experiment (peak 1, Figure 6). This population had an apparent radius of gyration of 106 nm with a compact random coil form ($a \approx 0.38$). However, the main population of conjugates had an apparent radius of gyration of approximately 47 nm with a more expanded random coil form ($a \approx 0.8$). This latter population corresponded to the nonaggregated ON−polymer conjugates, as confirmed by the apparent number average molecular weight ($\overline{M}n_{,app}$) of 345 000 g/mol measured by SEC-MALLS in 0.1 M phosphate buffer, pH 6.8.

In Figure 7, we have attempted to depict conjugate conformation in aqueous media. Regarding the form parameter and the apparent radius of gyration calculated from viscometry and light-scattering experiments, different structures can be proposed. For conjugates obtained by the coupling reaction, the conformation was essentially in a compact random coil form. With an apparent radius of gyration of 80 nm, it could be suggested that in this case, ON−polymer conjugate chains were essentially entangled, forming huge and compact aggregates (Figure 7). On the other hand, the strategy of direct ON synthesis produced conjugates in a more expanded form with an apparent radius of gyration around 40 nm. This time we supposed that the molecule could simply be folded up on itself maintaining a nonassociated expanded structure in solution.

It was also demonstrated that the number of ONs per copolymer chain varied from one method to another. For conjugates obtained by the coupling reaction, this number rose from 3 to 18. It was not possible to graft a larger amount of ONs per polymer chain because of the decrease in the coupling yield. Indeed, referring to the last experiment that led to 18 ONs/P[MAMVE] chain, the observed coupling yield was already down to 10%. In contrast, conjugates obtained by direct synthesis contained a larger number of ON, from 11 to 109. However, conjugates were not pure, with either method, since a percentage of free ONs was evidenced. So, to examine the influence of free ONs on the VIDAS signal, conjugates were purified at different stages. After characterization, all these conjugates have been used in hybridization assays in order to evaluate their performances in the capture phase.

Use of the ON−Copolymer Conjugates in the Detection of HBV DNA. An efficient sandwich hybridization assay on the automated VIDAS immunoanalysis instrument has been previously developed by bioMérieux and our laboratory (*29*), using specific probes to detect highly conserved regions of HBV DNA. Optimized probe sequences used for the capture and detection phases of the test are described in Table 1. In the capture phase, ON1 and ON1b were used, according to the conjugate synthesis method. The ON−copolymer conjugates described previously were tested for their ability to improve the detection limits of HBV DNA target (Figure 2). ON1−P[MAMVE], ON1−P[MAE], and ON1b−P[MAE] resulting from the two different methods of synthesis were evaluated at the capture phase. ON1−P[MAMVE] conjugate obtained by the coupling method was used as the reference for the diagnostic test described here, as it was considered to be the best candidate to improve capture phase efficiency (*18*). In both cases, the same ON3−P[NVPNAS] conjugate was used in the detection step.

Effect of Free ON on VIDAS Signal. As discussed above, conjugates were contaminated by free ONs. Consequently, it was necessary to study the effect of the conjugate purity on the VIDAS signal. To do so, the two conjugates ([7] and [16]) were progressively purified by successive filtrations, using Centricon with a 100 000 g/mol cutoff, and the purity checked by SEC analysis. For both conjugates, ELOSA experiments were run at all stages of the purification. The test was performed using 10^{10} copies/mL of HBV target (*30*). As we can see on Figure 8, the effect of the free ON part on the signal differed from one conjugate to another. For conjugates obtained by the coupling reaction, the effect was minor (Figure 8a). An increase of 1.1 of the RFU was observed with an increase from 10 to 87% of the conjugate purity. In contrast, for conjugates obtained by direct synthesis, the effect was not negligible (Figure 8b). the RFU signal increased with conjugate purity up to 60%, and then remained stable. To clearly understand the real action of the free ON part in mixtures of conjugates at the capture step, various ELOSA experiments were run, by addition of a percentage of 5′ aminolinked free ON increasing progressively (from 10 to 100%) to an initial solution of conjugates purified at about 93%. Conjugate [6] (Table 2) for conjugate obtained by the coupling reaction and conjugate [14] (Table 3) for the conjugate obtained by direct synthesis were used. RFU signals were recorded and summarized in Figure 9. It appeared that from 7 to 60% of ON in the capture solution, no effect on the RFU signal was observed for conjugate obtained by the coupling reaction, whereas for conjugate obtained by direct synthesis, the free ON population immediately reduced the signal intensity. Thus, in this latter case, a competition was evidenced between ONs and conjugates

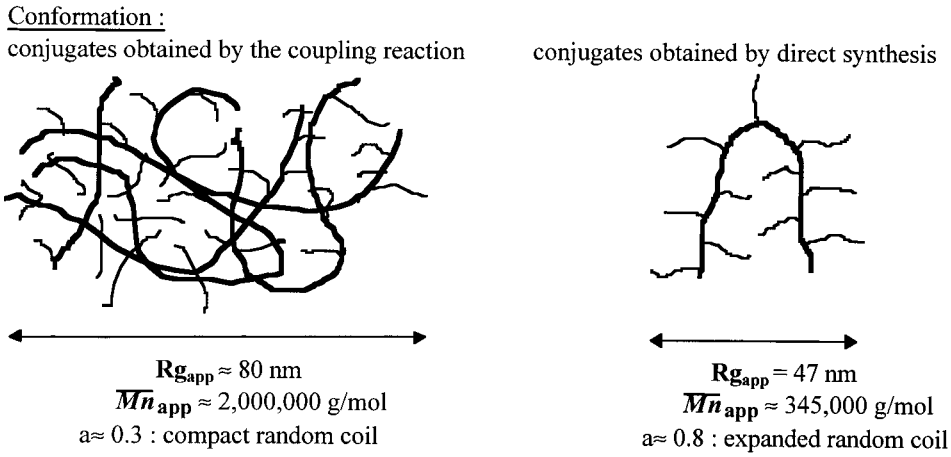

Figure 7. Modeling of conjugate conformation in 0.1 M phosphate buffer/20 mM NaCl pH 6.6. $R_{g,app}$ = apparent radius of gyration and a = form parameter calculated from the Mark−Houwink-Sakurada relationship: $[\eta] = KM^a$.

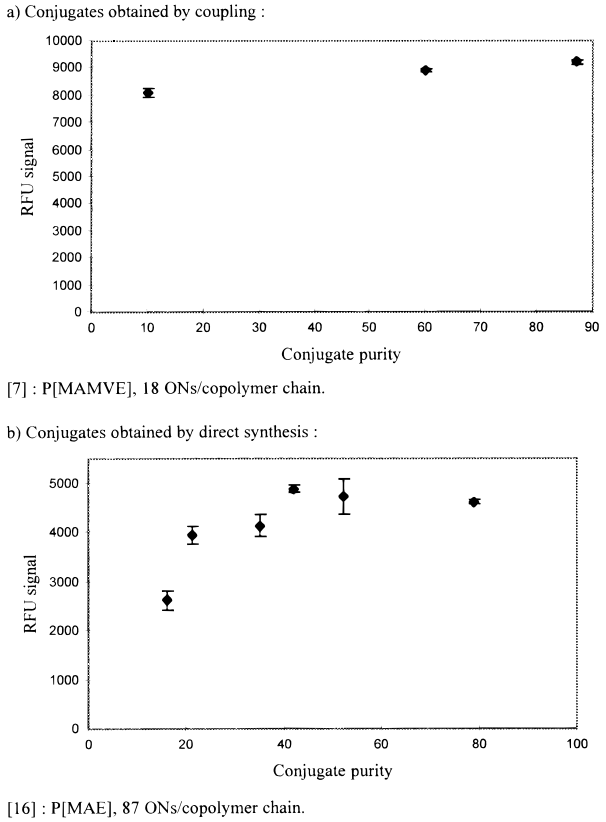

Figure 8. Effect of the conjugate purity on the VIDAS signal. Mean values of duplicate measurements.

for adsorption onto the SPR surface during the capture step. Above 60% of ON in solution, both signals rapidly decreased.

From these studies, it can be concluded that conjugates obtained by the coupling reaction could be used without any purification up to a level of 60% of ONs in the crude product. In contrast, conjugates obtained by direct synthesis required a purification step, because of competition between free ONs and conjugates for coating onto the SPR surface.

Effect of the ON Number per Polymer Chain on the VIDAS Signal. As emphasized in the conjugate structure part, the number of ONs per copolymer chain changed from one conjugate to another, according to the method of synthesis. The effect of this difference on the VIDAS signal was therefore assessed. For all conjugates used

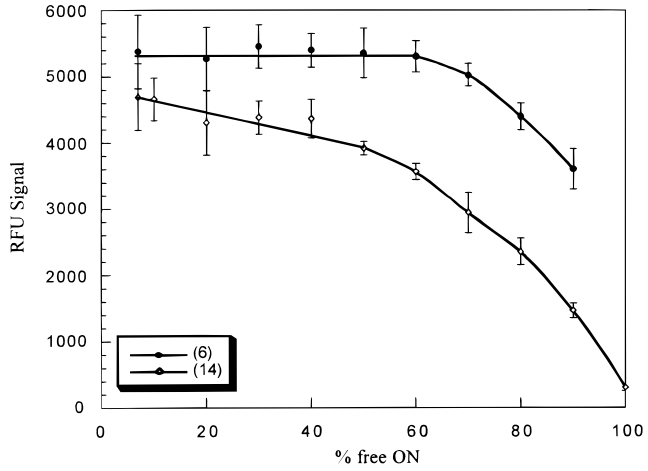

Figure 9. Effect of the percentage of free ON in the capture solution on the VIDAS signal. Mean values of duplicate measurements for a set of three experiments. [6]: P[MAMVE] (obtained by coupling, 93% conjugate purity, 13 ON/copolymer chain). [14]: P[MAE] (obtained by direct synthesis, 93% conjugate purity, 65 ON/copolymer chain).

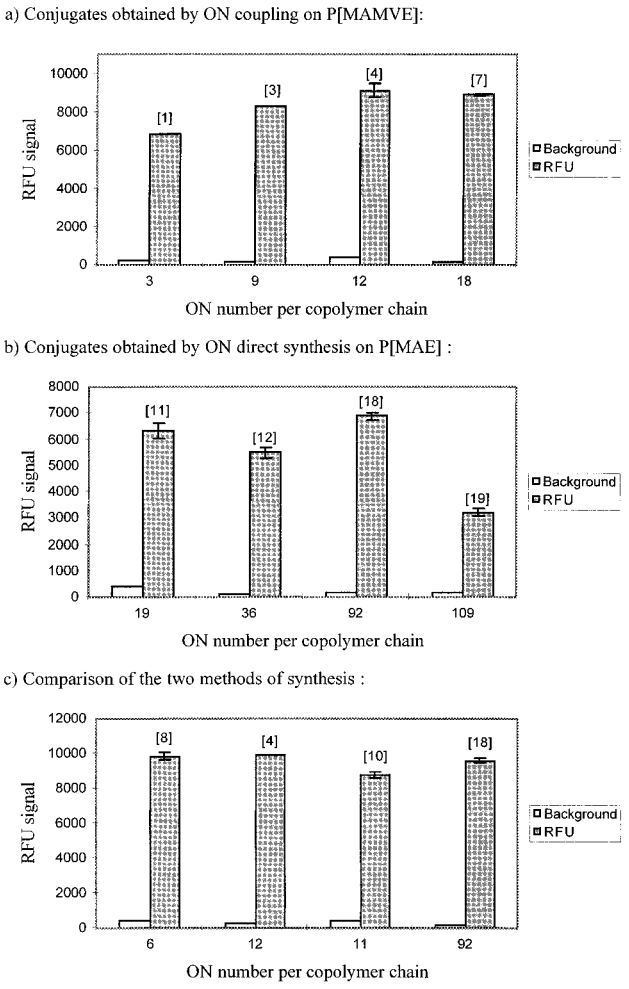
in the experiment, purity was raised to 60% (from 68 to 88%) to directly correlate the result with the influence of the ONs tethered to the copolymer chain. The hybridization test was performed using 10^{10} copies/mL of HBV target. As shown in Figure 10, conjugates exhibited different behaviors. For conjugates obtained by the coupling reaction (Figure 10a), the RFU signal was increased until 12 ONs/copolymer chain and then remained stable. The rise in the signal could be explained by both the increase in the number of ONs and the aggregated form. Indeed, the higher the number of ONs per polymer chain, the more numerous the aggregates observed on chromatography. For conjugate [1], the percentage of aggregated form was close to 55% whereas for conjugate [4], it was close to 80%. Consequently, it seemed that aggregates might play an important role in the capture phase of the ELOSA test. For conjugates obtained by direct synthesis (Figure 10b), the signal intensity remained stable for experiments run with conjugates [11], [12], and [18] (from 19 to 92 ONs/chain). Concerning the most functionalized conjugate (109 ONs bound to a polymer chain that bears around 210 maleic anhydride-ethylene units), the decrease was certainly due to steric hindrance phenomena. Finally, two conjugates obtained by the coupling reaction ([4] and [8]) and two conjugates obtained by direct synthesis ([10] and [18])



Conjugates [8], [10], [18] : P[MAE] ; conjugate [4] : P[MAMVE]

Figure 10. Effect of the number of ONs per polymer chain on the VIDAS signal. Mean values of duplicate measurements. The purity of all conjugates was raised to 60%.

were compared (Figure 10c). For conjugate [8] synthesized with P[MAE], no more than 6 ONs by chain can be obtained. Indeed, as in the case of P[MAMVE], it was not possible to couple a larger amount of ON because of the coupling yield decrease. To control the effect of the copolymer on the VIDAS signal, the two conjugates obtained by the coupling reaction ([4] and [8]) were compared. As can be seen, the RFU signal was identical with both P[MAE] conjugate [8] and P[MAMVE] conjugate [4]. In both cases, the maximum of ONs per polymer chain was reached, leading to the formation of aggregates. As previously discussed, these two parameters (high ON number and aggregate form) were essential for the improvement of test sensitivity. But no other effect was observed on the signal in relation to the length or the comonomer nature of the polymer used. Conjugate [10] was obtained by direct synthesis. In this case, the ON number on P[MAE] was low (11 ONs/chain) and the resulting VIDAS signal was compared to experiments run with conjugates [4] and [8]. It was observed that the signal for conjugate [10] was slightly inferior to those with conjugates [4] and [8]. But, when the number of ONs per chain was increased (conjugate [18]), the RFU signal was partly recovered.

In conclusion, a higher number of ONs for conjugates obtained by direct synthesis could balanced the "aggregate" parameter that improves VIDAS sensitivity.

Comparison of the Two Conjugates. Conjugates [4] and

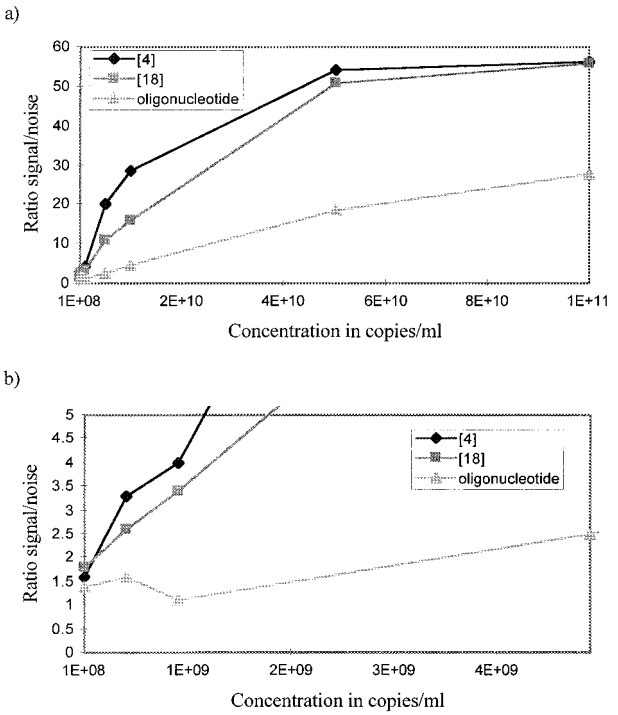


Figure 11. Comparison of conjugates in VIDAS. [4]: P[MAMVE] (obtained by coupling, 87% conjugate purity, 12 ON/copolymer chain). [18]: P[MAE] (obtained by direct synthesis, 80% conjugate purity, 92 ON/copolymer chain).

[18] were compared in a hybridization test using a set of diluted HBV targets from 10^8 to 10^{11} copies/mL. The capture oligonucleotide (ON1, Table 1) was used as a control.

In Figure 11, the signal/noise ratio versus the concentration of HBV target is represented. As can be seen, the ratio increased with the concentration of targets to reach a plateau at 5×10^{10} copies/mL. To determine the sensitivity limit of the conjugates, a cutoff of 2 for the signal/noise ratio, was applied. As shown in Figure 11b, sensitivity was the same for both conjugates, i.e., about 10^8 copies/mL, whereas the capture oligonucleotide used as reference had a sensitivity limit near to 5×10^9 copies/mL. Hence, an amplification factor of 50 was reached by using the conjugates in the capture step.

In conclusion, conjugates obtained by direct synthesis were as efficient as those obtained by the coupling reaction. In both cases, the detection limit was close to 10^8 copies/mL, using P[NVPNAS] conjugate in the detection step.

Quantitation of the ON Number Adsorbed onto the VIDAS SPRs. To clearly understand what occurred during the coating step, an attempt was made to quantify the number of ONs adsorbed on the SPR surface. To do so, radioactive labeling of nucleic acid material was envisioned. The conjugate obtained by the coupling reaction ([5]) and ON1 used as the control were labeled at their 3′ position, whereas conjugates obtained by ON direct synthesis ([10] and [13]) were labeled at their 5′ position. After purification, these "hot" molecules were mixed with a solution of "cold" compounds, at 150 nM. In this case, the concentration of radiolabeled molecules added was negligible. After coating and washing, SPRs radioactivity was measured and the number of picomoles (N) adsorbed were determined according to the following equation:

$$N = \frac{\omega}{A_s} \times \frac{1}{R} \quad (3)$$

where ω is the number of counts per minute (cpm) of the SPR, A_s, the specific activity (cpm/pmol) of compounds, and R, the ratio of the amount of labeled product versus the total amount introduced.

Moreover, it was controlled that neither the SPR screen radioactive signal nor the presence or absence of liquid in the SPR disturb the measure.

As can be seen in Figure 12, a major difference is observed between conjugates and ON1. Indeed, about 1 pmol was adsorbed on the SPR for ON1, whereas from 3 to 7 pmol of nucleic acid material were adsorbed using conjugates. This result was in agreement with VIDAS experiments, which have demonstrated that the use of conjugates versus ON enhanced the signal. Between the conjugates [5] and [13], no difference was clearly evidenced. The conjugate obtained by the coupling reaction gave an average value of 6.4 pmol and about 5.3 pmol of oligonucleotides were coated with the conjugate obtained by the second method. It was also remarked that the standard deviation of ±3.1 pmol observed for conjugate [5] after six experiments seemed to emphasize a lower reproducibility of the coating in this case. Results were correlated with VIDAS experiments where the detection limit was the same with both conjugates, but the signal at 10^{10} copies/mL was slightly higher with conjugate [5] (results not shown). The number of ONs per chain for conjugate [5] was much lower than that of conjugate [13], signifying that the layer of conjugates coated onto the surface was more important in the first case. On the contrary, conjugate [13] obtained by ON direct synthesis was less efficiently adsorbed on the SPR surface, but the resulting amount of ONs coated was almost the same as for conjugate [5]. Between conjugates [5] and [10], a significant difference was observed. Indeed, an average of 2.8 pmol of ONs were coated with conjugate [10] obtained by direct synthesis. In this case, the number of ONs per chain was the same for both conjugates. So the difference in coating could be explained by their difference of structure. Unlike conjugate [10], conjugate [5] was essentially in an aggregated form. It appeared that this latter conformation favored conjugate coating on the SPR surface. Between conjugates [10] and [13], a real difference in coating was also observed. Indeed, for conjugate [13] twice as many picomoles of ONs were adsorbed. As their structure was the same, this difference could be explained by their number of ONs bound to the copolymer chain. These results were in agreement with VIDAS experiments where the signal was higher for conjugate [13] (VIDAS signal was identical for conjugates [13] and [18]).

CONCLUSION

The goal of this study was to assess the effect of conjugate (ONs−polymer) structure on their capacity to increase the detection signal of an ELOSA type diagnostic test.

For this purpose, two different methods of synthesis were studied. One method consisted of coupling 5′ amino modified ONs to P[MAMVE] or P[MAE] reactive polymer and the second methods relied on direct synthesis of ONs from the P[MAE] polymer previously grafted onto CPG support.

It was evidenced by SEC and SEC-MALLS−viscometry that the first method led to a main population of aggregated conjugates, in a compact coil conformation in solution, whereas the second strategy produced nonaggregated conjugates, in an expanded random coil form. Another difference was in the number of ONs linked to the polymer chain. The coupling method allowed a limited number of ONs per chain to be tethered (18 ONs/P[MAMVE], 6 ONs/P[MAE]) in order to keep a correct coupling yield. In contrast, the latter strategy was more efficient, permitting a range from 11 to 109 ONs per P[MAE] chain.

Both conjugates were evaluated for amplification of the detection signal of an HBV DNA hybridization sandwich test developed on a bioMérieux VIDAS instrument. Only the capture step of the test was investigated in this work and the improvement of detection sensitivity was demonstrated with both conjugates. Then, the effect of the free ON population present in the crude products of synthesis was evaluated. A low influence was observed for conjugates from the first method meaning that aggregated conjugates were adsorbed preferentially onto the surface of the VIDAS SPR, during the coating step. In contrast, conjugates obtained by ON direct synthesis appeared to be in competition with free ON population. Their nonaggregated structure was closer to that of a nucleic acid fragment and the higher the percentage of free ON population, the poorer the signal. Finally, it was demonstrated that the use of P[MAE] instead of P[MAMVE] for conjugates obtained by the coupling reaction did not affect the capture efficiency of the test.

After selection of the best conjugates from the two different methods and optimization of their purity, the detection limits of the ELOSA test were improved by both conjugates by a factor 50 compared to the capture oligonucleotide probe used as the reference. At this stage of the work, the question was to know whether one type of conjugate was adsorbed more efficiently on the SPR surface, offering more ONs to capture DNA target, thereby improving test sensitivity, or, on the contrary, one of them simply offered after coating a majority of more accessible ONs for the capture step. An experiment of ^{32}P labeling of the ONs linked to the polymer chain demonstrated that in fact the amount of oligonucleotides coated on the surface was almost the same for both conjugates. As the number of ONs per chain was much lower for the macromolecules obtained by the coupling reaction, this signified that the thickness of the conjugate layer on the SPR surface was much more important in this case. This can be explained by the aggregated compact structure which may favor the adsorption of a bulky layer of conjugates. Regarding capture phase effectiveness, a higher number of ONs tethered to the polymer chain can balanced the lack of aggregates for

conjugates obtained by ON direct synthesis. On the contrary, the second kind of conjugates obtained by direct synthesis may flatten onto the SPR surface because of its more expanded conformation, thereby limiting the amount of molecule coated and possibly, to some extent, the accessibility of few ONs.

In conclusion, it should be interesting to investigate the synthesis of artificial aggregates which could be grafted onto the surface of a CPG support to develop direct ON synthesis. This kind of macrostructure, with a high number of tethered ONs, should be a suitable candidate as a probe for the capture phase of an ELOSA diagnostic test.

ACKNOWLEDGMENT

We wish to thank J. M. Lucas and A. Domard for viscometry analyses and helpful discussions. We also thank M. H. Charles for her precious help in VIDAS experiments, G. Oriol and V. Cheney for ^{32}P labeling, training and advice, and the Fondation Merieux for financial support.

(30) It is important to notice that, in the range of target concentrations from 10^{10} to 10^{12} copies/mL, the relative fluorescent unit (RFU) signal drastically increases to saturate at about 10 000. Consequently, RFU signal fluctuated a lot in this very sensitive area, from 1 day to another. Therefore, results recorded from one series of experiments run at the same time could easily be compared, whereas those corresponding to tests run on different days could not be correlated. In this context, only data obtained from the same set of assays have been compared and discussed in this work.

High-Generation Polycationic Dendrimers Are Unusually Effective at Disrupting Anionic Vesicles: Membrane Bending Model

Zhi-Yi Zhang and Bradley D. Smith*

Department of Chemistry and Biochemistry, University of Notre Dame, Notre Dame, Indiana 46556. Received February 17, 2000; Revised Manuscript Received June 15, 2000

The membrane disruption properties of high generation (G4 to G7) poly(amidoamine) (PAMAM) dendrimers are evaluated and compared to linear poly(lysine). The G6 and G7 dendrimers are unusually effective at inducing leaky fusion of anionic, large unilamellar vesicles, as determined by standard fluorescence assays for lipid mixing, leakage, and contents mixing. Both G7 dendrimer and poly(lysine) are able to disrupt sterically stabilized vesicles that are coated with poly(ethylene glycol). A G7 dendrimer/DNA complex with a 1:1 concentration ratio of dendrimer surface amines to DNA phosphate groups is unable to induce leakage of 3:7 POPA-PE vesicles; however, extensive leakage is observed when the surface amine to phosphate stoichiometry is ≥3:1. Thus, the DNA/dendrimer complexes that typically induce high levels of cell transfection are also able to induce high levels of vesicle leakage. The G7 dendrimer does not induce membrane phase separation in 3:7 POPA-PE vesicles, but an inverse hexagonal phase is observed by ^{31}P NMR. The enhanced membrane disruption is interpreted in terms of a membrane bending model. A rigid, polycationic dendrimer sphere uses electrostatic forces to bend a malleable, anionic membrane and induce bilayer packing stresses. This bending model is biomimetic in the sense that protein-induced membrane bending is currently thought to be an important factor in the fusion mechanism of influenza virus.

INTRODUCTION

Dendritic polymers have a promising future as drug delivery vehicles (*1*, *2*) and as cell transfection agents (*3*−*14*). The hope is that dendrimers will enhance efficacy by improving delivery issues such as targeting, stability, and bioavailability. At present, the field is in its infancy, and the literature contains little discussion of how delivery is likely to occur at the molecular level. In particular, the current understanding of how dendrimers interact with bilayer membranes is quite weak. A major problem is the complexity and heterogeneity of the biomembrane matrix which makes it difficult to interpret results. Similarly, enhanced cell transfection has been reported using polydisperse mixtures of fractured dendrimers as DNA carriers (*3*); however, it is difficult to rationalize these results without knowing more about these complex delivery systems. In an effort to better understand the underlying supramolecular chemistry, we have chosen to study the interaction of monodisperse dendrimers with vesicle membranes.

This paper describes the effects that commercially available polycationic polyamidoamine (PAMAM)[1] dendrimers have on anionic unilamellar vesicles. The PAMAM dendrimers have an ethylenediamine core (Scheme 1) and are prepared by an iterative sequence of reactions (*2*). The number of surface amine groups doubles with each generation and the dendrimer diameter increases incrementally (Table 1). Generations 4 (G4) and below have open structures and ellipsoidal shapes, whereas G5 and above have closed-shell structures and are spherical (*2*, *15*). The goal of the study was to ascertain if PAMAM dendrimers interact with vesicle membranes in a size- or shape-dependent manner. We have evaluated the membrane disruption ability for dendrimer generations G4 to G7, and we find that, compared to linear poly(lysine), the higher generations are unusually effective at disrupting anionic vesicle membranes. A biomimetic membrane bending model is proposed to explain this observation.

EXPERIMENTAL PROCEDURES

All phospholipids including NBD-PE and Rh-PE were purchased from Avanti Polar Lipids. Py-PE, Py-C10-HPM, R18, ANTS, and DPX (Molecular Probes), poly(lysine) HBr salts (Sigma, polydispersity of 1.2), and 49KD-poly(glutamic) acid sodium salt (Sigma, polydispersity of 1.2) were purchased and used without further purification. The 4.7 kb pEGFP-N1 vector (Clontech) was propagated in *Escherichia coli* and purified using a QIAGEN tip and the associated QIAGEN protocol. Fluo-

PAMAM Dendrimers. The dendrimers were purchased from Dendritech. An ongoing concern in dendrimer science is sample purity. It is not straightforward to unambiguously establish the structural purity of high-generation dendrimers. The two most likely impurites are larger dendrimer−oligomers and smaller low-generation structures. A chromatographic analysis of the G7 dendrimers used in this study, conducted by the vendor, indicated that the sample was approximately 90% monodendrimer, 7% oligodendrimer, and 3% low-generation material. Thus, we cannot rule out the possibility that a fraction of the membrane disruption activity induced by the G7 dendrimer sample may be due to a small amount of highly active oligodendrimer impurity. However, even if this is true, the proposed model for dendrimer-induced membrane disruption would be essentially unchanged.

Vesicle Preparation. A solution of lipids in chloroform was evaporated using a rotary evaporator (<30 °C), and the resulting film was dried under vacuum for at least 1 h. The vesicles were dispersed in (1) 25 mM ANTS in 40 mM NaCl/5 mM TES (pH 7.4), (2) 90 mM DPX in 5 mM TES (pH 7.4), or (3) 12.5 mM ANTS/45 mM DPX/20 mM NaCl/5 mM TES (pH 7.4) with the aid of a Vortex mixer. Pyrex glass beads were added before vortexing to facilitate removal of the lipid film from the sides of the flask. The resulting opaque dispersion was frozen in an ethanol/dry ice bath and then allowed to thaw in a water bath at 35−40 °C. This freeze−thaw cycle was repeated 10 times. The resulting mixture was extruded, at room temperature, 29 times through a 19 mm polycarbonate filter (Nucleopore) typically with 100 nm diameter pores using a hand-held Basic LiposoFast device purchased from Avestin. The size of vesicles was routinely checked by dynamic light scattering using a Coulter N4 plus instrument. Separation of untrapped marker compound was achieved by dialysis (15 000 MW cutoff) against 150 mM NaCl.

Lipid Mixing Assays. Extents of lipid mixing were determined using three types of fluorescence probe dilution assays (*16*, *17*). The first two assays use anionic probes whereas the third uses a zwitterionic probe.

NBD-PE/Rh-PE Assay. One population of vesicles contained the probes NBD-PE and Rh-PE (0.6% each), whereas another population was unlabeled. Excitation was set at 470 nm and fluorescence emission was measured at 530 nm using a 515 nm filter. Labeled vesicles were mixed with an equal population of unlabeled vesicles (final lipid concentration was 50 μM) in 3 mL, pH 7.4, of buffer (100 mM NaCl/5 mM TES). Lipid mixing results in an increase in NBD-PE fluorescence intensity due to diminished quenching as the two probes are diluted. The residual fluorescence was taken as 0% lipid mixing, and 100% mixing was set using vesicles containing 0.3% of the probes. Control experiments showed that NBD-PE fluorescence is not affected by interactions with the polycations. For example, addition of polycations to solutions of probe-containing vesicles that had been disrupted with Triton X-100 produced no change in fluorescence.

R18 Assay. Excitation was set at 560 nm and fluorescence emission was measured at 590 nm. The 2% R18 labeled vesicles (5 μM) were mixed with unlabeled vesicles (45 μM) in 3 mL of 100 mM NaCl/5 mM TES (pH 7.4) buffer. The initial fluorescence was taken as 0% lipid mixing and 100% mixing was determined by addition of Triton X-100 to give 0.5%(w/v).

Py-PE assay. Excitation was set at 320 nm and fluorescence emission was measured at 395 and 470 nm. The ratio of I_{470nm}(ex) to I_{395nm}(mon) was determined as a function of time. The 5% labeled vesicles (5 μM) were mixed with unlabeled vesicles (45 μM) in 3 mL of 100 mM NaCl/5 mM TES (pH 7.4) buffer. Vesicles (50 μM) containing 0.5% of Py-PE were used to calibrate the ratio of I_{470nm}(ex)/I_{395nm}(mon) corresponding to 100% lipid mixing.

Leakage Assay. The fluorophore ANTS and its collisional quencher DPX were co-encapsulated in a single population of vesicles. Leakage results in an increase in ANTS fluorescence intensity due to dimished quenching as the two probes are diluted (*17*). Control experiments established that both dendrimer and poly(lysine) slightly enhance the fluorescence of ANTS but the presence of excess poly(glutamate) restores the original fluorescence intensity. Excitation was set at 355 nm and fluorescence emission was measured at 530 nm using a 515 nm filter. At $t = 0$ s, vesicles (50 μM lipid) containing ANTS/DPX were dispersed in 3 mL of 100 mM NaCl/5 mM TES (pH 7.4) buffer, and the residual fluorescence was taken as 0% leakage. At $t = 100$ s, the system was treated with polycation, and at $t = 300$ s, poly(glutamate) was added to eliminate extraneous signal due to polycation/ANTS interaction. The fluorescence intensity corresponding to 100% leakage was determined by addition of 0.3% (w/v) Triton X-100.

Contents Mixing Assay. Attempts to measure aqueous contents mixing using the Tb^{3+}/DPA asssay (*17*) were unsuccessful due to light scattering problems. The use of sodium inositol hexaphosphate as a vesicle deaggregation agent was not helpful in our hands (*18*). The calcein/Co^{2+} assay (*19*) could not be employed due to precipitation of a dendrimer/Co^{2+} complex. A problem with the ANTS/DPX assay (*17*) was enhancement of leaked ANTS fluorescence upon interaction with the

dendrimer; however, the presence of excess poly(glutamate) reverses the polycation/ANTS interaction and restores the original ANTS emission spectrum. At $t = 0$ s, vesicles containing ANTS were mixed in 3 mL of 100 mM NaCl/5 mM TES (pH 7.4) buffer with an equal concentration of vesicles containing DPX (final lipid concentration was 50 μM). At $t = 100$ s, the system was treated with polycation, and at $t = 300$ s, poly(glutamate) was added. The initial fluorescence was taken as 0% contents mixing, and a solution of ANTS/DPX-containing vesicles (50 μM) in 3 mL of 100 mM NaCl/5 mM TES (pH 7.4) buffer was used for the calibration of 100% contents mixing.

^{31}P NMR. Aqueous lipid dispersions were prepared by vortexing 50 mM POPA/PE (3:7) in 1.0 mL of an aqueous buffer (100 mM NaCl, 5 mM TES, pH 7.4) and then adding of G7-PAMAM dendrimer or 100K-poly(lysine) (10 mM of surface amines). Prior to the NMR measurements, 0.1 mL of D_2O was introduced into the samples. The ^{31}P NMR spectra (121 MHz) were acquired at 25 °C using a phase-cycled Hahn spin−echo sequence (*20*). In each case, about 1000 scans were collected with a recycling delay of 3 s and line broadening of 100 Hz. The chemical shifts are relative to small phosphatidylcholine vesicles at 0 ppm.

Dendrimer Internalization Assays. Three different methods were used to detect dendrimer entry into 3:7 POPA/PE vesicles.

HPTS/DPX Assay (21). A dispersion (311 μL) of G7-PAMAM, the water-soluble anionic dye HPTS, and 3:7 POPA/PE vesicles (200 nm) was incubated for 200 s at 25 °C and then added to a gently stirred solution of 40 mM DPX (2689 μL) (final concentrations: G7-PAMAM surface amine 10 μM, HPTS 1.0 μM, and phospholipids 1.0 mM). The intensity of the HPTS emission at 510 nm was measured using the pH-independent excitation wavelength of 413 nm (I). In a separate experiment, the HPTS intensity was measured for a sample that contained water instead of 40 mM DPX (I_{100}). Finally, aqueous Triton X-100 was added (0.5% w/v) to the DPX containing sample and the intensity of the HPTS emission at 413 nm was remeasured (I_0). The percentage of internalized HPTS was calculated as $(I - I_0)/(I_{100} - I_0) \times 100\%$.

NBD-Taurine Assay. To a mixture of G7-PAMAM (5 μM of surface amine) and NBD-taurine (0.5 μM) in 3 mL of buffer (100 mM NaCl, 5 mM TES, pH 7.4) were added 3:7 POPA/PE vesicles (50 μM; 100, 200, or 400 nm). After incubation at 25 °C for 200 s, the dispersion was treated with poly(glutamate) (250 μM of surface carboxylate), and then 200 s later, the intensity of the NBD-taurine emission at 530 nm using excitation wavelength of 470 nm was measured (I_{100}). Sodium dithionite (30 mM) was added and the NBD-taurine emission was measured after 10 min (I). Finally, aqueous Triton X-100 was added (0.5% w/v) and the NBD-taurine emission was measured (I_0). The percentage of internalized NBD-taurine was calculated as $(I - I_0)/(I_{100} - I_0) \times 100\%$.

NBD-G7 Assay. An NBD−dendrimer conjugate (10% NBD−G7) with 10% of the surface dendrimer amines labeled with NBD was prepared by stirring a mixture of G7-PAMAM (9.1 mg, 40 μmol surface amine) and 7-nitrobenz-2-oxa-1,3-diazol-4-chloride (NBD-Cl, 0.8 mg, 4.0 μmol) in methanol (500 μL) in the dark at room temperature for 18 h. TLC (silica gel/chloroform) indicated that the NBD-Cl was consumed. The solvent was evaporated to give a yellow solid which was used without purification. To a solution of 10% NBD−G7 (10 μM of surface amine) in 3 mL of buffer (100 mM NaCl, 5 mM TES, pH 7.4) was added 3:7 POPA/PE vesicles (200 nm, 1.0 mM). After incubation at 25 °C for 200 s, the intensity of the 10% NBD−G7 emission at 530 nm was measured using excitation wavelength of 470 nm (I_{100}). Sodium dithionite (30 mM) was added and the emission was measured after 10 min (I). Finally, aqueous Triton X-100 was added (0.5% w/v) and the 10% NBD−G7 emission was measured (I_0). The percentage of internalized 10% NBD−G7 was calculated as $(I - I_0)/(I_{100} - I_0) \times 100\%$.

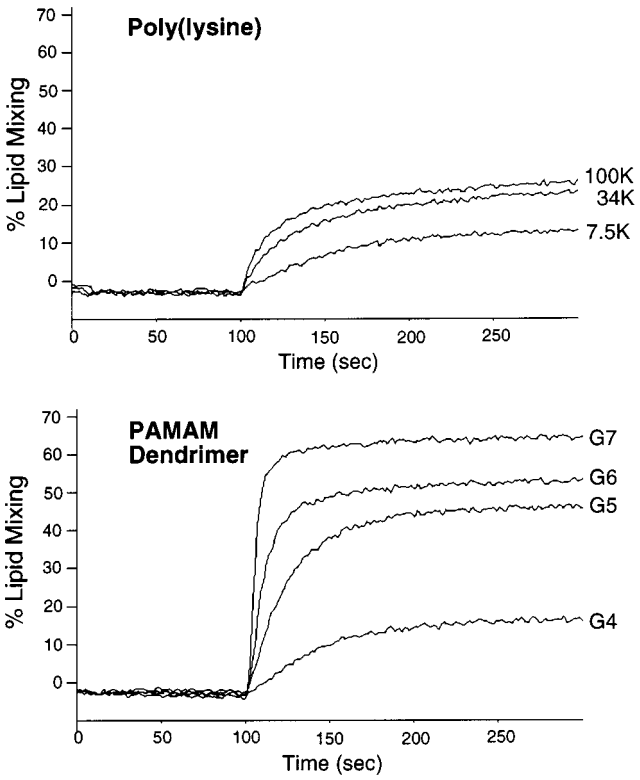

Figure 1. Lipid mixing of 3:7 POPA/PE vesicles at pH 7.4 and 25 °C. A population of vesicles containing NBD-PE/Rh-PE was mixed with an equal amount of unlabeled vesicles (final [phospholipid] = 50 μM), and treated with polycation at $t = 100$ s. In each case, the concentration of polymer surface amines was 10 μM.

RESULTS

Lipid Mixing. The polycation-induced intermixing of lipid bilayers was monitored using three different fluorescence probe dilution assays (*16, 17*) Generally, the resonance energy transfer pair of NBD-PE and Rh-PE was employed. Since these probes are anionic and the fusogens are polycationic, it was important to eliminate the possibility of artifacts due to probe transfer, phase separation, and probe/polycation interaction. Therefore, a number of the lipid-mixing experiments were repeated using the R18 probe or the zwitterionic Py-PE. In essentially all cases, the lipid mixing results were found to be probe independent.

The first vesicles examined were anionic, large unilamellar vesicles (LUVs, 100 nm diameter) composed of 3:7 POPA/PE. Two equal populations of 3:7 POPA/PE vesicles were mixed at $t = 0$ s (final concentration of phospholipid was 50 μM). One population contained the NBD-PE and Rh-PE, whereas the other was unlabeled. An aliquot of polymer was added at $t = 100$ s, to give a final concentration of polymer surface amines of 10 μM. As shown in Figure 1 and Table 2 (entry 1), the extent of lipid mixing increased only slightly with the molecular weight of poly(lysine), but increased markedly with dendrimer molec-

ular weight. Furthermore, a high-generation dendrimer was more effective than a poly(lysine) with a similar number of surface amines. When excess poly(glutamate), a strong binder of polycations (*22*), was added to the vesicles before the polymer, no lipid mixing occurred, indicating that electrostatic interactions are driving vesicle aggregation and the subsequent lipid mixing.

The effect of polycation concentration on lipid mixing was examined using G7 dendrimer and 100K-poly(lysine). As shown in Figure 2a, the general trend is the same for both polycations; that is, the extent of lipid mixing of 3:7 POPA/PE vesicles initially increases with concentration, reaches a maximum, and then decreases (*18*, *23*, *24*) At low concentrations, the polycations cross-link and aggregate the anionic vesicles, but at higher concentrations the polycations coat the vesicles and hinder close approach. In the case of poly(lysine), lipid mixing was a maximum when the concentration ratio of surface amine to POPA was 1, an observation that has been noted before (*23*). In the case of G7 dendrimer, lipid mixing was maximal when the ratio of surface amine to POPA was about 3. The higher charge ratio is likely due to the rigid and spherical structure of the dendrimer which can only contact a vesicle with a fraction of its available surface amines. Thus, a higher concentration of surface amines is needed to reach the optimal level of cross-linking and charge neutralization.

The results of vesicle composition studies are summarized in Table 2 (entries 1−7). When the fusion inhibitor POPC (*18*, *25*) was used instead of PE, almost no lipid mixing was observed with G7 dendrimer (compare entries 1 and 3). However, significant lipid mixing occurred when the fraction of POPA was increased (compare entries 3 and 5). Interestingly, there was little or no lipid mixing induced by 100K-poly(lysine) when PS was used instead of POPA (compare entries 1 and 2 and 5 and 6) or even when the LUVs were composed of 100% PS (entry 7). This observation is in agreement with a previous study using LUVs (*18*), but contrasts with a report that poly(lysine) is able to fuse SUVs containing PS (*23*).

As summarized in Table 3, the presence of 2% PEG-2000-DOPE in 3:7 POPA/PE vesicles greatly decreases the extent of lipid mixing induced by $CaCl_2$ (entry 10). In this case, aggregation of the sterically hindered vesicles, a requisite step for fusion, is greatly inhibited (*26*). In contrast, both G7-PAMAM dendrimer (entries 12 and 13) and 100K-poly(lysine) (entries 14 and 15) are still able to induce the sterically stabilized vesicles to undergo significant amounts of lipid mixing. A study of lipid mixing as a function of G7 dendrimer concentration resulted in a bell-shaped profile that closely matches that seen with conventional 3:7 POPA/PE vesicles (Figure 2).

The effect of added NaCl on polycation-induced lipid mixing of 3:7 POPA/PE vesicles is summarized in Table 4. Surprisingly, the extent of lipid mixing increases with increasing NaCl concentration. This relationship is the reverse to that observed with Ca^{2+}-mediated fusion (*27*).

Leakage. Leakage was measured using the ANTS/DPX fluorescence assay (*17*) As shown in Figure 3 and Table 2 (entry 8), low and high molecular weight poly(lysine) induced very little leakage. The same result was obtained with the low-generation dendrimers but the G6 and G7 dendrimers induced rapid and drastic leakage. When excess poly(glutamate) was added before the polycations no leakage occurred. Leakage from conventional and sterically stabilized 3:7 POPA/PE vesicles was

[a] [phospholipid] = 50 μM, 5 mM TES buffer, pH 7.4, 25 °C, lipid mixing uncertainty ± 5%. [b] Concentration ratio of polycation surface amines to POPA was 2:3.

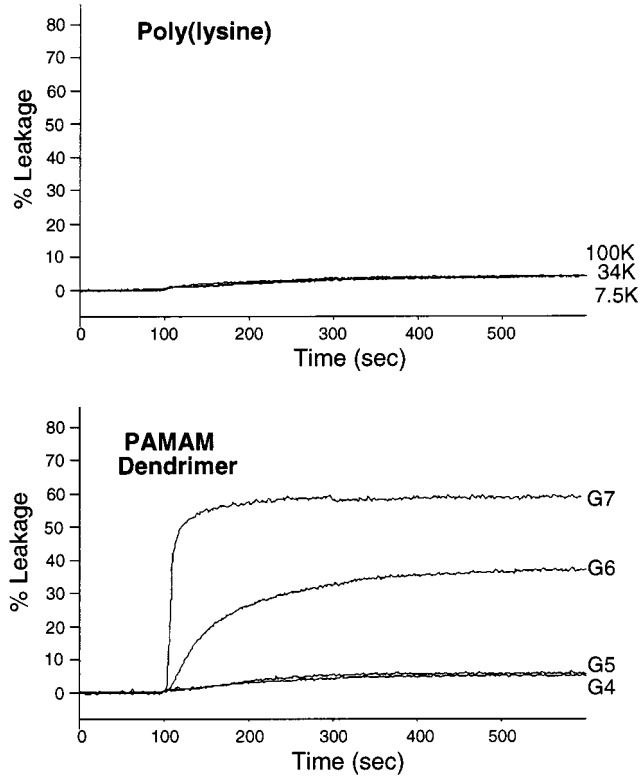

Figure 3. Leakage from 3:7 POPA/PE vesicles (100 nm, [phospholipid] = 50 μM, pH 7.4, 25 °C) containing ANTS/DPX. The vesicles were treated with polymer at t = 100 s (in each case, the concentration of polymer surface amines was adjusted to 10 μM), and with poly(glutamate) (500 μM carboxylates) at t = 300 s.

monitored as a function of G7-PAMAM concentration. As shown in Figure 4, both systems exhibit bell-shaped dependencies that are very similar to the lipid mixing profiles in Figure 2.

The leakage of ANTS/DPX from 3:7 POPA/PE vesicles at pH 7.4 (100 mM NaCl/5 mM TES) and 25 °C induced by complexes of DNA and G7 dendrimer is shown in Figure 5. DNA (pEGFP-N1 vector, 4.7 kb, the plasmid codes for enhanced green fluorescent protein and is commonly used to measure cell transfection efficiency)

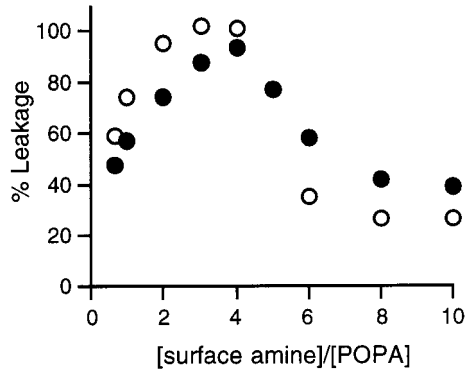

Figure 4. Leakage as a function of the concentration ratio of G7-PAMAM surface amines to POPA (pH 7.4, 25 °C); (○) 3:7 POPA/PE vesicles (100 nm, [phospholipid] = 50 μM); (●) sterically hindered 3:7 POPA/PE vesicles containing 2% PEG-2000-DOPE. Uncertainty ± 5%age units.

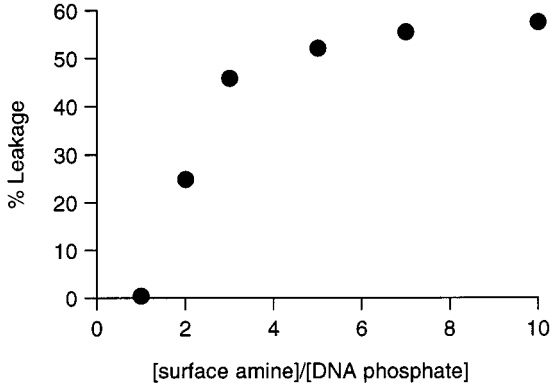

Figure 5. Leakage from 3:7 POPA/PE vesicles (100 nm, 50 μM lipid, pH 7.4, 25 °C) containing ANTS/DPX, induced by G7 dendrimer/DNA complexes at different concentration ratios of dendrimer surface amine to DNA phosphate groups. In each case, the concentration of G7 dendrimer surface amines was 10 μM.

and G7 dendrimer were mixed at different concentration ratios of dendrimer surface amine to DNA phosphate group. After 5 min, the dendrimer/DNA complexes were added to the vesicles (50 μM phospholipid) at pH 7.4 (100 mM NaCl/5 mM TES). In each case, the final concentration of G7 dendrimer surface amines was 10 μM. No leakage was observed when the surface amine/DNA phosphate ratio was unity, whereas the leakage induced by a surface amine/DNA phosphate ratio of 3:1 was 80% of the extensive leakage induced by G7 dendrimer alone. Previous work has shown that monodisperse particles are formed when the surface amine/DNA phosphate ratio is 3:1, with diameters around 100 nm and ζ-potentials of +50 mV (*28*−*30*).

Contents Mixing. The amount of contents mixing of 3:7 POPA/PE vesicles, determined using the ANTS/DPX assay (*17*), is summarized in Table 2 (entry 9). Poly(lysine) induced a modest amount of contents mixing at

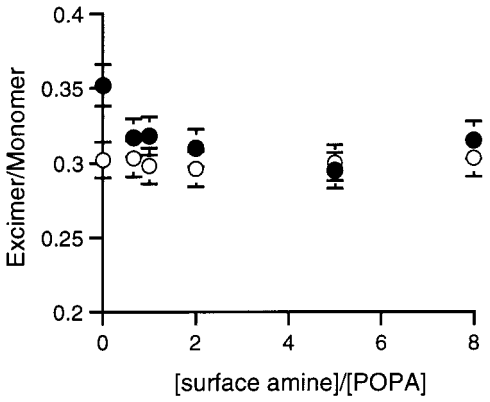

Figure 6. Excimer/monomer ratio as a function of the concentration ratio of G7-PAMAM surface amines to POPA (3:7 POPA/PE vesicles, 100 nm, 50 μM phospholipid, pH 7.4, 25 °C); (○) Py-PE; (●) Py-C10-HPM.

about the same rate as lipid mixing (see Figure 1). Very little contents mixing was observed with G6 and G7 dendrimers because leakage was so rapid and extensive.

Membrane Fluidity. Pyrene-containing lipids are used as probes to detect lateral phase separation and changes in membrane fluidity (*31*, *32*). Polycations have been shown to induce phase separation in certain anionic membranes, which is reflected by an increase in the pyrene excimer/monomer ratio (*31*), whereas in other cases, an observed decrease in excimer/monomer ratio has been interpreted as a decrease in the rate of lateral diffusion (*31*, *32*). Two pyrene-containing probes were used in this study, zwitterionic Py-PE and anionic Py-C10-HPM. Addition of increasing amounts of G7 dendrimer to 3:7 POPA/PE vesicles containing 5% Py-PE (50 μM lipid, pH 7.4) resulted in no detectable change in the excimer/monomer ratio (Figure 6). Addition of increasing amounts of G7 dendrimer to 3:7 POPA/PE vesicles (50 μM lipid, pH 7.4) containing 5% Py-C10-HPM produced a U-shaped dependence, with an initial decrease in the excimer/monomer ratio followed by a subsequent increase (Figure 6). The data indicates that G7 dendrimer does not induce phase separation in 3:7 POPA/PE vesicles, does not effect the lateral diffusion of the zwitterionic PE, but does slow the diffusion of the anionic POPA. The U-shaped dependence on excimer/monomer ratio has been noted before (*31*−*33*) and is attributed to the gradual delocalization of positive sites as the membrane surface becomes saturated with polycation.

^{31}P NMR spectroscopy. ^{31}P NMR line shapes are often used to identify changes in membrane morphologies (*34*). For example, ^{31}P NMR was employed in conjuction with freeze−fracture techniques to show that the near-spherical polycationic protein, cytochrome *c*, induces anionic cardiolipin-containing membranes to undergo a phase change from bilayer to inverse hexagonal, H_{II} (*35*). In contrast, linear poly(lysine) does not induce such a morphology change to inverse membrane curvature (*36*). A similar result is seen in Figure 7, which shows the change in ^{31}P NMR line shapes upon treatment of 3:7 POPA/PE vesicles (50 mM lipid, pH 7.4, 5 mM TES, 100 NaCl) with polycation. In the absence of polycation the typical bilayer pattern is observed (Figure 7A). Addition of poly(lysine) (10 mM of surface amines) results in precipitation with no major change in line shape (Figure 7B). Addition of G7-PAMAM dendrimer (10 mM of surface amines) also produces a precipitate, but there is concomitant formation of hexagonal II phase as reflected by the reduced line width and the characteristic reverse peak asymmetry (Figure 7C) (*34*, *35*)

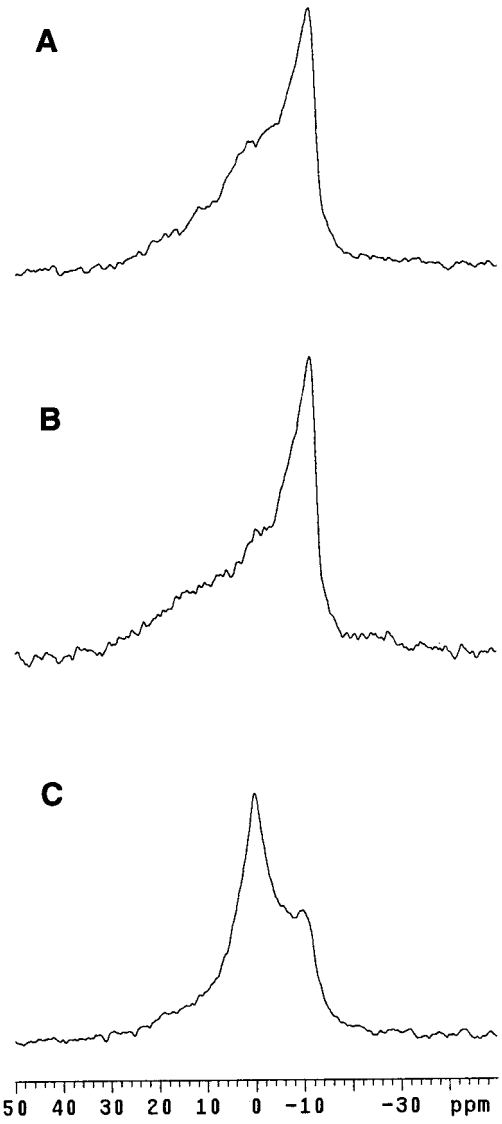

Figure 7. ^{31}P NMR spectra of 3:7, POPA/PE vesicles (50 mM phospholipid) in 5 mM TES, 100 mM NaCl, pH 7.4, 25 °C. (A) no addition, (B) addition of 100K-poly(lysine) (10 mM surface amines), (C) addition of G7-PAMAM dendrimer (10 mM surface amines).

No Dendrimer Internalization. Three related assays were used to determine if the G7-PAMAM dendrimers were internalized by 3:7 POPA/PE vesicles at pH 7.4. The first method was recently described by Tedesco and Matile (*21*). Vesicles (3:7 POPA/PE, 200 nm) were treated with dendrimer (at low surface amine to POPA) and the anionic fluorescent dye HPTS. If the dendrimers entered the vesicle by an endovesiculation mechanism, then presumably some HPTS should also be internalized at the same time. The internalized HPTS can be detected because it is protected from the externally added quencher DPX (*21*). The second method employed the anionic water soluble dye NBd-taurine as a replacement for HPTS and used externally added sodium dithionite as a chemical quencher of the NBD-taurine (*37*) Both methods were unable to produce evidence for internalization of the anionic dyes. A third method resorted to covalent attachment of the NBD dye to the PAMAM dendrimer. A dendrimer−NBD conjugate (10% NBD−G7) was prepared with 10% of the surface dendrimer amines labeled with NBD. Incubation of the 10% NBD−G7 conjugate with excess 3:7 POPA/PE vesicles, and subsequent chemical quenching by dithionite again showed no evi-

dence for internalization of the NBD−G7 conjugate. We conclude that the dendrimers are not internalized into a protective environment within the vesicles, although the results do not rule out the possibility that dendrimers enter the vesicles but remain accessible to the quenching probes.

DISCUSSION

Membrane Disruption Using Poly(Lysine). Peptidyl polycations such as poly(lysine) are well-known to bind tightly to anionic vesicles [each basic residue contributes about 1 kcal/mol to the membrane binding energy (*38*, *39*)] and promote vesicle−vesicle interaction. The specific outcome (aggregation, leakage, lipid mixing, contents mixing) depends on the composition and size of the vesicles. For example, poly(lysine) promotes the aggregation and complete fusion of anionic SUVs (*23*, *40*), whereas treatment of LUVs with poly(lysine) usually results in hemifusion, i.e., lipid mixing only and no mixing of aqueous contents (*18*, *41*). The increased fusogenicity of SUVs is attributed to the greater membrane curvature strain (*42*).

During the course of this study we confirmed a previous report (*18*) that poly(lysine) is able to promote the lipid mixing of PA-containing LUVs more effectively than PS-containing LUVs (entries 1, 2, 5−7, Table 2). This may be due to the different structures that poly(lysine) forms on the membrane surfaces. It is well-established that poly(lysine) is a random coil in neutral solution, but adopts a β-sheet on a PA membrane surface (*43*−*45*), and forms α-helices on a PS membrane surface (*46*). The same conformations but with reduced content are also observed in mixed PA−PC (*47*) and PS−PC (*46*) vesicles. In addition, there is evidence that poly(lysine) induces significant lateral phase separation in PA−PC vesicles (*44*, *45*, *48*) but not so in PS−PC (*46*) or PS−PE vesicles (*32*). Thus, poly(lysine) β-sheets on a PA surface appear to induce more lipid mixing than α-helices on a PS surface. The β-sheet structures may force a closer approach of apposed dehydrated surfaces, and/or increase the number of surface defects due to lateral phase separation (*49*).

Membrane Disruption Using PAMAM Dendrimers. High-generation PAMAM dendrimers are unusually effective at disrupting anionic vesicles. Specifically, G6 and G7 dendrimers rapidly induce large amounts of lipid mixing and leakage of aqueous contents (Figures 1 and 3). They are much more effective than low-generation PAMAM dendrimers or poly(lysine) of any molecular weight, even when the polymer concentrations are adjusted so that the number of exposed surface amines is constant. For example, G7 dendrimer (20 nM of polymer) induces four times more lipid mixing and twelve times more leakage in 3:7 POPA-PE vesicles (50 μM total lipid) than an 8-fold higher concentration of G4 dendrimer (160 nM of polymer).

Both G7-PAMAM and 100K-poly(lysine) are able to disrupt sterically hindered, PEG-containing vesicles that are otherwise resistant to Ca^{2+}-induced fusion (Table 3, Figure 2, and Figure 4). Apparently, the polycations are able to overcome the surface hydration barrier provided by the external PEG chains and force the apposed membranes to undergo lipid mixing. Similarly, Ca^{2+}-mediated fusion is strongly inhibited by increasing NaCl concentrations (*27*), but the lipid mixing induced by PAMAM dendrimers and poly(lysine) actually increases with NaCl concentration (Table 4). Na^+ ions are thought to affect fusion in opposing ways (*50*). They can associate with the anionic bilayer surface and promote lipid mixing because of charge neutralization. Conversely, they can inhibit vesicle aggregation by increasing the thickness of the repulsive hydration layer at the membrane surface (*50*). It appears that even in the presence of high NaCl concentrations, 100K-poly(lysine) and especially G7-PAMAM dendrimer are still able to cross-link the vesicles (*38*, *39*) and, because of increased charge neutralization, induce enhanced lipid mixing.

In general, the best cell transfection results with PAMAM dendrimers are observed with high-generation homologues and when the ratio of dendrimer surface amines to DNA phosphate groups is greater than unity (*3*−*14*, *29*). The dendrimer/DNA complexes formed under these conditions are irregular polycationic aggregates (*29*, *51*). We find that a G7 dendrimer/DNA complex with a 1:1 concentration ratio of dendrimer surface amines to DNA phosphate groups is unable to induce leakage of 3:7 POPA-PE vesicles; however, extensive leakage is observed when the surface amine to phosphate stoichiometry is $\geq$3:1 (Figure 5). Thus, the polycationic DNA/dendrimer complexes that typically induce high levels of cell transfection also induce the highest levels of vesicle leakage. The dendrimer/vesicle interaction is strongly dependent on the vesicle membrane composition. The polycationic dendrimers disrupt different types of anionic vesicles, especially PE-containing vesicles (Table 2). They do not disrupt zwitterionic PC vesicles (*52*, *53*) or anionic vesicles containing a high fraction of PC (Table 2). This membrane selectivity may explain some of the differences in transfection efficiencies and cell toxicities observed with different cell lines (*3*−*14*).[2]

Membrane Bending Model. Why are the higher generation dendrimers better at disrupting anionic membranes? Although a definitive answer cannot be provided at this time, it is worth emphasizing that high-generation PAMAM dendrimers are monomolecular weight polycations with spherical shapes of known diameters (Table 1) and that these structural attributes greatly simplify any analysis of their supramolecular properties. What can be stated with some certainty is that the observed membrane disruption is not due to a simple detergent effect. PAMAM dendrimers are highly water-soluble polycations [essentially all of the surface amine groups are protonated at neutral pH (*54*)]. The outer surface of a high-generation PAMAM dendrimer is highly congested and unlikely to be deeply penetrated by a phospholipid (*2*, *15*, *55*, *56*). Recent EPR studies show that there is very little interaction between G2-PAMAM dendrimers and zwitterionic DMPC vesicles (*52*). A modest interaction is observed with G7 dendrimers which leads to a partially perturbed bilayer structure, but the integrity of the membrane is preserved (*52*).

With anionic vesicles, the interaction is an electrostatic attraction between a malleable, anionic bilayer membrane (radius of curvature $\sim$50 nm), and a rigid, cationic dendrimer sphere (radius of curvature $\sim$4 nm). This leads to dendrimer-induced membrane bending as shown in Figure 8. When a polycationic dendrimer binds to the

[2] The vesicle disruption events reported in this paper are much faster than the process of cell transfection which occurs over a period of hours. However, it should be noted that the vesicles were typically composed of POPA/PE, an unnatural vesicle composition that was used specifically because of its relative instability and the expectation that the vesicles would magnify any disruption effect. At present it is not known if high generation PAMAM dendrimers have a special ability to disrupt biological membranes.

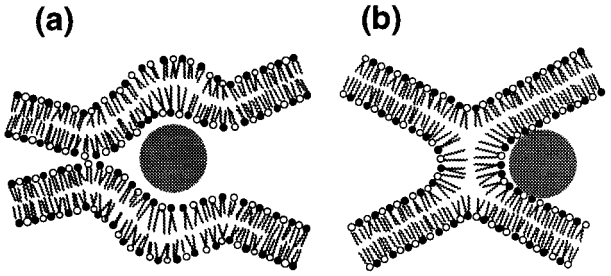

Figure 8. Schematic representation of dendrimer-induced bending of bilayer membranes. Lipids with black headgroups represent anionic phospholipids, the others may be zwitterionic phospholipids. (a) Cross section of a polycationic dendrimer that cross-links the exterior surfaces of two anionic vesicles. Electrostatic forces bend the bilayer surfaces and induce local regions of inverse curvature. (b) Cross-section of a polycationic dendrimer bound to two hemifused vesicles at the periphery of the vesicle-vesicle contact point.

exterior of an anionic vesicle, electrostatic forces bend the bilayer surface (*57*), and induce a local region of inverse curvature (*58*), which in turn induces packing stresses (*59*). If a dendrimer is situated at the connection point of two or more vesicles (Figure 8a) then the packing stresses lead to enhanced lipid mixing. Lipid mixing at a contact point on one side of the dendrimer produces the hemifused intermediate shown in Figure 8b. The structure has inversely curved surfaces at the periphery of the vesicle−vesicle contact point (*57*−*60*). We propose that high-generation polycationic dendrimers facilitate lipid mixing by electrostatically stabilizing these inversely curved, anionic surfaces (Figure 8b).[3] The crucial structural factors are the dendrimer's polycationic charge, rigid spherical shape, and highly congested exterior surface. The following observations support this hypothesis. (i) The vesicle disruption effect is specific for high-generation PAMAM dendrimers and is diminished with low-generation dendrimers or linear poly(lysine) of any molecular weight. (ii) Vesicle disruption is greatly diminished when POPC is used instead of PE (Table 2, compare entries 1−4). The PC headgroup is larger and more heavily hydrated than the PE headgroup (*58*) and it is energetically more costly for bilayers containing PC to adopt inverse curvature (*18*, *57*−*60*). (iii) ^{31}P NMR (Figure 7) shows that G7 dendrimer acts like the near-spherical polycationic protein, cytochrome *c* (*35*), and induces bilayer membranes to adopt an inverse hexagonal II phase. Linear poly(lysine) does not induce such a change to inverse curvature. (iv) The area per surface amine for PAMAM dendrimers decreases with each generation, and by G7 is about 70 Å^2/surface amine (see Figure 37 in ref *2*) which is close to the headgroup area for a typical fluid-phase bilayer membrane. Thus, the matched spacing between surface groups may lead to optimal charge neutralization and optimal membrane bending strain. (v) The dendrimer-induced membrane bending model is biomimetic in the sense that protein-induced membrane bending is thought to be an important factor in the fusion mechanism of Influenza virus (*62*, *63*).

[3] The hemifused intermediate shown in Figure 8b is often referred to as a stalk, and is an intermediate in the stalk fusion mechanism. However, the stalk hypothesis describes the fusion of uncharged membranes where electrostatic effects are minimal. Thus, this study of anionic membranes is not a test of the stalk hypothesis, but it does raise the possibility that some biological fusion systems may operate by a mechanism that is similar to that described in Figure 8b (*61*).

In addition to membrane bending, other factors may be contributing to the dendrimer's enhanced vesicle disruption ability. One possibility is lateral phase separation, which is thought to be an important factor in Ca^{2+}-mediated fusion (*50*). Polycations have been shown to induce phase separation in a number of anionic membrane compositions (*33*, *44*, *45*, *48*, *64*) but not so in others (*32*, *46*). We are unable to detect dendrimer-induced phase separation in 3:7 POPA/PE vesicles (Figure 6), but we cannot rule out transient microdomains. Another factor that cannot be discounted at present is an interaction between the dendrimer and the membrane surface. Poly(lysine) is thought to be situated above the polar headgroup region of the membrane, with perhaps a water monolayer between (*38*, *39*, *65*). An unusual structural feature with high generation PAMAM dendrimers is the densely packed spherical surface, which may not be properly hydrated for steric reasons. Thus, the dendrimers may possess an unusual ability to interact with, or dehydrate, the polar headgroups at the bilayer surface which may lead to enhanced fusion.

Drug Delivery and Cell Transfection. The membrane bending model suggests that dendrimers may be useful as fusion catalysts. Indeed, a polycationic G9 dendrimer was recently shown to dramatically enhance the fusion of reteroviral-infected murine cells (*66*). Thus, it may be possible to use dendrimers to improve vesicle-mediated drug delivery. The dendrimers could promote vesicle−cell fusion which would allow vesicle-encapsulated drugs to enter the cell.

As drug delivery vehicles, dendrimers can be viewed as either endo receptors with the drugs encapsulated in the dendrimer internal cavities (*1*, *2*, *56*) or they can be used as exo receptors with drugs bound to the dendrimer surfaces. An example of the latter approach is cell transfection. The recent commercial availability of PAMAM dendrimers has led to their increased use as cell transfection agents (*3*−*13*). Cell transfection is a complicated multistep process, but in many cases, it appears that transfection is mediated by endocytosis, and there is evidence that exit from the endosome is the step that controls transfection efficiency (*28*). Our results show that high generation PAMAM dendrimers have an unusual ability to disrupt bilayer membranes, which suggests that they may be able to permeate from endosomes. We tested this idea by trying to detect dendrimer entry into vesicles. Our lack of success does not necessarily mean that PAMAM dendrimers cannot pass through endosomal membranes.[2] It may be that the outward curvature of the vesicles prevents dendrimer influx. In the case of endosomal exit, the transport process is efflux which should be more favorable because the membrane curvature is reversed. Nonetheless, our inability to detect dendrimer internalization emphasizes the point that other cell transfection mechanisms have been proposed. For example, the enhanced transfection has been attributed to the dendrimer acting as a proton sponge in the acidic endosomes which leads to osmotic swelling and endosome lysis (*3*). Another possibility is increased resistance to DNA degradation (*29*, *30*). Finally, fractured dendrimers have been reported with enhanced transfection activities, an observation attributed to their more flexible structures (*3*, *8*). It is apparent that further studies are needed to clearly delineate the factors controlling gene delivery using PAMAM dendrimers (*29*, *30*, *51*).

CONCLUSION

We find that high-generation, polycationic PAMAM dendrimers are able to disrupt anionic vesicles much better than low-generation dendrimers or linear poly(lysine). The high-generation dendrimers also have a special ability to induce anionic membranes to adopt inverse curvature. The results are rationalized in terms of a dendrimer-induced membrane bending model. Although the model is somewhat speculative, it does provide a simple physical picture that suggests how polycationic dendrimers may act in various drug delivery and cell transfection applications.

ACKNOWLEDGMENT

We thank Y. Vandenburg for preparing the DNA plasmid samples and Dr. J. Zajicek for assistance with the ^{31}P NMR. This work was supported by the National Institutes of Health (GM 59078).

Synthesis of Multiacyl Poly(ethylene glycol) for the Conjugation of Cytochrome *c* to Phospholipid Vesicle

Haruki Ohkawa, Yuji Teramura, Shinji Takeoka, and Eishun Tsuchida*

Department of Polymer Chemistry, Advanced Research Institute for Science and Engineering, Waseda University, Tokyo 169-8555, Japan. Received March 6, 2000; Revised Manuscript Received August 14, 2000

To conjugate water-soluble macromolecules on the surface of phospholipid vesicles, we synthesized a poly(ethylene glycol) (PEG)-lipid having four acyl chains using a lysine (Lys)-type monodendron structure. One end of the diamino-PEG was amidified with Lys, and then two amino groups of the Lys moiety were amidified with two Lys derivatives which had been acylated with two stearoyl groups. The other end of the PEG was activated with a triazine group or a pyridyldithio group. The hydrate of the lipid mixture of dipalmitoylphosphatidylcholine, cholesterol, dipalmitoylphosphatidylglycerol, and the PEG-lipid at a molar ratio of 5/5/1/0.3 was extruded in order to prepare the phospholipid vesicles with the average diameter of 270 ± 20 nm. The coupling ratio of cytochrome *c* with the PEG-lipid was monitored by HPLC, detecting the pyridyl 2-thione liberated from the pyridyldithio group and determining it to be 26% on the basis of the incorporated PEG-lipid.

INTRODUCTION

Phospholipid vesicles or liposomes acting as vehicles for water-soluble, insoluble, or amphiphilic substances are one of the potent candidates for drug delivery systems (DDS). There are many reports on vesicles bearing immunoglobulins (immunoliposomes) or receptor proteins (proteoliposomes) that produce such site-directories (*1*−*4*). In general, these proteins are covalently coupled to the surface of the vesicles using hydrophobic anchors such as fatty acids, diacylphosphatidylethanolamine, or diacylphosphatidylinositol via various conjugation techniques. For the incorporation of transferrin (80 kDa) (*5*) or immunoglobulin G (150 kDa) (*6*), four or five acyl chains are considered to be desirable as anchors rather than two acyl chains or one diacylphospholipid.

On the other hand, the incorporation of poly(ethylene glycol) (PEG) on the surface of the vesicle, so-called PEGylation, is a useful method for the stabilization of vesicles (*7*−*9*). This modification is effective for the long-term preservation of the vesicle dispersion or the prolongation of the lifetime of the intravenously injected vesicles. However, PEGylation should mask the recognition abilities of the site-directing vesicles because it prevents the interaction of foreign molecules with the vesicular surface. Therefore, the functional water-soluble molecules should be coupled with the terminal of the PEG extending from the surface of the vesicle. There are various coupling methods, i.e., *N*-hydroxysuccinimide (NHS)-activated (*10*), triazine-activated (*11*), or isocyanate-activated PEG (*12*) to target the amino group, and pyridyldithiopropionate (PDP)-activated PEG (*13*−*15*) to target the mercapto groups via a thiol-disulfide exchange reaction (*16*).

Though the coupling with PEG-diacylphosphatidylethanolamine is useful for the incorporation of small molecules such as amino acids (*17*, *18*) or folic acid (*19*), it would sometimes be difficult for the incorporation of functional water-soluble macromolecules. This is because the hydrophobic anchor is too small to tether the large molecules onto the surface of the bilayer membrane. In fact, a considerable amount of the PEG-lipid should dissociate from the surface if the molecular weight of the PEG is greater than 5000 (*20*), and when the molecular weight was 12 500, at least four stearoyl chains should be necessary for stable conjugation. Silvius and Zuckermann reported the influence of the PEG molecular weight and the acyl chain length of the PEG-lipids on the interbilayer transfer rate (*21*). They insisted on the importance of the hydrophobicity of the anchor part for effectively decreasing the transfer rate.

We have synthesized new PEG derivatives with a reactive group at one terminal of the PEG and a large multiacyl hydrophobic group at the other terminal of the PEG using a lysine-dendron structure. Its hydrophobicity could be adjusted by changing the generation number of the dendron which would be sufficient to allow the receptor proteins to be immobilized on the surface of the vesicles (*20*).

In this study, we synthesized a tetraacyl PEG-lipid, where the PEG terminal was activated with PDP or triazine, and cytochrome *c* as a typical water-soluble protein marker was conjugated with the surface of the vesicle via the PEG-lipid by modification of a method reported by Haselgrübler *et al* (*22*).

EXPERIMENTAL SECTION

Materials. NH_2-PEG-NH_2 (MW 1900) was purchased from Fluka Chemical Co. (Switzerland) and reprecipitated twice from ether. L-Lysine, dicyclohexylcarbodiimide (DCC), triazinetrichloride, and *N*-hydroxysuccinimide (NHS) were purchased from Kanto Chemical Co. (Tokyo, Japan). The triazine was purified by recrystallization twice from methanol. The others were used without purification. 9-Fluorenylmethyl chloroformate (Fmoc-Cl), di-*tert*-butyl dicarbonate [$(Boc)_2O$], dithiothreitol (DTT), succinimidylpyridyldithiopropionate (SPDP), and cytochrome *c* were purchased from Wako Pure Chemicals Industries, Ltd. (Osaka, Japan). These reagents were used without further purification. Presome (DPPC/cholesterol/DPPG: 5/5/1, by mol) was purchased from Nippon Fine Chemical Co. (Takasago, Japan).

Methods. (i) Thin Layer Chromatography. Plastic sheets coated with 0.2 mm silica gel 60 without a fluorescent indicator (Merck, Germany) were used for thin-layer chromatography. Eluent I was a mixture of chloroform, methanol, and water at a ratio of 8/3/1 by vol. Eluents II and III were the mixtures of chloroform and methanol at ratios of 4/1 and 9/2, respectively. Spots were detected with I_2. The existence of amino groups was detected by spraying a 10 wt % aqueous ninhydrine solution and heating to around 100 °C.

(ii) Synthesis of HO-Lys-(Boc)$_2$. According to the conventional method, L-Lys was dissolved in dioxane, $(Boc)_2O$ was added and stirred for 6 h. After the confirmation of the disappearance of the TLC spot stained by ninhydrine, the mixture was reprecipitated from hexane and recrystallized twice from hexane/ethyl acetate. Yield: 75%. R_f value, IR, ^{1}H NMR data were consistent with the literature (*20*).

(iii) Synthesis of NH$_2$-PEG-Lys-(Boc)$_2$. NH_2-PEG-NH_2 (5.49 g, 2.89 mmol) was dried in vacuo for 3 h at 70 °C. HO-Lys-$(Boc)_2$ (1.00 g, 2.89 mmol), DCC (656 mg, 3.18 mmol), NHS (366 mg, 3.18 mmol), and (dimethylamino)-pyridine (DMAP, 353 mg 2.89 mmol) were then dissolved in dry chloroform (20 mL) and stirred for 1 h at 5 °C. After filtration to eliminate dicyclohexylurea (DCU), the solution was added dropwise to the solution of NH_2-PEG-NH_2 dissolved in 15 mL of dry chloroform. The reaction mixture was stirred for 6 h at room temperature (RT), followed by evaporation and reprecipitation from cold ether (−20 °C). The precipitate was dissolved in chloroform and subjected on silica gel with flash chromatography (eluent I). After eluting with 100 mL of solvent, the silica gel including NH_2-PEG-Lys-$(Boc)_2$ was picked up and eluted again with 200 mL of solvent. The solution was evaporated, dried in vacuo, and NH_2-PEG-Lys-$(Boc)_2$ (3.22 g) was obtained as a pale yellow highly viscous liquid. Yield: 50%. R_f (eluent I) 0.35−0.50; IR (cm^{-1}, film on NaCl) 3510, 2868, 1648, 1100; ^{1}H NMR ($CDCl_3$, 500 MHz) δ 1.09−1.28 (m, 8H, $-CH_3$, 2-aminopropyl/$-CH_2$, γ-lysine), 1.42−1.48 (m, 20H, $-CH_3$, Boc/ $-CH_2$, δ-lysine), 2.62 (broad, amine), 3.60 (broad, PEG).

(iv) Synthesis of Fmoc-PEG-Lys-(Boc)$_2$. NH_2-PEG-Lys-$(Boc)_2$ (1.00 g, 0.45 mmol) was dissolved in dry chloroform (10 mL) and stirred for 30 min under an argon atmosphere. Fmoc-Cl (190 mg, 0.76 mmol) and DMAP (31 mg, 0.25 mmol) were then added and stirred for 13 h at RT. After the confirmation of the disappearance of the TLC spot stained by ninhydrine, the precipitate was filtered, evaporated and dissolved in 40 °C of benzene. The precipitate was filtered and reprecipitated twice from cold ether (−20 °C). The filtrate was dried in vacuo and purified by flash chromatography (eluent II), and 890 mg of Fmoc-PEG-Lys-$(Boc)_2$ was then obtained as a pale yellow highly viscous liquid. Yield: 81%, R_f (eluent II) 0.35−0.50; IR (cm^{-1} film on NaCl) 3332, 2868, 1714, 1648, 1108; ^{1}H NMR ($CDCl_3$, 500 MHz) δ 1.09−1.28 (m, 8H, $-CH_3$, 2-aminopropyl/$-CH_2$, γ-lysine), 1.42−1.48 (m, 20H, $-CH_3$, Boc/ $-CH_2$, δ-lysine), 2.62 (broad, amine), 3.60 (broad, PEG), 7.22−7.69 (m, 8H, Fmoc)

(v) Deprotection of the Boc Groups. Fmoc-PEG-Lys-$(Boc)_2$ (800 mg, 0.326 mol) was dissolved in a mixture of chloroform (10 mL) and trifluoroacetic acid (TFA, 15 mL) and stirred for 4 h at −20 °C under nitrogen atmosphere. The white precipitate was filtered off and precipitated twice from cold ether (−20 °C). The precipitate was dissolved in 100 mL of benzene and freeze-dried. Fmoc-PEG-Lys (688 mg) was obtained as a pale yellow gellike solid. Yield: 94%. Deprotection was confirmed from a ninhydrine test and the disappearance of Boc signal on ^{1}H NMR.

(vi) Synthesis of Lys-(stearoyl)$_2$. Lys-$(stearoyl)_2$ was synthesized according to our previous method (*20*). Lys (5.00 g, 34.2 mmol) was dispersed in dry benzene including benzyl alcohol (14.6 g, 135 mmol) and *p*-toluenesulfonic acid (14.7 g, 85.4 mmol) and refluxed for 7 h, removing the produced water until the turbid Lys dispersion became transparent. The reaction mixture was reprecipitated three times from ether. At this stage, the carboxyl group of Lys was protected with benzyl ester (yield: 91%). R_f (eluent II) 0.80; IR (cm^{-1}, film on NaCl) 3331, 2915, 1748, 1641; ^{1}H NMR ($CDCl_3$, 500 MHz) δ 0.85 (t, 6H, $-CH_3$, stearoyl), 1.27(m, 58H, $-CH_2$/$-CH_2$, γ-lysine), 1.46 (m, 2H, $-CH_2$, δ-lysine), 1.58 (m, 4H, N$-$CO$-$C$-CH_2$), 1.66−1.81 (m, 2H, $-CH_2$, β-lysine), 2.20 (dt, 4H, $-$N$-$CO$-CH_2$), 3.16(m, 2H, $-CH_2$, ϵ-lysine), 5.18 (s, 2H, $-CH_2-C_6H_5$), 7.35 (m, 5H, $-C_6H_5$).

To this ester (1.28 g, 2.20 mmol) dissolved in chloroform, the equivalent amount of triethylamine, 2.2 equiv amounts of stearic acid and DCC were added and stirred for 8 h at RT. Bzl-O-Lys-$(stearoyl)_2$ was then obtained with a high yield (1.29 g, 71%). This compound was deprotected under a NaOH condition. After recrystallization from chloroform three times, 934 mg of Lys-$(stearoyl)_2$ was obtained. Yield: 88%. Deprotection was confirmed from the disappearance of signals assigned to a benzyl group with ^{1}H NMR.

(vii) Synthesis of NH$_2$-PEG-Lys-(Lys)$_2$-(stearoyl)$_4$. Lys-$(stearoyl)_2$ (571 mg, 0.841 mmol), DCC (178 mg, 0.861 mmol), and NHS (99 mg, 0.861 mmol) were dissolved in a mixture of chloroform (15 mL) and TEA (1 mL) and stirred for 2 h at 5 °C. DCU was eliminated by filtration, then Fmoc-PEG-Lys (688 mg, 0.306 mmol) was added and stirred for 36 h at RT. The solvent was evaporated, and the reaction mixture was dissolved in chloroform and precipitated twice from ether. The filtrate was then extracted with methylene chloride (300 mL) and dried in vacuo. Thus, Fmoc-PEG-Lys-$(Lys)_2$-$(stearoyl)_4$ was obtained. R_f (eluent III) 0.68 (not stained by ninhydrine); IR (cm^{-1}, film on NaCl) 3318, 2917, 2850, 1714, 1625, 1108; ^{1}H NMR ($CDCl_3$, 500 MHz) δ 0.84 (t, 6H, $-CH_3$, stearoyl), 1.09−1.28 (m, $-CH_3$, 2-aminopropyl/$-CH_2$, γ-lysine/$-CH_2$, stearoyl), 1.42−1.48 (m, 6H, $-CH_2$, δ-lysine), 1.58 (m, 4H, N$-$CO$-$C$-CH_2$), 1.66−1.81 (m, 6H, $-CH_2$, β-lysine), 2.20 (dt, 8H, $-$N$-$CO$-CH_2$), 3.16(m, 6H, $-CH_2$, ϵ-lysine), 3.60 (broad, PEG), 7.22−7.69 (m, 8H, Fmoc).

Fmoc-PEG-Lys-$(Lys)_2$-$(stearoyl)_4$ was dissolved in the mixture of 0.1 N NaOHaq, methanol, and chloroform (10/5/0.5, by vol) and stirred for 3 h at 5 °C. The precipitate (Fmoc salt) was removed by filtration, dried in vacuo, and 378 mg of NH_2-PEG-Lys-$(Lys)_2$-$(stearoyl)_4$ was obtained as a pale yellow solid. Total yield: 37%. Deprotection was confirmed from a ninhydrine test and disappearance of Fmoc signal in ^{1}H NMR.

(viii) Synthesis of Triazine-PEG-Lys-(Lys)$_2$-(stearoyl)$_4$ (A). Triazinetrichloride (10.5 mg, 5.69×10^{-2} mmol) was dissolved in 3 mL of dry acetonitrile and substituted with nitrogen gas. The solution was cooled to −20 °C with an ice-NaCl bath. To the solution a dry acetonitrile solution containing NH_2-PEG-Lys-$(Lys)_2$-$(stearoyl)_4$ (A) (50 mg, 1.43×10^{-2} mmol) and diisopropylethylamine (2.22 mg, 1.72×10^{-2} mmol) was added dropwisely and stirred for 8 h. The mixture was washed with 700 mL of cold ether until unreacted triazinetrichloride was completely eliminated. The filtrate was extracted with benzene and freeze-dried. Triazine-PEG-Lys-$(Lys)_2$-$(stearoyl)_4$ (48.0

mg) was obtained as a pale yellow powder. Yield: 95%. R_f (eluent II) 0.33−0.51 (not stained by ninhydrine); IR (cm^{-1}, film on NaCl) 3318, 2917, 2850, 1624, 1109; ^1H NMR ($CDCl_3$, 500 MHz) δ 0.84 (t, 6H, $-CH_3$, stearoyl), 1.09−1.28 (m, $-CH_3$, 2-aminopropyl/$-CH_2$, γ-lysine/$-CH_2$, stearoyl), 1.42−1.48 (m, 6H, $-CH_2$, δ-lysine), 1.58 (m, 4H, N−CO−C−CH_2), 1.66−1.81 (m, 6H, $-CH_2$, β-lysine), 2.20 (dt, 8H, −N−CO−CH_2), 3.16(m, 6H, $-CH_2$, ϵ-lysine), 3.60 (broad, PEG).

(ix) Synthesis of PDP−PEG-Lys-(Lys)$_2$-(stearoyl)$_4$ (B). NH_2-PEG-Lys-$(Lys)_2$-$(stearoyl)_4$ (127 mg, 3.79×10^{-2} mmol) was dissolved in 2 mL of a mixed solvent containing chloroform, methanol, and 0.1 N−NaOH in a volume ratio of 10/5/0.4 and stirred under a nitrogen atmosphere for 1h. SPDP (14.8 mg, 4.75×10^{-2} mmol) was then added and stirred for 13 h at 5 °C. Benzene was added to the mixture, freeze-dried, and reprecipitated twice from ether. PDP−PEG-Lys-$(Lys)_2$-$(stearoyl)_4$ (B) (101 mg) was thus obtained as a white powder without any byproducts. Yield: 75%. R_f (eluent II) 0.44−0.59 (not stained by ninhydrine); IR (cm^{-1}, film on NaCl) 3318, 2917, 2850, 1714, 1624, 1109; ^1H NMR ($CDCl_3$, 500 MHz) δ 0.84 (t, 6H, $-CH_3$, stearoyl), 1.09−1.28 (m, $-CH_3$, 2-aminopropyl/$-CH_2$, γ-lysine/$-CH_2$, stearoyl), 1.42−1.48 (m, 6H, $-CH_2$, δ-lysine), 1.58 (m, 4H, N−CO−C−CH_2), 1.66−1.81 (m, 6H, $-CH_2$, β-lysine), 2.20 (dt, 8H, −N−CO−CH_2), 3.16(m, 6H, $-CH_2$, ϵ-lysine), 3.60 (broad, PEG), 7.05−8.43 (m, 4H, $-C_5NH_4$).

(x) Preparation of Vesicles Modified with A and B. Presome (53.9 mg, 97.5 mol %) and A (8.5 mg, 2.5 mol %) or B (8.5 mg, 2.5 mol %) were dissolved in 200 mL of benzene and freeze-dried. The mixed lipid powder was then dispersed into 100 mL of phosphate-buffered saline (PBS) and stirred for 5 h. After concentration to 15 mL by ultrafiltration (cutoff: 120 000, 45 mmϕ, Advantec Co.), the vesicles were prepared by an extrusion method. The final pore size of the membrane filters (FM series Fuji Film Co. Tokyo) were 220 nm to prepare the vesicles of about 250 nm in average diameter, which was measured by a dynamic light-scattering method (COULTER submicron particle analyzer, model; N4−SD). The incorporation ratio of the PEG-lipids (A and B) was measured by the ^1H NMR spectrum, where the choline methyl protons of DPPC were detected at 3.33 ppm (in $CDCl_3$), and the methylene protons of the PEG chain at 3.65 ppm (*23*).

(xi) Conjugation with Cytochrome c: A-Vesicle. A solution (2 mL) containing 1 mg of cytochrome *c* was added to the A-vesicle dispersion (3 mL) and stirred at 5 °C. After 0.5, 1, and 2 h, 20 μL of dispersion was sampled for an HPLC [LC-8A, Shimadzu Co., Japan, column: TSK-GEL $G3000SW_{XL}$ 7.8 mmϕ × 300 mmh, flow-rate: 1 mL/min, solvent: PBS (pH 7.4)] measurement detected at 210 and 330 nm. Cytochrome *c* was detected at 330 nm.

B-Vesicle. First, a mercapto group was introduced to cytochrome *c* by SPDP as described previously (*16*). An ethanol solution (50 μL) containing SPDP (1.6×10^{-4} mmol) was added to cytochrome *c* (2 mg, 1.6×10^{-4} mmol) dissolved in 1 mL of PBS, and stirred for 1 h at RT. Excess DTT was added and stirred for 0.5 h at 5 °C. The cytochrome *c* was purified by gel permeation chromatography (Sepharose G-25: Pharmacia). Conjugation of the cytochrome *c* to the B-vesicle was carried out in the same way as A-vesicle. The amount of cytochrome *c* conjugated to the B-vesicle was estimated by quantitation of the 2PT formed by thiol-disulfide exchange, which had a specific absorbance at 343 nm. The reaction was monitored with HPLC detected at 210 and 343 nm. After 3 h, 1 mL of the reaction mixture was sampled, and DTT (0.3 mg) was added and stirred for 0.5 h to detect the amount of the unreacted PDP group from 2TP. The HPLC measurement was then carried out to study the reaction ratio of the PDP group, namely, the amount of cytochrome *c* conjugated with the surface of the vesicle via disulfide linkage.

RESULTS AND DISCUSSION

Synthesis of PEG Derivatives. To immobilize proteins on the surface of the vesicle, we designed PEG-lipids having a triazine or a PDP, which can react with the amino group or the mercapto group of the proteins, respectively. An orthogonal synthetic procedure was applied for the syntheses of the PEG-lipids using the diamino-PEG, Fmoc, and Boc as protecting groups (Scheme 1).

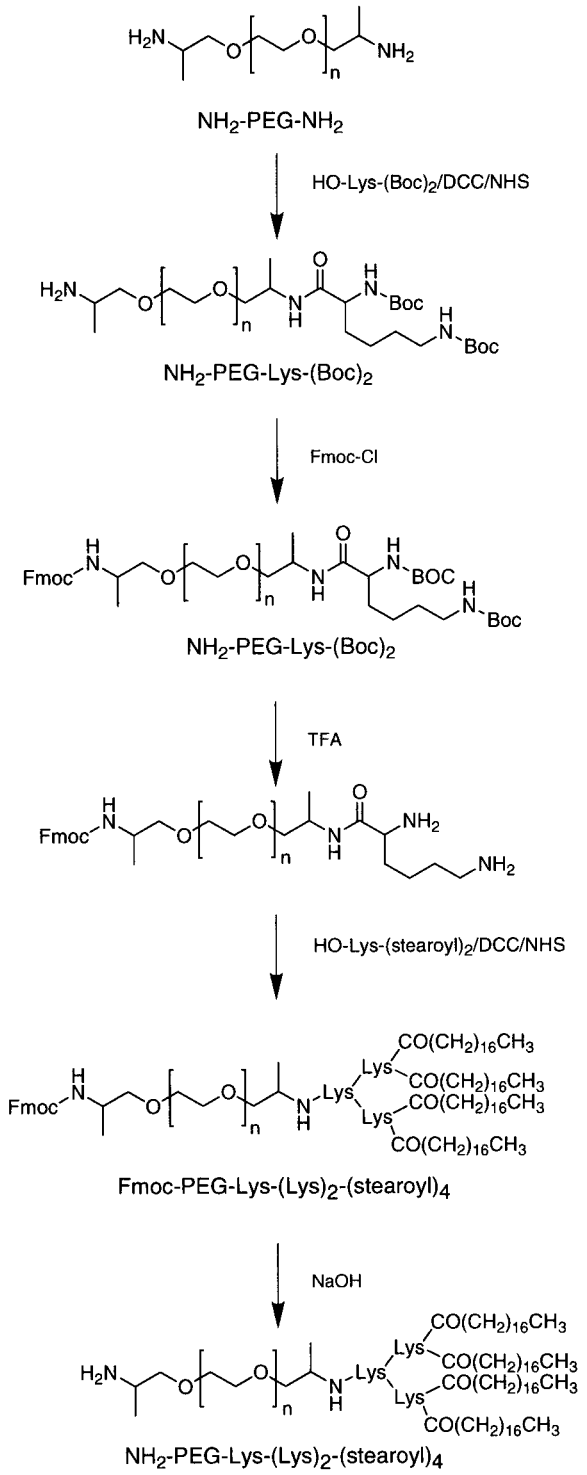
Lysine, of which two amino groups were protected with Boc, was bound to one terminal amino group of the PEG. This reaction was performed using a DCC-additive method. The low yield was caused by the difficult purification though flash chromatography was utilized for the purification. During elution, the bands of the PEG derivatives were broadened and overlapped each other. Next, the reaction of the other terminal amino group of the PEG with Fmoc-Cl stoichiometrically proceeded. The deprotection of the Boc groups was carried out with TFA, and the resulting amino groups were reacted with two equivalent amounts of distearoyl lysine using a DCC-additive method. Thus, a PEG derivative with four acyl chains at one end and a Fmoc group at the other end was obtained. Four acyl chains were confirmed based on the ^1H NMR spectra, where the integral ratio of the Fmoc group to the terminal methyl groups of the acyl chains was 8/12 (Figure 1A).

The PEG derivative with four acyl chains was treated with NaOH for the deprotection of the Fmoc group to obtain NH_2-PEG-Lys-$(Lys)_2$-$(stearoyl)_4$. The deprotection was confirmed with TLC using a ninhydrine-staining method. The intermolecular hydrogen bonding at the lysine dendron group might reduce the solubility in chloroform, which was indicated by the IR spectra where the C=O stretching band appeared in 1624 cm^{-1}. The low solubility or gelation of the compound made the treatment difficult. Since purification was not performed by chromatography, it was reprecipitated from cold methylene chloride. Very interestingly, the solubility of the compound became high if the terminal amino group was changed to the triazine or PDP group. This suggests the involvement of the terminal amino group in the intermolecular hydrogen bonding.

The activation of the PEG derivatives was accomplished according to Scheme 2. An excess amount of triazine was added to the solution of NH_2-PEG-Lys-$(Lys)_2$-$(stearoyl)_4$ for the synthesis of only the monosubstituted derivative. After a reaction in dried acetonitrile, the unreacted triazine was removed by precipitation with ether until the TLC spot attributed to triazine disappeared. A single spot on the TLC indicated no impurities.

The activation with SPDP was performed under basic conditions and a nitrogen atmosphere so as not to produce byproducts such as disulfide derivatives or the protonated pyridyl group. We did not use pyridine as a base because it is difficult to remove the pyridine without heating. The PDP group is weak against heat treatment. When we used aqueous NaOH as the base, the solvent and impurities could be easily removed by filtration after freeze-drying the solution and dissolving it in benzene. On the basis of the ^1H NMR spectrum (Figure 1B), the

Scheme 1. Synthesis of NH_2-PEG-Lys-$(Lys)_2$-$(stearoyl)_4$



integral ratio of the peaks at 7.05−8.43 (PDP) and 0.84 ppm (CH_3 protons of stearoyl chains) shows that the PDP group was almost quantitatively attached to the other terminal of the PEG.

Preparation of vesicles modified with A and B. We found that the mixed lipids containing the tetraacyl PEG-lipids was hard to hydrate, therefore, we hydrated the lipids with a large volume of PBS and concentrated it by ultrafiltration before extrusion. Vesicles with diameters of 258 nm (**A**-vesicles), and 290 nm (**B**-vesicles) were prepared by the extrusion method. Extrusion through membrane filters with a 3μm pore size was difficult when

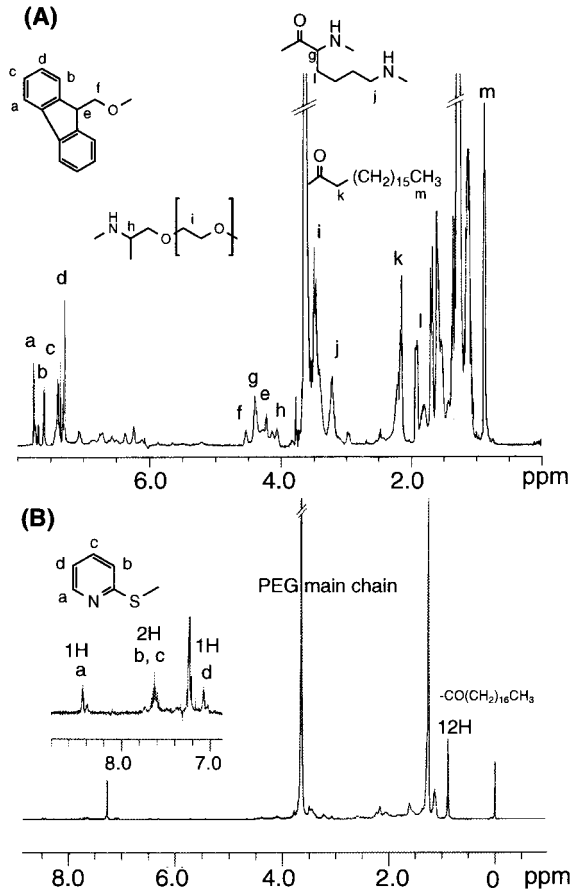


Figure 1. ^{1}H NMR spectrum (500 MHz) of PEG derivatives. (A) Fmoc-PEG-Lys-$(Lys)_2$-$(stearoyl)_4$ in $CDCl_3$ (enlarged). The Fmoc group has specific signals around 7.2−7.7 ppm. The integral ratio of Fmoc protons to methyl protons belonging to the stearoyl chain was 8/12, indicating that four acyl chains were attached at the other termini of PEG. (B) PDP-PEG-Lys-$(Lys)_2$-$(stearoyl)_4$ in $CDCl_3$. Inset is an enlargement of the signals around 7.0−8.4 ppm, which were assigned to a PDP group. This indicates that the Fmoc group was substituted with a PDP group.

compared with the extrusion of vesicles without the PEG-lipid. It is suggested that a part of the PEG-lipids would not completely dissolve due to the strong intermolecular hydrophobic interaction and hydrogen bonding (*20*).

As shown in Figure 2, the PEG-lipid (B) was incorporated into the vesicle; a signal from the PDP group could be detected at around 7.3 ppm together with the methylene peak of the PEG (3.64 ppm) and the choline methyl peak of the phospholipids (3.32 ppm). This indicates the existence of PDP groups on the surface of the vesicles. In the same way, it is considered that triazine groups exist on the A-vesicles, though the ^{1}H NMR signals assigned to the triazine could not be detected (triazine does not have any protons). Instead, the amount of PEG existing on the surface of the A-vesicle can be estimated from the ^{1}H NMR spectra (*23*). The incorporation ratios of the PEG-lipids, A and B, into the vesicle were 54 and 61%, respectively, indicating some were filtered out. We are now trying the incorporation of the PEG-lipid to the vesicles after preparation of the vesicles or the detergent dialysis method in order to improve the incorporation ratio. It is noted that the diameter of the vesicles did not change for at least 2 months as shown in Table 1, suggesting that PEG chains extending from the surface of the vesicle should contribute to the high dispersing ability.

Scheme 2. Activation of NH_2-PEG-Lys-$(Lys)_2$-$(stearoyl)_4$ with Triazine or SPDP for Synthesis of Amino or Mercapto-Attacking Reagents

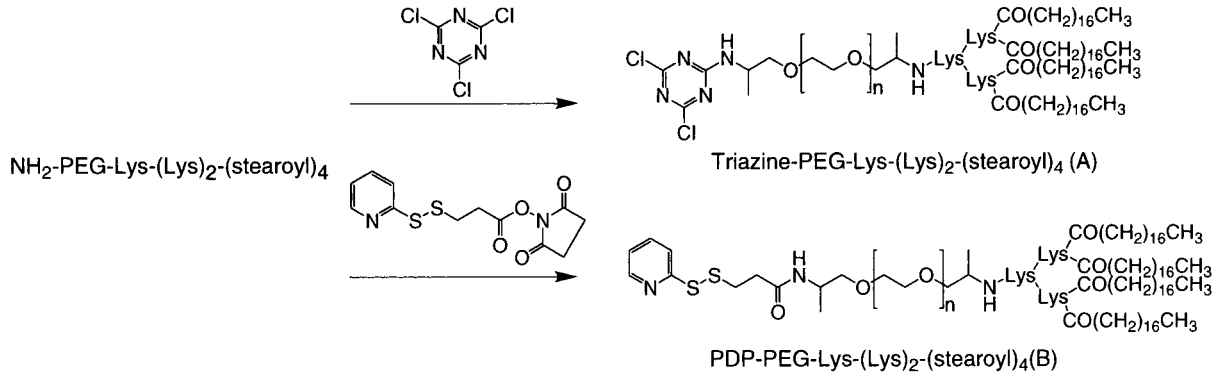

Table 1: Characterization of Vesicles Containing A and B

	A	B
diameter[a] (nm)	258 ± 42	290 ± 45
diameter[b] (nm)	263 ± 69	302 ± 51
diameter after conjugation (nm)	361 ± 140[c]	304 ± 66[d]
incorporation ratio[e] (%)	54	61
molar ratio of PEG (mol%)	1.4	1.5
exposed PEG[f] (mol%)	0.35	0.38

[a] Measured after extrusion. [b] Measured 2 months after. [c] Measured after 3 h mixing. Increase of diameter was observed. [d] Measured after 3 h mixing. [e] Quantitated by ^{1}H-NMR spectra (500 MHz, in $CDCl_3$). [f] Calculated as the vesicle with two bilayer membranes.

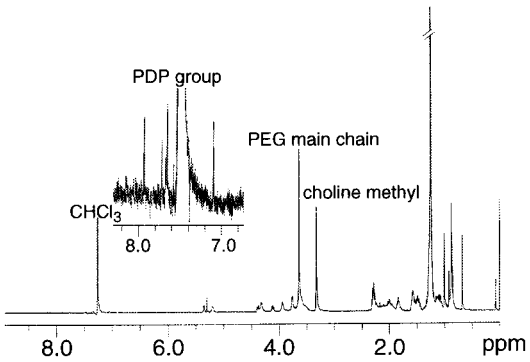

Figure 2. ^{1}H NMR spectrum (500 MHz) of the vesicle containing PDP activated PEG-lipid B in $CDCl_3$. The signals assigned to the methyl protons of the phosphatidylcholine and methylene protons of PEG were detected together with that of the PDP group, indicating the incorporation of the PEG-lipid into the phospholipid vesicle.

Conjugation with Cytochrome c to the Vesicle. The conjugation of cytochrome *c* to the surface of the vesicles via the triazine-activated PEG-lipid (A) was monitored by HPLC. As shown in Figure 3, the elution times of the vesicle and cytochrome *c* were 5 and 10 min, respectively. The coupling between the PEG-lipid and cytochrome *c* was completed within 30 min because the peak of cytochrome *c* did not change after 30 min. After 3 h, the integral value of the vesicle peak increased due to the increase in the diameter of the vesicles to 361 ± 140 nm (Table 1). This would not be caused by the aggregation of vesicles but by the cross-linking of vesicles through cytochrome *c* and the triazine group of PEG on the surface of the vesicles. Therefore, we added amino acids such as glycine in order to deactivate the remaining activated group.

In the case of the triazine-activated vesicles, though cytochrome *c* was surely detected in the vesicle fraction

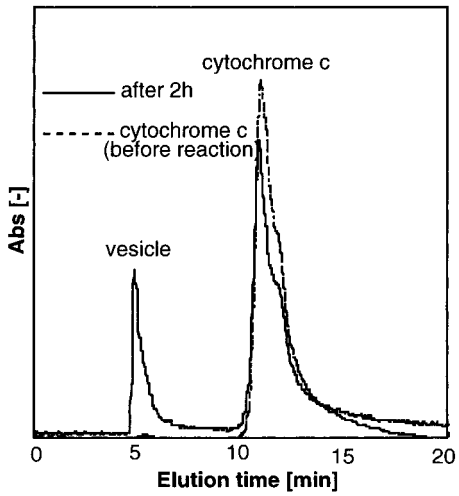

Figure 3. Conjugation of cytochrome *c* to the A-vesicle. The elution speed was 1 mL/min. For the detection of cytochrome *c*, 330 nm was used. The solid line is the elution curve of the mixture after 2 h reaction. The dotted line is the elution curve of the cytochrome *c* solution, containing the same amount of cytochrome *c* as the reaction mixture.

Table 2: Quantitation of Consumed PDP Groups by HPLC Analysis

A: consumed PDP after 3 h mixing	2.54×10^{-8} mol
B: consumed PDP by DTT	7.19×10^{-8} mol
yield: $[A/(A + B)] \times 100$	26.3%

by HPLC, it is difficult to distinguish the cationic cytochrome *c* merely adsorbed on the negatively charged surface of the vesicles from that covalently bound to the surface. We used the PDP-activated vesicle (B-vesicle) because the 2PT release was accompanied by the reaction of the PDP-activated PEG with cytochrome *c*. 2PT shows a specific absorption band at 343 nm as evidence of coupling. By combination with HPLC, 2PT is isolated and quantified in order to determine the amount of the coupled proteins (*24*). We adopted the constant elution curve obtained after 3 h mixing for analysis. The elution times of the vesicles, cytochrome *c*, and 2PT were 5, 10, and 15 min, respectively, as shown in Figure 4. The concentration of the unreacted PDP groups exposed on the surface of the vesicle was measured by adding excess DTT. Although DTT also shows a small absorption at 343 nm (*24*), the elution time (13 min) of DTT was different from that of 2PT (15 min in HPLC). The yield was then calculated from the ratio of the integral values of the peak assigned to 2PT (Table 2).

As a result, 26% of the PDP groups reacted with the cytochrome *c*, because the number of bilayer membranes

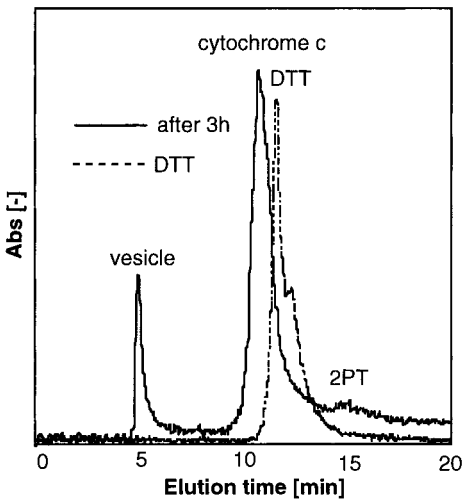

Figure 4. Conjugation of cytochrome *c* to the B-vesicle. The elution speed was 1 mL/min. The detection wavelength was 343 nm which was the λ_{max} of 2PT. The solid line is the elution curve of the mixture after 3h reaction. Peaks assigned to the vesicle, cytochrome *c*, and 2PT were detected after 5, 10, and 15 min, respectively. The dotted line is the elution curve of DTT. The difference in the elution times of DTT (13 min) and 2PT (15 min) allows to determine the amount of 2PT namely cytochrome *c* conjugated to the B-vesicle.

of the vesicles (250 nm) prepared by an extrusion method is approximately two as described in the literature (*25*). A 1.53 mol % amount of the PEG-lipid (B) would be incorporated into the vesicles, and 0.38 mol % was calculated to be exposed outside the vesicles. The consumed PEG-lipid was then at most 0.10 mol % (0.38 mol % × 0.26); namely, the concentration of cytochrome *c* on the surface of the vesicle was 0.10 mol % on the basis of the lipids existing on the surface of the vesicle. This means that about 400 cytochrome *c* molecules were conjugated on one vesicle. Such a low yield was also reported in a similar experiment for the conjugation of IgG to a vesicle (*22*).

The relatively low reaction ratio (26%) of cytochrome *c* conjugation might be explained in terms of the location of the PDP groups. Namely, one possibility is that the hydrophobic PDP group would exist in the core region of the entangled PEG and be shielded by the steric hindrance of the PEG chain. The other is that the hydrophobic PDP group would be inserted into the hydrophobic part of the bilayer membrane. If the coupling of cytochrome *c* with the PEG-lipid (B) would be carried out by using mixed micelles comprising surfactants such as sodium cholate, which are not bilayer forming surfactants, the reaction ratio should be improved in the case of the latter hypothesis.

We isolated the cytochrome *c*-conjugated vesicles by ultracentrifugation (33 000 rpm, 1 h) and applied them to the HPLC (210, 330 nm for detection) after redispersion. Only one peak was detected in the void volume, which was attributed to the vesicles. The same experiment was performed for the vesicles comprising DPPC/choresterol/DPPG/DPPE (5/5/1/0.29) where cytochrome *c* was conjugated with the DPPE by SPDP in the same way. We confirmed a new peak besides the peak in the void volume in the HPLC elution curve after every ultracentrifugation (data not shown). It was considered to be the assemblies of the cytochrome *c*-conjugated DPPE, indicating that some portion of the cytochrome *c*-conjugated DPPE would be dissociated from the vesicles. The above data support the stable conjugation of cytochrome *c* on the surface of the vesicle by the tetraacyl PEG-lipid rather than by the diacyl PEG-lipid. This trend agrees with the data that the PEG, with a molecular weight of 12 500 (approximately as large as that of cytochrome *c*), would be stably conjugated on the surface of the vesicles if coupled with the tetraacyl anchor (*20*).

CONCLUSIONS

An effective incorporation of the large hydrophobic part into PEG-lipids was designed in order to realize the conjugation of large water-soluble macromolecules or receptor proteins on the surface of the vesicle. We synthesized heterobifunctional PEG derivatives with four stearoyl chains attached to the terminal of a lysine dendron with PDP or triazine as the reactive groups at the other terminal of the PEG, and confirmed the coupling of cytochrome *c* to the activated PEG-lipids in the bilayer membrane. The stable conjugation of larger macromolecules would be possible if the generation number of lysine dendrons would be increased for the further introduction of acyl chains.

An anchor-chain molecular system was constructed for controlled orientation and high activity in enzyme immobilization. A streptavidin recognition peptide (streptag) coding sequence was fused to the 3′ end of the phoA gene, which codes for *E. coli* alkaline phosphatase (EAP). Both the wild-type (WT) and the Asp-101 → Ser (D1O1S) mutant were modified with the streptag sequence with or without the insertion of a flexible linker peptide [-(Gly-Ser)$_5$-] coding sequence. The fused genes were cloned into the vector pASK75 and expressed in the periplasm of the host cell *Escherichia coli* SM547. The proteins were released by osmotic shock and purified by ion-exchange chromatography. Enzyme activities of all proteins were measured spectrophotometrically with *ρ*-nitrophenyl phosphate as the substrate. Specific activities of D101S-streptag and D101S-linker-streptag enzymes were increased 25- or 34-fold over the WT, respectively. These fusion proteins were then immobilized on microtiter plates through streptag−streptavidin binding reaction. After immobilization, the D101S-linker-streptag enzyme displayed the highest residual activity and the ratio of enzyme activities of the linker to nonlinker enzymes was 8.4. These results show that the addition of a linker peptide provides a spacer so as to minimize steric hindrance between the enzyme and streptavidin. The method provides a solution for controlled enzyme immobilization with high recover activity, which is especially important in construction of biosensors, biochips, or other biodevices.

INTRODUCTION

Understanding the properties of immobilized proteins is critical to the optimal design of biosensors, bioseparations, bioreactors, and the production of bioelectronic devices will undoubtedly demand much better control of the positioning and assembly of biomolecular materials as well as high retention of biological activity. Protein patterning, the defined spatial localization of molecules on a surface, is a powerful approach to generate molecular arrays for analytical or bioelectronic applications and similarly demands a high degree of molecular control over the orientation of the molecules on the surface.

In most circumstances, however, immobilization chemistries require a significant amount of enzyme. Likewise, immobilized enzymes very often show reduced reaction rates and product yields (*1*). This is mainly due to the multisite attachment, multiple orientations, and steric hindrance that result from nonspecific chemical cross-linking of protein to surface. Attempts have been made to solve the problems by more precisely defined protein−surface interations. Examples include site-specific attachment to gold surfaces by introducing a single cysteine residue into the cysteine-free enzyme (*2*), orientational control of enzymes by the use of nonporous hydroxyalkyl methacrylate solid support (*3*), and oriented immobilization of antibodies by the use of immobilized protein A or G (*4*).

One of the most promising methods is to use fusion protein technology. Fusion proteins, comprising separate protein sequences have been widely used as aids to expression and purification of recombinant proteins. The gene for the protein of interest is fused to a sequence that codes for a protein or peptide, which in turn binds to a specific molecular structure on the surface. Many of these expression/purification systems are commercially available, and their basic characteristics have been reviewed (*5*). These fusion sequences can also be used to immobilize proteins on surfaces for sensing or molecular electronic applications. The efficiency of immobilization depends on the carrier, immobilization method, and initial enzyme concentration. Gritsch et al. (*6*) described the binding of a poly (His) fusion protein to surfaces coated with metal-chelating self-assembled lipid monolayers. Recently, a method was described for photopatterning surfaces with biotin (*7*) and biotinylated EAP bound via a streptavidin bridge. An alternative to biotinylation is to use a streptavidin binding peptide sequence (streptag). The streptag sequence was created by selection from a genetic fusion peptide library by its ability to bind to streptavidin in a specific and reversible manner (*8*). Streptavidin is usually preferred to avidin, due to its lower nonspecific binding characteristics and high resistance to denaturation (*9*).

An EAP-streptag fusion protein system has been characterized (*10*) and, although the activity of the fusion protein was lower than WT, the work demonstrated the potential use of the avidin−biotin system for protein immobilization under mild conditions.

Escherichia coli alkaline phosphatase (EC 3.1.3.1, EAP) is a homodimeric zinc metalloprotein that has been

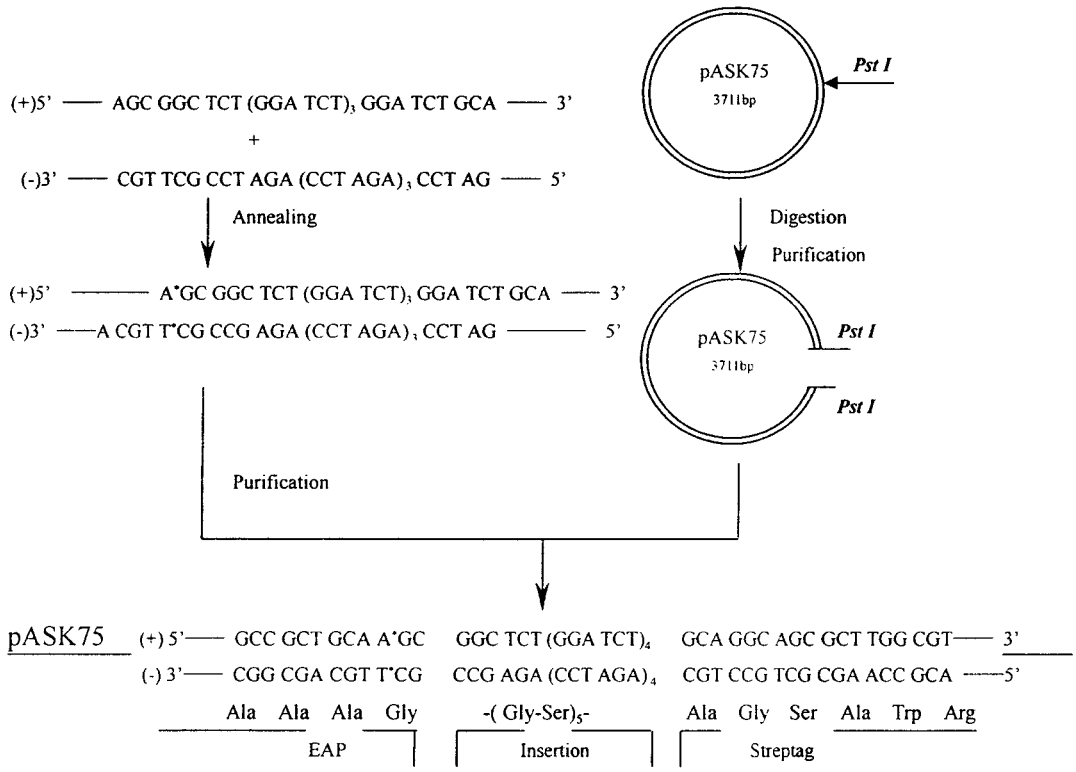

Figure 1. Strategy of linker insertion. An asterisk (*) indicates modified amino acid residues, which leads to elimination of the restriction enzyme site at the 5′ termination of linker. The insertion fragment must be designed to be subject to the enzyme *Pst*I. The synthesized oligos contain an overlap at both ends to adapt to the catalytic reaction of *Pst*I.

extensively characterized (*11*−*13*). Its broad substrate specificity means that the enzyme activity can be readily measured when immobilized using either colorimetric or fluorescent end-point detection. The major drawback of the enzyme in analytical applications is its relatively low activity. Several point mutations in the vicinity of the active site have been shown to alter the enzymatic activity. In particular, data from the introduction of a serine hydroxyl group at position 101 suggests that the mutant enzyme achieves a quicker catalytic turnover by allowing faster product release (*14*, *15*).

Since direct fusion of streptag to EAP led to a 50% loss of enzyme activity (*7*), we sought to improve on this by inserting a linker peptide between the C-terminus of EAP and the streptag sequence. This was thought to provide a sufficiently flexible spacer for both proteins to remain in native conformation. This may improve the control of the orientation of enzyme during immobilization, so resulting in a high recovery activity.

EXPERIMENTAL PROCEDURE

Materials. Agar, agarose, ampicillin (Amp), *ρ*-nitrophenyl phosphate (pNPP), and streptavidin were purchased from Sigma Chemical Co. Tryptone and yeast extract were obtained from England OXOID. Restriction endonucleases were products of either GIBCO BRL or Promega Co. Kits used for the extraction of plasmid and the isolation of DNA fragments from agarose gels were purchased from QIAGEN. T4 DNA ligase was obtained from GIBCO BRL.

A stirred cell system used for protein concentration was purchased from FILTRON. A Titertek Uniscan microplate reader was used to measure the activity of the immobilized enzymes. Purification was accomplished using a Q Sepharose (Sigma) ion-exchange chromatography column. The single strand oligonucleotide coding for the linker peptide was commercially obtained from Sangon (Shanghai, China). The *E. coli* strain SM547 and the plasmid pEK48 kindly donated by professor Kantrowitz and pASK75 was purchased from Biometra.

Construction of Fusion Proteins. The EAP-streptag fusion proteins were generated by cloning phoA into the plasmid pASK75 (*10*). The linker peptide oligonucleotide was annealed into double-strand DNA prior to mixing with pASK75, which had been previously cut with *Pst*I (Figure 1). The mixture was treated with T4 DNA ligase overnight at 14 °C, followed by transforming into competent *E. coli* SM547 cells and plating on LB medium plates containing 100 *μ*g/mL Amp and 40 *μ*g/mL 5-bromo-4-chloro-3-indolyl phosphate (BCIP) (w/v). Twelve of the blue colonies (displaying EAP activity) were selected, and plasmid DNA was isolated. Each of the plasmid candidates was first checked for the correct size by agarose gel electrophoresis and then analyzed by PCR. A plasmid, which contained the correct inserted linker peptide sequence, was isolated. The construction of plasmids containing the mutation was accomplished by cutting both plasmid pASK75 and the D1O1S mutant plasmid pEK48 (X.-E. Zhang et al., unpublished results) with the restriction enzymes *Tth*111 I and *Bstx*I. Digestion with these enzymes produced a fragment of the *pho*A gene containing the mutational site. The strategy was to replace the fragment from the mutant plasmid pEK48. To ensure that the fragment from the WT gene was not able to religate, the pASK75 backbone was removed from an agarose gel after electrophoresis using QIAquick Gel Extraction Kit. Transformation into competent *E. coli* SM547 cells was performed. The mixture was plated on LB medium plate. The isolation of the target plasmid was accomplished as before. DNA sequencing results also confirmed that the linker peptide and the new mutational sites were introduced.

Protein Purification. Cells were grown at 37 °C in LB medium containing 100 *μ*g/mL Amp with shaking

until the absorbance at 600 nm reached 0.5. Expression was then induced by the addition of isoprophylthio-β-D-galactoside (IPTG) (for cells containing pEK48) or Tetracycline (for cells containing pASK75) to a final concentration of 1 mM or 0.2 μg/mL (w/v), respectively. After the bacterial cells were grown for 20 h, they were harvested by centrifugation. The fusion protein was released by osmotic shock according to the method of Brockman and Heppel (*16*). The supernatant containing the fusion proteins were combined and purified using Q Sepharose ion-exchange chromatography.

Initially, the column was washed with 20% ethanol (v/v) and then equilibrated with 10 mM Tris (TMZP buffer, 100 mM Tris containing 1×10^{-3} M $MgCl_2$, 1×10^{-4} M NaH_2PO_4, 3.1×10^{-3} M NaN_3, and 1×10^{-5} M $ZnSO_4$, pH 7.4). The protein was applied to the column in the same buffer and unbound protein was eluted with equilibration buffer. The protein was eluted using a salt gradient in the TMZP buffer, and 8 mL fractions were collected and tested for EAP activity. Proteins were concentrated using the FILTRON stirred cell system. Final protein preparations were stored at −20 °C in TMZP buffer. Protein concentration and purity were determined by using Bio-Rad Assay Kit with bovine serum albumin as the standard and SDS−PAGE, respectively.

Kinetic Assays. EAP is catalytically active at relatively high pH values. The enzyme is most active at pH 10.0, and accordingly, all reactions were carried out at that pH in 1 M Tris buffer. ρNPP was used as an EAP substrate to measure the enzymatic activities spectrophotometrically and, hence, determine the kinetic parameters. The release of ρ-nitrophenolate (ρNP) was monitored at 405 nm. A total of 3 μL of enzyme solution was added to the microtiter wells containing 33 μL of 3 M Tris-HCl (pH 10.0) and 64 μL of ρNPP (50 mM Tris-HCI buffer; 1 mM $MgCl_2$; pH 10.0). The reaction mixture was incubated for 1 min at 25 °C. The absorbance at 405 nm in each well of the plate was then read after subtraction of the blank value for each dilution.

The activity assays after immobilization were performed as described below. A total of 100 μL of 100 μg/mL streptavidin was applied to each well of the microtiter plate and incubated for 1 h at 4 °C. The plate was washed three times with distilled water and subsequently blocked for 4 h in 3% BSA solution (w/v). After washing, 100 μL of 10 μg/mL EAP fusion protein was added and incubated for 30 min. Unbound enzyme was removed by washing three times. Finally, 100 μL of ρNPP solution (20 mM ρNPP and 1 M Tris-HCl, pH 10.0) was added. The color signal was developed for 2 min. The absorption values were determined using a microplate reader and data were reported as A_{405} values for the sample wells after subtraction of the blank value. The measurements were repeated three times.

Protein Immobilization. One microliter of 100 μg/mL streptavidin was applied to each well of the glass slide and incubated for 4 h at 4 °C. After removal of the solution, the plate was blocked with 3% BSA solution (w/v), and incubated for 4 h. After washing, 1 μL of 10 μg/mL EAP fusion protein was applied and incubated for 2 h. Unbound enzymes were removed by washing three times with distilled water. Finally, 1 μL of NBT/BCIP (another EAP substrate, diluted 4:4:25 in buffer supplied by the HuaMei manufacturer) was added. Color change was seen within 10 min. Unless stated otherwise, the experiments were performed at room temperature (25 °C).

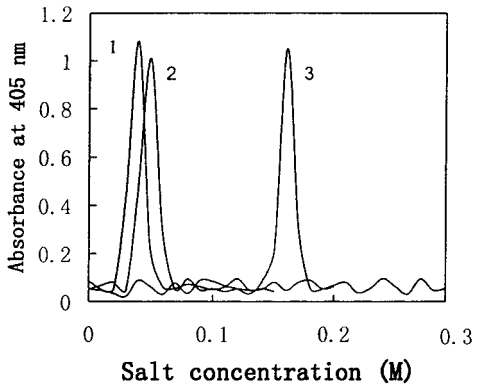

Figure 2. Elution pattern of the proteins. Peak 1, EAP-streptag; peak 2, EAP; peak 3, EAP-linker- streptag.

RESULTS

Alteration of Elution Peak. All proteins had the same elution peak profile, but required different ionic strengths of the eluting buffer. The WT and fusion protein containing streptag can be eluted from the column by using 0 to 0.1 M NaCI concentration gradient solution. However, the WT was eluted at 0.058 M NaCI, while the WT-streptag fusion protein was eluted at 0.046 M NaCl. The insertion of linker peptide required a higher ionic strength and was eluted at 0.17 M NaCl (Figure 2). All samples were eluted at the same flow rate and dissolved in the same buffer.

Kinetic Properties of EAP Fusion Proteins. Table 1 lists the EAP fusion proteins that were constructed and the kinetic constants. Replacement of Asp 101 by Ser in EAP has a large effect on k_{cat}. The k_{cat} and K_m of WT EAP streptag fusion protein are similar to the wild-type. The fusion protein D101S-streptag has about a 9- and 11-fold increase of k_{cat} value over the WT and WT-streptag fusion protein, respectively. The insertion of the linker into the D101S-streptag fusion protein resulted in slight increase of k_{cat} value. The k_{cat} of fusion protein D101S-linker-streptag is 15 times higher than the fusion protein WT-streptag. The k_{cat}/K_m ratio for each of the enzymes is almost identical with the corresponding value for the WT enzyme, since the increment in k_{cat} is compensated for by increase of 23- and 40-fold in the K_m of the D101S-streptag and D101S-linker-streptag fusion enzymes, respectively (Table 1). Therefore, despite the higher catalytic activity of the mutant enzymes each is still as effective a catalyst as the WT enzyme.

The D101S-streptag shows about 40-fold K_m increases over the WT. The introduction of a linker led to a 0.6-fold decreased K_m value relative to the nonlinker mutant, whereas it has the highest specific activity value. This result suggests that the D101S-linker-streptag fusion protein has the highest catalytic efficiency and a higher affinity to the substrate comparing with the fusion protein D101S-streptag. The activity assay after immobilization showed that D101S-linker-streptag also developed the highest residual activity. After immobilization (in microtiter plate), the ratio of residue enzyme activities of the D101S-linker-streptag and D101S-streptag was 8.4, but the ratio of the enzyme activities of the same proteins before immobilization is 2.0. Figure 3 showed the enzyme activity of the fusion proteins after immobilization and nonimmobilization with or without the insertion of the linker peptide. The catalytic activities of the fusion proteins in solution were higher than that in immobilized conditions. But enzymes without linker peptide gave a sharply decreased catalytic activity, while

[a] U = μmol of the substrate ρNPP hydrolyzed/mg of protein/min. [b] The k_{cat} values are calculated per active site from the V_{max} using a dimer molecular weight of 94 000 (*11*). The buffer system is 1.0 M Tris-HCI, pH 10.0. The MW of streptag and linker peptide is about 1100, respectively.

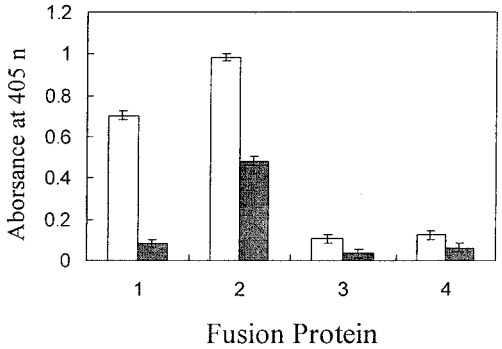

Figure 3. Effect of linker on the degree of residual activity on the polystyrene surface. The fusion proteins were assayed in the absence and presence of linker. Enzyme activity was expressed relative to the activity of the fusion protein in absence of linker. Data represent the mean of three duplicates from one experiment. Key 1, immobilized D101S-linker-streptag (□) and D101S-streptag (■); key 2, nonimmobilized D101S-linker-streptag (□) and D101S-streptag (■); key 3, immobilized WT-linker-streptag (□) and WT-streptag (■); key 4, nonimmobilized WT-linker-streptag (□) and WT-streptag (■).

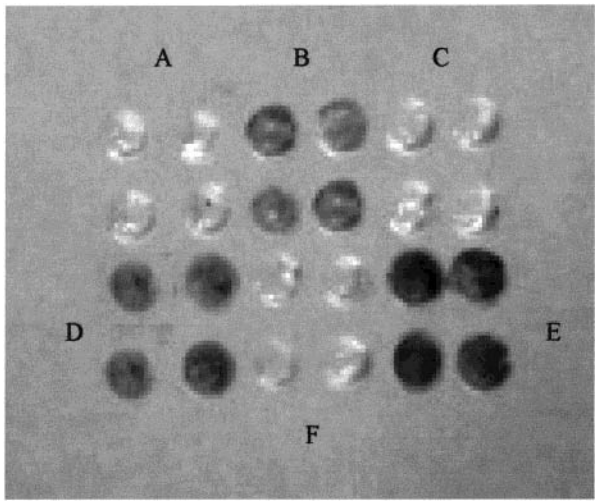

Figure 4. Immobilization of the proteins on glass chip. The positions of the three positive reactions (each loaded four duplicates) and three negative reactions are indicated. Experimental detail is in the text. (A) Denotes the detection of EAP; (B) denotes the detection of EAP-linker-streptag; (C) denotes the detection without substrate; (D) denotes the detection of D101S-streptag; (E) denotes the detection of D101S-linker-streptag; (F) denotes the detection without the streptavidin.

the enzymes with the insertion of linker peptide had a higher recover activity.

Immobilization on Glass Support. Immobilization of the fusion proteins was performed on the surface of a glass slide with four duplicates of each sample. The slide with immobilized proteins was thoroughly washed with distilled water followed by adding the NBT/BCIP and incubated for 10 min. Color then developed. Relative recovery activities of the fusion proteins were evaluated according to the depth of the color spots. As shown in Figure 4, the sequence of depth of the color was D101S-linker-streptag, D101S-streptag, and WT-linker-streptag. Results from the variance analysis and *t*-test also showed that the color among three candidates has extremely notable discrimination, the average margins between arbitrary two of the three candidates (25.75; 35.25; 9.5) are greater than the value of $t_{0.01} \times S_D$ (8.52). No detectable signal was observed when WT, which was used as an experiment control, was spotted on the glass surface by the same procedure.

DISCUSSION

The active sites of enzyme are less rigid and more sensitive to slight changes of conformation during immobilization. General immobilization process, e.g., chemical cross-linking or covalent binding, usually results in alterations in the level of enzyme activity. There are numerous chemical groups on the surface of the enzyme for immobilizing enzyme onto solid supports. For example, there are 40 lysine residues in the EAP structure, most of them are located on the surface of the enzyme with exposure of their amido groups, providing random chemical binding sites. Some of the amido groups are right in the active sites, which may result in poor recovery activity if chemical reagents are used for immobilization. The conception of using EAP-streptag system is to avoid random immobilization as that the C-terminal of the enzyme protein domain, where the streptag fused to, is the unique binding site, leaving the active sites opening toward the bulk solution. The streptag here acts as an anchor. The problem of less activity of the EAP-streptag is overcome by insertion of the linker peptide. This linker peptide is composed of glycine and serine. Glycine is the simplest amino acid, with no ionizable carbon side chain. The absence of a side chain gives the polypeptide backbone at glycine residues much greater conformational flexibility. The side chain of serine is short and hydrophilic due to the presence of a hydroxyl group. The peptide composed of these two amino acids forms a stable α-helix (as viewed by Swiss Protein Data Bank Viewer, SPDBV) in water solution (Figure 5). When the immobilized EAP was secluded away from the support surface by using this long and hydrophilic anchor-chain or spacer arm, it exhibits minimal steric hindrances that could be promoted by the streptag and the proximity of the support surface. The data showed the evidence that catalytic activities of the fusion proteins with linker are much higher than that of the fusion proteins without linker.

Charges on the streptag and the relative position of the peptide and the EAP in aqueous solution affect the elution during ion-exchange chromatography. The streptag peptide contains 10 amino acids (SAWRHPQPGG), of which, only two (R and H) are basic amino acids. The side chain of arginine consists of three hydrophobic

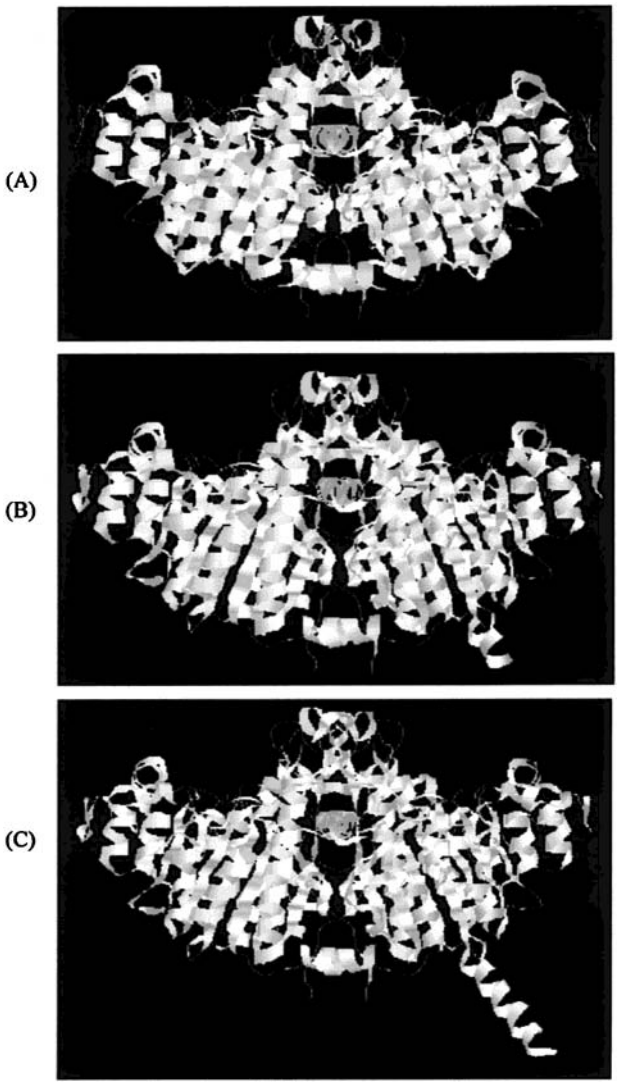

Figure 5. Three-dimensional structure of the EAP (A), EAP-streptag (B) and EAP-linker-streptag (C). The linker peptide shows α-helix at the C-terminal of EAP.

methylene groups and the strong basic δ-guanido group, of which pK'_R is 12.48 and is ionized over almost entire pH range, i.e., it is positively charged in our experimental condition (pH 7.4). Histidine is one of the strongest bases with a pK'_R of 6.20. It is not surprising that EAP-streptag fusion protein needs a lower ionic strength to be eluted from column as the tag has two extra positively amino acids (R and H) than WT. But what is surprising is the large different elution ionic strength between EAP-streptag and EAP-linker-streptag. It is not due to any charge in the linker as the linker is composed of amino acids (G and S) that are neutral at pH 7.4. It is thought that this large difference is due to the linker altering the position of the tag relative to the EAP, the co-effect of the linker, and streptag peptide on the surface of the enzyme, or some unknown interaction between proteins that may lead to charges exposing or covering. That needs to be further verified.

CONCLUSION

We have successfully obtained a higher recover activity by the insertion of a linker peptide between EAP and streptag. The proposed anchor-chain method could serve as a model to build other fusion protein systems and is optimistic to achieve better orientation control of enzyme immobilization, which is potentially useful in high quality construction of biosensors, biochips, and biodevices.

Homogeneous DNA Hybridization Assay by Using Europium Luminescence Energy Transfer

Shinji Sueda, Jingli Yuan, and Kazuko Matsumoto*

Department of Chemistry, Waseda University, 3-4-1 Okubo, Shinjuku-ku, Tokyo 169-8555, Japan. Received March 20, 2000; Revised Manuscript Received September 4, 2000

Homogeneous DNA hybridization assay based on luminescence resonance energy transfer (LRET) from a tetradentate β-diketonate europium chelate, 4,4′-bis(1″,1″,1″,2″,2″,3″,3″-heptafluoro-4″,6″-hexanedion-6″-yl)-chlorosulfo-*o*-terphenyl (BHHCT)-Eu^{3+} (λ_{ex} = 340 nm and λ_{em} = 615 nm), to an organic dye, Cy5 (λ_{ex} = 643 nm and λ_{em} = 669 nm) has been developed, in which two DNA probes whose sequences comprises the whole complementary strand to the target DNA, are used; one probe having a biotin label on the 3′-terminus and the other a Cy5 label on the 5′-terminus. After hybridization, streptavidin labeled with BHHCT-Eu^{3+} was added to the hybridization solution, and in the presence of the target DNA, the sensitized emission of Cy5 was observed when the hybridized complex was irradiated at 340 nm. In the absence of the target DNA, no emission was observed from Cy5.

INTRODUCTION

DNA hybridization assay has been widely used as a research tool for gene expression analysis and diagnosis of infectious and genetic diseases (*1*−*4*). Most of the currently available methods are, however, time-consuming and tedious because the method requires immobilization of the target DNA on a solid support for separation of the unhybridized probe DNA from the hybridized DNA duplex. In this regard homogeneous DNA hybridization assay using fluorescence resonance energy transfer (FRET) is attractive (*5*−*8*), in which two DNA probes, each being complementary to the two different sequences of a target DNA, are used. One probe has a donor dye, while the other an acceptor dye. The target DNA is detected in a homogeneous manner by monitoring the sensitized emission of the acceptor. So far all the systems developed employ organic dye pairs. In such systems, however, substantial background emission is caused both by the donor emission and the directly excited acceptor emission, even though the emission is monitored at the wavelength of the acceptor (*8*).

To circumvent this problem, we have directed our attention to the use of lanthanide chelate (*9*−*14*) as the energy donor. Emission profiles of lanthanide chelates are very sharp usually having fwhm of ca. 10 nm, and the excitation and the emission maximums are far separated. For instance, Eu chelates are excited in the UV region (∼340 nm) and exhibits luminescence at 615 nm. Therefore, the sensitized emission band of the organic acceptor can be easily distinguished from that of the lanthanide chelate donor and also from the excitation light in the UV region. Moreover, the lifetimes of lanthanide chelates are very long (∼1 ms) and as a result, the sensitized emission of the acceptor also becomes long-lived. Thus, by employing time-resolved luminescence measurement, the directly excited emission of the acceptor which is short-lived, can be eliminated (*11*−*14*).

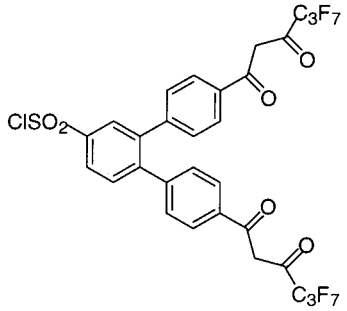

Figure 1. Structure of BHHCT.

Our group has developed a tetradentate β-diketonate europium chelate, 4,4′-bis(1″,1″,1″,2″,2″,3″,3″-heptafluoro-4″,6″-hexanedion-6″-yl)-chlorosulfo-*o*-terphenyl (BHHCT)-Eu^{3+} (Figure 1), which has been successfully used in time-resolved fluoroimmunoassay (*15*−*19*), and also in the detection of DNA immobilized onto a solid support (*20*). In the present study, a homogeneous DNA hybridization assay system based on LRET has been developed by using BHHCT-Eu^{3+} as the donor and an organic dye, Cy5 as the acceptor.

The principle of the method is illustrated in Figure 2, in which two DNA probes, one having a biotin label on the 3′-terminus and the other a Cy5 label on the 5′-terminus, are used. The two probes are complementary to the contiguous regions of a target DNA, such that when hybridized to the target DNA, the two labels come close each other. After hybridization, streptavidin labeled with BHHCT-Eu^{3+} chelate is added to the solution, and when the target DNA is present, the two labels come close and the energy transfer occurs from the Eu^{3+} chelate to Cy5. In the absence of the target DNA such phenomena cannot occur. Therefore, by monitoring the sensitized emission of Cy5, the target DNA can be detected in the homogeneous solution without immobilization and separation steps.

EXPERIMENTAL PROCEDURES

The Labeling of Streptavidin with BHHCT-Eu^{3+} Chelate. All procedures including synthesis of BHHCT

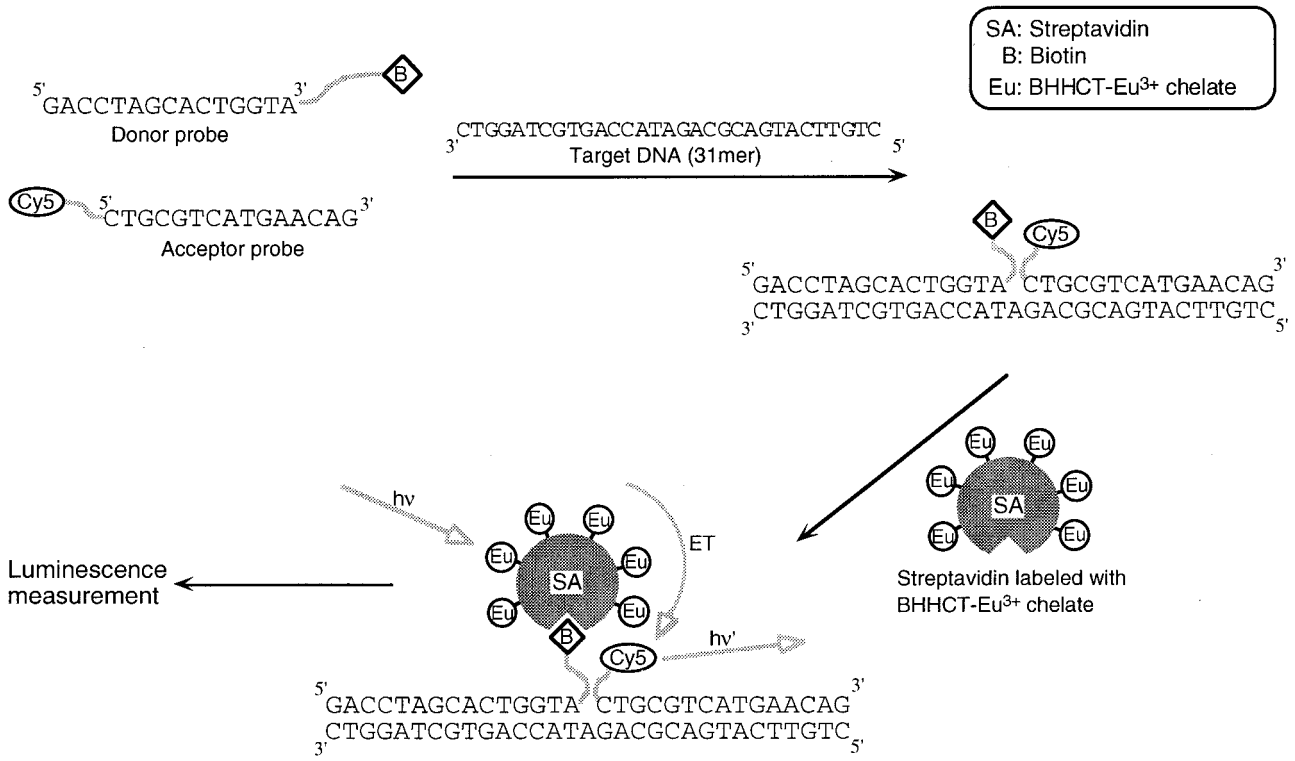

Figure 2. Principle of the homogeneous DNA hybridization assay.

were discussed in the previous paper (*15*). The procedure for labeling of streptavidin (SA) with BHHCT-Eu^{3+} was reported, but is slightly modified in the present study as in the following. To 0.1 M carbonate buffer (pH 9.1) (33 mL) containing 5 mg (8.3×10^{-5} mmol) of SA was added an ethanol solution (0.2 mL) containing 4 mg (4.9×10^{-3} mmol) of BHHCT. After the solution was stirred for 1 h at room temperature, it was dialyzed twice against 4 L of 0.1 M $NaHCO_3$ containing 0.25 g of NaN_3, first for 24 h and then for 7 h. The labeling ratio of BHHCT to SA was determined as $SA(BHHCT)_{20}$ by using the absorbance of the labeled SA solution and the molar extinction coefficient of BHHCT. The complexation with Eu^{3+} was achieved by dilution of the labeled SA solution (1 mL) with 50 mM Tris-HCl buffer (pH 7.8) (24 mL) containing equimolar $EuCl_3$ to BHHCT and incubation for 2 h at 55 °C.

Preparation of the target oligonucleotides (target DNAs) and the modified oligonucleotides (probe DNAs).

Figure 3 shows the target oligonucleotides and modified oligonucleotides used in the present work. All oligonucleotides were prepared on a fully automated DNA synthesizer according to a standard phosphoramide coupling method. Introduction of biotin and Cy5 into the oligonucleotides was achieved by using Biotin TEG CPG and Cy5 Phosphoramidite (GLEN RESEARCH), respectively. The purification of oligonucleotides was carried out with reversed-phase HPLC.

Hybridization Condition. The target oligonucleotides and probe oligonucleotides were mixed at a desired ratio in a buffer containing 10 mM Tris-HCl (pH 7.8) and 0.5 M NaCl. Oligonucleotides were annealed by heating at 50 °C for 15 min and cooling to room temperature.

Luminescence Energy Transfer Measurement. To the solution of the hybridized oligonucleotides was added the solution of BHHCT-Eu^{3+}-labeled SA at a molar ratio of SA to the biotinylated DNA of 1:1. The final concentrations of the probe DNAs and labeled SA were 50 nM. After the solution was incubated for 1 h at room temperature, the luminescence was measured with the excitation at 340 nm. All the luminescence measurement was done on a LS-50B (Perkin-Elmer) fluorometer equipped with a Xenon discharge lamp. A 420 nm cut off filter was employed to eliminate the second-order scattering light. In the time-resolved luminescent measurement, the samples were excited with pulse light of the Xenon lamp, and the spectra were recorded over a gate period of 300-μs after 40-μs delay time.

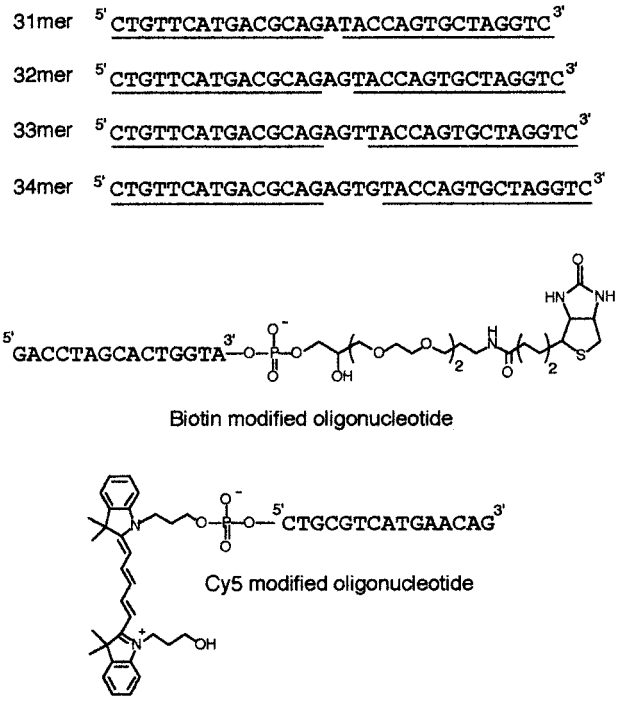

Figure 3. Sequences of the target oligonucleotides (target DNAs) and the modified oligonucleotides (probe DNAs) used in the present study. The binding sites of the probe DNAs on the target DNAs are underlined.

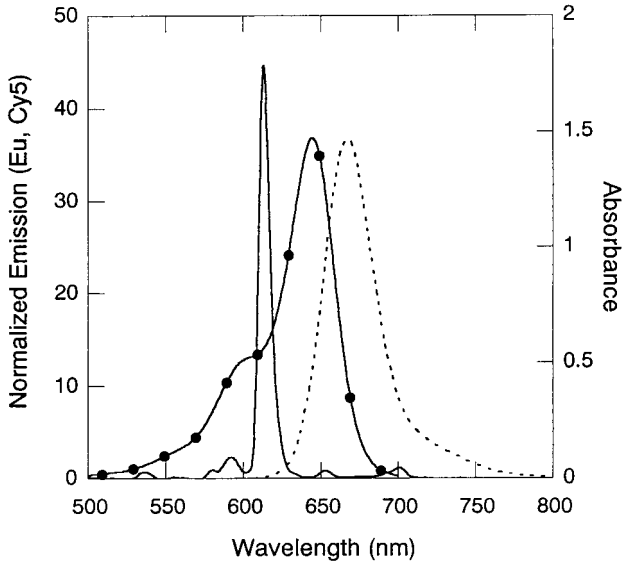

Figure 4. Spectra of BHHCT-Eu^{3+} chelate bound to SA and Cy5 bound to the oligonucleotide. The solid line is the emission spectrum (λ_{ex} = 340 nm) of BHHCT-Eu^{3+} chelate, and the dashed line and solid line with circles are the emission spectrum (λ_{ex} = 643 nm) and absorption spectrum of Cy5, respectively.

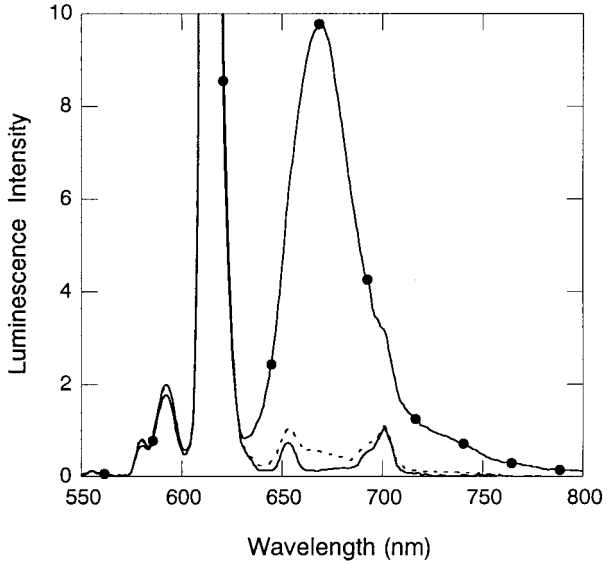

Figure 5. Normal (not time-resolved) emission spectra in the presence (solid line with circles) and absence (dashed line) of the target DNA (31mer). The spectrum of SA labeled with BHHCT-Eu^{3+} chelate alone is also shown (solid line). The concentrations of the probe DNAs, the target DNA, and SA were 50 nM.

RESULTS

Spectral Characteristics of the Donor and Acceptor. Figure 4 shows the emission spectrum of BHHCT-Eu^{3+} chelate bound to SA, and the emission and absorption spectra of Cy5 bound to the oligonucleotide. The emission peak of the Eu^{3+} chelate overlaps on the absorption spectrum of Cy5, satisfying the requirement for luminescence resonance energy transfer. It is also noteworthy that the emission intensity of the Eu^{3+} chelate at the Cy5 emission maximum 669 nm is very weak; the emission intensity of the Eu^{3+} chelate at 669 nm is 280 times lower than that of 615 nm maximum. Such low emission intensity of the donor at the emission wavelength of the acceptor is very important for monitoring the sensitized emission of Cy5.

Energy Transfer Measurements. Figure 5 shows the normal (not time-resolved) emission spectra in the presence and absence of the target DNA, 31mer. As expected, the sensitized emission of Cy5 is observed in the presence of the target DNA, but not in the absence of the target DNA. In Figure 5, the emission spectrum of SA labeled with Eu^{3+} chelate alone (without DNAs) is also shown as the control. Comparison of this spectrum (solid line) with that in the absence of the target DNA (dashed line) shows that slight emission of Cy5 is observed even in the absence of the target DNA. This slight emission is derived from the direct excitation of Cy5 at the wavelength used in this study. However, this emission is very weak compared with that of the sensitized emission of Cy5; as a result, the ratio of the signal to background at 669 nm is very high, approximately 20:1. Such a high signal/background ratio cannot be achieved in the systems using only organic dyes as the donor−acceptor pair.

Similar measurement was carried out with time-resolved mode, and Figure 6 shows the observed time-resolved emission spectra. Similar to the normal luminescence measurement, the sensitized emission of Cy5 was observed by addition of the target DNA. What is different from the normal measurement is that the emission spectrum of the Eu^{3+} chelate alone (solid line) is almost same as the spectrum in the absence of the target DNA (dashed line) with an identical intensity at 669 nm. This means that the directly excited band of Cy5 observed in the normal luminescence measurement can be eliminated by time-resolved measurement. However, the emission intensity of the Eu^{3+} chelate is much stronger in the time-resolved measurement than that of the sensitized emission of Cy5, because the lifetime of the sensitized emission, even though it is increased by FRET, is still shorter than that of the Eu^{3+} chelate. Consequently, the signal/background ratio is somewhat small, 14:1, but the ratio is still superior to those obtained for the organic dyes.

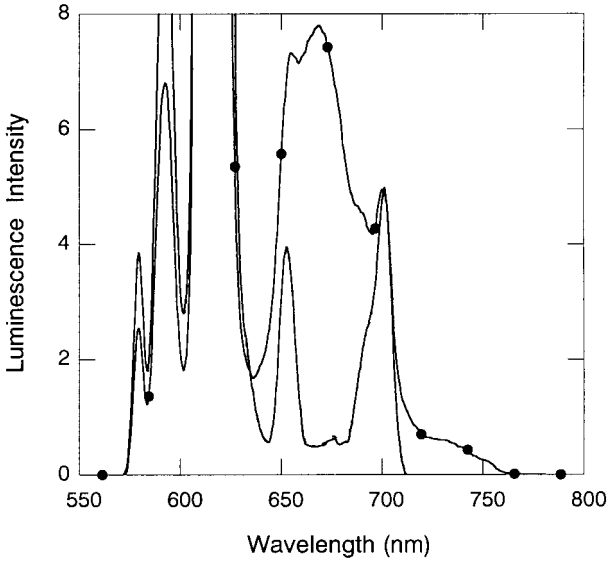

Figure 6. Time-resolved emission spectra in the presence (solid line with circles) and absence (dashed line) of target DNA (31mer) and SA labeled with BHHCT-Eu^{3+} chelate alone (solid line). The spectra were obtained with 40-μs delay time and 300-μs gate time.

Effect of the Unhybridized Spacer Length between the Two Hybridized Sequences on the Target DNA. The effect of the unhybridized spacer length between the two hybridized sequences on the target

34mer	0.93

[a] The values are based on the normal luminescence measurement.

DNAs was examined. For this purpose, target DNAs of 31mer, 32mer, 33mer, and 34mer were prepared, each having 1, 2, 3, and 4 inserting bases, respectively, between the hybridized sequences (Figure 3). The luminescence behaviors in the presence of these target DNAs were compared. Table 1 shows the relative intensities of the sensitized emission at 669 nm in the presence of each target DNA. The emission intensity is decreased as the number of the bases between the hybridized sequences is increased. However, the difference is smaller than expected for the well-known dependence of the efficiency of energy transfer on the R^{-6}, where R is the distance between the donor and the acceptor. This may be accounted for by the fact that the distance between donor and acceptor is flexible due to the molecular fluctuation. Biotin is tethered to the oligonucleotide via a long linker of 22 atoms. Moreover, in the present systems, multiple Eu^{3+} chelates labeled to a SA molecule act as the energy donor. From the viewpoint of the practical use, this little dependence of the energy transfer on the distance is advantageous because close contact of the two hybridized sequences are not strictly necessary in order to get effective sensitized emission. That is, wide variety of sequences of the probe DNAs can be employed in the experiment, and this makes the present system more flexible and adaptable to any DNA assay, compared to the previous energy-transfer DNA assays (*8*). In the previous assay, optimum distance between the donor and the acceptor usually exists, and the DNA probes must be designed in a more strict way to obtain the most efficient energy transfer.

Sensitivity of the Detection Method. The sensitivity of the present method was examined by using the 31mer as a target DNA. Figure 7 shows the plot of the Cy5 emission intensity at 669 nm against the concentration of the target DNA. The plot is based on the normal luminescence measurement. Almost the same plot was obtained by the time-resolved luminescence measurement. The detection limit was determined as the concentration corresponding to the twice amount of the background standard deviation. In both measurement modes, detection limit was about 200 pM when 50 nM of the probe DNA was used. By using lower concentrations of the probe DNA, the detection limit would be improved.

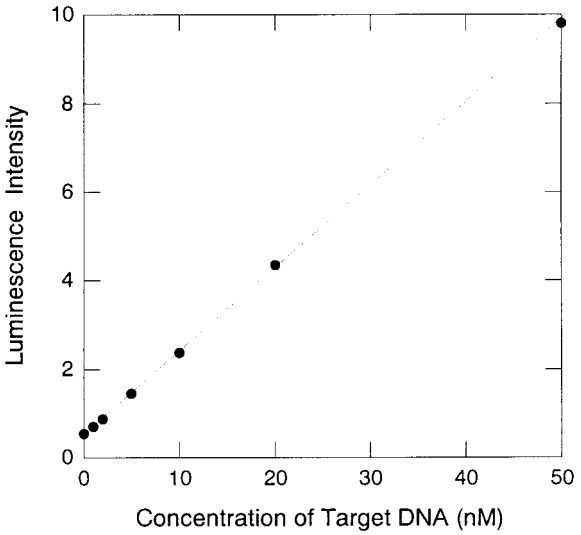

Figure 7. The plot of the Cy5 emission intensity at 669 nm against the concentration of the target DNA (31mer). The data are based on the measurement by normal luminescence mode.

DISCUSSION

In the present work, homogeneous DNA hybridization assay based on energy transfer from BHHCT-Eu^{3+} chelate to Cy5 has been developed. The characteristics of the method are the followings. First, the signal/background ratio at the sensitized emission wavelength is superior to that obtained by using organic dyes as the donor−acceptor pair. This is because the emission intensity of the europium chelate is quite weak at the maximum emission wavelength of Cy5. The other reason is that the Cy5 emission due to the direct excitation is efficiently eliminated by time-resolved luminescence detection. This direct emission of Cy5 is also very effectively suppressed even in the normal luminescence detection, since Cy5 is scarcely excited at the excitation wavelength for the europium chelate, 340 nm (the molar extinction coefficient of Cy5 at 340 nm is about one-seventieth of that at its maximum absorption wavelength, 643 nm). Thus, high signal/background ratio can be achieved even without time-resolved detection, and this shows the great advantage of using Eu chelates as the donor.

Another characteristic of the present method is that the sensitized emission occurs very effectively, since the europium chelate is multiply labeled onto the probe DNA by using the streptavidin−biotin interaction. The multiple europium chelates act as the sensitizer for Cy5, causing strong sensitized emission of Cy5. The intensity of the sensitized emission at 669 nm is about half the magnitude of the intensity observed by direct excitation of Cy5 at its absorption maximum wavelength (643 nm) by using the same instrument equipped with a Xenon lamp. In the most energy transfer experiment reported so far, the ratio of the donor to acceptor is one to one, and the excitation efficiency of the acceptor is not sufficiently high. However, multiple labeling of the conventional donor organic dyes is not useful to enhance the fluorescence of the acceptor, since multiple labeling dose not always increase the donor emission due to self-quenching (*21*). For europium chelates, self-quenching is not a problem, since they have a large Stokes' shift.

In the present method, two detection modes can be employed, one is the normal luminescence mode, and the other is the time-resolved mode. Considering the signal/background ratio alone, the former is better than the latter in the present model systems using synthetic oligonucleotides as the target DNAs. However, in the case of natural DNA samples containing many impurities, the time-resolved detection mode might be more favorable because the background emission caused by the impurities can be effectively eliminated. The effort for clarifying this point and the detailed study concerning the relation of the energy transfer efficiency and the distance between the two probes remain to be made.

Maleimide-Functionalized Lipids that Anchor Polypeptides to Lipid Bilayers and Membranes

John T. Elliott[†] and Glenn D. Prestwich*

Department of Physiology and Biophysics, The University at Stony Brook, Stony Brook, New York, Department of Medicinal Chemistry, The University of Utah, Salt Lake City, Utah. Received March 27, 2000; Revised Manuscript Received June 13, 2000

Two maleimide-containing diacylglycerol derivatives were synthesized to permit the anchoring of short peptides and longer polypeptides to phospholipid bilayers and membranes. The maleimide was introduced at the site normally occupied by a phospholipid headgroup. The first lipid, the dipalmitoyl ester of 1-maleimido-2,3-propanediol, was developed as a membrane anchor for extracellular domains of transmembrane proteins. The second anchoring lipid, in which the 3-position contained a 6-aminohexanoate, was designed for convenient modification with amine-reactive reporter groups. Specifically, the NBD fluorophore, 7-nitrobenzo-2-oxa-1,3-diazole-aminohexanoic-*N*-hydroxysuccinimide ester, was attached to give an fluorescent anchoring reagent. Next, these reagents were applied to the anchoring of a C-terminally cysteamine-modified 8 kDa polypeptide that comprises the extracellular N-terminal domain of the human thrombin receptor, a transmembrane protease-activated receptor (PAR-1). Gel filtration and fluorescence analysis showed that the fluorescent lipopolypeptide spontaneously inserted into preformed phospholipid vesicles, but it did not insert into whole cell membranes. In contrast, the dipalmitoyl derivative could only be reconstituted into artificial membranes by mixing the lipopolypeptide and phospholipid before vesicle formation. These results suggest that biophysical interactions governing the lipopolypeptide insertion into artificial and cellular membranes may differ. The thiol-reactive lipidating reagents should be valuable materials for studying the structure and function of peptides and polypeptides at phospholipid bilayer surfaces.

INTRODUCTION

Lipid modification of soluble peptides and polypeptides confers amphipathic character to the molecules and typically changes their behavior in aqueous solutions. The amphiphiles have a tendency to aggregate, form micelles and vesicles, and associate with phospholipid bilayers. This property makes it possible to use acylated peptides and polypeptides to investigate biophysical phenomena that occur on cellular membranes. Versatile reagents for the synthesis of lipopeptides are thus an important requirement for the success of such studies. We describe herein two new thiol-reactive lipids and the attachment of these reagents to a thiol-functionalized recombinant 8-kDa polypeptide.

Synthetic lipoconjugates can be used to evaluate the biophysics of protein−membrane interactions. Membrane binding properties of signal transduction and oncogenic proteins that are palmitoylated or myristoylated in vivo have been examined with lipopeptides that represent the native proteins (*1*−*3*). Naturally occurring lipopeptides that function as bacterial cell wall components (*4*), biosurfactants (*5*), or antibiotics (*6*) have been investigated using artificially synthesized analogues under in vitro and in vivo conditions. Lipid conjugates of peptides have also been used to study biologically relevant structural conformations that are induced at phospholipid membrane surfaces (*7*). A lipid modification can significantly increase the lifetime of the membrane-bound complex, thereby improving the data obtained from a structural study. For example, the structural properties of peptide hormones CCK (*8*), gastri (*9*), and yeast α-factor (*10*) were studied in membrane-bound preparations using this approach.

A variety of synthetic methods are available for preparing lipid conjugates of peptides and polypeptides. Acylations can be performed at reactive amino acid side chains (*11*, *12*) or during peptide synthesis on solid-phase resins (*13*−*16*). In the former method, conjugation via a thiol group is convenient because thiol function is often unique in a primary sequence (i.e., Cys). In addition, molecular biology techniques allow site-specific incorporation of cysteine residues when the peptides or polypeptides are produced in cellular systems (*17*). The maleimide group is routinely used as a thiol acceptor, as it exhibits high selectivity and reactivity under essentially neutral aqueous conditions. Several maleimide-based lipidating reagents are commercially available. Two reagents are based on a heterobifunctional four- or six-carbon linker conjugated to the phosphatidylethanolamine headgroup (Avanti Polar Lipids, Alabaster, AL). Another features a 3500 Da poly(ethylene glycol) extending from the phospholipid headgroup (Shearwater Polymers, Huntsville, AL), but the flexible tether introduces considerable uncertainty as to where coupled peptide would reside relative to the membrane surface.

To study the extracellular polypeptide domains of transmembrane membrane proteins, we required a reagent that could anchor a sulfhydryl-containing peptide

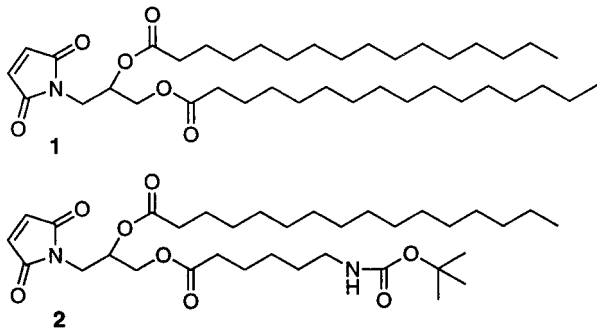

Figure 1. Structures of the maleimido-lipids. Lipid **2** contains a BOC protecting group on the primary acyl chain. Upon BOC removal, the amino-acyl chain can be modified with amine reactive reporter groups.

to a phospholipid bilayer. For our application, it was important that the conjugation site was confined to the region of a phospholipid bilayer normally occupied by the headgroups. Thus, two lipids that contained maleimide functional groups on a diacylglycerol-like backbone were prepared (Figure 1). The first lipid, Pam_2Mal (**1**), was constructed with two palmitoyl chains to serve as a membrane anchor. The second lipid, BOC-AH−PamMal (**2**), was prepared with a palmitoyl and a BOC-protected[1] 6-aminohexanoyl chain. The protected amino-acyl chain was introduced so the lipid could ultimately be modified with amine reactive reporter groups (e.g., fluorophores) to allow facile quantitation and localization of the lipoconjugate (*18*). In this study, the lipid was derivatized to give the fluorescent lipidating reagent 7-nitrobenzo-2-oxa-1,3-diazole-6-aminohexanoyl-AH−PamMal (NBD-PamMal) (**10**).

To evaluate the utility of the lipids, a soluble 8 kDa polypeptide representing the N-terminal extracellular domain of the G protein-coupled human thrombin receptor (PAR-1) (*19*) was selectively derivatized at a C-terminal cysteamine with Pam_2Mal and NBD-PamMal. The lipopolypeptides were assessed for their ability to associate with artificial and cellular membranes by gel filtration and fluorometric assays. The results from this study demonstrate that these new thiol-reactive lipidating reagents will be valuable for preparing lipoconjugates that can be anchored into phospholipid membranes, and can be employed for biological structure and function studies.

EXPERIMENTAL PROCEDURES

Materials and General Methods. NMR spectra were collected on a Varian Gemini 300 instrument. High-resolution FAB-MS was performed at The University of California, Riverside, mass spectrometry facility. MALDI-MS was performed on a Bruker Protein-TOF system using a 3,5-dimethoxy-4-hydroxy-cinnamic acid (sinapinic acid) matrix (CASM, University at Stony Brook, Stony Brook, New York). Uncorrected melting points were determined on a Fisher-Johns apparatus. The purity of the compounds was estimated by TLC, reversed-phase HPLC (RP-HPLC), mass spectrometry and NMR. *N*-Methoxycarbonylmaleimide (NMM) was obtained from Sigma Chemical (St. Louis, MO). Chemical reactions were carried out in HPLC grade solvents and reagent grade solvents were used for silica gel chromatography (flash grade). Phospholipids were purchased from Avanti Polar Lipids (Alabaster, AL). HPLC purifications were performed on an LKB/Bromma 2152 system and the eluate was monitored at 220 or 280 nm. BOC-6-aminohexanoic acid (*20*) and CBZ-(±)-1-amino-2,3-propanediol (*21*) were prepared as previously described.

TLC Stains. Lipid products were identified with 10% phosphomolybdic acid in ethanol (EtOH). Primary amines were detected with 5% ninhydrin in EtOH. Maleimides were identified as previously described (*22*). Fluorescent lipid products were visualized directly under long-wavelength UV illumination (~350 nm).

CBZ-Amino-2,3-dipalmitoyl-propane (4). CBZ-Amino-propanediol **3** (0.45 g, 2.0 mmol) was mixed with palmitic acid (1.22 g, 4.8 mmol) and (dimethylamino)-pyridine (DMAP, 0.49 g, 4.0 mmol) in $CHCl_3$ (20 mL). Diisopropylcarbodiimide (DIC, 790 μL, 5.0 mmol) was added and the mixture was stirred for 16 h at room temperature. The solvent was removed by rotary evaporation and the residual oil was dissolved in methanol (MeOH) (ca. 50 mL) and stored at −20 °C for 1 h. Precipitated material was collected by filtration, redissolved in $CHCl_3$ (1−2 mL) and recrystallized with MeOH. The product was collected by filtration and dried under vacuum. A white solid (0.81 g, 87% yield) was obtained: FAB-MS for $C_{43}H_{75}NO_6$, MH^+ at *m/z* 702.5679 (calcd 702.5673); mp 49−50 °C; ^{1}H NMR (300 MHz, $CDCl_3$) δ 0.83−0.87 (t, 6 H), 1.17−1.23 (m, 48 H), 1.54−1.60 (m, 4 H), 2.24−2.31 (m, 4 H), 3.36−3.48 (m, 2 H), 4.08−4.28 (m, 2 H), 4.96 (b, 1 H), 5.08 (s, 2 H), 7.24−7.34 (m, 5 H). The product was observed on TLC, $R_f = 0.57$ in hexane (Hex):EtOAc (2:1).

CBZ-Amino-3-(BOC-6-aminohexanoyl)-2-propanol (5). CBZ-Amino-propanediol **3** (1.2 g, 5.3 mmol) was mixed with BOC-6-aminohexanoic acid (1.17 g, 5.0 mmol) and DMAP (0.65 g, 5.3 mmol) in $CHCl_3$ (30 mL). The solution was cooled to 0 °C and dicyclohexylcarbodiimide (DCC, 1.65 g, 8.0 mmol) was added. The major product was observed by TLC, $R_f = 0.51$ in EtOAc:Hex (2:1). After 24 h, the urea byproduct was removed by filtration. The solvent was evaporated and the residue was dissolved in a small volume of $CHCl_3$:EtOAc:Hex (3:2:1). The mixture was purified on silica gel by eluting with EtOAc:Hex (2:1). A clear oil was obtained after solvent removal (1.1 g, 45% yield): FAB-MS for $C_{22}H_{34}N_2O_7$, MH^+ at *m/z* 439.2465 (calcd 439.2444); ^{1}H NMR (300 MHz, $CDCl_3$) δ 1.29−1.35 (m, 2 H), 1.41−1.48 (m, 11 H), 1.58−1.65 (m, 2 H), 2.30−2.35 (m, 2 H), 3.07 (br t, 2 H), 3.16−3.47 (m, 2 H), 3.64 (br s, 1 H), 3.93 (m, 1 H), 4.04−4.14 (m, 1 H), 4.64 (br s, 1 H), 5.09 (s, 2 H), 5.43 (br s, 1 H), 7.29−7.33 (m, 5 H).

CBZ-Amino-2-palmitoyl-3-(BOC-6-aminohexanoyl)-propane (6). Secondary alcohol **5** (1.1 g, 2.5 mmol) was mixed with palmitic acid (0.77 g, 3.0 mmol) and DMAP (0.31 g, 2.5 mmol) in $CHCl_3$ (25 mL). DCC (0.64 g, 3.13 mmol) was added and the solution was stirred for 16 h at room temperature. The mixture was cooled (−20 °C) and the urea byproduct was removed by filtration. The

[1] Abbreviations: BOC, di-*tert*-butyl-dicarbonate; CBZ, carbobenzyloxy protecting group; CHRF-288, megakaryoblastic cell-type; DCC, dicyclohexylcarbodiimide; DIC, diisopropylcarbodiimide; DMPC, 1,2-dimyristoyl-*sn*-glycero-3-phosphocholine; DMPG, 1,2-dimyristoyl-*sn*-glycero-3-phosphoglycerol; DTT, dithiothreitol; Hex, hexane; NBD, 7-nitrobenzo-2-oxa-1,3-diazole; NBD-Cl, 4-chloro-NBD; NBD-X-NHS, NBD-6-aminohexanoic-*N*-hydroxysuccinimide ester; NMM, *N*-methoxycarbonyl-maleimide; NTTR, extracellular N-terminal domain of the human thrombin receptor (residues Glu^{30}-Ser^{99}); NTTR-ML, NTTR-dipalmitoyl lipid conjugate; NTTR-(NBD)ML, NTTR-fluorescent lipid conjugate; NTTR-SH, NTTR with a C-terminal sulfhydryl group; PAR-1, protease activated human thrombin receptor; PB, phosphate buffer; POPC, 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphocholine; RP-HPLC, reversed-phase HPLC; S2, *Drosophila melangaster* cell-line; TEA, triethylamine; TX-100, Triton X-100.

solvent was removed by rotary evaporation and the remaining residue was dissolved in small volume of $CHCl_3$:EtOAc:Hex (2:1:1), purified on silica gel with EtOAc:Hex (1:1), and concentrated to give a clear oil (1.6 g, 95% yield): FAB-MS for $C_{38}H_{64}N_2O_8$, MNa^+ at *m/z* 699.4590 (calcd 699.4560); ^{1}H NMR (300 MHz, $CDCl_3$) δ 0.82−0.87 (t, 3 H), 1.19−1.68 (m, 41 H), 2.20−2.30 (m, 4 H), 3.04−3.08 (t, 2 H), 3.37−3.44 (m, 2 H), 4.05−4.12 (m, 2 H), 4.23−4.28 (m, 1 H), 5.06 (m, 3 H), 7.27−7.35 (m, 5 H); TLC, $R_f = 0.52$ in Hex:EtOAc (2:1).

1-Amino-2,3-dipalmitoyl-propane (7a). CBZ-protected lipid **4** (2.0 g, 2.8 mmol) was dissolved in warm absolute EtOH (100 mL) containing 5% Pd/C (ca. 500 mg). The solution was saturated with H_2 (ca. 2 atm) and shaken for 6 h at room temperature. $CHCl_3$ (100 mL) was added to the solution, the catalyst was removed by filtration through Celite, and the solvent was removed in vacuo to give a white solid. The product migrated slightly above the origin on TLC in Hex:EtOAc (2:1) and stained positive with ninhydrin.

Pam_2Mal (1). Amino lipid **7a** (300 mg, 0.48 mmol) was mixed with NMM (147 mg, 0.94 mmol) and tetrabutylammonium hydrogen sulfate (150 mg, 0.44 mmol) in $CHCl_3$ (4 mL) on ice. TEA (66 μL, 0.64 mmol) was slowly added over 5 min, and the solution was stirred for an additional 10 min. The solution was removed from the ice and saturated $NaHCO_3$ (8 mL) was added to the organic layer while being vigorously stirred. The maleimido-lipid was observed in the organic layer by TLC, $R_f = 0.83$ in Hex:EtOAc (2:1). After 3 h at room temperature, the phases were separated by low speed centrifugation and the reddish organic layer was concentrated in a rotary evaporator. The residue was dissolved in a small volume of $CHCl_3$:Hex:EtOAc (3:2:1) and the maleimido-lipid was purified on silica gel with a Hex:EtOAc (2:1) and concentrated to give a white crystalline product (211 mg, 69% yield): FAB-MS for $C_{39}H_{69}NO_6$, MNa^+ at *m/z* 670.5005 (calcd 670.5023); mp 62−63 °C; ^{1}H NMR (300 MHz, $CDCl_3$) δ 0.83−0.87 (m, 6 H), 1.16−1.23 (m, 48 H), 1.51−1.61 (m, 4 H), 2.21−2.33 (m, 4 H), 3.68−3.81 (m, 2 H), 4.04−4.25 (m, 2 H), 5.19−5.24 (m, 1 H), 6.69 (s, 2 H). The maleimide proton peaks were observed at 6.69 ppm. The product could be stored as a powder at −20 °C or as a 50 mM solution in $CHCl_3$ at −80 °C for at least one year with less than 5% maleimide hydrolysis.

BOC-AH-PamMal (2). Lipid **2** was prepared using the identical procedure described above for the CBZ removal and maleoylation of dipalmitoyl lipid **4**. The 1-amino-2-palmitoyl-3-(BOC-6-aminohexanoyl)-propane lipid (**7b**) was a clear oil. The maleoylated product (**2**) was observed by TLC ($R_f = 0.5$), developed in Hex:EtOAc (2:1), and purified on silica gel with Hex:EtOAc (2:1). After solvent removal and overnight drying in vacuo, a clear oil was obtained. The oil crystallized into a white waxy solid after standing overnight at −20 °C (277 mg, 69% yield): FAB-MS for $C_{34}H_{58}N_2O_8$, MNa^+ at *m/z* 645.4113 (calcd 645.4091); mp 37−39 °C; ^{1}H NMR (300 MHz, $CDCl_3$) δ 0.82−0.87 (t, 3 H), 1.22−1.67 (m, 41 H), 2.21−2.34 (m, 4 H), 3.07 (br t, 2 H), 3.66−3.81 (m, 2 H), 4.03−4.25 (m, 2 H), 5.18−5.25 (m, 1 H), 6.69 (s, 2 H). The product was stored at −20 °C for at least 5 months without detectable maleimide hydrolysis.

Modified Route to NBD-6-aminohexanoic-NHS Ester (NBD-X-NHS, 9). $NaHCO_3$ (0.63 g, 7.5 mmol) and 6-aminohexanoic acid (0.66 g, 5.0 mmol) were added to H_2O (5 mL). NBD-Cl (0.5 mg, 2.5 mmol) dissolved in MeOH (20 mL) was added and the mixture was stirred at 60 °C for 30 min (*23*). The solution was cooled in ice, acidified to pH 2.0 with concentrated HCl, and the MeOH was removed by rotary evaporation. Excess water (ca. 50 mL) was added and the suspension was homogeneously dispersed by bath sonication. A fine black powder was collected on a 0.45 μm cellulose acetate filter (Fisher Scientific), washed with water, and dried under vacuum. The total yield of crude NBD-6-aminohexanoic acid was 0.6 g (81% yield). Next, the crude NBD-6-aminohexanoic acid (250 mg, 0.85 mmol) and *N*-hydroxysuccinimide (120 mg, 1.02 mmol) were dissolved in acetone (10 mL); DIC (200 μL, 1.28 mmol) was added and the solution was stirred for 16 h at room temperature. The solvent was removed under reduced pressure and the residue was suspended in MeOH (8 mL) in a sonicator bath. The insoluble material was collected by centrifugation (6000*g* for 10 min), washed with MeOH (2 mL), and dried under vacuum. The total yield was 200 mg (57% yield) and the product was greater than 85% pure as determined by RP-HPLC (0−80% CH_3CN/0.1% TFA in 40 min, 1 mL/min, on a C_8 semianalytical column) and NMR (data not shown).

NBD-PamMal (10). The aminohexanoyl chain of lipid **2** (50 mg, 80 μmol) was quantitatively deprotected in $CHCl_3$:TFA (1:1, 1 mL) for 90 min at room temperature. The solvent was evaporated under N_2 and the residue was redissolved in a small amount of $CHCl_3$, and reconcentrated in vacuo to eliminate residual TFA. Next, the deprotected AH−PamMal (**8**) was dissolved in 90%$CHCl_3$/10%MeOH (1 mL), and then NBD-X-NHS **9** (31 mg, 80 μmol) and TEA (27 μL, 200 μmol) were added. The product NBD-PamMal was identified by TLC developed in EtOAc:Hex (2:1, $R_f = 0.09$) or EtOAc ($R_f = 0.32$). The sample was mixed for 60 min at room temperature, concentrated in vacuo to give an orange residue; this oil was dissolved in a small volume of $CHCl_3$:EtOAc:Hex (2:2:1) and purified on silica gel with EtOAc:Hex (2:1) to remove a major fluorescent byproduct, followed by elution with EtOAc. A highly fluorescent product was obtained as an orange oil (64.2 mg, 83% yield). FAB-MS for $C_{41}H_{61}N_6O_{10}$, MNa^+ at *m/z* 821.4428 (calcd 821.4425); ^{1}H NMR (300 MHz, $CDCl_3$) δ 0.83−0.87 (t, 3 H), 1.16−1.84 (m, 38 H), 2.18−2.35 (m, 6 H), 3.21−3.28 (m, 2 H), 3.51−3.53 (m, 2 H), 3.72−3.75 (m, 2 H), 4.02−4.29 (m, 2 H), 5.22−5.25 (m, 1 H), 5.78 (m, 1 H), 6.14−6.17 (d, 1 H), 6.70 (s, 2 H), 8.45−8.48 (d,1 H). Less than 5% of maleimide hydrolysis was detected by ^{1}H NMR. The product was stored at −80 °C as a 50 mM stock solution in $CHCl_3$.

Preparation of the Thrombin Receptor Tether Polypeptide (NTTR-SH). The complete details of the molecular biology and protein purification (*24*) will be published elsewhere. The method is briefly described here. The cDNA encoding the extracellular N-terminal region of the human thrombin receptor (PAR-1) (*19*) Glu^{30}−Ser^{99}, was amplified by PCR and subcloned into the pET-31b polypeptide expression system (Novagen, Milwaukee, WI). After expression, purification and preparative CNBr cleavage, the C-terminal homoserine lactone of the 66 amino acid polypeptide was derivatized with the free-base form of cystamine (*25*) in DMSO essentially as described (*17*). The disulfide containing polypeptide was purified by HPLC, reduced with dithiothreitol (DTT), and again purified by HPLC to generate the 8 kDa polypeptide with a C-terminal cysteamine (called NTTR-SH). The total yield was generally greater than 70% for a 25 mg scale reaction.

Lipid−Polypeptide Conjugation. Either Pam_2Mal **1** or NBD-PamMal **10** (3.0 μmol, 60 μL from 50 mM stock in $CHCl_3$) was mixed with *n*-octyl-glucopyranoside (0.1 mmol, 100 μL from 1 M stock in $CHCl_3$) in a glass test

tube. The solvent was evaporated with a stream of nitrogen, and the residue was dried under vacuum for 2 h. NTTR-SH (5 mg, 0.6 μmol) dissolved in degassed 50 mM phosphate buffer (PB), pH 7.0 (1 mL), was added to the detergent/lipid film. The tube was filled with argon and sealed with Parafilm, and the suspension was homogenized by sonication. After stirring for 2 h at room temperature, the sample was dehydrated in a Speed-Vac. $CHCl_3$ (0.7 mL) was added and the excess lipid, and detergent was extracted with brief bath sonication. The lipopolypeptide was recovered with the addition of MeOH (0.7 mL) and centrifugation (14000*g* for 10 min). The pellet was air-dried and dissolved in 200 μL of DMSO. Water (1 mL) was added and any insoluble material was removed by centrifugation (14000*g*). The supernatant was injected onto a semipreparative C_4 HPLC column (Vydac, 1.0 × 250 mm) and the lipoconjugate was purified with the gradient 20 to 100% B over 60 min at 2 mL/min; mobile phase A, 0% CH_3CN/0.052% TFA; mobile phase B, 90% CH_3CN/0.06% TFA. Product fractions were concentrated in a Speed-Vac, dissolved in water and lyophilized to give polypeptide conjugated to Pam_2Mal **1,** designated NTTR-ML, and the fluorescent lipopolypeptide conjugate from NBD-PamMal **10**, designated NTTR-(NBD)ML. The identity and purity of the products were determined by analytical HPLC, MALDI-MS, UV spectroscopy and fluorometry. Both lipopolypeptides were freely soluble in water and MeOH at concentrations of at least 4 mg/mL.

Reconstitution of Lipopolypeptides into Phospholipid Membranes. Reconstitution experiments were performed with approximately a 200:1 phospholipid to lipopolypeptide molar ratio unless otherwise indicated. 1,2-Dimyristoyl-*sn*-glycero-3-phosphocholine (DMPC) (7 mg, 10 μmol) was transferred into a small round-bottom flask and the solvent was removed under N_2 and then overnight in vacuo. NTTR-ML (23 nmol, 500 μL of a 46 μM stock solution in MeOH) was added to the lipid and homogeneously dispersed by bath sonication. The MeOH was removed by rotary evaporation and the residue was placed under vacuum for 8 h. The lipid film was hydrated with 50 mM PB, pH 7.2 (1 mL), and the contents were transferred to a glass test tube. The tube was filled with argon, sealed with Parafilm, and bath-sonicated (Heat Systems, Farmingdale, NY) for 30 min at 37 °C. Large multi-lamellar vesicles were removed by filtration through a 0.45 μm PVDF membrane (Whatman) and the samples were stored at 37 °C until used (*26*). Lipid loss from filtration was determined by including 0.1 mol % NBD-DMPE in the phospholipid sample and measuring the change in fluorescence after Triton X-100 (TX-100) (2% final concentration) was added to samples corresponding to before and after filtration. The lipid loss varied from 50% for DMPC to 10 for 20% (molar ratio) 1,2-dimyristoyl-*sn*-glycero-3-phosphoglycerol (DMPG)/1,2-dimyristoyl-*sn*-glycero-3-phosphocholine (DMPC) and 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphocholine (POPC) vesicle samples. The lipopolypeptide loss from filtration was determined by the fluorescamine assay used in the gel filtration studies described below. The quantity of lipopolypeptide recovered after filtration corresponded to phospholipid recovery (data not shown). The fraction of the lipopolypeptide on the exterior of the vesicles was estimated by comparing the fluorescence intensity of reconstituted vesicle samples treated with fluorescamine before or after solubilizing with 2% TX-100 (*27*).

Spontaneous insertion of NTTR-(NBD)ML into preformed vesicles was achieved by adding NTTR-(NBD)-ML (10 nmol, 10 μL of 10 μM stock in H_2O) directly to a vesicle preparation (ca. 2 mM lipid) and mixing by gentle pipet action. The insertion process could be monitored fluorometrically. NTTR-(NBD)ML (10 nmol) was added to 25 mM PB, pH 7.2 (1 mL), in a fluorescence cuvette. The sample was excited at 475 nm and the emission was monitored at 530 nm. Lipid vesicles (DMPC, 200 μL, from 10 mM stock), prepared as described above without the addition of lipopeptide, were added to the cuvette and the increase in fluorescence was recorded. Similar experiments were also performed with 20% DMPG/DMPC (molar ratio), POPC, and 20% POPG/POPC (molar ratio) vesicles.

Spontaneous insertion of NTTR-(NBD)ML into whole cells was also attempted. Human platelets (outdated, University Blood Bank, The University at Stony Brook), CHRF-288 (R. W. Johnson Pharmaceutical Research Institute) and *Drosophila melangaster* cell-lines (S2) (Invitrogen) were prepared by collecting the cells under low speed centrifugation and resuspending the cells in phosphate-buffered saline, pH 7.4, containing 5 mM EDTA. The final cell density was approximately 10^9 and 10^7 cells/mL for platelets and CHRF-288 or S2 cells, respectively. Cells (100 μL) were added to a NTTR-(NBD)ML sample and changes in fluorescence intensity were monitored at 25 °C. After the fluorescence intensity change had come to equilibrium, POPC vesicles were added determine the quantity of lipopolypeptide that remained in solution and was able to interact with the artificial membranes.

Gel Filtration Analysis of Reconstituted Lipopolypeptides. The extent of lipopolypeptide reconstitution into lipid vesicles or whole cells was determined by incubating the samples at 25 or 37 °C for up to 6 h, followed by separation on CL-6B Sepharose (Pharmacia, 1.5 × 28 cm) with 25 mM PB, pH 7.2. The gravity-driven flow rate was ~0.6 mL/min and 5 min fractions were collected. The 10-nm separation between excitation and emission wavelengths was used to reduce the intensity of scattered light at the detector. Fractions containing vesicles or whole cells could be identified visually as cloudy suspensions or by measuring scattered light intensity (λ_{ex} = 400 nm; λ_{em} = 410 nm) with a fluorometer. Fractions containing the nonfluorescent lipopolypeptide, NTTR-ML, were determined by a fluorescamine assay (*28*): TX-100 (2% final concentration) and TEA (0.1% final concentration) were mixed with an aliquot (1 mL) of each fraction. Fluorescamine (20 μL, 10 mM in dioxane) was added to each sample, and the sample was vortexed for 1 min. Relative concentrations of NTTR-ML in each fraction were determined fluorometrically (λ_{ex} = 395 nm; λ_{em} = 475 nm). Samples containing NTTR-(NBD)ML were determined by adding TX-100 (2% final concentration) to an aliquot (1-mL) of each fraction and measuring the fluorescence intensity of the NBD fluorophore (λ_{ex} = 475 nm; λ_{em} = 535 nm). Control gel filtration experiments were performed with the NTTR polypeptide (unconjugated) preincubated with vesicles and with each lipopolypeptide in the absence of vesicles and whole cells.

RESULTS

Design and Synthesis of the Maleimido-Lipids. Two new maleimide-based lipid reagents were synthesized to permit conjugation with thiol-containing polypeptides and other biomacromolecules (Figure 1). 1-Aminopropanediol was chosen as the glycerol-like backbone for lipid construction. Maleoylation could then be performed at the primary amine to position the conjugation site proximal to the headgroups in a phospholipid membrane

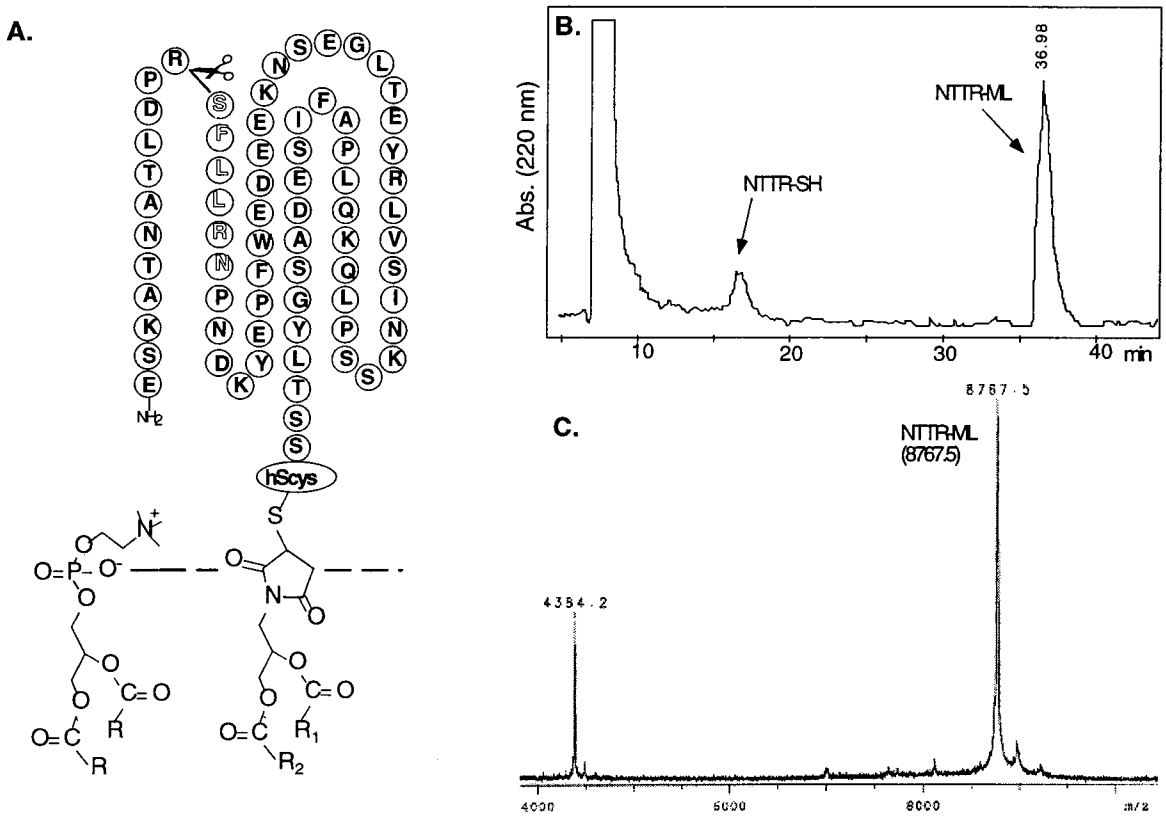

Figure 2. Lipid modification of the N-terminal extracellular domain of the human thrombin receptor. (A) The primary structure of the lipopolypeptide prepared from a maleimide lipid (**1** or **10**) and the 8 kDa polypeptide (NTTR) from the human thrombin receptor (Glu^{30}–Ser^{99}) is shown. The thrombin cleavage site between Arg^{41} and Ser^{42} is indicated by the scissors. The sulfhydryl group at the C-terminal of the thrombin receptor polypeptide (NTTR) is generated with cystamine as described in the text. The maleimide lipid is shown adjacent to a phospholipid to illustrate the expected location of the conjugation site with respect to a phospholipid bilayer. The orientation of the polypeptide does not imply any structural characteristics. R_1 is palmitoyl or NBD-X-aminohexanoyl and R_2 is palmitoyl. (B) HPLC chromatograms after NTTR-SH was coupled to Pam_2Mal (**1**). The hydrophobic modification increased the retention time on a C-4 semipreparative column by 20 min. Similar results were obtained after NTTR-SH was conjugated to NBD-PamMal (**10**). (C) MALDI-MS analysis of the NTTR-ML product. A single product with a mass at 8767.5 Da was observed (calcd 8762.9). The second mass peak is a doubly charged ion.

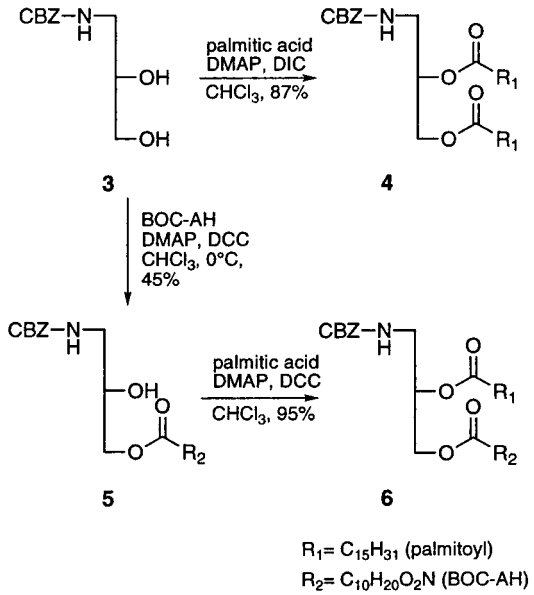
(see Figure 2A). The dipalmitoyl derivative Pam_2Mal (**1**) was constructed to ensure that the conjugated polypeptide would remain anchored into a phospholipid bilayer. Binding studies have shown that molecules acylated with two long hydrocarbon chains can exhibit long lifetimes in a membrane-bound complex ($t_{1/2}$ exceeding several hours) (*29*). The BOC-protected AH–PamMal reagent (**2**) was constructed to serve as a phospholipid membrane anchor that could be conveniently modified with amine reactive reporter groups. BOC was chosen as the amino acyl protecting group since it could be removed under acidic conditions that would not alter the maleimide group (*22*, *30*).

After CBZ protection, the diol was acylated in the presence of DMAP and a carbodiimide (Scheme 1). Use of *N,N*-diisopropylcarbodiimide during the formation of the dipalmitoyl derivative allowed simultaneous crystallization of **1** and extraction of the urea byproduct with MeOH, thereby eliminating a chromatographic step. Sequential acylation of CBZ-1-amino-propanediol with BOC-6-aminohexanoic acid at the primary alcohol followed by palmitic acid at the secondary alcohol took advantage of the differential reactivity between the primary and secondary alcohols (*31*). Quantitative hydrogenolysis of the CBZ protecting group unmasked the primary amine used for maleoylation.

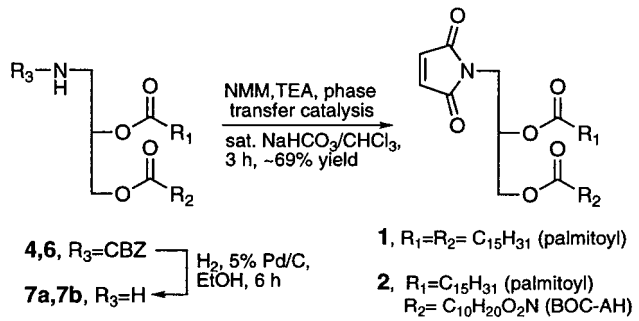
Maleoylation of Lipids. NMM maleoylates primary amines under mild aqueous conditions (*22*). Maleimide cyclization is dependent on bicarbonate ion; thus, the

Scheme 1. Assembly of Lipid Acyl Chains



reactants must be partially soluble in aqueous $NaHCO_3$. Since the amino lipids **7a** and **7b** were completely insoluble in aqueous solutions, maleoylation was accomplished in a two-phase system containing a phase transfer catalyst (Scheme 2). An amide–imide intermediate (*22*) was initially formed in the $CHCl_3$ phase and the

Scheme 2. Maleoylation of Lipids



addition of $NaHCO_3$ with vigorous mixing resulted in cyclization to the maleimide. Maleimido-lipids **1** and **2** were recovered in greater than 65% yield with this procedure. The overall reaction rate was approximately 6-fold lower than that reported for the totally aqueous system (*22*). The biphasic system described here should be useful for preparation of other lipid, drug, or fluorophore-conjugating reagents that are not compatible with standard maleimide-forming procedures (*32*−*34*).

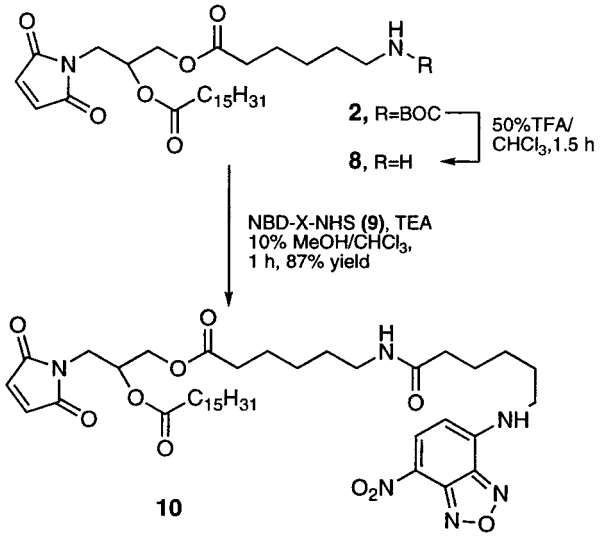
Amino Acyl Deprotection and Fluorescent Modification of Lipid 2. BOC protected AH−PamMal (**2**) was designed to improve the experimental versatility of the conjugating reagent. This lipid was found to be very stable upon storage, thus it can be prepared on a semipreparative scale and utilized as required with different amine reactive reporter groups. We chose to modify the lipid with NBD-X-NHS ester, since the derivatization produces a molecule similar to well-characterized fluorescent phospholipids (*35*) and phosphoinositides (*31*, *36*, *37*). In addition, NBD is an environmentally sensitive fluorophore that exhibits a large increase in quantum yield in the presence of hydrophobic environments (*38*).

BOC-AH−PamMal (**2**) was quantitatively deprotected with TFA; no hydrolysis of the maleimide group was observed. Maleimide hydrolysis was undetectable when the deprotected lipid was incubated for 1 h in an organic solvent system (90% $CHCl_3$/10% MeOH with 5 mol equiv of TEA) commonly used for amine acylation with activated reagents. Modification with NBD-X-NHS ester using this solvent system afforded NBD-PamMal (**10**) in 80% yield (Scheme 3). Most activated amine-reactive reporter groups can be used to acylate the amino-acyl lipid under similar conditions. Direct reaction of AH−PamMal (**8**) with NBD-Cl resulted in a number of side products, and the corresponding NBD-lipid could only be purified in a 1% final yield (data not shown).

The synthesis of NBD-6-aminohexanoic-NHS ester (**9**) presented here offers an economical way to prepare large quantities of this reagent. It does not require chromatography and results in a 50−60% overall yield of amine reactive product. The major impurity (less than 15%) is a nonreactive, nonfluorescent hydrolyzed product of NBD-Cl that does not interfere with coupling reactions. This protocol should be applicable to large scale preparations of fluorescent bioconjugates.

Lipid Conjugation to the NTTR Polypeptide. Generation of the thrombin receptor extracellular domain, NTTR, with a C-terminal sulfhydryl group provided the opportunity to conjugate the polypeptide to the maleimido-lipids. Detergent was required to solubilize the lipid and polypeptide, but only *n*-octyl-glucopyranoside, but not SDS or TX-100, resulted in homogeneous suspensions. The lipopolypeptides were easily purified by HPLC on a C_4 column (Figure 2B). MALDI-MS analysis of

Scheme 3. Deprotection and Fluorescent Modification of the Amino-Acyl Chain of Lipid 2



NTTR-ML indicated the formation of a single lipid conjugate with the correct mass (Figure 2C). The observed mass was 8767.5 Da (calcd 8762.9 Da). The fluorescent NTTR-(NBD)ML lipopolypeptide did not generate reproducible MALDI-MS values, but the HPLC chromatogram indicated that only a single new product was created (t_R = 29 min) after the reaction. The conjugation yields were >70% (4 mg) as judged by the preparative HPLC chromatogram (Figure 2B). Lipopolypeptide formation was not observed when the maleimido-lipids were incubated with the NTTR polypeptide that did not contain a free sulfhydryl group.

We attempted to form lipoconjugates by adding NTTR-SH directly to DMPC vesicles containing 2% maleimide lipids. Conjugates could not be detected by HPLC or MALDI-MS suggesting the maleimide group was not available in a sufficiently reactive environment for coupling to occur.

Reconstitution of the Lipopolypeptides into Phospholipid Vesicles. Analysis of the gel filtration chromatograms after application of each lipopolypeptide in the absence of phospholipid vesicles revealed that they elute before the unconjugated 8 kDa NTTR polypeptide (Figure 3A). This suggested that a majority of the lipopolypeptide (>90%) is aggregated in a micellar form at the concentrations (ca. 50−100 nM) used in these experiments. It also indicated that the CMC value for the lipopolypeptides is lower than 50 nM. Analysis of the micelles on a 50 kDa limit size-exclusion gel showed the lipopolypeptides eluted one fraction after the void volume, thereby suggesting the micelles were composed of between 6 and 9 monomers (data not shown).

Both lipoconjugates were tested for the ability to spontaneously insert into phospholipid vesicles. This method of lipopolypeptide incorporation is beneficial in many biochemical applications since it can be performed under gentle in vivo conditions and results in lipoconjugates on the exterior of the membrane surface. Spontaneous insertion of NTTR-ML into DMPC or POPC vesicles after 10 h at 37 °C or 1 h at 50 °C could not be observed using gel filtration analysis (data not shown). The elution profiles of these preparations were identical to NTTR-ML in the absence of vesicles indicating the lipopolypeptide remained in micellar form (Figure 3A). Greater than 90% of NTTR-ML did reconstitute into vesicles when the phospholipids and lipopolypeptide were premixed before

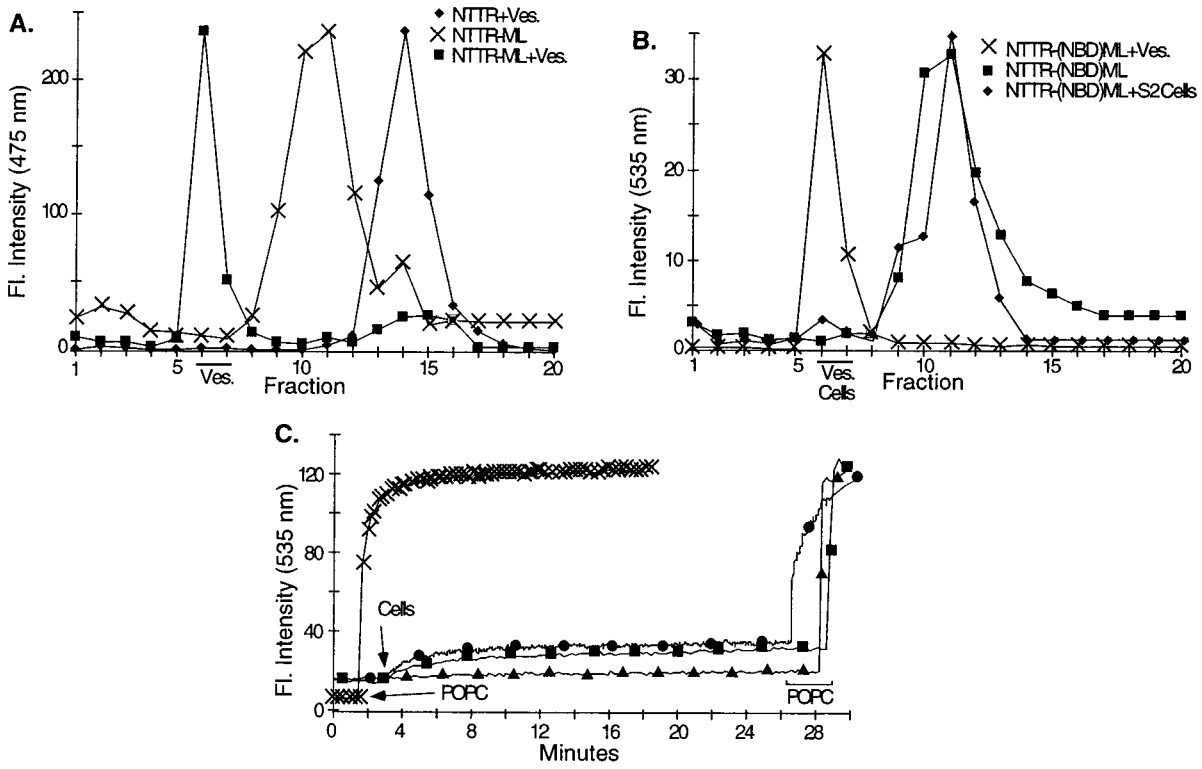


Figure 3. Gel filtration (CL-6B Sepharose) and fluorometric analysis of lipopolypeptide association with phospholipid membranes. (A) Co-mixture of NTTR-ML with DMPC before vesicle formation resulted in greater than 90% incorporation of the lipopolypeptide in vesicles found in the void volume (fractions 6 and 7) (■). The NTTR polypeptide (unconjugated) does not associate with phospholipid membranes (◆). NTTR-ML in the absence of lipid membranes eluted between the vesicle and the free polypeptide fractions indicating the lipopolypeptide is in micellar form (×). A similar chromatogram was observed when NTTR-ML was incubated with preformed DMPC or POPC vesicles (37 °C at 5 h) indicating NTTR-ML does not spontaneously insert into artificial membranes. NTTR-ML concentrations were measured with a fluorescamine assay. (B) NTTR-(NBD)ML was added to DMPC or POPC vesicles and incubated for 5 min before gel filtration analysis. NBD fluorescence was totally associated with the vesicle fractions indicating NTTR-(NBD)-ML spontaneously inserted into the artificial membranes (×). The fluorescent lipopolypeptide in the absence of vesicles eluted with a profile similar to NTTR-ML indicating NTTR-(NBD)ML exists in micellar form (■). Whole cells (results from *Drosophila* S2 cells are shown in the figure) were incubated with NTTR-(NBD)ML before subjecting the cells to gel filtration analysis (◆). Less than 1% of the total fluorescence was recovered in the void volume indicating the lipopolypeptide did not incorporate into whole cell membranes. Similar results were observed with human platelets and CHRF-288 cells. The chromatograms suggested NTTR-(NBD)ML remained in a micellar structure. (C) Spontaneous insertion of NTTR-(NBD)ML into POPC vesicles could be monitored fluorometrically. In micellar form, the NBD fluorophore was quenched [(×) before 2 min]. A 20-fold increase in fluorescence intensity was observed upon the addition of POPC vesicles (×). Addition of human platelet (■), CHRF-288 (▲) or *Drosophila* S2 (●) whole cells induced less than 15% change in fluorescence. Gel filtration results indicated that the increase was not due to spontaneous insertion into the cell membranes. After ca. 25 min, the addition of POPC vesicles to the cell mixtures resulted in the expected fluorescence increase indicating the lipopolypeptide remained in solution (in micellar form) and preferentially interacted with the artificial membranes.

hydration and sonication (Figure 3A). Approximately, 66% (±10%) of the lipopolypeptide was accessible on the outer surface of the vesicles as determined by the fluorescamine assay described in the Experimental Procedures. The unconjugated NTTR polypeptide did not associate with phospholipid vesicles after incubation for several hours at 37 °C (Figure 3A). It eluted approximately four fractions after the lipid derivative indicating that it exists as a smaller molecular weight entity (e.g., monomer) in solution.

NTTR-(NBD)ML did spontaneously insert into preformed vesicles as indicated by complete recovery of the lipopolypeptide in the void volume from the gel filtration column (Figure 3B). Similar results were obtained with 20% DMPG/DMPC and POPC vesicles. Since the quantum yield of the NBD fluorophore is environmentally sensitive, we were able to monitor lipopolypeptide insertion fluorometrically. The fluorescence intensity of NTTR-(NBD)ML reached maximum value (ca. 15-fold increase) within 2 min after vesicle addition suggesting the lipopolypeptide was completely inserted within this period (Figure 3C). This was confirmed by gel filtration, which showed complete lipopolypeptide association with vesicles after only a 5 min incubation (Figure 3B). The increase in quantum yield is likely a result of two environmental changes in the vicinity of the fluorophore. First, the NBD fluorophore becomes positioned into a hydrophobic phospholipid membrane environment. Second, the intermolecular quenching that exists when the lipopolypeptide is in a micellar state is eliminated upon phospholipid membrane association.

Spontaneous insertion of NTTR-(NBD)ML or NTTR-ML into whole cell membranes after 6 h (28 °C for S2 cells, and 37 °C for platelets and CHRF-288 cells) was not observed by gel filtration analysis. Figure 3B shows the results from gel filtration analysis of NTTR-(NBD)-ML incubated with the S2 cells at 28 °C for 6 h. Less than 1% of the NBD fluorescence was recovered in the void volume where the S2 cells were observed by light scattering measurements. Similar results were obtained after gel filtration analysis of NTTR-(NBD)ML preincubated with platelets and CHRF-288 cells (data not shown). The ability of the fluorescent lipopolypeptide to associate with whole cells was also examined fluorometrically. After a 25 min incubation of the fluorescent lipopolypeptide with platelets, CHRF-288 or S2 cells, the fluorescence intensity increased less than 15% when compared to the increase observed upon phospholipid

vesicle addition (Figure 3A). This result suggested that the addition of whole cells could promote an environmental change around the NBD fluorophore, but gel filtration analysis indicated that high-affinity membrane association did not occur. The reasons for the small fluorescent changes are unknown, but the fact that NTTR-(NBD)ML did not spontaneously insert into all three cell-types demonstrated that the behavior was not a cell-specific phenomena. Once the NBD fluorescence reached equilibrium after cell addition (ca. 25 min), the addition of POPC vesicles resulted in an immediate increase in fluorescence to levels that were obtained with only the addition of POPC vesicles (Figure 3C). This suggested that the fluorescent lipopolypeptide remained in solution (in micellar form) and preferentially inserted into the artificial vesicles.

DISCUSSION

Two maleimide-based lipidating reagents were prepared to anchor sulfhydryl-containing peptides and polypeptides into phospholipid membranes. The lipopolypeptide conjugates prepared from each of the lipids were shown to form soluble micellar structures in aqueous solutions. This behavior is consistent with that of lipid-based amphiphiles. Interestingly, the ability of the lipid conjugates to interact with phospholipid membranes appeared to be dependent on the chemical details of the lipid modification and the type of biological membrane. To further understand this phenomenon, it is worth summarizing the properties that govern the interaction between lipid-based amphiphiles and phospholipid membranes.

Two models have been proposed to characterize the interaction between amphiphiles (e.g., lipopeptides) and biological membranes. The first model depicts amphiphile insertion through a monomer intermediate. In this model, the probability of spontaneous insertion is dependent upon the equilibrium between micelle and monomer formation (i.e., CMC value), the rate of monomer escape from the micelle and the rate of monomer insertion into the acceptor membrane (*39*, *40*). The steady-state concentration of free monomer is not necessarily important since studies have shown that spontaneous insertion can occur at amphiphile concentrations that are above their CMC values (*39*, *41*). The dipalmitoyl-based lipopolypeptide, NTTR-ML, appears to be above its CMC value as demonstrated by the gel filtration data. However, the chromatogram also suggests that up to 10% of the conjugate may exist in smaller aggregates or in monomeric form (Figure 3A). This lipopolypeptide did not insert into artificial membranes at room temperature, after 10 h at 37 °C, or 1 h at 50 °C, indicating that it does not exist in a form that allows interaction between the conjugate lipid chains and the membrane surface. In terms of the monomer intermediate model, this suggests that monomer escape and insertion rates were not significantly affected by the increases in temperature. The fluorescent derivative, NTTR-(NBD)ML, did spontaneously insert into POPC, DMPC, and 20% DMPG/DMPC vesicles at room temperature. This indicates that the surface charge and acyl chain composition of the acceptor membrane did not have a significant impact on the NTTR-(NBD)ML insertion process. This lipopolypeptide appears to be above the CMC value at experimental concentrations, although the tailing chromatogram suggests that some portion of NTTR-(NBD)ML may exist as smaller aggregates or monomers (Figure 3B).

The only difference between the dipalmitoyl lipid derivative and the fluorescent lipid derivative is the chemical structure of the primary acyl chain. This indicates the acyl moieties of the lipopolypeptide influences the interaction with artificial membranes. The mechanism by which the fluorescent lipopolypeptide promotes spontaneous insertion is unclear. However, the reduced hydrophobicity of the NBD-labeled acyl chain could influence the monomer escape and insertion rates. It has been shown that an NBD group on a phospholipid acyl chain localizes to the polar headgroup environment, thereby altering the structure of the associated hydrocarbon chain (*35*). The fluorescent lipopolypeptide did not insert into whole cell membranes. This suggests that a property of whole cell membranes that is not exhibited in the artificial membrane systems significantly lowers the fluorescent lipopolypeptide insertion rate.

The second model that has been used to describe an amphiphile insertion process depicts insertion as dependent on a direct interaction between the amphiphile micelle and the phospholipid membrane (*9*, *42*). In this model, collisions between the fluorescent NTTR-(NBD)-ML micelles and the artificial phospholipid vesicles would be responsible for inducing conditions that allow insertion. The same conditions are apparently not achieved when the fluorescent lipopolypeptide micelles collides with whole cell membranes. Two main differences between the artificial and cellular membrane systems exist. First, the sizes of the membrane structures differ. The sonicated vesicles are small in diameter (20−200 nm) (*43*) and the cells used in this experiments are between 2 and 10 μm in diameter. The second difference is that whole cells have a surface richly adorned with glycoproteins and integral proteins. The protein component of the cellular membranes may have prevented NTTR-(NBD)ML association with the cellular surface, but previous reports have shown that various lipidated peptides (*7*, *44*, *45*) and proteins (*46*−*48*) are capable of spontaneous insertion into whole cell membranes. The size of the molecular headgroups, the method of lipid attachment, and the amino acid sequences vary in these studies, thus it is difficult to identify specific factors that prevent the NTTR lipid conjugates from incorporating into cellular membranes. It is possible that the chemical structure of the maleimido-lipids and the specific amino acid sequence of the NTTR polypeptide inhibit insertion into whole cells. Studies of phospholipid transfer from vesicles to whole cell membranes indicate that the transfer rate is dependent on the chemical structure of the acyl chains, backbone, and headgroups of the lipids (*29*, *49*).

The lipid reagents described here were conjugated to an 8 kDa polypeptide (NTTR) from the N-terminal of the human thrombin receptor (protease activated receptor-1, PAR-1) (*19*). These model compounds were prepared to test the ability of the lipids to anchor the polypeptide into phospholipid membranes. The lipoconjugates were also prepared as probes that would be useful for examining structural and biochemical properties of the human thrombin receptor activation mechanism. The G-protein coupled PAR-1 receptor is a seven transmembrane receptor that exhibits an extended extracellular N-terminus. The receptor is activated when thrombin proteolytically cleaves the N-terminus, thereby generating the tethered ligand for the receptor. The NTTR polypeptide is identical to the N-terminal portion of the receptor prior to the first transmembrane segment and includes the thrombin cleavage site (Figure 2A).

The C-terminal lipid modifications used in this study were proposed to mimic the first transmembrane segment of the receptor. Structural features exhibited by the polypeptide while it is anchored into a phospholipid

membrane were considered to be more closely representative of those that may be present in the native receptor (*24*). The NTTR lipid conjugates were also postulated to be useful as biochemical probes for investigating the rate of thrombin receptor cleavage on whole cellular membranes. Specific membrane-associated proteins have been implicated in altering the catalytic activity of thrombin on cellular membrane (*50*). A polypeptide representing the thrombin receptor N-terminus that could be anchored into cellular membranes would aid in characterizing the in vivo elements that influence the rate of thrombin receptor cleavage on a cellular membrane surface. Unfortunately, these studies were prevented by the inability of the NTTR lipopolypeptide to insert into whole cell membranes.

In summary, a general and convenient method for the lipidation of thiol-containing biological molecules was presented. The maleimide-based lipoconjugating reagents Pam_2Mal (**1**) and NBD-PamMal (**10**) are selective for sulfhydryl groups, which can be introduced into proteins, peptides, nucleic acids, or carbohydrates by either chemical or genetic methods. The extracellular N-terminal domain of the human thrombin receptor was derivatized with each lipid as a model system. The lipidated products were formed in high yield and could be reconstituted into artificial phospholipid membranes, although the reconstitution protocols were different for the two conjugates. The lipopolypeptides could not be reconstituted into whole cell membranes for reasons that are not clear. The conjugating reagents will aid in the preparation of acylated peptides and polypeptides for investigating structural and biochemical phenomena that occur at membrane surfaces.

ACKNOWLEDGMENT

We would like to thank Dr. B. S. Coller (The University at Stony Brook, Stony Brook, NY, USB, and Mt. Sinai Medical Center, New York, NY) and Dr. B. E. Maryanoff (R.W. Johnson Pharmaceutical Research Institute, Spring House, PA, RWJPRI) for financial and scientific support. Dr. Q.-M. Gu and Dr. J. F. Marecek (USB) provided valuable insights during development of the synthetic methods. The PAR-1 cDNA was gift from Dr. W. Bahou (USB). Dr. C. Derian (RWJPRI) supplied the CHRF-288 cells and C. Coburn (USB) supplied the *Drosophila* S2 cells.

The aim of this study was to localize ^{99m}Tc and ^{188}Re radionuclides to tumors, using a bispecific antibody (bsMAb) in a two-step approach where the radionuclides are attached to novel peptides incorporating moieties recognized by one arm of the bsMAb. A chemically cross-linked human/murine bsMAb, hMN-14 × 734 (Fab′ × Fab′), anti-carcinoembryonic antigen [CEA] × anti-indium-DTPA was prepared as a prelude to constructing a fully humanized bsMAb for future clinical application. *N*,*N*′-*o*-Phenylenedimaleimide was used to cross-link the Fab′ fragments of the two antibodies at their hinge regions. This construct was shown to be >92% pure and fully reactive with CEA and a divalent (indium)-DTPA-peptide. For pretargeting purposes, a peptide, IMP-192 [Ac-Lys(In-DTPA)-Tyr-Lys(In-DTPA)-Lys(TscG-Cys-)-NH_2 {TscG = 3-thiosemicarbazonylglyoxyl}], with two indium-DTPAs and a chelate for selectively binding ^{99m}Tc or ^{188}Re, was synthesized. IMP-192 was formulated in a "single dose" kit and later radiolabeled with ^{99m}Tc (94−99%) at up to 1836 Ci/mmol and with ^{188}Re (97%) at 459−945 Ci/mmol of peptide. [^{99m}Tc]IMP-192 was shown to be stable by extensive in vitro and in vivo testing and had no specific uptake in the tumor with minimal renal uptake. The biodistribution of the hMN-14 × murine 734 bsMAb was compared alone and in a pretargeting setting to a fully murine anti-CEA (F6) × 734 bsMAb that was reported previously [Gautherot, E., Bouhou, J., LeDoussal, J.-M., Manetti, C., Martin, M., Rouvier, E., and Barbet, J. (1997) Therapy for colon carcinoma xenografts with bispecific antibody-targeted, iodine-131-labeled bivalent hapten. *Cancer 80* (Suppl.), 2618−2623]. Both bsMAbs maintained their integrity and dual binding specificity in vivo, but the hMN-14 × m734 was cleared more rapidly from the blood. This coincided with an increased uptake of the hMN-14 × m734 bsMAb in the liver and spleen, suggesting an active reticuloendothelial cell recognition mechanism of this mixed species construct in naive mice. Animals bearing GW-39 human colonic cancer xenografts were injected with bsMAb (15 μg) and after allowing 24 or 72 h for the bsMAb constructs to clear from the blood (hMN-14 and murine F6 × 734, respectively), [^{188}Re]IMP-192 (7 μCi) or [^{99m}Tc]IMP-192 (10 μCi) was injected at a bsMAb:peptide ratio of 10:1. Tumor uptake of [^{99m}Tc] or [^{188}Re]IMP-192 was 12.6 ± 5.2 and 16.9 ± 5.5% ID/g at 3 h postinjection, respectively. Tumor/nontumor ratios were between 5.6 and 23 to 1 for every major organ, indicating that early imaging with ^{99m}Tc will be possible. Radiation absorbed doses showed a 4.8-, 7.2-, and a 12.6 to 1.0 tumor to blood, kidney, and liver ratios when ^{188}Re was used. Although this new bsMAb pretargeting approach requires further optimization, it already shows very promising targeting results for both radioimmunodetection and radioimmunotherapy of colorectal cancer.

INTRODUCTION

Radioimmunodetection (RAID)[1] and radioimmunotherapy (RAIT) of cancer rely on the selectivity of radiolabeled antibodies directed against tumor-associated antigens binding to and then subsequently being retained in a tumor while clearing from normal tissues. For imaging, radioactivity uptake in a tumor must exceed that of surrounding tissue within a reasonable period of time and with sufficient signal for detection. For RAIT, the amount of radioactivity delivered must be sufficient such that over a period of time the tumor will be exposed to a radiation dose to effect cell killing. The first dose-limiting toxicity for RAIT, in applications to date, has been hematological. This is due to the high radiosensitivity of red marrow and the relatively high amount of radioactivity circulating in the blood; that is a direct consequence of the extended biological half-life of an intact IgG. Thus, increasing tumor/blood ratios while still delivering an adequate absolute amount of radioactivity to a tumor is an important goal for improving RAIT.

Pretargeting approaches are being investigated as methods proven to be effective for increasing tumor/blood ratios. In a pretargeting method, an antibody conjugate containing a secondary recognition moiety is targeted to tumor, and then allowed to clear from nontarget tissues. Sometime later, a low molecular weight, fast-clearing, radiolabeled ligand recognized by the secondary recognition moiety of the pretargeted antibody conjugate is given. Diverse reagents for antibody-directed pretargeting approaches have been described (Hnatowich et al., 1987; Paganelli et al.,1988; Goodwin et al., 1988; Stickney et al., 1991; Bamias and Epenetos, 1992; Hawkins et al., 1993; Bos et al., 1994). Most have successfully shown improved tumor/nontumor radioactivity ratios as compared to a radiolabeled antibody alone, albeit often at a cost of substantially reduced absolute amounts of radioactivity in the targeted tumor. However, both Axworthy et al. (1994) and Boerman et al. (1999) have reported that the absolute amount of radioactivity delivered to tumors by pretargeting approaches can be comparable to levels achieved with a radiolabeled antibody alone, and could be achieved without sacrificing excellent tumor-to-nontumor ratios.

Two pretargeting methodologies have been reported most prominently, those using avidin−biotin and the other bispecific antibody (bsMAb) reagents. An avidin−biotin approach has the advantage of an exceptionally high binding affinity between the pretargeted antibody conjugate (either a biotin or avidin/streptavidin antibody conjugate) and the radiolabeled ligand (either avidin/streptavidin or biotin) (Rosebrough, 1993; Karacay et al.; Sharkey et al., 1997; Wilbur et al., 1998; Cremonesi et al., 1999). It also has the major disadvantages of the high immunogenicity of the avidins (Chinol et al., 1998), of serum biotinidases that can cleave many biotin conjugates, and the presence of endogenous biotin that can compete for avidin binding sites during pretargeting procedures. Although the alternate bsMAb approach does not engender as high component binding affinities and immunogenicity as the avidin−biotin approach, molecular engineering may be used ultimately to significantly reduce or even eliminate any immunogenicity of the bsMAb construct (Carter and Merchant 1997; Coloma and Morrison, 1997). Also, low molecular weight radiolabeled conjugates (haptens) can be designed that are endogenously unrecognized and are enzymatically resistant. Finally, bsMAb pretargeting results can be improved even more by incorporating radiolabeled bivalent, rather than monovalent, haptens in what has been termed an "affinity enhancement system" (AES) (LeDoussal et al., 1989).

In clinical studies of AES, imaging with an ^{111}In-labeled bivalent peptide hapten [*N*-α(^{111}In/In-DTPA)Tyr-*N*-ϵ(^{111}In/In-DTPA)Lys] given after a pretargeted bsMAb exhibited excellent results in several tumor types (LeDoussal et al., 1990; LeDoussal et al., 1993; Vuillez et al., 1997; Barbet et al., 1998). In these studies, tumors were pretargeted with a murine bsMAb, F6 × 734 (Fab′ × Fab′), anti-carcinoembryonic antigen (CEA) × anti-indium diethylenetriaminepentaacetic acid (DTPA). Although imaging results were impressive, in one study up to 61% of the patients eventually developed a human anti-murine antibody (HAMA) response (Le Doussal et al., 1993). The approach is now being extended to RAIT using the same bsMAb with an ^{131}I-labeled dipeptide (Vuillez et al., 1999). Efforts are currently underway to prepare a fully humanized construct for clinical studies. However, as a prelude to this, a human/murine bsMAb, hMN-14 × 734 (Fab′ × Fab′)(anti-CEA × anti-indium-DTPA) has been prepared and tested in animals. Since a humanized antibody might have different clearance and distribution properties in mice than a fully murine construct, comparisons were made to the murine F6 × murine 734 (Fab′ × Fab′) bsMAb that has been used by the French group.

Unfortunately, the 734 MAb, raised against indium-DTPA, was found to bind too weakly to yttrium-DTPA to enable any progress toward a yttrium-based bsMAb RAIT agent, and thus preclinical RAIT studies have used radioiodinated (I-131) bivalent haptens (Gautherot et al., 1997, 1998, 2000). Although an ^{131}I-based agent may be a highly effective therapeutic, it is important to investigate higher energy nuclides, such as ^{90}Y and ^{188}Re, since these may be more suitable for tumors >1 cm in diameter. The nuclear properties of ^{188}Re [$T_{1/2}$ 16.9 h; 2.12 and 1.96 MeV beta, 71 and 25% abundant; 155 keV imageable gamma, 15% abundant] would make it an ideal therapeutic isotope when bound to a fast-clearing bivalent hapten in the bsMAb approach. Like ^{99m}Tc, ^{188}Re is produced carrier-free (enabling high specific activity labeling of haptens) via a convenient generator system (Knapp et al., 1994). For imaging, ^{99m}Tc has multiple advantages over ^{111}In, including low cost, ready availability, ideal nuclear properties (140 keV γ-emission) for γ cameras, reduced radiation exposure to the patient and a shorter half-life (6 h). Thus, in this report, the initial development and preclinical testing of the human/murine hMN-14 × 734 (Fab′ × Fab′) hybrid bsMAb, and the progression from an [^{111}I]DTPA bivalent hapten to an imaging/therapy ^{99m}Tc/^{188}Re-based bivalent hapten are described.

MATERIALS AND METHODS

Antibodies and Peptides. hMN-14 IgG was prepared as described (Sharkey et al., 1995). The F(ab′)$_2$ of hMN-14 was derived by pepsin digestion and purified by protein A and ion-exchange chromatography. The anti-indium-DTPA antibody 734 F(ab′)$_2$ (Le Doussal et al., 1990) and F6 × 734 (Fab′ × Fab′) bsMAb were supplied by Immunotech (Marseilles, France). A rat anti-idiotypic antibody to hMN-14, termed WI2 (Losman et al., 1994), was used in some of the analytical work with hMN-14-containing MAbs to verify lack of discernible impact on the latter's binding site. The CEA used for immunoreactivity testing was obtained from Scripps (La Jolla, CA).

The hMN-14 × 734 bsMAb was prepared by the chemical coupling of the two reduced Fab′ fragments using *N*,*N*′-*o*-phenylenedimaleimide (PDM) by a published method (Glennie et al., 1987). Briefly, MAbs were reduced separately to their Fab′-SH fragments by incubation with 10 mM 2-mercaptoethylamine at 37° C for 1 h. The 734-Fab′-SH was converted to 734-Fab′-maleimide by reaction with 4 mM PDM at room temperature for 1 h. The Fab′-SH (hMN-14) and Fab′-maleimide (734) intermediates was isolated by centrifuged size-exclusion chromatography (Penefsky, 1979; Meares et al., 1984). The hMN-14 × 734-Fab′ × Fab′ conjugate was produced by reaction of a 1:1 mixture of the two fragments overnight at 4° C. It was purified on a SE (size exclusion) HPLC analytical column (Bio-Sil SEC-250, Bio-Rad, Richmond, CA), equipped with an in-line absorbance detector (Waters 486 or Beckman 167), set at 280 nm. The column was eluted at 1 mL/min with 0.2 M sodium phosphate, pH 6.8, containing 0.02% sodium azide. Only the center portion of the peak corresponding to the bsMAb was collected and used in these studies. The level of monospecific 734-F(ab′)$_2$ in hMN-14-F(ab′)$_2$ bsMAb

IMP-156: Ac-Phe-Lys(DTPA)-Tyr-Lys(DTPA)-NH_2

IMP-192: Ac-Lys(DTPA)-Tyr-Lys(DTPA)-Lys(TscGC)-NH_2, where TscGC is thiosemicarbazonyl-glyoxyl-cysteinyl-

preparations was determined by mixing radiolabeled bsMAb with CEA, followed by SE-HPLC analysis. The level of monospecific hMN-14-F(ab′)$_2$ in hMN-14- × 734-F(ab′)$_2$ bsMAb preparations was determined using a DTPA conjugate of an irrelevant cdr-grafted MAb, hLL2, having the same framework as hMN-14 (Leung et al., 1995). The nonradiolabeled bsMAb and DTPA-hLL2 were mixed and applied to SE-HPLC with in-line UV analysis at 280 nm. In both assays, the percentage of product failing to shift to a higher MW on SE-HPLC was indicative of the levels of monospecific MAbs present in the preparations.

Intermediates for the peptide syntheses were obtained from Advanced ChemTech (Louisville, KY). The chelate-peptide bivalent hapten conjugates shown in Figure 1 (termed IMP-156 and IMP-192) were synthesized using standard solid-phase methods. Briefly, for the IMP-192 peptide, the "Fmoc-based" methodology and Rink amide resin were used. Starting with N^{alpha}-Aloc-Lys($N^{epsilon}$-Fmoc)-OH attached to the resin, N^{alpha}-Fmoc-Cys(Trt)-OH was then added to the side chain of lysine followed by the addition of the 3-thiosemicarbazonylglyoxylic acid (TscG). The latter was prepared by mixing thiosemicarbazone and glyoxylic acid together in a 1:1 ratio in methanol, and evaporating the solvent to generate the desired agent, which was used without further purification. The Aloc group was removed from the lysine using palladium(0)-catalyzed hydrostannolysis (Dangles et al., 1987), the other amino acids were added (N^{alpha}-Fmoc-Tyr(But)-OH, N^{alpha}-Fmoc-Lys($N^{epsilon}$-Aloc)-OH), the N-terminus was acetylated, and the lysine side-chain protecting groups were removed. The two DTPAs were then added to the lysine side chain using a monoactivated DTPA derivative. This was prepared by dissolving DTPA in methanol containing a 300-M excess of a 1.0-M solution of tetrabutylammonium hydroxide. The reaction mixture was rotary evaporated and the residue was dissolved in 100 mL of DMF. The DMF solution was then concentrated under hi-vacuum on the rotary evaporator. This process was repeated two more times to remove methanol. The residue was then dissolved in DMF and reacted with 1 equiv of *O*-benzotriazole-*N*,*N*,*N*′,*N*′-tetramethyl-uronium-hexafluoro-phosphate (HBTU). The reaction, with 6 equiv of the activated DTPA, proceeded overnight, and was repeated until the resin gave a negative ninhydrin test (Kaiser et al., 1970). The peptide was then cleaved from the resin and purified by reversed-phase HPLC. IMP 156 was synthesized in an analogous manner. Structures were confirmed by electrospray mass spectral analysis (IMP-156, MH^+ 1377; IMP-192, MH^+ 1590).

Radiolabeling. ^{125}I and ^{111}In were obtained from NEN Life Science Products (Boston, MA). The bsMAbs were radioiodinated using the chloramine-T method (Greenwood and Hunter, 1963) and purified using centrifuged size-exclusion columns. A typical ^{111}In labeling of IMP-156 is as follows. ^{111}In chloride (1.4 μL, 373 μCi) was mixed with 4.2 μL of 0.5 M sodium acetate, pH 6.1, and IMP-156 (3.3 μL, 4.9×10^{-5} M) in 0.5 M sodium acetate, pH 6.1, was added. After 20 min at room-temperature nonradioactive indium acetate (12.1 μL, 7.5×10^{-5} M in 0.5 M sodium acetate, pH 6.1), was added to bind remaining DTPA moieties.

Fresh sodium [^{99m}Tc] pertechnetate was purchased from Syncor (Kenilworth, NJ) or Mallinckrodt (Pine Brook, NJ). Sodium [^{188}Re] perrhenate was eluted from an in-house $^{188}W/^{188}Re$ generator (Oak Ridge National Laboratory, Oak Ridge, TN) with 0.9% sodium chloride solution. Radiolabeled peptides were analyzed on a Waters 4000 HPLC system having a reversed-phase Waters 8 × 100 mm radial Pak cartridge filled with a C-18 Nova-Pak 4 μm stationary phase. The column was eluted at 3 mL/min with a linear gradient of 100% 0.1% trifluoroacetic acid (TFA) in water to 100% 0.1% TFA in 90% acetonitrile/10% water over 10 min. At 10 min, the flow rate was increased to 5 mL/min and remained at 100% 0.1% TFA in 90% acetonitrile/10% water for 5 min before reequilibration to initial conditions. Both a Waters 486 absorbance detector, set at 220 nm, and an in-line radiation detector (Packard Radiomatic Flo-One or Ludlum) were used for detection.

For subsequent ^{99m}Tc and ^{188}Re radiolabeling, IMP-192 was formulated into lyophilized, single vial, "instant" kits containing excess cold indium. ^{99m}Tc kits contained 78 μg of IMP-192, with 100 μg Sn (II) for pertechnetate reduction, ascorbic acid, and a 6-fold excess of cold indium to peptide, for binding to DTPA. These vials were reconstituted with up to 40 mCi of ^{99m}Tc pertechnetate in 1.5 mL of saline. After 10 min at room temperature, the lead-shielded vials were heated in a boiling water bath for 15 min. For ^{188}Re labeling, kits contained 50 μg of IMP-192, with 660 μg of Sn(II), ascorbic acid, and indium at the same 6:1 indium-to-peptide ratio. These were reconstituted with 17 mCi of freshly eluted ^{188}Re perrhenate in 1.2 mL of saline. For ^{188}Re labeling, vials were heated 1 h in a boiling water bath. In both cases, after cooling, the radiolabeled peptide was diluted in 1.0% human serum albumin (HSA) for animal biodistribution studies.

Purity of the di-indium-DTPA peptides after ^{99m}Tc and ^{188}Re radiolabeling was evaluated by reversed-phase HPLC (as above), as well as ITLC using saturated sodium chloride as eluent. Unbound isotope eluted with the HPLC void volume, and the radiolabeled peptide eluted at 7.2 min. The ability of the radiolabeled peptides to bind to the bsMAbs was evaluated by SE-HPLC. The elution profiles of the radiolabeled bsMAbs and peptides alone were compared to those obtained after mixing the peptides with 734 F(ab)′$_2$, or with hMN-14 × 734-F(ab)′$_2$ bsMAb, at various ratios. Also, radiolabeled peptides were added to preformed mixtures of CEA and bsMAb, prior to similar SE-HPLC analyses, to investigate the ability of the peptides to bind to CEA-bound bsMAbs.

In Vitro Stability and Binding Studies. The in vitro stability of the bsMAb in human serum was tested by incubating the ^{125}I-labeled bsMAb at 37 °C in fresh, sterile-filtered serum taken from a normal donor. Samples were analyzed by SE-HPLC before and after mixing with CEA or WI2. A series of in vitro stability studies were performed on the ^{99m}Tc complex of IMP-192 diluted in 0.9% sodium chloride solution, fresh human serum, 1% HSA (prepared diluted in 0.9% saline from 25% HSA; Alpine Biologics, Blauvelt, NY), and 10 mM cysteine. Aliquots were withdrawn and tested by RP-HPLC at

early (1−2 h) postdilution time points and after overnight incubation.

The ability of components to retain binding to each other was analyzed using radiomatic size-exclusion HPLC and radiolabeled bsMAb and peptides. ^{111}In or ^{99m}Tc/^{188}Re-labeled peptide was injected onto HPLC alone, and immediately after mixing with variable amounts of bsMAb. Incubations were done in the presence of 1% HSA to minimize the possibility of nonspecific binding. When indicated, further incubations of radiolabeled bsMAb, including those radiolabeled by premixing with radiolabeled peptides, were carried out with CEA, WI2 or DTPA-hLL2. Preformed complexes of CEA and bsMAb were treated with radiolabeled peptide to demonstrate binding of the radiolabeled peptide to the antigen−bsMAb complex. In all incubations, components were mixed at room temperature and injected onto HPLC immediately, since component binding was very rapid, and did not change with increasing incubation times or temperatures. The precise mole ratio of these mixtures is given in the Results.

In Vivo Stability and Animal Targeting Studies. All animal experiments were carried out with IACUC-approved protocols. Studies were conducted in 5−8-week-old, female BALB/c or athymic nude mice (CR-Nu-Nu; Taconic, Germantown, NY). Standard lab chow and water were given ad libitum, and water was supplemented with Lugol's iodine solution (1 mL/500 mL) whenever radioiodinated agents were to be administered to animals. The GW-39 human colonic tumor cell line (Goldenberg et al., 1966; Goldenberg and Hansen, 1972) was used to demonstrate targeting to this CEA-producing tumor. It was propagated as serial, subcutaneous xenografts in nude mice, as described elsewhere (Sharkey et al., 1997). All test articles were injected intravenously in the lateral tail vein in 0.1−0.2 mL. At the designated time, groups of animals were anesthetized with sodium pentobarbital, bled by cardiac puncture, and then euthanized by cervical dislocation. Tumors and major organs were removed and weighed. The number of animals per grouping for each study is provided in the Results. The gastrointestinal tissues were counted in toto to include their contents. Whenever possible, urine was removed from the bladder at necropsy, weighed, and counted. Tissues, including weighed blood, were placed in 4-mL vials and counted in a γ-counter using appropriate windows for the isotopes. With paired isotopes, windows were set to eliminate or minimize dual-channel crossover, and figures were corrected for crossover counts, when needed, by reference to empirical measurements of radionuclide standards. In addition, in dual isotope studies, tissues were counted immediately and at a later time, for ^{125}I only, after the short-lived ^{99m}Tc and ^{188}Re nuclides had decayed.

In vivo stability was evaluated in BALB/c mice. ^{125}I-labeled bsMAbs (5 μCi, 15 μg) were administered and necropsies were performed at 1, 2, 4, and 24 h postinjection. Sera were obtained from these animals at these time points. Retention of binding to CEA, and also to [^{111}In]IMP-156, was examined by SE-HPLC analyses of the serum samples before and after mixing them with CEA or [^{111}In]IMP-156, using energy windows set for ^{125}I (0−30 keV) or ^{111}In (80−420 keV), respectively. In the pretargeting experiments, animals received tracer amounts of ^{125}I-labeled bsMAbs (5 μCi, 15 μg/animal), to quantitate tissue uptake of the bsMAb. In each pretargeting study, the amount of peptide given was based on a constant ratio of 10:1 (moles of antibody initially injected to the moles of peptide injected). It is important to emphasize that this ratio was not optimized to provide the best targeting results.

The methodology used to calculate radiation doses in mice has been reported (Sharkey et al., 1990). Radiation dose estimates were determined by first integrating the trapezoidal regions (for tumors) or exponential regions (for normal tissues) defined by the time activity data. For the trapezoidal fit of the tumor, the radioactivity at time zero is assumed to be zero, but for most normal tissues, the μCi/g at time zero is estimated from the exponential decay curve. If there is no exponential decay, the microcurie per gram at time zero is estimated by extrapolating the line described by the first data pair to the *y*-axis (i.e., μCi/g). The resulting integral for each organ is converted to centigray per millicurie with the use of *S* values appropriate for isotope and organ weight by assuming uniformly distributed activity in small unit density spheres (Siegel and Stabin, 1988).

RESULTS

Antibody and Peptide Preparation: Radiolabeling, Immunoreactivity, and In Vitro Stability. On the basis of the starting amount of Fab′, the final yield of the hMN-14 × 734-F(ab′)$_2$ bsMAb after purification was ∼25%. UV analysis at OD$_{280}$ of SE-HPLC profiles showed the product as a single peak. When this product was mixed with a high molecular weight indium−DTPA conjugate (i.e., [In]DTPA-hLL2-IgG), 92−93% of the UV profile shifted to a higher molecular weight, indicating that less than 8% of the product was possibly monospecific hMN-14-F(ab′)$_2$ or nonimmunoreactive bsMAb. Immunoreactivity testing with CEA and the peptides are described below.

The IMP-156 and IMP-192 peptides assayed as single peaks on RP-HPLC and could be stored in bulk for long periods at −20 °C when lyophilized as their TFA salts. When added at a 20-fold molar excess, ^{111}I was quantitatively incorporated in the IMP-156 within 20 min. After radiolabeling was complete, residual DTPA sites on IMP-156 were saturated by addition of a 6-fold molar excess of indium to peptide (approximately 3:1 to available DTPA). The IMP-192 peptide, formulated and lyophilized into single vial kits containing indium-saturated DTPA, was reproducibly labeled with sodium ^{99m}Tc pertechnetate at up to 1836 Ci/mmol in high yield (94−99%), obviating the need for any postlabeling purification. IMP-192, similarly saturated with indium-saturated DTPA, was labeled with ^{188}Re in high yield (96−97%), at a specific activity of 459−945 Ci/mmol of peptide.

A series of SE-HPLC studies were performed to show the binding of the hMN-14 × 734 bsMAb to either IMP-192 or IMP-156 (Figure 2, upper and lower panels, respectively). The radiolabeled peptides eluted around 14 min (Figure 2A). Since the peptides were diluted in HSA, this was a further indication that they would not associate with this serum protein. Furthermore, when mixed with hMN-14 or CEA alone, the peptide continued to elute at its native-size, indicating no nonspecific binding to these proteins (not shown). After incubating with a molar excess of the hMN-14 × 734 bsMAb (unlabeled), all radioactivity from the two peptides shifted to a higher molecular weight, with the main peak at nearly 9.0 min (Figure 2). It should be noted this elution time is earlier than the antibody alone, which elutes at 10.7 min (refer to Figure 4A). This is because the peptides are divalent and capable of binding to 2 bsMAb molecules. When the peptide was added to the bsMAb that had been premixed with a molar excess of CEA, >90% of the peptide

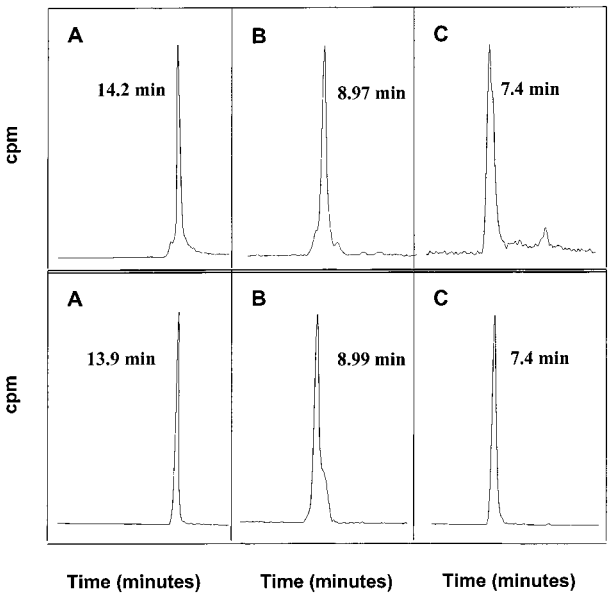

Figure 2. Upper panel. SE-HPLC chromatograms of (A) [^{99m}Tc]IMP-192, (B) [^{99m}Tc]IMP-192 mixed with hMN-14 × 734 bsMAb at 1:47 peptide: bsMAb mole ratio, and (C) [^{99m}Tc]IMP-192 added to hMN-14 × 734 bsMAb premixed with CEA, at 1:7 peptide:bsMAb and 1:10 bsMAb:CEA ratio. Lower panel. SE-HPLC chromatograms showing binding of hMN-14 × 734 to indium-DTPA and CEA. (A) [^{111}In]In-IMP-156, (B) Panel A mixed with hMN-14 × 734 bsMAb at 1:24 peptide:bsMAb mole ratio, (C) [^{111}In]In-IMP-156 added to hMN-14 × 734 bsMAb premixed with CEA. The bsMAb:CEA and peptide:bsMAb mole ratios were 1:10 and 1:24.

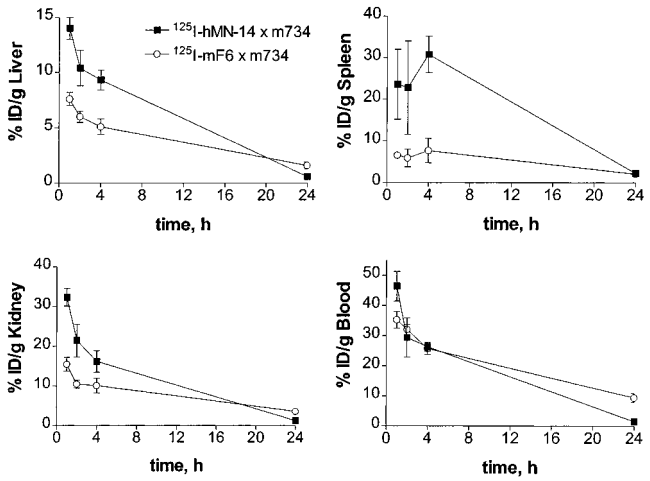

Figure 3. Tissue uptake of [^{125}I]hMN-14 × 734 and [^{125}I]F6 × 734 bsMabs in liver, spleen, kidney, and blood of BALB/c mice, five animals per time point per each bsMAb.

radioactivity migrated to a higher molecular weight, indicating the ability of the 734 arm of the bsMAb to bind to the peptide after first binding to CEA (Figure 2C). The fact that all of the radiolabeled peptides shifted to the higher molecular weight (i.e., to the elution time of a CEA−bsMAb complex rather than the elution time of the bsMAb alone) was further evidence that the bsMAb is essentially free of any cross-linked, immunoreactive 734-F(ab′)$_2$ moiety that theoretically might have formed during preparation of the bsMAb. If this product were present, a portion of the radiolabeled peptide would have eluted at either 10 min (antibody alone) or around 8 min (antibody-antibody complexes formed with the divalent peptide). Indeed, when the radiolabeled peptides were added to a molar excess of the 734 F(ab′)$_2$, all of the radioactivity migrated to the higher molecular weight

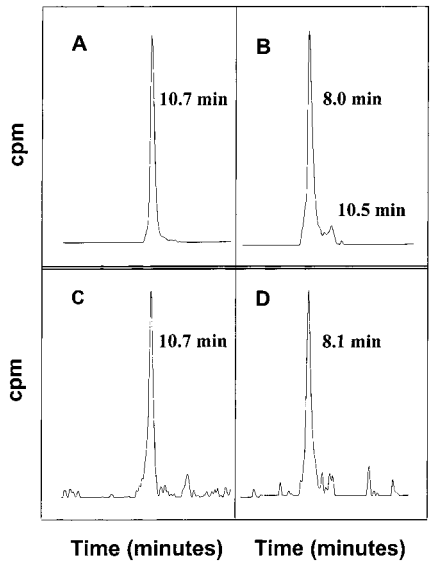

Figure 4. SE-HPLC chromatograms of (A) [^{125}I]hMN-14 × 734 bsMAb, (B) panel A mixed with CEA at 1:10 molar ratio, (C) serum from BALB/c mice 4 h post [^{125}I]hMN-14 × 734 bsMAb injection, and (D) panel C mixed with excess CEA.

fraction, but as expected, when CEA was added, no further shift was seen in the profile because of 734's lack of reactivity with CEA (not shown). Similar studies were carried out with the F6 × 734 bsMAb, which showed identical results (not shown).

To assess the stability of the bsMAb in serum, aliquots of [^{125}I]hMN-14 × 734-F(ab′)$_2$ were incubated at 37 °C in fresh human serum and then examined by SE-HPLC over 3 days. There was no loss of radioiodine from the antibody, but at 72 h, approximately 4−7% of the radioactivity migrated at a higher molecular weight, which suggested the development of a small amount of aggregate. There was no evidence of any product degradation to Fab′ fragments. It is important to note that the UV profile of the native nonradiolabeled product has not shown any tendency to aggregate or dissociate over a period of 12 months. At each time the radiolabeled bsMAb was tested, a portion was also mixed with a molar excess of either CEA or the anti-idiotypic MAb, WI2. Greater than 90% of the freshly prepared ^{125}I-labeled bsMAb migrated to a higher molecular weight, and by 72 h, there was no change, indicating excellent immunoreactivity retention of the radiolabeled bsMAb. Thus, there was no evidence of instability in vitro. Again, similar studies with the F6 × 734 bsMAb, except that CEA was used to illustrate antigen binding, showed identical results (not shown).

In vitro stability studies were also performed with the [^{99m}Tc]IMP-192, using a preparation that showed 99% of ^{99m}Tc bound at time zero. This product was diluted 10-fold in 10 mM cysteine, physiological saline, or human serum (37 °C). Testing at 1, 1.5, and 2.0 h later, respectively, 98−99% of the ^{99m}Tc remained bound to IMP-192. Upon retesting at 19−20 h postdilution, the percentages of ^{99m}Tc remaining bound to the IMP-192 were 89, 96, and 96%, respectively.

In Vivo Stability and Animal Targeting Studies. To assess the stability of the hMN-14 and F6 bsMAbs in vivo, separate groups of BALB/c mice were injected i.v. with 5 μCi (15 μg) of the [^{125}I]bsMAbs. Necropsies were performed at 1, 2, 4, and 24 h after the injection. In addition to quantifying the uptake in the tissues at these times, a portion of the serum was examined by SE-HPLC to assess the molecular integrity of the bsMAb. Signifi-

cant differences were seen in the distribution properties of the hMN-14 and the murine F6 bsMAb constructs (Figure 3). Overall, there was a higher level of the hMN-14 bsMAb in the normal tissues than the murine F6 bsMAb construct at 1 and 4 h. There was nearly a 2-fold higher uptake in the liver and kidneys and almost 4−5-fold higher uptake in the spleen, which also displayed a high variability in uptake. There was less pronounced differences in the blood concentrations at these earlier times, but by 24 h, the level of hMN-14 × 734-F(ab′)$_2$ in the blood was 1.5 ± 0.2% ID/g compared to 9.4 ± 1.5% ID/g for the F6 × 734-F(ab′)$_2$. Analysis of the SE-HPLC elution profiles of the serum revealed no significant degradation of either antibody through 4 h (Figure 4, panels A and C, only hMN-14 bsMAb shown). Adding CEA to bsMAb prior to or after it had been injected into animals made little difference in the HPLC profile of the bsMAb−CEA complexes formed (Figure 4, panels B and D). Identical results were obtained with the F6-based bsMAb. Analysis of the molecular profile of the [^{125}I]hMN-14 bsMAb at 24 h was not possible, due to insufficient radioactivity remaining in the serum. However, analysis of the profile of the F6 bsMAb revealed that it maintained its molecular integrity (not shown). Thus, the bsMAbs in blood are circulating as intact entities, and are capable of binding to both indium−DTPA complexes and to the target antigen. The differences in distribution properties of these two antibodies, especially the enhanced uptake in the spleen, suggest a recognition of the hMN-14 × 734-F(ab′)$_2$ by reticuloendothelial cells, which is different from that of the murine × murine F6 bsMAb construct. This ultimately results in a more rapid blood clearance of the hMN-14 bsMAb.

The bispecific binding specificity of the bsMAbs in serum taken from mice was assessed. Twenty microliters of serum was incubated with a prescribed amount of [^{111}In/In]IMP-156 (0.2 μCi, 4.1 × 10^{-13} mol). The radioactivity profile in the samples was then analyzed by SE-HPLC using an in-line radiation detector with a restricted ^{111}In window. The percentage of [^{111}In/In]IMP-156 that shifted to RT of the bsMAb was 100, 95, and 95 at 1, 2, and 4 h, respectively, for hMN-14 × 734-F(ab′)$_2$. Serum taken at 24 h after the bsMAb injection showed only 10 and 61% of the peptide eluted bound to the hMN-14 × 734-F(ab′)$_2$ and F6 × 734-F(ab′)$_2$, respectively. Retrospective analysis of the amount of bsMAb in the serum, based on the specific activity of the [^{125}I]bsMAb, suggested that this reduction was simply due to an insufficient amount of bsMAb in the serum at 24 h to bind all of the [^{111}In/In]IMP-156 that was added to the serum in vitro. However, the amount of [^{111}In/In]IMP-156 that comigrated to the molecular size of the bsMAb was in agreement with the amount of bsMAb remaining in blood based on the biodistribution data (Figure 3). For example, at 4 and 24 h, there was 26.4 and 1.5% of the [^{125}I]hMN-14 bsMAb in the serum, which corresponded to 7.9 × 10^{-13} and 4.6 × 10^{-14} mol in 20 μL of serum. Since 4.1 × 10^{-13} mol of peptide (containing 8.2 × 10^{-13} mol of DTPA) was added to each serum sample, the maximum portion of the peptide that could be bound was 96 and 11.2% (4 and 24 h), respectively.

The biodistribution of the [^{99m}Tc]IMP-192 alone was also examined. In BALB/c mice, it had an extremely rapid blood clearance, with only 0.3% ID/g remaining in circulation at 1 h postinjection (Table 1). The radioactivity was cleared from the body predominantly by urinary excretion, with 169 ± 95% ID/g in the urine within 1 h (or 6.9 ± 6.8% based on the total urine volume collected). Analysis of urine collected from mice injected with

[a] Values represent the mean with the standard deviation for three animals at each time interval. Values in parenthesis at the 1- and 24-h time intervals indicate the average percentage of [^{99m}Tc]IMP-192 in the total tissue mass (total blood volume estimated to be equal to 7.4% of the body weight).

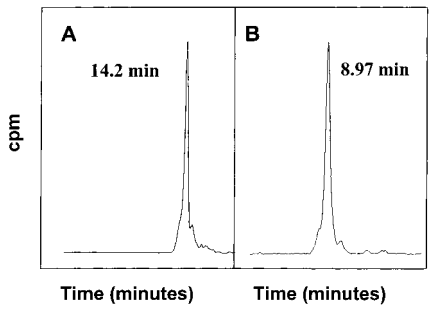

Figure 5. SE-HPLC trace of (A) urine collected from mouse injected with bsMAb and later with [^{99m}Tc]IMP-192 and (B) panel A mixed with excess hMN-14 × 734 bsMAb.

[^{99m}Tc]IMP-192 showed that it contained the intact peptide, since the radioactivity eluting at 14.18 min on SE-HPLC was shifted to a retention time corresponding to that of bsMAb upon addition of hMN-14 × 734-F(ab′)$_2$ (Figure 5). A minor fraction of the [^{99m}Tc]IMP-192 radioactivity was also observed in the small and then the large intestine, suggesting this as another route of excretion. The kidney uptake was about 4% ID/g at 1 h postinjection, but reduced to 1.21 ± 0.08% ID/g by 24 h.

The whole-body clearance of the peptide alone, or if given in a pretargeting setting, was tested in tumor-bearing nude mice (Figure 6). Groups of five mice were given two different amounts of the [^{99m}Tc]IMP-192 peptide, either 1.5 × 10^{-11} mol (28 μCi) or 1.5 × 10^{-10} mol (280 μCi). A separate group of animals was first given the 15 μg of the hMN-14 × 734 bsMAb and then 16 h later, the peptide was given. Animals were placed in a dose calibrator at various times after the peptide injection to determine the residual radioactivity remaining. To correct for radioactivity decay, 28 or 280 μCi of [^{99m}Tc]-IMP-192 were placed in vials and these were read in the dose calibrator before the whole-body readings. The percentage remaining in whole body was calculated from these readings. This study showed >85% of the radioactivity cleared from the animals within 2 to 3 h. This is consistent with the finding in BALB/c mice that the

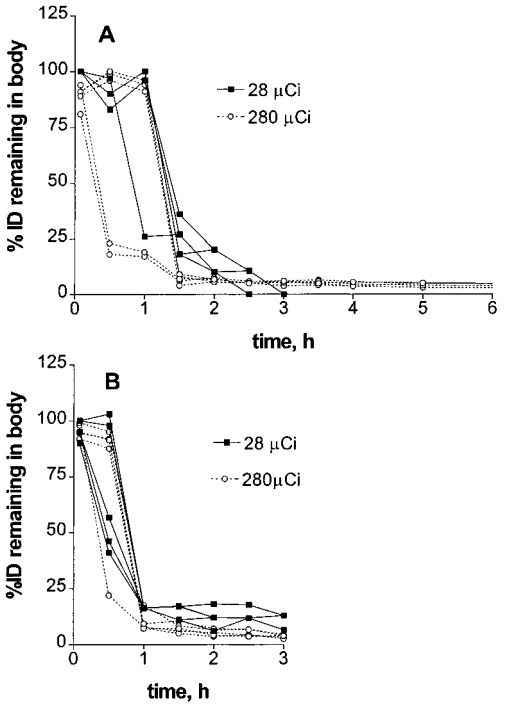

Figure 6. Whole-body clearance (biological) of [^{99m}Tc]IMP-192 (28 μCi, 1.5 $\times$ 10^{-11} mol or 280 μCi, 1.5 $\times$ 10^{-10} mol, (A) alone or (B**)** given 16 h after hMN-14 $\times$ m734 bsMAb was given. Animals were placed in a dose calibrator at 5 and 30 min and then again at 1, 1.5, 2.0, 2.5, 3.0, 4.0, 5.0, and 6 h after the peptide alone, or through 3 h for animals given the bsMAb.

majority of the peptide is cleared from the body through urinary excretion rather than fecal elimination. There was no evidence that increasing the amount of peptide affected the clearance rate, and even animals given the bsMAb 16 h earlier cleared the peptide at a similar rate.

Pretargeting Studies. To examine the targeting ability of the radiolabeled peptide when used in conjunction with the bsMAb, a study was first performed to assess the temporal relationship between the bsMAb and peptide injections. Nude mice bearing GW-39 human colonic cancer xenografts were first given intravenous injections of 150 pmol (15 μg) of the hMN-14 $\times$ 734-F(ab′)$_2$ or the F6 $\times$ 734-F(ab′)$_2$ containing a trace amount of each antibody radiolabeled with ^{125}I. At either 4, 16, 24, or 48 h after the hMN-14 bsMAb, 15 pmol of [^{99m}Tc]IMP-192 was given. A separate group of animals was given the identical amount of [^{99m}Tc]IMP-192 alone. In all groups, the tissue distribution was examined 3 h after the radiolabeled peptide was given. Table 2 shows the results obtained using the hMN-14 bsMAb. An important relationship is the bsMAb and peptide percent uptake in the tumor and blood at each time. When the peptide was injected 4 h after the bsMAb, the concentration of the bsMAb in the blood was too high, and thus a majority of the peptide was bound to the bsMAb in the blood rather than in the tumor. As the bsMAb in the blood cleared, a higher percentage of peptide is found in the tumor, with optimal tumor uptake of the peptide between 16 and 24 h, despite the lower amount of bsMAb in the tumor than at 4 h. Tumor/nontumor ratios continued to improve as the time from the bsMAb injection increased. For example, tumor/blood ratios were 3.6 $\pm$ 1.4 when the peptide was given 24 h after the bsMAb, but this increased to 11.3 $\pm$ 2.2 when an interval of 48 h was given. However, it is noteworthy that the percent uptake per gram of tumor also decreased, and thus, for therapeutic purposes, the earlier addition of the peptide may be preferred. Tumor uptake of the [^{99m}Tc]IMP-192 given alone was only 0.10 $\pm$ 0.02% ID/g, indicating that there is selective uptake of the peptide due to the bsMAb in the tumor. Another noteworthy item was the observation that in the animals given the radiolabeled peptide 4 h after the bsMAb, there was a very high percentage of ^{125}I radioactivity in the stomach. Since the uptake of [^{99m}Tc]-IMP-192 in the stomach was so much lower (i.e., 1.8%), the ^{125}I radioactivity in stomach likely represents a catabolized product. This is very likely since as was seen in Figure 4, there was considerable early accretion of the [^{125}I]hMN-14 bsMAb in the liver and the spleen. Although no significant amount of nonantibody-associated ^{125}I radioactivity was found in the serum at these early times, there is a clear indication that a rapid degradation of the radiolabeled hMN-14 bsMAb is occurring with uptake and excretion of the radioactivity through the GI tract.

On the basis of the previous biodistribution of the ^{125}I-labeled bsMAb alone (Figure 2), there did not appear to be any evidence that the bsMAb's distribution or blood clearance was altered by the addition of the peptide. This was confirmed in a separate study where the bsMAb was given alone or the peptide was given 16 h after the bsMAb. Tumor and blood uptake of [^{125}I]bsMAb alone was 3.7 $\pm$ 1.5 and 1.9 $\pm$ 0.3, respectively, and 2.5 $\pm$ 0.3 and 0.8 $\pm$ 0.08% ID/g at 19 and 27 h, respectively. In the animals given the [^{125}I]bsMAb followed 16 h later with the peptide, tumor and blood uptake was 3.4 $\pm$ 1.1 and 1.7 $\pm$ 0.2% ID/g, respectively, at 19 h, and by 27 h, [^{125}I]-bsMAb uptake was 3.6 $\pm$ 0.9 and 0.8 $\pm$ 0.10% ID/g for tumor and blood, respectively.

By virtue of having the highest tumor uptake and reasonable tumor/nontumor ratios for radiolabeled peptide, 24 h was selected for further evaluation with the hMN-14 bsMAb. Because of the slower blood clearance of the F6 antibody, an interval of 72 h was selected for the following pretargeting studies.

A time course study was designed to assess the distribution of the ^{99m}Tc- and ^{188}Re-labeled IMP-192 over a 24- and 72-h period, respectively. These results are shown in Tables 3−6. By allowing time to let the individual bsMAb clear from the blood, it was evident that even within just 30 min after the [^{99m}Tc]IMP-192 injection, there was a higher uptake of the peptide in the tumor than in any of the normal tissues (Tables 3 and 4). Tumor uptake of the [^{125}I]hMN-14 bsMAb ranged between 5 and 6% ID/g through 3 h after the [^{99m}Tc]IMP-192 injection and was reduced to 3.3 $\pm$ 0.7% ID/g by 24 h (Table 3). During this same time period, the average tumor uptake of the [^{99m}Tc]IMP-192 was between 11 and 14% ID/g, reducing to 8.7 $\pm$ 3.3% ID/g at 24 h. Tumor/blood ratios for the hMN-14 bsMAb pretargeting system were 2.7 $\pm$ 0.7 within 30 min of the [^{99m}Tc]IMP-192 injection and peaked at 16.1 $\pm$ 6.4 at 24 h after injection. The tumor/blood ratio in animals given only the [^{99m}Tc]-IMP-192 was 0.29 $\pm$ 0.14 at 3 h (Table 2) compared to 7.3 $\pm$ 2.3 in the pretargeting system at this same time (Table 3). Even tumor/kidney ratios were >1.0 within 30 min in each bsMAb pretargeting system. In contrast to when the [^{99m}Tc]IMP-192 was given alone, higher concentrations of the peptide were seen in the blood and the other normal tissues in the pretargeting system (e.g., liver, spleen, lungs). This is expected since there was still residual bsMAb remaining in the blood and tissues even at these later times following the bsMAb injection. Thus, the bsMAb-bound peptide would have a delayed clearance in comparison to the peptide alone.

Table 2. Biodistribution of [^{99m}Tc]IMP-192 in Nude Mice Bearing GW-39 Tumors[a]

[a] Animals were either given the [^{99m}Tc]IMP-192 alone (1.5×10^{-11} mol) or the animals first received [^{125}I]hMN-14 × 734-bsMAb (1.5×10^{-10} mol), and then after 4, 16, 24, and 48 h, they received the radiolabeled peptide. All values were obtained 3 h after the [^{99m}Tc]IMP-192 (1.5×10^{-11} mol), injection and are presented as the mean ± standard deviation with five animals per interval. The average GW-39 weights for each respective group in order shown were 0.113 ± 0.043, 0.102 ± 0.008, 0.120 ± 0.029, 0.404 ± 0.277, and 0.512 ± 0.352 g.

[a] Nude mice bearing GW-39 human colonic cancer xenografts were given [^{125}I]hMN-14 × m734 (Fab′ × Fab′, 5 μCi, 1.5×10^{-10} mol). Twenty-four hours later, [^{99m}Tc]IMP-192 (10 μCi, 1.6×10^{-11} mol) was injected. All times given in the tables are the means and standard deviations at the hours indicated after the [^{99m}Tc]IMP-192 injection (five animals per time point). The average GW-39 weights for each respective group in order shown were 0.382 ± 0.106, 0.373 ± 0.062, 0.265 ± 0.094, and 0.358 ± 0.110 g.

Interestingly, the percent injected dose per gram of the [^{99m}Tc]IMP-192 in tumors was similar in animals pretargeted with either the F6 bsMAb or the hMN-14 bsMAb, despite the nearly 2-fold higher amount of the F6 bsMAb in the tumor (Table 4). This is most likely explained by the fact that there was also nearly 2-fold more F6 bsMAb than hMN-14 bsMAb in the blood, which would have reduced the amount of [^{99m}Tc]IMP-192 available for tumor binding. As stated earlier, these studies were not conducted under conditions to optimize each targeting system fully.

The pretargeting studies were repeated using [^{188}Re]-IMP-192 in place of [^{99m}Tc]IMP-192, at the same 10:1 bsMAb to IMP-192 ratio (Tables 5 and 6). Because of the longer half-life of ^{188}Re, biodistributions were performed at 3, 24, 48, and 72 h following [^{188}Re]IMP-192 injection. Again, uptake of the [^{188}Re]IMP-192 was higher in the tumor than all the normal tissues as early as 3 h after injection, due to both the rapid clearance of small molecular weight [^{188}Re]IMP-192 and the ready recognition of the radiolabeled peptide by the tumor-localized bsMAb. In contrast to tumor uptake of the [^{188}Re]IMP-192 alone (7 μCi, 1.5×10^{-11} mol of peptide), which at 3 h was 0.36 ± 0.15 (Table 5), [^{188}Re]IMP-192 tumor uptake was 16.9 ± 5.5% ID/g when used with the hMN-14 bsMAb pretargeting system. Overall, no meaningful differences were seen between the ^{99m}Tc- and the ^{188}Re-labeled peptide in either bsMAb pretargeting system at 3 and 24 h, times that were common for the two studies.

Dosimetry. To predict the therapeutic potential of [^{188}Re]IMP-192 in animals pretargeted with hMN-14 734 bsMAb, the biodistribution studies were used to calculate radiation-absorbed doses to the tissues and tumor (Table 7). Even under these conditions which were not fully optimized, the tumor is predicted to receive a radiation dose nearly 12-fold higher than the liver, 7 times higher than the kidneys, and 5-fold higher than the blood. Radiation doses to the gastrointestinal tract, most notably the stomach, were higher than the other organs.

DISCUSSION

Pretargeting is a very attractive modality for the delivery of radionuclides to tumors for both RAID and RAIT, although its complexity requires multiple problems to be solved before it can be applied optimally in a clinical

[a] Nude mice bearing GW-39 human colonic cancer xenografts were given [^{125}I]hMN-14 × m734 Fab′ × Fab′ (5 μCi, 1.5 × 10^{-10} mol). Twenty-four hours later, [^{188}Re]IMP-192 (7 μCi, 1.6 × 10^{-11} mol of peptide) was injected. All times given in the tables are the means and standard deviations at the hours indicated after the [^{188}Re]IMP-192 injection (five animals per time point). The data for the [^{188}Re]IMP-192 alone is 3 h after its injection. The average GW-39 weights for each respective group in order shown were 0.098 ± 0.042, 0.160 ± 0.065, 0.136 ± 0.036, and 0.266 ± 0.168. ND, insufficient radioactivity in normal tissue to reliably calculate percent uptake.

setting. Previously, we examined a streptavidin−antibody conjugate/radiolabeled biotin pretargeting approach analogous to the one described by Axworthy et al. (1994). These investigators were able to deliver the same amount of radioactivity to a tumor using radiolabeled biotin as was possible with a radiolabeled antibody conjugate. We also found that excellent tumor/nontumor ratios could be achieved with reasonable absolute tumor uptake using such a system (Sharkey et al., 1997). While animal studies continue to evaluate the therapeutic benefit of the antibody−streptavidin/radiolabeled biotin pretargeting approach in comparison to directly radiolabeled antibody, we continue to have serious concerns with the system, particularly because of the immunogenicity of streptavidin (Chinol et al., 1998). Knowing of the possibilities for future engineering (Carter and Merchant 1997; Coloma and Morrison, 1997) of a humanized agent with minimal, if any, immunogenicity, efforts were undertaken to investigate a bispecific antibody pretargeting approach useful for RAIT.

For these initial studies, we decided to evaluate our humanized antibody to CEA, hMN-14, since this is presently being used in clinical trials. This antibody was paired with the murine antibody specific for [In]DTPA, termed 734, that was used previously by the French investigators with their murine anti-CEA antibody, F6 (Chetanneau et al., 1990). Using established technology (Glennie et al., 1987), a Fab′ fragment of each of these MAbs was coupled site-specifically in their hinge-regions via a thioether linkage to produce a bispecific F(ab′)$_2$. Rigorous SE-HPLC analyses were performed to show bsMAb purity to be greater than 90%, with excellent

retention of binding both to CEA and to [^{111}In/In]DTPA. All of radiolabeled bivalent hapten, [^{111}In/In]IMP-156, could be shifted to a higher molecular weight fraction when combined with bsMAb and CEA, indicating that all of the binding 734 arm was associated with a hMN-14 arm. About 92−93% of the bsMAb migrated to a higher molecular weight by SE-HPLC when combined with [In]DTPA-LL2-IgG, indicating that 7−8% hMN-14 × hMN-14 (Fab′ × Fab′) was likely present. Since it would be preferable to have excess monospecific anti-CEA MAb present rather than excess monospecific anti-DTPA MAb, the 734 Fab′ was selected to be activated with the dimaleimide. In vitro, the hMN-14 × 734 bsMAb was comparable to the previously described all-murine F6 × 734 bsMAb, in that both molecules maintained molecular integrity, as well as capacity for binding to CEA or indium-DTPA.

The murine F6 anti-CEA × 734 construct was used primarily as a positive control to show that substituting the hMN-14 in bsMAb would not affect the quality of the bsMAb. In vitro studies certainly confirmed this, but in vivo, an unexpected rapid blood clearance of the hMN-14 × 734-F(ab′)$_2$ (humanized × murine) compared to the F6 × 734-(Fab′)$_2$ (murine × murine) was found. Thioether-linked F(ab′)$_2$ is not susceptible to reduction and, indeed, was previously shown to have an extended blood circulation time compared to a natural F(ab)$_2$ fragment (Siddiqui et al., 1995), so the linkage chemistry could not explain the rapid clearance seen with the humanized-murine hybrid bsMAb. SE-HPLC was used to assess catabolic products in the serum (e.g., Fab′ fragments or even smaller molecular weight byproducts). Given the amount of radioactivity administered to the animals, the radiolabeled hMN-14 × 734 bsMAb could only be evaluated over 4 h. During this time, there was no evidence of catabolic byproducts to suggest an instability of the bsMAb. Previous studies with hMN-14 F(ab′)$_2$ in mice have shown a similar rapid blood clearance (Leung et al., 1999) in comparison with the corresponding murine F(ab′)$_2$, and we have also noted differences in the clearance properties of murine IgG$_1$ and murine IgG$_{2a}$ and of human IgG$_1$ in nude mice (Sharkey et al., 1991). This observation was ultimately traced to varying amounts of murine IgG$_{2a}$ in different strains of mice (Reddy et al., 1998), but it is uncertain whether a similar mechanism can explain the differences in the clearance of bsMAb fragments, since these molecules lack the Fc-portion of the immunoglobulin molecule that is most frequently associated with its recognition by immune cells. However, an initially high uptake was noted in both the spleen and liver for the hMN-14 bsMAb in comparison to the all murine F6 bsMAb, suggesting that there is a recognition mechanism involved in this enhanced clearance. The elevated uptake of radioiodine in the stomach was a further indication that the hMN-14 bsMAb was likely being catabolized in these organs. The humanized MN-14 × murine 734 bsMAb F(ab′)$_2$ is presently being prepared for clinical use, where it will be possible to reassess its distribution and clearance. However, since clinical studies comparing the murine MN-14 and humanized MN-14 IgG revealed very similar distribution and clearance properties (Sharkey et al., 1995), it is more likely that this preclinical observation is unique to the mouse model. Thus, it might be better to use murine bsMAbs in murine models, as this would maintain the species similarities that will ultimately occur when a fully humanized bsMAb is used clinically.

Despite the observed differences in the clearance rate of the two bsMAbs, the subsequent targeting of both the [^{99m}Tc]- and [^{188}Re]IMP-192 peptides to either conjugate was excellent. Even though a higher tumor uptake was observed with the radioiodinated F6-based bsMAb compared to the hMN-14 bsMAb, initial tumor uptake of the radiolabeled peptide in both pretargeting systems was very similar. This was clearly due to differences in the amount of bsMAb remaining in the blood at the time the peptide was given. This illustrates the importance of fully optimizing the relationship between the amount of bsMAb remaining in the blood at the time the peptide is

given. The best radiolabeled peptide ratios correlated with the highest bsMAb tumor uptakes and the lowest bsMAb blood levels. It is also important to note that there was no evidence that the injection of the radiolabeled peptide affected the blood clearance rate or the organ distribution of the bsMAb. Given the divalent nature of the peptide, it is possible that complexes of 2 bsMAb molecules could form in the blood, and they might be cleared differently or even cause the bound peptide or antibody to distribute differently in the organs. It is possible that at the concentrations of the bsMAb and peptide used in these studies and the times that were examined failed to detect altered kinetics and distribution. This issue should be reexamined once an optimized therapeutic system is developed. Indeed, as shown by Gautherot et al. (1998, 2000), careful optimization is required to achieve superior therapeutic results.

The IMP-156 is not suitable for therapeutic applications with Y-90, because the 734 MAb was unable to bind tightly to the yttrium−DTPA complex. Additionally, [^{90}Y]-DTPA species, wherein one carboxyl group is unavailable due to amide bond formation, are well-known to have poor in vivo stability (Harrison et al., 1991). Although a species containing mixed DOTA and DTPA chelates may be prepared, the similarities of labeling chemistries between yttrium and indium might make selective indium labeling of DTPA and yttrium labeling of DOTA problematic. Another option would be to prepare a new anti-yttrium-DOTA MAb so that a new bsMAb could be used, but this too would restrict the applicability of such a bsMAb to this single system. Instead, we are presently exploring a single peptide-binding MAb that could be used with a peptide that itself could be modified to accommodate multiple binding possibilities. The approach taken here was to work with the 734 antibody, but to construct a new peptide with another binding specificity. Since the chemistries involved in technetium/rhenium radiolabeling are quite distinct from those used in indium chelation, this presented an opportunity to explore the selective radiolabeling of a Tc/Re chelate-peptide that also contained indium−di-DTPA. This peptide, IMP-192, was assembled with a thiosemicarbonylglyoxylcysteinyl group (TscGC), which is a thiol-containing ligand for Tc/Re. It was then formulated with excess nonradioactive indium to saturate DTPA chelate sites and lyophilized into single-vial kits containing stannous ion, for later reconstitution with either ^{99m}Tc or ^{188}Re. ^{99m}Tc-formulated kits were ^{99m}Tc labeled at 1836 Ci/mmol/mmol of peptide (94−99% incorporation), while kits formulated for ^{188}Re were labeled at 459−945 Ci/mmol (96−97%). Successful labeling of both Tc and Re IMP-192 kit formulations indicated that the presence of free and DTPA-bound indium did not interfere with ^{99m}Tc or ^{188}Re labeling of the TscGC chelate. Further studies are planned to determine if higher specific activities can be achieved for therapeutic applications.

Biodistribution studies of [^{99m}Tc]IMP-192 and [^{188}Re]-IMP-192 bivalent haptens alone in normal BALB/c mice showed rapid blood clearance. As with the IMP-156 peptide, the presence of the two DTPAs on the IMP-192 peptide probably aids in rapid renal excretion, and it was gratifying to find that attachment of the TscGC moiety did not materially change the behavior of the IMP-192 di-DTPA peptide. In addition, the in vitro and in vivo studies clearly demonstrate stability of these complexes, with unchanged radiolabeled IMP-192 excreted in urine at early time points postinjection. Unlike radiolabeled biotin (Rusckowski et al., 1996; Sharkey et al., 1997), there was no evidence of selective tumor accretion (i.e., tumor/nontumor ratios > 1.0) of the radiolabeled IMP-192 peptide when administered alone to mice.

Using this pretargeting system, tumor-to-liver, -kidney, -lungs, and -blood ratios were between 3- and 22.9:1 at 1 and 3 h after the [^{99m}Tc]IMP-192 peptide was given, indicating that early imaging will be possible. In comparison, a [^{99m}Tc]Fab′ anti-CEA, prepared by direct labeling of hinge-region thiol groups, and tested in the same preclinical tumor model, gave tumor-to-liver, -kidney, -lungs, and -blood ratios of 1.6-, 0.06-, 1.2-, and 0.9-to-1 at 2 h postinjection (Hansen et al., 1990). With the hMN-14 × 734-F(ab′)$_2$ bsMAb pretargeting method, even the kidney shows a positive tumor-to-nontumor ratio at only 30 min postinjection of [^{99m}Tc]IMP-192. The pretargeted [^{188}Re]IMP-192 peptide gave tumor-to-nontumor ratios between 14.7- and 63.8-to-1 for the major tissues by 24 h postinjection of the ^{188}Re-labeled peptide, and ratios were decidedly positive for each tissue even by 3 h postinjection of the [^{188}Re]IMP-192. For comparison, a ^{188}Re direct-labeled IgG in a similar tumor xenograft model (LS-174T) showed tumor-to-nontumor ratios at 24 h postinjection of 1.8- to 6.1:1, and none of these ratios was positive at 2 h postinjection (Griffiths et al., 1991). Of particular note with these ^{99m}Tc- and ^{188}Re-labeled peptides is the absence of renal retention of the radiometal when compared to radiometal-labeled MAb fragments developed for RAID and RAIT (Behr et al., 1995).

The excellent tumor/nontumor ratios and very reasonable tumor uptakes already suggest that this bsMAb−peptide combination has promising RAID and RAIT applications. RAIT prospects would be improved further if an increase in absolute tumor uptake of radioactivity at these same tumor-to-tissue ratios could be achieved. In the present studies, only small doses of the bsMAb (i.e., 15 μg) were given to each animal, but for RAIT, higher bsMAb protein doses will be used to increase the number of peptide-binding sites localized to the tumor. The use of other bsMAb constructs could also increase the amount of bsMAb localized in the tumor. For instance, use of bsMAb comprising a divalent anti-CEA combined with either a monovalent or even a divalent anti-hapten antibody is of interest. Changing bsMAb valency would increase the size of the bsMAb and likely slow its blood clearance, and then more time would be needed before radiolabeled peptide administration to allow for adequate blood clearance of the bsMAb. Others (Axworthy et al., 1994; Schuhmacher et al., 1995) have used clearing agents to reduce the blood level of nonlocalized pretargeting agents after maximum tumor uptake has been achieved, although clearance mechanisms involving blockade of secondary binding sites can adversely affect subsequent targeting of the low molecular weight RAID/RAIT agent. In this regard, we have an anti-idiotypic MAb (WI2) to the MN-14 anti-CEA arm, which was successfully used for clearance in previous work with MAb-streptavidin studies (Sharkey et al., 1997) and has since been humanized (Losman et al., 1999). We are presently evaluating alternate bsMAb targeting with hMN-14 IgG × 734-Fab′, and hMN-14 F(ab′)$_2$ × 734-Fab′ conjugates, to assess valency and molecular size issues. Ultimately, bsMAbs will be prepared through molecular engineering (Coloma and Morrison, 1997; Merchant and Carter, 1997), at sizes indicated best for either RAID or RAIT application from the current studies. The molecular engineering approach will also provide an opportunity to enhance the productivity and availability of bsMAb constructs, while simultaneously minimizing or eliminating any immunogenicity.

In summary, these studies provide highly promising

preclinical targeting data with human-murine and murine-murine bsMAb $(Fab')_2$. Furthermore, a novel peptide containing metal-selective chelates for indium and for ^{99m}Tc and ^{188}Re radiolabeling allows parallel development for both RAID and RAIT applications. The pretargeting results presented here suggest that early time-point imaging using [^{99m}Tc]IMP-192, with the high tumor-to-tissue ratios versus major internal organs achieved, could provide a new standard for RAID. The data are also very encouraging for therapy with [^{188}Re]IMP-192.

ACKNOWLEDGMENT

We thank Immunotech S. A., Marseilles, France, for providing supplies of the F6 and 734 antibodies. We also thank Ms. H. Spiegelman, L. Reed, and L. Osorio for their assistance with the animal studies and Mr. T. Jackson for radiolabeling. Supported in part by USPHS Grants CA 81760 and CA 37895 from the NIH.

Preparation and Evaluation of Tumor-Targeting Peptide−Oligonucleotide Conjugates

Walter Mier,* Ramon Eritja,† Ashour Mohammed, Uwe Haberkorn, and Michael Eisenhut

Department of Nuclear Medicine, Universitätsklinikum Heidelberg, INF 400, 69120 Heidelberg, Germany and European Molecular Biology Laboratory, Meyerhofstrasse 1, 69117 Heidelberg, Germany. Received April 20, 2000; Revised Manuscript Received July 23, 2000

Enormous progress has been made in the development of antisense oligodeoxynucleotides (ODNs) as therapeutic agents inhibiting gene expression. Unfortunately, the therapeutical application of ODNs is still held back because of the low cellular uptake and the lack of specific transport into particular cells. In this paper, we report a drug-targeting system using somatostatin receptors (SSTRs) which are overexpressed in various tumors. Phosphorothioate ODNs were covalently linked to Tyr^3−octreotate, an analogue of somatostatin. The peptide was assembled by solid-phase synthesis, oxidized to form the cyclic disulfide, and subsequently derivatized with a N-terminal maleimido functionality. 5′-Thiol derivatized phosphorothioate-ODNs directed against the protooncogene *bcl-2* were conjugated to this maleimido-modified peptide. Binding studies revealed that the conjugates retain specific binding with nanomolar affinities to SSTRs (IC_{50}-values between 1.83 and 2.52 nM). Furthermore, melting studies with complementary DNA revealed that the terminal conjugation of the ODNs did not significantly affect their hybridization affinity.

INTRODUCTION

Antisense therapy holds great promise for the treatment of gene-related disorders. Still, the major obstacle for an efficient antisense therapy is the low internalization rate into target cells. Even though ODNs[1] are large, negatively charged molecules, they are to some extent transported through the cellular membranes. This uptake is achieved by pinocytosis and processes which are known to be concentration and energy dependent. Depending on the ODN, the cell line and experimental conditions, the uptake rate ranges 1−20%.

Numerous attempts have been made to increase the intracellular bioavailability and to enable specific internalization into selected cell types. A highly efficient and versatile system for uptake enhancement is encapsulation into liposomes. Within liposomes, ODNs are preserved from serum nuclease degradation. Taking advantage from various coating modifications which increase stability and uptake, liposomes have become valuable shuttles for ODNs (*1*). ODNs attached to hydrophobic moieties, such as lipids (*2*), cholesterol (*3*), or geraniol (*4*), show increased antisense effects. However, these effects have always been controversially discussed because of sequence unrelated effects and the lack of a plausible mechanism. Cellular internalization of cationic molecules by adsorptive endocytosis has been exploited by several procedures. For example, cellular import can be increased with ODN−polylysine complexes (*5*) or ODNs conjugated to avidin (*6*). Conjugation of PNA with a monoclonal antibody to the rat transferrin receptor enabled the transport through the blood brain barrier (*7*). This approach led to a 28-fold uptake rate as compared to the unmodified ODN analogue. The complexes formed when mixing ODNs with porphyrin possess enhanced stability and cellular delivery by an unknown mechanism (*8*). The ubiquitously expressed receptors for vitamin B_6 can be addressed with ODNs conjugated to vitamin B_6 (*9*). These conjugates were believed to be taken up by potocytosis. A unique targeting system for liver cells has been developed using the asialo-glycoprotein receptors (*10*). Residues of β-D-galactose within the asialo-glycoprotein mediate the selective uptake of the conjugated ODN into the liver. These findings should stimulate the search for selective targeting vectors which enable enhanced receptor-mediated delivery into other tissues. Peptides which bind to integrins (*11*) and the EGF-receptor family (*12*) represent examples of peptide vectors which have been employed for ODN-transport. These peptides bind to distinct receptors, which upon binding, mediate endocytosis of the peptide−ODN complex. Conjugates of ODNs with penetratins (*13*) or signal peptides (*14*, *15*) acquire increased uptake rates due to the membrane translocation properties of these peptides. Hitherto no targeting system with selectivity for cancer cells and high capacity sufficient for antisense therapy has been found to be effective in vivo.

Somatostatin is a cyclic tetradecapeptide found in the hypothalamus. It is an important regulating peptide which exerts inhibitory effects on the secretion of growth hormones. The SSTRs are known to be overexpressed by a variety of neoplastic tissues such as small cell lung cancers, breast tumors, brain tumors, and many other

(mainly endocrine) tumors. Therefore, the membrane-associated SSTRs represent potential molecular targets for selective delivery into tumor cells. Because of the short biological half-live of the natural somatostatin (<3 min) in vivo, many analogues have been developed. Octreotide, a cyclic octapeptide with an improved specificity and a half-live of about 90 min (*16*) has become the most successful analogue. Recently, it has turned out that octreotate, the carboxylic acid derivative of octreotide, offers improved pharmacological properties and should therefore be an interesting alternative to octreotide (*17*).

A large number of tumor types show aberrant gene expression of the protooncogene *bcl-2*. These abnormalities result in an overexpression of *bcl-2* protein. This protein is known to inhibit apoptosis. Antisense ODNs have been used to inhibit *bcl-2* expression in cellular studies (*18*). The model ODN used in the present studies is a 20-mer that corresponds to a selected part of the coding sequence within the genome of human *bcl-2* cDNA (*19*). Besides their high enzymatic stability, phosphorothioates have been shown to be highly potent in inhibiting *bcl-2* expression (*18*). Therefore, the ODN conjugates were prepared as phosphorothioates.

Even though octreotate contains only eight residues, the synthesis is complicated by several structural features. In particular, cyclization of the disulfide bond does not converge with the introduction of amine- and thiol-reactive groups necessary for conjugation. Hence, a synthetic protocol, which allows the solid-phase formation of the disulfide bond and subsequent attachment of the reactive group has been developed.

In addition to the synthesis, we report herein data on binding specificity to the SSTRs and binding specificity to the corresponding ODNs. These experiments were performed to scrutinize whether the ODN−Tyr^3−octreotate conjugates fulfill the major prerequisites for receptor mediated uptake and antisense effect.

EXPERIMENTAL PROCEDURES

General. The peptides were analyzed and separated by liquid chromatography (HPLC) on a Gyncotech P-580 system (Germering, Germany) equipped with a variable SPD 6-A UV detector and a C-R5A integrator (both Shimadzu, Duisburg, Germany). The columns used were Nucleosil C_{18}, 5 μm, 250 × 4 mm (Macherey & Nagel, Düren, Germany) and LiChrosorb RP-select B 10 μm, 250 × 10 mm (Merck, Darmstadt, Germany). The ODNs were purified on a Waters liquid chromatography system on PRP-1 material 7 μm, 305 × 7 mm (Hamilton, Bondauz, Switzerland). UV measurements as well as the melting studies were performed with a computer interfaced Varian Cary 13 UV−vis spectrophotometer. Mass spectrometry analysis of the peptides and of the oligonucleotides was performed on a matrix-assisted laser desorption ionization time-of-flight mass spectrometer (MALDI-1, Kratos Instruments, England). ^1H and ^{13}C NMR spectra of compound **4** were recorded on a Bruker AM 250 spectrometer and are expressed as δ units relative to CD_3OD (δ = 49.3 for ^{13}C). The peptides were synthesized manually with an in-house manufactured SPPS reactor. The oligodeoxynucleotides were synthesized on an Applied Biosystems model 394 DNA synthesizer or on an PerSeptive Expedite 8900 synthesizer. Lyophilization was performed on a Christ (Osterode, Germany) α1-2 lyophilizator. Membrane-binding experiments were performed using an in-house manufactured filtration apparatus.

Reagents. All standard synthesis reagents were purchased from Merck (Darmstadt, Germany). The chemicals for peptide synthesis were obtained from Novabiochem (Läufelfingen, Switzerland). *N*-Maleimido-6-caproic acid, thallium(III)trifluoroacetate, and TIS were obtained from Fluka (Buchs, Switzerland). The chemicals for the oligonucleotide synthesis were obtained from Perkin-Elmer Applied Biosystems (Norwalk, Connecticut) or PerSeptive Biosystems (Hamburg, Germany). The sulfurization-reagent EDITH was from PerSeptive Biosystems. The thiol linker phosphoroamidite was purchased from Glen research (Sterling, Minnesota). Anhydrous solvents were obtained from Merck, PerSeptive Biosystems, and SDS (Peypin, France). NAP-10 gel filtration columns were from Pharmacia (Uppsala, Sweden). Protein was determined using the Bradford assay (Sigma). Water was purified by a Milli-Q water system from Millipore (Eschborn, Germany). Tyr^3−octreotide was prepared by SPPS. Radioisotope $Na^{125}I$ was purchased from Amersham Pharmacia Biotech (Freiburg, Germany). [^{125}I]Tyr^3−octreotide was prepared by iodination of Tyr^3−octreotide using the chloramine-T method according to the method of Bakker et al. (*20*). The product was purified by HPLC and stored at −80 °C. The complementary unmodified phosphodiester and phosphorothioate ODNs for the melting temperature analysis 5′-GTTCTCCCAGCGTGTGCCAT-3′ (antisense) and 5′-ATGGCACACGCTGGGAGAAC-3′ (sense) were synthesized by standard procedures.

Synthesis of the Maleimido-Peptide 4. The peptide was assembled by Fmoc chemistry on 1 g of Fmoc-Thr-(^{t}Bu)-Wang resin (0.61 mmol/g). N^α-Fmoc amino acids with the following side chain protecting groups were employed: Cys(Acm), Lys(Boc), Thr(^{t}Bu), D-Trp(Boc), and Tyr(^{t}Bu). All couplings were performed in DMF. The peptide chain was constructed manually according to a modified in situ neutralization cycle (*21*). Briefly, this cycle consisted of a 2-fold decoupling (1 and 5 min) with 50% piperidine in DMF and 10 min coupling with 4 equiv of the Fmoc-amino acid (0.4 M in DMF, incubated for 5 min with 3.9 equivof HBTU and 6 equivDIPEA). After completion, the resin (1.75 g dry weight) was treated with piperidine in DMF to deprotect the terminal α-amino-group of the peptide. An aliquot was cleaved and analyzed by HPLC indicating formation of **1** with a yield of >90%. A total of 200 mg of the resin-bound peptide **1** was cyclized at room temperature with a 2-fold molar excess of thallium(III)trifluoroacetate in DMF. As determined by analysis of a small aliquot, formation of **2** was essentially complete within 1 h. After thorough washing, *N*-maleimido-6-caproic acid was coupled as described above, the resin was washed and dried under vacuum overnight. Cleavage was performed with 5 mL of 37:1:1:1 TFA/H_2O/phenol/TIS for 2 h at room temperature. The resin was filtered and washed. The peptide was precipitated by the gradual addition of *tert*-butyl-methyl ether at 4 °C. Purification was accomplished by reversed-phase HPLC on the RP-selectB column using a gradient of 20% B → 50% B in 7.5 min and 50 → 100% B in 5 min (A = H_2O and B = acetonitrile, both containing 0.1% TFA), flow rate = 4 mL/min. Under these conditions, the peptide was eluted at 10.2 min. After lyophilization, 44 mg of **4** (43.6% overall yield) was obtained as a fluffy powder. The purified peptide was characterized by mass spectrometry. Anal. calcd for $C_{59}H_{75}N_{11}O_{15}S_2$ $[M + H]^+$: *m/z* 1243.4. Found: 1244.2. ^{13}C NMR (CD_3OD) δ = 20.02 (q), 20.58 (q), 22.89 (t), 26.28 (t), 27.14 (t), 27.70 (2 C) (t), 29.24 (t), 31.42 (t), 36.75 (t), 38.40 (t), 39.34 (t), 40.19 (t), 40.65 (t), 46.45 (t), 46.52 (t), 53.86 (d), 54.16 (d), 54.43 (d), 55.18 (d), 56.42 (d), 57.68 (d), 59.68 (d), 60.55 (d), 68.55 (d), 69.09 (d), 110.41 (s), 112.33 (d), 116.23 (2 C)

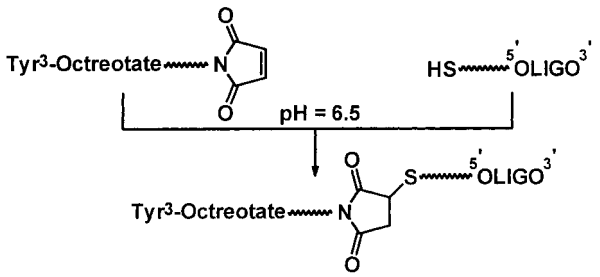
Synthesis and Purification of the 5′-Thiol ODNs. The all-phosphorothioate ODNs, 5′-GTTCTCCCAGCGTGTGCCAT-3′ (antisense), 5′-ATGGCACACGCTGGGAGAAC-3′ (sense), and 5′-TACCGTGTGCGACCCTCTTG-3′ (nonsense), were synthesized using β-cyanoethyl phosphoramidite chemistry at the 1 μmol scale. Acetylation was performed by 0.1 M acetic anhydride/tetrahydrofuran (THF) and 0.1 M imidazole/THF. Sulfurization was affected by using the EDITH reagent. The commercially available six-carbon thiol linker phosphoroamidite (1-*O*-dimethoxytrityl-hexyl-disulfide-1′-[(2-cyanoethyl)−(*N*,*N*-diisopropyl)]-phosphoramidite (Glen Research) was coupled to the 5′ end. The final coupling was followed by an acetonitrile wash. The resin was dried under a stream of argon and treated with concentrated ammonia containing 0.1 M DTT at 55 °C for 12 h to simultaneously affect deprotection of the thiol protection as well as cleavage from the resin (*22*). The resin was removed by filtration and rinsed with concentrated ammonia. Rotary evaporation of the resultant solution afforded a clear residue which was dissolved in sterile water. To remove excess DTT, the solution was passed through a NAP-10 gel filtration column. The fractions containing the ODN were immediately used for conjugation to the peptide.

Synthesis of the Tyr³−Octreotate−Oligodeoxynucleotide Conjugates. The 5′-thiol-ODNs in eluent buffer were added to a the maleimido-peptide **4** (5-fold excess) in aqueous 0.1 M TEAA, pH 6.5, containing 20% DMF. The pH was adjusted by adding 1 M TEAA, pH 6.5. The mixture was incubated at room temperature for 4 h after which time analytical HPLC indicated complete conjugation. Buffers A, 5% acetonitrile in 0.1 M TEAA, pH 6.5, and B, 70% acetonitrile in 0.1 M TEAA, pH 6.5, were employed for purification of the conjugates by RP-HPLC. A linear gradient of 0 to 100% B (2 mL/min) in 30 min was used. The conjugates eluting at 22.3 min were collected and lyophilized. Yields were between 34 and 42% (based on the amount of the starting 5′-thiol-ODNs). The conjugates were characterized by MALDI-TOF-analysis using 3-hydroxy-picolinic acid as matrix and a sample preparation essentially as described by Langley et al. (*23*): **5**, m/z = 7822.9 $[M + H]^+$ ($C_{258}H_{335}N_{79}O_{120}P_{20}S_{23}$ calcd, 7819.96 g/mol); **6**, m/z = 7936.8 $[M + H]^+$ ($C_{260}H_{331}N_{95}O_{112}P_{20}S_{23}$, calcd, 7936.07 g/mol); and **7**, m/z = 7823.1 $[M + H]^+$ ($C_{258}H_{335}N_{79}O_{120}P_{20}S_{23}$, calcd 7819.96 g/mol).

Melting Temperature Analysis of Hybridization. Melting studies were performed in stoppered quartz cells (1 cm path length) at 260 nm. Samples were prepared as 0.5 OD solutions of the two complementary oligomers in 1 mL of buffer. The buffer was 50 mM Tris/HCl, pH 7.5, containing 0.15 M NaCl. The melting curves were measured using a temperature gradient from 30 to 90 °C with a ramp rate of 0.5 °C/min. Prior to analysis, all samples were annealed by heating to 90 °C for 5 min and subsequently cooled slowly to room temperature. Analysis was carried out using the Varian thermal software. All T_m values were calculated from the first derivative of the melting curve and represent the average (±standard deviation) of several analyses. Uncertainty in the T_m data is estimated at ±0.5 °C based on repetitions of experiments.

Scheme 1. Preparation of the Tyr³−Octreotate−ODN Conjugates



SSTR Binding Assays. The concentration of the conjugates was determined using an estimated extinction coefficient. The extinction coefficient of the conjugate was assumed to be the sum of ϵ_{ODN} and $\epsilon_{peptide}$: $\epsilon_{260nm} = \sum$-[(nA × 15.4 + nC × 7.3 + nG × 11.7 + nT × 8.8) × 0.9] + (nTrp × 3.8 + nTyr × 0.5 + nPhe × 0.2). Using this equation, the following ϵ-values were obtained: **5** = 1.8 × 10^5, **6** = 2.1 × 10^5, and **7** = 1.8 × 10^5. For the binding assays, rat cortex membranes were resuspended at a protein concentration of 500 μg/mL in incubation buffer. Per assay, 100 μg of protein were employed. The incubation buffer was 10 mM HEPES, pH 7.6, containing 5% BSA fraction V, $MgCl_2$ (10 mM), and bacitracin (20 μg/mL). The cell membranes (200 μL) were mixed with 30 μL of incubation buffer containing increasing concentrations of the competitor (conjugates **5**−**7**) (10^{-5}−10^{-10} mol/L). Approximately 20.000 cpm [^{125}I]Tyr³−octreotide (ca. 20 pM) in 70 μL of incubation buffer was added. After 1 h at room temperature, the incubation was stopped by quick filtration trough Whatman GF/B glass fiber filters prewetted with buffer containing 1% BSA. The filters were washed with ice-cold buffer (10 mM Tris, 150 mM NaCl), and the bound radioactivity was counted in a γ counter. Nonspecific binding, as determined by measuring binding in the presence of excess unlabeled octreotide (10^{-6} mol/L), was approximately 10−20% of the total binding. Specific binding was defined as total binding minus nonspecific binding. Results are expressed as specific binding obtained from triplicate experiments.

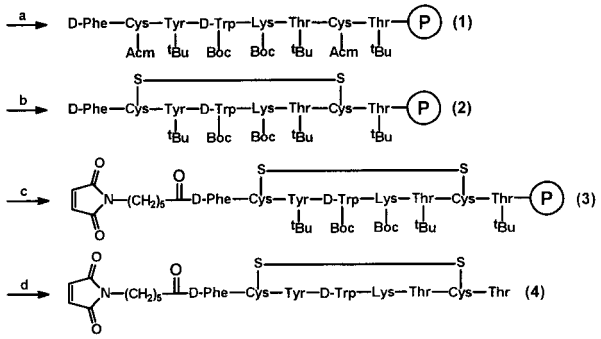
RESULTS

Synthesis Strategy. To obtain targeted analogues of ODNs, conjugation to the SSTR affine Tyr³−octreotate was performed. Therefore, the peptide was functionalized with a maleimido group and the ODNs were modified with a sulfhydryl group. Upon reaction, a stable thioether bond is formed (Scheme 1).

According to the Merrifield strategy, Tyr³−octreotate was synthesized on a solid support (Scheme 2). The tyrosine was introduced to enable radioactive labeling with iodine. Conjugation of the maleimido moiety to the peptide prohibited subsequent cyclization of the disulfide. Therefore, the success of this peptide synthesis was mainly depending on the elaboration of a protocol for on-resin cyclization.

Attempts to synthesize **2** using trityl protecting groups for cystein were impeded by incomplete couplings. This failure was probably due to the nonpolar aggregations of the lipophilic trityl groups. Using the smaller and polar Acm-protecting group, these problems could be circumvented. As determined by deprotection and HPLC-analysis of an aliquot, **1** was formed in SPPS in more than 90% yield. The deprotection/oxidation was attempted by different protocols [$AgBF_4$ followed by DMSO/HCl (*24*), I_2 (*25*), and $Tl(TFA)_3$ (*26*)]. The oxidation with

Scheme 2. Preparation of the Maleimido Modified Tyr^3−Octreotate[a]



[a] (a) Stepwise elongation, (b) $Tl(TFA)_3$, (c) Mal-$(CH_2)_5$COOH, HBTU, DIPEA, (d) TFA, H_2O, phenol, TIS.

$Tl(TFA)_3$ using a 2-fold molar excess proved to produce the highest yields. The Trp-residue is known be susceptible to modifications during disulfide bond formations. Boc-protection of the D-Trp-moiety was found to be inevitable to obtain **2** in high yields.

Edwards et al. (*26*) have observed severe problems with the on-resin cyclization of octreotide. To definitely confirm the integrity of **4**, NMR analysis was performed. Both the ^{13}C NMR spectrum as well as the ^1H NMR spectrum (data not shown) were in accordance with the structure of **4**, no byproducts could be observed.

Upon oxidation, the ^{13}C NMR resonance of the β-carbon atoms of cystein is shifted considerably downfield (e.g., from $\delta = 25.5$ to $\delta = 38.9$ for cystein in glutathione). Consequently, this chemical shift can be used to determine the oxidation status of disulfide bridged peptides. The ^{13}C NMR signals of the two C_β of cystein in compound **4** appeared at 46.4 and 46.5 ppm, indicating formation of the disulfide bond. The chemical shift of carbons attached to disulfides is sensitive to changes in solvent and pH (*26*), to which this particular high shift can be attributed.

Three 20-mer phosphorothioate ODN sequences complementary to *bcl-2* (sense, antisense, and nonsense sequence) were synthesized on solid support. The six-carbon thiol linker (1-*O*-dimethoxytrityl-hexyl-disulfide-1′-[(2-cyanoethyl)-(*N*,*N*-diisopropyl)]-phosphoramidite was attached to the 5′end. Cleavage was performed in aqueous NH_3 containing 0.1 M DDT at 55 °C overnight. Under these conditions, deprotection of the disulfide protection of the thiol-linker as well as cleavage from the resin was simultaneously achieved. Excess DTT was removed by gel filtration using double-distilled water as eluent. To prevent dimer-formation, the thiol ODNs were immediately conjugated to the maleimido-peptide. Failure to do that led to strongly varying coupling yields. In addition to the thiolated compound, the formation of an ODN byproduct which was not reactive to the maleimido peptide (probably the dimer) was observed and could not be suppressed.

Purification of this ODN and incubation with DTT resulted in slow conversion to the reactive ODN. Attempts to substitute DTT by tris(2-carboxyethyl)phosphine (*27*) led to complex mixtures containing little or no product. Large excess of DTT was found to afford the lowest rate of dimer formation, resulting in reliable good coupling yields.

The conjugation reaction was performed on the basis of the synthesis technique previously described (*28*). Thus, the thiol modified ODNs were added to a solution of **4** in buffer containing DMF at pH 6.5. After 4 h, conjugation had reached completeness, as determined by HPLC. The chromatogram of the crude product mixture showed four peaks. These peaks corresponded to the truncated sequences and the unthiolated oligonucleotide at 16.8 min, the ODN-dimer byproduct at 19.2 min, the conjugate at 21.1 min, and excess maleimido peptide at 24.8 min (Figure 1). Due to the significant differences in size and polarity, the conjugates could be easily separated by HPLC from the side products and excess **4**.

Melting Temperature Analysis. Melting temperature analysis was utilized to determine influences of the peptide moiety on the hybridization efficiency of the antisense ODN−peptide conjugate for its complementary strand. The dissociation of duplexes formed from equimolar concentrations of the ODN conjugates and an unmodified 20-mer ODN target was examined. Measurements were carried out in triplicate. The T_m of the parent unmodified 20-mer phosphodiester sequence was found to be 73.1 ± 0.2 °C. As compared to this, the T_m values of the conjugates **5** (65.0 ± 0.0 °C) and **6** (63.8 ± 0.5 °C) appeared to be relatively low. The T_m of a phosphorothioate ODN is known to be decreased by about 0.5 °C per nucleotide as compared to a corresponding phosphodiester ODN (*29*). Therefore, the T_m curves were typical of those obtained with unmodified ODNs. To prove this, the analogous unmodified phosphorothioate ODNs were prepared. The resulting T_m values of the antisense (64.8 ± 0.5 °C) and the sense strand (66.2 ± 0.5 °C) confirmed that the prediction was correct. In Figure 2 the T_m curves of the duplex containing the conjugates **5**, **6**, the unmodified phosphorothioate ODNs, and the unmodified duplex are compared. These results indicate that the peptide moiety at the 5′-terminus of the 20-mer ODN does not interfere with the hybridization efficiency.

Receptor Binding. To allow examination of competitive displacement, the concentrations of the conjugates were determined accurately using their extinction coefficients. Figure 3 shows the progressive displacement of

[^{125}I]Tyr^3–octreotide from rat cortex membranes. The three conjugates investigated bound with high affinity in the low nanomolar range. The IC_{50} values of **5**, **6**, and **7** were 1.83 ± 0.17, 2.52 ± 0.43, and 1.88 ± 0.47 nM, respectively. The similar affinities suggest that the sequence of the ODN does not significantly affect the receptor affinities.

DISCUSSION

The receptors of the hormone somatostatin are known to be overexpressed in various tumors. The ODN conjugates reported herein were designed to be targeted to these plasma membrane receptors. The SSTRs exhibit a high capacity as transport vehicles, e.g., for cargos as big as gold particles (*30*). Furthermore, they show high specificity, as known from octreoscan ([^{111}In]-DTPA-D-Phe^1-octreotide), a radiopharmaceutical for tumor scintigraphy (*31*). Therefore, analogues of somatostatin are ideal transport vehicles for the targeting of tumor cells. These assumptions have very recently been supported by the successful conjugation of cytotoxic compounds to somatostatin derivatives (*32*, *33*). Using a postsynthetic approach, the conjugation of disulfide-bridged peptides

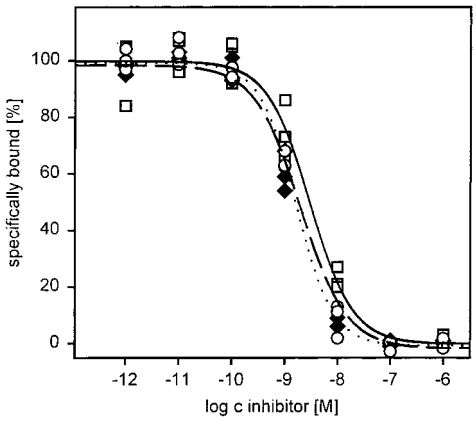

Figure 3. Displacement of [^{125}I]Tyr^3–octreotide from rat cortex membranes (triplicate measurements). The ordinate represents the percent specific binding which is total binding minus binding in the presence of the ODN conjugates **5** (□, straight line), **6** (○, dotted line), and **7** (◆, dashed line).

such as octreotide is complicated. This problem could be solved by coupling of thiol modified ODNs with a maleimido-derivatized peptide. To our knowledge this is the first report of a synthesis which enables the production of stable conjugates of ODNs with disulfide-bridged peptides.

The major targets of conjugates targeted to SSTRs are the receptor subtypes 2 and 5, which are predominantly expressed in SSTR-positive tumors. The feasibility of the ODN conjugates to target SSTRs was demonstrated by receptor binding studies with rat cortex membranes, which mainly express SSTR2. The IC_{50} values of the conjugates were in the low nanomolar range, thus, demonstrating high affinity binding to SSTRs. Investigation of the hybridization properties revealed that the peptide at the 5′-terminus of the 20-mer ODN does not influence the binding to complementary ODNs. These results provide a basis for the improvement of selective uptake of ODNs into tumors and therefore hold promise for further development and application of antisense therapy. Further development of these conjugates investigating their biodistribution, stability, and bioactivity in vivo is in progress.

ACKNOWLEDGMENT

This project was supported by a grant from the Deutsche Forschungsgemeinschaft (Ei 130/15-3). The authors would like to thank D. Keane and M. Wiersma for skilful assistance in ODN synthesis. Essential support for the establishment of receptor binding assays from Dr. Barbara Stolz, Novartis Pharma AG, Switzerland, is gratefully acknowledged.

Concerted Intercalation and Minor Groove Recognition of DNA by a Homodimeric Thiazole Orange Dye

Jakob Bunkenborg,[†] Nikolai I. Gadjev,[‡] Todor Deligeorgiev,[‡] and Jens Peter Jacobsen*,[†]

Department of Chemistry, University of Southern Denmark, Odense University, Odense M, DK-5230 Denmark, and Faculty of Chemistry, University of Sofia, 1126 Sofia, Bulgaria. Received April 28, 2000; Revised Manuscript Received September 15, 2000

The thiazole orange dye TOTO binds to double-stranded DNA (dsDNA) by a sequence selective bis-intercalation. Each chromophore is sandwiched between two base pairs in a (5′-CpT-3′):(5′-ApG-3′) site, and the linker spans two base pairs in the minor groove. We have used one- and two-dimensional NMR spectroscopy to examine the dsDNA binding of an analogue of TOTO in which the linker has been modified to contain a bipyridyl group (viologen) that has minor groove binding properties. We have investigated the binding of this analogue, called TOTOBIPY, to three different dsDNA sequences containing a 5′-CTAG-3′, a 5′-CTTAG-3′, and a 5′-CTATAG-3′ sites, respectively, demonstrating that TOTOBIPY prefers to span three base pairs. The many intermolecular NOE connectivities between TOTOBIPY and the d(CGCTTAGCG):d(CGCTAAGCG) oligonucleotide in the complex shows that the bipyridyl-containing linker is positioned in the minor groove and spans three base pairs. Consequently, we have succeeded in designing and synthesizing a ligand that recognizes an extended recognition sequence of dsDNA as the result of a concerted intercalation and minor groove binding mode.

INTRODUCTION

The study of molecular recognition and in particular the chemical requisites for the formation of specific drug−DNA[1] complexes has been an active research area (Johnson and Boger, 1996). The goal is to rationally design novel molecules, capable of sequence-specific DNA-recognition, by exploiting a combination of both steric and hydrogen bond donor−acceptor complementarity. The very high affinity for DNA exhibited by bis-intercalating agents make them interesting candidates for the design of bimodal DNA-binding molecules by combining this high affinity with the sequence selectivity exhibited by minor groove binding agents.

Recent work in our laboratory has focused on ^{1}H NMR studies of the binding-mode and sequence selectivity of *N*,*N*,*N*′,*N*′-tetramethyl-*N*,*N*′-bis-{3-[4-[(3-methyl-2(*3H*)-benzothiazolilyden)methyl]quinolinium-1-yl]propyl}-1,3-propandiammonium tetraiodide (TOTO, Scheme 1) with various dsDNA oligonucleotides (Bondensgaard and Jacobsen, 1999; Petersen et al., 1999; Bunkenborg et al., 1999; Jensen et al., 1998; Johansen and Jacobsen, 1998; Petersen and Jacobsen, 1998; Faridi et al., 1997; Stærk et al., 1997; Hansen et al., 1996; Spielmann et al., 1995; Jacobsen et al., 1995). We have shown that TOTO binds sequence selectively to double-stranded DNA (dsDNA) by bis-intercalation. Each chromophore is sandwiched between two base pairs in a d(5′-py-*p*-py-3′):d(5′-pu-*p*-pu-3′) site, and the linker spans two base pairs in the minor groove. We have examined the binding of TOTO to various dsDNA oligonucleotides and found that the 5′-CTAG-3′ sequence (or analogues of that) is the most favorable binding motif (Bunkenborg et al., 1999).

The thiazole orange chromophore of TOTO has been shown to prefer to intercalate at a d(5′-C*p*T-3′):d(5′-A*p*G-3′) base pair step. The bis-intercalation of TOTO obeys the nearest neighbor exclusion principle with the linker spanning two bases in the minor groove. The short positively charged polyamine linker of TOTO contributes to the d(5′-T*p*A-3′):d(5′-A*p*T-3′) minor groove preference due to the favorable negative electrostatic potential in the AT-step minor groove (Bunkenborg et al., 1999). Earlier we have synthesized derivatives of TOTO with extended methylene linkers between the quinolinium ring and the quaternary ammonium nitrogen. One of these derivatives was found to predominantly bis-intercalate in the 5′-CTGAG-3′ site (Stærk et al., 1997), but a longer polyamine linker than the one in TOTO reduces the sequence selectivity (Bunkenborg et al., 1999).

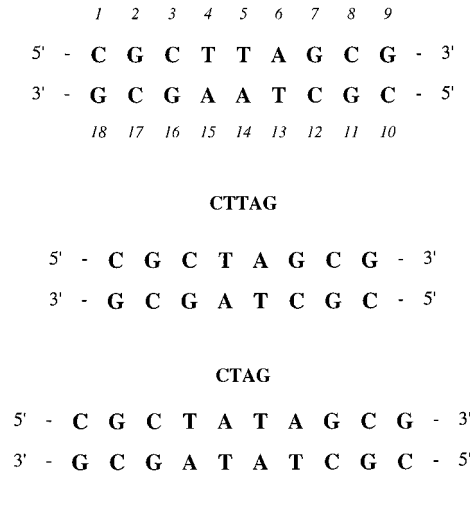
How do we avoid the reduction in sequence selectivity when trying to extend the recognition sequence for new TOTO analogues? A rather obvious suggestion is to replace the flexible linker with a more rigid element endowed with some of the typical minor groove binding characteristics. The 4,4′-bipyridyl (viologen) element is well suited for this purpose because it forms a rigid positively charged aromatic linker. Viologen has been shown to endow bis-intercalators with a preference for AT base pairs by serving as a minor groove binder (Takenaka et al., 1997). Consequently, we have synthesized (Deligeorgiev et al., 2000) and investigated the DNA-binding properties of a TOTO analogue with the polyamine linker substituted by a 4,4′-bipyridyl containing linker: *N*,*N*′-bis-{3-[4-[(3-methyl-2(*3H*)benzothiazolilyden)methyl]quinolinium-1-yl]butyl}-4,4′-bipyridinium tetraiodide (TOTOBIPY, Scheme 1). In this paper, we present the results of one- and two-dimensional ^{1}H NMR studies of complexes between dsDNA and TOTOBIPY. We have investigated the binding of TOTOBIPY to three different dsDNA sequences containing the 5′-CTAG-3′, the 5′-CTTAG-3′ and the 5′-CTATAG-3′ sites, respectively. All these sequences contain two d(5′-C*p*T-3′):d(5′-A*p*G-3′) base pair steps as preferred by the thiazole orange chromophore of TOTO, but separated with a different number of base pairs. Thus, we were able to show that TOTOBIPY preferentially spans three base pair steps as the result of a concerted intercalation and minor groove binding mode. The many intermolecular NOEs of the TOTOBIPY−CTTAG complex demonstrates that the BIPY-element is situated in the minor groove as expected.

EXPERIMENTAL PROCEDURES

Materials. Purified DNA oligonucleotides were purchased from DNA Technology (Aarhus, Denmark) and used without further purification. The non-self-complementary single-stranded DNA oligomers were added to an equivalent amount of the complementary strand and duplexes formed by annealing from 80 °C to room temperature over 2 h. In this work, three different oligonucleotides have been used (Scheme 2).

TOTOBIPY was synthesized as described earlier (Deligeorgiev et al., 2000). A stock solution of TOTOBIPY in DMSO-d_6 was used for complex formation with the dsDNA oligonucleotides by the procedure described earlier (Jacobsen et al., 1995). A phosphate buffer containing ethylenediaminetetraacetic acid (EDTA) to complex paramagnetic ions, 2,2-dimethyl-2-silapentane-5-sulfonate (DSS) as a chemical shift reference and NaN_3 as antibacterial agent was added, giving a final concentration in the NMR sample of 10 mM P_i (pD = 7.0), 0.025 mM EDTA, 0.1 mM DSS, and 0.01 mM NaN_3. The complexes were redissolved in 500 μL of 99.96% D_2O (from Cambridge Isotope Laboratories) to yield a concentration of 2 mM. For experiments in H_2O, a mixture of 90% H_2O/10% D_2O (500 μL) was used. The samples remained stable for months.

Scheme 2. Numbering Schemes for the Three dsDNA Duplexes Used



NMR Experiments. All NMR experiments on the DNA−dye complexes were performed on a Varian Unity 500 MHz NMR spectrometer and a Varian INOVA 750 MHz NMR spectrometer. NOESY spectra in D_2O were acquired with a mixing time of 200 ms using 2048 complex points in t_2 and a spectral width of 5000 Hz for a total of 512 t_1-experiments with 64 scans each at 298 K. For the CTTAG−TOTOBIPY complex, an additional NOESY spectrum in D_2O was acquired at 750 MHz with a mixing time of 200 ms using 4096 complex points in t_2 and a spectral width of 7500 Hz for a total of 600 t_1-experiments with 48 scans each at 298 K. NOESY spectra in H_2O were acquired using 2048 complex points and a spectral width of 10 000 Hz using a NOESY pulse sequence where the last 90° pulse was replaced by a pulse containing a notch to suppress the water signal (Stein et al., 1995). This ensured suppression of the water signal together with a linear excitation profile over the whole spectral width.

TOCSY experiments in D_2O were acquired with mixing times of 90 ms using 2048 complex points in t_2 and a spectral width of 5000 Hz with total of 512 t_1 experiments with 64 scans each. DQF-COSY experiments in D_2O were acquired using 2048 complex points in t_2 and a spectral width of 5000 Hz with total of 1024 t_1 experiments with 64 scans each.

The acquired data were processed using FELIX (version 97.2, Biosym/MSI, San Diego, CA). The spectra were assigned in the conventional way as described in the literature (Wijmenga and van Buuren, 1998).

Molecular Modeling. A model structure of the CTTAG−TOTOBIPY complex was obtained by restrained molecular dynamics (RMD) calculations using the *Discover* program (MSI, San Diego, ver. 2.9.7) with a modified AMBER force field. Modifications were made to take the thiazole sulfur atoms and the bipyridyl group into account. Graphical displays were obtained by the *Insight*II program (MSI, SanDiego, ver. 97.2).

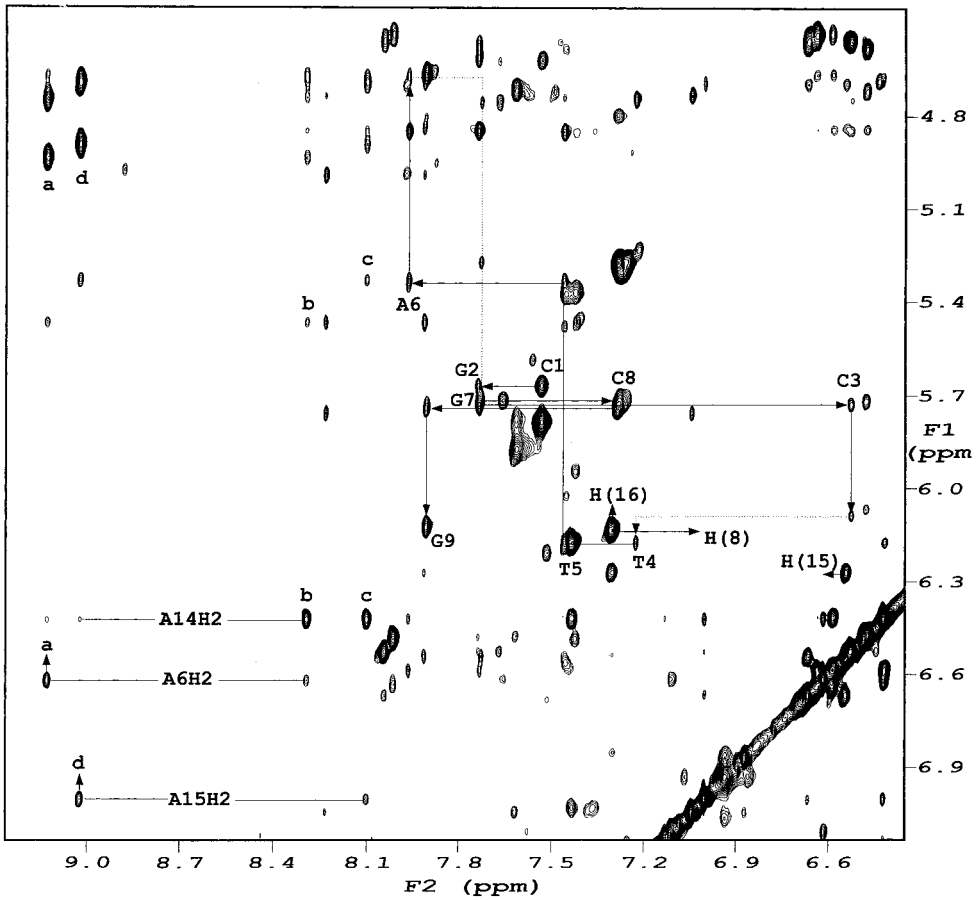


Figure 1. The aromatic to H1′ region of a 750 MHz NOESY spectrum (mixing time of 200 ms) of the CTTAG-TOTOBIPY complex at 25 °C. The sequential $H1'_{(n-1)}$-$H6/H8_{(n)}$-$H1'_{(n)}$ connectivity pattern is shown with solid lines for the 5′-CGCTTAGCG-3′-strand. Interruptions at the 5′-C3pT4-3′ and the 5′-A5pG6-3′ binding sites are indicated with broken lines. A few crucial cross-peaks between TOTOBIPY and the DNA are indicated and in the asymmetric complex there are four distinct bipyridyl proton resonances (Figure 2). Intramolecular cross-peak of the chromophore in TOTOBIPY are also indicated.

The dsDNA strands were built in *InsightII*, and the TOTOBIPY ligand was docked manually into the binding site. Restraints between hydrogens on the DNA and the ligand were obtained from the 200 ms NOESY spectrum using the isolated spin pair approximation. The restraints were divided into classes of weak, medium, and strong connectivities. The three base pairs at each end of the dsDNA were fixed in the B-DNA form by generic restraints. Twenty structures were calculated using the following RMD protocol: initially 100 and 1000 cycles of steepest descent and conjugate gradient energy minimizations, respectively. This was followed by 28 ps of RMD (steps of 1 fs) with the following temperature profile: 600 K for 4 ps and then cooled to 200 K in 50 K steps of 3 ps each. Force constants of 50 kJ/mol were used. Finally, the structures were energy minimized using conjugate gradient until the derivative was less than 0.01 Å.

RESULTS

d(CGCTTAGCG):d(CGTAAGCG) (CTTAG) Oligonucleotide. The mixture of CTTAG + TOTOBIPY yields a spectrum with sharp lines from a single major form (~90%). The NOESY spectrum of this CTTAG−TOTOBIPY complex exhibits the characteristic features of dsDNA sequential connectivities from aromatic H6/H8 protons to both intra- and interresidue H1′ and H2′/H2″. However, the sequential connectivities are interrupted at the 5′-C3*p*T4-3′, 5′-C12*p*T13-3′, 5′-A6*p*G7-3′, and 5′-A15*p*G16-3′ base pair steps. This is clear evidence of bis-intercalation. Interruption of the sequential NOE connectivities is also observed in the cross-peak pattern of the methyl group of T4 and T13 for which the peak to C3 H6 and C12 H6, respectively, are missing. The NOESY spectrum of the complex in H_2O shows the normal Watson−Crick NOE connectivity pattern (Wüthrich, 1986).

The internal NOE connectivities in the chromophore of TOTOBIPY are a distinct feature of the NOESY spectra of the complex. Cross-peak patterns connect H16-H15-H14-H13, H8-$CH_3$6-H4-H3-H2-H1, and H9-H10, respectively. A very strong cross-peak between H8 and H16 and a cross-peak pattern connecting H9-H10-H13 establish the assignments of the individual protons and the conformation of the TOTOBIPY ligand. Resonances in the linker of TOTOBIPY were assigned by combined use of TOCSY and NOESY cross-peaks. On the basis of the cross-peak pattern in the NOESY spectrum, we conclude that the relative conformation of the two ring systems in each chromophore is that indicated in Scheme 1.

A large number of cross-peaks between TOTOBIPY protons and protons on the oligonucleotide was observed. A few of them are indicated in Figure 1 and further illustrated in Figure 2. These intermolecular cross-peaks clearly show that TOTOBIPY bis-intercalates in the (5′-CTTAG-3′):(5′-CTAAG-3′) site. In detail, sequential connectivities for the 5′-T4A5A6-3′ and 5′-T13T14A15-3′ sequences show that no intercalation takes place in this part of the oligonucleotide, proving that the linker spans

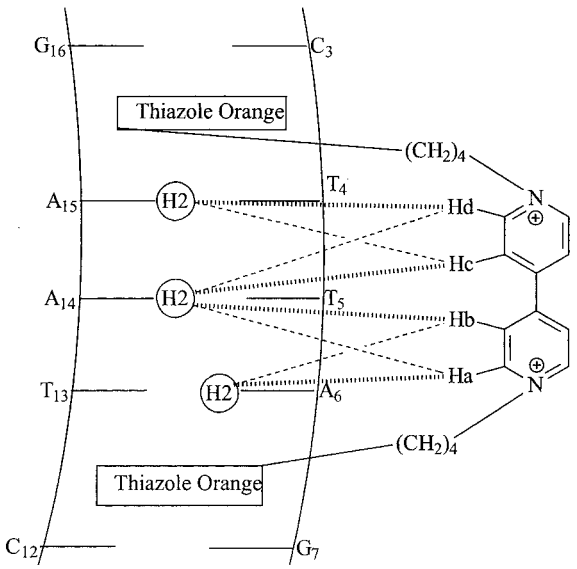

Figure 2. A few of the observed intermolecular NOE connectivities observed between the bipyridyl protons of the linker and the H2 on the adenines. Strong connectivities (| | |) and medium connectivities are both indicated (- - -).

three base pairs. Interruptions in the sequential $H1'_{(n-1)}$-$H6/H8_{(n)}$-$H1'_{(n)}$ pattern confirm the binding site. The aromatic protons on A6 and G7 have cross-peaks to H15 and/or H14 on one of the chromophores while the aromatic protons on A15 an G16 have cross-peaks to H15 and H14 on the other chromophore. Furthermore, an upfield shift of approximately 0.8 ppm of the methyl group proton resonances of T4 and T13 is observed while the methyl resonance of T5 is unchanged. All together, this establishes bis-intercalation in the 5′-C|*TTA*|G-3′ binding site with the linker spanning the three central bases. Cross-peaks in the NOESY spectrum unambiguously show that the linker is positioned in the minor groove. This is demonstrated by a large number of cross-peaks of which some are illustrated in Figure 2.

A remarkable feature of the complex of CTTAG−TOTOBIPY is the occurrence of only four resonances from the 4,4′-bipyridyl moiety. This suggests that the bipyridyl is undergoing rapid rotation within the NMR time scale.

On the basis of the observed NOE connectivities between TOTOBIPY protons and protons on the oligonucleotide, a model of the CTTAG−TOTOBIPY complex was calculated by restrained molecular dynamics. A picture of the model is shown in Figure 3. The model was obtained by using 22 intermolecular restraints to position the TOTO chromophores and 11 restraints to position the bipyridyl ring system in the minor groove. These constraints did not embrace the equivalence of the protons at the bipyridyl group due to the dynamic rotation. Consequently, the model obtained must not be mistaken for a representation of the structure of the complex. The model correctly positions the chromophores at the intercalations sites and the linker in the minor groove, but it does not claim to include detailed structural and dynamic properties of the complex.

d(CGCTAGCG)$_2$ (CTAG) Oligonucleotide. TOTOBIPY forms more than one complex with the CTAG oligonucleotide. Consequently, the 1D NMR spectrum had broad lines due to exchange between the complexes. Severe overlap in the 2D NMR spectra prevented conclusive evidence that would allow identification of the binding sites of TOTOBIPY, but the methyl group resonances suggest that there are two major forms present in almost equal amounts. One is a symmetric complex with single methyl resonance upfield shifted 0.8 ppm. Such an upfield shift is normally observed in binding sites containing a thymidine (Jacobsen et al., 1995; Hansen et al., 1996) and indicates normal bis-intercalation in the (5′-C|*TA*|G-3′)$_2$ binding site. The other major form has one downfield shifted methyl resonance and one ordinary methyl resonance suggesting an asymmetric complex with nonnearest neighbor bis-intercalation in the (5′-C|*TAG*|C-3′)$_2$ site.

d(CGCTATAGCG)$_2$ (CTATAG) Oligonucleotide. The mixture of CTATAG + TOTOBIPY yields two or more complexes with one major asymmetric form. This complex was established as containing a bis-intercalated TOTOBIPY in the 5′-T|*ATA*|G-3′ binding site with the linker spanning three central bases. Once again the linker suits a three base pair step. Basically, there are two identical such binding sites in the palindromic sequence, the other one being the 5′-C|*TAT*|A-3′ site. The line broadening is due to exchange between these two sites.

DISCUSSION

The sequence selectivity and the binding mode of the TOTOBIPY analogue to the three dsDNA oligonucleotides examined in this work is very similar to the one of TOTO. In the CTAG oligonucleotide, both TOTO and TOTOBIPY bind to the 5′-CTAG-3′ site, but in the case of TOTOBIPY, there also exists another major component in which the ligand is bis-intercalated in isolated intercalation sites: (5′-C|*TAG*|C-3′)$_2$. This demonstrates that the partiality of the TOTO chromophore for the (5′-C*p*T-3′):(5′-A*p*G-3′) site competes with the preference of the linker to span three base pairs. An equivalent situation is observed in the CTATAG duplex where more than one complex is formed with TOTOBIPY but still with a three base step spanning major form.

The model of the TOTOBIPY−CTTAG complex summarizes the major structural features. The thiazole orange chromophores are situated in their favorite positions in the two (5′-C*p*T-3′):(5′-A*p*G-3′) sites with the benzothiazole ring systems sandwiched between the purines. All these features are in good accordance with our earlier thiazole orange studies, and thus, the introduction of a new linker has not perturbed the positioning of the chromophores. As evidenced by a number of linker−DNA NOE connectivities, the linker is positioned in the minor groove, but the occurrence of only four resonances from the bipyridyl moiety suggest a dynamical averaging due to a fast rotation on the NMR time scale. This rapid rotation may be considered as an indication of the lifetime of the complex or as an indication of the wide space in the minor groove that allows rotation of the linker while bound to the dsDNA. However, there are no exchange cross-peaks between resonances of the two chromophores indication that the exchange is slow on the NMR time scale. Furthermore, the structure of dsDNA is dynamic and flexible. Consequently, the rotation of the linker might be coupled to the dynamic motions of the duplex without requiring a particular wide minor groove.

Earlier, we have shown (Stærk et al., 1997) that approximately three methylene groups from the chromophore are required to position the middle part of the linker correctly in the minor groove. A model of the TOTOBIPY ligand shows that this middle part of the linker in this dye has a length of approximately 10.5 Å. This length is suited for spanning about three base steps

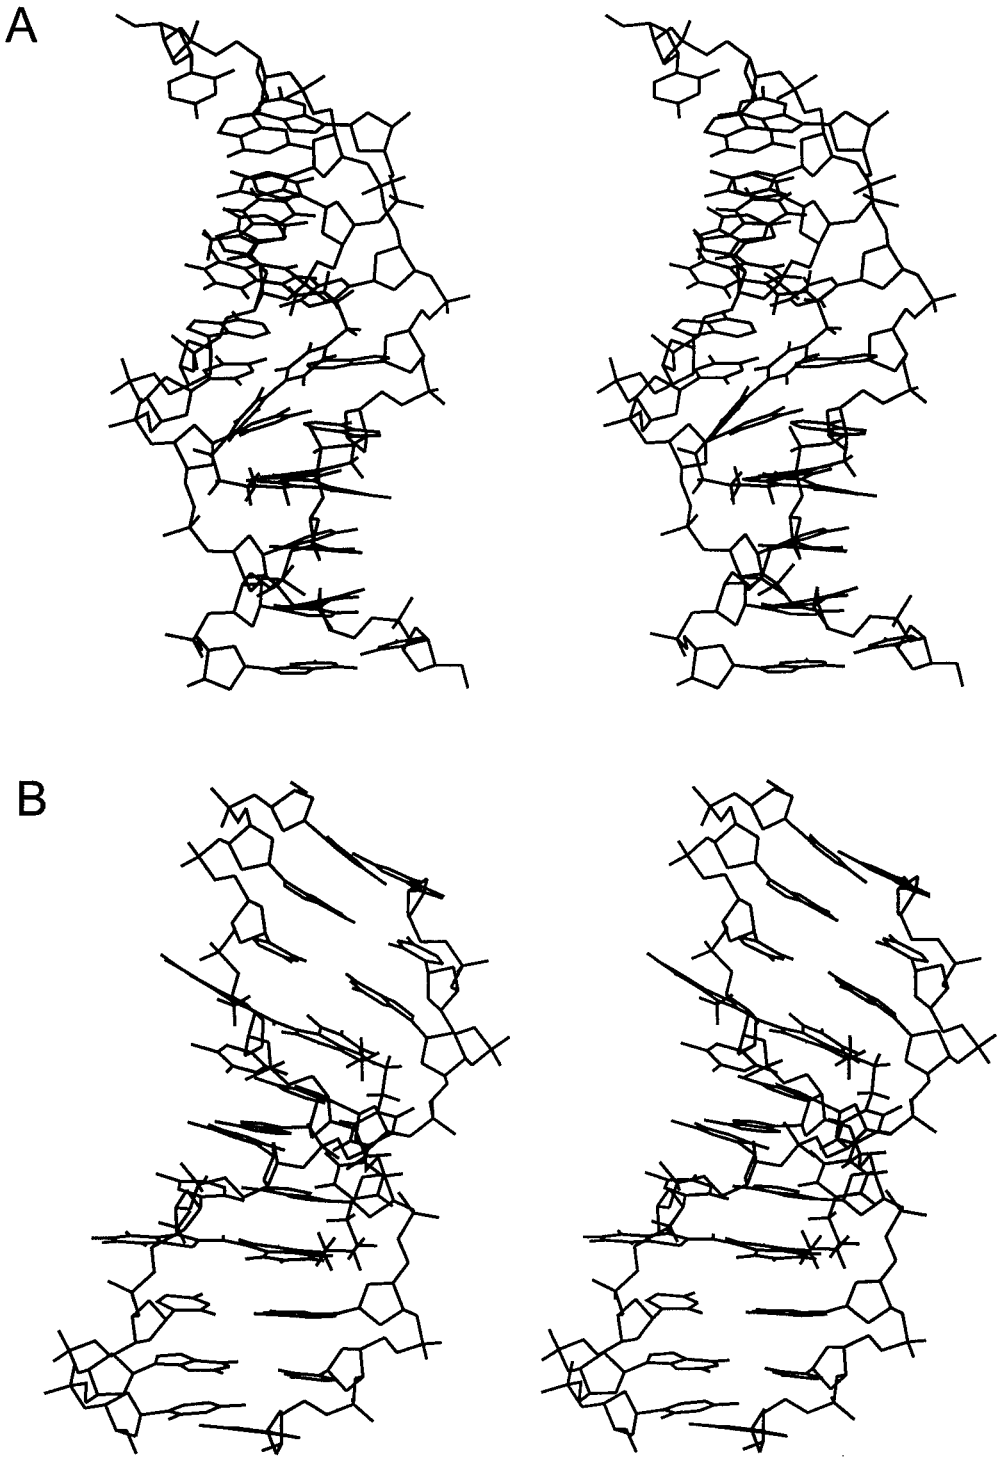

Figure 3. Stereoview of the model of the CTTAG-TOTOBIPY complex obtained by restrained molecular dynamics calculations. The model at the bottom is viewed into the minor groove. The model at the top is turned 90°.

but too short for spanning four. In the CTTAG duplex, TOTOBIPY was observed to give nonnearest neighbor bis-intercalation in oligonucleotides with isolated (5′-CpT-3′):(5′-ApG-3′) base pairs separated by three base pairs. This sequence contains the preferred intercalation sites separated by three base pairs and does thus fulfill both binding requirements of TOTOBIPY. Consequently, we have succeeded in designing and synthesizing a ligand that recognizes DNA in a concerted intercalation and minor groove binding mode that extends the recognition sequence.

In our earlier attempts to elongate the binding sequence, we have tried adding additional methylene groups to the flexible polyamine linker (Bondensgaard and Jacobsen, 1999; Stærk et al., 1997). Although the TOTO13 with the longest linker was capable of spanning three base steps there was a loss of selectivity, e.g., TOTO13 formed more than one complex with the 5′-CTTAG-3′ sequence (Stærk et al., 1997) with a major form in the 5′-C|*TTA*|G-3′ site. The rigid TOTOBIPY only forms one complex and thus the rigid linker seems to hold the chromophores in place. Shedding flexibility and enhancing affinity by introducing rigid elements seems to be a general trend. The importance of the linker has been extensively investigated (Assa-Munt et al., 1985a,b) for acridine bis-intercalators. It was found that while

uncharged polymethylene linkers lead to rapid exchange of the bis-intercalator between different intercalation sites in a $d(AT)_5$:$d(AT)_5$ duplex, the introduction of positively charged spermine linker stabilized the complex due to a retarding of the migration of the intercalator between different binding sites. A further loss of flexibility with a concomitant enhancement in binding affinity was gained by introducing a rigid pyrazole linker. Likewise, a significant improvement in DNA affinity was noted on exchanging a polymethylene linker with a diphenyl-ether (Cory et al., 1985). The affinity gain seems mainly to stem from van der Waals contacts with the walls of minor groove and loss of motional freedom—both of these necessitating steric complementarity between the linker and the target sequence. The bipyridyl linker is probably more sequence selective than the flexible polyamine linker, because the rigid linker will sterically clash with the guanine amino-group protruding into the minor groove while the polyamine linker can adapt more easily. The linear geometry of bipyridyl is probably not optimal for minor groove binding as can be surmised from the family of crescent-shaped minor groove binders (e.g., berenil, distamycin etc). However, the unwinding caused by the intercalating chromophores seems to make this isoconcavity demand less severe.

Thiazole orange (TOTO) and oxazole yellow (YOYO) homodimer polyamine dyes bind avidly to dsDNA by bis-intercalation with a high fluorescence enhancement upon binding (Rye et al., 1992; Glazer and Rye, 1992). The enhancement is attributed to the loss of rotational freedom between the thiazole and quinolinium moieties of the chromophores when inserted between the DNA nucleobases (Larsson et al., 1994). The unaltered chromophore positioning indicates that the new linker does not interfere with the fluorescence properties. Both TOTO and YOYO have been found to cause photocleavage of DNA, though the mechanism depends of the dye:DNA ratio (Åkerman and Tuite, 1996). At high dye:DNA ratios, externally bound dye cleaves in an oxygen-dependent manner, and this mechanism is more efficient than the oxygen-independent cleavage by bis-intercalated dye occurring at lower dye:DNA ratios. Earlier studies have shown that an electron transfer from intercalated ethidium to externally bound methyl-viologen can be photoinduced (Fromherz and Rieger, 1986) and that the one-electron reduced viologen reacts with oxygen leading to cleavage of DNA. A viologen linker containing acridine bis-intercalator has been shown to photocleavage dsDNA (Takenaka et al., 1992). The sequence-selective binding of TOTO-TOTOBIPY combined with its potential photocleaving properties makes it an interesting molecule for further studies.

ACKNOWLEDGMENT

We thank The Instrument Centre for NMR-Spectroscopy of Biological Macromolecules at The Carlsberg Laboratory, Copenhagen granted by The Danish Natural Science Research Council for providing spectrometer time at the 750 MHZ spectrometer. Finally, The Danish Natural Science Research Council and The Technical Research Council are acknowledged for financial support.

Radiolabeled Guanine Derivatives for the in Vivo Mapping of O^6-Alkylguanine-DNA Alkyltransferase: 6-(4-[^{18}F]Fluoro-benzyloxy)-9*H*-purin-2-ylamine and 6-(3-[^{131}I]Iodo-benzyloxy)-9*H*-purin-2-ylamine

Ganesan Vaidyanathan,*[,†] Donna J. Affleck,[†] Christina M. Cavazos,[‡] Stewart P. Johnson,[§] Sriram Shankar,[†] Henry S. Friedman,[||,⊥] Michael O. Colvin,[||] and Michael R. Zalutsky[†]

Two radiolabeled analogues of 6-benzyloxy-9*H*-purin-2-ylamine (O^6-benzylguanine; BG) potentially useful in the in vivo mapping of O^6-alkylguanine-DNA alkyltransferase (AGT) were synthesized. Fluorine-18 labeling of the known 6-(4-fluoro-benzyloxy)-9*H*-purin-2-ylamine (FBG; **6**) was accomplished by the condensation of 4-[^{18}F]fluorobenzyl alcohol with 2-aminopurin-6-yltrimethylammonium chloride (**4**) or 2-amino-6-chloropurine in average decay-corrected radiochemical yields of 40 and 25%, respectively. Unlabeled 6-(3-iodo-benzyloxy)-9*H*-purin-2-ylamine (IBG; **7**) was prepared from **4** and 3-iodobenzyl alcohol. Radioiodination of **9**, prepared from **7** in two steps, and subsequent deprotection gave [^{131}I]**7** in about 70% overall radiochemical yield. The IC_{50} values for the inactivation of AGT from CHO cells transfected with pCMV-AGT were 15 nM for IBG and 50 nM for FBG. The binding of [^{18}F]**6** and [^{131}I]**7** to purified AGT was specific and saturable with both exhibiting similar IC_{50} values (5−6 μM).

INTRODUCTION

A number of alkylating agents such as 1,3-bis(2-chloroethyl)-1-nitrosourea (BCNU), 1-(2-chloroethyl)-3-cyclohexyl-1-nitrosourea (CCNU), 5-(dimethyltriazeno)-imidazole-4-carboxamide (DTIC), and Temozolomide are used in the chemotherapy of various cancers (*1*). The cytotoxicity of these and related alkylating agents stems from their ability to alkylate DNA guanine residues at their O^6-position. Nitrogen mustard alkylating agents such as cyclophosphamide were thought to produce their cytotoxicity through the alkylation of the N^7-position of guanine (*2*); however, it has been recently demonstrated that a significant part of the cytotoxicity of this agent also is mediated by the O^6-alkylation of guanine residues (*3*).

The DNA repair protein O^6-alkylguanine-DNA alkyltransferase (AGT) reverts alkylator cytotoxicity by transferring the O^6-alkyl group from the modified DNA guanine to cysteine-145 in its active site, thereby restoring a normal guanine at the site of the modified base (*4*). However, the resultant alkylated AGT is inactivated for subsequent dealkylations. Because of this, the ability of tumor cells to be resistant to the toxic effects of alkylating agents is dependent on cellular AGT levels; the higher the AGT content, the less effective will be the tumor killing by alkylator therapy. Elevated levels of AGT are known to result in resistance of human gliomas to nitrosoureas (*5*). Indeed, inactivation of AGT by administration of its substrates such as O^6-methylguanine and O^6-benzylguanine (BG) has been shown to increase the cytotoxicity of alkylators such as CCNU and BCNU in human tumor cell lines (*6*, *7*) and xenografts (*8*).

Levels of AGT in human tumors vary considerably among different tumor types as well as patients with a particular malignancy (*9*, *10*). Thus, prior knowledge of AGT levels in individual tumors could greatly facilitate the process of optimizing the efficacy of chemotherapy. Although a few in vitro techniques to quantify AGT levels in tumor tissue have been described (*11*−*13*), none of these are suitable for use in humans. Our objective was to develop radiolabeled BG analogues which bind selectively to AGT with the goal of mapping AGT levels in cancer patients in a noninvasive fashion by external scintigraphy. Potential applications of this technique include the selection of patients most likely to benefit from alkylator therapy, monitoring the effect of these drugs on AGT levels during the therapeutic course, correlating therapeutic success with endogenous AGT, and evaluating the clinical effectiveness of AGT-inactivating agents such as BG.

Positron emission tomography (PET) is a functional imaging modality that can probe altered biochemical pathways and in some cases be used to assess metabolic levels quantitatively (*14*). Fluoroine-18 has a 1.8 h half-life and is the most commonly used radionuclide for PET. To be useful for imaging AGT levels, the radiolabel needs to reside within the alkyl group attached to the O^6-position of the guanine because this group is the one that is transferred to the protein. This criterion is reinforced by the results of a study evaluating a ^{18}F-labeled guanine derivative with the ^{18}F attached at the N^9 position as a fluoroethyl group (*15*). It was hoped that, once dealkylated, the guanine residue attaches to the protein in a noncovalent fashion. However, as we would predict, this

derivative was not useful for AGT imaging. Fortunately, 6-(4-fluoro-benzyloxy)-9*H*-purin-2-ylamine (O^6-4-fluorobenzylguanine, FBG) is among the purine and pyrimidine derivatives that have been shown to be AGT inactivators (*16*−*20*). The ability of FBG to inactivate AGT in HT29 cell-free extracts and intact cells was shown to be similar to that of BG itself (*16*). Thus, if an appropriate synthesis could be devised, [^{18}F]FBG could be a valuable tool for assessing the AGT levels by PET.

Iodine has a spectrum of radionuclides with different physical properties that are appropriate for external imaging. For example, ^{123}I ($t_{1/2}$ = 13 h) is an excellent radionuclide for use in single photon emission tomography (SPECT). Iodine-124 ($t_{1/2}$ = 4.2 d) has been used for PET. For this reason, the development of radioiodinated analogues of BG also is important. The preparation of radioiodinated guanosine derivatives has been described (*21*); however, their AGT binding properties were not reported. While O^6-4-chlorobenzylguanine (CBG) and O^6-4-bromobenzylguanine (BBG) have been prepared and shown to be good analogues of BG (*17*), to our knowledge, the synthesis and biological activity of 6-(iodo-benzyloxy)-9*H*-purin-2-ylamine (O^6-iodobenzylguanines; IBG) have not been reported. Because a variety of substituents are tolerated in the benzene ring of BG (*16*), an iodinated derivative is expected to be a good analogue of BG as well.

In this study, we have developed methods for the preparation of 3-IBG, and the labeled compounds [^{18}F]FBG and 3-[^{131}I]IBG. In CHO cells transfected with pCMV-AGT, 3-IBG was shown to be more potent than FBG in inactivating AGT. In vitro studies using purified AGT demonstrated specific binding of [^{18}F]FBG and 3-[^{131}I]IBG to AGT.

EXPERIMENTAL SECTION

General. All chemicals were purchased from Aldrich Chemical Co. except as noted. FBG (unlabeled) was obtained as a gift from Dr. Robert Moschel of National Cancer Institute-Frederick Cancer Research and Development Center, Frederick, MD. Sodium [^{131}I]iodide in 0.1 N NaOH was supplied by DuPont-New England Nuclear (North Billerica, MA). [^{18}F]Fluoride activity was produced on the Duke University Medical Center CS-30 cyclotron via the ^{18}O(p,n)^{18}F reaction by irradiating [^{18}O]H_2O in a small volume (300 μL) silver target. The activity was delivered to a solution of Kryptofix (10 mg in 1 mL of CH_3CN) and potassium carbonate (1 mg in 5 μL of water) in a glass tube and then evaporated with argon in an oil bath at 80 °C. The dried activity was resolubilized in 50−100 μL of dry DMSO.

Melting points were determined on a Haake Buchler apparatus and were uncorrected. High-pressure liquid chromatography (HPLC) was performed using one of three systems: (1) two LKB model 2150 pumps, an LKB model 2152 control system, an LKB model 2138 fixed-wavelength UV detector, and a Beckman model 170 radioisotope detector; data were acquired using CIO-DAS08/JR internal and CIO-MINI137 external boards and Labtech DataLab/WIN software (www.computerboards.com); (2) a Beckman System Gold HPLC equipped with a model 126 programable solvent module, a model 168 diode array detector, a model 170 radioisotope detector, and a model 406 analogue interface module; or (3) a Perkin-Elmer Series 4 Liquid Chromatograph connected to a Perkin-Elmer LC-95 UV−vis spectrophotometer detector and a Perkin-Elmer LCI-100 Laboratory Computing Integrator. Methods were programmed using a Perkin-Elmer 6312 display terminal. For reversed-phase chromatography, a Waters μBondapak C18 (10 μm, 3.9 × 300 mm) column or a 3.9 × 300 mm Bondclone 10 (10 μm) C-18 column (Phenomenex, Torrance, CA) was used. Normal-phase HPLC was performed using a 4.6 × 250 mm Partisil (10 μm) column (Alltech, Deerfield, IL). Analytical TLC was performed on aluminum-backed sheets (Silica gel 60 F_{254}), and normal-phase column chromatography was performed using Silica gel 60, both obtained from EM Science (Gibbstown, NJ). Column chromatographic fractions were collected using a Gilson model 203 micro fraction collector (Middleton, WI) or a ISCO Foxy 200 fraction collector (Lincoln, NE), and products identified by TLC. In some cases, an ISCO UA-6 UV−vis detector was placed between the column outlet and the fraction collector to identify fractions. Preparative thick layer chromatography was performed using 20 × 20 cm, 1000 μm plates (Whatman, Clifton, NJ). Before applying the sample, the plates were run in ethyl acetate to clean the plates of any adsorbed impurities. Radio-TLC was initially analyzed using a System 200 Imaging Scanner (BioScan, Washington, DC.) and then cut into strips and counted using an automatic gamma counter (LKB 1282, Wallac, Finland). NMR spectra (^{1}H-300 MHz and ^{13}C-75 MHz) were obtained on a Varian Mercury 300 spectrometer. Chemical shifts are reported in δ units; solvent peaks were referenced appropriately. Mass spectra were obtained on a Hewlett-Packard GC/MS/DS model HP-5988A instrument or on JEOL SX-102 high-resolution mass spectrometer. Elemental analyses were provided by Galbraith Laboratories (Knoxville, TN).

6-(4-[^{18}F]Fluoro-benzyloxy)-9*H*-purin-2-ylamine ([^{18}F]FBG). *p*-[^{18}F]Fluorobenzaldehyde was prepared following previously described procedures (*22*). Briefly, 50−100 mCi of [^{18}F]fluoride was resolubilized in DMSO (50−100 μL), added to 1−2 mg of 4-formyl-(*N*,*N*,*N*-trimethyl)anilinium trifluoromethane sulfonate in a 5-mL Reacti vial, and the mixture was heated in an oil bath at 150 °C for 10 min. The cooled reaction mixture was diluted with water and passed through an activated C18 solid-phase cartridge (Waters). The cartridge was further washed with water (5−10 mL), and 4-[^{18}F]fluorobenzaldehyde was finally eluted with methylene chloride (1−2 mL). The methylene chloride solution was dried with sodium sulfate and passed through a silica cartridge to remove any polar byproducts. Methylene chloride was removed using a rotary evaporator[1] until a volume of about 0.1 mL was reached and the residual solution was transferred to a 1-dram vial.

DIBAL (0.1 mL, 1 M solution in methylene chloride) was added to the above activity and the capped vial was left at room temperature for 10 min. After evaporating the methylene chloride, 1 mL of water was added carefully to the residual activity followed by 50−100 μL of concentrated HCl. The resultant 4-[^{18}F]fluorobenzyl alcohol was extracted from this solution with 3 × 1 mL of ethyl acetate. The combined ethyl acetate fractions were dried with sodium sulfate and concentrated on the rotary evaporator.

The above solution was transferred to a 1-mL Reacti vial and evaporated to dryness. To this dried activity, potassium *tert*-butoxide (50 μL; 1 M in THF) was added and THF was evaporated under an argon flow. The residue was resolubilized in dry DMSO (Pierce, Rockford, IL; 50 μL) and the capped vial was heated at 100 °C for 5 min. The quaternary salt **4** (ref *23*; 1−2 mg) was added

[1] Use of argon to evaporate methylene chloride results in substantial loss of activity. Even with a rotary evaporator, it is important that the evaporation is stopped before the mixture dries.

to the above solution and the mixture was heated for an additional 10 min at 100 °C. [^{18}F]FBG ([^{18}F]**6**; t_R = 18−20 min) was isolated from this reaction mixture by reversed-phase HPLC (system 1) using the Bondaclone column eluted with 0.1% TFA in 15:85 acetonitrile:water at a flow rate of 1 mL/min. The HPLC fractions containing [^{18}F]**6** were evaporated with argon to remove most of the acetonitrile, diluted with water, and passed through a solid-phase cartridge (tC18 ENV Sep Pak; Waters) activated with ethanol and water. The cartridge was washed with 5 mL of 0.9% saline, and the activity was eluted with 0.25 mL portions of ethanol. Most of the activity elutes in fractions 3−5. These pooled ethanol fractions were concentrated, and for in vitro assays, the activity was reconstituted in Tris-buffer.

6-(3-Iodo-benzyloxy)-9*H*-purin-2-ylamine (3-IBG). Sodium hydride (60% in mineral oil; 80 mg, 2 mmol) was added to a solution of 3-iodobenzyl alcohol (498 mg, 2.13 mmol) in dry DMSO (0.5 mL), and the resultant yellow solution was stirred at room temperature for 1 h. The quaternary salt **4** (229 mg, 1 mmol) was added to the mixture and the stirring continued for another 2 h. Acetic acid (170 μL) was added to the clear, homogeneous reaction mixture which was then added with vigorous stirring to about 30 mL of ether. The resultant precipitate was filtered, washed with ether and subsequently with water, and dried over P_2O_5 under vacuum to give 218 mg (60%) of **7**: mp 118−120 °C. HPLC (system 3): Bondapak column was eluted with 0.1% TFA in 30:70 acetonitrile:water at 1 mL/min; t_R = 6.0 min as compared to 8−9 min for 3-iodobenzyl alcohol; ^{1}H NMR (DMSO-d_6) 5.46 (s, 2H, benzylic), 6.28 (br s, 2H, NH_2), 7.21 (t, 1H, *m*-ArH; J_{H-H} = 8.5), 7.52 (d, 1H, *o*-ArH; J_{H-H} = 8.5), 7.72 (d, 1H, *p*-ArH; J_{H-H} = 8.5), 7.84 (s, 1H, *o*′-ArH), 7.87 (s, 1H, H-8), 12.45 (br s, 1 H, NH); ^{13}C NMR (CD_3OD) 67.77 (benzylic), 97.40 (ArC-I), 128.37 (guanine C-5 and *o*-ArCH), 131.19 (*o*′-ArCH and *p*-ArCH), 137.99 (*m*-ArCH and *ipso*-ArC), 138.07 (guanine CH-8 and C-6), 140.34 (guanine C-2 and C-4); MS (FAB$^+$) *m/z*: 368 (MH^+). HRMS calcd for $C_{12}H_{11}IN_5O$ (MH^+) *m/z*: 368.0008. Found: 368.0013 ± 0.0009. Anal. calcd for $C_{12}H_{10}IN_5O$: C, 39.26; H, 2.75; N, 19.08. Found: C, 39.03; H, 2.87; N, 18.17.

6-(3-Iodo-benzyloxy)-9-(2-trimethylsilanyl-ethoxymethyl)-9*H*-purin-2-ylamine (SEM-3-IBG). THF was evaporated from a 1 M solution of potassium *tert*-butoxide in THF (0.83 mL, 830 mmol).[2] To the residue was added **7** (300 mg, 0.82 mmol) followed by DMF (silylation grade; Pierce, 4.2 mL). The mixture was stirred at room temperature under argon for 1 h and cooled to 0 °C, and SEM-chloride (138 mg, 0.83 mmol) was added dropwise. The reaction was allowed to proceed overnight and worked up by partitioning between ethyl acetate and water. Silica gel chromatography using 40:60 ethyl acetate:hexane afforded 105 mg (26%) of **8** as an oil/low melting solid: ^{1}H NMR ($CDCl_3$) −0.02 (s, 9H, −$SiMe_3$), 0.93 (m, 2H, −Si-CH_2−), 3.58 (m, 2H, −Si-CH_2-CH_2-O−), 4.83 (br s, 2H, NH_2), 5.44 (s, 2H, benzylic), 5.50 (s, 2H, −N-CH_2-O−), 7.09 (t, 1H, *m*-ArH; J_{H-H} = 7.7), 7.48 (d, 1H, *o*-ArH; J_{H-H} = 7.5), 7.65 (d, 1H, *p*-ArH; J_{H-H} = 7.8), 7.74 (s, 1H, H-8), 7.86 (s, 1H, *o*′-ArH); ^{13}C NMR ($CDCl_3$); −2.05 (−$SiMe_3$), 17.06 (−CH_2-$SiMe_3$), 66.17 (−Si-CH_2-CH_2-O−), 66.28 (benzylic), 71.14 (−N-CH_2-O−), 93.41 (C-I), 114.48 (guanine C-5), 126.57 (*o*-ArCH), 129.29 (*m*-ArCH), 136.20 (*o*′- and *p*-ArCH), 137.86 (ArCH-*ipso*), 138.72 (guanine CH-8), 153.66 (guanine C-6), 158.52 (guanine C-2), 159.87 (guanine C-4). 9-(2-Trimethylsilanyl-ethoxymethyl)-6-(3-trimethylstannanyl-benzyloxy)-9H-purin-2-ylamine. A mixture of **8** (50 mg, 0.1 mmol), hexamethylditin (210 mg, 0.64 mmol), and dichlorobis(triphenylphospine)palladium(II) (35 mg, 0.05 mmol) in 3 mL of dioxane was heated at reflux under argon for 1 h. Dioxane was removed from the dark reaction mixture and the residue was resuspended in ethyl acetate. The suspension was filtered through a bed of Celite, and the bed was washed thoroughly with ethyl acetate. The filtrate was concentrated to obtain an oil. This oil was applied to a bed of silica gel and very nonpolar impurities were removed by eluting with hexane. The required product and other byproducts were isolated from the silica gel bed by eluting with ethyl acetate. Ethyl acetate was removed from this solution and the residual oil was subjected to preparative TLC using 40:60 ethyl acetate:hexane to obtain 39 mg (73%) of **9** as a white solid: mp 135−136 °C; ^{1}H NMR ($CDCl_3$) −0.03 (s, 9H, −$SiMe_3$), 0.29 (s, 9H, −$SnMe_3$), 0.92 (m, 2H, -CH_2-$SiMe_3$), 3.57 (m, 2H, −Si-CH_2-CH_2-O−), 4.87 (br s, NH_2), 5.43 (s, 2H, benzylic), 5.55 (s, 2H, −N-CH_2-O−), 7.31−7.61 (m, 4H, ArH), 7.72 (s, 1H, H-8); ^{13}C NMR ($CDCl_3$) −9.37 (−$SiMe_3$), −1.32 (−$SnMe_3$) 17.80 (−CH_2-$SiMe_3$), 66.87 (−Si-CH_2-CH_2-O−), 68.47 (benzylic), 71.84 (−N-CH_2-O−), 127.90 (guanine C-5), 128.28 (*o*-ArCH), 128.56 (*m*-ArCH), 129.24 (*o*′- and *p*-ArCH), 135.47 (ArCH-*ipso*), 135.60 (C−Sn), 135.94 (guanine CH-8), 139.27 (guanine C-6), 154.28 (guanine C-2), 159.31 (guanine C-4); MS (FAB$^+$) *m/z* cluster peaks at 536 (MH^+). 6-(3-[^{131}I]Iodo-benzyloxy)-9*H*-purin-2-ylamine (3-[^{131}I]IBG). *A. Two-Step Approach.* To a $^1/_2$-dram vial containing 0.2 mg of **9** was added 1−2 μL of ^{131}I in 0.1 N NaOH (about 1 mCi) followed by 10 μL of a 3:1 (v/v) solution of acetic acid:30%H_2O_2. The mixture was sonicated for about 30 s, injected onto a normal-phase HPLC column and eluted with 0.2% acetic acid in 50:50 ethyl acetate:hexane at a flow rate of 1 mL/min. The required product [^{131}I]**8** (t_R = ∼13 min) was isolated in more than 90% radiochemical yield.

Solvents from HPLC fractions containing [^{131}I]**8** were evaporated to a small volume, transferred to a $^1/_2$-dram vial, and the solvents were again evaporated to dryness. The residual radioactivity was treated with trifluoroacetic acid (50 μL) for 5 min at room temperature. Most of the trifluoroacetic acid was evaporated with an argon flow and triturated with 50 μL of ethyl acetate twice to ensure its complete removal. Methanolic ammonia (50 μL) was added to the vial, the vial vortexed, and methanol and ammonia were evaporated off under a flow of argon. The radioactivity was reconstituted in methanol and injected onto a normal-phase HPLC column eluted with 0.1% acetic acid in ethyl acetate at a flow rate of 1 mL/min. The desired [^{131}I]**7** (t_R = ∼13 min) was isolated in 55−60% radiochemical yield. Under these HPLC conditions, both 3-iodobenzyl alcohol and **8** were not retained in the column. To ensure the authenticity of the final product a TLC of it was performed in 5% (v/v) methanol in ethyl acetate along with the unlabeled standard. The retention factor for **7** was 0.3 while that for 3-iodobenzyl alcohol and **8** were 0.8 and 0.9, respectively.

[2] Alternatively, an equivalent amount of sodium hydride was used with similar results.

Alternatively, the deprotection of [^{131}I]**8** to [^{131}I]**7** has also been accomplished with tetra-butylammonium fluoride (TBAF) in THF. For this, TBAF (50 μL, 1 M in THF) was added to a vial containing the residue of [^{131}I]**8**, and the capped vial was heated at 65−70 °C for 25 min. THF was evaporated, and the activity was reconstituted in a mixture of 25 μL of methanol and 5 μL of acetic acid and injected on to a normal-phase HPLC as described above. The radiochemical yield was 85−90%.

B. Single-Step Approach. After radioiodination of **8**, solvents were removed by coevaporating twice with a few microliters of benzene. The residual activity was heated with 50 μL of TBAF in THF for 25 min at 65−70 °C. After evaporating THF, the activity was processed as above and [^{131}I]**7** was isolated by normal-phase HPLC in 70% radiochemical yield.

Cell Culture and Transfection. CHO−K1 cells were maintained in α-MEN (Gibco, Grand Island, NY) containing 10% fetal bovine serum. CHO cells were transfected with a plasmid expressing human AGT (*24*) using FuGENE (Roche Molecular Biochemicals) according to the manufacturer's protocol for transfection of adherent cells. After 48 h, Geneticin (Gibco) was added at a concentration of 500 μg/mL. Clones were isolated from individual cell foci.

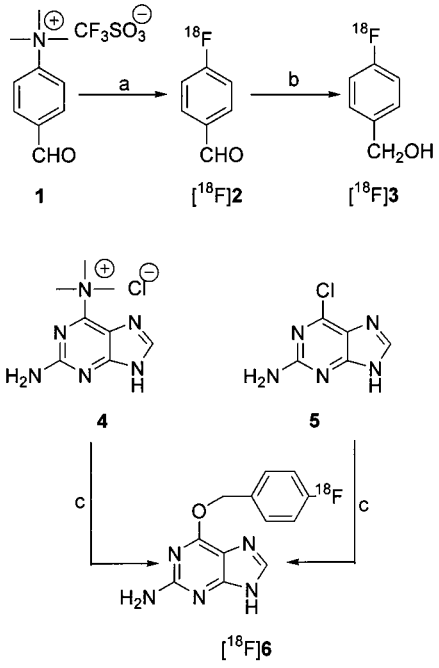
AGT Activity Assays. Inactivation of cellular AGT was measured by adding varying concentrations of FBG or IBG to cell cultures that had reached 80−90% confluence. After 4 h of drug treatment, cell extracts were prepared and the AGT activity was measured by assaying the loss of [^{3}H]-O^6-methylguanine from a [^{3}H] methylated calf thymus DNA substrate as described (*6*). The results are expressed as the percentage of the AGT activity present in cell cultures that were not treated with FBG or IBG. For each concentration, the assay was performed in duplicates.

In Vitro Binding of FBG or IBG by AGT. Purified human AGT with a $(His)_6$ tag (*25*) was generously provided by Dr. Anthony E. Pegg of Hershey Medical Center, Pennsylvania State University. About 50 000 counts of [^{18}F]FBG or [^{131}I]IBG were added in the presence or absence of increasing amounts of cold FBG or IBG, respectively, to 10 μg of AGT or to control for nonspecific binding, BSA. The incubation was done in 0.1 mL of 50 mM Tris-Cl, pH 7.5, 5 mM DTT, and 0.1 mM EDTA in the presence of 10 μg of calf thymus DNA. After incubation for 30 min at 37°, the protein was precipitated by the addition of 200 μg of carrier BSA and 1 mL of cold 12% TCA. The precipitated proteins were collected on GF-C (Whatman) filters which were washed extensively with 5% TCA. The results are expressed as the percentage of input activity retained on the filter. For each concentration, the assay was performed in triplicates. The assay was performed twice for both [^{18}F]FBG and [^{131}I]IBG.

RESULTS AND DISCUSSION

Chemistry. It is highly desirable that radiochemical syntheses be performed with the least number of steps possible, particularly for short half-life radionuclides such as ^{18}F (110 min). A prerequisite for insertion of ^{18}F onto a benzene ring by nucleophilic substitution is that the ring contains a suitable leaving group, such as $-NO_2$ or a quaternary ammonium triflate, that is positioned ortho or para to a strongly electron-withdrawing group such as a NO_2 (*26*, *27*). It may be possible to prepare a FBG precursor, such as the one with a $-NO_2$ or a quaternary ammonium group in the place of fluorine, from which [^{18}F]FBG may be produced in a single step. However, this chemistry will not be facile due to the lack of a suitably placed electron-withdrawing group in the molecule. To circumvent this, it was necessary to first prepare ^{18}F-labeled **3** and couple it to the guanine skeleton (Scheme 1). Although the chemistry of [^{18}F]**3** has been reported (*28*, *29*), a slightly different set of conditions was used for its preparation. *p*-[^{18}F]Fluorobenzaldehyde, [^{18}F]**2**, was prepared as reported (*22*). Reduction of [^{18}F]**2** was initially accomplished with $NaBH_4$ in ethanol at 80 °C. However, this involved removal of the initial solvent methylene chloride from a solution of [^{18}F]**2** and reconstitution of [^{18}F]**2** in ethanol. In addition to the extra time needed, this process resulted in a considerable loss of activity due to the very volatile nature of [^{18}F]**2**. It was found that a commercially available solution of DIBAL in methylene chloride was very effective in converting [^{18}F]**2** to [^{18}F]**3** at room temperature. It should be pointed out that the development of a technique to prepare [^{18}F]**3** by on-column reduction of [^{18}F]**2** using $NaBH_4$ has been reported very recently (*30*). Using our procedure, preparation of [^{18}F]**3** from [^{18}F]fluoride could be accomplished in about an hour in an overall decay-corrected radiochemical yield of 50%.

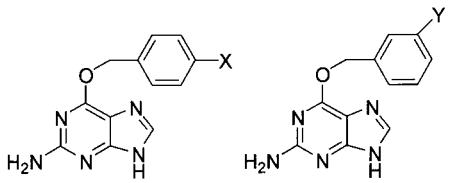
Scheme 1[a]



[a] (a) [^{18}F]Fluoride, DMSO. (b) DIBAL, CH_2Cl_2. (c) **3**, Pot. *tert*-butoxide, DMSO.

Unlabeled FBG was originally prepared by the treatment of 2-amino-6-chloropurine (ACP) at 100−130 °C for over 24 h with an excess of the sodium salt of 4-fluorobenzyl alcohol in 4-fluorobenzyl alcohol as solvent (*16*). These conditions are not adaptable to ^{18}F labeling. Even if one started with curie quantities of [^{18}F]**3** and microgram amounts of ACP, the concentration of **3** would be substantially substoichiometric. In addition, the long reaction time is not suitable with ^{18}F. We initially attempted this chemistry by conducting the reaction in a solvent such as THF or DME without success. A number of O^6-hetarylguanines have been prepared in excellent yields based on an earlier report (*31*) using **4** (*23*), instead of ACP, as the starting material (*20*). These reactions proceeded under mild conditions and involved easy workup. The procedure essentially involves the treatment of **4** with the preformed sodium alcoholate (2 equiv of sodium hydride and 5.6 equiv of desired alcohol)

Chart 1



X = F (**6**); Br (**10**); $SnMe_3$ (**11**); I (**12**)

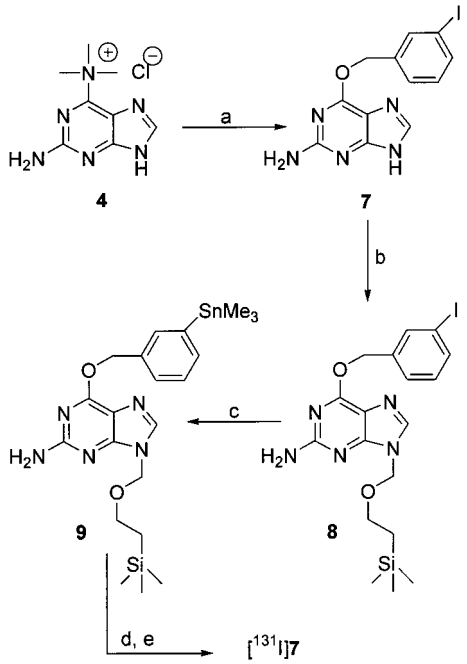
Y = I (**7**); $SnMe_3$ (**13**)

in DMSO at room temperature for 1 h. We have shown that treatment of the preformed sodium salt of 4-fluorobenzyl alcohol (using sodium hydride) with equimolar quantity of **4** in DMSO at room temperature resulted in the formation of **6** in more than 80% yield (HPLC) in 30 min. Subsequently, it was also possible to convert ACP to **6** by doing the reaction in DMSO, albeit at a higher temperature. Treatment of ACP with 2 equiv of the potassium salt of 4-fluorobenzyl alcohol (using potassium *tert*-butoxide) in DMSO at room temperature did not result in the formation of **6**. However, heating the reaction mixture at 130−140 °C for 30 min resulted in about 40% conversion of ACP to **6** as determined by HPLC (details of these reactions not given in the Experimental Section). To augment the rate of the radiochemical reaction of [^{18}F]**3** with **4**, a higher reaction temperature was used. Typically, [^{18}F]**3** was heated with a base in DMSO for 5 min at 100 °C (to ensure deprotonation), and heated again for 10 min after the addition of **4**. Sodium hydride was initially used as a base, but owing to cumbersome handling of sodium hydride, a readily available and easily measurable solution of potassium *tert*-butoxide in THF was used subsequently, giving equally good results. Although in some cases decay-corrected radiochemical yields of about 70% have been obtained for this coupling reaction, the yield generally was around 40%.[3] Little or no radioactivity corresponding to [^{18}F]**3** eluted in reversed-phase HPLC. The remainder of the radioactivity was retained in the column, suggesting the possibility of a highly nonpolar byproduct(s). About 7−9 mCi of [^{18}F]**6** was obtained starting from 100 mCi of resolubilized [^{18}F]fluoride in about 2 h. Although the specific activity of the final product has not been determined systematically, no coeluting carrier peak was generally observed on HPLC. Nonetheless, unlike receptor-based radiopharmaceuticals, very high specific activity is not necessary for O^6-alkyl guanine derivatives and may even be counterproductive because transfer of alkyl groups by AGT follows a second-order kinetics (*32*, *33*).

One of the most commonly used techniques for the preparation of radioiodinated compounds is the radioiododestannylation of the corresponding tin precursor. Initially, we envisaged the preparation of **11** (Chart 1) from the reported compound **10** (*17*). It may be possible to prepare **12** or its radioiodinated analogue by the halodestannylation of **11**; however, attempts to convert **10** to **11** by treatment with hexamethylditin and bistriphenylphosphine palladium dichloride in dioxane were unsuccessful. This was probably due to the insolubility of **10** in dioxane.

Guanine chemistry is often challenging due to the amphoteric nature of guanine derivatives (*34*). Chemical manipulations can be made more facile if the starting compound can be converted to a nonpolar derivative by the introduction of a protecting group. For example, such a strategy has simplified the preparation of polar guanidines (*35*). Guanine derivatives modified with different moieties at the N^9-position have been reported (*36*−*38*). These derivatives have sufficient nonpolar nature to permit purification by silica gel chromatography. Although some of these N^9-substituents (*36*, *38*) may be potentially used as protecting groups, the reported work was not done with that objective. While protecting group methodology has been applied to adenine chemistry (*39*), to our knowledge, such a strategy has not been reported for guanine derivatives themselves. We prepared several ACP surrogates with protecting groups such as trimethylsilylethyl, trimethylsilylethyoxymethyl (SEM), *tert*-butyloxymethyl, and pivaloyloxymethyl at the N^9-position, and converted some of these to their O^6-(substituted)benzyl derivates.[4] For the present work, we used the SEM protecting group. Recently, SEM and *p*-methoxyphenylmethyl (MPM) protecting groups were used to facilitate the coupling of 6-halopurine to glycosylamines (*40*).

Scheme 2[a]



[a] (a) 3-Iodobenzyl alcohol, NaH, DMSO. (b) Pot. *tert*-butoxide, SEM-Cl, DMSO. (c) Hexamethylditin, $(Ph_3P)_2PdCl_2$, dioxane. (d) I-131. H_2O_2, HOAc, sonication. (e) TFA or TBAF.

Although it should have been possible to convert N^9-SEM-ACP to **8** (vide supra), we used an alternative approach as shown in Scheme 2. Compound **7** was prepared from **4** and commercially available 3-iodobenzyl alcohol in 60%[5] isolated yield and converted to **8** by treatment with sodium hydride or potassium *tert*-butoxide and SEM-Cl. The unoptimized isolated yield of **8** from this reaction was only 26%. In contrast, yields of 50−85% have been reported for modification of amines with a SEM group (*41*−*43*). The N^7-regioisomer is a byproduct in the *N*-alkylation of guanines; however, the N^9/N^7 ratio generally is very high (*37*). We did not attempt to isolate the N^7-regioisomer of **8** if any was formed. Compound **8** was smoothly converted to **9** using the palladium-catalyzed stannylation.

Radioiodination of **9** to [^{131}I]**8** was performed easily by sonication for 30 s with ^{131}I and a mixture of acetic acid

[3] In a few reactions, ACP was substituted for **4**; however, the decay-corrected radiochemical yield was only about 25%.

[4] Details will be reported elsewhere

[5] The yields reported in this paper for unlabeled compounds are from one or two trials and are not optimized.

and hydrogen peroxide. The radiochemical yield was more than 90%. Tetrabutylammonium fluoride (TBAF) and TFA are among reagents that have been used for the removal of the SEM group. We initially used TFA for converting [^{131}I]**8** to [^{131}I]**7** based on preliminary results for the deprotection of N^9-(trimethylsilylethyl)-ACP (TMSE-ACP) to ACP. TMSE-ACP was treated with TBAF in DMF or DMSO at room temperature and at 60 °C. TMSE-ACP remained intact at room temperature up to 1 h tested. Analysis of the reaction mixtures left at room temperature for 20 h and those heated at 60 °C for 5 min by HPLC showed several byproduct peaks. On the other hand, a single product peak corresponding to ACP was observed when TMSE-ACP was treated with TFA for 5 min at RT. Treatment of [^{131}I]**8** with TFA at room temperature for 5 min gave 55−60% radiochemical yield of [^{131}I]**7**; 15−20% of unreacted [^{131}I]**8** was recovered. Conducting the reaction for a longer time did not improve the radiochemical yield. A combination of radio-TLC and normal-phase and reversed-phase HPLC was used to verify that the final product was indeed IBG and not the 3-iodobenzyl alcohol. Very little if any of 3-iodobenzyl alcohol was detected in the reaction mixture. In addition, the final product bound to AGT specifically (vide infra) which further supports its authenticity. It was surprising that TFA treatment did not cleave the ethereal linkage between guanine and the benzyl moieties because the instability of BG to acidic conditions has been reported (*44*). This may be due to the lack of water in the reaction mixture or a rate factor may be involved. It should be pointed out that both IBG and FBG were stable during reversed-phase chromatography involving 0.1% TFA in water (pH 2) as a cosolvent.

No deprotection was observed when [^{131}I]**8** was treated with a 1 M solution of TBAF in THF at room temperature up to 30 min, and [^{131}I]**8** was recovered quantitatively. Increasing the reaction temperature to 70 °C resulted in the formation of [^{131}I]**7** in a time-dependent fashion. A maximum radiochemical yield of 85% was obtained after about 25 min, at which time essentially only one radioactive peak corresponding to IBG was seen on HPLC. This is contrary to the results described above for the deprotection of TMSE-ACP with TBAF at macro molar levels. The possible reasons for this are the presence of a better leaving group at the O^6-position in TMSE-ACP and the difference in reaction rates at macro molar and tracer levels.

The above procedures involve two normal-phase HPLC separations. Although it was possible to perform the two steps in the same pot consecutively, there was an unlabeled peak coeluting with the desired radioactive peak when the final mixture was subjected to normal-phase HPLC. This was presumably **13** (Chart 1) because the same peak was seen when **9** was treated with TBAF and injected onto the HPLC. Use of reversed-phase HPLC may be necessary to separate **7** and **13**. However, isolating [^{131}I]**7** from reversed-phase HPLC fractions involves a solid-phase extraction and removal of a solvent such as ethanol or methanol. Because it is much easier to evaporate ethyl acetate, the two normal-phase HPLC procedure is preferred.

Inactivation of AGT Activity by FBG and IBG. Because IBG is a new compound, its ability to inactivate AGT was determined using CHO cells transfected with pCMV-AGT to express AGT. In parallel, the ability of FBG to inactivate AGT under the same conditions also was measured. As shown in Figure 1, IBG inactivated AGT from these cells to a degree higher than that inactivated by FBG. The effective dose of FBG required

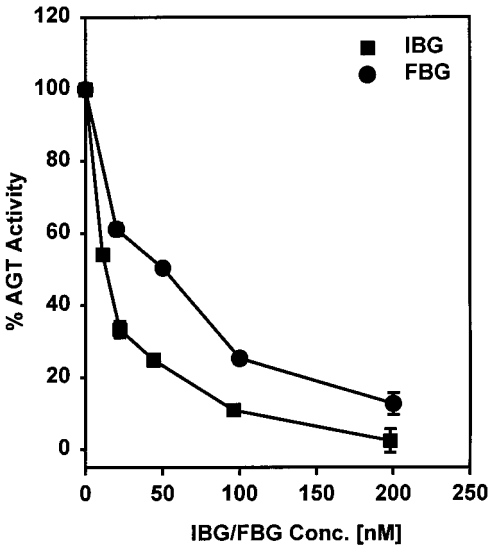


Figure 1. Inactivation of cellular AGT activity by unlabeled FBG and IBG. CHO cells transfected with pCMV-AGT were incubated with varying concentrations of IBG (■) or FBG (●) for 4h and the AGT activity associated with the cells was determined. The results are expressed as the percentage of the AGT activity present in cell cultures that were not treated with FBG or IBG.

to produce 50% inactivation of AGT (IC_{50}) was 50 nM, a value similar to that reported for FBG in HT29 human colon tumor cells (*16*). On the other hand, IBG had an IC_{50} of 15 nM, suggesting that it is more potent than FBG in inactivating AGT. These results demonstrate that introduction of an iodine at the meta-position of the benzyl group in BG did not result in a loss of AGT-inactivating ability.

Binding of Radiolabeled FBG and IBG to Purified AGT. To investigate whether AGT recognizes radiolabeled FBG and IBG as substrates, the efficacy of transfer of their radiolabeled benzyl groups to AGT was determined using the purified protein. For [^{18}F]FBG, the percent of input activity that bound to AGT increased with increasing concentrations of unlabeled FBG reaching a maximum of about 90% at 0.5 μM of FBG (Figure 2). At concentrations higher than 2 μM, saturation was observed. An IC_{50} of 5 μM was calculated. About 60% of radiolabeled IBG bound to AGT over a wide range of concentrations (Figure 3) with saturation noticed at concentrations higher than 3 μM. The IC_{50} for IBG was about 6 μM. These relatively high IC_{50} values further suggest that higher specific activity will not be a requirement for these radiopharmaceuticals. In both cases, the binding was specific as demonstrated by the fact that very little radioactivity was bound to the nonspecific protein BSA with maximum observed AGT to BSA binding ratios of 661 and 35 for [^{18}F]FBG and [^{131}I]IBG, respectively. These results are qualitatively similar to that obtained with O^6-(*p*-hydroxy[^{3}H]methylbenzyl)-guanine, the only other BG derivative labeled at the benzyl part of the molecule (*45*).[6]

Although IBG inactivates AGT from cells to a greater degree than FBG, [^{18}F]FBG had a higher binding to the purified protein than [^{131}I]IBG. This may be due to differential transmembrane transport of the two compounds as a result of differences in their lipophilicity. The lipophilicities of IBG and FBG were not determined per

[6] The preparation of ^{13}C- and ^{14}C-labeled O^6-benzylguanosines has been reported (*46*).

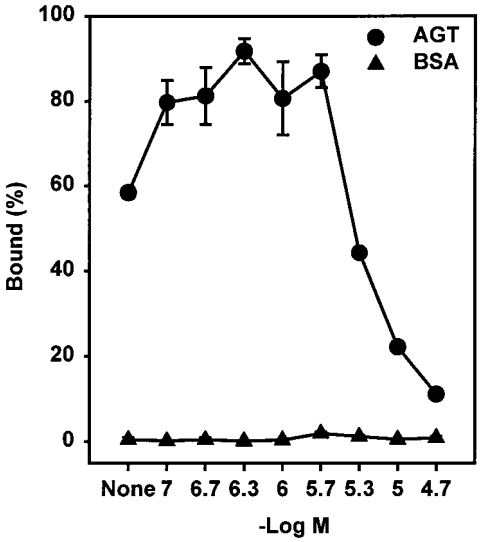

Figure 2. Binding of [^{18}F]FBG to purified AGT as a function of unlabeled FBG concentration. [^{18}F]FBG was incubated for 30 min at 37 °C, in the presence or absence of increasing amounts of unlabeled FBG, with 10 μg of AGT (●), or to control for nonspecific binding, 10 μg of BSA (▲) in a Tris-buffer. The protein associated activity was determined by TCA precipitation.

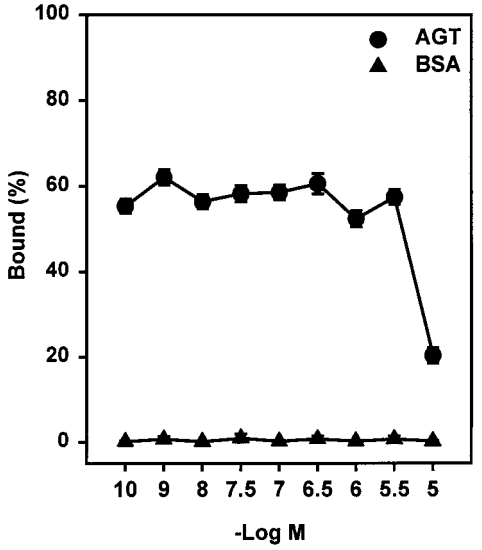

Figure 3. Binding of [^{131}I]IBG to purified AGT as a function of unlabeled IBG concentration. The assay was performed as detailed under Figure 2 by incubating [^{131}I]IBG with AGT (●) or BSA (▲).

se. Intuitively, IBG is expected to be more lipophilic. Reversed-phase HPLC has been used to determine lipophilicities (*47*). In comparison to FBG, a higher percentage of acetonitrile was needed to elute IBG from a reversed-phase column, suggesting that IBG is more lipophilic. However, it should be pointed out that the more nonpolar 4-fluorobenzyl alcohol elutes earlier (t_R = 10−11 min) than FBG (t_R = 18−20 min) under identical reversed-phase HPLC conditions.

CONCLUSION

A new iodine-substituted BG derivative has been prepared and shown to be potent in inactivating AGT activity in CHO cells transfected with AGT. Methods have been developed for the efficient syntheses of [^{18}F]FBG and [^{131}I]IBG, both of which bound specifically to purified AGT. These two radiolabeled BG analogues could be potential agents for the in vivo mapping of AGT. The iodinated derivative may also be a convenient laboratory tool for investigation of action and inactivation of AGT. We are currently working on other BG derivatives, especially fluoromethylbenzylguanine, a ^{18}F-labeled analogue of which could be prepared in a single radiochemical step.

ACKNOWLEDGMENT

This work was supported by Grants CA74817 and CA42324 from National Institutes of Health. Generous gifts of unlabeled FBG from Dr. Robert Moschel of National Cancer Institute and purified AGT from Dr. Anthony Pegg of Pennsylvania State University are gratefully acknowledged. The authors want to thank Marc Silvey and Bent Schoultz for their excellent technical assistance.

Dimethyl Suberimidate Cross-Linking of Oligo(dT) to DNA-Binding Proteins

Mark S. Dodson*

Department of Biochemistry and Molecular Biophysics, University of Arizona, Tucson, Arizona 85721-0088.
Received May 9, 2000; Revised Manuscript Received September 2, 2000

Dimethyl suberimidate is a bifunctional reagent that is used for cross-linking the protein components of oligomeric macromolecules. In this report, dimethyl suberimidate is shown to specifically cross-link oligo(dT) of varying lengths to the DNA-binding subunits of a multimeric helicase-primase encoded by herpes simplex virus type 1. This result indicates that dimethyl suberimidate and other imidoester cross-linking reagents may be useful for characterizing the interaction of oligo(dT) with proteins that bind single-stranded DNA.

INTRODUCTION

Chemical cross-linking reagents are commonly used to stabilize nucleoprotein complexes for analysis by a variety of experimental techniques (*1*−*9*). Most cross-linking reagents function to covalently join reactive groups on the polypeptide moieties of a nucleoprotein complex. Covalent joining of proteins to the nucleic acid component of nucleoprotein complexes is generally less efficient since the necessary reactive groups are fewer in number and may not be exposed. Currently only a few reagents, such as aldehydes, methylene blue, and difluorodinitrobenzene, have been used to directly cross-link protein to DNA (*9*−*11*). Thus, additional reagents that cross-link protein to DNA would be useful.

Herpes simplex virus type 1 (HSV-1) encodes a DNA helicase-primase that consists of three different polypeptides, UL5, UL52, and UL8 (*12*). Sequence homology and mutagenesis studies indicate that UL5 and UL52 confer the helicase and primase activities, respectively (*13*−*15*). The UL8 subunit does not bind DNA (*16*). A heterodimeric subassembly consisting of UL5 and UL52 (UL5/52) exhibits all of the activities associated with the holoenzyme, including an ATPase activity that is potently activated by oligo(dT) (*17*−*19*). The minimal length of oligo(dT) that effectively binds to UL5/52 and activates its intrinsic ATPase activity is about 16 nucleotides (*19*). Here it is reported that the bifunctional protein cross-linking reagent dimethyl suberimidate (DMS) can specifically cross-link oligo(dT) to the UL5 and UL52, but not to the UL8, subunits of the HSV-1 helicase primase. This result indicates that imidoesters may serve as useful reagents for characterizing the interaction of DNA-binding proteins with single-stranded DNA ligands.

MATERIALS AND METHODS

Reagents. The UL5/52 subassembly and UL8 were purified as described (*18*, *19*). Deoxythymidine oligonucleotides were obtained from Midland Certified Reagent Co. (Midland, TX). [γ-^{32}P]ATP at 6000 Ci/mmol, bis-acrylamide, ammonium persulfate, and *N*,*N*,*N*′,*N*′-tetramethylenediamine (TEMED) were from Amersham Life Sciences (Piscataway, NJ). T4 polynucleotide kinase and acrylamide were from Life Technologies (Gaithersburg, MD). High-range molecular weight protein standards consisting of myosin, β-galactosidase, phosphorylase b, bovine serum albumin (BSA), and ovalbumin were from Bio-Rad (Hercules, CA). Triethanolamine and dimethyl sulfoxide (DMSO) were from Sigma (St. Louis, MO). DMS was from Pierce (Rockford, IL).

Cross-Linking Assays. Reaction mixtures (10 μL) contained 25 mM *N*-(2-hydroxyethyl)piperazine-*N*′-(3-ethanesulfonic acid) (HEPES), pH 7.5, 3.5 mM $MgCl_2$, 75 mM NaCl, 10% glycerol, 2 mM dithiothreitol (DTT), and the indicated amounts of end-labeled oligo(dT), UL5/52 subassembly, and UL8. The mixtures were incubated for 20 min at 22 °C followed by the addition of 1.5 μL of freshly prepared 180 mM DMS dissolved in either DMSO or 0.5 M triethanolamine buffer, pH 8.5. The mixtures were incubated for 15 min, and another 1.5 μL of DMS solution was added followed by an additional 15 min of incubation. The mixtures were then precipitated by the addition of trichloroacetic acid to a concentration of 10% followed by centrifugation at 12000 × g at 4 °C. The protein pellets were washed with 100 μL of acetone, dissolved in 12 μL of loading buffer consisting of 200 mM Tris-HCl, 10% (v/v) glycerol, 20 mM DTT, and 0.6% SDS, and the cross-linked products were then separated on a denaturing SDS−7.5% polyacrylamide gel. The gels were autoradiographed using an intensifying screen for 12 h at −80 °C followed by staining with Coomassie Brilliant Blue. A Molecular Dynamics PhosphorImager was used to quantitate the results.

RESULTS

Cross-Linking of Oligo(dT) to the HSV-1 Helicase−Primase. In this study, mixtures containing UL5/52 were incubated with radiolabeled oligo(dT)$_{16}$, treated either with DMSO solvent alone or with DMSO containing DMS, and the products were then separated by SDS−PAGE. The gel was then subjected to autoradiography followed by staining with Coomassie Blue to visualize the UL5 and UL52 subunits (Figure 1). No difference was observed in the Coomassie-stained bands between the untreated control and the DMS cross-linked sample (Figure 1A, lanes 1 and 2, respectively). This result indicated that DMS did not cross-link UL5 and UL52

Table 1. Relative Extents of DMS Cross-Linking of Oligo(dT)$_{16}$ to Proteins

polypeptide	relative fraction cross-linked[b]
UL5	1.00
UL52	0.64
myosin (200 kDa)	0.08
β-galactosidase (116 kDa)	0.05
phosphorylase (97 kDa)	0.03
BSA (66 kDa)	0.14
ovalbumin (45 kDa)	0.02

[a] The cross-linked products shown in lanes 2 and 3 of Figure lB were quantitated using a Phosphorlmager. [b] The fraction of probe that was cross-linked to each protein relative to the amount of probe that was cross-linked to UL5 is shown.

together under the conditions used. However, in the autoradiograph, two prominent bands were observed in the lane containing the DMS-treated sample that were not observed in the lane containing the untreated sample (Figure 1B, lanes 1 and 2). The mobilities of these two bands corresponded to the mobilities of UL5 (99 kDa) and UL52 (114 kDa). This result indicates that the oligo(dT)$_{16}$ probe was cross-linked to UL5 and UL52. Quantitation of the cross-linked products indicated that 0.14 and 0.09% of the probe were cross-linked to UL5 and UL52, respectively. Similar results were also obtained using labeled oligo(dT)$_{20}$ as the probe and triethanolamine as the solvent for DMS (data not shown). The amount of probe that was cross-linked to UL5 was consistently higher than the amount that was cross-linked to UL52, with the ratio being 1.43 ± 0.08 to 1.

DMS Cross-Linking of Oligo(dT)$_{16}$ to UL5 and UL52 Is Specific. The specificity of DMS cross-linking of oligo(dT)$_{16}$ to UL5 and UL52 was assessed in the above experiment by comparing the ability of DMS to cross-link the DNA to the control proteins used for molecular weight standards (Figure 1A, lane 3). Only faint traces of the probe were cross-linked to the molecular weight standards (Figure lB, lane 3). The extent of cross-linking to UL5, UL52, and the control proteins was quantitated and compared (Table 1). Cross-linking of the DNA to the control proteins ranged from 5-fold (BSA) to 50-fold (ovalbumin) less than that observed for UL5 and UL52.

Effect of the Length of Oligo(dT) on DMS Cross-Linking of UL5/52. The DMS cross-linking of oligo(dT) to UL5/52 was repeated in the presence and absence of a 3-fold molar excess of UL8 using oligo(dT) species ranging from 12 to 28 nucleotides in length. An excess of UL8 was used to ensure that the heterotrimeric

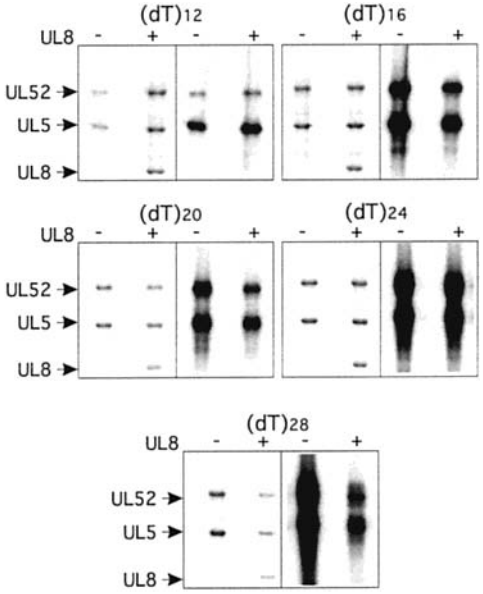

Figure 2. Effect of oligo(dT) length and of UL8 on cross-linking of DNA to UL5/52. Mixtures containing 0.8 μM ^{32}P-labeled oligo-(dT) of the indicated length and 0.6 μM UL5/52 were cross-linked with DMS in the presence or absence of 1.8 μM UL8, and then separated by SDS−7.5% PAGE as described in the Materials and Methods. The left two lanes of each panel show a Coomassie-stained gel containing UL5/52 alone or UL5/52 and UL8. The right two lanes of each panel show the autoradiogram of the gel. The mobilities of the subunits are indicated on the first panel.

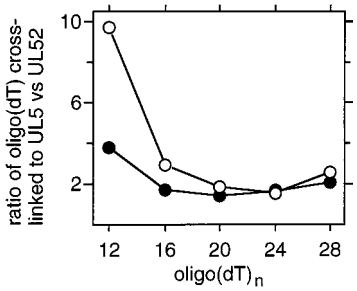

Figure 3. Relative extents of cross-linking of oligo(dT) of varying lengths to UL5 and UL52 in the presence and absence of UL8. The data from Figure 2 were quantitated using a PhosphorImager. The ratio of DNA cross-linked to UL5 versus UL52 is plotted for oligo(dT)s of the indicated lengths. Data are the averages of two separate experiments. Filled symbols, UL8 absent; open symbols, UL8 present.

holoenzyme would be stably formed (*20*). Again, cross-linked products that corresponded to the mobilities of UL5 and UL52 were observed for all lengths of oligo(dT) that were used (Figure 2). No species that correlated to cross-linking of the DNA to UL8 were observed. The relative extents of cross-linking of the oligonucleotides to UL5 and UL52 were quantitated by determining the ratio of the amount of UL5-cross-linked DNA to UL52-cross-linked DNA (Figure 3). This ratio is unaffected by variations in the specific activities of the labeled probes or by variations in the amount of sample loaded on the gel. For oligo(dT)s of 16 or more nucleotides in length, about twice as much DNA was cross-linked to UL5 as was cross-linked to UL52. UL8 had little effect on this ratio. However, this ratio was changed substantially when oligo(dT)$_{12}$ was used as the ligand. In the absence of UL8, about four times as much DNA was cross-linked to UL5 as to UL52. In the presence of UL8 this ratio increased to about 10 to 1.

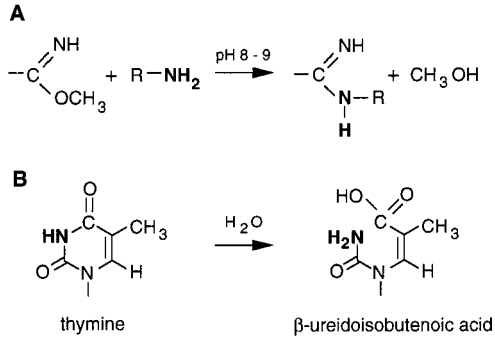

Figure 4. Proposed mechanism for DMS cross-linking of oligo(dT) to protein. (A) The imidoester reaction scheme; (B) hypothesized opening of the thymine ring to yield a primary amine that can participate in the imidoester reaction.

DISCUSSION

Because of its lack of secondary structure, oligo(dT) is frequently used for characterizing the interactions of helicases with DNA ligands (*1*, *8*, *19*, *21*−*23*). We had originally intended to use DMS as a reagent for determining if oligo(dT) induces oligomerization of the HSV-1 helicase-primase. Under the conditions used for DMS cross-linking, we were unable to detect the formation of oligo(dT)-induced oligomers of the HSV-1 helicase-primase. However, we observed that the DNA became covalently cross-linked to UL5 and UL52. This result was unexpected since oligo(dT) lacks the functional groups that are necessary to react with imidoester-based cross-linking reagents. The studies presented in this report indicate that DMS-mediated cross-linking of oligo(dT) to UL5 and UL52 is specific since several non-DNA-binding proteins are cross-linked far less effectively to oligo(dT). The modest amount of cross-linking of oligo(dT) to BSA can be accounted for by a previous observation that BSA weakly binds DNA (*24*). The specificity of cross-linking of oligo(dT) to UL5 and to UL52 is further demonstrated by the failure of DMS to cross-link oligo(dT) to the non-DNA-binding UL8 subunit of the holoenzyme. This covalent cross-linking of oligo(dT) to protein by DMS is a novel result that has not been previously observed.

To demonstrate the utility of DMS as a tool for characterizing nucleoprotein complexes, we used DMS cross-linking to compare the ability of UL5 and UL52 to bind oligo(dT) ligands of varying lengths. For oligo(dT) ligands longer than 16 nucleotides, the ratio of the amount of DNA that is cross-linked to UL5 and UL52 is fairly constant, even in the presence of UL8. Shorter ligands are not cross-linked to either protein as efficiently as the longer DNA species. In the presence of UL8, the amount of oligo(dT)$_{12}$ that is cross-linked to UL5 is 10-fold greater than for UL52. The poor cross-linking of oligo(dT)$_{12}$ to UL5/52 agrees with previous nitrocellulose filter binding and enzymatic activation studies which showed that oligo(dT) ligands shorter than 16 nucleotides are poorly bound by UL5/52 and are also poor activators of the DNA-dependent ATPase activity of UL5/52 (*19*). Our cross-linking results demonstrate that the minimal length of the DNA-binding site in UL5 is shorter than in UL52 and that the UL8 subunit affects the interaction of short oligonucleotides with the UL5/52 subassembly.

DMS cross-links primary amines on proteins by an imidoester reaction (Figure 4A) (*25*). Since there are no primary amines on deoxythymidine, the observation that DMS cross-links oligo(dT) to UL5 and UL52 is puzzling. One explanation could be that the oligonucleotides become trapped by a "caging" effect in which the DNA becomes pinned beneath cross bars of DMS that link some of the residues which form the DNA-binding sites. However, these caged structures would be expected to dissociate when denatured in the SDS−PAGE loading buffer. Alternatively, upon binding of oligo(dT) to UL5 or UL52, some thymine residues may be rendered partially susceptible to hydrolysis or damage at the 3 and 4 positions of the pyrimidine ring. This could yield a β−ureidoisobutenoic acid moiety containing a primary amino group that could participate in the imidoester cross-linking reaction (Figure 4B).

The total fraction of labeled oligo(dT) that was cross-linked to protein in our study was about 0.25%. This figure is roughly comparable to the extent of halogenated oligo(dT) that can be cross-linked to UL5 and UL52 by brief exposure to long wave UV light (*23*).

It is often necessary to test several methods in order to identify one that can be successfully used for cross-linking a specific set of macromolecules. Few methods are available for covalently cross-linking proteins to DNA. Here we have shown that imidoester cross-linking reagents such as DMS offer an alternative to these other methods. In contrast to methylene blue (*10*), DMS can effectively cross-link single-stranded nucleic acids to protein, and, in contrast to aldehyde-based cross-linkers, DMS can yield cross-linked species that retain enzymatic activity (*1*). In addition, DMS may be more appropriate than UV light for cross-linking DNA to proteins in the presence of nucleotides or other UV-absorbing compounds. Thus, the observation that imidoesters such as DMS can covalently cross-link protein to DNA expands the limited repertoire of methods that are available for studying the interaction of DNA with DNA-binding proteins.

ACKNOWLEDGMENT

This research was supported in part by Grant RPG9705601NP from the American Cancer Society. The author thanks Dr. Lauren Murata and Nicoleta Constantin for helpful discussions, critical reading of the manuscript, and assistance with production of the figures.

The amino acid homopolymers, poly-L-lysine and poly-L-ornithine, have been modified by the covalent attachment of palmitoyl and methoxypoly(ethylene glycol) (mPEG) residues to produce a new class of amphiphilic polymers—PLP and POP, respectively. These amphiphilic amino acid based polymers have been found to assemble into polymeric vesicles in the presence of cholesterol. Representatives of this new class of polymeric vesicles have been evaluated in vitro as nonviral gene delivery systems with a view to finding delivery systems that combine effective gene expression with low toxicity in vivo. In addition, the drug-carrying capacity of these polymeric vesicles was evaluated with the model drug doxorubicin. Chemical characterization of the modified polymers was carried out using ^{1}H NMR spectroscopy and the trinitrobenzene sulfonic acid (TNBS) assay for amino groups. The amphiphilic polymers were found to have an unreacted amino acid, palmitoyl, mPEG ratio of 11:5:1, and polymeric vesicle formation was confirmed by freeze-fracture electron microscopy and drug encapsulation studies. The resulting polymeric vesicles, by virtue of the mPEG groups, bear a near neutral ζ-potential. In vitro biological testing revealed that POP and PLP vesicle−DNA complexes are about one to 2 orders of magnitude less cytotoxic than the parent polymer−DNA complexes although more haemolytic than the parent polymer−DNA complexes. The polymeric vesicles condense DNA at a polymer:DNA weight ratio of 5:1 or greater and the polymeric vesicle−DNA complexes improved gene transfer to human tumor cell lines in comparison to the parent homopolymers despite the absence of receptor specific ligands and lysosomotropic agents such as chloroquine.

INTRODUCTION

Self-assembled systems such as those arising in aqueous media from phospholipids (liposomes) (*1*) and synthetic surfactants (niosomes) (*2*) have been used as drug (*3*, *4*) and gene (*5*) delivery systems. Our studies are concerned with a new class of polymeric vesicles for drug and gene delivery. Previously, drug delivery polymeric vesicles have been prepared from an amphiphilic derivative of the carbohydrate glycol chitosan (*6*). However, the current polymeric vesicles have been prepared from amino acid based polymers and are being evaluated as gene and possibly drug delivery systems.

For gene therapy to become a reality, there is a need for the development of innovative delivery systems which produce clinically significant expression levels in vivo while still remaining nontoxic and nonimmunogenic (*7*). These materials also have to be produced in large quantities and to pharmaceutical standards. Many of the systems that are currently being utilized, both viral and nonviral, are unable to fulfill these requirements, and hence, there are a large number of new gene delivery systems being investigated in the hope that a few will show promise.

Viral systems (*8*) have been studied extensively and include a wide variety of viral types such as retroviruses, adenoviruses, adeno-associated viruses, herpes simplex virus, and the HIV-based lentivirus. All have various inherent disadvantages (*9*) such as safety concerns and scale-up difficulties.

A vast range of nonviral systems has been developed in an attempt to overcome some of the shortfalls of viral systems. These are mainly cationic liposomes (lipoplex) (*7*, *10*), cationic polymers (polyplex) (*11*−*13*) or a combination of cationic liposomes and cationic polymers (lipopolyplex) (*14*).

Gene targeting in vivo requires that the carriers avoid early uptake by the reticuloendothelial system (RES) as well as nonspecific uptake due to electrostatic interactions. The excess positive surface charge of many cationic lipid complexes promotes nonspecific interaction with cells (*15*) which seriously hampers any targeting efforts (*16*). Additionally, the excess positive charge may also reduce the stability of the complex (*17*) and consequently enhance the degradation of DNA[1] in vivo. Hence one of the desirable attributes of a nonviral gene delivery system would be a neutral surface charge. The incorporation of targeting ligands, however, is necessary to achieve more specific targeting of carriers (*18*). Current cationic liposomal vectors largely resist targeting, as they tend to transfect the first capillary bed they arrive at after

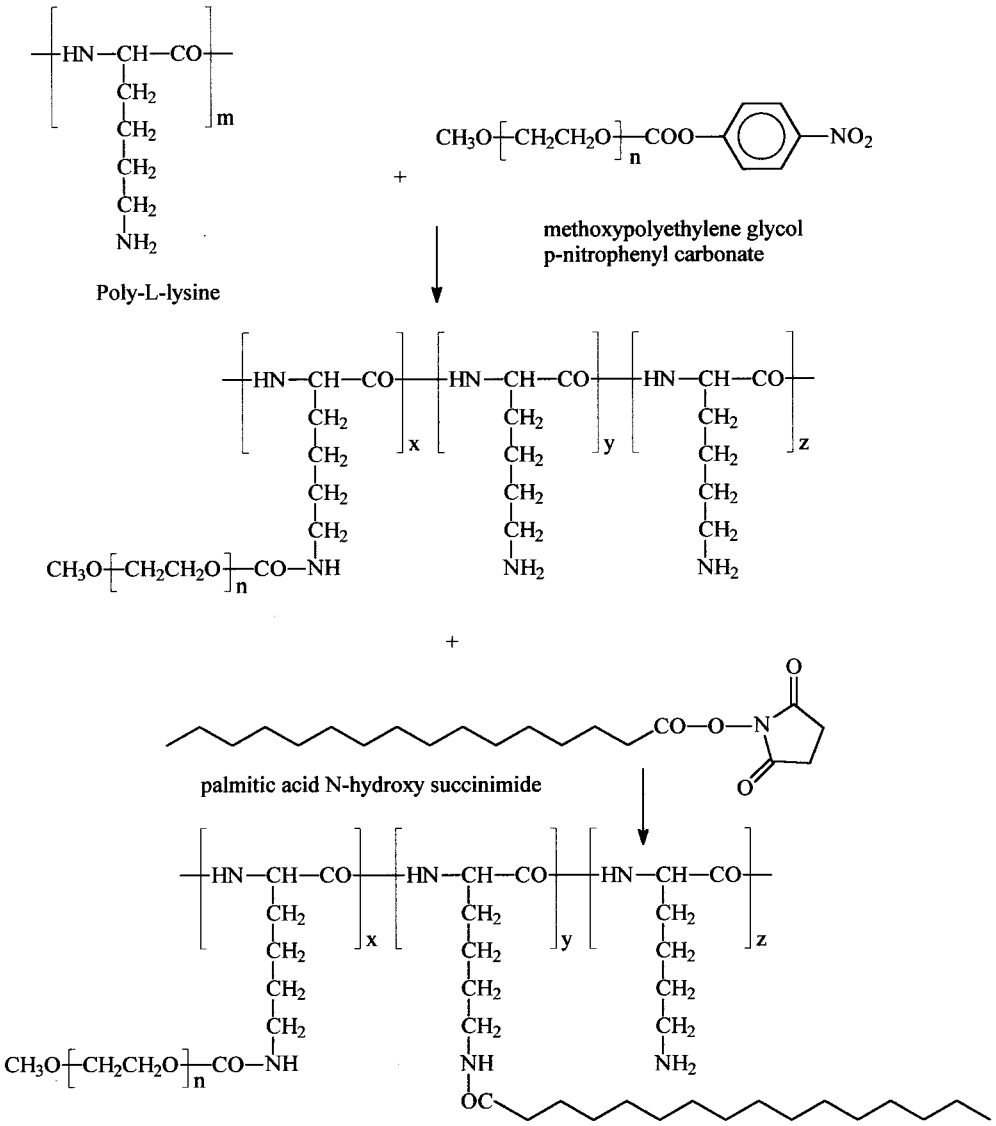

Figure 1. Synthesis of amphiphilic amino acid based polymers as exemplified by the synthesis of a poly-L-lysine based amphiphilic polymer using activated mPEG (mPEG Mw = 5000) and activated palmitoyl compounds, $n = 123$, $m \approx 114$.

intravenous administration—namely the lung endothelium (*19*). While a degree of gene targeting may be achieved with cationic polymers bearing targeting ligands, success has been limited and protein expression is low and transient due probably to the degradation of cationic polymer complexes in the blood and body fluids (*18*). The degradation of liposome complexes in vivo, for example, may be modulated by a poly(ethylene glycol) (PEG) surface (*20*), which may also improve transfection in vivo (*20*). The PEG surface, apart from limiting DNA degradation, will also equip gene carriers with a "stealth" facility and should allow prolonged circulation on intravenous administration (*21*) with possibly a more sustained biological effect. Hence, a PEG-coated surface is also a desirable attribute of a gene delivery system.

The present work describes the synthesis and characterization of amphiphilic amino acid based polymers, their assembly into polymeric vesicles bearing a near neutral surface charge, and their biological characterization as possible gene and drug delivery systems.

MATERIALS AND METHODS

Materials. Poly-L-lysine hydrochloride (PLL, MW 15000−30000), poly-L-ornithine hydrochloride (PO, MW 15000−30000), sodium tetraborate decahydrate, methoxypoly(ethylene glycol) (mPEG)-*p*-nitrophenyl carbonate, palmitic acid *N*-hydroxysuccinimide, phosphate buffered saline (PBS) tablets, and deuterated solvents were obtained from Sigma−Aldrich Co., U.K. Other organic solvents were obtained from Merck, U.K. Sodium hydrogen carbonate was supplied by Fluka, U.K. Plasmids (pCMVsport β-gal) were obtained from Life Sciences, U.K., and tissue culture media from GibcoBRL, U.K.

Synthesis of Modified Poly-L-Amino Acid Polymers. Synthesis was carried out as depicted in Figure 1. The conjugation of methoxypoly(ethylene glycol) (mPEG) to the amino acid homopolymers was carried out according to a modification of the method of Monfardini and others (*22*). PLL or PO (400 mg) was dissolved in sodium tetraborate (0.08 M, 240 mL) and methoxypoly(ethylene glycol)-*p*-nitrophenyl carbonate (mPEG Mw = 5000, 800 mg for PO and 720 mg for the PLL synthesis reaction) added over a 3 h period. The mixture was stirred for a total of 15 h at room temperature protected from light and the product subjected to exhaustive dialysis (Visking tubing, Molecular weight cut off = 12000−14000) against 5 L of water for 24 h with six changes. The conjugation of the palmitic acid groups to the mPEG-poly-L-amino

acid polymers was derived from a method described previously for the synthesis of palmitoyl glycol chitosan (*6*). Sodium hydrogen carbonate (1 g) was dissolved in the dialysate and a solution of palmitic acid *N*-hydroxysuccinimide (260 mg) in absolute ethanol (320 mL for PO or 312 mL for PLL synthesis reaction) was added dropwise. The reaction mixture was then stirred for 72 h and protected from light, and the product was again dialyzed exhaustively against water as described above. The dialysate was freeze-dried, and the freeze-dried material dissolved in chloroform (400 mL). The chloroform solution was filtered to remove unreacted PLL and the filtrate evaporated under reduced pressure at 30−40 °C until the volume had been reduced to about 20 mL. This solution was then added dropwise to diethyl ether (500 mL), and the precipitate collected by filtration. Thus, contaminating palmitic acid, which dissolves in diethyl ether, was removed. To obtain a dry powder, the precipitate was freeze-dried. The poly-L-lysine based amphiphilic polymer (PLP) and the poly-L-ornithine-based amphiphilic polymer (POP) were presented as off-white powders.

^{1}H NMR. ^{1}H NMR (with integration) and ^{1}H correlation spectroscopy experiments (Bruker AMX 400 MHz spectrometer, Bruker Instruments, U.K) were performed on solutions of POP and PLP in $CDCl_3$, palmitic acid N-hydroxysuccinimide in $CDCl_3$, PLL and PO in D_2O and methoxy-polyethylene-glycol-*p*-nitrophenyl carbonate in D_2O. ^{1}H NMR of PLP samples was performed at elevated temperature (48 °C), but all other samples were analyzed at ambient temperatures (25 °C).

Assay for Free Amino Groups. The proportion of free amino groups in the modified polymers may be measured by a comparative titration of the free amino groups in both the unmodified and modified polymers using trinitrobenzene sulfonic acid (TNBS) (*23*). The TNBS assay was carried out by dissolving POP/PLP (5 mg) in methanol (10 mL); 3 mL of this solution was diluted to 10 mL with sodium tetraborate (0.1 M). To a 3 mL aliquot of this methanolic sodium tetraborate solution was then added TNBS solution (75 μL, 0.03 M). The resulting solution was mixed thoroughly and incubated at room temperature for 30 min. The absorbance was read at 420 nm (Unicam UV-1, Unicam Ltd, U.K.), and the weight percent of unmodified polymer was computed from a standard curve prepared using the unmodified polymers, poly-L-lysine and poly-L-ornithine, as appropriate. This experiment was carried out in triplicate.

Gel Permeation Chromatography−Laser Light Scattering. GPC/LLS with refractive index detection was carried out on polymer samples to ensure complete removal of low molecular weight and polymeric (unreacted mPEG-*p*-nitrophenol carbonate and mPEG carboxylic acid) impurities. Poly-L-lysine hydrobromide, mPEG-*p*-nitrophenyl carbonate, and mPEG grafted poly-L-lysine solutions, each dissolved in acetate buffer (0.3 M CH_3COONa/0.2 M CH_3COOH, pH 4.4), were analyzed on a PSS Hema-Bio 300 column (300 × 8 mm, particle size = 10 μm, exclusion limit for dextran = 500 000) and a PSS Hema-Bio 40 column (300 × 8 mm, particle size = 10 μm, exclusion limit for dextran = 3 000 000). The mobile phase was acetate buffer (pH 4.4). Detection was via a Waters 2410 refractive index (RI) detector at 850 nm (Waters Instruments, U.K.) and a Wyatt Mini Dawn static laser light scattering detector equipped with a 20 mV semiconductor diode laser (vertically polarized, λ = 690 nm) at three angles (45, 90, and 135°), Optokem Instruments, U.K. PLP and palmitic acid *N*-hydroxysuccinimide ester samples dissolved in chloroform were analyzed on a Waters Styragel HR 4E column (300 × 7.8 mm, mixed bed pore size, exclusion limit for polystyrene = 50−100000) and a Waters Styragel HR 5E column (300 H 7.8 mm, mixed bed pore size, exclusion limit for polystyrene = 2000−4000000). The mobile phase was chloroform. All the sample solutions were injected at a loading concentration of 1−3 mg/mL (200 μL each injection) using a Waters 717 plus Autosampler, and all the measurements were carried out at room temperature.

Polymeric Vesicle Preparation. POP/PLP vesicles were prepared by sonication of POP/PLP (5 mg) and cholesterol (chol, 2 mg) in phosphate-buffered saline (1 mL, pH 4.0 or 7.0) for 15 min, using a probe sonicator (Soniprobe instruments, U.K.). To prepare doxorubicin-loaded vesicles, POP (5 mg), chol (2 mg), and a solution of doxorubicin (2 mL, 1 mg mL^{-1}) in PBS (pH 4) were probe sonicated (2 × 2 min) and then filtered (0.45 μm), or alternatively PLP (10 mg), cholesterol (4 mg), and a solution of doxorubicin (4 mL, 1 mg mL^{-1}) in PBS (pH 4) were probe sonicated and filtered as described above. To separate unentrapped doxorubicin, the dispersion was ultracentrifuged (150000*g* × 1 h) and the supernatant removed. The pellet was reconstituted in PBS (2 mL, pH 4).

Polymeric Vesicle Sizing and ζ-Potential Measurements. The sizes and ζ-potential (in PBS, pH 7.4) were measured using a Malvern Zetasizer 1000 (size measurements only) or a Malvern Zetasizer 4 (ζ-potential measurements), both from Malvern Instruments, U.K. All measurements were performed at 25 °C. Before the start of each measurement, standards (polystyrene latex beads, 300 nm, Sigma Co., U.K., and Malvern Zetasizer standard, Malvern Instruments) were analyzed. All *z*-average mean and ζ-potential data obtained from the standards agreed with that stated by the manufacturer. The viscosity of the disperse phase was 0.893Cp and the dielectric constant for the ζ-potential measurements was 79.

Doxorubicin Quantification. The doxorubicin loaded vesicles (0.1 mL) were disrupted by dilution with 2-propanol (1 mL) and then diluted with PBS (pH 4). The amount of doxorubicin released form the disrupted vesicles was measured fluorimetrically ($\lambda_{excitation}$ = 480 nm, $\lambda_{emission}$ = 560 nm, Perkin-Elmer LS-50B spectrofluorimeter, Perkin-Elmer, U.K). The doxorubicin standard curve was linear over the range 0.2−10 μg mL^{-1}. This experiment was carried out in triplicate.

Freeze-Fracture Electron Microscopy. Freeze-fracture electron microscopy was used to visualize the polymeric vesicles. Specimens were fast frozen by being plunged into liquid propane/isopentane at −180 °C and transferred cold into a high vacuum freeze-fracture system. Specimens were fractured with a BalTec complementary replica device at −100 °C, and the exposed faces replicated with platinum carbon at 45 °C and backed by carbon at 90°. Replicas were cleaned in acetone/alcohol, rinsed in distilled water, dried on Formvar-coated grids, and finally imaged using a LEO (Zeiss) 902 energy-filtering electron microscope.

Polymeric Vesicle Interaction with DNA. Plasmid (pCMVsport β-gal, Life Technologies, Paisley, U.K) was grown in *Escherichia coli* and plasmid purification was carried out using a QIAGEN Endo-toxin free Giga Plasmid Kit (QIAGEN, Hilden, Germany) according to the manufacturer's instructions. Purity was confirmed by agarose gel electrophoresis (*24*).

The reduced fluorescence of ethidium bromide (EthBr) was used to probe for DNA condensation by the polymeric vesicles. EthBr fluorescence increases significantly (factor

40 compared to unbound EthBr) on intercalation with double-stranded DNA (*25*). The electrostatic interaction between the anionic DNA and cationic groups of the carrier on formation of the DNA−vesicle complex reduces the number of EthBr binding sites, a process termed condensation, ultimately reducing the fluorescence intensity of the EthBr solution.

Complexes of POP and PLP vesicles with DNA were prepared at polymer:DNA ratios of 20:1, 10:1, 5:1, 2.5:1, 1.25:1, 0.625:1, and at various time points the fluorescence intensity ($\lambda_{excitation}$ = 526 nm, $\lambda_{emission}$ = 592 nm) of the complexes determined in the presence of EthBr (40 μg mL^{-1}). The DNA concentration in the cuvette was kept constant (100 μg mL^{-1}), and the polymeric vesicle dispersion medium PBS (pH 4) and a solution of DNA in PBS (pH 4) served as controls.

Haemocompatibility. Approximately 5 mL of human blood was centrifuged (1000*g* × 10 min). The erythrocyte pellet was isolated, washed twice with PBS (pH 7.4) at 4 °C by resuspending the pellet in PBS (pH 7.4), followed by centrifugation (1000*g* × 10 min). The pellet was weighed and a 3% w/w dispersion of the erythrocytes prepared in PBS (pH 7.4). Varying concentrations of the polymeric vesicle−DNA formulations (100 μL) were added to the erythrocyte suspension (100 μL) in 96-well microtiter plates. PBS and Triton X-100 (1% w/v) served as negative and positive controls, respectively. After incubation for 4 h, the microtiter plate was centrifuged (1000*g* × 10 min), the supernatant (100 μL) transferred to a new microtiter plate, and the absorbance measured at 570 nm. Values were corrected for background readings obtained for polymeric vesicles only. The haemolysis given by the Triton-X solution was considered to be 100% while the haemolysis given for the PBS solution was taken as 0%. The results were thus expressed as percentage haemolysis.

Cytotoxicity. A human lung carcinoma cell line (A549, ATCC CCL-185) and a human epidermoid carcinoma cell line (A431, ATCC CRL-1555) were both maintained in Dulbecco's minimum essential medium (DMEM) supplemented with 10% foetal calf serum (FCS) and 2 mM glutamine (GibcoBRL, U.K.) at 10% CO_2 and 37 °C.

The cytotoxicity was assessed by the measurement of the IC_{50} value in a standard MTT (3-[4,5-dimethylthiazol-2-yl]-2,5-diphenyltetrazolium bromide thiazolyl blue indicator dye) assay (*26*). Briefly, 96-well microtiter plates were seeded with 700 cells/well and incubated for 72 h. Dilutions of the polymeric vesicle−DNA formulations (100 μL) in tissue culture medium (Opti-Mem) were incubated with the cells for 4 h. The samples were then replaced with fresh DMEM daily and incubated for 72 h. After this period, the indicator dye (50 μL, 50 mg mL^{-1}) was added to each well and incubated with the cells for 4 h in the dark. The medium and indicator dye were then removed and the cells lysed with dimethylsulfoxide (200 μL). After addition of Sorensen's glycine buffer (25 μL), the absorption was measured at 570 nm. Values were expressed as a percentage of the control to which no vesicles were added.

Transfection Experiments. Cells were seeded in 96-well microtiter plates at 1 × 10^4 cells/well and incubated overnight in a humidified, 10% CO_2 atmosphere at 37 °C. From preliminary transfection experiments (data not shown) and the EthBr assay, the optimal vesicle:DNA ratio was established.

Equal volumes of polymeric vesicle suspensions and plasmid DNA (pCMVsport-β-gal) solutions (100 μg mL^{-1}) were mixed and incubated at room temperature for 30−45 min. The cell incubation medium was replaced by Opti-MEM (100 μL) and the appropriate dilution of the polymeric vesicle−DNA complex (100 μL). Hence, each well received either 2.5 or 1.25 μg of DNA applied at a concentration of 25 or 12.5 μg mL^{-1}. After incubation for 4 h (10% CO_2, 37 °C), the mixture was replaced by DMEM (200 μL) supplemented with FCS (10% v/v), glutamine (2 mM), penicillin (100 IU mL^{-1}), and streptomycin (100 μg mL^{-1}).

The β-galactosidase activity was determined 48 h post-transfection by measuring *o*-nitrophenyl β-D-galactopyranoside (ONPG) cleavage using a photometric assay. After washing with PBS (pH 7.4), cells were lysed by the addition of lysis buffer (0.1% w/v Triton-X, 0.25 M Tris base, pH 8, 70 μL/well) and three freeze−thaw cycles. PBS (pH 7.4, 50 μL) and a solution of ONPG (1.5 mg mL^{-1}, 150 μL) in buffer (sodium dibasic phosphate, 60 mM; magnesium chloride, 1 mM; potassium chloride, 10 mM; β-mercaptoethanol, 50 mM, pH 8) were added to each well. After incubation at 37 °C for 30 min, absorbance at 405 nm was determined in a plate reader and compared to the on-plate β-galactosidase standard curve.

Statistics. Statistical significance was assessed using one way analysis of variance (ANOVA) via the statistical software package Minitab 10.5 for Windows.

RESULTS

Polymer Synthesis and Characterization. Two dialysis steps combined with dissolution of the product in chloroform, the filtration of undissolved material and the final precipitation of the product in diethyl ether, were sufficient for the purification of the modified polymers. The absence of low molecular weight contaminants in the modified polymers was verified by gel permeation chromatography−refractive index output as exemplified for PLP in Figure 2. The reactants palmitic acid *N*-hydroxysuccinimide (retention volume, Rv = 19.5 mL) and unreacted mPEG (Rv = 17.5 mL) were not detected, and the main polymer peak eluted with a Rv = 16.5 mL (Figure 2). After the synthesis of mPEG−poly-L-lysine, unreacted mPEG is detected as a shoulder to the right of the main peak in the light scattering and refractive index detector plots. This shoulder disappears after dialysis.

From the NMR data, the proton assignments of POP were found to be δ 0.88 ppm = CH_3 (palmitoyl), δ 1.25 ppm = CH_2 (palmitoyl), δ 1.60 ppm = CH_2 (palmitoyl, β to carbonyl), δ 2.16 = CH_2 (palmitoyl, α to carbonyl), δ 3.38 ppm = CH_3 (methoxy PEG), δ 3.45−3.82 ppm = CH_2 (PEG) and for PLP at elevated temperature, δ 0.88 ppm = CH_3 (palmitoyl), δ 1.26 ppm = CH_2 (palmitoyl), δ 1.4−1.6 CH_2 (δ protons on lysine and β protons on palmitoyl) δ 2.1−2.6 ppm = CH_2 (α proton on palmitoyl and β and γ protons on lysine) δ 3.15 ppm = CH_2 (ϵ proton on lysine) δ 3.38 ppm = OCH_3 (mPEG), δ 3.45−3.83 ppm = CH_2 (mPEG), δ 4.22pm = CH (α proton on lysine), δ 6.35−6.61 ppm = NH_2 (lysine) δ 7.15 ppm = NH (lysine), δ 7.2 ppm = CH (chloroform). From the ratio of palmitoyl CH_3 and mPEG OCH_3 for each polymer, the ratio of palmitoyl groups to mPEG groups was calculated as 5:1 POP and 4.9:1 for PLP. Originally, the NMR spectra of POP and PLP did not show peaks for the amino acid backbone, indicative of a limited mobility of the modified polymer backbone. This limited mobility of the polymer backbone was confirmed by recording the ^{1}H NMR spectra of PLP at elevated temperature (48 °C), and peaks for the main-chain groups were then observed. The proton assignments for the unmodified polymers are as follows: poly-L-ornithine, δ 1.8 ppm = CH_2 (β and γ protons on

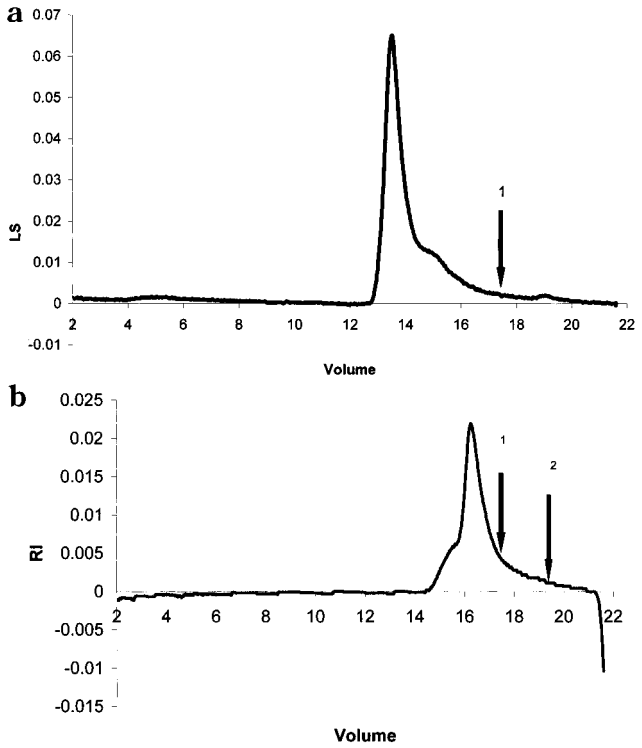

Figure 2. Gel Permeation with (a) multiangle laser light scattering detection and (b) refractive index detection chromatographs of PLP. See Materials and Methods for chromatography conditions. LS = light scattering detector output, RI = refractive index detector output, 1 = point of peak elution of unreacted mPEG, detectable by the light scattering and refractive index detectors as a distinct shoulder, 2 = point of peak elution of the unreacted PNS, detectable by the refractive index detector only.

ornithine), δ 3.0 ppm = CH_2 (δ proton on ornithine) δ 4.3 ppm CH (α carbon on ornithine) and poly-L-lysine δ 1.5 ppm = CH_2 (δ proton on lysine), δ 1.8 = CH_2 (β and γ protons on lysine), δ 3.1 = CH_2 (ϵ proton on lysine), δ 4.4 ppm CH (α proton on lysine).

The TNBS assay (*23*) was used to evaluate the degree of modification of poly-L-ornithine and poly-L-lysine. The amount of accessible amino groups was found to be 1.30 ± 0.04 mmol g^{-1} (n = 3) for POP and 1.32 ± 0.18 mmol g^{-1} (n = 3) for PLP. Clear solutions of PLP and POP in a methanol−aqueous mixture were analyzed. Complete dissolution of PLP and POP is essential if all the unreacted amino groups are to be accessible to the TNBS reagent. The ratio of amino, palmitoyl, and mPEG groups may be assessed if the ratio of palmitoyl to mPEG groups is known using eqs 1−3, which exemplify the calculations for PLP:

$$x + y + z = \mathrm{DP} \tag{1}$$

$$\frac{y}{x} = 5 \tag{2}$$

$$\frac{128z}{5127x + 367y + 128z} \times 100 = 16.9 \tag{3}$$

where x = the number of mPEG groups, y = the number of palmitoyl groups, and z = the number of unreacted lysine groups, DP = the degree of polymerization, 16.9 = the weight percent of unreacted poly-L-lysine, and 5 = the ratio of palmitoyl groups to mPEG groups. Solving for x, y, and z, yields a ratio of free lysine, palmitoyl lysine, mPEGylated lysine of 10.9:5:1. The equivalent ratio for POP is 10.7:5:1. Hence, each PLP chain with a manufacturer's stated degree of polymerization for poly-L-lysine of 123 has on average 7 mPEG groups, 36 palmitoyl groups, and 80 free amine groups, while each POP chain with a manufacturer's stated degree of polymerization for poly-L-ornithine of 97 has on average 6 mPEG groups, 29 palmitoyl groups and 62 free amine groups.

Table 1. Size of PLP and POP Vesicles with DNA, Mean of at Least Three Measurements

sample	size (nm)	polydispersity
POP/CHOL, DNA 20:1 (freshly complexed)	476	0.06
POP/CHOL, DNA 20:1 (6.5 h old)	593	0.47
PLP/CHOL, DNA 20:1 (freshly complexed)	375	0.43
PLP/CHOL, DNA 20:1 (6.5 h old)	426	0.06

Polymeric Vesicle Characterization. Polymeric vesicles prepared from this new class of amphiphilic polymer and cholesterol were visualized by freeze-fracture electron microscopy. Although images of filtered samples are shown in Figure 3, there was no difference in the vesicle morphology when unfiltered samples were imaged. The vesicles diameter measured by photon correlation spectroscopy was 400−600 nm and remained stable for more than 9 months at 4 °C (Figure 2). The vesicles encapsulated doxorubicin at levels of 11.7 ± 1.5 mg g^{-1} PLP and 14 ± 4.2 mg g^{-1} POP, respectively (mean ± sd, n = 3).

Both POP and PLP vesicles condense DNA at polymer to DNA weight ratios of 5:1 or greater. Complexation occurred almost instantaneously and was found to be stable for up to 46 h (Figure 3). These results were also confirmed by agarose gel electrophoresis DNA retardation studies (data not shown). Complexation of the vesicles with DNA did not result in a large change in size (Table 1) and vesicles were present after complexation of the polymeric vesicles with DNA (Figure 3, panels c and d).

The results of the TNBS assay reveal that 5 g of PLP or POP contain 6.5 mmol of free amino groups and since 1 g of DNA contains 3 mmol of phosphate groups, a polymer, DNA weight ratio of 20:1, as used for biological testing, results in a positive to negative charge ratio of 8.7:1. A poly-L-lysine, DNA weight ratio of 5:1, as used for biological testing, would give a positive to negative charge ratio of 10.2:1, and a poly-L-ornithine, DNA weight ratio of 5:1 gives a positive to negative charge ratio of 11.3. The weight ratios used for biological testing were chosen based on the results of the ethidium bromide assay.

The ζ-potential of the polymeric vesicles and polymeric vesicle DNA complexes was seen to become more positive as the level of polymer increased although in essence the ζ-potential was near neutral at the polymer, DNA ratios (20:1) used for the transfection study (see below and Table 2). This is due to the shielding of the positively charged amino groups by the mPEG chains on the outside of the vesicles. The ζ-potential of the unmodified polymer, DNA complexes was extremely positive at the weight ratios (5:1) used for the transfection studies (Table 2).

Haemocompatibility. The haemolytic activity of PLP vesicle−DNA complexes is significantly higher than that of the parent compound (Figure 5), which is not surprising given the amphiphilic character of these new vesicle forming polymers. The haemolytic activity of POP vesicle

poly-L-ornithine	5:1	+10.3

DNA complexes is also increased with respect to the parent polymer at the highest concentration tested only.

Cytotoxicity Results. Vesicles based on the modified polymers POP and PLP were found to be about 1 order of magnitude less toxic than the unmodified polymers in the A549 and A431 cell lines. IC_{50} values of 0.075 mg mL^{-1} (POP), 0.074 mg mL^{-1} (PLP), 0.007 mg mL^{-1} (PLL), and 0.004 mg mL^{-1} (PO) were found in the A431 cell lines, and IC_{50} values of 0.051 mg mL^{-1} (POP), 0.063 mg mL^{-1} (PLP), 0.007 mg mL^{-1} (PLL), and 0.005 mg mL^{-1} (PO) were found in the A549 cell lines (Figure 6, panels a and b). Complexing the polymeric vesicles with DNA still resulted in a 1−2 orders of magnitude improvement in toxicity when compared to the parent polymers. IC_{50} values of 0.028 mg mL^{-1} (POP), 0.083 mg mL^{-1} (PLP), 0.005 mg mL^{-1} (PLL), and 0.004 mg mL^{-1} (PO) were found in the A431 cell lines, and IC_{50} values of 0.912 mg mL^{-1} (POP), 0.396 mg mL^{-1} (PLP), 0.005 mg mL^{-1} (PLL), and 0.005 mg mL^{-1} (PO) were found in the A549 cell lines (Figure 6, panels c and d).

Transfection Results. POP and PLP vesicles were able to transfect both A549 and A431 cells at a polymer, DNA weight ratio of 20:1 (Figure 7). The use of receptor specific ligands such as folate (*27*), transferrin (*28*), or

galactose (*29*) or lysomotropic agents such as histidyl residues (*30*) or chloroquine (*31*) was not necessary. DNA was used at a high (25 μg mL^{-1}) and a low (12.5 μg mL^{-1}) concentration level, and the unmodified polymers were no superior to DNA alone in every case. In the A431 cell line (Figure 7a), PLP vesicles were significantly better than all other formulations at the lower (12.5 μg mL^{-1}) DNA concentration level being 7.8 times as efficient as poly-L-lysine and 4.9 times as efficient as DNA alone. Also in the A431 cell line, PLP vesicles were significantly better than the unmodified polymer and DNA at the higher (25 μg mL^{-1}) concentration level being 2.4 times as efficient as poly-L-lysine and 2.1 times as efficient as DNA alone.

In the A549 cell line, all formulations were indistinguishable at the lower DNA concentration level. However, at the higher DNA concentration level POP vesicles were significantly better than DNA alone or the parent polymer PO, being 4.5 times better than DNA and 2.3X better than PO, respectively. Also in the A549 cell line at the higher DNA concentration level, PLP vesicles were significantly better than DNA alone and the parent polymer PLL, being 3.5 times better than DNA alone and 2.3 times better than the unmodified polymer PLL, respectively.

This data demonstrates that the polymeric vesicle formulations are able to improve the transfection efficiency of the poly-L-amino acid polymers significantly with increases of up to 8-fold in some cases.

DISCUSSION

We report here the formation of polymeric vesicles prepared from a new class of amphiphilic polymer. The arrangement of the polymer in the bilayer is most probably as depicted in Figure 8. We have shown previously that hydrophobic modification of hydrophilic carbohydrate polymers is an elegant method for the preparation of polymeric vesicles (*6*). Such polymeric vesicles show good stability on storage and have been tested as drug delivery systems (*32*). The vesicles based on these new amphiphilic polymers PLP and POP were also able to encapsulate drugs such as doxorubicin HCl (MW 543.5) with a capacity of more than 10 mg/g of polymer and hence could potentially serve as drug carriers.

The polymeric vesicles efficiently condense DNA (Figure 4) and may thus be anticipated to confer some protection from nucleases in vivo. They are less cytotoxic than the parent polymers (Figure 6) and transfection competent in vitro with an efficacy better than that of the parent linear polymer in most cases (Figure 7). However, due to the amphiphilic nature of PLP, polymeric vesicles are more haemolytic than the parent homopolymer PLL. POP vesicles are no more haemolytic than the parent polymer PO except at the highest concentration. It remains to be seen whether haemolytic activity observed in vitro will preclude their use by the intravenous route in vivo. Preliminary animal experiments to be reported in a subsequent communication revealed no gross toxic effects when CD1 mice were administered 0.5 mg of PLP via the intravenous route while animals administered 0.25 mg of PLL suffered fatalities within hours.

Although the PLP- and POP-based systems may be useful for drug delivery, they were primarily designed as gene delivery systems that combine a number of properties, which have emerged as being potentially important for in vivo gene delivery and which only exist in disparate systems to date.

Modification of the Poly-L-amino Acid Homopolymer. The conjugation of residues such as galactose (*29*), transferrin (*28*), or asialofetuin (*33*) to poly-L-lysine has been used to facilitate receptor-mediated uptake and targeting of polyplexes. The hydrophilic substitution of poly-L-lysine ϵ-amino groups has also been shown to improve the transfection efficiency in vitro (*34*). A 30−50% modification through coupling of δ-gluconolactone reduced the number of amino groups available for interaction with the DNA. The improved dissociation of the polyplex has been suggested as a possible reason for the higher transfection efficiency. This effect may also be involved in the improvements that we observed after the modification of PLL and PO with both lipophilic and hydrophilic moieties. From ^{1}H NMR and TNBS data the degree of substitution in both the POP and PLP polymer can be estimated to be in the order of 33mole%. Polymeric vesicles interacted strongly with plasmid DNA despite this reduction in charged groups available for binding. The reduction in ethidium bromide fluorescence at a polymer, DNA weight ratio of ≥5:1 (a charge ratio of ≥2:1) indicated that DNA was efficiently condensed by the polymeric vesicles. The 2:1 amino-to-phosphate ratio required for DNA condensation is not surprising consid-

Cytotoxicity in (a) A431 cells and (b) A549 cells after incubation with POP and PLP vesicles−DNA complexes (polymer, DNA = 20:1; (+/−) charge ratio = 9:1) and PLL and PO−DNA complexes (polymer DNA = 5:1, (+/−) charge ratio = 10.5:1) for 4 h and (c) A549 cells and (d) A431 cells after incubation with POP and PLP vesicles and PLL and PO polymers for 4 h ($n = 3 \pm$ sd). (■) PLP, chol (5:1) vesicles, (●) POP, chol (5:1) vesicles, (○) PO, (□) PLL.

ering that some of the positive charges are located in the inner leaflet of the polymeric vesicle (Figure 8). However, the exact ultrastructure the polymeric vesicle:DNA complex remains unclear and although intact vesicles are still visible on electron micrographs of the complexes, some additional discrete much smaller units (10−50 nm) were also observed. There was no evidence that DNA was embedded into multilamellar structures as has been reported for cationic lipids (*35*).

Grafting of liposome membranes with 5−10 mol % PEG (MW 2000−5000) dramatically reduces the binding of plasma protein to particulate drug carriers which in turn prevents the rapid vesicle clearance by the reticuloendothelial system, thus reducing blood clearance and extending circulation times (*14*, *36*). Poly-L-lysine−DNA complexes are also rapidly cleared from the systemic circulation with a plasma half-life of 5 min (*37*). Consequently, attempts have been made to utilize the stabilizing properties of PEG chains by synthesizing PLL-PEG block copolymers (*38*, *39*), thus reducing the interaction with serum proteins and attempting to improve the stability of the polyplexes in vivo.

The conjugation of mPEG groups to the amino acid homopolymers reported here, apart from contributing to the amphiphilic nature of the polymer, also serves to shield the positive charges on the surface of these polymeric vesicles, rendering the vesicles with an essentially neutral ζ-potential (−4.16 to +4.65 mV, Table 1). This compares favorably with the ζ-potentials reported by others (*37*) for PLL, DNA complexes at an amine-to-phosphate ratio of 2:1, +30 mV for such mass ratios of greater than 4:1 (*13*), and our data which gives a value of +10 and +18 mV for PO−DNA (5:1 weight ration) and PLL−DNA (5:1 weight ratio), respectively. All measurements performed in our laboratories were performed in PBS (pH 7.4), and hence, any shielding of the charges by the presence of dissolved salts affected all formulations in equal measure. This electroneutrality also suggests that large proportions of the mPEG chains are exposed on the outside of the polymeric vesicle−DNA complex. The formation of a complex with DNA by these electrically neutral polymeric vesicles is possible because of the fluidity of the mPEG chains, which will allow the negatively charged DNA short periods of access to the positively charged amino groups. Most protocols for the formulation of transfection competent lipoplexes or polyplexes require the use of an excess positive charge for the efficient condensation of the plasmid DNA (*15*). Such complexes carry a net positive charge, which is reflected in their extremely positive ζ-potential (>10 mV). The electrostatic interaction between the negatively charged cells and the positively charged complexes facilitates nonspecific binding and subsequent endosomal uptake (*15*). This is advantageous in vitro but poses a problem for the targeted delivery of such carriers and/or delivery in vivo (*40*). It is also one of the main reasons for the frequently observed accumulation of complexes in the first capillary bed that they encounter after injection, i.e.,

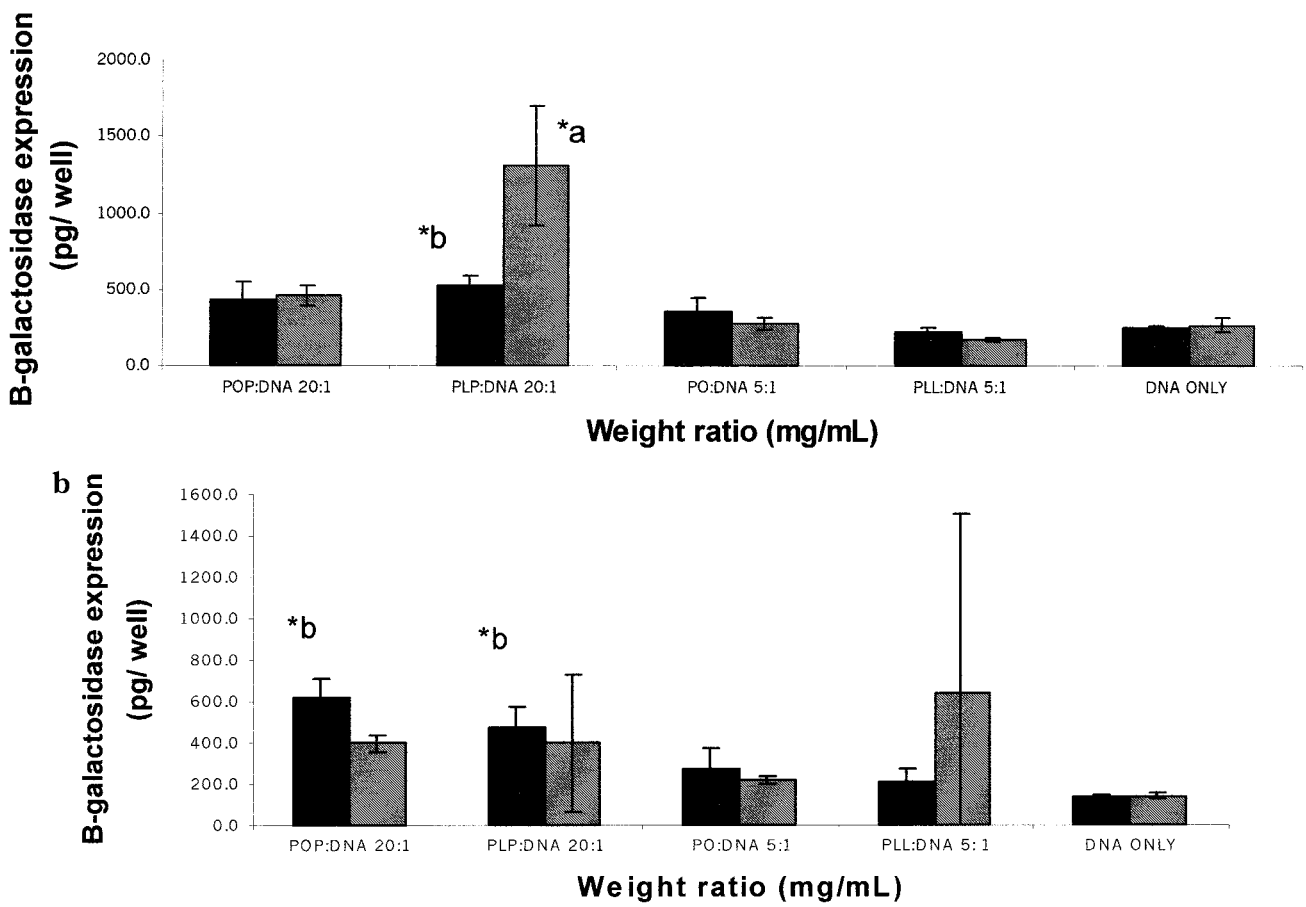

Figure 7. Transfection of pCMVsport-b-gal in (a) the A431 cell line and (b) the A549 cell line with polymeric vesicle formulations, ($n = 3 \pm$ sd), solid bars = 25 μg mL^{-1} DNA and hatched bars = 12.5 μg mL^{-1} DNA, (*a) statistically significant difference ($p < 0.05$) between PLP, chol (5:1) vesicle−DNA formulations and all other formulations and (*b) = statistically significant difference ($p < 0.05$) between polymeric vesicles and parent homopolymers.

the lung (*19*). Targeting of nonviral vectors, i.e., via ligands that bind to specific receptors, is hampered by the presence of excess positive and negative charges (*16*).

The incorporation of PEG in conventional liposomes involves the conjugation of PEG chains to diacyl or dialkyl groups. The properties of such carriers may change, however, with time, as the intermembrane transfer of such conjugates can be quite substantial (*41*). In fact the exchange is rapid enough to allow the "PEGylation" of preformed vesicles within minutes to hours (*42*). Such events will be minimized with the use of polymers bearing pendant PEG groups such as PLP and POP. The complexation of these macromolecules with DNA provides further noncovalent anchorage of PEG groups and is likely to increase the long-term stability of these particulates further.

The polymeric POP and PLP vesicles represent a hybrid system with a unique mixture of polymeric and vesicular properties. The conjugation of lipophilic elements has been used in the past to modify the properties of PLL (*43*). This "lipopoylysine" was based on a low molecular weight poly-L-lysine (MW 3000) to which an average of two dialkylphosphatidyl ethanolamine groups per molecule were conjugated which improved the transfection efficiency by a factor of 100 compared to the unmodified PLL. (*43*). More recently, Kim and others coupled stearyl fatty acid chains to PLL and used this conjugate in conjunction with low-density lipoprotein (LDL) to form complexes of 100 nm which were transfection competent (*44*). However, there have been no reports detailing the attachment of both hydrophobic and hydrophilic elements to amino acid homopolymers. The attachment of palmitoyl groups as well as mPEG groups provided the present polymer with the amphiphilic character required for assembly into vesicles.

Cholesterol. Helper lipids such as DOPE are popular constituents of lipoplexes (*45*). DOPE is generally considered to be one of the most potent helper lipids in vitro (*46*). It acts presumably by facilitating the endosomal escape of the lipoplex (*47*). A number of groups have, however, reported its limitations in vivo and suggested cholesterol as a superior alternative (*20*, *48*). We have therefore chosen cholesterol as the second constituent of our polymeric vesicle system. The inclusion of cholesterol in the systems has also been aimed at increasing the bilayer stability. Neutral gene delivery systems that contain cholesterol have improved half-lives in the bloodstream of mice (*49*). Cholesterol incorporation in the bilayer plus the polymeric nature of the vesicles should provide a more stable complex by preventing serum proteins inserting into the bilayer (*49*), which is thought to be important in the rapid clearance of complexes from the bloodstream (*37*). It is not clear at this time whether the effects of cholesterol in vivo are based on the improved stability or its effects as helper lipid, i.e., improving the intracellular trafficking of the complex.

Cytotoxicity and Haemocompatibility. The amphiphilic derivatives are about 1−2 orders of magnitude less cytotoxic than the respective parent homopolymers (Figure 6). However, the amphiphilic nature of the polymers also means that they interact more strongly with biological membranes. The interaction with eryth-

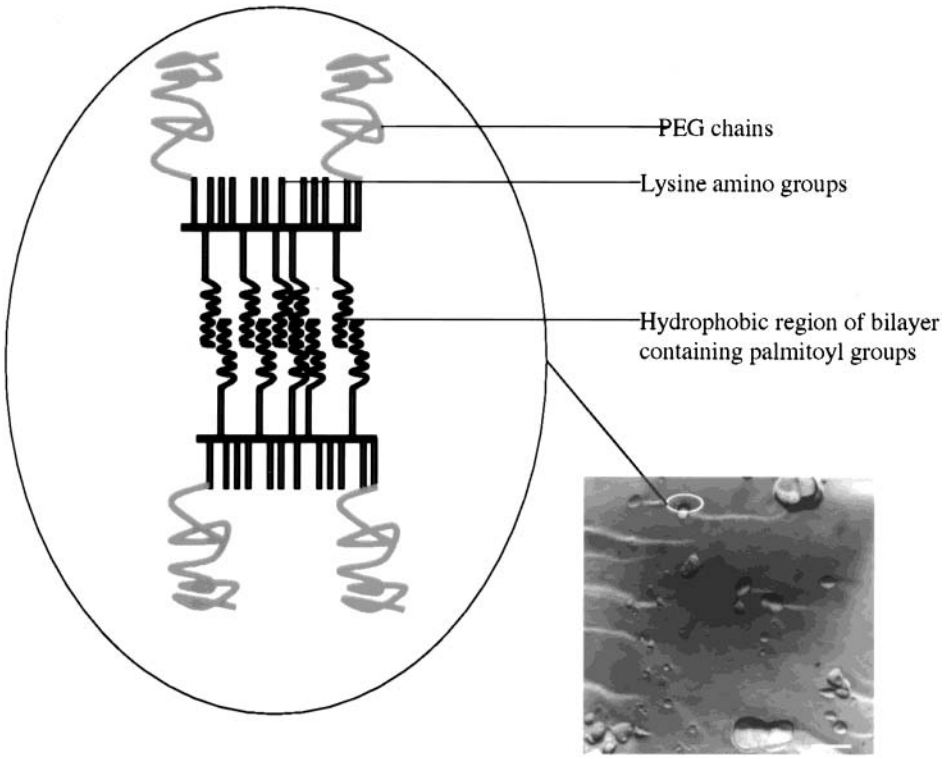

Figure 8. Schematic representation of the organization of the amphiphilic amino acid based polymer in the bilayer.

rocyte membranes and their subsequent lysis has been observed after the administration of cationic lipids and could limit the use of these carriers (*50*), and although the complexation of the cationic lipids to DNA reduces the haemolytic potential (*51*), this may still present a problem for the use of high doses of DNA in humans (*52*). The PLP vesicles show more haemolytic activity than the nonamphiphilic parent polymer−PLL (Figure 6). This could limit their further development as gene delivery systems.

Transfection. The modifications that we have introduced into the homopolymers PLL and PO were designed with the specific problems of in vivo gene delivery in mind. The properties that define a good carrier for in vivo application differ considerably from those, which have been shown to give rise to efficient transfection in vitro. It is not surprising then that the correlation of transfection ability in vitro and in vivo has frequently been shown to be poor (*53*).

Nevertheless, we have studied the ability of our POP- and PLP-based polymeric vesicles in two types of carcinoma cell lines as a preliminary screen. Both types of vesicles transfected both A549 and A431 cells (Figure 7). Transfection efficiency was more than doubled compared to the original polymeric systems and in one case was found to be eight times better. At the higher PLP−DNA concentration in the A431 cell line, transfection efficiency is compromised by the cytotoxicity of the carrier (Figure 7), as the IC_{50} in this cell line for PLP-DNA complexes is 0.083 mg mL^{-1}, but a concentration of 0.5 mg mL^{-1} PLP was applied when DNA concentrations of 25 μg mL^{-1} were used. Higher cell densities were used in the transfection experiments in order to make meaningful observations. With the A549 cell lines a similar polymeric vesicle−DNA concentration of 0.5 mg mL^{-1} and 25 μg mL^{-1}, respectively, did result in an improvement in transfection efficiency when compared to the parent polymers or DNA alone. This is due to the fact that the IC_{50} of POP−DNA and PLP−DNA complexes was higher in this cell line at 0.912 and 0.396 mg mL^{-1}, respectively. This variability in in vitro response underlines the limitations of in vitro assays. While in vitro assays can serve as a crude pointer to efficacy, the results are probably unconnected to the potential of the POP and PLP polymeric vesicles for in vivo gene delivery. The present POP/PLP−DNA complexes bear a neutral surface charge which would probably reduce nonspecific binding to the cells and subsequent uptake (*15, 54*) in vitro. Yet this neutral surface charge would allow specific targeting in vivo once the complexes are conjugated with targeting ligands.

We are currently developing ligand-carrying POP- and PLP-based systems that should allow specific uptake by receptor expressing cells. We are also studying the influence of the modification we have described in this paper on the in vivo transfection efficiency of these systems.

CONCLUSION

Poly-L-amino acids on modification by the attachment of hydrophilic mPEG groups and hydrophobic palmitoyl groups yield a new class of amphiphilic polymers. These polymers form polymeric vesicles in the presence of cholesterol and have been designed with the ultimate aim of producing effective gene transfection levels in vivo, while remaining safe. Such polymeric vesicles are less cytotoxic but more haemolytic than the parent homopolymers. It remains to be seen whether this haemolytic activity will preclude their use via the intravenous route and limit their use to other parenteral routes. The transfer of DNA into live mammalian cells is improved by the use of these polymeric vesicles when compared to the parent homopolymers. This new class of polymeric vesicles bears all the attributes that have been recognized as being favorable for efficient gene delivery in vivo, i.e., the presence of cholesterol, a neutral surface charge and a mPEG surface. They can also support the attachment of targeting ligands for gene targeting.

ACKNOWLEDGMENT

The authors would like to acknowledge Ms. Soryia Siddique who was involved in the early part of this work and Dr. Jane Plumb for useful discussions on the tissue culture experiments.

Targeting the DNA Cleavage Activity of Copper Phenanthroline and Clip-Phen to A·T Tracts via Linkage to a Poly-*N*-methylpyrrole

Marguerite Pitié,[†] J. David Van Horn,[‡] Denis Brion,[‡] Cynthia J. Burrows,*[,‡] and Bernard Meunier*[,†]

Laboratoire de Chimie de Coordination du CNRS, 205 route de Narbonne, 31 077 Toulouse Cedex 4, France, and Department of Chemistry, University of Utah, 315 South 1400 East, Salt Lake City, Utah 84112.
Received May 19, 2000; Revised Manuscript Received September 18, 2000

To target DNA A·T tracts, a three-ring polyamide containing an *N*-methylpyrrole amino acid has been linked, on solid support, to carboxylic derivatives of phenanthroline and dimers of phenanthroline: 2-Clip-Phen, 3-Clip-Phen, or 2-Clip-Phen containing a long tether. After metalation by $CuCl_2$, the DNA cleavage activities of the different conjugates were compared on a restriction fragment. Cleavage patterns showed that the polyamide moiety of conjugates directs the cleavage activity in the vicinity of A·T tracts but the precise cleavage selectivity of these conjugates was dependent on the type of phenanthroline residue linked to the poly-*N*-methylpyrrole entity.

INTRODUCTION

Molecules able to irreversibly modify nucleic acids have received considerable interest because of their potential application as biological tools or as drugs. In addition, compounds that cleave nucleic acids in a sequence-specific manner are useful as reagents for accessing structural and genetic information (*1*−*3*).

1,10-Phenanthroline is a versatile ligand able to chelate copper to give mono-Phen or bis-Phen complexes at the oxidation state + I or + II (*4*). The $(Phen)_2Cu^{I}$ complex in the presence of hydrogen peroxide efficiently cleaves double-stranded DNA by oxidative attack on deoxyribose units from DNA's minor groove (*5*, *6*), while the Phen-Cu^{I} complex is less efficient (*7*). DNA cleavage products include 5′- and 3′-monophosphate ester termini, free bases, 5-methylenefuranone, and a small amount of 3′-phosphoglycolate (*8*−*10*). Hydrogen peroxide can be generated close to the DNA by $(Phen)_2Cu^{II}$ itself in the presence of a reductant and molecular oxygen. Since these Phen complexes have poor sequence selectivity, different conjugates between phenanthroline and targeting DNA ligands (oligonucleotides, Hoescht-33258, DNA binding protein, ...) have been prepared in order to enhance the cleavage specificity (*11*−*17*). However, these chimeric compounds contain only one phenanthroline unit, which is not the best situation for DNA cleavage since the highest cleavage activies have been observed with a Phen:Cu ratio of 2:1.

We have recently prepared 2- and 3-Clip-Phen derivatives containing two Phen ligands linked at the 2′- or 3′-position by a serinol bridge in order to favor the 2:1 Phen:Cu stoichiometry (*18*, *19*). The oxidative nuclease activity of the copper complexes of these new ligands was found to be higher than with Phen itself, by a factor 2 for 2-Clip-Phen but by a factor 60 for 3-Clip-Phen. Conjugates of 2-Clip-Phen with the natural polyamine spermine (a minor groove binder) (*20*) or intercalators such as acridine derivatives (*21*) have shown an enhanced nuclease activity. Analyses of the cleavage pattern of 2-Clip-Phen or its spermine conjugate have revealed, however, that this ligand cleaves DNA practically without sequence selectivity (*20*).

The DNA cleavage selectivity of Clip-Phen derivatives was expected to be enhanced by covalent attachment to specific DNA recognition elements. While there are several potentially suitable DNA binding compounds, we chose to attach Clip-Phen to a well-characterized distamycin-like binder (see ref *22* and references therein). Distamycin is a tri-*N*-methylpyrrole derivative that tightly binds to the minor groove of DNA through a combination of electrostatic interactions, hydrogen bonds, and van der Waals contacts. While this natural product preferentially binds five successive A·T base pairs, several modifications have recently been reported which allow the targeting of multiple sites. In addition, new methods for the preparation of such compounds on a solid support provide the basis for further flexible control of sequence specificity by hybrid nucleases (*23*, *24*).

Since several factors contribute to the specificity of chimeric reagents prepared with 1,10-phenanthroline, we describe here the preparation of four new conjugates. The distamycin analogue linked to a solid support was attached to Phen, 2- and 3-Clip-Phen or to 2-Clip-Phen-hexyl derivatives (see Figure 1). Their DNA cleavage activity has been compared in the same experimental conditions on a restriction fragment.

MATERIALS AND METHODS

Materials. Boc-*β*-alanine-4-carbonylaminomethyl)-benzyl-ester-copoly(styrene-divinylbenzene)resin (Boc-*β*-Pam-resin, 0.5 mmol/g) was from Advanced Chem. Tech. Chloroform was dried on basic aluminum oxide. Other commercially available reagents and all other solvents were purchased from standard chemical suppliers and used without further purification.

1,2,3-Benzotriazol-1-yl-4-[(*tert*-butoxycarbonyl)amino]-1-methylpyrrole-2-carboxylate (*23*), 2-succinoyl-amino-1,3-bis(1′,10′-phenanthrolin-2′-yloxy)propane [2-Clip-Phen-COOH] (*20*), 2-succinoyl-amino,1-(1′,10′)phenanthrolin-2′-yloxy)ethane [2-Phen-COOH] (*20*), 3-Clip-Phen (*19*), and 2-Clip-Phen-hexylamine (*21*) have been prepared as previously described. Boc-Py-Py-Py-*β*-Pam resin precursor was synthesized by manual solid-phase synthesis method (*23*) on Boc-*β*-Pam-resin (0.5 mmol/g).

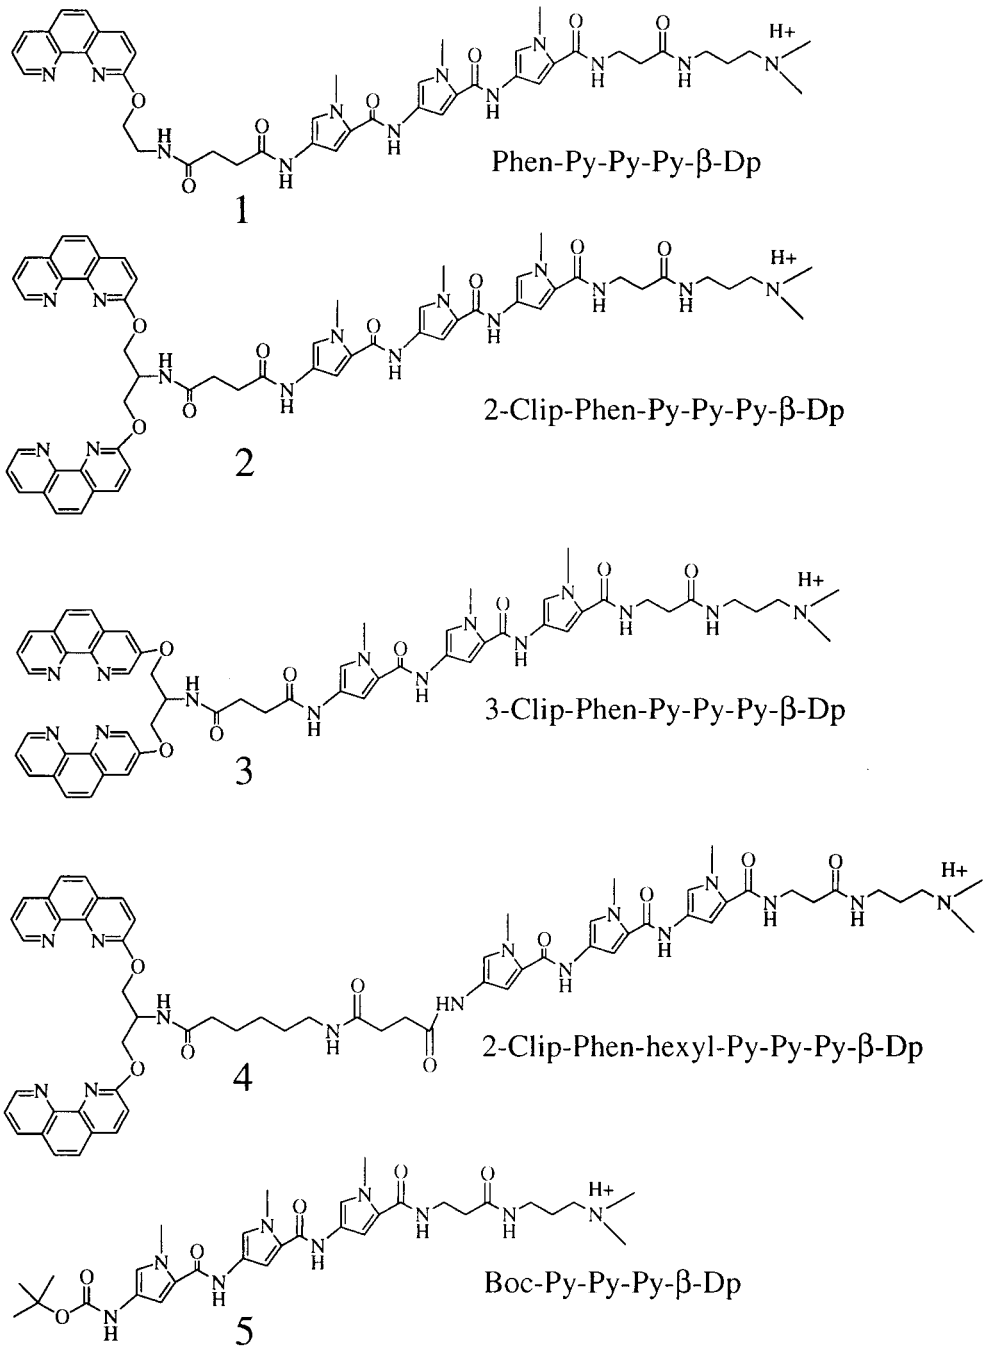

Figure 1. Structures of poly-*N*-methylpyrrole-Clip-Phen (or Phen) conjugates.

HPLC analyses were performed on a reversed-phase Alltima C18 100A 10 μm column (250 × 4.6 mm) from Alltech in 0.1% (v/v) TFA with acetonitrile eluant at a flow rate of 1 mL/min, gradient elution 1.5% acetonitrile/min; the chromatograms were monitored at 255 nm. Preparative HPLC was carried out on a reversed-phase Alphabond C18 10 μm preparative column (150 × 22.5 mm) from Alltech, 0.1% TFA, 1.5% acetonitrile/min, 5 mL/min, or on a reversed-phase Nucleosyl C18 10 μm semipreparative column (250 × 6.2 mm) from Interchim, 0.1% TFA, with 21−28% acetonitrile in 30 min linear gradient, 3 mL/min.

2-Succinoyl-amino-1,3-bis(1′,10′-phenanthrolin-3′-yloxy)propane (3-Clip-Phen-COOH). To a solution of 3-Clip-Phen (59 mg, 0.13 mmol) in 6 mL of dry $CHCl_3$ was added succinic anhydride (30 mg, 0.36 mmol), and the mixture was heated at reflux for 1 h. The product was precipitated after cooling by addition of diethyl ether and centrifuged at 3000 rpm. The pellet was then redissolved in 2 mL of a solution of $CHCl_3/CH_3OH$ (9/1) then precipitated again by diethyl ether to give 3-Clip-Phen-COOH as a pale brown powder (48 mg, 66%). ^{1}H NMR ($CDCl_3$, 250 MHz): δ 9.10 (dd, 2 H, J = 4.5 and 2.0 Hz), 8.85 (d, 2 H, J = 3.0 Hz), 8.47 (d, 1 H, J = 8.0 Hz), 8.17 (dd, 2 H, J = 8.0 and 2.0 Hz), 7.68 and 7.53 (AB, 2 × 2 H, J = 9.0 Hz), 7.55 (dd, 2 H, J = 8.0 and 4.5 Hz), 7.29 (d, 2 H, J = 3.0 Hz), 4.95 (m, 1 H), 4.21 (m, 4 H), 2.84 (m, 4 H). MS (FAB, positive mode, MNBA) m/z 548 (M + H). UV−vis (CH_3OH): 238 nm (ϵ = 75 200 M^{-1} cm^{-1}), 272 nm (ϵ = 54 400 M^{-1} cm^{-1}), 294 nm (sh, ϵ = 29 300 M^{-1} cm^{-1}), 314 nm (sh, ϵ = 10 000 M^{-1} cm^{-1}), 328 nm (ϵ = 7000 M^{-1} cm^{-1}), 348 nm (ϵ = 4700 M^{-1} cm^{-1}).

2-Clip-Phen-hexyl-COOH. To a solution of 2-Clip-Phen-hexyamine (200 mg, 0.35 mmol) in 40 mL of $CHCl_3$, succinic anhydride (100 mg, 0.96 mmol) was added and the mixture was heated at reflux for 1 h. After evapora-

tion of the solvent, the crude product was redissolved in hot methanol, precipitated at −20 ° C and filtered to give 2-Clip-Phen-hexy-COOH as a white powder (133 mg, 56%). ^{1}H NMR (CD_2Cl_2, 500 MHz): δ 9.15 (dd, 2 H, J = 4.0 and 1.5 Hz), 8.42 (d, 1 H, J = 6.5 Hz), 8.30 (dd, 2 H, J = 8.0 and 1.5 Hz), 8.09 (d, 2 H, J = 9.0 Hz), 7.73 and 7.67 (AB, 2 × 2 H, J = 8.5 Hz), 7.65 (dd, 2 H, J = 8.0 and 4.0 Hz), 7.13 (m, 1 H), 7.12 (d, 2 H, J = 9.0 Hz), 5.06 (m, 2 H), 4.86 (m, 3 H), 3.12 (m, 2 H), 2.55 (t, 2 H, J = 7.0 Hz), 2.43 (t, 2 H, J = 7.0 Hz), 2.22 (t, 2 H, J = 7.0 Hz), 1.49 (m, 2 H), 1.35 (m, 2 H), 1.19 (m, 2 H). MS (FAB, positive mode, MNBA) m/z 661 (M + H). UV−vis (CH_3-OH): 226 nm (ϵ = 96 500 M^{-1} cm^{-1}), 276 nm (ϵ = 63 800 M^{-1} cm^{-1}), 296 nm (sh, ϵ = 20 300 M^{-1} cm^{-1}), 322 nm (ϵ = 4000 M^{-1} cm^{-1}), 346 nm (ϵ = 2200 M^{-1} cm^{-1}).

General Protocol of Conjugate Synthesis. Boc-Py-Py-Py-β-Pam resin (ca 0.05 or 0.15 mmol, estimated from initial resin substitution) was placed in a glass peptide synthesis vessel and the Boc group was removed just before use with a 80% TFA/CH_2Cl_2/0.5 M thiophenol solution as previously described (*23*). The resin was then washed with DMF (1×) and CH_2Cl_2 (2×). The carboxylic acid derivative of phenanthroline (40 mM) was activated with 3 equiv of HOBT (1-hydroxybenzotriazole) and 1.7 equiv of DCC in DMF/DIEA (diisopropylethylamine) (2/1) for 5 min; then this mixture was added to the resin and agitated (20 h, room temperature). The synthesis was monitored by analytical HPLC with an aliquot of resin heated in DMAPA [3-(dimethylamino)-1-propylamine] 5 min at 90 ° C (disappearance of the Py-Py-Py-β-Dp peak at 22 min associated to the formation of the conjugate-product peak at 25, 26, or 27 min for conjugates **1**, **2** and **3**, and **4**, respectively). Resin was then isolated by filtration and washed sequencially with an excess of DMF (1×) and CH_2Cl_2 (2×) before being heated in DMAPA for 15 h at 55 ° C. The reaction was then filtered to remove the resin.

Phen-Py-Py-Py-β-Dp (1). Phen-COOH (123 mg, 0.36 mmol) was activated by DCC/HOBT and added to the Py-Py-Py-β-Pam-resin (ca 0.15 mmol). The crude product was obtained in 3 mL of DMAPA then diluted with H_2O and purified by preparative HPLC. Since the isolated product was contaminated by DMAPA, 50% of the material was repurified by preparative HPLC to give, after lyophilization, Phen-Py-Py-Py-β-Dp (**1**) as a yellow powder (22 mg, 25% recovery).^{1}H NMR (DMSO-d_6, 500 MHz): δ 9.90 (s, 2 H), 9.88 (s, 1 H), 9.37 (br s, 1 H), 9.24 (br s, 1 H), 8.90 (br s, 1 H), 8.51 (d, 1 H, J = 8.5 Hz), 8. 47 (br s, 1 H), 8.13 (br s, 1 H), 8.06 (m, 3 H), 7.36 (d, 1 H, J = 8.5 Hz), 7.22 (s, 1H), 7.17 (s, 1 H), 7.15 (s, 1 H), 7.05 (s, 1 H), 6.88 (m, 2 H), 4.67 (m, 2 H), 3.84 (s, 3 H), 3.82 (s, 3 H), 3.81 (s, 3 H), 3.61 (m, 2 H), 3.39 (m, 2 H), 3.12 (m, 2 H), 3.03 (m, 2 H), 2.75 (d, 6 H, J = 4.5 Hz), 2.36 (t, 2 H, J = 7.0 Hz), 1.75 (m, 2H). MS (ES, positive mode, in CH_3CN/H_2O [1/1] with 0.1% TFA) m/z 861.6 (862 calcd for M + H), 431.6 (z = 2, M + 2 H). UV−vis (H_2O): 222 nm (ϵ = 53 400 M^{-1} cm^{-1}), 280 nm (ϵ = 42 600 M^{-1} cm^{-1}), 310 nm (sh, ϵ = 29 200 M^{-1} cm^1). t_R(analytical HPLC): 25 min.

2-Clip-Phen-Py-Py-Py-β-Dp (2). 2-Clip-Phen-COOH (172 mg, 0.32 mmol) was activated by DCC/HOBT and added to the Py-Py-Py-β-Pam-resin (ca 0.15 mmol). The crude product was obtained in 3 mL of DMAPA then precipitated by addition of diethyl ether. The pellet was redissolved in water acidified with formic acid and purified by preparative or semipreparative HPLC. The conjugate was obtained after lyophilization as a yellow powder (24 mg, 11% recovery). ^{1}H NMR (DMSO-d_6, 500 MHz): δ 9.93 (s, 1 H), 9.89 (s, 2 H), 9.31 (br s, 1 H), 9.16 (d, 2 H, J = 3.5 Hz), 8.82 (dd, 2 H, J = 4.5 and 1.2 Hz), 8.82 (1 H), 8. 39 (d, 2 H, J = 9.0 Hz), 8.05 (m, 2 H), 8.00 and 7.93 (AB, 2 × 2 H, J = 8.5 Hz), 7.93 (1 H), 7.33 (d, 2 H, J = 9.0 Hz), 7.21 (d, 1 H, J = 1.5 Hz), 7.16 (s, 2 H), 7. 05 (d, 1 H, J = 2.0 Hz), 6.88 (d, 1 H, J = 1.5 Hz), 6.87 (d, 1 H, J = 2.0 Hz), 4.92 (m, 3 H), 4. 83 (m, 2 H), 3.84 (s, 3 H), 3.81 (s, 3 H), 3.80 (s, 3 H), 3.38 (m, 2 H), 3.11 (m, 2 H), 3.01 (m, 2 H), 2.75 (d, 6 H, J = 4.5 Hz), 2.63 (m, 4 H), 2.35 (t, 2 H, J = 7.0 Hz), 1.74 (m, 2 H). MS (ES, positive mode, in CH_3CN/H_2O [1/1] with 0.1% TFA) m/z 1069.9 (1070 calcd for M + H), 535.7 (z = 2, M + 2 H). UV−vis (H_2O): 218 nm (ϵ = 75 300 M^{-1} cm^{-1}), 276 nm (ϵ = 51 700 M^{-1} cm^{-1}), 316 nm (sh, ϵ = 28 400 M^{-1} cm^{-1}). t_R (analytical HPLC): 26 min.

After DMAPA/diethyl ether precipitation, the conjugate could also be redissolved in DMSO and precipitated by addition of water to give the unprotonated conjugate (17% of recovery). ^{1}H NMR (DMSO-d_6, 250 MHz): δ 9.93 (br s, 2 H), 9.91 (s, 1 H), 9.21 (dd, 2 H, J = 4.2 and 1.5 Hz), 8.85 (d, 1 H, J = 6.5 Hz), 8.56 (dd, 2 H, J = 8.1 and 1.5 Hz), 8.47 (d, 2 H, J = 8.7 Hz), 8.03 and 7.95 (AB, 2 × 2 H, J = 8.6 Hz), 8.02 (m, 1 H), 7. 95 (m, 1 H), 7.83 (dd, 2 H, J = 8.1 and 4.2 Hz), 7.36 (d, 2 H, J = 8.7 Hz), 7.32 (d, 1 H, J = 1.5 Hz), 7.29 (d, 1 H, J = 1.5 Hz), 7.24 (d, 1 H, J = 1.5 Hz), 7.14 (d, 1 H, J = 1.5 Hz), 6.99 (d, 1 H, J = 1.5 Hz), 6.95 (d, 1 H, J = 1.5 Hz), 4.92 (m, 5 H), 3.96 (s, 3 H), 3.93 (br s, 6 H), 3.52 (m, 2 H), 3.19 (m, 2 H), 2.70 (m, 4 H), 2.45 (t, 2 H, J = 7.0 Hz), 2.42 (t, 2 H, J = 7.0 Hz), 2.25 (s, 6 H), 1.65 (m, 2 H). UV−vis (CH_3OH): 230 nm (ϵ = 114 600 M^{-1} cm^{-1}), 276 nm (ϵ = 85 000 M^{-1} cm^{-1}), 292 nm (sh, ϵ = 23 500 M^{-1} cm^{-1}).

3-Clip-Phen-Py-Py-Py-β-Dp (3). 3-Clip-Phen-COOH (48 mg, 0.09 mmol) was activated by DCC/HOBT and added to the Py-Py-Py-β-Pam-resin (ca 0.05 mmol). The crude product was obtained in 1 mL of DMAPA then precipitated by addition of diethyl ether. The pellet was redissolved in water acidified with formic acid and purified by preparative or semipreparative HPLC. The conjugate was obtained after lyophilization as an orange powder (7 mg, 10% recovery). ^{1}H NMR (DMSO-d_6, 500 MHz): δ 9.92 (s, 1 H), 9.89 (s, 1 H), 9.88 (s, 1 H), 9.45 (br s, 1H), 9.13 (d, 2 H, J = 4.0 Hz), 8.96 (d, 2 H, J = 2.0 Hz), 8.85 (m, 2 H), 8.57 (d, 1 H, J = 7.0 Hz), 8.23 (d, 2 H, J = 2.0 Hz), 8.07 (m, 5 H), 7.98 (m, 2 H), 7.19 (s, 1H), 7.17 (s, 1 H), 7.15 (s, 1 H), 7.03 (s, 1 H), 6.88 (s, 1 H), 6.84 (s, 1 H), 4.73 (m, 1 H), 4.52 (m, 4 H), 3.84 (s, 3 H), 3.81 (s, 3 H), 3.79 (s, 3 H), 3.39 (m, 2 H), 3.12 (m, 2 H), 3.02 (m, 2 H), 2.75 (d, 6 H, J = 4.5 Hz), 2.56 (m, 4 H), 2.35 (t, 2 H, J = 7.0 Hz), 1.75 (m, 2H). MS (ES, positive mode, in CH_3CN/H_2O [1/1] with 0.1% TFA) m/z 535.6 (z = 2, 535.5 calcd for M + 2 H), 357.5 (z = 3, M + 3 H). UV−vis (H_2O): 234 nm (ϵ = 69 400 M^{-1} cm^{-1}), 278 nm (ϵ = 48 600 M^{-1} cm^{-1}), 298 nm (sh, ϵ = 41 500 M^{-1} cm^{-1}). t_R (analytical HPLC): 26 min.

2-Clip-Phen-(hexyl)-Py-Py-Py-β-Dp (4). 2-Clip-Phen-hexyl-COOH (59 mg, 0.09 mmol) was activated by DCC/HOBT and added to the Py-Py-Py-β-Pam-resin (ca 0.05 mmol). The crude product was obtained in 1 mL of DMAPA then precipitated by addition of diethyl ether. The pellet was redissolved in water acidified with formic acid and purified by preparative HPLC. The conjugate was obtained after lyophilization as a yellow powder (5 mg, 7% recovery). ^{1}H NMR (DMSO-d_6, 500 MHz): δ 9.89 (s, 2 H), 9.85 (s, 1 H), 9.30 (br s, 1 H), 9.15 (d, 2 H, J = 4.5 Hz), 8.80 (br s, 2 H), 8.63 (d, 1 H, J = 6.5 Hz), 8. 40 (d, 2 H, J = 9.0 Hz), 8.05 (m, 2 H), 8.00 and 7.93 (AB, 2 × 2 H, J = 8.5 Hz), 7.96 (m, 1 H), 7.83 (t, 1 H, J = 7.0 Hz), 7.33 (d, 2 H, J = 9.0 Hz), 7.20 (s, 1 H), 7.16 (s, 1 H), 7. 14 (s, 1 H), 7. 05 (s, 1 H), 6.88 (s, 1 H), 6.85 (d, 1 H),

MS (ES, positive mode, in CH_3CN/H_2O [1/1] with 0.1% TFA) m/z 592.0 ($z = 2$, 592.0 calcd for M + 2 H), 497.1 ($z = 2$, M + 2 H − 197), 395.2 ($z = 3$, M + 3 H). UV−vis (H_2O): 222 nm ($\epsilon = 73\,800\ M^{-1}\ cm^{-1}$), 276 nm ($\epsilon = 51\,500\ M^{-1}\ cm^{-1}$), 308 nm (sh, $\epsilon = 33\,200\ M^{-1}\ cm^{-1}$). t_R (analytical HPLC): 27 min.

Boc-Py-Py-Py-*β*-Dp (5). Boc-Py-Py-Py-β-Pam-resin (ca 0.03 mmol) was heated in 0.5 mL of DMAPA 15 h at 55 ° C. The resin was removed by filtration and the crude product was precipitated by addition of diethyl ether. The pellet was washed with diethyl ether and dried under vacuum before being redissolved in CH_2Cl_2 and precipitated by addition of diethyl ether. The pellet was dissolved in water acidified with trifluoroacetic acid and purified on semipreparative HPLC ($t_R = 20$ min) and lyophilized to give Boc-Py-Py-Py-β-Dp as a white powder (9 mg, 40% recovery). ^{1}H NMR (D_2O, 250 MHz): δ 6.75 (m, 2 H), 6.56 (br s, 1 H), 6.46 (d, 1 H, $J = 1.5$ Hz), 6.40 (d, 1 H, $J = 1.5$ Hz), 6.29 (br s, 1 H), 3.54 (s, 6 H), 3.53 (s, 3 H), 3.42 (t, 2 H, $J = 6.6$ Hz), 3.20 (t, 2 H, $J = 6.6$ Hz), 3.00 (m, 2 H), 2.72 (s, 6H), 2.41 (t, 2 H, $J = 6.5$ Hz), 1.83 (m, 2 H), 1.38 (s, 9 H). MS (ES, positive mode, in CH_3CN/H_2O [1/1] with 0.1% TFA) m/z 640.4 (640.77 calcd for M + H). UV−vis (H_2O): 226 nm ($\epsilon = 21\,500\ M^{-1}\ cm^{-1}$), 306 nm ($\epsilon = 25\,800\ M^{-1}\ cm^{-1}$). t_R (analytical HPLC): 35 min.

Cleavage of 5′-^{32}P-End-Labeled DNA. End-labeled restriction fragment was prepared by sequential digestion of supercoiled pBR322 plasmid DNA with *Eco*RI restriction endonuclease, alkaline phosphatase, [γ-^{32}P]ATP and T4 polynucleotide kinase and then *Rsa*I restriction endonuclease (*25*). The ^{32}P-end-labeled 167 base pair fragment was purified by 8% preparative nondenaturing gel electrophoresis and isolated.

Metalations of the different ligands used in DNA cleavage experiments were carried out using a 1.25 mM $CuCl_2$ concentration with 1 equiv of ligand in water for 1 h at room temperature before dilution of the complex with water to 125 or 25 μM.

Cleavage reactions were carried out in 50 μL total volume containing calf thymus DNA (86 μM nucleotide concentration) and 10^4 cpm of the ^{32}P-end-labeled restriction fragment in 10 mM sodium phosphate buffer (pH 7.2), 100 mM NaCl. After preincubation with complex (1 or 5 μM) for 30 min at room temperature, DNA cleavage was initiated by addition of an aqueous solution of ascorbate (2 μL, 2.5 mM) and samples were incubated for 1 h at 37 °C. 2 μL of a 0.1 M EDTA solution and 8 μL of sodium acetate buffer (3 M, pH 5.2) were then added and samples were precipitated with 120 μL of ethanol. Pellets were rinsed with ethanol and lyophilized. One part of the samples was redissolved in 50 μL of piperidine 0.2 M and heated for 30 min at 90 °C before being lyophilized. Fragments of DNA were analyzed by denaturing 8% polyacrylamide gel electrophoresis. The gels were dried under vacuum and then analyzed using phosphorimagery (Molecular Dynamics). Fragments were identified with respect to Maxam-Gilbert G-sequencing (*26*).

RESULTS AND DISCUSSION

To increase the sequence selectivity of DNA cleavage by Clip-Phen derivatives on a succession of A·T base pairs, four conjugates with the distamycin analogue Py-Py-Py-β-Dp have been prepared (Figure 1). Conjugate **1**, having a less voluminous and sterically constrained nuclease part with only one phenanthroline, has been synthesized for comparison with the efficacy of the two phenanthrolines of Clip-phen derivatives in the cleavage pattern of the conjugates. Conjugates **2** and **3**, with, respectively, 2- and 3-Clip-Phen, allowed analysis of the effect of the bridge position between the two phenanthroline entities of Clip-Phen on the cleavage pattern.

The aliphatic linker between Clip-Phen and poly-*N*-methyl-pyrroles is relatively short (only four single bonds) in conjugates **2** and **3**. Previous reports have been shown that the length of the junction influences both cleavage efficiency and cleavage pattern. Since significant increases in specificity have been obtained in different laboratories for conjugates of poly-*N*-methyl-pyrroles including longer aliphatic linkers (see ref *21* and references therein), conjugate **4** (with 10 single bonds in the spacer) has been prepared for comparison with conjugate **2**. We chose a long 5-methylene spacer in order to increase the flexibility of the linker.

Synthesis Strategy (Figure 2). Phenanthroline amine derivatives were transformed in carboxylic acids by reaction with succinic anhydride. The poly-*N*-methyl-pyrrole portion was synthesized manually on solid support in seven sequential steps from Boc-β-Pam-resin and the Boc-*N*-methyl-pyrrole-OBt synthon (obtained in eight steps from pyrrole) according to Dervan methodology (*23*).

It is known that poly-*N*-methyl-pyrroles are unstable when their N-terminal amine function is unprotected, so we chose to attach the phenanthroline part on this fragile amine in order to protect it without any other modification of conjugates (*23*). This synthetic strategy allowed us to realize the coupling reaction with phenanthroline derivatives on the solid support. This method also provided facile purification (excess of reagents being easily removed and washed by filtration) and avoided isolation of the unstable peptide with the unprotected N-terminal primary amine.

Optimization of the coupling conditions was conducted with the 2-Clip-Phen-COOH derivative. Various attempts to obtain a corresponding activated ester in pure form failed. They included activation of small quantities of 2-Clip-Phen-COOH (less than 0.2 mmol) with DCC/HOBT (1-hydroxybenzotriazole), BOP [(benzotriazol-1-yloxy)tris(dimethylamino)phosphonium]/HOBT or DCC/NHS (*N*-hydroxysuccinimide). In the end, 2 equiv of the carboxylic acid were activated by DCC/HOBT in a DMF/DIEA (diisopropylethylamine) solution, and the crude activation mixture was directly injected into the reaction vessel containing the resin supporting the poly-*N*-methylpyrrole which had been deprotected just before use. After a washing step, the conjugate was cleaved from the support by aminolysis of the resin ester linkage in hot (55 °C) DMAPA [3-(dimethylamino)-1-propylamine] (*23*).

We tried to purify the different conjugates by diluting the crude mixture dissolved in DMAPA with 4 vol of water followed by separation of the product by HPLC on a C18 reversed-phase column. This strategy was tested for purification of conjugate **1**, but it appeared that, at the end of the purification, the conjugate was contaminated with DMAPA and usual small quantity of TFA used in the elution solvant (0.1%; v/v) was unable to neutralize all the amine. Thus, another step of HPLC purification was necessary to remove residual DMAPA from the conjugate. Since alkalinization can damage the C18 column, and conjugates with 2- or 3-Clip-Phen are insoluble in a DMAPA/water mixture, the conjugate dissolved in DMAPA was instead precipitated by addition

Figure 2. (Box) Boc-*N*-methylpyrrole-OBt ester (Boc-Py-OBt) used for peptide synthesis. *Phen*-COOH: 2-Phen-COOH, 2-Clip-Phen-COOH, 3-Clip-Phen-COOH, or 2-Clip-Phen-hexy-COOH.

of diethyl ether in order to remove the major part of the excess amine. The crude product was then dissolved in acidified water and purified by HPLC to give a water-soluble protonated conjugate in a global yield ranging from 7 to 25%. Modifications of the reaction times between the phenanthroline derivative and the peptide, the use of increased equivalents of phenanthroline derivative and activators, or activation of the carboxylic acid group with BOP/HOBT or HBTU [*O*-(benzotriazol-1-yl)-*N*,*N*,*N*′,*N*′-tetramethyluronium hexafluorophosphate] led to similar yields.

Only the global recovery yield of the nine successive steps of the conjugate synthesis can be estimated from the manufacturer's information about the resin substitution. The yield of the coupling reaction between the phenanthroline derivative and the peptide was difficult to determine: (i) The coupling reaction between the phenanthroline derivative and the peptide was monitored by HPLC on aliquots of resin heated in DMAPA by observing the appearance of the conjugate and the disappearance of the unreacted peptide during the reaction. However, various attempts to isolate the unprotected peptide from the resin failed. Only degradated product has been isolated after addition of TFA on the resin in order to remove Boc residues followed by cleavage with DMAPA. Thus, the quantity of unreacted peptide might be underestimated during HPLC monitoring. (ii) Peptide **5** (protected on the N-terminal amine for stability reason), corresponding to the last step before reaction with the phenanthroline derivative, was purified under the same conditions of the conjugates **1**−**4**. During the HPLC purification step, the synthesis seemed efficient since only traces of aborted peptide sequence were

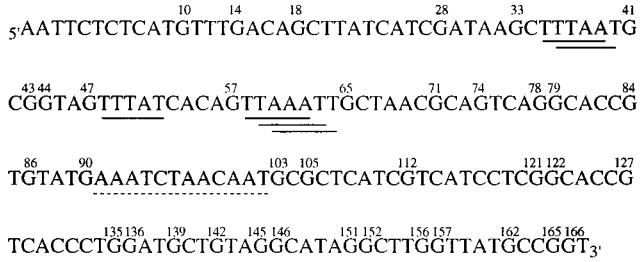

Figure 3. Sequence of the *Eco*RI−*Rsa*I restriction fragment. Preferential binding sites for the distamycin analogue (5 succesive A·T base pairs) are underlined. A secondary binding site observed during cleavage is shown (dashed underline).

observed but only 40% of peptide was recovered. This means that the theoretical peptide quantity can be overestimated in the coupling with the phenanthroline derivative. (iii) During HPLC purification, conjugates were eluted as very broad peaks difficult to collect without loss of material. The peak resolution was better for compound **5** compared to that of conjugate **1**, the worse being for conjugate **4**. Yields were in good correlation with the difficulty of purification.

To reduce the loss of product during the HPLC step, another purification method was optimized in the case of conjugate **2**. After diethyl ether precipitation, the crude product was redissolved in DMSO and precipitated with water. In this case, the conjugate was obtained in the unprotonated form with a better yield (17% versus 11% for HPLC purification).

DNA Cleavage Activity. Conjugates **1**−**4** were metalated with 1 equiv of $CuCl_2$, and their DNA cleavage activities were studied. Comparison of the DNA cleavage

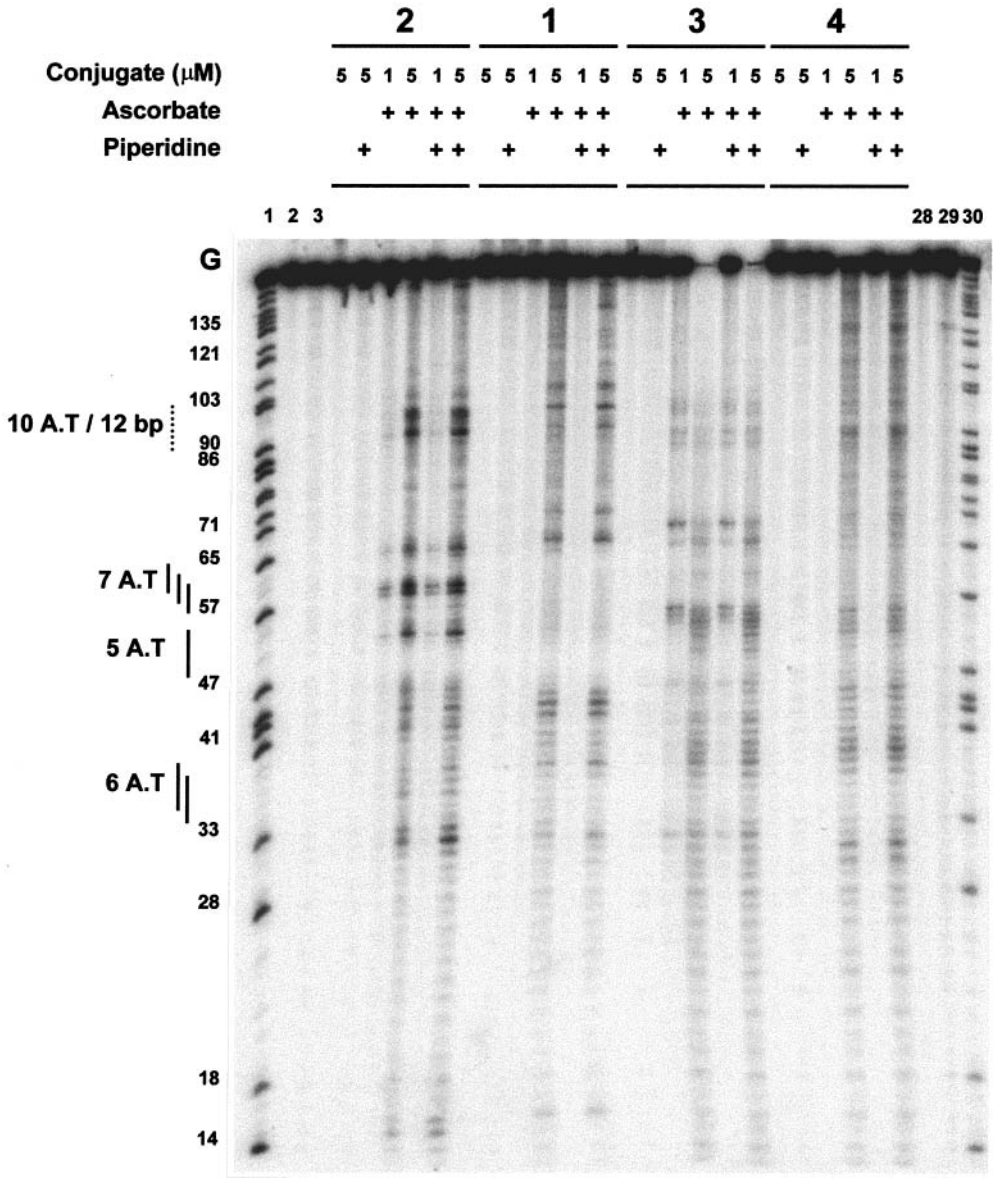

Figure 4. Cleavage of the *Eco*RI-*Rsa*I restriction fragment (10^4 cpm in the presence of 86 μM of random DNA) by conjugates **1**, **2**, **3**, and **4** (1 or 5 μM). The cleavage reaction proceeded for 1 h at 37 °C in the presence of 100 μM ascorbate in 10 mM sodium phosphate buffer (pH 7.2) with 100 mM NaCl. The final concentration of conjugate and piperidine treatment (0.2 M, 30 min at 90 °C) are indicated on the top of the gel. Control experiments were performed with 5 μM of conjugate without ascorbate. Lanes 1 and 30: Maxam−Gilbert G. Lane 2: control DNA. Lane 3: control DNA with piperidine treatment. Lane 28: control ascorbate. Lane 29: control ascorbate with piperidine treatment.

selectivity of these complexes was carried out with the *Eco*RI/*Rsa*I restriction fragment of 167 base pairs from the plasmid pBR322 that was 5′-end labeled with ^{32}P (Figure 3). This restriction fragment contains three sites of high affinity for the distamycin analogue with five, six, and seven successive A·T base pairs, respectively. This sequence has been previously tested for DNA cleavage with (2-Clip-Phen)$CuCl_2$ (results not shown) and with the copper complex of a 2-Clip-Phen-spermine conjugate (*20*), and in both cases, no cleavage specificity was observed.

The DNA target (10^4 cpm) was incubated in the presence of random double-stranded calf thymus DNA (86 μM in nucleotide) with different concentrations of conjugates, and results obtained for 1 and 5 μM of complexes are shown Figure 4. Initiation of the redox activity of these copper complexes was realized by addition of 100 μM ascorbate in the presence of air. The resulting samples were analyzed by PAGE before and after piperidine treatment. Such treatment was performed to reveal all damage mediated by conjugates on their DNA target [direct cleavages (*1*, *27*) and alkali-labile oxidations including base damage (*28*)]. Cleavage sites were determined by comparison with a Maxam−Gilbert G-sequencing lane (*26*).

The four conjugates induced a nonrandom cleavage pattern as confirmed by phosphorimager scanning (Figure 5). Cleavages were confined to localized sites around the three regions containing the successive A·T base pairs highlighted. A secondary binding site was also observed at another A·T rich sequence in which 10 out of 12 base pairs are A·T. This region is also known to be a binding site for distamycin since cleavages at this sequence have been previously observed with the iron complex of EDTA−distamycin conjugate (*29*). No modification of the cleavage pattern was observed after piperidine treatment, indicating that these conjugates performed direct DNA breaks, probably due to deoxyribose oxidation, as is precedented for copper complexes of phenanthroline (*1*).

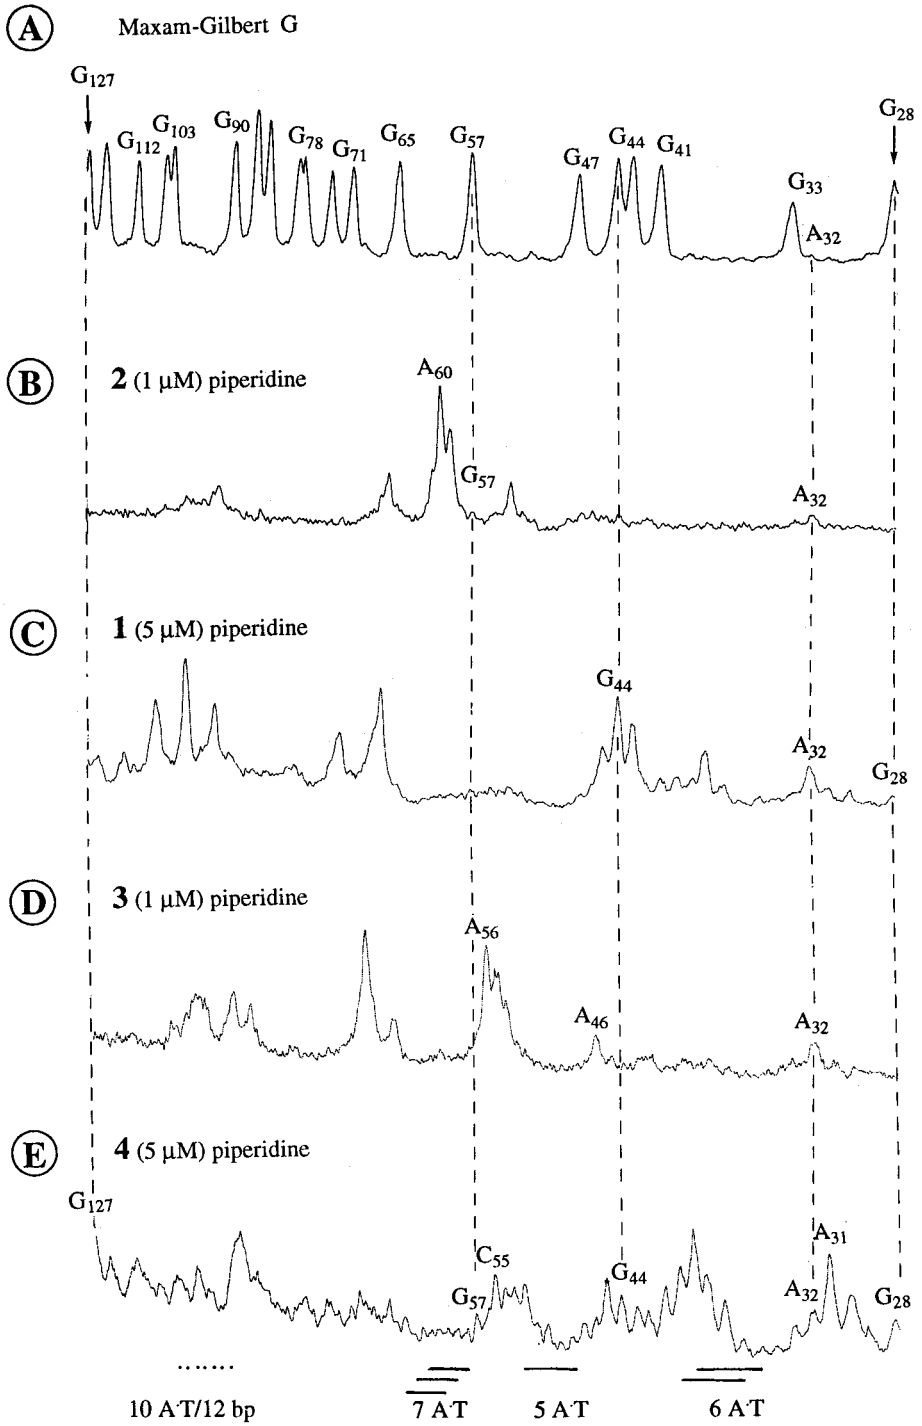

Figure 5. Phosphorimager scanning between G_{28} and G_{127} of the cleavage patterns of the *Eco*RI−*Rsa*I restriction fragment by copper complexes of conjugates **1**, **2**, **3**, and **4** then piperidine treatment. Lane A: Maxam−Gilbert G. Lane B: 1 μM of **2**. Lane C: 5 μM of **1**. Lane D: 1 μM of **3**. Lane E: 5 μM of **4**.

Differences have been observed in the cleavage pattern of each conjugate. As expected, conjugate **3**, with 3-Clip-Phen, was the more active; with 5 μM of the hybrid molecule, nearly all the target was cleaved (compare the residual full-length target in lanes 19 and 21 with other cleavage patterns, Figure 4). At this concentration of **3**, the cleavage pattern was less selective and quantity of small fragments increased dramatically in comparison with cleavage pattern observed for 1 μM of **3** (lanes 18 and 20, Figure 4). This was probably due to multiple cleavages of fragments generated from the target by initial oxidation damage because, for 1 μM of complex, breaks were selectively located around the poly-*N*-methylpyrrole binding sites (see also lane D, Figure 5). Conjugates **1** and **4** were less active DNA cleavers since breaks were only observed with 5 μM complex (lanes 13 and 15 for **1** and lanes 25 and 27 for **4**, Figure 4). The poor DNA cleavage activity of **1** can be explained by the presence of only one phenanthroline unit in the conjugate, complexes of (Clip-Phen)$CuCl_2$ or with two 1,10-phenanthrolines for one copper being known to be more active. The lower cleavage efficiency observed with conjugate **4** indicates that the increase of the tether length between the two parts of conjugate has a negative effect on the cleavage activity. The cleavage pattern obtained with conjugate **4** also showed more diffuse

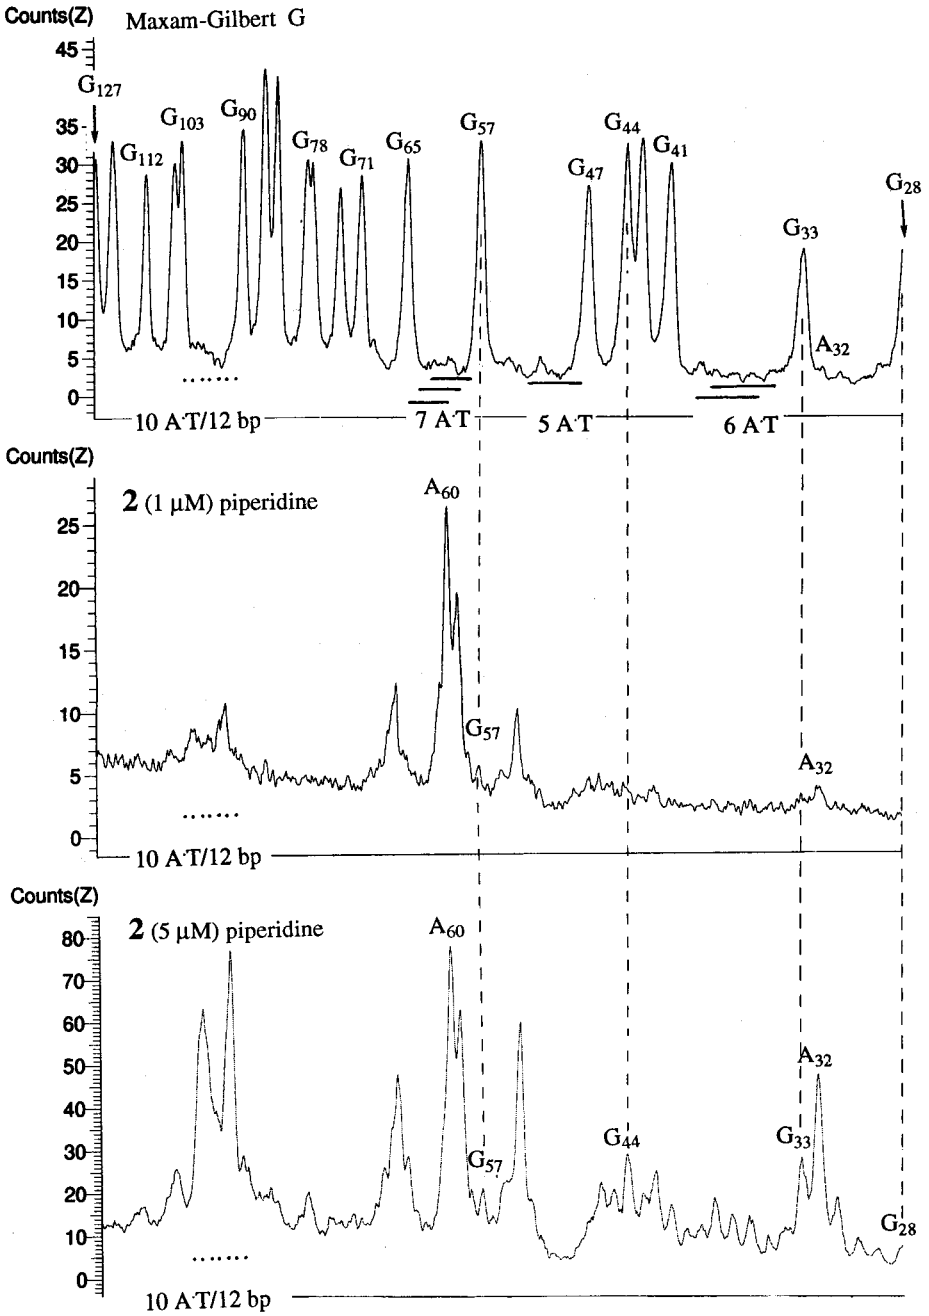

Figure 6. Phosphorimager scanning between G_{28} and G_{127} of the cleavage patterns of the *Eco*RI−*Rsa*I restriction fragment by 1 and 5 μM of copper complex of conjugate **2** then piperidine treatment.

breaks (lanes 25 and 27 Figure 4 and lane E Figure 5). This fact can be attributed to the tether being too long, which allowed the nuclease entity of the conjugate to oxidize a large number of nucleotides around the binding site. A loss of specificity was also observed with **4**.

Major cleavages were observed in the G_{33} to G_{71} region which includes the higher affinity binding site with seven successive A·T base pairs (three overlapping primary binding sites for the poly-*N*-methylpyrrole entity of the conjugates) in the vicinity of other primary binding sites of five and six successive A·T base pairs (Figures 4 and 5). Cleavages were essentially observed on nucleosides on the 5′- and 3′-sides of the higher affinity binding site with a nucleoside preference specific to each conjugate.

In the case of conjugate **2**, cleavage was also observed inside the A·T box (lanes 6−9, Figure 4, and lane B, Figure 5). A comparison of the phosphorimager scanning of the cleavage patterns obtained for 1 and 5 μM of **2** (Figure 6) showed that the cleavage inside the seven A·T base pairs box was preferential for 1 μM of **2**, the quantity of cleavage on the 5′- and 3′-sides of this higher affinity site, the five and six A·T boxes or in the secondary binding site (where 10 out of 12 base pairs are A·T) increasing dramatically for higher concentration of **2** (5 μM).

A comparison of cleavage patterns obtained with copper complexes of **2** and **3** has been done for different experimental conditions including the variation of the concentration of copper complexes, the nature of the buffer (phosphate or Tris), salts (NaCl and $MgCl_2$), and reductant (ascorbate or mercaptopropionic acid), in the presence or not of random double-stranded calf thymus DNA. As it can be observed in Figures 4 and 5, copper complex of **3** (the conjugate with 3-Clip-Phen) cleaved always on the 5′- and 3′-sides of the seven A·T base pairs box when the preferential cleavage site for the copper

complex of **2** (the conjugate with 2-Clip-Phen) was inside this seven A·T box (results not shown).

Another difference in the cleavage pattern was also observed in the case of conjugate **1** (with only one phenanthroline) which was unable to cleave efficiently the sequence between the seven and the five A·T boxes (lanes 13 and 15, Figure 4, and lane C, Figure 5).

These results show that when the peptide part of the conjugates can orient the cleavage around a binding site, a fine specificity of cleavage can be modulated by the position of the bridge joining C2 or C3 of the phenanthroline units of Clip-Phen or by the choice of a system with only one phenanthroline.

CONCLUSION

This work shows that Clip-Phen copper complexes are versatile DNA cleavers which can be easily targeted on a particular DNA sequence by linkage to a specific DNA binder like a poly-*N*-methylpyrrole. The fine-tuning of the cleavage is due to the type of Clip-Phen used in these conjugates and to the tether length. It must be noted that the conjugate based on the 3-Clip-Phen was the most efficient one, indicating that the position of the serinol bridge between the two Phen units has a key role in the redox activity of the ligated copper. Our next goal will be to study if the conjugation of Clip-Phen derivatives also has an influence on the DNA cleavage chemistry of these artificial nucleases.

Low Molecular Weight Disulfide Cross-Linking Peptides as Nonviral Gene Delivery Carriers

Donald L. McKenzie,[†] Elizabeth Smiley,[‡] Kai Y. Kwok,[‡] and Kevin G. Rice*[,†,‡]

Divisions of Medicinal Chemistry and Pharmaceutics, College of Pharmacy University of Michigan, Ann Arbor, Michigan 48109-165. Received May 26, 2000; Revised Manuscript Received August 31, 2000

Cross-linking peptides have been developed by inserting multiple Cys residues into a 20 amino acid condensing peptide that polymerizes through disulfide bond formation when bound to DNA resulting in small, highly stable DNA condensates that mediate efficient in vitro gene transfer [McKenzie et al. (2000) *J. Biol. Chem. 275*, 9970−9977]. In the present study, a minimal peptide of four Lys and two terminal Cys residues was found to substitute for Cys-Trp-$(Lys)_{17}$-Cys, resulting in DNA condensates with similar particle size and gene expression in HepG2 cells. Substitution of His for Lys residues resulted in an optimal peptide of Cys-His-$(Lys)_6$-His-Cys that, in addition to the attributes described above, also provided buffering capacity to enhance in vitro gene expression in the absence of chloroquine. The reported structure−activity relationships systematically explore peptides with combinations of Lys, Cys, and His residues resulting in low molecular weight peptides with improved gene transfer properties.

INTRODUCTION

The size and homogeneity of carrier molecules play a critical role in the success of a nonviral gene delivery system. These two parameters impact the toxicity, antigenicity, and the ability to systematically optimize gene delivery carriers for in vivo applications. A variety of Lys-containing polypeptides (*1*−*5*), dendrimers (*6*, *7*), and polymers such as polyethylenimine (PEI)[1] (*8*, *9*) have been tested for in vitro and in vivo gene delivery. The molecular weight of polylysine or polyethylenimine typically used for gene delivery ranges from 25 000 to over 300 000 amu (*4*, *8*). The high molecular weight (HMW) and heterogeneity of these polymers (*9*, *10*) significantly complicates the ability to develop chemically well-defined conjugates and develop structure activity relationships to optimize gene expression.

Low molecular weight (LMW) carriers could circumvent these problems, provided that they mediate in vitro and in vivo gene transfer as efficiently as their HMW counterparts. Peptides as short as 20 amino acids are able to form small DNA condensates that mediate efficient in vitro gene transfer (*11*−*13*); however, these fail as carriers when tested in vivo due to their lower affinity for DNA, prompting attempts to stabilize LMW carriers bound to DNA to increase their in vivo gene expression (*14*). Trubetskoy et al. inserted stable cross-links onto preformed peptide DNA condensates with heterobifunctional agents resulting in condensates that were active in transfecting cells in culture (*15*, *16*). Adami et al. used glutaraldehyde to cross-link peptide DNA condensates but found an inverse relationship between cross-linking level and in vitro gene expression (*17*). Blessing et al. and Ouyang et al. both incorporated a single sulfhydryl into cationic detergents that underwent dimerization after binding to DNA to form lipids that increased gene expression (*18*, *19*). Recently, LMW peptides possessing multiple Cys residues were introduced as gene delivery agents that form multiple interpeptide disulfide bonds when bound to DNA (*20*). After internalization by the cell, reduction of the cross-linked peptide DNA condensate yielded enhanced levels of gene expression.

In addition to stabilizing peptide DNA condensates, the delivery system needs to facilitate the escape from lysosomal trafficking and delivery of DNA to the cytosol. Several groups have reported methods to facilitate endosomal escape of DNA condensates in vitro by the addition of chloroquine or fusogenic peptides to the transfecting media (*21*−*23*). While these effectively enhance gene transfer in vitro, only recently have fusogenic peptides proven effective for in vivo gene delivery (*23*).

PEI and dendrimers contain secondary and tertiary amines that apparently serve to buffer the endosomal compartment, resulting in osmotic lysis (*24*). Midoux and Monsigny have extended this concept by conjugating His to the side chain of polylysine resulting in a polypeptide that buffers endosomes and enhances gene transfer (*25*).

In the present study, a panel of peptides containing two to eight Lys, one to five His, and either two or three Cys residues was synthesized and evaluated for DNA binding and gene transfer efficiency, in an attempt to further decrease the size of cross-linking peptide carriers and to incorporate endosomal buffering capacity. The results demonstrate that it is possible to substitute short cross-linking peptides for longer sequences, further advancing the concept of LMW cross-linking peptides as novel gene transfer agents.

[a] Masses are calculated as the average mass of the free base.

MATERIALS AND METHODS

N-Terminal Fmoc-protected amino acids, 9-hydroxybenzotriazole (HOBt), diisopropylcarbodiimide (DIC), and diisopropylethylamine were obtained from Advanced ChemTech (Lexington, KY). Substituted Wang resin for peptide synthesis was obtained from ChemImpex (Wood Dale, IL). *N*,*N*-Dimethyformamide, trifluoracetic acid (TFA), acetic acid, acetonitrile, piperidine, and acetic anhydride were purchased from Fisher Scientific (Pittsburgh, PA). LB media, LB agar, D-luciferin, and luciferase from *Photinus pyralis* (EC 1.13.12.7) were obtained from Boehringer Mannheim (Indianapolis, IN). HepG2, COS 7, and CHO cells were from the American Type Culture Collection (Rockville, MD). Inactivated "qualified" fetal bovine serum (FBS) was from Gibco BRL (Grand Island, NY). Bradford reagent was purchased from Bio-Rad (Hercules, CA), and thiazole orange was a gift from Beckton Dickinson Immunocytometry Systems (San Jose, CA). SYBR-Gold was purchased from Molecular Probes, Inc. (Eugene, OR). The 5.6 kb plasmid pCMVL encoding the reporter gene luciferase under the control of the cytomegalovirus promoter was a gift from Dr. M. A. Hickman at the University of California, Davis (*26*). Endotoxin free plasmids were purified from *Escherichia coli* on a Qiagen ultrapure column used according to the manufacturer's instructions, yielding plasmid DNA that was 50:50 supercoiled and open circular as determined by agarose gel electrophoresis. Peptide synthesis was performed on a computer interfaced model 90 Advanced ChemTech solid-phase peptide synthesizer (Lexington, KY). Peptide purification was performed using a semipreparative (10 μm) C_{18} RP-HPLC column from Vydac (Hesperia, CA) on a computer-interfaced HPLC and fraction collector from ISCO (Lincoln, NE). Electrospray mass spectrometry (ES-MS) was performed using a Finnigan LCQ mass spectrometer (San Jose, CA) interfaced with an analytical HPLC from Hitachi (San Jose, CA) using an analytical C18 (5 μm) reversed-phase column from Vydac.

Peptide Synthesis and Characterization. Peptides **1**−**3** (Table 1) were synthesized as previously described (*11*, *20*). All other peptides were synthesized using standard Fmoc procedures with HOBt and DIC double couplings followed by N-capping with acetic anhydride to avoid deletion sequences. The trityl group was used to protect the side-chains of both Cys and His while the Lys side chain was protected with *tert*-butoxycarbonyl. Peptides were cleaved from the resin, and side-chain protecting groups were simultaneously removed by reaction with TFA/EDT/water (95:2.5:2.5 v/v/v) for 1 h at RT.

Peptides were purified to homogeneity using RP-HPLC by injecting up to 6 μmol onto a Vydac C_{18} semipreparative column (2 × 25 cm) eluted isocratically at 10 mL/min with 0.05 v/v% TFA and 2% acetonitrile while monitoring the UV absorbance at 220 nm. The major peak eluting near 20 min was pooled from multiple runs, concentrated by rotary evaporation, lyophilized, and stored dry at −20 °C. Purified peptides were reconstituted in 0.1% TFA (degassed with nitrogen) and characterized by LC-MS by injecting 5 nmol onto a Vydac C18 reversed-phase HPLC column (0.47 × 25 cm) eluted at 1 mL/min with 0.1 v/v% acetic acid containing 0.02 v/v% TFA and an acetonitrile gradient of 0 to 5% over 15 min. The RP-HPLC eluent was directly infused into the electrospray ionization source of a Finnigan LCQ mass spectrometer and mass spectral data was obtained in the positive mode. The amino acid sequence was verified by data dependent ms/ms analysis (*27*, *28*).

The concentration of each purified peptide was determined by fluorescamine analysis using peptide **2** as a standard (*29*). The concentration of each peptide was further verified by ^{1}H NMR using acetone as an internal calibrant. The final purified yield of each peptide was approximately 30%.

The mean pK_a for His residues in peptides **12**−**16** was determined by ^{1}H NMR (*30*−*32*). Each peptide (1 μmol) was prepared in 500 μL of 90:10% v/v of H_2O:D_2O with 0.02% v/v acetone as an internal standard. ^{1}H NMR spectra were obtained on a Bruker 500 MHz spectrometer operated at 23 °C. The pH was measured over the range of 2.5−9.5 using a microelectrode following the addition of 10 μL aliquots of 10 mM sodium hydroxide. The chemical shift of the H2′ proton (8.5−7.6 ppm) was determined at each pH. The mean pK_a was calculated by plotting pH versus the chemical shift as described previously (*30*).

The buffering capacity of peptides **7** and **12**−**16** (Table 1) were compared by dissolving 100 nmol of the acetate salt form of each peptide into 1 mL of 150 mM sodium chloride. The initial pH of 5.5 was titrated down by adding 5 μL aliquots of 5 mM hydrochloric acid while measuring pH using a microelectrode.

Peptide DNA Condensation. Peptide−DNA condensates were prepared by combining 50 μg of DNA in 500 μL of Hepes-buffered mannitol (HBM) (5% w/v mannitol, 5 mM Hepes, pH 7.5) with 0.1−6.5 nmol of peptide in 500 μL of HBM while vortexing to form peptide−DNA condensates with a calculated primary amine to phosphate charge ratio between 0.25 and 8.0 (NH_4^+:PO_4^-). The condensates were allowed to cross-link for 30 min prior to performing physical measurements. The binding of each peptide to DNA was assayed by combining peptide DNA condensates (50 μL) with 950 μL of HBM containing 0.1 μM thiazole orange. The fluorescence of the intercalated dye was measured using an LS50B fluorometer (Perkin-Elmer, U.K.) by exciting at 500 nm while monitoring emission at 530 nm with the slit width set at 15 and 20 nm, respectively. Fluorescence blanks were subtracted from all values before data analysis.

The kinetics of disulfide bond formation of peptides bound to DNA was analyzed indirectly by monitoring the displacement of SYBR-Gold from DNA condensates. Peptide−DNA condensates were formed by combining 20 μg of DNA in 500 μL of HBM containing 1 × SYBR-Gold with 500 μL (26−52 nmol) of peptide in HBM containing 1 × SYBR-Gold to achieve a charge ratio of 4:1 (NH_4^+:PO_4^-). The fluorescence intensity (λ_{ex} 495 nm, λ_{em}

600 nm) was continuously monitored for 30 min to determine the kinetics of cross-linking.

The particle size and ζ potential of peptide DNA condensates were determined by quasielastic light scattering (QELS) using a Brookhaven ZetaPlus. Particle size analysis was performed in triplicate at a DNA concentration of 50 μg/mL in HBM at a charge ratio of 4:1 and a scattering angle of 90°. Data analysis utilized a multimodal volume distribution option included with the instrument. ζ Potential was also determined using 50 μg/mL peptide DNA condensates prepared at a 4:1 charge ratio in HBM. The reported ζ potential was averaged from 10 determinations.

Shear Stress Stability. The relative stability of peptide DNA condensates were examined using a salt sonication assay (*17*). Peptide DNA condensates (200 μL of 50 μg/mL) were formed as described above, incubated at RT for 30 min and then combined with 0−200 μL of 5 M sodium chloride and normalized to 400 μL with HBM to achieve a final sodium chloride concentration of 0, 0.2, 0.4, 0.8, 1.0, 1.5, 2.0, and 2.5 M. Each sample was sonicated for 30 s with a 100 W Microson XL-2000 ultrasonic probe homogenizer (Kontes, Vineland NJ) with a vibrational amplitude of 5 to fragment uncondensed DNA. DNA condensates were digested with 30 μg of trypsin for 12 h at 37 °C, electrophoresed on a 1% agarose gel electrophoresed in TEA buffer for 2 h, then visualized by ethidium bromide staining and destaining prior to photography on a transilluminator.

In Vitro Gene Expression. HepG2 cells (1.5×10^5) were plated on 6 × 35 mm wells and grown to 50% confluency in MEM supplemented with 10% FBS, penicillin, and streptomycin (100 units/mL), sodium pyruvate (100 mM), and L-glutamine (2 mM). Transfections were performed in MEM (2 mL/35 mm well) with 2% FBS with and without 80 μM chloroquine. Peptide DNA condensates (10 μg of DNA in 0.2 mL HBM) were added dropwise to triplicate wells. After a 5 h incubation at 37 °C, the medium was replaced with MEM supplemented with 10% FBS. After 24 h, cells were washed twice with ice-cold phosphate-buffered saline (calcium and magnesium free) and then treated with 0.5 mL of ice-cold lysis buffer (25 mM Tris chloride, pH 7.8, 1 mM EDTA, 8 mM magnesium chloride, 1% Triton X-100, and 1 mM DTT) for 10 min. The cell lysates were scraped, transferred to 1.5 mL microcentrifuge tube, and centrifuged for 7 min at 13000*g* at 4 °C to pellet cellular debris.

Lysis buffer (300 μL), sodium-ATP (4 μL of a 180 mM solution, pH 7, 4 °C), and cell lysate (100 μL, 4 °C) were combined in a test tube, briefly mixed, and immediately placed in the luminometer. Luciferase relative light units (RLU) were recorded on a Lumat LB 9501 (Berthold Systems, Germany) with 10 s integration after automatic injection of 100 μL of 0.5 mM D-luciferin (prepared fresh in lysis buffer without DTT). The RLUs were converted into fmol using a standard curve generated by adding a known amount of luciferase (0.01−100 fmol with specific activity of 2.5 nanounits/fmol) to 35 mm wells containing 50% confluent cells and lysis buffer. Protein concentrations were measured by Bradford assay using bovine serum albumin as a standard (*33*) which determined statistically equivalent ($p > 0.1$) amounts of protein when transfecting with each peptide DNA condensate. The amount of luciferase recovered in each sample was normalized to milligrams of protein and reported as the mean and standard deviation obtained from triplicate transfections.

LipofectAce (Gibco BRL, 1:2.5 w/w dimethyl dioctadecylammonium bromide and dioleoyl phosphatidylethanolamine) was used to mediate gene transfection according to the manufacturer's instructions. The ratio of DNA to LipofectAce was optimized for HepG2 cells. An optimal DNA/LipofectAce ratio was achieved by dissolving 10 μg of DNA in 100 μL of serum free media (SFM) followed by adding 60 μL of LipofectAce prepared in 140 μL of SFM. The LipofectAce DNA complex was then diluted with 1.7 mL of SFM and used to transfect HepG2 cells for 5 h followed by replacing the transfecting media with media supplemented with 10% FBS. The cells were incubated for a total of 24 h, harvested, and analyzed for luciferase as described above.

COS 7 cells (72 000) were plated in 35 mm wells and grown for 24 h to 50% confluency in DMEM (Gibco BRL) supplemented with penicillin and streptomycin (100 U/ml), L-glutamine (4 mM), and 10% FBS. The cells were transfected as described for HepG2 cells. CHO cells (72 000) were grown for 48 h as described above in Ham's F12 media supplemented with penicillin (100 units/mL), streptomycin (100 μg/mL), and 10% FBS then transfected as described above.

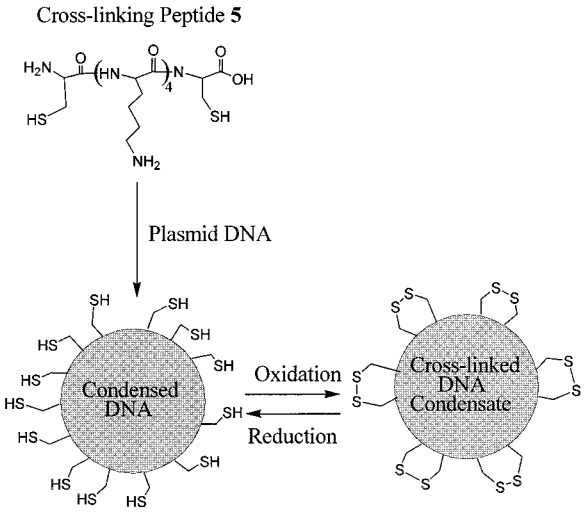

Figure 1. Formation of peptide DNA condensates. Short polylysine peptides containing multiple Cys residues bind to plasmid DNA and spontaneously polymerize through disulfide bond formation resulting in stable peptide DNA condensates.

RESULTS

The number of Lys residues in a DNA condensing peptide can influence the particle size, stability, and gene transfer efficiency of peptide DNA condensates (*11*). Peptides with fewer than 13 Lys residues form increasing larger DNA condensates that dissociate from DNA below a physiological salt concentration (0.15 M) (*11*, *34*). Peptide **1** possesses 18 Lys residues and forms small DNA condensates that are stable in 0.4 M sodium chloride and mediate efficient in vitro gene transfer. However, substitution of an additional Cys residue into this sequence results in cross-linking peptide **3** that significantly increases both the stability of DNA condensates and the in vitro gene transfer efficiency (*20*). Cross-linking peptides function by forming interpeptide disulfide bonds between adjacent peptides bound to DNA resulting in covalent linkages that revert once exposed to the reducing environment of the cell (Figure 1). Here we hypothesize that cross-linking peptides may be further decreased in size while retaining their ability to form small, stable DNA condensates with enhanced gene transfer efficiency. To investigate this, tetra, hexa, octa, and deca peptides **4**−**7** were prepared by systematically

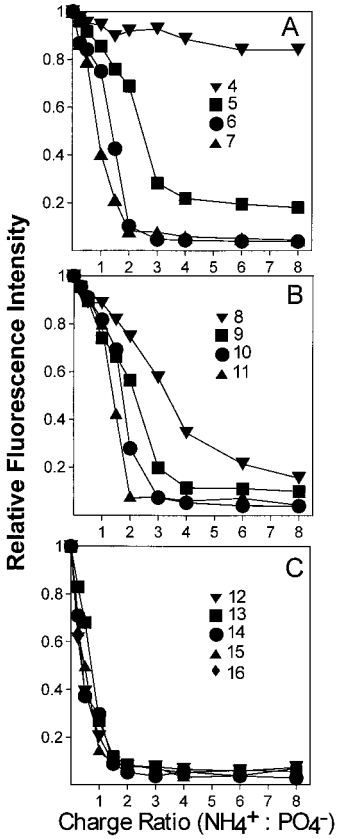

Figure 2. Binding of peptides to DNA. Thiazole orange was used as a displaceable intercalator dye in a peptide titration assay to determine the charge ratio needed to form DNA condensates. Panel A illustrates condensates formed with peptides **4**−**7**, panel B, represents condensates formed with peptides **8**−**11** and panel C shows condensates formed with peptides **12**−**16**. See Table 1 for peptide structures.

increasing the number of Lys residues while keeping the C- and N-terminal Cys residues constant (Table 1). Similarly, penta-, septa-, nona-, and undecapeptides **8**−**11** were prepared by increasing the number of Lys residues while keeping three constant Cys residues (Table 1).

Each peptide was synthesized and purified to homogeneity by RP-HPLC resulting in a purified yield of approximately 30%. LC-MS analysis identified a single peak with molecular weight corresponding to the predicted sequence (Table 1). LC-MS/MS analysis also established y and b fragment ions corresponding to the sequence of the fully reduced peptide. Peptides were maintained in the fully reduced form at pH 2 in deoxygenated 0.1% TFA. However, at neutral pH, and in the absence of a DNA template, cross-linking peptides rapidly oxidized to form disulfide bonds yielding a mixture of cyclic products (data not shown).

To establish the peptide to DNA stoichiometry needed to form DNA condensates, the displacement of thiazole orange from DNA was measured by a decrease in fluorescence intensity as a function of increasing peptide concentration. Titration of DNA with peptides **4**−**7** across charge ratios of 0.25−8:1 (NH_4^+:PO_4^-) resulted in a decrease in the thiazole orange fluorescence that reached a minimum for fully formed peptide DNA condensates (Figure 2A). Peptides **6** and **7** were equivalent at displacing thiazole orange resulting in a maximal inflection at a charge ratio of 2:1. Peptide **5** was less efficient, requiring a charge ratio of 3:1 to condense DNA whereas peptide **4** was even less effective at displacing thiazole

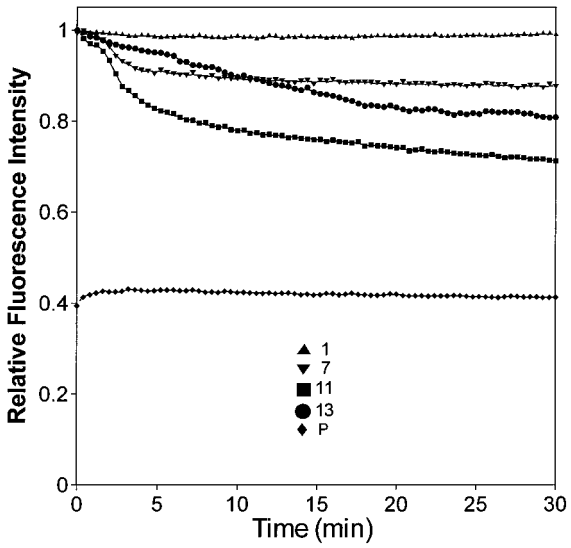

Figure 3. Kinetics of peptide cross-linking on DNA. SYBR-Gold fluorescence intensity was continuously monitored to determine the kinetics of peptide cross-linking on DNA. Representative plots illustrating the kinetics of cross-linking using peptide **7**, **11**, and **13** are compared to the constant fluorescence resulting from non-cross-linking peptide **1** or polylysine$_{1007}$ (**P**) binding to DNA.

orange and apparently failed to form DNA condensates even at a charge ratio of 8. Similar results were obtained for peptides **8**−**11**, establishing that peptide **8** was only able to weakly condense DNA at a charge ratio of 6−8:1 whereas peptides **9**−**11** efficiently displaced thiazole orange resulting in a fluorescence minimum at a charge ratios of 2−4 (Figure 2B). On the basis of these results, subsequent studies utilized a peptide to DNA charge ratio of 4:1 to compare DNA condensates prepared with peptides **5**−**7** and **9**−**11**.

The kinetics of peptide cross-linking on DNA was evaluated using SYBR-Gold as an intercalator dye which, unlike thiazole orange, retains a significant degree of DNA binding and fluorescence intensity even at high peptide:DNA stoichiometry (*20*). Instantaneous formation of peptide DNA condensates using peptides incapable of cross-linking such as **1** or polylysine$_{1007}$, results in a constant SYBR-Gold intensity over time with magnitude inversely related to the affinity of the peptide for DNA (Figure 3). Alternatively, a time-dependent decrease in SYBR-Gold fluorescence intensity results from displacement of fluorophore due to peptide cross-linking on DNA (Figure 3). The results illustrated for peptides **7** and **11** are representative of **4**−**7** and **8**−**11**, respectively, each of which caused a decrease in the SYBR-Gold fluorescence intensity over time reaching an asymptote in 30 min or less indicating reaction completion (Figure 3). Even though cross-linking peptides generate long polymers that form stable DNA condensates as discussed below, the rapid condensation of DNA within seconds followed by the slower process of sulfhydryl cross-linking over 30 min, is apparently less efficient at displacing SYBR-Gold. This leads to a difference in the relative fluorescence intensity at equilibrium for DNA condensates prepared using cross-linking peptides versus polylysine$_{1007}$.

Direct evidence of peptide cross-linking on DNA was determined by measuring the stability of peptide DNA condensates using a salt sonication assay (*17*). Peptide **1** protected DNA from fragmentation up to a sodium chloride concentration of 0.4 M, above which, higher salt concentrations led to dissociation of the peptide and

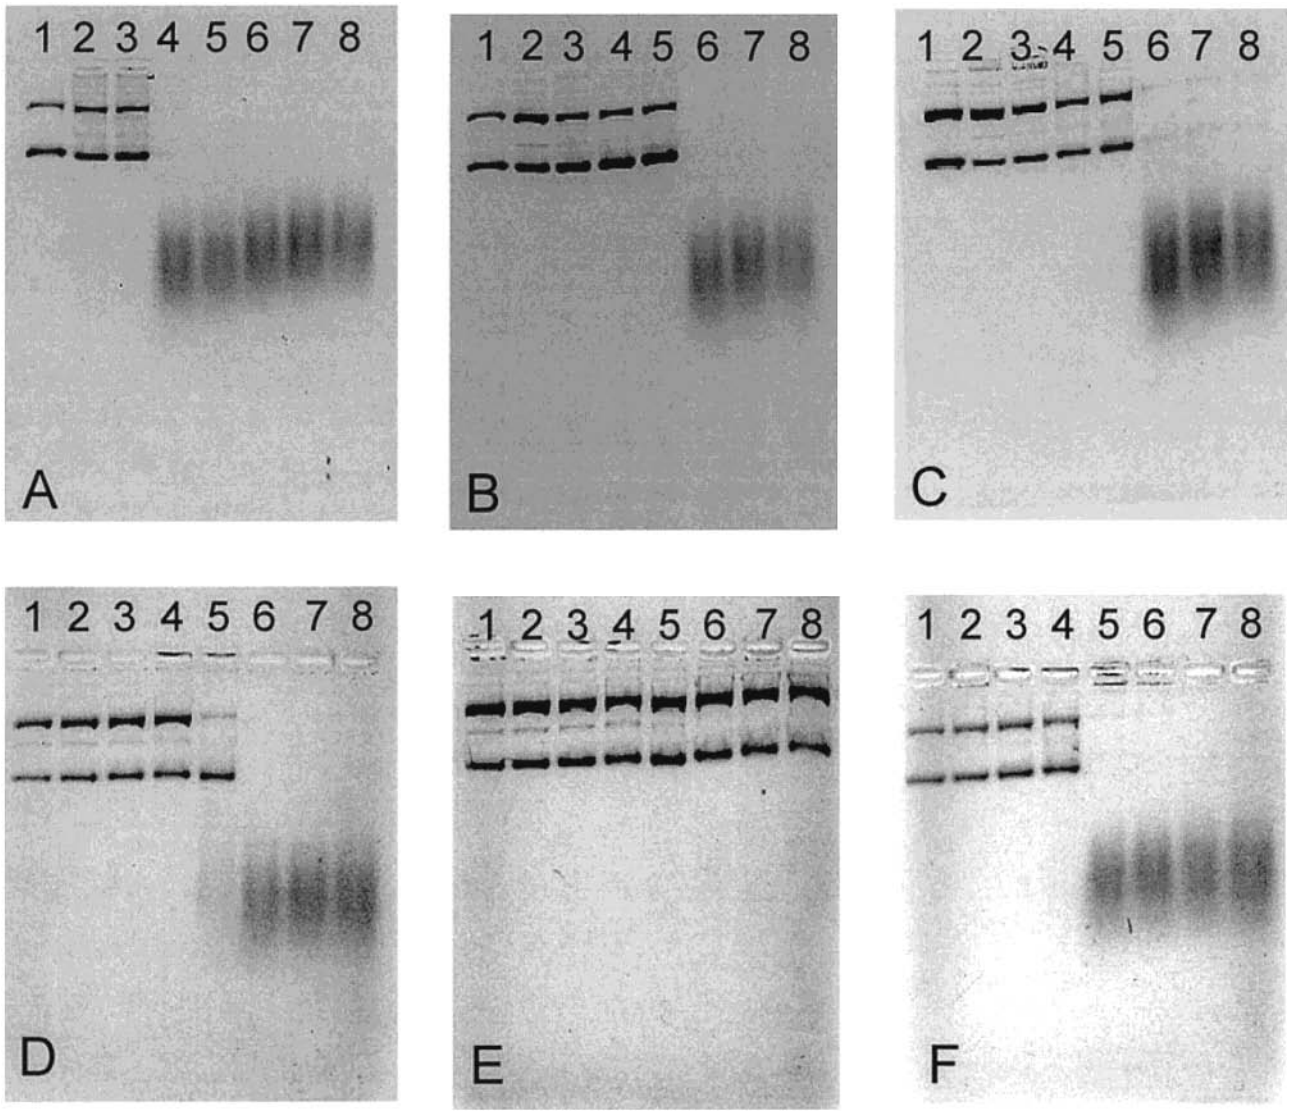

Figure 4. Shear stress stability of peptide DNA condensates. The stability of peptide DNA condensates were analyzed by gel electrophoresis following 30 s sonication in the presence of increasing concentrations of sodium chloride. DNA condensates were formed using peptide **1** (A), **3** (B), polylysine$_{1007}$ (C), **7** (D), **11** (E), and **12** (F). Lanes 1−8 represent sodium chloride concentrations of 0, 0.2, 0.4, 0.8, 1.0, 1.5, 2.0, and 2.5 M sodium chloride, respectively. The results establish DNA condensates prepared with peptides **3**, **7**, and **12** are nearly as stable polylysine$_{1007}$ DNA condensates whereas peptide **11** DNA condensates are completely stable in 2.5 M sodium chloride.

sonicative induced fragmentation of the DNA (Figure 4A). Polylysine$_{1007}$ DNA condensates were found to dissociate above 1 M sodium chloride establishing their greater stability (Figure 4B). Although peptide **3** possesses a similar number of Lys residues as **1**, peptide **3** DNA condensates were also stable in sodium chloride concentrations up to 1 M before dissociation led to sonicative degradation of the DNA (Figure 4C). The enhanced stability of peptide **3** DNA condensates is due to disulfide bond formation since preoxidation of **3**, or reduction of peptide **3** DNA condensates with TCEP, reverted the stability to that of peptide **1** DNA condensates as demonstrated previously (*20*). By comparison, peptide **7** DNA condensates dissociate between 0.8 and 1 M sodium chloride indicating that they are nearly as stable as peptide **3** and polylysine$_{1007}$ DNA condensates (Figure 4D). This result is in contrast to peptide **2** DNA condensates which dissociate below 0.1 M sodium chloride due to the inability to undergo sulfhydryl cross-linking (*34*). Peptides **5** and **6** produced DNA condensates that were somewhat less stable (0.4−0.6 M, not shown) than those produced by peptide **7**, but were still much more stable than peptide **2** DNA condensates (*34*). The stability of peptide **11** DNA condensates established that the addition of a third Cys residue resulted in complete resistance to dissociation up to 2.5 M sodium chloride (Figure 4E). Likewise, peptide **9** DNA condensates resisted dissociation up to 1.5 M sodium chloride, and peptide **10** DNA condensates were stable up to 2.5 M sodium chloride (not shown).

The particle size and ζ potential of each peptide DNA condensate were compared at a charge ratio of 4:1 and a cross-linking time of 30 min. As indicated above, peptide **4** failed to appreciably bind to DNA and could not form DNA condensates detected by QELS. The mean diameter of DNA condensates formed with peptide **5**−**7** was less than 55 nm and compared favorably to DNA condensates prepared using peptide **1** (Table 2). However, the mean diameter of DNA condensates prepared with peptides **9**−**11** were significantly larger (738−1668 nm), most likely resulting from interparticle cross-linking of the internal Cys due to the high molar concentration (163−325 nmol/mL) required to form peptide **9**−**11** DNA condensates (Table 2). In each case, peptides **1**−**3**, **6**, **7**,

[e] Peptide concentration at 4:1 charge ratio was too high for stable signal.

10, and **11** DNA condensates prepared at a charge ratio of 4 had a positive ζ potential ranging from +18−37 mV (Table 2).

The in vitro gene transfer efficiency of peptide **1**, **3**, **5**−**7**, and **9**−**11** DNA condensates prepared at a charge ratio of 4:1 were directly compared in three different cell lines (Figure 5). In each cell line tested, peptide **3** enhanced gene expression by 10−40-fold over peptide **1** DNA condensates (Figure 5). Comparison of peptide **3** to that of peptide **5**, **6**, and **7** DNA condensates indicated that the gene expression in HepG2 cells was maintained when decreasing peptide length by eliminating Lys residues (Figure 5A). This is in contrast to published results on peptide **2** which only forms large DNA condensates of 2.4 μm diameter that transfect HepG2 cells with 4-orders of magnitude-less efficiency relative to peptide **1** (*11*). The gene expression in COS 7 cells was inexplicably 5-fold lower for peptide **7** relative to peptide **3**, **5**, and **6** DNA condensates despite otherwise identical physical properties (Figure 5B). The finding that peptide **5** mediated 3-orders of magnitude lower gene expression in CHO cells relative to peptide **3**, **6**, and **7** (Figure 5C) might be due to the decreased reducing capacity of CHO cells (*35*−*37*). Since peptide **5** DNA condensates theoretically possess twice as many disulfide bonds as peptide **7** DNA condensates, CHO cells that produce lower levels of cytosolic glutathione (*35*−*37*) may be less efficient at reducing endocytosed peptide **5** DNA condensates resulting in lower gene expression.

DNA condensates formed with peptide **9**, **10**, and **11** yielded overall lower levels of gene expression in each cell line relative to peptide **7** DNA condensates (Figure 5). This is most likely related to the large particle size (Table 2) which appeared to be inversely related to gene expression in all three cell lines (Figure 5)

The gene expression mediated by peptide DNA condensates is enhanced approximately 10-fold due to the presence of 80 μM chloroquine in the transfecting media which serves as a lysotropic agent (*24*). Midoux and Monsigny have demonstrated that derivatization of polylysine with His produced DNA condensates that buffer the endosomal compartment and thereby substitute for chloroquine in enhancing peptide mediated gene

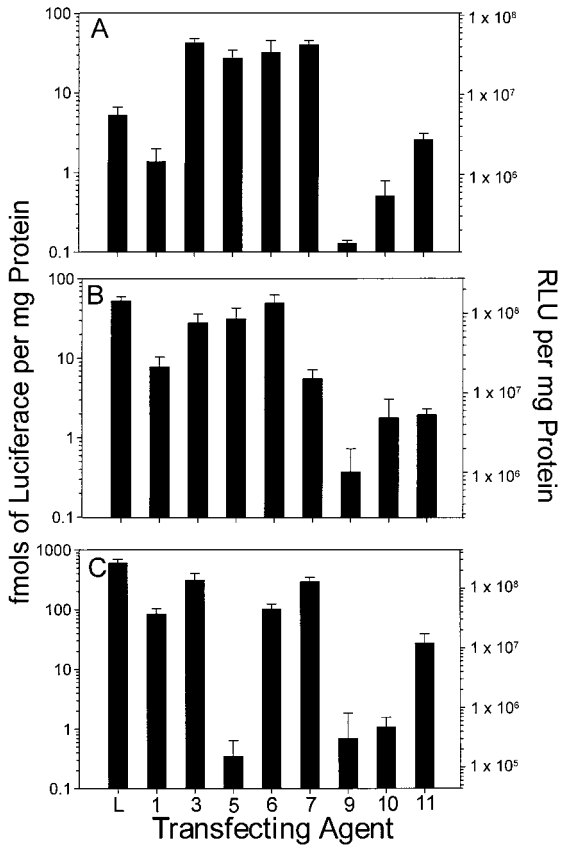

Figure 5. Luciferace expression in HepG2, COS 7, and CHO Cells. The luciferace reporter gene expression for each peptide DNA condensate was measured in HepG2 (A), COS 7 (B), and CHO (C) cells using 80 μM chloroquine during the transfection. Each result represents the mean and standard deviation of three determinations. See Table 1 for peptide structures. L represents LipofectAce.

delivery (*25*). To determine if a similar approach could be applied to enhance the gene transfer of LMW cross-linking peptides, one to five His residues were substituted for Lys residues in **7** to prepare peptides **12**−**16** (Table 1). For this experiment, substitutions were made into **7** as opposed to **6** to allow up to five His residues to be installed while still retaining three Lys residues to mediate binding of the peptide to DNA.

Titration of peptides **12**−**16** with plasmid DNA demonstrated each was equally effective at displacing thiazole orange from DNA, resulting in fully condensed DNA at a charge ratio of 2:1 (Figure 2C). Likewise, analysis of the cross-linking kinetics of peptides **12**−**16** while bound to DNA established reaction completion in approximately 30 min as illustrated by the results for peptide **13** (Figure 3). In each case, a slower cross-linking distinguished His peptides **12**−**16** from that determined for peptides **5**−**11** which may relate to an altered conformational state when **12**−**16** are bound to DNA. Application of the salt sonication assay demonstrated that, like peptide **7**, peptides **12**−**16** formed stable DNA condensates that dissociated above 0.8 M sodium chloride as illustrated using peptide **12** DNA condensates (Figure 4F). In contrast to the similarities between peptide **7** and **12**−**16** described above, particle size analysis revealed that DNA condensates formed with peptides **12**−**16** possessed mean diameters ranging from 87 to 320 nm that increased in proportion to the number of His residues, compared to DNA condensates formed with peptide **7** that had a mean diameter of 53 nm. Despite the larger particle size, peptides **12**−**16** DNA condensates prepared at a charge

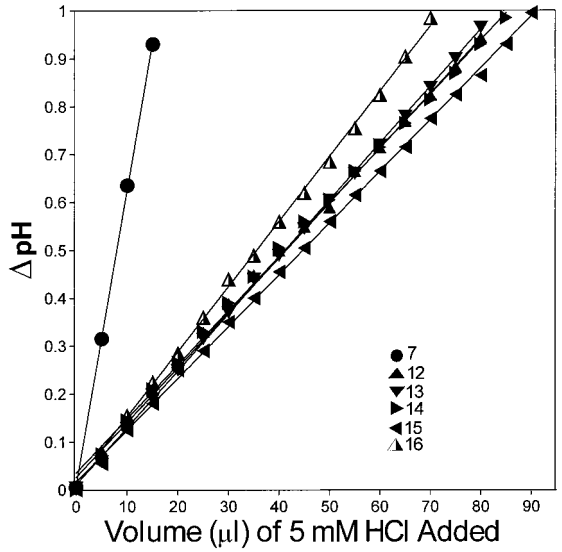

Figure 6. Peptide buffering capacity. The change in pH was monitored for peptides **7** and **12**−**16** by titrating 5 μL aliquots of 5 mM hydrochloric acid into 100 μL of a 0.5 mM peptide solution in 150 mM sodium chloride.

ratio of 4 each had a positive ζ potential ranging from +20−31 mV (Table 2).

The pK_a of cationic polymers such as PEI or dendrimers that buffer endosomes is generally between 5.5 and 7.5 (*24*). To determine if the His residue(s) in peptides **12**−**16** buffer in a similar range, an NMR-based titration established the immidazole side chain in each peptide had a pK_a between 5.5 and 6.0.

Peptides **12**−**16** were compared to peptide **7** in a pH titration experiment to determine if the number of His residues in **12**−**16** would correlate with increasing buffering capacity (Figure 6). Although there was no correlation between and the apparent buffering capacity and the number of His residues in peptides **12**−**16**, each His containing peptide did buffer more efficiently than peptide **7**.

The gene transfer efficiency of peptide **12**−**16** DNA condensates were compared to condensates prepared with peptide **1** and **7** in three cell lines (Figure 7). In the absence (−) of chloroquine, peptide **1** DNA condensates mediated 10−15-fold lower gene expression relative to in the presence (+) of 80 μM chloroquine in each cell line (Figure 7). Peptide **12**− DNA condensates possessing 10% His content mediated 3-fold higher gene expression compared to peptide **7**− DNA condensates in HepG2 cells (Figure 7A). Increasing the His content to 20 or 30% in peptides **13**− and **14**− resulted in a 4-fold enhancement in gene transfection relative to peptide **7**− DNA condensates in HepG2 cells (Figure 7A). The combined contribution of cross-linking and His resulted in gene expression levels for peptide **13**− and **14**− DNA condensates that were equivalent to peptide **1**+ DNA condensates in HepG2 cells (Figure 7A). Peptide **15**− and **16**− DNA condensates were progressively less effective in mediating gene transfer in HepG2 cells despite possessing His content of 40 and 50%, respectively (Figure 7A), presumably the result of an increase in particle size (Table 2). In contrast to the results in HepG2 cells, peptide **12**−**14**− failed to enhance gene expression in COS 7 cells relative to peptide **7**− DNA condensates (Figure 7B). Likewise, the gene expression of peptide **14**− and **15**− DNA condensates were also significantly less in COS 7 cells relative to condensates prepared with peptide **12**− and **13**−. The same comparison in CHO cells established

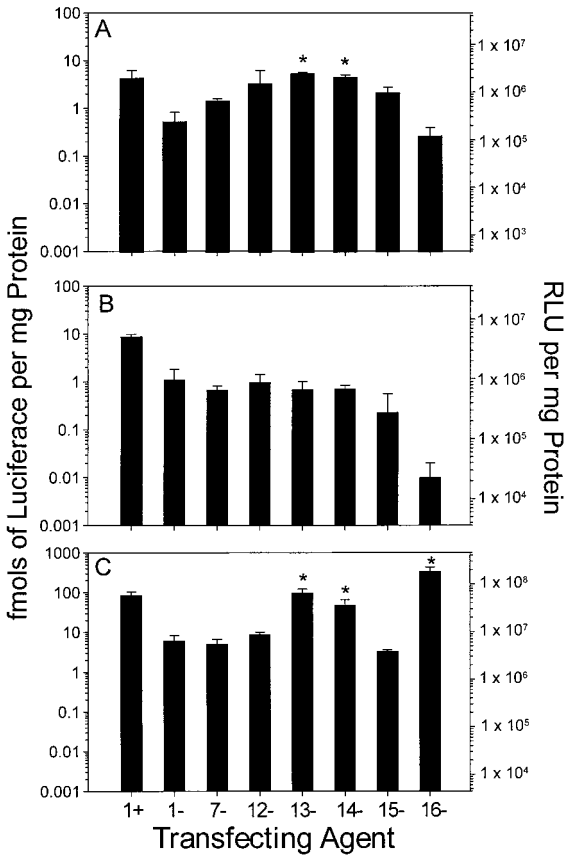

Figure 7. Luciferace expression of endosomal buffered DNA condensates. The luciferace reporter gene expression for peptide DNA condensates in the presence (+) or absence of chloroquine (−) were compared in HepG2 (A), COS 7 (B), and CHO cells (C). Each experimental result represents the mean and standard deviation of three determinations. (*) $p < 0.05$ relative to peptide **7**−. See Table 1 for peptide structures.

that peptide **13**−, **14**−, and **16**− DNA condensates mediated a 10−15-fold enhancement in gene expression relative to peptide **7**− DNA condensates (Figure 7C). The enhanced gene expression of peptide **16**− DNA condensates in CHO cells is an inexplicable result that has been reproduced several times and appears to be contradictory to the trends observed in HepG2 and COS 7 cells.

DISCUSSION

The high molecular weight and polydispersity (*4*, *7*, *9*, *10*) inherent to many nonviral gene transfer agents complicates regiospecific derivatization, characterization, and formulation with DNA. The design of LMW gene transfer agents is an attractive alternative since these can be systematically optimized and may present fewer side effects when used clinically.

In previous studies, we determined peptide **1**, possessing 18 Lys residues, was a minimal peptide to form small (<80 nm) DNA condensates that are stable in 0.4 M saline and transfect cells in culture as efficiently as higher molecular weight polylysine peptides (*11*). Decreasing the number of Lys residues to further shorten chain length such as in peptide **2**, not only led to an increase in the particle size and a three-order of magnitude decrease in the in vitro gene expression level, but also to a loss of stability in normal saline (0.15 M) due to a decrease in DNA binding affinity (*11*, *34*).

The stability of LMW peptide DNA condensates directly relates to in vivo efficacy. Without the aid of a cross-linking strategy, i.v. dosed peptide **1** DNA conden-

sates lack stability in the circulation and are rapidly metabolized without mediating gene expression (*14*). Glutaraldehyde cross-linking provides a means to stabilize LMW DNA condensates for in vivo use but still requires the use of a 20 amino acid peptide to form small condensates.

LMW peptides possessing multiple Cys residues have been proposed as novel gene transfer agents that temporarily form HMW peptides following polymerization on DNA (*20*). Peptide **3** DNA condensates have been shown to form small particles that are comparable in stability to polylysine$_{1007}$ DNA condensates (*20)* (Figure 4). A proposed mechanism involves subsequent reduction in the cell, resulting in the release of DNA and enhanced gene expression relative to peptide **1** DNA condensates. On the basis of these results, we hypothesized that cross-linking peptides could potentially overcome the stability, particle size, and gene transfer limitations described above for very short polylysine peptides. To test this hypothesis, peptides **4**−**11** were compared for their ability to bind, condense, and stabilize DNA and mediate in vitro gene expression.

The results demonstrate peptide **5** as a minimal structure possessing four Lys and two terminal Cys residues that rapidly cross-links on DNA to form small condensates that are stable in 0.4 M salt and mediate gene expression equivalent to peptide **3** DNA condensates in two of the three cell lines tested (Figures 2−5). Peptide **4**, with only two Lys residues, lacked appreciable affinity for DNA and had a greater propensity to undergo internal disulfide bond formation versus template polymerization and was thereby unable to condense DNA.

As anticipated, decreasing the overall length of the peptide from 20 down to 10 residues had little effect on the stability of the cross-linking peptide DNA condensates. Peptide **7** DNA condensates, consisting of eight Lys and two terminal Cys residues, possess the same stability as peptide **3** and polylysine$_{1007}$ DNA condensates (Figure 4). As demonstrated previously, adding an internal Cys to peptide **3** allows for interpeptide cross-linking in addition to linear polymerization which further increases the stability of DNA condensates to above 2.5 M sodium chloride (*20*). Similarly, peptide **9**−**11** DNA condensates were found to be improved in stability although the particle size was much larger. This cannot be the result of too few Lys residues since the particle size of DNA condensates prepared with peptide **5** possessing four Lys residues was 10-fold smaller than that determined for those prepared with peptide **11** possessing eight Lys residues. It is more likely that the internal Cys in peptides **9**−**11** contributes both to interpeptide as well as interparticle cross-linking which occurs rapidly since the particle size determined for peptide **7** or **11** DNA condensates did not change appreciably between 30 min and 24 h. Taken collectively, the data suggest that a small DNA condensate particle size can be achieved with a short, 6−10 amino acid peptide, possessing two terminal Cys residues. Within this size range, additional Cys residues improve stability but significantly increase particle size and thereby decrease in vitro gene expression. Including multiple Cys residues into a 20 amino acid peptide circumvents the problem of increasing particle size (*20*). Although this information is fundamental to the design of a variety of gene delivery systems, when applied to the design of i.v. dosed targeted gene delivery systems, the relationships described for LMW cross-linking peptides binding to DNA will likely change when these are derivatized with poly(ethylene glycol) and targeting moieties such as *N*-glycans (*38*, *39*).

Peptide **7** was selected to determine if substitution of one to five His residues could further enhance expression. The results establish that peptide **13**− and **14**− DNA condensates possessed 4−10-fold enhanced gene expression relative to peptide **7**−, dependent on cell type (Figure 7). Likewise, the gene expression mediated by peptide **1**+ or **13**− DNA condensate in HepG2 and CHO cells were equivalent (Figure 7). These results are in agreement with a previously established mechanism of endosomal buffering for His derivatized polylysine peptides (*25*) and extend this concept by demonstrating that LMW cross-linking peptides can also serve to buffer endosomes and enhance gene expression.

In conclusion, we have extended the concept of LMW cross-linking peptides by identifying the minimal Cys and Lys peptide that polymerizes while bound to DNA leading to enhanced gene expression. The concept of endosomal buffering has been extended by determining the number of His residues in a LMW cross-linking peptide needed to enhance gene expression. Further work is necessary to determine if LMW cross-linking peptides can be used to systematically increase the level of gene expression in vivo.

Synthesis of Polyamidoamine Dendrimers Having Poly(ethylene glycol) Grafts and Their Ability To Encapsulate Anticancer Drugs

Chie Kojima,[†] Kenji Kono,*[,†,‡] Kazuo Maruyama,[§] and Toru Takagishi[†,‡]

Department of Applied Materials Science, Graduate School of Engineering, Osaka Prefecture University, 1-1 Gakuen-cho, Sakai, Osaka 599-8531, Japan, and Department of Applied Bioscience, Research Institute for Advanced Science and Technology, Osaka Prefecture University, 1-2 Gakuen-cho, Sakai, Osaka 599-8570, Japan, and Faculty of Pharmaceutical Sciences, Teikyo University, Sagamiko, Tsukui-gun, Kanagawa 199-0195, Japan

Polyamidoamine dendrimers having poly(ethylene glycol) grafts were designed as a novel drug carrier which possesses an interior for the encapsulation of drugs and a biocompatible surface. Poly(ethylene glycol) monomethyl ether with the average molecular weight of 550 or 2000 was combined to essentially every chain end of the dendrimer of the third or fourth generation via urethane bond. The poly(ethylene glycol)-attached dendrimers encapsulating anticancer drugs, adriamycin and methotrexate, were prepared by extraction with chloroform from mixtures of the poly(ethylene glycol)-attached dendrimers and varying amounts of the drugs. Their ability to encapsulate these drugs increased with increasing dendrimer generation and chain length of poly(ethylene glycol) grafts. Among the poly(ethylene glycol)-attached dendrimers prepared, the highest ability was achieved by the dendrimer of the fourth generation having the poly(ethylene glycol) grafts with the average molecular weight of 2000, which could retain 6.5 adriamycin molecules or 26 methotrexate molecules/dendrimer molecule. The methotrexate-loaded poly(ethylene glycol)-attached dendrimers released the drug slowly in an aqueous solution of low ionic strength. However, in isotonic solutions, methotrexate and adriamycin were readily released from the poly(ethylene glycol)-attached dendrimers.

INTRODUCTION

Dendrimers are unique synthetic macromolecules with highly branched structure and globular shape (*1*−*3*). Because molecular size and generation of dendrimers are increased stepwise via the repetition of a reaction sequence, their size and structure are highly controllable and their molecular weight distribution is generally very narrow (*3*−*5*). In addition, their interior has been shown to be capable of encapsulating various molecules (*6*−*8*). Therefore, application of dendrimers to drug delivery systems has been of great interest, although their use in this field has remained largely unexplored (*9*).

Several attempts have been made to design dendrimers as drug carriers. It has been shown that drug molecules can be combined to dendrimers through covalent bond. For example, Zhuo et al. prepared polyamidoamine (PAMAM)[1] dendrimers with a cyclic core and attached an anticancer drug 5-fluorouracil to the dendrimers (*10*). Also, methotrexate (MTX) was conjugated to the chain ends of hydrazide terminated poly(aryl ether) dendrimers (*11*). Because dendrimers have a large number of terminal groups to which drug molecules can be conjugated, they can carry drugs at a high density.

Another strategy to the design of dendrimers for drug delivery is their use as a container which encapsulates drug molecules. It has been shown that dendrimers with a hydrophobic interior and hydrophilic chain ends are able to solubilize hydrophobic compounds in aqueous solutions (*12*−*14*). Also, small guest molecules can be physically entrapped in the interior of dendrimers with rigid shells, as reported by Meijer and co-workers (*6*, *15*). These studies indicate that dendrimers can act as an unimolecular nanocapsules for small guest molecules.

Considering the use of dendrimers for drug delivery, it is necessary that they are nontoxic and biocompatible. However, it has been demonstrated that widely used dendrimers, such as PAMAM dendrimers and poly(propylene imine) dendrimers bearing primary amino group termini, are quite cytotoxic, and also these dendrimers were cleared rapidly from the circulation when administered intravenously (*16*, *17*).

It has been shown that covalent attachment of poly(ethylene glycol), which is a nontoxic and nonimmunogenic water-soluble polymer, to proteins decreases their immunogenicity and increases their circulation time (*18*, *19*). In addition, a number of studies have demonstrated that poly(ethylene glycol) chains grafted to surfaces of polymer micelles and liposomes suppress their interaction with plasma proteins and cells and prolong their circulation time in the blood (*20*−*24*). Margerum et al. reported that the incorporation of several poly(ethylene glycol) chains to PAMAM dendrimer-based macromolecular polychelates, which were prepared as contrast

agents for magnetic resonance imaging, could increase their blood elimination half-lives (*25*). On the basis of these findings, it seems that dendrimers covered with poly(ethylene glycol) grafts are attractive compounds as drug carriers in vivo. Such molecules are expected to encapsulate drugs in their dendrimer moiety and reveal biocompatibility due to their hydrophilic shell consisting of poly(ethylene glycol) grafts. In earlier studies, several novel polyether dendrimers having poly(ethylene glycol) grafts have been synthesized by collaboration with Fréchet et al. (*26*, *27*). Also, recently, oligoethylene glycol-terminated dendrimers have been synthesized by other groups and some of them have been shown to encapsulate guest molecules in aqueous solutions (*17*, *28*, *29*).

In this study, we designed PAMAM dendrimers having poly(ethylene glycol) grafts as a novel drug carrier having an interior for encapsulation of drugs and a biocompatible surface. The PAMAM dendrimers were chosen because these dendrimers are widely used and well characterized among dendrimers prepared so far. Poly(ethylene glycol) monomethyl ether (M-PEG), with the average molecular weight of 550 or 2000, was attached to chain ends of PAMAM dendrimers of the third or fourth generation. Their ability to encapsulate anticancer drugs, adriamycin (ADR) and MTX (Figure 1), was investigated. Influences of the dendrimer generation and the M-PEG molecular weight on their encapsulation ability have been described.

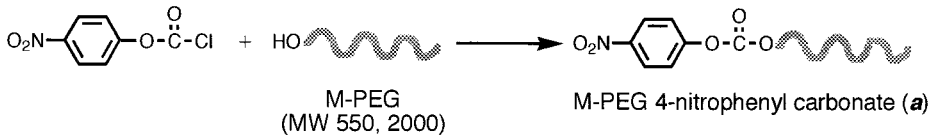
EXPERIMENTAL PROCEDURES

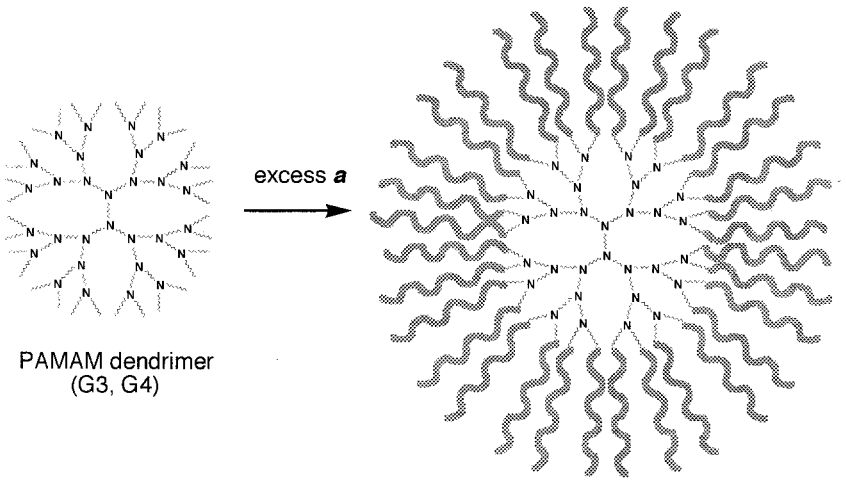
General Methods. PAMAM (Starburst) dendrimers of the third and the fourth generations and M-PEGs with the number average molecular weights of 550 [M-PEG(550)] and 2000 [M-PEG(2000)] were purchased from Aldrich Chemical (Milwaukee, WI). 4-Nitrophenyl chloroformate was obtained from Tokyo Kasei Kogyo (Tokyo, Japan). Tris(hydroxymethyl)aminomethane (Tris), tetrahydrofuran (THF), dimethyl sulfoxide, and *N*,*N*-dimethyl formamide were supplied from Kishida Chemical (Osaka, Japan). ADR-HCl was kindly donated by Kyowa Hakko Kogyo (Tokyo, Japan). MTX was purchased from Sigma (St. Louis, MO). THF was purified by distillation. Dimethyl sulfoxide was distilled under vacuum. ^{1}H and ^{13}C NMR spectra were recorded on a JEOL JNM-LA 400 instrument. The proton chemical shifts (δ) are given relative to internal $CHCl_3$ for $CDCl_3$ solutions and to internal HOD for D_2O solutions. Carbon chemical shifts are given relative to internal sodium 3-(trimethylsilyl)-propionate-2,2,3,3-d_4 for D_2O solutions and to $CDCl_3$ for $CDCl_3$ solutions. The number average molecular weight (Mn) and the weight average molecular weight (Mw) of dendrimers were estimated by gel permeation chromatography (GPC) on a system equipped with a series of two columns (Showa Denko Shodex KD805L and KD803) with differential refractive index detection (Jasco RI-930) using *N*,*N*-dimethylformamide as the eluent. Poly(ethylene glycol) was used as the standard for calibration.

Synthesis of M-PEG 4-Nitrophenyl Carbonate. M-PEG 4-nitrophenyl carbonate was prepared via the reaction of M-PEG with 4-nitrophenyl chloroformate (Scheme 1). M-PEG(550) (3.6 mmol) was dissolved in THF (100 mL). To the solution were added 4-nitrophenyl chloroformate (7.2 mmol) and triethylamine (7.2 mmol), followed by stirring for 24 h at room temperature. M-PEG 4-nitrophenyl carbonate was recovered by evaporation of the reaction mixture and purified using a Sephadex LH-20 column (Pharmacia, ϕ 3.5 cm $\times$ 120 cm) with methanol as the eluent. Yield: 63%. The M-PEG(2000) 4-nitrophenyl carbonate was prepared via the same procedure except for the volume of THF (360 mL) and the reaction time (2 days). The crude product (10 g) was purified by recrystallization from chloroform-diethyl ether (15:1, 320 mL). Yield: 78%. ^{1}H NMR ($CDCl_3$) δ 3.38 (s, OCH_3), δ 3.34−3.80 (m, CH_2CH_2O), δ 4.42 (m, $OCOOCH_2$), δ 7.37 (d, aromatic), δ 8.26 (d, aromatic). ^{13}C NMR ($CDCl_3$): δ 58.97 (OCH_3), δ 68.25, 68.54, 70.25, 70.63, 70.73, and 71.85 (OCH_2CH_2), δ 121.72, 125.23, 145.30, and 152.41 (aromatic), δ 155.42 (OCOO).

Synthesis of M-PEG-Attached PAMAM Dendrimers. The M-PEG-attached PAMAM dendrimers were synthesized via the procedure shown in Scheme 1. To a solution of the third generation (G3) PAMAM dendrimer (14 μmol) in dimethyl sulfoxide (10 mL), M-PEG 4-nitrophenyl carbonate (0.9 mmol) was added and the solution was stirred for 5 days at room temperature. The solution was diluted with distilled water and dialyzed using a dialysis bag (molecular weight 12000−14000 cut off) against distilled water for 24 h. The crude compound was lyophilized and then purified either by a Sephadex G-75 column (Pharmacia, ϕ 4 cm $\times$ 45 cm) using water as the eluent in the case in which M-PEG(2000) was used, or by a Sephadex LH-20 column using methanol as the eluent in the case in which M-PEG(550) was used. M-PEG-attached PAMAM dendrimers with the fourth generation (G4) was prepared by the same procedure except for the amount of the dendrimer (7 μmol). In addition, the acetylated G3 PAMAM dendrimer was prepared by the reaction of the G3 dendrimer (8 mg) and acetic anhydride (4 mL) at 40 °C for 2 h and subsequent dialysis against water. The acetylated G3 dendrimer was recovered by lyophilization. Yields of M-PEG(550)-attached G3, M-PEG(2000)-attached G3, M-PEG(550)-attached G4, M-PEG(2000)-attached G4, and acetylated G3 dendrimers were 77, 32, 79, 39, and 69%, respectively. ^{1}H NMR for M-PEG-attached dendrimers (D_2O) δ 2.28 (br, Hc), δ_{PAMAM} 2.51 (br, He), δ_{PAMAM} 2.70 (br, Hd), δ_{PAMAM} 3.09−3.14 (m, Ha,Hb, Hf), δ_{M-PEG} 3.23 (s, OCH_3), δ_{M-PEG} 3.46−3.72 (m, CH_2CH_2O), δ_{M-PEG} 4.05 (br, $NHCOOCH_2$). ^{13}C NMR for M-PEG-attached dendrimers (D_2O): δ_{PAMAM} 35.3 (Cc), δ_{PAMAM} 39.4 (Cf), δ_{PAMAM} 41.8 (Cb), δ_{PAMAM} 42.5 (Ca), δ_{PAMAM} 51.9 (Cd), δ_{PAMAM} 54.1 (Ce), δ_{PAMAM} 177.1 and 177.5 (CONH); δ_{M-PEG} 60.8 (OCH_3), δ_{M-PEG} 66.9, 61.7, 72.2, 72.4, and 73.8 (OCH_2CH_2), δ_{M-PEG} 161.0 (NHCOO). (See Figure 2).

Scheme 1. Synthesis of M-PEG-Attached PAMAM Dendrimers





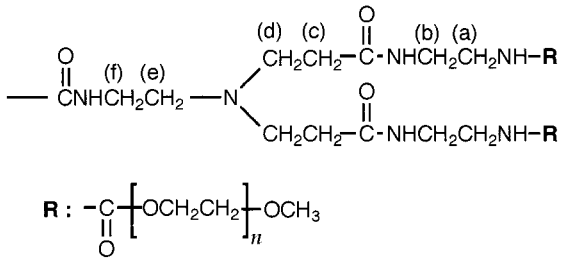


Figure 2. Structure of a part of M-PEG dendrimer.

Encapsulation of Drugs by M-PEG-Attached PAMAM Dendrimers. For the evaluation of encapsulation of ADR by the M-PEG-attached PAMAM dendrimers, a given volume of an ADR-HCl in *N*,*N*-dimethylformamide solution (0.5 mg/mL) was added to the M-PEG-attached PAMAM dendrimer (10 mg) and stirred for 24 h at room temperature in the dark. The solution was evaporated and the residue was further dried under vacuum. Chloroform (2 mL) was added to the dry mixture of the M-PEG-attached dendrimer and ADR and stirred for 6 h to extract a M-PEG-attached dendrimer−ADR complex. The solution was centrifuged at 15 000 rpm for 10 min and the supernatant (1 mL) was evaporated to dryness under vacuum. The dry residue was dissolved in 10 mM acetate-buffered solution of pH 4.5 (1 mL) and the absorbance at 481 nm was measured to determine the amount of ADR. For the encapsulation of MTX by the dendrimers, a given volume of an aqueous MTX solution (1.0 mg/mL) was added to the M-PEG-attached dendrimers (5 mg), stirred for 24 h at room temperature in the dark, and then the mixed solution was lyophilized. Chloroform (1 mL) was added to the residue and stirred overnight in the dark. The chloroform solution of the dendrimer−MTX complex was filtered through a poly(tetrafluoroethylene) membrane (pore size, 200 nm). The filtrate was evaporated, and the residue was dried under vacuum. The obtained dry dendrimer−MTX complex was dissolved in 0.01 M NaOH (2 mL). An aliquot (100 μL) of the solution was added to an aqueous 0.1 M Tris-HCl solution (pH 8.0, 900 μL), and the absorbance at 372 nm was measured to determine the amount of MTX.

Release of Drugs from M-PEG-Attached PAMAM Dendrimers. The release of ADR and MTX from the M-PEG-attached dendrimers was estimated as previously reported (*26*). The M-PEG-attached PAMAM dendrimer containing ADR was prepared by adding 3 equiv of ADR-HCl to 1 equiv of dendrimer via the above procedure. The ADR-containing dendrimer was dissolved in phosphate-buffered saline (PBS) (pH 7.4, 1.0 mL) and transferred to a dialysis bag (molecular weight 12000−14000 cut off). The dialysis bag was immediately placed in 20 mL of PBS and the fluorescence intensity of ADR in the outer phase was monitored using a spectrofluorometer (Shimadzu RF-5000). The excitation and monitoring wavelengths were 471 and 554 nm, respectively. For the evaluation of the MTX release from the M-PEG-attached PAMAM dendrimers, the MTX-loaded dendrimer was prepared by adding 24 equiv of MTX to 1 equiv of the dendrimer and dissolved in 1 mM Tris-HCl-buffered solution (pH 7.4, 2.0 mL) either containing or not containing 150 mM NaCl. The solution was transferred to a dialysis bag, placed in 20 mL of the same Tris-HCl-buffered solution, and the absorbance of MTX at 372 nm in the outer phase was followed using a spectrophotometer (Jasco V-520).

RESULTS AND DISCUSSION

Synthesis and Characterization of M-PEG-Attached PAMAM Dendrimers. We examined conjugation of poly(ethylene glycol) chains to amino groups at chain ends of the PAMAM dendrimers through urethane bonds (Scheme 1). Thus, M-PEGs with the molecular weights of 550 and 2000 were reacted with 4-nitrophenyl chloroformate to obtain M-PEG 4-nitrophenyl carbonate. Two equivalents of the reactive M-PEG were added to 1 equiv of the terminal amino group of the G3 or G4 PAMAM dendrimer. Figure 3 shows the ^{1}H NMR spectra for the PAMAM G3 dendrimers (A) and M-PEG(550) used

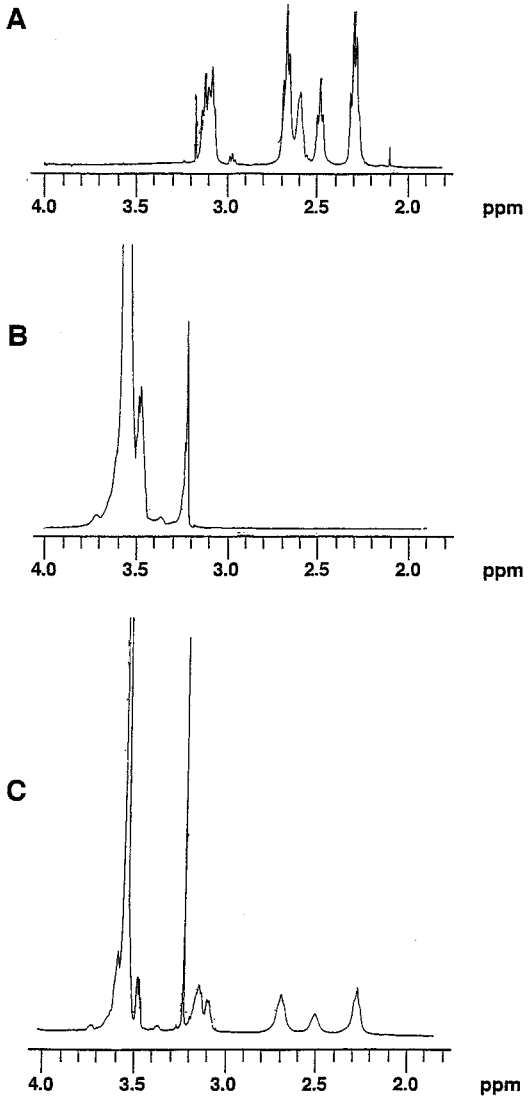

Figure 3. ^{1}H NMR spectra for PAMAM G3 dendrimer (A), M-PEG(550) (B), and M-PEG(550)-G3 dendrimer (C) in D_2O.

for the synthesis (B), and the resultant M-PEG(550)-G3 dendrimer (C). It is apparent that the spectrum of the M-PEG(550)-G3 dendrimer contains signals originating from both the PAMAM G3 dendrimer and M-PEG(550). From the integral ratio of the signal at 2.2−2.3 ppm, which corresponds to the protons of methylenes next to carbonyl groups of the dendrimer, to the signal at 3.23, which corresponds to the protons of the terminal methyl group of M-PEG(550), the average number of M-PEG-(550) chains in the M-PEG(550)-attached G3 dendrimer was estimated to be 33, which agrees with the number of terminal amino groups of the dendrimer. This result implies that an M-PEG chain is combined to every chain end of the dendrimer.

The attachment of M-PEG chain to the chain end of the dendrimer was further confirmed by ^{13}C NMR spectra for these dendrimers (Figure 4). The PAMAM G3 dendrimer showed peaks at 43.7, which corresponds to the carbons next to the terminal amino groups (Figure 4A). However, in the spectrum of the M-PEG-attached dendrimer (Figure 4B), the peak at 43.7 ppm completely disappeared and, instead, a new peak appeared at 42.5 ppm, indicating that every terminal amino group was combined to an M-PEG chain.

The average number of M-PEG chains in the M-PEG-attached PAMAM dendrimers prepared was evaluated

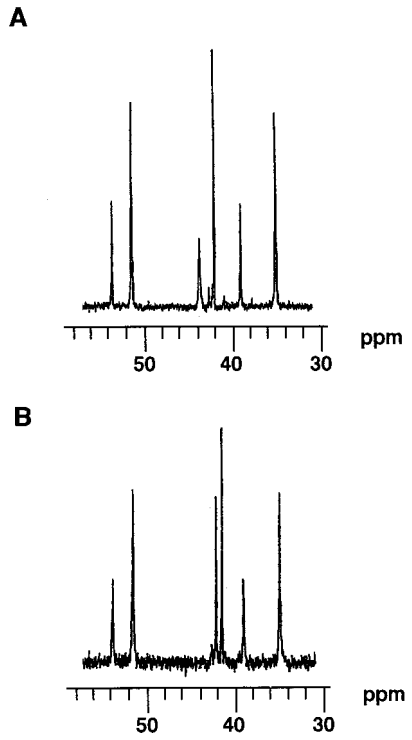

Figure 4. ^{13}C NMR spectra for PAMAM G3 dendrimer (A) and M-PEG(550)-G3 (B) dendrimer (C) in D_2O.

Table 1. Synthesis of M-PEG-Attached Dendrimers

dendrimer	no. of terminal amino group (mol/mol)	no. of M-PEG/dendrimer (mol/mol)	
		in feed	attached
acetylated G3	32	excess	30
M-PEG(550)-G3	32	64	33
M-PEG(2000)-G3	32	64	35
M-PEG(550)-G4	64	128	65
M-PEG(2000)-G4	64	128	63

from their ^{1}H NMR spectra and listed in Table 1. The average number of M-PEG chains attached to the G3 and G4 dendrimers were 33−35 and 63−65, respectively, and are in close agreement with the number of terminal amino groups of the corresponding dendrimers. These results indicate that essentially every terminal amino group combined with an M-PEG chain.

The molecular weights of the M-PEG-attached PAMAM dendrimers were evaluated by GPC analysis. Typical chromatograms for samples of the M-PEG(550)-G4 and the M-PEG(2000)-G4 dendrimers as well as M-PEGs used for the preparation of these modified dendrimers were shown in Figure 5. Peaks of free M-PEG(550) and free M-PEG(2000), which appear at the retention volume of ca. 21 and ca. 20 mL, respectively, were not seen in the chromatograms of these M-PEG-attached dendrimers, indicating that these samples did not contain free M-PEGs. These M-PEG-attached dendrimers showed a sharp peak at ca. 15 or ca. 16 mL, suggesting that their molecular weight distribution is very narrow. However, these sharp peaks were accompanied by small shoulder peaks corresponding to species with higher molecular weights. It is known that commercially available M-PEG is frequently contaminated with telechelic PEG diol. The PEG diol contained in the starting material may have become derivatized with two 4-nitrophenyl carbonate groups on both terminals of its chain by the reaction with 4-nitrophenyl chloroformate. This molecule could cross-link PAMAM dendrimers. Formation of cross-linked

product due to the contamination of PEG diol of the commercially available M-PEG has been observed previously (*26*).

The weight average molecular weight (Mn), the number average molecular weight (Mw) and the polydispersity index (Mw/Mn) for the M-PEG-attached PAMAM dendrimers and the acetylated G3 PAMAM dendrimer were estimated from the peak of the chromatogram and listed in Table 2. As mentioned above, the Mw/Mn ratios for these modified dendrimers were generally close to 1, indicating that their molecular weight distribution is very narrow. However, these molecular weights of the modified dendrimers estimated by GPC were much lower than their nominal molecular weights, indicating that these molecules are very compact as was previously observed in the case of the starburst dendrimers and other types of dendrimers (*1*, *30*).

Tomalia et al. (*1*) have reported that the hydrodynamic diameters of PAMAM dendrimers can be estimated by using a size-exclusion chromatography column calibrated with poly(ethylene glycol) standards and applying an equation developed by Hester and Mitchell (*31*). According to the method of Tomalia et al., the hydrodynamic diameters of the acetylated G3, the M-PEG(550)-G3, and the M-PEG(2000)-G3 dendrimers were estimated to be approximately 3.5, 6.4, and 12.5 nm, respectively, in *N*,*N*-dimethylformamide on the basis of their number average molecular weights. Also, the hydrodynamic diameters of poly(ethylene glycol)s with molecular weights of 550 and 2000 were estimated to be ca. 1.5 and 2.7 nm in the same solvent, using the equation of Hester and Mitchell (*31*) and the relationship between the intrinsic viscosity and the molecular weight of poly(ethylene glycol) reported by Ritscher and Elias (*32*).

In comparison of the hydrodynamic diameters of these modified G3 dendrimers, it is found that difference in the hydrodynamic diameters between the M-PEG(550)-G3 and the acetylated G3 dendrimers is 2.9 nm, which is about twice the hydrodynamic diameter of PEG(550). Thus, it may be considered that the poly(ethylene glycol) chains exist outside of the PAMAM dendrimer and cover its surface. Similarly, difference in the hydrodynamic diameters between the M-PEG(2000)-G3 and the acetylated G3 dendrimers was calculated to be 9 nm. This value is much larger than twice the hydrodynamic diameter of PEG(2000). Therefore, it may be considered that M-PEG chains attached to the dendrimer surface take on an extended conformation. Although these M-PEG-attached G3 dendrimers have the same number of the grafted M-PEG chains, the polymer segment density around the dendrimer surface might be higher for the M-PEG(2000)-G3 dendrimer than the M-PEG(550)-G3 dendrimer. Therefore, the longer M-PEG chain might take on an extended conformation due to repulsion between the neighboring chains. The hydrodynamic diameters of PEG(550)-G4 and PEG(2000)-G4 dendrimers were estimated by the same method to be 8.2 and 14.7 nm, respectively.

Encapsulation of Drugs by M-PEG-Attached PAMAM Dendrimers. Since the PAMAM dendrimer has a basic and hydrophobic interior, we expected that the M-PEG-attached PAMAM dendrimers could encapsulate and retain drugs with a hydrophobic or acidic character by their PAMAM dendrimer moieties in aqueous environments. Thus, we first examined the preparation of the M-PEG-attached dendrimers encapsulating ADR, because ADR is one of the most effective and widely used anticancer drug with a hydrophobic nature.

The M-PEG-attached PAMAM dendrimers were mixed with varying amounts of ADR-HCl and extracted with chloroform. ADR-HCl is essentially insoluble in chloroform. When the primary amino group of ADR is deprotonated, it becomes soluble in chloroform (*33*). However, it has been shown that the amino group of ADR becomes protonated below pH 7 (*34*, *35*), whereas protonation of tertiary amino groups of PAMAM dendrimers occurs below 3.7 (*1*), showing that basicity of the ADR amino group is much higher than that of the dendrimer tertiary amino groups. Therefore, it is unlikely that deprotonation of the ADR amino group is induced in the presence of M-PEG-attached PAMAM dendrimers. Thus, ADR transferred to the chloroform phase is considered to be in the form of a complex with the M-PEG-attached dendrimer.

Figure 6 represents the number of ADR molecules per M-PEG-attached dendrimer in the chloroform phase after the extraction. As the amount of ADR supplied to the modified dendrimer increased, the number of ADR associated with the dendrimer increased and then reached a constant, maximum value. The maximum numbers of ADR molecules per dendrimer for the M-PEG(550)-G3, the M-PEG(2000)-G3, the M-PEG(550)-G4, and the M-PEG(2000)-G4 dendrimers are ca. 1.2, 2.3, 1.6, and 6.5, respectively.

We expected that the M-PEG-attached dendrimers having the larger PAMAM dendrimer moiety would reveal a higher encapsulation ability. In fact, the M-PEG-(2000)-G4 dendrimer showed the highest ability among these M-PEG-attached dendrimers. However, the encapsulation ability of the modified dendrimer depends not

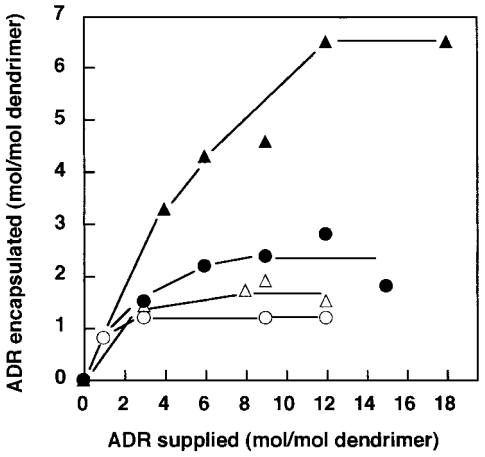

Figure 6. Encapsulation of ADR by M-PEG(550)-attached (open symbols) or M-PEG(2000)-attached (closed symbols) PAMAM G3 (○, ●) and G4 (△, ▲) dendrimers. The number of ADR encapsulated per dendrimer was shown as a function of the ADR/dendrimer molar ratio in feed.

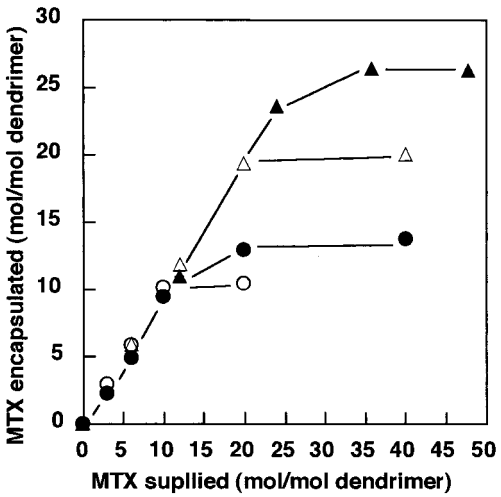

Figure 7. Encapsulation of MTX by M-PEG(550)-attached (open symbols) or M-PEG(2000)-attached (closed symbols) PAMAM G3 (○, ●) and G4 (△, ▲) dendrimers. The number of MTX encapsulated per dendrimer was shown as a function of the MTX/dendrimer molar ratio in feed.

only on the size of the PAMAM dendrimer moiety but also on the chain length of the M-PEG attached to the dendrimer moiety: although the M-PEG(550)-G4 and the M-PEG(2000)-G4 dendrimers have the same PAMAM dendrimer moiety, the former revealed much lower ability than the latter. This fact indicates contribution of the M-PEG layer for the encapsulation of ADR. M-PEG(550) chain may be too short to cover and stabilize the ADR-bound dendrimer moiety. It is also possible that the attachment of long M-PEG chains to the dendrimer chain ends changed conformation of the dendrimer chain, making inner space of the dendrimer larger. Another possibility may be that the M-PEG-rich region of the dendrimer surface solubilized ADR molecules. We observed that ADR was not extracted with chloroform containing the same amount of free M-PEG. However, when concentration of the free M-PEG was further increased, ADR could be transferred to chloroform phase. The amount of transferred ADR increased with increasing the M-PEG concentration in the chloroform phase. This fact may support the possibility of ADR molecules being solubilized in the surface M-PEG layer. It seems that ADR molecules may distribute in both the interior and the M-PEG layer of the dendrimers surface. However, the location of ADR in the M-PEG-attached dendrimers remains to be elucidated at present.

As already mentioned, the PAMAM dendrimer has a basic interior. Therefore, the M-PEG-attached PAMAM dendrimers are expected to exhibit a greater encapsulation ability against acidic drugs than ADR. Thus, next we investigated encapsulation of MTX, which has two carboxyl groups (Figure 1) and has been used for the treatment of various malignant diseases (*36*). The M-PEG-attached dendrimer−MTX complexes were obtained via the extraction with chloroform from mixtures of the modified dendrimers and varying amounts of MTX. The number of MTX molecules associated with one dendrimer molecule as a function of the MTX/dendrimer ratio in feed was shown in Figure 7. As was observed in the case of the encapsulation of ADR, the number of MTX molecules associated with the modified dendrimer increased with increasing amount of MTX supplied and finally reached a constant and maximum value. The maximum numbers of MTX molecules associated with the M-PEG(550)-G3, the M-PEG(2000)-G3, the M-PEG(550)-G4, and the M-PEG(2000)-G4 dendrimers are approximately 10, 13, 20, and 26 mol/mol of dendrimer, respectively. Apparently, the number of the encapsulated drugs by the modified dendrimers increased when MTX was used, compared to the case of ADR. Since these drugs have similar molecular weights, this result suggests that the electrostatic interaction resulted from the acid−base reaction between the dendrimer and MTX is effective for the encapsulation of MTX by the dendrimers. It has already been reported that the PAMAM dendrimers exhibit a high affinity against various acidic compounds (*14*, *37*). As was the case of ADR encapsulation, the number of MTX encapsulated by the dendrimer was affected both by generation of the PAMAM dendrimer moiety and by chain length of the M-PEG graft.

Release of Drugs from M-PEG-Attached PAMAM Dendrimers. To obtain information about the release of ADR from the M-PEG-attached dendrimers, the drug-loaded M-PEG(2000)-G4 dendrimer was dissolved in PBS and dialyzed against PBS. The increase in the ADR concentration in the outer phase was followed and compared with the case of dialysis of free ADR. We observed that the concentration of ADR in the outer phase increased at about the same rate in both cases (data not shown). A similar result was obtained for the dialysis of ADR-loaded M-PEG(2000)-G3 dendrimer (data not shown). These facts suggest that ADR was readily released from the modified dendrimers in PBS. Probably, hydrophobic interaction between ADR and the dendrimer is not strong enough to retain the drug in the interior of the PAMAM dendrimer moiety.

The release of MTX from the M-PEG-attached dendrimers was also investigated by the same method. The MTX-loaded M-PEG(2000)-G4 PAMAM dendrimer was dissolved in 1 mM Tris-HCl-buffered solution of pH 7.4 and dialyzed against the same solution. The time course of MTX concentration in the outer phase during the dialysis was shown in Figure 8. Apparently, the MTX concentration of the outer phase increased more slowly in the case of MTX encapsulated in the M-PEG-attached dendrimer than the case of free MTX, indicating that MTX was gradually released from the modified dendrimer. As mentioned above, MTX was tightly bound to the dendrimer by the electrostatic interaction with the interior of the PAMAM dendrimer and, hence, dissociation of MTX from the dendrimer was suppressed to some

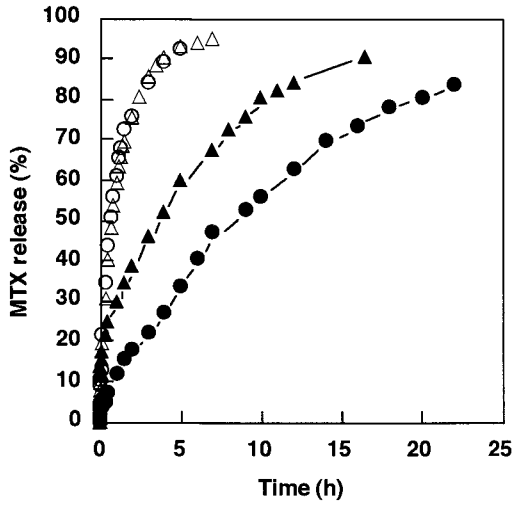

Figure 8. Release of MTX from the M-PEG(2000)-attached G4 dendrimer. The MTX-loaded M-PEG(2000)-G4 dendrimer (○, ●) or free MTX (△, ▲) dissolved in 1 mM Tris-HCl-buffered solution (pH 7.4) containing (open symbols) or not containing (closed symbols) 150 mM NaCl and dialyzed against the same solution. The time course of MTX concentration in the outer phase during the dialysis was shown in the figure.

extent. However, when the dialysis was performed in the presence of 150 mM NaCl, no difference in the release rate was observed between MTX encapsulated in the M-PEG-attached dendrimer and free MTX. Because the electrostatic interaction is weakened by the shielding effect of Na^+ and Cl^-, MTX can dissociate readily from the dendrimer under this condition.

In conclusion, we designed PAMAM dendrimers having M-PEG grafts as a novel drug carrier and showed that M-PEGs with the molecular weights of 550 and 2000 were combined to essentially every chain end of the dendrimer with the generation 3 or 4 via the urethane bond. Also, we prepared the M-PEG-attached dendrimers encapsulating anticancer drugs, ADR and MTX. While the encapsulation ability of the M-PEG-attached PAMAM dendrimers was found to vary, depending on both the molecular weight of M-PEG and the generation of the dendrimer, up to 6.5 ADR molecules and up to 26 MTX molecules could be loaded in the M-PEG(2000)-attached G4 dendrimer, which exhibited the highest ability among the dendrimers prepared in this study. Unfortunately, these drugs were released readily from the M-PEG-attached PAMAM dendrimers in isotonic solutions, probably because the affinity of the dendrimer to these drugs is not strong enough to retain these drugs in their interior. However, it is expected that the M-PEG-attached dendrimers may show higher retention ability for more hydrophobic drugs. Also, introduction of hydrophobic groups into the dendrimers would improve their ability to retain drugs. Thus, findings obtained in this study should provide an important information for the design of dendrimers as drug carriers. We are currently attempting to prepare M-PEG-attached dendrimers with enhanced ability for encapsulation and retention of drugs as well as M-PEG-attached dendrimers having targeting ligands.

[^{99m}Tc]Annexin V can be used to image organs undergoing cell death during cancer chemotherapy and organ transplant rejection. To simplify the preparation and labeling of annexin V for nuclear-medicine studies, we have investigated the addition of peptide sequences that will directly form endogenous chelation sites for ^{99m}Tc. Three mutant molecules of annexin V, called annexin V-116, -117, and -118, were constructed with N-terminal extensions of seven amino acids containing either one or two cysteine residues. These molecules were expressed cytoplasmically in *Escherichia coli* and purified to homogeneity with a final yield of 10 mg of protein/L of culture. Analysis in a competitive binding assay showed that all three proteins retained full binding affinity for erythrocyte membranes with exposed phosphatidylserine. Using $SnCl_2$ as reducing agent and glucoheptonate as exchange agent, all three proteins could be labeled with ^{99m}Tc to specific activities of at least 50−100 μCi/μg. The proteins retained membrane binding activity after the radiolabeling procedure, and quantitative analysis indicated a dissociation constant (K_d) of 7 nmol/L for the annexin V-117 mutant. The labeling reaction was rapid, reaching a maximum after 40 min at room temperature. The radiolabeled proteins were stable when incubated with phosphate-buffered saline or serum in vitro. Proteins labeled to a specific activity of 25−100 μCi/μg were injected intravenously in mice at a dose of 100 μg/kg, and biodistribution of radioactivity was determined at 60 min after injection. Uptake of radioactivity was highest in kidney and liver, consistent with previous results obtained with wild-type annexin V. Cyclophosphamide-induced apoptosis in vivo could be imaged with [^{99m}Tc]annexin V-117. In conclusion, annexin V can be modified near its N-terminus to incorporate sequences that form specific chelation sites for ^{99m}Tc without altering its high affinity for cell membranes. These annexin V derivatives may be useful for in vivo imaging of cell death.

INTRODUCTION

Membrane phospholipids are distributed asymmetrically in most cells (*1*, *2*). Phosphatidylserine (PS)[1] is normally retained on the intracellular face of the plasma membrane, but this distribution is altered in some physiological and pathological states. PS exposure is part of the normal platelet procoagulant response, and it also occurs during apoptosis, where it may serve as a signal to promote phagocytosis of apoptotic cells and their fragments (*3*). We have recently used annexin V to detect PS exposure in vivo. Annexin V labeled with radioiodine and ^{99m}Tc was used to detect thrombus formation in experimental animals (*4*, *5*). [^{99m}Tc]Annexin V was used to detect cell death in vivo in animal models (*6*−*10*). Because of the clinical applicability of this work in monitoring cancer chemotherapy and rejection of transplanted organs, there is interest in developing new annexin V derivatives with improved imaging properties or greater ease of use.

Some naturally occurring proteins have been labeled directly with technetium, which presumably chelates with favorably disposed atoms from the peptide backbone and/or amino acid side chains. However, this approach lacks generality, and the results are unpredictable for any particular protein. More recently, specific peptide sequences, modeled after short peptides such as mercaptoacetyltriglycine (*11*−*14*), have been introduced into recombinant proteins in order to create endogenous chelation sites for technetium. For example, George et al. (*15*) attached the sequence GGGGC to the C-terminus of two recombinant single-chain Fv antibody proteins. They showed that these proteins could be labeled with ^{99m}Tc to high specific activity. Bogdanov et al. (*16*) showed specific Tc chelation to a construct of green fluorescent protein with the added C-terminal sequence LGGGGC-GGGCGI. In another approach, Waibel et al. (*17*) showed Tc chelation to a recombinant protein containing five or six histidine residues at the C-terminus. Pietersz et al. (*18*) prepared a hybrid protein consisting of metallothionein fused to a single-chain Fv molecule, which was labeled with Tc by transchelation from a precursor protein containing Zn.

It would be advantageous to label annexin V directly with ^{99m}Tc, without requiring attachment of exogenous chelation groups. The N-terminal region of annexin V is

Table 1. Oligonucleotides Used for Construction of Vectors

oligonucleotide ame	vector	oligonucleotide sequence (5′ to 3′)
JT-289	pJ116	TATGGCATGTGGCGGTGGCCA
JT-290	pJ116	TATGGCCACCGCCACATGCCA
JT-295	pJ117	TATGGCAGGTGGCTGTGGCCA
JT-296	pJ117	TATGGCCACAGCCACCTGCCA
JT-297	pJ118	TATGGCATGTGGCTGCGGTCA
JT-298	pJ118	TATGACCGCAGCCACATGCCA

a suitable site for attachment of additional peptide sequence, since previous work has shown that attachment of small (*19*) and large (*20*) sequences does not alter membrane binding affinity, nor does it affect expression or folding of the recombinant protein in *Escherichia coli*. The three-dimensional structure of annexin V also shows that the N-terminal region is located on the opposite side of the molecule from the membrane binding site (*21*).

In this study, we have prepared three novel derivatives of annexin V that contain N-terminal extensions of seven amino acids that are specifically designed to chelate technetium. One derivative is predicted to form an N_2S_2 chelation site, and two are predicted to form an N_3S site. These derivatives can be produced in high yield by expression in *E. coli*, and they can be labeled to high specific activity with technetium.

MATERIALS AND METHODS

Materials. Recombinant annexin V was produced in *E. coli* as described (*22*). Fluorescein-annexin V was prepared as described (*23*). Sodium glucoheptonate was from Sigma. $SnCl_2{\cdot}2H_2O$ was from Aldrich. Annexin V was derivatized with succinimidyl 6-hydrazinopyridine-3-carboxylate (abbreviated HYNIC) as described (*6*). Erythrocytes with exposed PS (4CPlus Normal Control, part number 7546923) were from Beckman-Coulter (Miami, FL).

Construction and Verification of Plasmids. Several plasmids were constructed to express mutant forms of annexin V in *E. coli* under control of the phage T7 promoter. The parent expression vector was pET12a, available from Novagen Corporation (Madison, WI).

Construction of Vector pJ115, Encoding Annexin V-115 with Cys-316→Ser Mutation. A 232-bp *Bst*BI−*Bam*HI restriction fragment was first isolated from plasmid pANXVC-S-N6 (*19*), also known as pJ110, which encodes a modified annexin V with the Cys-316 → Ser mutation. The same restriction fragment was then removed from plasmid pET12a-PAP1 (*22*), which encodes wild-type annexin V, and the mutated *Bst*BI−*Bam*HI fragment was inserted to form plasmid pJ115. This plasmid was subjected to DNA sequence analysis to verify that the intended mutation had been correctly introduced.

Construction of vectors pJ116, pJ117, and pJ118, encoding the mutant molecules annexin V-116, annexin V-117, and annexin V-118.

For each vector to be constructed, sense and antisense oligonucleotides (with sequences given in Table 1) were designed to encode the desired peptide sequence and to have *Nde*I restriction sites at both ends. Equimolar amounts of sense and antisense oligonucleotide were phosphorylated and annealed to form a double-stranded cassette with *Nde*I-compatible single-stranded ends. The double-stranded oligonucleotide (3.8 ng) was ligated with plasmid pJ115 (0.42 μg) that had been previously digested with *Nde*I and dephosphorylated. The ligation mixture was transformed into *E. coli* strain DH5α. Plasmid DNA was prepared from ampicillin-resistant colonies and screened by PCR for the presence of the desired insert. DNA sequence analysis was then performed on positive clones to verify the presence of the desired insertion and the absence of other adventitious mutations.

Expression and Purification of Proteins. Plasmids pJ116, pJ117, and pJ118 were each transformed into *E. coli* strain BL21(DE3) for cytoplasmic expression. Each clone was grown overnight to saturation at 37 °C with shaking in Terrific Broth containing carbenicillin (50 μg/mL). The cells were separated from culture medium by centrifugation for 10 min at 2560*g* and washed in ice-cold buffer (50 mmol/L TrisHCl, 150 mmol/L NaCl pH 8.0). Bacteria were disrupted by sonication in ice-cold 50 mmol/L Tris·HCl, pH 7.2, 10 mmol/L $CaCl_2$, 1 mmol/L β-mercaptoethanol, and then centrifuged for 20 min at 22530*g*. The supernatant was discarded and the annexin V bound to bacterial membranes was released by resuspending the pellet in 50 mmol/L Tris·HCl, pH 7.2, 20 mmol/L EDTA, 1 mmol/L β-mercaptoethanol. Bacterial membranes were removed by centrifugation for 20 min at 22530*g* and the supernatant containing the annexin V was dialyzed against 20 mmol/L Tris·HCl, pH 8.0, 1 mmol/L β-mercaptoethanol. The dialysand was applied to a Mono Q HR 16/10 column (Pharmacia, Piscataway, NJ) and eluted with a gradient of 0 to 1 mol/L NaCl in the same buffer. The annexin V mutants all eluted at approximately 0.22 mol/L NaCl. The purified protein was concentrated by ultrafiltration to approximately 5 mg/mL, dialyzed against 20 mmol/L HEPES, pH 7.4, 100 mmol/L NaCl, and stored in aliquots at −70 °C. The final yield was approximately 10 mg/L of bacterial culture, with a purity of ∼98% as judged by SDS−PAGE.

Labeling of Proteins with ^{99m}Tc. Unless noted otherwise, mutant proteins were labeled with ^{99m}Tc as follows. A 1-mg aliquot of protein was incubated with 1 mmol/L dithiothreitol for 15 min at 37 °C. This material was then purified on a Sephadex G-25 column (0.9 × 2.8 cm) previously equilibrated with deoxygenated 20 mmol/L sodium citrate, pH 5.2, 100 mmol/L NaCl. This material was stored in glass vials at −20 °C in aliquots of 100 μg in 100 μL of the same buffer. For Tc labeling, glucoheptonate was used as the exchange agent. A solution containing 20 mmol/L sodium glucoheptonate and 10 mmol/L sodium HEPES was adjusted to pH 6.6 and deoxygenated with argon. $SnCl_2{\cdot}2H_2O$ was added to 128 μg/mL, and 1-mL aliquots were dispensed into borosilicate glass vials, lyophilized, capped with Teflon-lined screw caps under argon, and stored at −20 °C. For radiolabeling, 100 μL of $^{99m}TcO_4$ in 0.9% NaCl was added to 200 μL of tin/glucoheptonate (from a lyophilized aliquot freshly reconstituted with 1 mL of deoxygenated H_2O). To this was added 100 μg (100 μL) of reduced protein. The reaction was incubated for 60 min at room temperature.

For labeling of HYNIC−annexin V, tricine was used as the exchange agent. The tin/tricine reduction/exchange reagent was prepared as previously described (*24*); the final composition of the reagent was 200 mmol/L tricine, pH 7.1, 128 μg/mL $SnCl_2.2H_2O$. This reagent was dispensed in 1-mL aliquots into borosilicate glass vials, lyophilized, capped with Teflon-lined screw caps under an argon atmosphere, and stored at −20 °C. For radiolabeling, a 100-μg lyophilized aliquot of HYNIC−annexin V was reconstituted with 100 μL of H_2O, and 100 μL of $^{99m}TcO_4$ in 0.9% NaCl was added. Freshly reconstituted tin/tricine reagent (200 μL) was then added and the reaction mixture was incubated for 15 min at room temperature.

Radiolabeled proteins prepared by either method were purified by applying the reaction mixture (400 μL) to a Sephadex G-25 column (0.9 × 2.8 cm) previously equilibrated with PBS and eluting the column with 1000 μL of PBS. Percent protein-bound radioactivity was determined by ITLC on oven-dried silica gel plates with PBS as solvent. For studies of radiolabel stability in serum, percent protein-bound radioactivity was determined by centrifugal ultrafiltration (3 min at 1860*g*) through a membrane with a 10 000-Da cutoff (Centricon-10 filter, Amicon, Danvers, MA). Radiolabel stability was also assessed by gel filtration on a Superose-12 column (1 × 30 cm) connected to an FPLC system. The column was equilibrated with PBS and eluted at a flow rate of 0.5 mL/min at room temperature.

Cell Binding Assays. The affinity of nonradioactive proteins for cell membranes was determined by their ability to compete with fluorescein-annexin V for binding to erythrocytes with exposed phosphatidylserine (*20*). Mutant proteins were added at various concentrations to 1 mL of a solution containing 5 nmol/L fluorescein-annexin V and 8.3 × 10^6 erythrocytes in a buffer consisting of 10 mmol/L HEPES−Na, pH 7.4, 136 mmol/L NaCl, 2.7 mmol/L KCl, 5 mmol/L glucose, 1 mg/mL BSA (buffer HNKGB) plus 2.5 mmol/L $CaCl_2$. The sample was incubated for 15 min at room temperature. The cells were centrifuged for 3 min at 8300*g*, the supernatant removed, and the fluorescein-annexin V bound to the pelleted cells was released by resuspension in 950 μL of HNKGB buffer containing 5 mmol/L EDTA. The sample was centrifuged again, the supernatant removed, and the concentration of fluorescein-annexin V in the supernatant determined by fluorometry. The results of this assay are summarized as the concentration of competitor protein that inhibits 50% of the binding of fluorescein-annexin V, abbreviated IC_{50}.

The ability of radiolabeled proteins to bind to cell membranes was determined with a similar procedure. Radiolabeled protein at 10 nmol/L final concentration was added to duplicate tubes containing a final volume of 1 mL of buffer HNKGB plus 2.5 mmol/L $CaCl_2$. One tube then received 4.2 × 10^8 erythrocytes. After a 15-min incubation at room temperature, both tubes were centrifuged for 3 min at 8320*g*. Radioactivity was measured in 800 μL of the supernatants. The percentage of radioactivity bound to the cells was calculated from 100 × [1 − (supernatant counts in the presence of cells)/(supernatant counts in absence of cells)].

Quantitative titrations were performed to determine the dissociation constant for protein-membrane interaction as previously described (*25*). Radiolabeled protein (3−150 nmol/L) was added to 1 × 10^7 erythrocytes in buffer HNKGB plus 2.5 mmol/L $CaCl_2$. After a 15-min incubation at room temperature, bound and free ligand were separated by centrifugation through a silicone-oil barrier, and the radioactivity bound to the pelleted cells was determined by scintillation counting; this was converted to number of molecules bound per cell by dividing by the known specific activity. The concentration of free ligand was determined by measuring the radioactivity remaining in the supernatant, corrected for the fraction of nonbindable tracer. The dissociation constant was determined by using nonlinear least-squares analysis to fit the data to a model of noncooperative binding to homogeneous sites.

Biodistribution and Imaging Studies. Each annexin V mutant protein (100 μg) was labeled with ^{99m}Tc (10 mCi) using the glucoheptonate procedure as described above and purified on a Sephadex G-25 column (1.5 × 5 cm) eluted with PBS. The eluate appearing between 2 and 4 mL was pooled. For biodistribution studies, 50 μL (=1.5 μg, 40−150 μCi) of this eluate was injected via the tail vein into 8−10 week old Balb/c mice (Veterinary Services, Department of Comparative Medicine, Stanford University) weighing between 20 and 25 g. Organs and other targets of interest were harvested from groups of 5−7 mice at 60 min after injection; the sample tissues were weighed and then underwent scintillation counting. Samples were counted in a Packard Cobra II gamma counter (Packard, Meriden, CT) with energy windows set between 120 and 170 keV. Scintillation well data were expressed as the percentage of injected dose (%ID) and %ID per gram of tissue (%ID/g) for each sample. Scintillation counting data were adjusted for tail vein infiltration, decay, and background as described previously (*6*).

116: NH_2Ala-Cys-Gly-Gly-Gly-His-Met-Annexin V

117: NH_2Ala-Gly-Gly-Cys-Gly-His-Met-Annexin V

118: NH_2Ala-Cys-Gly-Cys-Gly-His-Met-Annexin V

Figure 1. Primary structures of annexin V mutants. Each mutant protein contains the indicated N-terminal extension of seven amino acids, followed by amino acids 2−320 of human annexin V (*29*). The naturally occurring Cys residue at position 316 has also been mutated to Ser in all three proteins. The initiator methionine residue is not shown because it is removed posttranslationally (*30*). For convenience, the mutant molecules are given arbitrary numerical designations.

For imaging studies, young male (150−200 g, 8−10 week old) Sprague−Dawley rats (Simonsens, Gilroy, CA) were housed and treated in a humane manner in accordance to institutional animal subjects guidelines. Animals were treated with 150 mg/kg of cyclophosphamide (Sigma) reconstituted in 1 mL of PBS and injected intraperitoneally. All animals were then imaged at either 0 or 24 h after cyclophosphamide treatment, followed by sacrifice and well counting of selected tissues. Animals were injected via tail vein with 0.5−1 mCi (37 MBq, 20−40 μg protein/kg) of radiolabeled annexin V 1 h prior to radionuclide imaging and sacrifice. At the time of imaging, rats were sedated with a mixture of 80 mg/kg acepromazine and 40 mg/kg ketamine injected intramuscularly. A Technicare 420 mobile scintillation camera (Technicare; Solon, OH) equipped with a low energy, high resolution parallel hole collimator was used to record the [^{99m}Tc]annexin V distribution. Data were recorded using a 20% window centered on the 140 keV photopeak of ^{99m}Tc into a 256 × 256 matrix of a dedicated computer system for digital display and analysis (ICON; Siemens, Hoffman Estates, IL). All images were recorded for a preset time of 10 min. Region of interest (ROI) image analysis was performed to determine relative counts in one femur (corrected for background in the adjacent soft tissue of the thigh) in comparison to that of the whole body. The result was expressed as the percent of the whole body activity. *P*-Values were calculated using the student *t*-test with a one-tail test for significance assuming equal variances of test and control groups. *P*-values of 0.05 or less were considered significant. Average values are presented along with their associated standard deviations.

RESULTS

Protein Production and Characterization. Three mutant proteins were designed to have N-terminal sequences potentially suitable for chelation of Tc (Figure 1). Annexin V-116 and annexin V-117 were predicted to form an N_3S chelate, while annexin V-118 was predicted

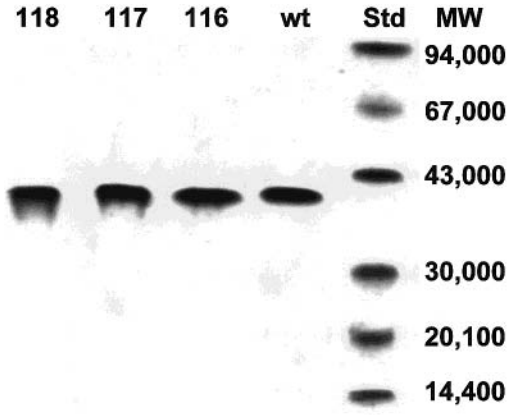

Figure 2. SDS−PAGE analysis of mutant proteins. Recombinant wild-type annexin V and the three mutant annexin V molecules were reduced with β-mercaptoethanol, analyzed on a 10 to 15% gradient gel on a Pharmacia PHAST system, and stained with Coomassie Brilliant Blue.

Table 2. Membrane Binding Activity of Mutant Proteins[a]

protein	IC_{50} (nmol/L)
annexin V	6.8 ± 0.7
annexin V-116	9.3 ± 0.4
annexin V-117	10.3 ± 2.5
annexin V-118	10.0 ± 2.8
HYNIC-annexin V	10.1 ± 2.0

[a] IC_{50} values were determined for unlabeled proteins by competition assay as described in the Materials and Methods. Results are given as mean ± SD with $n = 9$ for annexin V and HYNIC-annexin V and $n = 2$ for mutants 116, 117, and 118.

Table 3. Radiochemical Yield, Purity, and Bioactivity of Labeled Proteins

protein	% radiochemical yield[a]	% radiochemical purity[a,b]	% radioactivity bound to erythrocytes[c]
annexin V	3.9 ± 1.6	not applicable	not applicable
annexin V-116	89.5 ± 5.7	94.4 ± 2.0	77.5 ± 3.5
annexin V-117	88.8 ± 2.0	92.2 ± 1.2	78.1 ± 3.8
annexin V-118	89.9 ± 1.9	94.2 ± 0.6	78.7 ± 3.6
HYNIC-annexin V	97.0%	99.0%	83.9 ± 2.5

[a] Results are given as mean ± SD with $n = 2$ for annexin V, $n = 4$ for mutants 116, 117, and 118, and $n = 1$ for HYNIC-annexin V. [2] % Radiochemical purity was determined by ITLC after purification by gel filtration. [3] Results are given as mean ± SD with $n = 4$ for mutants 116, 117, and 118, and $n = 7$ for HYNIC-annexin V.

to form an N_2S_2 chelate. The single cysteine residue present at position 316 of native annexin V was also mutated to serine to eliminate the possibility that this residue might form a weak binding site for technetium. The structures of all constructs were verified by DNA sequencing. All three proteins could be expressed cytoplasmically in *E. coli* and purified in high yield (10 mg pure protein per liter of bacterial culture) under conditions similar to those used to produce wild-type annexin V (*22*, *26*). SDS−PAGE analysis (Figure 2) showed that all three mutants could be produced in highly pure form. As expected, all three mutant proteins (326 amino acids in length) also migrated with the same apparent molecular weight as wild-type annexin V (319 amino acids).

The bioactivity of the mutant proteins was verified by measuring their ability to compete with wild-type annexin V for binding to erythrocyte membranes with exposed PS (Table 2). All three proteins displaced fluorescein-annexin V with nearly the same relative affinity as wild-type annexin V, indicating that attachment of the N-terminal heptapeptide did not interfere with membrane binding either directly or indirectly. The mutant proteins also had the same IC_{50} values as HYNIC−annexin V, which has been previously used to detect PS exposure in vivo.

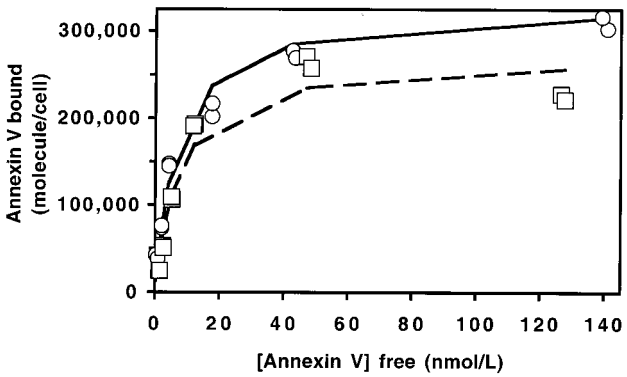

Figure 3. Quantitative cell binding curve. Red blood cells with exposed PS were incubated with varying amounts of [^{99m}Tc]-annexin V-117 (squares) or [^{99m}Tc]HYNIC−annexin V (circles); bound and free ligand were then separated as described in the Materials and Methods and the amount of cell-bound and unbound radioactivity was determined by scintillation counting. The data were fit to a model of noncooperative binding to homogeneous sites. The calculated binding parameters for annexin V-117 were $K_d = 7.3$ nmol/L, $B_{max} = 272\,000$ sites/cell; corresponding values for HYNIC−annexin V were 6.9 nmol/L and 330 000 sites/cell.

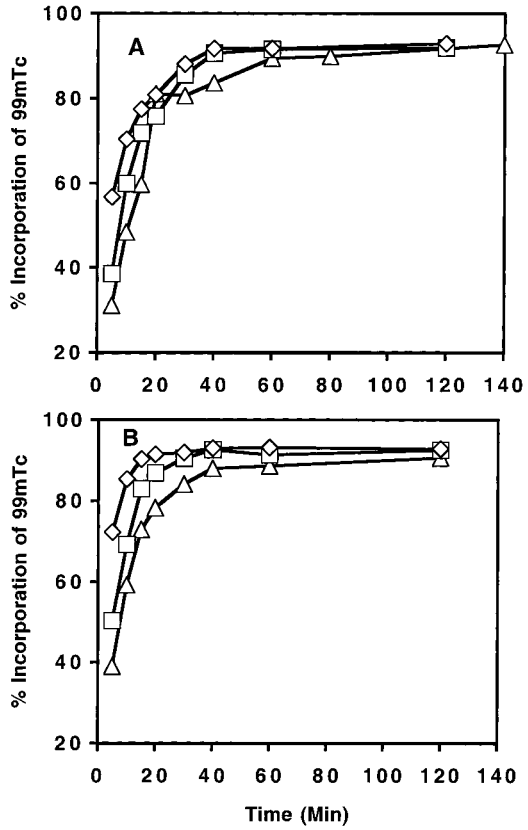

Figure 4. Time course of radiolabeling. Protein (50 μg) was reacted with $^{99m}TcO_4$ (100 μCi), and ITLC was performed on aliquots taken from the reaction mixtures at the indicated times. (A) Labeling at room temperature (22 °C); (B) Labeling at 37 °C. (△) Annexin V-116, (□) annexin V-117, (◇) annexin V-118.

Radiolabeling with ^{99m}Tc. The three mutant proteins were tested for their ability to chelate technetium. As

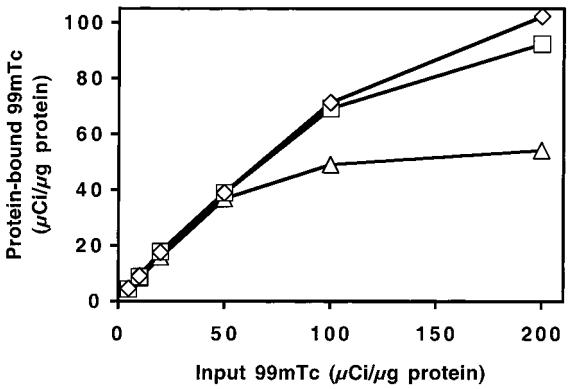

Figure 5. Radiolabeling as a function of technetium/protein ratio. Protein (5−20 μg) was added to technetium (100−500 μCi) to achieve the indicated ratio of technetium to protein. After 60 min at room temperature, ITLC was performed on the reaction mixture to determine percent incorporation of radioactivity into protein. The specific activity was then calculated from the input ratio of technetium to protein multiplied by the percent incorporation of radioactivity into protein. Symbols: as in Figure 4.

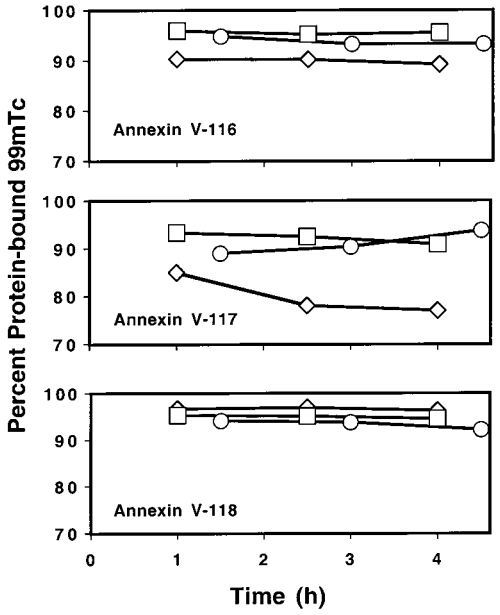

Figure 6. Stability of radiolabeled proteins in vitro. Protein was radiolabeled to a specific activity of 1−2 μCi/μg and purified by gel filtration chromatography as described in the Materials and Methods. Radiolabeled protein was then incubated at a concentration of 250 μg/mL at room temperature in either PBS (diamonds), PBS + 5 mmol/L DTPA (squares), or a 1:1 mixture of PBS and human serum (circles). Aliquots were taken at the indicated times and percent protein-bound ^{99m}Tc was determined.

shown in Table 3, all three proteins incorporated most of the added pertechnetate, as measured by ITLC of the reaction mixture. The percent incorporation was comparable to the value obtained for HYNIC−annexin V under the same conditions. In contrast, there was almost no labeling of wild-type annexin V, indicating that the observed radiolabeling was specifically due to the added N-terminal sequences in the mutant molecules. The radiolabel remained attached to protein after removal of labeling reagents by gel filtration chromatography, as indicated by the high radiochemical purity of gel-filtered proteins.

To verify that the radiolabeled proteins retained membrane binding activity, radiolabeled proteins were incubated with erythrocytes in the presence of calcium,

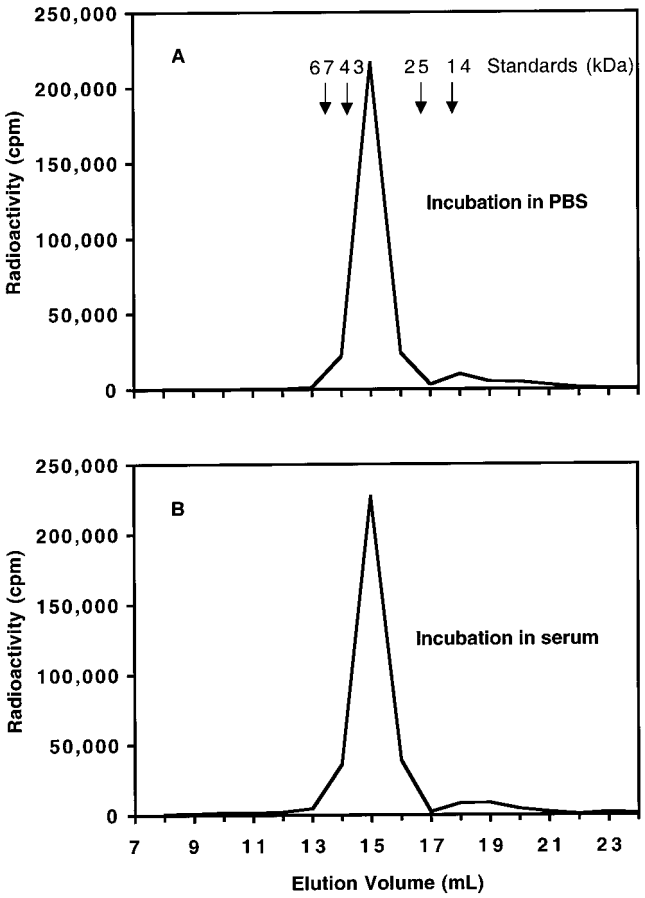

Figure 7. Gel filtration analysis of [^{99m}Tc]annexin V-117. (A) [^{99m}Tc]Annexin V-117 (50 μg in 600 μL of PBS) was incubated for 2 h at room temperature and then analyzed on a Superose-12 column as described in the Materials and Methods. Radioactivity was determined in 1-mL column fractions. The *arrows* indicate the elution positions of globular protein standards with the indicated molecular masses. B. [^{99m}Tc]Annexin V-117 (50 μg in 300 μL of PBS) was mixed with 300 μL of human serum, incubated for 2 h at room temperature, and then analyzed on a Superose-12 column.

and the percentage of radioactivity bound to cells was measured (Table 3). All three proteins showed comparable levels of binding, and this level was comparable to the binding of [^{99m}Tc]HYNIC−annexin V tested under the same conditions.

Quantitative titrations were performed to determine the affinity of the radiolabeled protein for cell membranes with exposed PS. As shown in Figure 3, [^{99m}Tc]annexin V-117 showed high-affinity saturable binding to erythrocytes with exposed PS; the binding curve was essentially identical to that obtained with [^{99m}Tc]HYNIC−annexin V. The measured dissociation constant was 7 nmol/L, consistent with previous results obtained for binding of [^{125}I]annexin V to platelets and erythrocytes (*25, 27*).

Optimization of Labeling Conditions. The time course of labeling was rapid for all three mutants. As shown in Figure 4A, incorporation of ^{99m}Tc occurred rapidly at room temperature, reaching a maximum at 40 min for annexin V-117. The reaction was slightly faster at 37 °C, reaching a maximum at 30 min for annexin V-117 (Figure 4B). For convenience, a 60-min reaction at room temperature was chosen for most subsequent experiments.

To determine if proteins could be labeled to high specific activity, the technetium/protein was varied. As shown in Figure 5, the incorporation of ^{99m}Tc into protein

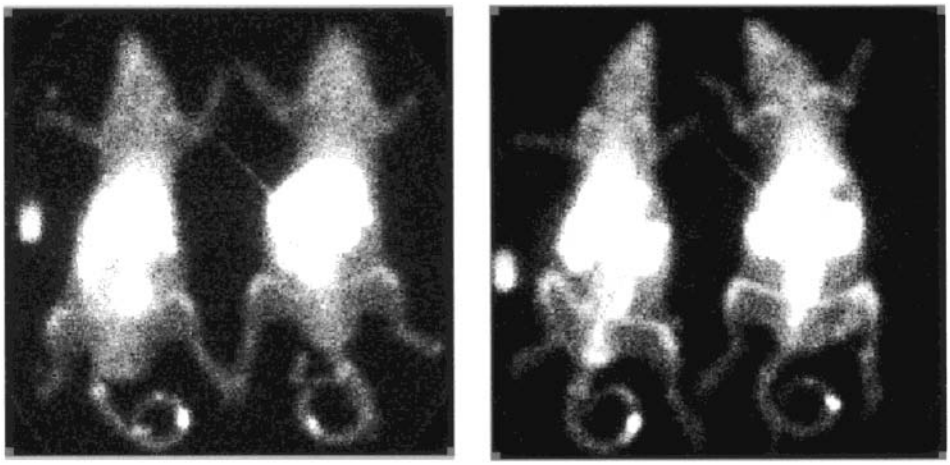

Figure 8. Imaging of apoptosis in bone marrow and spleen. Rats received either no treatment (control) or 150 mg/kg cyclophosphamide (+ cyclophosphamide). After 24 h, they received 0.5 mCi of [^{99m}Tc]annexin V-117 injected via the tail vein. One hour later, images were recorded for 10 min from animals in the supine position.

increased with increasing amounts of added $^{99m}TcO_4$; specific activities of ~100 μCi/μg were readily obtainable for annexin V-117 and annexin V-118.

Stability of Radiolabeled Proteins in Vitro. The stability of the radiolabeled protein in vitro was determined after challenge with phosphate-buffered saline, DTPA (5 mmol/L), and serum (Figure 6). ITLC analysis showed that all three mutant proteins retained the radiolabel over a period of several hours, indicating that the Tc−protein chelate was of high affinity.

These results were confirmed by gel filtration chromatography of [^{99m}Tc]annexin V-117 (Figure 7A). After incubation of [^{99m}Tc]annexin V-117 with PBS for 2 h, almost all of the radioactivity eluted in the same position as monomeric annexin V-117 (M_r 36 000); there was no evidence for multimeric protein aggregates. Similarly, gel filtration chromatography of [^{99m}Tc]annexin V-117 after a 2-h incubation with human serum showed that the radioactivity still eluted in the same position as monomeric annexin V (Figure 7B). Thus, there was no evidence for transchelation of ^{99m}Tc to other serum proteins over a time period consistent with the normal blood clearance time of annexin V (see Discussion).

Biodistribution of Radiolabeled Proteins in Mice. Labeled proteins were injected intravenously in mice and biodistribution was determined 60 min later (Table 4). Uptake was highest in kidney and liver. The overall pattern of uptake was similar to results obtained with [^{99m}Tc]HYNIC−annexin V, indicating that the N-terminal additions to the three mutant molecules had not drastically altered their biodistribution.

Annexin V-117 Imaging of Cyclophosphamide-Treated Rats. To verify that annexin V-117 would be suitable to detect apoptosis in vivo, we used a model of cyclophosphamide-induced apoptosis in rats. Imaging of cyclophosphamide-treated rats clearly showed increased uptake of annexin V-117 in the femurs and spleen compared to control animals (Figure 8), consistent with our earlier studies with HYNIC−annexin V (*6*). Cyclophosphamide-treated rats (N = 5) demonstrated a 56% increase in femoral uptake determined by ROI analyses 24 h after treatment compared with controls (N = 4) (0.325 ± 0.084% versus 0.209 ± 0.056% whole body uptake, respectively; p = 0.0262). Well counting of excised femurs revealed a borderline (p = 0.065) increase of annexin V-117 uptake in treated as compared with control animals (0.239 ± 0.079% ID/g versus 0.167 ± 0.028% ID/g, respectively). Well counting of excised spleens showed a significant 59% increase (p = 0.0303) in splenic uptake in treated animals compared with control (3.27 ± 1.04% ID/g versus 2.06 ± 0.332% ID/g, respectively).

Table 4. Biodistribution of Mutant Molecules in Mice[a]

	% injected dose per organ			
organ	annexin V-116	annexin V-117	annexin V-118	HYNIC−annexin V
carcass	31.94	23.05	21.73	32.64
kidney	17.96	6.17	5.99	39.16
liver	11.24	5.97	10.36	16.59
small intestine	3.50	4.18	6.20	3.31
stomach	3.35	1.69	4.20	0.88
large intestine	1.79	1.15	3.22	0.88
tail	0.79	0.72	0.48	0.71
lung	0.83	0.40	0.60	0.61
blood	0.24	0.36	0.49	0.39
spleen	0.56	0.28	0.42	0.88
bone	0.19	0.14	0.15	0.18
heart	0.11	0.07	0.07	0.14

skeletal muscle	0.03	0.03	0.03	0.03
brain	0.02	0.02	0.02	0.01

[a] Results are mean values for n = 5 to 7 animals.

DISCUSSION

We have successfully produced mutant forms of annexin V that have endogenous chelation sites for ^{99m}Tc. These mutant molecules retain bioactivity, as measured by their ability to bind with high affinity to cell membranes with exposed PS. Membrane-binding activity is preserved both before and after labeling with ^{99m}Tc. Labeling of these molecules with ^{99m}Tc is very simple and rapid, and high specific activities can be achieved. Presence of endogenous chelation sites on these proteins greatly simplifies production of material suitable for ^{99m}Tc labeling: the recombinant proteins can be used directly, without the need for complex and time-consuming procedures for attachment of organic Tc chelation groups. The annexin V mutants are also chemically homogeneous, in contrast to the heterogeneous labeling that usually occurs with amine-directed bifunctional organic-labeling reagents.

The mutant annexins show good radiolabel stability in vitro. They are stable to challenge by PBS and serum in vitro for at least several hours, and there is no evidence for transchelation of ^{99m}Tc to other serum proteins during in vitro incubation (Figures 6 and 7). It should be noted that annexin V is very rapidly cleared from the blood; less than 5% of initial radioactivity is present 2.5 h after intravenous injection (*4*, *5*). Annexin V also does not bind to normal erythrocytes, leukocytes, or platelets in whole blood (*28*). These results imply that radiolabeled annexins will be confined to the plasma fraction of blood in vivo, and they will be stable in this compartment until they have been cleared into other body compartments.

The mutant annexins also showed good in vivo radiostability, as judged by the relatively low excretion of ^{99m}Tc in the stomach. Annexin V-117 showed the greatest radiostability in vivo, as judged by the lowest level of ^{99m}Tc present in the stomach (Table 4). This was somewhat surprising, since the N_2S_2 structure in annexin V-118 might be expected to chelate technetium more tightly than the N_3S structure present in annexin V-117. Given its overall combination of properties, annexin V-117 seems the most promising derivative for further development as an in vivo imaging agent.

The biodistribution of annexin V-117 may have several advantages for clinical imaging compared to HYNIC−annexin V. In normal animals, there is only 16% as much uptake in the kidney and 36% as much uptake in the liver, which reduces radiation dose to those organs and may allow the imaging of renal transplant rejection. Bone marrow uptake is also lower in normal control animals, without compromising the relative increase in uptake in the marrow seen in response to cyclophosphamide-induced apoptosis. There is also less uptake in the carcass (probably due to increased excretion in the urine), which will improve target-to-background ratio for most imaging studies. The only comparative disadvantage of annexin V-117 is moderately increased excretion in the stomach and intestines compared to HYNIC−annexin V.

The peptide sequences described in this study (Figure 1) also provide new alternatives for introduction of chelation sites into other proteins. It appears that the sequences described here are comparable to the sequences previously used to label other recombinant proteins in the degree of ^{99m}Tc incorporation and the stability of the label (*15*, *16*). Although we used an N-terminal location for these peptides because that is optimal for annexin V, they would also be likely to work in either an internal or a C-terminal location.

A Nonviral DNA Delivery System Based on Surface Modified Silica-Nanoparticles Can Efficiently Transfect Cells in Vitro

Received June 1, 2000; Revised Manuscript Received September 18, 2000

Diverse polycationic polymers have been used as nonviral transfection agents. Here we report the ability of colloidal silica particles with covalently attached cationic surface modifications to transfect plasmid DNA in vitro and make an attempt to describe the structure of the resulting transfection complexes. In analogy to the terms lipoplex and polyplex, we propose to describe the nanoparticle−DNA complexes by the term "nanoplex". Three batches, Si10E, Si100E, and Si26H, sized between 10 and 100 nm and with ζ potentials ranging from +7 to +31 mV at pH 7.4 were evaluated. The galactosidase expression plasmid DNA pCMVβ was immobilized on the particle surface and efficiently transfected Cos-1 cells. The transfection activity was accompanied by very low cytotoxicity, with LD_{50} values in the milligrams per milliliter range. The most active batch, Si26H, was produced by modification of commercially available silica particles with *N*-(6-aminohexyl)-3-aminopropyltrimethoxysilane, yielding spherical nanoparticles with a mean diameter of 26 nm and a ζ potential of +31 mV at pH 7.4. Complexes of Si26H and pCMVβ plasmid DNA formed at w/w ratios of 10 were most effective in promoting transfection of Cos-1 cells in the absence of serum. At this ratio, >90% of the DNA was associated with the particles, yielding nanoplexes with a net negative surface charge. When the transfection medium was supplemented with 10% serum, maximum gene expression was observed at a w/w ratio of 30, at which the resulting particle−DNA complexes possessed a positive surface charge. Transfection was strongly increased in the presence of 100 μM chloroquine in the incubation medium and reached approximately 30% of the efficiency of a 60 kDa polyethylenimine. In contrast to polyethylenimine, no toxicity was observed at the concentrations required. Atomic force microscopy of Si26H−DNA complexes revealed a spaghetti-meatball-like structure. The surface of complexes prepared at a w/w ratio of 30 was dominated by particles half-spheres. Complex sizes correlated well with those determined previously by dynamic light scattering.

INTRODUCTION

The past decade has witnessed the arrival of a range of new synthetic transfection agents, including cationic peptides, dendrimers, polyethylenimine, and novel lipids (*1*−*5*). The efficiency of nonviral transfection systems has improved several orders of magnitude. However, this is not due to the discovery of new transfection reagents per se, but also a product of the grown understanding of the biological processes that take place during transfection and the rational manipulation of these. Milestones include the concept of receptor targeting (*6*) and endosomal escape (chloroquine, endosomolytic peptides and viruses, proton sponges) (*3*, *7*−*9*). Currently, research groups are seeking ways to facilitate the nuclear transfer of transfected DNA after it has entered the cytoplasm (*10*, *11*) or to circumvent this problem by cytoplasmic gene expression (*12*). Exhaustive reviews on these topics have been published recently (*13*−*15*). Along with the more detailed understanding of transfection, the most advanced transfections agents are getting increasingly complex and might already be termed transfection "systems". These will carry a number of functional components that can be more or less integrated: (1) a plasmid or other suitable form of DNA, (2) a DNA carrier, (3) one or more receptor ligand, (4) an endosomolytic factor, (5) a nuclear localization signal, (6) a biocompatible shell and structures to link these functions. With the rising number of necessary components it is becoming increasingly difficult to tightly control the synthesis of such complexes. Wagner and colleagues have successfully employed a system that, in its most complex form, consists of DNA, polylysine or polyethylenimine, a streptavidin−biotin linker, inactivated adenovirus, and transferrin (*16*).

In an attempt to provide alternative DNA carriers for the assembly of such gene transfer systems, we have evaluated the potential of cationically modified silica nanoparticles as a transfection reagent. The ability of these particles to bind and to protect plasmid DNA was shown recently (*17*).

Many polycationic transfection agents are limited in their in vitro transfection efficiency by a pronounced reduction in cell viability. Frequently, the peak in transgene expression is paralleled by the onset of cytotoxicity (*2*, *3*, *18*, *19*). Although some mechanistic studies have

shown the immobilization of membrane patches (*20*), lipid redistribution (*21*), or the thermodynamic stabilization of lipid bilayers by polycations (*22*), the processes that mediate the in vitro toxicity of polycations such as polylysine or polyethyleneimine is not understood. Recent approaches to reduce the toxicity of polymer-based transfection systems include the optimization of formulation parameters (*19*) or the modification of the polymer side chains by glycolylation (*23*). Attention was therefore also paid to the effect of the newly synthesized DNA delivery vehicles on the viability of the exposed cell cultures.

EXPERIMENTAL PROCEDURES

Synthesis of Cationic Silica Nanoparticles. Silica particles surface modified with aminoalkylsilanes were produced as reported previously (*17*). Briefly, batches Si10E and Si26H were synthesized by modification of commercially available silica particles (IPAST, NISSAN Chemical Industries, Tokio, Japan) with *N*-(2-aminoethyl)-3-aminopropyltrimethoxysilane (AEAPS) or *N*-(6-aminohexyl)-3-aminopropyltrimethoxysilane (AHAPS). Twenty grams of particle suspension (corresponding to 6 g of particle dry weight), 20 g of water, and 12 mL of concentrated acetic acid were stirred for 16 h at 80 °C with 7.2 g of AEAPS (Si10E) or 6 g of AHAPS (Si26H). The product was chilled, mixed with 25 mL of ethylene glycol, rotated for 2 h under vacuum at 50 °C, and dialyzed five times for 24 h against 20 L of deionized water. For the synthesis of Si100E, silica particles were generated by the method of Stoeber (*31*) and subsequently modified with one weight equivalent of AEAPS. A mixture of 8 g of triethoxysilane (TEOS) and 13 g of ammonium in 250 mL of ethanol was subjected to a controlled hydrolysis and condensation reaction for 16 h at room temperature. The particles were collected by centrifugation, washed five times and modified with 4.36 g of AEAPS as described above. AEAPS, AHAPS, and TEOS were purchased from ABCR (Karlsruhe, Germany).

Degree of Modification of Si26H. The relative carbon content of unmodified and modified silica particle was measured on a C/H-analyzer, RC-412 (Leco, St. Joseph), using 100−200 mg of particle dry weight. The increase in carbon content was then related to the molecular weight of the hydrolyzed modificator (AHAPS) of 209 g/mol. This allowed the calculation of the degree of cationic modification of the base particle in moles of nitrogen per gram of particle dry weight.

Light Scattering Measurements of ζ Potential and Particle Size. ζ Potential titration curves were obtained using a Malvern Zetasizer 4 (Malvern, U.K.). The instrument was calibrated routinely with a −55 mV standard. Particle size was determined by photon correlation spectroscopy on a ALV 5000 (Laser Vertriebsgesellschaft mbH, Langen, Germany) at a scattering angle of 90° (sampling time 300 s).

Atomic Force Microscopy (AFM). Si26H−DNA complexes were mixed at a w/w ratio of 30 in distilled water, adsorbed to the surface of silicium wafers and the wet surface was examined by atomic force microscopy on a Nanoscope IIIa in tapping mode using a Si_3N_4 cantilever with a spring constant of 34 N/m. Scanning was performed at a scan speed of 2 Hz with a resolution of 512 × 512 pixels. The tip loading force was minimized to avoid structural changes to the sample.

Ethidium Bromide Exclusion Test. For the measurement of ethidium bromide exclusion, DNA was diluted in 50 mM Hepes (pH 7.4) to yield a final concentration of 10 μg/mL, mixed with the desired amount of particle suspension or polymer solution and incubated for 3 min. The final reaction volume was 2 mL in all cases. One milliliter of ethidium bromide (800 ng/mL), or water for the detection of background fluorescence, was added to one-half of the sample and the fluorescence was measured at λ_{ex} = 366 nm and λ_{em} = 590 nm in a F-2000 fluorescence spectrophotometer (HITACHI, Japan).

Table 1. Physicochemical Characteristics of Si10E, Si100E, and Si26H

particle	size (nm) (range)	IEP (pH)	$\zeta_{pH7.4}$ (mV) ($\zeta_{max,}$ fitted)	mol of N/ g of SiNP	spacer in amino-alkylsilane
Si10E	10 (8−12)	8.1	+17 (+44)	nd	ethyl
Si100E	145 (70−220)	7.7	+7 (+56)	nd	ethyl
Si26H	26 (16−50)	8.6	+31 (+57)	0.000 48	hexyl

Agarosegel Electrophoresis. Nanoparticle−DNA complexes were prepared by mixing in 200 μL of 25 mM Hepes (pH 7.4) at a plasmid concentration of 20 μg/mL and electrophoresed on agarose gel (0.7%, ethidium bromide included for visualization) for 2 h at 70 V. Images were taken using a UV transilluminator and a Geldoc2000 gel documentation system (Bio-Rad, Munich, Germany). Band integration and background correction was performed using Molecular Analyst, version 1.1 software (Bio-Rad).

Cosedimentation Analysis. To measure the removal of DNA from the solution, nanoparticle−DNA complexes were prepared as described above and subjected to centrifugation at 21.000*g* for 15 min at room temperature. The concentration of soluble DNA in the supernatant was determined with Hoechst 33 258 dye (*24*).

Cell Culture. Cos-1 cells were obtained from DSMZ (Braunschweig, Germany) and maintained in Dulbecco's modified eagle's medium (DMEM), supplemented with 10% fetal calf serum (Gibco BRL). Cells were incubated at 37 °C with 5% CO_2 in air and subcultured every three to four days using trypsin/EDTA.

Transfections and Cytotoxicity Assay. For transfection, Cos-1 cells were plated in 96-well plates or 16-well chamber slides (Greiner) at a density of 10.000 cells/well and allowed to adhere overnight. Nanoparticle−DNA complexes were prepared by adding the desired amount of particle suspension to 20 μg/mL (final concentration) plasmid DNA in water. After 15 min equillibration at room temperature, the complexes were diluted with one volume of 2xDMEM with or without 20% FCS and 200 μM chloroquine. The semiconfluent monolayers were washed once with PBS and incubated with 100 μL of the test suspension for 4 h at 37 °C with 5% CO_2 in air. The cells were washed once with PBS and incubated for a further 48 h in DMEM + 10% FCS. Cytotoxicity of NP and NP−DNA complexes was determined in a separate set of experiments using the WST-1 assay (Boehringer Mannheim, Germany) according to the manufacturer's instructions. All assays were performed in six replicates.

***β*-Galactosidase Detection.** To assay the average cellular expression of β-galactosidase, cells were washed once with PBS and lysed with 100 μL of 0.2% Triton X-100 (SIGMA) in PBS per well for 30 min at 4 °C. Fifty microliters of lysate was mixed with 50 μL of fresh reaction solution (5 mM 4-methyl-umbeliferryl-β-D-galactoside, 100 mM D-galactose, and 2 mM $MgCl_2$ in PBS, pH 7.4) and incubated for 4 h at 37 °C. The reaction was stopped by the addition of 100 μL 0.2 M glycine-NaOH

(pH 10.3) and the fluorescence (λ_{ex} = 360 nm and λ_{em} = 460 nm) was measured in a Cytofluor II microplate fluorescence reader (Perseptive Biosystems, Bedford, MA). Purified recombinant β-galactosidase (SIGMA, Deisenhofen, Germany) was used as standard. Total protein content was determined from 25 μL of lysate using the BCA assay (Pierce).

For X-Gal staining, cells were fixed with 4% paraformaldehyde for 5 min at room temperature and stained with 1 mg/mL X-Gal (peqlab, Erlangen, Germany) in PBS for 4 h or overnight.

DNA. The β-galactosidase expression plasmid pCMVβ was purchased from ATCC (Manassas, VA) and transformed into *Escherichia coli DH5*α. A Gigaprep from 2500 mL of overnight culture was performed according to the manufacturers instructions (QIAGEN, Hilden, Germany). The DNA was precipitated in 70% ethanol and reconstituted in water to 1 mg/ml.

Other Chemicals. Polyethylenimine with an average molecular weight of 60 kDa according to the manufacturer's information was purchased from SIGMA (Deisenhofen, Germany).

RESULTS

Transfection Activity of NP−DNA Complexes. The ability of Si10E, Si100E, and Si26H to transfect the pCMVβ reporter gene plasmid at a fixed concentration of 10 μg/mL into Cos-1 cells was tested in serum-free and serum-containing medium in the absence and presence of 100 μM chloroquine. As shown in Figure 1A, all tested SiNPs were able to promote transfection. The efficiency was influenced by a number of parameters including the w/w ratio of SiNP:DNA, presence of FCS and presence of chloroquine. The pattern of transfection activity in response to the variables was similar for all nanoparticles.

Presence of 100 μM chloroquine in the transfection medium generally enhanced transfection by all nanoparticles, although there was substantial variation in magnitude. The effect of chloroquine was especially pronounced in the presence of serum, where it could enhance transfection by more than 10-fold for all nanoparticles.

There was also an optimum for the w/w ratio of particle to DNA. In the absence of serum but presence of chloroquine, this was 20, 10, and 10 for Si10E, Si100E, and Si26H, respectively. Above this optimum, a slight but constant decrease in galactosidase activity was observed. This, however, was not accompanied by a reduction in cellular protein content (not shown).

Addition of serum did not affect or improve the efficiency of transfection by all SiNPs. While this effect was relatively small or in some cases only marginal when Si10E or Si100E were used, the improvement of transfection by Si26H complexes prepared at a ratio of 30 was more than 10-fold. The addition of chloroquine and serum in combination improved galactosidase expression by 2 orders of magnitude, reaching approximately 30% of the levels achieved with polyethylenimine−DNA polyplexes prepared at a N/P ratio of 7.5 (w/w = 1). At this ratio, pEI-DNA polyplexes showed the highest level of galactosidase expression in Cos-1 cells in our lab. However, maximum transfection activity coincided with 50% reduction in cellular protein levels when pEI was used as transfection agent.

Figure 1, panels B and C, show the influence of the SiNP to DNA ratio on the resulting galactosidase expression levels in more detail. Low but significant enzyme levels were detectable at w/w ratios of 3. In both cases,

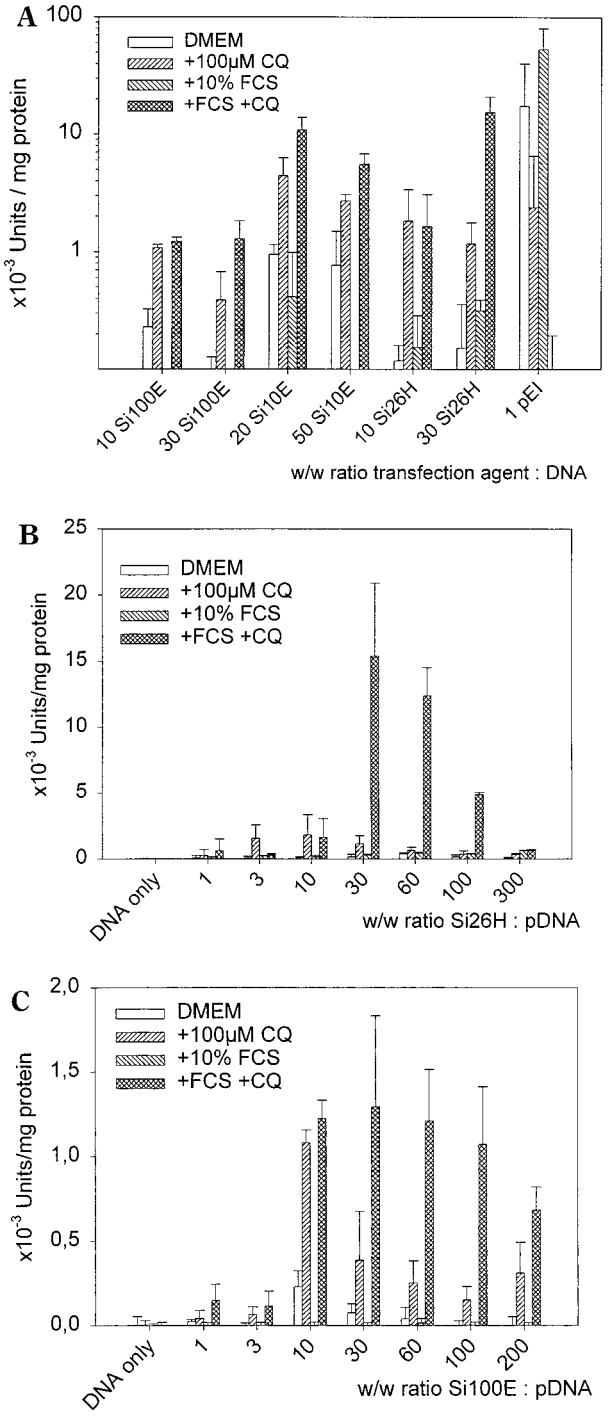

Figure 1. Transfection with pEI, Si10E, Si100E, and Si26H. Semiconfluent Cos-1 cells were incubated with transfection complexes as described in the Materials and Methods. Expression of β-galactosidase was determined using the fluorogenic substrate 4-methyl-umbelliferryl-β-D-galactoside. A total of 10^{-3} enzyme units corresponds to approximately 2 ng of enzyme, and the detection limit was 10 pg of enzyme/well.

transfection in the absence of serum peaked at a ratio of 10. When more particles were added, the activity slowly declined. Supplementation of the transfection medium with 10% of fetal calf serum shifted the curve to higher SiNP:DNA ratios with a maximum at a w/w ratio of 30. Gene expression in experiments performed without the addition of 100 μM chloroquine was at a 2−10-fold lower level but paralleled this course.

Incubation with naked DNA did not result in measurable levels of galactosidase expression in this experimen-

Si26H	2.5 mg/mL	>6 mg/mL
pCMVβ	>1 mg/mL	>1 mg/mL
chloroquine	7.5 mM	9.5 mM

[a] Semiconfluent Cos-1 cells grown on 96-well plates were incubated for 4 h with increasing concentrations of the transfection agent in DMEM or DMEM + 10% fcs, supplied with fresh medium and assayed for viability (WST-1 assay) after a further 48 h of growth in DMEM supplemented with 10% fcs.

tal setup. The transfection activity of SiNP−DNA complexes based on 10 and 30 weight equivalents of Si100E and Si26H was confirmed by histochemical staining with X-Gal (not shown).

In Vitro Cytotoxicity of the Transfection Reagents. All transfection reagents were characterized with regard to their effect on the viability of Cos-1 cell monolayers under the same conditions as used for transfection experiments. The LD_{50} values are summarized in Table 2. Only polyethylenimine significantly reduced the viability at concentrations required for efficient transfection. All nanoparticles tested displayed a 50% lethal concentration well above 1 mg/ml. Panels A and B of Figure 2 compare the cytotoxicity of polyethylenimine, the nanoparticle Si26H, and their complexes with plasmid DNA. When applied in concentrations used for transfection, pEI and pEI−DNA complexes reduced viability by up to 50%, while no significant toxicity could be detected for Si26H and its complexes with DNA. In the absence of serum, the factor between the Si26H concentration required for optimum transfection and the LD_{50} of the corresponding complexes was approximately 25. Addition of serum further reduced the cytotoxicity (Figure 2B).

AFM. Atomic force microscopy of Si26H−DNA complexes revealed a structure that can be described with the spaghetti-meatball model. Figure 3 shows a typical example at high resolution. The surface was dominated by Si26H nanoparticles, while DNA strands were not visible and appeared to be localized in the interior. Although the DNA strands could not be resolved within the complex, it can be concluded from the absence of submicron aggregates in DNA-free samples that DNA is wound around and sandwiched by multiple nanoparticles to become physically condensed and covered by these. The size of the resulting complexes was found to be in the range between 100 and 200 nm.

Correlation of Physicochemical Parameters. There was a strong correlation between the nanoparticle-induced decrease in ethidium bromide intercalation, the electrophoretic immobilization of DNA and its removal from solution by centrifugation (Figure 5). All three parameters show significant binding of plasmid DNA at w/w ratios Si26H:DNA above 1, reaching 50% at ratios between 4 and 5. At ratios above 10, >90% of the plasmid was bound to the particle surface as determined by agarosegel electrophoresis (Figure 4). Cosedimentation analysis predicted only 80% binding at this ratio. Upon addition of more Si26H, the DNA binding reached 100%. The exclusion of ethidium bromide from the complex, however, never exceeded 90%.

Si26H−pCMVβ complexes with w/w ratios of 10, 30, 100, and 300 were analyzed for their surface charge by ζ potential measurement (Figure 5). Addition of 10 weight equivalents of Si26H increased the ζ potential from approximately −70 mV for free plasmid DNA to −34 ± 5 mV. At a ratio of 30, the complexes displayed a ζ potential of +25 ± 5 mV, which did not increase further upon addition of more Si26H (28 ± 5 mV at 100:1 and 24 ± 5 mV at 300:1).

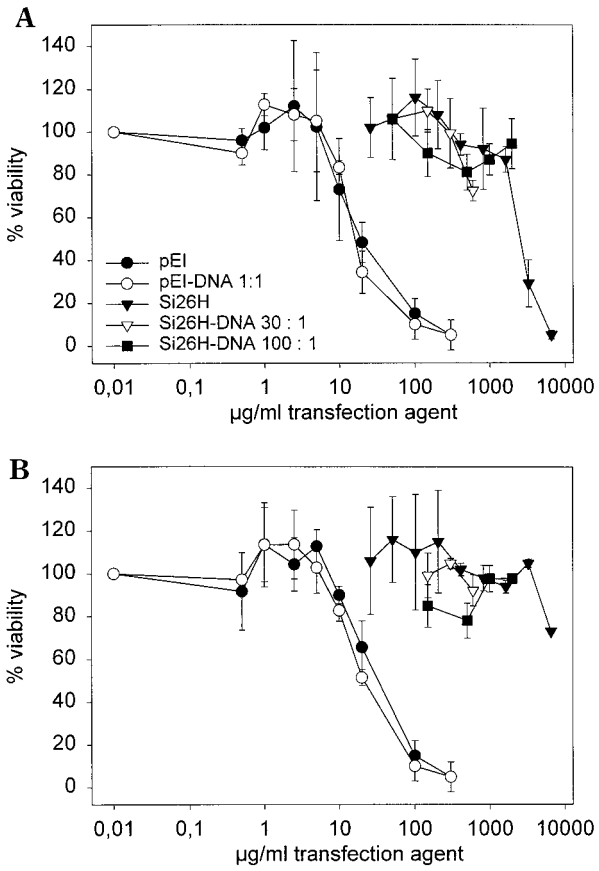

Figure 2. Comparative in vitro cytotoxicity of polyethylenimine and Si26H and their complexes with DNA. Semiconfluent Cos-1 cells grown on 96-well plates were incubated for 4 h with increasing concentrations of pEI, Si26H, or transfection complex in (A) DMEM or (B) DMEM + 10% fcs, supplied with fresh medium and assayed for viability (WST-1) after a further 48 h of growth in DMEM supplemented with 10% fcs. Concentrations always relate to pEI or Si26H.

To relate the w/w ratio Si26H/DNA to the balance of positive and negative charges, the average content of the charge carriers nitrogen and phosphate per gram of Si26H and plasmid DNA, respectively, was calculated. On the basis of the carbon analysis of the unmodified base particle (IPAST) and Si26H, the degree of modfication could be estimated for Si26H as 0.000 48 mol of nitrogen/g of particle dry weight (Table 1). The phosphate content of DNA can be calculated as 0.003 mol of phosphate/g of DNA, assuming an average molecular weight of 330 g/mol of nucleotide. Hence, the w/w ratios Si26H/DNA of 1, 10, and 30 correspond to N/P ratios of 0.16, 1.6, and 4.8, respectively (Table 3).

DISCUSSION

For the purpose of gene transfer, DNA has successfully been complexed with a range of materials including polycationic polymers and cationic liposomes or included in chitosan micro- and nanoparticles. Attempts have also been made to adsorb DNA onto the surface of colloidal particles. So far, dendrimers which are typically smaller than 10 nm and organic nanoparticles that are around

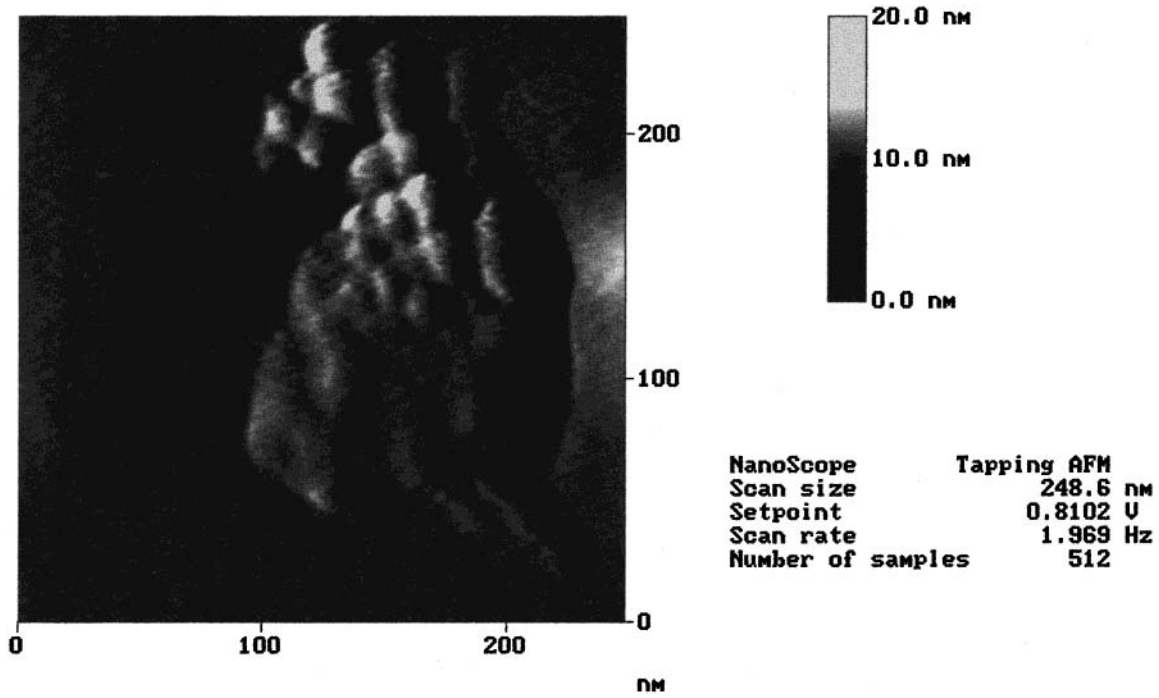

Figure 3. Atomic force microscopy of Si26H−DNA complexes. A suspension of Si26H was added to plasmid DNA to give final concentrations of 20 μg/mL DNA and 600 μg/mL Si26H. The sample was applied to silicium wafers and allowed to adsorb for 30 min at room temperature. Imaging was performed in tapping mode on a Nanoscope IIIa using a Si_3N_4 cantilever with a spring constant of 34 N/m.

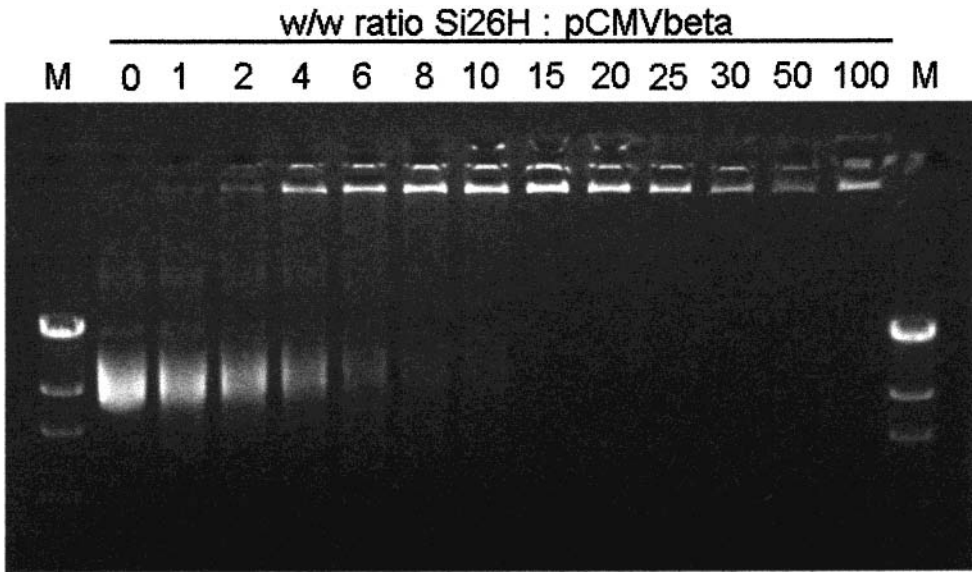

Figure 4. Agarosegel electrophoresis of Si26H-pDNA complexes. Lanes M show DNA marker IV, other lanes correspond to Si26H−pCMVβ complexes prepared at the w/w ratio given on top. The DNA was visualized by ethidium bromide staining and UV transillumination.

300 nm have been evaluated (*3*, *25*). We have synthesized cationically modified silica nanoparticles with sizes of 10−100 nm, that can adsorb DNA, resulting in complexes typically between 100 and 300 nm that should be suitable for cellular uptake. It could now be demonstrated that these particles are also able to efficiently transfect plasmid DNA into cultured cells.

All of the three particle batches tested resulted in measurable and significant galactosidase activity, while DNA alone was inactive. The ratio of particle:DNA optimal for transfection correlated well with the DNA-binding behavior. As shown by agarosegel electrophoresis and cosedimentation analysis, 10 equiv of Si26H were sufficient to bind >90% of the plasmid DNA. The transfection efficiency in the absence of serum peaked at the same ratio. Interestingly, the resulting complexes still displayed a negative surface charge as shown by ζ potential measurements. This confronts with the paradigm that either a high positive charge or specific cellular recognition is necessary for transfection. The addition of fetal calf serum further improved gene expression after transfection with these complexes. This effect was especially pronounced for Si26H−DNA complexes prepared at ratios above 10, which did also display a positive surface charge. This is surprising, as most polyplexes are either not or negatively affected by serum (*26*). On the underlying mechanism can only be speculated. Both a

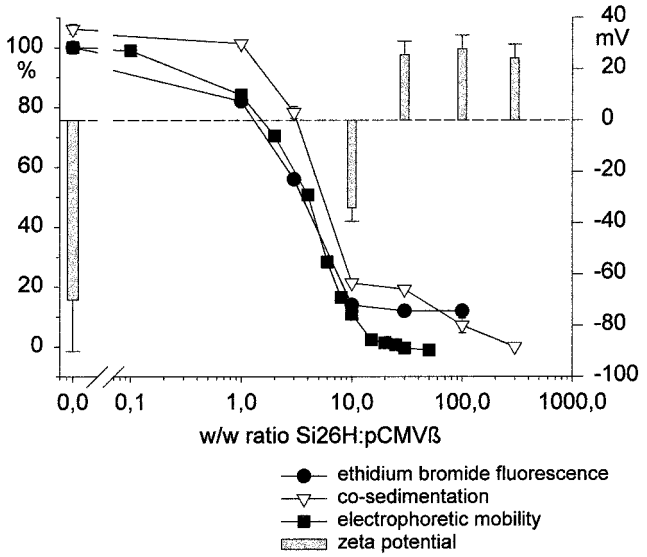

Figure 5. Physicochemical characterization of Si26H−DNA complex formation. Plasmid DNA was incubated with increasing amounts of Si26H at pH 7.4 in 50 mM HEPES for 10 min. Ethidium bromide exclusion from Si26H−DNA complexes, immobilization of DNA in the agarosegel by Si26H, removal of soluble DNA from solution by Si26H, and subsequent centrifugation and the ζ potential of the formed complexes were determined as described in Experimental Procedures.

Table 3. Conversion of w/w Ratios into N/P Ratios for Si26H−DNA Complexes

w/w ratio	N/P ratio[a]
1	0.16
3	0.48
10	1.6
30	4.8

[a] Assuming 0.00048 mol of N/g of particle and average 300 g/mol nucleotide.

physical stabilization or enhancement of cell binding by either specific or unspecific mechanisms would appear feasible.

Another feature of all investigated NP−DNA complexes is that transfection was strongly enhanced by the presence of chloroquine in the transfection medium. As chloroquine is thought to act either via inducing endosomolysis or delaying the endosomal decomposition (*8*), this would suggest that the complexes are internalized by endocytosis and routed to the endosomal/lysosomal compartment. This is not surprising as this pathway is thought to be used by most polyplexes (*9*, *14*, *27*, *28*). However, there is still no agreement on the mode of action of chloroquine, and induction of complex dissociation is discussed as an alternative mechanism to endosomolysis (*29*). Some of the polymers used for transfection, e.g., polyethyleneimine, possess an intrinsic endosomolytic activity, which has been associated with the buffering effect during endosomal acidification. Such polymers require higher nitrogen/phosphate (N/P) ratios of at least 6 for DNA complexation at neutral pH than nonendosomolytic polymers such as poly-L-lysine. Polylysine complexes are usually most effective in the presence of chloroquine and at N/P ratios between 2 and 4 (*30*). For Si26H−DNA complexes, we calculated a conversion factor w/w ratio to N/P ratio of 0.16 based on the carbon analysis of Si26H and an average molecular weight of 330 g/mol nucleotide. This correlates well with the negative ζ potential at w/w = 10 (N/P = 1.6) when it is taken into account that the immobilized imino and amino groups are not fully protonated under these conditions. It would also suggest, that Si26H should, in regard to endosomolysis, rather behave like polylysine than polyethyleneimine. Increasing the buffering capacity of these cationically modified silica nanoparticles might therefore represent a rational approach to improve their potential as transfection agent.

There are a few unique features that make the surface-modified silica nanoparticles described here appear as a promising DNA carrier for transfection systems. Although there are concerns that SiO_2 can exert adverse effects by the induction of NFκB (*31*), colloidal silica is biologically inert and showed much lower cytotoxicity than polyethylenimine. Silica is widely used in cosmetics and pharmaceuticals, for instance as highly disperse SiO_2 (Aerosil) as an excipient for solid oral dosage forms. Furthermore, existing technology could be applied to link ligand molecules via remaining functional groups onto the surface of SiNP−DNA complexes to mediate specific interactions. At least at a sufficient ratio SiNP:DNA, the complex surface is dominated by particle half-spheres, as shown by atomic force microscopy. It does not seem unreasonable to assume, that these half-spheres are not directly involved in DNA binding and carry functional groups that will allow further chemical modification without disturbing the structure of the complex. The facts that lyophilizing and autoclaving SiNP should, in principle, be possible, are further aspects that might make them an attractive addition to the existing repertoire of DNA vectors.

ACKNOWLEDGMENT

This work is part of the interdisciplinary research program "Biologically composed materials and systems" sponsored by the Department of Education, Culture and Science of the Saarland. We thank the "Fonds der Chemischen Industrie" for financial support. U.B. wishes to thank "Stiftung Deutscher Naturforscher Leopoldina" (BMBF/LPD-9901/8-6). Mrs. N. Zghoul is thanked for critical proof-reading of the manuscript.

Nucleosides and Nucleotides. 204. Synthesis of Oligodeoxynucleotides Containing 6′α-[*N*-(Aminoalkyl)carbamoyloxy]-carbocyclic-thymidines and the Thermal Stability of the Duplexes and Their Nuclease-Resistance Properties†

Yoshihito Ueno, Naoko Karino, and Akira Matsuda*

Graduate School of Pharmaceutical Sciences, Hokkaido University, Kita-12, Nishi-6, Kita-ku, Sapporo 060-0812, Japan. Received June 13, 2000; Revised Manuscript Received August 28, 2000

To construct the nuclease-resistant oligodeoxynucleotides (ODNs) with natural phosphodiester linkages, we synthesized ODNs that contain 6′α-[*N*-(aminoalkyl)carbamoyloxy]-carbocyclic-thymidines (**4**, **5**, and **6**). The stability of these ODNs to nuclease hydrolysis was examined by using snake venom phosphodiesterase (3′-exonuclease) and nuclease S1 (endonuclease). It was found that the ODNs containing **4**, **5**, or **6** were more resistant to both the enzymes than the unmodified ODN. These nuclease-resistant properties are noteworthy, since they have natural phosphodiester linkages. Next, the thermal stabilities of duplexes consisting of these ODNs and either the complementary DNA or RNA were studied by thermal denaturation. The ODNs that contain **4** were found to enhance the thermal stability of the duplexes with the complementary DNA, while those containing **5** or **6** decreased the thermal stability of the ODN−DNA duplexes. On the other hand, all ODNs that contained **4**, **5**, or **6** decreased the thermal stability of the ODN−RNA duplexes.

INTRODUCTION

Oligodeoxynucleotides (ODNs)[1] that are capable of inhibiting cellular processes at the translational level by base pairing with mRNA are known as antisense ODNs (*1*−*4*). Since unmodified ODNs with natural phosphodiester linkages are rapidly hydrolyzed by nucleases found in cell culture media and inside cells, many types of backbone-modified ODNs have been synthesized and used for antisense studies (*5*). Phosphorothioate ODNs, in which one nonbridging phosphate oxygen is replaced by sulfur, are some of the most widely used backbone-modified antisense ODNs. Phosphorothioate ODNs are markedly more resistant to hydrolysis by nucleases than unmodified ODNs and activate RNase H that selectively cleaves the RNA-strand of a DNA−RNA duplex (*2*). However, it is known that their binding affinity for RNA is lower than that of an unmodified ODN (*6*). Furthermore, phosphorothioate ODNs sometimes exhibit non-sequence-specific activity (*7*−*9*).

On the basis of this background information, we have developed new antisense ODNs which have natural phosphodiester linkages and which are also resistant to nucleases. We hypothesized that the natural phosphodiester ODNs carrying basic amino alkyl chains near their phosphodiester moieties might be resistant to nucleases. Since nucleases hydrolyze phosphodiester linkages by a general acid−base catalysis mechanism, including acidic and/or basic amino acid residues at their active sites, the presence of a basic amino group near the phosphodiester moiety of ODNs may prevent nucleolytic hydrolysis by forming an ionic bond with the acidic phosphodiester moiety of ODNs. It is also possible that the amino group attached to ODNs interrupts the catalytic system of nucleases by bonding with an acidic amino residue or by repulsing a basic amino acid residue at the enzyme active sites.

Indeed, we found that ODNs containing a 2′-deoxyuridine analogue **1** which carries an aminoalkyl-linker at the 1′-position (Figure 1) were more resistant to nucleolytic hydrolysis by both snake venom phosphodiesterase (a 3′-exonuclease) and nuclease P1 (an endonuclease) than unmodified ODNs (*10*). We also synthesized ODNs containing a 2′-deoxyuridine analogue **2** which carries an aminohexyl-linker at the 5-position of uracil (*11*−*13*). These ODNs were more resistant to nucleolytic hydrolysis by both snake venom phosphodiesterase and nuclease S1 (an endonuclease) than unmodified ODNs, and were very stable in a medium containing 10% fetal calf serum (*12*, *13*). Furthermore, we found that the ODNs containing a thymidine analogue **3** which carries an aminoethyl-linker at the 4′-position were significantly resistant to nucleolytic hydrolysis by both snake venom phosphodiesterase and DNase I (an endonuclease) and were very stable in PBS containing 50% human serum (*14*). These results indicate that ODNs that have been suitably modified by aminoalkyl-linkers are resistant not only to exonucleases but also to endonucleases, even when they have natural phosphodiester linkages.

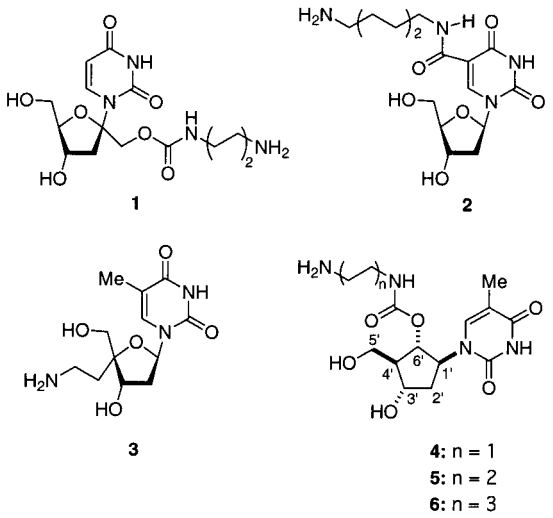

Figure 1. Structures of the modified nucleoside analogues and an atom-numbering system for 6′α-substituted-carbocyclic-thymidines.

On the other hand, it has been reported that ODNs containing a carbocyclic-thymidine, where the furanose ring oxygen is replaced by a CH_2 group, increase thermal stabilities of ODN−RNA duplexes, but nuclease stability against snake venom phosphodiesterase is inadequate for biological applications (*15*, *16*). More recently, Altmann et al. reported that ODNs containing 6′α-aminobutoxy-carbocyclic-thymidine are stable enough in 10% heat-inactivated fetal calf serum although stability against endonuclease was not examined; however, they decrease thermal stabilities of ODN−RNA duplexes (*17*).

It is well-known that naturally occurring polyamines, such as spermidine and spermine, bind strongly to DNAs (*18*−*20*) and stabilize duplex (*21*, *22*) and triplex formation (*23*−*25*). The enhanced thermal stability of duplexes and triplexes is explained by the reduction of the anionic electrostatic repulsion between the phosphate moieties and the cationic amino groups. From these findings, we envisioned introducing an aminoalkyl-linker with a suitable length at the 6′α-position of a carbocyclic-nucleoside. If successful, we would then be able to synthesize the ODNs that enhance the thermal stability of ODN−RNA duplexes and that are also resistant to both exo- and endonucleases by the effect of the aminoalkyl-linker.

In this paper, we report the synthesis of ODNs that contain 6′α-[*N*-(aminoalkyl)carbamoyloxy]-carbocyclic-thymidines (**4**, **5**, and **6**). Stability of these ODNs to nucleolytic hydrolysis by snake venom phosphodiesterase and nuclease S1, and the thermal stability of duplexes of these ODNs with either the complementary DNA or RNA, were studied.

RESULTS AND DISCUSSION

Synthesis. The synthesis of ODNs containing **4**, **5**, or **6** was accomplished in a DNA synthesizer by using a suitably protected 6′α-[*N*-(2-aminoethyl)carbamoyloxy]-carbocyclic-thymidine (**14a**), 6′α-[*N*-(4-aminobutyl)carbamoyloxy]-carbocyclic-thymidine (**14b**), or 6′α-[*N*-(6-aminohexyl)carbamoyloxy]-carbocyclic-thymidine phosphoramidite (**14c**). The synthesis of the 3′-phosphoramidite derivatives **14a**, **14b**, and **14c** is shown in Scheme 1. The hydroxyl group of the epoxide **7**, which was prepared according to the literature procedure (*26*), was silylated using TIPSCl to give the triisopropylsilanyloxy derivative **8** in 90% yield. Treatment of **8** with thymine and NaH in DMF at 145 °C afforded the desired epoxide-opened product **9** in 45% yield with a recovery of **8** in 27% yield. Hydrogenolysis of the benzyl group of **9** gave the diol derivative **10** in 82% yield. Then, the primary hydroxyl group of **10** was protected with a DMTr group to yield **11** in 90% yield. Compound **11** was converted into the carbonylimidazolide, which was reacted with 1,2-diaminoethane, 1,4-diaminobutane, or 1,6-diaminohexane. Without purifying the products, the amino groups were protected with a trifluoroacetyl group to give **12a**, **12b**, and **12c** in 84, 93, and 73% yields, respectively. After desilylation of **12a**, **12b**, and **12c** by TBAF, **13a**, **13b**, and **13c** were then phosphitylated by a standard procedure (*27*) to give the corresponding nucleoside 3′-phosphoramidites **14a**, **14b**, and **14c**.

An unmodified DNA octadecamer (control) and octadecamers containing **4**, **5**, or **6** were synthesized in a DNA synthesizer. The average coupling yields of **14a**, **14b**, and **14c** were 98, 96, and 98%, respectively, using a 0.12 M

solution of the amidite derivatives in CH_3CN and 600 s for the coupling time. The fully protected ODNs (each 1 μmol scale) linked to the solid supports were treated with concentrated NH_4OH at 55 °C for 12 h. This was followed by C-18 column chromatography. Detritylation gave ODNs **15**−**21** (Table 1). Each ODN in this preparation showed a single peak by reversed-phase HPLC analysis. ODNs **18-E**, **18-B**, **18-H**, **21-E**, **21-B**, and **21-H** were analyzed by matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF/MS), and the observed molecular weights supported their structures.

Partial Digestion of ODNs with Snake Venom Phosphodiesterase and Nuclease S1. Since resistance to nucleolytic hydrolysis by nucleases is an important factor in antisense studies, the stability of ODNs containing **4**, **5**, or **6** to nucleolytic digestion was examined. Two kinds of nucleases, snake venom phosphodiesterase (a 3′-exonuclease) and nuclease S1 (an endonuclease), were used in this study. ODNs **21-E**, **21-B**, and **21-H** containing four molecules of **4**, **5**, or **6** were labeled at their 5′-end with ^{32}P and incubated with an appropriate nuclease, and the reactions were then analyzed by polyacrylamide gel electrophoresis under denaturing conditions (*28*).

When snake venom phosphodiesterase was used in the reactions, the control ODN **15** was hydrolyzed randomly by the enzyme after 120 min of the incubation (Figure 2a). In contrast, the phosphodiester linkages at the 5′-sides of **4**, **5**, and **6** were highly resistant to the enzyme (Figure 2, panels b, c, and d). Altmann et al. also reported that ODNs containing 6′α-aminobutoxy-carbocyclic-thymidine are stable in 10% heat-inactivated fetal calf (*17*). Several studies have demonstrated that 3′-exonuclease activities are the major cause of the degradation of unmodified ODNs in serum (*1*). Thus, our data is consistent with the result reported by Altmann et al.

Next, the ODNs were treated with nuclease S1. The phosphodiester linkages around **4**, **5**, and **6** were more resistant to enzymatic hydrolysis than those beside thymidine (Figure 3). The half-lives of ODN **15**, **21-E**, **21-B**, and **21-H** were 13, 37, 32, and 30 min, respectively. In our previous paper, we reported that the heptadecanucleotide containing four molecules of **2** was four times more stable to hydrolysis by nuclease S1 than an unmodified ODN. Also, the ODN containing **3** was about 90 times more stable to hydrolysis by DNase I. Therefore, it was found that the ODNs containing **4**, **5**, or **6** are as resistant to nuclease S1 (an endonuclease) as the ODN containing **2**.

UV Melting Studies of Duplexes. The stability of the duplexes composed of the octadecamers **15**−**21** and a complementary DNA, 5′-d[TGG AGA GAG AGA GAG AGA GAG GT]-3′ (**22**), was next studied by thermal denaturation in a buffer of 0.01 M sodium cacodylate (pH 7.0) containing 0.01 M NaCl. One transition was observed in the melting profile of each duplex. Melting temperatures (T_ms) and the ΔT_m^1 values [T_m(each ODN) − T_m(the control ODN **15**)] are listed in Table 2. The T_m values for the duplexes containing the nucleoside analogue **4** were greater than those of the control duplex (T_m = 51.6 °C), except for the duplex comprised of ODN **16-E** ($\Delta T_m^1 = -0.3$), but all of the T_m values for the duplexes containing analogue **5** or **6** were smaller than those of the control duplex. The stability of the duplexes was dependent on the number of the nucleoside analogues. The duplexes became more stable as the number of **4** increased, while the duplexes became less stable as the number of **5** or **6** increased. The duplexes consisting of ODNs **18-E** containing one molecule of **4** at the center ($\Delta T_m^1 = +2.0$) were more stable than those composed of ODNs **16-E** or **17-E** containing **4** near either the 5′- or 3′-end (ΔT_m^1s = −0.3 and +1.2, respectively). A 4.5 °C increase in T_m was observed for ODNs **21-E** containing four molecules of **4**.

The enhanced thermal stability of the duplexes containing **4** was thought to be due to a reduction of the electrostatic repulsion between phosphate moieties by the ammonium ion at the end of the *N*-(2-aminoethyl)-carbamoyloxy linker. To confirm the effects of the *N*-(aminoalkyl)carbamoyloxy linkers on the thermal stabilities of the duplexes, thermal denaturation was also performed under higher ionic strength (0.1 M NaCl). The

[a] Experimental conditions are described in the Experimental Section. [b] The complementary DNA, **22**. [c] The complementary RNA, **23**. [d] ΔT_m^1 = [T_m(each ODN) − T_m(the control ODN **15**)]. [e] ΔT_m^2 = [T_m(0.1 M NaCl) − T_m(0.01 M NaCl)].

ΔT_m^2 values obtained [T_m(0.1 M NaCl) − T_m(0.01 M NaCl)] were compared, as shown in Table 2. The ΔT_m^2 values for the duplexes containing **4** were smaller than those for the control duplex (ΔT_m^2 = +14.5). Furthermore, the ΔT_m^2 values for the duplexes containing **4** seemed to decrease as the number of **4** increased. These results suggest that the terminal ammonium ions in **4** effectively neutralize the phosphate negative charges. On the other hand, the ΔT_m^2 values for the duplexes containing **5** and **6** were also smaller than those for the control duplex, although the values were greater than those for the duplexes containing **4**. This result implies that the terminal ammonium ions in **5** and **6** also contribute to neutralize the phosphate negative charges.

When the ODN analogues containing **4**, **5**, or **6** form duplexes with the complementary DNAs, the *N*-(2-aminoethyl)carbamoyloxy, the *N*-(2-aminobutyl)carbamoyloxy, and the *N*-(2-aminohexyl)carbamoyloxy groups of **4**, **5**, or **6** should be accommodated in the minor grooves, since an O4′ position of a nucleoside is in the minor groove. The minor groove of a DNA−DNA duplex is known to be narrow and deep (*29*). Thus, the *N*-(2-aminobutyl)carbamoyloxy and the *N*-(2-aminohexyl)carbamoyloxy groups of **5** and **6** may not be well accommodated in the minor groove of ODN−DNA duplex. This steric hindrance may offset the favorable electrostatic interactions of the aminoalkyl linkers of **5** and **6**. On the other hand, in the central portion of the minor groove in

the native B-DNA dodecamer duplex, a spine of hydration was found to link with the nitrogen and oxygen atoms of some base moieties (*30*−*32*). Thus, another interpretation is that the bulky *N*-(aminoalkyl)carbamoyloxy groups of **5** and **6** may disorder the spine of hydration in the minor groove, while the small *N*-(aminoethyl)carbamoyloxy group of **4** may be well accommodated in the minor groove without disordering the spine of hydration.

Duplex formation of the octadecamers with the complementary RNA, 5′−r[AGA GAG AGA GAG AGA GAG A]-3′ (**23**) was next studied by thermal denaturation in a buffer containing 0.1 M NaCl. As shown in Table 2, all of the T_m values for the duplexes that contain the nucleoside analogues **4**, **5**, or **6** were smaller than those of the control duplex (T_m = 64.0 °C). The stability of the duplexes was dependent on the number of nucleoside analogues. The duplexes became less stable as the numbers of **4**, **5**, and **6** increased.

The 6′α-substituents of the carbocyclic-thymidines could be readily accommodated within a standard A-type DNA−RNA because the minor groove of A-type duplexes is shallow and flat (*29*). Thus, the results seem to be at least not based on simple steric reasons for the aminoalkyl-linkers. It has been reported that ODNs containing stretches of contiguous 6′α-methyl-carbocyclic-thymidine slightly decrease the thermal stability of the duplexes with complementary RNAs, while those containing stretches of contiguous 6′α-hydroxy-carbocyclic-thymidine increase the thermal stability of ODN−RNA duplexes (*32*, *33*). Thus, the duplex destabilization by the aminoalkyl-linkers might also be related to the release of water molecules from the minor grooves.

CONCLUSION

In this paper, we have reported the synthesis of ODNs containing 6′α-[*N*-(aminoalkyl)carbamoyloxy]-carbocyclic-thymidines (**4**, **5**, and **6**). Resistance of these ODNs to nuclease hydrolysis was examined by using snake venom phosphodiesterase (3′-exonuclease) and nuclease S1 (endonuclease). The ODNs that contain **4**, **5**, or **6** were more resistant to nucleolytic hydrolysis by both the enzymes than the unmodified ODNs. These nuclease-resistant properties are noteworthy, since they have natural phosphodiester linkages. The thermal stability of duplexes consisting of these ODNs and either the complementary DNA or RNA were studied by thermal denaturation. The ODNs that contain **4** were found to enhance the thermal stability of the duplexes with the complementary DNA, while those containing **5** or **6** decreased the thermal stability of the ODN−DNA duplexes. On the other hand, contrary to our expectation, it was found that all ODNs that contain **4**, **5**, or **6** decrease the thermal stability of the ODN−RNA duplexes. However, we believe that these results will serve as fundamental data for developing new antisense molecules.

EXPERIMENTAL PROCEDURES

General Remarks. NMR spectra were recorded at 270 MHz (^{1}H) and at 202 MHz (^{31}P) and are reported in parts per million downfield from TMS or 85% H_3PO_4. *J* values are given in hertz. Mass spectra were obtained by fast-atom bombardment (FAB) method. Thin-layer chromatography was done on Merck coated plates $60F_{254}$. The silica gel or the neutralized silica gel used for column chromatography was Merck silica gel 5715 or ICN silica 60A, respectively.

(1*S*,2*S*,3*S*,5*R*)-2-(Benzyloxymethyl)-3-(triisopropylsilanyloxy)-6-oxabicyclo[3,1,0]hexane (8). A mixture of (1*S*,2*S*,3*S*,5*R*)-2-(benzyloxymethyl)-6-oxabicyclo-[3,1,0]hexan-3-ol (*26*) (1.28 g, 5.80 mmol), TIPSCl (3.72 mL, 17.4 mmol), and imidazole (2.37 g, 34.8 mmol) in DMF (60 mL) was stirred at room temperature. After 16 and 25 h, further amounts of TIPSCl (1.24 mL, 5.80 mmol) and imidazole (0.79 g, 11.6 mmol) were added to the mixture. After 63 h, EtOH (2 mL) was added to the mixture, and the whole was stirred for 10 min. The mixture was concentrated in vacuo and was taken in EtOAc, which was washed with aqueous $NaHCO_3$ (saturated) and brine, dried (Na_2SO_4), and concentrated. The residue was purified by column chromatography (SiO_2, 50% EtOAc in hexane) to give **8** (1.87 g, 85% as an oil): FAB-MS *m*/*z* 377 (MH^+); ^{1}H NMR (270 MHz, $CDCl_3$) δ 7.35−7.28 (m, 5H), 4.50 (dd, *J* = 16.7, 12.1, 2H), 4.26 (d, *J* = 7.4, 1H), 3.52−3.40 (m, 4H), 2.39 (t, *J* = 5.5, 1H), 2.12 (ddd, *J* = 14.8, 7.4, 1.7, 1H), 1.96 (dd, *J* = 14.8, 1.6, 1H), 1.05 (s, 3H), 1.02 (s, 18H). HRMS (FAB) calcd for $C_{22}H_{37}O_3Si$: 377.2510. Found: 377.2495.

(1*S*,2*S*,3*S*,4*S*)-1-[3-(Benzyloxymethyl)-2-(hydroxy)-4-(triisopropylsilanyloxy)cyclopentyl]thymine (9). Thymine (4.04 g, 32.0 mmol) was added to a suspension of sodium hydride (60% oil dispersion, 213 mg, 5.33 mmol) in DMF (40 mL), and the mixture was stirred at room temperature. After 2 h, a solution of **8** (4.31 g, 10.7 mmol) in DMF (4 mL) was added to the mixture, and the whole was heated at 145 °C for 51 h. After the mixture was cooled, the mixture was partitioned between EtOAc and H_2O. The organic layer was washed with brine, dried (Na_2SO_4), and evaporated under reduced pressure. The residue was purified by column chromatography (SiO_2, 60% EtOAc in hexane) to give **9** (2.42 g, 45% as a pale yellow foam) with a recovery of **8** (1.09 g, 27%): FAB-MS *m*/*z* 503 (MH^+); ^{1}H NMR (270 MHz, $CDCl_3$) δ 8.42 (br s, 1H), 7.35−7.29 (m, 5H), 7.00 (s, 1H), 4.64 (dd, *J* = 17.7, 9.2, 1H), 4.53 (m, 2H), 4.31−4.19 (m, 2H), 3.79 (dd, *J* = 9.0, 4.3, 1H), 3.62 (dd, *J* = 9.0, 6.9, 1H), 2.95 (d, *J* = 2.5, 1H), 2.30−2.00 (m, 3H), 1.87 (s, 3H), 1.03 (s, 21H). Anal. calcd for $C_{27}H_{42}N_2O_5Si$: C, 64.51; H, 8.42; N, 5.57. Found: C, 64.37; H, 8.35; N, 5.45.

(1*S*,2*S*,3*S*,4*S*)-1-[2-(Hydroxy)-3-(hydroxymethyl)-4-(triisopropylsilanyloxy)cyclopentyl]thymine (10). A mixture of **9** (1.53 g, 3.04 mmol) and Pd-C (10%, 2.02 g) in EtOH (180 mL) was stirred under atmospheric pressure of H_2 at room temperature. After 10 h, the catalyst was filtered off with a Celite pad, and the filtrate was evaporated under reduced pressure. The residue was purified by column chromatography (SiO, 5% EtOH in EtOAc) to give **10** (1.03 g, 82% as a white powder): FAB-MS *m*/*z* 413 (MH^+); ^{1}H NMR (270 MHz, $CDCl_3$) δ 10.63 (br s, 1H), 7.05 (s, 1H), 4.68 (m, 1H), 4.56 (m, 1H), 4.41 (m, 1H), 4.13 (m, 1H), 3.98 (d, *J* = 11.2, 1H), 3.80 (m, 1H), 3.54 (br s, 1H), 2.60 (m, 1H), 1.98−1.94 (m, 2H), 1.82 (s, 3H), 1.06 (m, 21H). Compound **13c** (437 mg, 0.548 mmol) was phosphitylated as described in the preparation of **14a** to give **14c** (443 mg, 81% as a white foam): FAB-MS *m*/*z* 997 (MH^+); ^{31}P NMR δ 148.74, 148.66. HRMS (FAB) calcd for $C_{50}H_{65}F_3N_6O_{10}P$: 997.4448. Found: 997.4431.

Synthesis of ODNs. ODNs were synthesized on a DNA synthesizer (Applied Biosystem model 381A) by the phosphoramidite method. The fully protected ODNs were then deblocked and purified by the same procedure as for the purification of normal ODNs. That is, each ODN linked to the resin was treated with concentrated NH_4-OH at 55 °C for 12 h, and the released ODN protected by a DMTr group at the 5′-end was chromatographed on a C-18 silica gel column (1 × 10 cm, Waters) with a linear gradient of MeCN from 0 to 30% in 0.1 M TEAA buffer (pH 7.0). The fractions were concentrated, and the residue was treated with aqueous 80% AcOH at room temperature for 20 min, then the solution was concentrated, and the residue was coevaporated with H_2O. The residue was dissolved in H_2O and the solution was washed with Et_2O, then the H_2O layer was concentrated to give a deprotected ODN **16-E** (49), **17-E** (55), **18-E** (51), **19-E** (46), **20-E** (49), **21-E** (38), **16-B** (54), **17-B** (53), **18-B** (55), **19-B** (45), **20-B** (42), **21-B** (46), **16-H** (50), **17-H** (49), **18-H** (54), **19-H** (35), **20-H** (52), and **21-H** (43). The yields are indicated in parentheses as OD units at 260 nm starting from 1 μmol scale.

Matrix-Assisted Laser Desorption/Ionization Time-of-Flight Mass Spectrometry. Spectra were obtained on a Voyager Elite reflection time-of-flight mass spectrometry (PerSeptive Biosystems, Inc., Framingham, MA) equipped with a nitrogen laser (337 nm, 3-ns pulse). 3-Hydroxypicolinic acid (HPA), dissolved in H_2O to give a saturated solution at room temperature, was used as the matrix. Time-to-mass conversion was achieved by calibration by using the peak representing the C^+ cation of the charged derivative to be analyzed. ODN **18-E**: calcd mass, 5505; obsd mass, 5501. ODN **18-B**: calcd mass, 5533; obsd mass, 5529. ODN **18-H**: calcd mass, 5561; obsd mass, 5557. ODN **21-E**: calcd mass, 5805; obsd mass, 5801. ODN **21-B**: calcd mass, 5917; obsd mass, 5913. ODN **21-H**: calcd mass, 6030; obsd mass, 6027.

Partial Hydrolysis of ODNs with Snake Venom Phosphodiesterase. Each ODN labeled with ^{32}P at the 5′-end (10 pmol) was incubated with snake venom phosphodiesterase (0.4 μg) in the presence of Torula RNA (0.15 OD_{260} units) in a buffer containing 37.5 mM Tris-HCl (pH 8.0) and 7.5 mM $MgCl_2$ (total 20 μL) at 37 °C. At appropriate periods, aliquots of the reaction mixture were separated and added to a solution of EDTA (5 mM, 10 μL), then the mixture was heated at 100 °C for 5 min. The solutions were analyzed by electrophoresis on 20% polyacrylamide gel containing 7 M urea (*28*). Densities of radioactivity of the gel were visualized by a Bioimaging Analyzer (Bas 2000, Fuji, Co. Ltd.).

Partial Hydrolysis of ODNs with Nuclease S1. Each ODN labeled with ^{32}P at the 5′-end (10 pmol) was incubated with nuclease S1 (0.2 units) in the presence of Torula RNA (0.54 OD_{260} units) in a buffer containing 30 mM sodium acetate (pH 4.6), 1 mM $ZnSO_4$, and 280 mM NaCl (total 20 μL) at 37 °C. At appropriate periods, aliquots of the reaction mixture were separated and added to a solution of EDTA (5 mM, 10 μL), then the solutions were heated for 5 min at 100 °C. The solutions were analyzed by gel electrophoresis as described above.

Thermal Denaturation. Each solution contains each ODN (3 μM) and the complementary DNA **22** (3 μM) or RNA **23**(3 μM) in an appropriate buffer. The solution containing each ODN was heated at 90 °C for 5 min, then cooled gradually to an appropriate temperature, and used for the thermal denaturation studies. Thermal-induced transitions of each mixture were monitored at 260 nm on a Perkin-Elmer Lambda2S. Sample temperature was increased 0.5 °C/min.

Improvement of MRI Probes To Allow Efficient Detection of Gene Expression

Dagmar Högemann, Lee Josephson, Ralph Weissleder, and James P. Basilion*

Center for Molecular Imaging Research, Massachusetts General Hospital, Charlestown, Massachusetts. Received July 7, 2000; Revised Manuscript Received September 18, 2000

Recently, it has been demonstrated that magnetic resonance imaging (MRI) utilizing monocrystalline iron oxide nanoparticles (MIONs) targeted to an engineered transferrin receptor enables imaging of gene expression. However, the relatively high doses of iron oxides used indicated the need for improved MR imaging probes to monitor changes in gene expression in vivo. Using alternative conjugation chemistries to link targeting ligands and iron oxide nanoparticles, we present the development and characterization as well as improved receptor binding and MRI detection of a novel imaging probe. Iron oxide nanoparticles with a cross-linked dextran coat were conjugated to transferrin (Tf) through the linker molecule *N*-succinimidyl 3-(2-pyridyldithio)propionate (SPDP) to yield Tf-S-S-CLIO. The characteristics of this conjugate were evaluated in comparison to Tf-MION and Tf-CLIO generated by oxidative activation of the dextran-coat with subsequent reduction of Schiff's base. SPDP conjugation allowed approximately a 4-fold increase in the number of Tf molecules attached per iron oxide nanoparticle and resulted in a more than 10-fold improvement of binding and uptake by cells. This translated into an imaging probe that was 16 times better for imaging gene expression in a cellular MRI assay. This novel probe for MRI may substantially increase the sensitivity for the detection of endogenous or genetically induced transferrin receptor expression in small numbers of cells and may significantly reduce the imaging dose from over 100 mg/kg to doses of iron oxides that are currently used in clinical imaging.

INTRODUCTION

Real-time noninvasive imaging of gene expression in vivo is a major goal in molecular imaging research. The development of such technology would dramatically alter the way studies are performed. This technology would enable temporal monitoring of gene expression in single living animals during the development of disease or during administration of transgenes for gene therapy and eliminate the need for animal-intensive and labor-intensive studies. Several different imaging modalities have been exploited to image gene expression in vivo; however, none have the high spatial resolution achievable using magnetic resonance imaging (MRI). We have recently capitalized on the high spatial resolution of this technology demonstrating the utility of MRI for imaging gene expression in vivo and its utility for microscopically mapping transgene expression in tumor sections (*1*). To image gene expression in vivo, we previously employed an oxidative strategy of conjugating superparamagnetic monocrystalline iron oxide nanoparticles (MION) to transferrin (Tf). This resulted in targeting of the Tf-MION conjugate to tumors overexpressing engineered human transferrin receptor (ETR, a cell-surface internalizing receptor), cellular accumulation, and detection by MRI (*1*). However, the high doses of Tf-MION contrast agent needed for these studies emphasized the relatively low sensitivity of MRI for probe detection (*1*) and demonstrated the need to develop improved MR contrast agents for imaging gene expression.

In this report, we conjugate Tf to iron oxide particles using the cross-linking reagent *N*-succinimidyl 3-(2-pyridyldithio)propionate (SPDP) to generate a new MR probe and compare its properties with two conjugates prepared by the previously employed oxidative conjugation strategy. We found that the disulfide cross-linked Tf iron oxide conjugates (Tf-S-S-CLIO) had more Tf proteins per iron oxide particle, a higher affinity for the Tf receptor, and altered MR signal intensity in cellular uptake assays at 16-fold lower concentrations.

EXPERIMENTAL PROCEDURES

Synthesis of Iron Oxide Particles: MION, CLIO, CLIO-NH_2. MION-46 was prepared by reaction of iron salts with ammonium hydroxide in the presence of T10 dextran (*3*). Also, the preparation of cross-linked iron oxide nanoparticles, now defined as CLIO-10, has been described before (*4*). Briefly, a dextran-coated monodispersed iron oxide preparation was prepared and then cross-linked with epichlorohydrin and purified (*4*). To utilize SPDP as the linking reagent, it was necessary to add primary amines to the CLIO. To maintain a chemically defined dextran coat, amidation was performed on CLIO rather than MION particles. To produce iron oxide amine, CLIO-NH_2, CLIO was treated with ammonia and then dialyzed as described (*4*, *5*).

Synthesis of Tf-MION and Tf-CLIO (Figure 1, reactions A and B). To ensure conjugation of high affinity Tf to iron oxide particles, the integrity of holo-Tf (Sigma, St. Louis, MO) was confirmed photometrically prior to conjugation as described (*6*). Reaction of MION or CLIO with Tf was accomplished by partial oxidation of dextrans, reaction with Tf, and subsequent reduction of Schiff's bases as previously described (*2*) and as modified here. MION or CLIO was dialyzed against sodium acetate buffer (10 mM sodium acetate and 0.15

M NaCl, pH 6). Following dialysis, MION or CLIO was oxidized with sodium periodate (4 mg/mg iron) for 40 min, dialyzed against 0.15 M NaCl for 1 h and dialyzed against sodium bicarbonate buffer (20 mM sodium bicarbonate and 0.15 M NaCl, pH 8.7) for another 40 min. To conjugate MION or CLIO with human diferric Tf, Tf was added at a ratio of 1.7 mg/mg iron. After 3 h of incubation, Schiff's bases were reduced by addition of 15.9 mM sodium cyanoborohydrate and incubation overnight at 4 °C. Magnetic separation columns (Macs separation columns, Miltenyi Biotec, CA) were used to separate nonconjugated Tf from iron oxide particles. To calculate the number of Tf molecules per particle, the protein (BCA, Pierce, Rockford, IL) and iron concentrations of purified material were determined (*2, 7*). Results were expressed as the number of Tf molecules per particle assuming an average of 2064 Fe atoms/particle (*7*). The conjugates were stored in phosphate buffered saline (PBS), pH 8 at 4 °C.

Synthesis of Tf-S-S-CLIO (Figure 1, reaction C). *Derivatization of CLIO with 2-Pyridyl Disulfide.* CLIO-NH_2 was used to prepare 2-pyridyl disulfide derivatized CLIO. One milliliter of CLIO-NH_2 (26 mg of Fe; in 5 mM citrate buffer), 0.67 mL of PBS (pH 8), and 1.3 mL of 3.4×10^{-2} M (in DMSO) *N*-succinimidyl 3-(2-pyridyldithio)-propionate (SPDP; Molecular Biosciences, Boulder, CO) were incubated for 2 h at room temperature. Low molecular impurities were removed by filtration through Sephadex G25F columns equilibrated with PBS, pH 8. The pooled void volume had an iron concentration of 4.5 mg of Fe/mL.

To measure the number of 2-pyridyl disulfide groups attached, 50 μL of the solution were added to 75 μL of DTT (2×10^{-2} M) in PBS, pH 7.4. After 30 min at room temperature, a microconcentrator with a 30 kDa cutoff (Amicon, Beverly, MA) was used to separate the product of the reduction, pyridine-2-thione, from iron. The concentration of pyridine-2-thione was determined using an extinction coefficient of 8100 M^{-1} cm^{-1} at 343 nm. On average, 35 2-pyridyl disulfide groups were introduced per CLIO ($n = 3$). The compound was kept at 4 °C.

Thiolation of Human Diferric Tf (Tf-SH). Equal volumes of diferric Tf (10^{-3} M = 80 mg/mL) and iminothiolane (2.5×10^{-3} M in PBS, 2 mM EDTA, pH 8, degassed) were mixed and incubated for 1 h at room temperature in the dark. Unreacted iminothiolane was removed by filtration through a Sephadex G25F column equilibrated with PBS, 2 mM EDTA, pH 8. The absorption at 280 nm with an extinction coefficient of 1.2×10^5 M^{-1} cm^{-1} (*8*) was used to determine the concentration of Tf. The number of reactive sulfhydryl groups was measured at a wavelength of 412 nm after the addition of Ellman's reagent with an extinction coefficient of 13 600 M^{-1} cm^{-1} (*9, 10*). Under these conditions, a ratio of 0.7:1 sulfhydryl groups/Tf was achieved, and polymerization was not observed.

Synthesis of Tf-S-S-CLIO. Tf-SH (3×10^{-4} M concentration of Tf) and 2Py-S-S-CLIO (1.3×10^{-3} M concentration of 2-pyridyl disulfide groups) were mixed at equal molar ratios of Tf and 2-pyridyl disulfide groups in PBS, pH 8. The mixture was incubated for 18 h at room temperature. Unreacted Tf-SH was separated from Tf-conjugates using magnetic columns and the number of Tf molecules per particle was determined as above. The conjugates were stored in PBS, pH 8, either at 4 °C or shock frozen in liquid nitrogen and kept a −20 °C.

Cell Culture. Rat 9L gliosarcoma cells (Brain Tumor Research Center, San Francisco, CA) (*11*) or rat gliosarcoma cells stably overexpressing an altered form of the human transferrin receptor ETR (9L3.9 cells) (*1, 2*) were grown in Dulbecco's modified Eagle's medium (DMEM, Cellgro, Mediatech, Washington, DC) containing 10% fetal bovine serum (FBS, Cellgro). The medium was changed every 3 days. Transfected cells were periodically passaged with G418 to ensure integrity of the plasmid expression (*2*).

Competition Studies. Human diferric Tf (Sigma, St. Louis, MO) was radiolabeled with $Na^{125}I$ in the presence of IodoGen (Pierce, Rockford, IL). Unbound iodide was removed by centrifugation through Bio-Gel P6 spin-columns (Bio-Rad, Hercules, CA).

Competition studies were performed for the different conjugates in the presence of [^{125}I]Tf and compared to competition curves generated using different concentrations of unlabeled diferric Tf. Cells (9L wild-type or 9L3.9 cells) were plated at a density of 1×10^5 cells/well onto 24 well plates (Falcon, Becton Dickinson, Lincoln Park, NJ). The next day, different concentrations of unlabeled diferric Tf, thiolated Tf, Tf-MION, Tf-CLIO, or Tf-S-S-CLIO (0.25 nM to 2.5 μM in DMEM) were added immediately prior to the addition of [^{125}I]Tf (0.25 nM in DMEM). As a negative control 2Py-S-S-CLIO was mixed with Tf-SH in an amount equal to their respective concentrations in the Tf-S-S-CLIO conjugate and added to cells. After incubation for 1 h at 37 °C the cells were washed three times with Hanks' Balanced Salt Solution (HBSS, Bio-Whittaker, Walkersville, MD) and detached with trypsin (0.05% trypsin, 0.5 mM ethylenediaminetetraacetic acid). Cell-associated radioactivity was counted in a gamma-counter (1282 Compugamma CS, LKB Wallac, Sweden).

SDS−PAGE. Laemmli SDS−PAGE was used to determine the integrity of the different conjugates (*12*). Samples were mixed with SDS sample loading buffer and analyzed by gel electrophoresis using a 4% stacking gel and a 10% separating gel at a thickness of 0.75 mm. Where reducing conditions were required, 5% β-mercaptoethanol was added to the SDS sample buffer and samples were heated at 95 °C for 5 min. Nonreduced samples were not subjected to heating as controls demonstrated that this had no effect on the integrity of the conjugate (data not shown). Two micrograms of protein was loaded per lane. Gels were run at a constant voltage of 120 V and stained with Coomassie Brilliant Blue R-250.

Physical Properties and MR Imaging. The R1 and R2 relaxivities of Tf-MION, Tf-CLIO, and Tf-S-S-CLIO were measured using a 0.47 T tabletop minispec as described (*7*).

For MR imaging, 3.5×10^6 cells (9L wild-type or 3.9 clone) were seeded/10 cm culture dish. The next day, cells were incubated with the conjugates at different concentrations of iron in 2 mL of DMEM. Cells were incubated at 37 °C for 2 h followed by washing with HBSS, trypsinization, washing in DMEM with 10% FBS, and

centrifugation. After centrifugation, the cell pellets were resuspended in culture medium and transferred into 250 μL tubes. To form uniform pellets the cells were again centrifuged at 500 rpm for 2 min (Sorvall 7 RT, Kendro Laboratory Products, Newtown, CT). To prevent drying and susceptibility artifacts, the supernatant was not removed. The tubes were placed into a water bath at RT for MR imaging. The phantom allowed the simultaneous imaging of up to 50 different samples. MR imaging was performed with a clinical 1.5 T superconducting magnet (Signa 5.0; GE Medical Systems, Milwaukee, WI) using a 5-in. surface coil. The imaging protocol consisted of a T2 weighted spin−echo sequence (SE, TR 3000 ms, variable TE 16−100 ms). The 1.9 mm imaging slice was carefully placed to avoid partial volume effects. At a field of view of 8 cm^2 and a 256 × 256 imaging matrix each voxel has a size of 0.186 mm^3. Accordingly, in each tube a volume of 9.5 μL accounting for approximately 1.5 × 10^6 cells was imaged. After MR imaging, the viability of the cells was confirmed by trypan blue exclusion and was always greater than 95%. Signal intensity (SI) measurements of cell pellets were obtained by manual placement of regions of interest (ROI) on the cell pellets. ROIs were also placed on the surrounding water to determine the overall homogeneity of the image. Signal intensities plotted against the 10 different TEs showed the differences in T2 decay of each pellet. Curve fitting for exponential decay allowed the calculation of T_2 relaxation times ($SI = Ae^{(-T_E/T_2)} + B$, where SI is the signal intensity, T_E the echo time, A the amplitude, and B the offset for each incubation concentration of conjugate.

RESULTS

Synthesis of Tf-Iron Oxide Conjugates. Previous work demonstrated that the conjugation of Tf to periodate-treated MION decreased the affinity of the conjugated Tf for its receptor (*2*). We hypothesized that the contrast agent could be significantly improved if the affinity of conjugated Tf for transferrin receptor could be increased. To minimize the effects of conjugation on Tf−transferrin receptor binding, we utilized a chemical cross-linking reagent, *N*-succinimidyl 3-(2-pyridyldithio)propionate (SPDP), which has previously been shown to have excellent cross-linking efficiency while maintaining the biological activity of Tf (*10*). The synthesis schemes for all three types of iron oxide conjugates are shown in Figure 1. The use of a chemical cross-linking agent significantly improved the number of Tf molecules conjugated per iron oxide particle. Approximately 4 Tf molecules were bound/iron crystal in Tf-S-S-CLIO compared to 0.6−1.2 Tf/particle in Tf-MION and Tf-CLIO. Physical properties of the different conjugates are summarized in Table 1.

To determine if the conjugation and purification strategies above resulted in successful binding and adequate purity, SDS−PAGE was used to analyze the three different conjugates (Figure 2). A brown color, indicative of iron oxide nanoparticles before staining (upper panel), and a blue color after Coomassie Blue staining (lower panel) showed the co-localization of iron oxide nanoparticles and protein in the gel (lanes 3, 5, and 7). The Tf-MION (lane 3) and to a lesser extent also the Tf-CLIO conjugate (lane 5) contained compounds that migrated through the stacking gel presumably due to Tf bound to iron oxide particles of smaller size. The lack of detection of free Tf or protein degradation products showed that magnetic separation efficiently removed nonconjugated Tf from Tf-MION, Tf-CLIO, and Tf-S-S-CLIO preparations.

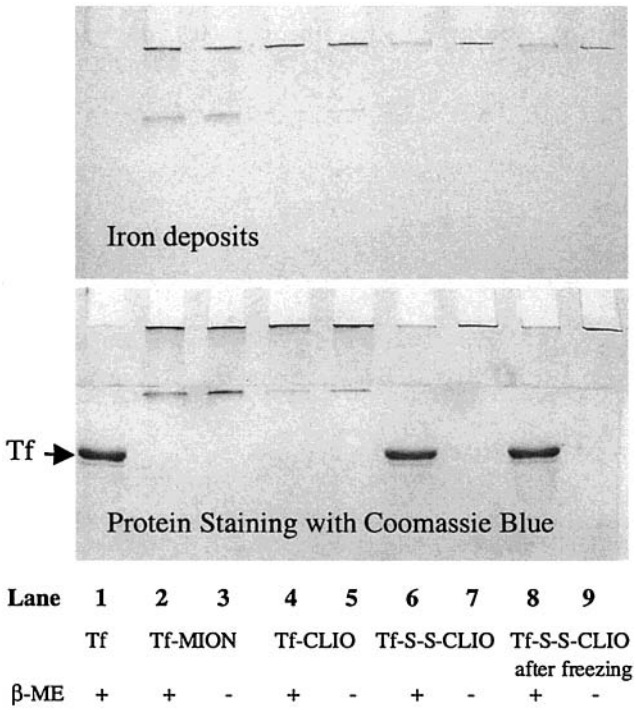

Figure 2. Nonreducing and reducing SDS−PAGE of Tf-MION, Tf-CLIO, and Tf-S-S-CLIO. Two micrograms of nonconjugated Tf (lane 1) or of Tf in each of the conjugates (lanes 2−9) were incubated in SDS-sample buffer with or without β-mercaptoethanol (β-ME), heat treated as indicated in the text and electrophoresed. Upper panel: Gel prior to staining for protein. Lower panel: Gel after Coomassie Blue staining. Arrow indicates migration of authentic Tf standard.

Boiling of Tf-S-S-CLIO in sample buffer containing β-mercaptoethanol, as expected, cleaved the disulfide bond, and no change in the integrity of Tf-S-S-CLIO was observed after prolonged freezing (Figure 2, lanes 6 and 8). In contrast, boiling of Tf-MION and Tf-CLIO in reducing SDS−sample buffer resulted in no release of Coomassie Blue detectable Tf.

Binding and Uptake of Tf, Tf-MION, Tf-CLIO, and Tf-S-S-CLIO. To compare the binding and uptake of the three compounds cells overexpressing a known amount of transferrin receptor, 9L3.9 cells (*1*, *2*) were incubated with a constant amount of [^{125}I]diferric Tf (0.25 nM) in the presence of increasing concentrations of either unlabeled diferric Tf, Tf-S-S-CLIO, Tf-CLIO, Tf-MION, unreacted Tf-SH and 2Py-S-S-CLIO, or 2Py-S-S-CLIO alone (Figure 3A). The concentration for which 50% of the cell associated radioactivity was displaced occurred at 18.7 ± 3.2 nM for diferric Tf and the IC_{50} for Tf-S-S-CLIO was 306.8 ± 21.2 nM. Although it was not possible to generate high enough concentrations of the other conjugates to obtain complete displacement curves, the binding and uptake of Tf-S-S-CLIO was significantly better (greater than 10-fold improved) than either the Tf-MION or the Tf-CLIO conjugates (Figure 3A).

MR Imaging of Tf-MION, Tf-CLIO, and Tf-S-S-CLIO. The next step in these studies was to determine

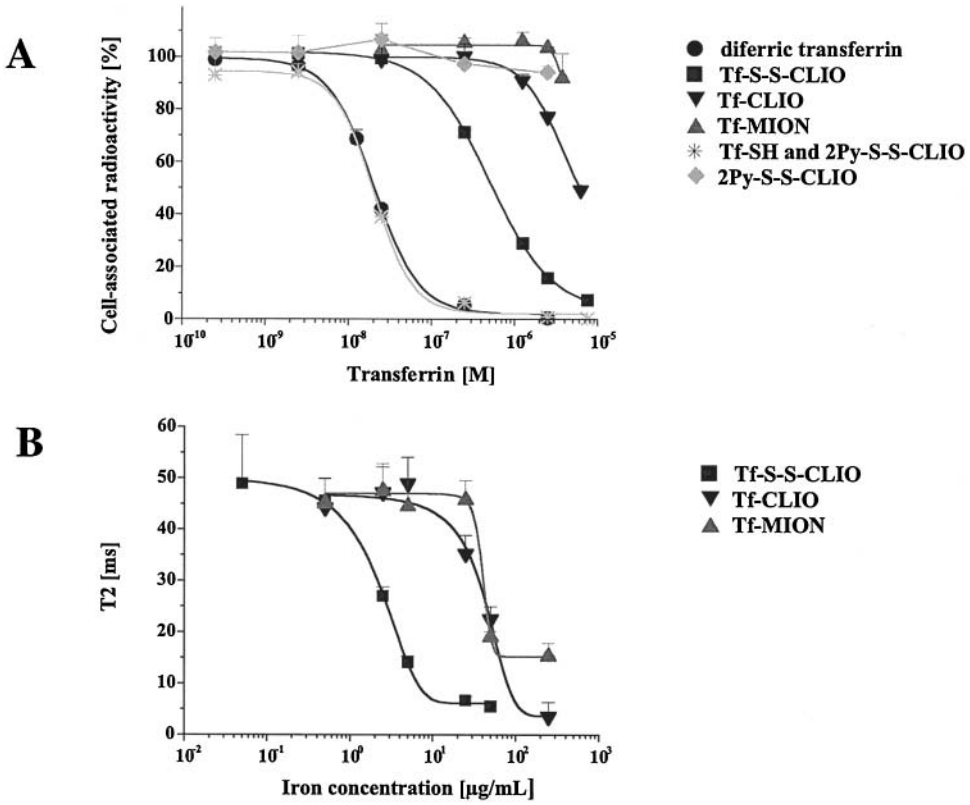

Figure 3. (A) Transferrin receptor competitive binding assay. To compare the relative affinity of the different conjugates and synthesis intermediates for the transferrin receptor a constant amount of [^{125}I]transferrin and increasing amounts of unlabeled diferric Tf, Tf-S-S-CLIO, Tf-CLIO, Tf-MION, Tf-SH freshly mixed with 2Py-S-S-CLIO, and 2Py-S-S-CLIO were co-incubated with cells and total cell associated radioactivity was measured. To account for differences in Tf molecules/particle for the different conjugates the amount of added conjugate was normalized for Tf concentration. 2Py-S-S-CLIO was added in an amount equal to its respective concentration in the Tf-S-S-CLIO conjugate. (B) Transverse relaxivity versus iron concentrations. MR imaging was performed at 10 different echo times (TE 16−100 ms) on the 9L3.9 cell phantoms to allow the calculation of T2 relaxation times. T2 relaxation times were plotted as a function of the concentration of Tf-iron oxide conjugates in the incubation media. The generated curves were used to compare the relative detection of the different imaging probes by MRI.

if changes in Tf-iron oxide binding and uptake would be translated into detectable changes in MR signal intensities. To quantify the changes in signal intensities, we calculated the changes as transverse relaxation times (T2) for each contrast probe at different iron concentrations (see Experimental Procedures). T_2 values were plotted versus the iron concentrations in the incubation media of the cells and used to compare the potency of the different conjugates resulting from binding and intracellular accumulation (Figure 3B). A 50% lower T_2 relaxation time was found after incubation of cells with 16-fold lower concentration of iron for Tf-S-S-CLIO than for Tf-CLIO or Tf-MION (Figure 3B). The changes in signal intensity measured at a single TE for the Tf-MION, Tf-CLIO, and Tf-S-S-CLIO imaging probes are displayed in Figure 4. Signal intensities were dependent on binding and uptake of the conjugates and highly specific for the transferrin receptor. Little to no signal changes were observed after incubation with 250 μg/mL nonconjugated MION or CLIO (data not shown) and a 1000-fold excess of nonconjugated diferric Tf completely inhibited a signal change in comparison to untreated controls.

MR Imaging of Different Levels of Receptor Expression in 9L and 3.9 Cells. Finally, we determined if the improved MRI contrast probe, Tf-S-S-CLIO, was capable of being used to image differences in receptor levels. To assess this, 9L rat glioma cells (9L wild-type) and a derivation of that cell line engineered to overexpress ETR (9L3.9 cells) were incubated with different concentrations of Tf-S-S-CLIO and imaged by MRI. A decrease in signal intensity was observed at much lower concentrations of Tf-S-S-CLIO in 9L3.9 cells compared to wild-type 9L cells (Figure 5). Since receptor-mediated binding for human diferric Tf is identical for both cell types (data not shown), the change in signal intensity most likely resulted from increased binding and uptake of the probe due to an increase in the number of receptors and possibly from changes in relaxivity. Endogenous expression of transferrin receptor could be detected in 9L cells at the highest concentration of contrast probe.

DISCUSSION

We have recently demonstrated that uptake of superparamagnetic monocrystalline iron oxide nanoparticles via the transferrin receptor can be imaged by MRI and correlated to receptor expression (*1*, *2*), while other groups have employed similar strategies to probe for endogenously overexpressed transferrin receptor (*13*) or to load cells with iron oxides (*14*). However, in their current form the targeted iron oxides used to assess transferrin receptor expression in vivo require administration of relatively high doses of Tf-MION (*1*). To improve probe binding and presumably reduce the dose of targeted iron oxide necessary to image transferrin receptor expression we utilized the chemical cross-linking reagent SPDP to generate Tf-S-S-CLIO. The studies presented here show that Tf-S-S-CLIO is an imaging probe that is 16-fold better for MR imaging of transferrin receptor expression and suitable to measure differences in endogenous receptor expression at much lower concentrations of probe.

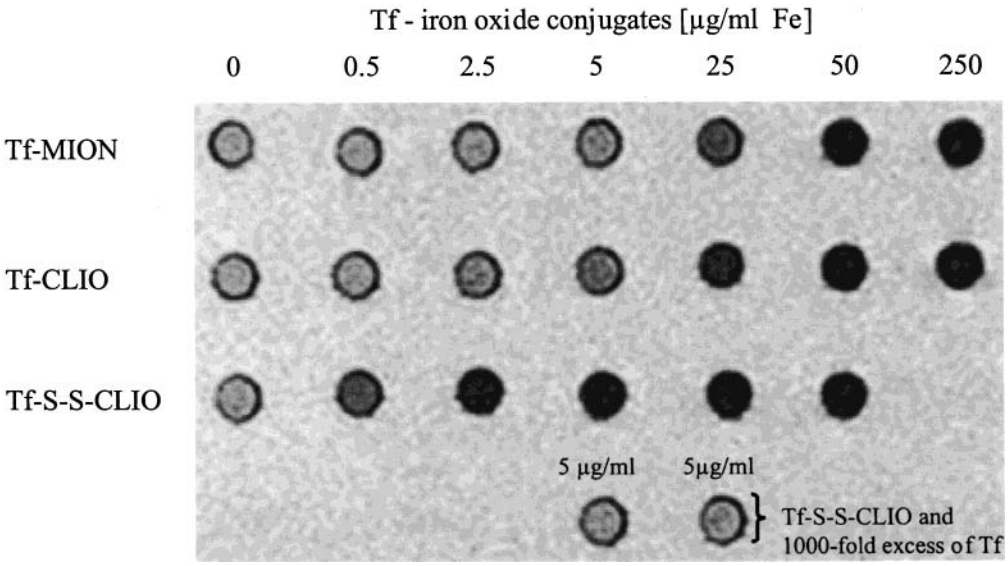

Figure 4. MR imaging of 9L3.9 cell phantoms. 9L3.9 cells, which overexpress TfR, were incubated with the indicated concentrations of Tf-iron oxide conjugates. After the incubation the cells were harvested, washed, pelleted into phantoms and imaged with a T2-weighted MR sequence (GE 1.5 T, Signa 5.0; Spin−Echo Sequence, TR 3000 ms/TE 100 ms). Note that the addition of excess diferric Tf resulted in no change in MR signal compared to untreated controls.

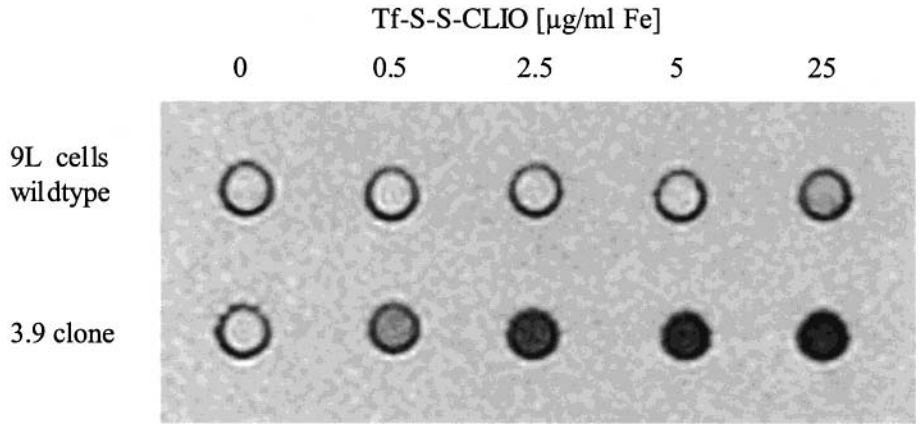

Figure 5. MR imaging of TfR expression. Wild-type 9L cells, expressing relatively low levels of TfR, or 9L3.9 cells, expressing relatively high levels of TfR, were incubated with the indicated concentrations of Tf-S-S-CLIO and imaged as phantoms. The relative difference in TfR expression is clearly visible by T2-weighted MRI (GE 1.5 T, Signa 5.0; Spin−Echo Sequence, TR 3000 ms/TE 50 ms).

The oxidative conjugation strategy that has been used in previous studies produces aldehydes on the dextran coat of the iron oxides. This method can result in multiple direct attachment points between Tf and the polysaccharide of the iron oxides. Therefore, a substantial loss in the biological activity of the protein may result from (1) conjugation to sites that are important for receptor binding or (2) particle interference with receptor binding. To minimize these effects we, sought to bind Tf and iron oxide particles via a linker molecule. We first identified reaction conditions that would produce biologically active Tf bearing a defined number of sulfhydryls (0.7−1.0/Tf) and have determined conditions that yield Tf-SH with binding characteristics indistinguishable from unreacted Tf (Figure 3A and data not shown). The reaction of activated iron oxide nanoparticles, 2Py-S-S-CLIO, with Tf-SH yielded a conjugate, Tf-S-S-CLIO, with approximately 4 Tf- molecules/particle compared to 0.6−1.2 for the oxidative conjugates (Tf-MION and Tf-CLIO). Even after adjustment for the increased number of Tf molecules per particle, the competitive binding assay revealed that Tf-S-S-CLIO has a 10-fold higher affinity for the transferrin receptor than Tf-MION and Tf-CLIO (Figure 3A). Since the difference in biological activity cannot be explained by the increase in particle associated Tf molecules, the improvement in binding of Tf-S-S-CLIO compared to either Tf-MION or Tf-CLIO suggests that the oxidative conjugation chemistry significantly interferes with the binding of the conjugates to the receptor. This may be due to chemical alteration of Tf, cross-linking to a site of Tf directly involved in receptor binding, significant particle-dependent sterical inhibition of Tf-transferrin receptor binding, or a combination of these. While none of these possibilities can be excluded, the binding characteristics of Tf-S-S-CLIO to the transferrin receptor suggest it is likely that sterical inhibition of Tf-MION and Tf-CLIO binding plays a role. Although Tf-S-S-CLIO binds the transferrin receptor much better than Tf-CLIO or Tf-MION, when compared to nonconjugated diferric transferrin Tf-S-S-CLIO is a significantly less effective competitor for [^{125}I]Tf (Figure 3A). Since, there was no detectable difference in the ability of Tf and Tf-SH to compete for [^{125}I]Tf (Figure 3A and data not shown), the difference between Tf and Tf-S-S-CLIO to compete in the displacement assay is likely due to steric hindrance and the overall size of the conjugate rather than being due to thiolation of Tf (i.e., chemical damage or attachment site). These data strongly suggest that

changing the proximity of the iron oxide nanoparticle and Tf can have a significant effect on the interaction of the conjugate with receptor. Furthermore, these data suggest that by lengthening the linker between Tf and the iron oxide it may be possible to synthesize a MR probe with still higher affinity for the transferrin receptor.

It has been reported that the type of disulfide bond formed by conjugation of thiolated Tf and 2Py-S-S-CLIO is relatively stable in plasma with a half-life of 8 h (*15*, *16*) making this a useful coupling chemistry for in vivo probes. The use of this linker chemistry to provide a chemically cleavable linkage between the Tf and CLIO was initially instituted to allow monitoring of the integrity of conjugated Tf following the coupling reaction (Figure 2). However, it is interesting to note that several studies where disulfide bonds have been used to target immunotoxins (*17*−*19*), opioid peptides (*20*) and antibody fragments (*21*) to cells have demonstrated that a labile disulfide bond was necessary for the expression of full activity of these agents. Whether these findings can be transferred to Tf-S-S-CLIO or whether a stable linker is preferable remains to be shown. Further studies to improve this probe in terms of stability, pharmacological profile, bioavailability, relaxation and number of Tf molecules per particle as well as the attachment of other targeting molecules are currently underway.

ACKNOWLEDGMENT

We would like to thank Dr. Anna Moore for her expert advice and help in performing the studies. The work was supported by NIH Grant RO1 CA 85240. Dr. Dagmar Högemann is a recipient of a fellowship from the Deutsche Forschungsgemeinschaft, Germany.

TECHNICAL NOTES

Selective Synthesis of Heterobifunctional Poly(ethylene glycol) Derivatives Containing Both Mercapto and Acetal Terminals

Yoshitsugu Akiyama, Hidenori Otsuka, Yukio Nagasaki,* Masao Kato, and Kazunori Kataoka*

Department of Materials Science & Technology, Science University of Tokyo, 2641 Yamazaki, Noda-shi, Chiba 278-8510, Japan, and Department of Materials Science, Graduate School of Engineering, The University of Tokyo, 7-3-1 Hongo, Bunkyo-ku, Tokyo 113-8656, Japan. Received March 30, 2000; Revised Manuscript Received July 13, 2000

A novel synthetic route to heterobifunctional poly(ethylene glycol) (PEG) derivatives containing both mercapto and acetal terminal groups was established in this study using anionic ring opening polymerization of ethylene oxide (EO) using potassium 3,3-diethoxypropanolate (PDP) as the initiator, followed by the successive conversion of the end-alkoxide group to a methanesulfonic group, and then to an ethyldithiocarbonate moiety. Molecular functionalities of the acetal and the mercapto terminal groups of the heterotelechelic PEG (acetal-PEG-SH) thus prepared were confirmed to 1.00 and 0.85, respectively, indicating that the reaction proceeds almost quantitatively. The obtained acetal-PEG-SH products, including 2-pyridyldithio derivatives, have a promising utility for bioconjugation in the fields of medicine and biology.

PEGylation, which refers to the modification of biomaterials and biomolecules using poly(ethylene glycol) (PEG), has become increasingly important in the fields of pharmaceuticals and biomedical engineering (*1*−*5*), because PEG is a nontoxic, hydrophilic polymer with low interfacial free energy in water and high-chain mobility inducing effective steric stabilization effects (*6*). Furthermore, it is well-documented that exogenous proteins appreciably reduce their antigenicity through PEGylation (*7*, *8*). Several types of PEGylated protein drugs such as adenosine deaminase, asparaginase, and interleukin 2 have been successfully applied in clinical applications (*9*−*11*). In the field of biomedical engineering, construction of tethered PEG brushes on various surfaces through PEGylation has become a major approach to reduce the nonspecific interaction of proteins and cells with biomedical devices. Further, a PEGylated layers may be utilized as a platform for specific molecular recognition and sensing if the free-chain-end of tethered PEG is available for further linking to ligand molecules (*12*). To this end, effective functionalization of the PEG chain-end is of particular importance, facilitating the development of heterotelechelic PEGs possessing different functional groups at each chain end. Indeed, several different approaches were reported for the preparation of heterotelechelic PEG through polymer reactions, starting from hydroxy-terminated homotelechelic PEG (*13*−*15*), yet they often involve many reaction steps with low yields and low selectivities.

The objective of our series of studies on heterotelecheric PEG is to establish novel synthetic routes for various types of heterotelechelic PEGs based on the ring-opening polymerization of ethylene oxide using a metal alkoxide initiator with a protected functional group. In this way, heterotelechelic PEGs possessing functional end-groups such as aldehyde, primary amine, carboxylate, hydroxide, vinyl benzyl, methacryloyl, tosyl, and monosaccharides have been already prepared (*16*−*19*).

We wish to report here the synthesis of a novel heterotelechelic PEG with a high potential utility in the field of bioconjugation: this PEG possesses an acetal group at one end and a mercapto group at the other end. The mercapto end-group is useful for bioconjugation for the following reasons: (1) the mercapto group reacts with several metal surfaces such as gold and silver to provide a reactive PEGylated layer on metal surfaces as a platform material for biosensors and biocatalysis; (2) recombinant DNA technology permits site-specific introduction of the mercapto (cysteine) group at the desired positions in the amino acid sequence of a particular protein. The mercapto-terminated PEG can then be selectively conjugated to the SH-side group of the genetically inserted cysteine residue of the protein, thus obtaining a site-specific PEGylated protein conjugate (*20*). The end-mercapto group of PEG can easily be converted into 2-pyridyldithio-group, which has even more practical value in the PEGylation fields (*21*).

In our strategy to prepare the α-acetal-*ω*-mercapto-PEG, the two-step synthetic method shown in Scheme 1 was employed. According to our previous report (*16*), PEG possessing an acetal group at the α-chain end was prepared by initiating polymerization of ethylene oxide using potassium 3,3-diethoxypropanolate (PDP) as follows: to dry THF (30 mL) in a 100 mL flask with a three-way stopcock under an argon atmosphere were added 3,3-diethoxypropanol (2 mmol) and potassium naphthalene (2 mmol) to form potassium 3,3-diethoxypropanolate (PDP). After stirring for 10 min, liquid EO (140 mmol; cooled below 0 °C) was added via a cooled syringe to the mixture. The mixture was allowed to react for 2 days at

room temperature. The alkoxide group at the ω-chain end was converted to the methansulfonyl group by the addition of an excess amount of methanesulfonyl chloride as follows: the mixture was added dropwise to a solution of 40 mmol of methanesulfonyl chloride in dry THF (5 mL) using doser at room temperature and stirred for 6 h followed by pouring into 1 L of diethyl ether to obtain the polymer as a white precipitate. The obtained polymer was dried in vacuo and then was analyzed by size-exclusion chromatography (SEC). From the SEC diagram shown in Figure 1, the number-average molecular weight (Mn) and the molecular weight distribution (MWD) were determined to be 3090 and 1.05, respectively. The polymer has a very narrow MWD, and its Mn was close to the calculated value derived from the monomer/initiator ratio, suggesting that the polymerization proceeds without any remarkable side reaction. Figure 2 shows the ^1H NMR spectrum of the obtained α-acetal-ω-methanesulfonyl-PEG. The signals appearing at 3.2 ppm (s, 3H) and 4.3 ppm (t, 2H) were assignable to the methyl and methylene groups adjacent to the sulfonic group, respectively. The clear triad signals based on the acetal methine and methyl protons appear at 4.6 and 1.1 ppm, respectively. The molecular weight of the α-acetal-ω-methanesulfonyl-PEG was then calculated from the intensity ratio of the oxymethylene peak of PEG (3.5 ppm) with the methyl peak in the acetal-moiety assuming the quantitative introduction of an acetal group to the chain end of each polymer molecule (DMSO-d_6, 80 °C). The calculated value of 2880 was in a good agreement with the Mn determined by the SEC analysis (Mn 3090). Furthermore, the ω-end functionality was calculated to be 98% using the ratio of the methyl protons in the methanesulfonic group with methyl protons in the acetal moiety (DMSO-d_6, room temperature). Consequently, NMR and SEC data confirmed that synthesis of the acetal-PEG-SO_2CH_3 was sufficient to proceed. Results of acetal-PEG-SO_2CH_3 synthesis under several conditions are summarized in Table 1. The yield of the polymers was sufficiently high, and their molecular weight can be easily controlled by changing the monomer/initiator ratio.

To convert the methane sulfonyl precursor end-group to the *O*-ethyldithiocarbonate group, the acetal-PEG-SO_2CH_3 was reacted with potassium-*O*-ethyldithiocarbonate in a dry THF/DMF (24:1) cosolvent (25 mL) as follows: to the obtained dry acetal-PEG-SO_2CH_3 (0.10 g), the 20-fold amount of potassium *O*-ethyldithiocarbonate in 25 mL of THF was added and stirred for 3 h at room temperature. The reaction mixture was then mixed with chloroform and washed with a saturated NaCl aqueous solution several times to eliminate impurities from the polymer sample. The organic phase was then concen-

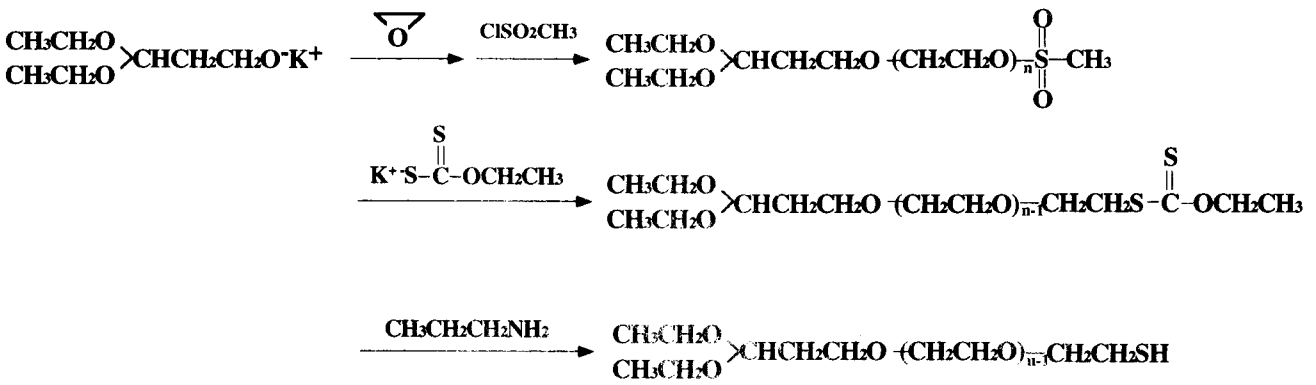

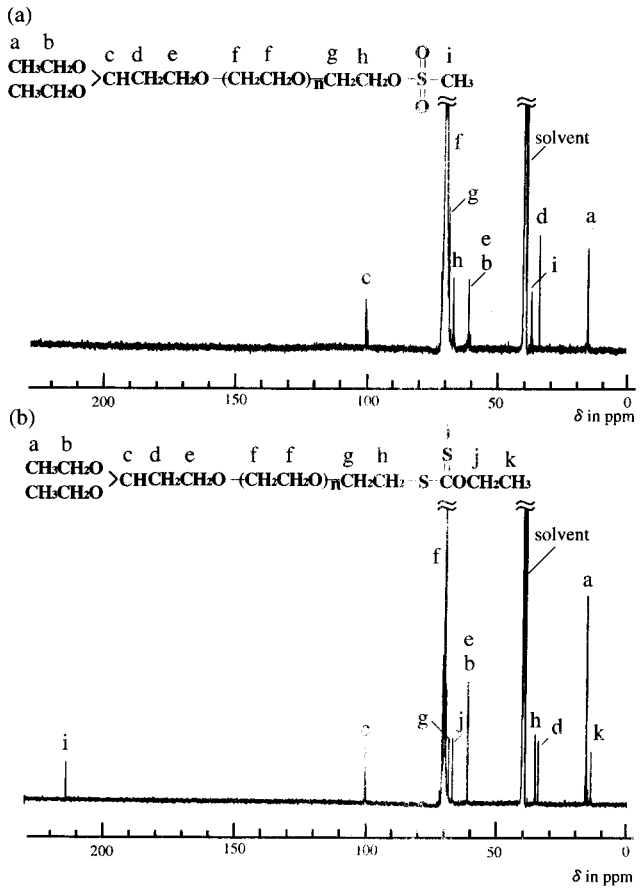

Figure 3. ^{13}C NMR spectra of (a) acetal-PEG-SO_2CH_3 and (b) acetal-PEG-S-C(=S)-OCH_2CH_3 (DMSO, room temperature).

trated by evaporation after drying with sodium sulfate followed by pouring into diethyl ether. The resultant white precipitate was collected and dried in vacuo. Figure 3 shows the ^{13}C NMR spectra of the polymer sample before and after the above reaction. Signals of the methansulfonyl-related carbons such as SO_2CH_3, CH_2-$CH_2OSO_2CH_3$, and $CH_2CH_2OSO_2CH_3$ appearing at 36.9, 68.4 and 66.6 ppm, respectively, completely disappeared in the sample when reacted with potassium *O*-ethyldithiocarbonate (Figure 3b). By contrast, the reacted sample presents new peaks in the ^{13}C NMR spectrum appearing at 214.5, 68.5, and 14.0 ppm, assignable to S-*C*(=S)OCH_2CH_3, S-C(=S)OCH_2CH_3, and S-C(=S)-OCH_2CH_3, respectively. These results clearly indicate quantitative conversion of the ω-methanesulfonyl group to the dithiocarbonate group, which was further confirmed by the ^1H NMR analysis shown in Figure 4. Signals of the methyl and methylene groups adjacent to the sulfonate group completely disappeared, while new peaks appeared at 1.3 (t; 3H) and 4.6 (q; 2H) ppm, assigned to the methyl and methylene groups adjacent to the ethyldithiocarbonate moiety, respectively. The ω-end conversion from methane sulfonate to the ethyldithiocarbonate moiety was again confirmed to be quantitative (97%) based on the ^1H NMR data [CH_2 (4.6 ppm) and CH_3 (1.1 ppm)]. It should be noted that the intensity of the signals derived from the acetal end-groups was unchanged throughout the reaction, indicating that the acetal group at the ω-end remained intact.

It is well-known that the dithiocarbonate group can be easily cleaved by an amine to generate a mercapto group (*12*). Thus, acetal-PEG-S-C(=S)OCH_2CH_3 can be regarded as a precursor of the thiol-ended heterobifunctional PEG. To confirm the generation of mercapto groups

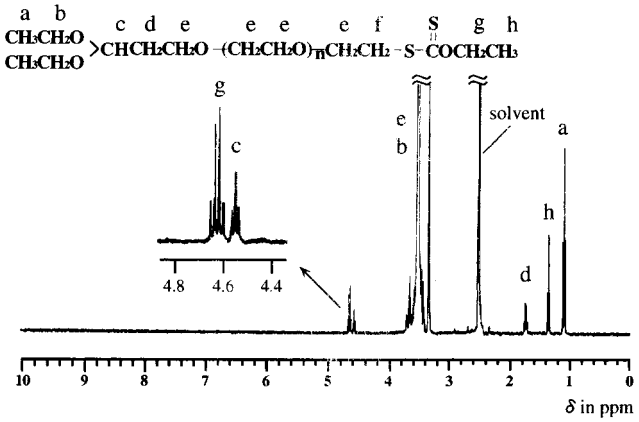

Figure 4. ^1H NMR spectrum of acetal-PEG-S(C=S)-CH_2CH_3 in DMSO at room temperature.

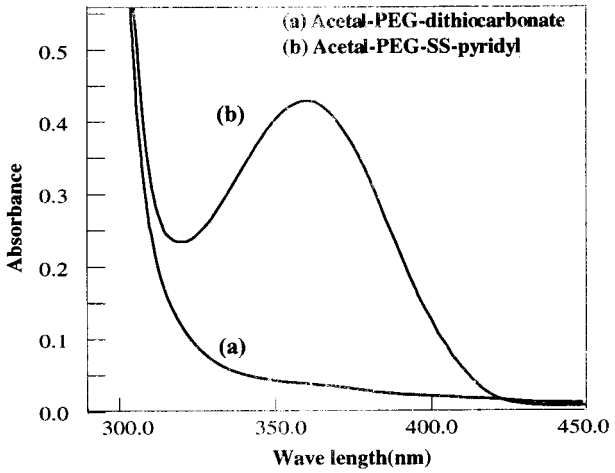

Figure 5. UV absorption spectra of PEG derivatives in MeOH (polymer concentration: 0.1 mM).

through the deprotection of the dithiocarbonate-end-group, acetal-PEG-S-C(=S)OCH_2CH_3 (80 mg) was treated with *n*-propylamine (0.17 mL, 80 times/PEG) in THF (2.0 mL). The mixture was stirred for 3 h at room temperature and then purified in the same manner as described above. The end mercapto group was analyzed by UV spectroscopy using 2-pyridyl disulfide (2-PDS) as a probe molecule: the obtained polymer in MeOH (0.1 mM) was reacted with 5-fold 2-PDS for 2 h at room temperature. The SH group reacts with 2-PDS to release 2-thiopyridon, which is quantified by UV absorbance at 360 nm (ϵ = 5.15×10^3). Figure 5 shows the UV spectra of acetal-PEG-S-C(=S)OCH_2CH_3 (a) and acetal-PEG-S-S-pyridyl (b) clearly demonstrating the existence of the SH-end-group in the sample. Using calibration based on the 2-PDS reaction with 2-mercaptoethanol, the functionality of the SH-end-group per heterotelechelic PEG was calculated to be 0.85. This lowered functionality than 1.0 may be due to the thiol oxidation during the process of purification, although the deprotection reaction itself using *n*-propylamine seems to proceed quantitatively.

In conclusion, the synthesis of a heterobifunctional PEG containing both mercapto and acetal terminal groups (acetal-PEG-SH) was successfully accomplished in this study by EO polymerization with potassium 3,3-diethoxypropanolate and subsequent end-capping with methanesulfonyl chloride. Acetal-PEG-SH was also successfuly converted to the 2-pyridyl derivertive (aceal-PEG-S-S-pyridyl) as follows: freshly deprotected acetal-PEG-SH (0.1 g) solved in dry MeOH (5 mL) was added

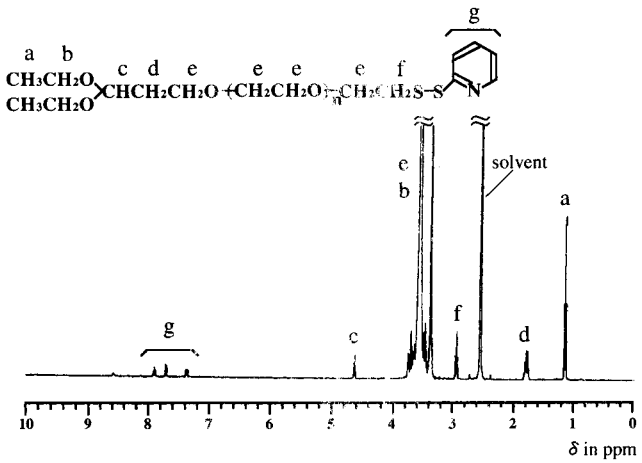

Figure 6. ^{1}H NMR spectrum of acetal-PEG-S−S-pyridyl in DMSO at room temperature.

dropwise to 2-PDS (0.2 g) in dry MeOH (10 mL) and stirred for 2 h at room temperature. The ω-end conversion of PEG from mercapto group to the 2-pyridyldithio group was confirmed to be 68% based on the ^{1}H NMR data shown in Figure 6 [ratio of pyridyl (7.3, 7.6, and 7.8 ppm) to acetal CH_3 (1.1 ppm)]. The obtained heterotelechelic acetal-PEG-SH and acetal-PEG-S-S-pyridyl have potential utility as heterocross-linkers in bioconjugation reactions as well as surface modifiers of metal substrates, including gold and silver, to construct a reactive PEG-brush layer.
